B. Class Ic agents (***propafenone, flecainide***) may be used for acute cardioversion and chronic rhythm control, but should be avoided in patients with CAD, severe LVH, or HFrEF, in which case they are proarrhythmic and increase mortality (CAST trial).[115] Moreover, they reduce the atrial rate and as such, the number of atrial impulses "bombarding" the AV node (reduce "concealed conduction"). This may inadvertently reduce the refractoriness of the AV node and ***increase the AV conduction and the ventricular rate.*** In addition, they may organize AF into atrial flutter with 1:1 conduction to the ventricles. Therefore, class Ic agents should be used with AV nodal blocking agents.

Class Ia disopyramide has potent anticholinergic effects and may be used in *vagally mediated AF* (nocturnal or postprandial) (ACC and ESC). ***Intravenous procainamide*** may be used for acute cardioversion: 50–80% efficacy, hypotension may occur but is infrequent (<10%), and proarrhythmia risk is very low (<1%). Procainamide is used cautiously but not absolutely contraindicated in stable HF or EF < 30% (PROCAMIO study), and it may be used in CAD and valvular disease (RAFF2).[41]

Because of their efficacy and limited extracardiac toxicity, class I agents are first-line therapy for patients without severe underlying heart disease, including hypertensive patients without substantial LVH. ***They may even be used in HFpEF and HFmEF***, as suggested by the EAST-AFNET4 trial, where class Ic were the most commonly used agents in HFpEF (~40%); they were used in HFmEF (20s%) and some stable CAD without safety concerns.[116] Another study suggests that they may be used in CAD with normal EF, wherein they were associated with lower mortality and VT than class III drugs.[117] They are absolutely avoided in patients with prior MI who also have low EF < 55% (CAST trial). They are also avoided in CAD with active or recurrent ischemia (e.g., angina or stress-induced ischemia): CAST analyses suggest that flecainide can trigger polymorphic VT during recurrent ischemia.

Instead of chronic treatment, they may be used as a "pill in the pocket," as-needed therapy for symptomatic AF recurrences, as they are the most effective agents in converting AF. Upon recurrence of AF symptoms, the patient is instructed to take one oral loading dose of flecainide or propafenone, with an expected conversion rate of >60% within 3–6 hours. This approach may be used in selected, highly symptomatic patients with infrequent recurrences of AF (e.g., between once per month and once per year), and should be tried in the hospital once to ensure safety.

IV vernakalant is an atrial selective class I and III agent, used for acute cardioversion (~60% success at 30 min). It is avoided in case of SBP <100, severe HF, or EF <30% (risk of hypotension + risk of VT in HF).

C. Side effects

All AADs can lead to bradyarrhythmias, ventricular arrhythmias, or torsades de pointes. Ventricular arrhythmias are related to an increase in QRS duration with class I agents, and to an increase in QTc interval with class III agents (dose dependent). Thus, heart rate and QRS and QTc intervals are monitored with these agents. Avoid class Ic drugs if QRS >120 ms at baseline or increases more than 25% with treatment. Avoid class III drugs if QTc is >460 ms at baseline, or increases to ≥500 ms or ≥15% with treatment, or a "double-humped" TU wave occurs.

Amiodarone has the lowest risk of proarrhythmia (<1%) despite QTc prolongation. It is the safest from the cardiac standpoint but is associated with non-cardiac side effects: pulmonary fibrosis in <3% of patients (reversible if detected early); hyper- or hypothyroidism; hepatitis; photosensitivity; neurologic side effects (ataxia, tremor, neuropathy, rare optic neuropathy). Non-cardiac death may be increased. Chest radiographs should be performed yearly; thyroid and liver profiles every 6 months; and fundoscopic eye exam at baseline, then as needed if symptoms occur. The effect of amiodarone on QTc is not immediate; it begins to appear after the fourth day and becomes pronounced at 1 to several weeks.

In general, AADs are initiated in the hospital to monitor QT and QRS intervals and arrhythmia occurrence over 3 days. Class Ic agents and amiodarone can be initiated in the outpatient setting if the patient has normal electrolytes, normal QT/QRS intervals, normal renal function, and does not have any structural heart disease.[2]

Appendix 3. Catheter ablation of atrial fibrillation, surgical ablation, AV nodal ablation

Up to 90% of PACs that trigger AF originate from the pulmonary veins, while the rest originate from other foci, most commonly SVC and posterior LA wall, which shares the same embryonic origin as the pulmonary veins. Therefore, catheter ablation of AF mainly consists of ***pulmonary vein isolation***. The more complete the pulmonary vein isolation, the better the long-term result. In patients with organic heart disease and large LA, additional triggers are possible and linear ablation of the atrial substrate may be necessary, particularly LA roof or LA posterior wall box isolation. Ablation across fractionated electrograms in the LA may subdivide the LA into smaller compartments that prevent the propagation of atrial wavelets; *yet, in a trial of persistent AF, linear LA ablation or fractionated electrograms ablation did not add any benefit to pulmonary vein isolation and was paradoxically harmful*, as the scar lines, per se, are proarrhythmic, and the more complex procedure may increase stroke and cardiac complications (STAR AF II).[118] This trial did not specifically address repeat ablation or ablation in HF, and additional lines were frequently used in HF trials such as CASTLE-AF (~50%) or AATC (80%). Also, ERASE-AF study showed that ablation of low-voltage areas in persistent AF reduces AF recurrence. Ablation is achieved via a point-by-point delivery of *radiofrequency energy* ("fire"), or a faster and simpler, one-step *cryoballoon* inflation across each pulmonary vein origin ("ice"), or *pulsed field* technique, a non-thermal energy that uses high-voltage electrical fields to create cell necrosis with less adjacent tissue injury such as pulmonary vein stenosis or phrenic nerve injury.

Catheter ablation is indicated for patients with *recurrent symptomatic paroxysmal or persistent AF who failed at least one antiarrhythmic drug. It may also be used as first-line therapy in HFrEF, paroxysmal AF, or persistent AF with no major risk factors for recurrence* (ESC, ACC). A meta-analysis that included paroxysmal and persistent AF found a 77% success rate for catheter ablation strategies (including patients who received multiple procedures and adjunctive antiarrhythmic drugs) vs. 52% for antiarrhythmic drugs at a follow-up of 14 months.[119] At the Cleveland Clinic, a 76% success rate was reported at 1 year, with a 24% recurrence rate (most recurrences were successfully treated with reablation, with >80% success rate at 4.5 years).[120] A similar need for re-ablation (24-33%) was seen in HF trials (CASTLE-AF, AATC and CAMERA-MRI trials).[77,78,83] The success is highest in patients with paroxysmal AF, no or minimal heart disease, no or minimal left atrial enlargement, and no severe lung disease. Ablation of persistent and longstanding persistent AF, or AF with HF, is associated with encouraging success rates and frequently requires several attempts (25% of patients in CASTLE AF). After ablation, 24-hour Holter monitoring or event monitoring is recommended every 3–6 months for at least 2 years. The most common outcome is total resolution of the arrhythmia on monitoring; yet, AF may recur with a lower AF burden and become asymptomatic or responsive to AAD. In fact, one study has shown that following ablation, only 58% have total resolution of AF, while 12% continue to have AF that is now totally asymptomatic. AF episodes are more frequently asymptomatic after ablation (79% vs. 52%). ***Thus, while catheter ablation may not cure AF, it reduces the total AF burden and duration and, as a result, the symptoms and the morbidity related to AF.***[121]

Early recurrence (2 days to 2 months) does not imply failure and may be attributed to local irritation and inflammation from ablation; most of these patients will have good long-term result. Patients are often treated with an AAD for 2–3 months to minimize these early recurrences.

In the landmark **CABANA trial**, patients with recurrent paroxysmal AF (≥2 episodes) or persistent AF, who for the most part had received antiarrhythmic therapy in the past, were randomized to AF ablation vs. medical therapy (mainly rhythm control in 88%, amiodarone in 32%, class Ic in 34%; median age 68; persistent AF 57%). At 4 years, ablation did not significantly reduce the composite primary endpoint (death, stroke, or bleeding, 8% vs 9.2%) but significantly, albeit slightly, reduced this outcome (7% vs. 10.9%) and mortality (4.4% vs. 7.5%) in the on-treated analysis.[28] MANTRA AF, STOP AF, and EARLY AF trials demonstrated that catheter ablation is an effective first-line treatment compared to antiarrhythmic drug therapy, mainly in the relatively young patient (50s–60s) with recurrent paroxysmal AF. AF ablation resulted in much less AF recurrence, AF burden, need for cardioversion, and progression to persistent AF at 1 year.[122,123] The goal of first-line early ablation is to control AF burden early on, which more robustly slows its self-perpetuating progression.

Ablation should be performed while the patient is adequately anticoagulated: warfarin may be continued throughout the procedure with INR 2–3, without a need for LMWH bridging. Regarding non-vitamin K oral anticoagulants, AF ablation may be performed with uninterrupted dabigatran or rivaroxaban, with the last dabigatran dose given the morning of the procedure (RE-CIRCUIT and VENTURE AF trials); yet minimal interruption of one dose before the procedure is safe as well.[2,124,125] Either way, supplemental doses of heparin are provided during the procedure. Anticoagulation should be continued for at least 3 months after the procedure regardless of CHA_2DS_2-VA score, as the injured atrial tissue may trigger clot formation.[2] Beyond 3 months, anticoagulation is dictated by CHA_2DS_2-VA score ≥2. *Anticoagulation should not be stopped over the long term, since catheter ablation is not a curative therapy for AF* (class I ACC and ESC guidelines).[2] Yet 2 trials, ALONE AF and OCEAN, suggest that patients with a median CHA_2DS_2-VA score of 2 (1–3) who undergo successful ablation—with no AF recurrence for at least 1 year, clinically and on Q6 months Holter—have low stroke risk with and without anticoagulation.[126]

Surgical ablation (maze procedure) consists of creating lines around the pulmonary veins, +/– biatrial ablation lines. The use of radiofrequency energy rather than cutting and sewing allows a faster and less morbid procedure. Ablation increases pump time by ~15 minutes and is indicated *along with any cardiac surgery* in a patient with persistent or paroxysmal AF (class I for mitral surgery, IIa for any cardiac surgery). Yet, as adjunct to mitral surgery, it was associated with a higher post-surgical requirement for pacemaker therapy vs. no ablation (21.5% vs. 8%), particularly if biatrial maze was done. The addition of biatrial lines did not further diminish the recurrence of AF, similarly to what was shown in a percutaneous ablation trial.[118,127] Surgical ablation may also be done as a *stand-alone thoracoscopic procedure* in patients who failed catheter ablation (it is more effective [FAST trial]).[128]

In patients with severely symptomatic, fast AF, where the rate cannot be controlled, and where a rhythm-control strategy has failed or is unlikely to succeed, AV nodal ablation with RV pacing is performed. This strategy is safe and markedly effective in improving symptoms. It also improves LV function in patients with reduced EF, where LV dysfunction is fully or partially related to the fast or irregular rate.[129,130] Better yet, AV nodal ablation with biventricular pacing is superior to RV pacing if EF <50%, regardless of NYHA class (more LV and HF improvement: PAVE, APAF and Block-HF trials) (class IIa recommendation, EF cutoff <50% per ESC, HRS, and ACC).[131–133] Left bundle branch area pacing may alternatively be considered.

In HF, AF ablation is the preferred treatment option regardless of whether AF is rate-controlled. If ablation fails or is not viable, AV nodal ablation + CRT may be considered to better control and regularize the rate regardless of whether QRS is narrow or wide. This may apply even when AF rate seems well controlled, particularly in the older patient (70s) with uncontrolled HF and HF hospitalizations (APAF-CRT, class IIa).[96,97]

In the particular case of persistent AF, EF ≤35%, *and LBBB ≥150 ms*:

- AF ablation is considered first. If it succeeds but EF remains <35%, CRT is implanted (without AV nodal ablation, as the rhythm is now sinus).
- If AF ablation fails or is not deemed a sustainable option, AV nodal ablation + CRT is more readily done than in cases without LBBB. AV nodal ablation is preferred to pure CRT even if AF is rate controlled, as 2/3 of patients do not achieve complete (>90%) biventricular pacing without AV nodal ablation, and regularizing the rhythm is beneficial per se.

Pulmonary vein stenosis is seen in <1% of patients after AF ablation, and is diagnosed by cardiac CT. *Stiff LA syndrome*, caused by LA fibrosis, may be seen after aggressive LA ablation. Both entities may cause new HF or worsening of HF after AF ablation; both are characterized by a discrepancy between LVEDP and a much higher PCWP, in the absence of MS. Stiff LA creates large V waves, whereas vein stenosis creates a flattened PCWP with flat A and V waves from the attenuated retrograde transmission of LA waves, with a PCWP-LV gradient even in end-diastole. PCWP should be measured in the four lung quadrants, as pulmonary vein stenosis may only involve one or two veins.

Phrenic nerve injury may be seen with cryoballoon ablation (3%), but is rarely permanent (<0.5%).

Appendix 4. INR follow-up in patients receiving warfarin: Non-vitamin K oral anticoagulants

Patients must stay within the intended INR goal for ≥60% of the time to derive the intended benefit from warfarin. While an INR goal of 1.5–1.9 has been proposed, cohort studies suggest a striking 2-fold increase in ischemic stroke risk at INR 1.5–1.9, approximating the risk of no anticoagulation, with a risk of intracranial hemorrhage similar to higher INR; therefore, an INR <2.0 is not recommended. The risk of intracranial hemorrhage remains flat until an INR of 4, beyond which this risk rises sharply (6-fold) and continues to rise exponentially (18-fold for INR >4.5) (Figure 10.3).[134]

Warfarin is usually initiated at 5 mg daily (consider a lower dose in elderly patients). *INR reaches a steady state at 7 days*, but is initially checked at 3–4 days. At 3–4 days: if INR <1.5, warfarin dose is increased; if INR ≥2, warfarin dose is decreased. An increase in stroke risk has been reported in the early initiation phase, and while bridging with LMWH is not often performed, it may be justified in patients with a prior stroke.

Four non-vitamin K oral anticoagulants (NOACs) have compared favorably to warfarin in AF, with regards to stroke risk, intracranial hemorrhage risk, and mortality (Table 10.8).[135–138] Their onset of action is quick (2–3 hours), their half-lives are 10–15 hours, and no monitoring is necessary (dabigatran prolongs PTT and rivaroxaban/apixaban/edoxaban prolong PT, which may be used to ensure compliance, not to monitor therapy). The selective inhibition of the clotting cascade and the lack of inhibition of the extrinsic pathway (factor VII) explain the reduction of intracranial hemorrhage with all of these agents. The downside includes the increase of mucosal (GI) bleeding with 3 of these agents. In addition, although approved for GFR 15–30 ml/min, major trials excluded patients with GFR <30 ml/min; therefore, the bleeding risk and the efficacy are unclear in advanced renal failure. Moreover, these drugs should not be used in AF with moderate or severe mitral stenosis or valvular mechanical prosthesis. Dabigatran and apixaban have been studied with mechanical prosthetic valves and are associated with a drastic increase in thromboembolic events (5% at 3 months with dabigatran, 4.3% vs. 1.2% per year with apixaban).[139,140] In fact, an overwhelming activation of the factor VII pathway, after blood contact with tissue factor expressed at the site of tissue or endothelial injury, may generate more thrombin than NOACs can inhibit; warfarin may be more effective, as it blocks factor VII activation, in addition to the intrinsic (factor IX) and common pathways (factor X and thrombin). Rivaroxaban was studied in AF with rheumatic MS and was associated with increased cardiac events vs. warfarin, including death (8% vs. 6.3% per year) and stroke (1.1% vs. 0.7% per year) (INVICTUS trial).[141]

On the other hand, NOACs may be used in moderate/severe valvular disease that is not MS as the landmark trials included moderate/severe MR, AI, AS, TR. Also, landmark trials of apixaban and edoxaban included patients with bioprosthetic valves and suggested their efficacy in this small subgroup.[143] The RIVER trial proved the efficacy of rivaroxaban in AF with mitral bioprosthesis.

Apixaban or dabigatran may be used in cirrhosis Child B, while rivaroxaban should be avoided. NOACs are generally avoided in Child C due to lack of data.[144] Regarding obesity with BMI >40 or weight >120 kg, apixaban and rivaroxaban at standard doses have proven effective. Yet, data are limited for all NOACs in case of BMI >50 or weight >150 kg.[144]

In an analysis of the landmark trials, the switch from a NOAC to warfarin was associated with an early increase in stroke risk, probably because NOAC was interrupted immediately upon warfarin initiation and INR was subtherapeutic for several days or

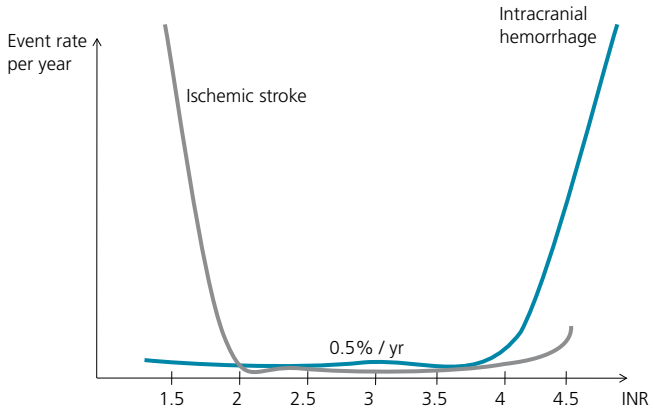

Figure 10.3 Yearly risk of stroke and intracranial hemorrhage with warfarin according to INR. The yearly intracranial hemorrhage risk is reduced from 0.5% per year to ~0.25% with the new anticoagulants. Data from Flaker et al. 2006.[68]

Table 10.8 Non-Vitamin K oral anticoagulants (NOACS, also called DOACs: direct oral anticoagulants) vs. warfarin.

	Dabigatran 150 mg BID RE-LY trial: median age 71.5, $CHADS_2$ score ≥1 (mean ~2.1) Also approved for DVT/PE, but not acutely (>5 days)	**Rivaroxaban 20 mg QD** ROCKET AF: median age 73, $CHADS_2$ score ≥2 (mean 3.5) ***Also approved for DVT/PE, acutely and chronically*** **Must be taken with food**	**Apixaban 5 mg BID** ARISTOTLE: median age 70, $CHADS_2$ score ≥1 (mean ~2.1) ***Also approved for DVT/PE, acutely and chronically***	**Edoxaban 60 mg QD** ENGAGE AF-TIMI 48: median age 72, $CHADS_2$ score ≥2 (mean ~2.8) Also approved for DVT/PE, but not acutely
Mechanism[a]	Thrombin inhibitor	Direct Xa inhibitor	Direct Xa inhibitor	Direct Xa inhibitor
Comparison to warfarin	↓ ischemic stroke ↓ intracranial hemorrhage (~70%) Same overall major bleeding ↓ death (~0.5%/yr) ↑ GI bleeding	Same ischemic stroke ↓ intracranial hemorrhage Same overall major bleeding ↓ death trend ↑ GI bleeding	Same ischemic stroke ↓ intracranial hemorrhage (~50%) ↓ **major bleeding** ↓ death No ↑ GI bleeding	↑ **ischemic stroke if GFR >95 ml/min (excessive drug clearance),** same ischemic stroke if GFR <95 ml/min ↓ intracranial hemorrhage ↓ major bleeding ↓ death trend ↑ GI bleeding
Renal failure	Renal elimination 80% GFR 15–30 → 75 mg BID Avoid if GFR <15	2/3 liver metabolism, 1/3 renal elimination For AF: GFR 15–50: 15 mg QD, and avoid if GFR <15 For DVT/PE therapy: avoid if GFR <30	75% liver metabolism, ~25% renal elimination of unchanged drug (***least affected by renal failure***) Reduce dose to 2.5 mg BID if *two of the following:*[c] creatinine >1.5 mg/dl, age >80, or weight <60 kg May be used in GFR <15 or hemodialysis patients	Renal elimination 50% GFR 50–95: 60 mg QD GFR 15–50: 30 mg QD Avoid if GFR <15 or >95
Antidote	Prothrombin complex may be used, not FFP (the downstream effect of FFP is blocked) Specific antidote: Idarucizumab *60% dialyzable*	Prothrombin complex may be used, not FFP	Prothrombin complex may be used	Prothrombin complex may be used
Notable drug interactions[b]	Not a CYP substrate P-glycoprotein intestinal and renal tubular efflux Dronedarone doubles dabigatran effect → Avoid combination Amiodarone may increase levels but may be used	CYP3A inhibitors Dronedarone, amiodarone, and diltiazem/verapamil raise rivaroxaban levels → better avoid	CYP3A inhibitors Dronedarone, amiodarone, and diltiazem raise apixaban levels → caution, but may be used	Not a CYP substrate P-glycoprotein intestinal and renal tubular efflux

[a]Warfarin inhibits the recycling of inactive, oxidized vitamin K (it eventually depletes active vitamin K rather than antagonizes its effect). Subsequently, it prevents the synthesis of the vitamin K–dependent coagulation factors II (thrombin), VII, IX, and X, and regulatory proteins C and S.
[b]**Rivaroxaban is the worst from a drug-interaction standpoint.** Digoxin does not have any significant interaction with any of these 3 drugs. Specific drug interactions may be more difficult to control with the new agents than with warfarin, where INR allows dose adjustment.
[c]Observational registries have shown that reduced-dose apixaban is associated with increased stroke and mortality risks in comparison with warfarin, including in hemodialysis patients.[142] This is likely the result of an inappropriate dose reduction in patients who do not fully fulfill the criteria, which leads to a significant increase in stroke risk without any bleeding reduction.

weeks.[145] During transition to warfarin, the continuation of the NOAC alongside warfarin for 3 days or until INR is ≥2 may mitigate the increase in stroke risk. When switching from warfarin to NOAC, warfarin is stopped and the NOAC is started when INR is <2 (~2 days).

NOACs have significant drug interactions; notably, increased NOAC drug levels and bleeding with diltiazem, amiodarone, and dronedarone.

Apixaban is likely the safest anticoagulant from a bleeding standpoint, particularly as it is least affected by renal function. In the AVERROES trial of apixaban vs. aspirin in AF (mean $CHADS_2$ = 2), **apixaban was associated with a similar major, minor, and intracranial bleeding risk as aspirin,** with a reduction in mortality and a 3-fold reduction in ischemic stroke.[146]

Appendix 5. Bridging anticoagulation in patients undergoing procedures

Case of warfarin – For patients treated with warfarin, the decision to totally withhold anticoagulation for 5 days before a procedure or to bridge depends on the underlying indication for anticoagulation and the CHA_2DS_2-VA score (ACC and ACCP guidelines):[147,148]

a. Low perioperative risk of thromboembolic events if anticoagulation is held for 5–7 days: AF with CHA_2DS_2-VA score of 0–4, DVT/PE >3 months
b. High perioperative risk: AF with CHA_2DS_2 -VA score of 7–9; recent stroke/TIA (<3 months) and less so, older stroke/TIA; mitral stenosis; mechanical valve; DVT/PE <3 months
c. The remaining patients have an intermediate risk (CHA_2DS_2-VA 5–6)

Based on an average annual risk of stroke of 5% with AF, the risk of stroke during 8 days of anticoagulant interruption should only be 0.1%. However, studies of perioperative interruption of anticoagulation suggest that the risk of arterial thromboembolism in the perioperative period is much higher than mathematically predicted (~0.5–1%). This is likely related to a rebound hypercoagulability that occurs after discontinuation of warfarin, or the procoagulant state of surgery. However, ***BRIDGE trial has not found a benefit of bridging in patients with a mean $CHADS_2$ score of 2.3 treated with warfarin***.[149] Embolic events were similar with or without bridging, even though warfarin was interrupted 5 days before the procedure and INR was subtherapeutic until 5 days after the procedure; major bleeding increased with bridging.[149] Similarly, the PERIOP 2 trial found that postoperative bridging with 4 days of LMWH increased bleeding without any benefit. Therefore, according to the ACC guidelines, ***bridging warfarin with LMWH or IV heparin is reserved for high-risk patients (b)***; in the remaining patients, anticoagulation is interrupted for up to a week without any bridging pre- or post-operatively.

Warfarin is stopped 5 days before the procedure (5 doses). LMWH is started 2.5 days later, after 2 doses of warfarin have been withheld, and is administered until 24 hours before the procedure. For example, for a Monday's surgery (day 0), the last warfarin dose is taken Tuesday evening (day –6), enoxaparin 1 mg/kg SQ BID is given on Friday (day –3), Saturday, and Sunday morning. Warfarin is resumed on the day of surgery, while therapeutic LMWH is resumed 24 hours after a low-bleeding-risk procedure (endoscopy, skin biopsy) or 48–72 hours after a high-bleeding-risk surgery (e.g., gastrointestinal surgery, orthopedic surgery, polyp resection). LMWH is continued for ~5 days, until INR is therapeutic.

For minor dental procedures, skin procedures, cataract surgery, or endoscopy without biopsy, warfarin continuation throughout the procedure is suggested (with the use of prohemostatic local agents in dental procedures).[147,148] Regarding NOAC, one dose may be held the morning of the procedure, i.e., the procedure is timed to the nadir of the NOAC level. Alternatively, *1-day NOAC interruption* or *2-day warfarin interruption (partial interruption)* allows partial reversal of anticoagulation, enough for minor procedures (ACCP guidelines).

Case of NOACs – NOACs are more easily managed perioperatively. They have a half-life of 10–15 hours, not much longer than LMWH, hence switching to LMWH is unjustified. They should be stopped 4 half-lives (~2 days) before major surgery, or 1 day before minor procedures (gastroscopy, colonoscopy without polyp resection). They are resumed 24–72 hours postoperatively, once the bleeding risk is reduced (24 hours after low-bleeding-risk procedures, 24 hours after neuraxial anesthesia, and 48–72 hours after high-bleeding-risk procedures).[147,148] Renal failure particularly affects the elimination of dabigatran, which is held for 4 days if GFR <50, and 5 days if GFR <30. Rivaroxaban and apixaban are less dependent on renal function and may be held for 2 days if GFR >30, and 3 days if GFR 15–30.

Cardiac procedures – *Transfemoral coronary angiography/PCI* is a procedure where NOACs are preferably held 1–2 days preoperatively and restarted 1–2 days postoperatively; warfarin is held ~4 days preoperatively.[147,148,150] Conversely, a *transradial* procedure has a lower bleeding risk, and neither warfarin nor NOAC needs to be held before or after the procedure.[147,148] The procedure is typically performed at the nadir of the last NOAC dose (12–24 hours after last dose) and, alternatively, 1 NOAC dose may be held.

Concerning pacemaker/ICD implantation, BRUISE-CONTROL has shown that continued warfarin with therapeutic INR (up to 3) at the time of the implantation has much less bleeding risk than warfarin interruption with heparin bridging. The BRUISE-CONTROL-2 trial has shown that continuation of NOAC throughout the procedure does not increase pocket hematoma compared to NOAC interruption; however, many operators prefer to withhold NOAC for 1–2 days before and after the implant. For *AF ablation*, VENTURE-AF and RE-CIRCUIT trials have shown that uninterrupted NOAC throughout the procedure is as safe or safer than uninterrupted warfarin.

Appendix 6. Management of elevated INR values and active bleeding

In the absence of bleeding (ACCP guidelines)[151]

- INR 4.5–10: Withhold warfarin; it takes ~2.5 days for INR to decline to <4. Grossly, the anticoagulant effect declines by ~50% every 2 days (half-life of warfarin being ~42 hours).
- INR >10: Administer oral vitamin K. The dose of vitamin K is generally a low oral dose of 1–2.5 mg, which allows a fast INR decline (~1 day). This dose may also be administered to patients with INR 4.5–10 when warranted for a procedure. Subcutaneous vitamin K is less well absorbed and should be avoided.

In case of major bleeding

For any INR elevation, rapid reversal of anticoagulation should be achieved with the use of fresh frozen plasma, or, preferably, prothrombin complex concentrate (25–50 units/Kg, depending on whether INR is >4 or <4). The latter is a concentrate of the *non-activated* factors that are reduced by warfarin (IX, X, II ± VII) at a concentration 25 times higher than the normal plasma, presented in a small volume that is swiftly administered and mixed with heparin to prevent hypercoagulation.

The effects of fresh frozen plasma and prothrombotic complex are short-lived (8 and 12 hours, respectively), and thus vitamin K administration is necessary for a sustained reversal of anticoagulation. A high dose of vitamin K is generally recommended (10 mg orally, or 5–10 mg by slow IV infusion) and is effective in normalizing the INR by 24 hours, faster than the small dose. The high dose is better avoided

in patients with metallic valves, as it may lead to a hypercoagulable state, but both ACC and ESC valve guidelines recommend the high dose in metallic-valve patients with uncontrollable bleeding, besides prothrombin complex concentrates.

In the case of life-threatening bleeding with NOACs, use prothrombin complex concentrates (25–50 units/kg) (Table 10.8).

Appendix 7. Left atrial appendage surgical and percutaneous closure

Surgical closure of the left atrial appendage (ligation, stapling, or excision) is considered in AF patients undergoing valvular surgery or CABG as adjunct to anticoagulation, not a replacement for it (class I).[2] The large LAOS III trial showed that closure reduces embolic events vs. no closure (4.8% vs. 7% at 4 years), but most patients continued anticoagulation, and occlusion was not a replacement for anticoagulation.[152] Ligation or stapling of the appendage, or even excision, is incomplete in up to 60% of patients, leaving a residual stump or flow on TEE, hence the residual stroke risk (incomplete appendage ligation may paradoxically increase clot formation).[153] Only a large STS registry analysis suggested that surgical LAA closure reduces thromboembolic events in a population that mostly did not receive anticoagulation.[154]

Another alternative to chronic anticoagulation is percutaneous closure of the LA appendage (e.g., Watchman or Amulet device), which was assessed in 2 landmark trials (PROTECT AF and PREVAIL).[155,156] Compared to warfarin, **Watchman is associated with more embolic strokes and less hemorrhagic strokes**, resulting in a similar all-cause stroke risk; and less major hemorrhage and cardiovascular mortality. Caveats: early procedural hazard (tamponade), short-term requirement for warfarin or NOAC + aspirin (6 weeks). At 6 weeks, if TEE rules out device thrombosis and peri-device leak >5 mm, aspirin + warfarin is switched to aspirin + clopidogrel for 4.5 months, then long-term aspirin only (PROTECT AF protocol). **It is noteworthy that 10% of thrombi form in the LA rather than the appendage** (more so in patients with HF or MS), which explains the higher embolic stroke risk vs. warfarin. In light of the safety of NOACs, the role of Watchman device is limited;[2] **it may be used in patients with increased long-term bleeding risk but not those with contraindication to anticoagulation,** as a high-risk antithrombotic regimen is required for 6 months after implantation (class IIa ACC, class IIb ESC). ESC guidelines allow foregoing the 6-week period of anticoagulation in patients receiving Watchman who have high bleeding risk, and in patients receiving Amulet, but 6 months of DAPT is still required.

Specific complications of LA appendage closure devices: Thrombus may form over the device in ~3% of the cases. Residual leaks around the closure device are common (~25% at 6 weeks and 1 year) and increase the stroke risk. Most leaks are small ≤5 mm, but even small leaks are associated with a small increase in stroke risk.[157] TEE or CTA is done at 6 weeks and 6 and 12 months: anticoagulation is recommended for leaks >5 mm as per PROTECT AF and PREVAIL protocols.

2 recent trials suggest LAA occluders (LAAO) are inferior to NOACs. (1) CLOSURE-AF: high-risk patients (CHA_2DS_2-VA 5) had higher mortality and bleeding with LAAO, driven by periprocedural risk; (2) CHAMPION-AF: moderate-risk patients had more ischemic strokes and similar total bleeding with LAAO, with 4.8% device thrombosis.

Appendix 8. A common situation: AF and symptomatic pauses or bradycardia

- Some patients have the "tachy–brady syndrome," in which a fast-rate paroxysmal AF alternates with sinus bradycardia. Sinus bradycardia may be worsened or triggered by the rate-controlling agents used to slow the paroxysms of AF. This mainly occurs in patients with "off-and-on" AF, in which the therapy for the "on" episodes is harmful for the "off" sinus periods. ***Particularly risky is the transition from AF to sinus rhythm: the overdrive-suppressed sinus node takes some time to "wake up,"*** leading to a long pause, and possibly syncope, at the junction of AF and sinus rhythm (Figure 10.4). Those patients are easier to manage if they persist in AF, allowing the use of AV blocking agents; otherwise, rhythm control must be attempted to prevent off/on AF and pauses. Since all antiarrhythmic drugs affect the sinus node (least so dofetilide), the main option is AF ablation. If rhythm control fails, place a permanent pacemaker and keep administering the rate-controlling agents.
- When AF becomes slow and regular, complete AV block with a junctional escape rhythm is diagnosed (usually 40–60 bpm). Even if asymptomatic, it dictates withdrawing the rate-controlling drugs followed by pacemaker placement if complete AV block persists. Also, AF pauses >5 seconds during wakefulness often dictate pacemaker placement even if asymptomatic, after withdrawing drugs (class I indication in older ACC guidelines).

Figure 10.4 Long sinus pause at the point of transition from AF (*top row*) to sinus rhythm (*bottom row*). This transition pause is the most common cause of syncope in patients with tachy-brady syndrome.

DC cardioversion in patients with a slow ventricular response

Patients with a slow ventricular response despite no rate-controlling drug probably have AV nodal disease and, along with it, sinus nodal disease. In these patients, AF is masking and "curing" their sinus node disease and bradyarrhythmia. In addition, AF may overdrive suppress the sinus node, which will take some time to "wake up" after AF cardioversion. They may develop sinus arrest after DC cardioversion, as they do after spontaneous cardioversion. Be ready to administer atropine or transcutaneous pacing if needed. Atropine may also be administered prophylactically before cardioversion.

Appendix 9. AF occurring post-cardiac surgery and AF related to acute transient triggers (trigger-induced AF)

AF occurs postoperatively in 20–40% of patients after **cardiac surgery** (more so with valvular surgery, older age, HF, history of AF). It usually occurs between days 1 and 5 and is related to catecholamines and to the pericardial and generalized inflammation. It resolves spontaneously within 2 days in 80% of the patients, and within 6–8 weeks in >95% of the patients. Unless unstable, DCCV is not usually needed as AF will convert spontaneously.

AF should be prevented with β-blockers preoperatively (= first choice) or amiodarone if β-blockers are contraindicated (= second choice; start amiodarone ~600 mg/day 1 week preoperatively and continue it at 200–600 mg/day for the duration of hospital stay). The combination of β-blockers and amiodarone may also be used and may be indicated in the highest-risk patients (i.e., history of AF or mitral valve surgery).[158]

When AF occurs, it is treated similarly to any acute AF. For rate control, *β-blockers* are primarily used; *amiodarone* may also be used for rate control in case of borderline blood pressure or acute HF (amiodarone may also accelerate AF conversion). DC cardioversion has a limited role in postoperative AF, as AF will likely recur early on (~45%) then convert spontaneously regardless of these measures. Yet, if needed, cardioversion may be safely performed with a low risk of stroke (0% in one series);[45] and amiodarone may be given for a brief period (e.g., 1 week) to reduce AF recurrences. **Prolonged amiodarone therapy is not warranted:** in one randomized trial of rate vs. rhythm control for postoperative AF, 60 days of amiodarone did not improve the already high rate of sinus rhythm at discharge and at 60 days (~95%), despite the study's higher-risk population with a high proportion of valvular surgery (57%).[159]

A large Danish registry showed that the stroke risk in post-CABG AF is significantly less than in nonsurgical AF (1.8%/yr vs. 3%, matched analysis) and is similar to post-CABG no AF. Most postoperative AF patients were not treated with anticoagulation and when used, anticoagulation did not reduce their mortality.[160] Moreover, a large American registry showed that anticoagulation at discharge was associated with a 4.5× higher risk of readmissions for major bleeding and no reduction in stroke.[161] A large meta-analysis of postoperative AF cohort studies, including the Danish registries, did not show any stroke reduction with oral anticoagulants.[162] Yet one Danish registry found that post-left valvular surgery AF was associated with a stroke risk similar to nonsurgical AF; mortality and stroke were reduced with anticoagulation.[160] Thus, anticoagulation may be justified for post-valvular surgery AF, or AF lasting more than 48 hours, and may potentially be limited to 60 days in the absence of recurrence, as was recommended in the CTSN trial (57% valvular surgery) and ACC guidelines.[159]

Trigger-induced AF – AF occurring in relation to **acute triggers** (sepsis, postoperative state, acute lung disease, pericarditis) will likely convert once these issues are treated. Acutely, it is treated like any newly diagnosed AF, with rate control, knowing that a rate of 110–120 bpm may be appropriate in these critical situations. β-Blockers are best in these high catecholamine states; but amiodarone, Landiolol, and digoxin may be the only drugs tolerated in patients with borderline or low BP. DC cardioversion may be performed if the rate is >150 bpm and the patient is unstable. Unfortunately, DC cardioversion may not be effective in patients with acute, unresolved triggers; amiodarone or landiolol may be their only therapeutic option.

One analysis of *AF triggered by sepsis, ACS, or acute pulmonary illness (pneumonia, COPD exacerbation)* showed that long-term anticoagulation was not beneficial and did not reduce long-term stroke.[163] In another analysis of AF triggered by sepsis, acute anticoagulation was not beneficial. Hence ACC does not favor anticoagulation for sepsis-induced AF (class IIb).[164] Regarding *AF triggered by surgery*, multiple studies suggest that the stroke risk associated with postoperative AF is higher with non-cardiac surgery vs. cardiac surgery and seems similar to spontaneous AF;[165] yet, *anticoagulation and antiarrhythmic therapy may not be warranted failing AF recurrence, severe underlying myocardial/atrial disease or dilatation, or persistence of the trigger* (e.g., chronic severe lung disease). Regarding AF in the setting of *hyperthyroidism*, ACC recommends anticoagulation until thyroid function returns to normal and sinus rhythm is maintained. In general, once in AF, sinus rhythm is difficult to restore until thyroid function normalizes. AF may spontaneously convert within 3 weeks of the eurthyroid state but often requires cardioversion.[166]

For both post-cardiac surgery AF and AF related to transient triggers, the focus should be on long-term ECG monitoring rather than systematic anticoagulation. This is done using self-recorded daily ECGs (via smartwatch or KardiaMobile) or prolonged rhythm monitors (30 days or more) to detect prolonged AF recurrences.

On the other hand, AF that occurs during STEMI or ACS is not simply a transient form of AF as the underlying condition (CAD) is chronic and ischemia may be recurrent. In this context, AF is probably best managed with long-term anticoagulation. Outside the acute triggers discussed above, AF is a recurrent and progressive disorder, even if recurrences seem rare in a particular patient.

Appendix 10. Brief asymptomatic runs of AF on device interrogation and association with stroke. Role of rhythm monitoring after cryptogenic stroke

In ASSERT study, which analyzed intracardiac electrograms of patients older than 65 years receiving a pacemaker, subclinical atrial tachyarrhythmias lasting >6 minutes were associated with a 2.5-fold increased stroke risk and an absolute stroke risk of 1.7% per year, albeit lower than the risk associated with clinical AF.[167] Those subclinical episodes were frequent, seen in ~34% of this population during 2.5 years of monitoring. However, ***further analysis of ASSERT showed that only AF lasting >24 hours was associated with an increased stroke risk,*** as high as the risk associated with clinical AF.[168] Similarly, another study, TRENDS, suggested that AF lasting >5.5 hours, rather than minutes, correlates with the stroke risk.[169] ***In addition, among ASSERT and TRENDS patients with subclinical AF and stroke, only 15% had their AF in the month preceding their stroke.***[170,171] This further argues against a causal relationship between brief AF and stroke.

Along those lines, ASSERT II study implanted loop recorders in patients >65 years old without pacemakers and without baseline AF, but with elevated $CHADS_2$ score and LA enlargement or high BNP; ~ half of the patients had a prior history of stroke/TIA. ASSERT II showed brief AF to be equally common in patients with and without stroke, further arguing against a causal relationship.[172] The incidence of any brief AF was ~34% per year of monitoring, falling to 7.1% per year for AF >6 hours and only 2.7% per year for AF >24 hours.

One-year rhythm monitoring using an implantable loop recorder in cryptogenic stroke has shown a high incidence of brief asymptomatic AF.[173] Yet again, a causal association with the index stroke is questionable. Prolonged monitoring is still warranted in cryptogenic stroke, with a focus on prolonged AF episodes. The median time to AF detection was 84 days in 1 study, and thus external 30-day event monitoring may not be enough.[174]

A subgroup of patients with cryptogenic stroke has signs of embolic stroke on imaging (cortical location, multiple infarcts), the so-called ***"embolic stroke of undetermined source (ESUS)."*** One may be inclined to attribute this stroke to covert AF, yet AF is the cause in <30% of the cases, and brief AF < 5.5–24 hours may just be coincidental, as suggested by the lack of temporal relationship in ASSERT and TRENDS. Other *thromboembolic sources* of stroke may be considered (LV or LA cardiomyopathy, cancer), but also *athero-embolic sources*: carotid and intracerebral atheromas (even if <50% stenotic) and aortic arch atheroma, which are not affected by anticoagulation.[175] In fact, studies of ESUS have found a high prevalence (>60%) of nonstenotic ipsilateral carotid plaque or intracranial complex plaque (positively remodeled, lipid rich, or ruptured), more prevalent than contralateral plaques. In 2 trials of ESUS, NOACs did not reduce stroke recurrence compared with aspirin (NAVIGATE-ESUS and RESPECT-ESUS).[176,177] In another trial, ARCADIA, which recruited ESUS with no AF but with atrial cardiopathy (↑ P wave, ↑ BNP, or LA dilatation), apixaban did not reduce stroke recurrence. In all 3 trials, AF was mostly ruled out by a brief 24- to 48-hr monitor; thus, some patients likely had subclinical AF, and despite that, NOACs were not beneficial and the stroke rate remained 4–5% per year.

Lacunar stroke, defined as small, subcortical stroke <2 cm in the white matter, basal ganglia or pons, is generally (>85%) due to small vessel disease, not embolism,[178] and does not benefit from anticoagulation. It may coexist with AF in older patients, but is not usually directly caused by AF (<10–15%).

Most often, anticoagulation is not warranted for subclinical AF < 24 hours detected on implanted electronic devices, based on the following 3 trials of subclinical AF anticoagulation:

- *LOOP trial* randomized individuals >70 years old with a stroke risk factor, including prior stroke in 17%, to an implantable loop monitor vs. usual care, followed by anticoagulation for any detected AF > 6 minutes. After a follow-up of ~5 years, loop monitoring detected AF in 32% of the individuals (vs. 12% in the usual care); this resulted in more anticoagulation, yet no stroke reduction compared to usual care, even in patients with prior stroke.[179] Of note, AF burden regressed over time in >50% of the cases, with full resolution in 20%.
- *NOAH-AFNET 6 trial* randomized patients >65 years who already had an implanted electronic device, mainly pacemaker, and in whom high atrial-rate episodes >6 minutes were detected, to NOAC (edoxaban) vs. placebo. The median duration of atrial arrhythmia was 2.8 hours (0.8–9.5 hours), 10% of patients had a prior stroke, and median CHA_2DS_2-VA score was 4 (3–5). NOAC did not reduce stroke risk (~1% per year) and was rather harmful, increasing major bleeding by 1.1% per year.[180]
- *ARTISIA trial* randomized patients who already had an implanted electronic device, mainly pacemaker, and in whom AF episodes 6 minutes to 24 hours were detected, to NOAC (apixaban) vs. aspirin. Mean age was 77, mean CHA_2DS_2-VA was 4, 28% had prior stroke, median AF duration per episode was 1.5 hours (0.2–5), and the number of AF episodes was mostly 1–5 in the last 6 months (17% had 6–50 episodes).[181] Although apixaban reduced stroke risk, the following major caveats argue against its routine use for subclinical AF: (i) the yearly stroke risk was low even without anticoagulation (1.24% per year), much lower than in clinical AF, and was only mildly reduced by apixaban by 0.46% per year. (ii) Major bleeding dramatically increased with apixaban by 0.8% per year (1.7% vs. 0.9%).

In summary, anticoagulation seems warranted for subclinical AF lasting >24 hours (ACC), but is generally not warranted for subclinical AF lasting <24 hours (especially <6 hours). However, AF is a progressive process, subclinical AF progressing to clinical AF at a rate of 6–9% per year, hence smart-device monitoring is recommended to detect the emergence of AF >24 hours or frequent AF >6 hours: (i) continuous heart rate monitoring using smartwatch irregular rate algorithm, and (ii) daily or twice-daily self-recording of ECGs.

Appendix 11. Value of smartwatches and KardiaMobile in AF self-monitoring: AF detection and follow-up

KardiaMobile device allows single-lead 30-second ECG recording between right and left fingers. On the other hand, **smartwatches** (Apple and Fitbit) provide 2 valuable techniques to detect AF:

1. Similarly to KardiaMobile, they allow 30-second recordings of ECG lead I between the electrode at the digital crown and the one at the back of the watch.

2. Apple Watch and Fitbit use PPG (photoplethysmography) to monitor the pulse rate and irregularities, and use algorithms to detect irregularities while the patient is stationary.[182,183] Apple algorithm analyzes 1 minute of pulse (called tachogram) every 2 hours while resting then every 15 minutes if irregularity is found; Fitbit continuously analyzes 5 minutes of pulse in an overlapping fashion. If multiple tachograms (5/6 with Apple, 11 with Fitbit) show irregularities, AF alert is sent, at which point the patient should self-record an ECG using the smartwatch to document AF. The algorithm has 84–98% specificity for AF (>84% of patients with AF notification during simultaneous ECG patch monitoring had concurrent AF on the ECG: 84% for Apple Watch, 98% for Fitbit). The sensitivity is lower (~70%) compared to implantable devices, because the algorithm only operates at rest and only seeks AF lasting >30 minutes (Fitbit) to 1 hour (Apple), and will thus miss short AF episodes that are, anyway, less significant clinically. Also, at baseline, Apple checks the PPG only once every 2 hours at rest (vs. continuous at rest with Fitbit). Although possibly missing short AF episodes, the algorithms are highly valuable for detecting clinically relevant spells and quantifying AF burden.

Of note, the watch also sends an alert for a pulse >120 beats/min while resting, but this notification is separate from the irregular pulse (AF) notification and does not imply AF unless the AF algorithm is triggered as well.

Role of smartwatches in AF detection (via daily self-recording of ECG + AF pulse algorithm):

- Smartwatches may be valuable in the general population older than 65 years or with AF risk factors to detect asymptomatic AF. However, as explained under subclinical AF, brief AF episodes <24 hours do not automatically warrant anticoagulation. Rather, these warrant monitoring for longer AF spells and **performing daily or twice-daily routine self-ECG recording (plus ECG recording in case of palpitations). AF lasting >24 hours will inherently be caught on a daily self-recorded ECG**; the lack of AF detection on self-recorded daily ECGs implies that AF burden is low and that spells, if they occur, are brief <24 hours and likely infrequent, with no clear benefit from anticoagulation.
- Smartwatches are valuable in patients who had transient AF in the setting of a major trigger (e.g., cardiac surgery or major illness), in whom chronic anticoagulation is not deemed necessary but becomes necessary if prolonged spontaneous AF spells are detected.
- In patients with known rhythm-controlled AF, AF self-monitoring allows us to gauge the **residual AF burden** and to distinguish AF from PACs or other rhythms during palpitations. A persistently high AF burden may warrant a change in antiarrhythmic strategy.
- In patients who underwent AF ablation and stopped anticoagulation 3 months later, the detection of AF by smartwatches dictates reinitiation of anticoagulation.

Appendix 12. Association of AF with cognitive decline/dementia

AF is associated with a 40% higher risk of dementia (vascular dementia and Alzheimer's), independent of clinical stroke and comorbid conditions. The link may be the 2.6-fold higher prevalence of silent cerebral infarctions in AF (including cortical or small deep white matter infarcts).[184,185] AF may cause these silent infarcts via an embolic process, but also via a hypoperfusion mechanism: beat-to-beat flow variability and pauses reduce cardiac output in AF patients, hence a particularly higher risk of dementia in AF patients with HF. Hypoperfusion may accelerate beta-amyloid deposits in the brain, an underlying mechanism of Alzheimer.

Several registries showed a reduction in dementia in AF patients receiving anticoagulation (vs. no anticoagulation).[186] This is particularly true with NOAC rather than warfarin according to some studies: chronic microbleeds that occur with warfarin may cause dementia and counteract any benefit of anticoagulation? In fact, INR time outside the therapeutic range correlated with more dementia.[187] Regardless, silent cerebral infarcts continue to occur in anticoagulated AF patients, and one large registry showed a reduction of dementia in anticoagulated AF patients treated with rhythm vs. rate control.[188,189] Two other registries showed a reduction of dementia with catheter ablation vs. pharmacological rhythm control or rate control.[189,190] This further suggests that alterations in cardiac output and cerebral flow induced by AF may underlie the mechanism of dementia.

QUESTIONS AND ANSWERS

Question 1. A 54-year-old man presents with shock (BP 75/50, obtunded). He is found to have atrial fibrillation at a rate of ~120 bpm. What is the next step?

Question 2. A 54-year-old man, known to have HF with LVEF of 25%, presents with decompensated HF. He is found to have AF at a rate of 125 bpm (newly diagnosed AF). How should AF be managed?

Question 3. A 72-year-old man with a history of hypertension is seen in the outpatient setting. He is asymptomatic. An irregular heart rhythm is found on exam; an ECG shows AF at a rate of ~110 bpm. What is the next step?

Question 4. A 69-year-old man is diagnosed with frequent recurrences of symptomatic paroxysmal AF. He has HTN and diabetes, and drinks alcohol daily. He has a history of CAD and underwent stent placement 3 years previously. He has CKD (creatinine 1.4 mg/dl, GFR 48 ml/min/1.73 m^2). Echo shows normal EF, LA enlargement (4.3 cm), and mild LVH (septum 12 mm). He has a history of bleeding peptic ulcer 2 months ago, requiring transfusion. His baseline heart rate is 72 bpm. Diltiazem (240 mg QD) did not relieve his symptoms (baseline heart rate is now 58 bpm). What is the next option?

A. Add flecainide or propafenone
B. Add dronedarone
C. Add amiodarone
D. Add sotalol
E. AF ablation

Question 5. Should the patient in Question 4 receive anticoagulation? He is already on aspirin 81 mg for CAD.

A. HAS-BLED score is 5. Anticoagulation should be avoided. Continue aspirin
B. CHA_2DS_2-VA score is 4. Anticoagulation should be started despite bleeding risk
C. Use dual antiplatelet therapy instead of anticoagulation to mitigate the bleeding risk
D. Percutaneous LA appendage closure

Question 6. The patient in Question 4 is placed on dronedarone. Which anticoagulant should he receive?

A. Dabigatran
B. Rivaroxaban
C. Apixaban
D. Warfarin

Question 7. A 62-year-old man presents with palpitations that started several days ago. He has a history of HTN but no significant cardiac history. BP is currently 115/65. He is mildly dyspneic and has bibasilar crackles. An admission ECG shows AF with a ventricular

rate of 140 bpm. A bedside echo shows LVEF of 35%. LA is mildly enlarged with LA size of 4 cm. Besides intravenous furosemide, what is the next step?
A. Urgent DC cardioversion
B. IV metoprolol
C. IV diltiazem
D. IV amiodarone or IV digoxin

Question 8. A 62-year-old man presents with palpitations that started several hours ago. He has a history of HTN but no significant cardiac history. BP is currently 115/65. He is mildly dyspneic and has bibasilar crackles. An admission ECG shows AF with a ventricular rate of 140 bpm. A bedside echo shows normal LV systolic function with LVH. LA is mildly enlarged with LA size of 4 cm. What is the next step?
A. Urgent DC cardioversion
B. IV metoprolol or IV diltiazem
C. IV amiodarone or IV digoxin

Question 9. Concerning the patient in Question 8, the AF rate is slowed to 80 bpm, and he becomes asymptomatic. Should DC cardioversion be considered?
A. No. Rate-control strategy is preferred
B. Yes. TEE with DC cardioversion is not urgent but may be performed the same day if possible
C. Yes. TEE with DC cardioversion should be considered at 24 hours

Question 10. A 78-year-old man had a pacemaker implanted 2 years ago for AV block. He has a well-controlled HTN and no prior history of HF or stroke. The last pacemaker interrogation shows 3 episodes of asymptomatic AF that lasted 1–2 hours each. What is the next step?
A. Amiodarone
B. Dronedarone or sotalol
C. No need for antiarrhythmic. No need for anticoagulation, as each AF episode lasted <24 hours
D. Anticoagulation, preferably with apixaban
E. Anticoagulation with warfarin

Question 11. Which of the following drugs is most effective for acute AF cardioversion, as assessed at 8 hours?
A. Oral flecainide load
B. IV amiodarone load
C. IV ibutilide
D. Oral dofetilide

Question 12. A 55-year-old man is morbidly obese (BMI 44), has HTN, HFpEF, and a history of AF 1 year ago that was treated with DC cardioversion and sotalol. He presents with palpitations and dyspnea, and is found to have AF, with a ventricular rate of 135 bpm and mild HF. He is rate-controlled with metoprolol and diltiazem. Echo shows LVEF of 60%, LVH (septum 14 mm), LA enlargement (4.7 cm) and mild pulmonary hypertension. Which statement is *incorrect*?
A. The likelihood of successful rhythm control is low. Despite AF-related initial symptoms, allowing AF to persist and adopting a rate-control strategy is appropriate
B. For a rhythm-control strategy to be successful, he has to lose >10% of his weight
C. Obesity and severe LA enlargement are the major predictors of AF recurrence in his case
D. AF ablation has a long-term success rate of 70% in this case
E. If rhythm control is adopted, amiodarone is the only antiarrhythmic drug that can be used

Question 13. If, in the patient of Question 12, rate control cannot be achieved and rhythm control fails (even with ablation), what is the next and definite treatment strategy for AF?

Question 14. Concerning AF pathophysiology, which of the following is *false*?
A. The most common histological finding in AF is LA fibrosis, more than LA dilatation
B. In AF, the atrial refractory period is heterogeneous
C. The electrical remodeling of AF is characterized by progressive lengthening of the atrial refractory period
D. The anatomic remodeling of AF is characterized by progressive LA dilatation

Answer 1. It is likely that AF is secondary to the shock state rather than causing it, especially when heart rate is <150 bpm (or <130 bpm in systolic HF). Thus, AF may not need to be immediately cardioverted, and one should look for other causes of shock (fever, sources of infection, trauma, bleeding, large MI). In the case of AF + shock, always consider other potential causes of shock before attributing it to AF.

Answer 2. In acute HF, the immediate cardioversion of AF does not usually lead to an immediate improvement, as the contribution of the atrial kick to the cardiac output is minute in decompensated states. Besides, the cardioversion is unlikely to be successful or sustained in this decompensated state. It is only warranted when the heart rate is >130 bpm and the acute HF is severe (shock, massive pulmonary edema). In this patient, HF should be treated with diuresis and vasodilators, and it is expected that AF slows down with HF therapy, as this reduces the atrial stretch; in fact, AF may convert with HF therapy. *Digoxin*, and if necessary, *amiodarone*, may be used to further improve the heart rate to <110 bpm acutely. Later on, at the stable phase, appropriate rate control with β-blockers and digoxin should be instituted to achieve a heart rate <100 bpm. For AF patients in a controlled hospital setting, β-blockers may be titrated slightly faster than usually allowed with HF. A rhythm-control strategy with elective DC cardioversion in the inpatient setting is often selected, particularly when AF is thought to be a major trigger to the current HF decompensation. AF catheter ablation should eventually be considered as first-line treatment in HF.

Answer 3. Approximately 21% of patients with a newly diagnosed AF are asymptomatic. AF is diagnosed incidentally on routine pulse exam. Since AF is asymptomatic, there is no indication for DCCV/rhythm control. The rate should be controlled to <100–110 bpm using a β-blocker or diltiazem as first-line therapy. Since the patient's CHA_2DS_2-VA score is 2, anticoagulation with warfarin or a NOAC is warranted.

Answer 4. B. The patient requires rhythm control considering the intolerable symptoms during AF recurrences. Class Ic drugs should be avoided in a patient with CAD. In a patient with CAD, dronedarone and sotalol are the first options. Amiodarone is the second option. Since he has CKD, dronedarone is preferred over sotalol. From the HTN/LVH standpoint, LVH is mild and so any of the drugs B–D are acceptable. While initiating dronedarone, diltiazem dose needs to be reduced, to avoid excessive sinus rate slowing; also, diltiazem raises dronedarone levels. AF ablation is considered after failure of drug therapy.

Answer 5. B. Patients with a high HAS-BLED score usually have a high CHA_2DS_2-VA score and a high stroke risk, the absolute stroke risk increasing more sharply than the bleeding risk. Thus, these patients derive an even greater net clinical benefit from anticoagulation than patients with a low HAS-BLED score. A high HAS-BLED score warrants the correction of bleeding risk factors rather than the exclusion of anticoagulation. The patient has 5 factors of the HAS-BLED score, 3 of which can be addressed (prior bleed, HTN, alcohol and antiplatelet use), and 1 of which, renal dysfunction, can be stabilized. To mitigate bleeding risk, ensure the following: proton pump inhibitor (PPI) therapy for peptic ulcer disease, *H. pylori* testing and treatment, hemoglobin stability, alcohol cessation, and HTN control. For renal dysfunction, ensure: proper hydration, avoid NSAIDs and unnecessary diuretic therapy. Beyond 1 year after stenting, aspirin may be discontinued if anticoagulation is used. LA appendage closure mandates high-level antithrombotic regimen for 6 months after closure; hence the short-term bleeding risk is not attenuated.

Answer 6. C. *From a drug interaction standpoint* – Dabigatran should be avoided in a patient receiving dronedarone. Rivaroxaban should be avoided in a patient receiving dronedarone or diltiazem. Apixaban has fewer interactions with dronedarone. *From a CKD standpoint* – Of the three NOACs, dabigatran is the most affected by renal dysfunction, apixaban is the least affected. Apixaban is favored. *From the standpoint of bleeding risk* – In this patient, who has a high bleeding risk, all of the three new oral anticoagulants have the advantage of a lower intracranial bleed than warfarin. However, dabigatran and rivaroxaban are associated with a higher gastric bleeding than warfarin and do not reduce the overall major bleeding risk, whereas apixaban does.

Answer 7. D. The patient has mild HF, which is likely triggered by AF. Unless the patient has severe HF with AF rate >130 bpm, urgent DC cardioversion is not indicated and is unlikely to be immediately beneficial or successful. Rate control is performed, followed by elective DC cardioversion. In HF with reduced EF, IV diltiazem is contraindicated, and IV metoprolol should be avoided acutely. IV digoxin or amiodarone may be used for rate control. Metoprolol may be used once HF has improved with diuresis. ***TEE and cardioversion are performed, but not urgently; they are delayed until the patient gets properly diuresed, to improve the efficacy and the sustainability of the cardioversion.***

Answer 8. B. As opposed to Question 7, this patient has HFpEF. Besides diuresis, diltiazem or metoprolol is appropriate for rate control. AF likely triggered HF decompensation in a patient with underlying LVH and diastolic dysfunction. Yet, unless the patient is in extremis and AF rate is >130 bpm (or >150 bpm outside HF), urgent DC cardioversion is unlikely to be immediately beneficial or successful; the benefit is rather a long-term benefit.

Answer 9. C. The patient has new-onset AF that was severely symptomatic. This favors rhythm control, although he is currently asymptomatic (he will likely be symptomatic when stressed). The young age <65 and HF (including HFpEF) favor rhythm control as well. The LA is not severely enlarged and AF is recent: this predicts the sustainability of a rhythm-control strategy. Since the patient has a 50–60% probability of spontaneous cardioversion at 24 hours, it is best to wait 24 hours before proceeding with DC cardioversion.

Answer 10. C. Data from TRENDS and ASSERT suggest that subclinical AF detected on device interrogation needs to last >5.5–24 hours to be associated with a stroke risk. For AF <5.5 hours, anticoagulation has a questionable value, and there is no clear temporal relationship between this AF and stroke. Pooled data from ARTISIA and NOAH AFNET-6 trials suggest that the benefit of NOACs is, at best, marginal in subclinical AF <24 hours.

Answer 11. A. Oral flecainide load is ~70% effective in cardioverting AF at 6–8 hours. IV ibutlide has a faster effect (~1 hour) but a 30–50% efficacy. IV amiodarone has a limited and delayed (≥24 hours) acute cardioverting effect. Dofetilide is not generally effective for acute cardioversion. Another effective alternative is IV procainamide (~50–60% cardioversion at 1 hour).

Answer 12. D. The extreme obesity is a major predictor of long-term failure of any form of rhythm control, whether drugs or AF ablation. The LA enlargement, the underlying heart disease (LVH, HF), and the prior AF episode further predict failure. Without weight loss, the long-term success of AF ablation is <40% in this patient (ARREST-AF trial). If rate control is difficult to achieve, rhythm control may be considered despite its low likelihood of success.

Answer 13. AV nodal ablation with ventricular pacing, including biventricular pacing for HF with any EF, as per APAF-CRT trial.

Answer 14. C. Atrial refractory period shortens in AF.

85. Jameel HA, Gierula J, Paton MF, et al. Chronotropic incompetence does not limit exercise capacity in chronic heart failure. J Am Coll Cardiol 2016; 67(16): 1885–1896. *TREPPE trial: Patients with HF (mild to severe EF) and sinus rhythm or AF who have PM or CRT underwent exercise testing with no rate response (allowing them to raise their rate on their own, as they are not PM dependent) or with rate response. The no-rate-response group had lower peak heart rate (100s-110) but no difference in pVO2 or exercise time*.
86. Gierula J, Paton WF, Lowry JE, et al. Rate-response programming tailored to the force frequency relationship improves exercise tolerance in chronic heart failure. JACC Heart Fail 2018;6:105–113 (Bowditch Revisited trial). *Patients with LVEF < 50% (32 ± 11) and pacemaker were paced at various rates, and contractility assessed at various rates (contractility assessed by the ratio SBP/LVESVI). The heart rate with peak contractility was 103 ± 22 in HF vs. 126 ± 15 in matched age control patients with normal EF and no HF (age 71). Importantly, patients of this trial underwent exercise testing: programming the rate response to a lower peak (as calculated in the prior phase), rather than a high peak of ~140 led to 50 seconds more exercise time and higher pVO2. 28% of patients had AF, and this did not seem to affect the heart rate of peak contractility*.

11 Atrial Flutter and Atrial Tachycardia

I. Atrial flutter 374
II. Focal atrial tachycardia 377
III. Multifocal atrial tachycardia (MAT) (or chaotic atrial tachycardia) 380
IV. Ectopic atrial rhythm 381
Questions and answers 381

I. Atrial flutter

A. Definition

Typical atrial flutter (Aflutter) is characterized by a macroreentrant RA circuit that runs in a frontal, right-to-left plane, the base of which is a narrow isthmus bordered by the IVC and crista terminalis posteriorly and the tricuspid annulus anteriorly (cavotricuspid isthmus, CTI) (see figures in Chapter 15). The crista terminalis, a fibrous band that separates the anterior and posterior parts of the RA, constitutes the electrical barrier in front of which the Aflutter circuit is sustained.[1]

The typical Aflutter circuit is counterclockwise in >90% of the cases, and clockwise in the remaining cases, where it is also called reverse typical Aflutter (Figure 11.1).

Atypical Aflutter is characterized by a macroreentrant circuit not involving the isthmus. It may involve the left atrium, a right atrial scar, or less commonly a left atrial scar from a prior cardiac surgery (e.g., congenital heart disease surgery, atrial cannulation or incision), or a left atrial scar from pulmonary vein isolation. In these cases, the scar serves as the barrier that allows Aflutter to become sustained. The circuit is smaller than the isthmus-dependent Aflutter, which means the reentrant loop is crossed more quickly, leading to a faster flutter rate and smaller flutter waves on the ECG. Note that CTI-dependent flutter is also common in these patients, and both CTI- and non-CTI-dependent macroreentrant circuits often coexist in the same patient.

B. Electrophysiological features

In order to be sustained, the Aflutter must travel slowly across the CTI, such that the initially excited area recovers its excitability by the time it is reached again, and gets reactivated. This large area of excitability is called the *excitable gap*. This excitable gap allows a premature stimulus or atrial pacing to initiate Aflutter, but also to terminate it. That is how overdrive atrial pacing can penetrate the Aflutter circuit and break it.[2] The excitable gap is larger in patients with a large RA. A small circuit with a small excitable gap eventually leads to collision of impulses inside the circuit and non-sustainability of Aflutter.

Aflutter may, thus, be spontaneously initiated by a PAC. It may also be initiated by transient AF. In the presence of the electrical barrier that acts as a line of conduction block, the microreentrant circuits of AF may eventually organize on one side of this block into a stable Aflutter. *AF is often easier to rate-control than Aflutter*. The high atrial rate of AF leads to partial (concealed) conduction of some atrial beats across the AV node, which makes it refractory to subsequent beats that would otherwise be conducted. The slower atrial rate in Aflutter allows the AV nodal conduction of a higher number of atrial beats (*less concealed conduction*).

On the other hand, Aflutter may trigger AF. Sustained Aflutter results in electrical and anatomical remodeling of the atrial tissue. For instance, the atrial refractory period progressively shortens with Aflutter, and only returns to baseline slowly after conversion of Aflutter. The longer the duration of Aflutter, the slower the recovery of the atrial refractory period. This atrial remodeling may lead to AF.

Drugs that slow the conduction across the CTI increase the excitable gap and allow Aflutter to perpetuate rather than terminate. Therefore, class I drugs (especially Ic) are not helpful for Aflutter therapy. Even worse, by slowing the reentrant circuit, they slow the atrial rate, which allows more atrial impulses to be conducted through the AV node. They convert 2:1 Aflutter into 1:1 Aflutter. They may also organize AF into 1:1 Aflutter. While used as a "pill in the pocket" for acute AF conversion, class Ic antiarrhythmics are generally avoided in Aflutter.

Aflutter tends to be an unstable rhythm, in the sense that it often converts to sinus rhythm or degenerates into AF. However, persistent or permanent Aflutter may be seen. Tachycardia-induced cardiomyopathy may be seen with a slow 2:1 Aflutter that does not attract medical attention early on.

C. Underlying pathology and anatomical substrate

Aflutter may be secondary to LA enlargement/left heart disease. LA disease serves as a substrate for PACs, AF, or atrial runs that enter the RA and initiate the macroreentrant circuit.

Aflutter may also be secondary to RA enlargement, which is often secondary to left heart disease or pulmonary disease. Most patients with left HF develop, at some point, an increase in RA pressure and a degree of RA structural abnormality that elicits Aflutter. Therefore, while right atrial pathology is notoriously an underlying disease (the circuit being a right atrial circuit), left heart disease, through both of the mechanisms explained above, is often the underlying provoker of Aflutter reentry (e.g., hypertension, CAD, valvular disease, any left HF, diabetes).

Aflutter is more commonly seen in men, and in tall patients. These patients have a larger RA and thus a larger excitable gap, which allows the macroreentrant circuit to be sustained.

A large proportion of Aflutter episodes (up to 60%) are triggered by an acute, possibly reversible predisposing event, such as surgery (especially cardiac or thoracic surgery) or acute medical or pulmonary illness (e.g., pneumonia, PE, COPD exacerbation, acute MI).[3] The remaining patients have underlying cardiac or pulmonary disease (HF is most common, COPD is second most common). Lone Aflutter, i.e., Aflutter without any comorbidity, is less common than lone AF. In one study of patients over 50 years old, only 2% of Aflutter cases were lone;[3] however, in other studies of patients undergoing Aflutter ablation, up to 40% of Aflutter cases did not have any underlying structural heart disease.[4,5]

D. ECG

The ECG is characterized by regular sawtooth atrial waves (called *flutter waves*). Look in leads II, III, aVF, and V_1 (Figures 11.1–11.4). Flutter waves are more widely negative than positive in leads II, III, and aVF—due to the retrograde activation of the left atrium—and are positive in lead V_1. In leads II, III, and aVF, the flutter waves do not return to an isoelectric baseline between the deflections, which gives the sawtooth morphology. In V_1, the positive waves may return to the isoelectric baseline; in fact, since lead V_1 overlies the RA, it mainly "sees" the local RA activity. In clockwise Aflutter, flutter waves are negative in V_1 and positive in the inferior leads.

The typical Aflutter rate is 240–350 per minute. A rate as low as 200 may be consistent with a slow Aflutter and is seen in the case of RA enlargement, wherein the Aflutter circuit is longer, or if drug therapy with class I antiarrhythmic agents or amiodarone is used (slows the conduction across the loop). The atypical Aflutter is usually faster (atrial rate of 350–450), with smaller flutter waves that return to the baseline between waves; the morphology of the flutter waves is similar to the morphology of P waves in atrial tachycardia, and depends on the site of origin of the Aflutter (RA, LA, low atrial).

Aflutter is usually conducted in a 2:1 fashion (2 flutter waves for 1 QRS: ventricular rate ~150 bpm). Conduction may be 4:1 in case of AV nodal disease or rate-slowing drug therapy. Odd conduction ratios (3:1, 5:1) are uncommon, except in the context of variable conduction. Variable conduction (e.g., 2:1, 4:1, and 3:1) usually leads to a regularly irregular rhythm, wherein identical R–R intervals are repeated cyclically. Variable conduction usually represents multilevel block in the AV node (Figure 11.5).

A conduction ratio less than 4:1 suggests a high-grade AV block with a junctional escape rhythm, especially if the QRS complexes are regular and fall erratically over the flutter waves without a constant P–QRS relationship.

1:1 AV conduction may be seen in patients with accessory pathways or in patients with a slow flutter rate, particularly patients receiving class I antiarrhythmic drugs.

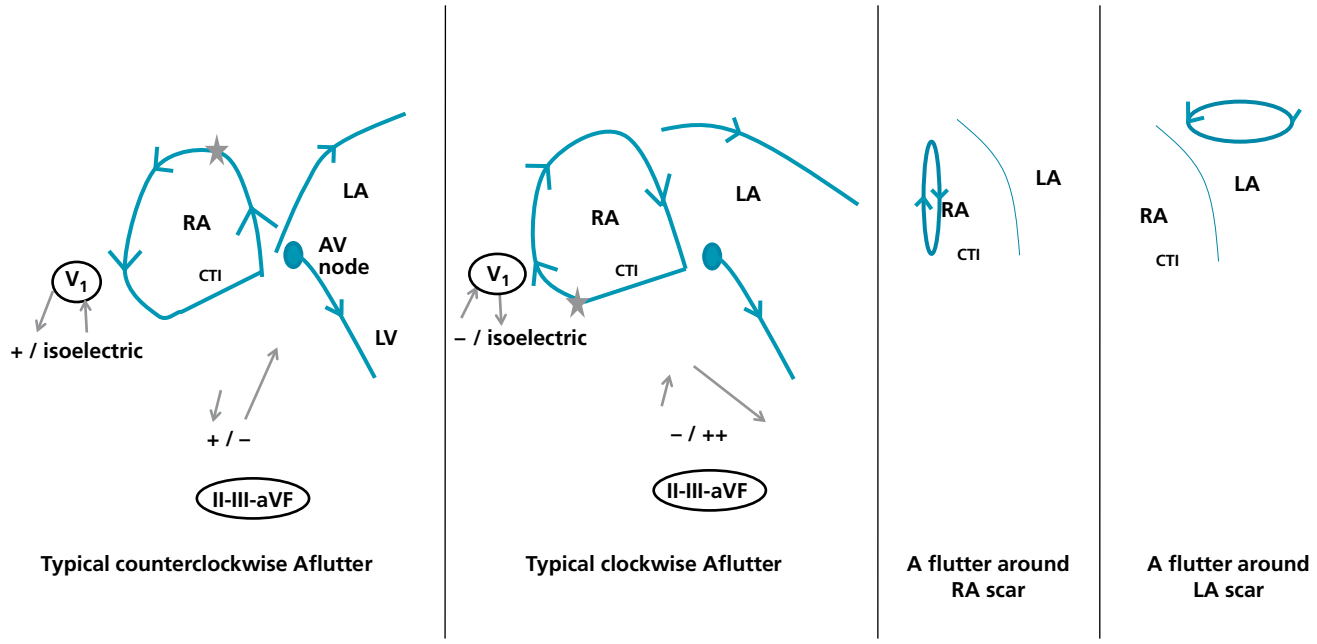

Figure 11.1 Flutter circuit with illustration of the net atrial vectors of depolarization (*gray arrows*) seen by the specific lead and the subsequent morphology of the flutter waves. The *gray star* indicates the starting point of the depolarization vector for illustration purposes. In typical counterclockwise flutter, the negative flutter wave mostly corresponds to retrograde LA activation and is wider than the positive wave: *slow F-wave downslope (LA), fast upslope (RA).* Lead V_1 overlies the RA and mainly sees the local current in the RA, hence the positive deflection in V_1, with possible return to isoelectric baseline between deflections.

Figure 11.2 Aflutter with flutter waves rate (F wave) ~300 per minute and 2:1 conduction. It is a typical counterclockwise Aflutter, with negative flutter waves in lead II. At first glance, it seems there is ST elevation where the asterisks (*) are placed. This is, in fact, the upslope of the flutter waves. ***(Bottom image)*** One way of diagnosing Aflutter is to imagine that QRS is removed, and then see what the atrial waveform looks like. A typical sawtooth pattern is subsequently seen.

The atrial waves of coarse AF may simulate flutter waves in lead V_1; in fact, V_1 overlies the RA and tends to magnify the RA waves (Figure 11.6). In addition, AF has multiple reentrant circuits, one of which, in the RA close to the isthmus, may be large enough to give a morphology of atrial flutter. These pseudo-flutter waves are slightly irregular and polymorphic and are only seen in lead V_1; in addition, the ventricular rhythm is totally irregular without any cyclical repetition of R–R intervals. This rhythm is sometimes called "AF-Aflutter," but in reality it is AF with one large RA reentrant circuit on top of hundreds of other atrial circuits. The rhythm behaves like AF in response to therapy, and is not cured with isthmus ablation.

E. Management of atrial flutter

1. Acute treatment

Acutely, Aflutter is managed like AF (rate control, anticoagulation). Approximately 55% of Aflutter episodes convert spontaneously, especially in the first 24–48 hours. If not:

- DC cardiovert after performing TEE to rule out LA thrombus. A low current dose (50 J) is usually effective. This is the only treatment necessary in patients with acute, reversible trigger.
- Perform overdrive pacing of the atrium at an atrial rate 60–100 bpm higher than the flutter rate, i.e., an atrial rate of ~400. This is done in the setting of dual-chamber pacemaker or ICD, using the non-invasive programmed stimulation (NIPS) window, or in the post-cardiac-surgery setting when temporary atrial pacing wires are in place. This effectively converts Aflutter in 80% of the cases. It may induce AF, which is usually easier to rate-control than Aflutter. Similarly to DC cardioversion, overdrive pacing is performed after TEE rules out LA thrombus.
- Continue rate control until catheter ablation of the Aflutter is performed. ***Ablation may be performed acutely if Aflutter is not thought to be secondary to a reversible process.***

2. Chronic treatment

When Aflutter occurs in the context of an acute disease process (pneumonia, COPD exacerbation, the first 3 months after cardiac surgery) and in the absence of severe underlying heart or lung disease or further Aflutter episodes, catheter ablation is not necessary, as Aflutter is unlikely to recur later;[6] DC cardioversion is performed if Aflutter does not revert spontaneously. In patients without an acute trigger for Aflutter, catheter ablation of the CTI is first-line therapy; this has a curative rate > 90%, and may be performed in the acute setting, while Aflutter is ongoing. There is no need for antiarrhythmic therapy or long-term anticoagulation after radiofrequency ablation, unless the patient has AF associated with Aflutter. Catheter ablation may be reattempted, with a high success rate, in case of recurrence. Class III antiarrhythmic drugs may be used in patients who refuse ablation, while class Ic drugs are preferably avoided. For an overview of Aflutter ablation, see Chapter 15.

Non-ablated paroxysmal or persistent Aflutter mandates chronic anticoagulation (according to CHA_2DS_2-VA score), except when it occurs transiently in the context of a clear acute disease process and in the absence of severe underlying heart or lung disease. After curative catheter ablation, and in the absence of concomitant AF, anticoagulation is required for 4 weeks only. However, because of the high rate of new-onset AF occurrence over the long term, close monitoring is recommended. This may include daily self-recorded ECG on smart devices (e.g., Apple watch), smartwatch AF detection via pulse monitoring algorithm, or periodic 30-day rhythm monitors.

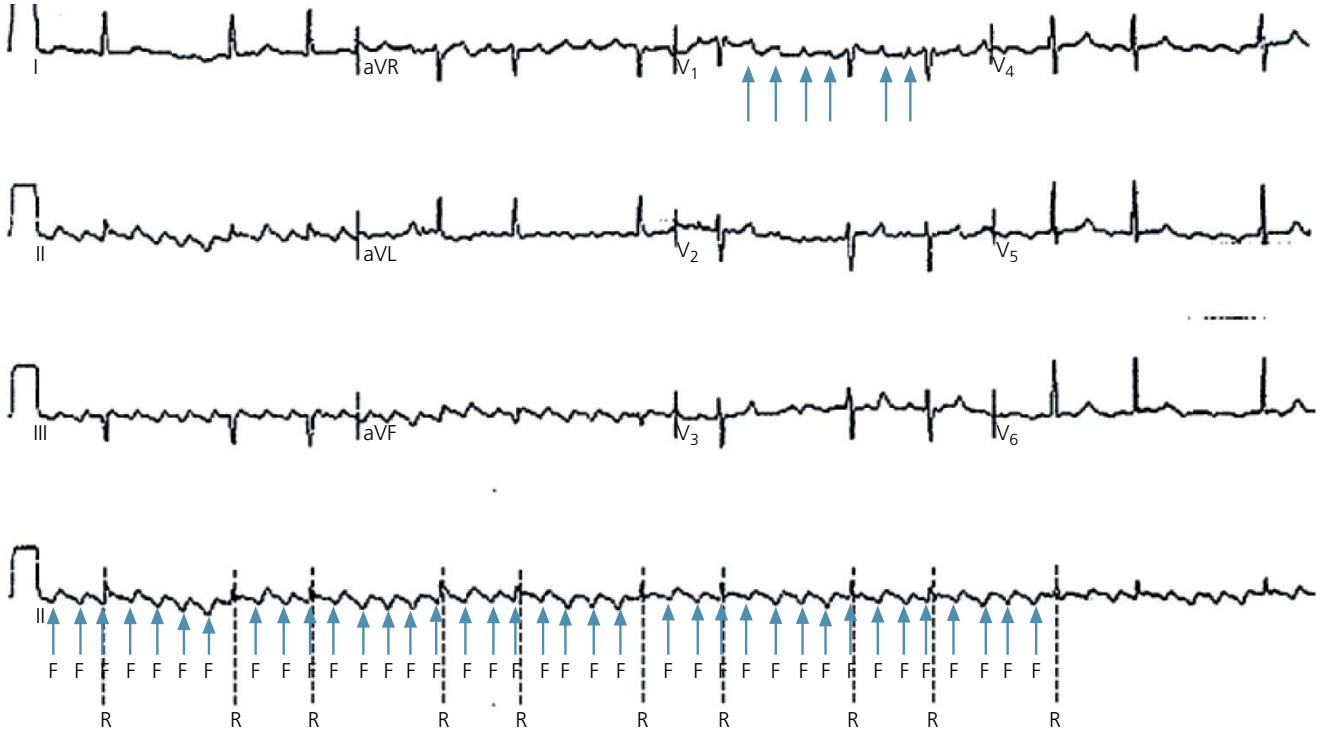

Figure 11.3 Typical counterclockwise Aflutter with variable conduction: 5:1, 4:1, 3:1. The rhythm is overall irregular, but there is some repetition of the same R–R intervals. The interval between the 1st and 2nd, the 3rd and 4th, and the 7th and 8th R–R are equal. Typical sawtooth Aflutter waves are seen in lead II. In V_1, there are upright P waves with an isoelectric baseline.

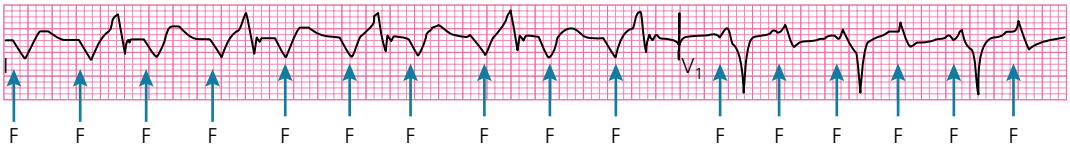

Figure 11.4 Another typical counterclockwise 2:1 Aflutter. See how F is negative in lead II, and positive in lead V_1, without return to baseline.

3. The association between Aflutter and AF

Aflutter is seen in 25–35% of AF patients. In some cases, Aflutter waves abut remodeled LA areas with dispersed repolarization, degenerating into multiple small reentries and wavelets (= AF). In others, AF becomes organized along the CTI and triggers Aflutter. In patients whose predominant rhythm is Aflutter, i.e., Aflutter episodes are more often documented on ECGs and Holter monitoring than AF, Aflutter ablation may prevent AF.

In general, AF occurs in ~25% of Aflutter cases at 1–3 years after CTI ablation, but in up to 82% of the cases at 3–4 years,[7] more so if LV dysfunction is present or if AF episodes were documented before Aflutter ablation.[4,5] If only Aflutter is documented, the occurrence of AF after CTI ablation is only 8% at 20 ± 14 months. Conversely, for those with a predominant Aflutter but a history of AF, the recurrence rate of AF is 38%, whereas for those with a predominant AF, the recurrence rate of AF is 86%.[5] Thus, Aflutter ablation markedly reduces AF occurrence over the long term only when Aflutter is the dominant arrhythmia.

Occasionally, AF may organize into Aflutter when treated with class Ic drugs (class Ic Aflutter) or with amiodarone. In this subgroup, CTI ablation with continuation of the Ic drug often results in control of both AF and Aflutter.

II. Focal atrial tachycardia

A. Electrophysiological mechanisms

Atrial tachycardia (AT) may be initiated by 3 different mechanisms: microreentry, automaticity, and triggered activity. The frequency of each of these mechanisms varies according to different studies, with each mechanism probably accounting for a third of atrial tachycardias.[8–10] One study suggested that > 80% of ATs are due to triggered activity. The automatic mechanism is rare in older patients, because automaticity decreases with age.

Reentry and triggered activity can be induced and terminated with programmed electrical stimulation. During EP testing of an ongoing AT, pacing at a slightly faster rate (interval 20–50 ms shorter), called entrainment pacing, should be performed from the presumed site of origin of the arrhythmia, i.e., site of earliest atrial activation. If pacing does not break the arrhythmia, look at the post-pacing interval: a

Figure 11.5 Rhythm in lead V_1 (*above*) and lead II (*below*) with a ladder diagram showing how variable AV block occurs. Two levels of second-degree block are present in the AV junction: 2:1 block high in the AV junction and 3:2 type I block low in the AV junction. Flutter waves are indicated by vertical lines in the atrial (A) portion of the diagram. Every other flutter wave is blocked high, at level 1. Of those impulses making it through level 1, one-third are blocked at level 2, and two-thirds are conducted to the ventricles (V). Overall, this translates into an alternation of 2:1 and 4:1 conduction. The QRS complexes following the short R–R intervals are wide because of a functional block in the right bundle branch (Ashman type of aberrancy). Reproduced with permission of Baylor University Medical Center from Glancy DL, Hanna EB. Bigeminal rhythm IV. Proc (Baylor Univ Med Ctr) 2010; 23: 311–12.

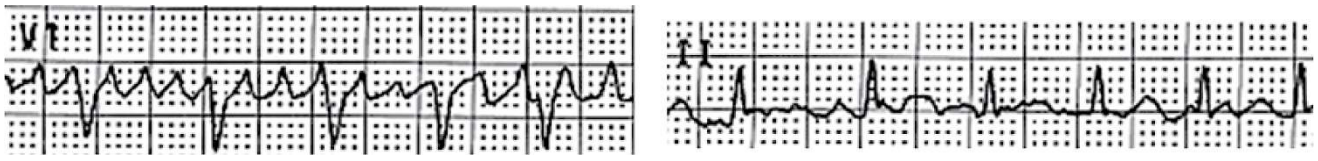

Figure 11.6 Coarse fibrillatory AF waves that simulate Aflutter in lead V1. Note their lack of consistent morphology and timing, and the lack of flutter waves in lead II.

post-pacing interval that is equal to the tachycardia cycle length usually implies that pacing was performed from the actual reentrant focus, and that the mechanism is reentry or possibly triggered activity; the A-wave morphology during pacing is similar to the tachycardia. If the atrium was entrained from outside the reentrant focus, the post-pacing interval will be equal to the tachycardia cycle length plus twice the distance between the pacing focus and reentry focus. On the other hand, automatic AT cannot be initiated or terminated with pacing or premature stimuli. An automatic focus is overdrive-suppressed during pacing, but "wakes up" after pacing cessation and may be a bit late and slow initially (long post-pacing interval even when pacing close to the AT focus).[9] Activation mapping, which assesses the site of earliest A activation during ongoing AT, is helpful in all focal AT types.

The surface ECG may help differentiate automaticity from reentry. In reentry, the PAC that initiates the arrhythmia may have a different P-wave morphology than the arrhythmia. In automatic tachycardia, the P wave that initiates the arrhythmia has a similar morphology to the P wave of the arrhythmia. An automatic mechanism tends to have a warm-up and warm-down phenomenon, but this is not very sensitive or specific.

Through its inhibition of cAMP generation, adenosine terminates atrial tachycardia secondary to triggered activity, and may transiently suppress atrial tachycardia secondary to automaticity by hyperpolarizing the myocardium. It has a variable effect on reentrant atrial tachycardias (some studies suggest no effect,[8] while others suggest a high rate of termination[11]).

Transient atrial tachycardias, lasting <30 seconds, are very common in patients with or without underlying heart disease, particularly older patients, and are benign and usually asymptomatic.[12] More *sustained* atrial tachycardia is often symptomatic and may be *paroxysmal*

or persistent (= incessant), with a risk of tachycardia-mediated cardiomyopathy (whether persistent or off-and-on paroxysmal).[13] Approximately 40% of patients with sustained AT have an underlying cardiovascular disease, particularly in the case of reentrant AT. In fact, reentrant AT in older patients is frequently associated with AF or Aflutter, and AT may initiate AF or Aflutter. ***Automatic AT and triggered-activity AT are mostly seen in patients < 60–70 years of age who often do not have structural heart disease.[9] The relative frequency of reentry increases and automaticity decreases beyond the age of 65***. AT, particularly automatic AT, may be related to acute metabolic abnormalities or acute illness (hypoxia, sepsis).

Atrial tachycardia with block (2:1 or, less often, 3:1 or Wenckebach) is usually due to digoxin toxicity or hypokalemia.

In one systematic review of atrial tachycardia, ~25% of patients with AT had LV dysfunction, and most of those cases (73%) were tachycardia-mediated cardiomyopathy that reversed after tachycardia termination.[13] Therefore, any case of AT and new-onset LV dysfunction should be considered a tachycardia-mediated cardiomyopathy, and an attempt should be made to ablate AT. A similar concept applies to AF or atrial flutter associated with new LV dysfunction.

B. Site of origin

AT most commonly originates from the RA (82%). It typically arises around the tricuspid annulus, the crista terminalis (most common 2 sites, ~35% each), the venous orifices (pulmonary veins, coronary sinus, IVC, SVC), or less commonly, interatrial septum or mitral annulus. It may also arise around prior scars (e.g., pulmonary vein isolation for AF). Approximately 10% of patients have multiple foci, particularly older patients or those with underlying structural heart disease, where the prevalence of multiple foci increases to ~25%.[13]

C. Natural history

AT may be seen at any age, the mean being 40 years old. Up to 65% of patients have spontaneous remission of AT with time, and a lack of recurrence with cessation of antiarrhythmic therapy. This is more common with automatic AT of young patients, especially those < 25 years of age.[14,15]

D. ECG

- Regular P wave rate, 100–200 per minute (< atrial rate of Aflutter, 200–340 per minute).
- Isoelectric baseline is seen between P waves (different from typical Aflutter).
- The first P wave of the tachycardia is often similar to the subsequent P waves of the tachycardia, particularly in automatic AT. This is different from other forms of SVT.
- Atrioventricular conduction is usually 1:1. *A conduction block (2:1) suggests digoxin toxicity or hypokalemia*.
- PR interval is normal or prolonged, RP interval is long (> half R–R interval). Thus, AT is usually a long RP tachycardia (as opposed to typical AVNRT and AVRT, which are short RP tachycardias).
- As with VT and bypass tract localization, look at the morphology in leads V_1, I-aVL, and II-III-aVF to localize the atrial origin of AT (Figure 11.7):
  - A negative P wave in leads II, III, and aVF implies a *low atrial origin* that simulates a retrograde P wave; a positive P wave in leads II, III, and aVF implies a *high atrial origin*.
  - A P wave that is positive in V_1 (looks to the right) and negative in the left lateral leads I and aVL (looks away from the left) is typical of a *left atrial origin*, with the exception of a right superior pulmonary vein origin (the latter simulates RA origin). Either way, the P axis and morphology are usually different from the sinus P wave in the same patient.

Difference between Aflutter and AT

Aflutter, whether isthmus- or non-isthmus-dependent, is due to macroreentry. Conversely, AT is due to microreentry or other mechanisms. For practical purposes, AT is distinguished from Aflutter by the following: (1) An atrial rate < 200 per minute is often AT, whereas an atrial rate > 200–240 per minute is often Aflutter; (2) AT is a focal rhythm, and thus, an isoelectric line is seen between P waves; Aflutter is a large macroreentry with constant atrial activity and no isoelectric line. It is important to differentiate AT from a slow Aflutter, for the following 2 reasons:

1. The mechanism is different. Aflutter implies macroreentry and is often isthmus-dependent and easily cured with ablation. AT is less easily mapped and ablated but may be broken by class I antiarrhythmics, β-blockers and CCBs.
2. Aflutter is associated with a thromboembolic risk and requires anticoagulation, whereas AT, by itself, may not mandate anticoagulation.[15] However, in older patients, AT is frequently associated with AF/Aflutter, which may necessitate anticoagulant therapy.

An atrial tachycardia with a low atrial origin resembles PJRT (incessant slow AVRT). In both cases, the P wave is retrograde-like, i.e., negative in leads II/III/aVF, and the RP interval is long.

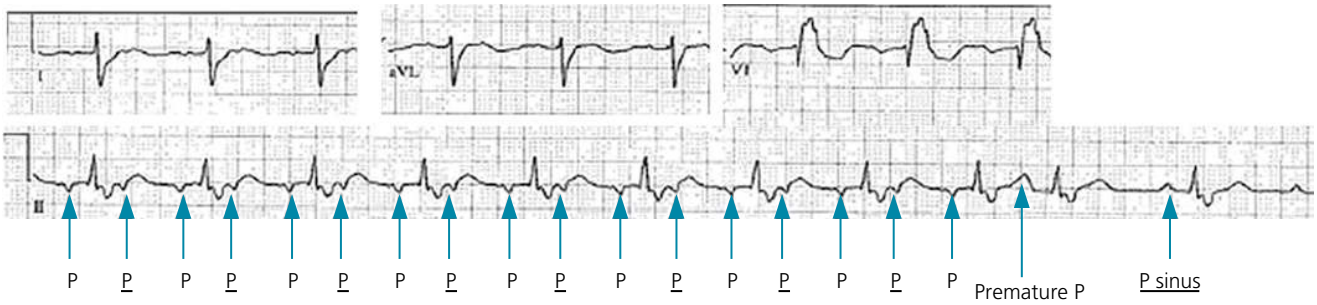

Figure 11.7 2:1 atrial tachycardia, with an atrial rate of ~140 per minute. P wave is negative in the inferior leads, implying a low atrial origin; it is negative in lead V_1 and upright in aVL, implying a right atrial origin. A premature P occurs and breaks the atrial tachycardia at the end of the recording. The change in the T morphology before the premature complex suggests the occurrence of a P wave different from the previous P waves (premature P). The fact that AT breaks with a PAC implies reentrant AT.

E. Treatment

1. Acute treatment

AT, particularly automatic AT, may be secondary to an acute illness that needs to be appropriately treated.

Sustained AT may be terminated with adenosine. Adenosine is mainly effective in triggered activity, and its overall efficacy in the termination of AT varies between 10% and 80%.[8–10] Similarly, AT due to triggered activity may be terminated with calcium channel blockers (CCBs) or β-blockers. These drugs have a variable effect on automatic and reentrant AT: adenosine and CCBs may suppress reentrant AT, and β-blockers may suppress automatic AT (in up to 50% of cases).[11] Those 3 agents should, therefore, be tried first.[6]

When CCBs and β-blockers are not effective in terminating the arrhythmia, they may continue to be used for rate control. However, AT is notoriously very difficult to rate-control, because of the relatively slow atrial rate and the subsequent lack of concealed AV conduction. This allows more atrial beats to conduct through the AV node (in sharp contrast with AF). In fact, in a patient who has a pacemaker, fast atrial pacing may slow down the ventricular rate by blocking the AV node.[1] Therefore, AT may need to be terminated with class I or III drugs (intravenous amiodarone or ibutilide). A better option would be to attempt AT ablation in the acute setting. In fact, once terminated, automatic AT is difficult to induce; in order to localize then ablate the AT focus, AT needs to be ongoing or induced. ***Mapping then ablating the AT in the acute setting and avoiding antiarrhythmic drugs may be the preferred approach in patients who are hemodynamically stable.***

In patients with a rate > 150 who are hemodynamically unstable, DC conversion may be contemplated. It is effective in reentrant and triggered-activity AT, but not in automatic AT.

Digoxin is better avoided, as it may initiate AT.

2. Long-term therapy

Regardless of the mechanism of AT, the focus can be ablated by applying radiofrequency energy. In the case of reentry, a critical segment of the reentry loop is ablated. Localization of the focus is performed after inducing AT, by looking for the site of earliest atrial activation during AT. The earliest A activation (at the AT focus) often precedes the ECG's P wave by 20–30 ms. Entrainment is then performed, and a post-pacing interval that is equal to the tachycardia cycle length confirms catheter location at the site of the reentry; this is mostly helpful in mapping reentrant AT and some triggered-activity ATs. Catheter ablation has an efficacy of 90%, with an 8% recurrence rate that is partly explained by the occasional presence of multiple foci.[14] Ablation of a left-sided tachycardia is associated with a higher failure rate (~15%). Ablation of foci located near the sinus node or in the low atrial septum, near the AV node, is associated with a higher rate of complications.

Chronic β-blocker or CCB therapy is an acceptable first-line therapy for patients who acutely respond to those 2 drugs or to adenosine. Catheter ablation is the most appropriate first-line therapy for patients with recurrent or incessant AT, or tachycardia-mediated cardiomyopathy; it is also used in AT refractory to initial drug therapy.[6] If ablation fails or if the patient prefers not to undergo ablation, antiarrhythmic therapy with class Ic or III drugs may be tried.

III. Multifocal atrial tachycardia (MAT) (or chaotic atrial tachycardia)

- MAT is an automatic atrial tachycardia characterized by:
  - Irregularly irregular atrial rhythm with an atrial and ventricular rate usually in the range 100–150 bpm
  - P–P and PR intervals are variable
  - P waves have ≥3 different morphologies
- If the atrial rate is <100 bpm, the rhythm is called *wandering atrial pacemaker* or *multifocal atrial rhythm*.
- Because it is irregular, MAT may mimic AF. Unlike AF, MAT has well-defined P waves.
- MAT is usually associated with acute pulmonary (COPD exacerbation) or cardiac issues (HF), electrolyte disorders, drugs (theophylline, digoxin), or sepsis.
- MAT is frequently preceded or followed by AF or Aflutter. In one series, it was associated with AF in 55% of cases.
- Treatment consists of correcting the underlying disease, in addition to potassium and magnesium repletion. Antiarrhythmic drugs are usually ineffective, but CCBs or β-blockers may help with rhythm rather than rate control, by suppressing the automaticity.

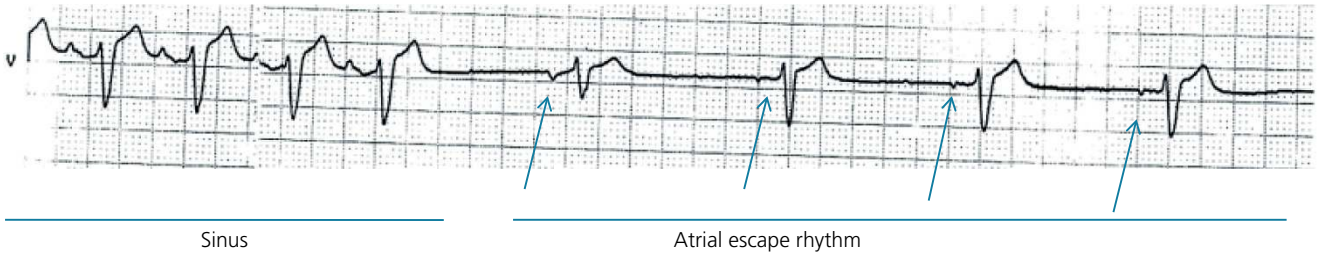

Figure 11.8 Atrial escape rhythm (rate ~50 bpm) that developed in a patient who had sudden slowing of the sinus rate (e.g., hypervagal situation). The arrows point to the ectopic P waves (morphology different from the sinus P waves).

IV. Ectopic atrial rhythm

An ectopic atrial rhythm is an automatic atrial rhythm characterized by an atrial rate < 100 bpm and a non-sinus P-wave morphology (Figure 11.8). It implies that a quiescent atrial pacemaker is starting to fire at a rate faster than the sinus rate. It may be an escape rhythm/beat in patients with a slow sinus rate or a sinus pause, or it may be an accelerated automatic rhythm. It is a benign rhythm and may be seen in subjects with or without structural heart disease, including young subjects with high vagal tone and sinus node slowing.

QUESTIONS AND ANSWERS

Question 1. (Questions 1 to 7 refer to the same patient.) A 42-year-old woman, without prior cardiac or hypertension history, presents with palpitations that have been ongoing for the last 2 hours. She has also experienced palpitations over the last 2 months, usually lasting up to 30 minutes. ECG shows atrial tachycardia, 1:1 conduction at a rate of 130 bpm, with a negative P wave in lead V_1, upright P wave in lead aVL, and negative P wave in the inferior leads. The patient is not dizzy and her BP is 125/80 mmHg. How would you ensure this is not 2:1 Aflutter?

Question 2. Adenosine is administered and does not break the AT. Intravenous metoprolol then diltiazem are administered, but they also do not break the AT nor slow the AV conduction. Echo shows a grossly preserved LV function. What is the likely mechanism of this AT?
A. Automaticity
B. Triggered activity
C. Microreentry

Question 3. Where is AT originating from?
A. LA
B. High RA
C. Low RA

Question 4. What is the next step?
A. DC cardioversion
B. Intravenous ibutilide or amiodarone
C. Allow the patient to stay in ongoing AT and attempt AT ablation within the next 24 hours

Question 5. A few hours later, while the patient is getting ready for the EP mapping and ablation, AT spontaneously converts to sinus rhythm. Attempts to induce AT in the EP laboratory fail, and thus AT cannot be mapped. What is the next step?
A. No further therapy. AT is unlikely to recur
B. Flecainide or propafenone
C. Sotalol
D. Amiodarone
E. Metoprolol or diltiazem

Question 6. If the patient has a breakthrough of persistent AT while receiving antiarrhythmic therapy, what would be the next step?
A. Increase the dose of antiarrhythmic therapy
B. EP study as soon as possible

Question 7. If the patient had a dual-chamber pacemaker, what would be the effect of overdrive atrial pacing on AT (overdrive atrial pacing at an atrial rate of 170 bpm)?
A. Cardioversion of AT, although a risk of degeneration into AF is present
B. No effect

Question 8. (Questions 8 to 10 refer to the same patient.) A 70-year-old man has a history of ischemic cardiomyopathy, with LVEF ~40%, and a dual-chamber ICD. He also has a history of paroxysmal AF. His baseline rhythm is a sinus rhythm with a very long and asymptomatic PR interval of 350 ms and intrinsic AV conduction, without V pacing. In order to avoid AV sequential pacing, his pacing mode has been programmed VVI 40 bpm. Over the last month, his ECG has been showing a persistent, typical Aflutter with 100% ventricular pacing at 40 bpm. Why does he receive ventricular pacing during Aflutter, not during sinus rhythm?

Question 9. The patient's EF appears to have declined to 35% on a repeat echo. He has slightly more fatigue during activity. What is the next step?
A. Keep him in Aflutter. Increase the VVI pacing rate to 60 bpm, with rate response
B. Aflutter ablation
C. Keep him in Aflutter. Upgrade the ICD to a BiV-ICD to prevent further decline of LV function that has occurred with RV pacing

Question 10. Since he has a dual-chamber pacemaker, what specific acute intervention could terminate Aflutter?

Question 11. A 66-year-old man underwent CABG 7 weeks previously. He has a normal EF and no prior history of atrial arrhythmias. He presents with exertional dyspnea; no palpitations are reported. He is found to have a typical Aflutter with 2:1 AV conduction (ventricular rate 140 bpm), and mild pulmonary edema on chest X-ray. He receives diuretic therapy, and Aflutter is rate-controlled with metoprolol (AV conduction ratio becomes 4:1). What is the next step?
A. DC cardioversion followed by 1 month of anticoagulation
B. DC cardioversion followed by long-term anticoagulation
C. Aflutter ablation
D. Keep Aflutter and continue rate-control strategy

Question 12. For the patient in Question 11, was metoprolol appropriate for rate control, considering that he has HF?

Question 13. An 82-year-old man has a history of ischemic cardiomyopathy with prior MI and LVEF of 30%. He presents with mild dyspnea and is found to have a regular SVT at a rate of 135 bpm. He is not in shock but has pulmonary edema. Adenosine is administered and unveils P waves that occur at a rate of 270 per minute. Those P waves are upright in lead V_1 and the inferior leads, and are narrow with an isoelectric line between P waves in V_1 and in the inferior leads. What is the diagnosis?
A. Isthmus-dependent (= typical) Aflutter
B. Non-isthmus-dependent (= atypical) Aflutter arising from the LA
C. Atrial tachycardia arising from the LA

Question 14. The patient in Question 13 receives metoprolol. It does not slow down AV conduction. What is the next step?
A. Aflutter ablation
B. DC cardioversion and chronic amiodarone therapy
C. Chronic rate control

Answer 1. Administer adenosine. Adenosine may break AT, when triggered activity is the mechanism. Otherwise, it may temporarily slow AV conduction and allow visualization of P waves, confirming P rate.

Answer 2. A. Considering the patient's age and the lack of underlying heart disease or potential atrial scars, the most likely mechanism is automaticity. Adenosine does not break automatic AT, but it may break triggered activity or, rarely, reentrant AT.

Answer 3. C.

Answer 4. C. In this young patient with persistent AT and multiple prior episodes, AT ablation is first-line therapy, especially when it originates from the RA (higher success rate with ablation than left AT). In order to ablate the AT focus, AT location has to be mapped with intracardiac recordings while AT is ongoing. Once the patient is in sinus rhythm, it is generally difficult to induce automatic AT. Therefore, it is reasonable to perform ablation within the next few hours, while AT is ongoing, as long as she is hemodynamically stable. In this case, avoid breaking the AT with ibutilide, amiodarone, or class Ic drugs; also, these drugs make AT induction more difficult.

Answer 5. B. Since the patient failed ablation, long-term medical therapy is justified. Metoprolol or diltiazem would have been a reasonable long-term therapy if they had been successful acutely. Flecainide and propafenone are likely more effective and less toxic than class III drugs for the long-term treatment of AT (ACC guidelines). Those drugs may be combined with a β-blocker or a CCB to improve efficacy, as per ACC guidelines.

Answer 6. B. Ask the patient to present to the hospital as soon as AT symptoms occur. An EP study should then be performed as soon as possible after presentation, while AT is ongoing, and before it spontaneously converts, so that it can be mapped.

Answer 7. B. Overdrive atrial pacing can break reentrant or triggered-activity AT, but not automatic AT.

Answer 8. The patient has underlying AV nodal disease. Aflutter, by increasing the number of atrial waves "hitting" the AV node, reduces the conduction speed across the AV node and increases its refractory period (the conduction and refractory period were already impaired). The AV node is, in fact, characterized by decremental conduction with fast atrial pacing. In addition, some of these waves partially penetrate the AV node and make it refractory to subsequent waves (concealed conduction). The AV conduction is overall reduced, which triggers VVI backup pacing.

Answer 9. B. The patient's fatigue is at least partly due to the low ventricular rate of 40 bpm, and thus increasing the VVI pacing rate to 60 bpm will likely improve his symptoms. However, the patient has another issue that needs to be addressed: he has a new, ongoing and harmful RV ventricular pacing with a resulting decline of LV function. One option would be to upgrade the device to a BiV pacemaker. A simpler option consists of ablating the Aflutter and reverting him back to his prior state of intrinsic ventricular conduction after a long PR interval. Moreover, re-establishing the atrial kick will improve EF and HF beyond ventricular synchrony. If his AV node remains dormant after Aflutter ablation, an upgrade to BiV pacing would be appropriate, while also maintaining the benefit of AV synchronous pacing.

Answer 10. Overdrive pacing of the atrium, at a rate faster than the Aflutter rate (e.g., 350–400 bpm), may convert Aflutter into sinus rhythm. Similarly to DC cardioversion, this should only be done if the patient has received 3 weeks of anticoagulation or if TEE rules out LA appendage thrombus. Similarly to DC cardioversion, this is not a definitive therapy of Aflutter in this patient, who has a high likelihood of recurrence.

Answer 11. A. Aflutter that occurs in the first 3 months after CABG, without a prior history of atrial arrhythmia, is likely a transient process that may not recur. Aflutter ablation may not be necessary. DC cardioversion is done, and 1 month of anticoagulation may be reasonable in the absence of further recurrences. If Aflutter recurs, ablation is warranted.

Answer 12. Yes, as his EF was recently normal. Metoprolol may be acutely used in decompensated HFpEF, but not in decompensated systolic HF, where digoxin or amiodarone may be needed for rate control.

Answer 13. B. The narrow P wave, the presence of an isoelectric segment, and the concordance of P polarity between V_1 and the inferior leads implies AT or atypical Aflutter, not a typical Aflutter. The atrial rate supports Aflutter rather than AT. The upright P wave in V_1 suggests LA origin.

Answer 14. B. Since the Aflutter is non-isthmus-dependent and originating from the LA, ablation is more difficult and less successful than ablation of isthmus-dependent Aflutter. Considering the patient's older age, DC cardioversion along with antiarrhythmic therapy is an appropriate strategy. In fact, for atypical Aflutter, first-line catheter ablation is a class IIa recommendation (rather than class I). Standalone rate control is less appropriate, as Aflutter appears to have triggered HF decompensation (poorly tolerated); besides, rate control has not been possible in this case.

12 Atrioventricular Nodal Reentrant Tachycardia, Atrioventricular Reciprocating Tachycardia, Wolff–Parkinson–White Syndrome, and Junctional Rhythms

I. Inappropriate sinus tachycardia (IST) and postural orthostatic tachycardia syndrome (POTS) 384
II. Atrioventricular nodal reentrant tachycardia (AVNRT) 384
III. Atrioventricular reciprocating tachycardia (AVRT) and Wolff–Parkinson–White (WPW) syndrome 387
IV. Junctional escape rhythm and accelerated junctional rhythm (or non-paroxysmal junctional tachycardia) 395

Questions and answers 397

I. Inappropriate sinus tachycardia (IST) and postural orthostatic tachycardia syndrome (POTS)

Sinus tachycardia is generally not a primary rhythm abnormality. It is secondary to cardiac, pulmonary, septic, or metabolic issues and is often an ominous sign (e.g., HF, large MI, shock, sepsis, acute bleed, anemia, hypoxia).

On telemetry monitoring, suspect supraventricular tachyarrhythmia rather than sinus tachycardia in the case of: (1) sharp onset and/or sharp offset of the tachycardia; (2) very steady rate (e.g., 134 bpm). Conversely, in sinus tachycardia, rate variability is seen.

IST – Inappropriate sinus tachycardia is a non-paroxysmal sinus tachycardia that is present most of the day, at rest and/or mild physical effort, out of proportion to any physiologic need. The resting sinus rate is >100 bpm and the mean 24-hour sinus rate on Holter is >90 bpm. IST is due to a dysautonomia that activates the sinus node's I_f current and is mainly seen in young women (<50 years of age). IST is associated with symptoms of palpitations, fatigue, and dizziness that may be improved with drugs blocking the sinus node. In fact, the use of an I_f current blocker, i.e., a sinus node blocker (ivabradine), eliminated >70% of IST symptoms in one study (class IIa recommendation in ACC guidelines). β-Blockers may also be effective, but may not be well tolerated in dysautonomic patients (class IIb). Sinus node ablation is only temporarily effective, as tachycardia may arise from other sinus sites after ablation, the main issue being autonomic dysfunction.

POTS – POTS is an orthostatic intolerance defined by an increase in sinus rate ≥30 bpm within 10 minutes of standing, without orthostatic hypotension or syncope. The supine heart rate is generally normal, in contradistinction with IST, where the supine heart rate is elevated and only mildly rises upon standing; yet both conditions may coexist. POTS is a form of cardiovascular deconditioning that starts after a period of bedrest (e.g., surgery, acute illness or viral illness) and may have a somewhat acute onset, sometimes in hospitalized patients. This deconditioning leads to reduced stroke volume, reduced renin-angiotensin activation (low blood volume), and peripheral autonomic denervation with lack of vasoconstriction. As such, sinus tachycardia is often useful in POTS because it maintains BP and compensates for the low stroke volume and vascular tone. Thus, β-blocker therapy worsens POTS symptoms, and POTS needs to be ruled out before using β-blockers in IST. Only one form of POTS, hyperadrenergic POTS, may benefit from a small propranolol dose.

II. Atrioventricular nodal reentrant tachycardia (AVNRT)

A. Mechanism (see Figure 12.1)

In AVNRT, the AV node has two pathways: fast pathway and slow pathway. Approximately 20% of normal individuals have dual AV node pathways, but most of them do not manifest AVNRT.

Normally, the AV node conducts impulses through the fast pathway.

The fast pathway conducts faster but has a longer refractory period than the slow pathway. After a PAC, the fast pathway may still be in its refractory period, whereas the slow pathway, having the short refractory period, has already recovered and conducts forward. The impulse then conducts retrogradely through the fast pathway if it has recovered; this leads to a typical ***"slow-then-fast" ("SF")*** AVNRT. If the fast pathway has not recovered from its refractory period, the impulse will lead to one QRS having a longer PR interval; arrhythmia is not initiated.

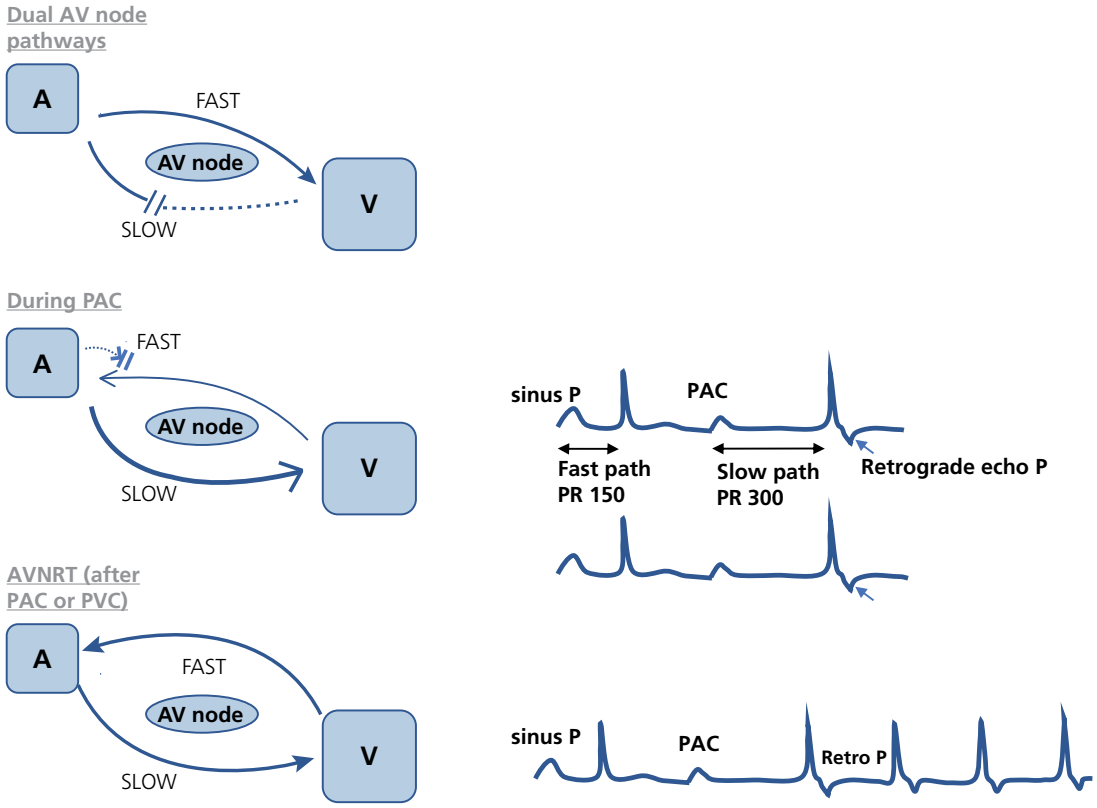

Figure 12.1 AVNRT usually starts with a PAC that has a long PR interval as it goes through the slow pathway. *The slow pathway is slower but has a shorter refractory period than the fast pathway*, allowing conduction of the PAC. If, at the time the impulse reaches the distal slow pathway, the fast pathway is still in its refractory period, the reentrant circuit of AVNRT will not launch. A few subsequent sinus P waves may keep conducting over the slow pathway (Figure 12.5).

If, at the time the impulse reaches the distal slow pathway, the fast pathway has recovered, a retrograde P wave will occur (echo P wave) and AVNRT will be initiated. The R–R interval can shorten over the course of the first few beats; it may lengthen during the last few beats before termination with AV nodal blocking agents. *Note:* Besides PAC, AVNRT may be initiated by a PVC that retrogradely invades and blocks the fast pathway, forcing the subsequent sinus impulse down the slow pathway, triggering slow-fast AVNRT (Figure 12.5). PVC may also conduct up the slow pathway and initiate atypical AVNRT, with conduction up the slow pathway and down the fast one.

Other, less common forms of AVNRT are the fast-then-slow AVNRT, and the slow-then-slow AVNRT. The *fast-then-slow AVNRT* is typically initiated by a PVC that travels retrogradely and blocks in the still refractory fast pathway; instead, the PVC conducts up the slow pathway and then down through the fast pathway if it has recovered, establishing a *fast down-slow up* reentry loop.*

AVNRT usually occurs in patients without underlying heart disease.

B. ECG

AVNRT typically manifests as a regular, narrow QRS complex tachycardia, with a ventricular rate of ~150–250 bpm (most often ~180 bpm).

P waves are retrograde and are usually hidden inside the QRS or at the terminal portion of the QRS (Figure 12.2). These P waves manifest as terminal r′ in V_1 and pseudo-S in the inferior leads, with a short RP (often<90 ms). P waves are often simultaneous to the QRS and therefore are clearly visible in only ~1/2 of the cases (Figures 12.2 and 12.3). Rarely, P waves may precede QRS, with a short PR interval<110 ms (Figure 12.4). If P waves cannot be identified in patients presenting with a regular narrow complex tachycardia, AVNRT is the most likely diagnosis.

The tachycardia being initiated by an ectopic atrial beat that goes down the slow pathway, the PR interval of this initial beat is longer than the sinus PR interval. As opposed to automatic atrial tachycardia, this initial ectopic P wave usually differs from the subsequent (retrograde) P waves and does not march out with them.

The atypical forms of AVNRT (fast–slow or slow–slow AVNRT) have a long RP interval, longer than 1/2 RR interval, and may thus simulate atrial tachycardia. The loop is overall slower than in typical AVNRT; thus, the atypical forms tend to be incessant tachycardias.

Occasionally, dual AV nodal pathways manifest on the baseline sinus rhythm. In this case, two different PR intervals are seen in sinus rhythm (Figure 12.5).

C. Treatment

1. Acute therapy

- Carotid massage- Vagal maneuver, particularly Valsalva that is followed, after the strain phase, by recumbent position and passive leg raise.
- Adenosine 6 mg IV (followed by 12 mg IV if the 6 mg dose is ineffective). Adenosine breaks AVNRT and AVRT by blocking the AV node. AVNRT and AVRT are the main arrhythmias that break rather than simply slow down with adenosine; atrial tachycardia can sometimes break with adenosine.
- Diltiazem IV or β-blocker IV is also effective.

* Fast-slow AVNRT is often slower than typical slow-fast AVNRT, as antegrade fast pathway conduction is slower than its retrograde conduction.

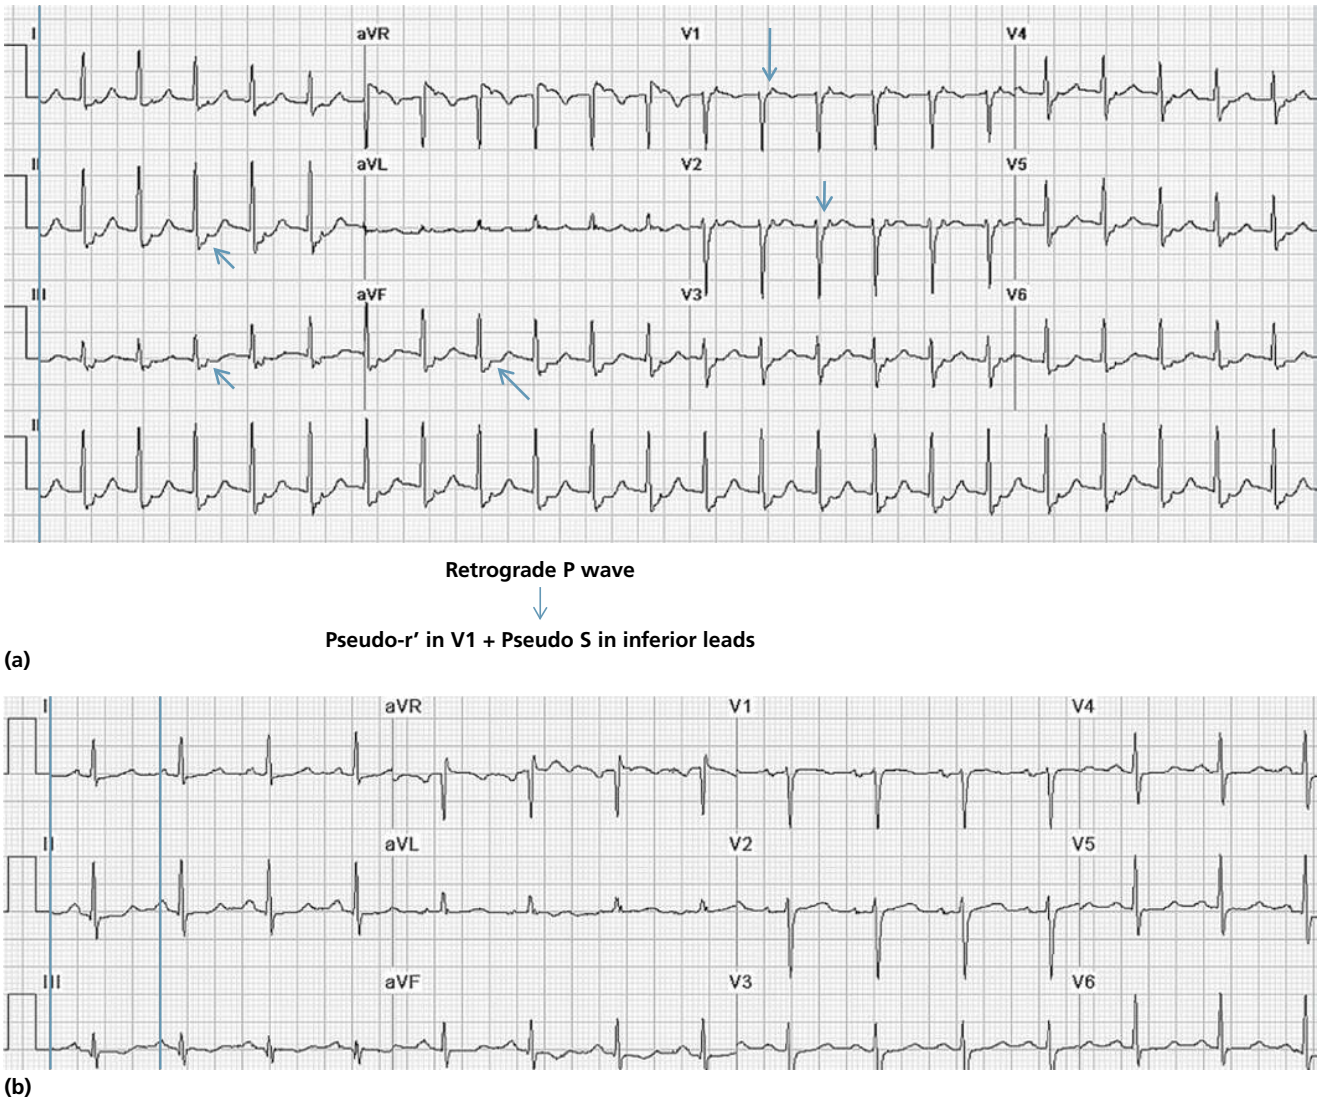

Figure 12.2 **(a)** Arrows point to the retrograde P wave that is superimposed on the ST segment, appearing as a notch on the ST segment. **(b)** An ECG of the same patient in sinus rhythm after adenosine therapy: note the difference in V_1–V_2 and in the inferior leads (no "pseudo-r'" or "pseudo S").

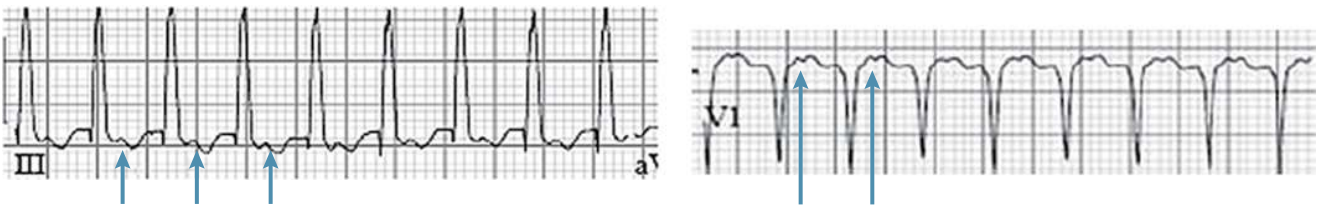

Figure 12.3 Narrow complex tachycardia with retrograde P waves (*arrows*) seen in leads III and V_1. RP is short, <1/2 RR interval; hence, atrial tachycardia is unlikely. In AVNRT, P wave typically falls within or immediately after QRS (RP interval < 90 ms), giving a pseudo-S shape in the inferior leads and pseudo-r' shape in V_1. In this case, P wave falls a bit further away and RP is > 90 ms; thus, the arrhythmia could be either AVNRT or AVRT.

Figure 12.4 P waves are seen just before the QRS, with a PR interval < 110 ms. In a narrow complex tachycardia, this suggests AVNRT, although it is only seen in 4% of AVNRTs.

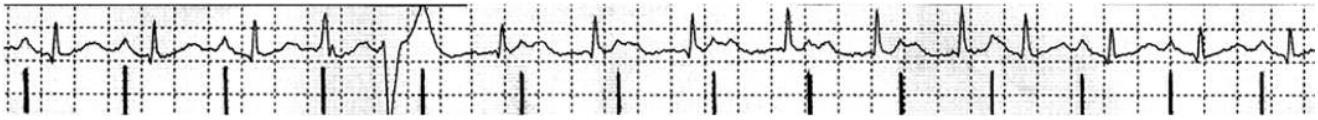

Figure 12.5 Sinus rhythm is present throughout the tracing. Vertical lines indicate P waves. Initially, the PR interval is normal (0.20 s), but after a couplet of PVCs (4th and 5th QRS complexes), the PR interval lengthens markedly. The PVC has retrogradely penetrated the fast pathway and blocked it. Hence, the AV conduction shifts from the fast pathway to the slow pathway. With the 7th sinus P wave after the couplet, the PR returns to normal. Reproduced with permission from Glancy DL, Hanna EB, Jain N. Long P-R intervals following certain ventricular premature complexes. J La State Med Soc 2010; 162: 185–6.

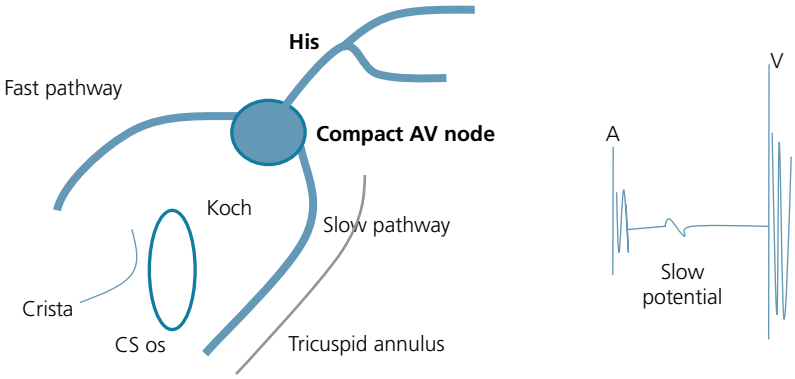

Figure 12.6 Anatomy of the slow pathway, fast pathway, and compact AV node. Note their potential relationship with a His catheter and coronary sinus catheter. The slow pathway (ablation target) is below the His and in front of the CS ostium. The Koch triangle, where the slow pathway lies, is bordered by the His, the coronary sinus, and the tricuspid annulus. The crista terminalis is behind the Koch triangle. A slow potential recorded across the slow pathway is shown. CS, coronary sinus.

2. Long-term treatment is required in case of frequent recurrences of sustained episodes

There are 2 options:

- Chronic β-blockers or CCBs. When AVNRT is infrequent, 1 dose of these drugs may be used intermittently upon each recurrence: for example, rapid-release diltiazem 120 mg, or *intranasal etripamil*, a rapid-onset (<3 min), short-acting CCB (pill-in-the pocket strategy).
- Radiofrequency ablation of the AV node's slow pathway is a second-line therapy after failure of drug therapy. It is indicated as first-line therapy in poorly tolerated AVNRT, recurrent AVNRT, or even one or infrequent episodes of well-tolerated AVNRT if the patient wishes complete control of the arrhythmia (class I recommendation).

Anatomically, the slow pathway is located inferiorly, along the tricuspid annulus in front of the coronary sinus os, whereas the fast pathway is located superior to the coronary sinus os. They both coalesce more distally to form the compact AV node then His, which is located anteriorly (Figure 12.6). The slow pathway is located anatomically using a His catheter and coronary sinus catheter, and electrically by searching for an area where both A and V deflections are recorded, along with a slow potential in between, not a His potential.

D. Termination

Spontaneous termination may occur if a PAC occurs at a time when it can enter the slow-pathway arm of the reentrant circuit without fully penetrating it. This PAC gets blocked and stops the reentry (Figure 12.7). Spontaneous termination may also occur when the vagal tone blocks the slow pathway.

Vagal tone and AV nodal blocking agents block the slow pathway, usually in a Wenckebach pattern. They terminate the AVNRT after a few cycles, when an impulse that has conducted retrogradely fails to reenter the slow pathway (Wenckebach block). The tachycardia often terminates with a retrograde P wave (close to the QRS).

In AVNRT, the atria and ventricles are not required for AV nodal reentry. Thus, if a PAC, a PVC, or atrial or ventricular pacing does not penetrate the AV nodal reentry, AVNRT will not be disrupted. On ECG, AVNRT appears to resume at the same rate after the PAC or PVC; in fact, the reentry circuit has not been affected at any time by this premature beat (Figures 12.14, 16.8).

III. Atrioventricular reciprocating tachycardia (AVRT) and Wolff–Parkinson–White (WPW) syndrome

A. Pathophysiology

AVRT and WPW syndrome are characterized by an accessory pathway (AP), also called bypass tract, that connects 1 atrium to 1 ventricle.

1. Approximately 30–60% of diagnosed *APs are concealed pathways*, *meaning they can only conduct retrogradely from the ventricle to the atrium*. A concealed AP is silent when the patient is in sinus rhythm and only manifests itself during a tachycardia that involves its retrograde conduction (orthodromic AVRT).

2. The remaining *APs are manifest pathways, meaning that they conduct from the atrium to the ventricle on a regular basis*, bypassing the slower AV nodal conduction. The manifest AP conducts faster than the AV node. The normal sinus impulse conducts through both the AV node and the AP. The relative contributions of the AP and the AV node depend on the conduction speed across the AP vs. AV node and how far left/laterally the AP originates. The conduction over the pathway leads to a delta wave and PR shortening, more evident when relatively more ventricle is stimulated through the AP.

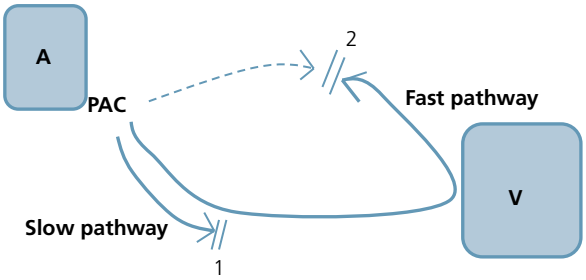

Figure 12.7 An appropriately timed PAC conducts down the slow pathway but cannot go deep enough as the distal parts of this pathway (1) or the fast pathway (2) are in the refractory period. Eventually, the reentrant cycle is broken and the next P wave is a sinus P wave. Depending on where the block occurs:

- There is no conduction to the ventricles or the atria (block 1), the tachycardia ends with the premature P wave.
- There is conduction downstream to the ventricle but no retrograde conduction to the atria (block 2); the tachycardia ends with a QRS.

A PAC may not penetrate the reentrant circuit at all if the whole slow and fast pathways are in the refractory period; in this case, the PAC does not affect the AVNRT, which continues unaffected. The tachycardia also ends with a P wave when the spontaneous vagal tone or AV nodal agents interrupt the tachycardia (they block the slow pathway).

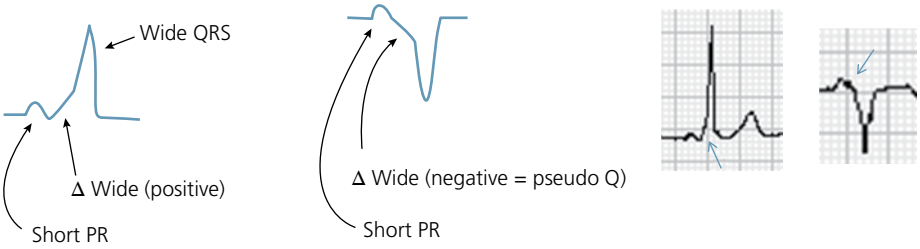

Figure 12.8 Electrocardiographic features of pre-excitation. Arrows point to the positive and negative delta waves.

This pathway conducts from the atrium to the ventricle and can conduct from the ventricle to the atrium. There are 4 possible AP locations: (1) left lateral, free wall (the most common, ~50% of APs); (2) right free wall (10–20%); (3) posteroseptal (20–30%); (4) anteroseptal (least common, ~5%). Approximately 5–10% of patients have multiple APs.

This AP "pre-excites" the ventricles and the phenomenon is called pre-excitation. *WPW pattern* is used to describe the baseline pre-excitation, while *WPW syndrome* is used when arrhythmias occur as a result of the manifest AP. WPW pattern is seen in ~0.2% of the population. It has a higher prevalence in Ebstein's anomaly and HOCM.

B. Baseline ECG is not affected by a concealed accessory pathway

C. Baseline ECG is affected by a manifest accessory pathway (pre-excitation or WPW pattern) (see Figures 12.8–12.10)

1. The baseline ECG is characterized by:
   - Short PR interval (<120 ms). The pre-excited PR is shorter than the AV nodal conduction but may not be short in the absolute sense.
   - Delta wave, which corresponds to the early onset of ventricular activation through the AP. Delta wave is a slur on the initial portion of QRS, *usually riding the P wave*. This slur may be negative, mimicking a Q wave.
   - Wide QRS >120 ms, with secondary ST–T abnormalities (directed opposite to QRS). As opposed to RBBB and LBBB, QRS is slurred and delayed in its initial rather than terminal portion. QRS may be narrower than 120 ms in up to half of pre-excitation cases, whenever the ventricular excitation spreading down the AP does not occur long enough before the excitation spreading down the AV node.
2. **The degree of pre-excitation depends on** (Figure 12.9):
   - *The relative amount of ventricular tissue stimulated through the AP vs. the AV node, which depends on the relative conduction speed through the AP vs. the AV node*. PR may be normal and delta wave may be absent in patients who have a fast AV nodal conduction and a left lateral AP. In the latter case, it takes a long time for the atrial impulse to reach the atrial insertion of the AP, by which time a slick AV node would have stimulated most of the myocardium: an increasing amount of ventricular muscle is excited through the normal AV pathway and a decreasing amount is excited through the anomalous pathway, which results in a less pre-excited QRS complex.
   - *The refractory period of the AP*, which is longer than the refractory period of the AV node. An AP with a long refractory period is more likely to block at a relatively slow heart rate (e.g., 100 bpm).

Always distinguish refractory period from conduction speed. AP can conduct very fast and lead to a very wide delta wave, yet have a long refractory period and thus block at a relatively slow heart rate. In this case, AP conducts the atrial waves *fast*, but *cannot conduct too many* atrial waves back-to-back. The A-to-V interval is short, but the V-to-V interval is not.

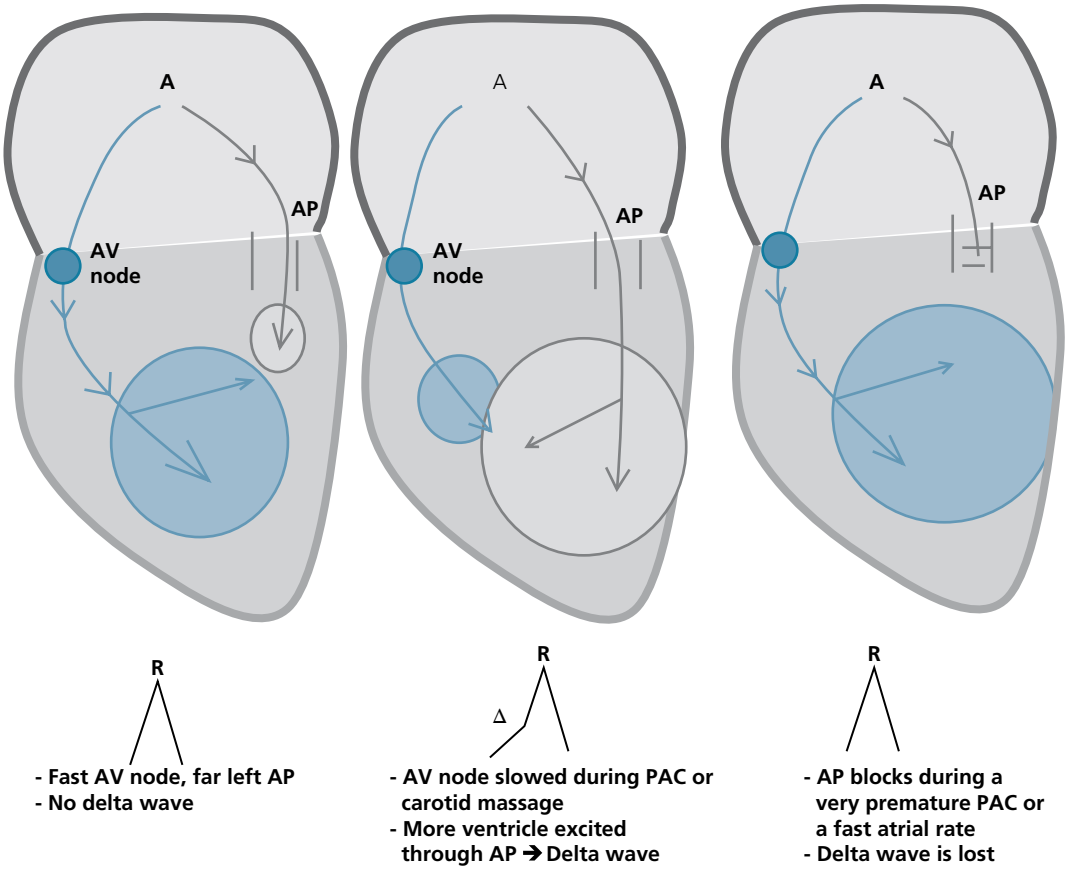

Figure 12.9 Amount of myocardium depolarized by the accessory pathway (*gray circle*) vs. the AV node (*blue circle*) depends on the speed of AV conduction, how far laterally the AP originates, and the refractory period of the AP. A PAC is slowly conducted through the AV node, which allows more ventricular mass to be depolarized through the AP. However, a very premature PAC may get blocked across the AP, which, although faster than the AV node, has a longer refractory period and is more likely to block its conduction.

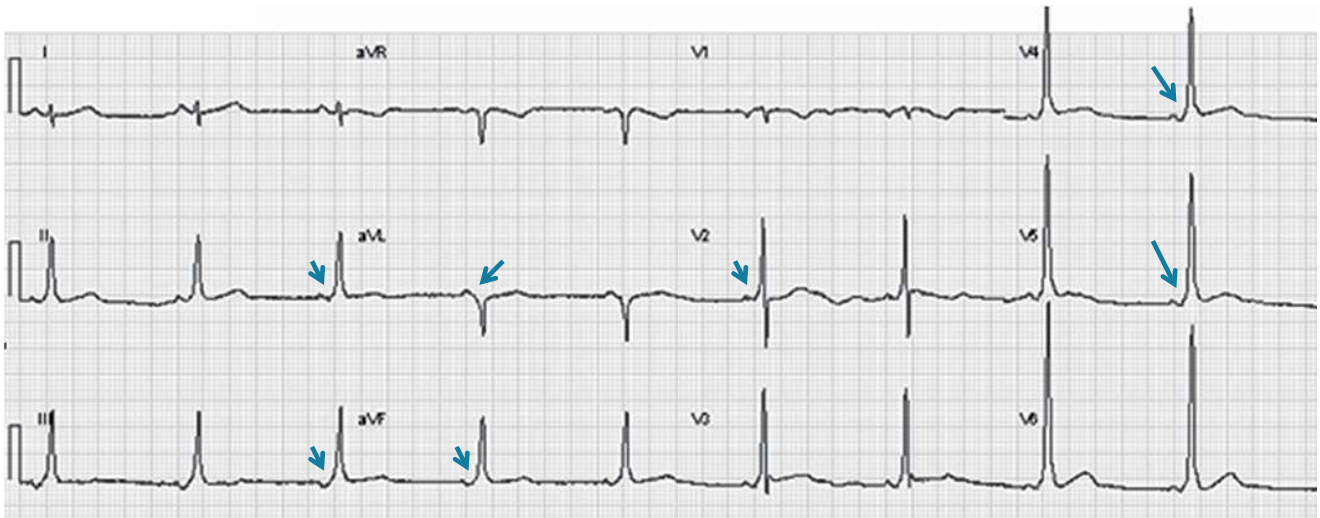

Figure 12.10 A slur is seen on the upslope of the QRS complex (e.g., leads II, III, aVF, V_2–V_6, as marked by the *arrows*). Also, note how the P wave is very close to the QRS complex (almost abuts it). The QRS seems negative in V_1 but the initial deflection, i.e., delta wave, is positive. The accessory pathway is left-sided, as delta is positive in V_1–V_2; it is left lateral, as delta wave is negative (pseudo-Q wave) in aVL.

3. When antegrade AP conduction and delta wave only manifest intermittently, or when the ECG criteria of pre-excitation are not completely fulfilled (PR slightly >120 ms, QRS 100–120 ms), pre-excitation and delta wave may be unveiled by:

- *Slowing the conduction over the AV node*, which leads to a proportionately larger amount of myocardium stimulated through the AP (adenosine, carotid sinus massage). This leads to a shorter PR interval and a wider delta wave. Since sinus bradycardia is many times associated with slowing of the AV nodal conduction (high vagal tone, drugs), delta wave is often more prominent during sinus bradycardia.
- *PAC*. Delta wave is typically wider during a PAC, and a progressive increase in prematurity of the PAC usually results in a progressive increase in the pre-excitation of the QRS complex. PAC results in prolongation of the conduction time through the AV node (increased AH interval), whereas the AP keeps a constant conduction time; thus, relatively more ventricular muscle gets excited through the AP. However, with a further increase in prematurity, the refractory period of the anomalous pathway is reached, and conduction is achieved through the AV node without any pre-excitation; this actually allows estimation of the refractory period of the AP (Figure 12.9). A similar phenomenon may be seen with progressively faster atrial pacing, wherein AV nodal conduction slows down allowing delta wave to become more prominent, until the AP refractory period is reached.
- In exertional sinus tachycardia, delta wave may diminish as a result of: (1) increased AV nodal conduction; or (2) long AP refractory period leading to a block of conduction in AP. A consistent lack of delta wave during tachycardia suggests the latter alternative.
- As opposed to aberrancy, the pre-excitation/delta wave is more likely to manifest after a long R–R interval.

If, despite those maneuvers, the only abnormality seen on the ECG is a short PR interval, the patient simply has accelerated AV nodal conduction rather than pre-excitation, i.e., a short AV delay that is within the spectrum of normal AV delays. It was suggested previously that this may be due to an atriofascicular bypass tract, especially if the patient develops SVT (Long–Ganong–Levine syndrome). However, this is very rarely the case.

D. Localization of the accessory pathway according to the baseline ECG

In order to localize the AP, it is key to identify the leads with negative delta waves. Delta is negative in the leads surrounding the origin of the AP, as AP will be pointing away from those leads. Analyze the right-sided lead V_1, the inferior leads, and the left lateral leads I and aVL:

- Lead V_1 provides an assessment of right vs. left pathway. A negative delta in lead V_1 (QS pattern) implies that AP is pointing away from the right side, and thus the pathway is right-sided. A positive delta wave in lead V_1 (R, RS, or RSr' pattern) implies a left-sided pathway.
- The inferior leads provide an assessment of anterior vs. inferior pathway. A negative delta in the inferior leads implies an AP that points away from the inferior wall, often a posteroseptal pathway.
- The lateral leads provide an assessment of left lateral vs. septal or RV pathway. A negative delta wave in the left lateral leads I and aVL often implies a left lateral pathway (Table 12.1, Figure 12.10).

The same rules apply to localizing the origin of VT. The orientation of QRS is analyzed in those same leads. There is one additional rule in VT: negative QRS concordance in all precordial leads V_1–V_6 implies an apical origin, a pattern not seen with delta wave or pre-excited SVT.

E. Types of tachyarrhythmias: mechanisms and initiation

1. Concealed accessory pathway (see Figure 12.11)

The pathway cannot conduct antegradely, and therefore it does not conduct during sinus rhythm; no delta wave is seen. However, partial, concealed penetration of the AP occurs at baseline and puts it in a refractory period, so that retrograde impulses coming from the ventricle cannot get conducted and cannot initiate reentry. This is called concealed conduction into the AP.

The AP has a longer refractory period than the AV node; thus, when a very premature PAC occurs, it cannot penetrate the AP to any degree, allowing the AP to rest. When the electrical activation reaches the ventricle, it can conduct retrogradely through the AP for 2 reasons: (1) the AP is capable of conducting retrogradely; (2) the AP has had time to rest and recover from the refractory period, since the PAC did not penetrate it at all. This initiates a reentry called **orthodromic AVRT**. As opposed to AVNRT, in orthodromic AVRT the atria and the ventricles are depolarized sequentially rather than simultaneously and distinct P waves are almost always seen, with a short RP interval<1/2 RR, but not too short (>90 ms). The ventricular rate is ~150–250 bpm.

Also, a PVC can initiate retrograde AP conduction and reentry because it occurs after the sinus-originating ventricular stimulation, at a time when the AP has recovered from the sinus-initiated concealed conduction and refractory period.

Table 12.1 Electrocardiographic localization of the AP.

	V_1		II/III/aVF	I, aVL
Left lateral	(+)		(+)	**(–)**
Right free wall	**(–)**		(±) (e.g., + in II, – in III)	**(+)**
Posteroseptal (near the coronary sinus)	(–) with sharp transition to (+) in V_2 if right posteroseptal	(+) if left posteroseptal	**(–)**	(+)
Anteroseptal (right)	(–), isoelectric, or biphasic		(+)	(+)

Those rules may apply to localizing the origin of PVC or VT based on the voltage of QRS in those leads. Lead I is more important than aVL in AP localization. Since the AP is basal, i.e., not close to the apex in any form, the QRS cannot be negative in leads V_4–V_6.

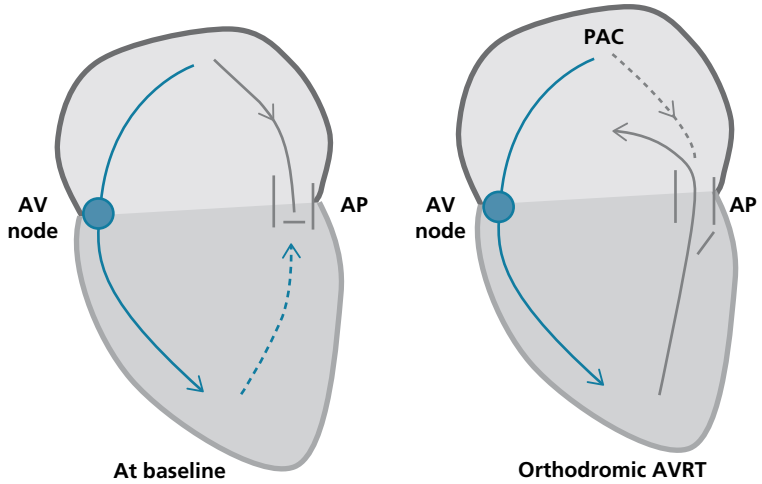

Figure 12.11 Concealed accessory pathway (AP).

The pathway cannot fully conduct antegradely; thus, it does not conduct during sinus rhythm and no delta wave is seen. Yet, partial penetration of the AP occurs at baseline and puts it in a refractory period, so that retrograde impulses coming from the ventricle get blocked and cannot initiate reentry. This is called concealed conduction into the AP. **The AP has a longer refractory period than the AV node; thus, when a very early PAC occurs (*right*), it cannot penetrate the AP to any degree, allowing the AP to rest.** When the electrical activation reaches the ventricle, it can conduct retrogradely through the AP, which has had time to rest and recover from the refractory period, since the PAC did not penetrate it at all. This initiates reentry (orthodromic AVRT).

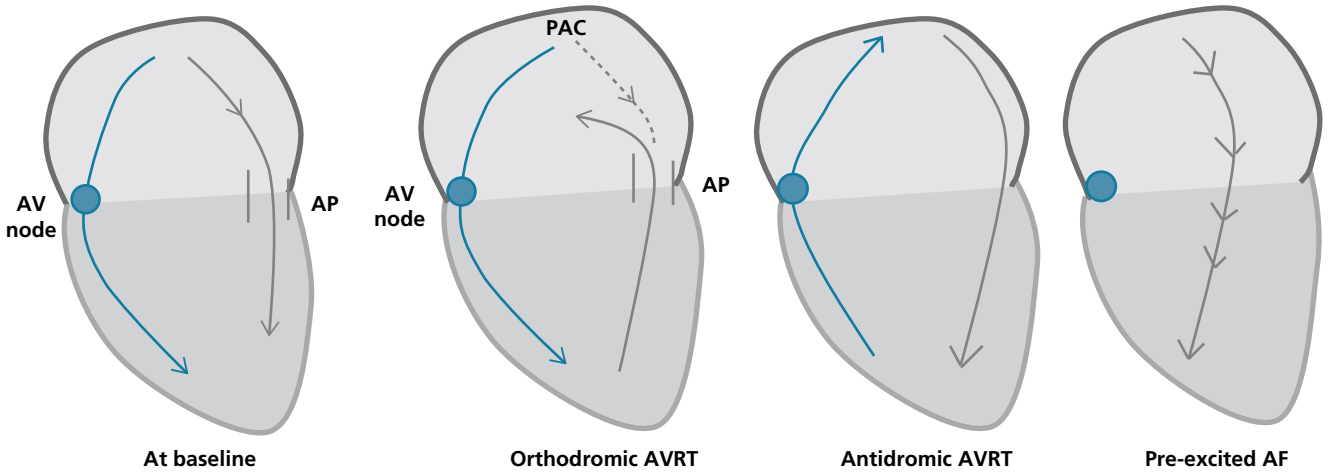

Figure 12.12 Manifest accessory pathway.

The AP can conduct both antegradely and retrogradely. The normal sinus impulse conducts through both the AV node and the AP. The conduction over AP leads to delta wave and PR shortening, more evident when relatively more ventricle is stimulated through the AP. The AP conducts faster than the AV node but has a longer refractory period than the AV node. Thus, when a very premature PAC occurs, the PAC conducts solely through the AV node without any delta wave and initiates reentry (orthodromic AVRT). *The larger the difference in refractory period between the AV node and the AP*, the more likely it is for a PAC to get blocked in the AP and initiate AVRT. Occasionally, the PAC conducts down the AP and leads to antidromic AVRT. AF or atrial flutter may conduct rapidly and antegradely over the accessory pathway.

2. Manifest accessory pathway (see Figure 12.12)

The AP can conduct both antegradely and retrogradely.

a. The AP is a myocardial structure that **conducts faster than the AV node; however, it has a longer refractory period than the AV node**. When a very early PAC occurs, **orthodromic AVRT** may occur (similar mechanism to the concealed AP). PVC can also propagate up the AP and initiate reentry.

b. It is rare for the PAC to solely conduct down the AP and not the AV node, because the AP usually has a longer refractory period than the AV node. However, the refractory period of the AP is occasionally very short, shorter than the AV node's refractory period; in this case, the PAC may block in the AV node and rather conduct down through the AP then up through the AV node (**antidromic AVRT**). Alternatively, in 30–60% of cases, antidromic AVRT involves multiple APs: a PAC conducts antegrade through one AP and retrograde through another (usually remote, contralateral). Since the ventricle is stimulated through a ventricular focus rather than the His bundle, the tachycardia is a wide complex tachycardia that has VT morphology. As opposed to VT, the pre-excited QRS complex cannot be negative in leads V_4–V_6, as the pre-excitation is usually basal rather than apical.

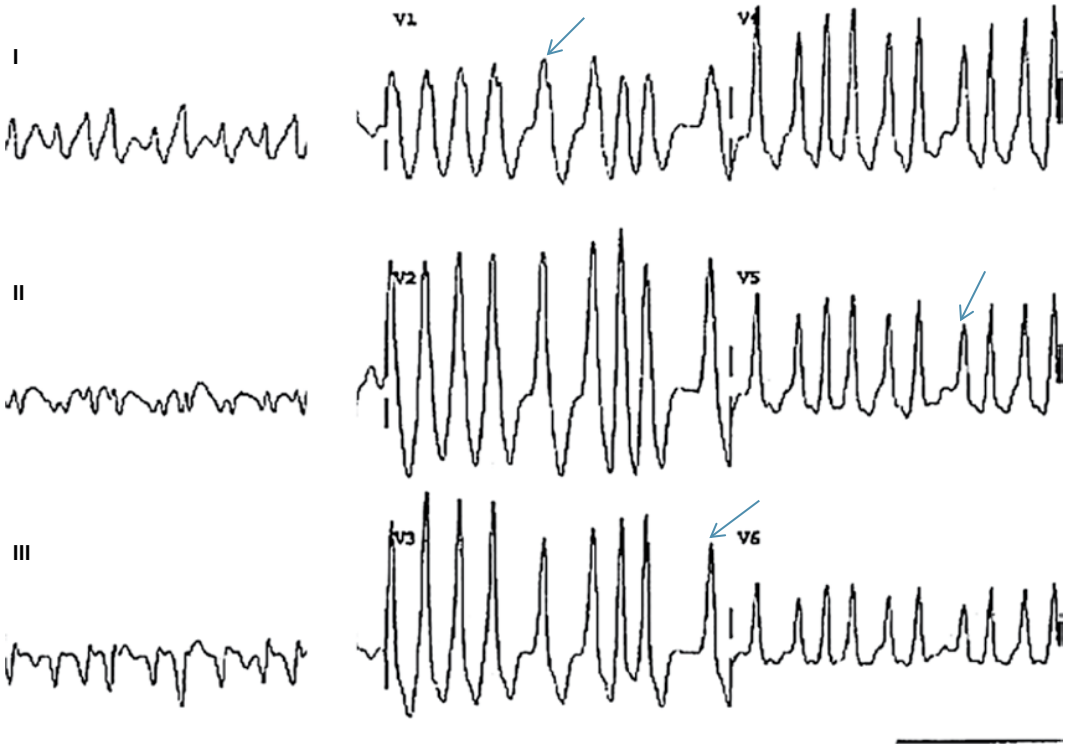

Figure 12.13 Irregular tachycardia with wide, polymorphic, bizarre-looking QRS, with VT rather than SVT features (positive QRS concordance in V_1–V_6, QRS morphology not consistent with RBBB or LBBB). This is a pre-excited AF in a patient with WPW. Note that, as opposed to aberrancy, QRS becomes wider after a longer R–R interval (*arrows*). AP is likely left posteroseptal (delta wave is negative in the inferior leads).

c. Pre-excited AF or atrial flutter: in this case, AF or atrial flutter conducts at a high rate from A to V over the accessory pathway (Figure 12.13). This leads to very fast (>200 bpm), very wide, bizarre-looking QRS complexes, without a typical bundle branch block morphology. By using the SVT/VT differentiation algorithm, pre-excited SVT typically has morphological VT features, yet the irregularity and the variable QRS morphology (variable pre-excitation) point to a pre-excited AF. This is the most dangerous tachycardia associated with the accessory pathway. Sudden death is, fortunately, rare, seen in <1% of patients with WPW pattern over the course of 10 years.

Patients with WPW are prone to develop AF, possibly because of reentry around the atrial insertion of the AP (prevalence of AF in young patients with WPW ~15–30%). Also, any AVRT can trigger AF and become poorly tolerated.

- "Irregular VT" is often AF with pre-excitation.
- As opposed to AF with Ashman aberrancy, AF with pre-excitation may be characterized by a QRS that gets wider after a long R–R interval. The long R–R interval allows the AP to recover from its refractory period.

Note that the AP behaves like atrial or ventricular myocardium during stimulation, not like the AV node; thus, the faster the tract is stimulated, the faster it conducts and the quicker it recovers from its refractory period, while the AV node further slows down. The lack of AV interval prolongation with incremental pacing is a hint to the presence of AP. However, depending on its refractory period, the AP may block at fast rates if it is a benign AP; it blocks in a Mobitz II fashion, rather than a Wenckebach fashion. In the particular case of AVRT, the occurrence of block ends the reentry.

Concealed pathway tachycardias are all orthodromic AVRT. Of tachycardias occurring with a manifest pathway (WPW syndrome), 75% are orthodromic AVRTs, 5% are antidromic AVRTs, and ~20% are pre-excited AF or atrial flutter (5% atrial flutter).

F. More electrophysiological mechanisms

A PAC or a PVC may occur at a particular time when it can partially penetrate the reentrant AVRT circuit but encounters a refractory period deep in the circuit and, therefore, gets blocked inside it; this terminates AVRT.

On the other hand, a PAC, PVC, or extrastimulus that does not block the arrhythmia resets the tachycardia. The atrium and the ventricle being parts of the reentrant circuit, if a premature complex depolarizes the atrium or the ventricle, the reentrant circuit cannot keep looping independently. It either gets blocked by the premature complex, or gets entrained by it (Figure 12.14). Similarly, any block of the atrial or ventricular impulse leads to cessation of the arrhythmia, as the reentry cannot continue without both atrial and ventricular excitations; 2:1 conduction cannot be seen with AVRT (conversely, 2:1 conduction may occasionally be seen with AVNRT if a block occurs in the AV node beyond the small reentrant circuit).

In orthodromic AVRT, if a functional BBB occurs on the same side as the accessory pathway, the reentrant circuit lengthens, and thus the cycle length of the tachycardia increases (Figures 12.15 and 12.16). In contrast, the occurrence of BBB does not affect the AVNRT rate, and in fact BBB is usually seen with faster rates.

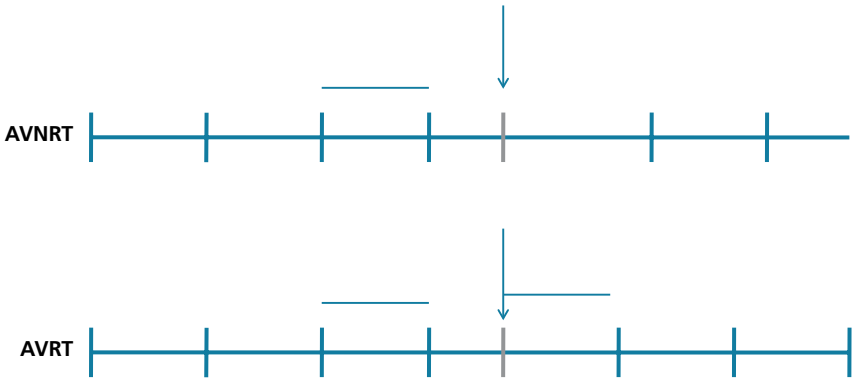

Figure 12.14 In AVNRT, the occurrence of a PVC (*gray bar*) either blocks the tachycardia, or, as in this case, gets conducted to the ventricles but does not change the reentry, which keeps looping at its own rate. The interval between the QRS preceding the premature beat and that following it is double the R–R interval of the tachycardia.

In AVRT, PVC either blocks the tachycardia, or, as in this case, gets conducted through the tachycardia and resets its cycle. The R–R interval that follows the premature beat is equal to the R–R interval of the tachycardia.

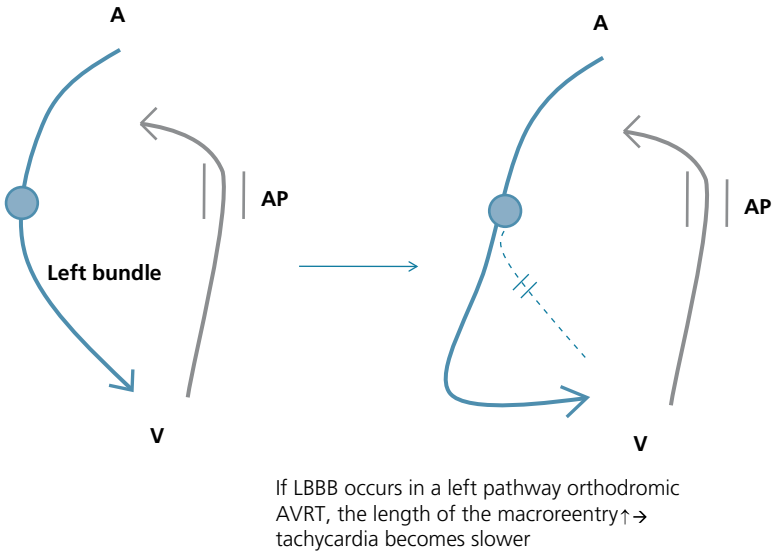

Figure 12.15 Bundle branch block during orthodromic AVRT.

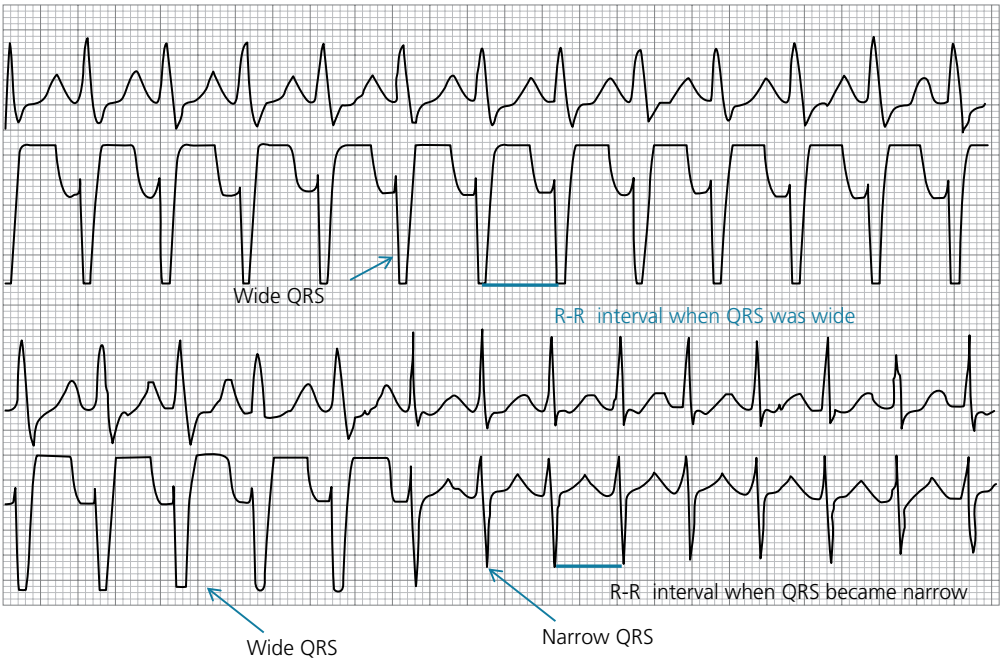

Figure 12.16 On this tracing, when the wide complex tachycardia becomes narrow, the R–R interval becomes shorter (the rate becomes faster). This implies orthodromic AVRT with transient block of the bundle branch ipsilateral to the AP (the bundle branch involved in the reentry). The transient BBB slows the tachycardia.

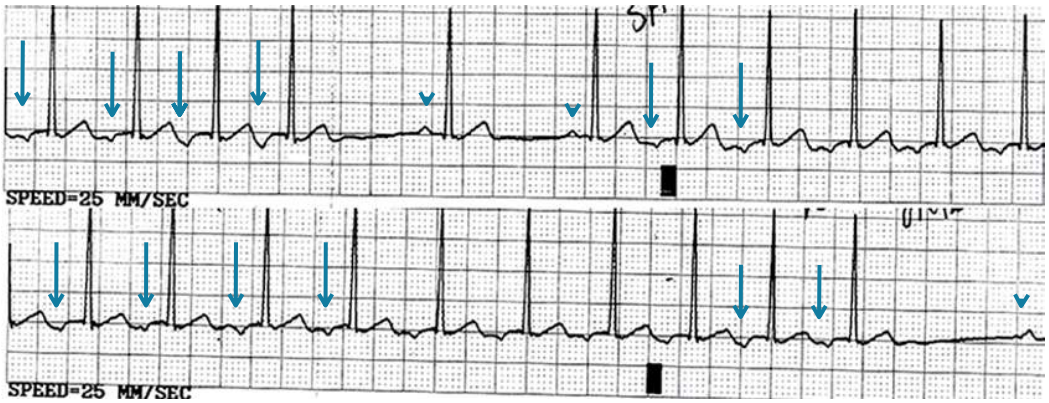

Figure 12.17 A 22-year-old woman with no prior cardiac history presents with runs of SVT interspersed with sinus beats. The SVT rate is ~105 bpm. Two types of P waves are seen: sinus P waves (*arrowheads*) and P waves related to SVT (*arrows*). RP interval is long (long RP tachycardia). The differential diagnosis of this SVT includes:

- Atrial tachycardia, with the focus being low in the RA or LA, near the AV node.
- Incessant AVRT (PJRT) with retrograde P waves, negative in lead II.

The recurrent runs interspersed with sinus beats indicate that the tachycardia is easy to initiate, which is consistent with PJRT. Each run starts with a PAC and seems to end with a QRS rather than the typical P wave of the run: this may be consistent with atrial tachycardia or PJRT (intermittent block of the slow retrograde AP).

A tachycardia that becomes slower when it becomes wider is orthodromic AVRT.

The retrograde conduction across the AP may be slow and decremental, which increases the cycle length of the tachycardia. AVRT ends up being slow (100–150 bpm) with a long RP interval. The cycle of the tachycardia is so long that, as the stimulation is spreading retrogradely through the AP, the AV node recovers from its refractory period. As opposed to the fast AVRT, at any particular point in time, most of the reentrant circuit is not in a refractory period. Thus, a PAC is unlikely to only partially penetrate the circuit and block the tachycardia; it is likely to get conducted through the reentry and reset the tachycardia. This is the large "excitable gap" concept seen with very slow reentry, which explains why this atypical AVRT is unlikely to break spontaneously and tends to be incessant and persistent for weeks, leading to a tachycardia-mediated cardiomyopathy. The tachycardia is called ***permanent junctional reciprocating tachycardia (PJRT)***. Even when this arrhythmia breaks, it is easy to reinitiate it. Owing to the slow retrograde conduction, any PAC or PVC easily conducts retrogradely all the way up the AP, as the AP is given time to recover from its refractory period (Figure 12.11). Similarly to other AVRTs, PJRT can be seen at any age, including in young patients without heart disease (Figure 12.17). In PJRT, the AP is usually a concealed posteroseptal pathway that only conducts retrogradely.

G. Treatment

1. Acute treatment

- Orthodromic AVRT in a patient with concealed AP is benign. Acute treatment is similar to AVNRT (vagal maneuvers, adenosine).
- Orthodromic AVRT in a patient with pre-excitation on the baseline ECG: adenosine is carefully considered. While adenosine does not shorten the refractory period of the accessory pathway, it can trigger transient AF in up to 12% of patients, which will decompensate a patient with WPW. β-Blockers and CCBs may be used, with a risk of accelerating antegrade conduction should AVRT convert to AF (class IIb).
- Antidromic AVRT and pre-excited AF/atrial flutter are wide QRS-complex tachycardias with QRS features of VT. They should be treated like VT. In a hemodynamically stable patient, intravenous class I or class III drugs (procainamide or ibutilide) may be used as they increase the AP's antegrade refractory period. Intravenous amiodarone is contraindicated in the ESC and ACC guidelines, as acute amiodarone has a β-blocker effect and may block the AV node more than the AP (conversely, chronic amiodarone may be used, as it increases the AP's refractory period). Notably, one systematic review suggests the safety of IV amiodarone and suggests its use when other IV drugs are unavailable (Circulation EP 2026).

In pre-excited AF, *AV nodal blocking agents do not favor antegrade AP conduction simply by blocking the AV node. Rather, they shorten the antegrade refractory period of the AP*, allowing more back-to-back conduction of atrial waves over this pathway. How do they shorten the AP's refractory periord? At baseline, in pre-excited AF, the impulses that spread through the AV node reach the distal ventricular insertion of the AP and intermittently penetrate it, making it more refractory (concealed conduction). AV nodal blocking agents prevent that, thereby indirectly shortening the AP's refractory period. Besides, they cause hypotension which shortens AP's refractory period via ↑ catecholamines.

2. Chronic preventive treatment

a. Orthodromic AVRT with concealed AP, i.e., no WPW pattern on the resting ECG: prevention and treatment are similar to AVNRT:
- Chronic or "pill-in-the-pocket" CCB or β-blocker (50% preventive efficacy)

or
- Ablation of the accessory pathway, which is preferred when AVRT is poorly tolerated

b. Any tachyarrhythmia, including orthodromic AVRT, with WPW pattern on the resting ECG:
- Ablation of the accessory pathway (class I recommendation).
- AV nodal blocking agents reduce the occurrence of orthodromic AVRT but have drawbacks: they may reduce the AP refractory period. Impulses conducted through the AV node reach the accessory pathway's distal tip and make it more refractory; blocking those

impulses reduces the AP refractory period. Should AF occur, AP will conduct more readily. Digoxin should be totally avoided in WPW syndrome, even if the original manifestation was orthodromic AVRT (ACC class III recommendation); β-blockers or CCBs may be used in selective cases, especially in combination with antiarrhythmic drugs or if it is established that AP has a long antegrade refractory period (class IIb recommendation).

- Antiarrhythmic drugs class I (flecainide or propafenone), amiodarone, and sotalol increase the antegrade and retrograde refractory periods across the accessory pathway. However, by increasing the antegrade refractory period, they increase the difference in refractory period between the AV node and AP, making it easier for a PAC to initiate orthodromic AVRT (Figure 12.12). Combining a β-blocker with the antiarrhythmic drug may circumvent this phenomenon. This is also less likely to occur with antiarrhythmic agents that have an AV nodal blocking effect (amiodarone or sotalol). Antiarrhythmic drugs (class Ic, amiodarone, sotalol) are given a class II recommendation for WPW syndrome in a patient who is not a candidate for, or prefers not to undergo, catheter ablation. Class Ic drugs are particularly effective (class IIa). Conversely, antiarrhythmic drugs are ineffective in PJRT, which is an orthodromic AVRT, and may aggravate it.

3. Asymptomatic pre-excitation/WPW diagnosed on a resting ECG

The risk of sudden death is low (0.05%–0.1% per year, <1% per 10 years), but may be higher, up to 0.5% per year in some subgroups. Sudden death is related to the antegrade rapid conduction of AF and depends on how short the antegrade refractory period of the AP is. About 30% of adults lose the capacity for antegrade conduction over 5 years of follow-up, and their risk of sudden death becomes negligible.

The risk of sudden death *does not depend on how fast* the AP conducts the atrial waves, as by definition the AP has a fast conduction; what is more important is *how many* back-to-back atrial waves the AP can conduct, which depends on the AP refractory period. The best predictor of sudden death is the assessment of the shortest pre-excited R–R interval during AF. An interval of ≤250 ms, i.e., ≤1.25 large box on standard ECG, implies an increased risk of cardiac arrest.

- Risk stratification on the baseline ECG:
  - Intermittent pre-excitation, particularly when intermittent on the same ECG, implies that the antegrade refractory period of the AP is long (Figure 12.20). Intermittent pre-excitation at disparate points in time may be related to intermittent increase in AV conduction in a patient with a left lateral pathway, rather than a long AP refractory period.
  - The presence of multiple APs, i.e., multiple delta morphologies on serial ECGs, implies a higher risk.
- Every asymptomatic patient should undergo either ***an invasive or a non-invasive assessment of the refractory period of the AP*** (especially if young, <30–40 years old) (class I indication for exercise testing, class IIa for EP testing, ACC guidelines 2015).
  - During exercise testing, an accessory pathway with a long refractory period will not be able to antegradely conduct. Thus, the loss of pre-excitation during exercise implies a long AP refractory period. However, delta wave may be lost because of increased AV nodal conduction during exercise rather than a block in the AP, and therefore only a *complete* and *abrupt* loss of pre-excitation during exercise testing confirms a long AP refractory period.
  - EP testing consists of inducing AF and measuring the shortest pre-excited R–R interval. If this interval is ≤250 ms (rate ≥240 bpm), it is reasonable to ablate the asymptomatic pathway (class IIa). Instead of inducing AF, rapid atrial pacing may be used as a surrogate. The mortality risk associated with ablation is low (<0.05%) and lower than the yearly risk of sudden cardiac death, which may justify AP ablation in these asymptomatic patients.

As opposed to the intermittent loss of delta wave on a resting ECG, the intermittent loss of delta wave during exercise is not definitely reassuring and does not necessarily imply a long refractory period (positive predictive value of only 40%); an invasive assessment is indicated at this point.

AF is the most common supraventricular tachyarrhythmia, followed by atrial flutter, then paroxysmal supraventricular tachycardias. Of the paroxysmal supraventricular tachycardias:

- 60% are AVNRT.
- 30% are AVRT (AVNRT and AVRT are also called paroxysmal junctional tachycardias).
- 10% are atrial tachycardia or sinus node reentrant tachycardia (SNRT). SNRT is secondary to a reentrant circuit inside the sinus node and is usually slower than AVNRT and AVRT (rate 100–200, often 130–140 bpm). SNRT looks identical to sinus tachycardia, except for having a very steady rate and an abrupt onset and termination, unrelated to any physiological trigger; it often resolves with carotid massage or adenosine. As compared to AVNRT/AVRT, there is a slightly higher incidence of underlying heart disease.

H. Additional WPW examples (Figures 12.18–12.21)

IV. Junctional escape rhythm and accelerated junctional rhythm (or non-paroxysmal junctional tachycardia)

A. Junctional escape beats or rhythm

The AV junction (= AV node and His bundle) has the property of "automaticity" that allows it to function as a latent pacemaker. This latent pacemaker is normally suppressed by the more rapid sinus activity but can become manifest if: (a) the sinus node is slow or suppressed, in which case the AV junction assumes the pacemaker function by default (junctional escape); (b) the AV junction's automaticity increases,

Figure 12.18 Two types of QRS complex are seen. This intermittent widening of the QRS may represent intermittent bundle branch block (BBB) or intermittent pre-excitation. Intermittent BBB usually occurs with an increase in rate, but that is not the case here. Moreover, the morphology of the wide QRS favors pre-excitation. A positive delta wave with a short PR interval is seen on the wide complexes in leads I and V_5, while a negative delta wave (pseudo-Q wave) is seen in the inferior lead. This intermittent conduction across the accessory pathway implies a long refractory period and an inability to consistently conduct even at a normal rate (good prognosis). The AP is likely posteroseptal (delta being negative in the inferior lead).

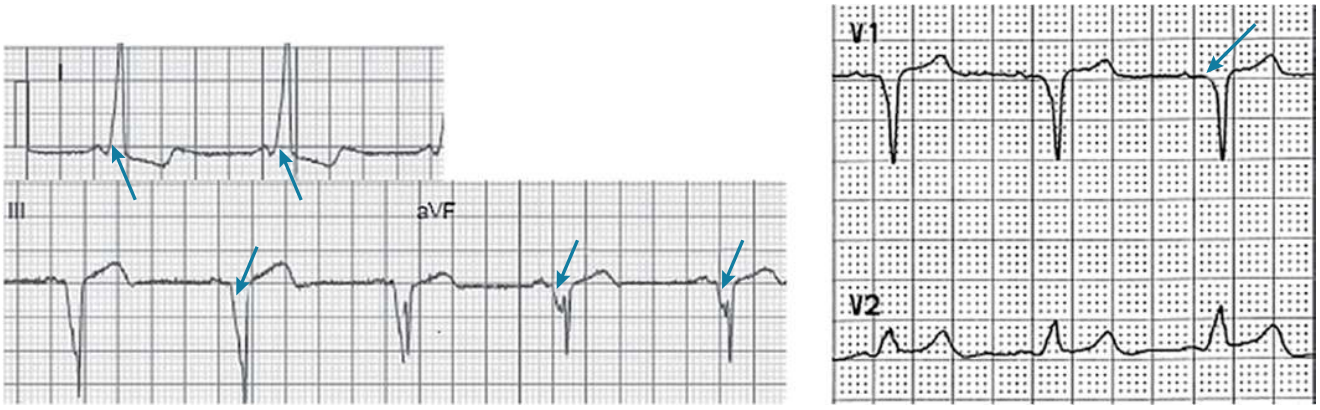

Figure 12.19 Another WPW pattern on a baseline ECG. Note the short PR, with P almost attached to R. There is a positive delta slur on the upslope of R wave in lead I, and a negative delta slur manifested as Q wave in leads III and aVF (delta marked by *arrows*). Delta wave is negative in the inferior leads, implying that the AP is posteroseptal, with the electrical depolarization going away from the inferior wall. The delta wave is positive in lead I, meaning that the impulse propagates toward the left lateral wall. Delta wave is negative in lead V_1, implying that the AP is right-sided, and thus the AP is right posteroseptal. The sharp delta transition in lead V_2 is consistent with a posteroseptal pathway.

Figure 12.20 Alternation of a narrow and an equidistant wide QRS (*vertical arrows*). Ventricular bigeminy is unlikely, since QRSs are equidistant. PR interval shortens and a delta wave is seen on the wider beats (*oblique arrows*). This is intermittent pre-excitation. Every other QRS conducts antegradely over an accessory pathway with a delta wave and a short PR interval (WPW). The next beat proceeds down the AV node rather than the accessory pathway, the accessory pathway being in a refractory period. This is 2:1 conduction over the accessory pathway at a high sinus rate. This alternation in pre-excitation on the same resting ECG is likely secondary to a long AP refractory period, which blocks every other beat. Intermittent pre-excitation on separate ECGs is less reassuring, as it may be due to increased AV nodal conduction, rather than AP block. Intermittent pre-excitation during exercise is also less reassuring. The pathway is likely a left lateral pathway (QRS is negative but delta is positive in V_1).

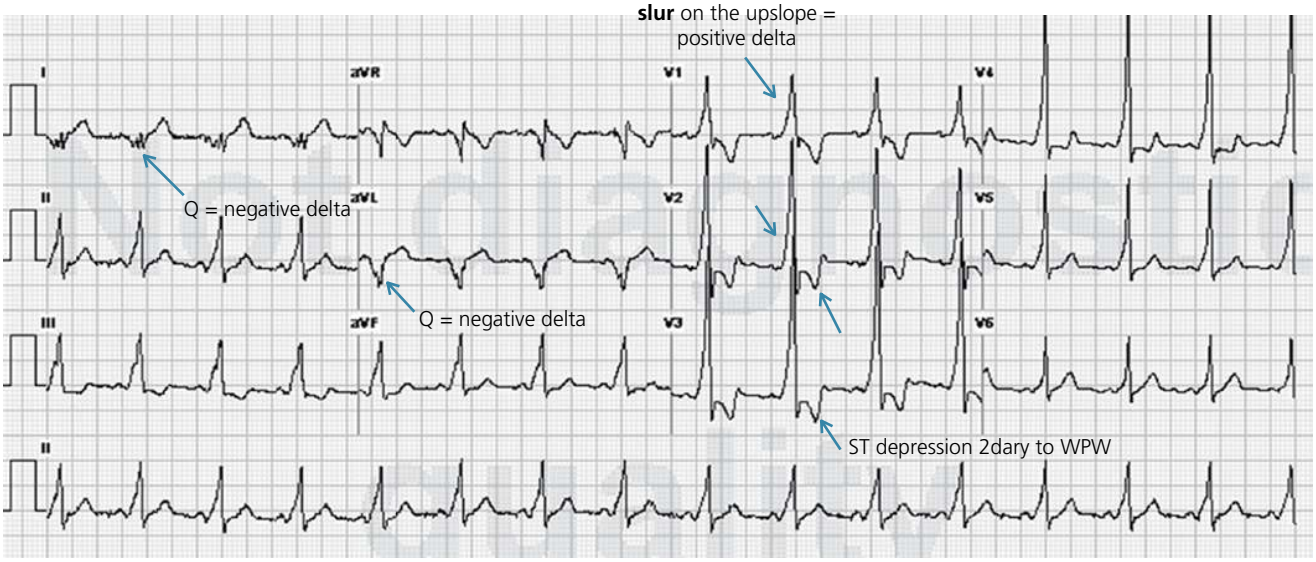

Figure 12.21 At first glance, this ECG shows a wide and tall R wave in V_1, Q wave in leads I and aVL, and ST-segment depression localized to leads V_1–V_3. This may suggest posterior and lateral Q-wave MI, and the ST depression suggests this MI is acute. On further ECG analysis:

1. PR is short, ~100 ms.

2. QRS is wide with delta wave: the P wave is "riding" the upslope of the R wave in leads V_1–V_6 and the downslope of Q in leads I and aVL. The upslope of QRS is slurred.

3. ST–T depression in V_1–V_3 is opposite in direction to the large QRS and likely secondary to the wide QRS.

The presence of the first two features defines a pre-excitation pattern. Pre-excitation may masquerade as MI: the Q waves are actually negative delta waves, and ST depressions or elevations are secondary to the wide QRS.

Localization of the pathway: look at leads V_1, I–aVL, and the inferior leads. Delta wave is negative in leads I and aVL, which is consistent with a left lateral pathway. The positive delta in V_1 and in the inferior leads is consistent with this. Left lateral pathway frequently leads to this positive QRS morphology in all precordial leads V_1–V_6.

allowing it to compete with the sinus node (accelerated junctional rhythm). The junctional escape has a rate of 30–60 bpm and may be associated with retrograde P waves or may compete with a slow sinus rhythm (isorhythmic AV dissociation).

B. Accelerated junctional rhythm

Accelerated junctional rhythm is an automatic rhythm arising from the AV node or the His bundle at a rate of 60–130 bpm, in contrast to the junctional escape rhythm that fires at a rate of 30–60 bpm. The rhythm is regular but may have a warm-up phase like any automatic rhythm.

Being relatively slow, the junctional rhythm competes with the sinus rhythm. Some sinus P waves fall distantly from the junctional QRS complexes and get conducted, whereas other P waves fall too close to the junctional QRS complexes and do not get conducted. There is dissociation between the sinus P waves and the junctional rhythm. This is isorhythmic (= competitive) AV dissociation.

On the other hand, the junctional rhythm may lead to retrograde P waves that inhibit the initiation and propagation of sinus P waves. These retrograde P waves may precede or follow QRS. When they precede QRS, the PR interval is usually <0.12 second.

The QRS is narrow but may be wide if a bundle branch block pre-existed. If it is wide, the rhythm simulates accelerated idioventricular rhythm (AIVR). The rhythm is considered junctional rather than ventricular if the wide QRS morphology is similar to the sinus-originating complexes or the baseline ECG. Otherwise, the rhythm is considered ventricular; the interposition of sinus-originating complexes that are narrow rules out a baseline bundle branch block and implies that the wide rhythm is ventricular.

This rhythm is generally due to underlying heart disease: acute MI (most commonly inferior MI, where it is a benign finding), digoxin toxicity, myocarditis, and post cardiac surgery. Occasionally, it occurs without underlying heart disease or represents a form of accelerated junctional escape in patients with sinus node disease or AV block.

QUESTIONS AND ANSWERS

Question 1. The accessory pathway:

A. Conducts faster than the AV node

B. Has a shorter refractory period than the AV node

C. Antegrade conduction of atrial fibrillation depends on how fast the accessory pathway conduction is

D. Antegrade conduction of atrial fibrillation depends on how short the refractory period of the accessory pathway is

Question 2. Delta wave is exaggerated:
A. During a premature atrial complex
B. After a premature atrial complex
C. During carotid massage
D. During exertional sinus tachycardia

Question 3. A negative delta wave in the left lateral leads often implies:
A. Left lateral accessory pathway
B. Right free wall accessory pathway

Question 4. Concerning the arrhythmias that may occur with accessory pathways:
A. Orthodromic AVRT can occur with both concealed and manifest APs
B. Antidromic AVRT can only occur with manifest AP
C. Only a PAC can initiate AVRT

Question 5. Features that differentiate a pre-excited tachyarrhythmia from ventricular tachycardia:
A. Both tachyarrhythmias have a QRS morphology that is not consistent with bundle branch block aberrancy
B. As opposed to ventricular tachycardia, a pre-excited atrial fibrillation is irregular and polymorphic
C. The pre-excited QRS complex cannot be negative throughout all of the precordial leads (negative concordance)

Question 6. A 35-year-old man presents with orthodromic AVRT. After the administration of adenosine, he converts to sinus rhythm with pre-excitation. Catheter ablation is considered, but he prefers medical therapy. What is the best regimen?
A. Metoprolol
B. Diltiazem
C. Flecainide or propafenone
D. Amiodarone, sotalol, or dofetilide

Question 7. A 30-year-old asymptomatic patient is found to have pre-excitation on an ECG performed before orthopedic surgery. What is the next step?
A. Ablation of the AP
B. Risk stratification using exercise ECG or looking for intermittent loss of pre-excitation on resting ECG
C. Risk stratification using EP study, measuring the shortest pre-excited R–R interval
D. No further workup, as he is asymptomatic
E. B or C

Question 8. In the asymptomatic patient with pre-excitation, which of the following implies a low-risk AP?
A. Intermittent loss of delta waves on ambulatory ECGs
B. Intermittent loss of delta waves on exercise ECG
C. Complete and abrupt loss of delta wave on exercise ECG
D. A and C

Question 9. Typical AVNRT is characterized by:
A. Slow pathway-then-fast pathway conduction (slow–fast), with a VA interval < 70 ms on intracardiac recording and RP interval < 90 ms on the surface ECG
B. Fast–slow conduction with RP interval < 70 ms on ECG

Answer 1. A, D.

Answer 2. A, C.

Answer 3. A.

Answer 4. A, B.

Answer 5. A, B, C.

Answer 6. C. Class Ic and III drugs increase the AP's antegrade and retrograde refractory period.Class Ic are likely more effective than class III, with more data supporting their use. Metoprolol and diltiazem are best avoided, in case the patient goes into pre-excited AF (yet, ACC guidelines allow their use in WPW patients whose only arrhythmia is orthodromic AVRT [grade IIb recommendation]).

Answer 7. E (B is given a class I recommendation, C is given a class IIa recommendation in asymptomatic pre-excitation).

Answer 8. D. If delta wave does not completely disappear during exercise testing, invasive assessment of the AP's refractory period is warranted.

Answer 9. A. Typical AVNRT is slow–fast AVNRT ("SF"). Fast–slow AVNRT is atypical with a long RP interval and a generally slower rate (even the fast pathway is a bit slow).

13 Bradyarrhythmias

I. AV block 400
II. Sinus node dysfunction 409
III. Bundle branch blocks, bifascicular and trifascicular block 412
Questions and answers 415

I. AV block

A. Types of AV block

1. First-degree AV block = PR interval >200 ms (may be as long as 1000 ms).

2. Second-degree AV block. Types (Figures 13.1–13.5):

- **i.** Mobitz type I (Wenckebach type): PR interval progressively prolongs until QRS drops, i.e., until a regularly occurring P wave is not followed by a QRS. This contrasts with SA block, where both P and QRS drop. To make the diagnosis, compare the PR that follows the blocked P wave (the shortest PR) with the PR that immediately precedes the blocked P wave (the longest PR).
- **ii.** Mobitz type II: QRS suddenly drops without a preceding PR change. *The baseline QRS is usually wide*. It may present as intermittently non-conducted P waves or as one non-conducted P wave that is not preceded by progressive PR prolongation and not followed by PR shortening. It is more ominous than Mobitz type I and is almost always a distal infranodal AV block. It progresses to a complete infranodal AV block commonly and suddenly.
- **iii.** 2:1 AV block (alternative drop of 1 QRS) could be equivalent to Mobitz I or Mobitz II AV block. If QRS is wide, the block is likely a Mobitz II equivalent. If QRS is narrow, the block is likely a Mobitz I equivalent. Also, look for periods of 3:2 conduction on a rhythm strip, as this may elucidate the Mobitz type of block.

3:2 AV block means that 2 consecutive P waves conduct while the third P wave gets blocked (i.e., 3 P waves with 2 QRS complexes). 4:3 block means 3 consecutive P waves conduct while the fourth P wave gets blocked. These blocks could be Mobitz I or II depending on the occurrence of progressive PR prolongation.

3:1 block means only 1 of 3 consecutive P waves is conducted (3 P waves with 1 QRS). This is also called *high- grade AV block* or advanced second-degree AV block and has the same implication as complete AV block. Unlike Mobitz II AV block, it can be a less ominous nodal or vagal AV block.

Second-degree AV block is characterized by group beating, in which a group of P–QRS complexes is followed by a pause, then the cycle repeats (Figures 13.2–13.5). The cycle length may be variable (2:1 alternating with 3:2, 4:3, 8:7, etc.). Think of second-degree AV block whenever there is a repetition of groups of beats.

In patients with a long Wenckebach cycle (e.g., 8:7), PR only slightly prolongs between the last beats, making PR prolongation unnoticeable. **PR prolongation is most easily addressed by comparing the PR immediately following the pause (the shortest) to the one immediately preceding it (the longest).** Also, R–R progressively shortens before the pause, and the R–R interval containing the blocked P wave is shorter than the sum of the shortest 2 R–R intervals (Figure 13.2).

Frequently, however, in case of a long Wenckebach period (e.g., 7:6), the R–R cycles preceding the block lengthen after the initial shortening.

3. Third-degree or complete AV block (Figures 13.6 and 13.7). No P wave is conducted.

A junctional or ventricular escape rhythm takes over. The ventricular rate is regular and unrelated to P waves (AV dissociation). **The PR distance is variable yet the R–R interval is regular**, providing evidence that none of these P waves is conducted. There are more P waves than there are QRS complexes.

High-grade or advanced second-degree AV block is a block in which the AV conduction ratio is 3:1 or worse. In one form, P waves and the escape QRS complexes are dissociated but P wave occasionally conducts: R–R intervals are mostly regular, with occasional R–R intervals that are shorter as they relate to the few conducted P waves.

In patients with *AF, a slow and regular ventricular response* implies complete AV block. A long AF pause, >3 seconds, generally implies high-grade AV block and is concerning when it occurs during wakefulness.

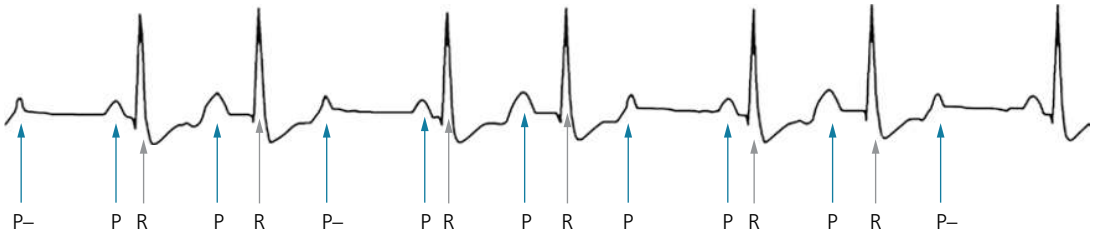

Figure 13.1 Wenckebach 3:2 AV block. P–P intervals are typically regular. P–, non-conducted P wave.

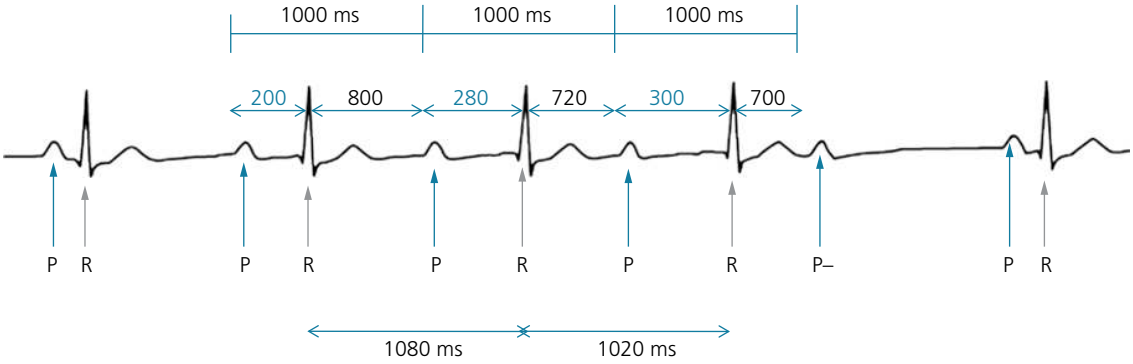

Figure 13.2 Wenckebach 5:4 AV block. P–P intervals are regular. **PR progressively lengthens, whereas R–R progressively shortens.** This is due to the fact that the absolute PR interval increases less with each cycle (e.g., PR 200 → 280 → 300), not compensating for the larger reduction of the preceding RP interval, P–P interval being stable.

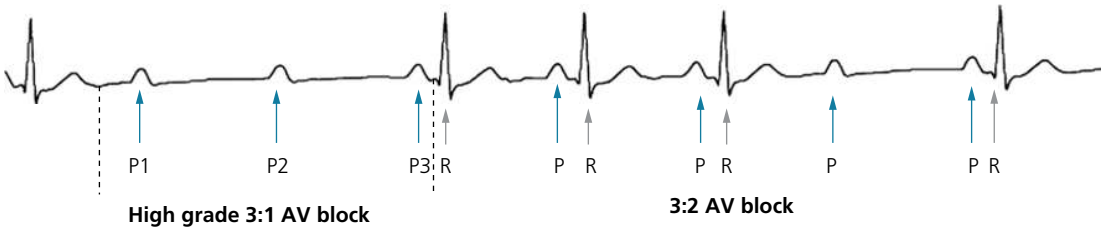

Figure 13.3 High-grade AV block alternating with Mobitz II AV block.

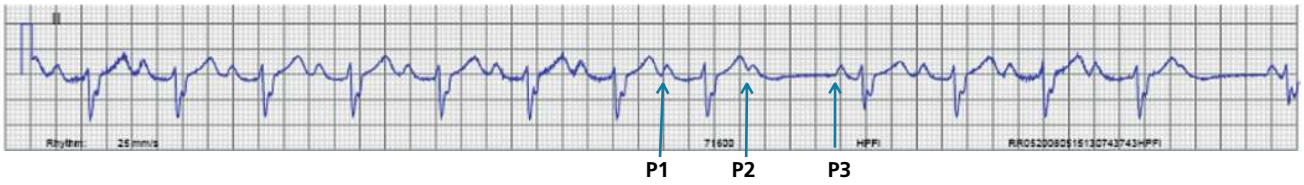

Figure 13.4 Wenckebach AV block. Two groups of beats are seen, which raises the suspicion of a second-degree AV block. P2 is not conducted: this could be AV block or block of a very premature PAC. P2 is not premature as it marches out with the preceding P waves → the diagnosis is AV block. The clue to Wenckebach is the progressive PR prolongation, especially manifest when comparing P3R to P1R (P3R < P1R).

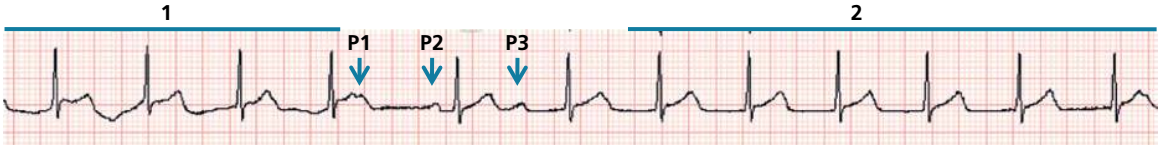

Figure 13.5 ECG of a patient presenting with palpitations. Looking at parts 1 and 2 of this ECG, no P wave is seen and one might think the patient has a junctional rhythm. *Whenever a junctional rhythm is initially presumed, consider the possibility of sinus rhythm with a very long PR interval.* The pause between 1 and 2 unveils the diagnosis. P waves are seen: P1 is a blocked P wave, P2 and P3 are conducted with a progressively longer PR interval. Thus, the patient has a Mobitz type 1 AV block with a very long cycle. Outside P2 and P3, PR interval is very long with P waves falling onto T waves (fusion of P and T). Palpitations are due to simultaneous atrial and ventricular contractions.

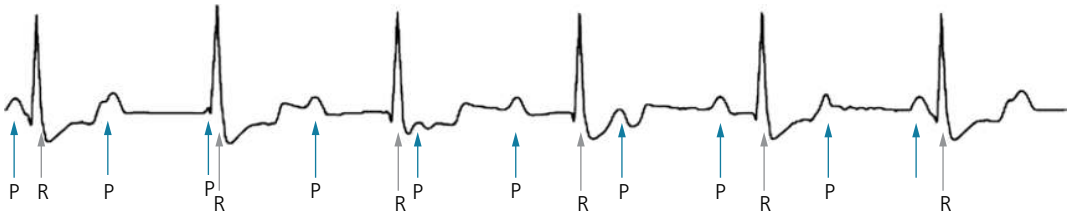

Figure 13.6 Third-degree AV block with regular P rate and regular QRS rate, unrelated to each other. Many P waves fall onto the QRS–T complexes and appear as notches over QRS or T. **PR interval is variable but R–R interval is regular, which implies that no P wave is conducted (AV dissociation) and, in this case, complete AV block.**

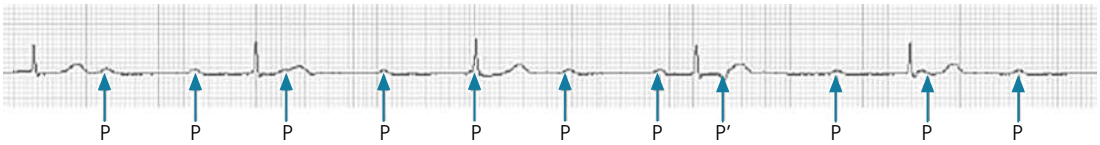

Figure 13.7 Regular, slow QRS rate of ~33 bpm. P rate is mostly regular at ~75 bpm. There is AV dissociation, with no evidence of any P-wave conduction (as also evidenced by the regular QRS escape rhythm). This is complete AV block. P′ could be a PAC or a retrogradely conducted P wave (patients with abnormal AV conduction may have a preserved VA retrograde conduction).

The escape is ventricular with a wide QRS complex if the block is infranodal (rate 20–40 bpm). The escape is junctional with a narrow QRS complex if the block is at the nodal level (rate 40–60 bpm); the junctional escape may be wide if a bundle branch block is present on the baseline ECG. Patients with complete AV block at the infranodal level with relatively preserved AV node may have preserved VA conduction, and retrograde P waves may be seen.

Look carefully for 2:1 AV block in any case of sinus bradycardia. 2:1 AV block may mimic sinus bradycardia when the blocked P waves fall on the preceding T waves and go unnoticed or get mistaken for U waves. Conversely, in patients with sinus bradycardia, U waves may be misinterpreted as blocked P waves, causing a false diagnosis of AV block. Blocked P waves are distinguished from U waves by the fact that they march out almost equidistantly with the P waves that precede the QRS complexes and have a similar morphology, whereas U waves do not. Also, P waves are often more peaked than U waves (Figure 13.8).

AV dissociation is present in all cases of complete AV block, but AV dissociation does not imply AV block. AV dissociation may be due to: (i) complete AV block, or (ii) competitive AV dissociation. A competing accelerated junctional or ventricular rhythm that is equal in rate to the sinus rhythm, or faster than it, may lead to AV dissociation. The latter is a *competing form of AV dissociation*, rather than an AV block form of AV dissociation. One form of competing AV dissociation is *isorhythmic AV dissociation*, in which the junctional or ventricular rhythm almost has the same rate as the sinus rhythm, allowing intermittent conduction of sinus P waves that are falling far enough from the QRS complexes (e.g., AIVR, accelerated junctional rhythm). One beat may be a sinus beat preceded by a P wave, the other may be a junctional beat dissociated from P wave and showing up at any deceleration of the sinus rate (Figure 13.9). **AV block is implied when a P wave falls far enough from the QRS complex yet does not get conducted.**

B. Causes of a pause on the rhythm strip

Outside the pause that follows an obvious PAC or PVC, a pause on a rhythm strip may be secondary to:

1. Sinus pause: no P wave is seen within the pause.
2. Second-degree AV block (Mobitz I or Mobitz II): a blocked P wave is seen within the pause. The blocked P wave marches out with the regularly occurring sinus P wave. Occasionally, however, if sinus arrhythmia is present, the blocked P wave of the AV block may not perfectly march out with the other P waves. A particular form of sinus arrhythmia seen with AV block (especially 2:1 AV block) is *ventriculophasic sinus arrhythmia*, in which the P–P interval containing a QRS is shorter than the P–P interval not containing a QRS (the QRS complex leads to a stroke volume that leads to reflex slowing of the P–P interval).
3. Blocked PAC (the most benign pause): the blocked P wave is a very premature P wave that falls in the AV nodal refractory period and does not get conducted. As opposed to AV block, the blocked P wave does not march out with the sinus P waves and often has a different morphology.
4. Concealed premature junctional complex (less common): a premature junctional complex (His complex) is rare, much less common than a PAC or a PVC. A blocked premature junctional complex prevents the conduction of the next sinus impulse through the His (still in refractory period), creating the impression of a Mobitz II AV block. The presence of conducted premature junctional complexes elsewhere on the rhythm monitor is a hint to this phenomenon.
5. In patients with intermittent AF, a long pause may occur at the junction between AF and sinus rhythm (the sinus node is "sleeping" during AF and needs time to wake up); this pause is a common cause of syncope in intermittent AF (Figure 13.10).

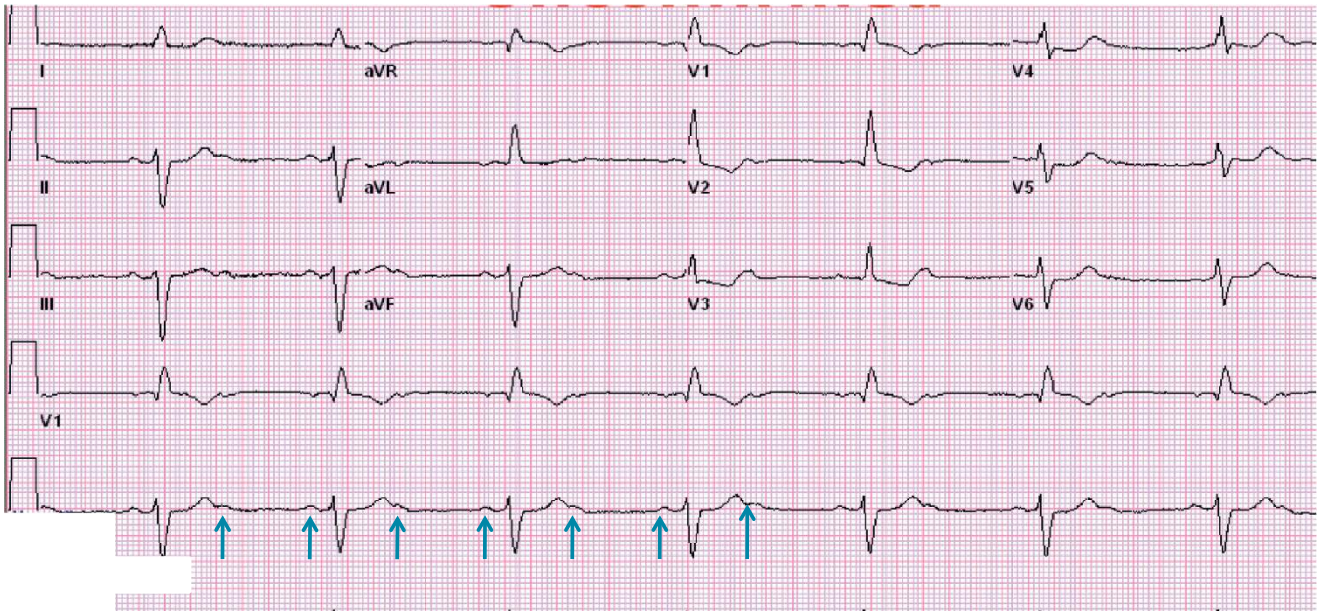

Figure 13.8 At first glance, the rhythm seems to be sinus bradycardia, ~40 bpm, and the waves that follow QRS complexes seem to be U waves. However, *in any sinus bradycardia of 40–50 bpm, verify whether the true rhythm is, in fact, a sinus rhythm of 80–100 bpm with 2:1 AV block*. The presumed U waves are actually P waves as they march out with P waves preceding the QRS complexes (*arrows*); also, these waves have a negative phase in some of the leads (V1, aVL), whereas normal U waves are very rarely negative in any lead. Of note, P waves may not march out exactly because of ventriculophasic sinus arrhythmia (P-P interval containing QRS is shorter). Thus, the rhythm is sinus rhythm with 2:1 AV block. In 2:1 AV block, one cannot tell if the dropped QRS is preceded by progressive PR prolongation or not, i.e., Mobitz I or II. In order to say Mobitz I or II in 2:1 AV block, analyze the following:

1. QRS width. If QRS is wide, the block is usually an infranodal block, i.e., Mobitz II; if QRS is narrow, the block is usually Mobitz I. The 2:1 AV block on the current ECG is, therefore, a Mobitz II AV block.
2. PR interval of the conducted beats. PR interval is normal in this case (~200 ms), implying that the block is unlikely to be at the level of the AV node.

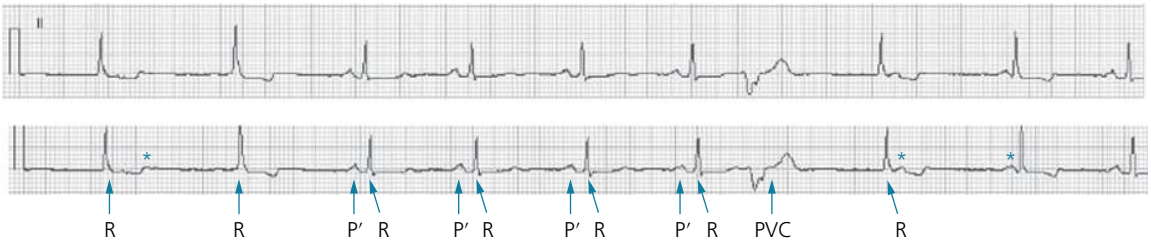

Figure 13.9 Outside the PVC, the rhythm seems regular. But on further analysis, there is some R–R irregularity.

Analyze the P–QRS relationship. Some QRS complexes seem to be preceded by P waves, with a consistent PR relationship (conducted P wave, noted as *P′*). On the other hand, some QRS complexes are not preceded by any P wave and are junctional QRS complexes. This suggests that a sinus rhythm and a junctional rhythm are competing at a rate of ~60 bpm. When the sinus rhythm slows a bit, the junctional rhythm takes over. *This is* ***isorhythmic AV dissociation***. Note that, during the junctional rhythm, sinus P waves occur regularly, dissociated from QRS and falling around it (marked by*). This is not AV block, as P waves get conducted when the competing junctional rhythm does not kick in. Note also that QRS of the junctional rhythm is a bit wider, suggesting a low junctional or fascicular origin.

Group beating on ECG (repetition of a series of beats followed by a pause) may be:
- Type I or II second-degree AV block or SA block
- Frequent PVCs or PACs, blocked or conducted, followed by a pause

In particular, a bigeminal rhythm, characterized by a repetition of 2 beats followed by a pause, may be due to:
- 3:2 AV block (type I or II): drop of every third QRS
- 3:2 SA block: drop of every third P–QRS
- PACs or PVCs occurring in a bigeminal pattern
- Non-conducted PACs occurring in a trigeminal pattern (after every second QRS)
- Atrial flutter with alternating 4:1 and 2:1 conduction (see Chapter 11, Figure 11.5)

On a rhythm strip, a *single blocked P wave* that is not premature and not preceded by progressive PR prolongation may be a Mobitz II AV block, particularly when it occurs outside a vagal situation (Figures 13.11 and 13.12). However, it may also be a Mobitz I block with small overlooked changes in PR interval or a vagotonic AV block secondary to a sudden increase in vagal tone; in the latter case, the sinus rate typically slows down around the blocked P wave, even if PR does not appear to prolong (Figure 13.13). Another possibility is a concealed blocked His premature complex (this is suggested by the presence, elsewhere on the rhythm strip, of His premature complexes that are conducted).

Figure 13.10 Long sinus pause at the point of transition from AF (top row) to sinus rhythm (bottom row). **This pause is the most common cause of syncope in patients with tachy-brady syndrome: off and on AF, with pause at every AF conversion.**

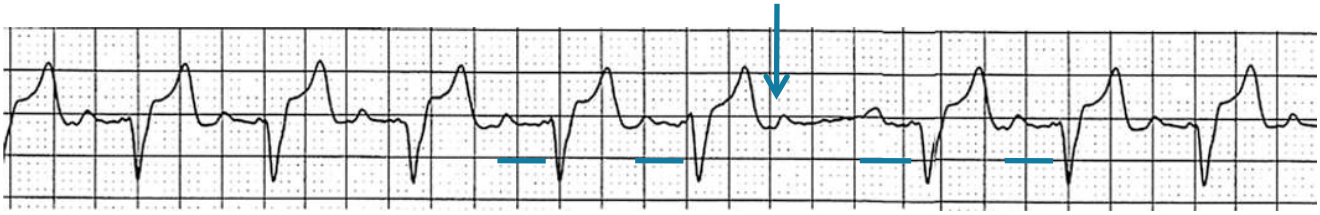

Figure 13.11 P blocks (*arrow*) without being premature and without progressive PR prolongation before the dropped beat, or PR shortening after the dropped beat. This implies Mobitz II AV block, *further suggested by the wide QRS*. The rate is ~80 bpm and the patient is asymptomatic, which may falsely suggest that the block is innocuous. In fact, this block is ominous because it is likely Mobitz II not Mobitz I, with a class I indication for pacemaker placement. ***That is why it is important to carefully analyze every small pause. A benign Mobitz I or a blocked PAC may simulate the malignant Mobitz II AV block***.

In Mobitz II, the first PR interval that follows the pause may be shorter than the steady-state PR interval outside the pause, which may lead to a misdiagnosis of Mobitz I. Two explanations: (1) the first QRS after the pause may actually be an escape beat falling over the P wave, simulating a short PR interval; (2) the first QRS may be narrow, as the bundles are given time to recover from their refractory periods; PR may seem shorter if it includes less isoelectric QRS.

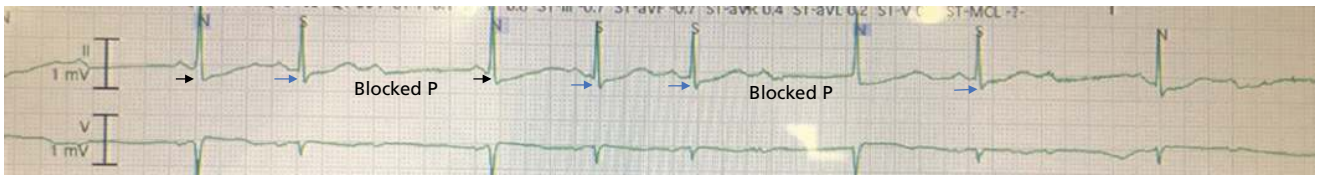

Figure 13.12 Is this Mobitz I or Mobitz II AV block? Note the episodically blocked P waves. It seems there is PR prolongation before P blocks, and the PR that follows the blocked P is shortened (*black arrow*), which suggests Mobitz I.

However, on further analysis, the QRS complexes preceded by the shorter PR interval are in fact junctional escape beats that nearly coincide with the P wave, hence the short PR interval is coincidental: P, per se, is not conducting to the QRS. The slightly different morphology of those beats, *marked as N*, is further suggestive of escape. Outside those escape beats, PR interval is steady (*blue arrows*). *Thus, this is Mobitz type II AV block. Those coincidental escape beats explain why in Mobitz II, the first PR interval that follows the pause may be shorter than the steady-state PR interval and may be misleading.*

Moreover, the short PR interval <200 ms is suggestive of Mobitz II AV block. QRS is however narrow, so this is Mobitz 2 block at the His level (not infra-His).

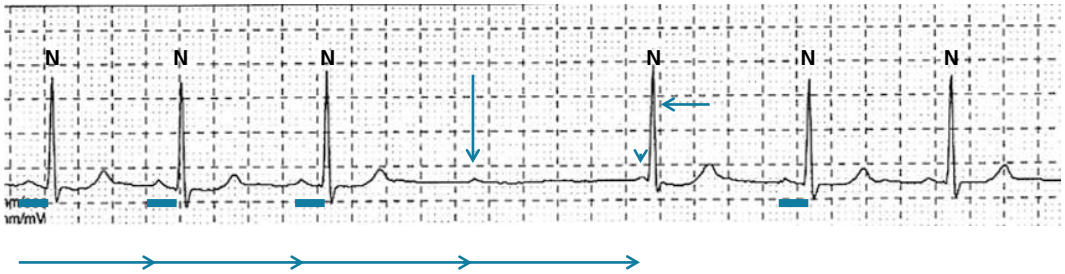

Figure 13.13 Note the block of a P wave (*vertical arrow*). This blocked P wave is not premature, and therefore the diagnosis is AV block. This blocked P wave is not preceded by any change in PR interval, even when PR intervals before and after the blocked P wave are compared (*bars*), which is concerning for a Mobitz II AV block. However, note that the P–P interval is progressively lengthening before and during the pause, a hint to an increase in vagal tone causing the AV block (*line of arrows*). Therefore, this is an AV nodal block, an equivalent of Mobitz I AV block. Also, the narrow QRS argues against Mobitz II AV block. Note that a junctional escape complex is seen after the pause (*horizontal arrow*) and coincides with the subsequent sinus P wave (*arrowhead*), preventing it from getting conducted: this is isorhythmic AV dissociation over one beat (rather than a conducted P with very short PR).

C. Location of the AV block

AV block may occur at the level of the AV node or at the infranodal level, i.e., at the His or the infra-His/Purkinje level (Figure 13.14). Infranodal AV block is ominous and, when complete, leads to a slow ventricular escape rhythm, or no escape at all. Usually, in infranodal AV block, the baseline QRS is wide as the fascicles have abnormal baseline conduction. Occasionally, the block is at the His level and the baseline QRS may not be wide.

Nodal AV block is less ominous and, when complete, leads to a faster, junctional, narrow escape rhythm. Location of the block in each type of AV block:

a. First-degree AV block is usually a nodal block, particularly if QRS is narrow. A PR interval >250 ms with a narrow QRS ~always implies a nodal block.

b. Mobitz I is often a nodal block, especially when QRS is narrow. When the QRS is wide, 75% of Mobitz I blocks are still nodal blocks, while 25% are infranodal blocks. A wide-QRS Mobitz I block with a maximal PR change of <50 ms is likely an infranodal Mobitz I block.

c. Mobitz II is an infranodal block, with a QRS that is often wide on the baseline ECG. If the baseline QRS is narrow, the block is likely infranodal at the level of the His bundle (~20% of Mobitz II block). Occasionally, what seems to be a narrow-QRS Mobitz II can be an overlooked Mobitz I with small overlooked increments in PR intervals, or can result from a sudden burst of vagal tone blocking one or several consecutive P waves.

d. 2:1 AV block: analyze the QRS width and the PR interval to define the site of the block:

- **i.** if QRS is wide, the block is likely infranodal; if QRS is narrow, the block is likely nodal.
- **ii.** PR interval has 2 components: nodal component (AH interval, normally <125 ms) and infranodal component (HV interval, normally <55 ms and shorter than the AH component). A PR interval >250 ms more likely results from a delay of the nodal component, i.e., an increase in AH interval; infranodal HV interval rarely prolongs enough to cause such PR prolongation. On the other hand, a PR interval that is <200–250 ms argues against a block at the AV nodal level.

Two additional modalities help elucidate the type of 2:1 AV block: *exercise testing* (Table 13.1) or *prolonged rhythm monitoring*.

e. Third-degree AV block or high-grade AV block (e.g., 3:1, 4:1) may be nodal or infranodal. As such, *it may be less ominous than Mobitz II AV block*. Determine the location of the AV block by the width and the rate of the escape. An escape rhythm that is wide usually implies an infranodal block; the rate is usually, but not necessarily, <40 bpm (Figure 13.15). VA conduction (retrograde P waves) implies an infranodal block as well.

Sometimes, a block is present at both levels: very prolonged PR interval with Mobitz II, very prolonged PR interval or Mobitz I AV block with bundle branch block, complete nodal AV block in a patient with an underlying bundle branch block.[1,2]

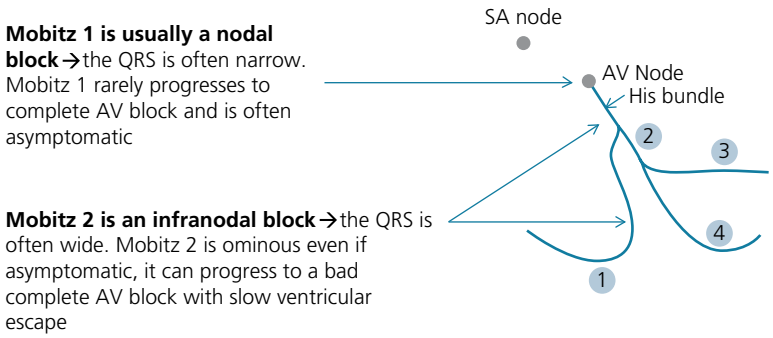

Figure 13.14 Mobitz I vs. Mobitz II AV block. (1) is the right bundle, (2) is the left bundle, (3) is the left anterior fascicle, (4) is the left posterior fascicle.

Table 13.1 Effect of atropine and exercise on AV block.

AV nodal block	Conduction ratio improves (AV node has rich autonomic innervations and is affected by cholinergic and sympathetic effects)
AV infranodal block	Conduction ratio remains unchanged or worsens His and Purkinje conduction is not substantially affected by the cholinergic system. On the other hand, the increase in sinus rate leads to more atrial depolarizations reaching the infranodal area. Many of these atrial depolarizations partially penetrate the infranodal area *without getting conducted all the way*; as such, they extend the refractory period and not only do they not conduct, they prevent subsequent beats from getting conducted. This is ***concealed conduction*** = blocked, partial conduction that does not show up on the ECG yet modifies the expected behavior of subsequent beats (*blocked P waves prevent the conduction of subsequent P waves*). A slower atrial rate is more likely to get conducted

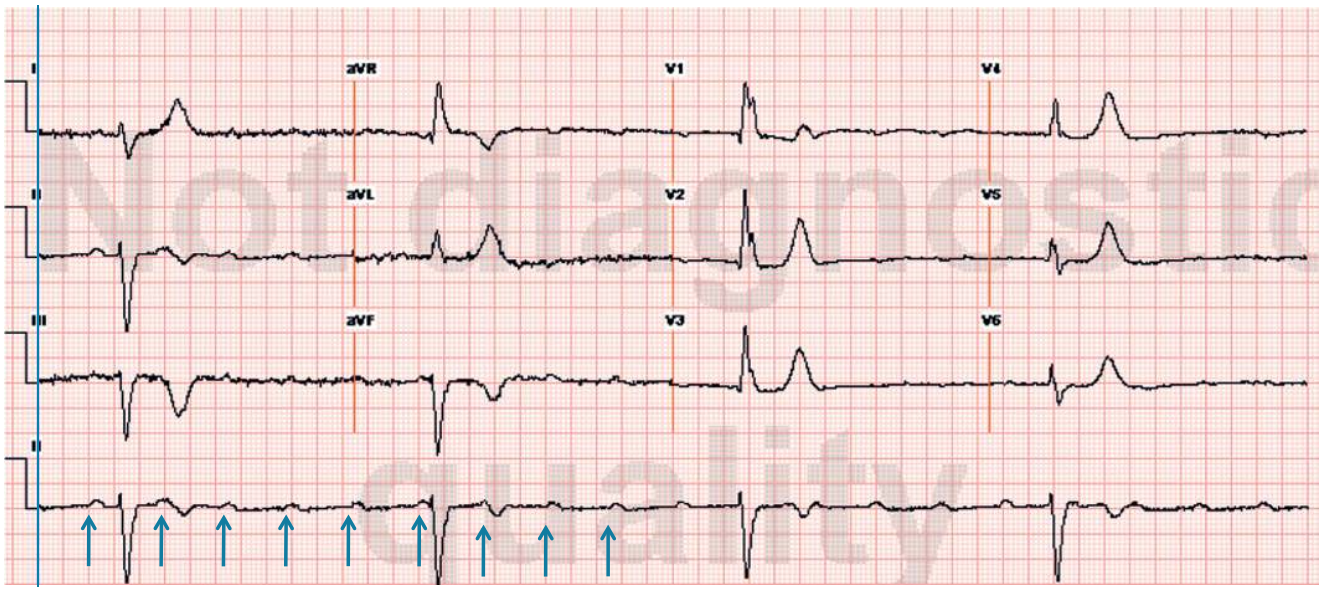

Figure 13.15 Complete AV block, with underlying sinus tachycardia (*arrows* point to sinus P waves), and a wide QRS escape at ~25 bpm. The escape has the morphology of pseudo-RBBB + LAFB. It may be a junctional escape with RBBB + LAFB; however, short of a baseline ECG showing RBBB + LAFB, the escape should be considered ventricular. The RBBB morphology suggests a left ventricular origin, while the LAFB morphology suggests a posterior origin. Overall, the block is infranodal and the escape originates from the LV posterior wall close to the posterior fascicle. The underlying sinus tachycardia indicates that the complete AV block is due to an intrinsic conduction disease, rather than a high vagal tone or drugs.

D. Causes

1. Degenerative, fibrotic disease is the most common cause of AV block (Lenegre); it may extend to the cardiac skeleton, such as the mitral annulus and the aortic valve (Lev). It is related to aging and atherosclerotic risk factors but may have an inherited premature component.
2. AV block may result from acute anterior or inferior ischemia, or chronic ischemic cardiomyopathy with diffuse myocardial fibrosis.

AV block occurring in association with acute inferior MI is usually secondary to increased vagal tone (first 24 hours) or to AV nodal stunning and edema (first few days), and is reversible within 1–2 weeks. AV block occurring with anterior MI is due to extensive infranodal myocardial stunning ± necrosis and is usually reversible but may become irreversible.

Only AV block that accompanies MI with ongoing ischemic ST changes is expected to reverse with revascularization. Advanced AV block associated with angina, incidental CAD, or ischemic cardiomyopathy is not expected to reverse with revascularization, unless it is purely exertional, and dictates pacemaker implantation.

3. Calcific valvular disease.
4. Any cardiomyopathy can affect the conduction system. Varying degrees of AV blocks are seen in up to 15% of dilated cardiomyopathies.
5. Drugs, electrolytes (hypo- or hyperkalemia, hypermagnesemia).
6. High vagal tone (sleep, vomiting, cough, athlete's heart) may lead to AV block at the nodal level. *Vasovagal syncope* may lead to a vagally mediated AV block, in which case AV block is part of the vagal reaction, not the sole cause of syncope (Figure 13.16).
7. AV block after cardiac surgery (~5–10% of valvular surgeries and congenital heart disease surgeries, in which AV block resolves in 2/3 of the cases). AV block usually resolves within 7 days, if at all.

8. *Lyme disease* leads to cardiac involvement in 1–5% of the cases, mostly high-degree AV block (80–90%), that is nodal and reversible. The degree of AV block can abruptly fluctuate. This AV block typically resolves within 1–2 weeks of antibiotic therapy but may persist for months; it is a *nodal AV block* that paradoxically worsens with exercise, leading to significant exercise limitation. Diagnosis is suggested by the context (outdoor exposure in endemic areas, tick bites, erythema migrans in the last 1–2 months) and established by serology.

Causes of AV block in the young

- Benign vagotonic AV nodal block during sleep (particularly athletes) or during vasovagal syncope
- **Sarcoidosis** and other autoimmune diseases (lupus, ankylosing spondylitis)
- Lyme disease
- Myocarditis and Chagas disease
- **Inherited channelopathies**, particularly *Lamin A/C mutation*, which also leads to dilated cardiomyopathy, and SCN5A mutation
- Congenital AV block: it may be inherited or secondary to fetal exposures (maternal lupus antibodies, toxins). It may appear in the neonatal period or later, in adulthood.

On Holter or telemetry monitoring, sinus pauses or AV block at night, including complete or high-grade AV block, suggest sleep apnea. Hypoxia increases vagal tone, leading to nodal AV block.

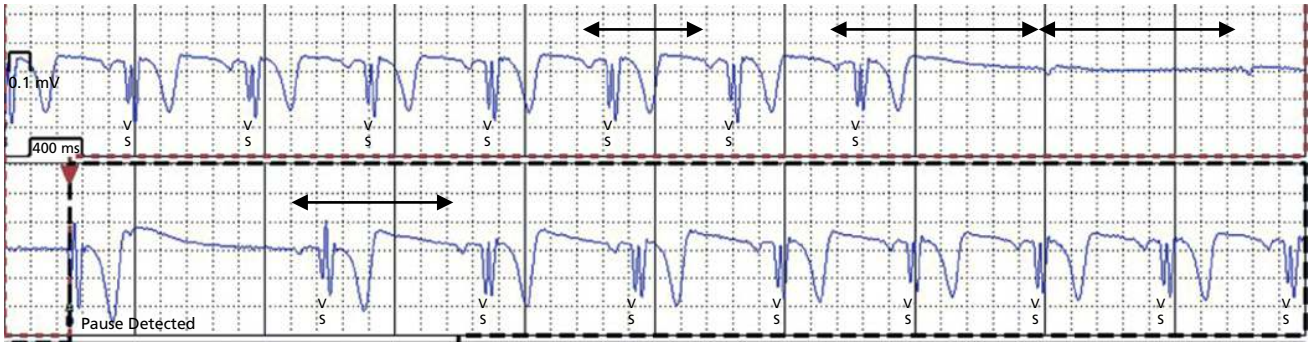

Figure 13.16 Episode of complete AV block on a loop recorder, with 3 non-conducted P waves, leading to a pause of 4 seconds and 1 junctional escape beat (next to the vertical *dashed line*). This occurred during wakefulness, in a patient with prior syncope. One is inclined to think that AV block is the cause of the patient's prior syncope. **However, always assess whether the AV block is vagally mediated.** The sinus P rate significantly slows down during the pause, with increased P-P interval, then progressively accelerates after the pause (*arrows*) → this indicates that a high vagal tone is causing the AV block. If AV block was intrinsic, sinus P rate would accelerate during the pause, not decelerate. Also, intrinsic AV block is typically initiated by a pause after a premature beat (deceleration-dependent AV block), not the case here. Thus, this AV block is vagal in nature, and the syncope is due to the vasovagal process rather than AV block per se; pacemaker therapy is not definitely indicated and may not affect syncope recurrence. Yet, pacemaker is reasonable in patients with recurrent vasovagal syncope and long pauses (>3 seconds for pauses coinciding with symptoms and >6 seconds for asymptomatic pauses) (ESC class I, ACC class IIb).

E. Treatment

1. Place a **permanent pacemaker** in the following AV block situations, after **ruling out reversible causes, such as a high vagal tone state or vasovagal syncope**, and after *withdrawing rate-slowing drugs* (Figure 13.16):[3]

- Symptomatic pauses (***≥3 seconds while awake***) or symptomatic bradycardia (***<50 bpm with AV block, <40 bpm without AV block, while awake***), regardless of the type of AV block. This means that any of following occurs ***concomitantly*** to bradycardia or pauses: syncope/near-syncope, severe fatigue, or decompensated heart failure. In the specific case of syncope, asymptomatic pauses >6 seconds during wakefulness may indicate pacemaker even when a clear association between the syncope and the bradycardia is not documented (ESC class I).
- Mobitz type II second-degree AV block, even if the patient is asymptomatic (class I recommendation).
- High-grade or third-degree AV block, even if the patient is asymptomatic, outside vagal AV block (class I). In patients with AF, AF pause >5 seconds occurring during wakefulness often indicates PM, even if asymptomatic, failing a reversible cause (class I in the old 2008 ACC guidelines).
- First-degree AV block or Mobitz type I second-degree AV block associated with symptomatic bradycardia or "pacemaker syndrome"–like symptoms (class IIa): this occurs with a very prolonged PR interval (≥300 ms), which makes the P wave very close to the precedent QRS. AV synchrony is lost, and the atria sometimes contract against closed valves (Figure 13.5). On echo, E and A waves are fused, the diastolic filling is reduced, and there is diastolic MR. Consequently, cardiac output is reduced and LA pressure is increased, which causes fatigue, dizziness, and dyspnea. Syncope, however, cannot be solely attributed to the long PR interval; rhythm monitoring + exercise testing may be performed to look for periodic high-grade AV block.

- ***In cases of 2:1 AV block, very long PR interval, or Mobitz type I AV block with questionable symptoms or location (wide QRS), either one of the following 3 tests may be performed to further assess AV block: (1) prolonged rhythm monitoring, (2) exercise testing, or (3) EP study (class II).*** A second- or third-degree AV block during *exercise* signifies that the AV block is infranodal and worsens with increased atrial activity; or AV block is ischemic. It dictates PM placement after ruling out ischemia. *EP study* measures the His–ventricle (HV) interval (>70 ms signifies severe infra-nodal AV block) and assesses the HV response to incremental pacing. An infranodal AV block mandates PM placement.

If the rate-controlling drug(s) is necessary (i.e., off-and-on AF or SVT), it may be reasonable to continue the drug(s) and place a permanent PM.

Also, an infranodal AV block is not much affected by β-blocker, CCB, or digoxin withdrawal, and therefore a PM may be indicated regardless of drug interruption.

2. Temporary medical therapy and pacing is indicated for advanced AV block associated with persistent hemodynamic changes. In this case, *atropine and/or catecholamines* are administered (class II recommendation).[3] Atropine does not improve infranodal block and may worsen it by increasing the ineffective impulses reaching the infranodal zone (this extends the time the infranodal zone is refractory); hence, while it may be tried, atropine is usually ineffective in infranodal blocks. Isoproterenol (or dopamine or epinephrine) may help with AV block at any level and may be used while awaiting permanent PM placement. IV aminophylline may be used in acute MI.

Transvenous pacemaker (placed through a transvenous sheath) has fallen out of favor because of a high rate of dislodgement, non-capture (up to 35%), and complications, even more so when kept >48 hours. *It more than doubles the risk of infection during eventual permanent pacemaker implantation*. It is still used as first-line therapy, particularly when permanent PM implantation is not planned soon, or may be reserved for patients who are not responding to catecholamines (class IIa, no class I recommendation).[3] A ***temporary-permanent pacemaker*** is more stable and reliable and is better used whenever a temporary pacemaker is required. It consists of an active-fixation permanent pacer lead, placed through a transvenous sheath and connected to a permanent pacing generator secured outside the body; this provides a much lower rate of lead dislodgement and allows patient ambulation.

Transcutaneous pacing may also be used; however, it does not reliably capture the ventricles and is painful (class IIb). It is not favored and is only used as a brief bridge to transvenous pacing in cases refractory to catecholamines. Transcutaneous pacing causes large and wide pacing spikes on the ECG, which precludes adequate assessment of capture; capture is ensured by cardiac auscultation, pulse check away from muscle twitches (brachial or femoral), pulse oximetry, or seeing true T waves after the spikes.

In reversible cases of AV block, medications or temporary pacing are used without the eventual need for a permanent PM: inferior MI, drug effect/overdose, hypervagotonic states, electrolyte disorders. AV block that occurs after cardiac surgery requires permanent pacing only if it persists over 5–7 days (or 24–48 hours in case of TAVR).[3]

Patients who require temporary pacing for a prolonged period of weeks, such as patients with an active infection in whom a permanent implant is avoided until the infection clears, or patients with a slowly reversible condition, such as Lyme disease, may receive a **temporary-permanent pacemaker.** Considering its reliability, it may also be used in patients requiring a shorter duration of pacing, as a superior alternative to transvenous pacing.

F. Other ECG examples of AV block (see Figures 13.17–13.20)

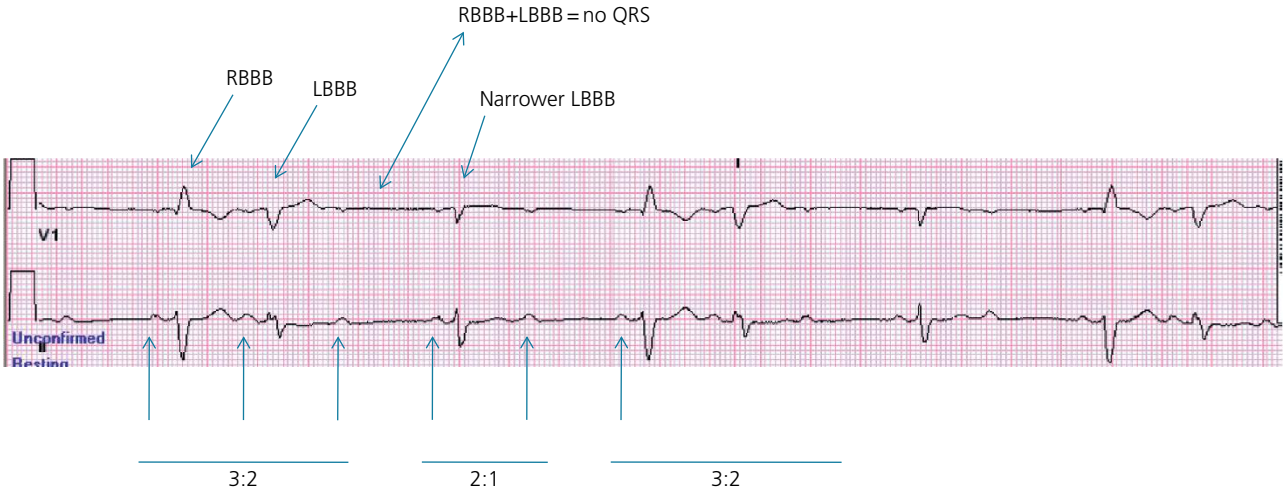

Figure 13.17 Second-degree Mobitz II AV block, with 3:2 block alternating with 2:1 block (*arrows* point to P waves). In lead V_1, one can see that on the conducted beats, RBBB alternates with LBBB. Besides Mobitz II, the alternation of RBBB and LBBB is indicative of infranodal AV block. In fact, QRS is dropped when both bundles simultaneously block in a patient with underlying RBBB, LBBB, or alternating RBBB and LBBB.

Figure 13.18 P waves and QRS complexes are dissociated on most beats, with most P waves not conducted to the ventricles (*blue arrows*). One knows that these P waves are not conducted by the fact that **the R–R interval is steady despite varying PR distance**; if some P waves were to conduct, the R–R interval would vary as well. Two P waves are conducted (*gray arrows*), and this is indicated by the fact that their R–R interval (*gray double arrows*) is shorter than the remaining, dominant, R–R interval (*blue double arrows*); and by the fact that QRS following these P waves is narrow (ventricular capture from a sinus-originating stimulation).

This AV dissociation could be due to: (1) AV block, or (2) competitive (interference) AV dissociation. AV block is the diagnosis here as enough time is provided for some P waves after one QRS and before the next QRS to conduct, yet they do not (*dashed arrows*). Therefore, this is a high-grade AV block with a fast ventricular escape rhythm (~55 bpm). The fact that one or more P waves are conducted precludes calling this rhythm complete AV block.

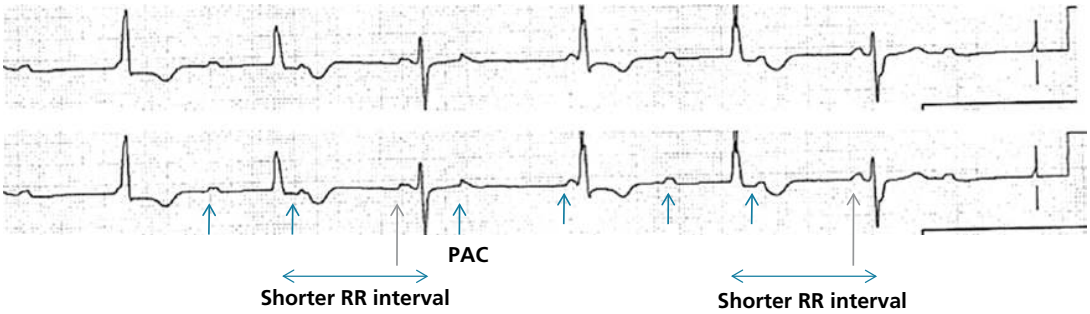

Figure 13.19 Another example of a high-grade AV block. Most P waves are not conducted (*blue arrows*) and a wide ventricular escape rhythm is seen. Occasionally, P wave conducts (*gray arrows*), and this manifests as a shorter R–R interval (*double arrows*) and a narrow QRS complex. Note that the P–P interval containing a QRS is shorter than the P–P interval that does not contain a QRS (ventriculophasic sinus arrhythmia). The PR interval of the conducted P waves is ~200 ms (not significantly prolonged), which, along with the wide escape, indicates an infranodal block.

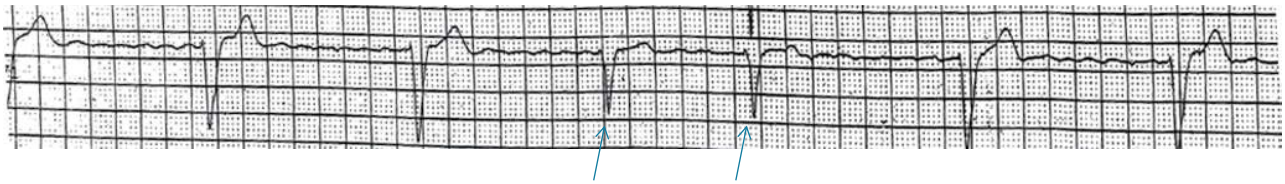

Figure 13.20 AF with a ventricular rate that is slow and mostly regular. This is AF with an almost complete AV block and a wide, regular escape rhythm that is ventricular in origin. Two narrower QRS complexes occur at a shorter R–R distance and signify occasional AV conduction. This is AF with a high-grade rather than a complete AV block.

II. Sinus node dysfunction

A. Types

1. Sinus bradycardia: sinus rhythm slower than 50 bpm.[3]
2. Sinoatrial (SA) exit block.
   - Second-degree SA block, Mobitz type I: progressive increase in the interval between the sinus node and the P wave (this interval is not seen on ECG), progressive shortening of the P–P and R–R intervals, then drop of one whole P–QRS. As opposed to Mobitz I AV block, P wave drops as well (Figures 13.21 and 13.22).
   - Second-degree SA block, Mobitz type II: sudden drop of one whole P–QRS complex (Figure 13.23). As opposed to AV block, P wave drops as well.
   - Third-degree SA block: drop of multiple P–QRS complexes. It is similar to a sinus pause, except that in SA block, P–P interval of the pause is a multiple of the baseline P–P interval.

   Clinically significant pauses are usually >3 seconds in an awake situation. A prolonged sinus pause leads to a junctional escape rhythm (a slow rhythm with no P waves). A prolonged sinus pause is called *sinus arrest* (Figures 13.24 and 13.25).

The most common differential of a sinus pause is a PAC that is not conducted and that is followed by a pause. In this case, a P wave is seen soon after QRS and may be within the T wave. Hence, the hint is: T-wave morphology changes before the pause. The most important differential is Mobitz I or Mobitz II AV block causing a blocked P wave.

Figure 13.21 4:3 Mobitz I SA block. Progressive lengthening of the sinus impulse-to-P-wave interval, with shortening of the P–P interval, before the drop of one full P–QRS complex. It mimics a sinus pause.

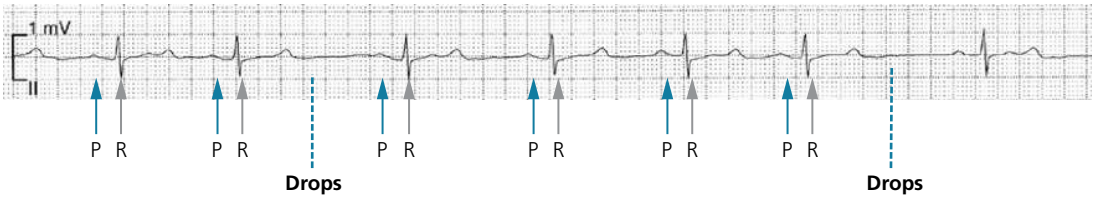

Figure 13.22 A whole P–QRS drops, which may be consistent with a sinus pause. On looking more carefully, the P–P as well as the R–R intervals progressively shorten before the P–QRS drops. This is a 5:4 SA Wenckebach block, not AV Wenckebach, as PR interval is constant and the whole P–QRS drops. This is not sinus arrhythmia, as in the latter, P–P interval progressively, rather than abruptly, lengthens (not an abrupt jump from the shortest P–P to the longest P–P).

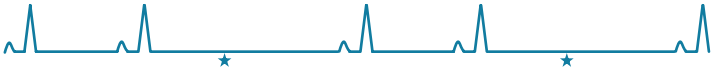

Figure 13.23 3:2 Mobitz type II SA block. Both P and QRS intermittently drop (stars).

Figure 13.24 Sinus arrest or complete SA block with a ventricular escape rhythm. The fact that the escape is ventricular (wide and slow, originating from below the AV node), proves that there is AV infranodal block in addition to the SA nodal block.

Figure 13.25 No P wave is seen → complete SA block vs. AF with small fibrillatory waves. The rhythm is a slow, wide complex rhythm at a rate of 30 bpm, suggesting a ventricular escape rhythm (slow and wide). This means that, in addition to the SA block, there is an infranodal AV block. In fact, in the absence of AV infranodal disease, SA block should lead to a junctional rather than ventricular escape rhythm.

3. Tachy–brady syndrome: sinus bradyarrhythmia interspersed with episodes of AF or atrial tachyarrhythmia. AF may be fast or slow, as AV nodal disease may coexist. Most importantly, a ***sinus pause may occur at the junction between AF and sinus rhythm*** (Figure 13.10).
4. Chronotropic incompetence: inability to increase the heart rate to 80% of the maximal predicted heart rate during exercise (which equals 220 minus age). The more complex *chronotropic reserve index* may be calculated: (peak HR – resting HR)/([220-age] – resting HR). Values <0.8, or <0.62 if on β-blockers, are considered low.
5. Sinus arrhythmia: phasic changes in P–P interval, often related to respiration. The sinus rate gradually increases with inspiration as the left output decreases; thus, P–P interval gets shorter with inspiration. The difference between the smallest and the longest P–P intervals is >120 ms or >10% of the smallest interval.

Sinus arrhythmia may be a sign of a healthy heart with good heart rate variability and a high vagal tone (especially in young patients). It is more common at slower heart rates. In the elderly patient, sinus arrhythmia is more often due to sinus node disease.

Also, the phasic P–P changes may not be related to respiration, in which case sinus arrhythmia is a sign of sinus node disease.

Ventriculophasic sinus arrhythmia may occur in complete AV block or 2:1 AV block. P–P interval containing a QRS is shorter than the P–P interval not containing QRS (i.e., P–P interval varies). The cardiac output is higher when there is QRS, which reduces the adrenergic tone and the subsequent sinus P rate.

Sick sinus syndrome is any of the preceding disorders (1–5) due to an intrinsic sinus node disease, often degenerative in nature. Tachy–brady syndrome is commonly associated: 40–70% of patients requiring pacemaker implantation for sinus node disease have or develop AF. Patients with sinus node disease may have AV conduction disease as well (AV block is seen in ~15% of patients initially, then develops at a rate of 2% per year). ***Episodic AF with conversion pause is the classic cause of syncope in sinus node disease*** and should be sought in case of syncope.

Notes

Any severe sinus bradyarrhythmia may lead to a junctional escape rhythm, typically at a rate of 40–60 bpm. The patient may not have P waves or may have slow sinus P waves that are dissociated from the narrow escape rhythm (Tables 13.2 and 13.3).

In the case of a junctional or ventricular accelerated rhythm (60–120 bpm), or escape rhythm (<60 bpm), the junctional/ventricular rhythm may compete with the sinus rhythm at a similar rate. One beat may be sinus preceded by a P wave, the other may be junctional showing up at any deceleration of the sinus rate. This is *isorhythmic AV dissociation* (2 competing rhythms) (Figure 13.26). This illustrates the fact that AV dissociation does not necessarily mean complete AV block; it may be that P wave does not get a chance to conduct, in the presence of a competing "isorhythmic" or faster junctional or ventricular rhythm. However, AV dissociation with a P wave that does not conduct despite a long pause signifies complete or high-grade AV block.

Table 13.2 Differential diagnosis of a regular, non-tachycardic (<100 bpm) narrow complex rhythm without P waves.

- Complete SA block with junctional escape or accelerated junctional rhythm
- AF with AV block and junctional rhythm (the small atrial fibrillatory waves may not be seen)
- Hyperkalemia

Either way, it is a junctional rhythm. Make sure it is not a sinus rhythm with a very long PR interval and a P wave hidden atop the T wave (Figure 13.5).

Table 13.3 Differential diagnosis of a regular, non-tachycardic wide complex rhythm without P waves.

- Complete SA block + AV block with ventricular escape or accelerated idioventricular rhythm
- AF with AV block and ventricular escape or accelerated idioventricular rhythm
- Hyperkalemia
- Junctional rhythm with a pre-existing BBB. In order to differentiate it from a ventricular rhythm, a supraventricular capture complex needs to be seen. A review of a baseline ECG or ECG performed after the arrhythmia resolves is also helpful.

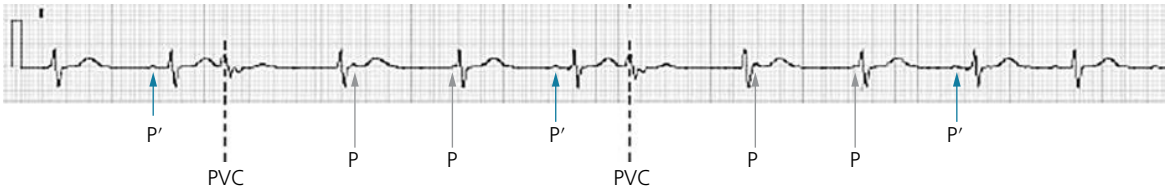

Figure 13.26 Outside PVCs, the rhythm seems regular, but, on further analysis, there is some R–R irregularity. Analyze the P–QRS relationship: some QRS complexes seem to be preceded by P waves with a consistent PR relationship (conducted P waves, called P′ and marked by *blue arrows*). On the other hand, some QRS complexes are not preceded by any P wave (junctional QRS). This suggests a sinus rhythm and a junctional rhythm competing at a rate of ~60 bpm. When the sinus rhythm slows a bit, the junctional rhythm takes over. Note that during the junctional rhythm, sinus P waves occur regularly, dissociated from the QRS complexes and falling around them, marked by the *gray arrows*. There is no AV block, as P wave gets conducted whenever it occurs long enough after the QRS and whenever the junctional rhythm does not kick in close to it.

B. Causes

- Idiopathic degenerative, age-related sinus node disease (most common cause of sinus node disease)
- Any chronic cardiomyopathy (e.g., ischemic, hypertensive, dilated) may lead to scarring of the SA node
- Drugs, hyper- or hypokalemia, hypothyroidism, obstructive jaundice
- High vagal tone (athlete, acute gastric illness)
- Acute STEMI is the only form of CAD that can cause reversible sinus node dysfunction
- Severe HTN may stimulate the carotid sinus receptors and lead to reflex bradycardia (the converse of hypotension and reflex tachycardia)

C. Treatment

A permanent pacemaker is indicated in the following cases, **outside of a vagal state or vasovagal syncope**, a drug side effect, or a metabolic effect (hypothyroidism):[3]

- Symptomatic sinus pauses >3 seconds or sinus bradycardia *<40 bpm* occurring during wakefulness, manifesting as syncope/near-syncope or HF. Note, however, that sinus node disease, even when symptomatic, is not life-threatening. As such, *instead of pacing, oral theophylline* (adenosine-receptor antagonist) may be considered for symptomatic sinus node disease, whether chronically or as a trial to see whether symptoms improve with increased rate (class IIb).
- Off and on AF and symptomatic pause after each AF conversion (sometimes aggravated by the necessary use of rate-controlling drugs for AF paroxysms). AF ablation may obviate the need for a PM.
- Chronotropic incompetence: fatigue with exertion related to the inability to appropriately increase heart rate during exertion, documented on stress testing. This is a weak class II indication, as the entity is poorly defined and lacks robust evidence for pacing benefit.

- Unexplained syncope associated with cardioinhibitory "carotid sinus hypersensitivity," in which a carotid massage induces SA and/or AV block with a pause >3 seconds. This applies even if syncope does not occur in a circumstance of spontaneous carotid sinus stimulation. In this case, carotid sinus massage unveils significant sinus node or AV node disease that is the likely mechanism of syncope. Syncope may not be directly related to carotid sinus stimulation.
- Unexplained syncope with severe sinus node dysfunction on EP study (prolonged sinus node recovery time). However, ***EP study is not highly sensitive or specific for the diagnosis of sinus node disease; monitoring is the best diagnostic modality for sinus node disease.***

Sinus bradycardia of ~40–50 bpm that coincides with fatigue is far more often a vasovagal mechanism, a medication side effect, or an incidental finding than a "symptomatic bradycardia." Sinus bradycardia, even if severe, is overwhelmingly a benign asymptomatic process that rarely requires ventricular pacing in the absence of AV conduction disease. Even **sinus bradycardia <40 bpm coinciding with near-syncope is frequently mediated by a vasovagal mechanism** or a medication side effect.

Important clinical tips

1. Beware that a **vasovagal mechanism** may lead to severe bradycardia <40 bpm and long pauses >3 seconds, sometimes a complete nodal AV block. ***In fact, syncope coinciding with long pauses, complete AV block, or severe sinus bradycardia is more often secondary to a vasovagal mechanism than conduction disease.***[4]

   In a vasovagal mechanism, symptoms and hypotension generally precede the rate slowing and pause, rather than follow them, and both the sinus rate and AV conduction diminish; pacing is not generally indicated per ACC (class IIb) but may be considered, per ESC, for patients older than 40 with recurrent vasovagal syncope associated with long pauses (>3 sec for pauses coinciding with symptoms) (class I ESC).
2. ***Whenever the symptomatic effect of a bradycardia is unclear, stress testing should be performed. A heart rate of 40 bpm at rest may be appropriate, as long it has the capacity to appropriately rise with exercise*** (to 80% of the maximal predicted heart rate).
3. ***A clinically relevant pause is a pause ≥3 sec during wakefulness,*** or any pause related to Mobitz II or infranodal AV block. Nocturnal sinus pauses >3 sec, nocturnal AV block >3 sec, or asymptomatic AF pauses >3 sec are frequently physiologic and indicative of a high vagal tone; they do not dictate PM placement.[4] They do, however, dictate a reduction of the offending drugs and screening for sleep apnea.
4. *Before making the diagnosis of a sinus pause, make sure that the pause is not an infranodal AV block or Mobitz II AV block with blocked P wave(s) – in which case a pacemaker is indicated even if the patient is asymptomatic.*
5. Severely decompensated HF is typically associated with a compensatory increase in heart rate that attempts to maintain cardiac output and ventricular emptying. A relative bradycardia (even 50–60 bpm) during the decompensated stage is a sign of chronotropic incompetence and may be the major trigger of decompensation. It warrants down-titration of the rate-slowing drugs, or consideration of PM therapy if the patient was not receiving those drugs.
6. Similarly, a mild or relative bradycardia (50–70 bpm) in a patient with symptomatic hypotension, who should otherwise be tachycardic, indicates that bradycardia is a contributor to hypotension and is diagnostic of chronotropic incompetence and a need to reduce β-blocker therapy, unless both bradycardia and hypotension are due to the same cause (such as a vasovagal syncope).

III. Bundle branch blocks, bifascicular and trifascicular block

A. Definitions

The His bundle branches into the right bundle and the left bundle, which branches into the left anterior fascicle and the left posterior fascicle (Figure 13.27). A bifascicular block implies a block in 2 of the 3 conduction fascicles, such as:

- LBBB
- Or RBBB + LAFB (~ RBBB with left axis)
- Or RBBB + LPFB (~ RBBB with right axis, which may also be RBBB + RVH)

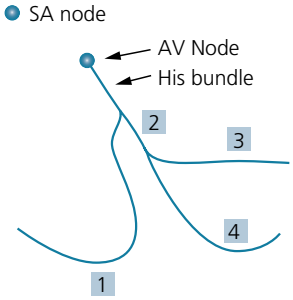

Figure 13.27 AV junction refers to the AV node + His bundle. Subdivisions: 1, right bundle; 2, left bundle; 3, left anterior fascicle; 4, left posterior fascicle.

A trifascicular block implies that all 3 fascicles have a conduction block. The block is incomplete in at least 1 fascicle, explaining the lack of a complete AV block. Trifascicular block may manifest as:

- Bifascicular block + increased PR interval: this is often a trifascicular block, but may also be a bifascicular block with a first-degree AV block.
- Alternating RBBB and LBBB, i.e., RBBB and LBBBB alternate on the same ECG or on different ECGs obtained up to several years apart.
- RBBB with alternating LAFB and LPFB.

B. Causes and prognosis – Consider the following 3 ideas:

1. In all comers, RBBB and LAFB are often isolated conduction disorders without underlying heart disease, while LBBB is often a reflection of underlying heart disease. The right bundle and the anterior fascicle are long and slender and have a single blood supply (LAD); this makes these structures vulnerable to injury or to the degenerative aging process earlier than the left bundle. The main left bundle and the posterior fascicle are short and thick, and both have dual blood supply (LAD and RCA); this makes those structures less vulnerable to injury. After cardiac contusion or cardiac compressions, transient RBBB is the most common block.

LAFB is common in the general population and often occurs without any underlying heart disease. RBBB is also common, and in patients without a clinical history of CAD or HF, RBBB is usually unrelated to any underlying heart disease. It is seen in otherwise healthy individuals and, in most long-term follow-up studies of patients with isolated RBBB and unsuspected CAD or HF at baseline, RBBB has not been associated with an adverse prognosis.[5–8] Only in one Danish study of older individuals (mean 64 years of age), complete RBBB has been associated with a 1.3 hazard ratio of long-term mortality and MI.[9]

On the other hand, because the left bundle and the left posterior fascicle are thick and more difficult to injure, LPFB and LBBB often appear in patients with underlying heart disease, typically a chronic myocardial process, ischemic or non-ischemic, with a dilated or hypertrophied myocardium. Cardiomyopathy is ***most often non-ischemic***, e.g., hypertensive, valvular, or genetic.

2. In middle-age asymptomatic patients (age 40–50s) with unsuspected heart disease and no severe hypertension, RBBB is a benign isolated conduction disorder, while LBBB is generally benign but has a questionable long-term prognosis. In this setting, LBBB is usually a pure, idiopathic degenerative conduction disorder with a low prevalence of cardiomyopathy or CAD (<10–15%). In this setting, LBBB has not been associated with future cardiac or sudden death, CAD risk or long-term mortality in some studies,[6,10–12] but not all of them.[5,13] It is more consistently associated with increased long-term risk of HF. In fact, even in these relatively young individuals with no baseline heart disease, LBBB, per se, may induce dyssynchrony, reduced diastolic time, HF and reduced EF over years/decades of follow-up (<5–20%);[5] LBBB may also be a subclinical marker of future cardiomyopathy.

In a young patient (<50) with RBBB, innocent aberration of the conduction system or athlete's heart is likely, but isolated right heart pathologies or subclinical cardiomyopathies should be sought, such as: ASD, ARVD, sarcoidosis, Chagas disease.

RBBB is twice as common as LBBB, and the prevalence of both increases with age and male sex. The prevalences of isolated (idiopathic) LBBB and RBBB are ~0.4% and 1%, respectively, at age 50 (40–60) vs. 6% and 13%, respectively, at age 80.[10]

3. While RBBB that occurs without myocardial disease is more benign than LBBB, RBBB that occurs in LV systolic dysfunction is at least as malignant as LBBB and is more frequently associated with ischemic cardiomyopathy and a larger scar burden than LBBB, more specifically a large anteroseptal scar.[14–18] The right bundle is supplied by the first septal branch, and thus RBBB may result from proximal LAD occlusion. The left bundle has dual supply, and thus LBBB does not usually result from an ischemic scar but from LV dilatation or hypertrophy; the increased wall stress and the patchy myocardial fibrosis lead to strain, fibrosis, and calcification of the left bundle. A new LBBB is more frequently the result of non-ischemic than ischemic cardiomyopathy (30% ischemic cardiomyopathy, in which case it is associated with extensive CAD).[19] ***LBBB rarely results from acute infarction*,** and if it does, it is usually a large infarction involving both the LAD and RCA territories.[14,15]

Note: Non-specific intraventricular conduction delay (IVCD) – While LBBB or RBBB may be solely due to disease of the bundle branch rather than myocardial disease, IVCD >120 ms often signifies myocardial disease with intramyocardial slowing of conduction, including LVH. The disease may be subclinical and the echocardiogram may be normal. Baseline IVCD was associated with higher mortality than LBBB over the long-term follow-up of relatively young individuals with unsuspected heart disease (40–55 years of age).[6] In young athletes, however, IVCD up to 140 ms is benign and may reflect physiologic hypertrophy or high vagal tone.[20]

C. Workup

Perform an echocardiogram to evaluate RBBB, LBBB, or IVCD. If there is no evidence of a cardiomyopathy and no clinical suggestion of CAD, the bundle branch block is most likely isolated and related to a degeneration of the conduction system and does not usually portend an impaired prognosis (especially with RBBB). Since LBBB more often reflects underlying cardiomyopathy, cardiac MRI may be done for LBBB if the echo or the clinical presentation is suspicious, seeking ARVD, sarcoidosis and other cardiomyopathies, including subclinical genetic cardiomyopathies. Ischemic evaluation, on the other hand, is reserved for only typical exertional chest pain.

RBBB is not usually associated with right-axis deviation. Frank right-axis deviation implies an associated RVH or LPFB.

LBBB that is due strictly to conduction disease usually has a normal or slightly leftward axis. A left axis is often seen when the LV is dilated. A right axis implies a dilated cardiomyopathy with RV and LV dilatation.

The wider the QRS (especially >150 ms, even more so >180 ms), the more likely it is for LV function to be impaired and cardiomyopathy to be present, whether with RBBB or LBBB; and in the case of LBBB, the more likely it is for LBBB to be a major driver of the cardiomyopathy.

D. Treatment

PM placement is not indicated for asymptomatic RBBB, LBBB, or bi- or trifascicular block without advanced AV block, except in the case of alternating RBBB + LBBB. The rate of progression of RBBB or LBBB to high-degree AV block is 1–4% per year.[5]

An unexplained, non-neurally mediated syncope that occurs in a patient with RBBB or LBBB is most likely due to AV block and often dictates PM placement. One study addressed patients with BBB (RBBB 60%, LBBB 40%) who had unexplained syncope, negative carotid sinus massage, and negative EP study (no inducible VT, infranodal block, or sinus node disease). After placement of a loop recorder, 42%

of these patients had recurrence of syncope (median 48 days), mainly attributable to complete AV block. Overall, 54% had significant bradyarrhythmic events.[21] Thus, pacemaker placement is reasonable in patients with unexplained syncope and bifascicular block or LBBB, and reduces event recurrence by 60%, as per PRESS trial (ACC class IIa).[22] Consider performing EP study prior to PM placement, not solely to investigate infranodal disease, as EP study was not sensitive enough to detect it in the above studies, but also to assess for VT inducibility (ACC class IIa recommendation). In fact, VT is inducible in ~14–30% of patients with BBB and syncope.[23–25]

E. Tachycardia or acceleration-dependent bundle branch block

Bundle branch aberration may be induced in normal individuals when tachycardia occurs beyond a certain rate or premature excitation occurs at a very short R–R interval, particularly when the preceding R–R interval is long (Ashman's aberrancy after a long-short R-R sequence). This physiologic aberration is more likely to affect the right bundle, which has a longer refractory period than the left bundle. It may be seen with extreme heart rates (e.g., SVT with rate >150–180 bpm), or may be initiated by a very premature beat having a long–short sequence.

On the other hand, rate-related BBB occurring at lower rates (<130 bpm) or longer R–R cycles is often pathologic and implies an underlying bundle branch disease; it may very well be seen at rates <100 bpm and is less dependent on a long–short sequence. In these patients the aberration may be LBBB or RBBB (more commonly LBBB), and it has the same diagnostic and prognostic value as BBB seen at rest.[26,27] During tachycardia, the diseased bundle has less time to recover from its long refractory period and subsequently blocks.

Let us suppose that LBBB occurs in a particular patient after the heart rate reaches 100 bpm (R–R cycle length of 600 ms). Once it occurs, the aberrancy may not resolve until the rate is much lower than 100 bpm. In fact, once LBBB has occurred, the supraventricular impulse travels down the right bundle, traverses the septum, and depolarizes the blocked left bundle retrogradely. The very early part of the left bundle depolarizes late, such that the time between left bundle depolarization and the next impulse is much shorter than the 600 ms cycle length that perpetuates the aberrancy (Figure 13.28). It is this *delay of "trans-septal activation"* that perpetuates aberrancy at lower rates. A similar phenomenon explains the perpetuation of Ashman's aberrancy even after the R–R interval lengthens; only the first R–R interval of the wide complex rhythm may be short.

The concept of bundle "fatigue" during tachycardia may also explain why it takes a slower rate to resolve it than to initiate it. BBB may reverse in a cyclic pattern, wherein it intermittently occurs every few beats before fully reversing.

F. Bradycardia or deceleration-dependent bundle branch block and AV block

Spontaneous diastolic (phase 4) depolarization, a property of the sinus and AV nodes, may occur in a diseased His-Purkinje system or bundle branch. This is more likely after a long diastole, at which time phase 4 depolarization may create a concealed action potential that prevents propagation of supraventricular impulses. Deceleration block implies significant underlying bundle branch disease and infranodal disease. In addition, these patients usually have tachycardia-dependent BBB, and the heart-rate range of normal conduction may be extremely narrow (e.g., 55–75 bpm), and inversely related to the amount of bundle injury.

Deceleration, pause-dependent AV block suggests infranodal AV block. In fact, ***infranodal AV block is typically triggered by a pause, such as a post-PVC pause*** (Figure 13.29).[28]

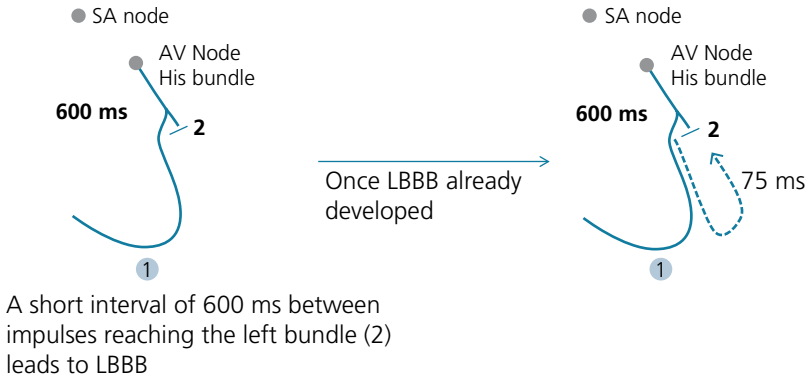

Figure 13.28 Suppose that a tachycardia-mediated LBBB has developed at a rate of 100 bpm (R–R interval = 600 ms). When the heart rate slows back down to <100 bpm, the LBBB persists. For a 600 ms interval between impulses reaching the AV node, it takes the left bundle that is now blocked an extra 75 ms to be depolarized, so that the interval between the left bundle depolarization and the next impulse is 600 – 75 = 525 ms. This perpetuates the LBBB even at a rate <100 bpm. The left bundle may recover once the cycle length is 675 ms (HR = 88).

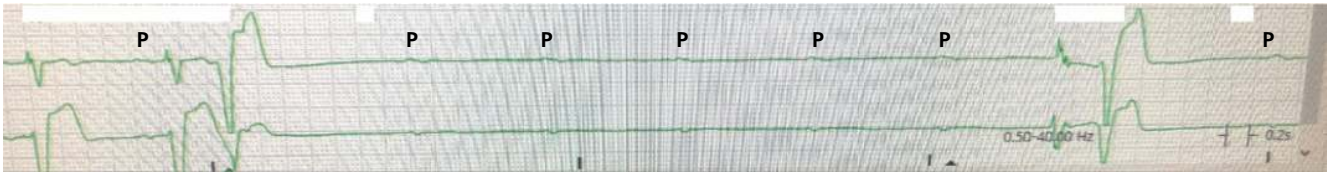

Figure 13.29 Complete AV block initiated by a post-PVC pause. This AV block is initiated by ventricular deceleration, which is pathognomonic for infranodal, very high-risk AV block (= deceleration or phase 4–induced AV block). The baseline LBBB further indicates infranodal disease. The patient is asymptomatic during this pause, but a pacemaker is indicated regardless. He underwent TAVR and developed LBBB then this pause 3 days postoperatively.

G. Alternating bundle branch block

This is an alternation of RBBB and LBBB on the same ECG or, much more commonly, on several ECGs obtained several days, months, or years apart. This usually implies an incomplete block of one bundle, e.g., left bundle (even if QRS >120 ms) and intermittent complete block of the other bundle, e.g., right bundle: the baseline ECG shows LBBB, but during deceleration or acceleration, RBBB develops and conduction occurs over the slow, but not completely blocked, left bundle.[29,30] Depending on the refractory period of the right bundle, conduction may resume over the right bundle intermittently on the same ECG, or may resume once the trans-septal activation is delayed enough to allow the right bundle to recover. In other patients, the baseline QRS is narrow, and some ECGs show RBBB, while others show LBBB; this pattern is more concerning, as complete BBB is developing alternately over each bundle, and it may be a stronger incentive for pacemaker implantation. In asymptomatic patients, the risk of progression to complete AV block is higher than with unilateral BBB. Pacemaker implantation is warranted even in asymptomatic patients, although most of these patients do not develop complete AV block over several months or 1 year of follow-up.[30]

QUESTIONS AND ANSWERS

Question 1. A 65-year-old man has occasional episodes of vague fatigue, and an event monitoring is performed. It shows the tracing of Figure 13.11. The patient was asymptomatic during this tracing. Should a PM be placed?

Question 2. A 65-year-old man has occasional episodes of vague fatigue, and a Holter monitoring is performed. It shows the tracing of Figure 13.13 during sleep. He is asleep and asymptomatic during the tracing. Should a PM be placed?

Question 3. A 65-year-old man has occasional episodes of vague fatigue. He is mostly bothered by palpitations. An ECG is performed (Figure 13.18). Should a PM be placed?

Question 4. A 65-year-old man had one episode of near-syncope after working in his yard, in a hot environment. His ECG shows AF with a spontaneously slow ventricular response of 55 bpm. The patient is not taking any rate-slowing drugs. A Holter monitor is performed. It shows a 3.5-second AF pause during sleep. Should a PM be placed?

Question 5. A 65-year-old man has severe nausea and vomiting. He has deep fatigue. He is known to have chronic AF. The emergency room monitor shows a pause of 4 seconds while the patient is awake. He has not had syncope, but is gagging. He receives chronic metoprolol for AF. What is the next step?

Question 6. A 65-year-old man had one episode of near-syncope after working in his yard in a hot environment. His ECG shows AF with a spontaneously slow ventricular response of 55 bpm. The patient is not taking any rate-slowing drugs. A Holter monitor is performed. It shows the rhythm strip of Figure 13.20 during sleep. Should a PM be placed?

Question 7. A 65-year old man complains of occasional episodes of dizziness. Rhythm monitoring is performed and shows the rhythm strip of Figure 13.9, during wakefulness. He had mild palpitations during the recording. Should a PM be placed?

Question 8. A 50-year-old woman presents with a syncope that occurred after prolonged standing. She has no prior cardiac history and does not take any medication. She still has malaise and feels tired and nauseated. ECG shows sinus bradycardia at a rate of 38 bpm. Should a PM be placed?

Question 9. A 65-year-old man has occasional episodes of dizziness at rest. His pulse at rest is consistently slow, ~45 bpm. ECG shows sinus bradycardia at 45 bpm. What is the next step?

A. PM placement
B. Prolonged rhythm monitoring (event monitor)
C. Stress testing
D. EP study
E. B or C

Question 10. A 58-year-old man is found to have LBBB of 125 ms on his ECG. He is hypertensive and asymptomatic. Which of the following statement(s) are true (multiple possible answers)?

A. Compared with RBBB, LBBB is more likely to be associated with underlying heart disease (cardiomyopathy, CAD) upon diagnosis or follow-up
B. Even in the absence of obvious underlying heart disease, LBBB, unlike RBBB, is associated with increased long-term mortality, HF and MI
C. In the presence of underlying myocardial or coronary disease, both LBBB and RBBB have the same adverse prognostic implication. RBBB may have worse implication in ischemic cardiomyopathy
D. In patients with cardiomyopathy, RBBB is often due to a large ischemic scar, while LBBB is most often due to ischemic or non-ischemic LV dilatation or hypertrophy
E. Echo is indicated to look for subclinical myocardial disease. In this case, hypertensive LV hypertrophy is the likely myocardial disease

Question 11. A patient has mild dizziness. He is not hypotensive. An ECG is performed (Figure 13.30). Which statement is correct?

A. This is high-grade AV block. PM is needed
B. This is intermittent AV dissociation without AV block. No need for PM
C. AV dissociation always implies AV block

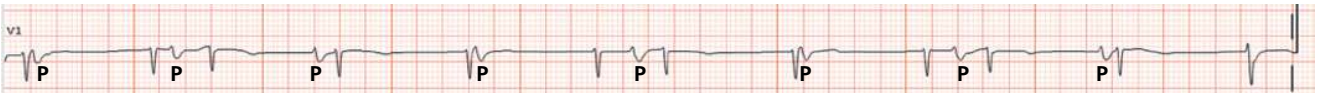

Figure 13.30

Question 12. A patient with complete AV block demonstrates retrograde P waves on some of the escape beats. Where is the location of the AV block?
A. Nodal AV block
B. His or infra-His AV block

Question 13. In Figure 13.29, AV block occurs after a PVC. Which is true regarding this AV block?
A. Deceleration-induced AV block, infranodal
B. Deceleration-induced AV block, nodal
C. Acceleration/PVC-induced AV block, infranodal

Answer 1. Yes. This is Mobitz type II AV block. It requires PM placement, even if asymptomatic and even if only 1 beat appears to drop.

Answer 2. No. This is a benign finding of increased vagal tone. Consider sleep study. No need for PM based on this tracing.

Answer 3. Yes. This is a high-grade AV block with a wide, ventricular escape. Even if he is asymptomatic (no syncope/near-syncope), a PM is definitely warranted. Palpitations are explained by AV dissociation and the simultaneous atrial and ventricular contractions at times, leading to cannon A waves.

Answer 4. No. AF pauses are common during sleep, and even pauses >3 seconds do not have therapeutic or diagnostic implications, per se. AF pause >3 seconds during wakefulness indicates PM placement in a patient who had non-vagal near-syncope at one point, even if the documented pause is not symptomatic per se. AF pause >5 seconds during wakefulness indicates PM placement even in the absence of prior symptoms (a marker of high-grade AV block). All of this assumes that the pauses are not due to vasovagal syncope or vagal mechanism, and that offending drugs have been removed.

Answer 5. This long AF pause occurred during wakefulness but was triggered by a high vagal tone (gagging, nausea), a transient cause. It does not indicate PM placement. Even metoprolol dose may not need to be reduced.

Answer 6. Yes. The rhythm strip shows a rate of ~40 bpm, which is acceptable and common at night. However, in this case, the 40 bpm rate is mostly a regular, ventricular escape rhythm, with a high-grade infranodal AV block. High-grade AV block with ventricular escape dictates PM placement, especially in a patient with prior near-syncope, even if it occurs at night.

Answer 7. No. The patient has episodes of accelerated junctional rhythm with isorhythmic AV dissociation. This is a competitive form of AV dissociation, without AV block. PM is not indicated based on this tracing. Palpitations are due to the simultaneous atrial and ventricular contractions.

Answer 8. No. The patient has severe sinus bradycardia that may initially seem symptomatic (malaise, recent syncope). However, considering the context of her syncope (prolonged standing) and the nausea, it is likely that the patient has had vasovagal syncope and lingering vasovagal symptoms along with sinus bradycardia. Rather than being the cause of syncope, sinus bradycardia is secondary to the vasovagal state. This patient was monitored for 24 hours. Symptoms progressively resolved, and sinus bradycardia improved to 55 bpm. To prove that her bradycardia was innocuous, a stress testing was performed. Her sinus rate appropriately increased to 165 bpm at peak exercise.

Answer 9. E. Sinus bradycardia of 40–50 bpm at rest is usually a normal, innocuous finding. Unless the sinus bradycardia is severe (<40 bpm while awake or pause >3 seconds while awake), dizziness is typically unrelated to the bradycardia. In order to prove the effect of a sinus bradycardia, stress testing is the best testing modality. ***Sinus bradycardia is innocuous if the sinus rate increases appropriately when needed most, during stress.*** Rhythm monitoring may be useful, seeking more severe bradycardia, AV block, or pauses during wakefulness. EP study is not sensitive enough for the diagnosis of bradyarrhythmias, particularly sinus node disorders.

Answer 10. All are true.

Answer 11. B. AV dissociation may be due to: (i) AV block, or (ii) competitive AV dissociation. Complete AV block is always associated with AV dissociation, but the reverse is not true. Figure 13.30 shows competitive, isorhythmic AV dissociation between the sinus rhythm and an accelerated junctional rhythm, competing at a nearly similar rate of ~50–60 bpm. The 3rd, 4th, 7th, and 10th QRS beats are intrinsically conducted via the sinus P wave, while the remaining QRS complexes are junctional beats, occurring at a fixed rate when no sinus-originating QRS occurs. P waves fall around those junctional QRS complexes: (i) when they fall too close to the junctional QRS, they are not conducted, e.g., first P and last P; (ii) when they fall close to it but not too close, they get conducted with a long PR, e.g., 2nd P; (iii) when they fall far from it, they get conducted with a normal PR, e.g., 3rd P, which suggests the lack of AV block.

Answer 12. B. Patients with complete infranodal AV block but relatively intact AV node may allow retrograde VA conduction through the AV node.

Answer 13. A. This is a complete AV block initiated by a post-PVC pause, i.e., by ventricular deceleration, which is pathognomonic for infranodal, very high-risk AV block.

Questions and answers 443

I. Indications for permanent pacemaker implantation[1]

1. Any symptomatic sinus bradyarrhythmia or AV block (symptomatic means near-syncope/syncope, severe fatigue, or active HF concomitant to bradycardia, generally <40 bpm, or <50 bpm in case of AV block, or pause >3 s while awake).

2. AV block (see Chapter 13, Section I.E):
- **a.** Mobitz II AV block even if it is asymptomatic
- **b.** High-grade or third-degree AV block, even if it is asymptomatic, unless secondary to a vagal mechanism
- **c.** Asymptomatic, severely prolonged HV interval (His-ventricle) >70 ms or infra-His block during incremental pacing on EP study
- **d.** Mobitz I or first-degree AV block leading to "pacemaker syndrome"-like symptoms.

3. Syncope with periods of sinus pauses or AF pauses >3 seconds or heart rate <40 bpm while awake, as evidenced by Holter or telemetry monitoring. More prolonged pauses >6 seconds may indicate pacing even when a clear association between the syncope and the bradycardia is not documented.

4. All this in the absence of a reversible cause, such as drugs, electrolytes, high vagal tone or vasovagal syncope, acute STEMI, or the immediate post-cardiac surgery state, in which a temporary transvenous PM may be indicated for temporary support.

If the bradyarrhythmia does not resolve after treatment of these causes, especially in the case of an acute anterior MI, a permanent PM is indicated. Also, if rate-slowing drugs are necessary to control frequent paroxysms of SVT, a PM is indicated.

II. Types of cardiac rhythm devices

Pacemakers (PMs) are designated by a 3- or 4-letter code: e.g., AAI, VVI, or DDD.

- 1st letter = chamber paced: A (right atrium), V (right ventricle), or D (dual, both chambers)
- 2nd letter = chamber sensed: A, V, or D
- 3rd letter = action taken by the PM when it senses an event: I (inhibits pacing), T (triggers pacing, like pacing V after sensing A), or D
- There is often a fourth letter, R, which indicates a rate-response mode. A rate response means the device has accelerometer or ventilatory sensors that increase the rate with activity.

A. VVI = ventricular demand pacing

A VVI PM has a single sensing and pacing lead in the right ventricle. It paces the ventricle when it sees that the interval between 2 QRS complexes is longer than the back-up limit, called the *lower rate interval*; a limit of 1 second, for example, corresponds to a heart rate (HR) of 60 bpm.

It does not see or pace the atrium, and does not make the ventricle track the atrium. In patients with sinus rhythm, VVI may lead to AV dissociation and loss of the atrial contribution to the cardiac output.

VVI pacing is mainly used in chronic AF, wherein the atrium cannot be paced or tracked. It may also be an acceptable option in older sedentary patients with AV block.

VVI pacing may lead to a ***pacemaker syndrome***. This is a syndrome of fatigue, dyspnea, and pre-syncope that results from: (i) loss of the atrial contribution to the cardiac output; (ii) some of the asynchronous atrial contractions occur during ventricular systole while the AV valve is closed, leading to increased atrial pressure. Moreover, ventricular pacing may lead to retrograde P waves; those retrograde P waves are an additional cause of atrial contraction during ventricular systole and may be a major contributor to the pacemaker syndrome.

B. DDD = AAI + VAT + VVI

DDD is a dual-chamber PM, with sensing and pacing leads placed in both the right atrium and the right ventricle.

- PM tracks the P wave and paces the ventricle whenever a P wave is not followed by a ventricular activity. After a P wave, PM waits a certain time before pacing the ventricle; this time is the *programmed AV interval*. This function is the VAT function or AV sequential pacing: PM sees the atrium ("A") then triggers ("T") the ventricle ("V"). It will appropriately track sinus tachycardia up to a certain rate (upper tracking rate).
- PM paces the atrium if P wave is absent (sinus node disease) and lets it spontaneously conduct to the ventricle (AAI function).
- PM sequentially paces the atrium then the ventricle in case of severe sinus node disease combined with severe AV block (AAI + VAT functions).

Notes

i. In patients requiring ventricular pacing, DDD is a more physiologic pacing mode than VVI. DDD preserves AV synchrony and the atrial contribution to the cardiac output, which may decrease left atrial pressure and augment cardiac output by 20–30% in comparison with VVI. It improves symptoms and quality of life in comparison with VVI and reduces the incidence of AF.

DDD pacing is indicated for sinus node disease and AV nodal disease. If the patient develops AF, DDD senses the excessive atrial activity and switches the pacing mode to VVI or DDI (mode-switch function).* Single-lead VVI PM is indicated if permanent AF is present at baseline.

ii. In pure sinus node disease, AAI PM may be placed. AAI senses the atrium and paces it when the atrial rate is slower than a certain limit; it does not sense or pace the ventricles. However, some of these patients have AV nodal disease as well (~15%), or progress to AV nodal disease (~2% per year), thus requiring V pacing at some point. When DDD pacing is performed in patients without AV nodal disease, ensure that only the atrium is paced with the DDD pacemaker, and let it normally conduct to the ventricles, thus minimizing RV pacing. The programmed AV interval should be long (250 ms if tolerated). RV pacing leads to dyssynchronous contractions within the LV and between the RV and LV, which may decrease LV function, especially in patients with pre-existing LV dysfunction. The avoidance of RV pacing reduces the risk of AF, stroke, and HF (posthoc data from MOST and DAVID trials).[2,3]

iii. RV pacing leads to a wide QRS complex, with typically LBBB morphology as the electrical activity spreads from the RV to the LV. Usually, the axis is deviated to the left, except in the case of RV outflow tract pacing, in which the axis is vertical (depolarization goes up to down). QRS should be negative in V_1–V_3 as in LBBB. However, a positive QRS may be seen in V_1–V_2 (in up to 10%), but never in V_3 in standard RV pacing. A positive QRS in V_3 signifies LV pacing, and thus BiV pacing or LBB-area pacing or septal perforation of the RV lead. Rarely, there are q or Q waves in leads I–aVL, but, as in LBBB, there should not be qR or QR in the precordial leads V_1–V_6 or the inferior leads (if present, these q waves are very specific for an anterolateral or inferior infarct).[4]

C. Biventricular pacemaker

A biventricular pacemaker (BiV PM, also called cardiac resynchronization therapy, CRT) is a pacemaker that typically has 3 leads: RA lead, RV lead, and LV epicardial lead placed via the coronary sinus. In a way, it is a DDD PM with an additional LV lead. This PM is indicated for HF (functional class III or IV) with an EF ≤35% and LBBB or RV-paced rhythm that delays the LV excitation and contraction. A wide QRS, particularly LBBB, is seen in 20–30% of patients with systolic HF. LBBB is associated with dyssynchronous LV contraction, i.e., the RV contracts before the LV (interventricular conduction delay) and the septal wall contracts before the posterolateral wall (intraventricular conduction delay). This leads to ineffective systolic function, as one wall contracts while the other stretches in the opposite direction, a reduction in stroke volume, a larger LV volume in systole, and subsequently, a maladaptive LV dilatation. BiV PM likely also benefits HF with EF < 35% and non-specific conduction delay > 150 ms, but is more questionable for RBBB (even >150 ms?) (Section IX.B).

Typically, BiV PM is used in patients who are not bradycardic. On the other hand, when patients with low EF (EF ≤ 35%, and even EF 36–50%) require PM placement for bradycardia, and when the ventricle is expected to be frequently paced (>20% per ESC and HRS), the implantation of a BiV PM rather than a right ventricular PM seems to be the best option regardless of NYHA symptoms.

The purpose of the BiV PM is to allow simultaneous contraction of the LV septal and posterolateral walls, as well as the RV and LV, to improve cardiac function. To be beneficial, it has to track the atrial rate and pace both ventricles ~100% of the time (>90–95%). It cannot be in a standby mode. The AV tracking interval needs to be programmed shorter than the intrinsic PR interval to ensure ventricular pacing. AV delay is also optimized to ensure appropriate diastolic filling (a long AV delay reduces diastolic filling and leads to fusion of E–A waves on echo; a very short AV delay leads to atrial contraction near systole and A truncation).

In AF, the BiV PM is programmed in VVI mode (no A tracking). The AV conduction has to be aggressively slowed so that the intrinsic QRS rate is slow, and the BiV pacing would pace the ventricles at a rate faster than the spontaneous ventricular rate. AV nodal ablation often needs to be performed to ensure consistent BiV pacing in patients with AF and an indication for BiV pacing.

The QRS of a BiV-initiated complex is typically narrower than the RV pacemaker-initiated complex and the baseline non-paced QRS, even though the QRS often remains wide. The morphology is not an LBBB morphology, and the QRS has at least 1 of the following 2 features: (i) prominent negativity in lead I, or (ii) prominent positivity in lead V1. If not negative, the QRS in lead I needs to have at least a q or Q wave. If the LV lead is positioned close to the LV apex, QRS may be negative in all precordial leads V_1–V_6, simulating RV apical pacing in those leads (Figure 14.1).

Examples of pacemaker ECGs are provided in Figures 14.2–14.6.

---

* In DDI, ventricular pacing does not track atrial activity. The atria get paced in case of sinus bradycardia, asynchronously to the sinus activity but in sync with ventricular pacing. In case of AF, the atria are not paced and V pacing does not track AF; it is a form of pacing that works for AF alternating with sinus rhythm, in the absence of a mode-switch option.

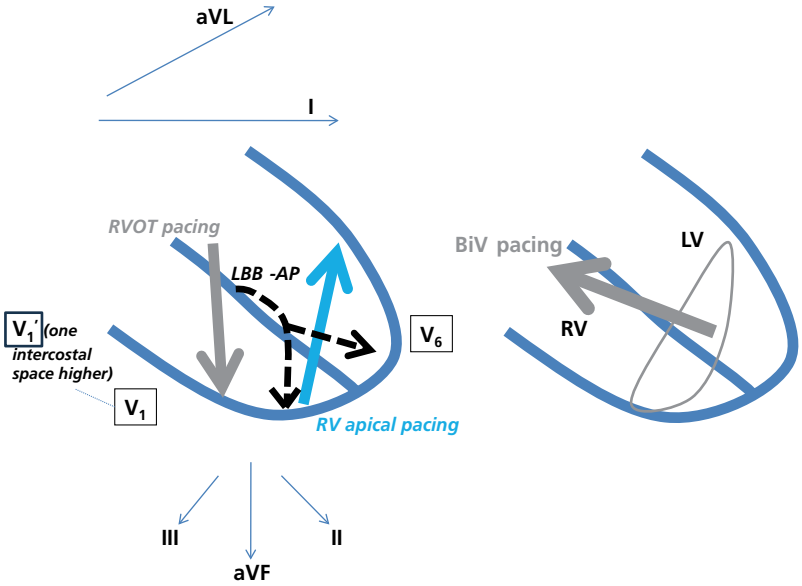

Figure 14.1 The paced QRS morphology varies according to the vector of depolarization. Analyze the QRS morphology in lead I, the inferior leads, and the precordial leads V_1–V_6.

In ***RV apical pacing***, the QRS is characterized by a left axis and by being negative in the inferior leads II, III, and aVF. It has an LBBB morphology, and similarly to LBBB, QRS may be negative in V_1–V_3 and upright in V_4–V_6, I, and aVL. However, the vector of depolarization may also be looking away from all precordial leads, leading to a deep negative QS in V_1–V_6, and may be looking away to the right, leading to a negative QRS in lead I. If the vector is looking to the right, the QRS may paradoxically be upright in leads V_1 and V_2, simulating LV or BiV pacing (especially if V_1 is high in relation to the heart).

In ***RVOT pacing***, the depolarization looks toward the inferior leads (vertical or right axis). QRS may be positive or negative in lead I. In the precordial leads, QRS simulates an LBBB morphology and, as opposed to RV apical pacing, cannot be negative all the way from V_1 through V_6.

In BiV pacing, the QRS: (1) is predominantly negative in lead I with a Q wave (QR or qR pattern), and (2) has a positive QRS or at least a prominent R wave in the precordial lead V_1. This is different from RV pacing, which occasionally has either 1 of these 2 features. If the LV lead is close to the apex, QRS may be negative in all precordial leads V_1–V_6, similar to RV pacing.

In ***LBB-AP***, QRS tends to be the narrowest and closest to physiological QRS activation; QRS tends to be <130–140 ms, with the greatest narrowing relative to baseline in patients with LBBB. QRS has an atypical RBBB morphology, sometimes with LAFB morphology if pacing is at the level of the posterior fascicle.

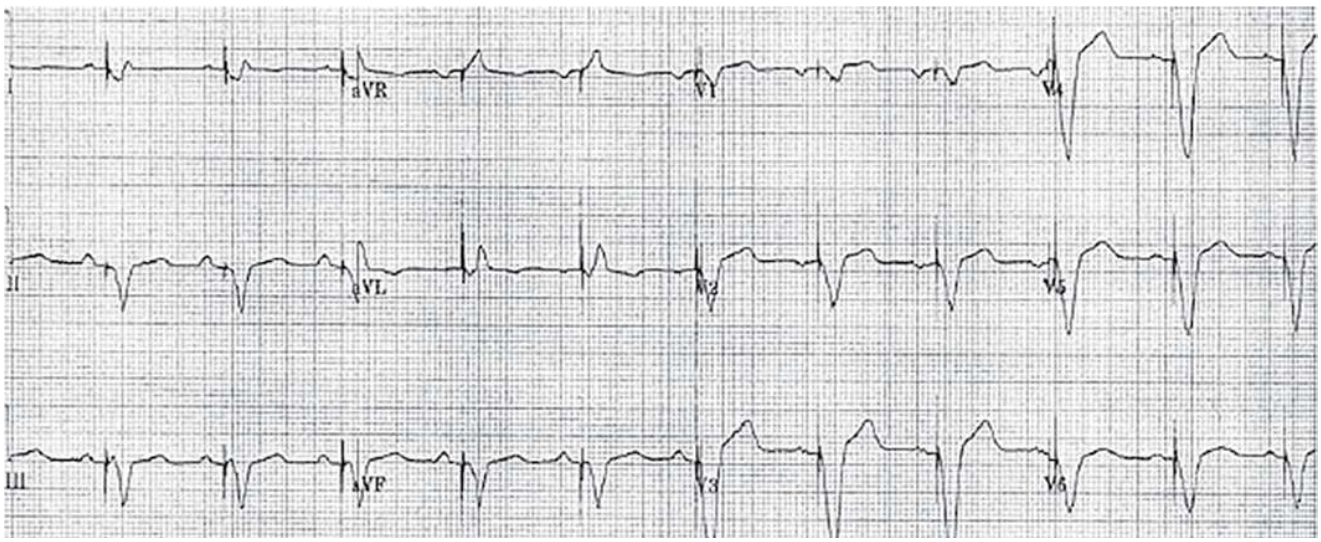

Figure 14.2 Ventricular pacing regularly tracking the sinus P activity (DDD PM, VAT action). The paced ventricular complexes have an LBBB morphology with QS or rS pattern that extends farther to the left (V_1–V_6) than in a typical LBBB (in which QRS often transitions to positive in lead V_4). The large Q wave in lead I is not typical of RV apical pacing but may be seen if the vector of depolarization is turned a bit rightward. BiV pacing is unlikely, because of the negative QRS in V_1–V_2. This is not RVOT pacing, because in RVOT pacing the depolarization vector is directed up to down, and the QRS is consequently [+] in the inferior leads.

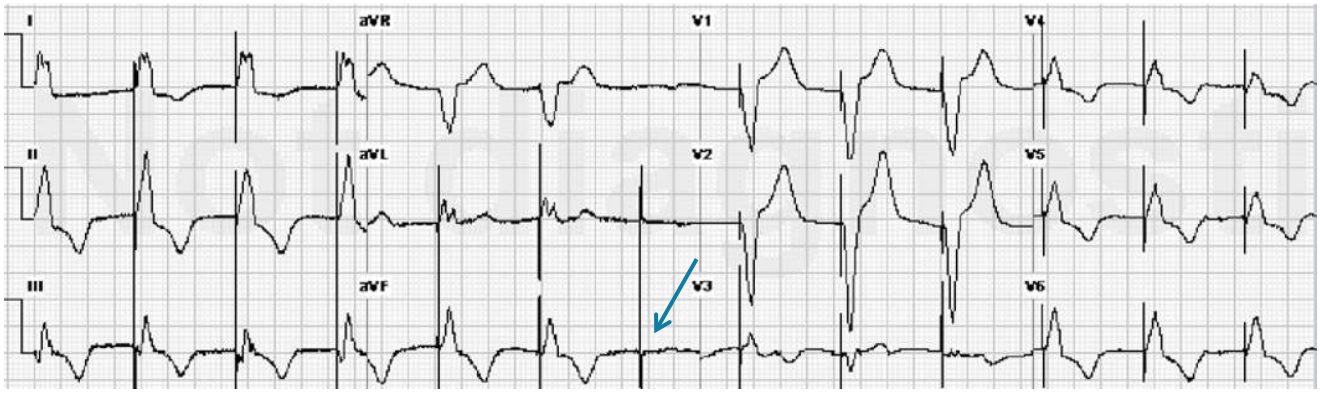

Figure 14.3 VVI pacing in a patient with no P wave (sinus arrest or subtle AF). RV lead is in the RVOT (QRS is positive in the inferior leads). Off/on failure to capture is noted (*arrow*, failure to capture). This is actually a temporary pacemaker. ***RVOT is an unstable position for a temporary pacemaker.***

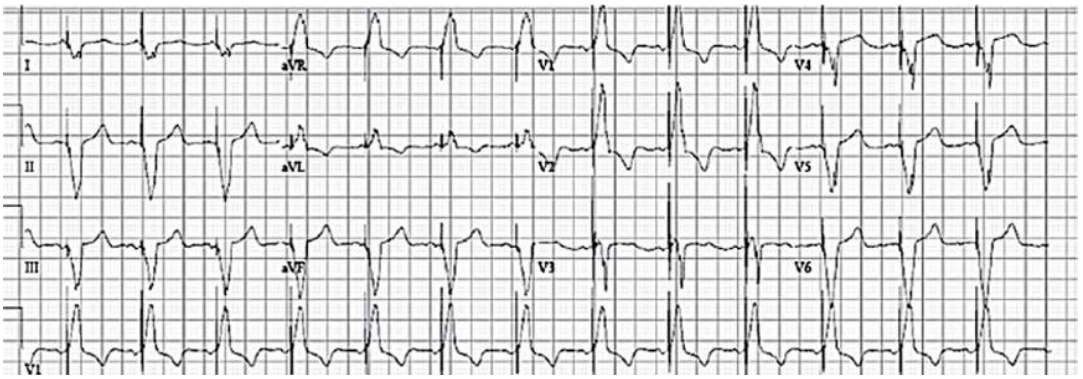

Figure 14.4 Ventricular pacing that consistently tracks a preceding sinus P wave. This is AV sequential pacing (probable DDD mode). Note that QRS is negative in lead I and starts with a Q wave, and QRS is positive in V_1: this is typical of BiV pacing. Also, PR is very short to ensure ~100% pacing, which is characteristic of BiV programming. Q or qR in lead I is rare in RV pacing, but is often present with BiV pacing (90%). If initially present with BiV pacing, the loss of Q wave in lead I is 100% predictive of loss of LV capture.

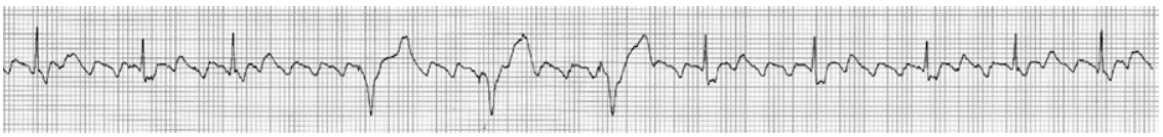

Figure 14.5 Atrial flutter with variable conduction. Note that when the R–R interval increases to >1200 ms (which corresponds to 6 large boxes, or a rate of 50 bpm), V pacing kicks in at an interval of 1000 ms (60 bpm). This is called *hysteresis*, wherein V pacing is initiated only when the heart rate drops well below the programmed pacing rate, allowing a reduction of V pacing.

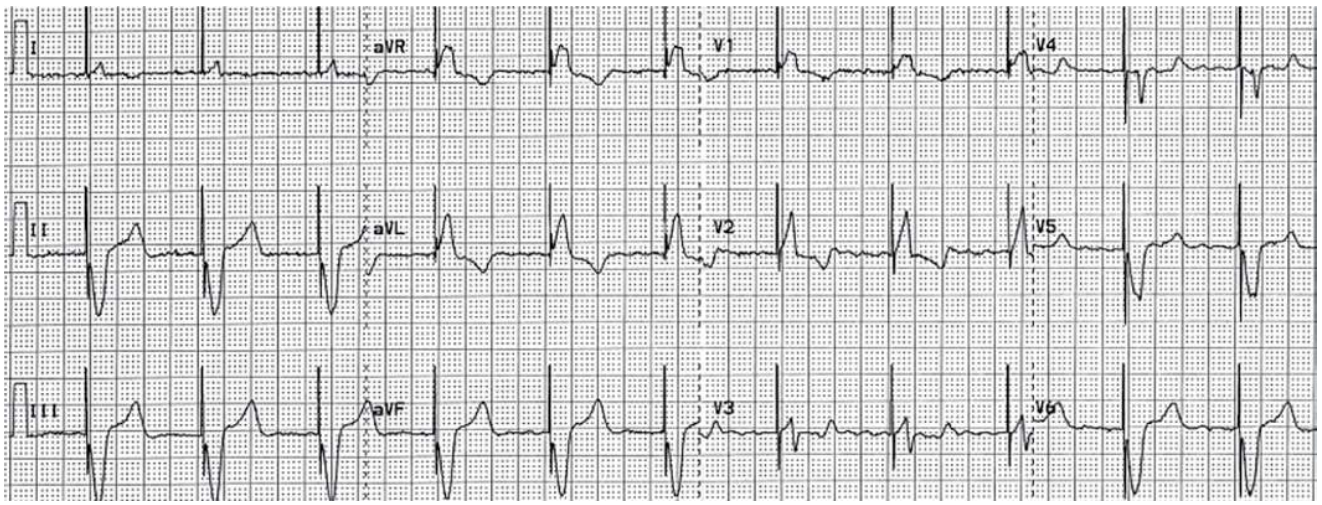

Figure 14.6 Prominent R wave in V_1–V_2 may suggest BiV pacing. However, there is no Q wave in lead I, which suggests that RV pacing is more likely (RV apical pacing by the fact that QRS is negative in the inferior leads and in V_4–V_6). **V_1 may be placed one intercostal space lower and the ECG repeated; QRS of V_1 should become negative in RV apical pacing.**

D. His bundle pacing and left bundle branch area pacing (LBB-AP) (conduction system pacing)

Similarly to LBBB, RV pacing induces inter- and intraventricular dyssynchrony, which may worsen LVEF and increase LV volume. Data suggest that RV pacing induces a significant EF decline *(≥10%)* in 12–20% of patients after 1–5 years, the so-called pacing-induced cardiomyopathy.[5]

Unlike the RV apex, pacing at the His level results in physiological, simultaneous activation of both ventricles along both bundles. In its early days, His pacing consisted of pacing the proximal His via a RA lead positioned over the atrioventricular septum, atop the tricuspid valve. The blocked left bundle being downstream from the His bundle, His pacing could not consistently overcome LBBB in patients with baseline LBBB. This was circumvented by high-voltage pacing to penetrate and capture the blocked left bundle but was marred by a high rate of left bundle non-capture in 25% of patients and even lack of ventricular capture in some patients.

Currently, conduction system pacing has shifted to distal His pacing (from the RV side) or left bundle branch area pacing (LBB-AP) or left posterior fascicular pacing. LBB-AP is achieved by pulling a curved lead back through the RV into the proximal and high ventricular septum. Once a His potential is captured, the lead is moved from this location towards the RV apex ~ 1–2 cm in RAO view (targeting the upper third of the septum in the anteroinferior plane). This lead is screwed several millimeters deeply in a way to pace the left side of the septum, the left bundle itself; it more consistently captures the left bundle than His pacing (lower pacing threshold). It may also be placed in the more distal septum, ~1/3 of the way from the apex, and lower in the anteroinferior plane to pace the left posterior fascicle. To ascertain proper lead position: (i) a left bundle potential is sought on the lead's EGM: this deflection occurs just before the surface QRS and is detected in 50–80% of cases; (ii) peak LV activation time is measured after pacing, from the pacing spike to the peak of R wave in leads V5–6, and is typically <90 ms in LBB-AP; (iii) paced QRS morphology shows an atypical RBBB. As the lead advances through the septum, QRS morphology progresses from septal pacing (wide) to nonspecific and then to specific LBB-AP. LBB-AP can be successfully achieved with low/stable pacing threshold and proper ECG response in 85% of patients.[6] Figure 14.7 illustrates an ECG of left bundle area pacing.

LBB-AP improves EF and likely clinical outcomes as much as BiV, and leads to a narrower QRS than BiV.[7] As such, His and LBB-AP pacing have been useful in 2 settings:[7–11]

i. In patients who require frequent ventricular pacing (>20–40%), they prevent LV dyssynchrony and HF events, whether EF is low or normal. They are particularly indicated in patients with ***EF 36–50%*** (class IIa, alternative to CRT, which also has class IIa for this EF). They may even be extended to *EF > 50%* (class IIb, HRS guidelines 2023). For *EF < 35%* requiring frequent ventricular pacing or induced by frequent RV pacing, CRT is still preferred to His and left bundle area pacing per HRS guidelines. Yet, His/left bundle area pacing remains an option if effective BiV pacing cannot be achieved or upon RV lead revision (class IIa).

ii. In patients with HF, EF ≤ 35%, and LBBB, CRT is the preferred therapy (class I), as there is a lack of large trials comparing clinical outcomes with BiV vs. His or LBB-AP pacing in EF ≤ 35%. Small trials of CRT vs LBB-AP in these HFrEF patients show conflicting results (Heart-Sync and PhysioCync trials). Yet, conduction system pacing is an alternative to CRT with experienced operators (class IIb) or when effective CRT pacing cannot be achieved with a coronary sinus lead (lack of functional or echo improvement with CRT) (class IIa).

E. Implantable cardioverter defibrillator (ICD)

An ICD has 1 (V) or 2 (A+V) leads. In addition to antitachycardia capacity provided by the special RV lead, it has single- or dual-chamber sensing and pacing capacities (VVI or DDD).

The V lead has 1 (RV) or 2 coils (RV+SVC) that allow the delivery of the shock energy. The vector of shock goes between the battery can and the coil; in patients with 2 coils, the vector may be modified to provide superior efficacy (e.g., can-to-RV, or can+SVC-to-RV). The ICD is best placed on the left side to allow the vector of shock to be orthogonal to the heart, fully traversing the myocardium.

ICD patients often do not require pacing. The pacing function is a standby function that should only be initiated at very low ventricular rates (e.g., 34–40 bpm). Harmful ventricular pacing should be prevented.

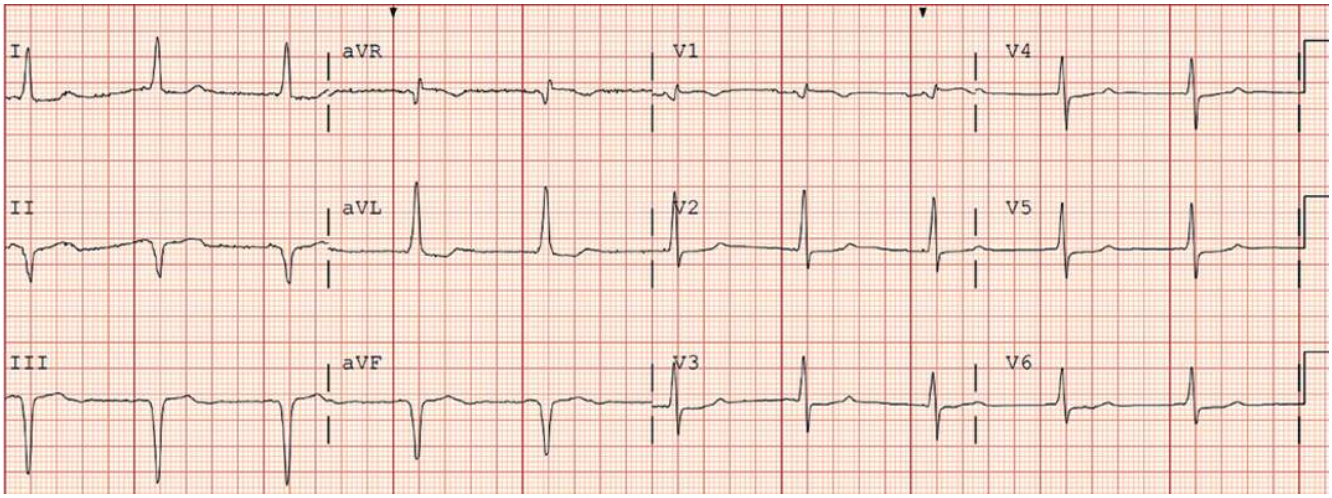

Figure 14.7 Left bundle area pacing at the level of the posterior fascicle. Note the W morphology in V1 (rSR' or qR or QR), as in RBBB morphology. RBBB morphology tends to be atypical, sometimes mild and incomplete, and there is no wide S in the lateral leads. QRS is usually relatively narrow in LBB-AP, <130 ms, and it narrows the most relative to baseline in LBBB. *Peak LV activation time*, measured from the onset of the pacing spike to the peak of R wave in leads V5–6, reflects how quickly the lateral wall is depolarized and is typically <90 ms in LBB-AP.

Note the negative QRS in the inferior leads, as in LAFB morphology: pacing originates from the posterior fascicular area.

The sensing function is what detects VF/VT. Typically, a certain ventricular rate is considered VT, regardless of its true origin. Many ICDs are programmed into 2 detection zones: VT and VF. Those 2 zones are differentiated by their rate (e.g., VT zone encompasses any ventricular rate of 170–250; VF zone encompasses ventricular rates >250). The ICD may have, on the other hand, SVT–VT discrimination algorithms, particularly the dual-chamber ICD, wherein the atrial lead can see the atrial activity:

i. Irregularity of ventricular activity during tachycardia → AF
ii. Progressive onset → sinus tachycardia
iii. More atrial activity than ventricular activity → SVT; more ventricular activity than atrial activity → VT
iv. No significant change in the morphology of the ventricular electrogram as compared to baseline → SVT

These discrimination algorithms are applied only for the VT zone. Any tachycardia in the VF zone is considered VF. Moreover, these discrimination algorithms *may* have a time out. For example, ICD may be programmed in such a way that if the tachycardia persists more than 5 minutes, it is treated as VT regardless of the initial diagnosis.

Typically, VT is initially treated with multiple cycles of antitachycardia pacing (ATP: overdrive ventricular pacing at a cycle length ~85% the tachycardia cycle length). If these fail, the ICD delivers a shock. If the tachycardia is fast enough to fall in the programmed VF zone, ICD immediately delivers a maximal shock. ATP enters the VT reentry cycle and breaks it in many patients; however, if the excitable gap of the reentry is wide, ATP may entrain the reentry at a faster rate, and may trigger further reentries that lead to VF. In fact, the most important ICD primary prevention trial (SCD-HeFT) recommended against ATP therapy and used a single-chamber rather than dual-chamber ICD, with shock therapy for tachycardia >187 bpm.[12]

According to the MADIT-RIT trial, a higher rate requirement of at least 200 bpm for initiation of VT therapy and 250 for VF zone, and/or a longer delay to therapy (12 seconds or 40 beats in the VT zone of 200–250 bpm, and 2.5 seconds in the VF zone ≥250 bpm), reduces shock therapies and mortality vs. lower rates and shorter delays. In the APPRAISE ATP trial, the use of one ATP sequence of 8 beats in the VT zone (VT 200–250 bpm), before shock, was effective in terminating VT in 54% of patients and reduced the overall rate of first-time shock by 1% per year (both appropriate and inappropriate shocks). However, ATP was mainly effective against monomorphic VT (not polymorphic VT or VF), and it accelerated VT into a storm in 3.7% of ATP-treated cases; as such, the overall shock burden was not reduced with ATP, but it remains a reasonable option for the VT zone, especially in patients with monomorphic scar VT.[13] As in APPRAISE trial, ATP is not generally used in the VF zone.[13]

F. Leadless pacemaker

Leadless pacemaker is a small pacemaker that encloses both the battery and the electrode in only ~1 cc and gets embedded in the RV (brand name examples: Micra, Aveir). It is inserted via a femoral venous sheath and is mainly used as a single-chamber RV pacemaker, VVI-R mode. When the battery is close to end of life, a new device is juxtaposed in the RV after deactivating the old device; the old device may also be retrieved. One model of single-chamber RV pacemaker (Micra AV) remotely senses the atrial mechanical contraction and attempts AV synchrony in a VDD mode, albeit with only 40–86% success (lower AV synchrony during higher heart rates and exercise). A newer dual-chamber system consists of 2 leadless pacemakers, one in the RA and one in the RV, which communicate wirelessly and attempt AV synchrony with a high success rate >90%.

Leadless pacemaker eliminates pocket and lead-related complications, and nearly eliminates the infection risk; it may even be implanted simultaneously to extraction of an infected transvenous pacemaker system. However, being mostly a single-chamber VVI-R pacemaker, it is mainly applicable to patients with permanent AF or those with dual-chamber pacemaker indication but a low expected pacing burden (e.g., paroxysmal AV block or sinus pauses). It is also favored in patients with no venous access or high infectious risk (e.g., hemodialysis patients).

It is implanted in the RV septum to reduce tamponade risk; high or mid-septum may reduce pacing-induced cardiomyopathy compared to apical septal pacing, but this is not LBB-AP as it does not penetrate the myocardium.

III. Pacemaker intervals

A. VVI

A VVI pacemaker is characterized by 2 basic intervals: (i) *lower rate interval* (the basic pacing rate), and (ii) *ventricular refractory period*, during which the pacemaker cannot sense any signal or reset its timing based on signals.

Even if the lower rate interval is 1 second, the pacemaker may not initiate pacing until a 1.5-second pause occurs. In other words, the pacemaker may not start pacing until the ventricular rate falls to 40 bpm, after which it will start pacing at 60 bpm. This is the hysteresis function of a pacemaker, meant to reduce the burden of ventricular pacing.

> Note that "interval" terminology, rather than "rate," is used in PM programming. The rate corresponding to a particular interval is equal to 60,000 divided by this interval. For example, if the lower rate interval is 1500 ms, the lower rate is 40 bpm.

B. DDD pacemaker's 4 basic intervals (Figure 14.8)

A DDD pacemaker is characterized by 4 basic intervals:[4,14]

a. *Lower rate interval* is the basic interval between paced P waves (the basic pacing rate). A hysteresis function may be established to delay the onset of atrial pacing.
b. *Ventricular refractory period* occurs after a sensed or paced ventricular event. This prevents the ventricular lead from sensing the residual energy from its own ventricular spike and from seeing and double-counting the QRS or the T wave.
c. *Post-ventricular atrial refractory period* (PVARP) begins immediately after the start of a ventricular event. An atrial activity falling in PVARP cannot initiate P-synchronous pacing. PVARP is meant to prevent: (i) sensing the ventricular activity by the atrial channel and tracking it (far-field), (ii) sensing and tracking a very premature PAC or a retrograde P wave occurring after a PVC. If the PM tracks those early P waves, pacemaker-mediated tachycardia (PMT) is initiated; a long PVARP protects against PMT. PVARP is initiated after a sensed or paced ventricular event.

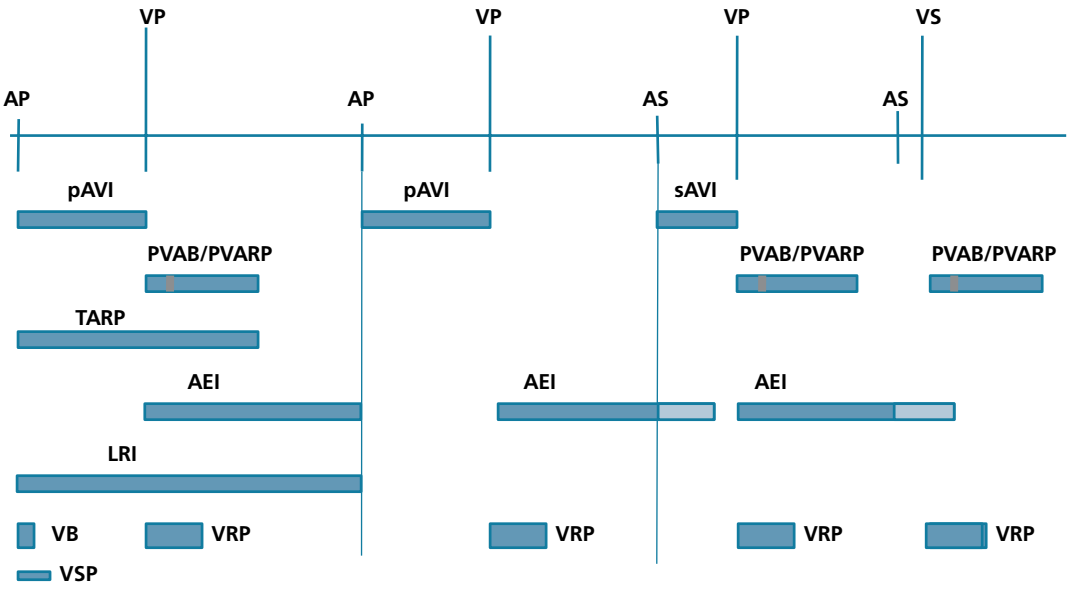

Figure 14.8 DDD pacemaker timing intervals.
AP, atrial paced event; AS, atrial sensed event; VP, ventricular paced event; VS, ventricular sensed event.
AEI, atrial escape interval after any ventricular sensed or paced activity (the occurrence of an atrial sensed event aborts AEI); LRI, lower rate interval; pAVI, paced atrioventricular interval; PVAB, post-ventricular atrial blanking period; PVARP, post-ventricular atrial refractory period; sAVI, sensed atrioventricular interval; VB, ventricular blanking (post-atrial); VSP, ventricular safety pacing.

d. *Programmed AV delay* from a sensed P wave (sAV) or a paced P wave (pAV) (A = atrial, V = ventricular). As opposed to the paced P wave, the PM senses an intrinsic P wave only after the atrial activity has spread for some time; therefore, the sensed AV interval is programmed shorter than the paced AV interval by ~30 ms.

C. Two other intervals are derived from the 4 basic intervals

a. *Atrial escape interval*, which is the V-to-A interval. After an intrinsic QRS or a PVC occurs, the pacemaker is reset. How long does it take for the pacemaker to pace the atrium? Atrial escape interval is the answer. The PM initiates a new atrial escape interval after any sensed or paced QRS. It is equal to (lower rate interval – AV interval)
b. *Total atrial refractory period* (TARP) = AV interval + PVARP

D. Upper rate behavior (see Figures 14.9, 14.10)

In the case of sinus tachycardia, the pacemaker senses the intrinsic sinus P waves and tracks them, leading to fast ventricular pacing. However, the pacemaker can only track the P waves up to a certain upper rate, called the *upper rate limit (e.g., 500 ms = 120 bpm)*. If the atrial rate is faster than this upper rate, the PM will only track some of the P waves. If this upper rate limit is equal to the TARP and if the atrial rate exceeds 120 bpm, the P wave that follows the paced QRS will fall into PVARP, which means that only every other P wave gets conducted; the patient's rate suddenly falls from 120 to 60 bpm (Figure 14.10). However, if PVARP is reduced in such a way that TARP is shorter than the upper rate interval (e.g., TARP = 400 ms, TARP rate 150 bpm), the ventricular rate will remain steady at 120 bpm even if the atrial rate exceeds 120 bpm. P waves will be conducted with progressively longer PR intervals. One P will drop every few cycles in a pseudo-Wenckebach fashion. When the atrial rate reaches 150 bpm (TARP), every other P wave gets conducted. Shortening the TARP, however, allowed a delay in onset of the 2:1 atrial conduction. PM can also be programmed to have an adaptive PVARP and AV delay that decrease with exercise, allowing a reduction in TARP and a delay of sudden rate drop.

Unlike patients with a dual-chamber PM, patients with BiV often need a higher upper rate limit (e.g., 140 bpm) to ensure consistent biventricular pacing at upper rates and prevent Wenckebach from occurring, particularly since higher sinus rates are seen in decompensated HF at rest and with activity. The prolongation of the paced AV delay (Wenckebach) that occurs as the atrial rate reaches the upper rate may allow an undesirable intrinsic AV conduction. A short PVARP is necessary to allow an increase in the upper rate, and thus, a rate-adaptive PVARP that automatically decrements at higher rates may be programmed.

E. Prevention of crosstalk[4,14]

Atrial-initiated ventricular blanking period

The pacer spike has a high voltage (measured in volts), much higher than the voltage of the intrinsic cardiac activity (millivolts). If the ventricular lead senses the atrial spike, ventricular pacing will be inhibited after atrial pacing. Therefore, atrial pacing automatically initiates a short interval called the *ventricular blanking period*, during which the ventricular sensing is totally blind to any signal. This only occurs after a paced atrial event (not an intrinsic atrial event).

A ventricular activity that is detected early after the atrial activity (<110 ms) but beyond the ventricular blanking period may be a far-field artifact or a PVC. The PM tends to immediately pace over it. As opposed to the blanking period, this activity cannot be ignored; in fact, if it turns out to be a PVC that is ignored, the ventricular pacing that follows the end of the AV delay would fall on the PVC's T wave and trigger VF.

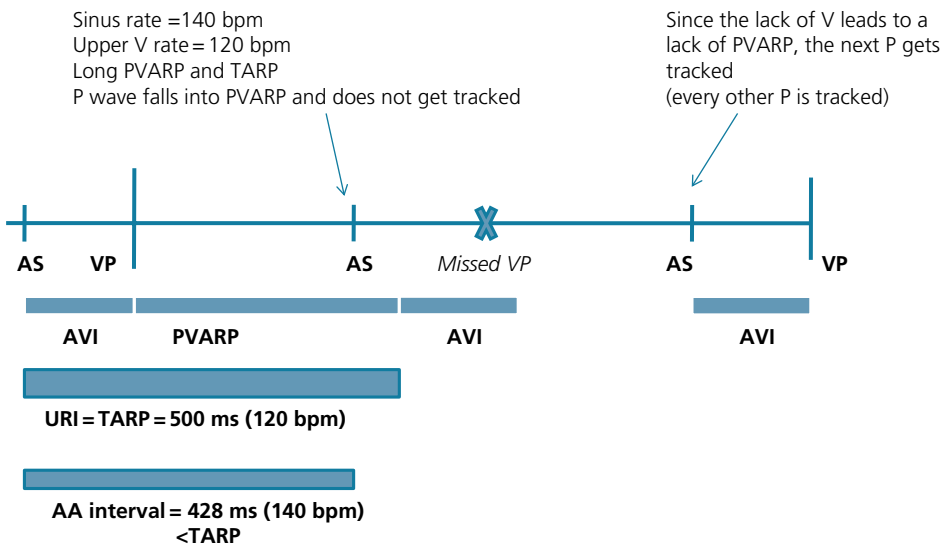

Figure 14.9 Sinus/atrial tachycardia with atrial rate > upper rate. Case where TARP (total atrial refractory period) = URI (upper rate interval), which leads to 2:1 ventricular pacing pattern. Other abbreviations as in Figure 14.8.

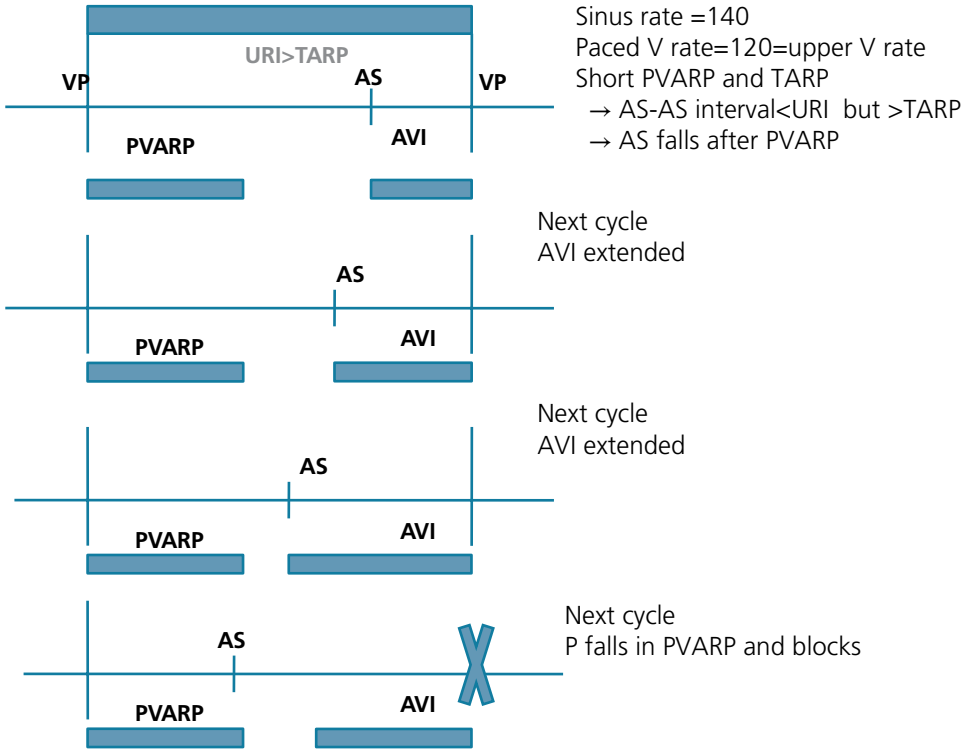

Figure 14.10 Sinus tachycardia with pseudo-Wenckebach ventricular pacing pattern. In contrast to Figure 14.9, PVARP is short with TARP < URI. This shortened PVARP allows AS to fall outside PVARP and get tracked. AVI extends after every cycle, until one beat drops. It is a pseudo-Wenckebach rather than a true Wenckebach pattern, as the R–R interval remains steady rather than shortens.

Conversely, it cannot be automatically considered PVC and allowed to reset ventricular pacing, as there is a high rate of atrial output artifacts within this zone (called afterpotentials). That is why, during this interval, any sensed activity by the V channel triggers immediate V pacing (*ventricular safety pacing*). ***On ECG, a spike in the middle of a PVC with a short PR interval implies safety pacing rather than undersensing.***

Ventricular-initiated atrial refractory period

The PVARP is meant to prevent the PM from tracking retrograde or premature P waves. The PM sees the atrial activity during most of the PVARP and counts it for mode-switch purposes, but does not track it with V pacing. However, the PVARP, whether initiated by a sensed or a paced QRS, contains a small interval called PVAB (post-ventricular atrial blanking), where the atrial channel does not even see any electrical

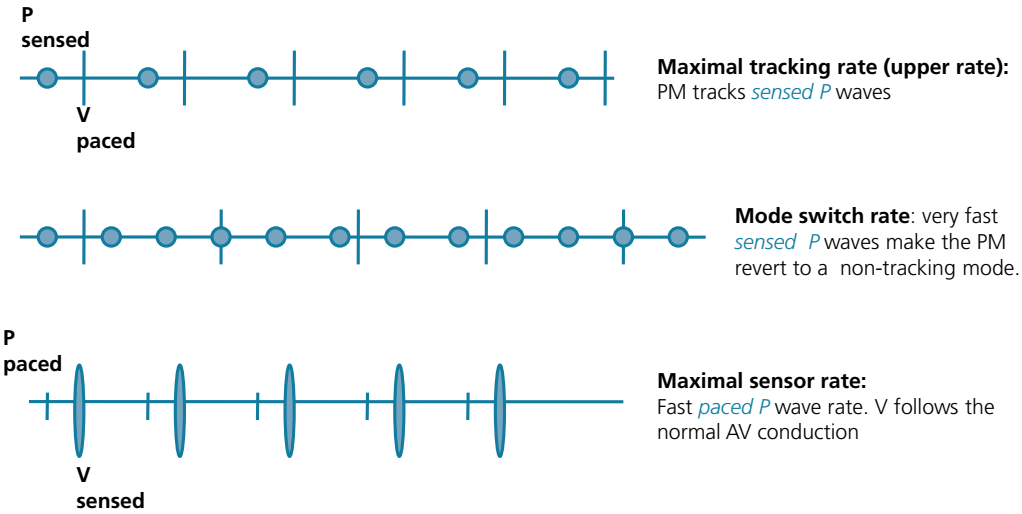

Figure 14.11 Difference between maximal tracking rate, mode-switch rate, and maximal sensor rate.

activity. In fact, in order to detect the small electrograms of atrial tachyarrhythmias, atrial sensitivity is programmed high, and may erroneously detect ventricular activity. PVAB prevents it from sensing ventricular activity and counting it as a P wave. PVAB and PVARP are initiated after both paced and intrinsic ventricular events (the atrial channel may sense the ventricular pacing spike but also the QRS ventricular complex, which is much louder than the atrial complex). Overcounting P waves, including those falling in a refractory period, leads to a harmful mode switch (to VVI).

F. Upper rate intervals (see Figure 14.11)

In a DDD pacemaker, the ***upper rate limit*** (or maximal tracking rate) designates the maximal ventricular pacing in response to an ***intrinsic/sensed atrial rate*** (e.g., tracking intrinsic sinus tachycardia in a patient with complete AV block).

The ***mode-switch rate*** is the maximal ***intrinsic/sensed*** atrial rate at which the pacemaker continues to track some of the atrial rate and pace the ventricle. Beyond the mode-switch rate, the pacemaker calls the atrial rhythm atrial tachyarrhythmia and reverts to a non-tracking mode (VVI-R). The mode-switch rate is higher, sometimes much higher, than the upper rate limit (e.g., the PM remains in DDD mode up to 170 bpm and continues to track some of the atrial waves, pacing the ventricle at the upper rate of 120 bpm).

In a DDD-R pacemaker, the ***upper sensor rate*** is the maximal ***paced*** atrial rate of a sensor-driven pacemaker. This is different from the maximal tracking rate, which refers to the tracking of intrinsic atrial activity.*

G. Magnet mode

Magnet mode is the pacemaker behavior when a magnet is applied over it. A magnet closes a reed switch in the generator and converts pacing to an asynchronous ventricular and/or dual pacing mode (VOO or DOO). This mode is useful as a means of breaking PMT (pacemaker-mediated tachycardia). Furthermore, the magnet rate is programmed in a way that indicates the status of the battery (e.g., a lower magnet rate indicates that the battery is close to end of life). A magnet is part of the modem used in pacemaker transtelephonic follow-up.

A magnet may be present in programmer heads, and this temporarily closes the reed switch, ending a PMT. However, after the programmer is turned on, the magnet effect is functional for only a short period of time.

In contrast to a PM, the application of a magnet on an ICD does not affect the pacing mode or the sensing function, i.e., the DDD pacing function of an ICD keeps its DDD pacing function. It does not affect arrhythmia detection either. It only inhibits antitachycardia therapy and shock.

IV. Leads (see Figure 14.12)

Leads detect electrical activity between 2 electrodes (anode and cathode) and deliver the output current between these 2 electrodes. A unipolar lead has one electrode at the distal tip, the metal of the can constituting the other electrode. The pacing current flows through a large circuit and may cause stimulation of the chest muscle and a large pacing spike on the ECG. Also, the sensing current is large and is prone to sensing myopotentials.

A bipolar lead has 2 electrodes on its distal end (ring and tip electrodes) creating a smaller sensing and pacing circuit. However, it has to contain 2 wires to conduct signals to and from both electrodes and needs to be slightly thicker. If the ring wire breaks, the lead converts to a unipolar mode.

A bipolar defibrillator lead contains 2 pacing electrodes and 1 or 2 defibrillator coils: 1 at the distal end (RV coil) ± 1 more proximal (SVC coil). After VT is sensed, the defibrillation circuit occurs between the can, which functions as an electrode, and the RV coil. Various configurations are possible (e.g., energy can be delivered between the can and the SVC coil as one pole, and the RV coil as second pole). Generator placement on the left side allows delivery of energy that is orthogonal to the heart and traverses it more effectively.

* The upper sensor rate of patients with preserved AV conduction may exceed the maximal tracking rate. In fact, in patients with preserved AV conduction, a high atrial sensor rate, higher than the tracking rate, will lead to a correspondingly high ventricular activity through the native AV conduction.

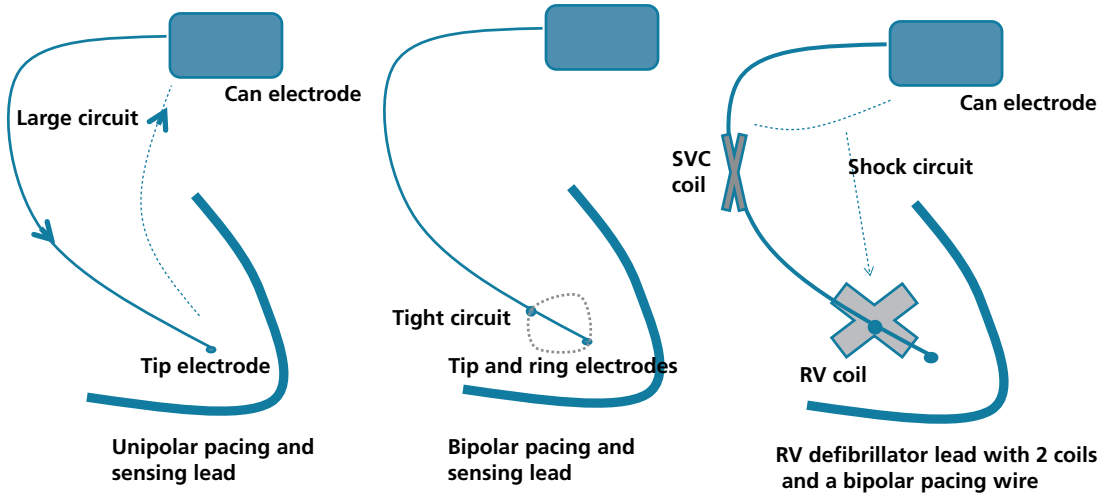

Figure 14.12 Various lead configurations for pacemakers (first 2 images) and ICD (third image).

The current that flows through the lead and is delivered to the myocardium depends on both the battery voltage delivered and the lead resistance/impedance. In fact: current (mA) = voltage/resistance. The battery voltage is typically 2.8 volts. The lead itself needs to have a high impedance to reduce the current that is being drained. The lead tip needs to have a low resistance to allow electrical flow to the myocardium. Note that the output voltage at the lead tip is derived from the battery voltage but is distinct from it and may be higher.

Upon new PM implantation, the voltage required at the lead tip (pacing threshold) rises over the first few weeks then goes down to a chronic baseline 8 weeks later. This is due to the initial inflammation at the lead tip and mandates programming of high pacing thresholds initially, followed by reprogramming 8 weeks later. A steroid-eluting lead prevents this phenomenon and allows chronically lower pacing thresholds.

Pacing leads are insulated, meaning they are covered with material that does not conduct electricity and prevents loss of current from the lead, allowing current to travel all the way to the myocardium.

V. Systematic PM/ICD interrogation using the programmer

A. Summary screen

Under summary/quick look/diagnostics (Figure 14.13), look at the following:

- Battery longevity: end of life (EOL) means the battery is depleted and can no longer consistently support PM functions. ERI (elective replacement indicator) means the battery voltage is reduced but will be able to support basic functions for up to 3 months.
- Pacing mode and percentage of ventricular pacing. The latter should be as limited as possible in patients without complete, chronic AV block. Conversely, ventricular pacing should be close to 100% in patients with a CRT device.
- Episodes of high atrial rate and episodes of automatic mode switch, indicative of atrial tachyarrhythmias. These may dictate rate-control therapies. Also, atrial tachyarrhythmias lasting >6 minutes have been associated with an increased risk of stroke. Frequent or prolonged periods of high atrial rate >120–140 bpm may be indicative of atrial tachyarrhythmias, sometimes below the mode-switch rate. A high atrial rate beyond a certain point (e.g., 140 bpm) should be programmed as a trigger for electrogram (EGM) recording. The EGMs of these atrial activities should be reviewed. The sudden onset and steady rate distinguish atrial arrhythmia from sinus tachycardia. If atrial arrhythmia is confirmed, the mode-switch rate may need to be reduced.
- Episodes of high ventricular rates (whether in the monitoring or treatment zone).
- Review stored EGMs, if any (arrhythmias).
- Check the programmed parameters:
  - Lower rate interval and AV delay. AV delay should be programmed long enough to promote intrinsic AV conduction.
  - PVARP.
  - Maximal tracking rate and mode-switch rate of sensed P waves.
  - Sensor-driven paced P-wave rate, and sensor-driven rate histogram. If a sedentary patient is having frequent sensor-driven rates, the rate-adaptive slope and the maximal rate may need to be reduced. The opposite may be necessary in a young active patient.

B. Lead impedance

Check impedances and impedance trends of A and V leads. Any significant change (>200 ohms) in lead impedance can indicate lead failure.

C. Capture testing

- *Test A capture in a DDD pacemaker*: in a patient with sinus rhythm, increase the atrial rate beyond the patient's intrinsic sinus rate. A high pacing output (in volts) is initially selected then reduced in small decrements until atrial capture is lost. The lowest value before loss of capture is the capture threshold.
  Testing is performed in DDD mode. In patients with intrinsic V activation, the loss of atrial capture is seen as a loss of ventricular sensed events; make sure the AV delay is long enough to allow intrinsic V activation for this test (if possible).
- *Test V capture in DDD pacemaker*: increase the atrial rate and set a short AV delay to ensure ventricular pacing during this test. Alternatively, testing may be performed in VVI mode. Gradual step-down of ventricular output is performed until V capture is lost.

Click here to go to "Quick look," i.e., the current screen

Click here to look at programmed parameters (e.g., type of pacing, AV delay, mode switch rate)

Click here to test capture and sensing

Figure 14.13 Example of a "quick look" or "summary" screen of pacemaker/ICD interrogation.

On the right, the 3 most important icons are indicated (data, parameters, and tests).

On top of the screen, 3 types of live recordings are shown: (1) surface ECG (uppermost recording), (2) intracardiac electrograms (EGM), which capture the actual signals occurring in each cardiac chamber (in this case, ventricular EGM is shown), and (3) marker representation, which indicates how the pacemaker sees and interprets these signals. AS and VS are sensed intrinsic atrial and ventricular activities, while AP and VP are paced atrial and ventricular activities. The pacemaker may interpret a signal as VS on the marker channel, while in fact it is a T wave oversensing, false signal, or far-field atrial sensing. ***Looking at the EGMs allows one to understand what the issue is; looking at the markers allows one to see how the pacemaker interprets or misinterprets signals***.

At the bottom left, capture thresholds, impedance, and the sensed amplitudes of A and V are shown.

- The output energy is determined by the *output voltage* as well as the *pulse duration*. Increasing the pulse duration increases the output; beyond 0.3 ms, increasing the pulse duration does not affect the output by much. Testing may be performed by varying the voltage at a constant pulse duration of 0.3–0.5 ms. The programmed output should be double the pacing threshold. Typically, the pacing thresholds for A and V are <2.5 volts at 0.5 ms, particularly with steroid-eluting leads.
- In temporary PMs, one typically programs the output in terms of generator current (milliamperes) rather than voltage. The temporary PM is usually a VVI PM, so testing is similar to the capture testing in VVI PM: increase the pacing rate and start pacing at a high output with small decrements until V capture is lost.

D. Sensing assessment

Sensitivity is the programmed wall below which the PM cannot detect electrical activity. The higher the wall is in millivolts, the less sensitive the PM is, and the more likely it is to dismiss noise but also, on occasions, native complexes. To test sensing of the V channel, set the PM in VVI mode and reduce the pacing rate below the patient's intrinsic rate (if the patient has a tolerable intrinsic rate). Start at a low millivolt sensitivity then slowly increase until the PM stops sensing intrinsic activity and starts pacing at the low set rate. Sensitivity should be set below that value. *Note that testing for sensing involves maneuvers opposite to those used in testing for capture (low rate and starting with the lowest setting)*.

In addition, current PMs measure the *sensed amplitude* of the intrinsic A and V activities. The sensed RV amplitude is typically >5 mV, while the sensed A amplitude is typically >2 mV. The sensitivity should be a half or a third this value. A very low sensitivity may detect myopotential noise or oversense T wave.

VI. Pacemaker troubleshooting

A. Undersensing or failure to sense

Ventricular undersensing is a situation in which the pacemaker does not see intrinsic QRS and thus does not get inhibited by it. This leads to overpacing, with pacing spikes occurring regularly, including early after intrinsic QRS complexes and unrelated to them.

Causes of undersensing:

- Lead damage: lead fracture, insulation break, or loose connection of the lead to the generator (loose set screw, mainly seen early after PM implantation).
- Inappropriate programming (low sensitivity).
- Undersensing of a PVC is possible and is not considered abnormal, especially when the PVC occurs shortly after QRS, within the ventricular refractory period. PVC may not reset the atrial escape interval, and the next P wave may fall close to the PVC.

- Undersensing of atrial activity may be seen in AF, where many of the small-amplitude atrial waves are not sensed by the device. This precludes mode switching and allows tracking of the waves that are sensed, an inappropriately fast tracking. This is treated by increasing the atrial sensitivity if AF is paroxysmal, or reprogramming the PM to a VVI mode if AF is permanent.

  Undersensing may also be seen in atrial flutter, where every other P wave falls in the blanking portion of PVARP and is not sensed. This precludes mode switching and allows tracking of the sensed P waves (e.g., atrial rate of 280 bpm, every other P is sensed and tracked at a fast rate of 140 bpm). It is treated by shortening the blanking period.

B. Oversensing

Ventricular oversensing is a situation in which the pacemaker senses electrical activity that is not QRS and considers it V, therefore inhibiting the ventricular output. It does not pace the ventricle when it should. This leads to underpacing and a paucity of pacer spikes.

Causes of oversensing:

- Lead fracture or insulation break creating false signals.
- Inappropriate programming.
- The ventricular lead senses from a distance the atrial spike and considers it a ventricular event (far-field crosstalk). This is reduced by creating a post-atrial ventricular blanking period.
- Oversensing of a tall T wave and considering it QRS.
- Oversensing of myopotentials (diaphragmatic contractions, especially with unipolar leads) and electromagnetic interference.

Undersensing leads to overpacing, and oversensing leads to underpacing.

C. Failure to capture

In this case, the pacer spike occurs appropriately but is not followed by any paced activity (a paced QRS is not seen).

Causes of failure to capture:

- Lead fracture or insulation break.
- Inappropriate programming.
- Battery depletion.
- An increase in capture threshold due to drugs (class Ic overdose), MI, hyperkalemia, hypoxia, acidosis.
- Atrial failure to capture may be due to unsuspected AF. Many of the fibrillatory waves are unseen/undersensed by the PM, which leads to undersensing and pacing over AF without capture.
- Failure to capture may also occur in case of undersensing a premature complex, with subsequent pacing very close to it, in the refractory phase. The latter case may occur normally (functional non-capture).

D. Manifestations of lead fracture and insulation defect

Lead fracture can cause undersensing and loss of capture, but also oversensing when both fractured ends abut each other, creating signals (false signals or "make-break artifacts").

The insulation material protects and conceals signals within the lead. An insulation break results in loss of current along the lead path and, consequently, loss of capture. This break also results in loss of sensed signals and, consequently, undersensing. Oversensing may also be seen, as signals coming from the surrounding structures easily penetrate the unshielded lead (Figure 14.14).

Oversensing, by itself, can lead to undersensing. For example, oversensing false signals puts the respective channel in a refractory period, during which an intrinsic complex may occur and be missed. ***A pattern of oversensing, undersensing, and intermittent loss of capture may occur with lead problems and progress to a chaotic pattern of pauses and overpacing***.

Lead fracture or insulation break is suspected from analysis of the lead impedance (a recent ↑ >200 ohms in case of fracture or ↓ >200 ohms in case of insulation break). Lead or insulation breaks may be intermittent, and may be associated with a normal impedance, sensing, and

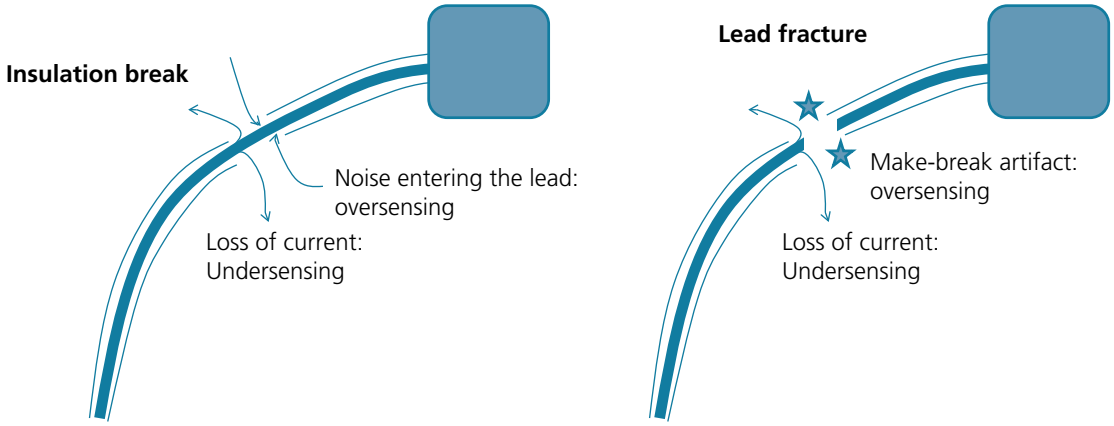

Figure 14.14 Insulation break and lead fracture.

capture at the time of interrogation. If an intermittent break is suspected, review stored EGMs looking for oversensed false signals, or perform Holter monitoring if the EGMs are unrevealing (PM may not store EGMs as it does not recognize that there is a problem). Also, perform maneuvers: move the generator in its pocket, move the ipsilateral arm (up and behind the back), perform a pulling maneuver with the ipsilateral arm, and assess capture during deep inspiration and after cough. CXR should be performed, but it does not always detect a lead fracture.

Some causes of lead problems: subclavian crush syndrome (the lead is crushed against the clavicle as it passes through the subclavian vein), twiddler syndrome (the lead twists on itself if the pocket is loose, especially in old patients), loose connector screws.

E. Absence of a pacemaker spike (or spikes) when there should be one

This is caused by oversensing, failure to capture with small overlooked pacer spikes, or total battery failure. Differentiate by magnet application, which solves oversensing but not the other two issues.

F. Pacemaker syndrome

This syndrome is seen in 10–20% of patients with VVI pacemakers. It results from the lack of atrial contribution to cardiac output *and/or* from atrial contraction against closed AV valves. It may also be seen in patients with P-synchronous DDD pacing if the AV delay is very long, such that P wave abuts the preceding QRS, particularly during exercise. Also, a long AV delay facilitates retrograde VA conduction: a long AV delay gives enough time for the atria to recover from their refractory period by the time the ventricular activity occurs. Retrograde P waves lead to atrial contraction against closed AV valves with a subsequent increase in atrial pressure and a reduction in cardiac output, i.e., pacemaker syndrome. While PVARP prevents retrograde P waves from inducing PMT, retrograde P waves remain harmful by inducing a pacemaker syndrome.

G. Pacemaker-mediated tachycardia (PMT) (see Figure 14.15)

PMT is a complication of DDD pacing. After a paced QRS or a PVC, retrograde atrial activation (VA conduction) may occur if the atria are not in their refractory period. Many (but not all) patients are capable of retrograde VA conduction; this is more likely in patients with intact AV conduction (PM placed for sinus node disease), but may interestingly be seen in those with complete AV block. The retrograde P wave may be tracked by the ventricular channel, leading to a short R–R interval close to the upper tracking rate of the pacemaker (usually 110–130 paced beats per minute). This cycle continues, leading to PMT.

In order for retrograde atrial activation to occur, the preceding atrial activity must be far (no atrial refractory period). *In order to be seen and tracked by the pacemaker, the retrograde P wave must also fall beyond the PVARP*. In *patients whose baseline atrial activity is paced*, PMT may be triggered by: (a) a PVC, wherein the atrium gets enough time to recover from its refractory period; (b) a preceding atrial non-capture, wherein the atrium does not get depolarized and thus is easy to stimulate retrogradely; (c) atrial undersensing with subsequent atrial overpacing and functional non-capture; (d) atrial oversensing of far-field QRS with initiation of AV delay without any atrial activity (Figure 14.15). *Whether baseline atrial activity is intrinsic or paced*, a PMT may be triggered by a PAC that is tracked at the upper rate limit with an extended AV delay. Whether atrial activity is intrinsic or paced, a very long AV interval may propitiate VA conduction by giving the atria time to recover from their refractory period.

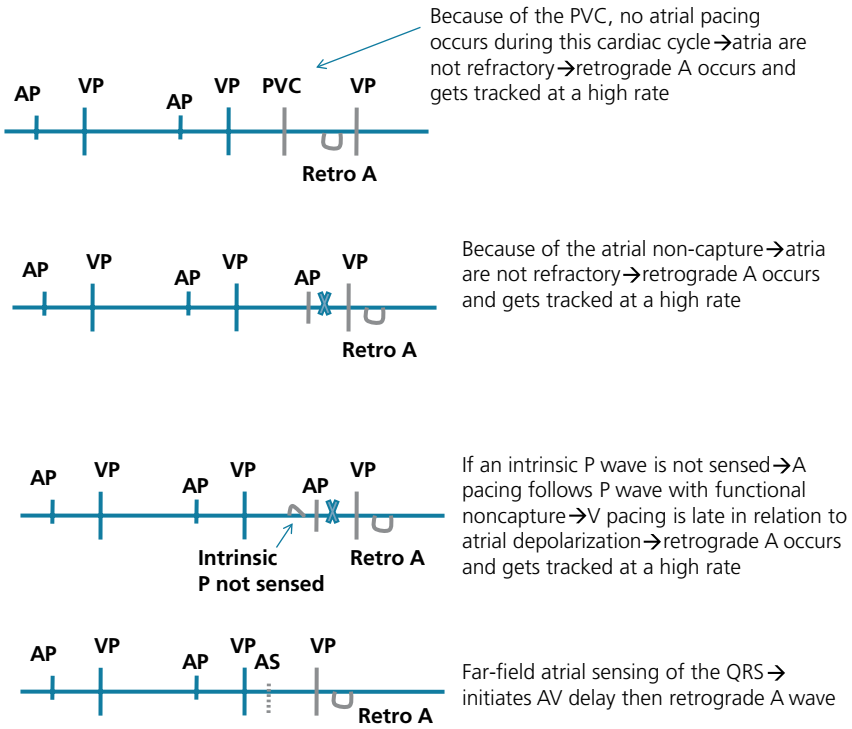

Figure 14.15 Triggers and mechanisms of PMT.

PMT is prevented by prolonging the PVARP (e.g., 300 ms) and further automatic prolongation of PVARP after a PVC. PVARP may be made dynamic: it prolongs after a PVC but shortens with tachycardia to allow upper rate behavior. When the ventricle is paced at a rate close to the upper rate, the differential diagnosis includes PMT or tracking of atrial tachycardia; in this case, a "PMT algorithm" allows the pacemaker to omit ventricular pacing once so that PMT, if present, will break. Acutely, a magnet inhibits any sensing, including P sensing, and stops PMT. Programming the PM to a non-tracking mode, such as AAI, VVI or DDI, also terminates PMT.

H. Differential diagnosis of a tachycardia occurring in a patient who has a DDD PM

- PMT, where the pacemaker tracks retrograde P waves.
- Atrial arrhythmia is getting tracked by the pacemaker for 1 of the following reasons:
  - The atrial rate is slower than the mode-switch rate.
  - The arrhythmia is atrial flutter with sensing and tracking of every other flutter wave, or AF with sensing of many, but not all, of the atrial waves; this alternate sensing prevents sensing the high rate and mode switching. Pacemakers usually allow for a refractory sense during PVARP, except when some of the AF or flutter waves fall in the blanking portion of PVARP.
  - AF waves and some atrial tachycardia waves have a small amplitude and may, consequently, fall below the programmed atrial sensitivity wall; therefore, many of them are not sensed by the device and do not trigger a mode switch.

    In all of these cases, P waves are getting tracked by the pacemaker. Differentiate from PMT by pacemaker interrogation and by placing a magnet. The P waves persist in the case of atrial arrhythmia, whereas the rhythm goes back to sinus in the case of PMT.

    The inappropriate P-wave tracking is treated by reducing the rate at which mode switch occurs, by increasing atrial sensitivity, or by reducing the PVAB so that alternate atrial waves do not fall in the blanking period.
- Oversensing myopotentials and tracking them.
- Any VT or SVT/AF that is being spontaneously conducted, independently of the pacemaker. In contrast to the above 3 diagnoses, the ventricular activity is intrinsic rather than paced (no V pacing spike).

PM and ICD magnet effect

Placing a magnet over a PM (including BiV PM without ICD) makes it lose its sensing functions. It switches to a VOO or DOO mode – that is, ventricular ± atrial asynchronous pacing at a particular magnet rate, with no sensing and no tracking of intrinsic activity. This can stop tracking retrograde P waves and PMT. The same magnet effect occurs in the first few seconds after placement of some programmer heads over the PM.

The magnet rate correlates with the battery life; the transtelephonic checkup assesses the PM response to magnet placement and the magnet rate.

A magnet over an ICD, including BiV-ICD, eliminates its antitachycardia and defibrillation function, but does not affect its pacing/sensing function (a DDD function remains DDD). Therefore, it does not stop PMT. It must be actively programmed to DOO perioperatively in cases of BiV or PM dependency.

I. Fusion and pseudofusion

A pacemaker spike may be seen within a QRS that is intrinsically conducted through the AV node, or just before or after it. A pacer spike may also be seen just before, just after, or within a PVC. This does not imply ventricular undersensing, as it takes time for the V channel to sense the intrinsic V activity. A ventricular pacing spike falling just before the intrinsic complex may lead to a fusion beat, i.e., fusion between the pacing complex and the intrinsic complex. A ventricular pacing spike falling too close to the intrinsic complex may not lead to any conduction of pacer activity, a phenomenon called pseudofusion. In this case, the lack of capture is called functional non-capture (Figures 14.16, 14.17).

On the other hand, in a patient receiving both atrial and ventricular pacing, a PVC may fall over the atrial spike. The ventricular activity will be perceived as a ventricular activity occurring within the early period after atrial pacing and will trigger ventricular safety pacing. Thus,

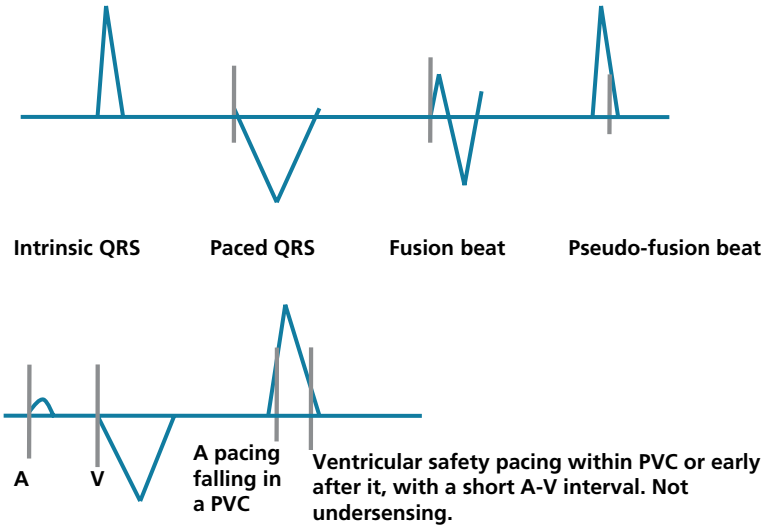

Figure 14.16 Fusion, pseudofusion, and ventricular safety pacing.

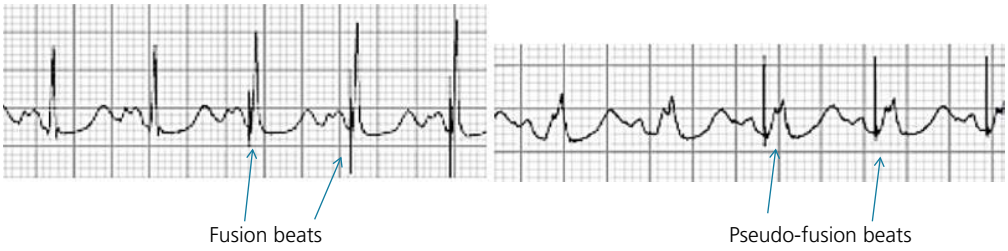

Figure 14.17 In fusion beats, the native conduction reaches the ventricle around the same time as the expected pacemaker spike, leading to a fusion between the native and paced QRS complex. In pseudofusion, the QRS seen is purely the result of the native conduction, the pacemaker spike does not result in any ventricular stimulation; the resulting QRS is similar in morphology to the intrinsic QRS.

in addition to the A pacing spike, a V pacing spike is seen within the QRS or ST–T at a very short AV delay (Figure 14.16). The ventricular safety pacing should not be perceived as undersensing.

A PVC that falls too close to the intrinsic or paced ventricular complex, within the ventricular refractory period, may not be sensed and thus may not reset the atrial escape interval.

J. Diaphragmatic stimulation

Diaphragmatic stimulation may occur when the atrial lead is laterally placed in the RA, which stimulates the right phrenic nerve. It may also occur with a coronary sinus lead that stimulates the left phrenic nerve (BiV PM). Left diaphragmatic stimulation may also be seen with the RV lead, but more so if it perforates into the LV. That is why perforation must be excluded whenever diaphragmatic pacing is observed.

Diaphragmatic stimulation may occur late after device placement, in which case it is usually related to an insulation break with loss of current into the surrounding muscles (diaphragm, deltopectoral muscles). Deltopectoral muscle stimulation is due either to the use of unipolar leads or to insulation break.

VII. Perioperative management of PM and ICD (during any surgery)

Electrocautery may lead to oversensing of electrical noise and inhibition of the PM output. Oversensing may also result in ICD shock.

Other possible complications: PM resets to a VOO mode, i.e., noise reversion mode; permanent damage to the pulse generator; or myocardial thermal injury at the lead tip, changing the sensing and pacing thresholds.

Preoperatively, cardiac rhythm devices are managed as follows:

1. PM: for pacer-dependent patients, as evidenced by the baseline ECG and by the device interrogation, program the PM to VOO or DOO mode preoperatively (asynchronous uninhibited pacing) or place a magnet over it.
2. ICD, including CRT-ICD: placing a magnet will inhibit the antitachycardia therapies, but will not lead to asynchronous pacing. Thus, if the patient has an ICD and is CRT- or pacer-dependent, a magnet is not enough. The pacing function is programmed preoperatively to VOO or DOO, and the VT therapies are turned off.

Either way, postoperatively, the PM or ICD needs to be interrogated to assess sensing and capture thresholds, to ensure there is no "phantom" reprogramming of the device (noise reversion mode), and to turn the ICD therapies on.

For external cardioversion or defibrillation in a patient who has a PM, place the paddles in the anteroposterior position and at least 4 inches (10 cm) away from the pulse generator (right parasternal, left paraspinal). The anteroposterior position ensures that the shock vector is not coaxial with the leads. Interrogate the PM after the procedure.

VIII. Differential diagnosis and management of the patient who presents with ICD shock(s)

The differential diagnosis of an ICD shock includes:
1. Appropriate shock for VT/VF: clinically, the patient often feels palpitations, malaise, or dizziness before the shock occurs. In the case of sudden and repeated episodes of VT (VT storm), look for triggers: active ischemia, decompensated HF, electrolyte imbalance, TdP (long QT due to drugs). In a patient with chronic cardiomyopathy, sudden back-to-back episodes of VT/VF may not have any particular trigger.

Manage the triggers, and, if necessary, place the patient on amiodarone + β-blocker, or sotalol.
2. Inappropriate shock for a supraventricular arrhythmia: the ICD considers any tachycardia above a certain programmed rate (e.g., 170 bpm) as VT and treats it as such, with antitachycardia overdrive pacing initially, then a shock if it persists. This may occur with AF, atrial flutter, AVNRT/AVRT, or sinus tachycardia during strenuous activity (clue to the latter: shock during strenuous activity).

The ICD may use SVT–VT discrimination algorithms to withhold on treating SVT.
3. Inappropriate shock due to oversensing:
- **a.** Oversensing T wave.
- **b.** Far-field sensing of the atrial spike.
- **c.** Myopotentials: oversensing myopotentials may be reproduced by asking the patient to exercise (move arms across shoulder, compress hands together).
- **d.** Electromagnetic interference (e.g., welding).
- **e.** Lead fracture or insulation break may also lead to oversensing of false signals (shock during repetitive shoulder movements). Hints: lead impedance changes with time, sometimes intermittently; interrogation shows extra spikes on the ventricular channel, particularly when performed during deep inspiration or during arm or can movement. Also, the situation in which the shock occurs helps with the diagnosis of lead issues, myopotentials, and electromagnetic interference.

4. In the MADIT II and SCD-HeFT trials, ~33% of patients experienced a shock by 2 years of therapy. A third of shocks were inappropriate (AF 44%, SVT 36%, oversensing 20%). In both those trials, the occurrence of any shock, appropriate or inappropriate, was associated with

a 2- to 4-fold increase in mortality from progressive HF.[15,16] A shock, whether appropriate (VT) or inappropriate (AF, SVT), implies a more severe underlying HF and thus a higher mortality by association. However, shock or even ATP may be directly harmful. In fact, the MADIT-RIT trial suggests that reducing VT therapies, whether ATP or shock, through alternative programming reduces mortality by 55%, which implies a direct role of unnecessary ICD therapies, including ATP, in speeding death.[17] Even what is considered appropriate therapy for VT is not always clinically appropriate, as many of these VTs are not sustained and spontaneously convert. An example of alternative programming used in MADIT-RIT consists of a higher rate requirement of at least 200 bpm for initiation of therapy, and a longer delay to therapy (e.g., 12 seconds or 40 beats in the VT zone 200–250 bpm, and 2.5 seconds in the VF zone ≥250 bpm). This restrictive strategy is used in primary prevention and may not apply to secondary prevention, where a lower threshold for intervention is applied, guided by the rate of prior VTs.

5. Management. An ED visit is usually required after an ICD shock, especially if the clinical status changes or multiple shocks occur. Interrogate the device to distinguish between situations 1, 2, and 3 above.[18] Look for triggers, assess HF status, and perform ECG and chest X-ray. In the absence of a reversible cause, institute an antiarrhythmic agent. Because amiodarone may increase the defibrillation threshold and VF detection threshold, the ICD defibrillation threshold may need to be retested after amiodarone institution. Also, amiodarone may slow VT below the detection zone; thus, a new, lower-limit VT monitoring zone should be instituted to see if this phenomenon happens.

In case of SVT, make sure SVT–VT discrimination algorithms are on (only applies to VT zone, not VF zone) and consider using a higher rate threshold for the institution of VT therapies. SVT may be treated with antiarrhythmic drugs.

IX. Evidence and guidelines supporting various pacing devices

A. DDD or AAI vs. VVI pacing

The Danish randomized trial of patients with sick sinus syndrome has shown that VVI pacing increases mortality (~1.5 times) in comparison to AAI pacing, and doubles the risk of AF and stroke. This is due to the deleterious effect of unnecessary ventricular pacing in a patient with sinus node disease.[19]

Other trials that enrolled an exclusive (UKPACE) or predominant AV nodal disease population (CTOPP) have overall shown that DDD vs. VVI pacing reduces the incidence of AF and improves quality of life, through preservation of AV synchrony and LA pressure, without affecting mortality.[20,21]

The MOST trial of DDD vs. VVI pacing has shown that regardless of the type of pacemaker used, ventricular pacing >40% of the time increased the risk of AF and HF. A similar result was obtained when AV sequential pacing at 70 bpm was compared with standby ventricular pacing in ICD patients in the DAVID trial (>40% V pacing worsens outcomes) and in a MADIT II analysis (>50% V pacing worsens outcomes).[2,3] Overall, V pacing >40% of the time vs. <40% is associated with a 3–4.5 times higher risk of HF hospitalization. However, while the highest risk is associated with >40% ventricular pacing, there is a linear and continuous increase in risk between 0% and 40% of ventricular pacing in the DAVID trial, and even more so in the MOST trial. The BUDAPEST-CRT trial and 2022 ESC pacing guidelines suggest the use of **20% cutoff for harmful RV pacing**.

The main lesson learned from these trials is that it is most important to reduce ventricular pacing. If ventricular pacing is necessary (AV block), the main advantage of DDD over VVI pacing is better symptom control and a reduction of AF incidence. Therefore, DDD pacing is recommended for patients with AV nodal disease, except if permanent AF is present. Minimal ventricular pacing should be ensured; for example, program the AV interval as long as 250 ms after a sensed P wave to promote intrinsic ventricular activation.[22] PR may be programmed long but rate-adaptive, wherein it is allowed to shorten when the atrial rate increases, to reduce potential symptoms from a long PR interval and improve upper rate behavior. *Limiting RV pacing should not come at the expense of excessive PR prolongation >250–300 ms*, as this may cause AV dyssynchrony and altered hemodynamics.

Single lead VVI remains the PM of choice in (i) permanent AF, and it is an acceptable therapy for: (ii) elderly sedentary patients or those with multiple comorbidities; or (iii) when pacing is only occasionally required, as in paroxysmal AV block.

Owing to the progressive risk of AV nodal disease over time, a DDD pacemaker is preferred over AAI pacemaker in patients with sinus node disease, with a long AV interval programmed (class I recommendation).

B. Mechanism of action of biventricular pacing (cardiac resynchronization therapy), evidence supporting its use, and clinical subsets

Patients with LBBB, particularly >150 ms, have mechanical dyssynchrony, wherein the right and left ventricles and various left ventricular walls contract at different times. Depolarization and contraction of the LV free wall and LV base is significantly delayed compared to that of the RV, the interventricular septum, and the apex (inter- and intraventricular dyssynchrony) (Figure 14.18).[23] This leads to inefficient LV contraction, as one wall contracts while the other is stretched in the opposite direction, which increases LV systolic volume and reduces stroke volume. LV further dilates with time as a result of reduced LV ejection. Moreover, the overall systolic time is ineffectively increased, which reduces the time provided for LV diastolic filling and thus increases LA pressure; dyssynchrony is thus detrimental to the diastolic function as well.

Dyssynchronous papillary muscle contraction and functional MR also occur with LBBB. If the posteromedial LV wall contracts before the anterolateral LV wall, the posterior leaflet is pushed up before the anterior leaflet, which precipitates or exaggerates leaflet non-coaptation; also, the posteromedial muscle relaxes while the anterolateral muscle is still contracting, which sustains leaflet non-coaptation.

Several trials, particularly MIRACLE, have shown that CRT improves symptoms and quality of life, reverses remodeling, reduces functional MR, and improves EF by ~5–7% in patients with EF ≤35%, QRS ≥130 ms, and functional class III or ambulatory class IV.[24] Two trials have established a benefit of CRT on hard outcomes in this population (COMPANION and CARE-HF).[25,26] In the COMPANION trial, CRT vs. no CRT was associated with a 34% reduction in HF hospitalization or HF death and a trend toward a 25% reduction in mortality; the combination of CRT and ICD was associated with the greatest reduction in mortality.[25] In the CARE-HF trial, CRT vs. no CRT was associated with a 36% relative reduction in mortality (20% vs. 30% mortality at 2.5 years). Note that COMPANION and CARE-HF only included a small proportion of class IV patients (<15%). Patients with refractory class IV HF who cannot tolerate chronic HF drugs or who have refractory volume overload are usually not good candidates for CRT, as CRT is generally not a good last-resort therapy. Yet, some data indicate that the latter patients with wide QRS >150 ms may derive a dramatic benefit from CRT.

Two trials addressed the use of CRT in patients with EF ≤35%, QRS ≥130 ms, and functional class II (MADIT-CRT and RAFT).[27,28] In the MADIT-CRT trial, CRT-ICD vs. ICD was associated with a reduction of HF hospitalizations and reverse remodeling in patients with low EF

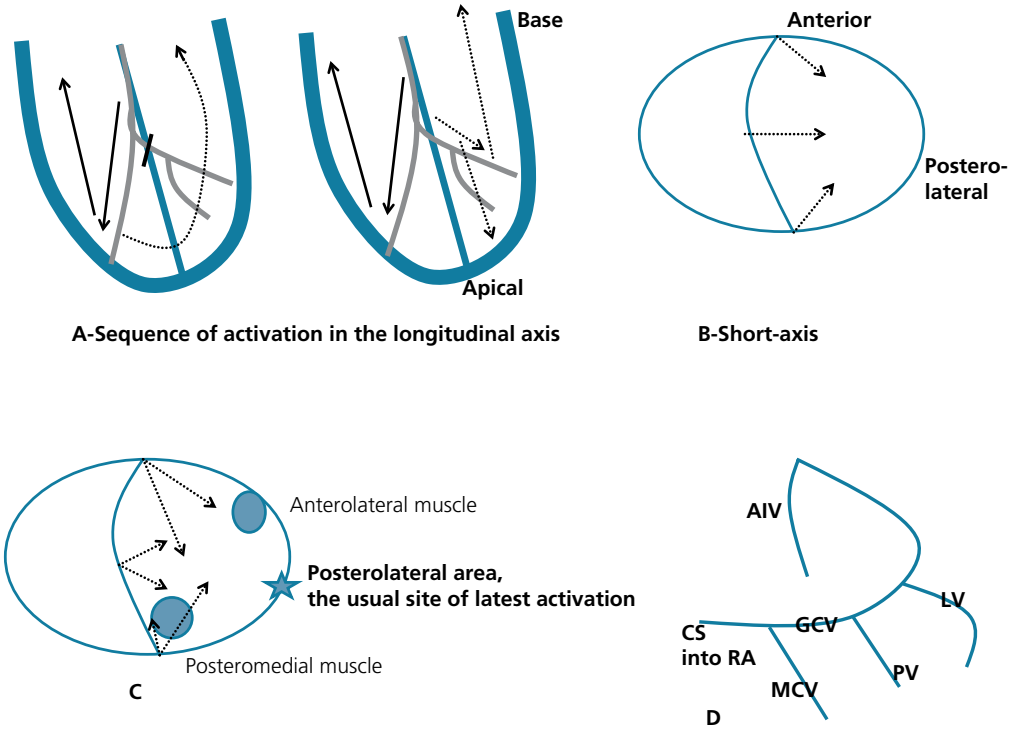

Figure 14.18 Various patterns of LV activation in LBBB. *Black arrows* indicate the spread of electrical activation across the conduction system, *dashed arrows* indicate the spread of activation across the LV.

(A) In most LBBB patterns, on the longitudinal axis, the LV is slowly depolarized from mid-level or apex to base. This is also the case in RV apical pacing, including RV pacing that is performed as part of BiV pacing.

(B) In LBBB, on the short-axis view, the LV is depolarized from the septum to the lateral wall. The depolarization starts at the anterior, mid, or posterior septum, and spreads toward the anterior wall and then the lateral wall. Combining both longitudinal and short-axis views, the *posterolateral basal* site is seen as the site of latest activation, but any *basal* site, including *anterior basal*, is relatively late.

(C) The pattern of activation of the papillary muscles is shown on a short-axis view. The posteromedial papillary muscle is activated sooner than the anterolateral papillary muscle; this is less prominent in the case of a more anterior trans-septal breakthrough of activation.

(D) Coronary venous anatomy. The lead should be placed in the posterior vein (PV) or, best, the lateral marginal vein (LV). The middle cardiac vein (MCV) runs adjacent to the PDA, and the anterior interventricular vein (AIV) runs parallel to the LAD. The lead should not be placed in those veins. Before reaching the RA, the coronary sinus (CS) is called the great cardiac vein (GCV).

and functional class I or II, but no reduction in mortality. In the RAFT trial, CRT-ICD vs. ICD was associated with a reduction in mortality of ~1.5% per year in patients with class II or III (80% of patients had class II). While the relative reduction in mortality may be similar in class II as in class III or IV, the absolute reduction is inherently lower in the lower-risk class II patients.

Besides the functional class, 2 other factors hamper the benefit from CRT in HF patients: QRS duration of <150 ms, and QRS prolongation from RBBB or non-specific delay as opposed to LBBB.

(a) QRS < 130 ms and QRS 130–150 ms

CRT in HF patients who have echocardiographic signs of dyssynchrony but a QRS <130 ms has not shown any clinical benefit, with a potential for harm (RethinQ and EchoCRT trials).[29] QRS prolongation >150 ms implies electrical and often mechanical dyssynchrony, hence the benefit of CRT in these patients. While it was thought at one point that QRS <130 ms might be associated with mechanical dyssynchrony that can be detected by echocardiography and reversed with CRT, hard outcome data did not support the use of CRT in this population. In fact, LV wall motion heterogeneities in these patients may be related to akinesia rather than dyssynchronous, delayed contraction. Akinesia is not a marker for CRT response; echocardiographic methods differ in their ability to discriminate truly delayed contraction from abnormal contraction.

Only 30–40% of patients with QRS 130–150 ms are responders to CRT. On subgroup analyses of three of the above trials (COMPANION, MADIT-CRT, and RAFT), the benefit from CRT was seen only in patients with QRS >150 ms; no benefit was seen in patients with QRS 130–150 ms.[30] The use of echocardiographic parameters of dyssynchrony may be most useful in selecting the subgroup of patients with QRS of 130–150 ms in whom electrical dyssynchrony implies mechanical dyssynchrony. In fact, in the CARE-HF trial, 2 out of 3 echocardiographic parameters of dyssynchrony were required to qualify for CRT in patients with QRS <150 ms. CARE-HF is the only major trial where this subgroup of patients had a strong trend toward clinical benefit.

Guidelines: As a result of this, CRT implantation is given a class I indication in patients with sinus rhythm, EF ≤35%, QRS ≥150 ms, LBBB morphology, and functional class II, III, or ambulatory IV. On the other hand, QRS 130–150 ms with LBBB morphology and functional class II–IV or QRS >150 ms with non-LBBB morphology is given a class IIa recommendation.[31] Before CRT implantation, it is recommended to provide maximal medical therapy and wait >40 days after MI, >3 months after revascularization of chronic ischemia, and >3 months in non-ischemic cardiomyopathy (similar to the waiting times before ICD placement).

(b) RBBB and non-specific intraventricular conduction delay

About 70% of HF patients with QRS >120 ms have LBBB; the remaining patients have RBBB or non-specific delay. While it seems, intuitively, that RBBB is not associated with left-sided mechanical dyssynchrony and that the use of CRT in patients with right bundle delay would not improve outcomes, RBBB in patients with HF actually means generalized conduction and electromechanical delay rather than discrete right bundle delay. Patients with RBBB may have delayed conduction in the left bundle as well, the ECG showing RBBB because of a longer right bundle delay: this is called **masked LBBB** and is characterized by a wide RBBB >150 ms with a broad, slurred, sometimes notched R in I and aVL (ESC 2021, pacing guidelines).

Therefore, non-LBBB patterns were included in all major trials. However, subgroup analyses of COMPANION, MADIT-CRT, and RAFT, as well as a large meta-analysis, have shown that a non-LBBB pattern does not derive a benefit from CRT.[32–35] A more recent meta-analysis further corroborated that RBBB (even >150 ms) does not benefit from CRT, but non-specific intraventricular conduction delay >150 ms derives a benefit similar to LBBB.[34,35] RBBB, per se, is associated with a higher risk of mortality than LBBB in HF registries and in the CARE-HF study, partly because the prognosis cannot be improved with CRT.[33,36] Thus, CRT is reasonable for functional class III/IV with QRS >150 ms and either non-specific conduction delay or possibly RBBB, in light of the pathophysiology described above and some clinical evidence (class IIa recommendation).[37] CRT is less reasonable for non-LBBB pattern with QRS 130–150 ms (class IIb recommendation). Echocardiographic assessment of left-sided activation delays and dyssynchrony may help fine-tune the CRT indication in these patients.

(c) Atrial fibrillation

i. ***CRT for HF purposes***. CRT is recommended in AF patients with HF, a low EF, and a wide QRS, similarly to patients in sinus rhythm (class IIa), as long as the rate is controlled enough to allow 100% ventricular pacing. AV nodal ablation is typically performed concomitantly, as 2/3 of patients do not achieve >90% BiV pacing without it; also, regularizing the rate improves HF outcomes.

ii. ***CRT for AF purposes***. If AV nodal ablation and pacing are performed to control the AF rate in a patient with EF ≤50%, CRT or LBB-AP is preferred to RV pacing as it prevents pacing-induced dyssynchrony and is given a class IIa recommendation, regardless of the functional class. One may, however, choose RV pacing early on, followed by CRT at a later time if EF does not simply improve with AV nodal ablation.

(d) Paced ventricular rhythm

Similarly to LBBB, RV pacing induces inter- and intraventricular mechanical dyssynchrony, which may worsen LVEF and increase LV volume. Even in patients with normal EF, RV pacing is associated with an ~7% reduction in EF vs. CRT; ~9% of patients with normal EF have EF reduction to <45% within 1 year of RV pacing.[38] Other data suggest that the incidence of RV pacing–induced cardiomyopathy, defined as EF decline ≥10% or to <50% if previously normal, is 12–20% after 1–15 years.[5] This applies to patients who are frequently RV paced, i.e., >20–40% of the time, and the effect is only expected to be more prominent in patients with reduced EF.

CRT prevents this deleterious negative remodeling and is associated with better symptom control compared to RV pacing in patients with normal or low EF, as has been shown in patients with permanent AF requiring AV nodal ablation (APAF trials).[39,40] Another randomized study (BLOCK HF) addressed patients with EF ≤50% and HF functional class I–III requiring ventricular pacing for AV block and showed that CRT reduces HF hospitalization and LV remodeling in comparison to RV pacing.[41] Also, pacing at the His level or the left bundle branch area, rather than the RV apex, allows a physiological, simultaneous activation of both ventricles without inducing dyssynchrony and is an alternative to CRT.[9–11]

Therefore, CRT or conduction system pacing is recommended in patients with EF ≤50% requiring ventricular pacing >20% of the time for AV block, regardless of the functional class (ESC class IIa recommendation for EF 36–50%, class I for EF ≤ 35%); this also applies to AF patients requiring AV nodal ablation and patients who already have RV pacemaker and suffer EF decline to ≤50% (HRS), especially ≤35% (BUDAPEST-CRT trial).[8,42] *CRT upgrade in patients who already have a pacemaker is more risky than de novo CRT implantation in pacing-naive patients, which may justify a lower EF cutoff ≤35% for CRT upgrade*: in BUDAPEST-CRT, CRT upgrade reduced death and HF by >60%.

The application of BiV pacing to patients with normal EF requiring ventricular pacing is premature, but those patients require echo follow-up to check for any ventricular deterioration and may be considered upfront for His or left bundle branch area pacing (HRS class IIb).

(e) Wide QRS and severe functional MR

Moderate or severe functional MR improves by at least one grade in 50% of CRT patients.[43] However, it persists in about 20–25% of CRT patients and, in an additional 10–15%, it may actually worsen after CRT. MR reversal parallels the degree of reverse remodeling achieved with CRT.[44]

(f) RV failure

RV failure is a powerful negative prognostic marker, but did not diminish the benefit from CRT in the CARE-HF trial.[45]

C. Response to CRT and LV lead position

Approximately 30% of patients receiving CRT do not have a beneficial response. A response to CRT therapy has been defined as an improvement of NYHA functional class or a reduction of LV end-systolic volume ≥15%, called reverse remodeling.[46] Several mechanisms explain the lack of response:

a. Treatment of patients with QRS 130–150 ms or RBBB, in whom electrical dyssynchrony does not necessarily imply mechanical dyssynchrony. This is the most common mechanism of non-response. Echocardiography may be used in these patients to determine mechanical dyssynchrony but is subject to inter-observer variability. No dyssynchrony parameter was able to meaningfully distinguish responders from non-responders in the PROSPECT trial.[47]

b. Lack of appropriate AV optimization (seen in 10% of CRT patients).

c. LV lead placement in a scarred region (pre-assessment with MRI may be useful).

d. Large amount of scarred myocardium (e.g., patients with ischemic cardiomyopathy and scarring of >50% of the myocardium are unlikely to benefit).[46,48]

e. LV lead positioning outside the area of latest activation on echocardiography.[46] The echocardiographic assessment of the site of latest activation before CRT implantation may allow targeted lead placement and significant improvement of LV response and clinical outcomes.[49]

f. LV lead positioned in the anterior or apical position rather than the lateral position. Lead position should be analyzed in a short-axis plane (anterior vs. posterolateral) and in a longitudinal plane (basal vs. apical). In most patients, the *posterolateral basal wall* is the site of latest activation; however, lateral LV lead position should be avoided in patients with a lateral scar. In the longitudinal plane, the *basal wall* is the site of latest activation (vs. the apex) (Figure 14.18). While one study suggests that the anterior wall is the site of latest activation in only ~10–25% of patients,[50] another study shows that an *anterior basal* position is acceptable, the apical LV position being the one to avoid.[51] This is particularly the case because the patient is also simultaneously paced from the RV apex, further making the LV base a late site of activation.

Unfortunately, patients with ischemic cardiomyopathy are less likely to have a left marginal vein for lateral LV lead implantation. Besides, lead placement is limited by constraints of left phrenic nerve pacing, lead stability, and pacing threshold.

In the absence of randomized data, if an optimal lateral vein is not accessible for LV pacing or if the lead is not stable in this position, it would be acceptable to implant the LV lead at a suboptimal site. If the patient does not respond adequately, LBB-AP or a surgical approach may be performed in a subsequent procedure.[50] A ***lateral CXR*** displays the location of the LV lead.

In general, in responders, an immediate hemodynamic improvement is seen with CRT: improvement of LV filling, reduction of LA pressure, and improvement of LV dP/dt, MR, and cardiac output. Reverse remodeling, LVEF improvement, and further MR reduction are progressively seen over 3–12 months.

Conversely, up to 25% of patients are super-responders, i.e., experience 15–20% improvement of LVEF (EF almost normalizes) in 6–12 months. A very wide LBBB, non-ischemic cardiomyopathy, female sex, and LA volume <40 ml/m^2 correlate with super-response.[44] In those patients, dyssynchrony may be the direct cause of LV dysfunction.

D. Optimization of AV delay in patients with CRT

CRT improves diastolic function by reducing systolic time, thus allowing more time for diastolic filling. However, an appropriate AV delay needs to be programmed to improve this diastolic filling. *First*, AV delay should be shorter than the intrinsic PR interval to allow consistent biventricular pacing. *Second*, the AV delay should not be too short; a very short PR makes A wave abut the ventricular systole (simultaneous AV contraction with interruption of A contribution to the diastolic filling). *Third*, a long AV delay leads to fusion of A wave with E wave and induces diastolic MR. The best AV delay is the one that allows clear E/A separation, with A wave ending at 40 ms after the QRS onset, corresponding to the exact onset of ventricular systole (Figure 14.19). This is achieved by setting the AV delay as long as possible while maintaining BiV pacing, then reducing it by 20-ms decrements until the optimal shape is achieved. Approximately 10% of patients will have improved diastolic filling profiles after optimization, which may convert a non-responder to a responder.[52,53] Some may also aim for the AV delay that leads to the highest LVOT or aortic valve VTI (the latter corresponding to the stroke volume).

E. Echocardiographic dyssynchrony parameters

Based on the RethinQ and EchoCRT trials, CRT should not be used and echo parameters of dyssynchrony should not be sought in patients with QRS <130 ms. Those parameters are subjective and have not been shown to correlate with CRT response in patients with QRS >130 ms either (PROSPECT trial).[47] However, they are probably still useful for 2 purposes:

a. The site of latest activation that is not akinetic or scarred may be targeted for appropriate lead positioning.

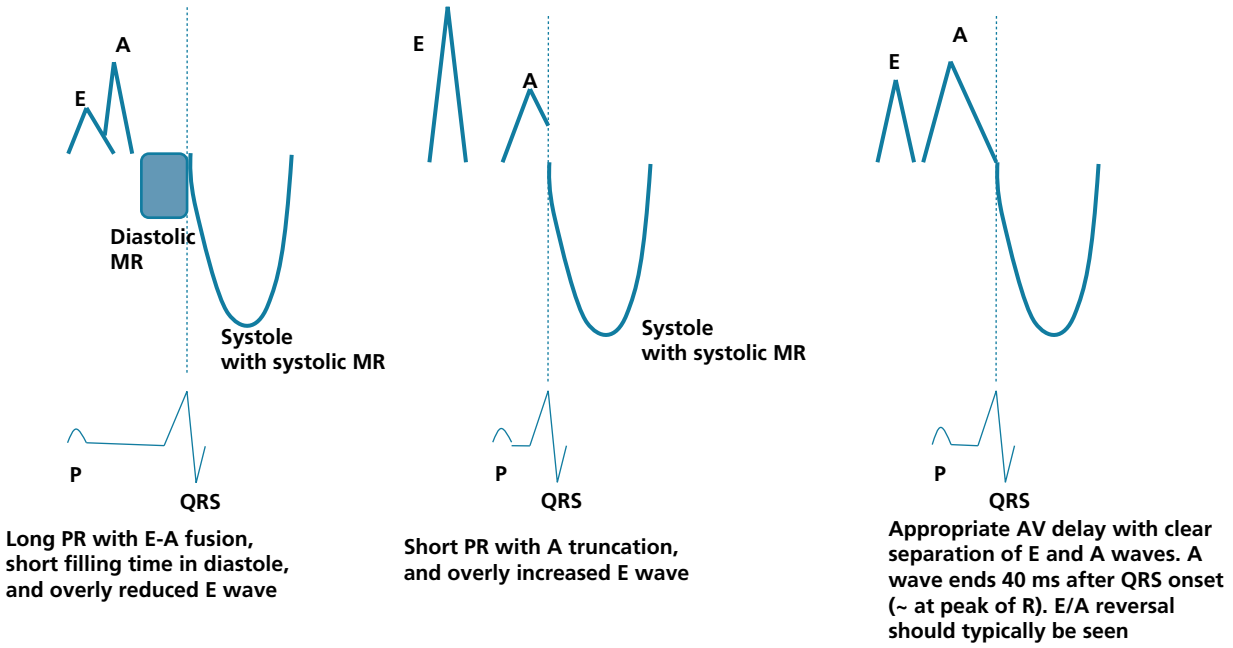

Figure 14.19 CRT: echocardiographic AV synchronization.

b. Select patients with QRS of 130–150 ms who are likely to respond to CRT. The only large trial where QRS of 130–150 ms appeared to derive a benefit close to QRS >150 ms is CARE-HF,[33] in which patients with QRS <150 ms required the fulfillment of 2 out of the following 3 criteria:

- Aortic pre-ejection delay of >140 ms: this is the delay between the onset of QRS and the onset of aortic flow (on the 3- or 5-chamber view)
- Interventricular delay of >40 ms: this is the difference between the left and right pre-ejection delay
- Septal-to-posterior wall motion delay >130 ms (on M-mode of parasternal views)

In addition, myocardial tissue Doppler or tissue speckle-tracking may be used in the short-axis and apical views to see the site of latest activation and to see the difference in peak tissue velocity between the septal and lateral walls. While the PROSPECT trial showed a low predictive yield of individual dyssynchrony parameters (in patients with QRS mostly >140 ms), one study suggested that dyssynchrony parameters are, in fact, useful in predicting which patients with QRS of 130–150 ms benefit from CRT.[54]

F. Importance of the change of QRS width after CRT

Several studies have shown that a reduction in QRS width after CRT implantation is associated with a positive response to CRT. On average, QRS shortens by 20–40 ms with CRT. This QRS shortening is mostly seen in patients with a baseline QRS >150 ms, in whom the QRS reduction is largest. Typically, non-responders do not exhibit any reduction of QRS or experience QRS widening.[55,56]

G. Arrhythmic death in patients with ICD

While ICD reduces arrhythmic death, patients with advanced HF eventually die of pump failure or recurrent MI, explaining how ICD may not affect the overall mortality in the early post-MI setting or in class IV HF (reduction of arrhythmic death with a relative increase in non-arrhythmic death). Moreover, while ICD drastically reduces arrhythmic death, it does not fully eliminate it for the following reasons (in order of frequency): (1) in patients with severe or decompensated HF, the sudden death may be pulseless electrical activity (PEA) rather than VF; also, *VF may evolve into PEA after defibrillation*, this being the most common cause of sudden death in patients with ICD; (2) failure to terminate VF with multiple shocks (ICD delivers a shock for a certain number of times, usually 6–8, then times out); (3) incessantly recurrent VT/VF, i.e., VT/VF that recurs immediately after successful therapy, over and over; (4) the ICD may undersense the VF fibrillatory waves, because of a low sensitivity setting or because of lead dysfunction.[57] Reasons (2) and (4) may justify defibrillation testing at the time of ICD implant, during which VF is induced, appropriate sensing ensured, and successful internal defibrillation achieved (with up to 35 J). An ineffective ICD shock may justify changing the lead position to create a different, more effective, shock vector; or changing the shock vector between the can and the coils. However, this defibrillation testing has not been shown to improve outcomes in the SAFE-ICD study, and thus may not be necessary in the primary prevention setting, when experienced operators appropriately place ICD leads.

Appendix. Cases of PM troubleshooting

On a pacemaker ECG, always assess the type of pacemaker by looking at A and V spontaneous activity, A and V pacing, and the A–V relationship; then assess for capture and sensing of the A and V chambers (Figures 14.20–14.35). Occasionally, the ECG or telemetry software places a pacer spike whenever it senses a high-frequency signal, such as artifact, AF wave, or QRS notching, even in the absence of pacing, which creates a false impression of PM malfunction.

During pacemaker interrogation of arrhythmias, 2 types of tracing are available: (1) intracardiac electrograms (EGMs), which record the actual signals from each cardiac chamber (A and V), and (2) the marker representation, which indicates how the pacemaker sees and interprets these signals; AS and VS mean sensed intrinsic atrial and ventricular activities, while AP and VP mean paced atrial and ventricular activities. The pacemaker may interpret a signal as VS on the marker channel, while it is in fact T-wave oversensing, false signal, or far-field sensing of an atrial spike. It calls a pacing attempt VP even if the pacemaker does not eventually capture the ventricle. **Looking at the EGMs allows one to understand what the issue is, while looking at the marker channel allows one to see how the pacemaker is interpreting or misinterpreting signals.**

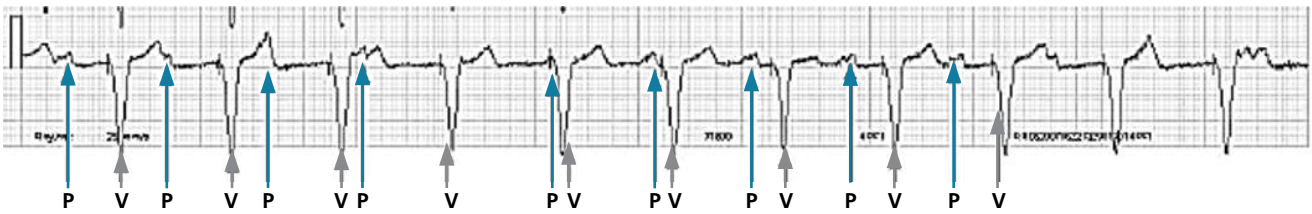

Figure 14.20 Regular V pacing without any spontaneous ventricular activity. Regular P waves are seen but are dissociated from the paced QRS complexes and not tracked by the PM. Thus, there is complete AV block but the PM is functioning in a VVI mode, in which it just senses and paces the ventricle and ignores P waves.

Assess capture and sensing. V capture is appropriate. V undersensing is assessed by the reaction of the PM to a spontaneous complex. Since there is no spontaneous QRS complex, it is not possible to comment on ventricular undersensing. There is no ventricular oversensing (which would lead to underpacing).

If the PM is programmed in a DDD mode but is behaving as VVI, the differential diagnosis would include: phantom reprogramming; end-of-life changes with mode conversion to VVI; atrial oversensing, making the PM "think" there is a fast atrial arrhythmia and switch to VVI mode; or atrial undersensing and subsequent lack of atrial tracking (lead problem). However, in case of atrial undersensing, atrial overpacing should be seen, which is not the case here.

Figure 14.21 DDD pacemaker with atrial pacing and AV sequential pacing.

Intermittently, the ventricle is paced at a short interval (fast). As this is AV sequential pacing, there must be a premature P hidden in this short interval that gets tracked by the pacemaker, rather than inappropriate fast pacing. Atrial bigeminy is, in fact, present and evidenced by the alternation of two different T morphologies (P hidden in T) (*arrows* indicate the premature P waves in leads V_1, V_2, V_4, V_5). The PAC falls on the T wave after PVARP ends, and so gets appropriately tracked by the ventricular channel at an interval close to the upper rate limit. PVARP is an interval after QRS during which P wave is not tracked.

Is this RV or BiV PM? QRS is positive in V_1; however, QRS is also positive in lead I with no Q wave. Thus, this is RV pacing. In ~10% of RV pacing, QRS may be positive in lead V_1; however, QRS should always become negative by lead V_3. Also, moving the V_1 electrode one intercostal space lower should make QRS negative.

Summary: Atrial bigeminy, normally functioning AV sequential pacemaker.

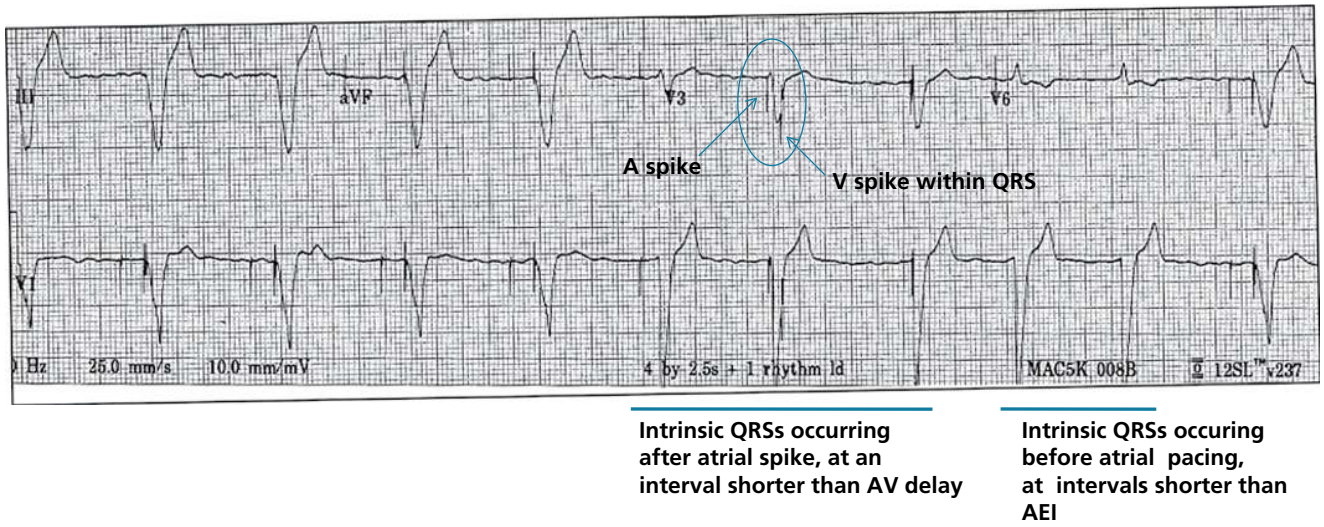

Figure 14.22 Atrial and ventricular pacing spikes are seen. The underlying rhythm is AF and is undersensed by the atrial lead, leading to inappropriate atrial pacing (the pacemaker should mode switch to VVI). The PM paces the ventricle at an AV delay that is appropriately timed to the atrial spike. Intrinsic QRS complexes are then seen in the middle of the strip. They occur after an atrial spike at an interval shorter than the pacing AV delay; or before atrial pacing occurs, at an interval shorter than the atrial escape interval. In the latter case, the atria do not get paced because the intrinsic QRS resets the atrial escape interval (AEI). In one particular beat (*circled*), the intrinsic QRS falls too close to the atrial spike, in the ventricular safety period, which makes the pacemaker immediately deliver a V spike at an interval shorter than the regular AV delay.

Final diagnosis: AF with atrial undersensing, normal AV sequential pacing (V pacing normally follows the abnormal atrial spike), pseudofusion complex with ventricular safety pacing.

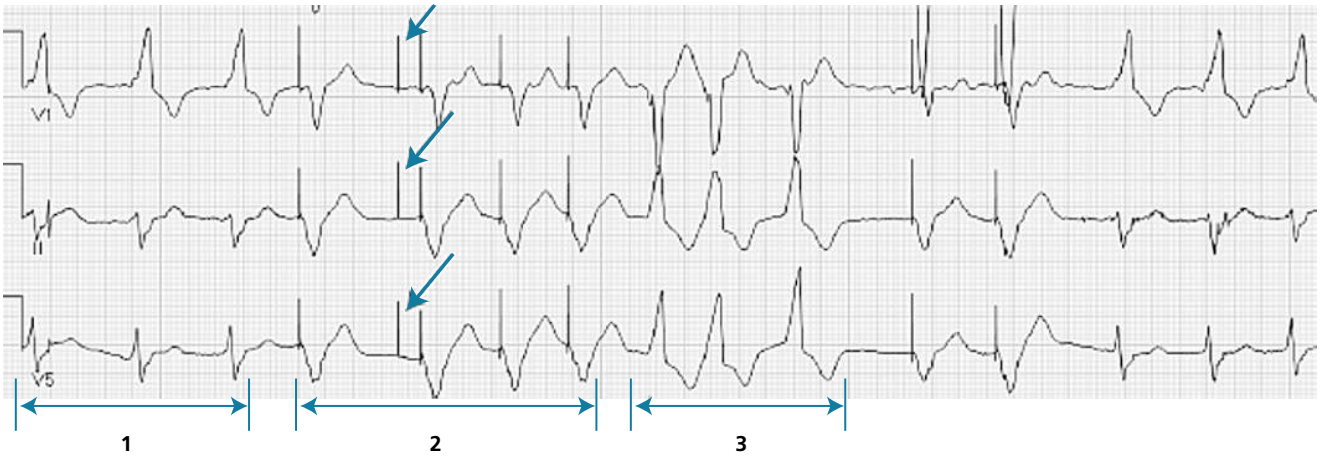

Figure 14.23 Ventricular pacing occurs at irregular intervals and one atrial pacing spike is seen (*arrow*). This is most likely a DDD pacemaker with AV sequential pacing. The pacemaker is tracking an underlying irregular atrial rate.

- The baseline rhythm appears to be AF. The pacemaker should sense the very fast atrial activity and mode-switch to a non-tracking mode (VVI) and pace at a regular rate. In this case, it seems that there is atrial undersensing, so that the pacemaker senses many of the atrial waves and tracks them irregularly at a fast rate (close to the upper rate interval of the pacemaker); however, it does not sense enough of these waves to mode-switch. The non-paced QRS complexes (sequence 3) are QRS complexes that are spontaneously conducted at the fast AF rate, inhibiting any V pacing.
- On one occasion, AF is not sensed for a longer time, which triggers an atrial pacing spike (*arrows)* at the atrial escape interval. However, the atrium is not captured because of AF (this is non-capture related to undersensing).
- Is it BiV or RV pacing? Three different QRS morphologies are seen. The morphology of beats 4–7 (*2*) fits with RV pacing. The first 3 beats (*1*) are not preceded by any spike, but may very well represent BiV pacing (QRS positive in V_1). Beats 8–10 (*3*) are different, fast, and may represent the native QRS complexes (LBBB morphology).
- The alternation between RV and BiV pacing morphologies means that LV capture is intermittently lost.

Summary: AV sequential BiV pacemaker with underlying AF rhythm. Atrial undersensing and lack of mode switch, with pacemaker tracking AF activity. Intermittent LV non-capture.

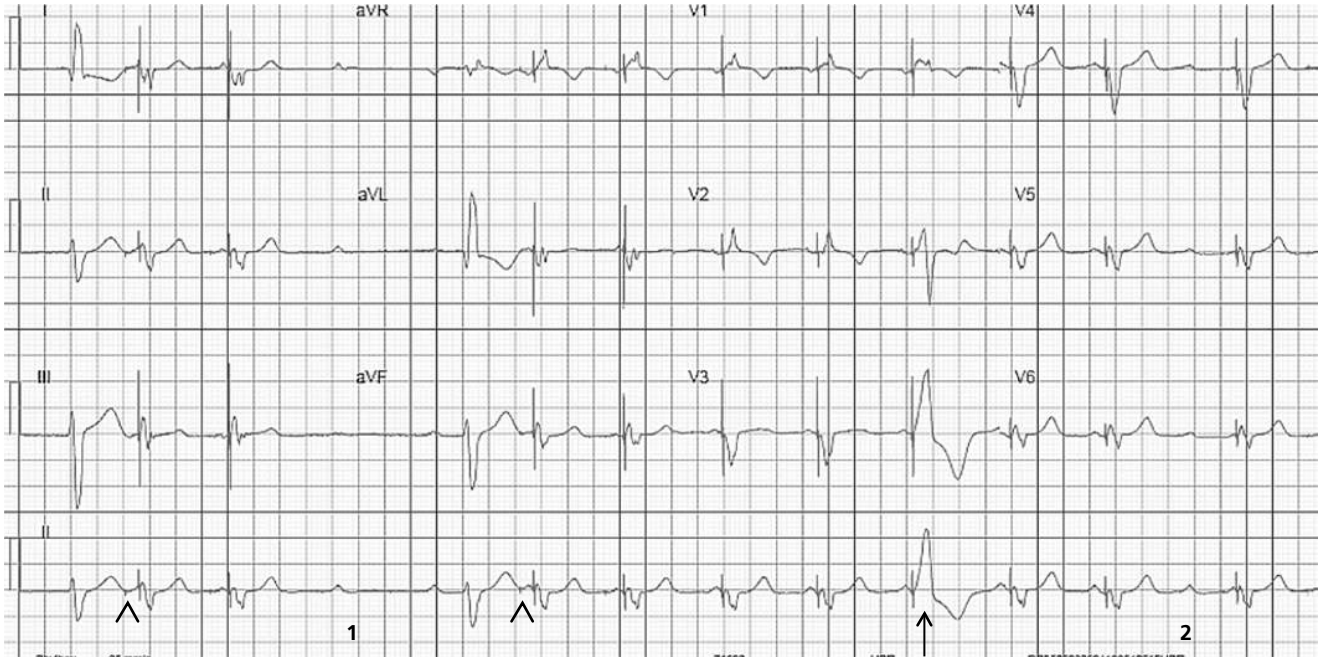

Figure 14.24 Ventricular pacing spikes are seen. They track sinus P waves at a short PR interval. At times, small atrial spikes are seen in lead II. This is a dual-chamber PM, likely DDD mode. Three issues are seen:

1. There is a long (*1*) and a short (*2*) pause (AV block) during which the ventricle is not paced, implying ventricular oversensing. P waves are not tracked during these pauses. ***Ventricular oversensing explains the lack of tracking of sinus P waves, rather than atrial undersensing***; ***atrial undersensing causes atrial overpacing and affects AV synchrony but does not lead to ventricular pauses***.
2. Ventricular undersensing is also present at times, as the A and V are paced too soon after an intrinsic QRS, implying that the intrinsic QRS is not sensed (*arrowheads* point to A pacing after the intrinsic QRS).
3. The paced QRS morphology is variable. The baseline paced morphology is positive in V_1–V_2, and negative (Q) in lead I, which means that the baseline pacing is BiV pacing. The very short PR interval supports this. One QRS is wider and is more positive in V_1–V_3 than the BiV-paced QRS, implying LV pacing and thus an intermittent loss of RV capture (*arrow*).

Conclusion: V oversensing and undersensing, intermittent loss of RV capture. The patient may have fracture of the RV lead, or loose connector set screws.

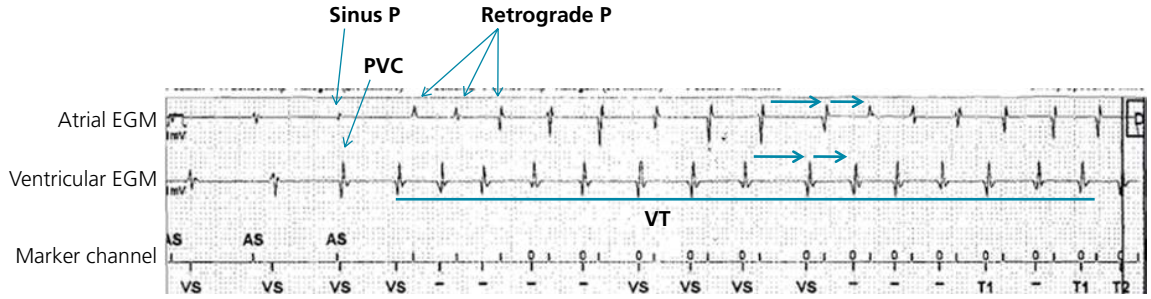

Figure 14.25 Intracardiac electrograms (EGMs) of VT. The atrial and ventricular EGMs are intracardiac ECGs capturing intracardiac activity; the atrial EGM captures the atrial activity A, while the ventricular EGM captures the ventricular activity V. The marker channel indicates how the PM interprets or misinterprets these activities. The tachycardia starts with a PVC falling over the sinus P wave, and is characterized by a number of V deflections = number of A deflections. The V activity drives the A activity; in fact, the tachycardia starts with a V, then A keeps tracking V. Whenever there is a change in the tachycardia interval, the V–V interval changes first, the A–A interval changes afterward (*arrows*). This indicates that the tachycardia is VT with 1:1 VA conduction.

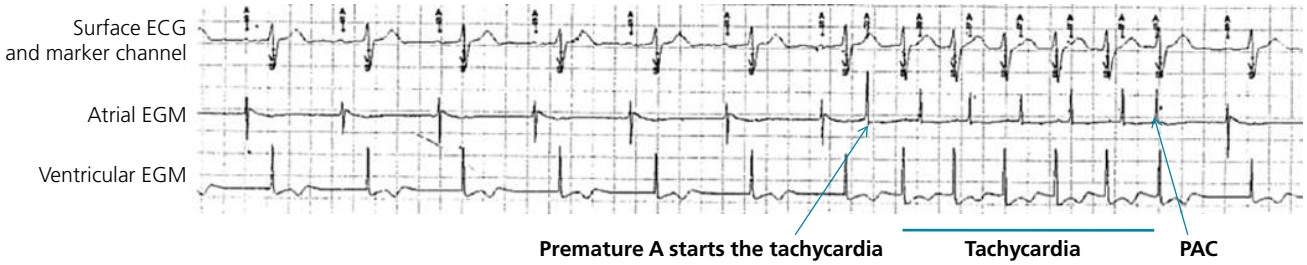

Figure 14.26 Electrograms of a tachycardia that starts with a premature A wave and ends with a PAC.

- *SVT vs. VT:* a tachycardia that starts with a PAC is often SVT, but a PAC may initiate VT as well. The tachycardia breaks with a PAC that does not conduct to the ventricles, implying SVT. The morphology of the V electrogram does not change after the onset of the tachycardia, also indicating SVT.
- *Type of SVT:* this is a short run of AVNRT, AVRT, or reentrant AT that breaks with a PAC. In contrast, automatic AT does not break with a PAC and is usually initiated by a PAC that has a morphology similar to subsequent A waves (not the case here).

The surface ECG may be a true surface ECG obtained with surface electrodes during PM interrogation; in patients with ICD, the vector between the SVC and RV coils may be used as an continuous internal ECG lead.

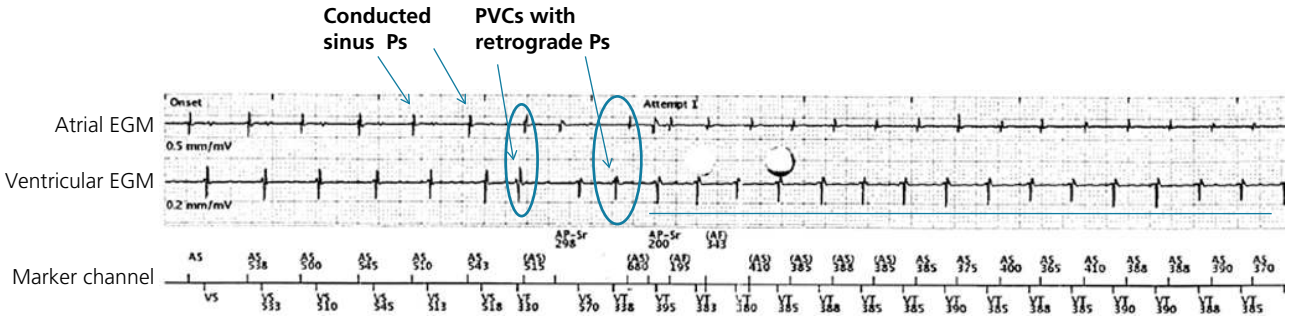

Figure 14.27 Tachycardia with number of V waves = number of A waves→ could be SVT or VT. It is unclear whether A drives V or V drives A, but since the tachycardia starts with a PVC it is more likely VT (it could also be AVRT, or less likely AVNRT or reentrant AT). Moreover, the morphology of the ventricular activity is different from the sinus-originating ventricular activity on the ventricular EGM, and similar to the second PVC, which suggests VT.

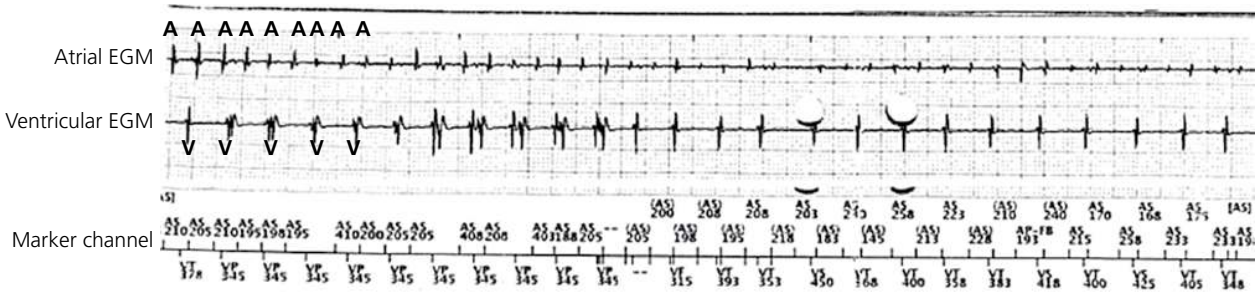

Figure 14.28 The analysis of the atrial and ventricular EGMs reveals more atrial waves than ventricular waves, implying SVT. Furthermore, A activity is irregular, which implies AF. The PM senses that the ventricular rate is in the VT zone (>150 bpm), and the marker channel calls the ventricular activity "VT" rather than "VS." Typically, to avoid unnecessary shocks, a higher rate is used for VT zone (>180–200 bpm), and SVT–VT algorithm is used.

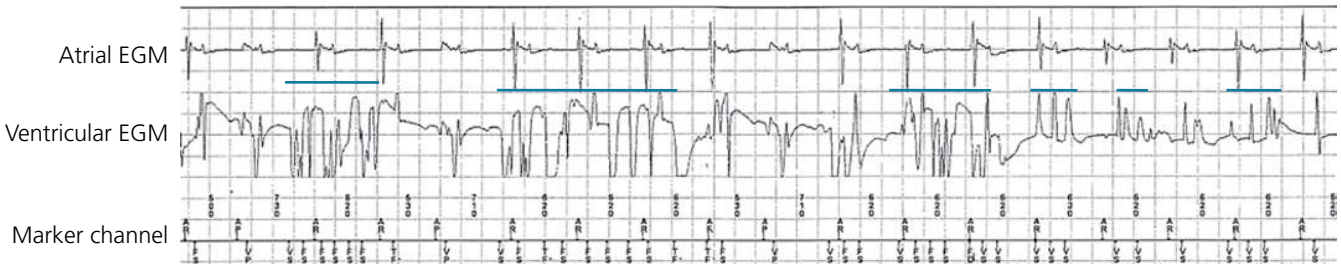

Figure 14.29 The patient presents with multiple shocks. The marker channel shows that the PM calls the ventricular activity "FS" (VF zone). On analysis of the ventricular EGM, the ventricular activity is of large amplitude (which is different from VF) and "noisy," with a V–V interval that is non-physiologic (some V–V intervals are <100 ms, even shorter than VF can generate) (*bars*). This is indicative of ventricular lead fracture with "make–break" false potentials.

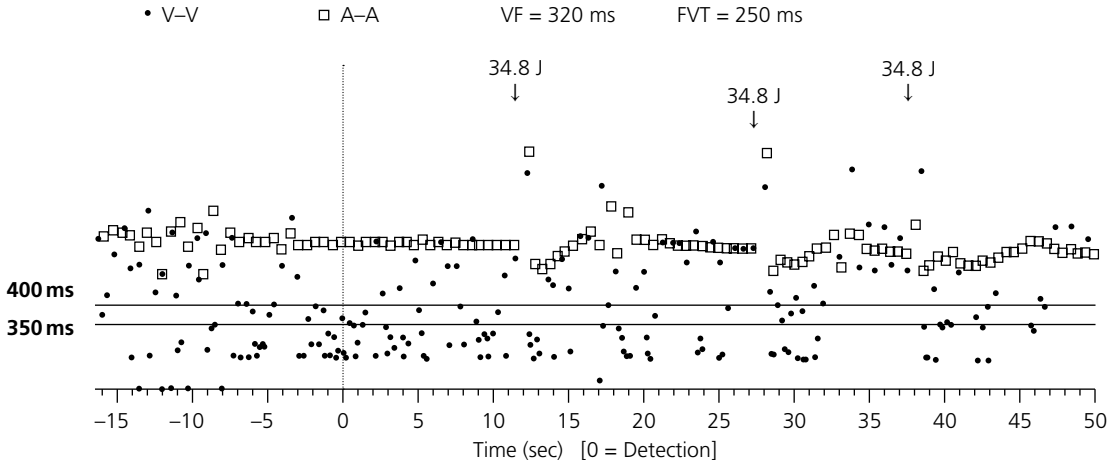

Figure 14.30 Electrogram interval plot (same patient as Figure 14.29). It represents the A–A interval of every A wave (*white squares*) and the V–V interval of every presumed V wave (*black dots*). Normally, the squares and the dots should be at the same horizontal level (same rate). Having a higher number of V waves at a shorter interval than the A waves implies VT, or, in this case, oversensing. The V–V intervals fall in the programmed VF zone (<350 ms). The V–V interval is too short (~100 ms).

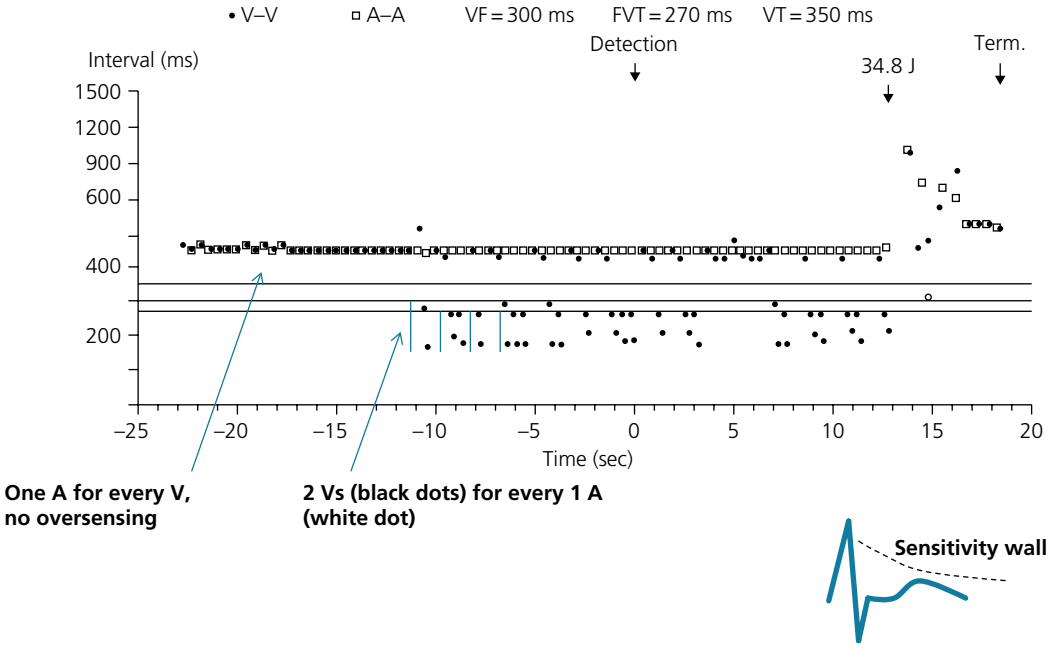

Figure 14.31 Interval plot showing at one point 2 V waves (*black dots*) for every A wave (*white dot*). The 2 V waves are lower than the A waves, correlating with the faster rate. The V waves are at 2 different levels, implying a V–V interval that alternates between 2 values. This gives the black dots (V–V interval) the morphology of a railroad. Railroad tracking usually implies double counting of the V waves during every cardiac cycle. This may be due to oversensing the T wave and calling it ventricular signal, far-field sensing of the atrial spike, or sensing the LV pacing activity by the RV lead if the RV–LV time interval is very long (unusual).

In ICD, as opposed to PM, the ventricular sensitivity wall progressively decrements after QRS to allow sensing of the low-amplitude VF waves. In order to prevent T-wave sensing, the decrement is progressive. T-wave oversensing may remain an issue, particularly in sinus tachycardia wherein T-wave amplitude increases, and particularly if the RV lead is positioned such that the vector between its 2 poles catches a small R wave with a large T wave. One may reduce V sensitivity or reprogram the decrement of sensitivity wall. One may also reprogram the sensing vector: instead of bipolar tip-to-ring sensing, program sensing between the tip and the RV coil (at the risk of increasing far-field sensing).

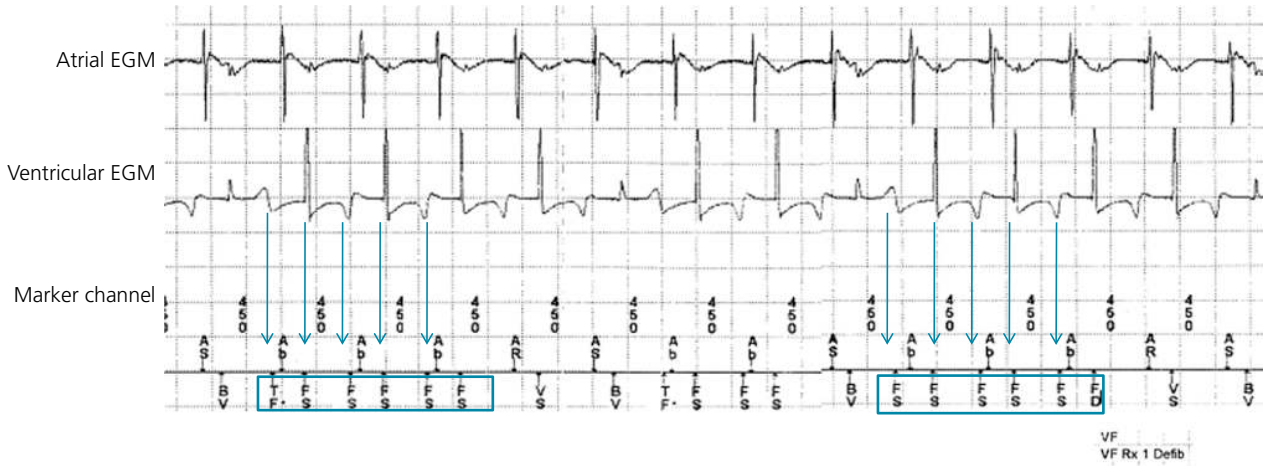

Figure 14.32 Electrograms and marker channel from the case shown in Figure 14.31. Note that the T wave is large on the ventricular EGM and is intermittently read as ventricular signal by the ICD on the marker channel (*arrows*). "VS" implies a sensed ventricular beat, "FS" implies a sensed ventricular beat that is falling at a very short R–R interval (VF rate zone). The ICD senses the T waves as QRS complexes and thus "thinks" that the rhythm is VF. One can understand what the device "thinks" by looking at the marker channel. This ICD was programmed in such a way that, if 12 of the last 16 beats fell in the VF zone, it would deliver a shock. A shock was eventually delivered in this case. The reason the last 16 beats do not all have to be in the VF zone is that the VF waves are of small amplitude and may be intermittently undersensed.

Concerning atrial sensing, on the marker channel, Ab describes an atrial beat that falls in the PVAB and is completely ignored by the device; AR describes an atrial beat that falls in the PVARP and does not get tracked. T wave being considered V complex, it initiates additional PVAB and PVARP intervals, far away from the true V complex. Therefore, *those atrial waves do not get tracked in a patient who needs BiV pacing, which is another untoward result of T-wave oversensing*. BiV pacing ("BV" on the marker channel) only occurs in the zones where T wave is not oversensed.

QUESTIONS AND ANSWERS

Question 1. A patient with an implanted ICD presents with palpitations. Device interrogation shows Figure 14.33(a), and later, Figure 14.33(b) with a faster ventricular rate. What is the diagnosis?

A. Atrial fibrillation in both (a) and (b)
B. Atrial flutter in both (a) and (b)
C. Atrial flutter in (a), atrial flutter and VT in (b)
D. Atrial flutter in (a), atrial fibrillation in (b)

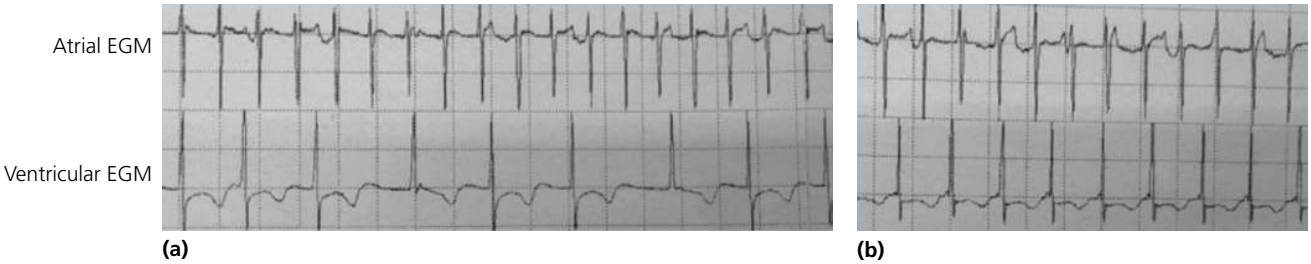

Figure 14.33

Question 2. A patient with DDD pacemaker presents with dizziness. His PM interrogation initially does not reveal a problem. A Holter monitor is placed (Figure 14.34). What is the diagnosis?

A. V oversensing
B. Lack of V capture
C. Atrial undersensing

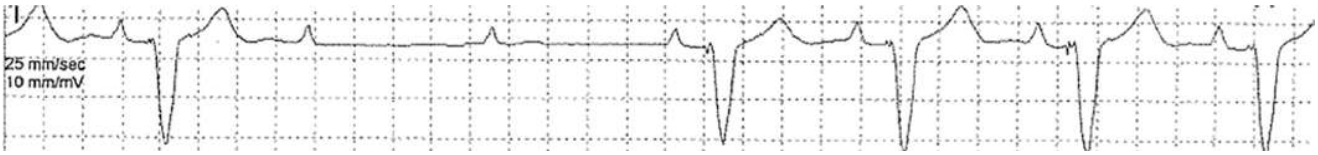

Figure 14.34

Question 3. Pacemaker interrogation of Question 2's patient is shown (Figure 14.35). What is the diagnosis?

A. Lead fracture
B. Lead insulation defect
C. Atrial oversensing
D. VT

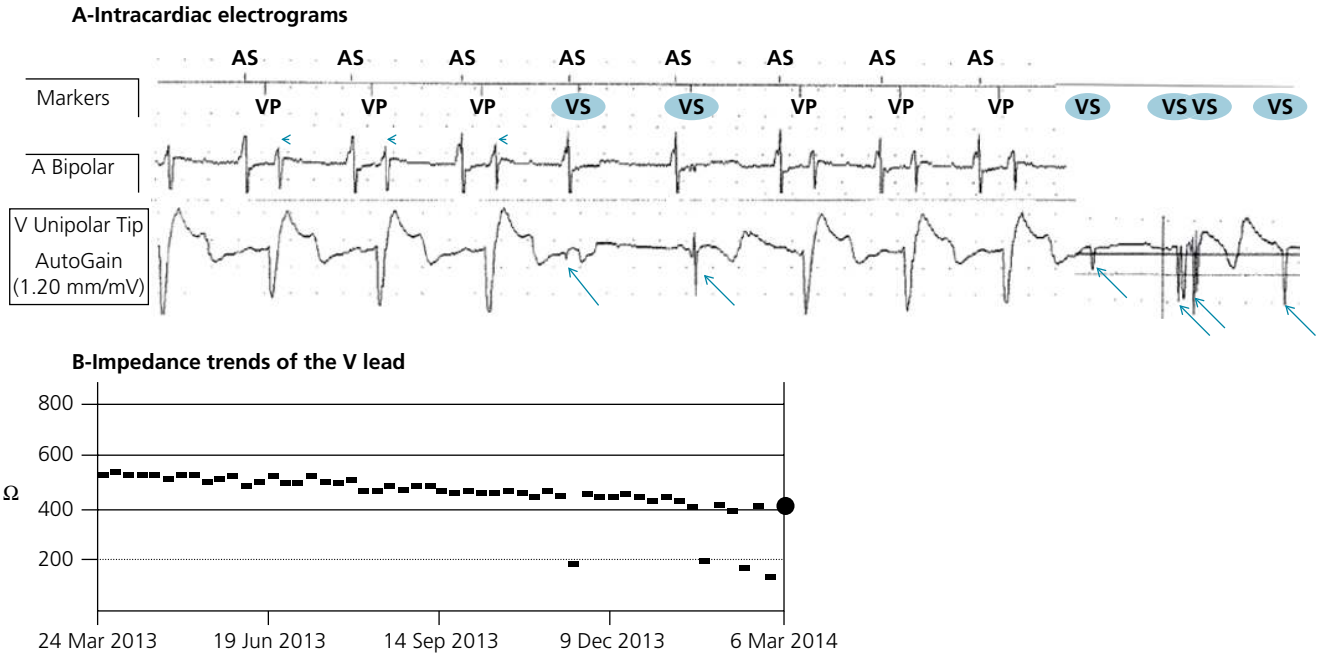

Figure 14.35

Question 4. What are 2 main causes of tachycardia wherein the ventricle is paced at 125 bpm? How to distinguish the 2 entities?

Answer 1. C. In (a), the number of A deflections is larger than the number of V deflections, which implies SVT. Atrial activity is regular with a regular A–A interval of ~200 ms (300 bpm), which implies atrial flutter with variable AV conduction. A few minutes later, in (b), the patient develops a faster ventricular rate. The atrial activity and A–A interval are unchanged; the ventricular activity has become regular and faster, with a V–V interval of 270 ms. The regular V–V interval that is not a multiple of the A–A interval suggests AV dissociation and implies the unusual presence of 2 arrhythmias: atrial flutter and VT. The V deflection and its T wave have changed in morphology between (a) and (b), which also suggests VT. VT reentry may have been triggered by the supraventricular tachycardia or by a drug-induced pause.

Answer 2. A. There are 2 non-tracked P waves with a pause. The lack of V pacing implies: (1) V oversensing; (2) lack of V capture (in which case V pacing spikes should be seen but may be small and overlooked on a Holter monitor). Atrial undersensing that prevents tracking of P waves is not a possibility; the latter should lead to atrial overpacing that is subsequently tracked by V pacing. **Atrial issues do not lead to a pause in V pacing.**

Answer 3. B. In Figure 14.35(a), the intracardiac electrogram shows noise on the ventricular channel *(arrows)*. The PM calls this noise intrinsic ventricular activity ("VS" on the marker channel). This is oversensing related to a lead issue. This oversensing prevents ventricular pacing. The "VS" is ventricular noise rather than true ventricular activity, as the morphology and timing are too erratic. However, if a simultaneous surface ECG is not performed, this noise may be confused with intrinsic V activity or VT, and the diagnosis may be missed. This is a case where the PM may not recognize and store the abnormality, or may call it brief NSVT, and where external Holter monitoring may be necessary to make the diagnosis. On a different note, see that the atrial channel is capturing the far-field ventricular activity *(arrowheads)*; however, the PM is not marking these signals on the A marker channel, suggesting that they are falling in the PVAB period.

In Figure 14.35(b), the V lead impedance trend shows an intermittent drop, suggestive of a lead insulation defect. This defect is intermittent, explaining that oversensing is intermittent. It may be exaggerated by shoulder movements. While awaiting placement of a new lead, the PM should be programmed in an asynchronous, non-sensing pacing mode to allow consistent pacing (VOO or DOO).

Answer 4. The 2 main causes are:

- Atrial tachycardia below the rate that triggers mode switch to a non-atrial tracking mode.
- Pacemaker-mediated tachycardia. The paced ventricle conducts retrogradely to the atria in case the atria have recovered from their refractory period (e.g., a preceding atrial non-capture, or PVC with lack of atrial pacing). Then, if this retrograde P wave falls outside the PVARP, it will get tracked by ventricular pacing, which perpetuates into a looping tachycardia. This tachycardia is usually at the upper rate interval, as the retrograde P wave would be barely outside PVARP.

To distinguish them, change the programming to a non-tracking mode (e.g., VVI) or place a magnet and see: If the atrial activity continues unscathed, atrial tachycardia is diagnosed; if the tachycardia breaks, PMT is diagnosed.

I. General concepts; intracardiac electrograms

Four main catheters are used: RA catheter, RV catheter, His catheter, and coronary sinus (CS) catheter. These catheters record electrograms (EGMs) and may also be used for pacing. The His and CS catheters typically have multiple recording electrodes (e.g., proximal, mid, and distal). The His catheter is placed through the RA just atop the junction of the atrial septum and tricuspid valve: the *proximal His* lies over this atrioventricular septum, while the *distal His* lies over the membranous ventricular septum and branches into 2 bundles at the muscular septum.

- ***RA recording*** is characterized by A wave (atrial activity).
- ***RV recording*** is characterized by V wave (ventricular activity).
- ***His recording*** is characterized by 3 waves: A, H (His activity), and V (Figures 15.1, 15.2). The A wave on His recording normally occurs slightly later than the A wave on RA recording, due to the delayed transmission of the atrial activity to the His catheter. The His spike is typically narrower and of smaller amplitude than the A and V waves, and looks like a narrow bar. The A-to-V amplitude ratio depends on whether the His catheter is over the RA side vs. RV side (distal His, V>>A).
- ***CS recording*** mainly shows A wave; it may show a far-field, low-amplitude V wave (Figure 15.2).

In order to identify the deflections on any channel, always correlate them with the surface ECG. This should always be the first step in analyzing intracardiac EGMs. The A wave coincides with the P wave, the V wave coincides with the QRS complex (~superimposed with QRS), and H is between A and V. ***Regardless of the channel, V waves line up with the QRS complexes.***

The AH interval corresponds to AV nodal conduction, while the HV interval corresponds to His + infra-His conduction. AH is measured from the onset of A on His recording to the onset of H, while HV is measured from the onset of H to the onset of the earliest ventricular activation, which is usually the onset of QRS on the ECG. The HV interval is the only interval where the surface ECG is needed not just for identification but for measurement as well; in fact, the electrocardiographic QRS often starts earlier than the His V wave, and is closer to the RV V wave, as the ventricular stimulation starts at the mid-ventricular wall then spreads up to the ventricular muscle around His. The normal AH interval is 60–120 ms, while the normal HV interval is 35–55 ms; HV is severely increased if >70 ms.

In the EP lab, programmed stimulation may be performed using 2 pacing techniques: (i) ***extrastimulus,*** where a progressively more premature extrastimulus S2 is introduced after a baseline pacing sequence S1 (~8-beat train S1, at a fixed cycle length of ~600 ms); the fixed S1 train establishes reproducible conduction intervals, which allows the isolated effect of the varying S2 to be analyzed; (ii) ***incremental pacing***, where an accelerating pacing train S1 is introduced, with gradual shortening of the cycle length within the train every few beats (= progressively faster pacing, not steady train).

II. AV conduction abnormalities

AH prolongation or, worse, A wave that is not followed by H and V waves, indicates AV block at the nodal level.

HV prolongation, or A wave that is followed by H but not V wave, indicates infranodal AV block and thus is more ominous and more readily dictates pacemaker placement, in a symptomatic or even asymptomatic patient (Figures 15.3, 15.4). The block may be intra- or infra-Hisian; H wave may be prolonged, fragmented or split in intra-Hisian block.

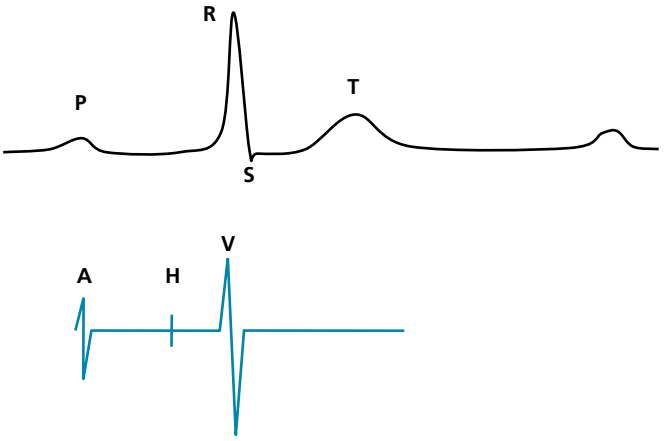

Figure 15.1 Normal His recording.

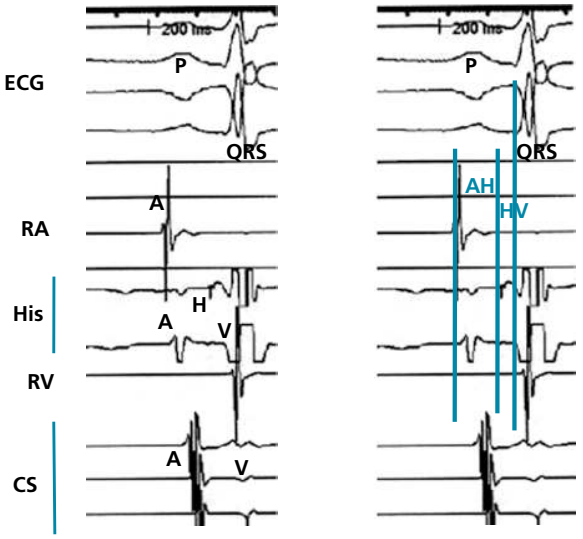

Figure 15.2 Example of a typical A, V, His, and CS recording. AH and HV intervals are shown. When looking at an intracardiac tracing, **always start by identifying the V wave, which corresponds to the electrocardiographic QRS**. The remaining intracardiac waves are mainly A waves. H wave is a small wave that is only seen on the His recording and may be overlooked. The CS recording mainly shows A waves (LA A waves), but low-amplitude, far-field V waves may also be seen.

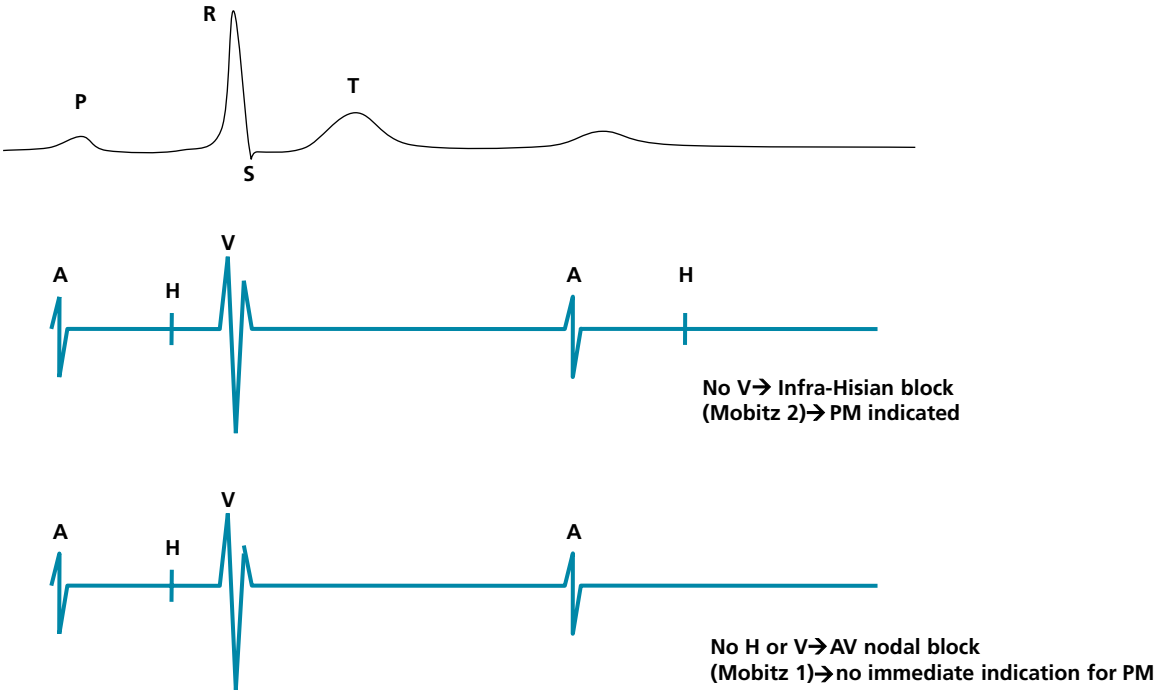

Figure 15.3 Types of AV block.

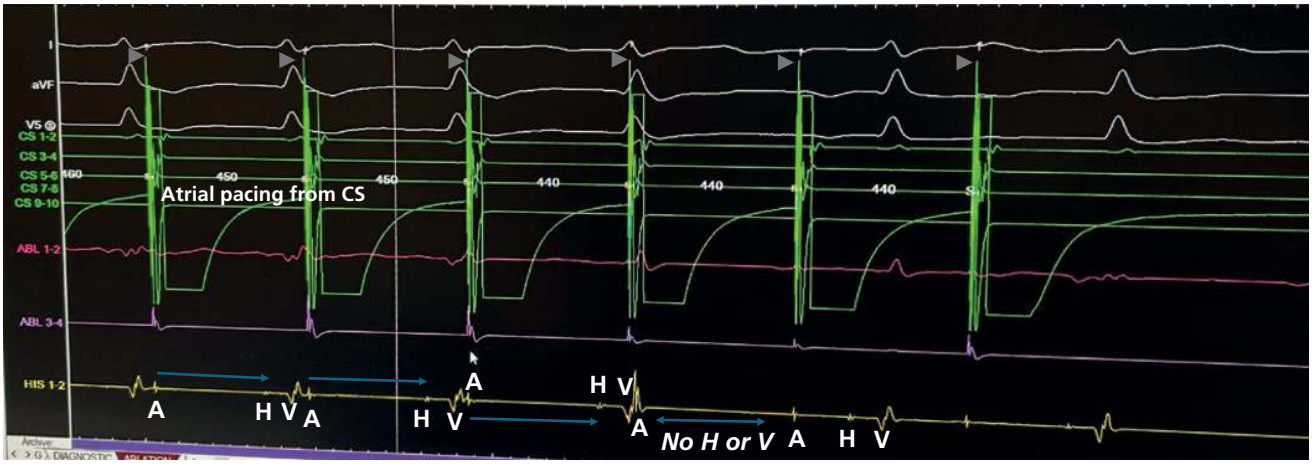

Figure 15.4 Incremental atrial pacing train is delivered with progressively shorter pacing intervals (460 → 450 → 440 ms). Atrial pacing is delivered via the CS, and A-H-V behavior on the His recording is observed. Note how the AH interval progressively lengthens on the His recording (*blue arrows*) until H and V drop, at the pacing interval of 440 ms: this is the Wenckebach cycle length. This Wenckebach behavior with incremental pacing is seen in normal individuals.

In the EP lab, the AV conduction may be stressed using the *incremental pacing* or the *extrastimulus technique* or *drugs* (procainamide).

Incremental pacing. The AV node is characterized by decremental conduction and longer refractory period with faster atrial pacing, which is opposite to the myocardial tissue. With progressively faster atrial pacing train, the AH interval normally increases, and a conduction block may normally be seen at the AV nodal level, which manifests as a drop of both H and V complexes in a Wenckebach pattern. The pacing interval at which this occurs is the Wenckebach cycle length, normally ≤ 450 ms (≥130 bpm). Wenckebach AV block occurring at a slower rate implies AV nodal disease. The HV interval should not change with pacing; an increase in HV interval (especially >70 ms) or a drop of V wave with fast atrial pacing indicates infranodal AV block.

Extrastimulus technique. Progressively more premature atrial extrastimuli are inserted until A fails to conduct to His. The earliest A–A interval at which A stops leading to H complex is the AV nodal effective refractory period. On the other hand, the earliest interval at which the premature extrastimulus does not lead to A complex is the atrial effective refractory period. Besides having slower conduction than the atrial and ventricular tissues, the AV node normally has a longer refractory period. An AV node effective refractory period >425 ms is abnormal.

III. Sinus node assessment

During fast overdrive atrial pacing (~30 seconds), and similarly to atrial fibrillation, the sinus node activity is inhibited. Upon cessation of atrial pacing, the sinus node needs time to recover its electrical activity. The duration of the pause between the last paced A complex and the recovery A complex is called the sinus node recovery time (SNRT). A diseased sinus node has a prolonged SNRT. The corrected SNRT is equal to SNRT minus basic cycle length, basic cycle length being the A–A interval prior to atrial pacing (e.g., SNRT 1100 ms, basic cycle length 700 ms, corrected SNRT = 400 ms). The corrected SNRT is normally <550 ms.

Also, a blunted sinus node response to atropine + propranolol (i.e., to the removal of the autonomic tone) implies sinus node disease.

Note, however, that rhythm monitoring (e.g., event monitor), which correlates symptoms with paroxysmal conduction blocks/sinus pauses, has the highest yield in establishing that conduction blocks are the cause of the patient's symptoms. Invasive EP evaluation of the AV or sinus node does not have a high sensitivity or specificity for conduction abnormalities. For example, the presence of sinus nodal disease or AV nodal block does not imply that the conduction abnormality underlies the patient's symptoms. ***Only the finding of HV infranodal block (a drop of V wave or HV interval >70–100 ms) is highly specific for a serious conduction disorder and usually mandates pacemaker placement regardless of symptoms.***

IV. Ventricular vs. supraventricular tachycardia

AV dissociation is easily characterized on EGM. *Identify V deflections, which line up with QRS complexes on the ECG; then identify the other deflections, seen on the atrial and His channels, which correspond to the A deflections*. VT is diagnosed if V deflections are more numerous than A deflections. SVT is diagnosed if A deflections are more numerous than V deflections. If A deflections are equal in number to V deflections, the tachycardia could be SVT or VT with 1:1 VA conduction. Assess the onset of the tachycardia (V or A) *and* which interval changes first (A–A or V–V). In VT, the tachycardia starts with a V deflection and the A–A interval's length tracks the V–V interval's length, meaning a change in A–A interval follows, rather than precedes, a similar change in V–V interval.

In VT, V deflections are typically more numerous than A deflections and are dissociated from them. However, V and A could be associated in a 1:1 fashion (1:1 VA conduction), or a 2:1 or 3:1 fashion (2:1 or 3:1 VA conduction). In VT with AV dissociation, His spikes are typically absent. In VT with AV association, His spikes may result from retrograde VA conduction.

V. Dual AV nodal pathways

Normally, after a premature atrial extrastimulus, the AV nodal conduction slows and AH interval increases (relative refractory period). With progressively more premature atrial extrastimuli, AH interval progressively increases, and at some point H and V may drop. If, however, with a small decrement of A–A interval (e.g., 340 ms to 330 ms), AH interval disproportionately increases, by >50 ms (as opposed to a slight

increase or a block), it is implied that the AV node has a fast and a slow pathway. While the fast pathway conducts the normal, sinus-initiated beats and the atrial extrastimuli, a very early extrastimulus falls in the absolute refractory period of the fast pathway and fails to conduct through it. Subsequently, this extrastimulus conducts over the slow pathway, leading to an AH jump (Figures 15.5 and 15.6). **The slow pathway has a slower conduction but a shorter refractory period**, hence the slow pathway conducts when the fast pathway is blocked. This may initiate AVNRT, if the fast pathway recovers quickly enough to allow retrograde conduction (slow–fast reentry).

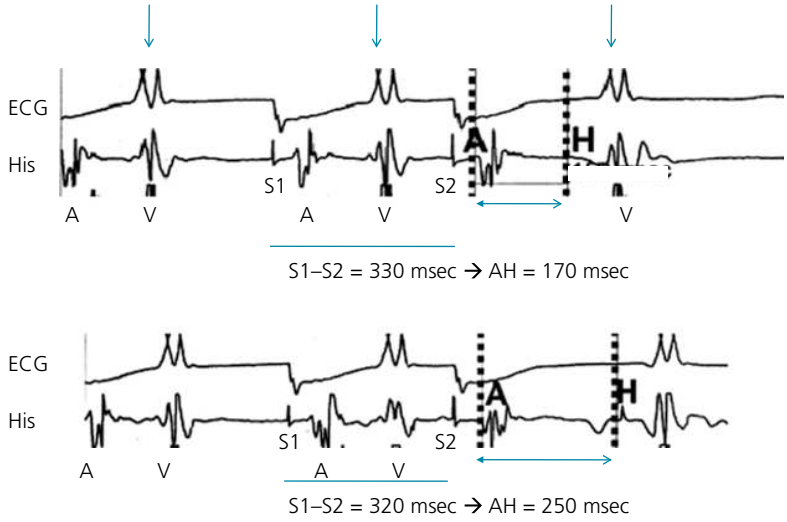

Figure 15.5 Arrows point to QRS complexes on the ECG, which are the starting point in intracardiac electrogram interpretation. S1 is a baseline pacing train, S2 is a premature pacing stimulus. A slightly earlier pacing stimulus (10 ms earlier) leads to a large jump in AH conduction interval >50 ms, indicative of the presence of dual AV nodal pathways. The latter conduction occurs over the slower pathway. This phenomenon is called **AH jump** after progressively premature atrial extrastimuli.

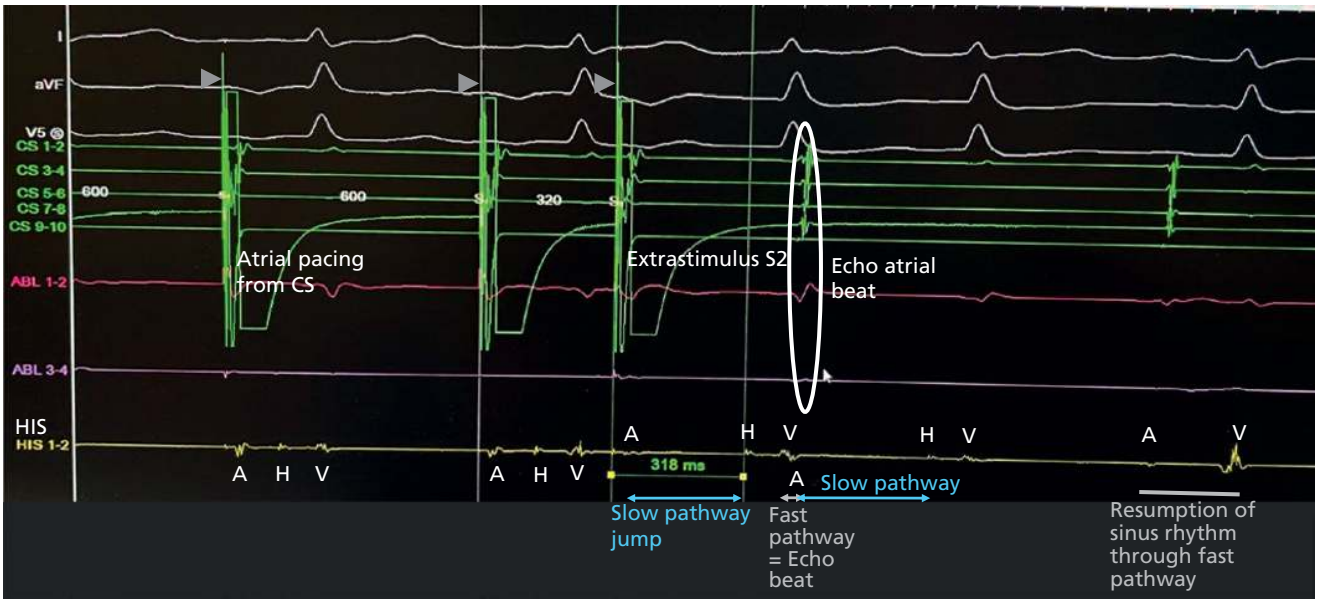

Figure 15.6 An atrial pacing train S1 delivered through the CS (600 ms) is followed by a premature extrastimulus S2 at 320 ms. This causes a dramatic jump in AH interval compared to a previous extrastimulus S2 of 330 ms. This jump implies conduction over a slow pathway when the fast pathway stops conducting. It is followed by quick retrograde conduction from V to A via the recovered fast pathway, the so-called echo beat. In fact, **AH jump is frequently accompanied by echo A beat.** This echo beat then conducts antegradely via the slow pathway. If echo beats keep repeating, AVNRT is established: AVNRT is a repetition of retrograde fast echo beats that loop antegradely through the slow pathway. This did not happen in this patient, and sinus rhythm resumed. *Note:* The gray arrowheads indicate the atrial pacing spikes. Note that the 600-ms pacing train S1 establishes a predictable A-H-V pattern on the His recording, so that the S2-induced changes are more easily observed.

VI. AVNRT

During AVNRT, A conducts down the AV node's slow pathway, which then conducts to V and A quickly and almost simultaneously (Figures 15.7, 15.8). The conduction to A occurs retrogradely through the fast pathway. **A tachycardia with almost simultaneous V and A deflections is usually AVNRT.** The VA interval is very short <70 ms and is not a true VA interval, as it is not the V that is conducting to the A.

VII. Accessory pathway, orthodromic AVRT, antidromic AVRT

An accessory pathway connects the A and the V. The accessory pathway may conduct from the atrium all the way to the ventricle at baseline (manifest pathway = WPW pattern), or may only partially conduct and not reach the ventricle (concealed pathway).

The accessory pathway has a faster conduction than the AV node but a longer refractory period. Thus, a PAC is more likely to conduct through the AV node than the accessory pathway. By the time the electrical activity reaches the ventricle, the accessory pathway may have recovered, and thus fast retrograde conduction may occur and lead to orthodromic AVRT (= AVRT with retrograde conduction through the accessory pathway). In this case, A conducts to V through His, then V rapidly conducts to A retrogradely through the fast-conducting accessory pathway (Figure 15.9). ***In contrast to AVNRT, A and V activities are not as close*** (VA interval >70 ms).

Antidromic AVRT is a reentrant AV tachycardia that conducts antegradely over the accessory pathway. It is unusual for a PAC to initiate antidromic AVRT, as it blocks through the accessory pathway before it blocks through the AV node (the accessory pathway has a longer refractory period than the AV node). Antidromic AVRT may occur in rare cases where the accessory pathway has a shorter refractory period than the AV node. In this case, A conducts to V through the accessory pathway, then V conducts back to A through His (Figure 15.9).

A CS catheter helps further differentiate AVNRT from AVRT and localizes the site of the accessory pathway (Figure 15.10). Analyze the His, CS, and RA channels and see the site of earliest A activity during the tachycardia: in AVNRT the earliest A activity is in His, followed by the proximal part of the CS catheter (*concentric* spread of atrial activity). Conversely, in AVRT, the earliest A activity is in the distal CS catheter (left-sided pathway), proximal CS catheter (posteroseptal pathway), or the RA (right-sided pathway). The site of earliest A activity in the RA or CS (proximal, mid, or distal) allows the localization of the accessory pathway site.

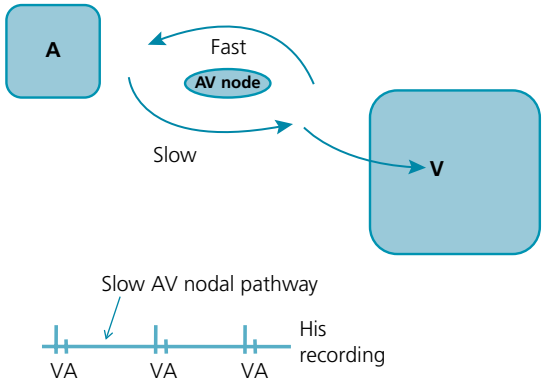

Figure 15.7 AVNRT. V and A almost coincide, with a VA interval <70 ms. On ECG, this corresponds to RP interval <90 ms.

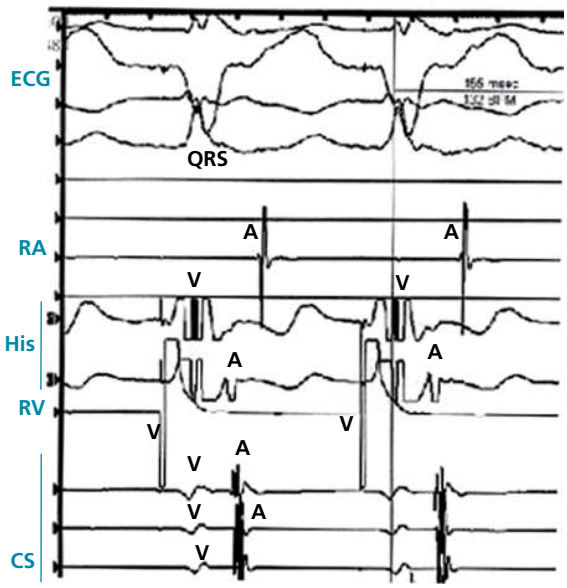

Figure 15.8 AVNRT. After V, the site of earliest A activation is located in the His catheter, then it spreads to the RA and LA (CS catheter). This is the so-called concentric A activation. VA interval is very short; in fact, V and A almost coincide.

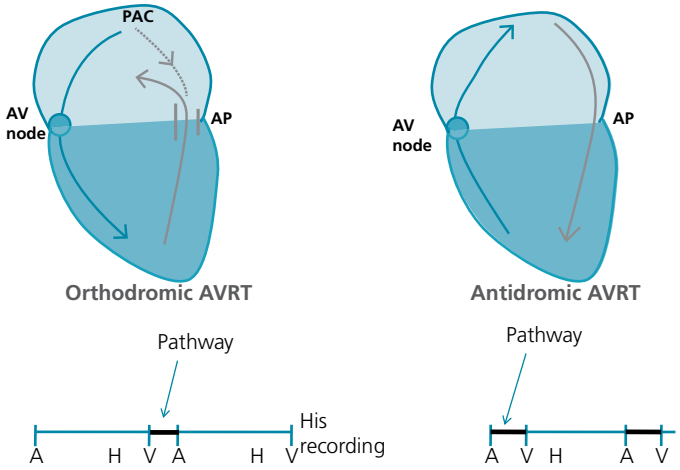

Figure 15.9 Activation sequence in orthodromic AVRT and antidromic AVRT. As opposed to AVNRT, in orthodromic AVRT the site of earliest A activation after V is either CS or RA, depending on the site of the accessory pathway, but not His (usually).

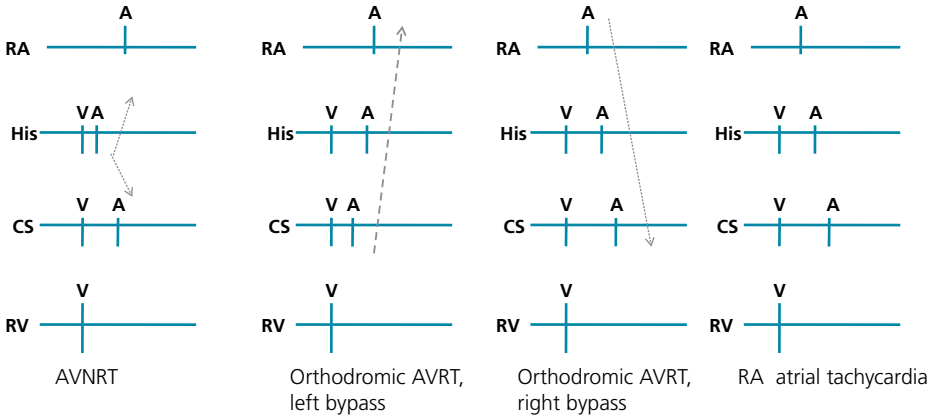

Figure 15.10 Earliest site of atrial activation during AVNRT, AVRT, and atrial tachycardia.

- In AVNRT, retrograde A is seen first in His, then proximal CS, then RA. Importantly, the VA interval is very short.
- In left-sided bypass tract AVRT, the earliest A activation is in the CS catheter (LA).
- In right-sided bypass tract AVRT, the earliest A activation is in the RA, followed by His (atrial septum) and LA.
- In atrial tachycardia, the earliest A activation is in the RA (RA AT) or the CS (LA), which may simulate AVRT. In AT, as opposed to AVRT and AVNRT, when one paces the ventricle and entrains the atrium then stops pacing, the junction between pacing and the AT rhythm is characterized by V–A–A–V. Also, V pacing may not capture the atrium at all, which keeps beating at its own rhythm and dissociates from the ventricle, which is different from AVRT, where the A and V cannot be dissociated.

During a baseline study, before arrhythmia induction, the accessory pathway may be diagnosed and localized through ventricular pacing and mapping of the retrograde atrial activation. Normally, retrograde atrial activation spreads through the AV node and the earliest atrial activation is in the His, followed by concentric spread to both atria (*concentric atrial activation* through His). If an accessory pathway is present, retrograde atrial activation will spread through this pathway into one of the atria first, then spread contralaterally (*eccentric atrial activation*). The earliest atrial activation is right, left, or posteroseptal (coronary sinus). Occasionally, the retrograde activation may appear normal if the pathway is anteroseptal.

In patients with antegrade accessory pathway, progressively earlier atrial extrastimuli do not lengthen the AV interval, which remains *flat* until a block occurs in the accessory pathway and conduction shifts to the AV node. This is different from the response of the AV node to extrastimuli and is a hint to the presence of an accessory pathway.

In the EP analysis of tachyarrhythmias and accessory pathways, induce the tachyarrhythmia with pacing and extrastimuli (e.g., atrial extrastimuli for SVT) then look for the site of earliest activation to localize the ectopic focus or the pathway (Figure 15.10). In the EP lab, rhythms are described in terms of their cycle length rather than rate, i.e., the length of time between 2 waves (cycle length = 60,000/rate).

Reentrant supraventricular arrhythmias can be induced with atrial extrastimuli that fall into the refractory period of one arm of the reentry loop (e.g., refractory period of the fast pathway in AVNRT, refractory period of the accessory pathway in AVRT, and refractory period of some atrial cells in AF or Aflutter). AVRT can be initiated with both ventricular or atrial extrastimuli. Automatic tachycardia, such as automatic AT, cannot be induced by pacing but may be induced with catecholamines (isoproterenol).

VIII. Atrial flutter

Atrial flutter is characterized by a macroreentrant RA circuit that runs in a frontal, right-to-left plane, the base of which is a narrow isthmus bordered by the IVC and crista terminalis posteriorly and the tricuspid annulus anteriorly (cavotricuspid isthmus, CTI) (Figures 15.11–15.14). The crista terminalis, a fibrous band that separates the anterior (tricuspid annulus) and posterior (IVC) parts of the RA, constitutes the electrical barrier that allows the atrial flutter circuit to be sustained.

A *halo mapping catheter* with 10–20 electrodes is placed in the RA, crossing the isthmus and overlapping with the atrial flutter circuit (almost in the same plane). These electrodes are activated sequentially in a counterclockwise fashion, leading to a "zigzag" shape of A deflections, with activation spreading from the proximal into the distal tip electrodes (Figures 15.15, 15.16). The *ablation catheter* is introduced through the IVC and advanced across the tricuspid valve, and its tip is torqued so that it is inferior to the coronary sinus catheter. The catheter is then withdrawn to the tricuspid annulus. Pacing through the ablation catheter is performed at this level while atrial flutter is ongoing; an adequate isthmus position is confirmed if the post-pacing interval is equal to the tachycardia cycle length. Radiofrequency

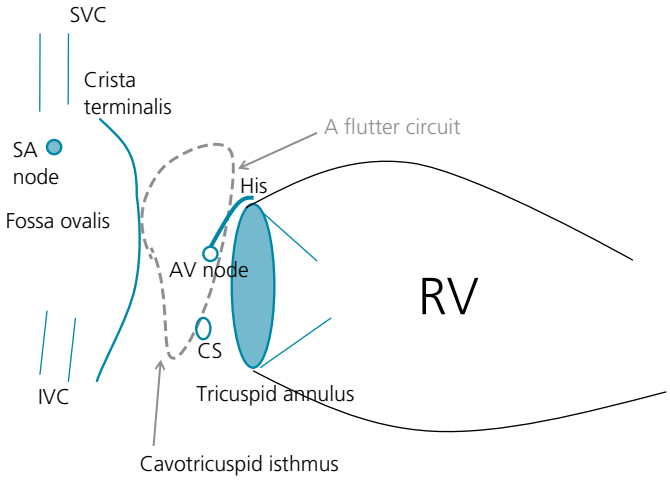

Figure 15.11 RAO view (side view) of the RA. The crista terminalis is a structure that separates the anterior and posterior parts of the RA. The cavotricuspid isthmus (CTI) is a narrow tunnel in front of the crista terminalis. The atrial flutter circuit loops in the CTI, parallel to the tricuspid annulus and anterior to the IVC and crista terminalis. Note that the AV node is located in the interatrial septum. The His bundle emanates from the AV node and extends to the membranous interventricular septum, just behind the aortic valve (noncoronary cusp); it gives the bundle branches at the junction with the muscular interventricular septum (the left bundle pierces to the left side of the septum). The triangle of Koch is formed by the coronary sinus, the tricuspid septal leaflet, and the tendon of Todaro (surrounding the AV node). CS, coronary sinus ostium.

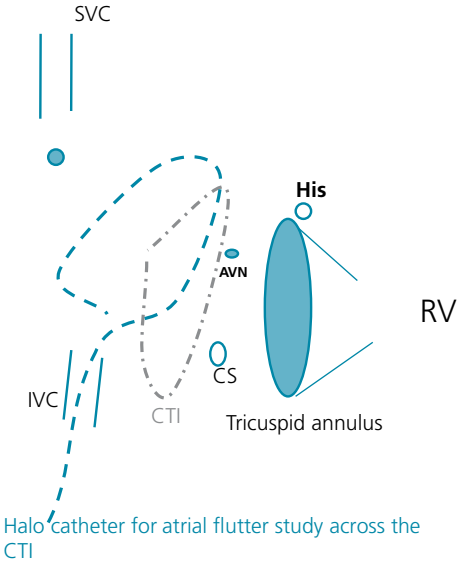

Figure 15.12 RAO view of the RA. Note the position of the halo mapping catheter, which is typically in a frontal plane, parallel to the tricuspid annulus and the atrial flutter circuit. AVN, AV node; CTI, cavotricuspid isthmus.

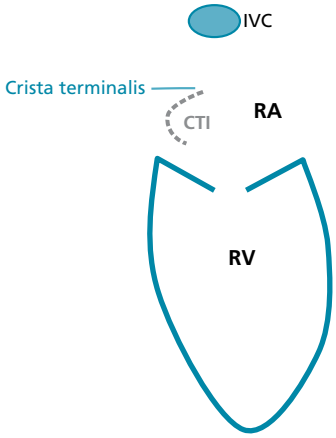

Figure 15.13 Axial view of the RA, RV, and cavotricuspid isthmus (CTI).

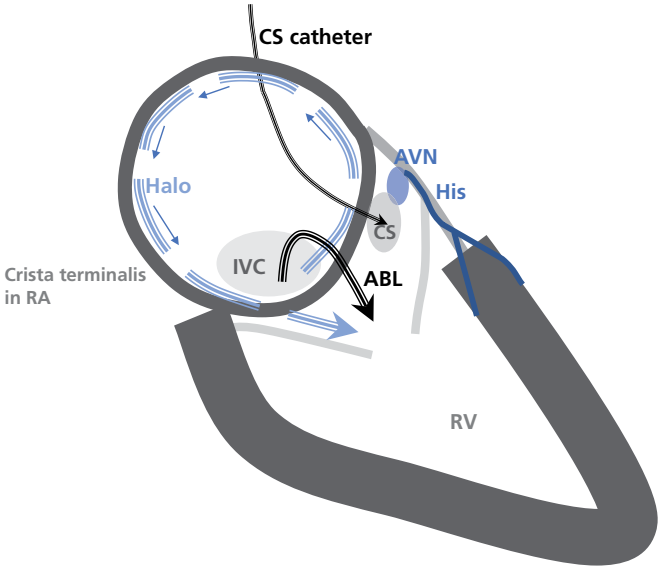

Figure 15.14 En face view of the RA and RV. Note the *crista terminalis* ridge, anterior to which the atrial flutter circuit organizes. The *halo catheter* (*circular blue arrow*) is positioned in the RA parallel to the crista terminalis, overlapping with the atrial flutter circuit. The *ablation catheter* (*ABL*) crosses the crista terminalis into the *cavotricuspid isthmus*.

The *coronary sinus* (*CS*) is anterior to the crista. The AV node (AVN) and His are over the membranous septum (interatrial septum for AV node, atrioventricular septum for proximal His, interventricular septum for distal branching His).

energy is subsequently used while the catheter is very slowly pulled back into the IVC; the CTI is thus ablated. To ensure complete CTI interruption, pacing through the coronary sinus catheter is performed after ablation. Normally, pacing through the coronary catheter spreads into both the lower and upper parts of the RA, leading to ~ simultaneous activation of proximal and distal halo catheter electrodes, with the latest activation being somewhere around the middle electrodes. However, when CTI ablation is successful, there is a block of conduction across the lower RA, leading to a one-way spread of conduction (Figure 15.17).

IX. Inducible VT

In patients with structural heart disease and unexplained syncope, one should attempt to induce VT. If inducible, the study is specific for ventricular arrhythmia as the underlying trigger of syncope and is a class I indication for ICD placement. If not, it does not necessarily rule out an underlying VT.

VT is induced by rapid ventricular pacing (at a V–V interval of 400 ms, for example) followed by inserting a single premature extrastimulus at a progressively tighter coupling interval (e.g., premature V stimulus at 320 ms, then 280 ms, then 240 ms). If VT is not induced, pace and insert double extrastimuli then triple extrastimuli. If arrhythmia is not induced from the RV apex, these same steps may be repeated from the RVOT.

An abnormal response is defined as the induction of **sustained monomorphic VT** >30 seconds with up to three extrastimuli, or sustained polymorphic VT/VF with up to double extrastimuli. Polymorphic VT/VF induced with triple extrastimuli is a non-specific response that may be seen in normal individuals. Some operators consider the induction of polymorphic VT with any type of stimulation a non-specific response; some operators accept non-sustained VT >10 beats as a positive study. The use of polymorphic VT or non-sustained VT as a positive endpoint lessens the specificity of the study. Only a sustained monomorphic VT <220 bpm can be mapped and potentially ablated.

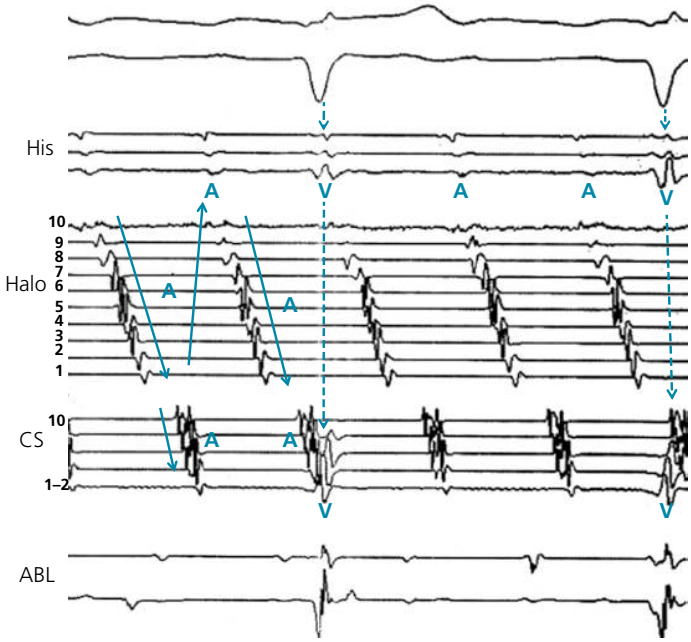

Figure 15.15 Atrial flutter mapping. Note the atrial activation along the halo catheter (10 to 1) with the zigzag shape (*solid arrows*). Electrodes 1, 2 are the distal tip electrodes, whereas electrodes 9, 10 are the proximal electrodes (see Figure 15.16). Note how the activation spreads in a counterclockwise fashion from 10 to 1, then reaches the coronary sinus and His bundle and reaches back to electrode 10. *The RA is constantly activated throughout the recording, with no quiescent isoelectric phase*.

As always, identify complexes on all channels by correlating with the QRS on ECG. On any channel, V is the complex that aligns with QRS (*dashed arrows*); the rest are A complexes.

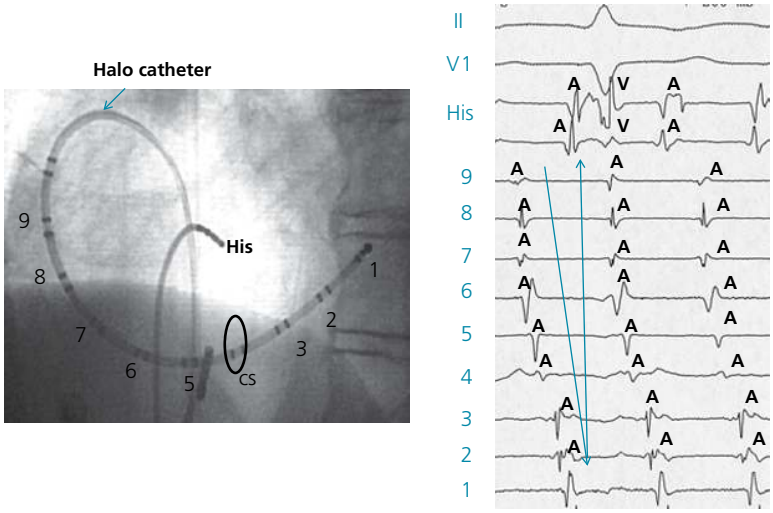

Figure 15.16 Another example of atrial flutter mapping across the right atrial halo catheter (electrodes 1–9). The fluoroscopic view is an LAO view, which provides an en-face view of the RA and splays the plane of the halo catheter, making it appear like a C or circle (as opposed to RAO view, which is aligned with the halo catheter plane and shows it in profile, Figure 15.12). Note how the atrial activity spreads from 9 to 1 and His in a counterclockwise fashion. Courtesy of Paul Lelorier, MD.

X. Mapping for ablation

Typically, in order to be mapped, an arrhythmia must be induced. Reentrant arrhythmias are induced and terminated with programmed electrical stimulation. Pacing at short cycle lengths (from A or V, depending on what arrhythmia one is trying to induce) decreases the refractory period of normal myocardial tissue and increases the conduction speed. This allows premature impulses to reach the reentrant circuit earlier, which increases the chance of initiating the reentrant arrhythmia. Pacing is performed at a fast and fixed cycle length for a number of beats, e.g., 8 beats (***steady pacing train S1***). Then, 1, 2, or 3 extrastimuli may be introduced at the end of pacing, at a short interval called the "coupling interval," shorter than the pacing cycle length (***extrastimulus technique, S2–S3–S4***). Alternatively, pacing may be done at progressively shorter cycle lengths (***incremental pacing S1***). It is easier to induce reentry when the difference in refractory period

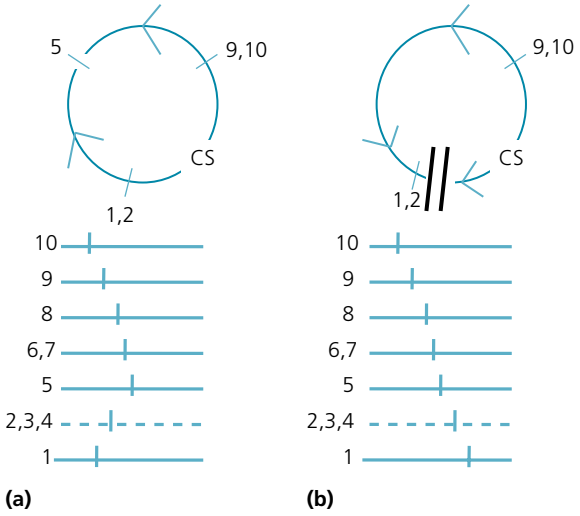

Figure 15.17 **(a)** Normal atrial activity along the halo catheter when one paces from the CS catheter (*in the absence of ongoing atrial flutter*). Note the bidirectional conduction into the upper and lower RA. **(b)** After ablation of the CTI, a conduction block occurs along the CTI, hence CS pacing generates a single propagating wavefront with sequential activation from 10 to 1. Additionally, pacing from the other side of the CTI block, at the *low lateral RA*, would elicit a single wavefront from 1 to 10. This is the ***bidirectional block***.

between the 2 arms of the reentry is large (*tachycardia zone*) and when the conduction velocity is very slow across part of the reentry (*excitable gap*). Also, ***the closer the catheter is to the reentrant circuit, the easier it is to induce or interrupt reentry with extrastimuli***. This is similar to quickly throwing a ball through a revolving door. The ball is the extrastimulus, the revolving door is the reentry. The closer one is to the door, the more likely it is for the ball to enter and entrain the revolving door. Furthermore, the slower the revolving door, the more likely it is for the ball to enter it. In fact, *the ability to induce an arrhythmia from one site often implies that the reentrant circuit is close to that site; this is a useful first step in mapping*. Pacing from various locations may be attempted to induce the arrhythmia, as this increases the likelihood of being close to the reentry. *SVT that is readily induced or interrupted with ventricular pacing is likely AVRT (AVNRT or AT is much less likely to be induced with ventricular pacing)*.

Being able to induce an arrhythmia from one site often implies that this site is part of the reentry loop or close to it. For example, if AVRT is more easily induced from LA than RA, a left-sided bypass is probable; inducing AT with LA pacing often implies left atrial origin.

In general, the functional reentry of AVNRT and atrial flutter is more difficult to induce than anatomical reentry, such as scar reentry or AVRT. Automatic arrhythmias (such as a subset of ATs) cannot be induced by programmed stimulation.

After inducing the arrhythmia, or if the arrhythmia is spontaneously present, the first step is to analyze the sequence of activation in order to diagnose the type of arrhythmia (Sections IV-VIII). Then, one may use A or V pacing to see how it affects the arrhythmia, and thus see if the atrial or ventricular myocardium is required for reentry.

Afterward, several types of mapping are performed to fine-tune the type and exact origin of the arrhythmia.

Pacing for the differential diagnosis of SVT

A short RP tachycardia (V–A interval) may be AVNRT, AVRT, or atrial tachycardia with a long AV conduction. The site of earliest A activity helps distinguish those tachycardias (Figure 15.10). Additionally, one may pace the ventricle then pace the atrium and see how this affects the tachycardia:

i. When ventricular pacing does not disrupt A activity, i.e., when A activity continues at the same rate, unaffected by V pacing, the reentry cycle of the SVT is not dependent on the ventricles → it is either AVNRT (nodal reentry) or atrial tachycardia. It is not AVRT.
ii. When atrial pacing does not disrupt V activity and the tachycardia, the reentry cycle is not dependent on the atria → it is AVNRT or VT.
iii. **As per (i) and (ii), when pacing dissociates A and V, a diagnosis is implied. However, when pacing one chamber entrains the other chamber, a specific diagnosis is not implied, and additional features are used.** Pacing the ventricle may entrain the atria in AVNRT via penetrating the AVNRT loop and accelerating it; upon cessation of pacing, the tachycardia resumes at its baseline rate. In this case, the junction between pacing and the tachycardia helps make the diagnosis. In AVNRT, the junction is a V–A–V–A junction, the first V and A being related to pacing, while the second V and A are related to the loop of the tachycardia. The V–V interval at this junction is longer than the V–V interval during AVNRT (long post-pacing interval, as the V pacing site is distant from the AV node reentrant circuit) (Figure 15.18).

In AVRT, the atria may get entrained during V pacing, through the AVRT loop, with the same pattern and sequence of atrial activation as during AVRT. The junction between pacing and the tachycardia is a V–A–V–A junction. However, unlike AVNRT, the V–V interval at this junction (post-pacing interval) approximates the V–V interval of the AVRT or is within 115 ms of it. This is because the ventricular pacing site is closer to the reentry circuit than in AVNRT.

In atrial tachycardia, the atrium may get entrained with V pacing without affecting the atrial focus or loop. Upon cessation of pacing, the A following the last paced V cannot descend down the AV node as it is still refractory. The atrial focus starts spreading again and atrial tachycardia resumes, causing a V–A–A–V junction. A pseudo V–A–A–V may occur in atypical fast-slow AVNRT, because the retrograde A

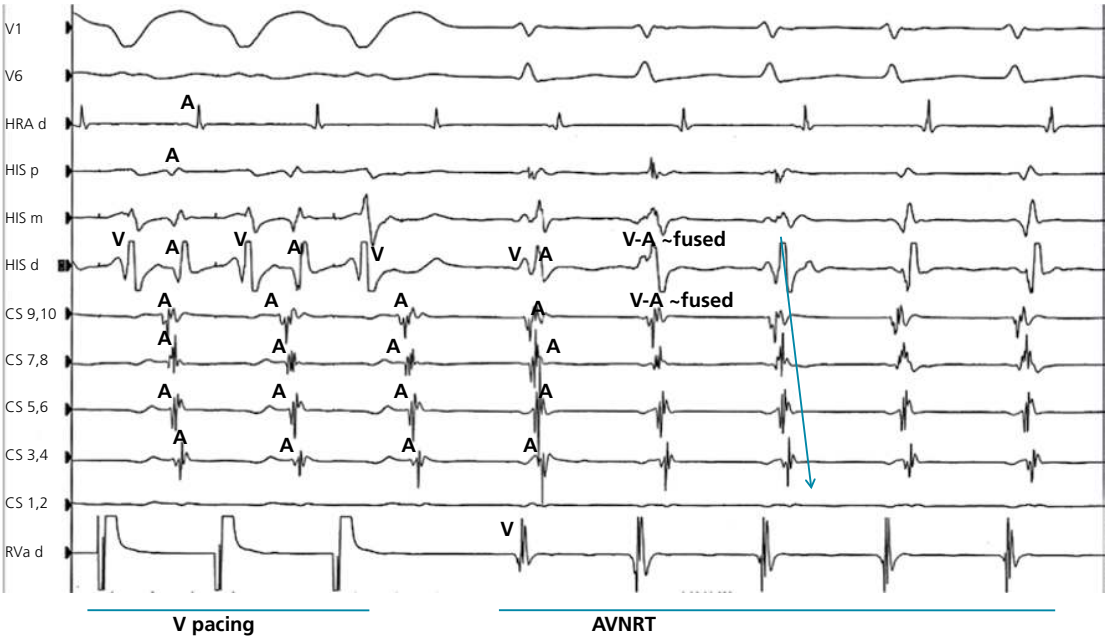

Figure 15.18 Ventricular pacing in a patient with AVNRT. Always start by aligning QRS complexes on the ECG with V complexes on all channels. The remaining complexes are, by default, A complexes. During RV pacing, the ventricle captures the atria retrogradely through the AVNRT loop. When pacing is stopped, the AVNRT loop resumes at its prior speed. The junction between pacing and the tachycardia is V–A–V–A, and the V–V interval at the junction (post-pacing V-V interval) is longer than the tachycardia cycle length (vs. equal to it or within 115 ms of it in AVRT). Outside pacing, note how the V and A almost occur simultaneously, with the earliest A being in the His, followed by CS then RA (direction of the *arrow*). V and A are almost fused together when V and A activations are initiated from the AVNRT loop, which is different from when RV is paced, where a clear interval is seen between V and A.

Conversely, in AVRT: (i) VA interval is >70ms; (ii) the sequence of retrograde atrial activation during V pacing may mirror that of the tachycardia; (iii) post-pacing V–V interval is ≤ tachycardia cycle length + 115 ms.

conduction is so slow that the VA interval may be longer than the paced V-V interval; this makes the last 2 A waves resulting from the last 2 paced V beats appear adjacent (VVAA).

Commonly in AT, the atria cannot be entrained from the ventricle as they continue to be activated by the AT focus. AV dissociation is created in this case. In AVRT and AVNRT, pacing usually enters the tachycardia reentry loop and either entrains it or breaks it. Occasionally in AVNRT, V pacing does not penetrate the loop, which creates AV dissociation (as the atria continue to get retrogradely activated by the loop).

Activation mapping

This addresses the *site of earliest activation* in relation to various RA, RV, His, and CS catheter electrodes, ± LA and LV catheters, after inducing the arrhythmia. The site of earliest activation during the arrhythmia corresponds to the location of the reentrant circuit. For example:

- In atrial tachycardia, the localized atrial electrogram at the site of earliest activation just precedes the ECG P wave.
- In VT, the localized ventricular electrogram at the site of earliest activation just precedes QRS.
- In mapping accessory pathways during orthodromic AVRT, look for the site of earliest A activation, i.e., see which part of the RA catheter or CS catheter (posterior septum, LA) is activated soonest after QRS. *This may also be performed without inducing AVRT*:
  - Pace the ventricle and look for the site of earliest retrograde atrial activation (concentric vs. eccentric atrial activation).
  - In antegrade accessory pathway, one may pace the atrium during sinus rhythm and see which part of the CS or RV catheter is activated first after A wave.
  - With atrial pacing at the site of the bypass tract, the A–V interval is very short, typically <60 ms. Also, the closer A pacing is to the bypass tract, the more pre-excited the electrocardiographic QRS is.
  - When the baseline QRS is pre-excited, V recording at the bypass tract shows a V wave occurring earlier than the electrocardiographic QRS.
  - A small sharp bypass potential may also be recorded at the site of the bypass tract.
  - In addition to the standard catheters, a catheter positioned across the tricuspid annulus and capturing both the A and V deflections may be used for mapping when a right-sided bypass tract is suspected (the shortest AV interval corresponds to the location of the bypass tract).

Entrainment mapping and post-pacing interval (see Figures 15.19, 15.20)

Let us take the example of an ongoing reentrant atrial tachycardia. After localizing the site of earliest activation, the atrium is paced from the electrode positioned at that site at a cycle length 20–50 ms faster than the tachycardia cycle length (*entrainment pacing*). The pacing is then interrupted. An interval between the last paced A wave and the post-pacing A wave that is equal to the tachycardia cycle length, as measured through the pacing electrode, confirms that pacing was performed from within the reentrant circuit. If the atrium was entrained from outside the reentrant circuit, the post-pacing interval will be equal to the tachycardia cycle length plus twice the transit time between the pacing focus and the reentrant circuit (Figure 15.19).

Additional features: (1) the morphology of the paced A wave and the tachycardia A wave are compared; if pacing was performed from the reentrant circuit, the morphologies are often similar; (2) pacing from within the reentrant circuit produces the same pattern of atrial

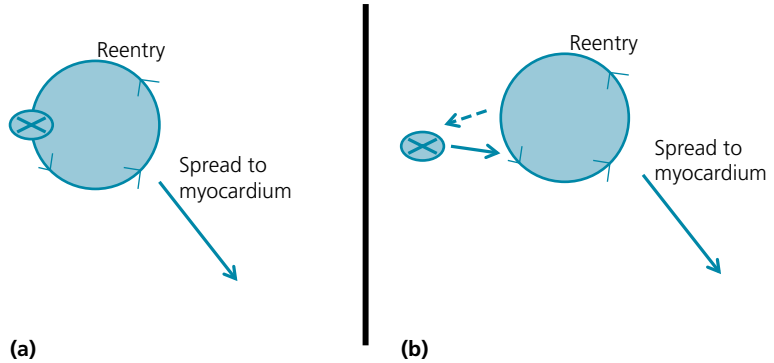

Figure 15.19 The reentry circuit is shown as a circle, the pacing point is shown as an X. **(a)** Entrainment pacing from inside the reentry circuit. After cessation of pacing, the reentry cycle continues at its own, slightly slower speed, and cycles back to the pacing point at about the same delay as the baseline reentry duration. Post pacing interval (PPI) ≤ tachycardia cycle length (TCL) + 20 ms. **(b)** Entrainment pacing from outside the reentry. After interruption of pacing, the reentry cycle continues at its own speed, and reaches the pacing point at a duration that equals baseline reentry time + time to the pacing site (*dashed arrow*). The post-pacing interval equals the tachycardia cycle length (reentry time) plus the time between the pacing site and the reentry (and back) (*arrows*).

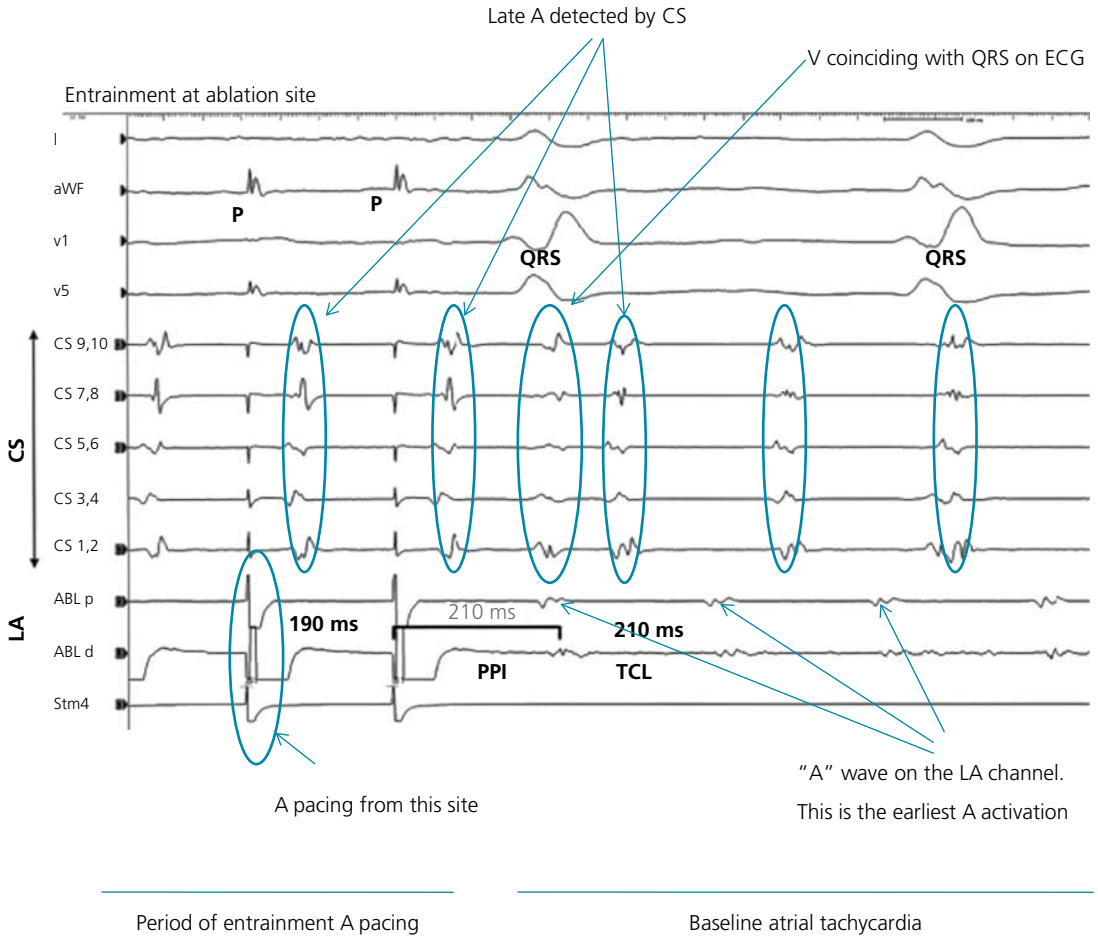

Figure 15.20 Entrainment of atrial tachycardia. The site of earliest A activation was identified to be in the LA, at the level of the LA electrode (non-paced tracings in the second half of the figure). Pacing from this early site accelerates the tachycardia and the post-pacing interval (PPI) approximates the tachycardia cycle length (TCL). In addition, pacing from this site reproduces the same sequence of atrial and late CS activation as the spontaneous tachycardia. Reproduced with permission of Elsevier from Markowitz SM, Nemirovsky D, Stein KM, et al. Adenosine-insensitive focal atrial tachycardia. J Am Coll Cardiol 2007; 49: 1324–33.

activation as the tachycardia; for example, in typical atrial flutter, overdrive pacing from the isthmus will produce the same zigzag sequence of activation as spontaneous atrial flutter.

This technique is useful for localizing the reentrant focus in AT and VT. It is also useful for atrial flutter, whether it appears isthmus-dependent on the halo and CS catheters (pace from the isthmus), or non-isthmus-dependent (pace from the presumed RA or LA flutter circuit site). Macroreentrant atrial flutter has no discrete site of earliest activation, as the atria display a continuous circular pattern of activation; yet, entrainment mapping and PPI remain useful for localization.

Pace mapping

For mapping of VT, pace the appropriate ventricle from various locations, seeking the location that exactly reproduces the QRS morphology of the VT. This location would be very close to the reentrant circuit.

Fractionated electrogram mapping

A portion of the reentrant circuit has a slow conduction, a prerequisite for reentry. This site of slow conduction is identified by a low amplitude, fractionated signal. This mapping can be performed during sinus rhythm.

Note that fractionated electrograms have a different significance in different arrhythmias. In VT, fractionated electrograms are seen over the area of slow conduction, i.e., the area that is critical to the maintenance of reentry; this is the area that should be ablated. In AF, fractionated electrograms signify continuous electrical activity and are actually microreentrant circuits.

XI. 3D electro-anatomical mapping

The Ensite NavX system consists of 3 pairs of patches placed around the patient's chest (front, back and sides) sending electrical currents in different directions through the chest. The analysis of voltage and impedance of thoracic structures allows the following ([1] and [2] correspond to anatomical mapping, while [3] is electrical mapping):

1. **Identification of the catheters** (mapping or ablation catheters) and real-time 3D display of the position and movements of all catheters and electrodes, without any need for fluoroscopy.
2. **3D construction of the cardiac anatomy.** This is done by sequentially moving a mapping catheter within a cardiac chamber and repeatedly touching its endocardial surface; the contact is recognized by the system and allows a fast point-by-point tracing of the chamber's contour. The operator assesses EGMs during the chamber's construction to confirm the catheter position, labels the chamber, and specifically enters some locations and labels them, such as His and coronary sinus, and specifically enters complex locations, such as pulmonary veins (guided by fluoroscopy and EGM).
3. **EP activation mapping.** The system captures the electrical activity from one or more designated mapping catheters moving across the endocardial surface, often with high electrode density. The timing of each point's activation is referenced to one selected EGM or ECG lead. This allows the eventual creation of an activation map that is color-coded, red being the area of earliest activation (in msec). As such, during an ongoing arrhythmia, the system identifies the site of earliest activation, which corresponds to the site of origin of a focal or microreentrant arrhythmia. This is *activation mapping* (Figure 15.21). The catheter can also identify zones of low voltage (scar, in red), and ablation sites may be tagged:

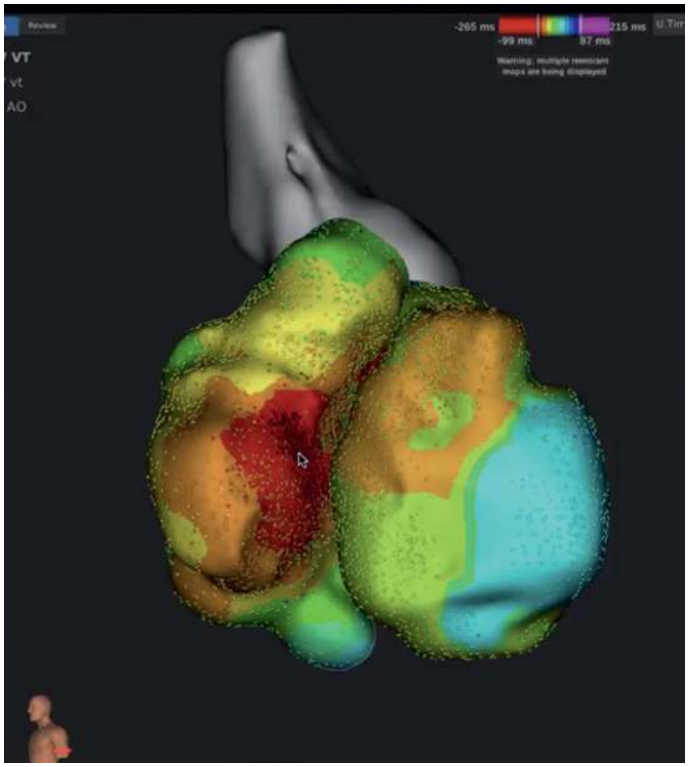

Figure 15.21 Activation mapping of VT. The red area *(arrow)* is the zone of earliest activation. It is in the RV, next to the septum. The manikin's orientation at the bottom left indicates in what direction we are looking at the heart: here, we are looking almost left laterally. If the manikin's back was shown, we would be looking at the heart from a posterior orientation.

this is *voltage mapping*. Some special catheters can reconstruct endocardial activation without touching the endocardium (non-contact mapping; this is achieved with balloon or basket catheters with high electrode density).

Another system uses magnetic fields delivered from beneath the patient's table (CARTO). Overall, these systems allow a faster and more precise delineation of arrhythmia origin, and a more limited use of fluoroscopy while displaying superior, 3D images of cardiac geometry and catheters. They may be used in simple or complex arrhythmias (AVNRT, WPW, AT, VT and AF). In addition, these systems have the capacity to integrate images from a pre-acquired cardiac CT, merging them with the anatomic mapping to improve the spatial accuracy, particularly for AF ablation.

I. Action potential (see Figures 16.1, 16.2)

II. Action potential propagation and mechanisms of arrhythmias

Two features characterize the propagation of the action potential: (1) how fast it propagates, i.e., conduction velocity; and (2) how fast it recovers and accepts new impulses, i.e., refractory period. Some tissues, like the slow AV nodal pathway, have a slow conduction yet a fast refractory period (in comparison to the fast AV nodal pathway). Other tissues, like the accessory pathway, have a fast conduction but a slow refractory period (in comparison to the AV node).

An arrhythmia may result from the following mechanisms:

1. *Reentry* (the most common mechanism, shown in Figures 16.3–16.6).
2. *Increased automaticity*. In this case, atrial or ventricular myocardial cells develop abnormal pacing capacity with spontaneous diastolic depolarization (e.g., accelerated idioventricular rhythm). Alternatively, after a pause, latent pacemaker cells may start firing in phase 4 (e.g., ventricular escape rhythm). Like sinus tachycardia, which is an automatic rhythm, an automatic arrhythmia generally displays a warm-up phenomenon at onset and warm-down phenomenon at offset.
3. *Triggered activity secondary to afterdepolarizations*. Afterdepolarizations are depolarizing oscillations in membrane potential that occur during the late part of phase 3 repolarization (early afterdepolarization, EAD) or during phase 4 (delayed afterdepolarization, DAD). If the afterdepolarization reaches a threshold potential, arrhythmia may be initiated (Figure 16.7). Afterdepolarization, whether EAD or DAD, is related to excessive intracellular accumulation of calcium. EADs are mainly seen during a very prolonged repolarization that allows spontaneous calcium release from the sarcoplasmic reticulum (e.g., after a pause or bradycardia). DADs, on the other hand, are promoted by a fast heart rate rather than a pause; the fast heart rate impedes reuptake of calcium into the sarcoplasmic reticulum, which increases intracytosolic calcium accumulation and thus the amplitude of DADs.

EAD-triggered activity may be due to a congenital or acquired long QT syndrome, electrolyte disturbances, or antiarrhythmic drugs. Automaticity and DAD-triggered activity are generally due to ischemia, catecholamine excess, hypoxia, acid–base disorders, or calcium overload from digoxin toxicity. Automaticity may also be due to cavity stretch.

A premature ventricular or atrial complex results from the same 3 mechanisms. In patients with heart disease, a change in sinus rate may create a ventricular reentry around the abnormal myocardial tissue, which could be isolated (PVC) or could become sustained into VT. PVC may also result from triggered activity arising from the abnormal tissue, which is a tissue prone to spontaneous depolarization, or fractionated late diastolic potential (a form of automaticity). Overall, the morphologies of the PVC and VT are frequently similar. Idiopathic PVCs arising from the RVOT are generally due to triggered activity.

All arrhythmias can exhibit a warm-up phenomenon, wherein the rate quickly accelerates upon initiation, but this is most characteristic of automatic tachycardias (such as automatic atrial tachycardia).

Induction of arrhythmias in the EP lab – *Reentry* can be initiated by pacing or by premature impulses. Reentry can be terminated by overdrive pacing or by premature impulses that enter the reentrant circuit and get blocked inside it, breaking it.

Conversely, pacing and premature impulses are not effective in initiating or terminating *automatic tachycardias*, which are thus difficult to induce in the EP lab. *In fact, in the EP lab, automatic tachycardia is, characteristically, a tachycardia that cannot be initiated or terminated*

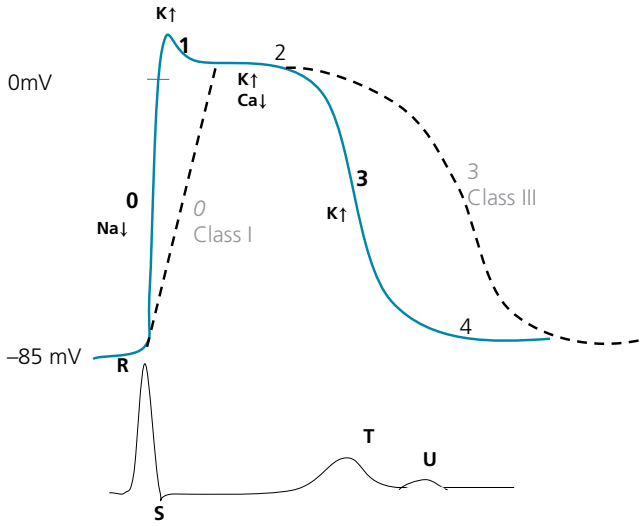

Figure 16.1 Action potential of atrial and ventricular myocardium. Phase 0 corresponds to myocardial depolarization and QRS on ECG, phases 1 and 2 (plateau) correspond to the ST segment, phase 3 corresponds to the T wave, and phase 4 corresponds to the TP segment. Phases 1–3 correspond to repolarization, during which the cells are refractory to a new depolarization (refractory period). All myocardial cells reach the same phase 2 plateau level around the same time, and thus the ST segment is normally a flat isoelectric segment without intramyocardial gradient. Conversely, the T wave is like the bell curve of the repolarization of all myocardial cells, some of which repolarize early, and some late. The width of T and the length of QT indicate, in a way, how heterogeneous and dispersed the repolarization is, and thus the risk of arrhythmia. The normal U wave is a diastolic wave related to the mechanical stretch of the myocardium in phase 4 (diastole). The abnormal U wave could be part of phase 4 (delayed afterdepolarization, DAD), or part of phase 3 in patients with prolonged repolarization (early afterdepolarization [EAD] seen in patients with prolonged QT). In the latter patients, the U wave is actually a T2 repolarization wave; their QT is a QTU interval, and the distinction between T and U may not be very relevant in these patients.

The depolarization of one cell causes the sodium channels of adjacent cells to open and depolarize. There are two properties of electrical propagation: **(1) conduction velocity**, which depends on phase 0; **(2) refractory period**, which depends on the duration of phases 2–3. A reduction in the steepness of phase 0 (dashed phase 0, class I AAD) leads to slower velocity and wide QRS, while a prolonged phase 3 (dashed phase 3, class III AAD) leads to a prolonged QT interval.

Phase 1 uses I_{Kto} (transient outward K channel), phases 2 and 3 use outward I_{Kr} and I_{Ks}, and phase 4 depends on inward I_{K1} and on Na/K pump, which pumps 3 Na out and 2 K in, creating the negative baseline intracellular potential (the cell potential is close to the equilibrium potential of K).

The action potential duration is increased at lower heart rates, and is reduced with tachycardia or β-adrenergic stimulation. It is mainly the duration of phase 3 that is affected with changes in heart rate.

↓ indicates the entry of the ion inside the cell; ↑ indicates the exit of the ion.

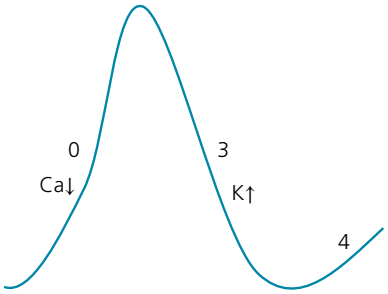

Figure 16.2 Action potential of the SA and AV nodes is characterized by a spontaneous depolarization in phase 4. In addition, phase 0 is characterized by calcium rather than sodium entry, explaining the effect of calcium channel blockers on slowing the SA and AV node. Phase 0 is also slower than phase 0 of the atrial and ventricular cells, thus explaining the slower conduction through the AV node. Phase 4 depends on the funny K and Na channel (If). Spontaneous phase 4 depolarization may be seen in ischemic atrial or ventricular cells (increased automaticity).

with programmed electrical stimulation. Also, as opposed to reentry, automatic tachycardias do not respond well to DC cardioversion, as the automatic focus keeps firing independently of the surrounding electrical stimuli. Note, however, that some reentrant rhythms—particularly functional reentry—may be difficult to induce as well.

Triggered activity can be spontaneous like automaticity, resulting from leakage of positive ions into the myocardial cell, but can also be induced with a premature beat or with a pause, particularly a pause introduced after fast pacing. Similarly to reentry, it may get entrained with pacing or terminated. Thus, during EP study, triggered activity resembles reentry. Since it depends on calcium channels, triggered activity may respond to calcium channel blockers (Table 16.1).

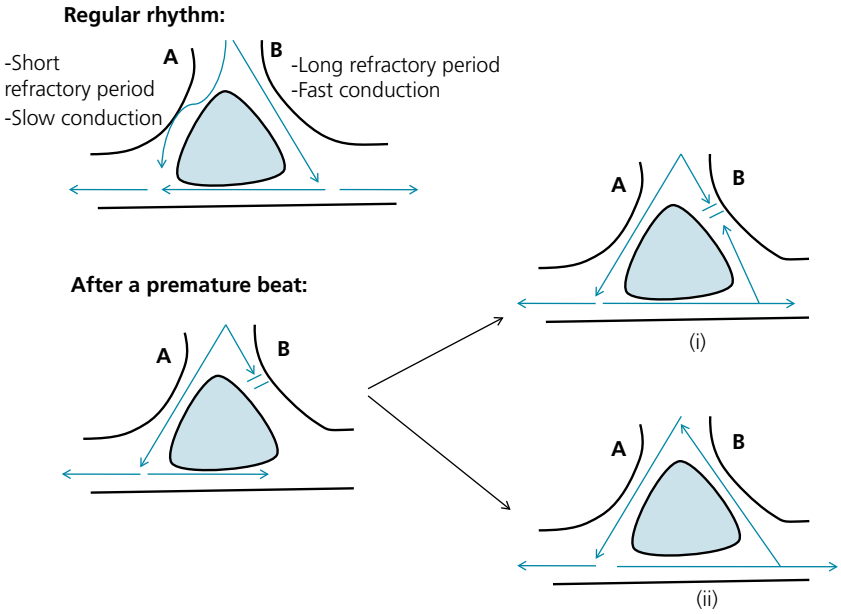

Figure 16.3 Illustration of reentry as a mechanism of tachyarrhythmia. In order to have reentry, adjacent myocardial areas (A and B) need to have **different refractory periods *and* different conduction velocities, separated by an anatomical or functional barrier. The pathway with the shorter refractory period needs to have a slower conduction.** The larger the difference in refractory period between A and B, the easier it is to initiate an arrhythmia; this difference between refractory periods is called the ***tachycardia zone***. The slower the conduction velocity in A, the more likely it is to sustain the arrhythmia (slow conduction leads to a large ***excitable gap*,** Figure 16.4).

When the rhythm is regular, the electrical activity spreads through both areas simultaneously (*top*). After a **premature beat**, region B is still in its long refractory period, but region A has recovered (*lower left*). The electrical activity spreads through region A, then meets the tail end of region B; at that time, if region B has not recovered from its refractory period, arrhythmia does not occur (i). Since A conducts slowly, region B may well recover from its refractory period, allowing conduction to spread retrogradely through region B (ii). Eventually, this retrograde impulse reaches A faster than the electrical activity originating from the sinus node reaches A. Since A has a short refractory period, the impulse may propagate through A and stimulate the whole cardiac chamber again. Thus, this circle keeps repeating itself, stimulating the myocardial tissue at a rate faster than normal: this is the reentrant tachyarrhythmia.

These areas of slow conduction and different refractory period are seen around a scar (prior infarct, fibrosis, cardiomyopathy), an ischemic area, or a functionally slow area (crista terminalis for atrial flutter, slow pathway of AVNRT) or fast area (accessory pathway of AVRT). Scarred myocardium is an anatomic barrier for reentry. **The peri-scar myocardium has a slow conduction, but shorter action potential and shorter repolarization than the surrounding tissue.** An area is functionally slow when fibers in that area are organized transversally rather than longitudinally; electrical activity spreads more slowly transversally than longitudinally through gap junctions.

PVC or ventricular pacing may have 3 effects on a reentry that involves the ventricle (VT, AVRT) (Figure 16.5):

- The PVC or ventricular pacing may conduct into the reentry and block it.
- The PVC or ventricular pacing may enter the reentrant circuit and become part of it. Pacing at a rate faster than the tachycardia cycle length may actually entrain the tachycardia, if the *refractory period is short enough and the excitable gap large enough to prevent pacing from being blocked in the reentry circuit*. This is evident on the ECG by the fact that the interval between the last paced beat (or PVC) and the next QRS, i.e., post-pacing interval, is equal to the R–R interval of the tachycardia (if pacing is close enough to the reentrant zone, which is usually the case if one can engage the reentry). This is called *resetting of the tachycardia*. Since fast pacing may shorten the cycle length of the tachycardia and accelerate it, antitachycardia pacing may be risky.
- In the case of VT microreentry, the ectopic or pacing focus may be far from the reentry, so that it conducts to the ventricles and prevents most or all of the ventricular myocardium from being activated through the reentry. The reentry, however, keeps looping independently, unaffected by the faraway pacing, with a post-pacing interval longer than the tachycardia cycle length. This does not usually happen with AVRT, where the reentry involves a large part of the ventricular myocardium; pacing either conducts through the AVRT or breaks it.

Ventricular pacing frequently fails to penetrate the reentry loops of atrial tachycardias, as these are remote from the ventricle. Usually, their cycle will not be affected, they keep looping independently of the QRS at their own pre-existing rate and atrial activity often becomes dissociated from ventricular activity. This AV dissociation may also occur with AVNRT when ventricular pacing fails to entrain its circuit; in this case, the nodal loop remains unscathed, dissociated from ventricular activity, and it retrogradely activates the atria (Figure 16.8).

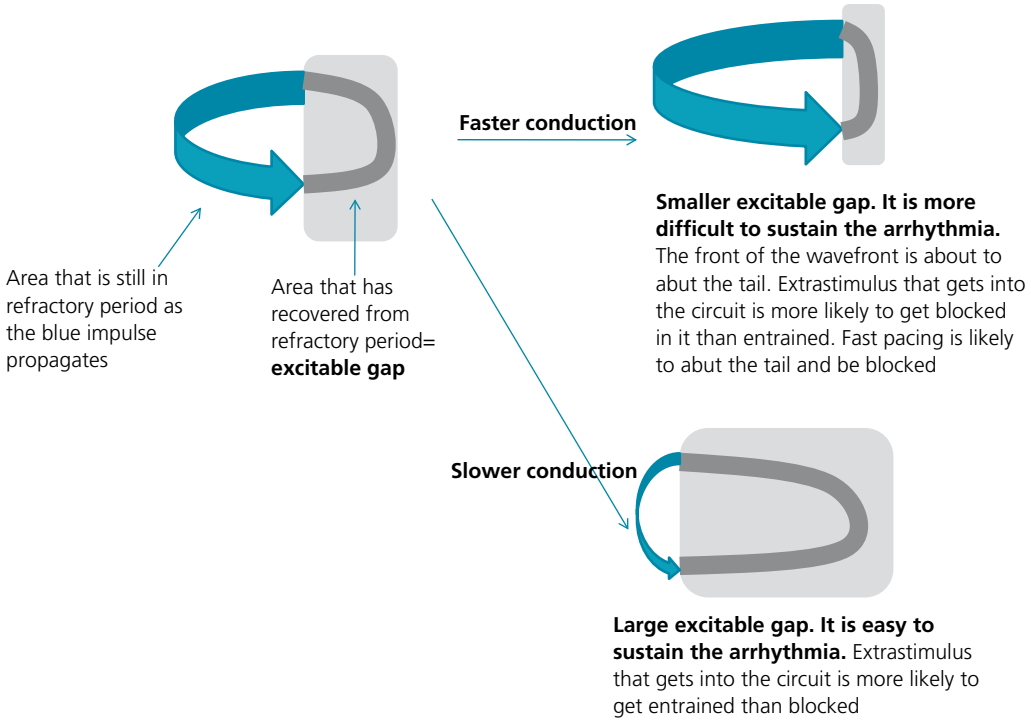

Figure 16.4 Slowing the conduction across the reentrant cycle reduces the area that is refractory per unit of time, i.e., increases the area that is excitable per unit of time, and allows the reentry to be sustained. The maintenance of the arrhythmia relies on (i) slow conduction, (ii) short refractory period, and (iii) large circuit (e.g., large scar, large RA in atrial flutter). A fast conduction combined with a long refractory period makes the 2 ends of the propagating wavefront (*blue arrow*) abut, meaning that the fast propagating wavefront reaches an area that is still in refractory period, which terminates the reentry. *This may happen when fast pacing engages the reentry loop and abuts the tail of the propagating wavefront*.

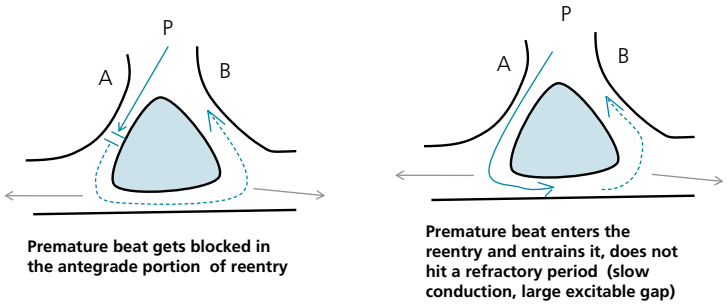

Figure 16.5 Termination of reentrant arrhythmias. The *dashed arrows* represent the wavefront of reentry that is in refractory period, the *straight blue arrows* represent propagation of a premature complex or pacing (P). In a patient with sustained reentrant arrhythmia, appropriately timed pacing penetrates path A but gets blocked in it as the distal part of A is in refractory period. The wavefront of reentry will then get blocked as path A is now refractory. The reentrant cycle is thus broken. If this is AVNRT, it may end with QRS if A is fully penetrated before the block.

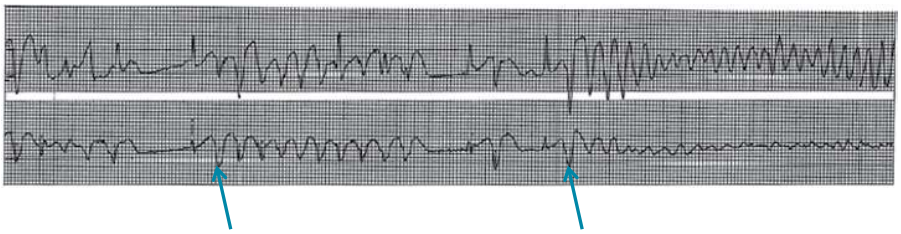
If pacing goes down A and progressively encounters tissue that has fully recovered (slow conduction), it will get conducted through the reentry cycle without breaking it.

Pacing may not be able to enter a refractory reentrant loop, which then keeps looping independently of its surroundings. Those surroundings may be activated through pacing (e.g., pacing the ventricle during VT), but the loop continues independently; when pacing is stopped, the loop restarts, activating the whole cardiac chamber.

III. General mechanism of action of antiarrhythmic agents

Antiarrhythmic agents act either by slowing the conduction across a reentry loop (particularly class I agents), or by increasing the refractory period (particularly class III agents):

1. Slowing the conduction is effective in suppressing the arrhythmia only when it creates an almost complete block across the reentry, allowing supraventricular activity to take over. Conversely, slowing the conduction without producing a block or lengthening the refractory period may, in fact, be arrhythmogenic by itself, as the myocardium becomes more frequently "free" from the refractory period and thus excitable. This increased excitable gap allows the arrhythmia to be sustained (Figure 16.4). Therefore, class Ia and Ic agents are typically avoided in patients prone to ventricular arrhythmias (low EF, CAD).



Reentry occurs when PVC hits a heterogeneous myocardium:

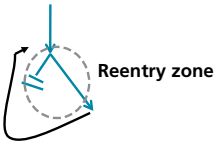


Figure 16.6 VF initiated by R-on-T phenomenon. In a patient with myocardial scar, myocardial disease, or ischemia, there is a ***heterogeneity of refractory periods across various myocardial areas.*** A PVC that occurs during T wave will encounter the refractory period of one area, but will conduct through another area, which initiates reentry.

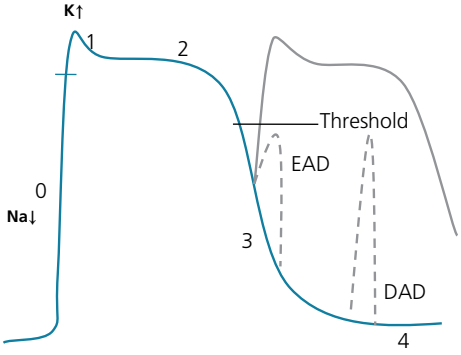

Figure 16.7 Once the EAD (early afterdepolarization) or DAD (delayed afterdepolarization) reaches a threshold, the sodium channels get activated and a second action potential is initiated.

Table 16.1 Differentiation of various mechanisms of arrhythmias.

	Reentry	Automaticity	Triggered activity
Induction and termination with pacing (= programmed electrical stimulation)	+	–	+
Catecholamine facilitation (isoproterenol)	+/–	+	+
After entrainment with pacing then interruption of pacing: post-pacing interval = tachycardia cycle length	+ if paced from the actual site of reentry (reentry resumes at its own speed)	–	+/–
Response to calcium channel blockers			+
Adenosine suppression of atrial arrhythmias	+/–	–	+

2. Increasing the refractory period halts reentry, as the propagating wavefront abuts an area that is refractory (Figure 16.4). Increasing the refractory period occurs through prolonging the repolarization. Caveat: *prolonging the repolarization* often exaggerates the *dispersion of repolarization*, which can initiate reentry cycles. In fact, the refractory period of some zones gets more prolonged than others, which widens the tachycardia zone, i.e., widens the difference in refractory periods between arms A and B in Figure 16.3. A prolonged repolarization may also trigger early afterdepolarizations. This proarrhythmic effect is seen with class III drugs, but less so with amiodarone, since the latter prolongs repolarization without exaggerating the dispersion of repolarization.

Class III antiarrhythmic drugs are K channel blockers (I_{Kr} channel). They block phase 3 of the action potential and thus increase the action potential duration and the refractory period and prolong QT (Figure 16.1).

Class Ic antiarrhythmic drugs are Na channel blockers (I_{Na} channel). They depress phase 0 and thus slow the conduction and may prolong the QRS but usually not the total action potential duration. *Class Ia* drugs slow the conduction through Na channel blockade but also prolong the action potential duration through some K channel blockade. *Class Ib* drugs shorten (rather than slow) phase 0 and subsequently shorten the repolarization and the refractory period; by shortening the refractory period across arm B, they narrow the difference

Figure 16.8 Narrow complex tachycardia. A wide complex is seen, likely PVC or aberrant PAC. The distance from the QRS that precedes this wide complex to the QRS that follows it is double the distance of the baseline R–R interval, implying that this complex does not interrupt the underlying tachycardia rhythm. Suppose the wide complex is a PVC. The fact that PVC does not affect the reentry implies that the ventricles are not part of the reentry cycle. This implies that the tachyarrhythmia is not AVRT. It can be AVNRT, wherein the nodal reentry continues independently of the atrial or ventricular activity, or atrial tachycardia, wherein the atrial microreentry or automaticity continues independently of ventricular activity.

In AVNRT, the reentry is in the AV node, and thus the atrial and ventricular myocardium are not required for reentry. Thus, PAC, PVC, or atrial or ventricular pacing does not necessarily disrupt the AV nodal reentry. Only if the atrial or ventricular extrastimulus propagates to the AV node at a particular time might the reentry cycle and the arrhythmia break. Also, in AVNRT, an occasional P or QRS may be dropped (antegrade or retrograde Wenckebach) but the tachycardia does not stop, indicating that the atria and ventricles are not required to maintain the tachycardia (≠ AVRT).

in refractory periods between arms A and B, thus narrowing the tachycardia zone, so critical for the initiation of reentry. Class Ib drugs also reduce automaticity, EAD, and DAD. They are mainly useful in acute ischemia; they minimally affect the normal tissue and have minimal effect on QRS and QT.

Class II drugs are β-blockers: they slow the conduction through the SA node and AV node without affecting the refractory period. In addition, they reduce automatic atrial and ventricular arrhythmias that are induced by ischemia or catecholamine excess (ACS, postoperative state, or sepsis). Catecholamine excess can lead to increased automaticity, triggered activity, and premature beats that initiate reentry in abnormal tissues.

Class IV drugs are calcium channel blockers. They slow the conduction through the SA node and AV node. They are also effective in triggered-activity atrial tachycardia and idiopathic VT.

β-Blockers and calcium channel blockers do not affect the Hisian and infra-Hisian conduction. Conversely, class I drugs do not affect the AV nodal conduction (except propafenone).

Digoxin inhibits the Na/K-ATPase, leading to increased intracellular Na and subsequent increase of intracellular Ca through the Ca/Na sarcoplasmic passive exchange, leading to its inotropic effect. It also increases vagal tone, leading to SA and AV nodal blocking effect. At toxic levels, calcium overload has a direct effect on the atrial, ventricular, and AV nodal tissue, leading to increased automaticity and delayed afterdepolarization.

Adenosine effects:

- Adenosine activates an outward potassium current ($I_{K,ADO}$), which leads to hyperpolarization of the *sinus node and AV node*, causing them to block conduction, thus terminating AVNRT, AVRT, and SNRT.
- Adenosine antagonizes the cardiac effect of catecholamines by inhibiting adenylcyclase, the enzyme that generates cAMP; thus, adenosine may terminate atrial or ventricular arrhythmias secondary to *catecholamine-triggered activity*.
- In the atrial tissue, the outward potassium current reduces the action potential duration, thus facilitating the induction of *reentrant* arrhythmias, such as AF, atrial flutter, or reentrant atrial tachycardia, in up to 12% of patients. Conversely, it may variably suppress reentrant atrial arrhythmias.
- Automatic atrial tachycardia may be transiently suppressed by the hyperpolarizing effect of adenosine, but owing to its incessant nature the tachycardia quickly resumes.

IV. Modulated receptor hypothesis and use dependence

Na and K channels go through various states: (i) resting state during phase 4, (ii) active/open state during the depolarization phase (Na channel) or the repolarization phase (K channels). Antiarrhythmic drugs have different binding capacity to these receptors depending on their state.

Drugs that mainly bind to the active state are more effective at fast heart rates (use-dependent), while drugs that bind to the resting state are more effective at slow heart rates (reverse use-dependent). ***Class I drugs are use-dependent and are more effective when the patient is actively having the tachyarrhythmia, while class III drugs are reverse use-dependent and are more effective in preventing the arrhythmia when the patient is in sinus rhythm***. Thus, class I agents are more effective in cardioverting than preventing AF, while class III agents may be more effective at preventing AF. Furthermore, the use dependency implies that the toxic effect of class I drugs, such as QRS widening and ventricular arrhythmia, is more likely seen during tachycardia; that's why stress testing is used to unveil toxicity after initiating class I therapy.

V. Concept of concealed conduction

Concealed conduction is a concept wherein blocked, non-conducted impulses that do not get recorded on the ECG (= concealed) manage to change the behavior of subsequent impulses. Concealed conduction is seen in the following situations:

- *Atrial fibrillation:* a relatively small proportion of AF waves fully conduct through the AV node, yet the non-conducted AF waves partially penetrate the AV node and make it refractory to subsequent waves. An increase in the number of AF waves leads to more frequent AV nodal penetration and refractoriness and a slowing of the ventricular rate. This explains why the ventricular rate in AF is generally slower and easier to control than the ventricular rate in atrial flutter (the faster atrial rate in AF leads to more concealed conduction across the AV node). This also explains why slowing the rate of the fibrillatory or flutter waves with class I antiarrhythmic drugs paradoxically increases the ventricular rate.

  The instantaneous rate in AF is inversely proportional to the instantaneous number of AF waves hitting the AV node.
- *Infranodal AV block:* an increase in the atrial rate with atropine worsens the infranodal conduction ratio.
- *A blocked premature His complex* does not leave any trace on the ECG, yet it prevents the conduction of the next sinus impulse through the His (still in refractory period), creating the impression of a Mobitz II AV block.
- *Deceleration-dependent bundle branch block*.
- In patients with first-degree AV block, a PVC may retrogradely depolarize the AV node prematurely, allowing early repolarization and full AV nodal recovery during the compensatory pause. The next sinus impulse conducts with a shorter PR interval. This is called "peeling back of the AV nodal refractory period" by the PVC.

VI. Specific examples of drugs (see also Chapter 10)

A. Class I

Class Ic drugs (flecainide, propafenone) are the class I drugs most commonly used in clinical practice. They are used for the treatment and prevention of atrial arrhythmias (AF, atrial tachycardia) in patients without any underlying structural heart disease. Class Ia drugs (quinidine, procainamide, disopyramide) are rarely used; disopyramide may be used as an antiarrhythmic and a negative inotrope in HOCM, while IV procainamide may be used in acute VT, acute AF, or pre-excited AF. Quinidine is used for short-coupled polymorphic VT, Brugada, and idiopathic VF. All class I drugs are preferably avoided in patients with a baseline QRS >120 ms, as they further impair infranodal conduction; they should be discontinued if QRS prolongs >25% after initiation of therapy. A stress test may be performed a week after therapy initiation to unveil QRS prolongation or arrhythmia with exercise/tachycardia. Note that all class I drugs have a *negative inotropic effect*.

Lidocaine is an intravenous class Ib that is only useful in ventricular arrhythmia, particularly VT secondary to acute ischemia.

In the CAST trial, the use of class Ic agents to suppress PVCs in patients with a history of MI and EF < 55% (mean 36% ± 10%) resulted in tripling of cardiac death secondary to arrhythmias and tripling of cardiac death secondary to MI and shock (~8% cardiac death at 10 months). This is related to their proarrhythmic effect (slowing conduction facilitates reentry), which increases sustained arrhythmias at baseline and even more so during exertional ischemia or MI. They raise defibrillation thresholds and may make VT/VF refractory to shock. The negative inotropic effect also contributes to the increased mortality and shock during MI. However, modern data suggest that they may be used in some structural heart diseases: (1) PVC-induced cardiomyopathy. (2) HFpEF and HFmEF, as suggested by EAST-AFNET4 trial. (3) Possibly stable CAD with normal EF, no MI <1 yr, and no ischemia. Ic drugs are absolutely avoided in patients with prior MI and low EF <55%, and in any CAD with ischemia.

- Class Ia and Ic agents slow the reentrant circuits, thereby reducing the rate of the fibrillatory AF impulses. The non-conducted atrial impulses partially penetrate the AV node and make it partially refractory to subsequent impulses (concealed conduction); thus, a reduction in the rate of atrial impulses allows more impulses to conduct through the AV node, which paradoxically increases the ventricular rate. Also, class I agents may organize AF into a slow atrial flutter with 1:1 conduction, again increasing the ventricular rate. Class I agents are ineffective in cardioverting atrial flutter and may actually allow it to sustain, as they slow the conduction across the large macroreentry, widening its excitable gap.
- Proarrhythmia should be considered whenever a patient on antiarrhythmic drugs presents with a new arrhythmia or even worsening of a pre-existing arrhythmia.

B. Class III (amiodarone, dronedarone, sotalol, ibutilide, dofetilide)

These drugs are proven efficacious for the treatment of atrial arrhythmias. Amiodarone and sotalol can be used for ventricular arrhythmias as well. Class III drugs prolong QT and are associated with a dose-dependent risk of TdP (~2% with sotalol or dofetilide, less so with amiodarone). They should be avoided in patients with QTc >460 ms at baseline (or >500 ms when QRS >120 ms), or if QTc increases by >15% or to >500 ms with therapy. The QT prolongation and risk of TdP are dose-dependent.

After initiating therapy with one of these drugs, patients should be hospitalized and monitored for 3 days with twice-daily ECGs (except amiodarone, where monitoring is often not necessary).

Specific examples of these drugs:

- *Amiodarone* mainly has class III and sympatholytic effects, but also class I and vasodilator effects. Acutely, amiodarone mostly causes a sympatholytic and class I effect; class III effect occurs later. Thus, the effect of amiodarone on ventricular repolarization is slow, with QT prolongation appearing at 4–10 days of therapy and peaking several weeks later. Also, in AF, the early effect is rate slowing (the effect on AF conversion being late).

  Amiodarone reduced total and arrhythmic mortality and progressive HF mortality in patients with ischemic or non-ischemic HF in the older GESICA trial, most of whom had NSVT. Amiodarone reduced arrhythmic death (but not total death) in the EMIAT and CAMIAT trials of post-MI patients with LV dysfunction. This was not shown in modern trials (SCD-HeFT), but as opposed to class I agents, amiodarone is a proven safe therapy in HF. Conversely, amiodarone significantly increased non-cardiac death in the AFFIRM trial, and non-significantly increased it in AVID (strong trend) and EMIAT trials.

Amiodarone prevents and treats atrial and ventricular arrhythmias in patients with or without underlying heart disease. It is available intravenously and orally.

- *Dronedarone* has a structure similar to amiodarone without the iodine moiety, and thus has reduced extracardiac side effects and a shorter half-life (1–2 days compared to 2 months). However, it is less effective than amiodarone in preventing AF.
- *Sotalol* has both class III and β-blocker effects; the β-blocker effect starts at low doses and is already half-maximal at 80 mg/day, while the class III effect starts at doses of 160 mg/day. Sotalol prevents AF, less effectively than amiodarone, and is mainly effective in AF associated with CAD (SAFE-T trial). Sotalol is also effective in preventing VT and shocks in patients with ICD.
- *Ibutilide* is an intravenous drug that acutely cardioverts AF.
- *Dofetilide* is efficacious in AF prevention. It has proven to be safe in HF and CAD (DIAMOND-CHF and DIAMOND-MI trials).

VII. Amiodarone toxicity

Thyroid toxicity

Amiodarone contains iodine and has the following effects on the thyroid system:

1. It inhibits the T4-to-T3 deiodinase. This leads to increased free T4, reduced T3, and increased TSH early on (first 3–6 months). This is a benign, normal phenomenon.
2. If the patient has a subclinical hypothyroidism, the excessive iodine delivered by amiodarone inhibits thyroid hormone synthesis. This is the Wolff–Chaikoff effect; normal individuals escape from the Wolff–Chaikoff effect, but not patients with thyroid abnormalities.
3. If the patient has an autonomous nodule or subclinical Graves disease, the thyroid autoregulation is disturbed and thus the excess of iodine leads to excessive thyroid hormone synthesis.
4. Amiodarone may lead to an inflammatory thyroiditis, with early hyperthyroidism, followed by normalization of the thyroid function in a few months. Radioiodine uptake study is not very helpful as it shows reduction of iodine uptake in thyroiditis but also in any patient taking amiodarone. It is suggested by elevated inflammatory markers (IL-6) and by thyroid ultrasound showing hyperemia.

If hypothyroidism is present at baseline or develops with therapy, amiodarone may still be used as long as levothyroxine therapy is provided and the thyroid function is closely monitored.

If hyperthyroidism develops, amiodarone should often be stopped. Due to the long half-life of amiodarone, the thyroid function will not improve for a few months. That is why it is acceptable to continue amiodarone for a few more days if necessary (e.g., VT). Hyperthyroidism is treated with β-blockers and thionamides; radioiodine therapy has no role in iodine overload states, and thyroidectomy may be necessary if thyrotoxicosis cannot be controlled. If thyroiditis is suspected, prednisone therapy is given for 1 month with subsequent taper; amiodarone therapy may be continued in this case.

Lung toxicity

Interstitial lung disease occurs at a rate of 0.5–1% per year. It may develop acutely in the first few days (rare), subacutely (weeks), or chronically. Acute and subacute presentations are febrile pneumonitis. The risk is likely higher if underlying lung disease, including COPD, is present, and if doses higher than 200 mg/day are used. Amiodarone lung toxicity often simulates pulmonary edema/heart failure progression. **Amiodarone toxicity should therefore be sought in any patient receiving amiodarone whose pulmonary function is not improving with diuresis and/or antibiotic therapy.** The earliest and most sensitive abnormality is a reduction of diffusion capacity (DL_{CO}). Therefore, it is important to perform a lung function study before initiation of therapy. This study should then be repeated every year if symptoms occur.

No diagnostic test is specific for amiodarone lung toxicity. Mononuclear cells on bronchoalveolar lavage are consistent with amiodarone therapy and do not necessarily imply toxicity. The clinical context, a refractory pulmonary process, and DL_{CO} are most useful for diagnosis. The lung toxicity is reversible only if diagnosed early, and generally improves with steroids.

Neuropathy, ataxia (dose-dependent), photosensitivity with blue skin discoloration corneal microdeposits (universal finding, benign), **optic neuropathy** (rare). Patients treated with amiodarone should receive chest X-ray, TSH, and liver function panel at baseline and every 6–12 months. Pulmonary function testing is done at baseline and is repeated as needed.

VIII. Effect on pacing thresholds and defibrillation thresholds

Class I agents and amiodarone increase defibrillation threshold, i.e., increase the energy requirement for defibrillation of VT/VF. Class I agents also increase pacing threshold, which may lead to a loss of capture, particularly in case of toxicity (e.g., propafenone toxicity).

1. ACUTE PERICARDITIS

I. Causes of acute pericarditis

The 4 most common causes are:

1. *Viral or idiopathic pericarditis* is the most common form of acute pericarditis (80–90%).
2. *Metastatic cancer*, where a moderate or large effusion is usually seen. Pericarditis, even without effusion, may be a marker of occult cancer: in a Danish registry, 6% of individuals with pericarditis went on to be diagnosed with cancer within 12 months.[1]
3. *Connective tissue disease* (lupus, rheumatoid arthritis, scleroderma).
4. *Infections* (HIV, tuberculosis, bacterial, fungal, Lyme disease). In patients with HIV infection, pericarditis may be secondary to HIV itself or to a concomitant infection, particularly tuberculosis.

Other common causes of pericarditis, occurring in specific contexts:

1. *Uremia*: an effusion is seen in >50% of patients with uremic pericarditis.
2. *Radiation*: acute pericarditis, with or without effusion, may develop during radiation therapy or soon afterward (<1 year). It often resolves, but ~20% of patients may progress to chronic pericarditis.[2] Conversely, late pericardial disease (>1–2 years) is often constrictive pericarditis, with or without effusion.
3. *Post-MI*: pericarditis can occur early post-MI or late (Dressler syndrome).
4. *Post-cardiac surgery*: pericarditis may occur early (in the first few days) or late (between 2 weeks and 2 months, similarly to Dressler syndrome and called *post-pericardiotomy syndrome*).
5. *Trauma* (blunt or penetrating).
6. *Post-cardiac injury*: catheter ablation, pacemaker implantation, LAA occlusion, cardiac surgery, even PCI. This was the *second most common etiology of acute pericarditis* in a modern registry.[3]

II. History and physical findings

A. Chest pain

- Chest pain is sharp, usually not constricting, and pleuritic, meaning it worsens with deep breath, cough, and certain positions (specifically lying down for pericarditis). It usually has a rapid, sometimes abrupt, onset. It radiates to the trapezius ridge (a typical radiation of pericarditis) and/or the left arm.
- Positional feature: pain is relieved by leaning forward and worsens with lying down, swallowing, or moving (including exertion), as all this worsens the friction of inflamed pericardial layers.
- Fever is often seen in pericarditis with inflammatory phenotype. Concomitant systemic findings may suggest a neoplastic, tuberculous, or autoimmune disease.

B. Friction rub

- The rub is due to the friction of the inflamed visceral and parietal pericardial layers. It is heard during systole, early diastolic filling, and atrial contraction (3 components). It is best heard at the left lower sternal border with the patient leaning forward. A sound with a single component is less specific for pericarditis as it may actually represent a murmur.
- The rub is dynamic (it comes and goes), and all 3 components may not be evident all the time, hence the importance of frequent examinations when pericarditis is suspected. It is heard in ≤1/3 of the cases.
- A rub may be heard with pericardial effusion when concomitant inflammatory pericarditis is present.

III. ECG findings

(For the differential diagnosis of STEMI vs. pericarditis, see Chapter 32)

A. Diffuse concave ST elevation in all leads except aVR and V_1

The axis of the subepicardial injury being the axis of the heart (~+45°), the ST elevation is most prominent in lead II and in the anterolateral leads, while the ST segment is often depressed in lead aVR, and sometimes V_1 (and occasionally V_2, III, or aVL, which are close to orthogonal to +45°).[4]

The ST segment is elevated at some point in >90% of patients, but normalizes in 1–5 days, often within 7 days. Thus, the ECG of pericarditis can look normal within a few days, at the time the patient presents. At any random point, ECG is abnormal in ~60% of patients.

The return of ST segment to baseline is followed, sometimes, by T-wave inversion that may last weeks or months. T wave may become biphasic before ST normalization, mimicking ischemia.

B. PR depression

The PR segment is depressed in 82% of patients, and this may be the earliest change. It is seen in all leads except lead aVR, where reciprocal PR elevation is always seen. While it commonly coexists with ST elevation, it can be an isolated change in ~25% of patients.

ST elevation and PR depression are mainly seen in idiopathic pericarditis, post-cardiac surgery pericarditis, and traumatic and hemorrhagic pericarditis.[5] They are rarely seen in uremic, malignant, or tuberculous pericarditis, probably because of associated processes masking the pericarditis pattern.

C. Low QRS voltage and QRS alternans

If an effusion is present, the ECG may show low QRS voltage and sometimes QRS electrical alternans (which means an every-other-beat alternation of two different QRS morphologies). P- and T-wave alternans, in which 2 different P- and T-wave morphologies alternate, increases the likelihood of a pericardial effusion. Sinus tachycardia associated with a low QRS voltage or QRS alternans suggests tamponade.

IV. Echocardiography

- **Echocardiography is usually normal, and frequently no effusion is appreciated ("dry" pericarditis).** A small effusion is seen in 40–60% of pericarditis cases.
- **Moderate or large effusions are uncommon, seen in 5% of acute pericarditis cases.** Idiopathic pericarditis is a less likely diagnosis in a patient with a moderate/large effusion but remains the most likely diagnosis; 25–50% of moderate or large pericardial effusions are idiopathic, whereas 80–90% of pericarditis cases with no or small effusions are idiopathic. An effusion increases the likelihood of a specific cause, such as malignancy, infection, or connective tissue disorder.
- LV dysfunction, sometimes segmental, suggests an associated severe myocarditis.

The diagnosis of pericarditis requires pleuritic chest pain (or occasionally dyspnea in the elderly), along with **at least 1 of the following 5 features** (0 = unlikely, 1 = possible, 2 = definite pericarditis):

(1) pericardial rub in <1/3; (2) typical ECG findings in up to 60% (widespread ST-segment elevation and/or PR depression); (3) elevated CRP in 80–90%; (4) pericardial effusion, usually small, in up to 60%; (5) MRI evidence of pericardial inflammation.

- CRP is usually abnormal, but 10–20% of pericarditis cases have normal CRP, the so-called "non-inflammatory phenotype"; this is often associated with autoimmune diseases and lower-grade inflammation.[6–8]
- ESR may be used but is less specific and rises and falls later than CRP. Conversely, a severely elevated ESR has a valuable diagnostic value and suggests tuberculosis or autoimmune disease.
- A low-titer ANA is very common in idiopathic pericarditis (~40%) and often does not have any clinical significance. ANA testing may be useful in high-risk pericarditis (see below).
- Cardiac MRI may be used to confirm the diagnosis in select cases: (i) associated myocarditis, or (ii) refractory or recurrent pericarditis, particularly if the other diagnostic criteria are not definite. The normal pericardium is poorly vascularized and does not uptake gadolinium, whereas the inflamed pericardium gets neovascularized and hyperemic and uptakes gadolinium; hence active pericardial inflammation is defined as: pericardial LGE or increased pericardial T2.

V. Myopericarditis and perimyocarditis

Various degrees of myocardial inflammation are seen in patients with pericarditis. In fact, the ST-segment elevation implies subepicardial myocardial involvement rather than just pericardial involvement, the pericardium being electrically silent. Therefore, a troponin rise is common in pericarditis. *Myopericarditis* implies mild myocardial involvement, as evidenced by an elevated troponin, with a normal EF and no wall motion abnormalities. Myopericarditis has a good prognosis and EF typically remains normal.[6–9] Troponin may be strikingly elevated (median 7 ng/ml, interquartile range 0.5–35 in one study).[9] Unlike in ACS, this elevated troponin does not portend an increase in long-term complications. However, a reduction of the NSAID dose is considered (e.g., aspirin 500 mg TID, which proved safe in one study),[10] exercise is restricted for 4–6 weeks, and return to athletic activity is considered only after 3 months and after normalization of ECG and LV, and in the absence of arrhythmias on Holter and stress test.

When the process predominantly involves the myocardium, it is termed *perimyocarditis* or pure *myocarditis* and manifests as (i) clinical HF or significant LV dysfunction, sometimes segmental, vs. (ii) acute STEMI mimicker. This predominant myocarditis may have ST changes of pericarditis or, more commonly, focal ST changes or Q waves mimicking STEMI. Coronary angiography is done to rule out ACS. Perimyocarditis with mild LV dysfunction (EF 40–50%) is associated with a good long-term prognosis and persistence of LV dysfunction in only 15% of patients.[9] Perimyocarditis with severe LV dysfunction portends an altered long-term prognosis with persistent LV dysfunction in up to 60% of patients.

VI. Treatment

Pericarditis is a self-limiting disease with no complication or recurrence in >70% of patients.

A. Initial therapy

1. A full anti-inflammatory dose of NSAID or aspirin is administered for 1–2 weeks. One dose is usually associated with a dramatic symptomatic effect. One regimen consists of the administration of a full-dose NSAID for a week, or better yet, until CRP normalizes (e.g., ibuprofen 600 mg TID, aspirin 750–1000 mg TID), followed by gradual tapering over 3 weeks, rather than abrupt cessation (e.g., taper ibuprofen by 200–400 mg per dose every week).[6–9,11]

2. The systematic use of colchicine (for 3 months) as an adjunct to NSAID during the first episode of pericarditis strikingly reduces the recurrence of pericarditis by 70% (COPE trial).[11] Colchicine therapy must thus be used systematically and is given a class I in ESC guidelines (0.6 mg BID if weight >70 kg, 0.6 mg QD if weight <70 kg).[8]

3. For pericarditis refractory to standard therapy (= persistent pain despite NSAID/colchicine), consider cardiac MRI to confirm pericardial inflammation and consider autoimmune disorders. The NSAID dose may need to be increased, as inappropriately low doses may explain some therapeutic failures. Ensure that colchicine is used. Glucocorticoids are generally avoided in acute pericarditis, as they increase the risk of recurrence, probably through the exacerbation of viral proliferation. Yet, glucocorticoids may be used in refractory cases or in autoimmune disorders (prednisone 0.2–0.5 mg/kg/day or ~20–25 mg/day, with slow tapering every 2–4 weeks, even slower when reaching a dose <15 mg/day).

Rilonacept is the preferred option for refractory pericarditis (see Section 1.VI.C).

4. Exercise restriction is warranted until clinical, ECG, and CRP resolution of acute pericarditis, for at least 1 month, as increased heart rate enhances the attrition of pericardial layers. In myopericarditis or perimyocarditis, exercise restriction of at least 3 months is recommended

in athletes. A normalization of the ECG, LV function, CRP, and MRI's myocardial and pericardial inflammation (T2) is required before gradual return to athletic activity.[6–8]

5. The following high-risk features increase the likelihood of a specific diagnosis (i.e., neoplastic, autoimmune, infectious) and the likelihood of complications, and therefore warrant hospitalization and a specific etiologic workup:[6–8,12]

- **a.** No response to 1 week of NSAID therapy
- **b.** Moderate or large effusion
- **c.** Subacute onset over days to weeks
- **d.** Fever >38 °C
- **e.** Clinical suspicion of a specific etiology

The specific etiologic workup consists of: HIV testing, PPD, ANA/rheumatoid factor, screening for specific cancers.

Also, myocarditis warrants hospitalization to monitor for clinical progression into progressive HF or VT/AV block.

B. Recurrent pericarditis

Between 15% and 30% of patients with idiopathic or autoimmune pericarditis develop recurrent pericarditis within 20 months after the initial episode, and pericarditis may keep relapsing for several months or years in up to 50% of those with recurrence.[13] Recurrence risk increases with each recurrent episode, and those with multiple recurrences may continue to experience them for several years.[14] Long-term treatment, for years or even indefinitely, may be necessary in some cases. It is due to an autoimmune process initiated by the initial viral infection, although persistent or recurrent infection is possible. A recurrence within 6 weeks of the initial episode is usually considered a persistence of the initial pericarditis and is called "incessant" rather than recurrent pericarditis.

In the absence of high-risk features, recurrent pericarditis is usually idiopathic and does not warrant specific workup (except possibly cardiac MRI to confirm pericardial inflammation).[6,7] Moreover, recurrent idiopathic pericarditis is usually milder than the initial pericarditis and is not associated with pericardial constriction; in fact, the risk of constrictive pericarditis is lower after a recurrence than after the initial episode of pericarditis.[15] This is because constrictive pericarditis is related to incessant, persistent inflammation that is severe, causing it to evolve into scarring, rather than the intermittent, mild, and resolving inflammation seen in recurrent cases. One-third of patients have pleuropericardial involvement during these recurrences.

For each recurrence, NSAID course is repeated and tapered more slowly over several months with CRP guidance. For example, ibuprofen 800 mg TID is initiated for 2–4 weeks, then **tapered by 200 mg every 2–4 weeks only if CRP is fully normal and symptoms are absent at that interval.**[8] If CRP is elevated, the same dose is kept and CRP rechecked 2–4 weeks later before re-attempting to taper it down. Also, colchicine is given at the standard full dose for ≥6 months. Only one drug is tapered at a time: if the patient is receiving steroids, taper prednisone first to a low dose of 10 mg, then taper NSAIDs, and keep full-dose colchicine until at least several weeks after tapering off NSAIDs and steroids.

C. Distinguish recurrent pericarditis from refractory recurrent pericarditis. Glucocorticoids may be used in refractory pericarditis but are avoided in recurrent pericarditis that can be controlled with a recurrent course of NSAID and colchicine. Refractory pericarditis is typically an ultimate form of recurrent pericarditis as it may recur upon steroid down-titration, i.e., a *steroid-dependent recurrent pericarditis*.

Prednisone ~20 mg QD is added only in refractory pericarditis, and is tapered by 2.5–5.0 mg every 2–4 weeks for doses >15 mg, and by 1–2.5 mg every 2–4 weeks thereafter, only if CRP remains normal with no symptoms (Figure 17.1).[6,7]

Rilonacept, an IL-1 inhibitor, is recommended for *refractory* pericarditis or *recurrent* pericarditis with ≥2 recurrences despite NSAID and colchicine (weekly subcutaneous injection). In the RHAPSODY trial, it was >95% effective in controlling CRP and the clinical symptoms of acute pericarditis, with a median **time to normalization of only 7 days**. It allowed successful tapering and withdrawal of steroids and other therapies in ~all patients over the course of 9 weeks. The duration of treatment was at least 3 months (median 22 months, up to 3 years).[16]

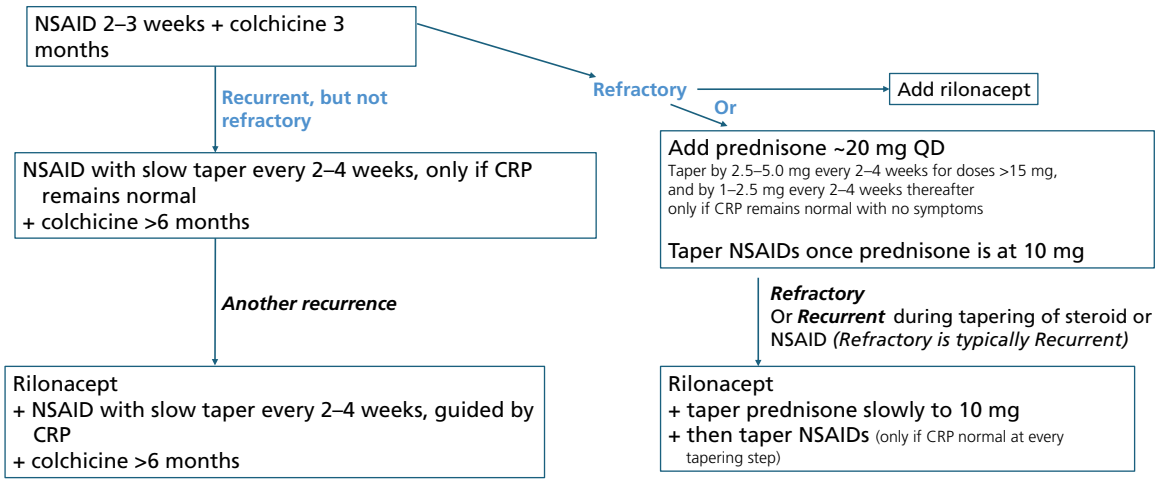

Figure 17.1 Management of acute, recurrent, and refractory pericarditis. Perform cardiac MRI to confirm pericarditis in refractory and +/– in recurrent cases.

However, 6 of 8 patients who discontinued rilonacept experienced a gradual recurrence, 3 months later, despite 2 years of therapy.[17] Thus, **the duration of treatment remains unknown and is likely needed for years in severe cases.** Anakinra, another IL-1 inhibitor, is also highly efficacious in recurrent pericarditis (Airtrip trial).

Rarely, cases refractory to all of the above therapies or requiring high steroid doses may be considered for radical pericardiectomy.[6,7]

In refractory recurrent pericarditis, return to exertion should preferably wait 3 months after control of symptoms and CRP and being steroid free. It is not clear whether exertion may be resumed while on IL-1 blockers, and further investigation is needed.

An international consensus recommends **cardiac MRI** for refractory or recurrent acute pericarditis to confirm the presence of pericardial inflammation and to confirm, in some cases, the need for IL-1 blockers or steroids. In general, both CRP and MRI are abnormal in such patients. Pericardial inflammation is diagnosed and quantified by assessing: (i) pericardial edema on T2 imaging; (ii) late gadolinium enhancement of the pericardium. The normal pericardium does not uptake gadolinium because it is poorly vascularized; only the inflamed, neovascularized pericardium does. Also, the fibrotic, calcific, non-inflamed pericardium does not uptake gadolinium. Cardiac MRI may be used to monitor therapy, but beware that **LGE lags behind clinical and inflammatory improvement by 6–12 months**. Thus, the persistence of LGE does not necessarily mean persistent inflammation and must be interpreted in the context of the patient's symptoms progression and CRP; MRI may be done at intervals of several months, e.g., 6 months.[3]

Note: 10–20% of acute and recurrent pericarditis cases are non-inflammatory with negative CRP and sometimes no inflammation on MRI; they may still benefit from IL-1 blockade but more so from steroids, as the underlying process is frequently autoimmune disease.[6–8]

D. If an effusion is present, look for a specific etiology (see Section 3, *Pericardial effusion*, below) and perform serial echocardiographic exams. Echo is repeated during the hospital stay to ensure stability of the effusion, then serial outpatient echo exams are performed to ensure stability or resolution of the effusion.

E. The occurrence of chronic constrictive pericarditis after acute idiopathic pericarditis is uncommon (<1%), and even less common after recurrent pericarditis.[11,12] Up to 9% of patients may have a transient constrictive physiology that results from the "rind" of acute inflammation rather than scar tissue and resolves in a few months (mean 2.1 months).[6,7,18]

2. TAMPONADE

I. Definition

Cardiac tamponade is a large (>300–500 ml) pericardial effusion compressing one or more cardiac chambers and leading to hemodynamic compromise.

In tamponade, the pericardial fluid distends the pericardium and raises the intrapericardial pressure to ~10–25 mmHg, compressing one or more cardiac chambers. In typical, circumferential tamponade, *this high intrapericardial pressure compresses all cardiac chambers in diastole until the pressure inside the 4 cardiac chambers equalizes with the intrapericardial pressure*. This leads to equalization of the diastolic pressures of the 4 cardiac chambers. The diastolic pressure in the right heart is lower than the left heart, hence the right-sided chambers are compressed first and equalize with the intrapericardial pressure first. Also, since the right-sided chambers have thin walls, they tend to collapse when the intrapericardial pressure is equal to or larger than their intracavitary pressure.

In acute conditions, the pericardium cannot distend and its pressure rises markedly with small volume changes. This explains how tamponade develops with a relatively moderate effusion (~200 ml). This also explains how the pericardium gets stretched in acute RV dilatation, leading to a "functional" constrictive pericarditis. Conversely, a slowly developing pericardial effusion induces tamponade only after a large volume of fluid has accumulated.

II. Pathophysiology and hemodynamics

The equalization of diastolic pressures is similar to what is observed in constrictive pericarditis. As opposed to constrictive pericarditis, however, the respiratory changes of intrathoracic pressure are transmitted to the cardiac chambers.[19,20] This explains why RA pressure decreases with inspiration, and thus venous flow from outside the thorax to the RA increases during inspiration (jugular venous pressure decreases, explaining the absence of Kussmaul's sign). Left-sided flow does not increase because both pulmonary veins and LV are exposed to the negative intrathoracic pressure. The increased venous flow to the right cavities makes the RV "push" against the LV in diastole, rather than "push" against the pericardium, since the high pericardial pressure prevents that (*ventricular interdependence*). This reduces LV filling in normal inspiration and explains the reduction of systolic arterial pressure by more than 10 mmHg with *normal* inspiration (pulsus paradoxus, which is an extreme form of RV–LV discordant filling).[21]

Also, as opposed to constrictive pericarditis, where the heart briefly expands in early diastole before getting constrained, the heart is compressed throughout all diastole in tamponade, including early diastole. Thus, there is no deep Y on the RA tracing and no diastolic dip on the RV tracing. There is a deep X in early systole as the RV annulus moves down and stretches out the compressed RA.[21]

In summary, tamponade is characterized by the following 3 hemodynamic findings:

1. Elevation and equalization of diastolic pressures of the 4 cardiac chambers, similarly to constrictive pericarditis: **CVP** = **PCWP** = diastolic PA pressure = RVEDP = LVEDP. This equalization of diastolic pressures may also be seen in severe RV failure that creates a functional pericardial constriction.

2. Elevated RA pressure with a **deep X descent** (mainly during inspiration) and a **flat Y descent**. The elevated RA pressure is equalized with the intrapericardial pressure on simultaneous RA–pericardial recording, particularly in expiration (Figure 17.2).

3. While the systolic aortic pressure is initially normal or even elevated as a result of the adrenergic release, **pulsus paradoxus** is present and pulse pressure is abnormal early on. On any arterial or aortic tracing, pulsus paradoxus means that systolic pressure decreases >10 mmHg with *normal* inspiration. In addition, the arterial waveform is narrow and the pulse pressure is reduced (arterial tracing is "short" and narrow) (Figure 17.3).

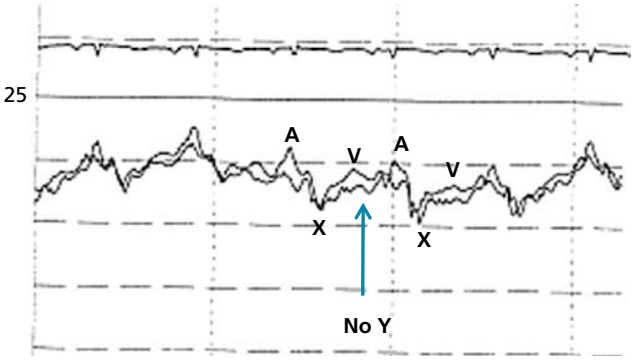

Figure 17.2 Simultaneous pericardial and RA pressures are recorded in tamponade, before pericardiocentesis. The RA and pericardial pressures are elevated and equalized (~20 mmHg); this defines tamponade. The 2 tracings are actually superimposed, particularly in expiration; the pericardial pressure falls a bit more than the RA pressure in inspiration. Furthermore, X descent is seen, but Y descent is flat (**mnemonic: Flat Y Tamponade = FYT**).

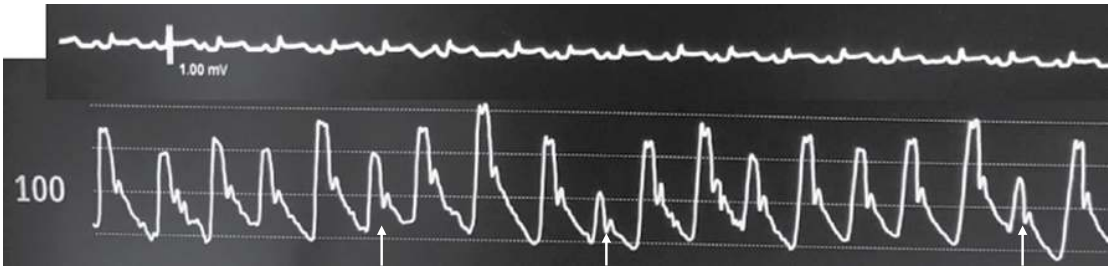

Figure 17.3 Pulsus paradoxus. Note the drop of systolic and pulse pressure during *normal* inspiration despite a regular rhythm (arrows). The arterial waveform also becomes narrower.

III. Diagnosis: tamponade is a clinical diagnosis, not an echocardiographic diagnosis

Tamponade is diagnosed when a *large pericardial effusion* is associated with *hemodynamic compromise*, i.e., any one of the following clinical findings:

1. Elevated JVP.

2. Pulsus paradoxus, which is a decrease of SBP of >10 mmHg during *normal, quiet inspiration*. Example: when using the BP cuff, the Korotkoff sounds are heard intermittently at a systolic pressure of 150 mmHg, then consistently (with each cardiac cycle) at a pressure of 120; therefore, the pulsus paradoxus is 30 mmHg. Avoid deep breathing during this measurement, as deep breathing is normally associated with an inspiratory drop of aortic pressure.

The blood pressure is normal or elevated early on. Ultimately, the blood pressure declines. An increase in systolic pressure up to 150–210 mmHg and diastolic blood pressure up to 100–130 mmHg is frequent in tamponade and occurred in up to one-third of tamponade cases in one report, particularly in patients with a history of hypertension who are sensitive to the catecholamine surge.[22] Hypertension does not imply preserved cardiac output; in fact, cardiac output is as low as in cases of normal arterial pressure, but increased peripheral vascular resistance preserves arterial pressure (pressure = flow × resistance). Patients with tamponade and hypertension have a reduction in blood pressure, reduction in systemic vascular resistance, and increase in cardiac output following pericardiocentesis.[22]

3. Sinus tachycardia that attempts to compensate for the low stroke volume. Tachycardia may be absent in hypothyroidism and sometimes uremia (sinus node disease).

4. Dyspnea/tachypnea/orthopnea with clear lungs. PCWP is increased up to 30 mmHg but the intracardiac and pulmonary venous volume is low, hence the *lack of pulmonary edema and lack of significant hypoxemia despite severe dyspnea.*

A decrease in heart sounds is characteristic of a large effusion but not necessarily tamponade. Even when an effusion is large, a friction rub may still be heard with inflammatory etiologies.

IV. Echocardiographic findings supporting the hemodynamic compromise of tamponade

(See also Chapter 33, Section VI)

1. RV collapse in diastole. This is the most specific echo finding in tamponade. In its earliest form, just a diastolic indentation of the RVOT is seen on the parasternal long-axis M mode.

2. RA collapse in early ventricular systole, when RA is emptiest. RA collapse lasting over one-third of the cardiac cycle is specific for tamponade. RA collapse is generally more sensitive but less specific for tamponade than RV collapse.

3. Inspiratory changes of transmitral and transtricuspid flow. An inspiratory decrease of left-sided transmitral E flow by >25%, or an expiratory decrease of right-sided transtricuspid flow by >40%, during *normal breathing*, suggests tamponade (this is equivalent to the pulsus paradoxus). This is the earliest echo sign of tamponade but is not specific: it may be seen in any dyspnea with deep respiratory pressures.

4. IVC dilatation with poor inspiratory collapse. IVC abnormality has a sensitivity of 97% and a specificity of 40% for tamponade. IVC is rarely normal in tamponade (the so-called low-pressure tamponade).

Findings on **hepatic venous Doppler**: the flat Y descent on the RA tracing corresponds to a *flat D wave on the hepatic venous Doppler. This contrasts with constriction, where D is prominent in inspiration. Yet, expiratory reversal of D is seen in both conditions, and constriction and tamponade grossly appear to have similar hepatic vein flow* (see Section 4.V Figures).

5. Other findings

- A rapid change in the effusion size suggests a threatened tamponade.
- An abnormal septal motion may be seen as a result of ventricular interdependence like in constriction. Respiratory septal shifts are seen in both tamponade and constriction but may be more visible in constriction as the ventricles are less compressed and fill more in diastole (Y descent), making the volume shifts more obvious.
- A swinging heart, i.e., a heart that changes position in a phasic manner, may be seen with a large effusion and corresponds to the electrical alternans seen on ECG. It does not necessarily imply tamponade.
- Strands in the pericardial fluid imply inflammation or bleeding and can be seen with most effusions, except transudative effusions. A pericardial "rind" is diffuse pericardial thickening, forming a thick band; it increases the likelihood of inflammatory constriction (effusive-constrictive pericarditis).

TEE, CT, or MRI may be performed when a loculated effusion with a regional tamponade is suspected.

V. Role of hemodynamic evaluation

The diagnosis of tamponade is established on clinical and echo grounds, and right heart catheterization is not usually necessary. However, if a Swan catheter is in place (e.g., post cardiac surgery), the following findings suggest tamponade: (i) an elevated CVP that approximates PCWP and PA diastolic pressure; (ii) a flat Y descent on RA tracing.

Also, right heart catheterization may be performed before and particularly after pericardiocentesis to document the hemodynamic improvement. Pericardial pressure is measured before drainage, in which case it is elevated (>0 mmHg) and equal to the RA pressure. ***Normalization of the pericardial pressure (to ≤0 mmHg) and of the RA pressure must be documented after drainage. In fact, the normal pericardial pressure is ≤0 mmHg. The lack of full hemodynamic improvement suggests effusive–constrictive pericarditis.***

VI. Special circumstances: low-pressure tamponade, tamponade with absent pulsus paradoxus, regional tamponade

A. Low-pressure tamponade

In patients who are hypovolemic, compression of intracardiac chambers (i.e., tamponade), particularly right-sided chambers, may occur at a lower intrapericardial pressure of 6–12 mmHg. In this case, there will be equalization of intrapericardial pressure and RA pressure at 6–12 mmHg. Thus, tamponade with pulsus paradoxus or hypotension occurs with a high-normal or only mildly increased RA pressure and jugular venous pressure.[21] Were it not for hypovolemia and the low right-sided filling pressure, this pericardial effusion would not yet be hemodynamically significant. Fluid administration may correct the pulsus paradoxus; however, excessive fluid administration may sometimes increase the right-sided volume, which further stretches the already distended pericardium and elevates its pressure, leading to a full-blown tamponade picture.[23,24] That is why fluids are helpful in hypovolemic patients with tamponade but may harm euvolemic or hypervolemic patients. In order to maintain a proper transmural pressure of the cardiac chambers, it is important to maintain a higher level of intracardiac pressure without excessive volume resuscitation (transmural pressure = intracavitary pressure minus pericardial pressure). Ultimately, patients with a low-pressure tamponade require pericardiocentesis since even at 6–12 mmHg, the intrapericardial pressure is at a steep portion of the pressure–volume relationship and is liable to rise with any change in pericardial volume (Figure 17.4).

B. Underlying RV or LV failure and causes of absent pulsus paradoxus (and of attenuated septal and E variations)

While it is easy to induce tamponade in case of hypovolemia, it is difficult to induce tamponade physiology in patients with severely increased right-sided or left-sided diastolic pressure.[21] In fact, it is harder for the pericardial pressure to compress both ventricles, and tamponade develops when pericardial pressure equilibrates with the lower-pressure ventricle. Moreover, the respiratory variation in venous return does not significantly change the cardiac output and the systolic pressure of the failing ventricle (flat portion of the Frank–Starling curve). The latter 2 mechanisms, that is, the lack of biventricular compression (and therefore lack of interdependence) and the lack of respiratory variation in ventricular output explain the lack of pulsus paradoxus. This situation may be seen in patients with cor pulmonale and in patients with end-stage renal disease and underlying left heart failure.

In addition, pulsus paradoxus may not be seen in: (1) ASD, where the increase in right-sided flow during inspiration is balanced by an increase in right-to-left shunt or reduction in left-to-right shunt, leading to less ventricular interdependence; (2) local tamponade

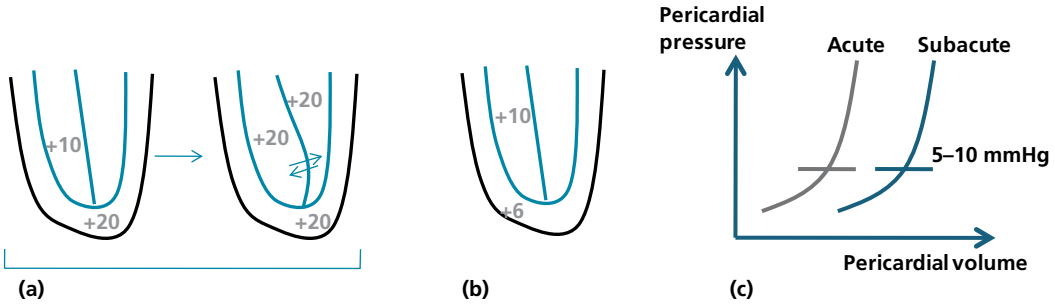

Figure 17.4 The normal pericardial pressure is negative and reaches 0 mmHg at end-expiration (–10 to 0 mmHg). **(a)** Tamponade occurs when the pericardial pressure exceeds the pressure of a cardiac chamber (e.g., RV), thus compressing it and making it equalize with it. Typically, both ventricles get constrained by the pericardial shell, such that their pressure rises and equalizes with the pericardial pressure. They expand at the expense of each other (*arrows*). **(b)** Even before the RV gets compressed by the pericardial pressure, the transmural pressure of the RV and the RV expansion are affected (RV diastolic pressure = 10, pericardial pressure = 6 → the RV transmural, expansile pressure is reduced to +4). **(c)** Compliance curve of the pericardium, showing how the pericardial pressure rises quickly beyond a certain pressure point, even before tamponade occurs (threatened tamponade). This curve is more leftward in sudden acute effusions, wherein the pericardium is not compliant.

(e.g., localized compression of one ventricle or atrium by a clot after cardiac surgery, leading to a localized increase in pressure); (3) AI, where the diastolic regurgitant flow damps down respiratory fluctuations of flow. In addition, pulsus paradoxus is difficult to detect in case of an irregular rhythm such as atrial fibrillation.

C. Regional tamponade

This occurs when only 1 cardiac chamber, a pulmonary vein, or the SVC or IVC is compressed by a loculated effusion (e.g., anterior loculation compressing the RV or RA, posterior loculation compressing the LV or LA). Since there is no uniform compression of the 4 chambers, there is no equalization of diastolic pressures and no ventricular interdependence/pulsus paradoxus. There is increased pressure of the compressed chamber, e.g., increased RA pressure or PCWP, and hypotension, which in the right context suggest tamponade (e.g., after cardiac surgery). However, loculation can also produce classic tamponade, presumably by tightening the uninvolved pericardium.

TEE or cardiac CT or MRI should be performed when a regional tamponade is suspected.

D. COPD and other causes of pulsus paradoxus and RV–LV respiratory discordance

Because of large intrathoracic pressure swings, COPD, asthma, morbid obesity, or positive-pressure ventilation may lead to discordance in RV and LV filling and pulsus paradoxus.

VII. Effusive–constrictive pericarditis

Some patients have a pericardial effusion with the hemodynamics of tamponade, i.e., pulsus paradoxus with elevated and equalized right- and left-sided filling pressures. However, upon drainage of the pericardial fluid, the hemodynamic compromise does not fully resolve. RV and LV diastolic pressures remain equalized, RA pressure remains >10 mmHg (or RA pressure declines by <50%), and the pericardial pressure may remain high. A flat RA Y descent (tamponade) may become deep (constriction) after drainage of the pericardial fluid. Effusive–constrictive pericarditis is an effusion that occurs on a background of constrictive pericarditis. In patients with a non-compliant pericardium, tamponade may occur with relatively little accumulation of fluid.

A relatively smaller pericardial effusion (e.g., 1.5–2 cm) with disproportionately severe hemodynamic compromise, such as severe JVP elevation, suggests effusive-constrictive pericarditis. Also, bloody effusions and fibrinous effusions with rind are frequently (up to 50%) constrictive.[25] On echo, some features suggest a constrictive rather than a tamponade physiology (medial E' > lateral E', very pronounced respiratory septal shifts).[25]

Effusive–constrictive pericarditis may be seen with pericarditis of any origin, particularly idiopathic, and is usually seen early in the disease course. In fact, up to 24% of constrictive pericarditis cases and 7–16% of tamponade cases have an effusive–constrictive pathophysiology.[26] Effusive–constrictive pericarditis is often an inflammatory constrictive pericarditis that is transient in up to 90% of the cases and resolves with anti-inflammatory therapy, except when caused by radiation.[26] It sometimes resolves quickly in cases of heavy rind.

VIII. Treatment of tamponade

Tamponade is initially temporized with fluid resuscitation. For example, administer one 500 ml fluid bolus at a time. Avoid excessive fluid resuscitation, as it may worsen pericardial distension and ventricular interdependence.

Similarly, avoid preload reduction (nitrates, diuretics). *Severe ventricular failure delays the onset of tamponade* and may seem "protective" against it. But this is not truly so, as these cases require diuresis, after which tamponade will occur and drainage will be required. Hence, they are closely monitored during diuresis and drained early or preemptively.

Pericardiocentesis is urgently indicated in tamponade, and the catheter is allowed to drain for ~3–5 days. Pericardiocentesis is often a definitive treatment of idiopathic effusions and late postoperative effusions, and at least a temporary treatment of malignant effusions.

A pericardial window is particularly useful for recurrences or loculated effusions (see below).

3. PERICARDIAL EFFUSION

A pericardial effusion without tamponade is not associated with hemodynamic compromise but may be associated with a dull ache and sometimes a pericarditic chest pain, particularly in the case of an inflammatory effusion. Dyspnea on exertion may occur and is, in fact, a manifestation of early tamponade. In order to be well tolerated and asymptomatic, a large effusion must be chronic. A large effusion is defined as an effusion larger than 2 cm (usually corresponds to >300–500 ml); moderate and small effusions are 1–2 cm and <1 cm wide, respectively. The effusion is measured as the

summation of the anterior and posterior echo-free spaces in *diastole.*[27,28] This measurement is smaller in diastole than systole, but the diastolic measurement is what accounts for the diastolic compression and for the ability to tap (must be >2–3 cm to allow a safe pericardiocentesis).

I. Causes of a pericardial effusion with or without tamponade

Several series of moderate to large pericardial effusions have reported a lower prevalence of idiopathic causes compared with acute pericarditis. *Similarly to acute pericarditis,* the five most common causes of a moderate or large effusion are:[6,7,27,29,30]

1. *Viral/idiopathic*. Viral/idiopathic pericarditis rarely leads to a large effusion or tamponade, yet is still the most common cause of effusion and tamponade. Approximately 30–50% of large pericardial effusions are viral/idiopathic. While most HIV effusions are small, a large HIV effusion has a high rate of progression to tamponade (PRECIA study).[31]
2. *Neoplastic* (lung, breast, lymphoma, melanoma). Malignancy causes 20–30% of pericardial effusions. Approximately 20% of patients with tamponade of unsuspected etiology are diagnosed with malignant effusion, this being their first cancer manifestation. ***A large asymptomatic effusion is less likely to be malignant than an effusion with tamponade, as the asymptomatic one is inherently slow and chronic***, unlike the rapidly progressive malignant effusion.
3. *Metabolic* (uremia or hypothyroidism).
4. *Connective tissue diseases*.
5. *Specific bacterial infection or tuberculosis*. Bacterial infections can spread from contiguous sites (pneumonia, empyema, ruptured valvular abscess, thoracic surgery) or hematogenously.

Other causes are seen in specific contexts:

1. *Post-cardiac surgery*. The effusion may be an early hemorrhagic effusion, occurring in the first postoperative week. The effusion may also occur late, >1 week postoperatively, secondarily to a post-pericardiotomy syndrome; it usually resolves within weeks.
2. *Post-MI*. The effusion may occur early (resolves slowly over months) or late (along with Dressler syndrome). An early small effusion is often not worrisome, per se, and may accompany post-MI pericarditis or HF. Conversely, an early moderate or large effusion suggests a threatening free wall rupture.
3. *Radiation therapy*. An early effusion (<1 year) may occur as part of an acute pericarditis and is sometimes recurrent. A late effusion (>1 year) is part of an effusive–constrictive pericarditis.
4. *HF or volume overload states (nephrotic syndrome, cirrhosis)*. Pericardial effusion is usually small or moderate in size, transudative, and only develops when right heart failure is present, as the pericardial veins drain in the coronary sinus. Isolated left heart failure does not lead to a pericardial effusion. A large pericardial effusion is rare but possible.[28]
5. *Hemorrhagic pericardial effusion*, from a penetrating or blunt trauma, free wall rupture post-MI, complication of PCI (coronary perforation) or complication of device implantation (RA or RV rupture). Outside these traumatic/rupture contexts, a bloody effusion may be seen with a broad range of etiologies, such as *malignant, viral, or infectious*, with a prognosis that depends on the underlying etiology.
6. *Drugs* (mainly *minoxidil* and drug-induced lupus: *hydralazine*, izoniazide).

> A large idiopathic pericardial effusion has a relatively low risk of progression to tamponade. Conversely, neoplastic, bacterial/tuberculous/HIV, and postoperative large effusions have a high risk of progression to tamponade. Hemorrhagic effusions have an imminent risk of tamponade.

II. Management of asymptomatic effusions and role of pericardiocentesis

A. General approach to a large asymptomatic effusion (Figure 17.5)

Two main concerns dictate the management of asymptomatic effusions: (i) etiology and (ii) risk of progression to tamponade. Up to 60% of patients with moderate/large pericardial effusions have a known medical condition, such as cancer, uremia, previous cardiac surgery, or connective tissue disease, which points toward a specific diagnosis.[27] The following strategy is suggested:

1. In the absence of a known medical condition that could cause a pericardial effusion, screen for some cancers, HIV/tuberculosis, and metabolic disorders using clinical findings and: CXR, mammography, chest CT; PPD, HIV; TSH, renal function, rheumatoid factor, ANA.
2. Check markers of inflammation (CRP, ESR), which, if elevated without any cancer/infection/autoimmune disease, suggest a pericarditic process (viral/idiopathic).[4]
3. If a *malignant* or *bacterial (including tuberculous)* etiology is suspected, pericardiocentesis is indicated both for its diagnostic and staging value and because of the high risk of progression to tamponade ("threatened tamponade").[6,7] This includes patients with known malignancy or whose initial screening suggests malignancy. Only 50% of effusions in cancer patients are due to malignant metastasis, the remaining being induced by viral or opportunistic infections, chemotherapy, obstruction of lymphatic drainage, or radiation; hence the additional diagnostic importance of pericardiocentesis in these patients.[32]

If a *hemorrhagic pericardial effusion* is suspected (traumatic, iatrogenic), pericardiocentesis is indicated because of the imminent risk of tamponade.

If an effusion is increasing in size, pericardiocentesis is warranted because of the risk of tamponade.

4. Ensure the patient is truly asymptomatic. Even when the intrapericardial pressure is lower than the right-sided pressures, the RV or RA transmural pressure (RV pressure minus intrapericardial pressure) is reduced, which impairs RV outward expansion and filling. For example, if the pericardial pressure is 6 mmHg and the RV diastolic pressure is 10 mmHg, the RV does not collapse toward the LV, but it cannot appropriately expand and the cardiac output is already reduced. Also, at this point, pericardial pressure is at a steep slope and there is at least a threatened tamponade (Figure 17.4).[33] In fact, one study has shown that almost all patients with a large asymptomatic effusion who underwent pericardiocentesis had a high intrapericardial pressure and a reduced RA transmural pressure.[28,32] Thus, vague symptoms of fatigue or dyspnea on exertion often represent early hemodynamic compromise and warrant pericardiocentesis. The same applies to the echo signs of pre-tamponade.

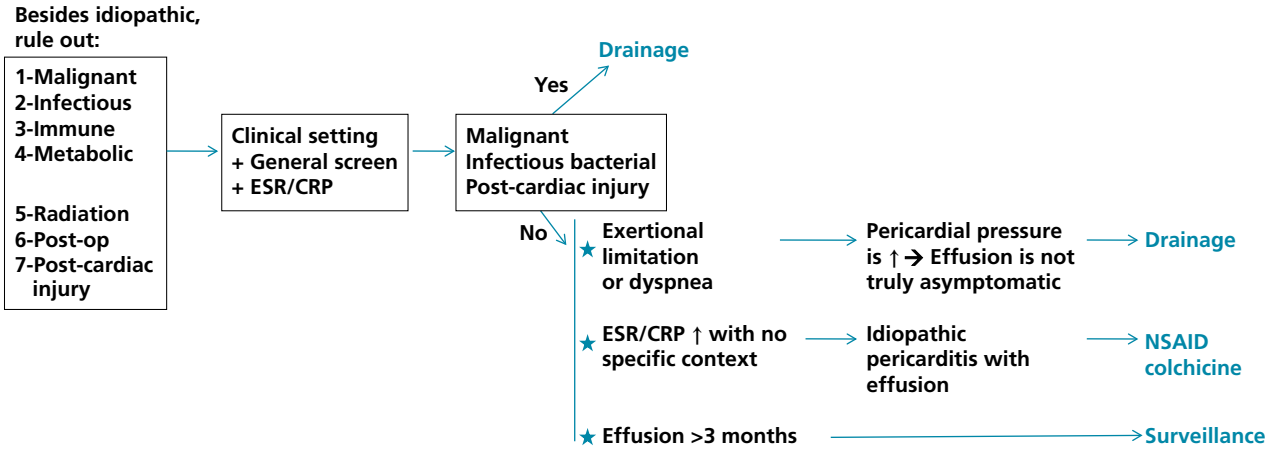

Figure 17.5 General approach to a large, asymptomatic pericardial effusion. It is inherently chronic: In order to be well tolerated and asymptomatic, a large effusion is typically chronic.

5. If all of the above is ruled out, the asymptomatic effusion is likely isolated, i.e., idiopathic. If the inflammatory markers are increased or if inflammatory signs are present (characteristic chest pain, friction rub, fever, or typical ECG changes), a pericarditic process is suspected and may be treated with NSAID and colchicine (class I indication).[6–8,32] For a recent effusion <3 months, close echo follow-up is warranted to detect improvement of the effusion (or lack thereof), on a weekly basis initially.[32] An autoimmune process is managed similarly.

6. A large asymptomatic effusion that persists for >3 months is *less likely to be malignant than a recent one, as malignant effusions tend to rapidly deteriorate*. It remains stable over time in most patients and frequently regresses at least partially; a specific cause does not usually emerge with time. While older data suggested a 33% hazard of abrupt progression to tamponade,[28] modern data indicate that this is rather uncommon, with an annual tamponade risk of ~2.2%, and the effusion often decreases in size over time.[34,35] Drainage is rather associated with a high risk of recurrence, sometimes of a larger effusion, and a risk of iatrogenic inflammatory pericarditis.[34,35] In fact, prognosis is worse in patients with post-drainage recurrences or complications than those managed conservatively. Besides, drainage does not usually establish a new diagnosis. Thus, **a conservative approach with routine echo surveillance Q3–6 months is preferred**.[8] When a large asymptomatic effusion is first diagnosed, it is wise to initially repeat the echo closely, e.g., in 1–2 weeks, to ensure it is not rapidly growing and it is truly chronic; then, monitoring interval is spaced to 3–6 months.

A pericardiocentesis has a therapeutic but also a diagnostic value. The overall diagnostic yield of a pericardiocentesis is ~30%,[36] but it is higher in neoplastic or bacterial effusions and much lower in chronic asymptomatic effusions. The yield in neoplastic effusions is >50% (50%[36] to 80%[28,30]). The pericardial fluid should be sent for cytology, cell count, bacterial and mycobacterial culture, and polymerase chain reaction of *Mycobacterium tuberculosis* (the latter is highly sensitive for tuberculous pericarditis).

B. Pericardiocentesis and open pericardiotomy (pericardial window)

Pericardiocentesis alone is often a definitive treatment of idiopathic pericardial effusion with tamponade; in one series, recurrences only occurred in 8% of patients over long-term follow-up.[6,7,38] However, another series suggested that recurrences are common and occur in 65% of patients with idiopathic large effusions.[28] The duration of catheter drainage may explain the discrepancy. This recurrence rate is higher in malignant effusions, although pericardiocentesis may still be tried as a first-line therapy or as a temporizing measure in the unstable patient. Since fluid reaccumulation most commonly occurs in the first 48 hours after drainage, pericardiocentesis with prolonged catheter drainage is associated with an acceptable risk of recurrence of malignant effusions (<20%), particularly in view of the fact that patients with malignant effusions have a median survival of 3.5 months only.[37] Hence, some authors recommend pericardiocentesis as a first and effective therapy in malignant effusions.[32]

A catheter should be left in the pericardial space at least until the drainage is <25 ml/24 hours. Prolonged catheter drainage for several days (e.g., 3–5 days), even after the drainage ceases, is preferred, as it provokes adherence that obliterates the pericardial space and reduces the risk of recurrence to <20–25%.[32,37,38] Also, the stretched pericardial space that is now empty creates a suction effect and a negative pressure gradient toward the pericardial cavity, which may cause fluid reaccumulation; prolonged drainage may prevent that.

Echo-guided pericardiocentesis may be performed through a *left subxiphoid* approach. The needle accesses the *inferior (diaphragmatic)* aspect of the pericardial space, *not the posterior/lateral* aspect. In a supine position, a free-flowing effusion accumulates on the posterior/lateral aspect; thus, the patient should be placed in an upright position to allow a free-flowing pericardial effusion to collect over the diaphragmatic aspect (Figures 17.6, 17.7). An effusion loculated at the posterior (lateral) aspect of the LV is not accessible; the same applies to an effusion loculated over the anterior aspect of the heart (RV free wall). An apical approach for the former and a parasternal approach for the latter may allow drainage. An apical approach is also simpler in obese patients, where it is difficult for the subxiphoid needle to cross the abdominal fat and get underneath the ribs. Pericardial pressure +/– right heart catheterization (RA pressure) are measured before but also after pericardiocentesis, to document the hemodynamic improvement.

Pericardiocentesis access sites:

- *Apical access:* 5th or 6th intercostal space, >5 cm from the sternum, as the needle aims to the space behind the heart via the apex; risk of pneumothorax. Advantages: short distance to the effusion and ability to use direct echo guidance.
- *Parasternal access:* 5th or 6th left or right intercostal space, immediately adjacent to the sternum (within 1 cm of it) to avoid injury to the internal mammary artery.

- *Left subxiphoid access:* the needle enters the skin ~3–4 cm below the ribs, and is initially angled steeply to get below the ribs, then flattened into an angle that mimics the path of the echo probe (the path that was used to visualize the effusion).

Open pericardiotomy consists of cutting a "window" in the parietal pericardium to allow it to chronically drain in the mediastinum, which prevents recurrences. This is also known as a "pericardial window" and is usually performed through a subxiphoid access. Pericardial tissue and biopsies obtained through this procedure should be sent for analysis. A pericardial window is considered in the following cases: (i) recurrence of a large effusion, (ii) loculation, (iii) recurrence expected (malignant effusion), or (iv) a surgical biopsy is required for diagnosis (malignant effusion). Pericardiocentesis is still warranted for acute tamponade while awaiting surgery. After a pericardial window, the open parietal pericardium may adhere to the visceral pericardium or the sternum, in which case the effusion may recur (<5%). Even after a window procedure, prolonged drainage may reduce recurrences.

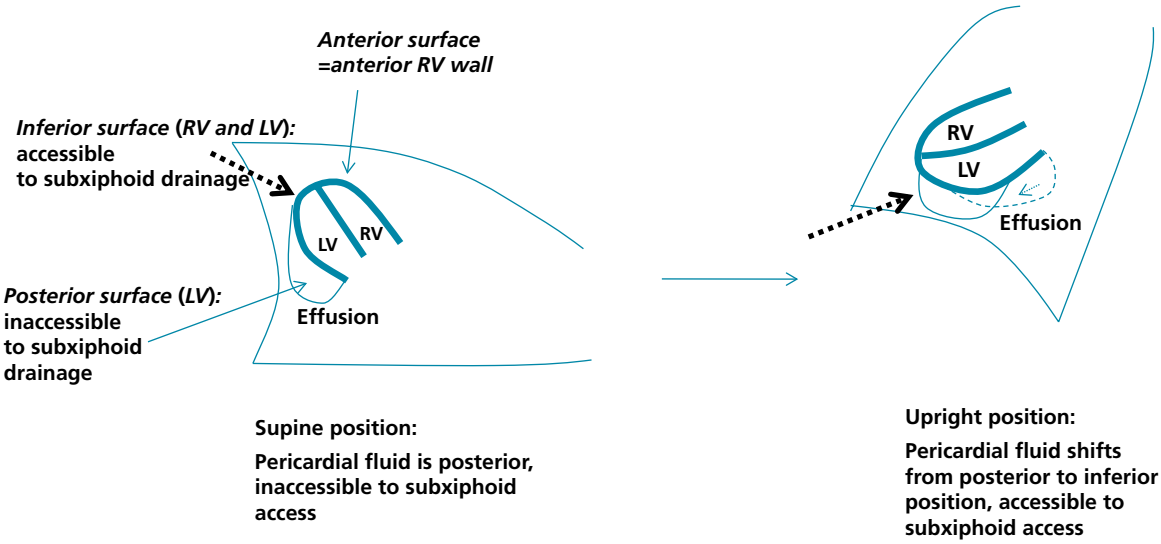

Figure 17.6 Heart surfaces in relation to the subxiphoid pericardiocentesis, in both supine and upright positions. On echo, the long-axis view and the apical 4-chamber view show the posterior part of the effusion, not the one that will be accessed by subxiphoid pericardiocentesis. The subcostal view best shows the inferior part of the effusion, next to the inferior diaphragmatic wall of the RV (next to the liver).

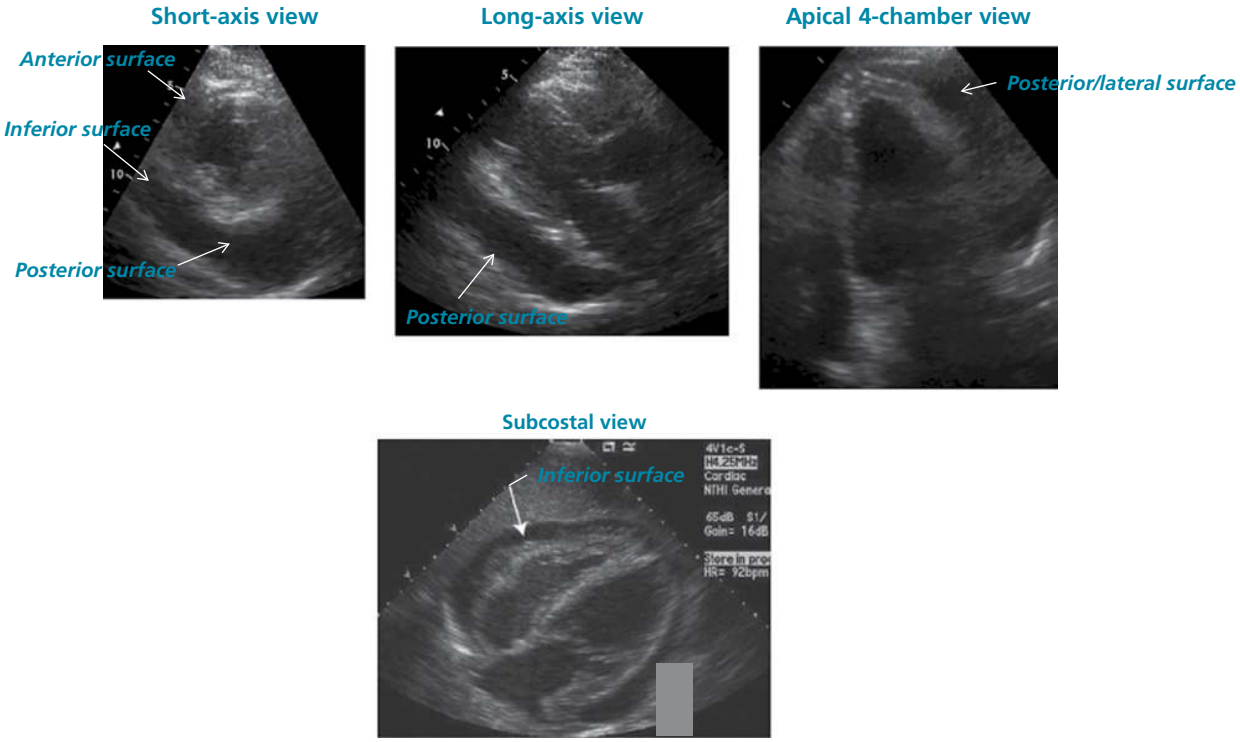

Figure 17.7 Various echo views showing the various heart surfaces in a patient with pericardial effusion. The long-axis and 4-chamber views show the posterolateral aspect of the effusion, accessible to apical access. The subcostal view shows the inferior aspect of the effusion next to the liver and is the one used to guide the left subxiphoid access.

III. Note on postoperative pericardial effusions (after cardiac surgery)

Postoperative pericardial effusions may occur early, in the first postoperative week, in which case they are hemorrhagic with a high risk of tamponade; they usually require urgent drainage.

Outside these early bleeding complications, inflammatory postoperative effusions are common and typically appear or progress over the first 8–10 days, then tend to spontaneously regress thereafter (called late postoperative effusions). In fact, by postoperative day 8, ~40% of patients have a small effusion, ~20% have a moderate effusion, and 1% have a large effusion. By postoperative days 20–30, most of these effusions resolve or improve (by 5–10 mm on average), but ~10% of patients still have a moderate effusion.[39–41] Large effusions have at least a 25% risk of progressing to tamponade within 30 days, while the risk with moderate effusions is ~10%; the risk may even be higher when these effusions persist longer.

These late effusions may be due to slow blood oozing in the pericardium or to a post-pericardiotomy syndrome, which is a pericardial and pleural inflammatory process occurring later than a week after surgery. In fact, half of these late effusions are hemorrhagic, while the other half are serosanguinous.

During cardiac surgery, the pericardium is opened and left open, which may seem protective against the development of a pericardial effusion. In reality, the edges of the cut pericardium may adhere to the sternum and create a new pericardial space, which is bound by the sternum anteriorly and the pericardium posterolaterally and superiorly. Moreover, the parietal pericardium may adhere to the visceral pericardium, thus closing the pericardial space. Hence, half of the postoperative pericardial effusions are circumferential, more so in case of tamponade, while the other half are loculated. Most loculated effusions are either anterior (meaning, over the RV) or posterolateral. Isolated loculation over the RA is less common (LA much less common).

Management

Moderate pericardial effusions warrant close echo follow-up (1–2 weeks) to document regression, especially if the patient is receiving anticoagulation. Small effusions may also require follow-up, especially if they develop early on (<7 days) or if the patient is receiving anticoagulants.[39–42]

Asymptomatic large pericardial effusions typically need to be drained, particularly if the patient is receiving anticoagulants.[39,42] Early drainage or close surveillance followed by drainage (in the absence of a quick improvement within a week) are both acceptable strategies in patients not receiving anticoagulants.

Echo-guided pericardiocentesis is a safe and effective treatment of late postoperative effusions requiring drainage. In 2 major series, most postoperative effusions were drained percutaneously, with a low recurrence rate of only 4%.[42] Subxiphoid pericardial window is another alternative, and is particularly useful for loculated effusions inaccessible percutaneously (posterior effusions), recurrent effusions, and possibly effusions occurring in patients receiving anticoagulants (higher recurrence risk).

NSAIDs have not been shown to significantly change the natural history of asymptomatic postoperative effusions (POPE trial), even though the mechanism of these effusions is thought to be inflammatory.[40] Nonetheless, NSAIDs may be useful in patients with increased CRP.

IV. Note on uremic pericardial effusion

Two forms of renal pericarditis are seen. One form occurs in acute or advanced chronic renal failure not undergoing dialysis (classic uremic pericarditis), while the second form occurs in patients undergoing adequate chronic dialysis with normal BUN and creatinine (dialysis-associated pericarditis).

Uremic pericardial effusion usually resolves after several weeks of intensive hemodialysis (heparin should be used cautiously during dialysis); unless tamponade is present, watchful management is appropriate.[5] The effusion occurring in patients adequately receiving chronic dialysis inconsistently responds to dialysis intensification. A pericardial window may be required.

4. CONSTRICTIVE PERICARDITIS

Constrictive pericarditis is due to pericardial scarring that takes years to develop, but in some instances it only takes a few months. The pericardium becomes a stiff "shell" that surrounds the right and left cardiac chambers and impairs their filling, leading to signs of right heart failure and symptoms of left heart failure. Both the visceral and parietal layers are fibrotic and adherent to the myocardium. A transient constrictive physiology without pericardial scarring may be seen after any pericardial inflammation (such as 9% of acute idiopathic pericarditis).[43]

I. Causes

The 3 most common causes of constrictive pericarditis are, in order of frequency: idiopathic, post-cardiac surgery, and post-mediastinal irradiation.[44,45]

Other, less common causes, are autoimmune (especially rheumatoid arthritis), post-infectious, traumatic, malignant.

Postoperative constrictive pericarditis may appear as early as 2 weeks or as late as 25 years after cardiac surgery, the majority of cases appearing 3–24 months postoperatively. The constrictive process has an incidence of ~0.1% and may be related to the post-pericardiotomy syndrome. Constrictive pericarditis occurring within 2 months postoperatively warrants medical therapy with anti-inflammatory agents, as this early process is often an inflammatory, transient constrictive process with limited fibrosis.

Constrictive pericarditis typically develops years after radiation therapy (range 1–40 years, median 13 years).

II. Pathophysiology and hemodynamics

The stiff pericardial shell results in 3 effects:

1. Early during diastole, the pressures of all 4 cardiac chambers increase enough to equalize with the pressure exerted by the stretched "shell," i.e., *a high pressure* of 15–25 mmHg.

2. The shell prevents the transmission of intrathoracic pressure to the cardiac chambers (dissociation between intracardiac and intrathoracic pressures).
3. Both LV and RV are constricted within this shell, so that a change in volume of one chamber reflects upon the other (ventricular interdependence).

These 3 effects explain the following pathophysiology:

- ***Diastolic pressure of all 4 cardiac chambers, diastolic PA pressure, and diastolic PCWP (~mean PCWP) all become high and equal to the pressure of the stretched pericardium (high equalization of diastolic pressures)***. *Thus, mean RA pressure = mean PCWP and RVEDP = diastolic PA pressure = LVEDP.*
- ***Ventricular dip–plateau pattern and deep atrial X and Y descents (high RA pressure with M or W shape)*** (Figure 17.8).
- ***During inspiration*** (Figure 17.9):[46–49]
  - In the absence of constriction, there is an inspiratory decrease in pulmonary venous pressure and an inspiratory decrease in LA pressure and LV pressure, such that the driving gradient between the pulmonary veins and the LV remains grossly unchanged, and the flow only minimally changes. In constriction, there is an inspiratory decrease in pulmonary venous pressure, but the LA and LV pressures are unchanged, so that the driving gradient between the pulmonary veins and the LV is reduced. This reduces flow toward the LV (manifested as reduced transmitral E velocity on Doppler). Owing to ventricular interdependence, the reduced LV volume "sucks" the RV during inspiration; thus, the RV "sucks" flow from the RA and the flow between the RA and RV increases (transtricuspid E velocity increases on Doppler). This explains the ***ventricular systolic discordance*** (RV systolic pressure increases whereas LV systolic pressure decreases during inspiration), which is ***ventricular interdependence with respiratory effect***.
  - The flow between RA and RV is mainly increased for a short period of time that corresponds to the deep Y descent (the deep diastolic Y descent on the RA tracing is mainly seen during inspiration).
  - Constriction prevents a decrease in RA pressure. Thus, the flow between SVC and RA decreases with inspiration, which ultimately leads to increased SVC pressure, hence the increased jugular venous pressure with inspiration (Kussmaul's sign).
  - IVC pressure, on the other hand, is not subject to the negative intrathoracic pressure changes. Thus, since RV-to-RA sucking is increased with inspiration in early diastole and early systole, this "sucks" flow from the IVC and increases IVC-to-RA flow, which manifests as increased hepatic forward flow on Doppler echocardiography. Also, the positive intra-abdominal pressure during inspiration augments the IVC flow. The hepatic antegrade S and D velocities increase with inspiration, then become reduced and even partially reversed with expiration (S corresponds to the systolic flow, i.e., X descent, while D corresponds to the diastolic flow, i.e., Y descent). Thus, *SVC and IVC pressures and flow patterns are divergent in constrictive pericarditis.*

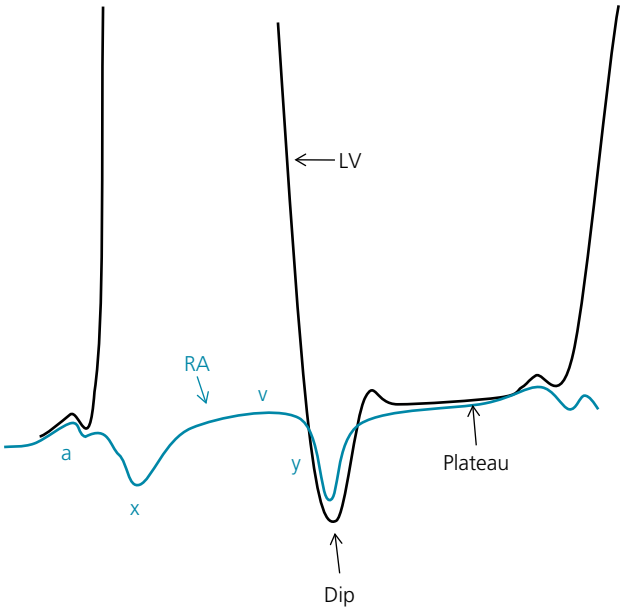

Figure 17.8 Simultaneous RA and LV pressure recordings in constrictive pericarditis. These demonstrate a dip–plateau pattern on the LV tracing, deep X and Y descents on the RA tracing, and equalization of diastolic pressures of LV and RA. In early diastole, upon ventricular relaxation, there is a sharp decrease of ventricular pressure with subsequent "sucking" from the atria in early diastole. However, due to constriction, the pressure in the ventricles quickly rises and equalizes with the pericardial pressure. This explains the *dip–plateau (square root)* shape of the RV and LV tracings in diastole and the *deep and brief Y descent* on the RA and LA tracings during the early diastolic "sucking." Y descent and the ventricular dip are superimposed. The height of the dip is ≥7 mmHg.

In early systole, upon downward movement of the valvular annulus, RA and LA pressures sharply decrease before they again promptly equalize with the pericardial pressure; this explains the *deep and rapid X descent*. X and Y descents are mainly deep in inspiration. Reproduced with permission of Demos Medical from Hanna (2012).[46]

While ventricular interdependence is present in both constriction and tamponade, a different mechanism is incriminated in each case: during inspiration, RV "pushes" LV in tamponade, whereas RV is "sucked" by LV in constrictive pericarditis. As opposed to constrictive pericarditis, LV flow is reduced in tamponade because of RV compression, not because of a lack of transmission of the negative intrathoracic pressure to the LV. In addition, because of the uniform pericardial fluid, the constraint is more uniform across both the LV and the RV in tamponade. **Thus, in tamponade: (1) ventricular interdependence is more prominent and leads to pulsus paradoxus, which is present in only one-third of cases of constriction; (2) the cardiac chambers are compressed throughout diastole, including early diastole, making Y descent flat (vs. deep in constriction); (3) RA pressure declines in inspiration (no Kussmaul's sign).**

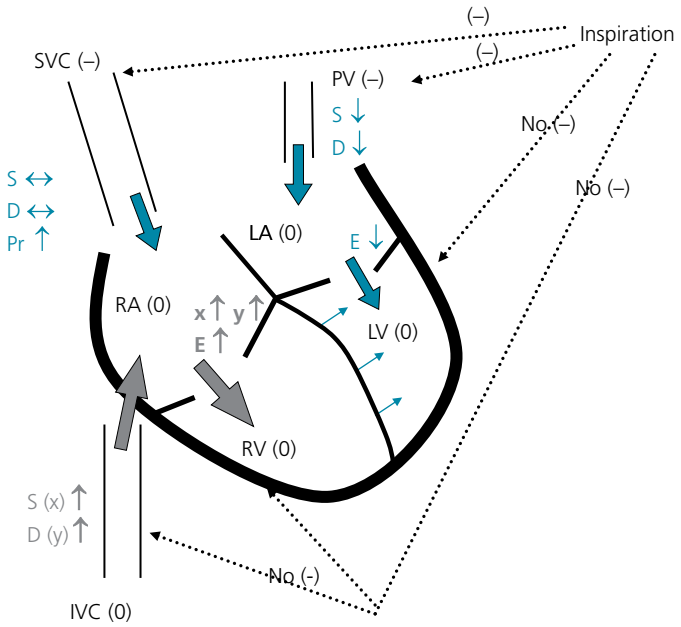

Figure 17.9 Sequence of events occurring during inspiration in constrictive pericarditis. *(–)* sign adjacent to a structure signifies there is transmission of the negative intrathoracic pressure to this structure, whereas *(0)* corresponds to the lack of transmission of the intrathoracic pressure to this structure. *Gray block arrows* signify increased flow between 2 chambers, while the *blue block arrows* signify reduced flow between 2 chambers. ↔ indicates lack of change.

During inspiration, the negative pressure is transmitted to PV and SVC but not to the intracardiac chambers or the IVC. This reduces blood flow between PV and LA, and thus between LA and LV, which "sucks" the ventricular septum to the left. This increases RV volume, which "sucks" blood from RA and IVC. It cannot suck blood from the SVC because the SVC pressure is initially reduced by the negative inspiratory effect. The flow between SVC and RA is unchanged while the flow between IVC and RA is increased. SVC pressure ultimately increases (Kussmaul's sign) and RA pressure remains unchanged or increases slightly because of increased IVC flow.

Note that normal individuals also have a respiratory variation in filling: in inspiration, RV fills more than the LV (vice versa in expiration), but this is subtle with no ventricular interdependence, as the RV expands outward and does not compress the LV. Hence filling changes are subtle, not enough to raise RV pressure and overcome the direct negative thoracic pressure.

D, diastolic flow wave of IVC, SVC, and PV on Doppler, corresponds to Y descent; E, mitral inflow Doppler wave; S, systolic flow wave of IVC, SVC, and PV on Doppler, corresponds to X descent; Pr, pressure change that ultimately occurs in the SVC; PV, pulmonary veins. ***D on echo is Y on pressure tracing, S is X (DY--SX)***. Reproduced with permission of Demos Medical from Hanna (2012).[46]

In pericardial processes, there are marked respiratory variations of flow, and thus **marked and discordant variations of RV and LV *systolic* pressures**, **without marked variation of *diastolic* pressures and atrial pressures** (shielding effect of the shell). The respiratory variations of flow, manifesting as discordant RV–LV systolic pressures and respiratory variations of S and D, are key diagnostic features of constriction. This is **ventricular interdependence with respiratory effect**.

III. Hemodynamic findings in constrictive pericarditis and differential diagnosis of constrictive pericarditis: restrictive cardiomyopathy, decompensated RV failure, COPD (Table 17.1)

In any **HFpEF**, besides the "standard" HFpEF (associated with age, obesity, HTN, AF), think of **3 HFpEF mimickers** and look for their ancillary features, particularly in a clinical picture of predominant right heart congestion:

1. Restrictive cardiomyopathy from: (i)infiltrative disease, such as amyloidosis (senile wild-type or young-onset genetic), Fabry, or sarcoidosis; (ii) or restrictive HCM (with or without obstruction). RV dilatation frequently coexists at late stages.
2. *Isolated or predominant RV failure*, including RV failure driven by atrial functional TR or late-stage HFpEF.
3. *Constrictive pericarditis*.

Table 17.1 Comparison of hemodynamic findings in constrictive pericarditis, restrictive cardiomyopathy, and severe ventricular failure.

Features shared by constrictive pericarditis, restrictive cardiomyopathy, and ventricular failure

1. Elevated and often equalized right- and left-sided filling pressures (elevated RA pressure and PCWP)
2. Ventricular dip–plateau pattern
3. Deep atrial X and Y descents with an atrial M morphology. In cardiomyopathies and particularly in severe TR, marked V wave and flattened X are sometimes seen and RA pressure may be >PCWP; these features are unlikely in constriction
4. RA Kussmaul's sign in all 3 conditions: no inspiratory drop of RA pressure, especially when RA>15 mmHg (Y becomes deeper and RA pressure may rise with inspiration)

Constrictive pericarditis	Restrictive cardiomyopathy or any decompensated LV failure	Decompensated RV failure
1. Equalization of RV and LV end-diastolic pressures (**RV = LV** in inspiration, **RV < LV** in expiration)	LV diastolic pressure may be > RV diastolic pressure by > 5 mmHg	Equalization of RV and LV end-diastolic pressure (**RV = LV** in expiration, **RV > LV** in inspiration)
2. Early diastolic gradient between PCWP and LV varies with respiration > 5 mmHg[a]	No significant change of PCWP–LV early diastolic gradient[a]	No significant change of PCWP–LV early diastolic gradient[a]
3. During respiration, there is a discordant change of the systolic areas of LV and RV (when RV pressure ↑, LV pressure ↓)	During respiration, there is a concordant change of the systolic areas of LV and RV	During respiration, there is a concordant change of the systolic areas of LV and RV
4. Systolic PA pressure < 55 mmHg	Systolic PA pressure may be >55 mmHg	

[a] In constriction, the LV diastolic pressure varies minimally with respiration, whereas the PCWP varies markedly, which explains the significant respiratory change of the early diastolic PCWP–LV gradient (lowest during inspiration). This reflects the *intracardiac-intrathoracic dissociation*. In other disease states, the LV diastolic pressure changes as much as the PCWP with respiration, hence the lack of significant change of the PCWP–LV early diastolic gradient.

A. Restrictive cardiomyopathy is characterized by poor relaxation and poor compliance of the RV and LV myocardium. As opposed to dilated cardiomyopathy, systolic function is relatively preserved (or mildly impaired) and the LV cavity is not dilated. The myocardial thickness is increased in infiltrative restrictive cardiomyopathies, such as amyloidosis, and may reach levels seen with hypertrophic cardiomyopathy (>20 mm). As opposed to hypertrophic or hypertensive cardiomyopathy, the increase in thickness is due to myocardial infiltration rather than myocardial hypertrophy, explaining the discrepancy between the low voltage and the Q waves on the ECG on the one hand and a thick myocardium on echocardiography on the other hand. As in any decompensated ventricular failure, LA and RA are markedly dilated, and functional atrial TR and MR, sometimes severe, may be seen. The RV may dilate at an advanced stage, and such a dilatation is a poor prognostic sign.[50]

Hemodynamically, restrictive cardiomyopathy has similar features to any decompensated ventricular failure. The stiff non-compliant myocardium acts as a "shell" explaining the following 4 restrictive findings: (1) elevated and frequently equalized left and right ventricular diastolic pressures, (2) ventricular dip–plateau pattern, (3) deep/rapid atrial X and Y descents, and (4) lack of respiratory decrease of mean RA pressure with inspiration (Kussmaul's sign). A prominent V wave and prominent X and Y descents are seen as a result of the poor atrial and ventricular compliances (atrial pressure goes sharply down then up in early diastole and early systole). *A different mechanism explains Kussmaul's sign:* the negative respiratory pressure gets transmitted to the RA, but the severely impaired RA compliance causes an inspiratory rise in RA pressure with the rise in preload, overcoming the direct negative respiratory pressure. As such, mean RA pressure remains steady or rises with inspiration, but Y deepens.

Ventricular interdependence may be present, especially if the RV is dilated and all chambers are constrained within the stiff myocardial shell, but there is no pronounced respiratory effect.

B. Severe ventricular failure (particularly RV failure)

The 4 restrictive findings may be seen in the right-sided cavities with any decompensated RV failure and in the left-sided cavities with any decompensated LV failure, and they are explained by the severely reduced ventricular compliance. In addition, the pericardium is stretched by the dilated ventricle(s) and becomes functionally constrictive, forcing the ventricles to expand at the expense of each other and to equalize their diastolic pressures. In fact, if the RV or LV develops *severe or rapid* volume overload, the pericardium does not have time to expand and accommodate the increased intracavitary volume. Thus, the equalization of right- and left-sided end-diastolic pressures is seen with severe ventricular failure.[51] The 4 findings may also be seen in severe TR or acute severe AI or MR, and are more readily seen with RV failure as the latter is thin and more readily dilates than the LV. In a way, the pericardium prevents further ventricular dilatation and afterload rise at the expense of "functional constriction."

In RV failure, the ventricular interdependence is not markedly affected by respiration, as the RV is already markedly distended and may not further distend with inspiration. In addition, the RV is at a flat portion of the Frank–Starling curve and cannot significantly increase its flow with the inspiratory rise in preload. Thus, the systolic discordance of RV and LV pressures is not as often or as markedly seen.

Only the discordance between LV and RV systolic pressures is highly sensitive and highly specific (>90%) for the diagnosis of constrictive pericarditis (Figure 17.10).[48] The second most specific feature is the respiratory change in the early diastolic gradient between PCWP and LV. The discordance and the respiratory changes are best evaluated during *deep respiration*. This contrasts with the clinical evaluation of discordance by pulsus paradoxus, and the Doppler evaluation of discordance by transmitral analysis, performed during *normal respiration*.

C. COPD and other causes of RV–LV respiratory discordance

While RV failure may lead to 4-chamber diastolic pressure equalization and abnormal RV and RA pressure tracings mimicking constriction, COPD may mimic another aspect of constriction. Because of large intrathoracic pressure swings, COPD or asthma or any severe dyspnea may lead to discordant RV and LV filling and pulsus paradoxus. This may also be seen in patients receiving mechanical ventilation and in

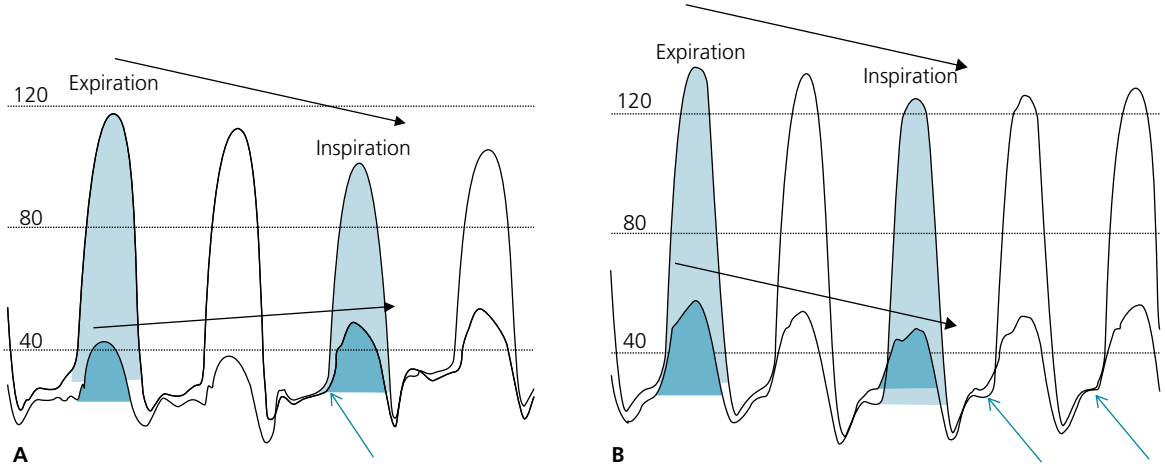

Figure 17.10 Simultaneous RV and LV pressure tracings in two different patients. **Analyze 3 elements on the RV–LV simultaneous tracing:** (1) in diastole, dip–plateau pattern of the LV and the RV; (2) in diastole, elevation and equalization of RV and LV end-diastolic pressures; (3) in systole, concordance vs. discordance of RV–LV systolic pressures. Both patients A and B have the dip–plateau pattern and the elevation and equalization of RV and LV end-diastolic pressures (in inspiration, *blue arrows*). Patient A has constrictive pericarditis: the LV and RV systolic areas, which correspond to stroke volume, change discordantly (*light and dark shaded areas*, respectively). Patient B has a restrictive myocardial disease: note the concordance of the LV and RV systolic areas. Analyze the discordance of the systolic areas under the curve ("bulk") rather than the systolic peaks.

Concordance pattern is analyzed by choosing the *peak inspiratory beat*, which is the beat preceded by the lowest diastolic dip, and the *peak expiratory beat*, which is the beat preceded by the highest diastolic dip. Thus, diastole helps determine which beats are selected for systolic analysis. Reproduced with permission from Elsevier from Talreja et al. (2008).[48]

sedated patients breathing deeply, as in many routine cardiac catheterization procedures. With the deep negative intrathoracic pressure, right-sided filling increases because a large volume is driven from outside the thorax to inside the thorax, which does not happen on the left side. RV and LV will have opposite phasic changes in volume and discordant systolic pressures. These discordant changes in RV–LV filling that lead to pulsus paradoxus may also be seen in normal subjects who are hypovolemic, i.e., are on the steep portion of the cardiac output–preload curve (Frank–Starling curve), and breathing deeply;* they are often absent in hypervolemic patients (non-preload-dependent). That is why discordant RV–LV filling is unusual in restrictive cardiomyopathy and severe heart failure.

The phasic changes in RV and LV filling are also present in normal subjects breathing quietly, but are very subtle. **In normal subjects, right-sided flow increases during inspiration, whereas the left-sided flow decreases, but RV and LV systolic pressures both concordantly and mildly decrease during inspiration, due predominantly to the direct effect of the negative intrathoracic pressure on the measured cardiac or vascular pressures, the effect of RV–LV filling discordance being minimal.** The same concordance phenomenon is seen in non-constriction and non-COPD disease states, such as restriction and RV failure. The filling discordance overwhelms the direct negative inspiratory pressure effect in cases of constrictive pericarditis, COPD, or large respiratory swings in hypovolemic patients.

In respiratory processes with deep respiratory swings, as opposed to constriction:

1. The end-diastolic pressures of the 4 cardiac chambers are not equalized (RA pressure and RVEDP < PCWP and LVEDP).
2. The respiratory pressure is transmitted to the cardiac chambers, and thus Kussmaul's sign is not seen (i.e., SVC and RA pressures are reduced with inspiration).
3. There is no dip–plateau pattern on the RV or LV tracing. RA pressure does not have a deep X and deep Y pattern and is usually normal.

On echocardiography, SVC flow may be used to differentiate respiratory processes/COPD from constriction. In constriction, SVC flow is dissociated from IVC and does not increase during inspiration (Kussmaul's sign), while in COPD, SVC flow increases in sync with the IVC. Thus, in constriction, the SVC Doppler velocities (S and D) show little change from inspiration to expiration, whereas in COPD, S and D velocities markedly increase in inspiration (S velocity in particular).[52] IVC and hepatic flow increases during inspiration and is reduced and partially reversed in expiration in both COPD and constriction.

IV. Practical performance of a hemodynamic study when constrictive pericarditis is suspected

Perform simultaneous LV-RV recording. ***Only the respiratory discordance between LV and RV systolic pressure areas is highly sensitive and highly specific (>90%)*** for the diagnosis of constrictive pericarditis. This is followed by the respiratory variability of the gradient between PCWP and LV in early diastole, reflective of intrathoracic-intracardiac dissociation.

Regarding the other invasive hemodynamic features, **equalization of LV-RV end-diastolic pressure is very poorly sensitive and specific** and may be seen in any cardiomyopathy. **Each one of the following 4 features, obtained by stand-alone right heart catheterization, is highly sensitive (93%) but poorly specific for constriction, meaning that the absence of one or especially several of them may rule out** constriction, but their presence does not rule it in. In practice, they much more commonly reflect cardiomyopathies

*Unlike pericardial disorders, this mild normal RV/LV discordance is not due to ventricular interdependence, as the ventricles are not constrained by the pericardium. In normal subjects, the negative inspiratory pressure sucks flow from the veins outside the thorax into the RA, raising right-sided flow, but does not raise flow between the pulmonary veins and the LA, as both are subject to the negative thoracic pressure, more so the pulmonary venous system. Because of the pulmonary transit time, the RV flow change gets transmitted to the LV later, during expiration.

and RV failure than constriction. Those 4 features are almost necessary but far from sufficient for the diagnosis of constriction (see Section IX):[47]

i. RA Kussmaul's sign = lack of respiratory drop in mean RA pressure. Also, RA has deep X and especially deep Y descent.
ii. PA systolic pressure <55 mmHg. PA pressure is unlikely to be >55 mmHg in constriction as RV stroke volume is low and LA pressure is not high enough to cause severe post-capillary PH. It is commonly >55 mmHg in restrictive cardiomyopathy.
iii. Dip–plateau RV and LV pattern with ≥7 mmHg height between the LV dip and the plateau, called rapid filling wave.
iv. RVEDP/RV systolic pressure ratio >1/3, a reflection of the high RVEDP and the relatively low RV systolic pressure <55 mmHg, as well as the low RV stroke volume (narrow RV pulse).

Some of the abnormalities of constrictive pericarditis are made more evident by hypovolemia, whereas others are made more evident with volume loading (500 ml over 10 minutes in the cath lab):

- The dip–plateau pattern and the deep and rapid RA X and Y descents, which are signs of severely reduced compliance, are better shown with volume loading and are masked with hypovolemia. In fact, RA pressure may be normal <8 mmHg or only mildly elevated (8–15 mmHg) with a normal pulse contour in hypovolemia (*occult constrictive pericarditis*).[53]
- The equalization of LV/RV diastolic pressures is better shown with volume loading.
- The discordant respiratory changes of LV and RV systolic pressures are better seen in hypovolemia (similar to the accentuation of pulsus paradoxus with hypovolemia). ***While a volume load creates more ventricular interdependence, the respiratory changes of ventricular interdependence become attenuated***.[54]

V. Echocardiographic features of constrictive pericarditis, and differentiation between constrictive pericarditis and restrictive cardiomyopathy (see Table 17.2)

In both constrictive pericarditis and restrictive cardiomyopathy, the right and left ventricular systolic functions are preserved, ventricular size is normal, and the atria are enlarged. However, in restrictive cardiomyopathy, there is no significant respiratory variation of the transmitral and the transtricuspid flows and no significant respiratory variation of the hepatic and the pulmonary venous flows (in contrast to constrictive pericarditis, where E velocity varies by >25% *during normal breathing*) (Figure 17.11, 17.12).[55] In restrictive cardiomyopathy and RV failure, the negative intrathoracic pressure tries to draw flow from the IVC and SVC branches; however, the RA and RV being poorly compliant and non-preload dependent, the venous flow does not change much with normal inspiration (IVC does not collapse on echo). **In constriction,** there are respiratory variations of transmitral, pulmonary venous, and hepatic venous flow regardless of the patient's rhythm (IVC is dilated but partially collapses). The respiratory variation may be absent in up to 12% of patients with constrictive pericarditis, particularly those with severe hypervolemia; the respiratory variation is unmasked by preload reduction, e.g., head-up tilting or sitting.[54] In AF, the respiratory variations are more subtle, and manifest as a paradoxical increase of E velocity after a short R–R cycle

Table 17.2 Echocardiographic differentiation between constrictive pericarditis and restrictive cardiomyopathy.

	Constrictive pericarditis	**Restrictive cardiomyopathy**
Similarities		
E/A	>0.8, and frequently >1.5	>1.5
E deceleration time	Reduced < 160 ms	Reduced < 160 ms
Ventricular size/systolic function	Normal	Normal
Atria	Mildly dilated	More markedly dilated
IVC	Dilated	Dilated
Differences		
Respiratory E variation (*during normal respiration*)	>25%	<25%
Medial annular E′ velocity	≥ 9 cm/s or >lateral E′	<9 cm/s
Hepatic venous flow respiratory variation	↑ S and D with inspiration ↓ S and D with partial reversal of flow in expiration	Minimal variation
Pulmonary venous flow respiratory variation	↑ S and D with expiration	Minimal variation
Septal motion on M-mode and 2D echo	Abnormal (septal bounce in diastole due to competitive filling of RV and LV)	Reduced
Color M-mode mitral valve velocity of propagation (Vp)	Normal (>55 cm/s) (implies normal diastolic recoil, like medial E′)	
Posterior wall motion in diastole on M mode	Dip–plateau (after early expansion, posterior wall remains flat in diastole)	Normal
Pulmonary pressure	<55 mmHg	May be > 55 mmHg
TR and MR	Infrequent	Frequent, may be severe
2D echo strain	Preserved except for lateral wall impairment	Diffusely impaired

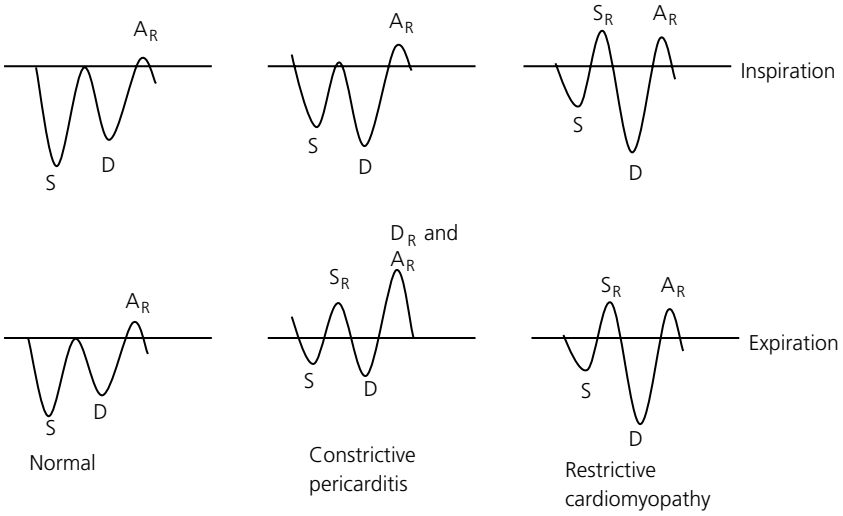

Figure 17.11 Respiratory variations of hepatic venous flow velocities. S flow corresponds to the X descent on RA pressure tracing, D flow corresponds to the Y descent (S = X, D = Y), and Ar flow corresponds to A wave. In constrictive pericarditis, S and D increase with inspiration (i.e., increase in X and Y descent); S and D decrease with expiration along with a terminal S reversal (S_R) and a terminal D reversal (D_R) [D reversal in expiration = DrE]. Minimal respiratory variations are seen in normal individuals and even less in restrictive cardiomyopathy. In the latter case, there is a reduction of S velocity (= X descent) with terminal S reversal (= V wave), and an increase of D velocity (= Y descent) and A reversal.

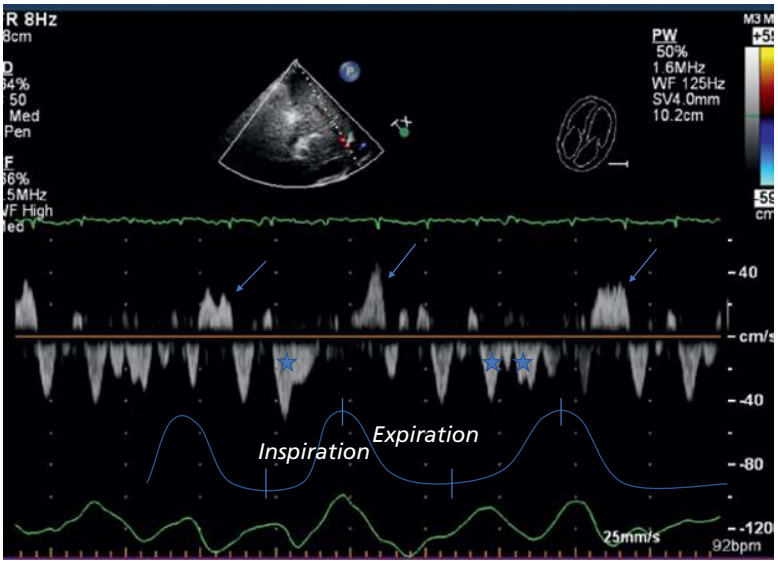

Figure 17.12 Hepatic vein Doppler in constrictive pericarditis, with respirometer. Note the pronounced reversal of D wave in expiration (D wave above the baseline, *arrows*). Conversely, forward D wave is pronounced in inspiration (*stars*). In expiration, the reversed D wave is larger than the same-beat forward D wave component, and almost matches the forward D wave of inspiration.

Simplified analysis technique: For simplicity, one may skip defining S/D/A and the respiratory phase. Just look at the waves below the baseline vs. above the baseline. *If at some points the wave above the baseline is equal to or larger than the wave below the baseline within the same beat (arrows)*, with dramatic changes between beats, intermittent D reversal is implied. Just ensure there is *no severe TR* with predominant S reversal.

and a paradoxical decrease of E velocity and pulmonary venous S and D velocities after a long R–R cycle, depending on the respiratory phase; hepatic venous flow reversal remains prominent with expiration regardless of R–R cycle and is often more helpful than the analysis of transmitral flow in AF.[56]

Furthermore, in restrictive cardiomyopathy as in any LV failure, the tissue Doppler velocity of the mitral annulus is reduced in diastole signifying reduced relaxation/recoil. In constriction, the medial annular velocity is preserved or elevated. In fact, the pericardial constraint limits the lateral expansion of the heart, which reduces the lateral recoil E′; the medial recoil E′ tries to compensate for the lateral constriction and becomes exaggerated despite elevated filling pressures, the so-called **annulus reversus** (medial E′ > lateral E′ or ≥9 cm/s). Only 3 conditions may have HF with high E′ velocity: constriction, AF, high-output HF.

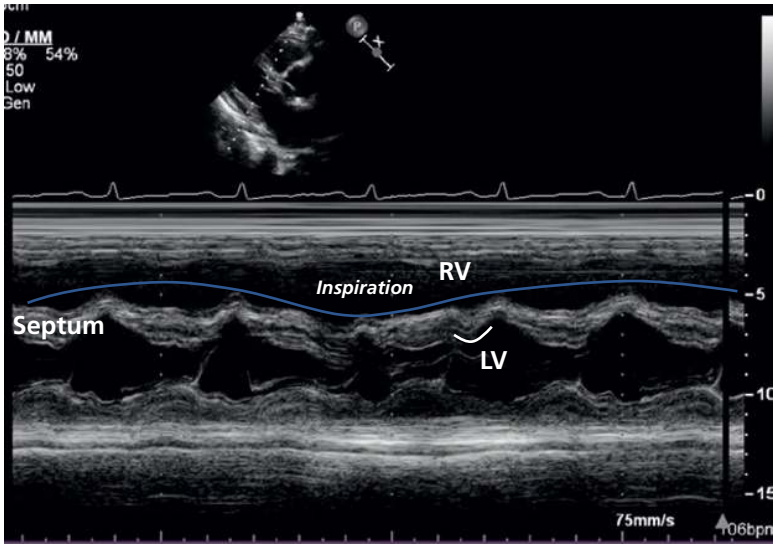

Figure 17.13 Septal M mode in a patient with constrictive pericarditis. Note the respiratory variation of septal position (*blue line*): septum is pushed toward the LV in inspiration. Also, note the unstable, "shuddering" septal position in diastole within the same beat, called septal bounce (*white line*).

Two septal motion abnormalities occur in constrictive pericarditis and are best identified on M-mode. These septal motion abnormalities are also seen in tamponade but may be less obvious as the cavities are more empty (Figure 17.13):

1. The septum is pushed toward the LV in inspiration; it is pushed toward the RV in expiration. This respirophasic septal shift in position is best seen by M mode. In RV volume overload, unlike constriction, the abnormal motion is systolo-diastolic rather than respiratory.
2. Even within the same diastole and the same respiratory cycle, an instantaneous change in the RV-to-LV push is seen (septal bounce). This signifies that the 2 chambers are constantly competing for space within the stiff pericardium.

In sum, according to a Mayo clinic analysis, **a combination of the following 3 criteria** is associated with the highest sensitivity (87%) and specificity (91%) for constrictive pericarditis:[57]

1. Respirophasic septal shift on M mode along with either:
2. Medial E′≥ 9 cm/s or ≥0.91x lateral E′. Medial E′ < 6 cm/s makes constriction very unlikely
3. Or hepatic vein reversed D/forward D ratio ≥ 0.79 in expiration (measured on the same expiratory beat)

Pronounced septal motion swings are mainly related to 3 processes: LBBB, severe RV volume overload, and constrictive pericarditis. Abnormal septal swings without LBBB or RV dilatation should suggest constrictive pericarditis in a dyspneic patient. A more detailed analysis of the septal motion is then done by M mode and the 2 additional echo features are sought: medial vs. lateral E′, and hepatic vein flow. Occasionally, respirophasic septal shift may be seen outside constriction in marked dyspnea with deep inspiratory pressure.

VI. Physical exam, ECG findings, BNP, pericardial thickness (CT/MRI)

A. Physical exam

1. *Signs of right heart failure,* sometimes isolated right heart failure. Constrictive pericarditis should always be considered in the differential diagnosis of isolated right heart failure:
- Increased JVP with the following features:
  a. Kussmaul's sign (i.e., increased JVP with inspiration, which may also be seen with severe RV failure)
  b. Deep X and Y descents on JVP exam
- Peripheral edema
- Ascites, hepatic congestion with jaundice (differentiate from cirrhosis by the elevated JVP and the hepatomegaly, vs. atrophic liver in cirrhosis).

2. *Symptoms of elevated LA pressure* (dyspnea, orthopnea). Similarly to tamponade, dyspnea occurs but pulmonary edema and hypoxemia do not usually occur because of the low volume reaching the left heart.
3. *Low-output signs* (fatigue).
4. *Pulsus paradoxus* in one-third of patients. Pulsus paradoxus is more common in tamponade than constriction, because of the more potent and uniform compression of both ventricles in tamponade (more extreme RV–LV discordance). Pericardial knock may be heard in diastole (occurs at the end of the ventricular dip, sounds like a high-pitched S_3).

B. ECG

The ECG is almost always abnormal: low QRS voltage (very commonly), and non-specific T-wave abnormalities (flat, inverted).

C. BNP

In restrictive cardiomyopathy, BNP is ~ always >200 pg/ml, whereas in idiopathic constrictive pericarditis, it is <200 pg/ml. BNP may be >200 pg/ml in other forms of constrictive pericarditis (e.g., post-radiation).

Severe right HF with a normal BNP suggests constrictive pericarditis or obese HF with full BNP deficiency.

D. Cardiac CT and MRI – Pericardial thickness

Pericardial thickness is usually increased (≥3 mm) in constrictive pericarditis and may be assessed by echo, CT, or MRI. However, a study using operative specimens has shown that 18% of patients with constrictive pericarditis have normal pericardial thickness, and those patients are as likely as patients with a thickened pericardium to benefit from pericardiectomy.[58] On the other hand, a thickened pericardium does not necessarily lead to constriction. About 50% of constrictive pericarditis cases are calcified on CT (slightly less so on X-ray).[59]

A thickened pericardium with severe late gadolinium hyperenhancement of the pericardium itself or edema on T2 suggests a reversible, inflammatory constrictive process. Cardiac MRI is recommended in the evaluation of constrictive pericarditis, mainly to look for inflammatory constrictive pericarditis that may resolve with medical therapy. It also helps confirm the diagnosis by further demonstrating respirophasic ventricular interdependence and pericardial thickening.

The diagnosis of constrictive pericardits is usually established by echo and corroborated by CT or MRI findings. Cath is not always necessary, and if done, both right and left heart cath are required.

VII. Transient constrictive pericarditis

Up to 17% of patients with constrictive pericarditis may have a transient (reversible) constrictive pericarditis. This may be seen with idiopathic, post-surgical, traumatic, infectious, or collagen vascular disease-associated constrictive pericarditis, particularly when the onset of symptoms is recent. In this case, inflammation and edema lead to pericardial thickening and stiffening without fibrosis. *Only radiation-induced constrictive pericarditis cannot be transient.* A pericardial effusion is often present (67%), sometimes large and often with rind. In fact, most cases of effusive–constrictive pericarditis are transient, insomuch that *the terms "transient constrictive pericarditis" and "effusive constrictive pericarditis" are often equivalent.* There are 2 subtypes of inflammatory constriction: (i) benign subtype in the context of acute pericarditis, often with effusion and inflammatory rind; this subtype is the most common and improves quickly. (ii) Sustained severe subtype with more severe hemodynamic compromise.[18,43,60] Prednisone, in combination with colchicine +/– NSAID, is used for at least 8–12 weeks in the severe subtype before clinical and imaging reevaluation. Intense therapy is warranted because the response is typically poor and slow, and IL-1 antagonist may be considered.[7] It may resolve within 6 months in up to 50% of patients only.

The following markers have been shown to identify a reversible (vs. persistent) constrictive pericarditis with a higher specificity (70–80%):[60]

a. On cardiac MRI; thick (≥3 mm) late gadolinium hyperenhancement of the pericardium. The normal pericardium and the fibrotic pericardium are poorly vascularized, and thus do not enhance with gadolinium; the fibrotic pericardium may mildly enhance. Conversely, severe gadolinium enhancement implies a predominantly inflamed, hyperemic rather than fibrotic pericardium.
b. Severely elevated markers of inflammation: CRP > 2.1 mg/dl, ESR > 41 mm/h.

VIII. Treatment

A. Survival and symptomatic improvement after pericardiectomy

Unless transient constrictive pericarditis is suspected, in which initial observation and anti-inflammatory therapy are warranted, constrictive pericarditis is treated with pericardiectomy. Complete pericardiectomy consists of removing the parietal but also the visceral pericardium from phrenic nerve to phrenic nerve and removing the diaphragmatic pericardium. The posterior pericardium is preferably removed, but this is not mandatory. The perioperative mortality is 6%, and varies with the etiology (~3% for idiopathic, ~20% for radiation-induced constrictive pericarditis). Similarly, long-term survival is excellent for idiopathic constriction, good for postoperative constriction, and poor for radiation-induced constriction (7-year survival 88% vs. 66% vs. 27%, respectively).[44,45] NYHA class IV, severe right HF, liver failure/ascites, renal failure, and especially radiation etiology are predictors of poorer long-term outcomes. Post-radiation pericarditis is often associated with myocardial, valvular, and coronary disease and mediastinal scarring that partially explain the mortality, the residual symptomatology, and the inability to completely resect the pericardium.

Symptomatic improvement is seen in ~80% of survivors.

B. Persistent diastolic dysfunction

Echocardiographic normalization of diastolic filling pattern occurs slowly over several months and is seen in ~40% of patients at 3 months and 60% at 6 months.[61] One-third of patients are left with a residual restrictive pattern while 10% have a residual constrictive pattern. The diastolic filling pattern normalizes in only ~25% of radiation pericarditis. Patients with a longer duration of symptoms are more likely to have residual diastolic dysfunction and symptoms at later follow-up. This is presumably due to:

a. Extension of the fibrotic process to the myocardium in longstanding constriction. In fact, a residual restrictive rather than constrictive process is responsible for the residual postoperative symptoms in most patients and may slowly improve with time.
b. Inability to fully resect the pericardium in patients with extensive scarring (residual constriction).

C. Systolic function

As a result of longstanding underfilling, LV myocardial atrophy occurs in patients with longstanding constrictive pericarditis. Plus, afterload is reduced, like in tamponade (positive pericardial pressure reduces ventricular transmural pressure and cavity radius). As such, afterload rises with pericardiectomy and with pericardiocentesis. This increased afterload, in conjunction with cardiac atrophy, may cause LV and RV systolic dysfunction and ballooning, especially as the ventricles are no longer constrained by the pericardium. Severe HF and low output result. This is the so-called "pericardial decompression syndrome" and is responsible for some of the early fatalities. In survivors, systolic function improves with time.

Significant TR is common in constriction because of RA enlargement, and may worsen postoperatively. If TR is severe, ESC suggests TR repair along with pericardiectomy.

Summary

Constrictive pericarditis clinically manifests as HF, particularly right HF, with elevated right- and left-sided filling pressures on echo, biatrial enlargement, yet normal right and left ventricular systolic function and size and normal LV wall thickness, simulating diastolic HF.

Keys to diagnosis: On echo → *Respiratory* variations of mitral/tricuspid inflow, septal position, and pulmonary/hepatic venous flow. On invasive hemodynamics → *respiratory* discordance of RV–LV systolic pressure areas. BNP is typically normal.

IX. Hemodynamic cases analysis (Figures 17.14, 17.15)

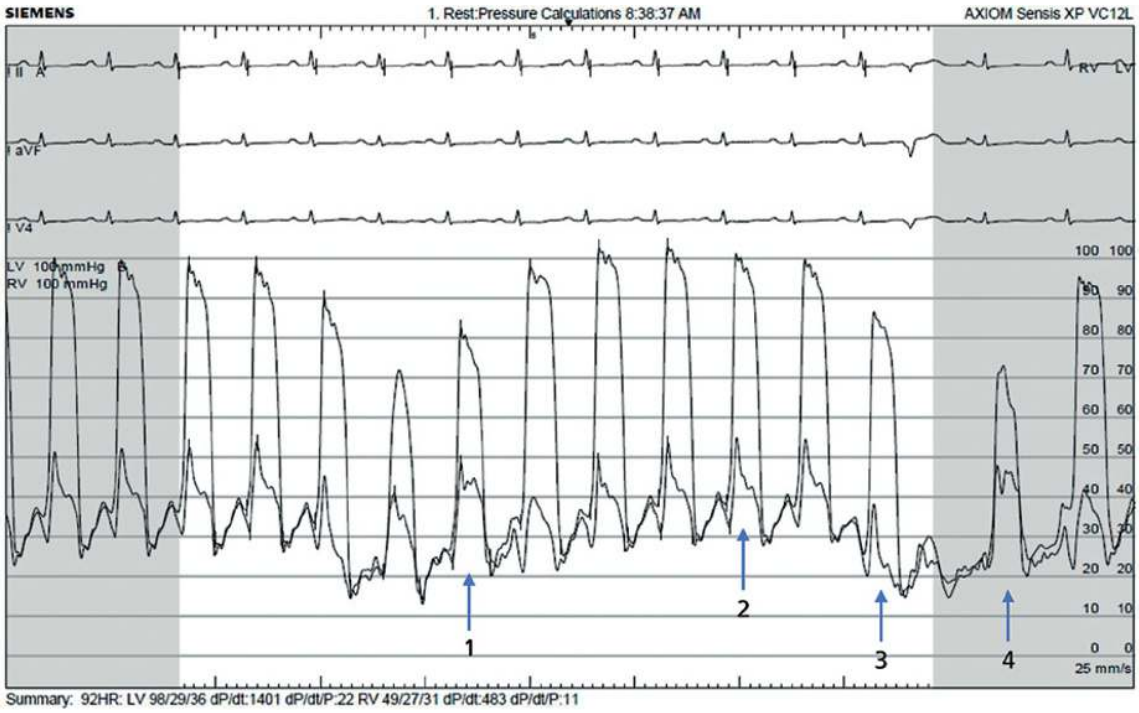

Figure 17.14 Simultaneous LV-RV recordings in a 61-year-old man with no medical history who presents with anasarca.

1. There is equalization of RV and LV ***diastolic pressures***. This is not a specific finding, and may be seen in RV failure, restrictive cardiomyopathy, or constriction.

2. To assess for ***systolic discordance***, pick the peak inspiratory beat and peak expiratory beat (beats 1 and 2). The LV area declines with inspiration while the RV area dramatically rises with inspiration. The RV peak itself declines but the RV area, which is more important because it corresponds to stroke volume, rises. The peak inspiratory beat (1) is identified as the beat preceded by the lowest diastolic dip, whereas the peak expiratory beat (2) is the beat preceded by the highest diastolic dip.

3. Analyze post-PVC behavior (beats 3 and 4): normally, and in cardiomyopathies, stroke volume rises after a PVC in both ventricles with no dramatic discrepancy. Conversely here, RV area dramatically increases while LV area declines, which suggests marked ventricular interdependence. The preload of one ventricle rises as the preload of the other ventricle declines, as they are both fighting for room in a constrained space and must expand at the expense of each other (rather than outward). This is a key value of PVC in constriction analysis. The post-PVC discordance exaggerates the respiratory discordance.

4. The significant RV stroke volume variability implies good stroke volume reserve, which argues against restrictive cardiomyopathy or intrinsic RV failure.

Diagnosis: idiopathic constrictive pericarditis.

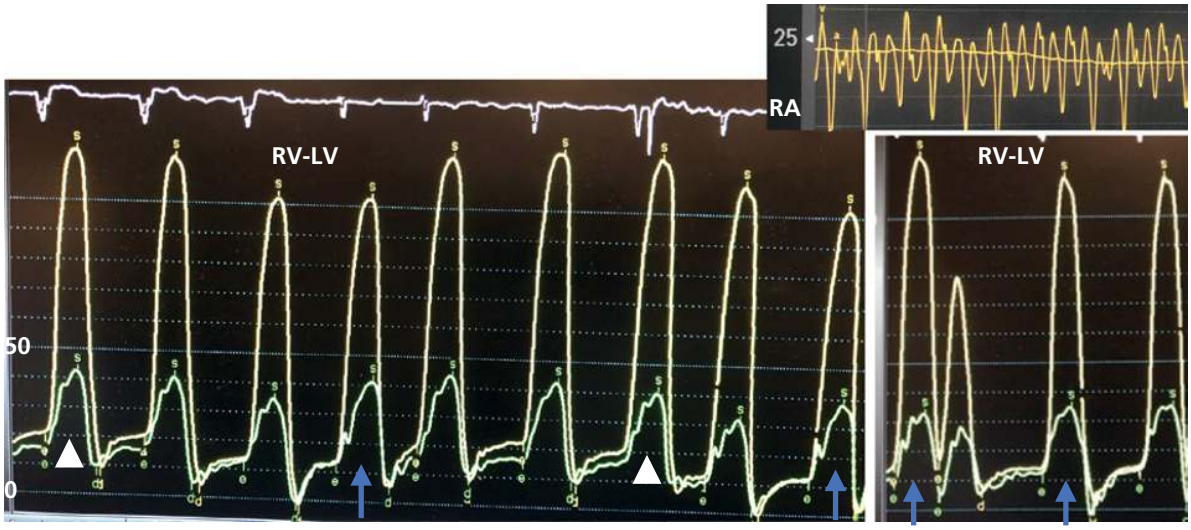

Figure 17.15 *(Left)* Simultaneous RV-LV pressure recording showing discordance of the RV and LV systolic bulks with respiration (*arrows* for inspiration, *arrowheads* for expiration). *(Right)* RV-LV discordance pre- and post-PVC (*arrows*). We see ***other right heart cath features that are necessary but not sufficient/not specific for constriction:*** (i) RA pressure Kussmaul's sign + deep X and Y descents *(top image)*; (ii) RV dip–plateau in diastole; (iii) RV systolic pressure <55 mmHg; (iv) RVEDP/RV systolic pressure >1/3, a reflection of the low RV stroke volume and high RVEDP.

Remember **5 hemodynamic tips for proper assessment of RV-LV systolic discordance:**

1. Record many tracings, during both QUIET and DEEP breathing.

2. Compare the *peak inspiratory beat*, which corresponds to the beat preceded by the lowest diastolic pressure dip, and the *peak expiratory beat*, which corresponds to the beat preceded by the highest diastolic pressure dip and the most LV-RV diastolic separation. Do not analyze general trends.

3. If all dips are too deep (underdamped), consider damping the tracings by aspirating some blood, so that the dips may be seen.

4. It is most important to analyze the systolic areas, i.e., the bulks of the rectangular pressures, rather than analyze peaks. The area is what corresponds to the stroke volume. On the peak inspiratory beats, the LV area declines while the RV area dramatically rises. Peaks may be discordant but may also appear concordant and misleading.

5. Induce PVCs and analyze post-PVC behavior. A well-timed PVC accentuates discordance, but not always. This depends on the length of the pause and the preceding R-R interval. AF or very irregular rhythm is not desirable, because repetitive short RR cycles may cause both the RV and the LV to be very empty and below the pericardial constraint, so much so that they become concordant post-PVC.

QUESTIONS AND ANSWERS

Question 1. A 58-year-old woman presents with atypical non-exertional and non-positional chest pain. She has no significant functional limitation. She is a smoker and hypertensive. Echo shows large circumferential pericardial effusion (2.5 cm sum diastolic diameter). JVP is normal, pulse is 80 bpm, and there is no pulsus paradoxus. All of the following are appropriate, *except for which one*?

A. Screen for breast cancer (mammogram) and lung cancer (chest CT)
B. Perform PPD, TSH, creatinine, and HIV testing, and assess joints and skin for rheumatologic disorders
C. Perform ESR and CRP
D. Drain the effusion for diagnostic purpose and to prevent tamponade
E. If CRP is elevated without a suspected malignant or immune process, treat with NSAID and colchicine

Question 2. A 65-year-old man, smoker, presents with severe dyspnea, progressive over several days. BP is 145/105 mmHg, pulse is 110 bpm, JVP is 14 cm H_2O, peripheral O_2 saturation 95%. Chest X-ray shows clear lungs but cardiomegaly. Echo shows a large pericardial effusion. Which one of the following additional findings is likely to be true?

A. On catheterization, RA pressure shows a deep Y descent and a flat X
B. RA pressure and RVEDP exceed PCWP and LVEDP
C. Tamponade is unlikely as the patient is hypertensive
D. Tamponade is unlikely as the patient has normal O_2 saturation
E. Pulsus paradoxus is likely to be present on exam
F. Pulsus alternans is likely to be present on exam, and electrical alternans may be present on ECG

Question 3. The patient in Question 2 undergoes pericardiocentesis. 1200 ml of blood-tinged fluid is removed. Which of the following is *incorrect*?

A. The likelihood of malignant effusion is ~30%
B. A subxiphoid approach targets the posterior aspect of the pericardial space, while an apical acess targets the lateral pericardial space
C. Pericardiocentesis followed by 3 days of drainage is often a definitive treatment of idiopathic effusions

D. Pericardiocentesis followed by 3 days of drainage is associated with a low effusion recurrence rate, even if the effusion is malignant (<25%)
E. The overall diagnostic yield of pericardiocentesis is ~30% and exceeds 50% in case of malignant effusion

Question 4. A 34-year-old man presents with chest pain and diffuse ST elevation and PR depression on the ECG. No rub is heard on exam. Echo is normal and CRP is elevated. Troponin is elevated at 0.6 ng/ml. Which of the following is *false*?
A. Diffuse ST elevation and PR depression without reciprocal ST changes may be consistent with anteroapical MI
B. ECG is consistent with pericarditis if all five of the following features are present: no Q waves, no tall or inverted T waves, no reciprocal ST depression except in aVR and V_1, ST elevation <5 mm and smaller than QRS, concave ST elevation
C. The troponin rise implies myopericarditis and impaired long-term prognosis
D. The risk of recurrent idiopathic pericarditis is 15–30%

Question 5. The patient in Question 4 is placed on NSAID. Which of the following is *incorrect*?
A. The patient needs to undergo routine workup for pericarditis: HIV, PPD, ANA/rheumatic factor
B. A reduced dose of NSAID is suggested
C. Adding colchicine to the initial therapy reduces recurrence
D. Exercise restriction is warranted for 4–6 weeks

Question 6. A 64-year-old woman with a history of radiation for left breast cancer 6 years previously presents with progressive dyspnea on exertion. JVP is elevated at 12 cm and pulsus paradoxus is present. Echo shows a 2.5 mm pericardial effusion with evidence of right-sided chamber compression. Pericardiocentesis is performed, after which RA pressure declines from 15 mmHg to 10 mmHg, and pericardial pressure improves but remains elevated at 10 mmHg. Which statement is *incorrect*?
A. Upon pericardial drainage of this patient, the flat Y descent gives place to an abnormally deep Y descent
B. Before pericardial drainage, RA pressure was not significantly declining during inspiration (as opposed to classic tamponade)
C. Before and after pericardial drainage, RV and LV end-diastolic pressures are equal
D. Before and after pericardial drainage, RV and LV systolic pressures are discordant
E. This condition is often transient and reversible

Question 7. A 52-year-old man presents with dyspnea on exertion. He has a distant history of tuberculosis while living in India. Echo shows normal-size LV and RV with normal systolic function yet abnormal septal motion (without any LBBB). The atria are mildly dilated. The IVC is mildly dilated but collapses properly (RA pressure of 5–10 mmHg). The respiratory variations of the mitral inflow and the hepatic venous flow (S and D) are exaggerated, with prominent S and D velocities in inspiration. During catheterization, the RA pressure is normal. Which of the following is *incorrect*?
A. Volume loading should be performed to show the typical RA waveform and RA pressure elevation
B. Volume loading attenuates RV–LV systolic discordance
C. The following 2 findings are highly specific for constrictive pericarditis: deep X and deep Y descents on RA tracing, and equalization of RV and LV end-diastolic pressures
D. Systolic discordance is the most sensitive and specific finding in constrictive pericarditis

Question 8. Concerning the prior case, which statement is true?
A. A normal BNP excludes constrictive pericarditis
B. The pericardial thickness is normal in 18% of patients with constrictive pericarditis (applies to MRI)
C. Late gadolinium hyperenhancement of the pericardium on MRI implies a scarred pericardium
D. The operative mortality of pericardiectomy is 3%

Question 9. Concerning constrictive pericarditis, which statement is *incorrect*?
A. Restrictive cardiomyopathy and RV failure may mimic three classic features of constriction: (i) deep X and Y on RA tracing; (ii) dip–plateau pattern on RV and LV tracings; (iii) equalized RV and LV end-diastolic pressures
B. Respiratory discordance of RV–LV systolic pressures best differentiates constriction from restrictive cardiomyopathy and RV failure
C. Respiratory discordance of constriction may be mimicked by COPD
D. In both constriction and RV failure, RA pressure may paradoxically increase with inspiration
E. On echo: severe pulmonary hypertension, severe MR or TR, or a reduced medial E′ are more consistent with constrictive pericarditis than restrictive cardiomyopathy

Question 10. As compared to constrictive pericarditis, in tamponade (multiple possible answers):
A. More ventricular compression occurs with more ventricular interdependence → Y descent is flat (vs. deep in constriction) and pulsus paradoxus is more common
B. Inspiratory pressure gets transmitted to the RA → RA pressure and JVP decline with inspiration (as opposed to constriction, where JVP increases and RA pressure remains unchanged or increases)
C. The hepatic venous flow shows a flat D wave (= Y descent), as opposed to the large D wave of constriction
D. The hepatic venous flow shows inspiratory rise of S and D in both constriction and tamponade

Question 11. Which statement concerning tamponade is *incorrect*?
A. RV failure and elevated RV diastolic pressure delay the onset of tamponade
B. In RV failure and elevated RV diastolic pressure, an isolated LV compression with isolated LV tamponade may occur
C. In patients with RV failure who develop tamponade, pulsus paradoxus may be absent (isolated LV tamponade without pulsus paradoxus)
D. Pulmonary hypertension, per se, even in the absence of RV failure, delays the onset of tamponade

Question 12. In order of frequency, what are the causes of acute pericarditis and what are the causes of pericardial effusion?
A. Idiopathic
B. Specific infections (tuberculosis, HIV)
C. Neoplastic
D. Autoimmune/collagen vascular disease
E. Cardiac injury (post-procedure or post-surgery)

Question 13. A 25-year-old, previously healthy woman presents with acute onset of severe chest pain, worse with supine position and with inspiration. ECG shows sinus tachycardia of 110 bpm with diffuse ST elevation. CRP is elevated. Echo shows a moderate-size 1 cm pericardial effusion. The patient has low-grade fever. Which of the following is *incorrect*?
A. Admit to hospital and perform HIV–PPD–ANA testing
B. Treat with ibuprofen 600 mg 4× daily until CRP normalizes, then taper ibuprofen over the ensuing 3 weeks. Symptoms typically resolve within 1 week of therapy
C. Start colchicine therapy only if symptoms persist or recur
D. Use corticosteroids only for pericarditis refractory to NSAID and colchicine
E. Restrict exercise until symptom resolution (restrict athletic activity for 3 months)

Question 14. Which of the following statements is (or are) true:
A. Kussmaul's sign strongly suggests constrictive pericarditis
B. Deep X and deep Y on RA tracing strongly suggest constrictive pericarditis
C. Equalization of end-diastolic pressures strongly suggests constrictive pericarditis
D. Constrictive pericarditis can be diagnosed by right heart catheterization
E. Constrictive pericarditis can be rule out by right heart catheterization

Question 15. A patient with tamponade undergoes mechanical ventilation. What is expected?
A. Hemodynamic collapse will worsen, but pulsus pradaoxus will attenuate
B. Both hemodynamic collapse and pulsus paradoxus worsen
C. BP improves, but pulsus paradoxus worsens

Question 16. Which of the following statements is true:
A. Mild RV-LV respiratory discordance is seen in normal subjects owing to ventricular interdependence
B. Positive pressure ventilation reduces RV stroke volume but increases LV stroke volume
C. Positive pressure ventilation increases LV stroke volume in decompensated LV failure

Answer 1. D. If asymptomatic without a suspected malignant etiology, echo is repeated in 1–2 weeks initially, then every 3–6 months to ensure stability. It may be treated with NSAID and colchicine if CRP is elevated. Asymptomatic effusion >3 months has a low risk of progression to tamponade and a low likelihood of malignancy; more harm may result from drainage compared to surveillance.

Answer 2. E. The patient has an effusion with evidence of hemodynamic compromise (tachycardia, elevated JVP); thus, he has tamponade. RA pressure is characterized by a flat Y descent, i.e., flat diastolic filling (mnemonic: **Flat Y Tamponade = FYT**). Y becomes progressively more flat as more fluid cumulates. RA, RVEDP, PCWP, and LVEDP are typically equalized to the pericardial pressure. Early on, in tamponade, the patient may be hypertensive. Importantly, even when hypertensive, the pulse pressure is relatively narrow and there is pulsus paradoxus on exam. Tamponade may lead to severe orthopnea yet the lungs are usually clear and O_2 saturation is normal. While electrical alternans is seen on ECG, pulsus paradoxus rather than pulsus alternans is found on exam. Pulsus alternans is a sign of severe HF.

Answer 3. B. A subxiphoid approach targets the inferior, not posterior, pericardial space. An apical approach may target the posterior/lateral pericardial space (Figures 17.6, 17.7).

Answer 4. C. The patient has 2 features of pericarditis (chest pain and consistent ECG), and an additional confirmatory finding (CRP). The elevated troponin implies myopericarditis. As long as EF is normal, the long-term prognosis of myopericarditis is good regardless of the rise in troponin.

Answer 5. A. Immune or infectious workup is only performed if symptoms persist despite NSAID, symptoms are subacute, severe constitutional symptoms/fever are present, or moderate effusion is present (in the latter case, also perform cancer screen). The elevated troponin, i.e., myopericarditis, warrants exercise restriction for 4–6 weeks in non-athletes, and 3 months in athletes (ESC guidelines).

Answer 6. E. The patient has effusive constrictive pericarditis related to radiation injury. The RA and pericardial pressures improve but do not normalize after drainage, Y descent becomes abnormally deep. Features of constrictive pericarditis are present before drainage (answer B). Answers C and D are seen with both tamponade and constriction. Effusive–constrictive pericarditis is often transient in idiopathic cases, but not in radiation-induced cases.

Answer 7. C. The patient likely has occult constrictive pericarditis with subtle suggestive signs on echo, particularly signs of excessive respiratory variation of hepatic flow, mitral flow, and septal position. The RA pressure is not increased as the patient is likely hypovolemic. Mild volume loading will unveil abnormalities of RA pressure. As opposed to the abnormalities of RA tracing, the systolic discordance of RV–LV is unveiled by hypovolemia or upright positioning rather than volume loading. Findings under answer C are not specific for constriction, and are commonly seen in patients with restrictive cardiomyopathy or isolated RV failure; yet, in the right context such as this case, they are strongly suggestive of constriction.

Answer 8. B. A normal BNP is the rule in idiopathic constrictive pericarditis. Late gadolinium enhancement of the pericardium usually implies an inflammatory pericardial process, often reversible with anti-inflammatory therapy. The operative mortality of pericardiectomy is ~6% (may be lower in idiopathic, low-risk cases).

Answer 9. E. The findings described in E are more consistent with restrictive cardiomyopathy than constriction.

Answer 10. All are correct.

Answer 11. D. Elevated RV diastolic pressure makes it hard for the pericardial pressure to equalize with the RV diastolic pressure, thus delaying RV compression and RV tamponade. In this case, tamponade occurs when pericardial pressure exceeds LV pressure. Since RV and LV are not compressed together, they are not interdependent; thus, pulsus paradoxus may be absent.

Answer 12. Acute pericarditis: A > C ~ D > B. In a study of 453 patients with acute pericarditis, 83% of cases were idiopathic, 5% were neoplastic, 7% were autoimmune, 3.5% were due to tuberculosis, and 0.7% were purulent.[12] Aside from those etiologies, a modern registry suggests that cardiac injury is the second most common cause of acute pericarditis (especially post-catheter ablation or pacemaker, or surgery).[62]
Pericardial effusion: A > B = C > D. In a study of 204 patients with pericardial effusion, 48% of cases were labeled as idiopathic, 16% were infectious, 15% were malignant, and 8% were due to collagen vascular disease (lupus, rheumatoid arthritis, and scleroderma).[22]

Answer 13. C. Colchicine is recommended along with NSAID as initial combination therapy for pericarditis (class I, ESC guidelines). Colchicine is used for 3 months. The significant effusion dictates initial inpatient monitoring.

Answer 14. Only E is true. A-D are false. The hemodynamic features A and B and other right heart findings (e.g., RVEDP/RV systolic pressure >1/3, PA systolic pressure <55 mmHg) are highly prevalent in constrictive pericarditis (>90%), and the absence of one and especially several of them somewhat rules out constrictive pericarditis. However, their presence does not rule in constriction as they most frequently reflect cardiomyopathies rather than constriction. C has poor positive and negative predictive values for constriction.

Answer 15. B. Positive ventilation reduces preload, eventually of both ventricles, as it reduces extrathoracic venous return. A change in preload of one ventricle eventually gets carried to the other ventricle at a different respiratory cycle. Regarding pulsus paradoxus, positive pressure ventilation exaggerates RV/LV discordance and pulsus paradoxus. As a general rule, low preload and hypovolemia exaggerate pulsus paradoxus by making RV and LV on the upslope, oversensitive portion of Starling curve; that is how pulsus paradoxus may be seen in normal individuals (hypovolemic and deeply sedated). The same idea is also used to assess volume responsiveness in mechanically ventilated patients (exaggerated variations of pulse pressure--> volume responsive).

In tamponade, the RV and LV are underfilled and avid for preload. Reducing preload makes them even more preload sensitive (upslope of Starling curve), so the discordant flow fluctuations will even be more dramatic. The only minor difference in mechanical ventilation is that it would be a reverse pulsus paradoxus, meaning aortic pressure rises in inspiration, which is the positive pressure.

Answer 16. C. Normally there is a mild RV/LV discordance with respiration, but unlike pericardial disorders, this is not due to ventricular interdependence, as the ventricles are not constrained by the pericardium. In normal subjects, the negative inspiratory pressure sucks flow from the veins outside the thorax into the RA, raising right-sided flow, but does not raise flow between the pulmonary veins and the LA, as both are subject to the negative thoracic pressure, more so the pulmonary veins. Because of the pulmonary transit time, the change in RV flow gets transmitted to the LV later, during expiration.

Regarding B, keep in mind that the outputs of both ventricles are the same per minute (unless there is shunt or severe valvular regurgitation on one side). So even with discordance, whatever change happens in the RV will happen in the LV eventually. Positive pressure reduces the gradient between extrathoracic IVC and SVC branches versus RA, so RV preload drops and RV output drops. On the left, during mechanical ventilation, LV preload increases in inspiration compared to expiration, but not compared to spontaneous breathing. Eventually, after analyzing each ventricle, it is better to think of the effect of a situation on the overall heart rather than each ventricle, as both ventricles will eventually be subject to the change, but at different respiratory cycles. A severely overloaded LV is not preload dependent; positive pressure reduces LV preload and afterload, both eventually raising LV stroke volume.

Questions and answers 515

1. ACYANOTIC CONGENITAL HEART DISEASE

I. Atrial septal defect (ASD)

A. Embryology (see Figure 18.1)

The interatrial septum has 2 parts:

- A lower part connected to the endocardial cushions at the valvular level and called ***septum primum***. The septum primum is ***thin and membranous***.
- An upper part called ***septum secundum***. The septum secundum is ***thick and muscular***.

These 2 septa meet and overlap. The overlap area is called *fossa ovalis*.[1,2]

In the fetus, the overlap area is not sealed, leaving a tunnel that allows blood to flow from right to left. This tunnel is called *foramen ovale*. In the fetus, oxygenated blood flowing from the IVC is directed toward the left heart through the septum secundum and foramen ovale, and is ejected into the ascending aorta, the brain, and upper body. Deoxygenated blood flowing from the SVC continues into the RV and is ejected into the high-resistance pulmonary circulation, then the descending aorta through the ductus arteriosus. Overall, the RV provides ~55% of the systemic cardiac output (lower body), while the LV provides ~45% of the systemic output (upper body). The pulmonary vascular resistance is elevated in the fetus, as a reaction to the poorly oxygenated lung, and the pulmonary arterial pressure is higher than the systemic pressure; at birth, the pulmonary resistance and pressure dramatically drop.

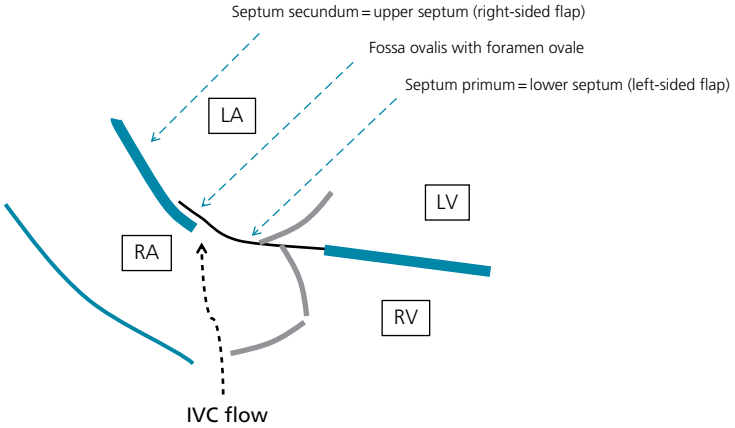

Figure 18.1 Interatrial septum. Embryologically, blood coming from the IVC is directed into the LA by the right-sided, septum secundum flap. The septum primum acts like a 1-way door that opens when the RA pressure rises, and closes when the LA pressure supersedes the RA pressure, closing the foramen ovale. The prominent, septum secundum boundary of the fossa ovalis is called limbus (on the side of the RA).

Embryologically, the septum primum was initially localized at the upper portion of the RA. It grew down and touched the endocardial cushions, then developed a defect in its middle and top portions (ostium secundum) to allow blood shunting. This defect got covered by a growing muscular septum secundum, which eventually met the septum primum.

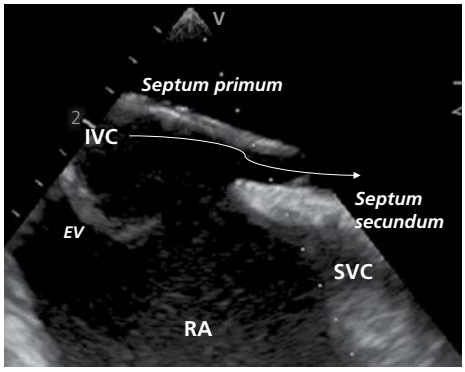

Figure 18.2 Bicaval TEE view showing a PFO between the septum primum (thin, at bottom) and the septum secundum (thick, on top). EV, Eustachian valve.

B. Pathology (see Figures 18.2–18.4)

1. At birth, the PA pressure significantly drops and the pulmonary arterial and venous flow significantly increase. As a result, the LA pressure rises and pushes the septum primum to seal the overlap area.[1] **If it does not seal, a *patent foramen ovale* (PFO) persists. PFO is a persistent tunnel or flap; this is different from the gap of an ASD**.[2]

2. If the 2 septa do not meet and overlap, a wide, open gap will exist between the 2 septa in the middle of the interatrial septum: this is called *ostium secundum ASD* (70% of ASDs).

3. If the septum primum does not connect with the endocardial cushions, a gap will be present at the lower level of the interatrial septum: this is *ostium primum ASD* (15–20% of ASDs). *No atrial septal tissue is seen above the base of the atrioventricular valves*.

Ostium primum ASD may be continuous with a defect of the membranous ventricular septum, in which case the defect is called *complete atrioventricular (AV) canal defect*, or *endocardial cushion defect*. The endocardial cushions are central embryonic structures that develop into the AV valves and the membranous ventricular septum. In complete AV canal defect, no tissue separates the AV valves; the AV valves are actually 1 valve at 1 horizontal plane, with an atrial and ventricular septal defect in the middle.

An ostium primum ASD without VSD is called *partial AV canal defect*. In the partial AV defect, the ventricular septum is closed by the endocardial cushions or by the septal tricuspid leaflet early in life, so that only a primum ASD is present. In another form called *transitional AV canal defect*, most of the ventricular defect is closed by the septal leaflets of the AV valve, so that only a small residual inlet VSD is seen and 2 AV valves are present. Thirty-five percent of patients with AV canal defect have Down syndrome, especially those with complete AV canal defects.

Whereas normally the tricuspid valve is a bit lower (more apical) than the mitral valve, the tricuspid and mitral valves are at the same level in AV canal defect, as the mitral valve plane is pulled down. The down-pulling of the mitral valve elongates the LVOT, creating a "goose neck" narrowing of the LVOT with potential LVOT obstruction (Figure 18.5). Mitral valve defects (cleft valve) are frequently seen and result in eccentric MR; tricuspid defects may also be seen.

4. Sinus venosus defect is a gap at the upper posterior part of the septum at the SVC–RA connection. It is almost always associated with some degree of anomalous pulmonary venous return, in which the right upper pulmonary vein, and sometimes a right middle or inferior pulmonary vein, drains into the RA.

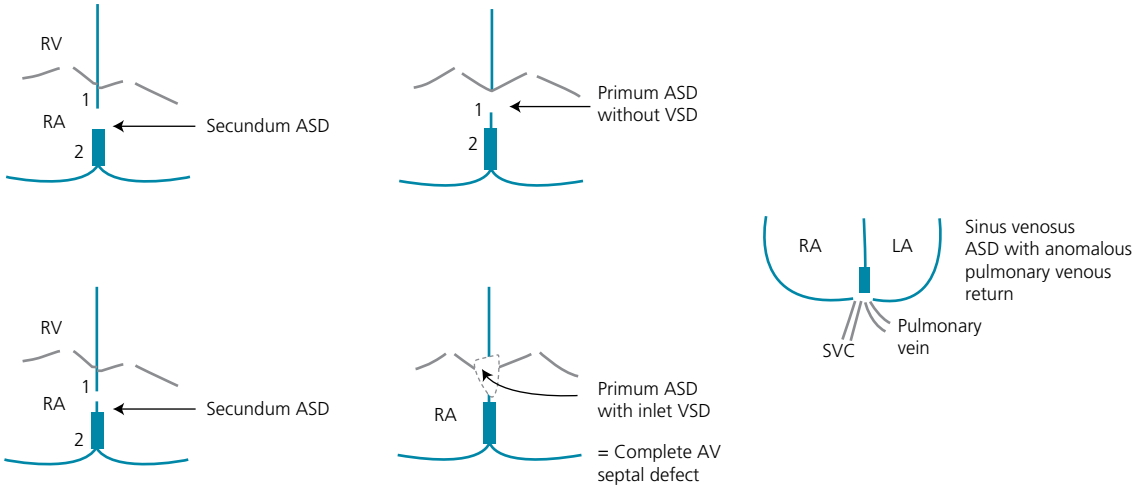

Figure 18.3 Types of ASD. Secundum ASD results from excessive involution of the top portion of the septum primum (→ does not meet the septum secundum). Primum ASD results from failure of the septum primum to reach the endocardial cushions. **Thus, beside primum ASD, secundum ASD is also a defect of the septum primum.** Septum primum is the thinner septum, marked by *1*; septum secundum is marked by *2*.

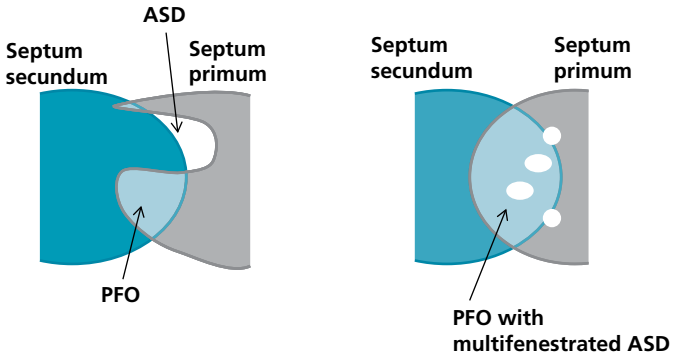

Figure 18.4 En face view of the interatrial septum. Occasionally, both a PFO and a small ASD may be present: ASD in one plane where the septum primum has excessively involuted, PFO in the other planes where the 2 septa continue to overlap. Alternatively, PFO may be present with multiple small ASD holes.

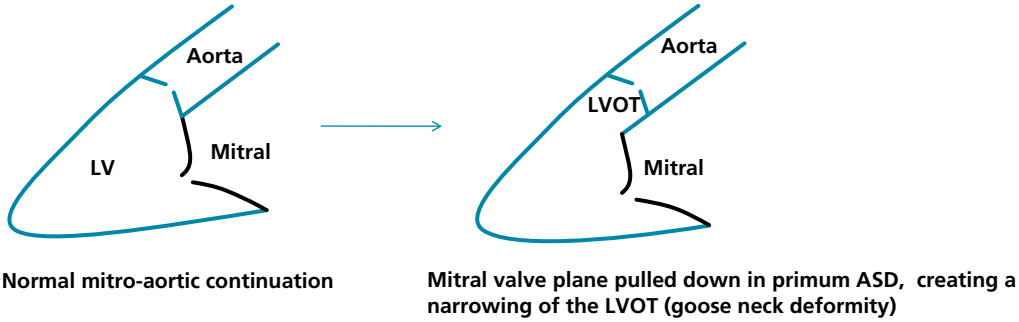

Figure 18.5 Goose neck deformity of the LVOT in primum ASD.

Partial anomalous pulmonary venous return may also be seen with secundum ASD. A right upper pulmonary vein draining into the RA or SVC is the most common anomaly, accounting for >90% of the anomalous venous return; a left pulmonary vein draining into the innominate vein may also be seen. If only 1 pulmonary vein is involved, the amount of shunting induced by the anomalous vein is, per se, mild. However, in conjunction with an ASD, the anomalous vein may significantly add to the shunt burden.

C. Consequences

1. A significant ASD is an ASD with a prominent left-to-right shunt leading to a pulmonary flow (Qp) 1.5 times larger than the systemic flow (Qs): Qp/Qs ≥1.5/1.0.

A large ASD is characterized by a Qp/Qs ≥2.

2. A significant ASD causes RA/RV volume overload, dilatation, and failure. This may, rarely, occur in childhood if the ASD is large. Most patients are minimally symptomatic in the first three decades; exercise intolerance and hemodynamic compromise occur later in adulthood (30s to 40s), and most patients are symptomatic by the age of 50. AF and right heart failure develop by the age of 40 in ~10% of patients, then become more prevalent with age. In fact, for the same ASD size, left-to-right shunting may become more severe with age, as LV diastolic dysfunction occurs and LA pressure rises. Also, LA enlargement that occurs with age stretches and widens the ASD. ASD does not, by itself, lead to LA enlargement unless AF occurs.

A complete AV canal defect, on the other hand, leads to a severe shunt and Eisenmenger syndrome early in infancy if not corrected. Paradoxical embolism may be seen.

3. ***Pulmonary hypertension (PH) may occur but is rarely severe, because the RV usually fails before severe PH develops. In a way, the failing RV constitutes a barrier that protects the pulmonary arteries from volume overload***. If PH is severe and ASD is <2 cm, a second causative diagnosis should be considered. Under 10% of ASDs develop significant pulmonary vascular disease with PVR >5 Wood units.[3,4] Cyanosis and reversal of the shunt to a right-to-left shunt often result from RV failure and the consequent rise of RA pressure, even without any PH.

D. Diagnosis

1. Exam:
- Fixed split S_2
- Scratchy systolic ejectional murmur at the pulmonic area (left upper sternal border) due to the increased right-sided flow. The murmur may mimic pulmonic stenosis. P_2 allows the distinction: P_2 is attenuated in PS but part of a loud split S_2 in ASD. Systolic TR murmur may also be heard.
- RV heave
- Increased JVP with a large V wave indicative of RV failure ± TR

RV heave is more prominent in RV volume-overload states, such as ASD, than in pressure-overload states (cor pulmonale, pulmonic stenosis).

2. ECG:
- Ostium secundum ASD: RBBB (usually incomplete), right axis deviation, R-wave notching in the inferior leads (crochetage), right atrial enlargement
- Ostium primum ASD: RBBB + left axis deviation ± prolonged PR interval (primum ASD damages the infra-Hisian conduction system)
- Sinus venosus ASD: ectopic atrial rhythm (non-sinus P waves)
- AF or atrial flutter may be present

3. CXR features: enlarged RV, enlarged central PA knob, and pulmonary plethora from increased flow.

4. Echo:
- TTE often establishes the diagnosis by visualizing the defect and the Doppler flow across it. The defect is usually >8 mm, as smaller defects usually close spontaneously in infancy and do not usually cause hemodynamic compromise. TTE can calculate Qp/Qs ratio (pulmonary to systemic flow ratio), which is equal to:

  (velocity [VTI] × diameter) at the RVOT, divided by (velocity [VTI] × diameter) at the LVOT

  TTE also shows RA and RV enlargement, consequences of any significant ASD.
- The subcostal view is orthogonal to the interatrial septum and is the best diagnostic view for ASD. Over 90% of secundum ASDs are seen in this view, which is also the best view for the sinus venosus defect and for assessment of shunt direction by spectral Doppler. However, the sinus venosus defect, or, rarely, other defects, may be missed by TTE. SVC view (right parasternal view) or superior angulation in a subcostal view may allow the diagnosis of sinus venosus defect. TEE permits better visualization if the diagnosis is suspected but not clearly established in a patient with RA/RV enlargement. Also, intravenous bubble injection may suggest the diagnosis of ASD in these patients. In PFO or secundum ASD, the bubbles fill the RA then the LA; in sinus venosus ASD, the bubbles simultaneously fill both the RA and LA.

RA and RV enlargement without any obvious cause (such as left HF) in an otherwise healthy adult should prompt a search for an overlooked ASD, especially sinus venosus ASD, or rarely, isolated partial anomalous pulmonary venous return.

5. TEE, and often CTA or MRA for preprocedural assessment of rims and anomalous pulmonary venous return.

6. Right heart catheterization is *rarely needed*, except for PH assessment if echo shows moderate or severe PH. It shows O2 saturation step-up ≥8% between SVC and PA, and it permits Qp/Qs and PVR calculation.

E. Treatment

1. Up to 62% of secundum ASDs may spontaneously close in the first year of life, especially ASD < 3–8 mm.

2. Closure of ASD is indicated when ASD is anatomically large >10 mm with one of the following hemodynamic features:
- Qp/Qs ≥1.5 in patients older than 1 year, including asymptomatic patients, as soon as possible. In infants <1 year old, wait to see if spontaneous closure occurs.
- Right-sided enlargement or failure. The calculation of Qp/Qs is particularly needed when ASD seems anatomically small and needs to be confirmed as the cause of RV failure, or when the shunt is bidirectional.

In case of pulmonary hypertension, ASD closure remains indicated if **there is still a net left-to-right shunt (Qp/Qs ≥1.5) and PVR is <1/3 SVR and <5 Wood units.**[5] ACC gives closure a class IIa if PVR is between 1/3–2/3 SVR or 5–8 (even 10) Wood units but improves to <5 Wood units with PAH therapy; in addition, Qp/Qs must be >1.5 or rise to >1.5 with therapy. Closure is contraindicated if PVR is >8 Wood units.

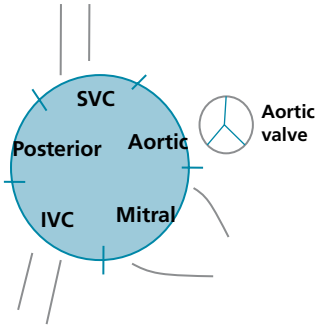

Figure 18.6 Interatrial septum viewed from the side. Various rims are identified. **The 3 best TEE views to visualize the interatrial septum are:**
- 0° 4-chamber view with a clockwise torque to the right (mitral and posterior rims)
- 30–50° aortic view with a clockwise torque to the right (aortic and posterior rims)
- Bicaval 90° view: from the 0° view torqued toward the right-sided structures, a 90° rotation allows visualization of the SVC and IVC (bicaval view) (SVC and IVC rims).

The mitral and IVC rims are septum primum, while the aortic and SVC rims are septum secundum; the 2 septa meet in the middle. An ostium primum ASD is characterized by an absent mitral rim, while a sinus venosus ASD is characterized by an absent SVC rim.

3. Note that ASD <10 mm in a patient older than 50–60 is often innocuous and unlikely to explain right heart failure or dyspnea (ESC). To the contrary, this small ASD may relieve RV failure or primary pulmonary hypertension via a pop-off right-to-left shunt. It may also relieve LV diastolic dysfunction, allowing the LA to decompress into the RA and reduce pulmonary edema. In fact, creating an 8-mm interatrial communication has been investigated as a therapy for HFpEF and has not shown RV or PA harm in patients with normal baseline PVR and RV function (induces a Qp/Qs of 1.27 only, despite the high LA pressure).[6]

4. Closure is performed percutaneously or surgically (direct surgical closure or patch closure). Percutaneous closure can be used for secundum ASD that is ≤38 mm in diameter with 5-mm rims and without severe TR or anomalous pulmonary venous return (Figure 18.6). TEE or CT/MRI assessment of the rims and of the pulmonary veins, especially the right upper pulmonary vein, is critical in determining if the patient qualifies for percutaneous closure.

Primum ASD and sinus venosus ASD are only treated surgically, as the lack of rims prevents device apposition.

5. ASD closure improves survival and functional status, especially when performed at an early age. Closure before the age of 25 establishes a normal longevity (Mayo registry).[3] Closure after the age of 40 in patients with right heart failure or Qp/Qs >1.5 does not re-establish normal longevity but still reduces long-term mortality by 70% and improves functional status.[4] A more modern registry suggests re-establishment of normal longevity at all ages, even >40 or 60 (JACC 2021).[4] The reduction of right heart volume starts early after closure, within 24 hours, and may continue for over a year. This reverse remodeling is more complete in younger patients.

While improving survival and functional status, closure in patients >40 years of age does not return the risk of stroke or AF to baseline levels.[4]

6. Secundum ASD does not require endocarditis prophylaxis. After correction and in the absence of a residual shunt, patients require endocarditis prophylaxis for 6 months only (i.e., until the surgical site endothelializes). If a residual defect persists, endocarditis prophylaxis is indicated lifelong.

II. Patent foramen ovale (PFO)

A cryptogenic stroke is a stroke that is unexplained by carotid disease, cardiac disease such as AF or LV thrombus, or prothrombotic coagulopathies (mainly antiphospholipid syndrome). Moreover, to make the diagnosis of a cryptogenic stroke, a lacunar stroke must be excluded (lacunar stroke being a small, deep white matter stroke < 15 mm in a patient with HTN, diabetes, or age >50). There is an association between PFO and cryptogenic stroke, patients with cryptogenic stroke having a higher prevalence of PFO than the normal population (~40–50% prevalence). This association is particularly established in patients < 55 years old and is uncertain in older patients.[7,8] PFO patients may have paradoxical embolization of a DVT or an in situ thrombosis formed at the PFO level, especially if the interatrial septum is hypermobile and ejects it.

PFO is common in the normal population (prevalence ~25%), and thus a causal relationship with a stroke is, at best, a diagnosis of exclusion. In some, but not all studies, a large shunt or the coexistence of an atrial septal aneurysm had a clearer association with stroke.[7,8] A large shunt is defined as >10–30 microbubbles or PFO tunnel width ≥2–4 mm, meaning that the separation between secundum septum and primum septum is ≥2–4 mm. An atrial septal aneurysm, defined as hypermobility of the thin septum primum >1 cm from midline, is less clearly associated with an increased stroke risk when isolated.[8] The combination of the following three patient characteristics increases the probability that the stroke is PFO-related: age < 55, cortical location of the stroke (as opposed to deep white matter or periventricular), and the lack of uncontrolled HTN, uncontrolled diabetes, and smoking (those are captured by PASCAL score, which adds PFO anatomical features).

PFO is diagnosed by TTE or TEE performed with microbubbles/agitated saline injected during Valsalva (bubble study). In case of PFO, these bubbles will go from the RA to the LA within 3–5 cardiac cycles during the Valsalva release phase. Even the shunting of one bubble to the LA indicates the presence of a right-to-left shunt. If it takes >3–5 cycles for the bubbles to appear on the left side, the shunt is at the pulmonary level (e.g., AV malformation). Normally, during quiet breathing, the LA pressure is larger than the RA pressure, thereby closing the septum primum toward the septum secundum and preventing any significant shunting, except very briefly. A physiologic right-to-left shunt occurs when the RA volume suddenly and largely increases at a time when the LA volume does not, which reverses the LA–RA pressure differential; this is seen during deep inspiration or during the release phase of the Valsalva maneuver. Conversely, the strain phase of Valsalva may reduce right venous return and right-to-left shunting. Of note, bubble injection via a lower extremity vein (into the IVC) is more likely to be shunted through the PFO.

Treatment of a cryptogenic stroke presumably due to PFO

- Aspirin or warfarin. Post-hoc analysis from PICSS, CLOSE and NAVIGATE-ESUS trials showed a trend toward 50% stroke reduction with anticoagulation over aspirin in PFO, which was significant in their meta-analysis.[7]
- In patients who had one or more cryptogenic strokes/TIAs, PFO closure is superior to medical therapy in reducing stroke recurrence, according to three randomized trials.[9–11] The risk of stroke recurrence after a cryptogenic stroke is relatively low, 5–6% at 5 years under antiplatelet therapy (as seen in all 3 PFO trials).[8–11] While low, this risk is cumulative over time and is particularly consequential in young patients over the long term. PFO closure reduces stroke risk by ~0.5% per year, which becomes significant upon long-term follow-up. PFO closure is indicated in young patients <55 years with cortical stroke and no smoking, diabetes, or HTN, and no AF on rhythm monitoring. In 2 of the 3 major trials and in a meta-analysis, the benefit appeared limited to patients with either a large PFO or an associated atrial septal aneurysm.[9,10]

A PFO can lead to a mild and insignificant degree of left-to-right (L–R) or right-to-left (R–L) shunting, depending on instantaneous RA–LA pressure differential and breathing cycle. PFO, per se, does not lead to a hemodynamically significant shunting or cavitary dilatation. Conversely, severe RA dilatation/pressure elevation may lead to a significant shunting across the PFO. *In fact, R–L shunting through a PFO in patients with RV failure is a compensatory, secondary process that relieves RV failure, and PFO is an innocent bystander rather than a primary shunt process*. For example, in severe primary pulmonary hypertension, R–L shunt may be seen through a PFO or a small ASD. This shunt is secondary to pulmonary hypertension rather than a cause of pulmonary hypertension, and is associated with improved survival. *Rarely*, significant R–L shunting occurs across a PFO despite a normal RA/RV; this shunt occurs in the upright position (platypnea–orthodeoxia syndrome) or during exertion. The diagnosis is made by documenting normal supine O_2 saturation with orthostatic or exertional O_2 desaturation that is otherwise unexplained.

A severely increased LA pressure may lead to a compensatory L–R shunt that relieves LA pressure and dyspnea, comparably to the interatrial shunt device.[6,12]

III. Ventricular septal defect (VSD)

A. Types (see Figure 18.7)

The interventricular septum has a small membranous portion and a large muscular portion. The muscular portion is divided into 3 zones (inlet between the atrioventricular valves, outlet beneath the great arteries, and trabecular). A VSD is either perimembranous or muscular:[13]

1. Perimembranous VSD is the most common VSD (70–80% of VSDs). It involves the membranous septum and extends *a bit* into 1 of the 3 muscular regions (inlet, trabecular, or outlet). An entirely membranous VSD is rare, as the membranous septum is a small fibrous center.
2. Muscular trabecular VSD is the next most common VSD.
3. Inlet VSD. The inlet septum separates the septal cusps of the mitral and tricuspid valves. Inlet VSD is mainly a defect of the muscular inlet septum, but the membranous septum is frequently involved. A gross deficiency of the inlet septum is associated with AV canal defect. Conversely, a small inlet VSD is not usually associated with AV canal defect.[13]
4. Outlet VSD (subarterial or infundibular VSD). The outlet septum separates the aortic and pulmonic valves. Outlet VSD is mainly a defect of the muscular outlet septum, but the membranous septum is frequently involved. When outlet VSD is very high and abuts both arterial valves, it is called supracristal VSD or doubly committed VSD (the crista supraventricularis being a muscular ridge in the RV outflow).

B. Consequences and associations

- A large VSD leads to a left-to-right shunt, with progressive pulmonary hypertension and progressively large volume circulating back to the LV and leading to LV failure from volume overload. As pulmonary hypertension becomes more severe, Eisenmenger syndrome and cyanosis occur.

A hemodynamically significant VSD leads to LV and LA dilatation and LV failure from the shunted L–R volume that recirculates back to the LV (almost like MR). Since the LV-to-RV shunt is systolic, the RV does not get overloaded in diastole and it is almost as if the LV pumps straight in the PA in systole; therefore *RV failure does not occur. Even when pulmonary hypertension develops, right-sided enlargement and tricuspid regurgitation are very unusual because the VSD allows decompression of the RV*. This is in contrast to ASD, where the shunted blood overloads the RV in *diastole* and leads to RV dilatation and failure and tricuspid regurgitation; in ASD, the LV is protected by the unloading that occurs at the LA level.[14]

Pre-tricuspid shunts (ASD) cause RA-RV enlargement, while post-tricuspid shunts (VSD, PDA) cause LA-LV enlargement.
Also, *unlike ASD, a large VSD readily causes pulmonary hypertension* as: (i) there is no RV failure shielding the PA from volume overload, and (ii) LV pumps its high pressure directly into the PA (PA pressure overload).

- A VSD, especially an outlet VSD, may be associated with aortic insufficiency. This results from high-velocity jet lesions, similarly to what occurs with subaortic membranous stenosis; also, the outlet defect diminishes the cuspal support and may lead to aortic cusp(s) prolapse. Outlet VSD may be associated with subpulmonic or subaortic stenosis; the subpulmonic stenosis may lead to a right-to-left shunt but protects from Eisenmenger syndrome.
  Any VSD may also be associated with a bicuspid aortic valve and coarctation of the aorta.
- The membranous septum has an interventricular portion but also a more proximal (posterior) portion that separates the LV from the RA. A Gerbode defect is a perimembranous VSD extending more proximal to the tricuspid insertion, leading to a high-velocity LV-to-RA shunt and RV failure, in addition to the LV-to-RV shunt (Figure 18.8).

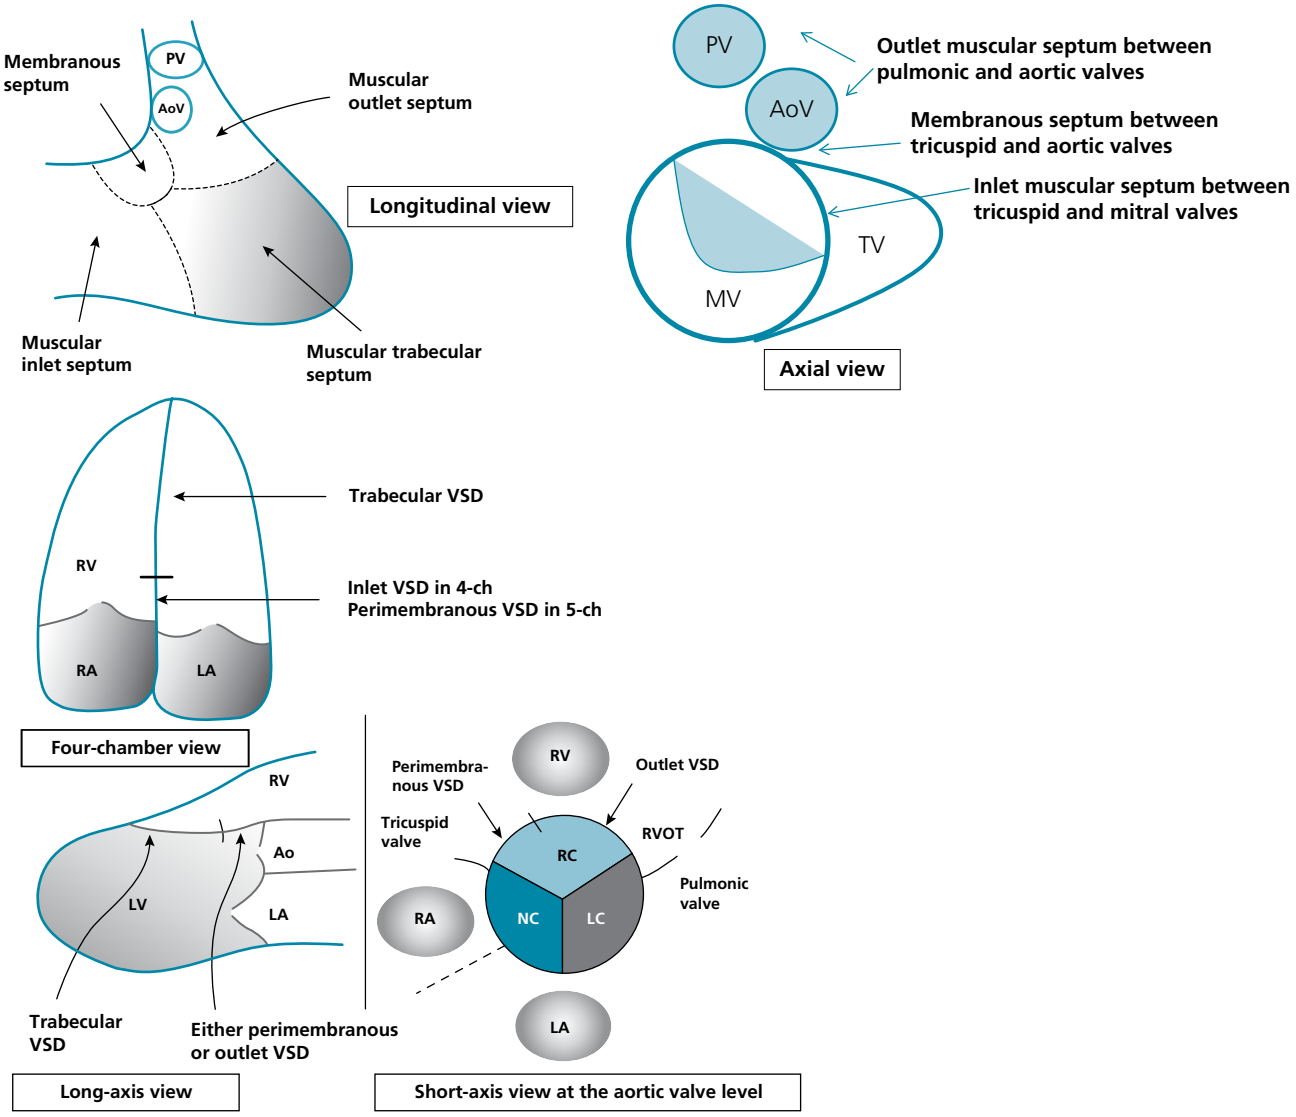

Figure 18.7 Anatomic and echocardiographic localization of VSD. The *membranous septum* is bordered by the septal tricuspid leaflet on the right and the subaortic area on the left; it is superior to the mitral valve. Perimembranous VSD is actually a superior/anterior form of VSD, and therefore it is seen on the long-axis echo view. *Inlet VSD* is bordered by the tricuspid valve on the right and the mitral valve on the left and is the one that continues with an atrial septal defect to form the AV canal defect.

Note that the pulmonic valve (PV) is higher and more anterior than the aortic valve (AoV), and the outlet septum is larger on the right than the left side. An outlet VSD that extends all the way to the PV is called supracristal VSD.

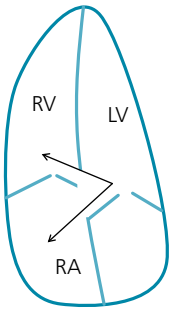

Figure 18.8 Gerbode defect on an **apical 5-chamber view**. Perimembranous VSD extends more proximal to the tricuspid valve and leads to LV–RA shunt, in addition to the LV–RV shunt. Being a perimembranous defect, it may not be seen on the 4-chamber view. The defect may have an inlet extension.

C. Exam and natural history

With the exception of bicuspid aortic valve, VSD is the most common congenital defect in children. A small VSD leads to a loud, harsh pansystolic murmur at the left lower sternal border, sometimes with a thrill, whereas a large VSD has a softer murmur. *Thus, a loud murmur implies a more benign VSD than a soft murmur*. Small VSDs are called restrictive because they allow only limited shunting.

Small perimembranous or trabecular VSDs have a high closure rate (50–80%) by 2–10 years of age. A perimembranous VSD may close by the apposition of the septal tricuspid leaflet, which sometimes forms a pouch at the level of the sealed defect.[15] A small VSD is hemodynamically insignificant, and remains so as the patient ages, but is associated with a risk of endocarditis.

Large VSDs (*non-restrictive*, Qp/Qs >2) have a low spontaneous closure rate and lead to left HF, then Eisenmenger syndrome in infancy or childhood. They are typically corrected early on, before 1 year of age. Moderately large VSDs (Qp/Qs 1.4–2) may be tolerated for years before leading to hemodynamic compromise later on, in adulthood, as LV systolic and diastolic pressures rise and increase L–R shunting.

Adults presenting with VSD usually have a small VSD that did not close spontaneously and is not leading to any hemodynamic compromise. Other possibilities are: patch leak of a surgically repaired VSD; moderate VSD that is leading to hemodynamic compromise in adulthood (unusual); or large, non-corrected VSD that led to Eisenmenger syndrome long before adulthood. Also, infective endocarditis and AI may be seen later in life with a small, seemingly insignificant adult VSD.

D. Diagnosis, location, and shunt fraction Qp/Qs are established by TTE

TTE allows estimation of the VSD size: a small VSD has a diameter smaller than 1/3 of the aortic root diameter, a large VSD is a VSD larger than the aortic root. A large VSD typically has a large Qp/Qs ratio (>2), a small velocity, and a small pressure gradient across it because of the high RV systolic pressure (non-restrictive VSD).

TTE may miss a small trabecular VSD but very rarely misses other types of VSD.

E. Treatment

Surgical closure (direct closure or patch closure) is indicated as soon as possible for:

- Significant VSD (moderately large or large non-restrictive) with a Qp/Qs ≥1.5 and without severe pulmonary vascular disease (as under ASD treatment).
- Large VSD with LV or LA dilatation or LV dysfunction.
- Outlet VSD with progressive AI, regardless of its size.

Perform the surgery soon in infancy if needed (at the age of 3–6 months). Postoperative patch leaks may be seen but rarely require reoperation. Occasionally, if VSD closure cannot be immediately performed, *PA banding* is performed to reduce the pulmonary flow and the risk of Eisenmenger syndrome before definitive surgery.

IV. Patent ductus arteriosus (PDA)

A. Definition and consequences

PDA is a persistent communication between the left pulmonary artery and the descending aorta just distal (~1 cm) to the left subclavian artery. It leads to left-to-right shunt and massive LV volume overload from the shunt volume that circulates back to the LV. LV failure, which is initially a high-output failure, subsequently ensues (left HF being the most common complication).

It can also lead to progressive pulmonary hypertension and Eisenmenger syndrome with shunt reversal to a right-to-left shunt. In this case, a differential rather than a generalized cyanosis is seen (cyanosis of the feet only). The right-to-left shunt occurs distal to the innominate artery, so that the O_2 saturation in the upper extremities is preserved, whereas the O_2 saturation in the lower extremities is low, explaining the differential cyanosis and clubbing, i.e., cyanosis that is much more prominent in the lower extremities. The origin of the left subclavian artery may be close enough to the ductus to receive unoxygenated blood, and therefore cyanosis and clubbing of the left hand may be seen. The right hand remains normal until a severely reduced cardiac output leads to generalized cyanosis.

Infectious endarteritis at the shunt level may also be seen.

B. Severity and presentation

Spontaneous closure of a PDA is unlikely in term infants older than 3 months or pre-term infants older than 12 months. A large shunt (Qp/Qs >2) is symptomatic in infancy and leads to Eisenmenger syndrome early on, as early as 8 months, if untreated.

A moderate shunt (Qp/Qs 1.5–2) may lead to hemodynamic compromise at a later age (childhood or adulthood, up to the third decade). A small shunt (Qp/Qs <1.5) presents as an isolated murmur.

A loud, continuous "machinery" murmur is heard at the first or second left intercostal space. As a result of the large stroke volume, the pulse pressure is wide with bounding pulses.

The continuous murmur of PDA is different from a systolic–diastolic murmur; the former has only 1 peak that occurs at S_2 or just before it, whereas the latter has 2 peaks. The continuous murmur of PDA is loudest at the left upper sternal border; if it is louder anywhere else, it suggests the diagnosis of a fistula, such as coronary fistula, or sinus of Valsalva aneurysm ruptured in the RV or the RA.

Remember that in both VSD and PDA, LV failure generally precedes Eisenmenger syndrome. LV failure is generally present by the time the patient develops Eisenmenger syndrome.

C. Diagnosis

Two TTE views allow the diagnosis of PDA: the suprasternal notch view *and* the parasternal short-axis view (pulmonary artery level). These views show a flow extending from the aorta to the left PA and establish the diagnosis in 42% of the patients. TEE establishes the diagnosis in 97% of the patients.[16] For echo shunt calculation, the flow across the RVOT is proximal to the shunt and corresponds to Qs, whereas the flow across the LVOT corresponds to Qp (the reverse is true in ASD and VSD).

D. Treatment

Intervention is indicated for the hemodynamically significant PDA (class I recommendation), but also for any audible PDA, which includes the small PDA with Qp/Qs <1.5, because of the risk of endarteritis (class IIa). Only the tiny, silent PDA does not warrant intervention. Transcatheter closure is the preferred therapy for PDA.

V. Coarctation of the aorta

Coarctation is a narrowing of the aorta around the level of the ductus arteriosus, and may be discrete or long and tubular. The site of coarctation is usually less than 1–5 cm distal to the left subclavian origin. In addition to the pre-stenotic dilatation, most patients with significant aortic coarctation have post-stenotic aortic dilatation, sometimes aneurysmal. Aortic coarctation is associated with a high prevalence and a wide variety of congenital cardiovascular anomalies (>50%). Approximately 75% of these patients have bicuspid aortic valves. Also, there is an increased prevalence of mitral valvular disease (parachute mitral valve, part of Shone complex), VSD, PDA, and intracranial berry aneurysm (10%). Aortic coarctation is usually diagnosed in an infant or child, but may remain asymptomatic until the young adult age, when the patient succumbs to severe HTN, HF, premature CAD, or intracranial hemorrhage (average survival of untreated coarctation is 34 years).

A. Diagnosis

1. *Clinical:* the patient presents with hypertension, a murmur, and a blood pressure discrepancy of >20 mmHg between the upper and lower extremities with a radial-to-femoral pulse delay. The blood pressure discrepancy may attenuate and become unnoticeable as more collaterals develop with age. The murmur is mid-systolic, heard best over the left upper sternal border, radiates to the back and spine, and may become continuous if the stenosis is severe enough to produce a diastolic pressure gradient.

CXR shows rib notching and a figure of 3, which is a double bubble of the descending aorta (pre- and post-stenotic dilatation).

2. *Hemodynamic:* a 20 mmHg peak-to-peak gradient defines significant aortic coarctation. In patients with collaterals, the aortic gradient may be reduced to 10–20 mmHg; acquired aortic ectasia, significant collateral flow, or left ventricular hypertrophy would define significant coarctation in this case.

The diastolic gradient is usually mild; in fact, collateral flow prevents a drop in distal aortic pressure during diastole but is not enough to prevent the systolic drop in pressure. On spectral Doppler of the abdominal aorta, the hallmark of coarctation is persistent antegrade flow in diastole, as the underfilled aorta keeps "requesting" flow in diastole (vs. early diastolic reversal in normal aorta).

3. *Echo* (suprasternal view), *and CT or MRI* are useful imaging modalities.

B. Treatment

The coarctation may be treated surgically: excision followed by end-to-end anastomosis with or without patch repair, or excision with placement of an interposition graft. This treatment may be performed in infancy in very severe cases, or in the first 5 years of life in less severe cases. The aorta reaches 50% of its eventual size at 3–5 years of age, such that, when surgery is performed at this age, a lack of growth of the surgical site does not translate into severe stenosis. A younger age at the time of initial repair translates into better long-term outcomes (less irreversible damage of the aortic wall and less LV hypertrophy). The best survivorship was observed in patients operated at 9 years of age or less.[17]

Coarctation may be treated percutaneously with angioplasty in patients older than 1 year. At less than 1 year of age, there is a high risk of recurrence and aneurysm formation after angioplasty. Stenting is the percutaneous treatment of choice in patients >30 kg, while angioplasty is the treatment of choice for patients >1 year and <30 kg, where the use of a stent is limited by aortic growth issues.[18]

C. Long-term sequelae

Residual hypertension is seen in a third of patients and may be related to residual coarctation or to the fact that longstanding hypertension permanently remodels the aortic wall.[19]

Residual coarctation or recurrent coarctation is seen in ~10–20% of patients after surgical repair. If focal, recoarctation is best treated with balloon angioplasty.

After surgical or percutaneous repair, patients have a long-term risk of aneurysm formation at the site of surgical repair, and late dissection, as the aorta itself is diseased. This warrants surveillance with MRI or CT every 5 years.

Late mortality is related to coronary artery disease (most common cause of late death), residual hypertension, associated valvular disease, and cerebral berry aneurysms. Brain MRA should be done at least once to rule out berry aneurysms.

VI. Other anomalies

Subvalvular aortic stenosis, supravalvular aortic stenosis, and pulmonic stenosis are discussed in Chapter 6. Additional anomalies:

A. Sinus of Valsalva aneurysm

Sinus of Valsalva aneurysm is a congenital localized dilatation of a single sinus of Valsalva (usually). It is different from the aortopathy of bicuspid aortic valve or Marfan disease, wherein all sinuses are enlarged, usually along with dilatation of the sinotubular junction and ascending aorta. The latter conditions may, however, have this localized form of sinus dilatation.

The sinus of Valsalva aneurysm often involves the right sinus and usually ruptures in the RV, at the age of 15–45. Less frequently, it may arise from the non-coronary sinus and rupture in the RA. It usually comes to attention after rupture and manifests as a continuous murmur, predominantly at the right sternal border, and a large left-to-right shunt with left HF from the volume overload circulating back to the LV (like VSD), but also right HF from the diastolic shunting into the RV. It may also lead to coronary compression and myocardial ischemia. Not infrequently, it may remain asymptomatic. It is frequently associated with VSD (~50%) and AI (~50%).

B. Scimitar syndrome

The pulmonary veins of the right upper lobe and most of the right lower lobe empty into the IVC just below the RA. The anomalous right pulmonary vein descending to connect with the IVC has the shape of a scimitar and may get compressed as it emerges through the lung. Similar to ASD, the scimitar shunt occurs proximal to the tricuspid valve, is usually small, and does not, by itself, lead to pulmonary hypertension. However, patients with scimitar syndrome have associated anomalies that explain most of the untoward effects and pulmonary hypertension:

- Hypoplasia of the right lung with hypolasia of the right pulmonary artery.
- Branches of the upper abdominal aorta (e.g., celiac artery) or the lower thoracic aorta supply part of the right lung and may lead to pulmonary hypertension and significant left-to-right shunting at the PA level.
- Associated congenital heart disease in 20–25% of the cases (ASD, PDA, coarctation of the aorta).

C. Persistent left SVC

Persistent left SVC is a condition wherein the left innominate vein drains directly into the coronary sinus, leading to the isolated finding of a dilated coronary sinus. Bubbles injected through a left arm vein briskly fill the coronary sinus (which does not normally fill). It is a benign condition per se, found in <0.5% of the population. It has a higher prevalence in patients with other congenital heart diseases (5–10%).

2. CYANOTIC CONGENITAL HEART DISEASE

I. Pulmonary hypertension secondary to shunt

A. Definition and mechanisms

Eisenmenger syndrome is the extreme form of irreversible pulmonary hypertension that results from left-to-right shunting. The high PA flow leads to a reactional increase in pulmonary vascular resistance, which eventually exceeds the systemic vascular resistance and leads to shunt reversal (the left-to-right shunt becomes a right-to-left shunt with cyanosis). Usually, in Eisenmenger syndrome, the systemic and pulmonary pressures are nearly equal, but more importantly, the ***pulmonary vascular resistance (PVR) exceeds the systemic vascular resistance (SVR)***. The shunt is purely a right-to-left shunt in the majority of the cases, but may be bidirectional (right-to-left and left-to-right).

At an early stage of left-to-right shunting, the pulmonary pressure may be elevated solely from the increased pulmonary flow. Pressure being equal to flow multiplied by vascular resistance, an increase in pulmonary flow (e.g., Qp/Qs=4) leads to a severe increase in pulmonary pressure even if PVR is normal. For example, a large VSD may lead to a large left-to-right shunting and an almost equalization of LV and RV systolic pressures and aortic and pulmonary pressures. However, early on, this increase in pulmonary pressure is due mainly to the increase in flow (not Eisenmenger syndrome). Later on, PVR progressively increases, eventually exceeding SVR: Eisenmenger syndrome with shunt reversal occurs (Tables 18.1, 18.2). Not every irreversible PAH is Eisenmenger syndrome: Eisenmenger is an extreme form of irreversible PAH where PVR exceeds SVR and shunt reversal occurs. ***Yet, irreversible PAH may already be present if PVR >1/3 SVR or ≥5 Wood units.*** Thus, in the evaluation of a shunt associated with severe pulmonary hypertension, the calculation of PVR is the most important next evaluation step. Pulmonary vasoreactivity is assessed by using 100% O_2 and pulmonary vasodilators in the following case:

- PVR that is [1/3–2/3] of SVR, or 5–8 Wood units. Yet, instead of vasoreactivity testing, both ACC and ESC rather recommend PAH therapy followed by later re-assessment of PVR (goal <5 and <1/3 SVR) and Qp/Qs (goal >1.5).

A significant response is characterized by a reduction of PVR to <1/3 SVR; also, the left-to-right shunt must increase and Qp/Qs must rise to >1.5. In the absence of a significant response, the pulmonary arterial remodeling is at an advanced and irreversible stage, and the shunt is not generally closed. If the shunt is closed at this stage, the right-sided pressure overload and the pulmonary hypertension may worsen postoperatively. In case of a significant response, the patient is treated with pulmonary vasodilators until the PA pressure declines to an operable range, then the shunt is closed.[20]

Eisenmenger syndrome is usually due to VSD (most common cause), PDA, or, less commonly, ASD. More specifically in ASD, shunt reversal and cyanosis may be seen without pulmonary hypertension. RV volume overload leads to RV failure, which leads to an increase in RA pressure, at times exceeding LA pressure. ***In ASD, the right-to-left shunt is often determined by RV failure rather than PA pressure, and hypoxemia may be seen without severe pulmonary hypertension***.[20]

Table 18.1 Stages of pulmonary hypertension in left-to-right shunt.

1.	– Flow-induced PH with normal PVR (PA ~ flow × PVR, if flow↑ → PA↑)
2.	– Reversible mild PAH: PVR <1/3 SVR and 2–5 Wood units → Closure is still indicated
3.	– Irreversible PAH: PVR >2/3 SVR or >8 Wood units → Closure is contraindicated. If PVR *1/3–2/3 SVR* or *5–8 Wood units*, give PAH therapy then re-evaluate PVR (ACC 2018 and 2025). Seek PVR decline to <1/3 SVR and <5 Wood units, and Qp/Qs rise to >1.5
4.	– Eisenmenger = extreme form of irreversible PAH: PVR >SVR *and* shunt reversal to a predominant or exclusive right-to-left shunt

PAH, pulmonary arterial hypertension; PH, pulmonary hypertension; PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

Table 18.2 Eisenmenger criteria.

Eisenmenger =	
1.	Latest form of irreversible shunt-induced PAH
2.	Reversal of shunt (becomes fully right-to-left or bidirectional)
3.	PVR ≥SVR

Eisenmenger syndrome does not occur with small VSD <1 cm or ASD <2 cm; when severe PAH is present, it is considered idiopathic and the latter lesions are rather coincidental (ESC guidelines).

In cases of ASD with elevated PVR and/or bidirectional shunting, *balloon occlusion testing* may be performed. Temporary balloon occlusion of the ASD is performed, and RA pressure, PA pressure, and PCWP are measured through a Swan catheter. A significant increase in right-sided pressures or a drop in CO indicates a significant risk of right-sided failure associated with ASD closure. On the other hand, a significant increase in LA pressure measured through the balloon occlusion catheter indicates that the patient has significant LV dysfunction (e.g., LVH with diastolic failure) and was getting relieved by the left-to-right shunting, i.e., the preload reduction. LV may not be able to cope with the acute increase in preload following ASD closure, which may lead to acute pulmonary edema. This is mainly seen when ASD is closed in an older population. ASD closure should be postponed and the patient appropriately treated with antihypertensive agents and diuretics before attempting closure.[21]

B. Clinical presentation of Eisenmenger syndrome

Eisenmenger syndrome that is secondary to VSD or PDA typically develops before the age of 2 years. Eisenmenger patients have a good functional capacity up until their 20s, then develop a progressive functional decline, cyanosis, atrial and ventricular arrhythmias (common), and hemoptysis. Hemoptysis results from the systemic arterial collaterals to the lung; it may be severe and is the cause of death in ~15% of patients. Right heart failure develops later. Stroke and brain abscess from paradoxical emboli may occur; polycythemia is also a factor.

Similarly to pulmonic stenosis, the RV does not fail and TR does not occur until late in the course of disease (age 40s). On the one hand, the congenital RV tolerates pressure overload more than the adult RV, and on the other hand, the right-to-left shunt allows RV or PA decompression, therefore delaying failure. This explains why Eisenmenger is much better tolerated than idiopathic pulmonary hypertension. RV heave is present, but the RV is not dilated; on JVP exam, A wave is large, but V wave and mean JVP are normal.

On exam, Eisenmenger is characteristically a ***silent cyanotic heart disease***, i.e., no murmur is heard. The equalization of pressures across chambers makes the right-to-left shunt a low-gradient, silent shunt. In fact, the presence of a VSD or a PDA murmur makes the diagnosis of irreversible pulmonary hypertension unlikely.

CXR is characterized by an enlarged central PA with rapid tapering and lung oligemia. The PA is sometimes calcified, which is not the case in idiopathic pulmonary arterial hypertension, where pulmonary hypertension is not as longstanding.

C. Treatment

The causal shunt should not be closed at this point, as the right-to-left shunt relieves the severity of pulmonary hypertension and prevents RV failure. Treatment consists of avoiding exacerbating factors, such as dehydration, systemic vasodilators (which increase right-to-left shunt), and excessive physical activity. Pulmonary vasodilators may be used (bosentan, sildenafil, IV prostacyclin) and have been shown to improve symptoms. Beware that pulmonary vasodilators may increase pulmonary flow and lead to pulmonary edema, in which case diuretics may be required. They may also have an untoward systemic vasodilatory effect. In advanced cases, lung transplant with repair of the cardiac defect may be performed.

In all cases of right-to-left shunt, hot conditions, systemic vasodilators, and sedation/anesthesia are risky and should be avoided as much as possible. They reduce SVR and thus increase the right-to-left shunt and may lead to hemodynamic collapse. Dehydration may also reduce the marginal right-sided flow and lead to hemodynamic collapse.

If a patient presents with a hyperviscosity syndrome (neurological symptoms accompanying polycythemia, usually hematocrit >65%), first rule out dehydration as a cause of polycythemia. If symptoms persist, phlebotomy with adequate fluid replacement may be considered. Also, search for microcytosis and iron deficiency even in patients with polycythemia, as iron-deficient red blood cells are less deformable and more prone to sludging. Polycythemic patients are prone to both thrombosis and bleeding. Phlebotomy is not indicated in the absence of symptoms.

II. Tetralogy of Fallot

A. Pathology and consequences

Tetralogy of Fallot has 4 components (Figure 18.9):

a. Outlet VSD with right-to-left shunt and cyanosis
b. RV outflow obstruction: the major site of obstruction is usually at the subvalvular, infundibular level. In addition, there is often a stenotic, bicuspid pulmonic valve and in 20%, the pulmonic valve is fully closed with no direct pulmonary flow (pulmonary atresia). There may also be a distal pulmonary arterial stenosis, i.e., pulmonary stenosis may be present at multiple levels.
c. Overriding of the aorta over the interventricular septum (<50% of patients). In addition, a right aortic arch is seen in 25% of patients. In the absence of an overriding aorta, the disorder is called *partial tetralogy*.
d. RV hypertrophy.
e. A fifth component, ASD (secundum ASD or primum ASD/AV canal defect), is seen in 15% of patients (pentalogy of Fallot).

The severity of this malformation and of the right-to-left shunt and cyanosis depends on the degree of RV outflow obstruction. A mild RV outflow obstruction may not lead to significant right-to-left shunting and the cyanosis may be mild or absent, in which case the entity is termed "pink tetralogy" or "acyanotic tetralogy." Pink tetralogy may become blue as the RV obstruction progresses with age.

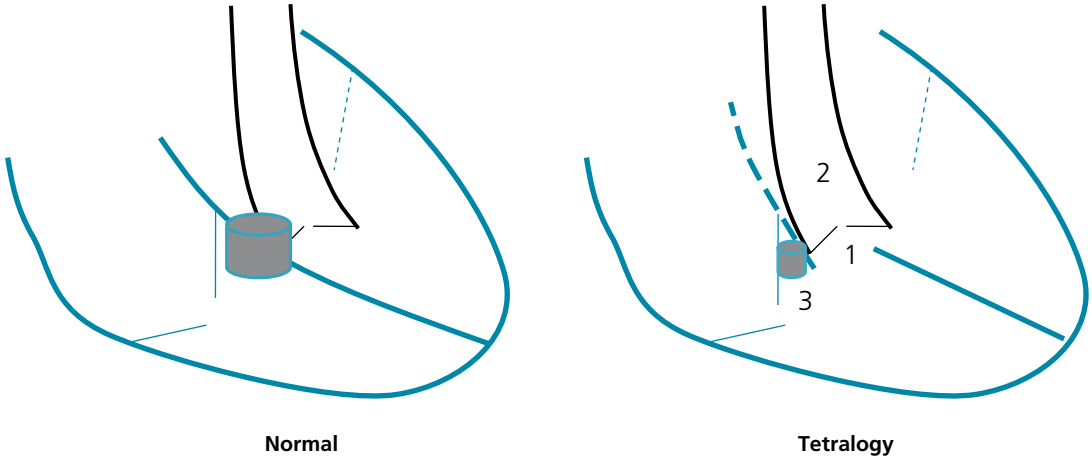

Figure 18.9 Anatomy in normal patients and in tetralogy of Falllot. In tetralogy, the outlet septum is not only defected but malaligned with the trabecular septum and displaced toward the RV. The aortic origin is rightward and overrides the VSD. The RV outflow tract (gray cylinder) is narrowed, partly from the septal deviation and partly from the fact that the aorta occupies the RV outflow, allowing right-sided blood to be directly ejected in the aorta.The VSD is different from non-tetralogy VSD in that the aorta overrides the VSD. 1, VSD; 2, overriding aorta; 3, RV outflow obstruction.

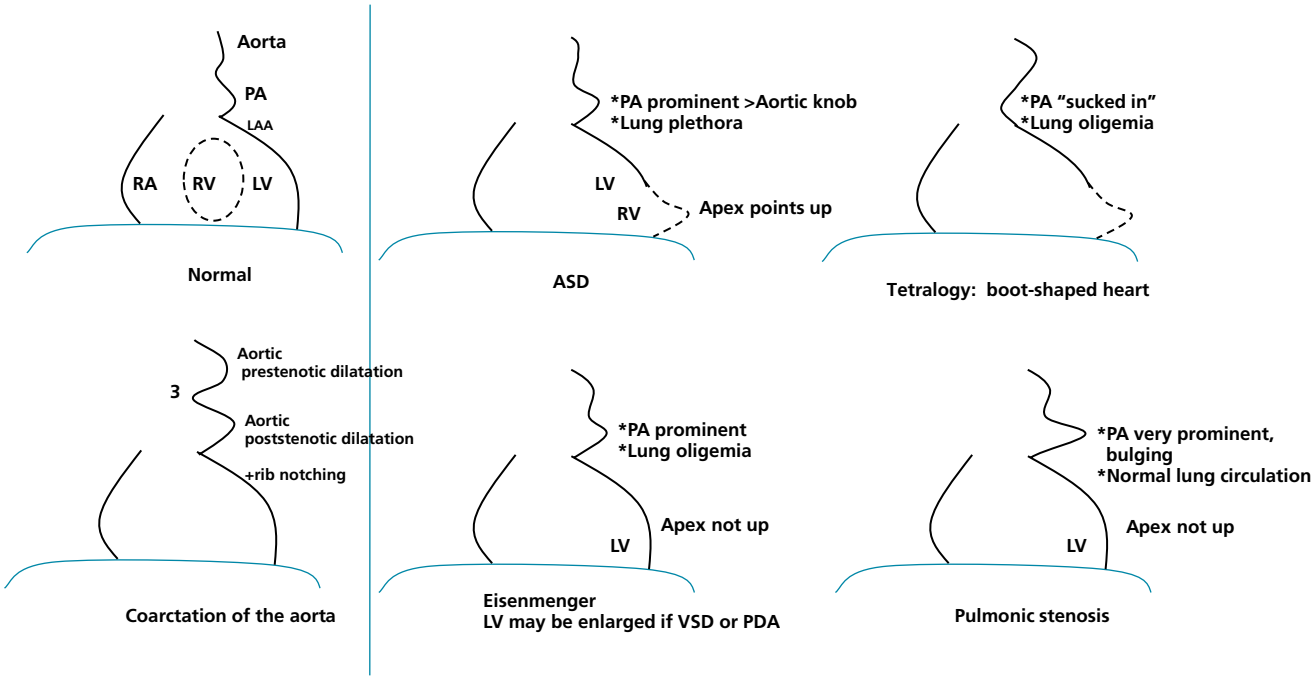

Figure 18.10 Radiographic cardiac and mediastinal silhouettes in various congenital heart diseases. In congenital heart disease, assess the following 4 features: (1) shape of the heart and apex; (2) proximal PA; (3) lung circulation; (4) normal vs. right-sided aortic arch.

A tetralogy spell is an acute fall in O_2 saturation that occurs when the pulmonary blood flow further declines because of reduced preload (e.g., dehydration) or increased right-to-left shunt (e.g., systemic vasodilatation [exercise]). It is relieved with systemic vasoconstriction or squatting, which reduces the right-to-left shunting, hydration, O_2 therapy, and propranolol (↓ RV outflow contractility and narrowing).

CXR shows a boot-shaped heart. The apex points upward because of RV enlargement, and the region of the left pulmonary artery (left hilum) has a sharp inward concavity. This is opposite to isolated PS, wherein the left PA area is enlarged from post-stenotic dilatation (Figure 18.10). Moreover, a decreased pulmonary vascularity and, sometimes, a right aortic knob with an absent left knob are seen (Figure 18.11).

As opposed to Eisenmenger, which is characterized by a silent cyanosis, tetralogy is characterized by a cyanosis and a systolic murmur that is secondary to RV outflow obstruction. The more severe the obstruction, the less flow goes through the RV outflow and the milder the murmur.

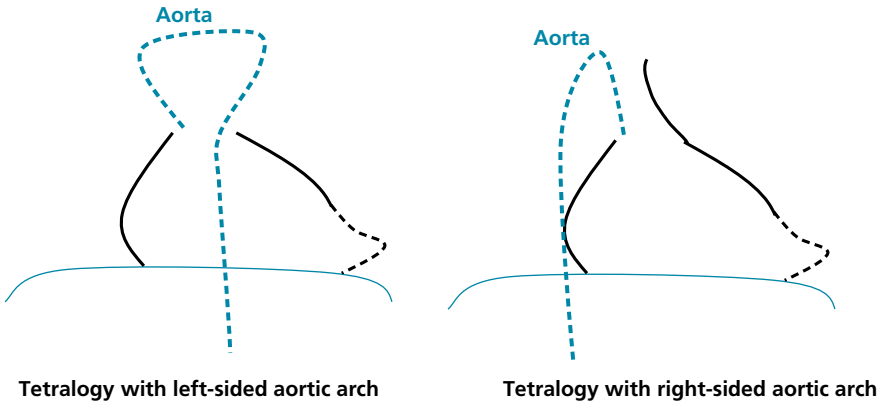

Figure 18.11 CXR in tetralogy with and without right-sided aortic arch.

B. Treatment

1. *Palliation with a Blalock–Taussig shunt (subclavian artery to pulmonary artery shunt) or Glenn shunt (SVC to PA shunt)*. These shunts increase pulmonary flow and serve as a bridge to a more complete correction. They are used when complete correction is not possible in the neonatal period or when PA is small and underdeveloped from underfilling. The systemic-to-PA shunt (e.g., Blalock–Taussig shunt) should not be kept too long, as it may lead to pulmonary hypertension and high-output LV failure, similarly to PDA.

2. *Surgical correction*. The VSD is closed with a patch. The infundibular muscular stenosis is resected and the RV outflow tract enlarged and patched all the way up to the pulmonic valve. Pulmonic valvotomy is performed in the case of pulmonic stenosis. This can be performed at any age, including the first few months of life. Freedom from late reintervention and normal exercise tolerance are expected in up to 90% of patients.[22]

3. Patients may present in adulthood with the following complications:

- Severe pulmonary regurgitation is very common and leads to progressive RV enlargement 10–20 years postoperatively. In fact, during surgical repair of tetralogy, the RV outflow is enlarged and patched all the way up to the pulmonic valve, which dilates the valvular annulus and disrupts the valve, making it incompetent; occasionally, the valve is even removed during surgical repair. Pulmonic valve replacement is required whenever severe RV dilatation, RV systolic dysfunction, or exercise limitation occurs.
- Persistent RVOT obstruction.
- Residual VSD with significant left-to-right shunt (this and the preceding two complications require surgical repair).
- Persistent RV dysfunction.
- Dilated aortic root, progressive AI secondary to VSD.
- VT, SVT, and sudden cardiac death, especially in the case of a persistent RV dysfunction or a very wide QRS >180 ms. One-third of late deaths are sudden. ICD is indicated in case of syncope or sustained VT.

The late occurrence of arrhythmia or QRS widening warrants a search for pulmonary regurgitation or other complications.

RV outflow obstruction protects from pulmonary hypertension, and thus patients with tetralogy do not usually develop this complication over the long term. Pulmonary hypertension in a patient with tetralogy may imply peripheral pulmonic stenosis, a mild RV outflow obstruction (before correction) that allowed for a left-to-right shunt, or a Blalock–Taussig shunt that produced pulmonary hypertension.

III. Ebstein anomaly

The insertion of 1 or 2 of the tricuspid valve leaflets (the septal ± posterior leaflets) is displaced toward the apex, which puts part of the RV in the atrium ("atrialization" of the RV and reduction of the "functional RV" mass, which reduces RV output). While the tricuspid valve is normally more apical than the mitral valve, in Ebstein, the distance between the septal tricuspid leaflet and the mitral annulus is excessive, i.e., >8 mm/m^2 of BSA. *The anterior tricuspid leaflet is never displaced but is elongated and tries to catch the low septal leaflet*.

Because of the tricuspid abnormality, patients with severe Ebstein anomaly may have severe TR. This is often the biggest issue, as TR leads to progressive RA enlargement, RV failure, and RV volume overload, worsened by the loss of parts of the functional RV. These patients end up with severe right heart failure. They typically present in young adulthood.

Fifty percent of patients have an associated ASD, with right-to-left shunting and cyanosis at some point. This shunt occurs when the RV fails and RA pressure increases, and early on it may only be exertional.

Twenty-five percent of patients have accessory pathways and SVT.

A. Natural history and exam

The natural history varies widely and depends on *3 factors*: degree of atrialization of the RV, degree of TR, and presence of right-to-left ASD shunt. Some patients develop symptoms as newborns or infants, while some occasionally remain asymptomatic until their 50s or 60s. Patients present with reduced exercise tolerance (reduced cardiac output), right heart failure, and sometimes right-to-left shunt with cyanosis, which may only be exertional early on.

Exam findings: TR murmur that increases with inspiration, loud and split S_1 secondary to the loud closure of the tricuspid valve, and split S_2 secondary to ASD. Pectus excavatum may be associated with this anomaly.

B. ECG and CXR

ECG is characterized by a Himalayan P wave, which is a gigantic, peaked P wave in lead II, as large as the QRS. RBBB may be present and is characteristically splintered, with RSR'S' pattern. PR may be short, consistent with WPW.

CXR shows an enlarged cardiac silhouette (gigantic RA). The lung vasculature is normal or reduced.

C. Treatment

Ebstein anomaly may be mild. It does not require surgery when the tricuspid displacement and the TR are mild. Surgical intervention, which mainly consists of tricuspid valve repair (rather than replacement) to correct the harmful severe TR, is indicated in cases of deteriorating functional capacity, progressive RV dilatation or RV systolic dysfunction, even if asymptomatic, or any cyanosis (class I indication). Cyanosis is associated with an increased risk of paradoxical embolization.

3. MORE COMPLEX CYANOTIC CONGENITAL HEART DISEASE AND SHUNT PROCEDURES

I. Functionally single ventricle and Fontan procedure

A. Fontan procedure

The Fontan procedure is a palliative surgery that redirects the systemic venous return directly to the pulmonary artery without passing through the RV (= atriopulmonary connection) (Figure 18.12). It is performed in patients who have a "functionally single ventricle," usually associated with cyanosis. This procedure relieves the chronic volume load on the systemic ventricle that is pumping to both the pulmonary and systemic circulations. *What is interesting is that blood flows passively to the PA without an interposed RV, as long as the PA pressure is not increased. In a way, humans who have a normal PA pressure may live without RV for many years or decades; the RV may be forgone for a passive conduit in patients with* ***a normal PA pressure***. The venous pressure must be high enough, higher than the pulmonary pressure, to let blood flow toward the pulmonary artery. The systemic venous pressure is, therefore, elevated chronically and allows forward flow. The RA is chronically and severely enlarged. The procedure cannot be performed in patients with pulmonary hypertension.[23,24]

B. Indications for Fontan

The Fontan procedure is indicated for:

- *Tricuspid atresia*: RV is hypoplastic and not connected to the RA (tricuspid valve is closed). Blood flows from the RA to the LA through an ASD, then the LV pumps to the PA through a VSD and to the aorta (Figure 18.12). Initially, these patients temporarily receive a Blalock–Taussig shunt to increase PA flow, then a bidirectional Glenn procedure, then Fontan.
- *Hypoplastic left heart syndrome*: the left heart and the proximal aorta are underdeveloped. The RV pumps to the PA and then the aorta through a PDA.
- *Double-inlet single ventricle*: double atria and AV valves drain into a single ventricle.

In all those complex anomalies, both right-to-left and left-to-right shunts are present.

C. Variations of Fontan: the 3 surgeries required in single-ventricle syndromes

One variation of Fontan consists of connecting the SVC to the right PA, and creating a tunnel that connects the IVC to the right PA; this variation reduces blood turbulence and the ensuing waste of blood-flow energy. Another variation consists of creating fenestrations of the conduit into the RA (and leaving a small ASD), which allows decompression of the venous circulation in case of pulmonary hypertension, so that blood still flows to the left heart and prevents collapse; this allows the performance of the Fontan procedure in patients with pulmonary hypertension.

Note that the Fontan procedure is not performed upfront in newborns and infants. Patients < 2 years of age have a high pulmonary resistance that may lead to Fontan failure. That is why patients with a single ventricle often require a 3-step procedure (Figure 18.12):[17]

1. In tricuspid atresia, a systemic-to-PA shunt is initially performed in newborns with poor pulmonary flow (***Blalock–Taussig shunt***). In patients with large VSD and high pulmonary flow, PA banding is performed.

Hypoplastic left heart syndrome is initially corrected with a ***Norwood procedure***. The main PA is disconnected from the its base and from the RV and closed with a patch. A direct communication is then created between the RV and the aorta, using the PA base as a conduit. A systemic artery-to-PA shunt, like a *Blalock–Taussig shunt*, is created for the pulmonary circulation. PDA is closed, while a large ASD is kept open for the pulmonary venous return.

2. As a second step, the systemic-to-PA shunt is taken down, and a ***Glenn bidirectional shunt*, which is a *hemi-Fontan***, is performed at 3–6 months of age. It consists of disconnecting the SVC from the RA and connecting it to the right PA, while the common PA is tied. SVC blood flows to the lungs, while IVC blood goes to the left side and recirculates (residual cyanosis); this avoids the risk of failure of full Fontan as pulmonary resistance is still increased in these very young patients, and is also useful in borderline cases with increased PA pressure.

3. At 2–5 years of age, the ***full Fontan*** is completed by connecting the IVC to the right PA through a tunnel or a conduit.

The first 2 steps improve pulmonary blood flow and hypoxemia, but the patients continue to have right-to-left shunting and some degree of cyanosis.

D. Exam and long-term complications

Fontan patients have a quiet auscultation without any significant murmur; a murmur suggests associated abnormalities. They survive until early adulthood (20s) before they develop failure of their single ventricle and arrhythmias.

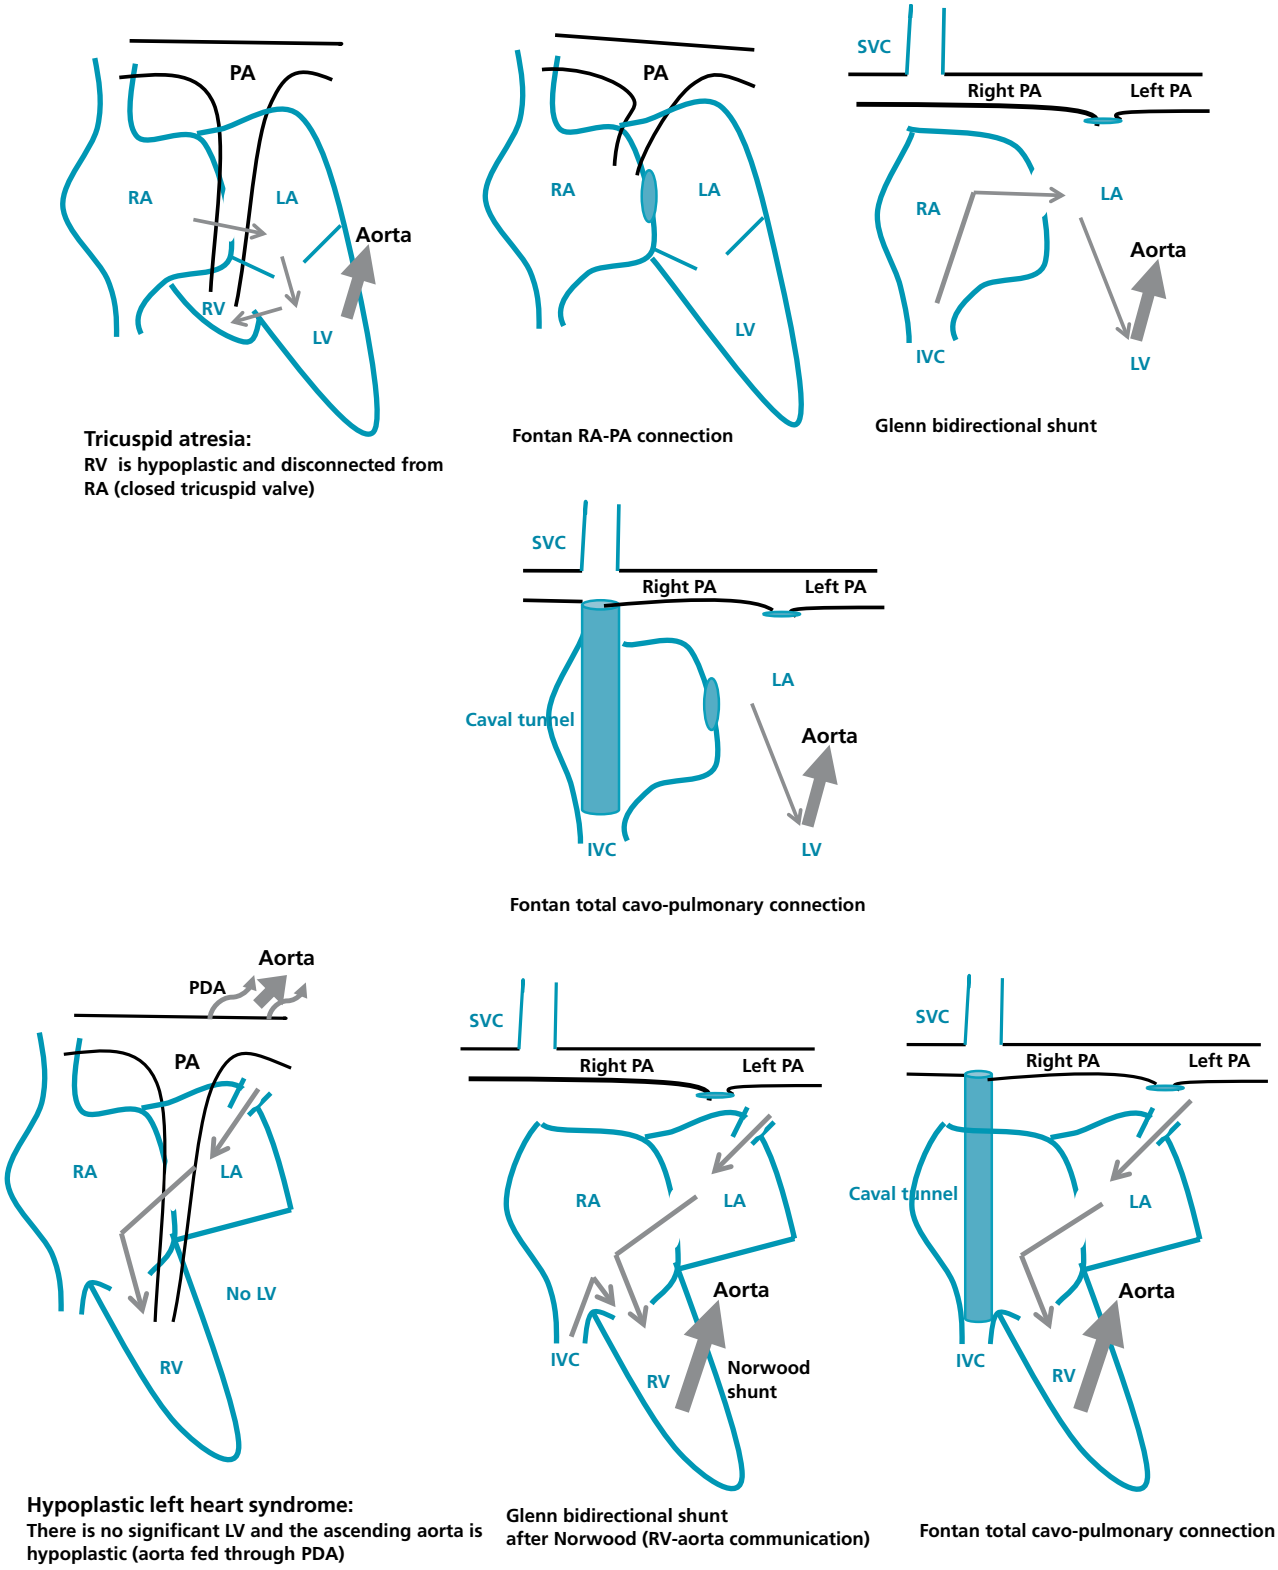

Figure 18.12 Tricuspid atresia and Fontan procedure **(top 2 rows). Hypoplastic left heart syndrome** and Fontan procedure **(bottom row).** Note: a Glenn bidirectional shunt is half of a total cavopulmonary connection: the SVC is disconnected from the RA, then connected to the right PA, while the common PA is tied up; the IVC continues to flow into the RA then the single ventricle (all of the IVC flow is right-to-left shunted). Later on, an IVC-to-PA tunnel is created, which converts Glenn into a Fontan procedure. When Fontan is done for tricuspid atresia, the pre-existing ASD is typically closed.

Long-term complications:

- Anastomotic obstruction (leads to increased venous pressure and reduced functional capacity)
- AF or atrial flutter is common
- Ventricular failure
- Thrombus formation in the RA, the venous system, or the Fontan circuit. Fontan patients frequently receive aspirin or warfarin prophylaxis to prevent thrombotic events
- Neoaortic dilatation after Norwood, or stenosis at the neoaortic anastomosis (a form of anastomotic coarctation)
- Protein-losing enteropathy, from the chronically elevated venous pressure, develops in 10% of patients and carries a poor prognosis (50% mortality at 5 years)

Eventually, patients with Fontan complications require cardiac transplantation.

A functionally single ventricle is the only congenital heart disease with cyanosis yet isolated LVH on ECG, rather than RVH.

II. Transposition of great arteries (TGA)

A. D-TGA

In d-TGA, the aorta originates from the morphological RV (RA–RV–aorta connection), and the pulmonary artery originates from the morphological LV (LA–LV–PA connection) (Figure 18.13). Some communication must exist between the 2 systems (ASD usually, sometimes VSD or PDA). These patients are cyanotic and die within the first year if untreated. Complex TGA is d-TGA associated with other major congenital abnormalities (PS, VSD).

The following surgeries may be performed in d-TGA:

- *Atrial switch (Mustard or Senning procedures)* consists of creating a baffle (tunnel) that redirects SVC/IVC flow to the LA/mitral valve, and a second baffle that redirects the pulmonary venous flow to the tricuspid valve. The problem is that the morphological RV behaves as the systemic ventricle and may ultimately fail after 20–30 years. TR, sinus node disease, and atrial arrhythmias may develop. Baffle leak may occur and lead to L–R or R–L shunt. Baffle obstruction may lead to pulmonary hypertension or peripheral venous hypertension. Baffle issues may be treated percutaneously. Severe failure of the systemic ventricle may warrant cardiac transplantation or 2-step arterial switch (banding the PA to allow hypertrophy of the anatomic LV, followed by arterial switch later on).
- *Arterial switch (Jatene procedure)* consists of transposing the PA and aorta to their respective ventricles. The aorta is transposed above its base, i.e., above the valve and the coronary level, and thus the coronaries need to be separately transposed and sutured to the new aortic base, previously left-sided PA. There is a long-term risk of ostial coronary stenosis, regurgitation of the neoaortic valve (actually a pulmonic valve), dilatation of the neoaortic root, and supravalvular stenosis of the PA and aorta at the anastomotic sites (may be treated percutaneously).
- *Rastelli procedure* is performed in patients with TGA + VSD + subvalvular PS. The LV is connected to the aorta with a patch passing through the VSD, and the RV is connected to the transected PA through a valved conduit.

B. L-TGA

In l-TGA, or congenitally corrected TGA, the LV and RV with their respective valves are transposed (RA–LV–PA circuit on the right, and LA–RV–aorta circuit on the left). The circulation is physiologically corrected, but the morphological RV supports the systemic circulation. L-TGA, when isolated, is well tolerated and may only come to attention in adulthood, at which time the RV and tricuspid valve supporting the systemic circulation start failing, and AV conduction disease frequently appears. The RV is not designed to support the systemic circulation, as unlike the LV, it has 2-layered rather than 3-layered walls, and even in L-TGA, it receives blood supply from a single coronary artery, RCA, insufficient for a systemic ventricle; in fact, RV coronary flow reserve is impaired and the RV is chronically ischemic in L-TGA. As a result, RV fails and the survival is only ~60% at the age of 30 (worse if severe TR). L-TGA is most commonly associated with other congenital anomalies, such as progressive regurgiation of the systemic (tricuspid) valve or VSD, triggering a diagnosis in childhood.

The letter "d" or "l" corresponds to the *location of the RV and aorta, which are always connected in TGA*. In d-TGA (dextro), the RV and aorta are on the right, the arteries are transposed; in l-TGA (left), the RV and aorta are on the left, the ventricles are transposed.

Even in L-TGA, the aorta has an anomalous origin that is left and anterior to the PA (unlike the normal origin, which is right and posterior) (Figure 18.14).

Tricuspid (lowermost) valve continues to be concordant with the RV and helps identify RV on echo.

Figure 18.13 D-TGA is characterized by RV–aorta on the right, while l-TGA is characterized by RV–aorta on the left. The transposed chambers are named in blue. The arrows on d-TGA describe the tunnels (baffles).

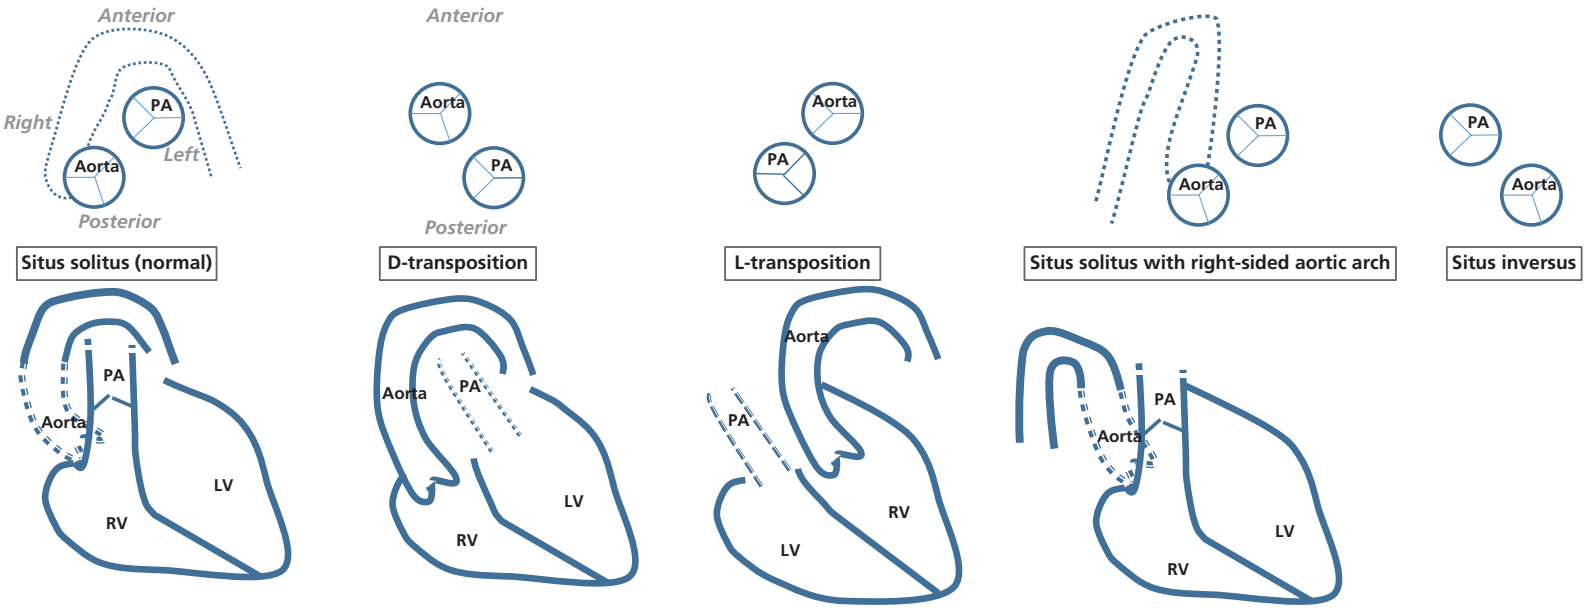

Figure 18.14 The *top images* are axial sections across the aorta and PA, while the *bottom images* are frontal views. Normally, the aorta is more posterior than the PA and to the right of it; it eventually turns to the left at the arch level. It is not in the same plane as the PA, it is rather oblique to it. In both TGAs, besides the abnormal RV-aorta communication, the aorta is anterior to the PA: anterior and to the right in D-TGA, anterior and to the left in L-TGA; **aorta and PA become parallel to each other, including on echo short- and long-axis views, a landmark of TGA.** Note that a right-sided aortic arch, seen sometimes in tetralogy of Fallot, is different from the anomalous origin of the aorta seen in TGA. In the bottom illustrations, *the interrupted lines indicate* posterior structures.

III. Other anomalies

A. Truncus arteriosus

In this case, only 1 trunk leaves the heart and branches into the PA and aorta. This trunk usually sits over both the RV and LV, which also communicate through a VSD. It is corrected early on by separating the pulmonary artery and connecting it to the RV.

B. Total anomalous pulmonary venous return

As opposed to the partial anomalous venous return that occurs with ASD, in which 1 or 2 pulmonary veins drain into the RA, in total anomalous venous return all 4 veins drain as a trunk into the RA, SVC, coronary sinus, or IVC, leading to a very large left-to-right shunt. Some degree of right-to-left shunting must be present to create a circulation. This anomaly must be corrected in infancy.

A murmur in an infant usually means:

- Ventricular outflow obstruction, such as congenital PS, AS, subvalvular obstruction, or tetralogy.
- A left-to-right shunt (such as VSD, PDA) before the equalization of right and left pressures, i.e., before the Eisenmenger stage, and without a right-sided obstruction that reverses the shunt (in tetralogy or PS, the VSD, by itself, may be silent).

A murmur at birth usually implies PS or AS. The murmur of VSD and PDA is not usually present at birth, as the right-sided pressures are still elevated at birth. VSD and PDA murmurs develop over the course of the first week.

Eisenmenger and Fontan patients are typically silent.

Note: In general, when a complex congenital patient requires a pacemaker, it is placed surgically in an epicardial fashion, not through a subclavian vein (because of the complex anatomy and because of right-to-left shunt and stroke risk).

IV. Isolated right-to-left shunting in adults (i.e., without left-to-right shunting): the 3 major forms

It is difficult to diagnose isolated right-to-left shunt by catheterization, as it requires sampling of all 4 pulmonary veins and proving a step-down between the pulmonary veins' average O2 saturation and systemic O2 saturation. Sampling all 4 pulmonary veins is not usually feasible. Sampling 1 vein, the left upper pulmonary vein, through a defect is feasible; in the right context, O2 step-down from this one vein corroborates right-to-left shunting. However, this O2 step-down between one vein and SA O2 does not establish right-to-left shunting, as the other pulmonary veins may have low O2 saturation with no step-down (the patient may have lung disease that is heterogenous, the left upper lobe being less involved in this case with its PV O2 sample being less hypoxic). As such, the diagnosis of right-to-left shunt is usually done clinically using 2 main features: (i) hypoxemia does not improve significantly with 1–3 L of O2 therapy and is in some cases intermittent and profound; (ii) in an adult, hypoxemia from right-to-left shunting at the cardiac level is related to 1 of 3 conditions that should be sought. These are the 3 clinical conditions:

1. The most common form of right-to-left shunt in adults is **primary PAH with secondary right-to-left shunting that is a compensatory pop-off mechanism at 2 levels**: (i) PFO, and (ii) physiological arteriovenous pulmonary anastomoses. Those shunts are a diversion from the plugged pulmonary flow and are helpful, as they attenuate RV failure and increase LV filling and output.

Overwhelmingly, in an adult with PAH and right-to-left shunt, the shunt is a compensatory PFO shunt, not a primary causal shunt with Eisenmenger. In fact, even if small defects are found (VSD <1 cm, ASD <2 cm), they do not account for severe PVR elevation and are rather helpful bystanders.

Hypoxemia improves with vasodilator therapy, as forward RV output improves and R–L shunt declines. Contrary to classic teaching, *hypoxemia may even improve with O2, as O2 is a pulmonary vasodilator that indirectly attenuates R–L shunt:* this is not a direct O2 effect on arterial O2 content, and high O2 flow is required (not just 1–3 L/min).

When asked to "rule out right-to-left shunt" in a hypoxemic adult with PAH, the clinical answer is: "the patient likely has a shunt, it is a compensatory good shunt, not a causal shunt."

2. Rarely, PAH is secondary to a left-to-right shunt that has fully reversed, i.e., Eisenmenger. Eisenmenger is rarely diagnosed in an adult with no prior congenital history in childhood. **Eisenmenger that develops in adults is rare** and is usually due to a large ASD or a moderate VSD or PDA, with slower hemodynamic compromise and longer course before reaching Eisenmenger stage than children's defects (such as large VSD or PDA). In fact, adults are more likely to be diagnosed at an earlier PH stage (stage 1 or 2 in Table 18.1); or, when diagnosed at stage 3 or 4, **the shunt has not fully reversed yet and there is still usually left-to-right shunting.** As such, ruling out left-to-right shunt by catheterization may inherently rule out right-to-left shunt in adults.

Also, the shunt must be caused by a large defect, easily visible on imaging, not just a positive bubble stream (not PFO or small ASD < 2 cm or VSD <1 cm).

3. Rarely, right-to-left shunt may be seen in a patient with no PAH and with relatively benign hemodynamics. This is the case of a **simple PFO** with normal RA pressure but with a **cardiac anatomy that favors IVC flow streaming into the PFO and right-to-left shunting**. Hypoxemia typically occurs with exertion or with upright position (platypnea-orthodeoxia syndrome). This develops despite mean RA pressure being lower than mean LA pressure (but not dramatically lower, LA pressure is not elevated). It is related to anatomic distortion of the interatrial septum that tilts it more horizontally or posteriorly, placing the PFO in line with the IVC flow (Figure 18.15).[25,26] This may be seen with aortic dilatation that pushes the atrial septum down and worsens with age, right pneumonectomy, or even abdominal surgery or weight changes. With upright position, the RA is emptier, which may further pull the septum down and horizontally, creating more shunting.[25]

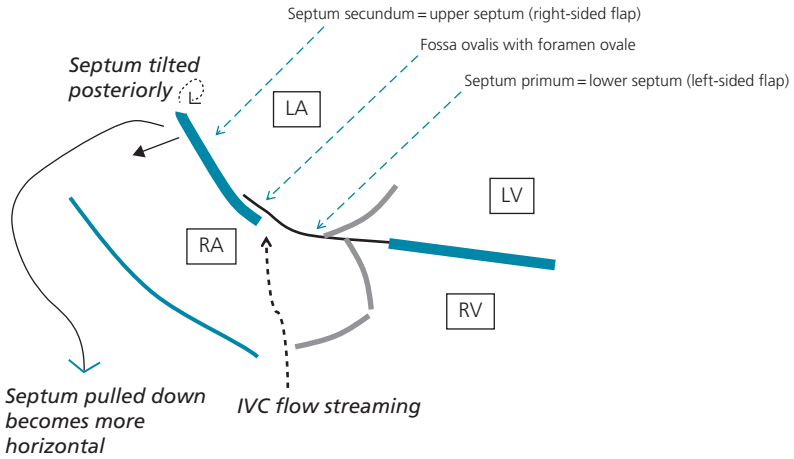

Figure 18.15 Anatomical shifts of the interatrial septum that may create IVC streaming into the PFO.

This PFO streaming process is rare and is only considered in a patient with unexplained positional or exertional hypoxemia that does not improve with O2 therapy.[24,25] It is ideally proven by catheterizing at least one pulmonary vein and showing O2 step-down between the pulmonary vein and the systemic O2 saturation.[25] Closing the PFO resolves hypoxemia in nearly all those carefully selected cases.[25]

4. A fourth form of right-to-left shunting in adults may be seen at the pulmonary level, across pulmonary AV malformations (cirrhosis, Osler-Weber-Rendu syndrome).

QUESTIONS AND ANSWERS

Question 1. A 20-year-old man presents with dyspnea on exertion and mild cyanosis on exertion. His exam reveals a split S_2 and a systolic murmur at the left sternal border. CXR shows cardiomegaly, enlarged PA, and lung plethora. Incomplete RBBB is seen on ECG. What is the most likely diagnosis?

A. ASD with large L–R shunt and some R–L shunt
B. Eisenmenger syndrome
C. Ebstein anomaly

Question 2. On echo, the patient in Question 1 has a large secundum ASD with bidirectional shunting, severe right-sided enlargement, and systolic PA pressure of 75 mmHg (systemic pressure 100 mmHg). He undergoes right heart catheterization: SVC O_2 sat 72%, PA sat 80%, PV O_2 sat 96%, arterial O_2 sat 90%. His PA pressure is 75/40 mmHg, and PVR is 6 Wood units. What is the Qp/Qs and what is the next step?

A. Qp/Qs is only 1.1. The shunt is now balanced bidirectional and should not be closed
B. Qp/Qs is 1.1. Provide vasodilator therapy and see if PVR declines and the shunt becomes left-to-right, with Qp/Qs becoming >1.5
C. Qp/Qs is 1.5. The patient qualifies for ASD closure
D. Regardless of Qp/Qs, the presence of right-sided enlargement indicates a need for ASD closure

Question 3. A 20-year-old man presents with dyspnea on exertion. He has a fixed split S_2, a systolic murmur, and RV heave. JVP is elevated. He is not hypoxic or cyanotic. Echo shows enlarged RV, secundum ASD of 1.5 cm with left-to-right shunting. Qp/Qs is calculated at 1.3. What is the next step?

A. Patient does not qualify for closure as Qp/Qs < 1.5
B. Perform catheterization to better assess Qp/Qs and decide about the need for ASD closure
C. Patient qualifies for ASD closure. Perform TEE and catheterization before closure

Question 4. A 15-year-old Fontan patient presents with cyanosis. What is the differential diagnosis?

A. Development of veno-venous collaterals (systemic veins communicate with pulmonary veins)
B. Fontan fenestration
C. Pulmonary arteriovenous malformations
D. Failing single ventricle
E. A + B + C + D
F. B + D

Question 5. A 32-year-old woman presents with progressive dyspnea on exertion and cyanosis. Arterial O_2 saturation is 86% at rest and drops to 78% with exercise. Exam shows elevated JVP and a loud, fixed split S_2. CXR shows cardiomegaly and lung oligemia. She denies a history of heart murmur during childhood. What is the most likely diagnosis?

A. ASD with Eisenmenger
B. Ebstein anomaly
C. Tetralogy of Fallot
D. VSD with Eisenmenger syndrome

Question 6. A 32-year-old woman presents with progressive dyspnea on exertion and cyanosis. Arterial O_2 saturation is 86% at rest and drops to 78% with exercise. Exam shows elevated JVP, a loud, fixed split S_2, and a systolic murmur at the left sternal border. CXR shows cardiomegaly and lung oligemia. What is the most likely diagnosis?
A. ASD with Eisenmenger
B. Ebstein anomaly
C. Tetralogy of Fallot
D. VSD with Eisenmenger syndrome

Question 7. Which of the following is *not true* of d-TGA?
A. RV and aorta are on the right, LV and PA are on the left
B. Mustard procedure is associated with a late risk of baffle leak, with R–L or L–R shunt
C. Mustard procedure is associated with a late risk of baffle obstruction, with a subsequent pulmonary hypertension (obstruction of the pulmonary venous baffle) or high SVC/IVC pressure (SVC/IVC baffle)
D. Rastelli procedure is not useful in d-TGA (only l-TGA)
E. In arterial switch, the original pulmonic valve serves as a neoaortic valve and has a risk of regurgitation
F. In arterial switch, the coronary arteries are separately moved and sutured to the base of the PA (now aorta), with a risk of late obstruction

Question 8. A 20-year-old man presents with dyspnea on exertion. He has a prior history of murmur during infancy but his parents were not compliant with follow-up. On exam, a holosystolic murmur is heard at the left lower sternal border. His LV is enlarged, S_3 is present, and he has crackles on pulmonary exam. Echo shows a moderate-size VSD with enlarged LV and normal RV. What is the next step?
A. Closure of VSD
B. Right heart catheterization to ensure VSD is hemodynamically significant. A small RV suggests VSD is not significant
C. Right heart catheterization to ensure the lack of severe pulmonary hypertension, followed by referral for closure
D. TEE

Question 9. A 25-year-old man with a prior history of tetralogy of Fallot corrected surgically presents with progressive dyspnea on exertion. His echo shows a dilated RV with increased velocity across the RVOT (2.5 m/s). What is the most likely diagnosis?
A. RVOT obstruction
B. Severe PR
C. Residual large VSD

Question 10. A 30-year-old woman presents with exertional chest pain. She has a short stature, a web neck, and increased distance between the eye corners. On exam, a 3/6 harsh mid-systolic murmur is heard at the left upper sternal border. Blood pressure checked in both arms is normal. What is the diagnosis?
A. Turner syndrome and coarctation of the aorta
B. Noonan syndrome and pulmonic stenosis
C. Down syndrome and complete AV canal defect
D. Williams syndrome and supravalvular AS

Question 11. A 20-year-old man has a history of a surgically treated coarctation of the aorta. What is the most common long-term sequela?
A. Recurrent coarctation
B. Aortic dissection or aneurysm
C. Hemorrhagic stroke (berry aneurysms) or ischemic stroke
D. CAD

Question 12. A 40-year-old man presents with new onset of dyspnea for the last month. He is not hypoxic. A continuous murmur is heard all over the precordial area. Echo shows severe pulmonary hypertension and pulmonic regurgitation but could not delineate a shunt. What is the diagnosis?
A. Patent ductus arteriosus
B. Sinus of Valsalva aneurysm ruptured in the RV (most common location) or RA
C. Sinus of Valsalva aneurysm ruptured in the RA (most common location) or RV
D. Severe primary PH with systolic flow murmur and diastolic murmur of pulmonic regurgitation

Question 13. Match each description (A–D) with the corresponding procedure (1–4):
A. Common PA is tied, SVC is connected to right PA, IVC continues to flow into the systemic ventricle
B. Common PA is tied, SVC is connected to the right PA, IVC is connected to the right PA through a tunnel
C. Disconnect PA from RV, connect aorta to RV using the PA base as a conduit, feed PA through a Blalock–Taussig shunt
D. Subclavian artery-to-PA shunt

1. Glenn bidirectional shunt
2. Blalock–Taussig shunt
3. Fontan procedure
4. Norwood procedure

Question 14. Select true or false for each statement

A. In the newborn, before performing a Blalock–Taussig shunt, use prostacyclin to keep the PDA open and allow an increase in pulmonary flow (tricuspid atresia) or systemic flow (hypoplastic left heart syndrome)

B. The three surgical steps in tricuspid atresia are: (1) subclavian artery-to-PA shunting if low PA flow, or PA banding if high PA flow through the VSD, (2) Glenn bidirectional shunt, (3) Fontan

C. In d-TGA, or congenitally corrected TGA, RV and aorta are on the left

Question 15. Associate each VSD with its location and the valves at risk:

A. Inlet VSD	**1.** No valve is affected
B. Perimembranous VSD	**2.** Between tricuspid and mitral valves
C. Outlet VSD	**3.** Between tricuspid and aortic valves
D. Trabecular VSD	**4.** Around aortic and pulmonic valves

Question 16. A 35-year-old man presents with exertional dyspnea and is found to have severe MR. He reports a history of heart surgery at the age of 4 for correction of "some shunt." What defect was it, and what do you expect on his ECG?

A. Secundum ASD, complete RBBB

B. Primum ASD, RBBB

C. Primum ASD, RBBB + left axis deviation

D. VSD

Question 17. A 35-year-old asymptomatic woman is found to have a loud holosystolic murmur on routine exam. BP 120/70 mmHg. Echo shows a perimembranous VSD with a peak velocity of 5 m/s, normal LA/LV size and RV size. PA pressure could not be estimated. What is the next step?

A. Right heart catheterization to assess PA pressure and Qp/Qs

B. VSD closure

C. Routine clinical follow-up. There is a small long-term risk of AI, TR, and endocarditis

D. Routine clinical follow-up and endocarditis prophylaxis before dental procedures

Question 18. Which of the following is true?

A. VSD causes RA and RV enlargement, more than left-sided enlargement

B. PDA causes both left-sided and right-sided enlargement

C. ASD and partially anomalous pulmonary venous return cause RA and RV enlargement without any left-sided effect

Answer 1. A. Eisenmenger syndrome is typically silent on exam, and is associated with lung oligemia rather than plethora on CXR. Cyanosis, exam, and ECG are consistent with Ebstein; however, in Ebstein, CXR usually shows lung oligemia. Thus, the most likely diagnosis is ASD with a degree of shunt reversal and cyanosis, particularly with exercise.

Answer 2. B. There is significant O_2 step-up on the right side (SVC to PA), implying a significant left-to-right shunt, and O_2 step-down on the left side (pulmonary vein to aorta), implying a significant right-to-left shunt.

Qp/Qs = systemic saturations/pulmonary saturations
= (arterial O_2 – SVC O_2)/(pulmonary venous O_2 – PA O_2) = 1.1 (see Chapter 37)

The shunt is bidirectional and almost balanced. However, the large O_2 step-up on the right side implies that a large residual left-to-right shunt is present, which may benefit from closure. In order to proceed with closure: (i) the net shunt must still be left-to-right with Qp/Qs ≥ 1.5, (ii) PVR must be < 1/3 SVR and < 5 Wood units or must be reversible with PAH therapy. In a suitable patient, pulmonary vasodilators reduce PVR and increase the left-to-right shunting, leading to a post-vasodilator Qp/Qs > 1.5.

Answer 3. C. The patient has RV failure on exam and RV enlargement on echo, along with ASD > 1 cm. This implies that ASD is causing hemodynamic compromise. A hemodynamically significant ASD qualifies for closure regardless of the calculated Qp/Qs, as long as no evidence of R–L shunt or severe pulmonary hypertension is present. Qp/Qs is likely miscalculated echocardiographically. In addition, the patient may have anomalous pulmonary venous return contributing to his shunt; this warrants TEE before closure (an anomalous pulmonary vein mandates surgical closure).

Answer 4. E.

Answer 5. A. The patient has cyanosis and no significant murmur on exam. She likely has Eisenmenger syndrome. Lung oligemia is consistent with this diagnosis. While VSD more commonly leads to Eisenmenger syndrome than ASD, VSD's Eisenmenger typically occurs early, in childhood. At the stage of Eisenmenger syndrome, VSD becomes silent on exam; however, the patient typically has a prior history of loud murmur, which is not the case here. Ebstein anomaly leads to similar findings, except for an additional TR murmur.

Answer 6. B. Patients with Ebstein anomaly may present at a late age, depending on the severity of TR, degree of atrialization of the RV, and the presence of ASD shunting.

Answer 7. D. The Rastelli procedure is used in d-TGA with VSD and subpulmonic stenosis.

Answer 8. C. VSD is hemodynamically significant and has led to LV enlargement and left HF. VSD typically leads to left HF rather than right HF; RV does not enlarge in VSD (unlike ASD). The patient does not seem to have Eisenmenger clinically, as he is not hypoxic and a murmur is still heard, implying large left-to-right shunting. Yet, in this older patient with longstanding VSD, catheterization is warranted to rule out severe and irreversible pulmonary hypertension.

Answer 9. B. All 3 diagnoses are possible causes of exercise limitation and elevated velocity across the RVOT, but PR is the most common long-term sequela following the surgical correction of the tetralogy of Fallot. RVOT obstruction leads to higher velocities and less RV dilatation than PR. Severe PR is common and may be tolerated for years; pulmonic valve replacement is recommended in case of exertional limitation, RV enlargement, or RV dysfunction, to prevent irreversible RV failure and VT.

Answer 10. B. The syndrome associations described in A, C, and D are accurate but do not correlate with the patient's exam. In most of those anomalies, facial features are present, such as increased distance between eye corners, elfin facies (Williams syndrome), and facial hypoplasia.

Answer 11. A. Recurrent or persistent coarctation occurs in 10–20% of patients. Options B–D are also possible complications.

Answer 12. B. A PDA that leads to severe pulmonary hypertension is a large PDA that manifests in infancy or childhood, usually along with shunt reversal (right-to-left shunt) and hypoxemia. Thus, PDA is unlikely to be the cause of dyspnea and pulmonary hypertension at this age. Also, the continuous murmur of PDA predominates at the left upper sternal area. Conversely, sinus of Valsalva aneurysm often remains asymptomatic for years, until it ruptures in the RV (right coronary cusp aneurysm) or RA (non-coronary cusp aneurysm), at an age between 15 and 45. The pulmonary hypertension is secondary to the increased right-sided flow. Option D is associated with a combined systolic and diastolic murmur with two peaks, rather than a continuous murmur. TEE, cardiac CT, or cardiac MRI usually allows the diagnosis of PDA or another shunt not seen on TTE.

Answer 13. A–1, B–3, C–4, D–2.

Answer 14. A true; B true; C false (l-TGA is the congenitally corrected TGA).

Answer 15. A → 2, B → 3, C → 4, D → 1 (see Figure 18.7, top images).

Answer 16. C. Primum ASD is frequently associated with a cleft mitral valve, and hence MR may occur early or later in life. Primum ASD frequently has RBBB + left axis on ECG. Regarding secundum ASD, it is most frequently associated with *incomplete* RBBB and QRS crochetage.

Answer 17. C. This is the most common form of VSD in adults: small innocuous VSD without long-term hemodynamic consequences, except for a small long-term risk of endocarditis and valvular damage from the high velocity across the VSD, especially AI. Catheterization is not needed, as there is no clinical or echo suggestion of hemodynamic effect: besides the normal left chambers, loud murmur and high velocity are consistent with a small restrictive VSD. In fact, PA pressure may even be calculated without TR jet: velocity across the VSD is 5 m/s → LV–RV systolic pressure = 4 × VSD velocity^2 → RV systolic pressure = 120 − (4 × 25) = 20 mmHg. Acyanotic congenital heart diseases, such as unrepaired VSD with left-to-right shunt, do not require endocarditis prophylaxis according to AHA. After the VSD is successfully closed, antibiotic prophylaxis is needed only during the 6-month healing period, or longer term if a residual shunt persists.

Answer 18. C. Pre-tricuspid shunts (ASD) cause RA-RV enlargement, while post-tricuspid shunts (VSD, PDA) usually cause LA–LV enlargement without right-sided enlargement. In VSD, the shunt is mostly systolic and pumped into the PA almost directly by the LV through the VSD; the RV is not overloaded in diastole, hence no RV failure occurs. An exception is aorta-to-RV shunt (e.g., from endocarditis or ruptured sinus of Valsalva aneurysm or coronary-to-RV fistula) where the RV gets overwhelmed in diastole even with a direct RV shunt, and where both right- and left-sided failures occur.

1. LOWER EXTREMITY PERIPHERAL ARTERIAL DISEASE

Most patients with lower extremity PAD are asymptomatic. Approximately 30–50% have intermittent claudication or atypical leg symptoms.[1–3] Patients may be asymptomatic because PAD is either mild or moderate-to-severe but collaterals are well developed. Patients may also be inactive because of comorbidities that prevent them from experiencing claudication.

Claudication usually remains stable or improves with conservative management. At 5 years, only 20% of patients have progressive claudication, and only 4% progress to critical limb ischemia (CLI).[1,4,5] **This explains why, in the absence of CLI, revascularization is only justified for very severe claudication.** On the other hand, diabetic patients, patients who continue to smoke, and patients with severely reduced ankle–brachial index (ABI) <0.5 have a particularly aggressive course, with CLI of 10–20% at 5 years.[5–7] In addition, progressive functional decline frequently occurs in these patients and may conceal disease progression.[7] Some studies suggest that patients <50 years of age may have a more aggressive course (~40% have unstable, progressive disease with multiple revascularizations and frequent progression to CLI).[8,9]

As opposed to the relatively benign course from a limb ischemia perspective, patients with PAD have a high rate of cardiovascular events and mortality that is at least equal to patients with CAD (5–7% yearly risk of cardiovascular death/MI/stroke with 3–5% yearly mortality risk).[10,11] The mortality drastically increases in subgroups of moderate PAD (ABI <0.7) and, even more so, severe PAD (ABI <0.5).[12] Patients with CLI have a 25% mortality risk at 1 year.

In comparison to isolated CAD, the mortality and event rate is doubled in patients with combined CAD and PAD. Aggressive risk-factor modification and CAD therapy is expected to improve cardiovascular events in PAD. ***Except for CLI, peripheral revascularization does not clearly reduce mortality or the long-term risk of limb loss.***

Two-thirds of patients with PAD have obstructive CAD of at least 1 vessel, with a high prevalence of 3-vessel CAD. One-fourth of patients have significant carotid disease.[13,14] This partly explains the high risk of cardiovascular events in these patients. Even in the absence of obstructive CAD, PAD patients usually have diffuse, sometimes heavy and calcified coronary atherosclerosis and are at a risk of MI, albeit a lower risk than patients with obstructive CAD.[10]

I. Clinical tips

Typical claudication is described as lower extremity discomfort, fatigue, or weakness initiated with exertion and resolving within 10 minutes of rest. Claudication is consistently reproduced by almost the same walking distance and is worse uphill. It does not occur with prolonged standing per se; it does not occur at rest or at night unless there is also a severe exertional component and signs of CLI on exam. Isolated nocturnal leg cramps without exertional limitation are neuromuscular in origin.

Leg pain is considered **atypical** when it occurs on exertion but also at rest without signs of rest ischemia. Other atypical symptoms include leg pain that starts with exertion but does not make the patient stop or does not quickly resolve upon cessation of activity. In patients with PAD, those atypical symptoms frequently represent mixed arterial and non-arterial, comorbid pain (PAD combined with neuropathy, spinal stenosis, or arthritis). PAD may not be the primary driver of symptoms (Table 19.1).

Claudication involves the buttocks, hips, and thighs in aortoiliac disease, simulating hip or spinal disease; the thighs in common femoral disease; and the calves in superficial femoral or popliteal disease. Patients with aortoiliac disease sometimes report weakness with walking rather than pain. While isolated internal iliac disease does not usually cause claudication, bilateral internal iliac disease may lead to buttock/hip claudication and erectile dysfunction with a normal ABI; the internal iliac arteries provide gluteal branches that may suffer in case of bilateral disease, depending on the degree of collateralization from the external iliac and common femoral circumflex branches.

Rarely, patients with isolated severe infrapopliteal disease develop foot claudication, which often simulates plantar fasciitis or vasculitic pain (thromboangiitis obliterans). More commonly, these patients present with ischemic, painful distal ulceration.

Isolated superficial femoral artery (SFA) disease with intact common femoral, profunda, and popliteal arteries is less symptomatic than disease in other segments. The profunda femoris, which is rarely diseased, usually provides robust collaterals to the popliteal artery, bypassing the diseased SFA. A diseased profunda particularly increases the risk of progression to CLI.

On physical exam, a normal posterior tibial (PT) pulse or dorsalis pedis (DP) pulse rules out significant PAD with 96% and 92% accuracy, respectively. A normal femoral pulse without bruit rules out aortoiliac PAD with over 90% accuracy. Thus, physical exam is highly accurate in ruling out significantly obstructive PAD. Conversely, only 50% of patients with abnormal femoral pulse or distal pulses have significant PAD; the combination of multiple pulse abnormalities more accurately predicts PAD.[3,15] Femoral pulse may be reduced because of body habitus or a deep femoral course. Owing to anatomical variation, DP is absent unilaterally or bilaterally in up to 10% of the population

Table 19.1 Differential diagnosis: arterial claudication, neurologic claudication (spinal stenosis), diabetic neuropathy, venous insufficiency.

	Arterial claudication	Neurologic claudication	Diabetic neuropathy	Venous insufficiency
Pain type	Cramp, tightness, or tiredness; anywhere from buttocks to feet "Difficulty walking" Weakness	Paresthesia, sharp or shooting pain bilaterally History of back pain	Paresthesia, burning or shooting pain Starts distally bilaterally and progresses proximally	Heaviness
Walking distance	Constant Worse uphill Pain not triggered by standing still	Variable Improves with walking uphill Pain may be triggered by standing still	Pain unrelated to exertion Occurs at night, at rest	Variable Pain worse at the end of the day rather than after a particular walk
Disturbance with standing	No	Yes	Not necessarily	Yes
Relief	Walking cessation	Sitting, leaning forward	Spontaneous	Leg elevation
Exam findings	Abnormal pulses, femoral bruits In advanced cases: • Pallor that worsens with leg elevation and slowly becomes blue with feet dangling (rubor cyanosis) • Cold feet, capillary refill >3 seconds • Loss of distal hair, nail dystrophy, skin atrophy • Disuse muscle atrophy	Abnormal sense and deep tendon reflexes	Hyperkeratosis of the skin and nails Abnormal sense and deep tendon reflexes	History of DVT Brown stasis dermatitis, varicose veins

(the anterior tibial artery may quickly taper at the ankle level, giving only a lateral tarsal artery; also, a peroneal perforating branch may be supplying the dorsum of the foot). DP palpation is improved by dorsiflexion of the foot, which prevents DP compression by tendons. PT is absent in 2% of the normal population.

II. Clinical classification of PAD – Critical limb ischemia, acute limb ischemia, atheroembolization

Grossly, there are 3 clinical forms of PAD: asymptomatic PAD, claudication, and CLI.

A. Rutherford classification

The Rutherford classification is commonly used and incorporates all these clinical forms of PAD into 6 categories: 0 = asymptomatic; 1–3 = claudication; 4–6 = critical limb ischemia, with 4 = rest pain; 5 = minor tissue loss/skin loss at the digits; 6 = major tissue loss with gangrene.

B. Critical limb ischemia (CLI)

CLI is defined as one of the following (in order of increasing severity): ischemic rest pain, non-healing ulcer, or extensive ulceration with gangrene. ***CLI is a chronic process that progresses over weeks or months and should be distinguished from acute limb ischemia (ALI)*** (Table 19.2). Traditionally, CLI occurs in patients with ABI ≤0.4, ankle pressure <50 mmHg, or toe pressure <30 mmHg. However, multiple studies have shown that up to 30% of patients with CLI have normal ABI, 15% of them have elevated ABI, and most have ABI in the mild-to-moderate rather than severe range.[16] ABI commonly underestimates the severity of PAD in CLI patients with predominantly infrapopliteal disease. This is related to the fact that tibial arteries are partially non-compressible (creating a falsely normal or elevated tibial pressure), but also to the fact that a substantial proportion of CLI patients have predominant pedal/below-ankle disease, sometimes with a "desert" foot (narrow or occluded plantar and metatarsal arteries). Toe–brachial index (TBI) is more reliable than ABI in CLI patients and should be systematically measured in this context. The clinical features of the wound and the low TBI suggest the need for angiography in patients with normal ABI.

Ischemic rest pain is typically a nocturnal pain that forces the patient to wake up and dangle his legs. On physical exam, CLI is characterized by a cool, dry, and fissured skin, lack of hair, dystrophic thick toenails, lack of superficial veins (flat skin), calf atrophy, and dependent rubor cyanosis. Ulcers often occur distally at the toe level and at pressure and friction points (between toes), or at the lateral malleolus level (Table 19.3). An ulcer occurring at another location for another reason may not heal if ischemia is present (mixed ulcer). Dependent rubor is an important marker of rest ischemia. To test for dependent rubor, raise the leg for 30–60 seconds, observe for pallor, then let it down and see how it slowly fills with a dusky red color suggestive of CLI, rather than quickly fills with a normal pink color.

In CLI, PAD is typically extensive with either one of the following:

i. Multilevel involvement (e.g., iliac and SFA, SFA and popliteal, SFA and profunda, SFA and infrapopliteal). Isolated SFA disease does not generally cause CLI, as robust collaterals develop through the profunda and "bypass" the SFA disease into the popliteal artery; additional disease should be sought in a patient with CLI and SFA disease.
Conversely, isolated common femoral or popliteal disease may affect flow similarly to a combination of SFA and profunda disease and may cause CLI.
ii. Isolated 2- or 3-vessel infrapopliteal involvement. In general, patients with isolated infrapopliteal disease do not develop CLI or significant claudication *unless both the anterior and posterior tibial arteries are involved or the common infrapopliteal inflow, i.e., distal popliteal artery, is severely diseased*. A single non-obstructed tibial vessel generally provides enough flow to prevent ulceration or claudication and to allow ulcer healing as long as the pedal loop that connects the AT and PT (plantar arch) and provides metatarsal arteries is intact.

Table 19.2 Acute limb ischemia vs. critical limb ischemia.

Acute limb ischemia	Critical limb ischemia
Persistent rest pain	***Intermittent*** rest pain (nocturnal) or non-healing ulcer
More severe pallor (marble); darker, more mottled cyanosis	
Sudden onset, progresses over hours or days	Progresses over weeks/months
Distal pulses inaudible on Doppler exam	***Distal pulses audible on Doppler exam***
Caused by acute embolization or acute thrombosis, with multiple distal emboli	Severe progressive atherosclerosis ± some thrombus
Emergent revascularization required	Non-urgent revascularization is required

Table 19.3 Types of lower extremity ulcers.

Ischemic ulcers	Neuropathic ulcers	Venous ulcers
Painful	Painless	Achy discomfort
Location: lateral malleolus, tip of toes, friction areas (between toes)	Plantar foot, metatarsal heads	Medial malleolus
Shape: black, white/pale, or blue, does not bleed	Red with increased blood flow	Shallow ulcer with red granulating exudative base
Ischemic signs (pallor, cold, cyanosis, capillary refill >3 seconds)	Presence of calluses, bone deformities	Stasis dermatitis: reddish-brown edematous skin
Absent pulses	Neuropathic signs on examination	
ABI ≤ 0.5		

Some ulcers have mixed neuropathic and ischemic features. Any ulcer or gangrene, whether neuropathic or ischemic, can become infected (wet gangrene). Also, consider the possibility of osteomyelitis with any ulcer.

In patients with CLI, it is important to provide ***one straight line of normal, unobstructed flow all the way to the plantar arch***; this is achieved by revascularizing all involved levels, checking pressure gradients across moderate iliac disease, and revascularizing at least 1 infrapopliteal vessel in patients with 3-vessel infrapopliteal disease. This is generally performed in 1 session. The treated infrapopliteal vessel is preferably the one that supplies the ulcerated area (each artery supplies a vascular territory called angiosome). However, as a first step, one may opt to revascularize the vessel that is easiest to percutaneously treat. Most often, this allows the ulcer to heal. If the ulcer does not heal, the patient is brought back for revascularization of the appropriate angiosome, according to the *angiosome concept*. In general, after appropriate revascularization, *ulcers heal slowly, by ~1 cm² per month*; hence therapy should be provided early, before extensive ulceration occurs. A superficial dry gangrene requires debridement and local care but often heals well after revascularization (amputation is not usually required).

This concept of aggressively achieving "one line of normal flow" only applies to CLI. ***A more perfect flow is needed to heal ulcers than to prevent them from occurring.*** In the absence of CLI, severe PAD may be observed and treated conservatively, as CLI infrequently develops; yet once a small ulcer occurs, revascularization becomes urgent.

In patients with severe claudication, revascularization of the inflow disease (e.g., iliac, SFA) provides enough symptom relief; infrapopliteal disease is not usually treated.

CLI is associated with a 25% mortality risk at 1 year and a 25% amputation rate, with only 50% amputation-free survival at 1 year. Amputation is required in patients who cannot be revascularized or who present at a stage of deep necrosis. Amputation is associated with the highest mortality (40% at 2 years).

C. Acute limb ischemia (ALI) and acute compartment syndrome

ALI is rest ischemia that develops over hours, sometimes days (occasionally weeks, generally <14 days), and is usually due to: (i) acute embolization from a cardiac or aortic origin (30% of cases); (ii) acute thrombosis of an underlying atherosclerotic stenosis or popliteal aneurysm (60% of cases); (iii) thrombosis in situ from a hypercoagulable state or traumatic injury/dissection; or (iv) graft thrombosis, which mainly occurs when there is obstructive disease at the inflow or outflow of the graft (e.g., disease progression in the common femoral or profunda past an aortofemoral graft; early or late anastomotic stenosis). *Regardless of the underlying process, multiple distal emboli are characteristic of ALI*. Acute thrombosis generally manifests less severely and less abruptly than acute embolization (days or weeks), as it occurs on top of chronic disease and pre-existing collaterals.

As opposed to ALI, CLI and non-healing ulcers are due to severe progressive atherosclerosis, frequently with some amount of thrombus, and develop over weeks or months (Table 19.2). CLI generally requires revascularization soon (days or 1 week), but not emergently. In ALI, the abrupt occlusion does not allow for the development of robust collaterals, which explains how ALI can lead to limb loss within a few hours (6 hours), dictating emergent reperfusion. In addition, distal embolization is universal in ALI and further accelerates tissue loss. ***Distal pulses are usually audible on Doppler exam in CLI, but often not in ALI***.

CLI progresses at a much slower rate than ALI yet provokes tissue loss and ischemic ulcers at a relatively earlier stage. ALI has the following progression:

Stage 1. Rest pain with audible, monophasic distal pulses by Doppler.
Stage 2. Very distal sensory loss with inaudible distal pulses by Doppler ("limb threatened"). The skin is initially "marble" white, then becomes dark purple and mottled as it fills with deoxygenated, stagnant blood.
Stage 3. Sensory loss beyond toe level or moderate motor loss ("limb immediately threatened").
Stage 4. Profound paralysis and/or major tissue loss (irreversible necrosis of muscles and skin).

Stage 1 dictates urgent revascularization, while stages 2 and 3 dictate emergent revascularization. Stage 4 requires early amputation, followed by revascularization to allow healing of the wound and the remaining viable tissue, limiting the need for a more extensive amputation in the future.

In ALI, stages 1 and 2 may be treated with a local thrombolytic infusion (12–48 hours) delivered through an endovascular approach. After the extensive thrombus burden and emboli are attenuated with thrombolysis, attention is turned toward the endovascular or surgical therapy of underlying/residual stenoses. For stage 3 ALI (motor loss or extensive sensory loss), ischemia needs to be emergently improved and one cannot wait 12–24 hours for thrombolysis to be effective. Surgical revascularization, if feasible, may need to be emergently performed at stage 3; moreover, at this stage, patients have a high risk of reperfusion injury and compartment syndrome and often need prophylactic fasciotomy during surgical revascularization.

Carefully monitor for reperfusion injury whenever ALI is reperfused and whenever any severe limb ischemia, whether ALI or CLI, is reperfused at or beyond the stage of motor loss (stages 3 or 4). This entails monitoring for systemic reperfusion syndrome (renal function, potassium) *and* local reperfusion syndrome. The latter manifests as calf swelling and induration, followed by impaired neurological and muscular functions. Early on, the patient has calf pain with passive stretching of the involved compartment; later on, paresthesias occur as a result of nerve injury, and finally, muscle weakness occurs (late sign that often implies permanent muscle damage). Anterior compartment syndrome being most common, the patient initially manifests tenderness on plantar flexion, followed by impaired dorsiflexion. The distal foot perfusion, capillary refill, and pulses are initially preserved despite the severe calf pain and muscular necrosis (this distinguishes compartment syndrome from ALI).

D. Atheroembolization

Atheroembolization is embolization of atheromatous cholesterol debris rather than thrombi, and is therefore different from ALI. It typically occurs after angiography or aortic surgery that sloughs off aortic atherosclerotic debris and leads to cholesterol embolization in the small vessels of the kidneys, dermis, lower extremities, and gastrointestinal tract. Yet, ~50% of the cases are spontaneous. Atheroembolism often induces progressive renal failure that develops a week or more after the procedure and is frequently irreversible. It leads to livedo reticularis, "blue toes," and distal cyanosis or gangrene despite preserved distal pulses, as the ischemia is due to small vessel occlusion. Obstructive PAD may, however, be present

and may reduce distal pulses, yet ***the ischemic findings are generally disproportionate to PAD and ABI***. No specific therapy is provided; limb ischemia often improves spontaneously in patients without a severely obstructive underlying PAD. Revascularization may be required in patients with severe PAD to allow healing, but invasive manipulations are better avoided in patients with only mild PAD, as these manipulations may induce further embolization. The role of anticoagulation is unclear (some data suggest benefit while other data suggest harm).

III. Diagnosis of PAD

A. Ankle–brachial index (ABI)

ABI has 2 purposes: (i) diagnosis of obstructive PAD and its severity; (ii) cardiovascular prognosis (the risk of death/MI of patients with a low ABI approximates or exceeds the risk of patients with CAD) (Table 19.4). If PAD is suspected in a symptomatic patient with an abnormal pulse exam, ABI is first performed, followed by a lower extremity arterial Doppler study if revascularization is considered.

Asymptomatic patients at a high risk of PAD need to be screened with ABI only, particularly if the pulse exam is abnormal (age >65, age 50–70 with diabetes or smoking). A low ABI correlates with increased mortality and dictates more aggressive medical therapy, but not further workup and revascularization, per se.

To calculate ABI, posterior tibial (PT) and anterior tibial (AT) pressures are measured using a well-sized BP cuff and a Doppler stethoscope, then the highest of these pressures is divided by the highest arm pressure.[1] ABI testing is ~85% sensitive and 100% specific for angiographically confirmed PAD.[1] ABI has the following 3 pitfalls: (i) ABI may be normal or falsely elevated in calcified, poorly compressible vessels; these vessels are not compressible even if the pressure and flow inside them are low (elderly, longstanding diabetes, or CKD); (ii) ABI may be normal at rest if sufficient collaterals are present; (iii) ABI may also be normal at rest in symptomatic patients with moderate aortoiliac stenoses.

Thus, when ABI is normal at rest but pitfall (ii) or (iii) is suspected, exercise ABI or an arterial Doppler study should be obtained. During exercise, peripheral vasodilatation occurs; a flow-limiting stenosis prevents blood flow from increasing enough to fill the dilated distal vascular space, and thus the distal pressure paradoxically decreases. This process translates into a low exertional ABI (ABI drops ≥20%, or >0.2) and explains how DP and PT pulses that are weak but palpable before exercise may become non-palpable after exercise. In fact, post-exertional pulse exam is valuable in the assessment of the PAD patient with only mild pulse abnormality.

Note: normal or elevated ABI in patients with CLI

When arterial non-compressibility is suspected in patients with a normal ABI or elevated ABI ≥ 1.4 (pitfall [i]), arterial Doppler should be done. Also, in all CLI patients, regardless of ABI, TBI should be measured, using a special small plethysmograph, as ABI frequently underestimates disease severity in CLI and is normal or high in up to 45% of cases. Medial calcinosis does not typically involve digital arteries, and thus digital arteries remain compressible when pedal arteries are not. TBI <0.6 indicates significant PAD. Patients with significant PAD have pulseless pedal pulses despite the high measured pedal pressure (*high pressure yet pulseless*). In patients evaluated for leg symptoms, an elevated ABI is associated with significant PAD in 60–70% and CLI in up to 37% of patients.[16,17] An elevated ABI has the same negative prognostic implication as a low ABI, more so in the presence of obstructive PAD.[16] Even without obstructive PAD, an elevated ABI implies a heavy amount of calcified atherosclerosis and predicts increased cardiovascular mortality.

Note: use of the higher ankle pressure (the higher of the AT and PT pressures) vs. the lower pressure in ABI calculation

The higher pressure correlates with the pressure through the arterial inflow into the best infrapopliteal vessel, and may best correlate with symptoms. A low ABI through only one of AT or PT, with a normal ABI through the other vessel, indicates single-vessel infrapopliteal disease with no significant inflow or femoral disease; this is unlikely to cause symptoms, since only 1-vessel runoff to the foot is usually enough to prevent severe symptoms or CLI. However, one study has shown that the use of the lower ABI better correlates with the risk of cardiovascular events, and therefore both numbers should be reported and accounted for.[18]

B. Ultrasound and Doppler study

A Doppler study is over 95% sensitive and specific for the diagnosis of obstructive stenoses. It is only indicated in patients with severe symptoms who qualify for angiography and revascularization (class I indication). It allows localization of the disease and planning for a potential peripheral intervention. A stenosis is characterized by a focal increase in velocity (>250 cm/s, or >2.5:1 in comparison to the proximal segment), and by a monophasic flow distal to the stenosis (Figure 19.1).

C. Segmental pressures and pulse volume recordings

Rather than just measuring the pressure at the distal ankle (ABI), 2 BP cuffs are placed across the thigh, and 2 are placed across the calf. The BP cuff transmits a flow waveform similar to the Doppler waveform, and a pressure waveform (called PVR), similar to the arterial pressure waveform, with a dicrotic notch in normal patients (Figure 19.1). In PAD, the flow waveform becomes monophasic, and PVR damps and loses its dicrotic notch. It is not as good as duplex study for localizing disease and its extent.

D. CT angiography (CTA)

CTA is particularly helpful when aortoiliac disease is suspected with absent femoral pulses, in which case CTA delineates the disease and allows the planning of a peripheral intervention. CTA has several pitfalls: (i) it may not properly delineate infrapopliteal disease; (ii) heavy calcifications may preclude accurate assessment of the severity of disease; (iii) additional radiation and contrast are used before the eventual intervention. Both duplex ultrasound and CTA carry a class I indication for pre-procedural planning, but duplex is advantageous, except in occlusive aorto-iliac disease.

E. Peripheral angiography is only performed when revascularization is indicated.

Table 19.4 Classification of PAD severity based on ABI.

1–1.3: normal	0.7–0.9: mild PAD	>1.3: non-compressible pedal vessels[a]
0.9–0.99: borderline	0.4–0.7: moderate PAD	
	<0.4: severe PAD	

[a] A high ABI is often associated with significant PAD, particularly in patients with claudication. A high ABI is associated with the same increase in cardiovascular mortality as a low ABI.

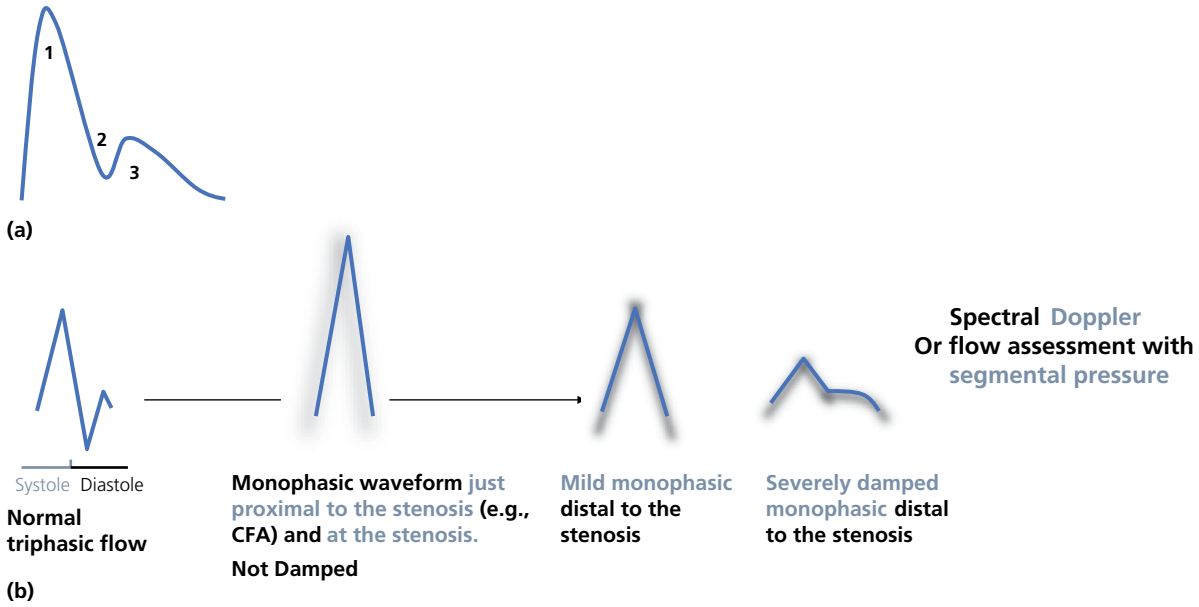

Figure 19.1 **(a)** The peripheral arterial pressure has 3 phases (1, 2, 3). The second phase corresponds to a brief reversal of flow in early diastole before the artery recoils and maintains its pressure. Phases 2 and 3 correspond to an exaggerated and "spread-out" dicrotic notch. The pressure waveform may be gauged by plethysmography, the so-called *PVR*. **(b)** The triphasic pressure waveform translates into a triphasic Doppler velocity waveform (sometimes biphasic, with a systolic spike and a diastolic reversal). *Distal to an arterial stenosis, the peripheral pressure loses its dicrotic notch and the Doppler loses the early diastolic flow reversal and becomes monophasic*. In this case, the arterial volume is reduced past the stenosis and does not allow a backflow in diastole, but rather requires a persistent forward flow throughout diastole. Beside stenosis, this lack of flow reversal may be seen in peripheral vasodilatation.

Across a stenosis, the velocity increases and the flow becomes monophasic, turbulent, with spectral thickening of the waveform (turbulent flow). Beyond the stenosis, the flow is damped and monophasic, with a persistent flow in diastole. Flow may also be monophasic just proximal to the stenosis (e.g., monophasic common femoral velocity when the proximal SFA is occluded).

IV. Medical therapy of PAD

Medical therapy consists of:

a. Smoking cessation, which reduces the amputation risk 10-fold and the mortality risk by 50%.[19] Over 85% of patients who quit smoking have an improvement in symptoms. Bypass graft failure is twice as high in smokers as in non-smokers.
b. Walking program (30 minutes a day for at least 3 days a week), which improves the walking distance 2-fold to 4-fold within 3 months. Early benefits are seen at 4 weeks.
c. Aspirin or clopidogrel. In the absence of percutaneous revascularization or prior MI, the combination is not clearly superior to aspirin or clopidogrel monotherapy for the prevention of cardiovascular events.[20]
d. Secondary prevention measures that reduce cardiovascular and coronary events: statin and aggressive therapy of hypertension and diabetes.
e. Cilostazol is a phosphodiesterase inhibitor that increases cAMP levels and induces vasodilatation. It effectively improves walking distance by ~50% and is useful in reducing in-stent restenosis and thrombosis (antiplatelet and antiproliferative effects). It has milrinone-like cardiac effects and is thus contraindicated in HF or recent MI (<6 months).
f. In VOYAGER PAD trial, a small dose of rivaroxaban, 2.5 mg BID, started early after percutaneous or surgical revascularization (<10 days), on top of aspirin (+/– clopidogrel in 50%, for <6 months), reduced limb events and cardiovascular events by 2.6% at 3 years, mainly acute thrombotic events.[21] Indirectly, rivaroxaban may be preferred over clopidogrel after PAD revascularization, particularly as clopidogrel has very limited data in this setting.

V. Revascularization for PAD

A. Indications

Revascularization is indicated for:

- CLI (absolute indication).
- Lifestyle-limiting claudication despite a 3-month exercise program, e.g., claudication upon walking <1 block or performing activities of daily living (relative indication).

PAD has a benign course from a limb's perspective, and, outside CLI, revascularization does not clearly alter the natural history of limb ischemia. Therefore, severe PAD with ABI ≤ 0.4 but without symptoms or ulcers is not an indication for revascularization per se. These asymptomatic patients may be debilitated and often have comorbidities that prevent them from walking and experiencing claudication. They do not have an immediate limb threat but have an increased risk of limb loss with any minor skin injury. They need to be routinely examined for the early occurrence of ulcers, which would dictate revascularization. *While tissue integrity may be preserved for several years in a patient with severe PAD, once tissue loss occurs, complete revascularization and a straight line of flow are required to allow the ulcer to heal, as soon as possible*.

B. Revascularization modalities: surgical bypass vs. percutaneous therapy

Lower extremity arteries are divided into 3 segments: aortoiliac, femoropopliteal, and infrapopliteal. The more distal the disease is, the lower the long-term patency is for any revascularization modality (Figure 19.2).

Surgical patency is *slightly* superior to that achieved with percutaneous revascularization at all levels, particularly for TASC C and D lesions at the femoropopliteal level (e.g., long SFA occlusion). A synthetic graft anastomosed to the popliteal artery below the knee or to a tibial artery is the only exception, as it has a very poor long-term patency, but its short-term patency may still serve to resolve CLI in a patient with no possibility for percutaneous intervention. A poor or small distal runoff reduces the long-term success of both strategies, particularly bypass surgery.

While having a superior long-term patency, historical comparisons show that surgery is associated with a much higher postoperative mortality than percutaneous revascularization (3–5% vs. 0.5%). In addition, surgery has a much higher risk of major periprocedural complications that include cardiovascular, renal, pulmonary, and bleeding complications (8–10% vs. 1–3%).[22,23] Two modern randomized trials compared the 2 strategies. In BEST-CLI, CLI patients with femoral and/or infrapopliteal disease had significant reductions of both major amputations and repeat revascularizations with *venous bypass* vs. percutaneous therapy, with similar mortality. Amputations were similar between *synthetic graft bypass* and percutaneous therapy. In the BASIL-2 trial, patients with CLI who specifically required infrapopliteal revascularization (with or without femoropopliteal revascularization) had lower mortality (p significant) and lower risk of major amputations (p non-significant) with percutaneous therapy compared to vein bypass.[24] In summary, those 2 trials suggest that **bypass surgery with a vein is superior to percutaneous therapy in CLI patients with above-knee disease, while percutaneous therapy may be preferred in patients with no vein conduit or patients requiring infrapopliteal revascularization**. In both trials, patients with CLI had high mortality regardless of the procedure: death occurred in 35% of patients in the BEST-CLI trial, and in 49% of the BASIL-2 trial, at 2+ years of follow-up.

In summary, percutaneous revascularization has the advantage of lower periprocedural mortality and complications, is the preferred option in patients with significant cardiovascular comorbidities or lack of venous conduits, and has a lower but acceptable long-term patency, particularly for TASC A, B, ± C lesions. It is recommended as a first-line therapy for TASC A and B lesions and is an acceptable first-line alternative for TASC C lesions, while TASC D lesions are generally treated surgically if the patient is an appropriate surgical candidate (Table 19.5).[1,25] A restenosis may be retreated with angioplasty if possible. After a second restenosis, surgery is considered. A failed

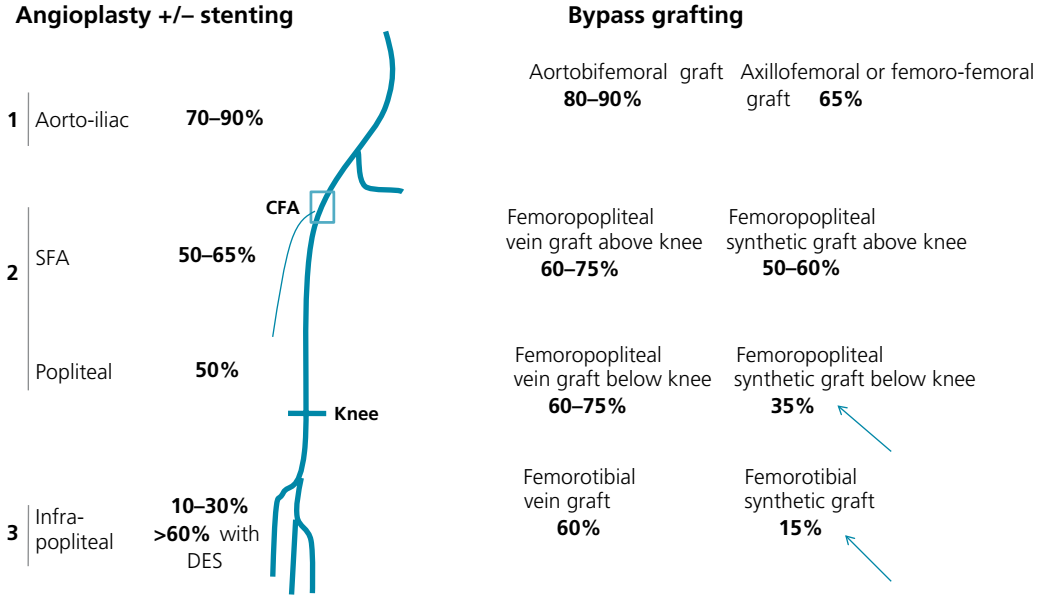

Figure 19.2 Three-year patency of percutaneous therapy and 5-year patency of bypass surgery. The long-term patency rate of percutaneous therapy for long, totally occlusive SFA disease >15 cm is ≤50%. *Arrows* indicate the cases where bypass grafting may have lower long-term patency than percutaneous therapy. Surgical patency rates obtained from the ACC guidelines document[1] and from Gray & Sullivan (1997).[19]

Table 19.5 Highlights of the TransAtlantic InterSociety Consensus (TASC) classification of angiographic extent and complexity.

Iliac disease
TASC C is a long total EIA occlusion, bilateral CIA occlusions, or extensive stenoses involving 2 segments, part of which may be occlusive (EIA and CIA, EIA and CFA, or both EIAs)
TASC D is a more *extensive total occlusion involving 2 major segments* (e.g., distal aorta and CIA, EIA and CIA, or bilateral EIAs); *or* non-occlusive but long disease involving all 3 segments: CIA, EIA, and CFA
Femoropopliteal disease
TASC C is SFA and/or popliteal disease or occlusion >15 cm, with or without calcification, but not total occlusion of both SFA and popliteal artery
TASC D is total occlusion that *involves 2 major segments* (e.g., total occlusion of the SFA that also involves the common femoral artery or popliteal artery, or total occlusion of the popliteal artery that extends into the infrapopliteal trifurcation)

More limited disease or occlusion is TASC A or B (for example, short CIA occlusion or SFA occlusion <15 cm is TASC B). TASC A and B lesions are generally treated with percutaneous therapy (as initial therapy). TASC C lesions can receive percutaneous or surgical therapy. TASC D lesions are generally treated surgically.
CFA, common femoral artery; CIA, common iliac artery; EIA, external iliac artery; SFA, superficial femoral artery.

angioplasty does not usually compromise future surgical therapy. Importantly, hybrid therapy is frequently used, especially in patients with CLI and multisegmental disease; for example, the iliac artery is stented while endarterectomy is performed for common femoral disease or femoropopliteal bypass is performed for SFA disease.

VI. Notes on the technical aspects of surgical and percutaneous therapies

A. Technical aspects of surgical therapy

1. Aortobifemoral grafting, femorofemoral and axillofemoral grafting

Aorotobifemoral bypass surgery consists of clamping the infrarenal aorta, suturing a synthetic graft to the aorta then the iliac arteries, followed by stapling of the distal aorta. This cuts the native flow through the aorta and diverts all of it through the graft into the common femoral arteries and retrogradely into the internal iliac arteries (Figure 19.3). This end-to-end anastomosis at the aortic level prevents competitive flow with the native iliac vessels and improves long-term patency. The native aorta is left patent in a few cases (end-to-side anastomosis at the aortic level), e.g., when the inferior mesenteric artery or a low accessory renal artery needs to be preserved or when no retrograde flow is expected into any internal iliac artery, as in patients with occluded external iliac arteries.

When the patient has severe complex disease on one side (e.g., right) and less complex disease on the other side (e.g., left), iliac stenting may be performed on the left and femorofemoral bypass graft used from the left femoral artery to the right femoral artery. Alternatively, an axillofemoral graft may be used for the right femoral artery. Those extra-anatomic bypass surgeries (femorofemoral, axillofemoral) are less complex than aortobifemoral surgeries and are particularly useful in high-surgical-risk patients; the long-term patency is, however, reduced.

When the common femoral artery (CFA) is not diseased, the distal anastomosis is performed at the common femoral level. However, when the disease extends into the CFA, the anastomosis is performed at the profunda level or, in a bifurcating fashion, to the profunda and SFA (if SFA is patent). SFA is a vessel subject to major motion stress and frequently occludes; thus, it is not a robust outflow for aortofemoral grafting, which should always involve the common femoral or the profunda (the graft provides robust flow to the profunda, which provides robust flow to the popliteal artery should SFA occlude).

2. Femoropopliteal or femorotibial bypass

A saphenous vein or a synthetic graft may be used. A venous graft is preferred, even more so for below-knee bypass. Even when the disease is distal, the proximal anastomosis is performed at the CFA level; endarterectomy of the CFA is performed if the CFA is diseased. Rarely, in patients with infrapopliteal disease yet intact femoropopliteal segments, a graft between the popliteal and a tibial artery may be performed.

B. Technical aspects of percutaneous revascularization

Femoral and infrapopliteal stenoses are usually treated through a *contralateral femoral access with a crossover sheath*. The same applies to external iliac disease. Conversely, isolated common iliac disease is usually treated through an ipsilateral femoral access. Even in the latter case, however, a contralateral access is required for imaging, mapping the ipsilateral access, and wire protection of the contralateral iliac artery. Thus, *contralateral femoral access is commonly the starting point of peripheral interventions*.

1. Iliac level

An excellent long-term result is achieved with iliac stenting, stenting being superior to plain balloon angioplasty at this level, both for immediate and for long-term patency.[26–28] A less successful but still acceptable long-term patency is achieved in TASC C or D lesions.[27,28] Balloon-expandable stents are generally preferred for common iliac disease because of a superior radial strength and an accurate positioning. In case of bilateral ostial iliac or aortoiliac disease, kissing stents may be positioned across both common iliac arteries. Both balloon-expandable and self-expanding flexible nitinol stents may be used for the external iliac arteries.

2. SFA and popliteal level

The SFA is subject to tremendous stress (bending, torsion, flexion, extension), which explains its frequent atherosclerotic involvement. When diseased, it frequently becomes totally occluded (up to 75% of significant SFA disease is totally occlusive). This stress at the SFA level explains the poor long-term result with percutaneous therapy of long occlusions >15 cm (TASC C lesions), where the long-term patency may not exceed 50%. As opposed to plain balloon angioplasty, the use of self-expanding nitinol stents has improved the long-term SFA patency, particularly for lesions of medium complexity and length 6–15 cm (Figure 19.4).[29,30] These stents are flexible and crush-recoverable,

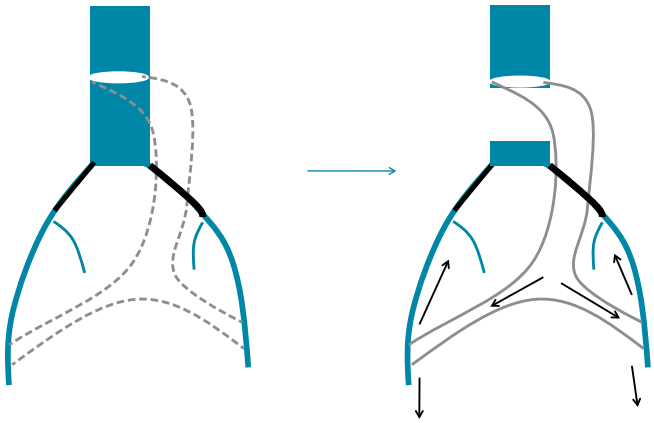

Figure 19.3 Aortobifemoral bypass grafting.

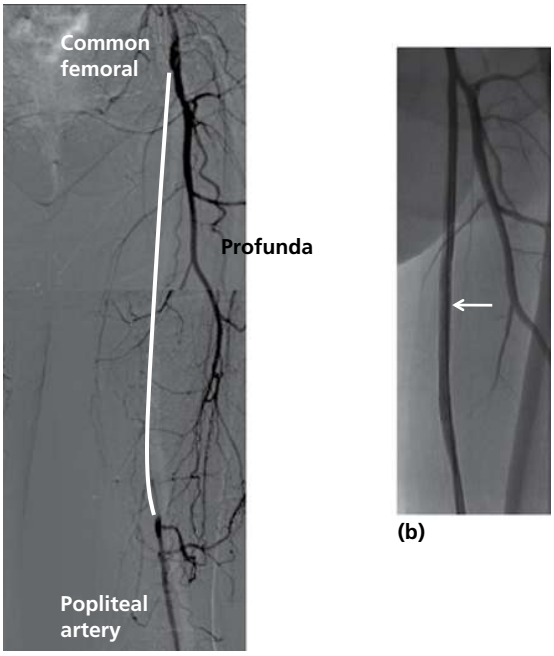

Figure 19.4 **(a)** SFA is totally occluded all the way from the ostium to the popliteal artery (the path of the occluded SFA is marked in *white*, TASC C lesion). It reconstitutes at the popliteal level through collaterals from the profunda, as is usually the case. **(b)** SFA after stenting (*arrow*).

yet still have ~5–15% risk of fracture; fracture increases the risk of restenosis and, more particularly, reocclusion (50% reocclusion risk when a circumferential fracture occurs).[31] Fracture is particularly increased with the length of the stented area (>16 cm) and with distal stenting around the popliteal level. Besides fracture, long stenting over 15 cm is associated with a high risk of restenosis (50%) and is not clearly superior to a strategy of **balloon angioplasty or atherectomy followed by drug-coated angioplasty and a more limited, focal stenting of segments achieving a suboptimal angioplasty result.**

Self-expanding drug-eluting (paclitaxel) stents are available and have a moderately higher patency than bare self-expanding stents. *Drug-coated balloons* deliver paclitaxel to the arterial wall upon inflation. Paclitaxel is hidden inside balloon folds during balloon advancement; then during balloon inflation, it is carried to the arterial wall via a hydrophylic excipient. Paclitaxel, per se, is a hydrophobic and lipophylic anti-proliferative drug with higher affinity for tissue binding than for blood; as such, it is maintained in the arterial wall for several months, leading to a higher 1-year patency than standard balloons.

SFA restenosis may be retreated percutaneously with balloon angioplasty or atherectomy, especially when restenosis is not occlusive. The long-term patency is, however, reduced to ~50%. This patency may be improved by 2 modalities: drug-coated balloons and laser atherectomy.

The popliteal artery may be stented if needed; in general, it is treated with atherectomy or balloon angioplasty as a first-line therapy. Stenting is initially avoided to elude the fracture risk and to preserve a landing zone for a future bypass. Note that the proximal popliteal artery, at the level of the adductor hiatus (about where it intersects with the femoral bone), is more subject to the stress of flexion and torsion than the mid-popliteal artery at the joint-space level. Stenting the popliteal artery exposes not only to a risk of stent fracture but also to a risk of excessive trauma at the edge of the stent (the stiff stent bends less than the adjacent artery). Yet, data suggest that stenting the popliteal artery is safe when necessary.[32]

3. Infrapopliteal level

As explained above, infrapopliteal disease does not lead to severe claudication or CLI unless the popliteal inflow or both the AT and PT are involved. Moreover, the proximal portions of all those vessels need to be involved to have calf claudication (usually distal calf). Infrapopliteal revascularization of at least 1 vessel is indicated in patients with 2-vessel involvement and:

- Ischemic ulcer (with or without multilevel disease, as part of establishment of a normal, straight line of flow to the foot)
  or
- Claudication with no upstream, iliofemoral disease. In the case of concomitant iliac or SFA disease, only revascularization of the iliac or SFA is initially performed; infrapopliteal revascularization may be secondarily performed if claudication remains severe.

The infrapopliteal vessels are treated with balloon angioplasty or atherectomy. While long-term patency is low, restenosis occurs after tissue has healed, and thus limb salvage rates exceed 80–90% after successful recanalization. *A healed tissue requires less flow to maintain its integrity than an ulcerated tissue*. Thus, restenosis does not usually result in recurrent CLI.

In addition, excellent long-term results have been achieved with coronary DESs.[33,34] The 3 arteries run deep in the muscular compartments of the leg and are well protected from trauma and fracture (anterior compartment for AT, posterior compartment for PT and peroneal). However, there are several pitfalls of stenting: (i) coronary DESs are short and several stents are often required to cover the typical, long disease; (ii) the genu of the AT is subject to compression and torsion; (iii) distally, at the ankle joint and below, the arteries are unprotected and subject to torque and extravascular compressive forces that will crush the stent.

C. Special case of the common femoral artery (CFA)

The CFA is located at the hip joint, and a stent at this location is subject to fracture. In addition, a CFA stent prevents the use of the CFA for future arterial access (e.g., coronary interventions) and may jail the profunda, which is the major supplier of collaterals to the SFA. A CFA stent may also preclude future femoropopliteal bypass. While plain angioplasty or atherectomy may circumvent these problems, a dissection or a poor angiographic result mandates stenting, and thus one cannot pre-emptively rule out the requirement for CFA stenting.

Conversely, the surgical therapy of CFA is relatively simple and consists of performing femoral endarterectomy and patch angioplasty through a small incision. The femoral plaque is removed followed by enlargement of the CFA and the ostia of the SFA and profunda with patch placement. It is a local and relatively quick surgery that may be performed under regional anesthesia with excellent long-term patency of up to 90% at 5 years.[35] If the disease extends distally into the femoral bifurcation and if the SFA is occluded, endarterectomy is extended to the profunda with a patch that sometimes covers the SFA (pitfall: this precludes future percutaneous therapy of the SFA).

Percutaneous therapy, particularly atherectomy, is an acceptable alternative when CFA stenosis has the following features:[36] short (≤2 cm), no heavy calcifications, and no extension to the femoral bifurcation. The lack of calcifications predicts the success of plain balloon angioplasty and atherectomy and a lower risk of dissection. If stenting is needed, it is best to use a short stent that does not involve the whole CFA, does not jail the profunda and leaves room for future arterial access.

VII. Management of acute limb ischemia

ALI is characterized by a large amount of thrombus and distal embolization. Whether due to native artery or graft thrombosis, stages 1 and 2 ALI are typically treated by percutaneous wiring of the thrombotic area, followed by positioning of an infusion catheter that allows local, intra-clot, slow delivery of thrombolytic therapy for 12–48 hours (e.g., r-tPA 1.5 mg/h for a few hours then 1 mg/h). Local thrombolysis achieves recanalization in 80% of patients and full thrombus dissolution in 70% of patients, and is as effective in saving the limb as immediate surgical recanalization.[37] Additional reduction of the thrombus burden may be achieved early on with a thrombectomy system (such as Angiojet rheolytic thrombectomy), but is plagued by a low efficacy in case of adherent, organized thrombus and a high rate of distal embolization. Thrombectomy may be used in selective cases of small and localized thrombus burden without evidence of distal embolization, and with the use of distal embolic protection. Angioplasty should not be performed early on, as it worsens embolization and distal perfusion.

Angiography is repeated after the thrombolytic infusion, and the underlying cause of thrombosis identified, such as severe atherosclerotic disease. The underlying disease is then revascularized percutaneously or surgically, depending on the anatomical complexity.

In case of a graft thrombosis: disease proximal to the graft, distal to the graft, or at the anastomosis is addressed after thrombolysis and treated surgically or with angioplasty/stenting.[37–39]

Patients with stage 3 ALI (motor loss or extensive sensory loss) cannot afford the long waiting period of thrombolytic therapy and often require immediate surgical thromboembolectomy with additional bypass surgery as appropriate.[1] The risk of reperfusion syndrome is increased at this stage and usually dictates adjunctive, prophylactic fasciotomy, which may further justify surgical therapy.

Patients with ALI have a high amputation risk of ~30% at 6 months, a mortality risk of ~15% at 6 months, and a high bleeding risk of ~12.5% when receiving thrombolytic therapy.[37] After acute therapy, these patients need to be assessed for a source of embolus (echo, CT of the thoracic and abdominal aorta looking for aneurysm, popliteal ultrasound looking for aneurysm).

VIII. Management of lower extremity ulcers (Table 19.6)

Table 19.6 Management of lower extremity ulcers.

1. Look for ischemia. Quickly revascularize an ischemic ulcer (days to 1–2 weeks)
2. Antibiotic therapy whenever there are infectious signs: red/warm borders, deep ulcer, pus, fever, elevated CRP/white cell count
3. Debride the necrotic tissue
4. Unload the limb by using a cane ± perform Achilles tendon lengthening in case of a neuropathic ulcer
5. Rule out osteomyelitis

   Clinically:
   - A deep ulcer that can be probed to the bone (= the bone can be palpated at the ulcer base) highly suggests osteomyelitis
   - An ulcer that is large and deep (>2 cm^2 in size or >3 mm in depth) suggests osteomyelitis

   Perform X-ray, which shows bone destruction in osteomyelitis (late finding, occurring several weeks later)

   ± *Perform MRI* (sensitive and specific, useful if the diagnosis is not established clinically)

   Osteomyelitis dictates bone debridement or limited amputation, along with longer antibiotic therapy. A non-surgical approach may also be adopted (per several series).

2. CAROTID DISEASE

Asymptomatic carotid stenosis >70% is associated with a 1.5–2% yearly risk of ipsilateral stroke, *much lower than the common perception*.[40,41] Moreover, this risk is only slightly higher for asymptomatic carotid stenosis >90% (~2.5% yearly stroke risk) and for progressive disease.[42] In fact, an analysis has shown that even the progression to complete occlusion is usually asymptomatic and is associated with a rather low stroke risk of <1% (this risk is 10% in other series, still relatively low).[43]

Symptomatic carotid stenosis >50% is associated with ~30% risk of stroke at 2 years, most of which occurs in the first 3 months (~15% at 30 days, 20–30% at 3 months) (NASCET, ECST trials).[44–47] The risk decreases with time from the event.

I. Assessment of carotid stenosis

In old trials, invasive angiography has provided the gold standard assessment of carotid stenosis. Two angiographic methods have been used to calculate stenosis severity, the NASCET and ECST methods (Figure 19.5). NASCET provides a more conservative estimate of the stenosis; it is the most widely used method and is adopted by the ACC guidelines to define treatment cutoffs.

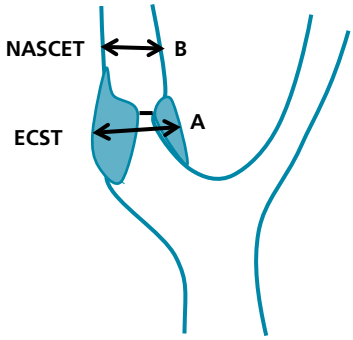

Figure 19.5 In the ECST method, the stenosis is measured in reference to the original carotid bulb diameter **(A)**. In the NASCET method, the stenosis is measured in reference to the distal internal carotid diameter **(B)**. A 50% stenosis by NASCET corresponds to ~65% stenosis by ECST.

Doppler ultrasound indirectly estimates the severity of a carotid stenosis by measuring the rise in velocity across the stenosis (severe stenosis >70% is suggested by systolic velocity across the bulb or internal carotid artery >230 cm/s or diastolic velocity >100 cm/s). It may overestimate the severity of a stenosis and therefore, when the stenosis range is equivocal (70–80% range), confirmation with another modality, CTA or MRA, is recommended. In general, after Doppler ultrasound suggests a severe stenosis, CTA or MRA is performed to confirm the finding, define the exact location of the disease, and look for intracranial disease in preparation for CEA. MRA may be performed without gadolinium contrast, although the latter improves arterial delineation. Unlike CTA, MRA is not affected by calcifications and is a better imaging modality in patients with heavy carotid calcifications. Invasive angiography is not usually needed, unless non-invasive studies yield discordant results or the plan is to perform carotid stenting. CEA may be performed based solely on the result of non-invasive studies.

II. Medical therapy of carotid stenosis

Medical therapy of carotid stenosis consists of:

- Aspirin or clopidogrel monotherapy.
- Aggressive treatment of HTN; statin therapy.
- In patients with prior stroke:
  - The combination aspirin–dipyridamole (Aggrenox) may be used, but did not prove superior to clopidogrel monotherapy.[48] The MATCH trial did not show any advantage of long-term aspirin–clopidogrel combination vs. clopidogrel monotherapy in patients with a recent stroke (<3 months), mostly lacunar stroke (>50%). The combination increased the rates of major and intracranial bleeding.[49] However, the CHANCE trial and a meta-analysis have shown that, in comparison with aspirin monotherapy, the very early initiation of aspirin–clopidogrel in the first 24 hours of a transient ischemic attack (TIA) or a minor stroke, and its continuation for 3 weeks only rather than long-term, reduces the risk of stroke within 3 months. This combination therapy, when administered early and for a brief period, proved useful because the highest risk of stroke is in the first 3 months, especially the first few days, after a TIA or a minor stroke (10–20%). Later and more prolonged therapy becomes less beneficial, and the benefit is counterbalanced by the bleeding risk.[50]
  - Warfarin is not superior to aspirin in case of stroke related to carotid disease and is associated with a higher bleeding risk.[51,52]

III. Revascularization of asymptomatic carotid stenosis

Two trials, ACAS and ACST, have shown that carotid endarterectomy (CEA) reduces the 5-year stroke risk in patients with asymptomatic carotid stenosis >60%, with a reduction of the yearly stroke risk from 2% to 0.5%, at the expense of an early periprocedural stroke hazard of 2%.[40,41] However, the benefit of CEA is not dramatic in asymptomatic patients, whose risk of stroke is relatively low despite a severe stenosis. Furthermore, medical therapy has improved since these trials (statin therapy, better HTN control).

In the modern era, 3 trials showed that CEA does not significantly reduce stroke compared to medical therapy in asymptomatic carotid stenosis >70%: ECST-2, SPACE-2 CEA, and CREST-2 CEA trials.[53,54] Regarding stenting of asymptomatic carotid stenosis >70%, the SPACE-2 stent trial did not show a benefit, but the CREST-2 stent trial demonstrated that stenting marginally yet significantly reduces the yearly stroke risk from 1.7% to 0.4%, at the cost of a periprocedural stroke risk of ~1.5%, which is unusually low (typical risk ~2.5%), and which reflects the careful selection of patients with favorable anatomy for stenting and the skills of the operators.[54] Thus, for asymptomatic carotid stenosis, the most important measure is aggressive statin, BP, and risk factor control. CEA is likely no longer favored, while carotid stenting may be selectively performed, keeping in mind its marginal benefit, in patients who are willing to accept the immediate periprocedural stroke risk.

IV. Revascularization of symptomatic carotid stenosis

Two major trials, NASCET and ECST, have shown that CEA reduces the 2- and 3-year stroke risk in patients with symptomatic carotid stenosis of 50–99%, more particularly patients with a stenosis of 70–99% (2-year stroke risk 9% vs. 26%). CEA or carotid stenting is given a class I indication for recently symptomatic carotid stenosis, meaning carotid stenosis with a prior TIA or non-disabling stroke ***in the prior 6 months***, if the periprocedural risk of death or stroke is <6%.

The recurrence risk being highest in the first 3 months (20–30% recurrence), surgery is most effective when performed within 2 weeks of the index event, and still very effective when performed 2 weeks to 3 months after the index event. The further away the clinical event is (>3 months), the less beneficial surgery is. While there has been a concern about hemorrhagic transformation when surgery is performed within 2 weeks of a stroke, several studies have shown that revascularization is relatively safe and protective from the much higher risk of

ischemic stroke recurrence during this period.[55–57] Thus, when indicated, the intervention should be done as soon as possible after the event, within 2 weeks (ACC guidelines),[58] and more specifically between 2 and 7 days (2019 AHA stroke guidelines).[59] Moreover, when thrombectomy is performed for acute stroke with intracerebral occlusion and a tandem cervical carotid stenosis is found, carotid stenting may be done either simultaneously or later (if good angioplasty result).

In symptomatic patients, the carotid stenosis must be >70% by non-invasive studies, or >50% by angiography to qualify for revascularization. Invasive angiography may be needed in symptomatic patients with carotid stenosis of 50–70% on non-invasive imaging to prove the severity of the stenosis, as non-invasive imaging frequently overestimates the true severity of a stenosis in this range.

V. Main risks of CEA and carotid stenting

Risk of perioperative stroke after CEA or carotid stenting:

- 1–2% when performed for asymptomatic carotid stenosis
- 3–4% when performed for symptomatic carotid stenosis

The risk of minor stroke is slightly higher with carotid stenting than with CEA. The perioperative stroke risk is followed by a 0.5%–1% stroke risk per year (0.5% for asymptomatic and 1% for symptomatic carotid stenosis). There is also a restenosis risk of 5–10%, mainly in the first 18 months (neointimal hyperplasia early on, recurrent atherosclerosis later on). To assess for restenosis, carotid Doppler is performed at 1 month and 6 months, then annually.

VI. CEA vs. carotid stenting

The SAPPHIRE trial has shown that in high-surgical-risk patients with symptomatic or asymptomatic carotid stenosis, carotid stenting provides a non-inferior alternative to CEA.[60]

The CREST trial enrolled average-risk surgical patients with symptomatic or asymptomatic carotid stenosis (stenosis was symptomatic in ~50% of patients). There was no difference between CEA and stenting for the combined risk of death/MI/stroke up to 4 years (~7%). CEA was associated with a higher risk of periprocedural MI, while carotid stenting was associated with a higher risk of minor strokes, mainly in patients older than 70 years (periprocedural stroke 4.1% with stenting vs. 2.3% with CEA). CEA was associated with ~5% risk of cranial nerve palsy, mostly transient (<1% persistent), and mostly consistent with hypoglossal nerve IX paralysis (dysphagia), X paralysis (hoarseness), or facial nerve paralysis.[61] When carotid stenting is performed, the use of embolic protection is mandatory. The procedure should be aborted if difficult anatomy precludes the use of embolic protection.

Decisions to perform CEA vs. carotid stenting may be individualized based on the patient's age, difficult angiographic anatomy (favors CEA), cardiopulmonary or neck comorbidities (favor stenting), and patient's preference, keeping in mind the higher risk of minor stroke with stenting and the higher risk of MI with CEA (Table 19.7).[58]

The combination of aspirin and clopidogrel is mandatory for 1 month after stenting, followed by aspirin monotherapy. A 2-week duration of dual antiplatelet therapy may be acceptable if necessary (SAPPHIRE trial).[60]

VII. Carotid disease in a patient undergoing CABG

Observational studies have consistently reported that the risk of stroke associated with CABG is ~2% in patients with no significant carotid stenosis and 3% in patients with asymptomatic severe carotid stenosis.[62–64] These figures, however, increase to ≥5% in those with bilateral carotid stenoses or a history of stroke or TIA. No clear evidence supports prophylactic CEA in CABG patients with unilateral (>80%) asymptomatic carotid stenosis. Most postoperative strokes occur in patients without any carotid disease (76%) or in patients with carotid disease receiving synchronous CEA–CABG.[64] In addition, primary carotid disease alone is responsible for less than 40% of postoperative strokes, the rest being due to aortic atheroembolization, postoperative hypercoagulable state, and atrial fibrillation.[62] However, there is agreement that prophylactic carotid intervention is still justified in CABG patients with a carotid stenosis >80% and a history of stroke or TIA in the last 6 months (class IIa),[53] and probably in patients with asymptomatic severe (>80%) bilateral carotid stenoses.

The timing of CABG and CEA is controversial. A systematic review has shown that death is highest for synchronous CEA–CABG, stroke is highest for staged CABG first–CEA second, and MI is highest for staged CEA first–CABG second.[62] A registry analysis suggests that the risk of stroke is higher in patients undergoing synchronous CEA–CABG as opposed to staged CEA first–CABG second.[64] *Concomitant CEA–CABG seems to be the least favored revascularization approach*. CABG alone is reasonable for patients with asymptomatic carotid stenosis and critical left main disease, refractory acute coronary syndrome, or other indications for urgent CABG. In contrast, patients with recent (<2 weeks) TIA and carotid stenosis >80% should be considered for urgent CEA if CABG can be safely deferred for several days.

Carotid stenting followed by CABG 3 weeks later is another alternative (clopidogrel is provided for 2 weeks after carotid stenting, then is interrupted for 5–7 days before CABG). Stenting pre-CABG, as opposed to CEA pre-CABG, is associated with lower periprocedural MI and complications in those patients with advanced CAD.[65–67]

Table 19.7 High-risk features for CEA and carotid stenting.

Features increasing CEA risk (carotid stenting may be preferred [SAPPHIRE criteria])	Features increasing the risk of carotid stenting (CEA is preferred)
High surgical risk from comorbidities:	• Age >70, much more if >80
• Major cardiac or pulmonary disease	**Technical reasons:**
High surgical risk for anatomical reasons:	• Circumferential, heavy carotid calcifications
• Prior neck surgery, prior neck radiation	• Tortuosity
• Postsurgical restenosis	• Type 3 aortic arch
• ±Contralateral occlusion	• Heavy aortic arch atherosclerosis
• High lesions above C2 or low lesions below the clavicle	• Visible thrombus

VIII. Subtotal and total carotid occlusions

In patients with *recently symptomatic* (recent stroke or TIA) *carotid near occlusion,* characterized by the 'string sign' (slow, faint antegrade filling with collapsed distal ICA), the risk of recurrent ipsilateral stroke is paradoxically lower than in those with 90–95% stenosis, and even 70–90% stenosis, dropping to ~2% per year after the acute phase (ECST trial). Reflecting this lower risk, CEA demonstrated no benefit in the ECST trial and only marginal benefit in the NASCET trial.[47,68] Similarly, the yearly stroke risk is low at ~2% in patients with symptomatic *total carotid occlusion*.[69] The reduced antegrade flow in subtotal and total occlusions lessens arterial emboli. However, recurrent ipsilateral stroke may still occur and is related to reduced perfusion, depending on the robustness of collaterals.[69] *Note that the stroke risk is very low with asymptomatic carotid occlusion*.

Medical therapy is the standard therapy for *total carotid occlusion,* partly because the stroke recurrence is low, and partly because recanalization is technically challenging.[70]

3. RENAL ARTERY STENOSIS

I. Forms of renal artery stenosis

There are 2 major forms of renal artery stenosis (RAS):

a. Atherosclerotic RAS, which typically involves the ostia of renal arteries. It is frequently accompanied by parenchymal renal disease, often secondary to hypertension or diabetes rather than RAS, which attenuates any potential benefit from renal artery revascularization. In a subgroup of patients with RAS, renal failure is secondary to renal ischemia and may be improved with revascularization (even CKD stages 4 and 5).

According to old data, atherosclerotic RAS is progressive, with 50% of significant lesions progressing over 2–3 years, and 5–10% progressing to a total occlusion. Yet, the correlation between the stenosis severity and the degree of renal dysfunction is weak, which emphasizes the importance of intra-renal injury in these patients. Renal atrophy correlates with the stenosis but also the severity of HTN.[71] Aggressive control of blood pressure and risk factors reduces RAS progression.

b. Fibromuscular dysplasia (FMD) is characterized by intimal *or* medial constriction without any intimal thickening on IVUS. The intima is thin but is rigid and constricted, a form of negative remodeling (fibroplasia). This may lead to serial areas of constriction (string of beads) or to one focally constricted area. The process often involves the mid- to distal parts of the renal artery and is frequently bilateral (60%) but may start unilaterally. It typically occurs in women 15–50 years old (female/male ratio = 8:1) and tends to progress. Progressive renal failure and renal atrophy are, however, unusual.[71]

Because of vasoconstriction, RAS-induced hypertension usually affects both the systolic and diastolic components of blood pressure and is not usually an isolated systolic hypertension.

II. Screening and indications to revascularize renal artery stenosis

A. Screen with renal arterial Doppler and consider renal revascularization for the following 3 groups:

- Recurrent, unexplained flash pulmonary edema/acute HF
- Refractory HTN (on ≥3–4 drugs at optimal dose, including a diuretic)
- Progressive azotemia, seen with bilateral RAS or unilateral RAS of a solitary kidney

B. Once RAS is diagnosed in 1 of the 3 scenarios above, assess non-invasively and invasively for:[72,73]

1. Lack of renal parenchymal disease
2. Functional significance of a stenosis (a lesion >50–70% is not necessarily significant hemodynamically)

Patients most likely to benefit are those with no intrinsic parenchymal renal disease *and* a functionally significant stenosis, rather than just an anatomically significant stenosis (Table 19.8, Figure 19.6). This combination proves that HTN and the decline in GFR result from reduced perfusion rather than severe intrinsic nephron damage (from diabetes, hypertension, or glomerulopathy). Only after assessment of these 2 features non-invasively, then invasively if needed, is stenting appropriate. *Invasively*, a lack of cortical blush and a lack of cortical vascularity are surrogates of nephropathy, while a high translesional pressure gradient is a surrogate of functional significance.

Table 19.8 Signs of advanced renal parenchymal disease and signs of functional significance of a renal artery stenosis.

Signs suggestive of advanced parenchymal disease
• Proteinuria >1 g/24 h
• Renal atrophy (renal size <8 cm)
• Renal resistive index >0.8, which indicates a high intrarenal microvascular resistance
• On renal angiography: poor cortical blood flow, cortical vascular pruning (no cortical ramifications)
Signs suggestive of functional significance of renal artery stenosis
• Renal asymmetry >1.5 cm without atrophy (conversely, atrophy implies advanced intrinsic damage)
• Creatinine rise >20% with ACE inhibitors, along with bilateral RAS
• Invasively: Translesional systolic pressure gradient under maximal hyperemia (papaverine) >21 mmHg[a] FFR <0.9[a]

[a] Measurements should be made with a pressure wire similar to the one used for coronary assessment, with the guide catheter disengaged into the aorta to allow measurement of simultaneous aortic pressure and post-stenotic pressure. Avoid gradient measurement using pull-back of the bulky catheter across the stenosis, as this may create a false obstruction. ***Adenosine is a renal vasoconstrictor*** and is not suitable to induce renal hyperemia; an intrarenal bolus of papaverine is used.

Figure 19.6 Compare the right and left kidneys. Note the right renal atrophy, the poor cortical blood flow (*horizontal blue arrow*) and the vascular pruning without distal ramification (*oblique blue arrows*), all of which are suggestive of severe parenchymal disease. The 90% renal artery stenosis (*black arrow*) should not be stented at this stage.

III. Notes

A. Benefit of percutaneous intervention in FMD vs. atherosclerotic RAS

The success rate of percutaneous intervention is higher for FMD than for atherosclerotic RAS. Also, RAS is more likely the sole cause of hypertension in FMD than in atherosclerotic RAS. In the latter, RAS may just be one factor or an incidental finding, the majority of these patients having pre-existing HTN or renal failure. Hence, there is a lower threshold for renal angioplasty in FMD. Also, in this case, angioplasty alone without stenting is often successful and is often curative of hypertension. High-pressure angioplasty is required to allow the stiff intima or media to yield.

B. ASTRAL and CORAL trials

These 2 trials randomized patients with unilateral or bilateral renal artery stenosis, hypertension, and moderate renal disease (mean GFR 40 ml/min in ASTRAL, 58 ml/min in CORAL) to stenting vs. medical therapy. Stenting did not improve blood pressure control or renal function.[74,75] Both trials had the following salient features:

- In most patients, renal failure was disproportionate to the degree of RAS. In fact, the majority of patients had renal failure, yet RAS was mostly unilateral. This indicates intrinsic parenchymal disease rather than renal ischemia, a process not affected by renal stenting (potentially aggravated by atheroemboli and contrast).
- ~40–50% of patients had RAS <70% obstructive, which may not be functionally significant.
- Most patients in ASTRAL had normal diastolic blood pressure (whereas RAS-induced HTN typically has a diastolic component).
- HTN was not very severe (SBP ~150 mmHg on 2–3 drugs), and was properly controlled by adding 1 more drug.

These trials indicate that the widespread application of renal stenting in hypertensive patients with RAS is not effective. Conversely, in other studies, appropriate stenting of carefully selected patients has dramatically improved blood pressure control, in over 85% of treated patients, and renal function.[73,76,77]

C. Role of ACE inhibitors or ARBs

ACE-Is may be used in patients with unilateral RAS. Since renal flow of the stenotic kidney may depend on the renin–angiotensin system, ACE-Is may worsen ischemia of the involved kidney. However, ACE-Is are the most effective antihypertensive agents in RAS, reduce the damage to the uninvolved kidney, and reduce the atherosclerotic progression in the involved renal artery. Thus, they may be used in unilateral RAS.[71]

In bilateral *significant* RAS, ACE-Is almost always lead to deterioration of the renal function, with over 20% creatinine rise within 4–14 days.[78] While the creatinine rise with ACE-Is is frequently due to other processes, such as low-output HF, hypovolemia, or underlying hypertensive nephropathy with microvascular obstruction, its occurrence in patients with bilateral RAS strongly suggests that RAS is hemodynamically significant and is appropriate for stenting (if hypertension is refractory). In a way, ACE-I therapy is a diagnostic test, and renal deterioration is reversible upon interruption of ACE-I therapy. Thus, in patients with hemodynamically significant bilateral RAS, ACE-Is are contraindicated. However, in the general population of bilateral RAS, ACE-Is are not absolutely contraindicated, as RAS may not be hemodynamically significant; they may be used with close follow-up of creatinine levels. A rise in creatinine would lead to cessation of ACE-I therapy.

4. SUPERFICIAL VENOUS INSUFFICIENCY, LYMPHEDEMA, AND PHLEBOLYMPHEDEMA

A. Superficial venous insufficiency

Peripheral edema is most commonly caused by superficial venous insufficiency from incompetent saphenous vein valves. The incompetence may involve the saphenous veins or their perforator branches communicating with the deep system. Lower extremity venous drainage against gravity and against abdominal pressure requires active foot and calf muscle pumping, as well as competent

valves. Venous insufficiency is caused by 5 major factors: obesity (increased abdominal pressure impairs venous return), prolonged standing over the years causing chronic stress on the vein valves and chronic injury, immobility, older age, and CCB therapy.

Venous insufficiency causes progressively: leg heaviness, then small superficial spider veins and telangiectasias, then visible and palpable ectasias of the saphenous vein (varicose veins), then significant edema, then trophic skin changes and ulcers. Superficial venous insufficiency is diagnosed by reflux study on peripheral venous Doppler (squeeze the leg and see if the forward flow is followed by a reflux backward). Treatment consists of lifestyle measures, such as avoiding prolonged sitting or standing, and compression stockings. In advanced cases with severe edema or venous ulcers, elimination of the superficial vein with incompetent valves may be done (surgical removal or percutaneous laser ablation). Ablation of an incompetent vein will force blood through the more competent veins and the deep veins, but this may add stress to the latter veins, which may sequentially fail over time and limit the procedural treatment options. The valves of the deep veins may fail as well, particularly if there is a history of DVT.

B. Lymphedema

Venous insufficiency is the most common cause of lymphedema (phlebolymphedema).[79] As venous hypertension worsens in the later stages of venous insufficiency, skin capillaries get damaged, thereby causing a leak of proteins, blood cells, and hemoglobin. This results in hemosiderin deposition and the development of stasis dermatitis. The lymphatic system initially drains some of the excess of proteins and fluid and attenuates the edema. However, chronic high lymphatic flow eventually damages the lymphatic vessels, which results in interstitial protein accumulation and more edema. The cumulation of hard proteins and hard induration (***lipodermatosclerosis***) defines the stage of phlebolymphedema; those proteins create further inflammation and protein cumulation/induration and a vicious cycle of progressive lymphatic damage.[79] *The following progression is seen: pitting edema, then stasis dermatitis with discoloration +/– ulcers (which is still venous insufficiency), then lipodermatosclerosis (lymphedema)*. Lipodermatosclerosis is a form of fibrosis of fat and deep dermis, a hard non-pitting edema. It may progress to hyperkeratosis and papillomatous skin. If the skin does not easily tent or pinch, especially at the dorsum of the second toe, it is indicative of lymph proteins and lymph fluid in the skin (Stemmer sign of the second toe). Lymphedema may be further potentiated by the recurrent cellulitis and ulcer infections that occur in venous insufficiency, which damage lymphatic vessels. Lymphedema usually involves the calves (inverted champagne bottle) and the dorsum of the feet and toes (sausage toes), with thick, sometimes papillomatous skin and deep creases at the joints, especially the ankles and the second toe. The second toe is swollen, but it cannot be tented and has deep creases.

Obesity is a common cause of venous hypertension and a risk factor for venous insufficiency, lipodermatosclerosis, and phlebolymphedema. There is an almost linear relationship between increased abdominal girth and increased abdominal pressure. Abdominal obesity increases intra-abdominal pressure that is transmitted through the vena cava and common iliacs directly to the femoral veins, exerting pressure on both the superficial and deep venous systems.

Cancer may be associated with various causes of edema, such as edema related to immobility or to malnutrition/hypoalbuminemia, but also venous edema from vena cava compression (superior or inferior) and DVTs. It may also be associated with lymphedema from lymphatic damage caused by lymphadenopathies, surgical node resection, radiation therapy, or recurrent infections such as cellulitis.[80] Notably, recurrent infections and trauma are secondary causes of lymphedema outside cancer as well.

Distinguish venous edema and lymphedema from *lipoedema*. Lipoedema is a type of lipodystrophy in which there is an increased deposition of fat in the lower part of the body, typically from the hips down to the ankles, but sparing the feet. Calves are enlarged but non-pitting and the fat often ends abruptly at the ankle, sparing the feet and toes (negative Stemmer sign). It frequently starts in teenage years, sometimes with a family history. In obese patients, lipoedema may eventually be associated with venous edema and lymphedema.[80]

Simple compression stockings do not work for lymphedema, as they push the fluid out but keep the proteins in the interstitium, further raising its oncotic pressure. Manual lymphatic compressions and inelastic figure-of-eight bandages wrapped in multiple layers work best; they function like a rigid wall that pumps the stagnant, hard lymph out during walking.[79]

QUESTIONS AND ANSWERS

Question 1. A 55-year-old man, smoker, presents with severe right calf and foot pain that has been progressive for the last 3 weeks. The pain is present at rest, persists throughout most of the day, and is worse at night. On exam, his great toe is mottled, purple, and distal pulses cannot be heard on Doppler. Motor exam is intact, but sensing is impaired at the tip of the great toe. Which of the following is correct?

A. This is critical limb ischemia by duration. Revascularization is warranted within a few days
B. The lack of pulses on Doppler, the persistent pain, and the severe cyanosis suggest acute limb ischemia rather than critical limb ischemia. Revascularization is urgent
C. The lack of pulses on Doppler and the severe cyanosis suggest acute limb ischemia rather than critical limb ischemia. Revascularization is emergent
D. The progression suggests acute limb ischemia from an embolic phenomenon

Question 2. A 70-year-old man with no known history of CAD has right calf pain when he walks 1 block. This is not lifestyle-limiting for him. He does not have any tissue loss. ABI is 0.5 on the right and 0.8 on the left. Which statement is correct?

A. Angiography and revascularization should be considered in light of the severity of right lower extremity PAD
B. His likelihood of CLI is >20% at 5 years
C. His claudication is likely to progress over the next few years
D. Peripheral revascularization would reduce his risk of limb loss
E. His risk of cardiovascular events and mortality is >5% per year

Question 3. A 58-year-old man, active, former smoker, complains of bilateral calf pain (right > left) after walking 1 block. This is impeding his daily walks. ABI is 0.6 on the right, 0.7 on the left. He tried a daily walking routine to improve his symptoms, without success. Angiography shows a totally occluded right SFA, ~15–20 cm in length, calcified, with reconstitution at the popliteal level. What is the next step?
A. Add cilostazol, recommend daily walking program, for 3 months
B. Percutaneous revascularization is not acceptable, as this is a TASC D lesion
C. Percutaneous revascularization is acceptable, as this is a TASC C lesion. The 1-year patency is ≤ 60%
D. Percutaneous revascularization is acceptable, as this is a TASC C lesion. The 1-year patency is >60%

Question 4. A patient presents with left great toe ulcer and dorsum of the foot ulcer. He has non-compressible left tibial vessels with ABI >1.5. His left distal pulses are not palpable. Which statement is *incorrect*?
A. The elevated ABI does not rule out significant PAD but rules out critical PAD
B. The elevated ABI has at least the same negative cardiovascular implication as a low ABI, especially in symptomatic patients
C. A toe–brachial index or arterial Doppler may be used to confirm the severity of PAD
D. Abdominal aortic angiography with bilateral femoropopliteal runoff is warranted

Question 5. The patient in Question 4 is found to have a severely diseased left external iliac, a heavily calcified, totally occluded left SFA, and severely diseased but patent AT, with a patent, non-obstructed PT. AT feeds the ulcerated area. What is the next step?
A. Perform stenting of the left iliac. If the ulcer does not heal, bring back for angioplasty/stenting of the SFA
B. Perform percutaneous therapy of both the iliac and the SFA
C. Perform percutaneous therapy of the iliac, SFA, and AT
D. Perform iliac stenting and femoropopliteal bypass

Question 6. A patient has severe left lower extremity claudication (Rutherford category 3). He has severe disease of the left external iliac, a totally occluded SFA, and infrapopliteal disease across the AT. What is the next step?
A. Perform stenting of the left iliac. If severe claudication persists, bring back for angioplasty/stenting of the SFA
B. Perform percutaneous therapy of both the iliac and the SFA
C. Perform percutaneous therapy of the iliac, SFA, and AT
D. Perform iliac stenting and femoropopliteal bypass

Question 7. Which statement is *incorrect*?
A. Surgical bypass has higher patency than percutaneous therapy for all lower extremity segments (aortofemoral graft, femoropopliteal graft, femorotibial graft) except when a synthetic graft is used for below-knee femoropopliteal grafting or femorotibial grafting
B. For initial revascularization, percutaneous therapy is generally preferred to surgical bypass because of the lower perioperative morbidity, mortality, and convalescence period
C. For infrapopliteal disease, femorotibial grafting is preferred to percutaneous therapy, as it allows better ulcer healing
D. For common femoral disease, femoral endarterectomy is the preferred therapy and is a relatively low-risk vascular surgery

Question 8. A patient has lifestyle-limiting claudication while walking one block, mostly involving the thighs. Distal pulses are palpable and femoral pulses are normal. Which statement is correct?
A. The patient likely has pseudo-claudication from hip osteoarthritis or spinal stenosis
B. Arterial claudication is possible. The patient may have moderate iliac or distal aortic disease, with normal flow and pulses at rest but insufficient flow and reduced pulses with exercise
C. Perform ABI
D. Perform ABI at rest and with exercise
E. B + D
F. B + C

Question 9. A patient presents with severe right foot pain, persistent for the last 2 days. His foot is mottled blue. What is the most important immediate step?
A. Emergent angiography and revascularization
B. Doppler the distal pulses and perform sensory and motor exam of the right lower extremity
C. CTA

Question 10. A 72-year-old man, heavy smoker, presents with pain, mottling, and cyanosis of his right great toe, which has been progressive over the last week. He has purple patches on his calf. The femoral pulse is mildly reduced (1+). The PT and DP are not palpable but have a good Doppler signal. The right ABI is 0.75; on Doppler, the flow is monophasic throughout the right lower extremity. CTA shows heavily atherosclerotic aorta and iliac arteries, with 80% right iliac stenosis. The femoral, popliteal, and infrapopliteal arteries are patent. Creatinine is 1.7 mg/dl. What is the next step?
A. Heparin and urgent stenting of the right iliac
B. Conservative management

Question 11. A 71-year-old smoker with a history of CAD has a right carotid bruit. He has no history of stroke or TIA. A carotid Doppler reveals a 260 cm/s velocity across the right internal carotid. Which statement is *incorrect*?
A. The yearly risk of stroke is 2%
B. CT or MRA may be needed to confirm the severity of the stenosis before an intervention
C. CEA is recommended but has only a marginal benefit in an asymptomatic patient
D. Revascularization with CEA is favored over stenting
E. Invasive angiography is not necessary before CEA
F. Before deciding whether stenting is an acceptable alternative, the carotid anatomy needs to be defined by invasive angiography

Question 12. A 64-year-old man, smoker, diabetic, has uncontrolled HTN (BP 160/80, on optimal doses of chlorthalidone, amlodipine, and lisinopril). Creatinine is 1.6 mg/dl (GFR 45). Renal Doppler suggests severe right renal artery stenosis. The renal resistive index is 0.85. Invasive angiography shows 80% right renal artery stenosis. What is the next step?

A. Renal artery stenting is unlikely to improve BP control or renal function

B. Renal stenting is warranted for refractory HTN

Answer 1. C. The patient has acute rather than critical limb ischemia, as evidenced by the absent pulses on Doppler, the constant (rather than intermittent) rest pain, and the degree of cyanosis. In this context, the distal sensory loss implies an emergent need for revascularization. This acute limb ischemia is, in fact, subacute and suggestive of in situ thrombosis (on top of severe atherosclerosis), rather than an abrupt embolic event.

Answer 2. E. The patient has claudication, without CLI (Rutherford 1–3). The risk of symptom progression over the next 5 years is 20% and the risk of progression to CLI is 4%, particularly if he quits smoking. Revascularization, at this point, can only improve symptoms, not the risk of limb loss. Since his symptoms are not severe, revascularization is not indicated. In contrast to the benign limb outcomes, the patient has a high risk of MI, stroke, and cardiac death.

Answer 3. C. The occlusion is a TASC C occlusion, as it is >15 cm (> TASC B), but does not extend to the popliteal or common femoral artery (which would make it TASC D). Percutaneous revascularization is an acceptable strategy for TASC C occlusions, albeit at a high risk of restenosis. Surgical bypass should be considered for restenosis. A is a wrong answer as the patient has already tried the conservative strategy of daily walking.

Answer 4. A. An elevated ABI with claudication or ulcer often corresponds to significant, obstructive PAD, sometimes critical (37% of symptomatic patients with elevated ABI have CLI). Also, a "pulseless" elevated ABI often implies obstructive PAD.

Answer 5. C. In case of critical limb ischemia, 1 unobstructed straight line of flow should be achieved. All diseased segments should be treated. At the infrapopliteal level, at least 1 artery should be unobstructed, preferably the artery supplying the ulcer if its recanalization is technically feasible (angiosome concept). In this case, the AT supplies the ulcer and should be treated.

Answer 6. A. In case of claudication, the goal is symptom control. When disease involves multiple segments, the inflow disease (iliac) may be treated first. Percutaneous therapy of the SFA may be performed in the same session but is not necessary. The patient may be brought back if symptoms persist. As opposed to CLI, in claudication, infrapopliteal disease does not need to be treated unless it is the only diseased segment.

Answer 7. C. The long-term patency of femorotibial graft, even venous graft, is not much higher than contemporary tibial percutaneous angioplasty/DES. Moreover, percutaneous therapy is good enough over the short and intermediate term to allow ulcer healing. Restenosis usually occurs after the ulcer has healed; much less flow is required to prevent an ulcer than to heal an ulcer. Restenosis does not usually result in recurrent CLI. In the BASIL-2 trial (CLI), percutaneous therapy for infrapopliteal disease was associated with lower mortality than venous bypass and a trend toward fewer amputations.

Answer 8. E. Pulses may be palpable and only mildly reduced in patients with true arterial claudication that is related to moderate aortoiliac disease. The lesion allows normal flow at rest, but cannot accommodate the dramatic increase in flow required from the iliac artery with exertion. During exercise, the required increase in flow across the iliac is far larger than that across the SFA, as the iliac supplies a much larger territory. ABI and pulses may be normal or mildly reduced at rest but drastically drop with exercise.

Answer 9. B. The patient's persistent foot pain and severe cyanosis are suggestive of acute limb ischemia. He typically requires emergent revascularization. However, a thorough exam is required to classify the stage of ALI. Pulses are typically absent on Doppler exam. In the absence of motor loss, percutaneous recanalization with local, prolonged r-tPA infusion is appropriate. If motor loss is present, surgical revascularization with fasciotomy is often more appropriate. Profound paralysis or acute tissue gangrene dictates amputation. CTA is a useful test later on (looks for aortic or popliteal aneurysm, as a source of emboli).

Answer 10. B. The patient has atheroembolization from the aortoiliac segments. This is evidenced by the discrepancy between the severity of foot ischemia and the rather mild impairment of pulses (good pulse signals) and the mild ABI reduction. In fact, *the patient has foot ischemia with much less ankle ischemia, implying very distal atheroemboli*. Stenting the right iliac may lead to more atheroembolization and may aggravate the foot ischemia. Conservative management and foot care is warranted; foot ischemia improves in most of these cases.

Answer 11. D. The yearly risk of stroke with asymptomatic stenosis is low. Modern trials, such as ECST-2, SPACE-2 CEA, and CREST-2 CEA trials, question the value of CEA in asymptomatic carotid stenosis. Carotid stenting provided a 1.3% yearly reduction of stroke risk in CREST-2 trial and may be considered. In addition, before finalizing the decision to stent, the patient must have appropriate anatomical features (no heavy calcium, tortuosity, type 3 arch).

Answer 12. A. The patient has unilateral RAS yet significant CKD, implying that CKD is related to intrinsic renal disease (from diabetes, HTN) rather than renal ischemia. The high renal resistive index implies intrarenal microvascular disease, i.e., intrinsic renal disease. Renal disease is likely the mechanism of severe HTN. Renal artery stenting is unlikely to improve outcomes in this patient.

20 Aortic Diseases

I. Aortic dissection 541
II. Thoracic aortic aneurysm 546
III. Abdominal aortic aneurysm 550

I. Aortic dissection

A. Two types of aortic dissection

- Type A dissection involves the ascending aorta, with or without any other part of the aorta. Type A dissection is the most common type of aortic dissection (>65% of aortic dissections), and generally requires emergent surgical correction.
- Type B dissection involves the descending aorta and/or the aortic arch, without extension to the ascending aorta. Involvement of the aortic arch without the ascending aorta is labeled as type B dissection (ACC guidelines). Non-surgical treatment is generally recommended, with surgery reserved for vital branch compromise.

Aortic dissection, whether type A or B, can be acute (onset within the last 2 weeks) or chronic.

B. Causes

The media of the ascending aorta is rich in elastic fibers. Medial degeneration consists of a loss of elastic fibers and predisposes to ascending aortic aneurysm and dissection. Medial degeneration may be seen with repetitive injury (HTN) and aging; in fact, the combination of age and HTN is responsible for aortic dissection in most patients.

More severe medial degeneration, called cystic medial necrosis, may occur in the contexts of bicuspid aortic valve, Marfan syndrome, or coarctation of the aorta.

The aortic wall stress drastically increases with aortic size. Thus, the risk of aortic dissection and progressive aortic dilatation is drastically increased in patients whose aorta is already dilated. The yearly risk of aortic dissection or rupture is 2% if the aortic diameter is 4–5 cm, and ≥7% if the aortic diameter is >5.5–6 cm. However, since a normal-size aorta is much more common than a dilated aorta, only 40% of aortic dissections occur in patients with an aortic diameter of 5.5 cm or more, while 10–20% occur in patients with an aortic diameter of 4 cm or less.[1]

C. Mechanisms of acute and chronic aortic dissection

The typical aortic dissection consists of an intimal tear that allows blood to penetrate a diseased medial layer and cleave this media longitudinally. The blood-filled space within the media is the false lumen. Distention of the false lumen with blood may cause the intimal flap to bow into the true lumen and obstruct the lumen or the branches causing ischemia (e.g., carotid, mesenteric, or renal artery). The false lumen may also extend into the branches and cause ischemia. Most intimal tears occur in the ascending aorta, within a few centimeters of the aortic valve, or in the descending aorta just distal to the left subclavian artery.

In chronic aortic dissection, one or more *spontaneous fenestrations* occur in the intimal flap, which allows the false lumen to decompress and allows blood to flow through it. The false lumen becomes a functional lumen. Flow to vital branches supplied by the false lumen is improved, and organ ischemia improves (Figure 20.1). In fact, one of the endovascular therapies of aortic dissection consists of creating fenestrations in the intimal layer.

D. Other acute aortic syndromes: intramural hematoma and penetrating atherosclerotic ulcer

Intramural hematoma is characterized by bleeding within the media from rupture of vasa vasorum vessels without any obvious intimal tear, and thus without communication with the true lumen. The diagnosis is made by CT, which may, however, miss it if not carefully sought. Intramural hematoma is best seen on the non-contrast CT sequence: it is a hyperdense (white) crescentic thickening of the aortic wall that does not further enhance with contrast. If only contrast CT is obtained, the white density in the aortic wall may be overlooked as it pales in comparison to the whiter intaluminal contrast. Moreover, invasive angiography misses intramural hematoma, owing to the lack of communication between the true and false lumens. The management is identical to the classical type A or B aortic dissection (intramural hematoma is more often distal, i.e., type B, than A). The prognosis and complications are similar to aortic dissection, and intramural hematoma often progresses to dissection, aneurysm, or rupture.[2,3]

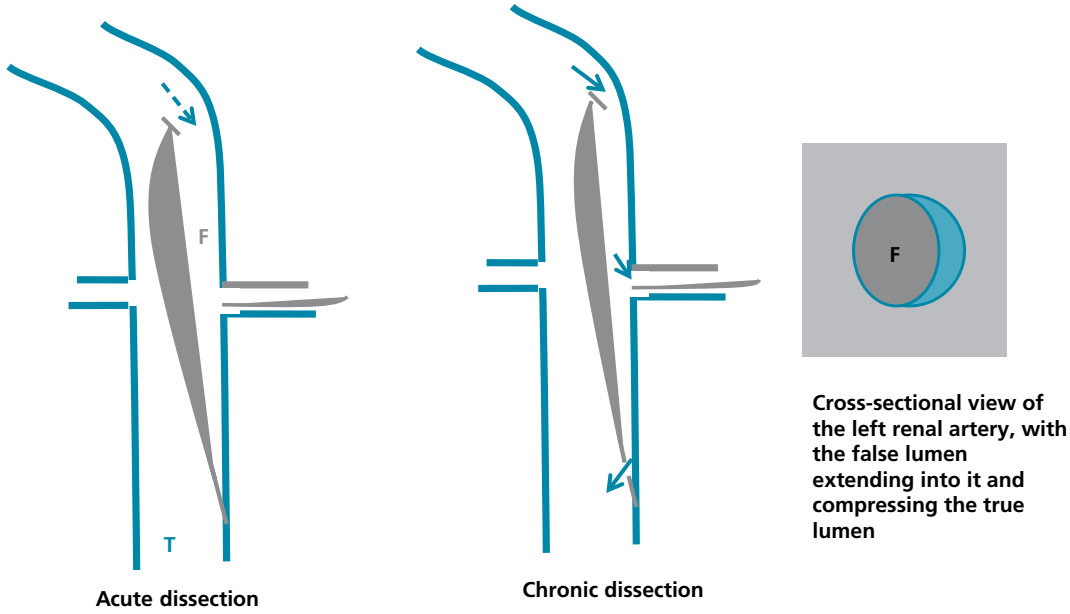

Figure 20.1 In acute aortic dissection, the false lumen (*F*) is tense with sluggish flow and becomes larger than the true lumen (*dashed arrow*). In chronic dissection, multiple tears occur in the intimal flap and allow the false lumen to decompress and blood to flow through it (*arrows*).

In this illustration, the dissection extends into the left renal artery rather than around it. Thus, the left renal artery is now practically supplied by the false lumen. There is no flow through the renal artery acutely, but once the false lumen decompresses, some flow is re-established through the false lumen of the renal artery, which becomes a functional lumen.

Penetrating atherosclerotic ulcer is an ulceration of an atherosclerotic lesion of the aorta, usually the descending aorta, that penetrates into the media and results in a localized hematoma. There is a focal aortic outpouching rather than a false lumen. However, this ulcer may progress to a typical aortic dissection or aortic perforation, and, over time, it often leads to the late formation of aortic aneurysm or contained aortic perforation, i.e., pseudoaneurysm. Atherosclerotic ulcer is often seen in elderly patients with a heavily atherosclerotic and ulcerated *descending aorta*, many of whom already have a descending or abdominal aortic aneurysm. CT can distinguish it from a typical dissection. A penetrating ulcer is generally treated conservatively with surveillance. The treatment is surgical in case of transmural extension with pseudoaneurysm or progressive aneurysmal dilatation.

E. Clinical suspicion

Three clinical features suggest the possibility of aortic dissection (IRAD registry):[4]

- Predisposing condition (aortic valve disease, known aortic aneurysm, Marfan, or family history of dissection).
- Suggestive symptoms: chest, back, or abdominal pain that is very abrupt (within seconds), severe (commonly worst-ever pain), or tearing. Contrary to common belief, the pain of aortic dissection is commonly sharp rather than tearing: tearing pain is described in 22% of cases in the IRAD registry. Nonetheless, when present, tearing pain, like worst-ever pain, fulfills this second clinical feature. Notably, in ~10% of patients, aortic dissection may even be painless and the patient presents with dissection complications, such as syncope, dyspnea, or peripheral ischemia.[5,6]

  Syncope occurs in ~10–20% of dissections and is related to tamponade, carotid obstruction, or baroreceptor activation.
- Suggestive exam findings: AI murmur (in 25–45%), pulse deficit or blood pressure differential between both arms (~20%), neurologic deficit concomitant to chest pain (5%).

The presence of 2 or 3 features makes aortic dissection highly probable. In the presence of 1 feature, the probability is intermediate and aortic imaging is warranted if the patient's symptoms are not clearly explained on chest X-ray or ECG. Up to 5% of aortic dissections have none of these features, but may be suspected by an abnormal aortic contour on chest X-ray.[4]

Aortic dissection should be suspected in any patient with chest pain and concomitant stroke, mental status changes, or peripheral ischemia.

F. Diagnosis

Chest X-ray shows widening of the aorta and mediastinal silhouette and/or widening of the aortic knob in 60–90% of patients (Figures 20.2, 20.3). A widened mediastinum is seen in ~50% of patients.[6] The "calcium sign" may be seen (outer displacement of the aortic knob calcium by more than 1 cm). TTE has ~70–80% sensitivity for type A aortic dissection,[7] and is improved by scanning the tubular aorta and by focusing on indirect signs rather than direct visualization of the intimal flap, such as: aortic dilatation with significant AI or aortic dilatation with fibrinous pericardial effusion. Aortic dilatation is most commonly in the 4–5 cm range.

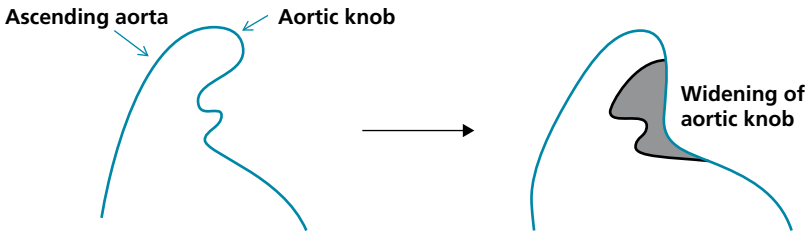

Figure 20.2 Chest X-ray in aortic dissection or dilatation.

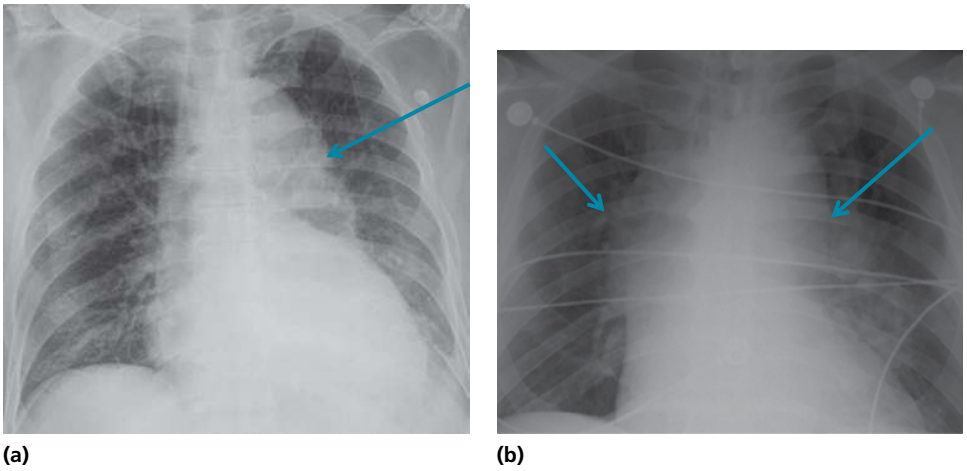

Figure 20.3 **(a)** Widening of aortic knob (*arrow*) indicative of descending aortic dissection or aneurysm. **(b)** Widening of the ascending aortic shadow (*right arrow*) and the descending aortic knob (*left arrow*). This patient has ascending and descending aortic dilatation and dissection.

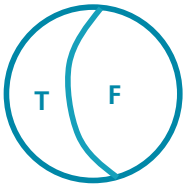

Figure 20.4 Axial cut across aortic dissection. True lumen (*T*) and false lumen (*F*) are shown.

Perform any of the following 3 gold-standard studies to establish the diagnosis and define the type of dissection:

- CT angiogram.
- MR angiogram.
- TEE. This has the additional potential of assessing acute AI and the coronary ostia. It is also advantageous if the patient is unstable, because TEE can be performed at the bedside.
- Invasive aortography used to be the gold standard. It is still useful if the ECG shows acute STEMI but the clinical picture suggests aortic dissection. In the latter case, aortography may be performed, followed by coronary angiography once dissection is ruled out.

Typically, the false lumen is larger than the true lumen because of its slower emptying (or lack of emptying). On a TEE short-axis cut: (i) the true lumen is compressed and crescentic, while the false lumen is oval; (ii) the false lumen has "smoke" and no flow, or less flow, on Doppler imaging (Figure 20.4).

G. Complications

- Aortic regurgitation (Figure 20.5).
- Aortic rupture into the pericardium, leading to tamponade.
- Stroke is seen in 6% of type A aortic dissections. It is due to carotid obstruction by an aortic flap or extension of the dissection into a carotid artery.
- STEMI is seen in 4% of type A aortic dissections. It is easier for the dissection to extend on the outer curve of the aorta into the RCA, explaining why two-thirds of MIs are inferior MIs (IRAD registry).[2] MI may be due to the false lumen compressing the coronary ostium or extending into it. In addition, ST depression or T inversion occurs in up to 50% of patients with type A aortic dissection, as a result of demand/supply mismatch or catecholamine-induced ST–T abnormalities.[8] Those ST–T abnormalities may mimic ACS and delay the diagnosis of aortic dissection.

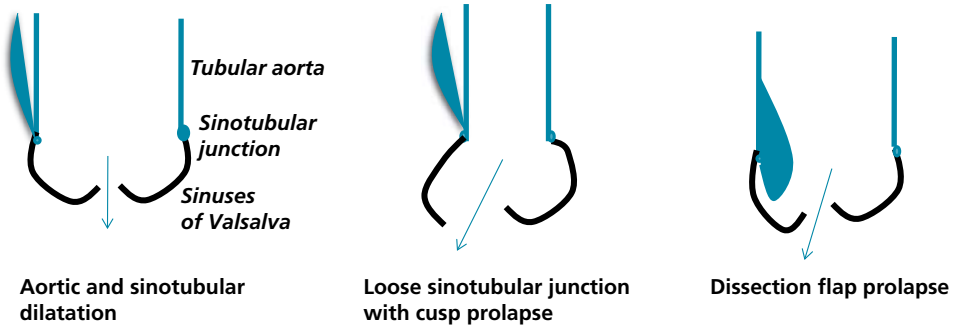

Figure 20.5 Mechanisms of aortic insufficiency (AI) with aortic dissection: (i) dissection dilates the sinotubular junction, preventing leaflet coaptation; (ii) dissection extends into the sinotubular junction, where the sinuses of Valsalva insert, resulting in leaflet prolapse and eccentric AI; (iii) dissection flap prolapses through the aortic orifice and prevents leaflet coaptation. AI may also be pre-existent, secondary to a bicuspid aortic valve. Note that the valvular leaflets (cusps) are attached to the *sinuses of Valsalva*.

- Hemorrhagic, large pleural effusion may be seen with descending aortic dissection. It results from aortic leakage into the mediastinal pleural space.
- Peripheral and mesenteric ischemia.

H. Treatment

1. Administer IV β-blockers to decrease the aortic wall stress dP/dt

- Aggressively control blood pressure with β-blockers ± vasodilators. IV labetalol or the combination of IV esmolol + IV nitroprusside may be used. β-Blockers reduce the stroke volume and thus reduce the pulse pressure (dP), the slope of aortic pressure rise in systole (dP/dt), and the frequency of aortic exposure to the pulse pressure. The aortic pressure rises gradually rather than sharply (↓ dP/dt). Diltiazem IV may be used if β-blockers are contraindicated. Morphine may be used for pain control.
- Goal: Mean BP 60–70 mm Hg, SBP <120 mm Hg, heart rate <60 bpm.[9]

2. Type A aortic dissection

Emergent surgery should be performed and consists of excising the dissected segment of the aorta and interposing a prosthetic graft. If the sinuses of Valsalva are dilated, the graft needs to extend to the aortic valve. If moderate or severe AI is present, the aortic valve is repaired (resuspend the leaflets); it may need to be replaced if severe intrinsic valvular disease is present. A composite graft consisting of an aortic graft and valvular prosthesis is used whenever the aortic valve needs replacement.

Except in a patient with PEA arrest, avoid preoperative pericardiocentesis for aortic dissection-induced tamponade. Pericardiocentesis may, in this context, reopen a clotted communication between the aorta and the pericardial space and precipitate hemodynamic collapse.

3. Type B aortic dissection

Aggressive blood pressure control is the initial therapy. Surgery is indicated for: (i) impending aortic rupture, such as aneurysmal dilatation of the false lumen; or (ii) peripheral ischemia, such as carotid, mesenteric, renal (renovascular HTN), spinal cord, or lower extremity ischemia.

Surgery may simply involve revascularization of the ischemic territories rather than extensive, laborious aortic repair.

Surgery is not typically indicated solely for persistent pain (pain being secondary to a distended false lumen).

Data from the IRAD registry suggests that extension to the aortic arch does not change the prognosis of type B dissection.

4. If surgery is not performed, the mortality risk with type A dissection is 1% per hour for the first 48 hours (~50% at 48 hours) and 85% at 2 weeks.

One study has shown that medically treated type B aortic dissection has the lowest 30-day mortality (10%), considerably lower than type B aortic dissection that requires surgical therapy (31%) or type A aortic dissection treated surgically (26%) or medically (>60%).[2]

Hypotension in a patient with aortic dissection may be:

- Pseudo-hypotension resulting from the obstruction of flow to one limb. Measuring blood pressure in all limbs may unveil this phenomenon.
- True hypotension resulting from tamponade or acute AI. A clinical shock with impaired mental status occurs. Patients with a truly severe hypotension are stabilized with fluid resuscitation and vasopressors if needed, until surgery is performed.

5. In survivors, there is a long-term risk of AI, recurrence of dissection, and secondary aneurysm formation, especially during the first 2 years. This mandates frequent CT/MRI monitoring every 3–6 months for the first 2 years then every 6–12 months afterward.

6. Chronic dissection (= dissection that occurred >2 weeks prior)
Whether it is type A or B, chronic medical therapy without surgical intervention is the initial treatment of choice at this point. Medical therapy consists of aggressive BP control (SBP <130 mmHg) with regular monitoring for aneurysm formation and size, extension of the dissection, and development of severe AI. *Aneurysmal dilatation of the aorta, particularly the false lumen, occurs frequently and dictates surgery*.

I. Notes on surgical techniques

1. Ascending aortic dissection
Cardiopulmonary bypass is initiated through a femoral vein–femoral arterial access, then deep hypothermic circulatory arrest is initiated for <30 minutes. This circulatory standstill allows suturing the graft distally, at the junction with the aortic arch; the distal ascending aorta is sewn and the suture strengthened with Teflon felt. The distal extent of the dissection into the arch or the descending aorta does not need to be replaced as long as the false lumen is sealed proximally; sealing of the false lumen in the ascending aorta prevents it from expanding and allows it to collapse. After performing the distal graft anastomosis, the graft is clamped, the patient is rewarmed, and cardiopulmonary bypass is reinitiated through a peripheral artery. The proximal dissection tear is then localized and the aorta is removed proximally to the tear, followed by proximal suturing of the graft.

If the dissection extends to the sinuses, or if the sinuses are dilated, the graft may be extended to the aortic valve, and the valve and coronaries reimplanted and sutured to the graft (David reimplantation). An abnormal valve may require the use of a composite aorta–valve graft.

2. Dissection extending into the aortic arch with malperfusion
If the dissection extends into the branches of the aortic arch with malperfusion, the involved branches may be debranched and bypassed from the ascending aortic graft (or ascending aorta if only the arch is involved).

3. Acute type B aortic dissection that requires therapy (peripheral ischemia)
Stenting the entry point may be all that is needed. Percutaneous stenting of the entry point with a stent graft prevents the expansion of the false lumen and leads to its thrombosis (class I recommendation). The false lumen shrinks, and even if it was extending into visceral arteries, this shrinking allows the expansion of the true lumen of these organs. In fact, stenting re-establishes flow to ischemic organs supplied or compressed by the false lumen and relieves ischemia in 76% of the obstructed branches (Figure 20.6).[10]

Other percutaneous procedures are alternatively performed: (i) distal fenestration of the intimal flap may be performed to decompress the false lumen and allow flow through it into the distal organs; (ii) the affected branch(es) may be stented through the true lumen to allow true luminal flow. Alternatively, bypass surgery of the ischemic territories (mesenteric, iliac) may be performed.

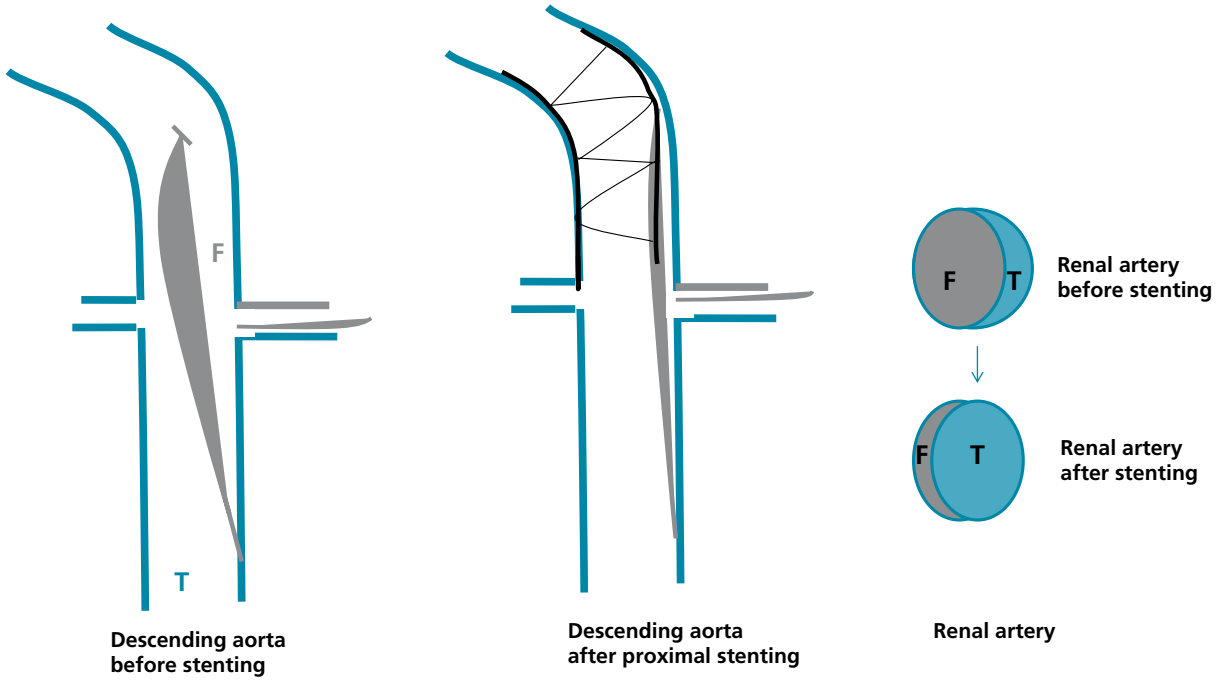

Figure 20.6 Descending aortic dissection with false lumen extending into the renal artery. A stent graft covering the proximal part of the dissection impedes flow through the false lumen. This makes the false lumen collapse and allows the true lumen to expand. If this does not re-establish flow across the renal artery or worsens flow across it (e.g., chronic dissection with functional false lumen flow), the true lumen of the renal artery may be stented, which allows it to expand and provide flow.

Chronic type B dissection may not benefit from the use of aortic stent graft as much as acute type B dissection. Because of spontaneous distal fenestration, the false lumen may have flow and may supply vital organs. The use of a thoracic stent graft is, however, necessary in case of aneurysmal dilatation of the aorta; in this case, arterial branches distal to the graft may need to be stented through the true lumen if ischemia develops (Figure 20.6).

II. Thoracic aortic aneurysm

While the ascending aorta is richer in elastic fibers than the descending aorta, the descending aorta is much more likely to become heavily atherosclerotic than the ascending aorta. This explains the differences in etiology of ascending vs. descending thoracic aneurysms. ***Ascending aortic aneurysm or dissection is caused by cystic medial degeneration, while descending aortic aneurysm is caused by atherosclerosis***. Only rarely, cystic medial necrosis extends to the descending aorta and leads to aneurysmal dilatation of the entire thoracic aorta. On a similar note, atherosclerosis infrequently leads to aneurysmal dilatation of the ascending aorta. *Arch aneurysms* are related to either medial degeneration or atherosclerosis, and are often an extension of an adjacent ascending or descending aneurysm.

Cystic medial degeneration may result from repetitive aortic injury occurring with age and HTN, or from connective tissue disorders (Marfan), or may be associated with bicuspid aortic valve or a history of aortic coarctation.

AI induces a large stroke volume and a high shear stress on the aortic wall, which worsens the aortic dilatation. However, severe aortic dilatation is not fully caused by AI. Rather, aortic dilatation is usually the cause of AI or is associated with the same connective tissue disorder as AI (e.g., bicuspid aortic valve). AS may also lead to some aortic enlargement as the high-velocity stenotic jet hits the aorta (post-stenotic dilatation).

Chronic aortic dissection may lead to progressive aortic dilatation and aneurysm formation because of the weakened media or the progressive enlargement of the false lumen.

A. Ascending thoracic aortic aneurysm (TAA)

Three levels of TAA must be distinguished (sinuses of Valsalva, sinotubular junction, and tubular aorta). Ascending TAA may involve the sinuses of Valsalva or may be limited to the tubular portion of the aorta, above the sinuses, as in many elderly hypertensive patients with TAA (Figure 20.7). Typically, aortic dilatation associated with bicuspid aortic valve or connective tissue disorders involves both the sinuses and the tubular aorta and may involve the annulus (in the latter case, it is called annuloaortic ectasia). Approximately 40–50% of patients with bicuspid aortic valve have aortic dilatation by the age of 30, most often involving the mid-tubular aorta but frequently involving the sinuses and the sinotubular junction as well.[11] In one study of all comers with bicuspid aortic valve (mean age of 43 years), the overall prevalence of aortic dilatation >37 mm was 79% at the mid-tubular aorta and 58% at the sinuses of Valsalva (aortic root). It is usually mild, <45 mm. The prevalence and severity of aortic dilatation increase with age.[11,12]

Dilatation that involves the sinuses or the sinotubular junction is the most common cause of severe AI requiring surgery.

1. Diagnosis

TTE provides good images for measurement of the aortic root at the sinuses of Valsalva, sinotubular junction, and early tubular aorta, but may totally miss the mid-ascending aorta. TEE allows more extensive aortic measurements, but cannot accurately assess the distal ascending aorta and the aortic arch; also, the cut may be oblique rather than central.

CT provides excellent diagnostic value for the whole extent of the aorta. However, axial measurements overestimate the true diameter of the aorta, especially in patients with an elongated, widely curved rather than vertical aorta. Also, axial cuts may miss an aneurysm at the level of the sinuses. Three-dimensional reconstruction overcomes these pitfalls (Figure 20.8).

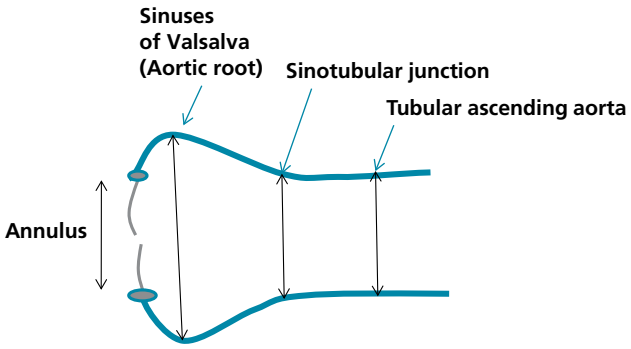

Figure 20.7 Various aortic measurements. The sinuses of Valsalva (aortic root), insert on the septum anteriorly and the mitral annulus posteriorly. The lowest attachment points (*gray dots*), form the valve leaflets and the aortic annulus, which functions as a virtual ring. The annulus is often stable and infrequently dilates, though expansion may occur in connective tissue disorders (bicuspid aortic valve, Marfan). The normal diameter at the sinuses should not exceed any of the following 2 values: 4 cm and 2.1 cm/m² (ESC 2024). The diameter of the proximal ascending aorta and of the sinotubular junction (junction of the tubular ascending aorta with the sinuses of Valsalva) should not exceed 3.8 cm and 2 cm/m².

Aortic dilatation may occur at the level of the ascending aorta and sinotubular junction (e.g., HTN), or may involve the sinuses of Valsalva. Aortic dilatation associated with bicuspid aortic valve and cystic medial necrosis (Marfan disease) often involves the sinuses as well as the aorta more distally. HTN often affects the aorta distal to the sinuses with less effect on the sinuses (e.g., in HTN, the sinotubular junction and tubular ascending aorta may be dilated with normal diameter at the sinuses).

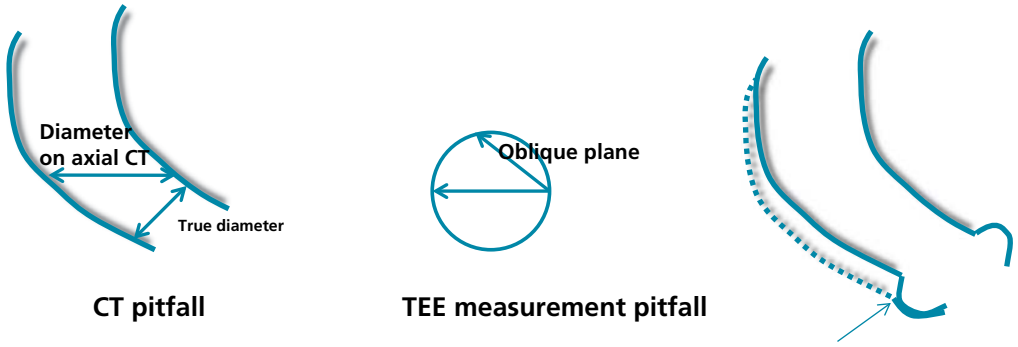

Figure 20.8 Pitfalls of aortic measurements by axial CT and TEE. On TEE or TTE, the aorta may be cut in an oblique plane and miss the major dimension, potentially underestimating the true aortic diameter. It may also be cut it in an oblique longitudinal plane, potentially overestimating its true diameter. Besides the size, the loss of indentation at the sinotubular junction (on CT or invasive angiography, *arrow*) suggests aortic dilatation.

2. Prognosis and surgical indications

Ascending TAA is associated with a yearly risk of aortic dissection and rupture of ≥7% when the aortic diameter exceeds 5.5–6 cm (the risk of dissection/rupture sharply increases to 15–34% at 6 cm); this yearly risk is 2% when the aortic diameter is <5 cm.[13,14] Since the surgical mortality approximates 5%, 5.5 cm is considered an appropriate surgical cutoff. Conversely, patients with Marfan have a 40% lifetime risk of aortic dissection or rupture, explaining the earlier need for surgical therapy in these patients. The ascending aorta of patients with bicuspid aortic valve grows more quickly and tends to dissect and rupture at a younger age than degenerative TAA; 25% of these patients require aortic surgery at 25-year follow-up, mainly for aortic dilatation or in conjunction with aortic valve surgery (the risk of aortic dissection in properly followed patients is actually low, ~1% at 25-year follow-up).[15]

While the aorta at the level of the sinuses of Valsalva is normally larger than the supracoronary tubular aorta, the same cutoffs are used for both levels to decide on the need for aortic surgery:[9]

- Aorta or sinuses ≥5.5 cm
- Aortic growth ≥0.5 cm/year in 1 year or 0.3 cm/year for 2 consecutive years (the growth is usually 0.1 cm/year)
- Aorta or sinuses ≥4.5 cm in patients undergoing aortic valve surgery
- Aorta or sinuses ≥5 cm in case of Marfan syndrome, other syndromic connective tissue disorders (Turner, aortic coarctation), heritable/familial non-syndromic thoracic aortic disease, or bicuspid aortic valve with a family history of aortic dissection. For bicuspid aortic valve without a family history of dissection or rapid growth, 5.5 cm is the aortic cutoff that indicates surgery.
- The cutoff may be altered depending on the patient's height in all categories of TAA, including genetic disease, bicuspid aortic valve, or even sporadic TAA, and surgery is indicated for a smaller aorta if aortic area/height ≥10 cm^2/m (aortic area being equal to 0.785 × $diameter^2$) (class IIa), or aortic diameter/BSA ≥3.08 cm/m^2 or aortic diameter/height ≥3.21 cm/m.
- Patients with the genetic Loeys–Dietz syndrome have a surgical indication at a cutoff of 4.4 cm.
- Turner syndrome has a surgical indication for an even lower cutoff of ≥2.5 cm/m^2 if associated with other risk factors for dissection (coarctation, HTN, bicuspid aortic valve).
- In all categories of aortic TAA, including sporadic TAA, a cutoff of 5 cm may be used if surgical risk is low and the surgeon is experienced.
- Chronic, unexplained chest or back pain. Pain results from impingement on adjacent structures and may predict a risk of aortic rupture. In acute rupture, acute severe pain, collapse, or rupture into an adjacent structure (pleura, bronchus) occurs.

Note: *Marfan* patients have: (1) overgrowth of long bones (fingers, arms, sternum [pectus]) without being necessarily tall; (2) joint laxity and hyperflexibility, including hyperextensible fingers backward (arachnodactyly), hyperflexible wrist, and the thumb sign (ability to extend the thumb beyond the ulnar aspect of the hand); (3) lens dislocation. *Loeys-Dietz* patients commonly have bifid uvula and hypertelorism and have very aggressive aneurysmal disease, with near-universal aortic aneurysms but also branch vessel aneurysms and mean age of death of 26 years.

3. Surgical treatment

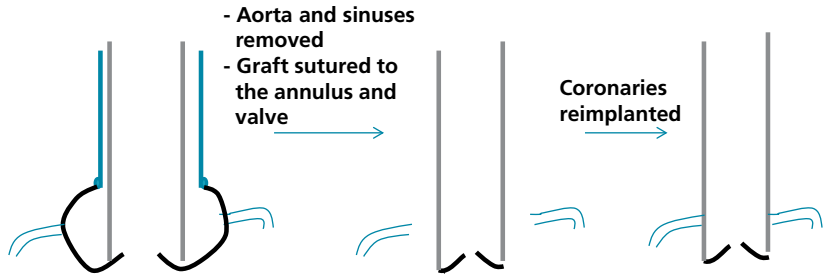
There are 3 forms of TAA repair:

I. If the sinuses are not dilated and the aortic valve is not significantly affected (no moderate or severe AS or AI), the ascending aorta is replaced and the graft sutured proximally at the sinotubular junction.

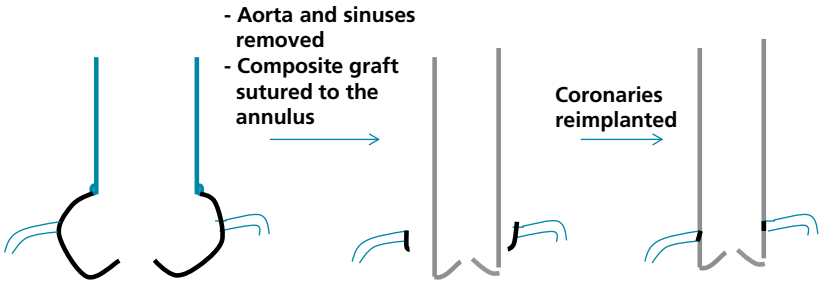
II. If the sinuses are dilated and the valve has significant regurgitation secondary to the aortic dilatation but is not significantly calcified or fibrotic, the native aorta and sinuses are removed (after freeing the coronary buttons), but the valvular leaflets are left in place and the aortic graft is extended all the way to the aortic valve. The graft is sutured to the aortic annulus and the aortic leaflets are resuspended if prolapsed. The coronary buttons are then sutured to the graft (David procedure, which may be performed even if the valve is bicuspid) (Figure 20.9).

III. If the sinuses are dilated and the valve has severe intrinsic abnormality, a composite graft (aorta and aortic valve) is used to replace both the aorta and aortic valve. The coronary buttons are sutured to the aortic graft (Bentall procedure), sometimes with the use of interposition graft (Cabrol procedure).

Hypothermic circulatory arrest may be needed for the distal anastomosis if aortic replacement is extended up to the aortic arch, without a good landing zone for aortic clamping and cardiopulmonary bypass. Hypothermic arrest is also needed if the aortic arch is additionally replaced.



Aortic graft with valve sparing/resuspension



Composite graft of the aorta and aortic valve

Figure 20.9 (i) The top image shows ascending aortic repair with valve sparing using the *David reimplantation technique*. In this technique, the graft is sutured to the aortic annulus and to the valve leaflets (valve resuspension inside the graft). Alternatively, *Yacoub remodeling technique* consists of conforming the aortic graft to 3 residual vertical tongues of the sinuses of Valsalva and suturing it to those tongues, obviating the need to touch the valve and annulus. Those tongues are the commissures, and coronary reimplantation is necessary with both techniques.
(ii) The bottom image shows aortic replacement with a composite graft (aorta + aortic valve, Bentall or Cabrol procedure).

4. Perioperative complications
Mortality (3–5%), MI (5–7%), stroke (2–5%).

5. Surveillance schedule
For dilatation of the sinuses or proximal ascending aorta, after initial diagnosis by TTE, the diameter and extension must be confirmed by CT or MRI. If the dilated segments are adequately visualized by echo with agreement between modalities, TTE can be used for surveillance; if the measurements differ ≥3 mm, CT/MRI must be used for surveillance. On average, the thoracic aneurysm grows by 0.1 cm per year.[13] The tensile wall stress increases with the aortic radius, and thus the larger the aorta, the faster it grows (Laplace law).

Frequency of surveillance (ESC 2024): (i) for aorta (sinuses or tubular aorta) 4–4.4 cm, confirm size by CT/MRI then repeat echo in 1 year; echo surveillance may be extended to Q2–3 yrs in case of stability. (ii) For aorta 4.5–4.9 cm: yearly imaging. (iii) For aorta 5–5.4 cm: imaging Q6 months.

After open repair of TAA, CT or MRI within 1 year and then every 5 years is reasonable in the absence of residual aortopathy; annual imaging is reasonable if there is residual aortopathy or abnormal findings on surveillance imaging.

It is reasonable for patients with bicuspid aortic valve to undergo, at least once, a screening with CT to assess for dilatation throughout the ascending aorta. Thereafter, follow the surveillance schedule outlined above. Echo is appropriate if the dilatation predominantly involves the sinuses, sinotubular junction, or proximal tubular aorta, with the condition that these segments are adequately visualized by echo.

B. Descending TAA
Two forms of treatment are available for descending TAA: (i) open replacement of the aorta with a graft, and (ii) percutaneous endograft placement (stent graft). Endograft placement has the potential advantage of being much less invasive with lower postoperative morbidity and mortality and is of particular value in poor surgical candidates. In fact, the postoperative mortality is 5–14% with open repair and is probably lower with endograft placement (~5%).[16,17] However, endograft is associated with a high rate of reinterventions (>15%, mainly for endoleaks) and possible attenuation of the mortality benefit over 5 years. Also, both open repair and endograft repair of the descending TAA are associated with a loss of intercostal branches and a risk of spinal cord ischemia and paraplegia. This currently occurs in 5–6% of open repairs, and is probably as likely to happen with endograft procedures. This risk is higher if the repaired aorta is long or if the patient has already had abdominal aortic aneurysm repair. *Note:* in the specific case of aneurysmal chronic type B dissection, endograft may worsen distal organ perfusion provided by the false lumen; also, the scarred chronic flap may prevent proper stent expansion, even at the edges.

In patients with extensive thoracoabdominal aneurysms, the endograft may have to extend into the distal aorta and cover branches, such as celiac, renal, or superior mesenteric artery. In those cases, in addition to the endograft, the covered branches need to be bypassed from the distal aorta or from branches distal to the endograft (e.g., mesenteric to celiac bypass, iliac to renal bypass) (Figure 20.10).[18] If an open repair is performed, these branches are reimplanted into the graft.

The cutoff for descending aortic repair is 5.5 cm with a preference for endovascular repair (ACC/ESC). For patients with extensive thoracoabdominal aortic aneurysm who have high surgical risk and no endograft option, the cutoff for open repair is 6 cm (ACC and ESC).[9]

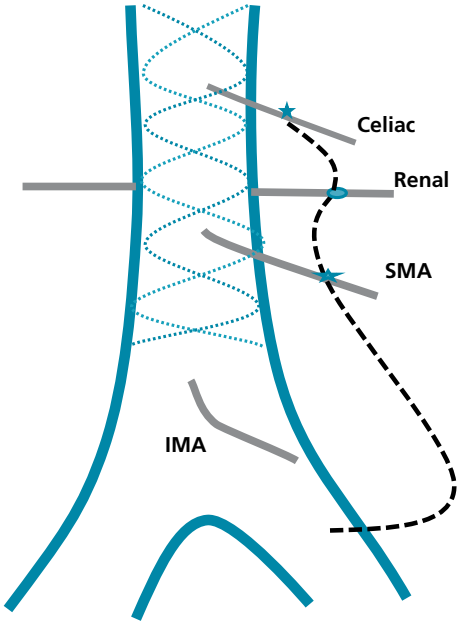


Figure 20.10 Throracoabdominal endograft covering the renal arteries, celiac trunk, and superior mesenteric artery (SMA). The latter branches are ligated and bypassed from the left iliac artery using a sequential graft. IMA, inferior mesenteric artery.

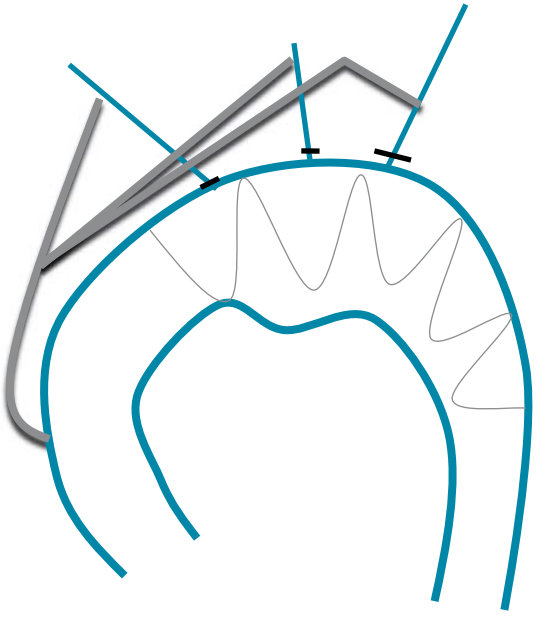

Figure 20.11 Debranching of the brachiocephalic vessels followed by antegrade placement of a stent graft into the arch and descending aorta through the ascending aorta. If the ascending aorta is dilated >4–4.5 cm, it may need to be replaced to allow a good proximal seal of the stent graft. The ascending aorta is replaced first, with hypothermic arrest for the distal anastomosis and cardiopulmonary bypass for the proximal anastomosis. If the ascending aorta does not need replacement, cardiopulmonary bypass may not be needed.

C. Aortic arch aneurysm

Treatment of aortic arch aneurysm is indicated when the aortic diameter is ≥5.5 cm. In low-risk patients, classic surgical correction is done; this involves removal of the brachiocephalic arteries en bloc at their common base, followed by replacement of the aortic arch with a graft and reimplantation of the brachiocephalic bloc (deep hypothermic arrest required). Alternatively, in patients with comorbidities, a stent graft may be positioned in an open antegrade fashion to cover the arch (and the descending aorta if needed), after debranching the brachiocephalic arteries and attaching them to the ascending aorta (hybrid procedure) (ACC guidelines) (Figure 20.11).[9] This is done without hypothermic arrest, and sometimes without a need for cardiopulmonary bypass, using a partial aortic clamp. Aortic arch procedures are associated with a high mortality that approaches 10% and a stroke risk of ~8–10%.

When aortic arch aneurysm is associated with ascending aortic aneurysm, the ascending aorta is replaced, the brachiocephalic vessels are then debranched and attached to the ascending aortic graft, and a stent graft is antegradely placed to cover the arch.

In patients with aneurysm involving the ascending aorta, arch, and descending aorta, a complex surgery called elephant trunk may be performed (replacement of the ascending aorta and arch, with part of the graft protruding into the descending aorta; this is followed by placement of an endograft in the descending aorta, attached to the protruded graft). Alternatively, an ascending aortic graft is placed, followed by debranching of the brachiocephalic vessels then endograft placement over the arch and descending aorta.

D. Traumatic transection of the aorta

Deceleration trauma leads to aortic transection, most commonly at the level of the isthmus, immediately past the left subclavian artery. Most of these individuals die immediately. The remaining patients form a pseudoaneurysm and may be treated surgically or with an endograft (class I indication). Stable patients may not need to be treated urgently.

Some undiagnosed patients go on to develop a chronic aortic pseudoaneurysm, which, as opposed to an aneurysm, is usually eccentric and saccular rather than fusiform. A pseudoaneurysm may also be postoperative or spontaneous (penetrating aortic ulcer). Since it implies a contained aortic rupture, it is appropriately treated with an endograft, regardless of size.

E. Medical therapy of TAA

β-Blocker therapy reduces stroke volume and thus reduces pulse pressure and ejectional wall stress (dP/dt or sharpness of pressure rise). However, only one small randomized trial supports its specific use in Marfan TAA.[19] Several trials and one meta-analysis, all conducted in Marfan syndrome, suggest that ARB reduces the rate of aortic dilatation in Marfan by half, including in patients taking β-blockers, with an additive effect (β-blockers have ~ similar effect to ARB in head-to-head trials).[20] Overall, in patients with TAA from any cause and no surgical indication, β-blocker therapy and aggressive blood pressure reduction with a β-blocker and an ARB are recommended per ACC, extrapolating from the results of Marfan trials (ACC guidelines recommend blood pressure reduction to the lowest point tolerated).

III. Abdominal aortic aneurysm

An arterial aneurysm is defined as a focal arterial dilatation over 1.5 times the normal baseline diameter or the expected normal diameter. Abdominal aortic aneurysm (AAA) is generally defined as an abdominal aorta >3 cm. AAA is often infrarenal, but may extend above the renal arteries and may be thoracoabdominal. Similarly to descending TAA, AAA is related to atherosclerotic weakening of the aortic wall, smoking being the primary risk factor for AAA. Genetics contribute to the occurrence of AAA, and AAA occurs in up to 30% of siblings of patients with AAA.[21]

Approximately 10% of patients with AAA have popliteal aneurysms, usually bilateral aneurysms, which should always be sought. On the other hand, ~40% of patients with popliteal aneurysms have AAA. The main risks of popliteal aneurysms are thrombosis, embolization, and limb ischemia rather than rupture.

A. Diagnosis

Ultrasound is the best screening tool, but CT generally provides more accurate sizing and better defines the extent of AAA and its relation with branch vessels (e.g., renal arteries). CT is a better modality in patients whose AAA is close to surgical cutoffs (>4 cm). MRI may alternatively be used.

The wall of AAA being usually laminated with thrombus, invasive angiography underestimates the true size of AAA.

AAA usually grows by 0.4 cm/year (faster than TAA, as the aortic pressure further amplifies distally).[16]

B. Surgical treatment of AAA, iliac aneurysm, popliteal aneurysm

In men, the yearly risk of rupture is 1.5% for AAA <5.5 cm, ~10% for AAA 5.5–7 cm, and 35% for AAA ≥7 cm.[22–24] Two studies have shown that in men with AAA <5.5 cm, surgical repair is associated with the same survival as surveillance and later repair.[22,23] However, AAA ruptures earlier in women (mean 5 cm in women vs. 6 cm in men) and 3 times more frequently; thus, earlier repair may be warranted in women.[16] In conclusion, repair is indicated for AAA ≥5.5 cm in men and 4.5–5 cm in women, AAA expanding >1 cm/year or 0.5 cm/6 months, or symptomatic AAA regardless of size. AAA is considered symptomatic when associated with atheroembolization or with prolonged episodes of hypogastric or back pain, lasting hours. A vague and non-specific abdominal pain may be attributed to AAA if no other explanation is found.

Surgical mortality is ~5% in elective cases (2% in low-risk patients); ~50% in emergent cases of aortic rupture.

Surgical treatment consists of opening the aneurysm longitudinally with clot removal, followed by transecting the aneurysmal pocket proximally and distally, then suturing a graft proximally and distally to the iliac arteries. The open aneurysmal sac is left in place and wrapped around the graft for support and protection from the bowels.

Common and internal iliac aneurysms are rarely isolated and frequently accompany AAA (up to 40% of AAAs). Rupture may occur when the aneurysm exceeds 3–3.5 cm in diameter, this being used as a threshold for repair. A popliteal aneurysm is treated when it exceeds 2 cm, preferably before limb ischemia occurs; when the latter occurs, the risk of limb loss is high.

C. Percutaneous endovascular aortic repair (EVAR)

EVAR involves stent graft placement at the level of the aneurysm, excluding the AAA from the circulation. It leads to a lower perioperative mortality than open repair. Endoleaks, however, frequently occur. An endoleak means that the aneurysm is not fully excluded from the circulation; it is identified by a persistent flow of contrast into the aneurysm (Table 20.1). Because of endoleaks, endovascular repair is mainly indicated for patients at intermediate or high operative risk with shorter life expectancy.

The EVAR-1 and DREAM trials have shown that, in comparison with open repair, EVAR is associated with a lower early mortality (1.8% vs. 4.3%), but a higher late mortality, such that the survival curves merge at 2 years.[25,26] There is a slightly higher risk of graft rupture with EVAR (up to 2% per year), and a significantly higher need for reinterventions for endoleaks (~20–30% at 6 years). In the particular case of

Table 20.1 Types of endoleaks.

Type 1	Poor sealing at the proximal or distal end of the graft.
Type 2	Retrograde endoleak from collateral flow. Leak from lumbar, inferior mesenteric, internal iliac, or middle sacral artery that are covered by the endograft but receive retrograde flow through collaterals[a]
Type 3	Fabric tear or stent frame fracture or separation

[a] Type 2 endoleak may be followed with serial CT scans and treated selectively if the aneurysmal sac grows.

AAA >6.5 cm, EVAR is associated with a high risk of late complications, because of inappropriate seal and inability to fully exclude AAA. Types 1 and 3 endoleaks have, however, been reduced with the newer generation of devices.

In patients unsuitable for open repair, EVAR is performed, but in those high-risk patients, even EVAR has a high early mortality (8%) and most patients die from comorbidities within 5 years, without a clear benefit of EVAR in terms of overall survival (EVAR-2 trial).[27]

The technical requirements for EVAR are: at least 1.5 cm of normal aorta (diameter <3 cm) between the renal arteries and the AAA to allow proximal anchoring of the device, minimal angulation of the AAA, patency of the superior mesenteric/celiac side branches (as the inferior mesenteric branch is covered by the endograft), and patent distal iliac vessels ≥7 mm in diameter. The endograft is a bifurcating endograft that covers the aorta and both iliacs. It has 2 parts: (i) a body and a right limb landing into the right iliac (deployed through a right femoral access), and (ii) a left limb landing into the left iliac (deployed through a left femoral access). For AAA that extends too far proximally, a *fenestrated endograft* may be placed across the renal arteries, followed by renal stenting with covered stents.

D. Surveillance for smaller aneurysms (3.0–5.5 cm)

CT or ultrasound is performed every 2–3 years for AAA <4 cm, every 12 months for AAA 4–4.9 cm, and every 6 months for AAA >5 cm (or 4.5 cm in women). β-Blockers are provided to reduce dP/dt, and blood pressure is aggressively reduced (e.g., <130/80 mm Hg). ACE inhibitors may be of particular benefit.[28] Rupture is more likely to occur in active smokers, and smoking cessation is therefore paramount.

Questions and answers 562

1. PULMONARY EMBOLISM

I. Presentation of pulmonary embolism (PE) and risk factors

A. Signs and symptoms

- Dyspnea and tachypnea are the most common findings; however, they may not be seen at rest and may be purely exertional.
- Tachycardia is common and is occasionally an isolated finding. Frequently, however, tachycardia is either *transient* or *relative* (80–90 bpm).
- Chest pain is usually a pleuritic pain in patients with distal emboli; angina-like pain may be seen in patients with large central emboli and secondary RV ischemia. Hemoptysis is seen with pulmonary infarction, often resulting from small distal emboli.
- Hypotension, syncope, and RV failure with increased JVP/RV heave/right-sided S_3 are seen with large PE and imply reduced hemodynamic reserve.
- Lower extremity edema or tenderness on palpation is seen in 50% of DVTs.

B. Risk factors (see Table 21.1)

Table 21.1 Risk factors for PE/DVT.

- Active cancer within the last 6 months, or active therapy for cancer
- Transient major risk factors within the last 4 weeks: surgery, trauma with fractures, hospitalization ≥3 days
- Transient minor risk factors: pregnancy, oral contraceptive therapy, travel >8 hours, leg injury without fracture, immobility at home ≥3 days
- History of PE/DVT
- Hypercoagulability
  - Genetic: factor V Leiden, prothrombin gene mutation, protein C or S deficiency, antithrombin III deficiency
  - Acquired: antiphospholipid syndrome, active cancer, myeloproliferative disorders, nephrotic syndrome
- Idiopathic: ~10% of patients with idiopathic PE/DVT will end up being diagnosed with cancer within the next year
- Other risk factors: age, smoking, obesity

II. Probability of PE

The clinical probability of PE is assessed using the Wells criteria, which essentially give weight to 3 features:[1]

- No alternative diagnosis for the patient's presentation, whether it is dyspnea, hypoxia <95%, chest pain, or tachycardia
- Major risk factors for DVT/PE
- Clinical signs of DVT or hemoptysis

The probability is high when 2 or 3 features are present, intermediate when only 1 feature is present, and low when none is present.

III. Initial workup

ECG, chest X-ray, and arterial blood gas (ABG) are initially performed to look for alternative explanations and for suggestive PE signs.

A. ECG

ECG findings in PE:

- Sinus tachycardia or "relative" tachycardia (80–100 bpm) is common.
- Right axis deviation, RVH/RBBB, P pulmonale.
- T-wave inversion in the anterior precordial leads, corresponding to RV strain.[2]
- Deep S in lead I, Q and T-wave inversion in the inferior lead III and sometimes aVF ($S_1Q_3T_3$). The deep S wave in lead I actually represents depolarization of an RV that has expanded down and to the right, and corresponds to right-axis deviation.[3,4]

These findings are not specific for PE and may be seen in any RV volume or pressure overload state, whether acute or chronic. In the right context, however, they are specific for PE. Sinus tachycardia is sensitive (~50–70%); each one of the other criteria is ~10–20% sensitive, and the combination of several of them is ~50% sensitive for the diagnosis of PE. When PE is large enough to produce marked hypoxemia or shock, several of those changes are almost always present, especially T inversion in V_1–V_3, which is present in 85% of massive or submassive PEs. A heart rate that is consistently ≤60 bpm in a patient who is not receiving rate-slowing drugs makes PE highly unlikely. *It is important to look at the admission ECG, as tachycardia may be transient*.

B. Arterial blood gas

Arterial blood gas usually shows hypoxia, hypocapnia, and a high A–a gradient (>10 mmHg at ambient air, >50 mmHg on high-dose O_2). O_2 saturation and A–a gradient are, however, normal in up to 20% of the patients.[5] An abnormal A–a gradient is non-specific and is seen in most pulmonary illnesses as a result of ventilation/perfusion mismatch. Hypercapnia is rare and frequently suggests a different diagnosis or an associated illness (e.g., COPD). Only a massive PE with massive increase in dead space can cause hypercapnia, per se.

C. Chest X-ray

Chest X-ray is grossly normal. It often shows some subtle abnormalities (linear atelectasis, pleural effusion, pulmonary artery cutoff sign).

D. D-dimer

D-dimer is a fibrin degradation product that results from the intrinsic, albeit ineffective, lysis of a clot. If the PE pre-test probability is not high, a negative D-dimer rules out PE. A positive D-dimer, on the other hand, is non-specific and may be seen with any inflammation, pregnancy, or active clotting for any reason, e.g., cancer, bleed, trauma, medical procedure, or even venipuncture. D-dimer should not be used in the high pre-test probability population, especially the cancer population (in whom falsely negative and positive results may be seen). Also, D-dimer cutoff should be adjusted for age: at age <50, D-dimer cutoff is 0.5 mg/L, and at age >50, the cutoff is age divided by 100 (e.g., 0.75 for a 75 year-old patient) (ADAPT-PE trial).[6]

IV. Specific PE workup

A diagnostic strategy is provided in Figure 21.1 (ESC).[1,5] If PE is highly probable and the bleeding risk is low, start IV unfractionated heparin (UFH) therapy, then establish a definitive diagnosis:

- *Spiral CT PE protocol* is very sensitive but may miss subsegmental, small PEs (Figure 21.2). Meta-analyses of long-term follow-ups of CT results have shown that CT is almost as accurate as pulmonary angiogram for ruling out PE. The negative predictive value is 95–99%, and

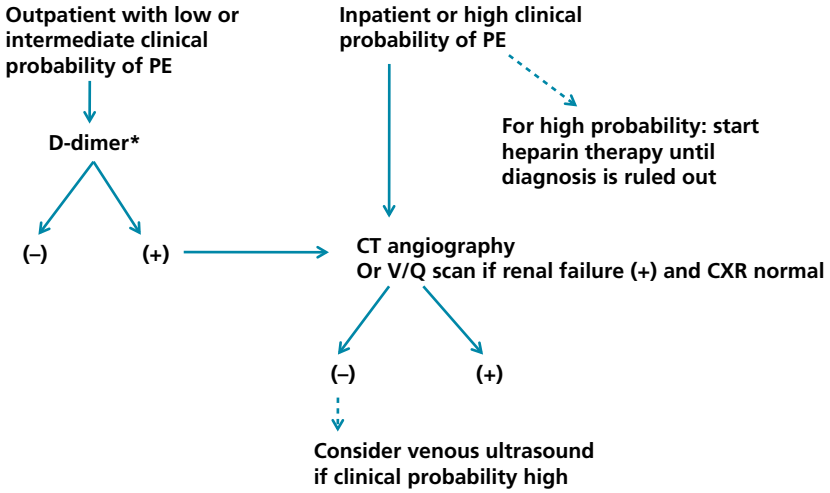

Figure 21.1 Algorithm for the diagnosis of pulmonary embolism.
*Most hospitalized patients have an elevated D-dimer because of comorbidities, inflammation, or blood draws. Hospitalized patients should undergo initial testing with an imaging study.

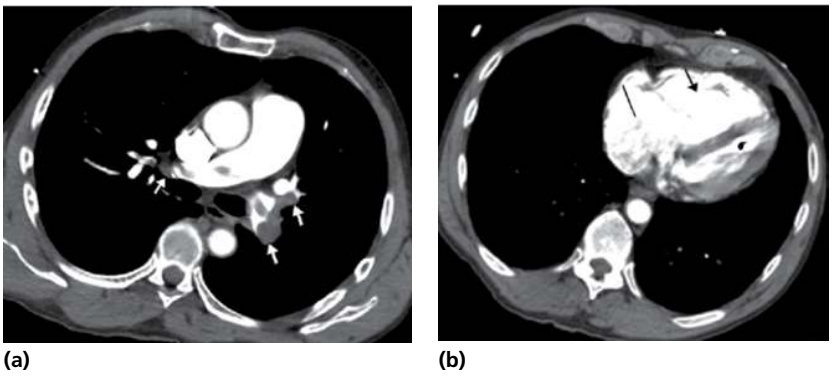

Figure 21.2 **(a)** Massive bilateral PEs in the proximal right and left pulmonary arteries, as evidenced by the filling defects (*arrows*). **(b)** RV (*arrow*) and RA (*line*) enlargement. RV and RA are the anterior structures; see how the RV is more than three times the size of the LV (*dot*). RA is also much larger than LA.

in patients with a negative study the rate of PE diagnosis or mortality on 3-month follow-up is very low (<1%).[7–9] Moreover, spiral CT can establish other diagnoses (pneumonia, pulmonary edema) and establish the severity of PE by looking at RV enlargement and interventricular septal bulge.

Caveat: an isolated subsegmental defect is commonly a false positive finding, hence it may not warrant anticoagulation once DVT is ruled out (ACCP guidelines, observational data).

While the thrombus often lyses within weeks of anticoagulant therapy, defects may persist on CT for over 6 months in up to 50% of patients, albeit becoming eccentric and non-occlusive (recanalized). Thus, on a repeat study, defects in the same territory do not necessarily imply recurrent PE.[10]

- *V/Q scan* is useful when its result is normal or "low probability," which either means there are no perfusion defects or there are perfusion defects that are matched with ventilation defects. V/Q scan is also useful when the result is "high probability," as noted by multiple unmatched perfusion defects. However, ~30–40% of the studies have intermediate probability results. Overall, V/Q scan is valuable if the chest X-ray is normal and the patient does not have any severe cardiopulmonary abnormality that would interfere with the result. It is also valuable in renal failure, when CT may be risky.
- *Pulmonary angiogram* is rarely used and does not have a higher yield than current-generation chest CT. It may be considered if the CT or V/Q scan is indeterminate yet the PE clinical probability is high.
- *Lower extremity venous ultrasound* is positive in ~70% of DVTs. It is useful as an additional test if V/Q scan or CT is indeterminate or negative but the PE clinical probability is high.[9] In addition, it may be performed before CT if renal failure is present and one is trying to avoid the performance of CT. The results are only reliable if positive, ruling in DVT (and PE in the right setting). Negative results do not lessen the PE probability.
- *In pregnancy:* When PE is suspected in pregnancy, start with lower extremity venous study. If it is negative, perform CT or V/Q scan, both of which are associated with a reasonably low fetal radiation.[5]

Transthoracic echo may show signs of RV strain in ~30–60% of PEs, and in almost all cases of submassive or massive PE.[11] RV strain manifests as: (i) RV dilatation (RV >30 mm on long-axis view, or RV >LV on four-chamber view); (ii) systolic PA pressure >35 mmHg; or (iii) D-shaped septum in systole (pressure overload). Systolic PA pressure >50 mmHg cannot be generated by an acutely failing RV, and thus PA pressure over 50 mmHg suggests some degree of chronicity. Without a proper TR jet, pulmonary hypertension is suggested by a notched RV ejection envelope across the pulmonic valve (W shaped, midsystolic ejection slowing) and a short acceleration time on the RVOT ejection envelope (time to peak velocity <60 ms). Rarely, a thrombus in transit is seen in the right-sided chambers (~4%); this is associated with a high mortality.

In a patient with shock and suspected PE, these echo features can make a presumptive diagnosis of PE and may be enough to justify thrombolytic therapy in this unstable context, even without further definitive diagnostic studies.[12,13] In those unstable patients, emergent TTE may also help rule out other causes of shock, such as MI or tamponade. TEE may show a saddle embolus in the proximal PA branches but is rarely needed.

The ***McConnell sign*** signifies hypokinesis of the RV free wall with normal RV apical motion. In hospitalized patients with RV dysfunction, this sign was initially described as highly specific for PE, but later data suggest limited sensitivity and specificity (both <70%).[14,15] This sign may be seen in RV infarct and chronic PH.

BNP and troponin I as prognostic markers. Troponin increases in 50% of patients with moderate-to-large PE associated with RV strain. Also, BNP often increases in large PE (the degree of increase in PE is less marked than in HF).

V. Submassive or intermediate-high risk PE, pulmonary hypertension, and thrombolysis

Acute pulmonary hypertension occurs when emboli obstruct >30% of the pulmonary vascular bed, or less so in a patient with prior cardiopulmonary disease. The thin RV is poorly tolerant of the acute rise in afterload and, as a result, fails and dilates; the dilatation further increases RV afterload and leads to a vicious circle of RV failure. RV dilatation compresses the LV and further reduces cardiac output. Hypotension may ensue and worsen RV ischemia, as the RV is more dependent on systolic blood pressure than the LV. Peripheral vasoconstriction and tachycardia acutely preserve the systemic pressure.

Thrombolytics achieve quick lysis of the PE (a few hours) and a quick, almost immediate improvement in pulmonary pressure and RV function in 92% of patients.[5,16] However, intrinsic thrombolysis is also potent and often dissolves a large part of the thrombus burden in patients receiving anticoagulation only, in a way that the hemodynamic superiority of thrombolysis over anticoagulation may be limited to a few days only. In addition, while acute pulmonary hypertension mainly results from the embolic obstruction per se, pulmonary vasoconstriction is a secondary contributor that improves over the course of therapy (vasoconstriction results from hypoxemia and from platelet-released serotonin and thromboxane).[17] Several studies suggest that 1 week after therapy, the degree of vascular obstruction on perfusion imaging and the degree of RV dysfunction are similar between thrombolysis-treated and anticoagulation-treated patients. PA pressure dramatically improves within a week of therapy, and heparin-treated patients often catch up with thrombolysis-treated patients.[12,18–21] Thus, thrombolysis is mostly useful in patients who are in shock, since those patients are unlikely to survive the first few days and catch up with thrombolysis-treated patients.

Massive PE or high-risk PE or Stage E is defined as shock, i.e., sustained hypotension (SBP <90 mmHg or 40 mmHg lower than baseline for over 15 minutes). This must be distinguished from the transient hypotension of syncope, which may imply reduced cardiac output reserve (submassive PE), but not massive PE.

Intermediate-high risk PE—formerly submassive PE—is defined as PE without shock but with the **triple combination of the following** (ESC):[5,12]

- Clinical features (any): hypoxemia with O_2 saturation <90% on ambient air, SBP <100 mmHg, pulse >110 bpm, or shock index (pulse/SBP ratio) >1. Baseline cancer or chronic cardiopulmonary disease also confers increased risk (sPESI score ≥ 1, see Section 1.VII.B).
- Imaging evidence of pulmonary hypertension or RV dysfunction: (i) systolic PA pressure >35 mmHg, often implying significant pulmonary hypertension as the RV cannot generate pressures >50 mmHg acutely; or (ii) RV hypokinesis or dilatation (RV/LV diameter >0.9 on echo or CT 4-chamber view).
- Biochemical evidence of RV injury (troponin beyond the "gray zone," e.g., >0.1 ng/ml) or RV dysfunction (NT-proBNP ≥ 600).

Intermediate-low risk PE is characterized by only 1 or 2 of the above features, while *low-risk PE* has none.[5] ACC guidelines call intermediate-risk PE *Stage C*, and specifically *C1, C2, or C3 when 1, 2, or 3* criteria are met. Massive PE is *stage E*. ACC introduced a new category, *Stage D* or incipient shock, wherein BP is normal but lactic acid is elevated. Stage D is grossly managed similarly to C3 (intermediate-high risk).

The term ***"saddle PE" is an angiographic term*** that describes a large thrombus sitting atop or "saddling" the main pulmonary artery or its bifurcation: it ***does not directly correlate*** with the clinical presentation, which may be intermediate-low risk, and it often responds to stand-alone anticoagulation. Massive and submassive PE are clinical terms that correlate with the size of PE but also with the patient's underlying cardiopulmonary reserve. Whereas most stable, anticoagulated patients catch up with thrombolysis-treated patients, data suggest that a subgroup of patients with **submassive PE** are at risk of *acute clinical deterioration* and *of persistent pulmonary hypertension and RV failure*.[12,22,23] In the landmark PEITHO trial of submassive PE, defined by a combination of both RV imaging features and troponin >0.06 ng/ml, systematic thrombolysis was compared with standalone anticoagulation; systematic thrombolysis reduced acute deterioration but did not affect the overall acute mortality and was associated with increased bleeding events, including a 2% rate of intracranial bleeding, mostly occurring in patients older than 75.[24] Hemodynamic deterioration requiring rescue thrombolysis occurred in only 5% of the control patients. Also, after 3 years of follow-up, thrombolysis was not associated with improved functional capacity, which was mildly

impaired in ~1/3 of patients, nor a reduction of chronic pulmonary hypertension (~infrequent, 3%).[25] Thus, **the widespread use of thrombolysis in submassive PE is not clearly superior to its selective use.** As such, standalone anticoagulant is an appropriate initial strategy, as many patients improve their PA and RV parameters quickly; ***thrombolysis is reserved for patients who do not improve their PA pressure within a few days, or those with persistent or deteriorating pre-shock state, even before hypotension occurs*** (persistent tachycardia, borderline BP, persistent severe hypoxia) (rescue thrombolysis: class I in ESC guidelines).[5,26]

While mostly effective in the first 2 days after the onset of PE symptoms, thrombolysis remains effective in patients who have had symptoms for 6–14 days, with 70% of the latter patients demonstrating improvement with thrombolysis on lung scan.[27] In practice, it is often difficult to define the onset of PE, especially in patients who have subacute symptoms of several weeks and who may have multiple emboli of various ages, some of which are acute;[27] thrombolysis may be attempted in patients with recent symptoms and persistent pulmonary hypertension. The benefit of thrombolysis is less time-dependent in PE than in MI or stroke for the following reasons: (i) thrombolysis is more effective in lysing a PA clot than a coronary or cerebral clot; 100% of the cardiac output goes through the pulmonary circulation, while only 5% and 15% of the cardiac output goes to the coronary and cerebral circulations, respectively; (ii) as opposed to a coronary occlusion, which quickly leads to MI and makes late thrombolysis futile, pulmonary arterial occlusion rarely leads to a large pulmonary infarction, as the pulmonary parenchyma receives most of its supply from the bronchial arterial circulation. Only small infarctions may be seen with distal emboli.

HI-PEITHO trial randomized intermediate-high risk PE to standard anticogulation vs local ***catheter-directed thrombolysis*** (~2 mg bolus then 1 mg/hr per lung for 7 hrs, total ~8–18 mg; IV UFH is administered at low dose during lytic infusion, ~300–600 u/hr). Similarly to systemic thrombolysis in PEITHO, catheter-directed lysis failed to reduce mortality, and only reduced the rate of clinical deterioration by ~6% (mostly "soft" clinical deterioration, not shock or intubation). RV size was similar at 48 hrs. The only difference with PEITHO is that major bleeding was not increased with catheter lysis and no patient developed ICH. Thus, ***catheter-directed therapy of 1 or both lungs is reserved for*** patients with massive or deteriorating submassive PE, particularly those at high bleeding risk with a full thrombolytic dose. Typically, catheter therapy consists of low-dose direct catheter infusion of alteplase over 7–12 hours, which is likely safer than IV thrombolysis.[5] Standalone catheter aspiration may alternatively be performed, using large catheter systems such as Inari FlowTriever (24 Fr catheter aspiration) or Penumbra (12 Fr); however, large catheters may obstruct the tricuspid apparatus and PA and decompensate tenuous patients.

Considering the high mortality of patients with submassive PE and free-floating right heart thrombus (>20%), those patients are best treated with systemic thrombolysis or surgical thromboembolectomy in an experienced center.[28] Catheter thrombectomy is risky in those patients, as it may dislodge emboli into the right circulation, but also the left circulation if PFO is present. Yet, large-bore AngioVac aspiration with extracorporeal pump has been described in several case series.

VI. PE and chronic pulmonary hypertension

A first episode of PE leads to a risk of *symptomatic* chronic thromboembolic pulmonary hypertension (CTEPH) of about 4% at 2 years, even without recurrence of PE.[29] This risk may be higher in patients whose initial presentation is submassive PE, according to older data,[22,23] but this was not the case in the large PEITHO trial (3% risk, not reduced by acute thrombolysis).[25] CTPH is treatable with surgical pulmonary thromboendarterectomy when the pulmonary obstruction is central (~70% of the cases), but not when it is distal and microvascular.

VII. Acute treatment of PE

A. Initial anticoagulation

One of the following 2 strategies may be initiated:

- Parenteral anticoagulation:
  - IV UFH, 80 units/kg bolus then 18 units/kg IV drip, with PTT monitoring Q6h. The PTT goal is 1.5–2.5 times normal.
  - Enoxaparin 1 mg/kg SQ Q12h, reduced to 1 mg/kg Q24h if GFR <30 ml/min (avoid in ESRD). Or fondaparinux 5–10 mg SQ Q24h. ACC guidelines prefer enoxaparin over UFH for its more consistent anticoagulation and lower PE recurrence; it is likely safe even if thrombolysis is eventually needed and is preferred by these guidelines in patients receiving IV thrombolysis or an endovascular procedure.
- Acute therapy with oral apixaban or rivaroxaban

Apixaban or rivaroxaban may be used as upfront therapy in low- or intermediate-low risk patients who have a low likelihood of requiring bailout thrombolysis.[5] Otherwise, parenteral anticoagulation is used the first 2–3 days, then switched to apixaban or rivaroxaban. In the absence of renal failure (GFR <30 ml/min) or high bleeding risk, LMWH or fondaparinux is preferred to UFH. Both agents have been shown to be at least as efficacious as UFH in PE, with a trend toward superiority and a similar bleeding risk.[30,31] In patients with a high bleeding risk, UFH is preferred because of its shorter half-life.

Note that the fondaparinux dose used for PE is higher than the dose used for ACS (2.5 mg SQ QD). Also, the starting dose of heparin is higher for PE than ACS. Based on the landmark heparin trials in ACS and PE, PTT goal is higher for PE (2–3× upper limit, 60–85 seconds) than for ACS (1.5–2× upper limit, 46–70 seconds).[32,33] In ACS, antiplatelet therapy and PCI is the mainstay therapy, and high-intensity anticoagulation is avoided. Conversely, in PE, anticoagulation is the mainstay therapy and subtherapeutic anticoagulation should be avoided for any duration.

Rarely, when chosen as the oral anticoagulant, warfarin is started on the first day, usually at a dose of 5 mg per day. A dose of 10 mg for 2 days allows faster achievement of INR goal and is recommended in young healthy patients, whereas a 5 mg dose is recommended in elderly patients or those with heart or liver failure (ACCP guidelines).[34,35] Anticoagulation reaches steady state in ~7 days. INR is checked at 3–4 days, when it is expected to be 1.5–1.9, and warfarin is titrated accordingly. UFH or LMWH should be continued until INR is therapeutic for 2 consecutive days.

B. Initial outpatient treatment of acute PE

For a PE with no high-risk clinical features (PE score index of 0) and no RV dilatation on CT, treatment may be initiated in the outpatient setting (ESC and ACCP guidelines).[5,35] Simplified PE score index (sPESI) consists of 1 point for each of the following: age >80, history of cancer, history of cardiopulmonary disease, O_2 saturation <90%, SBP <100, pulse >110. In one randomized trial of outpatient PE treatment, enoxaparin was initially used and followed by warfarin;[36] in a later trial of early discharge <48 hours, initial rivaroxaban was used.[37] Either anticoagulant strategy is acceptable (ACCP).

C. Indications for thrombolysis and thrombectomy and mechanical circulatory support

Thrombolysis results in a quick, almost immediate improvement of PA pressure and RV hemodynamics. However, by 1 week, pulmonary perfusion and RV function improve in most anticoagulated patients almost similarly to thrombolysis-treated patients, albeit more slowly (they often catch up with thrombolysis-treated patients). Thus, thrombolysis is indicated in the following patients (ACCP, ACC, ESC):[5,12,35]

- Massive PE where immediate improvement of hemodynamics is necessary (SBP <90 mmHg for over 15 minutes) (class I).
- Few select cases of intermediate-high risk PE. Thrombolysis is not routinely recommended in intermediate-high risk PE, even with both imaging *and* biomarker evidence of RV involvement (class III, ESC and ACCP). It is only indicated for patients who do not quickly improve their PA pressure within a few days of therapy or show signs of cardiopulmonary deterioration even if hypotension has not developed yet (class I ESC).

Alteplase is administered as a 100 mg intravenous dose over 2 hours. Heparin is restarted at the end of the alteplase infusion. Alternatively, a weight-based bolus of tenecteplase has been used (30–50 mg, dose similar to STEMI).[24]

As an alternative to systemic thrombolysis, and *with the same limited indications*, catheter thrombectomy and a low-dose local infusion of alteplase may be used (~0.5–1 mg/h, for a total of ~10–20 mg). *Some devices (e.g., Flow Triever) allow effective standalone thrombectomy without any thrombolysis*.

If shock persists despite thrombolysis, consider pulmonary angiography and mechanical thrombectomy for residual proximal clot burden. Alternatively or in combination, ECMO is considered: with ECMO, intrinsic thrombolysis often allows clot resolution within a few days of pure anticoagulation, hence mechanical thrombectomy is not always required.[38,39] ECMO is also considered for shock that persists despite clot resolution. RP Impella is considered as an alternative to ECMO only for persistent shock despite proximal clot resolution; otherwise, the pump may deliver blood up against a persistent PA obstruction. *Note:* Thrombolysis complicates the insertion of the large ECMO cannulae, but those may still be placed a few hours after thrombolysis.

In severe hypoxemia, try to focus on high flow O_2 and try to avoid sedation during procedures. ***Intubation and positive pressure ventilation may trigger hemodynamic collapse*** because of: (i) sedation, (ii) ↑ RV afterload and ↓ preload. Hence, a patient who needs intubation likely also needs thrombolysis pre-emptively; alternatively, one needs to be ready to perform ECMO ± thrombectomy peri-intubation.

D. IVC filter

According to the modern PREPIC-2 trial, which recruited high-risk PE (e.g., age >75, underlying cardiopulmonary disease, submassive PE), IVC filter does not provide any additional reduction of PE recurrence in patients receiving anticoagulation.[40] Furthermore, it doubles the DVT risk and may lead to IVC thrombosis (~25%) or adjacent organ penetration (~4%) over the long term.[5,41]

An IVC filter is therefore indicated in only one instance: Contraindication to anticoagulation, such as a recent major bleed, trauma, surgery (<3 weeks), or a history of intracranial hemorrhage. If the contraindication is likely to be transient, placement of a retrievable IVC filter is preferred. The retrievable filter has a hook that allows later removal, generally within a few weeks (up to 3–12 months with some devices).

Recurrent PE/DVT despite therapeutic anticoagulation is a relative indication for IVC filter. This situation is usually due to off-and-on periods of subtherapeutic anticoagulation, rather than a truly ineffective anticoagulation. Anticoagulation should be continued along with IVC filter placement, as the IVC filter will only increase the DVT risk. *Massive PE is not, per se, an indication for IVC filter, even massive PE that required thrombolysis*.

VIII. Duration of anticoagulation

In the absence of anticoagulation, the risk of recurrence of PE/DVT is highest in the first 3 months and may be as high as 20%.[5] Beyond the first 3 months, in the absence of anticoagulation, the yearly risk of recurrence of provoked PE/DVT is ≤3% (major risk factor 1%, transient minor risk factor 3%), while the yearly risk of recurrence of unprovoked PE/DVT is 3–10%.[35] A similar risk of recurrence is expected after anticoagulation is stopped, whether it is stopped at 3 months or 6–12 months.[5,42] A meta-analysis has shown that 3 months of anticoagulation vs. ≥6 months was associated with a similar risk of DVT/PE during the 2 years following cessation of anticoagulation.[43,44] Anticoagulation is associated with a 2–3% yearly risk of major bleeding, reduced by 40% with NOACs.

In unprovoked PE/DVT, certain risk factors are associated with a doubling of the risk of recurrence, making it close to 10%, whereas the lack of those risk factors reduces the recurrence risk to 3%. The risk factors for recurrence are:

- Recurrent DVT/PE.
- High-risk thrombophilias: cancer, antiphospholipid syndrome (highest risk factors, >8% per year), protein C or S deficiency, antithrombin III deficiency, homozygote factor V Leiden, or homozygote prothrombin gene mutation.
- Elevated D-dimer 1 month after stopping anticoagulation, which implies active subclinical clotting and increased thrombotic events.[45]
- Residual thrombus or defect on venous ultrasound, which increases the risk of a new DVT. The residual thrombus, even if old and organized, may serve as a nidus for further thrombus deposition or impair venous flow in a way that favors recurrent DVT.[46]
- Male sex (1.75-fold higher risk).

For unprovoked PE/DVT, extended anticoagulation beyond 3 months (possibly lifelong) is warranted, as long as the bleeding risk is low or moderate (Table 21.2).[5,35] This also applies to the PE/DVT provoked by minor transient risk factors (per ESC, but not per ACCP). Cancer patients have the highest risk of recurrence, ~20–30% within a year, and require extended therapy even if the bleeding risk is high (as long as cancer is active). LMWH is twice as effective as warfarin in reducing PE/DVT recurrence in cancer patients;[35,47] vomiting, fluctuant nutritional status, and liver dysfunction are common in these patients and alter the efficacy and safety of warfarin. **Initial treatment with NOACs has compared favorably to LMWH in 3 cancer trials.** Edoxaban and rivaroxaban more effectively reduced PE/DVT recurrences

Table 21.2 Duration of long-term anticoagulation.

1. Provoked PE or DVT (major transient risk factor)	3 months
2. Unprovoked idiopathic PE or DVT OR provoked by a major or minor risk factor but with enduring risk for recurrence (e.g., obesity)	>3 months (extended therapy) if the bleeding risk is low or moderate 3 months if the bleeding risk is high Consider D-dimer testing, venous ultrasound, and testing for thrombophilias to decide about pursuing therapy beyond 3 months
3. Recurrent PE or DVT	>3 months
4. High-risk thrombophilias	>3 months if the bleeding risk is low or moderate[a]
5. Active cancer within the last 6 months	Extended LMWH or NOAC: apixaban, edoxaban, or rivaroxaban

[a] Even with thrombophilias, limiting anticoagulant therapy to 3 months is appropriate in high-bleeding-risk patients (ACCP). Cancer patients have the highest risk of recurrence (20–30% within a year), followed by antiphospholipid syndrome and recurrent PE/DVT (recurrence risk >8% per year): these groups qualify for extended therapy even if bleeding risk is high (ESC). Extended therapy implies routine reassessment of bleeding risk and reconsideration of the duration of anticoagulation, and does not necessarily equate with indefinite therapy.

than LMWH, at the cost of a higher GI bleed; conversely, apixaban was at least as effective as LMWH, with no increased bleeding (CARAVAGGIO trial).[48,49] Thus, either LMWH or the above NOACs may be used in cancer patients.

For provoked PE/DVT: HI-PRO trial randomized patients with PE/DVT provoked by a major or minor factor, but with enduring risk for recurrence, to extended low-dose apixaban 2.5 mg bid vs. placebo. The risk of PE/DVT recurrence was indeed very high, 10% at 1 year, and reduced to 1.3% with apixaban (Piazza G, et al. NEJM 2025; 393:1166) PE/DVT was mostly provoked by surgery, trauma, acute medical illness, or immobility. The enduring risk factors mostly consisted of obesity (BMI>30), chronic immobility, lung disease, chronic inflammatory disease, atherosclerotic CVD, and HF.

When extended therapy is chosen, **a reduced-dose apixaban (2.5 mg BID) or rivaroxaban (10 mg daily) is favored after the first 6 months.** In 2 trials, these lower doses were as effective as standard doses and **did not increase major or even nonmajor bleeding in comparison with placebo or aspirin** (AMPLIFY-ext and EINSTEIN-CHOICE trials).[50,51] In the API-CAT trial of cancer patients, the lower apixaban dose resulted in less bleeding and mortality than the standard apixaban dose.[52]

Bleeding risk is high in the following patients: (i) age >75; (ii) previous GI bleed, especially when the cause is not reversible; (iii) chronic severe HTN; (iv) prior stroke; (v) requirement for dual antiplatelet therapy; (vi) baseline anemia Hb <10 g/dl; (vii) hepatic or renal disease.

While anticoagulation reduces the risk of PE/DVT recurrence by 90%, aspirin has been shown to reduce this risk by ~30%, and may be a reasonable alternative to anticoagulation in patients who have an intermediate, rather than high, risk of recurrence (ACCP) or patients who refuse or do not tolerate extended anticoagulation >3 months (ESC class IIb).[53]

IX. Thrombophilias

Thrombophilias are classified into high-risk and moderate-risk thrombophilias:[54]

- *High-risk thrombophilias:* antiphospholipid syndrome, protein C or S deficiency, antithrombin III deficiency, homozygote factor V Leiden or prothrombin gene mutation. Each one of the high-risk thrombophilias has a 1–3% prevalence among patients with a first PE/DVT and is associated with a 2.5× increase in the risk of recurrence.
- *Moderate-risk thrombophilias:* Heterozygote factor V Leiden or prothrombin gene mutation. While highly prevalent among patients with PE/DVT (15% and 5%, respectively), they only modestly increase the risk of recurrence by ~30% and do not merit extended anticoagulation per se (ESC).[5,54] They are highly prevalent in the general white population (5% for factor V Leiden and 2% for prothrombin mutation).

HIT is the highest-risk thrombophilia and should be considered in any hospitalized patient who develops DVT despite receiving heparin, along with a reduction in platelet count. Cancer and antiphospholipid syndrome are the second and third highest risk factors (recurrence >8% per year). The remainder of high-risk thrombophilias have up to 8% yearly risk of recurrence.

Thrombophilias do not modify the INR goal (2–3), and likely can be treated with NOACs, except for antiphospholipid syndrome (rivaroxaban was inferior to warfarin in one trial of antiphospholipid syndrome).[55] Indefinite warfarin anticoagulation is recommended in antiphospholipid syndrome (ESC class I), with an INR goal of 2–3; if thrombosis recurs while on warfarin, INR goal is best raised to 3–4 or factor X activity followed, particularly as antiphospholipid antibodies may falsely raise INR. Also, baseline INR is elevated in ~5% of patients, in which case factor X activity must be followed instead of INR and reduced to 25–35%.

After a DVT/PE, testing for thrombophilia is indicated in the following cases: (i) idiopathic DVT/PE; (ii) recurrent DVT/PE; (iii) DVT/PE at age <40; (iv) DVT at an unusual site, including upper extremity; (v) family history of DVT/PE. *Yet, if extended anticoagulation is planned anyway, the value of thrombophilia testing is questionable*. Antithrombin III and, occasionally, proteins C and S may decrease in acute thrombosis. In addition, antithrombin III is reduced with heparin, and proteins C and S are reduced with warfarin. Thus, measurement may be done acutely before initiation of anticoagulation, but if the levels of antithrombin III or protein C or S are abnormal, they need to be confirmed in a stable phase, after anticoagulation is discontinued (e.g., beyond 3 months). The genetic testing of factor V Leiden and prothrombin mutation may be performed at any time. *Cancer screening should also be performed*.

Antiphospholipid syndrome is tested using 2 modalities: (i) antibody testing (*anticardiolipin*, β_2-microglobulin); (ii) demonstration of prolongation of a clotting time, not correctable with the addition of normal plasma (= *lupus anticoagulant* = prolongation of PTT or Russell viper venom time). Since the clotting time is also prolonged by heparin therapy, it has no diagnostic value during heparin therapy.* To diagnose antiphospholipid syndrome, clinical thrombosis must be present, ALONG with either (i) or (ii), AND *persistence of (i) or (ii) on repeat testing* 3 months later.

* If PTT is prolonged at baseline (lupus anticoagulant), PTT cannot be used to monitor heparin therapy; use instead anti-Xa activity (target 0.3–0.7 units/ml) or LMWH.

In asymptomatic patients, thrombophilias drastically increase the risk of DVT/PE in relative terms (up to 15 times), but the absolute yearly risk of spontaneous DVT/PE remains low, ≤1%, even for antiphospholipid syndrome.[56] Asymptomatic thrombophilias do not warrant anticoagulation, but warrant the avoidance of additional risk factors (e.g., oral contraception) and appropriate prophylaxis during high-risk situations.

Thrombophilias are mainly associated with venous thrombosis. For most conditions, the association with arterial thrombosis (MI, stroke) is questionable and weak. Some conditions are associated with combined venous and arterial thromboses: antiphospholipid syndrome, HIT, malignancy (Trousseau syndrome), paradoxical embolism, and hematologic malignancies (myeloproliferative disorders, paraproteinemias, and paroxysmal nocturnal hemoglobinuria).

Also, a patient with HF and AF may be prone to both DVT and arterial embolism.

X. PE prognosis and long-term follow-up — CTEPH—CTED

When appropriately treated with anticoagulation, the mortality of low-risk PE without signs of RV failure is ≤1%. The mortality of submassive PE, including PE in patients with underlying cardiopulmonary disease, is 2–10%, while the mortality of massive PE is >10% and is improved with thrombolysis.[12]

PE patients are reassessed at **3 months**: those with persistent dyspnea or functional limitation and those with initial submassive PE are assessed by **(1)** echo (ESC). At that time, elevated TR velocity >3.4 m/s or, absent TR signal, elevated BNP + indirect PH signs warrant **(2)** V/Q scan to assess for persistent mismatched defects (ESC), as well as **(3)** right heart catheterization.[5] The indirect or borderline PH signs are: RV dilatation, abnormal septal motion, mid-systolic pulmonary flow or acceleration time <105 ms, TR velocity 2.9–3.4 m/s, or dilated IVC or PA >25 mm.

Residual pulmonary vascular obstruction is seen in ~20–50% on 1–12 months of follow-up, on CT or V/Q, but rarely leads to PH (only 3–4%).[10,57]

Chronic functional impairment is common after PE, with long-term persistent dyspnea in 1/3 of patients at 3 years, and reduction of peak VO_2 on cardiopulmonary stress testing in up to 47% of patients, regardless of thrombolysis (PEITHO trial). ***However, echo is largely normal in patients with or without functional limitation, and PH persists in only 3% of the patients who developed acute PH.***[5,25] This means that functional limitation after PE does not appear attributable to RV dysfunction, persistent PH, or even large residual thrombi, as it was not improved by acute thrombolysis in the PEITHO trial.[25] Muscular deconditioning, particularly in patients with obesity or cardiopulmonary comorbidity, is largely responsible for the frequently reported dyspnea and exercise limitation after acute PE.[5] Yet, a subset of patients with persistent post-PE dyspnea at 3 months and no PH have significant residual pulmonary vascular obstruction that could explain dyspnea. This is called **chronic thromboembolic disease** (CTED) and is characterized by pulmonary vascular obstruction that is less severe and extensive than CTEPH, with less adverse vascular remodeling and scarring. To make a CTED diagnosis in the absence of PH, objective features need to be present, such as (i) evidence of impaired pulmonary perfusion on V/Q scan or residual pulmonary obstruction on CT, AND (ii) exertional hypoxemia or increased pulmonary dead space with elevated VE/VCO_2 on CPET. Thus, in patients with persistent dyspnea and no concerning **(1)** echo features, perform either **(2)** V/Q scan or **(3)** CPET (seeking hypoxemia or ↑ VE/VCO_2). If either V/Q scan or CPET is *normal, CTED is excluded*. If one is abnormal, perform the other: only if *both (2) and (3)* are abnormal is CTED likely. Occasionally, RHC may be considered: RHC excludes PH and diastolic HF and seeks a purely exertional PH. The treatment of CTED is not clear, with no large data regarding thromboendarterectomy or pulmonary vasodilators.[58]

2. DEEP VEIN THROMBOSIS

I. Types

Proximal DVT involves the popliteal vein or the more proximal veins (i.e., the superficial femoral vein, which is a deep vein, or the iliac vein). It leads to PE in 50% of cases. Upper extremity proximal DVT involves the axillary vein or more proximal veins. Rarely, proximal DVT may result in severe venous congestion, so severe as to impede forward arteriolar flow and induce a pale then cyanotic acute limb ischemia (phlegmasia alba dolens, then phlegmasia cerulea dolens; "alba" means white, "cerulea" means blue). In contrast to acute limb ischemia from arterial occlusion, massive edema is present in phlegmasia and distal arterial pulses remain audible on Doppler exam.

Distal DVT is located below the popliteal vein and usually does not cause PE unless it extends proximally. Upper extremity distal DVT involves the brachial vein or more distal arm veins. Proximal extension occurs in 15% of patients, usually within 2 weeks of presentation.

II. Diagnosis

Clinical probability of DVT is based on three features: local DVT signs, DVT risk factors, and the absence of alternative diagnoses. When clinical probability is low or intermediate, D-dimer may be used to rule out DVT. When D-dimer is positive or the clinical probability is high, venous ultrasound and Doppler of the lower extremities is performed.

Ultrasound is 95% sensitive for proximal DVT, but only 50–70% sensitive for calf DVT. In addition, it cannot always diagnose isolated pelvic vein DVT (indirect signs of pelvic DVT may be seen). A DVT is diagnosed when a thrombus is directly seen, when the vein loses its full compressibility, or when venous flow loses its respiratory variations on spectral Doppler (monophasic flow, indirect sign of pelvic DVT). Of note, isolated pelvic DVT is relatively uncommon, as DVT typically starts distally and usually affects the femoral veins when the iliac veins are affected.

Beware of signs of old DVT that do not dictate acute anticoagulation: thick venous walls, small caliber, partially compressible. Scarred old clot looks white and laminated on the wall, unlike the darker and more mobile acute clot.

If the venous ultrasound does not suggest DVT but the clinical suspicion is high, D-dimer may be performed to definitely rule out DVT. If D-dimer is positive, it is recommended to repeat the ultrasound exam at 7 days (an extension of a calf DVT will be seen by that time). *If isolated pelvic DVT is suspected in a patient with severe thigh edema, venous CT or MRI may be performed*.

III. Treatment

Proximal DVT. Initial and long-term anticoagulation is similar to PE, except that therapy is more readily started in an outpatient setting, using rivaroxaban or apixaban.

Most patients with iliofemoral DVT, especially iliac DVT, do not recanalize, and at least 25% of patients will have venous claudication and post-phlebitic syndrome (50% of patients with iliac DVT).[59] Post-phlebitic syndrome may lead to venous ulcers in a third of patients. ACCP suggests against catheter-directed thrombolysis or thrombectomy, yet it may still be considered in patients with a low bleeding risk and a symptomatic iliac or common femoral DVT that does not quickly improve with anticoagulation.[12,35] In the ATTRACT trial, catheter therapy did not reduce the frequency of post-phlebitic syndrome; yet, it reduced its severity in very proximal, iliac or common femoral DVT, which may justify its occasional, selective use.[60] It is also indicated in the rare limb-threatening DVT (alba or cerulea). Thrombolysis should not be administered intravenously; rather, it is administered locally through a prolonged catheter infusion (e.g., 12–24 hours of local r-tPA infusion). It is used up to 14 days after onset of symptoms.

Knee-high compression stockings (30–40 mmHg) have not been shown to reduce post-phlebitic syndrome in one large trial and, thus, are not routinely recommended, but may be tried in symptomatic patients (ACCP).[35]

Distal DVT does not need to be treated with anticoagulation if it is asymptomatic, not extensive, or if the patient has a high bleeding risk. Serial venous ultrasounds for 1–2 weeks are recommended in these patients. If distal DVT is severely symptomatic or extends proximally, or the patient has cancer (onco DVT trial), anticoagulation is recommended for 3 months (rather than a shorter duration).

Superficial vein thrombosis is not necessarily treated with any anticoagulation but may be treated with a prophylactic dose of fondaparinux 2.5 mg QD or rivaroxaban 10 mg QD for 6 weeks, especially when extensive, symptomatic, or in the context of major DVT risk factors.

Upper extremity DVT usually occurs in patients with pacemakers or central catheters, mostly central catheters placed in cancer patients. If the catheter is functional and still required, it does not need to be removed. A minimum of 3 months of anticoagulation is recommended for a proximal upper extremity DVT: 3 months if the catheter is removed, or longer than 3 months if the catheter remains in place, for as long as it remains in place (especially in cancer patients) (ACCP). PE occurs less frequently with upper extremity DVT than lower extremity DVT (2–8%). This is related to the smaller size of upper extremity veins and, thus, the smaller clot burden. PE is more common with central-catheter-related DVT than thoracic outlet DVT.

SVC syndrome usually results from compression of the SVC by a mediastinal tumor, typically lung cancer. Complete SVC obstruction usually occurs when extrinsic compression is accompanied by intravascular thrombosis. If extensive thrombosis is present, catheter-directed thrombolysis followed by SVC stenting with a self-expanding stent is recommended.[61]

Upper extremity DVT may also develop in patients with *thoracic outlet obstruction*. Those are typically young athletic patients with hypertrophied cervical muscles and congenital narrowing of the space bounded by the clavicle and the first rib, where the brachial plexus, subclavian artery and subclavian vein traverse, leading to compression of these structures (sometimes compounded by an additional cervical rib). It may also develop in patients who heavily use their arm for athletic activity (venous microtrauma).[61] The brachial plexus is far more commonly involved (90%) than vascular structures, causing the so-called neurogenic thoracic outlet obstruction.

Upper extremity DVT may also be idiopathic; ~25% of idiopathic upper extremity DVTs may be related to an occult cancer.

3. IMMUNE HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) develops 4–16 days after initiation of heparin but may occur earlier, within minutes to hours, if the patient has been exposed to heparin within the last 3 months. It may develop days to weeks (up to 40 days) after heparin cessation in patients who have already been discharged from the hospital (delayed HIT). It is due to the formation of antibodies against the heparin–platelet PF4 complex.

I. Incidence

Approximately 2.5% of heparin-treated patients develop HIT. HIT is less common with prophylactic SQ heparin and 10 times less common with LMWH.

II. Diagnosis

Decrease in platelet count to <150,000 per microliter or decrease in platelet count >50% (even if the platelet count remains normal).

Also, heparin-induced skin necrosis at heparin injection sites, any thrombosis that occurs during effective therapy with heparin, or bilateral adrenal hemorrhages suggest HIT. Thrombocytopenia is rarely severe and is typically above 20,000 per microliter (median, 60,000 per microliter).

HIT antibodies should be ordered, and have a high diagnostic yield; however, they are not immediately available. The clinical context is used to determine the need for antithrombin therapy while antibodies are obtained for confirmation. HIT antibodies may be negative very early on; thus, a negative test may need to be repeated if the clinical suspicion of HIT is high. On the other hand, using ELISA assay, a slight increase in titers is very sensitive and may not reflect clinical HIT.

HIT is a prothrombotic state rather than a bleeding state. It leads to thrombosis in 50% of patients. this is called *heparin-induced thrombocytopenia and thrombosis syndrome (HITTS).* Thrombosis mainly occurs within the first few days of HIT, when the thrombosis risk is 6% per day. The thrombosis risk persists for up to 6 weeks after the discontinuation of heparin. Venous thrombi are 4 times more common than arterial thrombi.

III. Treatment

Whenever HIT is suspected, heparin and LMWH are discontinued. Thrombosis is sought on clinical grounds and on a lower extremity venous ultrasound. If there is any evidence of thrombosis, whether thrombosis for which heparin was given or thrombosis induced by HIT:

- Start a direct thrombin inhibitor (DTI): argatroban IV (hepatically cleared; not affected by renal function), or bivalirudin IV (enzymatic and renal clearance). Monitor PTT during treatment (>1.5×). Do not start warfarin acutely, as warfarin increases the risk of thrombosis and/or skin necrosis and gangrene in patients with HIT.

- Start warfarin late, after the platelet count has normalized (>150,000 per microliter) and after several days of treatment with DTI. Begin with a small dose and overlap with DTI for 5 days. DTI increases INR, and thus the INR goal *during the overlap* is twice the standard INR goal (>4). Give warfarin for at least 3 months (the duration of warfarin therapy depends on the underlying cause of DVT, as detailed above in Section 1, *Pulmonary embolism*).

Even in the absence of thrombosis or HITTS, HIT itself mandates the use of a DTI to prevent the associated high incidence of thrombosis. DTI is initiated as soon as possible, whenever there is a moderate/high suspicion of HIT, without awaiting the result of HIT antibody testing. DTI is continued until the platelet count returns to baseline, at which time warfarin is initiated and continued for ~30 days.

Limited reports, particularly with rivaroxaban, suggest that NOACs are effective in HIT or HITTS,whether as acute initial treatment or as a follow-through to IV argatroban,[62] and they are acceptable alternatives to DTI according to the American Society of Hematology.

In HIT, low platelets are not a contraindication to DTI, unless the patient is actively bleeding. Platelet transfusions should be avoided unless there is active bleeding.

Note: Anticoagulant therapies in a patient with a prior history of HIT

- DVT prophylaxis in a patient with a history of HIT: fondaparinux (anti-Xa) 2.5 mg SQ QD.
- Coronary intervention in a patient with a history of HIT: bivalirudin IV or argatroban IV.
- A patient with a history of HIT over 90 days ago can be anticoagulated with heparin for short durations, <3 days, as HIT antibodies have already cleared by that time and it takes 4 days to form new ones.

QUESTIONS AND ANSWERS

Question 1. A 60-year-old man presents with severe dyspnea and one syncopal episode. On admission, O_2 saturation is 87% on ambient air, BP is 125/75, and pulse is 85 bpm. Lungs are clear. Echo shows RV dilatation and hypokinesis with preserved apical contraction; PA pressure is 45 mmHg. CT shows multilobar PE. Troponin I is 0.4 ng/ml. The patient has no prior bleeding history and no prior stroke. What is the next step?

A. IV heparin
B. IV heparin + IV thrombolysis
C. IV heparin + IV thrombolysis + IVC filter

Question 2. A 45-year-old woman presents with acute dyspnea and hypoxia. SBP is ~100 mmHg, pulse is 110 bpm, and CT confirms the presence of a saddle pulmonary embolus involving the main PA branches. She is severely hypoxic and requires 5 liters of O_2 per minute to keep O_2 saturation >90%. Troponin I is 1 ng/ml. Echo shows severe RV hypokinesis and a worm-like structure in the RA, intermittingly flopping into the RV. What is the next step?

A. IV heparin
B. IV heparin + IV thrombolysis
C. IV heparin + surgical thrombectomy
D. IV heparin + catheter thrombectomy
E. B or C
F. C or D

Question 3. A 60-year-old woman had a PE with no identifiable trigger and no cancer on chest X-ray and mammography. She was given apixaban therapy for 3 months, uneventfully. She is asking about the need to continue therapy beyond 3 months. All the following statements are true, *except which one*?

A. Anticoagulation should be continued for at least 6 months
B. The risk of recurrence after discontinuation of anticoagulation is steady, whether anticoagulation is discontinued at 3 or 6 months
C. Thrombophilia testing, D-dimer testing (3 weeks after stopping anticoagulation), and lower extremity venous study help decide which patients are more likely to benefit from long-term therapy
D. The yearly risk of recurrence is 3% in the absence of any abnormality on thrombophilia or D-dimer testing, vs. 6–10% risk in the presence of any abnormality
E. She has a 10% probability of cancer diagnosis within the next year

Question 4. A 48-year-old woman had ankle surgery 2 weeks prior. She presents with dyspnea, arterial O_2 saturation 92% on ambient air, sinus tachycardia of 110, and SBP of 110 mmHg. CT chest shows bilateral PEs with RV dilatation. Echo shows systolic PA pressure of 50 mmHg. Troponin is mildly elevated. Which of the following is true regarding catheter-based therapy?

A. This patient has an indication for systemic or catheter-based thrombolysis
B. Catheter-directed thrombolysis improves RV function more and faster than anticoagulation alone
C. Catheter-directed thrombolysis improves RV function faster than anticoagulation alone
D. Catheter-directed thrombolysis is only effective for proximal PE

Question 5. A 55-year-old obese man had PE 2 weeks after an ankle sprain. His echo was unremarkable, and his troponin was mildly elevated. On his 3-month visit, he complains of mild exertional dyspnea and decline of functional capacity. Which of the following is true?

A. The risk of PE recurrence is similar in men and women
B. Anticoagulation is stopped at 3 months per ESC and thrombophilia testing performed
C. Obtain BNP. Echo is only repeated if BNP is elevated

D. If echo shows elevated PA pressure, V/Q scan is indicated
E. Cardiopulmonary stress test should be performed next

Question 6. A 55-year-old man had multilobar PE with acute pulmonary hypertension and RV dilatation, treated with anticoagulation. At his 3-month visit, he still complains of exertional dyspnea and mild functional limitation. Which of the following is true?
A. After submassive PE, PH resolves on follow-up in most patients (up to 97%)
B. PH is more likely to resolve had acute thrombolysis been used
C. This patient likely has residual pulmonary obstruction
D. Residual dyspnea after PE often indicates residual PH or residual pulmonary obstruction
E. Follow-up CT may be done next
F. B to E

Question 7. Which of the following is true?
A. PE with simplified clinical PE score of 0 and no RV strain may be treated as outpatient
B. Apixaban may be used as upfront therapy in all PE presentations
C. The combination of RV dysfunction by imaging and by cardiac biomarkers constitutes intermediate-risk PE
D. Isolated abnormality of RV imaging, or cardiac biomarkers, or PE score constitutes low-risk PE

Question 8. A 51-year-old man presents with syncope and is found to be in shock, with SBP 80 mmHg, hypoxemia 85% on ambient air, and AF with RBBB and a ventricular rate of 130 bpm. His BP does not improve with fluids, norepinephrine is initiated and he is intubated. Abundant bloody secretions are noted during tracheal suctioning. Bedside echo shows akinesis and dilatation of the RV, while the LV is small and hypercontractile. He develops a brief PEA arrest and is requiring escalation of vasopressors. What is the next step?
A. Intravenous thrombolysis
B. Chest CTA
C. TEE
D. Open surgical embolectomy
E. ECMO and anticoagulation without embolectomy
F. ECMO and anticoagulation with embolectomy

Question 9. A 70-year-old man presents with severe pneumonia. His oxygenation and hemodynamics worsen (SaO_2 85% on 5 L O_2, BP 80/50 mmHg, pulse 110 bpm, temperature 38.8° C), necessitating intubation and norepinephrine. A chest CT is performed and shows extensive bilateral consolidations consistent with pneumonia and ARDS. It also shows a right lower lobe subsegmental PE. He is anemic, Hb ~9 g/dl. What is the next step?
A. Continue DVT prophylaxis + lower extremity venous ultrasound
B. Initiate systemic full-dose IV heparin
C. Systemic thrombolysis
D. Catheter thrombectomy

Question 10. A 62-year-old man presents with acute dyspnea that started few hours ago. He also fainted while standing up and hit his head. SBP is 100 mmHg, SaO_2 is 92% on ambient air with tachypnea, pulse is 100 bpm. He is afebrile, JVP is normal, and lung exam is benign. Hs-troponin T is elevated at 80 ng/L, and NT-pro-BNP is 600. ECG shows inverted anterior T waves. Head CT is negative for any bleeding. Chest CTA shows a saddle embolus in the main PA, with a large RV > LV. What is the next step?
A. IV heparin only
B. Systemic thrombolysis
C. Mechanical thrombectomy

Question 11. A 45-year-old woman presents with unprovoked DVT. She is initiated on apixaban. Follow-up of hospital testing reveals elevated anticardiolipin levels. What is the next step?
A. Stop apixaban at 3 months
B. Continue extended therapy with apixaban (switch to 2.5 mg BID at 6 months)
C. Switch to warfarin (enoxaparin bridging), goal INR 2–3, extended therapy
D. Switch to warfarin (enoxaparin bridging), goal INR 3–4, extended therapy

Answer 1. A. With heparin therapy, this patient will likely catch up with thrombolytic-treated patients. Data suggest that thrombolysis may be beneficial in some patients with both radiological and biomarker evidence of RV dysfunction (submassive PE), 5% of whom do not catch up with thrombolytic-treated patients; in those patients, thrombolysis reduces acute deterioration, but not clearly long-term risk of pulmonary hypertension. Yet, considering its risk and the frequent catch-up phenomenon, thrombolysis is only indicated if cardiopulmonary deterioration occurs (routine thrombolysis is given class III in intermediate-risk PE by the ESC guidelines).

Answer 2. E. While the patients of Questions 1 and 2 both have submassive PE, the current patient is clearly a higher-risk patient within the large spectrum of submassive PE. SBP is lower, tachycardia is persistent with heart rate/SBP ratio >1 (shock index >1), and hypoxemia is more severe, suggesting that she is less stable and less likely to improve with heparin only. Moreover, the thrombus in transit is a very high-risk finding that advocates for more aggressive therapy (sudden death may occur if it moves into the PA). Catheter thrombectomy may dislodge the clot and may lead to right- and left-sided emboli (if PFO is present) and has less retrospective data than thrombolysis or surgical embolectomy.

Answer 3. A. Three months is the highest-risk period for PE/DVT recurrence and is the mandatory duration of therapy. But anticoagulation is preferably continued >3 months in all patients with low bleeding risk.

Answer 4. C. According to ULTIMA trial, catheter-based thrombolysis using an ultrasonic catheter (EKOS) results in a more rapid reduction of RV/LV ratio than anticoagulation alone at 24 hours, but there is no evidence it improves the RV function at 1 month, and it is likely that anticoagulation alone eventually catches up with catheter-based thrombolysis days later, as in Hi-PEITHO trial.

Answer 5. D. The risk of PE recurrence is 1.75-fold higher in men than women. In unprovoked PE or PE provoked by minor risk factors (e.g., ankle sprain rather than fracture or surgery), anticoagulation is preferably continued >3 months, regardless of thrombophilia testing (class IIa). This is particularly the case with enduring PE risk factors, such as obesity. Echo should be performed at 3 months in patients with residual dyspnea or asymptomatic patients with baseline intermediate-high risk PE. This patient's baseline PE is intermediate-low risk (normal RV/PA by imaging), but he has dyspnea. Both echo and BNP are done; BNP is particularly helpful in patients with borderline echo findings (unclear PA pressure, indirect PH signs). V/Q scan and right heart catheterization are justified for high-risk echo +/– BNP features (ESC). Cardiopulmonary testing may be used when echo is normal, seeking an occult cardiopulmonary cause of dyspnea.

Answer 6. A. Residual pulmonary vascular obstruction is seen in ~15–20% on follow-up, on CT or V/Q, but rarely leads to PH (only 3–4%). Chronic functional impairment is common after PE (up to 47%). However, echo is largely normal in patients with or without functional limitation, and PH persists in only 3% of patients with acute PH. Functional limitation after PE does not appear attributable to RV dysfunction, persistent PH, or large residual thrombi, and thus, it is questionable whether acute thrombolysis has any effect on it. Muscular deconditioning, particularly in obese patients with comorbidities, is largely responsible for this exercise limitation after acute PE. Echo should be performed to assess for PH and if abnormal, V/Q scan is done, then right heart catheterization. There is no ESC recommendation for using CT on follow-up, although some may use it instead of V/Q scan to diagnose residual vascular obstruction.

Answer 7. A. Apixaban may be used as upfront therapy in low or intermediate-low risk PE. Higher risk PE is better treated parenterally early on, in case escalation of therapy is needed. C is intermediate-high risk PE, while D is intermediate-low risk PE.

Answer 8. E. In massive PE (shock), diagnosis is assumed based on clinical, ECG, and echo grounds, and CT is not mandatory before advanced therapies, as the patient may further collapse during CT delays. The patient's massive hemoptysis is a contraindication to thrombolysis. Embolectomy may be considered, but recent data demonstrate that in these critical patients, ECMO plus anticoagulation often (73%) improve pulmonary angiographic obstruction and recover RV function by allowing intrinsic thrombolysis to occur over 3–5 days, without needing thrombolysis or surgical or catheter-based embolectomy.[63] Many high-risk PE centers favor ECMO over surgical embolectomy, considering the high surgical mortality. ECMO is valuable whenever thrombolysis is contraindicated or fails to stabilize hemodynamics. Catheter embolectomy is not expedite enough in extreme hemodynamic compromise and PEA arrest, where thrombolysis or ECMO is more appropriate.

Answer 9. A. The clinical presentation is clearly explained by severe pneumonia with septic shock and ARDS. PE is small, peripheral, and incidental and not the cause of hemodynamic compromise. More importantly, **isolated subsegmental PE** is often a false positive finding with intra- and inter-individual variability in reporting. So, when the overall picture is not consistent with PE, those small possible PEs may not warrant anticoagulation (per ACCP), particularly in this anemic patient with higher bleeding risk; consider lower extremity venous ultrasound and repeat CT scan a few days or weeks later.

Answer 10. A. This patient has submassive or intermediate-high risk PE, with clinical signs of severity (shock index of 1 [SBP/pulse], mildly reduced SaO_2) and abnormal RV by imaging and biomarkers. It is not massive, as there is no persistent hypotension (he only had transient hypotension/syncope). Based on the PEITHO trial, systemic thrombolysis does not improve mortality or long-term dyspnea or pulmonary hypertension (which is rare even in submassive PE, ~3–4%), and the risk of deterioration is only 5% with standalone anticoagulation. The patient is only considered for thrombolysis or mechanical thrombectomy in 24–48 hours, in case of persistent or deteriorating pre-shock state. In the setting of head trauma, thrombectomy is preferred to thrombolysis if deterioration occurs. Even with a normal head CT, head trauma translates into a higher risk of intracranial bleed with thrombolysis. Saddle PE is an imaging description that implies a high thrombus burden but does not directly correlate with clinical severity and does not dictate thrombectomy or thrombolysis per se; most such patients have normal hemodynamics and respond well to simple anticoagulation, and the saddle description is much inferior to the clinical classification in predicting outcomes.[64,65]

Answer 11. C. Antiphospholipid syndrome is the only high-risk thrombophilia where NOACs are inferior to warfarin; NOACs may even be used in cancer and HITT, but not antiphospholipid syndrome. The goal INR is 2–3. In case of recurrent DVT/PE while on therapeutic warfarin, or in case of elevated baseline INR, warfarin is adjusted according to factor X activity (reduce it to 25–35%). Moreover, antiphospholipid testing must be repeated at 3 months to confirm antiphospholipid syndrome.

Questions and answers 583

1. SHOCK IN GENERAL AND SEPTIC SHOCK

See Chapter 39 for ventricular support devices.

I. Shock definition and mechanisms

Shock is defined as sustained hypotension *along with* evidence of low tissue perfusion (oliguria <30 ml/h for 1 hour, cold or mottled extremities, altered mental status, or elevated serum lactate level >2 mmol/L). Hypotension is usually defined as a mean systemic pressure <65 mmHg or a systolic pressure <90 mmHg for over 30 minutes, or requirement for catecholamine infusion to maintain systolic pressure ≥90 mmHg.[1–6] Systemic pressure may be higher in shock patients with chronic hypertension; a decline in systolic pressure of >40 mmHg is commonly used to define hypotension in the previously hypertensive patient. Based on modern data, SCAI defines shock as *clinical hypoperfusion rather than hypotension*; hypotension is not necessary for the definition of shock and early shock may be normotensive.

There are 4 *mechanisms of shock*: (1) hypovolemia; (2) cardiac pump failure, as in left or right cardiogenic shock; (3) vasodilatory shock, also called distributive shock (septic shock, anaphylactic shock, shock from excessive amount of sedatives and vasodilators); (4) obstructive shock, where LV filling is prevented by a right-sided obstruction, such as pulmonary embolism, tamponade or severe PAH.

Right heart catheterization establishes the shock mechanism by assessing the 3 determinants of shock (Table 22.1):

1. Right- and left-sided filling pressures (CVP, PCWP). The normal CVP is <8 mmHg. If CVP <8 mmHg, particularly <4 mmHg, and PCWP <15 mmHg in a patient with shock, there is likely a hypovolemic component of the shock.
2. Cardiac output (CO). The normal cardiac index is 2.2–4.0 L/min/m^2. If cardiac index <2.2 → cardiogenic component of the shock
3. Systemic vascular resistance (SVR). Normal SVR is 700–1500 dyn.s.cm^{-5}. If SVR <1000 in shock → vasodilatory component of the shock

Clinically, left heart cardiogenic shock is defined as a shock with clinical or radiographic evidence of pulmonary congestion, or with the following combination on right heart catheterization: cardiac index <2.2 L/min/m^2 + PCWP >15 mmHg.[1,2]

Some shock states may be mixed. In septic shock, one may have a hypovolemic component and a cardiogenic component with reduced myocardial contractility, the so-called septic cardiomyopathy, seen in as many as 30–50% of cases. Furthermore, in septic shock, cardiac output needs to be high enough to match the increased tissue demands and the vasodilated circulation, and to compensate for the

Table 22.1 Hemodynamic findings in the 4 different types of shock.

	CVP	PCWP	Cardiac index	SVR	SvO_2
Hypovolemic	↓	↓	↓	↑	↓
Cardiogenic	↑	↑	↓	↑	↓
Low SVR	↓	↓	↓, normal, or ↑	↓	↓, normal, or ↑[b]
Obstructive[a]	↑	↓	↓	↑	↓

[a] Disproportionately elevated PA pressure and CVP in comparison to PCWP suggest pulmonary embolism or precapillary pulmonary hypertension.
In tamponade or isolated RV shock, equalization of CVP and PCWP is often seen.
[b] In septic shock, SvO_2 may be low early on before fluid resuscitation and before CO eventually rises. SvO_2 then rises in the hyperdynamic maldistributive phase.

maldistribution of flow. In septic shock, while blood flow to the tissues is increased, the microcirculation of injured tissue is plugged and there is tissue edema. As such, blood and O_2 do not reach the most injured tissue and are rather diverted to hyperperfuse less injured tissue within the same organ, or blood is shunted via AV communications; this is the maldistribution of flow within the same organ. ***A cardiac output that is "normal" in absolute value may be inappropriate in the context of septic shock; this is suggested when tissue perfusion is low (lactic acid ↑) despite normalization of the systemic pressure***.

While cardiogenic shock is classically described in patients with acute large MIs, it is also seen in patients with chronic severe cardiomyopathy and decompensating factors, such as acute infection, tachyarrhythmia, excessive vasodilators or sedation, cases where the limited cardiac output reserve cannot match the dilated circulation. In addition, volume overload, by itself, increases ventricular filling pressures, which reduces myocardial perfusion and contractility; and it increases afterload, which further reduces cardiac output.

In the SHOCK trial of cardiogenic shock secondary to acute MI, 20% of patients had reduced CO and elevated PCWP but relatively low SVR (<1000). This was related to a concomitant infection or to a systemic inflammatory response associated with nitric oxide release in cardiogenic shock.[7] In cardiogenic shock, SVR increases to maintain systemic pressure; SVR that is "normal" in value in the absence of vasodilator therapy is, in fact, relatively low.

A shock state with a wide pulse pressure is characteristic of septic shock, AI, or any vasodilatory condition (cirrhosis, vasodilatory drug excess).

Always remember adrenal shock (Addisonian shock), in which 3 mechanisms of shock are present (hypovolemia, low SVR, and myocardial depression). Importantly, functional adrenal failure may result from septic shock. Also, consider adrenal shock in patients who are acutely sick and who have been receiving chronic steroid therapy; their chronically suppressed adrenal glands cannot generate stress doses of steroids.

II. Goals of shock treatment

Increase mean arterial pressure (MAP) to >65 mmHg *and* provide good tissue perfusion, manifested as:[6]

- Urine output >0.5 ml/kg/h, with a stable creatinine.
- Reduction of lactate levels by ≥20% at 2-hour intervals, eventually to <2 mmol/L.
- Mixed venous O_2 saturation (SvO_2) ≥65–70%.
- Sinus rate <120 bpm.
- Warm skin with capillary refill ≤2 seconds.

One study addressed a target MAP of 65–70 mmHg vs. 80–85 mmHg in septic shock and found no difference in mortality and overall adverse events, except for more AF in the higher MAP arm (from higher vasopressor doses). Only in patients with underlying chronic hypertension did the higher MAP goal reduce the incidence of severe renal failure and the requirement for acute dialysis.[8]

Note on SvO_2 and cardiac power output

SvO_2 is the mixed venous O_2 saturation, which is the O_2 saturation of the venous return, best sampled from the pulmonary artery (PA being the chamber where the venous blood achieves its best mixing from all sources). It may also be appropriately sampled from an SVC line. It is the result of O_2 delivery to the tissues minus O_2 consumption by the tissues. If O_2 delivery does not match O_2 demands, O_2 extraction will be high, which reduces the venous O_2 content and SvO_2.

SvO_2 is thus a marker of how well O_2 delivery matches O_2 consumption, and a guide to appropriate shock therapy. It is affected by 3 factors: CO, hemoglobin, and arterial O_2 saturation. In the absence of anemia or hypoxemia, a low SvO_2 <60–65% implies that the cardiac output is inappropriate, even if high in absolute value.

In septic shock, despite increased CO, there is maldistribution of flow within the same organ, wherein the most injured and hypoxic tissue is hypoperfused (microvascular plugging, tissue edema preventing O_2 delivery) while blood gets diverted to the healthier tissues. This functional O_2 shunting causes SvO_2 to be normal or high despite tissue hypoxia. SvO_2 may be low early on before fluid resuscitation and before CO rises; SvO_2 then rises in the hyperdynamic maldistributive phase. A high SvO_2 despite shock and despite high lactic acid is suggestive of distributive shock.

Both an adequate mean arterial pressure and an adequate cardiac output are required for end-organ perfusion; this is represented by the cardiac power output (CO × mean arterial pressure/451).

In summary, 2 variables reflect the appropriateness of CO: (1) SvO_2 correlates with how well CO matches tissue O_2 demands; (2) cardiac power output correlates with how well CO matches the systemic vascular resistance.

III. Sepsis and septic shock

Sepsis is defined as end-organ dysfunction caused by a dysregulated response to an infection. Sequential organ failure assessment (SOFA) score quantifies this organ dysfunction and consists of 6 organ system variables: renal function, PaO_2/FiO_2 ≤300, hypotension, mental status, platelet and bilirubin levels. To define sepsis, SOFA score ≥2 is required, i.e., severe abnormality of 1 variable or moderate abnormality of 2 variables.[9] In addition, serum lactate level reflects tissue hypoxia and is used in the early management of sepsis. The term "severe sepsis" is no longer used, as all sepsis cases are severe.

Septic shock is a subset of sepsis defined as persistent hypotension (mean BP ≤65 mmHg or SBP <90 mmHg), refractory to 1–2 L of fluid resuscitation and requiring vasopressors, with lactate levels >2 mmol/L.[9]

The Surviving Sepsis guidelines recommend **aggressive early (≤1 hour) treatment in septic shock but also in sepsis with lactate ≥2 mmol/L, even without hypotension.** This is the **"hour-1 bundle"** of sepsis therapy.[10,11] As such, 1–2 L of crystalloid fluids is recommended within the first hour, and 30 ml/kg within the first 3 hours. If the patient remains hypotensive despite 1–2 L of fluids within 30–60 minutes, vasopressors are quickly initiated to target a mean arterial pressure ≥65 mmHg, as in the ProCESS trial.[3–6] The CENSER trial further validated early low-dose norepinephrine in the first hour. Additional fluid boluses are guided by the 30 ml/kg target—while monitoring for clinical congestion—or alternatively, by fluid responsiveness parameters.[6] Hypoperfusion is monitored clinically and via serial 2- or 4-hour lactate levels ("lactate clearance").[6]

Hemodynamic mechanisms in septic shock

In septic shock, 3 vascular processes occur: (i) systemic vasoplegia from inducible NO, (ii) venous dilatation that increases venous capacitance and reduces venous return, (iii) microcirculatory flow reduction and maldistribution. The latter is due to microvascular plugging with inflammatory cells and microthrombi, but also to capillary leak and tissue edema, which impairs O_2 delivery to tissues. Although tissue blood flow and O_2 delivery are increased, they do not reach injured tissues because of microvascular plugging and are rather shunted via AV communications or directed to less injured tissues; this is the ***maldistribution of flow within the same organ at the microcirculatory level, wherein the most injured and hypoxic tissues are hypoperfused while the healthier tissues are hyperperfused*** (heterogeneity of blood flow, e.g., within the intestines, kidney, liver, myocardium). Less importantly, this maldistribution of flow may also occur between organs at the macrovascular level: flow to the injured splanchnic tissues is poor, while flow to skin, muscle, and fat is sometimes increased (although skin flow is commonly impaired in a patchy fashion with skin mottling and delayed capillary refill time). In addition, there is cellular dysfunction and impaired tissue O_2 uptake. All this explains why septic patients may have severe tissue hypoxia and lactic acid elevation despite high cardiac output and O_2 delivery, and despite normal or high mixed venous O_2 saturation (O_2 is shunted away from suffering tissues). In fact, a high SvO_2 with high lactic acid is suggestive of distributive shock; even more, the higher the SvO_2 >70–80% in a patient with persistently high lactic acid, the worse the prognosis of septic shock.[12,13] CO_2 continues to diffuse to the venous bed in those suffering tissues, and as such, an arterio-venous difference of P_{CO2} >6 mmHg is a good prognostic marker of tissue hypoxia in septic shock, better than SvO_2.

Cardiac output needs to be high enough to match the increased tissue demands and the vasodilated circulation, and to compensate for the maldistribution of flow (maintain flow to the selectively hypoperfused tissues). Fluid resuscitation is required to fill the dilated arterial circulation and to compensate for the venous pooling and capillary leak. Transient myocardial depression *with EF reduction occurs in ~50% of patients, but CO remains high and is maintained by tachycardia and LV dilatation*. Stroke volume = LVEDV × EF: if EF is 30%, but LVEDV dilates to 230 ml and heart rate increases to 130 → CO = (230 × 0.3) × 130 is ~9 L/min. This is a common scenario in septic shock.

Septic shock goes through 2 or sometimes 3 hemodynamic phases: (i) initial hypodynamic phase with *underfilled circulation, hypovolemia*, and normal or low cardiac output, where SvO_2 is reduced; then (ii) the full-blown *hyperdynamic* phase, particularly after fluid resuscitation, with high CO and high SvO_2, even if tissue ischemia persists; EF is commonly depressed despite the high CO; (iii) a late *hypodynamic myocardial* phase in patients who develop profound myocardial depression and a low cardiac output state, where SvO_2 declines again: this occurs in a small subset of septic shock, and may be more likely in patients who do not mount a compensatory LV dilatation that raises stroke volume, or those with prolonged septic shock and prolonged hyperdynamic state and sinus tachycardia for several days, where the myocardium eventually succumbs to the high preload and the catecholamine toxicity.[14]

IV. Pitfalls in septic shock fluid management

- Serum lactate is a marker of tissue hypoxia but may also result from increased glycolysis without hypoxia in a high catecholamine state. Serum lactate is not a specific marker for sepsis and should not be used to justify aggressive fluid administration. Lactate may increase in HF decompensation.
- The 30 ml/kg early fluid recommendation is derived from what was used in the 3 modern trials of early, clinically guided sepsis therapy. However, no controlled data support this exact number. In those trials, ~5 L was given in the first 6 hours.[3–5]
- Patients without a definite diagnosis of sepsis whose symptoms may be explained by HF, or patients with evidence of fluid repletion, such as peripheral edema (e.g., combined HF-sepsis or sepsis decompensating HF) should not receive this aggressive fluid resuscitation and may rather be treated straightaway with inopressors and diuretics.
- ***Beyond the first 24 hours, a restrictive rather than a liberal fluid strategy, with fluid de-escalation and diuresis, is associated with improved outcomes.*** This was shown in ARDS net trial (patients were randomized at a mean of 43 hours after ICU admission, and 35% were in shock).[15] The CLOVERS trial demonstrated that implementing a ***restrictive fluid strategy even earlier in septic shock (within 3–4 hrs, median ~60 min)—after the initial 1–3 L of fluids*** (median ~2 L)—is safe and yields mortality, renal, and respiratory outcomes similar to a liberal strategy.[16] The restrictive arm prioritized early vasopressor uptitration and halted fluid boluses and maintenance beyond the first 1–3 L. Yet, 250–500 mL boluses were still permitted for refractory hypoperfusion: the restrictive arm received ~1.2 L of fluids within 24 vs. 3.5 L in the liberal arm (after the initial ~2 L). The CLASSIC trial produced similar findings in septic shock <12 hrs (1–7 hrs). Outside of sepsis, the RELIEF trial also showed that a restrictive strategy in the first 24 hrs after major abdominal surgery resulted in similar mortality to a liberal approach (albeit with a slightly higher AKI risk).

- Regarding fluid administration in sepsis:
  - *Fluid boluses are aggressively administered the first 1–3 hours, to establish perfusion ("rescue" phase).
  - *Fluids are then maintained at a slower, steady rate in the first 3–24 hours, to maintain perfusion ("optimization" phase). CLOVERS and CLASSIC trials suggest the safety of fluid restriction in this time window.
  - *Fluids are de-escalated ("de-resuscitated") beyond the first 24 hours aiming for a negative fluid balance, possibly with the help of diuretic therapy as in the ARDS net trial (diuretics are avoided if ongoing septic shock). Even non-cardiogenic pulmonary edema benefits from this restrictive fluid strategy/diuresis. Fluids are aggressively used in the first day to fill the dilated, leaky circulation and establish perfusion but have by now leaked into the extravascular space, more so as the intravascular system constricts and shrinks in volume, which causes pulmonary edema and tissue ischemia (tissue edema impedes O_2 transport to cells and causes ischemia).[17] In fact, over 85% of the volume of administered crystalloids redistributes to the extravascular space in 2–4 hours.
  - *Diuretics are not always necessary in the late phase of sepsis. At around day 3, as vascular system constricts and capillary leak declines, neurohormonal renal stimulation is reduced, which may lead to *spontaneous diuresis* (the "flow" phase of sepsis).[17] Vascular constriction is a 2-edged sword that leads to worsening tissue edema, but also to increased renal flow and diuresis.
  - ***Beyond the first 1–3 L or first 1–3 hours, fluids are better restricted and titrated based on dynamic measures of fluid responsiveness*** (Section 3).[6] Short of that, generally aim for conservative fluid management beyond 24 hours.

V. Immediate management of any shock, focused on septic shock

The shock and the volume status are quickly classified by history and physical exam, with a focus on (Figure 22.1):

- Cardiac history.
- Pulmonary edema, elevated JVP, and peripheral edema, which are signs of volume overload. Unlike pulmonary edema, peripheral edema does not necessarily preclude fluid resuscitation *acutely* in cases of septic or hemorrhagic shock.
- Fever and potential sources of infection.
- ECG, chest X-ray, and quick ultrasound interrogation of the jugular vein, lungs, and heart are performed.

A. Intravenous fluid boluses

In the absence of pulmonary edema, a fluid bolus of 1–2 L is quickly administered in less than an hour (<20 minutes for the first liter) (PRoCESS trial).[3] Fluid administration is the first therapy of hypovolemic and low-SVR shocks; patients who have peripheral edema or elevated JVP are hypervolemic and are generally not fluid responsive, but may *occasionally* be fluid responsive at the onset of septic or hemorrhagic shock.

Beyond the first 1–2 L: (i) more fluids may be administered concomitantly with vasopressors until normal perfusion occurs *or* until signs of fluid repletion develop, such as elevated JVP >10–12 cm[3,18] (ii) Preferably, fluids may be restricted and given based on dynamic maneuvers of fluid responsiveness.

B. If the patient remains hypotensive despite the quick initial 1–2 L of intravenous fluids or if signs of fluid repletion are present (elevated JVP, pulmonary edema, decreased O_2 saturation)

1. Norepinephrine or, less favorably, dopamine is started (norepinephrine ≥0.05 mcg/kg/min, dopamine ≥3 mcg/kg/min). These 2 drugs are effective whether the shock is cardiogenic or distributive, until more is figured out. **Vasopressors are best started early, simultaneously to fluids, after 1–2 L have been administered.** Fluids may then be restricted, *or* continued until signs of fluid repletion develop.[16]

2. In a cardiogenic context, inotropes are administered: dobutamine is started at 3 mcg/kg/min if SBP >80 mmHg, whereas norepinephrine or dopamine is started if SBP <70–80 mmHg. Dopamine may be administered at 3–10 mcg/kg/min (at this level, dopamine has mixed α + and β + effects, $\beta + > \alpha +$).

3. In a septic context, vasopressors are administered: norepinephrine (mixed α + and β + effects, that is, vasoconstrictive and inotropic effects), followed by vasopressin, then phenylephrine (pure α + effect, without β + or inotropic effect).

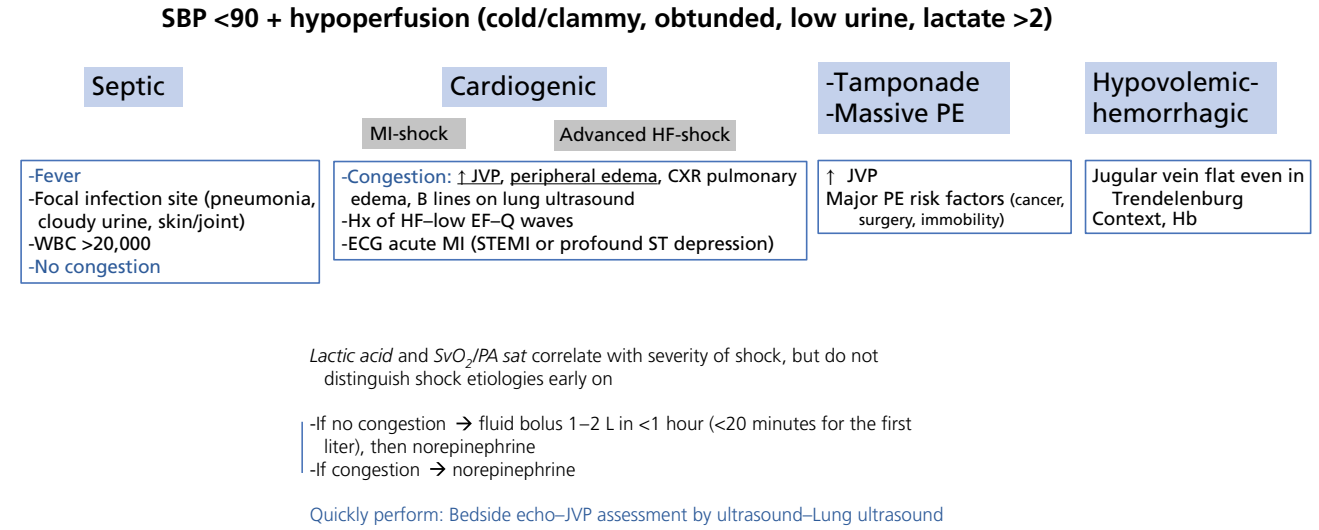

Figure 22.1 Approach to shock. Bedside ultrasound assists in management (echo, jugular vein, lungs).

4. At this point, along with these initial measures:
- A central venous line is mainly used if peripheral access is insufficient. CLOVERS showed that vasopressors may be safely administered via a peripheral access.[16] In equivocal cases, it may be placed to monitor CVP and help assess the volume status and SvO_2. A pulmonary artery catheter (Swan-Ganz) is not routinely needed and has not improved outcomes in any of the following settings: acute lung injury with or without septic shock (ARDS net trial), septic shock and/or acute lung injury (French PAC trial), all critically ill patients (PAC-MAN trial), and severe HF (ESCAPE trial).[19–22]
- An arterial line is not mandatory; it has not been mandated in the modern sepsis trials, and it is suggested but not mandated by the sepsis guidelines. It may be used for BP monitoring in any shock requiring inotropes and/or vasopressors (weak recommendation).
- Echocardiography is performed.
- If the diagnosis remains in doubt and the patient does not improve despite the initial measures, a PA catheter may be placed to diagnose the mechanism of shock and pulmonary edema. It is also valuable in cardiogenic shock, to guide therapy.

C. In the context of septic shock, if low perfusion signs persist despite achieving the target systemic pressure and despite a presumably normal volume status

Assess fluid responsiveness and give 500 ml fluid challenge, over 30 minutes, if the patient is fluid responsive (may repeat it). If not fluid responsive, consider that the cardiac output or the systemic pressure is still inadequate even if normal or high in absolute value. At this point, inotropes may be administered, primarily if the LV or RV is significantly depressed on echo (Figure 22.2).

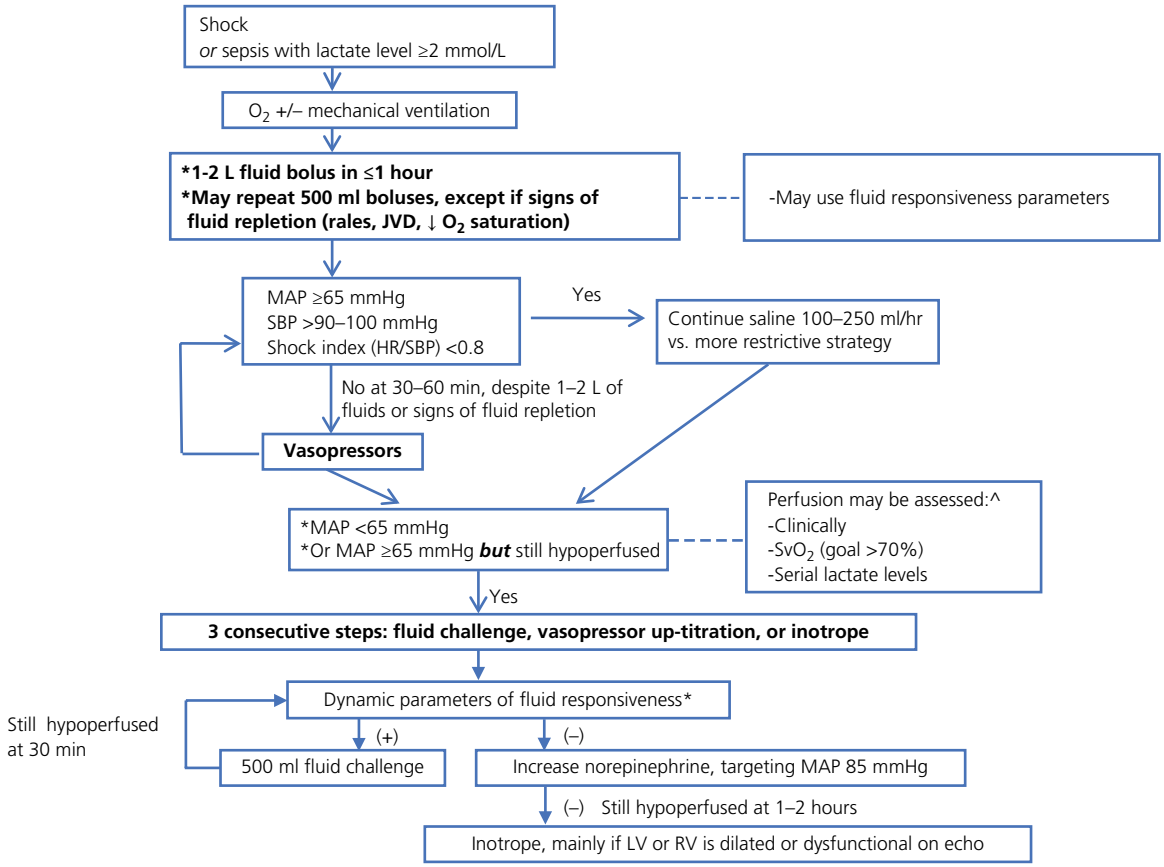

Figure 22.2 Aggressive early therapy of septic shock (the first 3 hours). The old term "early goal-directed therapy" implied the use of a central venous line with monitoring of CVP and SvO_2, but this is not necessary.

^Perfusion may be monitored via:
- Clinical parameters of hypoperfusion: oliguria, mottled skin, capillary refill time >3 seconds, altered sensorium.
- Lactate clearance: a reduction of lactate levels ≥20% at 2-hour intervals suggests an improvement in tissue perfusion.
- SvO_2: SvO_2 >70% suggests proper tissue perfusion in the hypodynamic early hours of sepsis, but not later on

****Fluid responsiveness is assessed via:***
- Aortic VTI or pulse pressure variation with positive ventilatory pressure in patients mechanically ventilated (≥15% or 13%, respectively → fluid responsive); or IVC collapse >15%
- Aortic VTI or pulse pressure variation with passive leg raising for 30–60 seconds in patients breathing spontaneously or mechanically ventilated (>15 or 10%, respectively →fluid responsive)

This algorithm is inspired by the ProCESS and ANDROMEDA trials.[3,6] MAP, mean arterial pressure.

D. Provide adequate oxygenation (arterial O_2 saturation >90–95%), and adequate hemoglobin level

Intubate and mechanically ventilate in the case of any respiratory distress or obtundation. Respiratory effort can consume up to 30% of the cardiac output. Mechanical ventilation, by relieving the work of breathing, helps improve tissue perfusion.

In the absence of acute hemorrhage, red blood cells should only be transfused when hemoglobin decreases to <7–7.5 g/dl, with a target hemoglobin level of 7–9 g/dl (TRICC and TRISS trials).[23,24] The original trial of early goal-directed therapy used a target hemoglobin level of 10 g/dl in the first 6 hours of resuscitation; however, this did not prove necessary in 3 later early resuscitation trials.[3–5]

In septic shock, steps A–D should lead to reversal of hypotension and good tissue perfusion **within 3 hours of starting therapy** (= early sepsis therapy).[3–6,18] CVP and SvO_2 may be used as a guide to therapy, as in the first trial of early goal-directed therapy.[18] However, this is not necessary, and reliance on clinical parameters of perfusion is often sufficient, as shown in 3 other trials of **early, clinically guided sepsis therapy** (ProCESS, ProMISE, and ARISE trials) (Figure 22.2).[3–5]

E. Perform a quick workup in parallel to the previous steps

ECG, chest X-ray, BNP, cardiac biomarkers, complete blood count, and blood/urine/sputum cultures are obtained. Line infections are considered, and in case of doubt, lines older than 48 hours are removed and replaced. Infectious foci are sought (e.g., abdomen, joints, skin).

Bedside echocardiography is performed:

- Echocardiography rules out tamponade, cardiogenic shock from LV failure, acute valvular disorders, and massive PE with acute RV failure.
- Echocardiography helps determine:
  - RA, LA, and PA pressures, which help guide fluid therapy.
  - Fluid responsiveness. Significant variability of aortic VTI with mechanical ventilation or passive leg raising implies fluid responsiveness.

F. Start empiric broad-spectrum, one or several antibiotics whenever there is any suspicion of sepsis (start the antibiotics within 1 hour of this suspicion)

Treat the potential source of infection (e.g., drain any abscess, remove central lines).

G. Administer stress doses of steroids for a shock that persists several hours despite high doses of at least 1 vasopressor, or for the patient who uses steroids chronically

2. CARDIOGENIC SHOCK DEFINITION, STAGES, AND MANAGEMENT

I. Definition[25–28]

Shock is defined **as hypoperfusion, using a combination of clinical and biomarker features (lactate, acute kidney injury, shock liver).** More specifically, *an elevated lactate >2 mmol/L* is the backbone of the SCAI definition of true shock (***true shock = SCAI stage C = classic shock***). Congestion with hypotension <90 mmHg, tachycardia, low SvO_2, or low cardiac index <2.2 L/min/m^2 *but without elevated lactate* is consistent with pre-shock (***SCAI stage B***): ***patients with chronic severe HF, or acute-on-chronic HF, frequently have chronically impaired hemodynamics, such as a cardiac index of 1.8 L/min/m^2 and low SBP of 90 mmHg, yet normal lactate and ALT***. This is because of the chronic increase in peripheral O_2 extraction which compensates for low CO (and which translates into low mixed venous O_2 saturation). Hence acute-on-chronic HF shock better tolerates hemodynamic compromise than acute MI shock.

Most patients with shock, i.e., clinical hypoperfusion, are hypotensive. However, ***hypotension (SBP <90 mmHg) is not necessary for the definition of shock***: patients with hypoperfusion and preserved BP (*early shock*) have a higher risk of death than patients with hypotension and preserved perfusion (pre-shock); the highest mortality is in patients with hypoperfusion and hypotension (9% vs. 17% vs. 38%, respectively).[25,28]

ESC guidelines concur and state that hypoperfusion is more important than SBP <90 mmHg and that low SBP is not a prerequisite for defining shock. There is a *"normotensive shock"* with profound evidence of hypoperfusion and tissue hypoxia by lactate levels. Moreover, low cardiac output is not enough to define hypoperfusion and shock; there should be profound evidence of cellular hypoperfusion, mainly high lactate, or elevated ALT (>200 U/L), or less specifically, oliguria and AKI (creatinine >1.5× baseline); in those patients, BP is maintained by severe vasoconstriction.

II. SCAI stages[25,26]

Shock requires inotropic or mechanical support (***SCAI stage C = Classic***, *baseline lactate 2–5 mmol/L*). If perfusion does not improve then normalize with small-to-medium doses of 1 vasoactive agent or with 1 mechanical device—i.e., if the patient requires multiple vasoactive agents, high doses of one vasoactive agent, or both a drug and a mechanical device, ***SCAI stage D (= Deteriorating)*** is present (lactate is frequently >5 mmol/L, ALT is >500, patient is nearly anuric). If shock continues to deteriorate despite the latter escalation (high doses of multiple vasoactive agents, plus 1 or 2 mechanical devices), ***stage E (= Extremis)*** is present; the patient is typically unconscious with lactate >10 mmol/L (Figure 22.3, Table 22.2).

Also, consider the **trajectory**: the management of a stage D shock with lactate of 4 and SvO_2 of 50% while on IABP and 2 vasoactive agents depends on the preceding course of those parameters (improving vs. deteriorating). ***The longer the shock persists***, the more it evolves from a **hemodynamic stage *to a* metabolic stage *with progressive irreversibility of end-organ dysfunction***: hemodynamic correction at this late stage will not prevent the irreversible metabolic damage. **Early upscaling of hemodynamic treatment** is key to survival.

III. Categories

Consider the **2 major categories of cardiogenic shock (Figures 22.4, 22.5, Table 22.3): *(i) acute MI*** (type 1 MI, typically STEMI or large NSTEMI with ongoing significant ST elevation or ST depression) vs. ***(ii) acutely decompensated chronic HF***. The latter has on average

- **Stage B = Pre-shock** congestion + borderline or low BP with normal lactate
  Impaired invasive hemodynamics: PCWP >15 +/– low CI <2.2 L/min/m^2+/– low SvO_2 <60%

- **Stage C (Classic) = Hypoperfusion + congestion + often hypotension SBP <90**
  Lactate >2 (2–5) or ALT >200
  Requires 1 vasoactive drug OR 1 mechanical support device and stabilizes
  + Swan-Ganz catheter

- **Stage D (Deteriorating) = Hypoperfusion + hypotension are persistent, do not improve then normalize with:** small-to-medium dose of 1 vasoactive agent OR 1 mechanical device
  Lactate 5–10 or refractory or worsening
  Or ALT >500 U/L
  Or Urine further declining ~anuric

  Requires, with upscaling : ≥2 vasoactive agents OR high dose of 1 vasoactive agent OR 1 drug + 1 device or upscaling mechanical device

- **Stage E = Extremis = Deteriorating despite**
  - High doses of multiple vasoactive agents
  - AND 1 or 2 mechanical devices (≥3 drugs and/or 3 devices)
  OR SBP <60, lactate >10 , pH <7.2, anuric – Often unconscious

Figure 22.3 SCAI shock stages. A low cardiac output or low BP with preserved perfusion (lactate, ALT, renal function) is classified as pre-shock (stage B), not shock. Stage C may be further divided in C1 (hypoperfusion with preserved SBP >90mmHg) and C2 (hypoperfusion with SBP <90 mmHg).

Table 22.2 Practical illustration of SCAI shock stages with examples.

INITIAL classification of shock upon initial assessment:
- Initial stage C: lactate 2–5 mmol/L
- Initial stage D: lactate 5–10 or ALT >500
- Initial stage E: lactate >10 or SBP <65 or pH <7.2 (those lactate values do not apply to post-cardiac arrest patients)

Depending on TRAJECTORY, you RE-CLASSIFY. Examples:
- Initial stage C stabilizes on 1 medium inopressor dose, and lactate trends down or normalizes, but is still requiring 1 inopressor: remains stage C
- Initial stage C but lactate is trending up, or you need to escalate inopressor → becomes stage D. In the interim, before knowing whether the patient will stabilize on this inopressor, shock may be called "late-stage C" and MCS is reasonable for that, especially in STEMI.
  Shock would be early-stage D if it stabilizes with 1 higher inopressor dose or 2 medium inopressor doses, vs. more advanced stage D if it keeps destabilizing or keeps requiring higher doses. Regardless, this stage, as well as "late-stage C," benefit from MCS within a few hours of onset (<24 hours), particularly Impella CP in STEMI shock.
- Initial stage D stabilizes with 2 inopressors and lactate is trending down: remains stage D as long as 2 inopressors are required for stabilization. Consider MCS. But this is better than the stage D that requires further up-titration of drugs.
- If a third drug or a combo of 3 is required (e.g., 2 drugs and 1 device), this is stage E.
- If initial stage E stabilizes quickly on 2 drugs, or 1 drug + 1 device, and lactate is trending down: becomes stage D (or even C if only 1 drug or 1 device is used). If shock stabilizes but only with a combo of 3–4: remains stage E, until you down-scale to 2 or less.

MCS is reasonable for late-stage C, OR initial or subsequent stages D and E as long as it is implemented within a few hours (<24 hours) of destabilization.

lower EF, lower CO, higher PA pressure, and similar or lower BP, but chronic adaptive cellular O_2 extraction allows a lower lactate level and a much better acute prognosis (in-hospital mortality ~50% for MI shock vs. 26% for non-MI shock).[25,26,29,30]

Acute MI shock is defined as shock with **profound *and* persistent ST abnormality**, rather than the mere presence of underlying multivessel CAD or severe troponin elevation, the latter being highly prevalent in any cardiogenic shock. In fact, **the only 2 shock trials that showed a benefit from an early intervention solely recruited STEMI patients**, rather than NSTEMI or decompensated HF: (i) the original SHOCK trial, which showed a benefit of revascularization; and (ii) the DanGer shock trial, which showed a benefit of Impella CP.[31] ***Shock from cardiomyopathy with severe left main/3-vessel CAD but no ongoing type 1 MI, i.e., no ST elevation or persistent profound ST depression, does not require immediate revascularization (this is often decompensated HF shock rather than acute MI shock).*** *Indeed, the patient may have transient ST depressions secondary to shock and underlying CAD (type 2 MI)*. In this case, diurese and optimize the shock before PCI to reduce PCI risk (improve LVEDP and SBP before PCI). PCI may acutely aggravate HF and shock for the following reasons:

i. Supine positioning and contrast loading increase preload, LVEDP, and myocardial ischemia
ii. Procedural sedation
iii. PCI causes intermittent myocardial flow impairment from balloon inflation, difficult stent delivery, no reflow, side branch loss, or reperfusion injury. This is particularly pronounced if the guiding catheter partially occludes the coronary ostium with ventricularized pressure, and it will not be tolerated if LVEDP is elevated or BP is borderline.

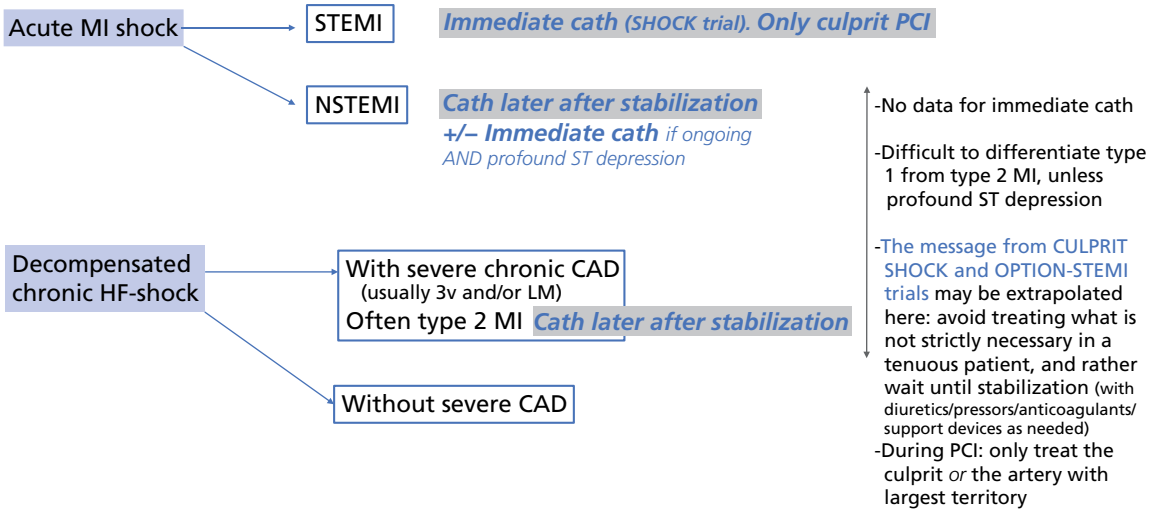

Figure 22.4 The 4 major categories of shock. The only subgroup with proven benefit from immediate angiography and revascularization is STEMI shock. No trial specifically addressed NSTEMI shock.

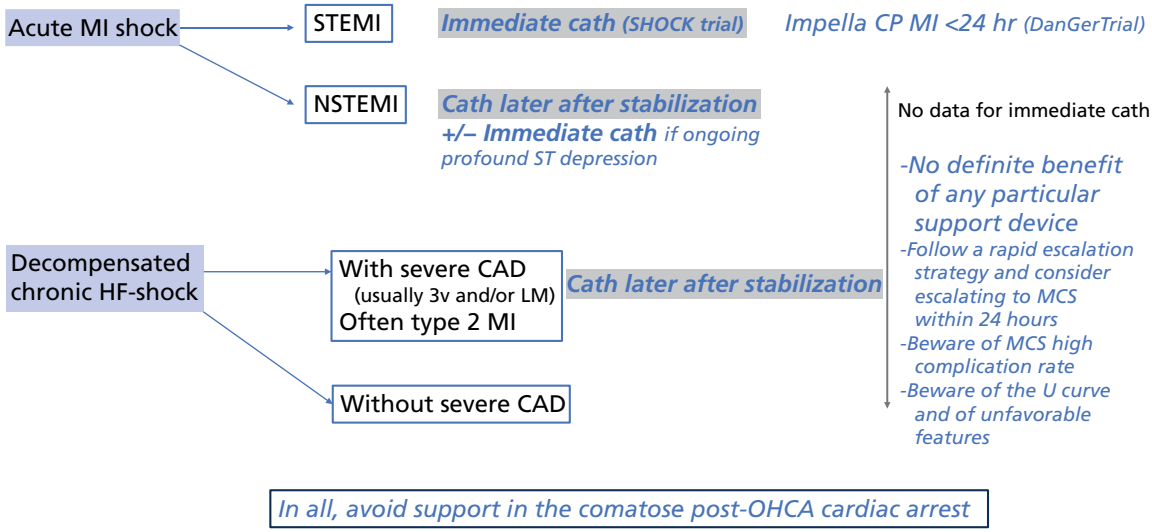

Figure 22.5 Further expansion of Figure 22.4, the 4 major categories of shock. The only subgroup with proven benefit from immediate revascularization and from Impella support device is STEMI shock. No trial specifically addressed NSTEMI shock.

Table 22.3 Causes of cardiogenic shock.

1. Acute MI: shock is related to LV dysfunction (~75%), RV shock, mechanical complication (~12%)
2. Cardiogenic shock without acute coronary event:
   - Chronic ischemic or non-ischemic cardiomyopathy (progressive), especially with decompensating factors: acute infection, arrhythmia, excessive sedation or vasodilator therapy, cases where the limited cardiac output reserve cannot match the dilated circulation. Also, volume overload, by itself, increases ventricular filling pressures and reduces myocardial perfusion and cardiac output.
   - Acute cardiomyopathy: fulminant myocarditis or stress cardiomyopathy
   - Acute valvular disease, especially valvular insufficiency
   - Fast and prolonged tachyarrhythmia, or inappropriate bradycardia
   - Prolonged cardiopulmonary bypass (post-pump shock)

IV. Treatment[26,27]

A. Acute revascularization (Figures 22.4, 22.5)

Management differs according to the 2 shock categories: ***acute MI shock*** requires immediate coronary angiography + reperfusion. Only treat the culprit artery, not multiple vessels: only treat what is strictly necessary in a tenuous patient. The message from the CUPRIT SHOCK trial is that the quicker the PCI during ongoing shock, the better is the outcome.

On the other hand, ***decompensated chronic HF*** without evidence of ongoing large type 1 MI, i.e., *without ongoing ST elevation or profound ST depression*, does not require immediate angiography or revascularization, *even in a patient with underlying left main/3-vessel CAD*; rather, diurese and optimize the shock then revascularize more electively, which allows the patient to better tolerate PCI.[26] The message from CULPRIT SHOCK and OPTION-STEMI trials may be extrapolated here: avoid treating what is not strictly necessary in a tenuous patient, and rather wait until stabilization (with diuretics/pressors/support devices as needed). The CAD may be a stabilized NSTEMI in case of transient profound ST depression, but is more often chronic CAD causing chronic cardiomyopathy, with additional triggers prompting shock and type 2 MI (e.g., AF, infection, salt indiscretion).

In clinical trials, the mortality of MI shock had not changed since the initial SHOCK trial and remained at ~50%: acute culprit artery revascularization improved it by 13%, from ~63% to 50%. Only Impella in STEMI-related shock with no out-of-hospital cardiac arrest further reduced mortality by 13% (DANGER shock trial). There was no benefit of IABP in IABP-SHOCK II, or multivessel revascularization in the CULPRIT-SHOCK trial, or ECMO in the ECLS shock trial.

B. Four sequential steps

Aside from coronary angiography, 4 sequential steps are used in the management of cardiogenic shock (Figures 22.6, 22.7): (1) volume management (diuretics) for stage B and possibly for normotensive stage C, (2) small-to-medium doses of an inotrope/vasopressor for stage C, then (3) short-term mechanical circulatory support (MCS), then (4) up-titration of inotropes/vasopressors and upscaling of the MCS, as needed.

Inopressor selection – *SBP <80 mmHg or predominant RV shock → Norepinephrine

*SBP >80 mmHg → Dobutamine or milrinone (no bolus, start low drip)

Mechanical circulatory support – MCSs likely have a ***U-shape benefit****:* no benefit in inotrope-responsive shock stage C, and possibly no benefit after many hours or days of deteriorating shock stage D with high doses of inopressors, at which time the multiorgan injury is irreversible (Figure 22.8). As such, **MCS does not need to be initiated early in stage C patients responsive to a moderate inotrope dose, but it needs to be quickly initiated within 1–2 hours if there is no early response to inopressors: quickly escalate to MCS, do not wait until the next day, i.e., until the irreversible metabolic phase of shock!** Depending on shock severity and progression, a higher-level MCS may need to be initiated or quickly escalated to (IABP < Impella < ECMO). RV support may also be considered, particularly if RV parameters remain impaired despite LV support.

In fact, the main goal of shock algorithms is to ***escalate therapies and MCSs quickly and sequentially in less than a few hours, guided by lactate (Q2 hours) and invasive right heart cath hemodynamics, with a focus on Impella CP in STEMI-related cardiogenic shock <24 hours.*** Only 2 interventions have shown a mortality benefit in shock, specifically STEMI-related shock: culprit revascularization and Impella CP. Otherwise, no one specific therapy has improved outcomes per se; rather, it is the rapid, protocol-driven escalation that improves outcomes.

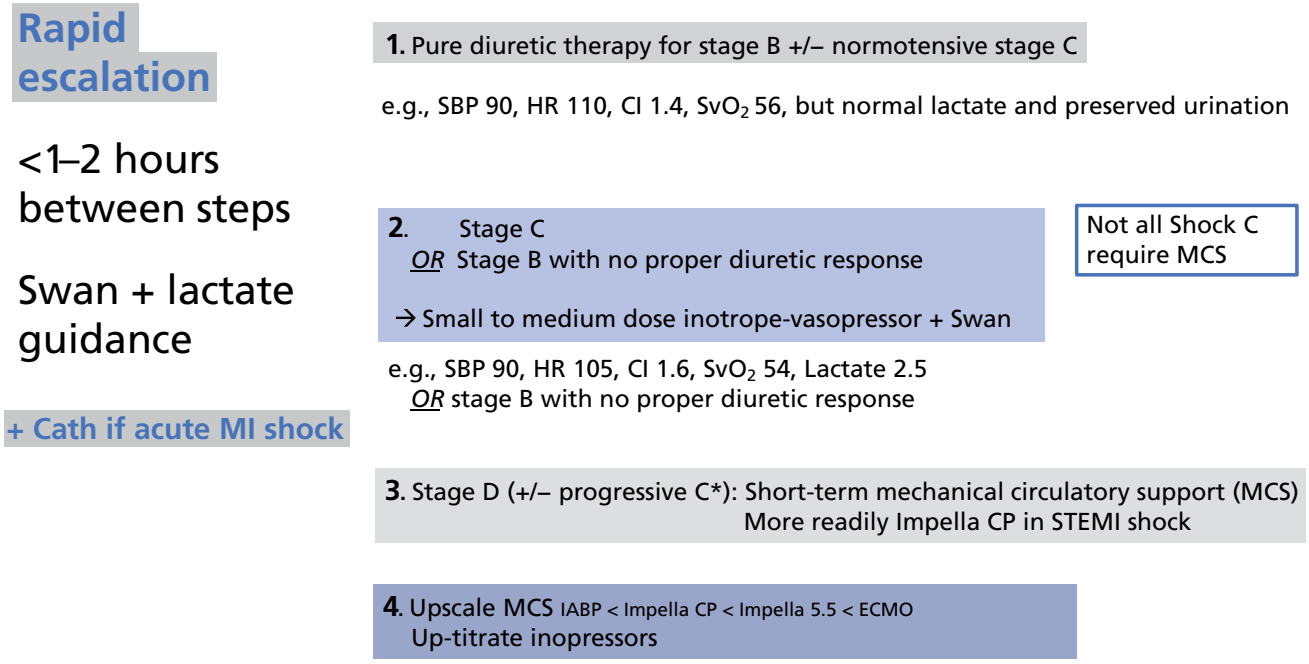

Figure 22.6 Rapid therapy escalation in cardiogenic shock. Inotropic agents are initiated in hypotensive stage C, or in stage B unresponsive to diuretics. Impaired invasive hemodynamics, per se, are not an indication for inotropic therapy.

Swan catheter is critical in stage C and beyond, mainly to guide the timely escalation of therapy (based on PCWP, CPO, and RV parameters: RA pressure and PA pulsatility index).

Grading of norepinephrine doses: low dose, <0.1 mcg/kg/min; medium, 0.1–0.5 mcg/kg/min; high, >0.5 mcg/kg/min. Grading of dobutamine dose: high, >5 mcg/kg/min.

*For initial stage C with uptrending lactate during inopressor titration, and before knowing how quickly the patient will stabilize, shock may be called "late-stage C" and MCS is reasonable for that, especially in STEMI.

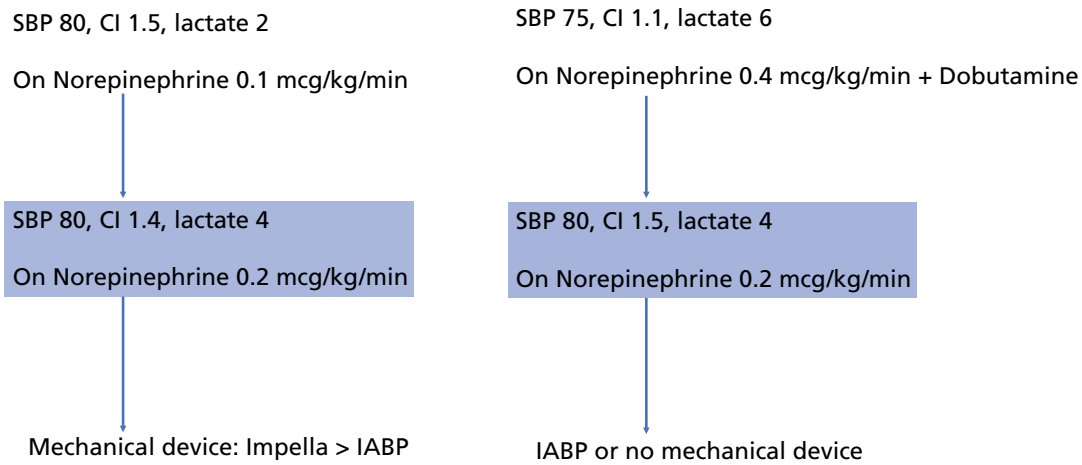

Figure 22.7 Two patients with similar hemodynamics (*blue boxes*), but different trajectories. On the left, shock is stage D with a deteriorating trajectory, hence LV support is warranted with Impella CP. On the right, the shock is stage D but improving, hence less mechanical support or no mechanical support is needed.

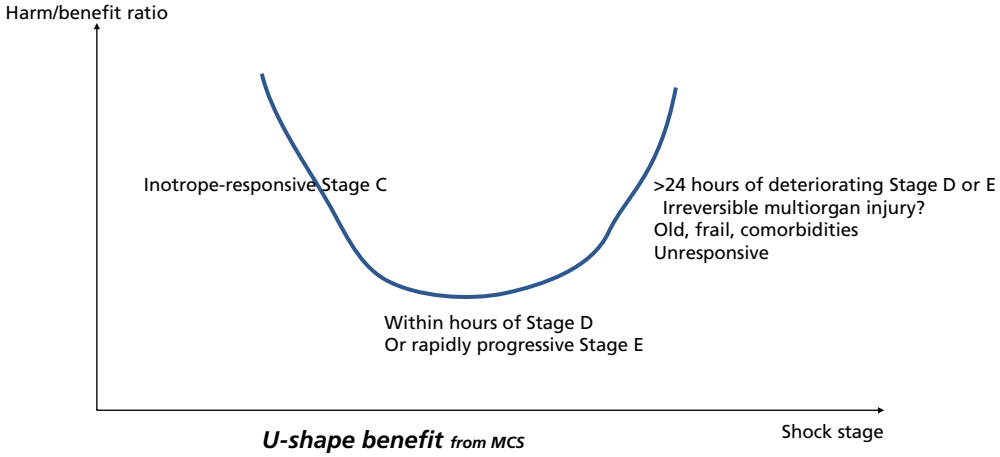

Figure 22.8 U-shaped benefit from MCSs: no benefit in inotrope-responsive shock stage C, and possibly no benefit after many hours or days of deteriorating shock stage D with high doses of inopressors, at which time the multiorgan injury is irreversible *(metabolic stage of shock)*. Also, the benefit is questionable in older patients >75–80 with many comorbidities.

MCSs have **pitfalls:**

1. IABP improves CO by up to 0.8 L/min only, is dependent on a rise of intrinsic LV CO, and does not reduce LV workload. Impella CP unloads the LV while providing an output of up to 3.5 L/min (the worse the LV, the higher the Impella output). It is placed through a transfemoral route or, if severe PAD is present, a transaxillary route. The main risks of Impella are hemorrhagic and ischemic vascular access complications, and hemolysis.

2. IABP failed to improve outcomes in the IABP-SHOCK II trial.

3. ECMO failed to improve outcomes in 2 major trials (ECLS-SHOCK and ECMO-CS).

4. Impella CP reduced mortality in STEMI shock (DanGer trial), but was associated with a significant increase in bleeding and vascular complications, and on subgroup analyses, *no benefit was seen in women and potential mortality harm was noted in patients older than 77*.

These MCS pitfalls prevent them from being first-line therapy, but they remain indicated *early on* if low or medium inopressor dose fails and the patient has favorable survival features. Account for the U curve and for the patient's age (especially >75), neurologic status (Coma Scale <9, i.e., absence of motor response to voice → unfavorable), duration of shock (shock progressing >24 hours → unfavorable), and baseline comorbidities and frailty.

C. How to choose MCS? LV predominant vs. RV predominant vs. biventricular shock

1. For predominant LV shock, consider the following devices, in order of LV support: IABP < Impella CP < Impella 5.5 (surgically placed via axillary artery) < VA-ECMO with LV unloading. ***In STEMI shock*** requiring support, Impella CP is favored as initial MCS. ***In decompensated HF shock***, the higher the pressor requirement and lactate level, and the lower the CPO, the more Impella CP or 5.5 is favored as initial MCS (vs. IABP).

2. For biventricular shock, LV support may be initiated, and hemodynamics reassessed. If shock persists after LV support (refractory lactate, pressors, CPO <0.6), consider these 2 scenarios:

a. RV parameters are severely impaired (PA pressure index <1, RA pressure >15–20 mmHg): place Impella RP or Pro-Tek Duo or VA-ECMO.

b. RV parameters are not severely impaired: escalate LV support (Impella 5.5, VA-ECMO).

D. Swan catheter is critical in stage C and beyond. It often has more of a therapeutic value than a diagnostic value, and mainly serves to *guide the timely escalation of therapy*:

- Monitor the treatment response of: PCWP, cardiac index, SvO_2, and cardiac power output CPO (= CO × mean BP/451)
- Assess the response of RV parameters (RA, PA pulsatility index, RV stroke work), and whether RV support is needed
- Select the specific MCS based on the severity of CPO and cardiac index impairment, as well as RV parameters

Cardiac power output (in Watts, or Joules/s) is a variable that integrates CO but also the pressure generated by the heart, i.e., how much the heart can overcome the peripheral vascular resistance. In other words, cardiac power is the energy rate generated by the heart into the systemic vasculature. Cardiac power output in Watts = (flow × pressure) = (CO × mean systemic arterial pressure)/451. Normal cardiac power output at rest is 1 Watt and increases with stress up to 6 Watts. It is considered significantly abnormal when <0.6, and it was the most powerful hemodynamic predictor of outcomes in the SHOCK trial.

PA pulsatility index is a strong marker of RV failure, as good or better than RA/PCWP in many studies. PA pulsatility index = PA pulse pressure/RA pressure. The worse the RV function, the smaller the RV stroke volume (PA pulse pressure) and the higher the RA pressure, so much that, at one point, RA pressure exceeds PA pulse pressure. A value <1.85 is abnormal, and <0.9 implies severe RV failure (<0.9 is validated in MI shock).

E Heart rate management: brady- and tachyarrhythmias

A patient with shock is expected to be tachycardic. In fact, tachycardia attempts to raise an inappropriately reduced cardiac output. A "normal" heart rate of 50–70 bpm is inappropriate in shock and may dictate temporary pacing.

Tachyarrhythmias: The heart rate that provides the highest CO in the acutely ill is ~100–110s for decompensated HFrEF and 100–120s for HFpEF. As explained in Chapter 4, in HFrEF, the maximal CO seems to be achieved with a HR ~100–110s bpm in sinus rhythm or AF (Bowditch revisited trials). Beyond this rate, CO often does not rise because of the loss of Bowditch effect in the energy and metabolically depleted systolic HF; hence contractility declines at higher rates.

AF should be acutely rate controlled to <120 bpm. Non-permanent AF should ideally be cardioverted in cardiogenic shock, especially in low EF with AF rate >120 bpm. Even if it is not the direct cause of the shock, AF is an aggravating factor. Cardioversion improves heart rate and thus LV energetics, and also improves CO, not so much by restoring the marginal atrial kick, but by making the heart rate regular: for the same rate of 100 bpm, a regular 100 bpm generates a higher CO compared to irregular 100 bpm (up to 18% higher).[32] Yet, DC cardioversion is plagued by the hazard of sedative drugs and a high risk of immediate AF recurrence in acute HF. Hence pharmacological cardioversion with IV amiodarone may be the more realistic option. Amiodarone is also, usually, a top rate-control option in shock, besides IV landiolol (± digoxin, which is less effective in high catecholamine states).

F. Mechanical ventilation

Most patients with cardiogenic shock are mechanically ventilated, as in various shock trials (~75–80%). Respiratory effort can consume up to 30% of the cardiac output, hence mechanical ventilation helps improve tissue perfusion, besides reducing LV preload and afterload. This is particularly important in patients about to undergo PCI, as PCI further aggravates HF and oxygenation early on (supine position, sedation, PCI's coronary flow interruptions). Unless respiratory distress and O2 saturation quickly improve with IV furosemide, intubate the patient before PCI to avoid full-blown decompensation during PCI.

V. Additional notes regarding Impella CP, timing of Impella insertion, IABP, and ECMO

Impella CP dramatically improves mortality in select STEMI-related cardiogenic shock. The DanGer trial randomized very select STEMI patients with cardiogenic shock <24 hours, SBP <100 mmHg, and lactate >2.5 mmol/L undergoing primary PCI to Impella CP vs. standard therapy (PCI and inopressors).[31] Resuscitated out-of-hospital cardiac arrest was excluded unless the patient was responsive. These are some salient features: median lactate 4.6 (3.4–7), median EF 25% (15–30), shock mostly stages C (56%) and D (28%), duration of symptoms ~4 hours (2–12 hours), anterior MI 71%, median SBP 84 mmHg (72–91), median age 67 (58–76), resuscitated cardiac arrest ~20%, multivessel CAD 71%, Impella placed before PCI in 47% of patients overall (and in 85% of patients randomized before PCI). By very selectively choosing STEMI shock that is recent and severe, not prolonged and not post-prolonged cardiac arrest, Impella CP reduced 6-month mortality from 58% to 45%. More benefit was seen in patients with mean BP <63 mmHg or multivessel CAD. Mortality was mainly reduced in patients randomized within 12 hours of symptom onset, ***potential harm was noted in patients older than 77*** *(52% higher mortality trend with Impella)*,[33] and no benefit was seen in women (partly because of smaller LV and smaller femoral access, but mainly because women were older and presented later). Impella was used for a median of 60 hours (30–87 hours). VA-ECMO was required in 12% of the Impella arm and 18% of the conservative arm. ***Impella increased survival at the cost of a much higher complication rate among survivors:*** major bleeding 22% vs. 12%, acute dialysis 42% vs. 27%, limb ischemia ~5.5% vs. 1%, and more sepsis. The higher need for dialysis is partly because more patients survived, but also potentially because of hemolysis; none of the dialyzed patients continued to require dialysis at 6 months.

Timing of Impella insertion in STEMI undergoing primary PCI – For a shock that is deteriorating and requiring more than medium inopressor doses, it is reasonable to place Impella before PCI as an early measure to stabilize the patient, unload the LV and reduce its O_2 demands, and perform a safer PCI with better tolerance of PCI's coronary flow interruptions and less reperfusion injury. For a shock stabilizing on low or medium inopressor doses, Impella may be placed after PCI, or not at all if hemodynamics continue to improve (inopressor dose stable or down-titrated).

IABP – IABP failed to improve survival in MI shock in the IABP-SHOCK 2 trial, partly because ~45% of patients were post-cardiac arrest and 33% had NSTEMI. Nonetheless, the *routine* use of IABP in MI shock is given a class III recommendation in the ESC and ACC ACS guidelines.

Decompensated HF-shock appears to derive more benefit from IABP than MI-shock. In fact, IABP improves SvO_2, cardiac power output, and PCWP in decompensated HF-shock,[33] whereas the effect is limited in MI-shock (ISAR-SHOCK trial). This is likely related to the following: (i) HF-shock is more afterload sensitive than MI-shock, as LV is more dilated in HF-shock (hence more wall stress, which equals more afterload); (ii) HF-shock is more severely vasoconstricted than MI-shock, where inappropriate vasoplegia may be present.[34] However, Altshock-2 trial failed to show a survival benefit of early IABP in HF-shock, compared with upscaling inopressors to medium/high doses before inserting IABP or higher MCS.[35] Only 13% of the latter patients required IABP and 4% required higher MCS.

No benefit of routine or immediate ECMO in stages C, D, or E cardiogenic shock, but a rapid escalation strategy remains appropriate *(inopressors followed by rapidly progressive but not immediate MCS)* – The ECLS-SHOCK trial randomized MI patients with cardiogenic shock stages C to E and lactate >3 mmol/L (median ~7) to immediate ECMO in the cath lab vs. medical therapy. ECMO was placed after PCI (52%) or before it. Shock was stage C (50%), D (18%), or E (32%). In the medical therapy group, 12% required ECMO and another 15% received another MCS, mainly Impella CP. Mortality was similar in both groups (~49%), and more complications occurred with ECMO (more bleeding [23% vs. 10%] and severe ischemic vascular complications). Notably, only 5.8% of ECMO patients received venting, and this was considered only in the following cases: no aortic waveform pulsatility, no aortic valve opening on echo, or increasing LV diameter/volume on echo.[36] Importantly, there were 2 major caveats in the patients included: 78% were post-cardiac arrest, 1/3 were NSTEMI, and the median EF was 30%; this is unlike the DanGer shock trial, which focused on pure MI shock by selecting STEMI and by excluding post-cardiac arrest cases.

Similarly, the ECMO-CS trial failed to show the benefit of immediate ECMO vs. a strategy of inopressor escalation followed by MCS (shock stage D or E secondary to MI or decompensated HF). The 2 groups had the same high mortality rate (~50%), with large trends toward less bleeding, leg ischemia, and stroke in the conservative arm. The 42% of conservative patients who eventually required ECMO had similar mortality (52%) to the immediate ECMO patients (50%), with no signs of harm from waiting.[37]

VI. How to wean and explant Impella and any MCS

A. Criteria to wean (Table 22.4)

Similarly to the aggressive escalation of shock therapies, de-escalation of devices and drugs is sought after 1–2 days of patient stabilization, as the longer a device is in place, the more complications occur. Danger shock maintained full support for 48 hours before attempting to wean, and Impella support was kept for a median of 60 hours. Three categories of hemodynamics are followed closely in any shock patient:[38] (i) systemic perfusion (lactate), which is initially checked every 1–2 hours during escalation, then once lactate is trending down and hemodynamics have stabilized, it is checked every 12–24 hours; (ii) systemic hemodynamics, meaning BP and BP pulsatility >30 mmHg; and (iii) invasive Swan hemodynamics. Echo may help and may be used as the 4th parameter (improvement of LV/RV sizes and contractility, MR/TR improvement).

When the patient meets the 3 axes of hemodynamic criteria on small doses of 1 ± 2 inopressors, the MCS support may be weaned down (Table 22.4). If the favorable hemodynamic criteria continue to be met despite minimal device support for 2 hours, the device is ready to be explanted.

B. Protocols of weaning Impella and IABP

There are 2 Impella weaning methods:[38] (i) slow weaning, wherein the power P level (e.g., P8) is reduced by ~2 P levels every 4 hours to reach P2; (ii) fast weaning, wherein support is reduced by ~2 P levels every 5–10 minutes quickly to P2. Slow weaning is most used and is best for advanced HF shock, or MI shock with less LV recovery on echo. Fast weaning may be considered in acute MI with excellent LV recovery on echo.

At each level of weaning, recheck the 3 major hemodynamic categories (lactate, BP pulsatility, invasive CO/SvO_2/PCWP/RA). If they deteriorate, resume full support for 24 hours and re-attempt weaning 24 hours later; address the cause of failure (e.g., more diuresis, small vasodilator dose).

If hemodynamics remain stable at low support level, the device may be explanted. Stop anticoagulation and explant Impella once ACT <160 seconds.

Regarding IABP, it is weaned from 1:1 support to 1:2 for 2 hours, then 1:3 for 2 hours. If the hemodynamic parameters remain stable after >1–2 hours (several hours) of 1:3 support, IABP may be removed after stopping anticoagulation (1:1 support is maintained while anticoagulation is off).

Table 22.4 Criteria to wean then explant Impella and any MCS.

*Patient must be on ≤ low-dose inopressors (1 ± 2)
*FiO_2 <40% with PEEP <10 or extubated
*Normalized perfusion and hemodynamics on high Impella support level:
1. lactate <2 mmol/L, urine >30 ml/hr
2. SBP >90 mmHg with aortic and pulmonic pulsatility despite continuous flow pump (aortic pulsatility >30 mmHg)
3. SvO_2 >55%, cardiac index >2.2, CPO >0.6, RA and PCWP only mildly abnormal (<12 and <18)
4. ± May use echo RV and LV parameters (LVOT VTI >10–12 cm, ↓ MR/TR, reduced LV-RV size, and ↑ contractility compared to baseline)

The double arrow indicates the 3 categories of hemodynamic measures that need to be met and evaluated regularly in any shock patient.

C. In patients who are mechanically ventilated, should the patient be extubated before removal of Impella/IABP?
An argument may be made for either strategy:

- Extubation while on Impella or IABP support: during extubation, both LV preload and LV afterload significantly rise, and as such, MCS relieves the stress of extubation and increases its success.
- The counterargument is that patients are more likely to tolerate MCS removal if they are intubated with proper O_2 supply and low work of breathing, and more likely to remain still in a supine position during device removal (sedated). This strategy is more frequently followed, including in DanGer shock, where duration of mechanical ventilation was, on average, significantly longer than Impella support.

VII. Mixed septic-cardiogenic shock

There are 2 potential clinical scenarios.

A. Septic shock in a patient with underlying cardiomyopathy
Case example: 65 years old, SBP 80, oliguric, obtunded. History of EF 30% with old anterior Q waves and LVH on ECG, but no congestion (normal JVP, no peripheral edema, no diffuse B lines on lung ultrasound). Fever 101° F, WBC count 21 with bandemia. CXR shows alveolar right lower lobe opacities, increased interstitial markings, and no pleural effusion.

Discussion: During septic shock, LV must increase its output to fill the massively dilated circulation (low afterload) and to compensate for the *maldistribution of flow*.

With underlying HF, CO reserve is limited; CO does not rise appropriately to match the dilated circulation; hence it is easier to be in shock during sepsis. This is septic shock facilitated by the heart.

CO may be normal or low normal in absolute value (e.g., CI 2–2.2 L/min/m^2), but inappropriate with increased lactate level. There is usually no need for LV mechanical support, but the standard aggressive early fluid resuscitation of 1–2 L is avoided, and the patient may rather be treated straightaway with inopressors and diuretics. If the patient is not congested clinically and has a normal JVP with positive fluid responsiveness parameters, a gentle fluid amount may be used early in the first few hours only, but <1–2 L.

Right heart catheterization may help in select cases where the cardiac vs. septic contributions to shock are unclear. In mixed shock, CO is low or low normal but inappropriate for shock, and SVR is low and inappropriate for shock (<800–1000 IU).

B. Septic shock with secondary acute septic cardiomyopathy
Case example: 65 years old, SBP 80, oliguric, obtunded. No cardiac history and no clinical congestion. Fever 101° F, WBC count 21. CXR shows alveolar right lower lobe opacities, increased interstitial markings, and no pleural effusion. Echo shows global LV and RV dysfunction with EF of 30%. He has new AF with a ventricular rate of 140s bpm.

Discussion: Regardless of prior cardiac history, septic shock is commonly associated with **septic cardiomyopathy** (30–50%). This EF decline is secondary to: (i) the septic shock's cytokines; (ii) the high catecholamine toxicity, particularly when sinus tachycardia persists for days; and (iii) sometimes the aggressive fluid resuscitation, as the LV poorly tolerates volume overload and high-output state, particularly an LV insulted by cytokines, hypoxia, and malperfusion. (iv) It may also be aggravated by **acute AF**. This acute cardiomyopathy usually recovers within 5–10 days and is **frequently associated with normal or sometimes high CO**: CO is normal or high because of sinus tachycardia and LV dilatation, which maintains stroke volume despite low EF. Sinus tachycardia, when mediated by a persistently high catecholamine state >24 hours, may become counterproductive and lead to more myocardial depression and decline of BP; hence in one small trial of septic shock patients with persistent rate >95 bpm at >24 hours, from a persistent hyperdynamic phase of shock, esmolol paradoxically improved lactate, stroke work, norepinephrine requirements, and mortality (Morelli et al. JAMA 2013; 310: 1683). Later trials, however, were largely neutral and questioned this benefit.

A more advanced acute cardiomyopathy may be seen in 2 cases: (i) myocarditis that is secondary to the same viral illness; (ii) late hypodynamic phase of septic shock seen in a small subset of patients.

Management is similar to scenario A: avoid aggressive fluid resuscitation and rather treat straightaway with inopressors and diuretics. *Administer amiodarone for rate control (<120 bpm) and to potentially cardiovert*; electrical cardioversion is marred by the risk of sedation and the high probability of early recurrence; hence amiodarone or Landiolol is usually the best treatment option. *Rarely, if CO is profoundly reduced with CI <1.5–2 L/min/m^2, particularly with associated* myocarditis*, LV support may be needed (Impella or ECMO)*. IABP is unlikely to be helpful as afterload is generally reduced in this mixed shock.

3. FLUID RESPONSIVENESS

Fluid responsiveness addresses the improvement of cardiac output (>10%) with fluid administration. In chronic systolic HF, PCWP >15 mmHg or CVP >8 mmHg predicts the lack of fluid responsiveness; in diastolic HF or acute systolic HF, PCWP >20 mmHg predicts the lack of fluid responsiveness (Chapter 5). In fact, diuresis may improve cardiac output in these cases. However, ***while CVP and PCWP are helpful in establishing the mechanism of a shock and treating HF and cardiogenic shock, they only weakly predict fluid responsiveness outside HF***, particularly when they are not severely reduced or severely elevated (e.g., CVP between 4 and 12 mmHg). In addition, a high CVP does not rule out volume responsiveness in a critically ill patient (e.g., sepsis, trauma) who does not have a history of systolic HF, especially if atrial, venous, or ventricular compliance is impaired, as is sometimes seen with hypoxia (Figure 22.9). Thus, some patients with a normal or high CVP are fluid-responsive, while many others with a low CVP are not and are better managed with a conservative fluid strategy. In the ***ARDS net trial*** of patients with acute lung injury +/– shock, a conservative fluid strategy *beyond 24 hours* of presentation led to better ventilatory and pulmonary outcomes than a liberal fluid strategy. The CVP goal was 4–8 mmHg in the conservative arm (depending on hypoperfusion) vs. 10–14 mmHg in the liberal arm. PCWP goal was 8–12 mmHg in the conservative arm vs. 14–18 mmHg in the liberal arm. Furosemide was recommended to most patients in the conservative strategy even if they had signs of hypoperfusion (except if persistent shock and requirement for vasopressors), and the fluid balance was maintained slightly negative.[15]

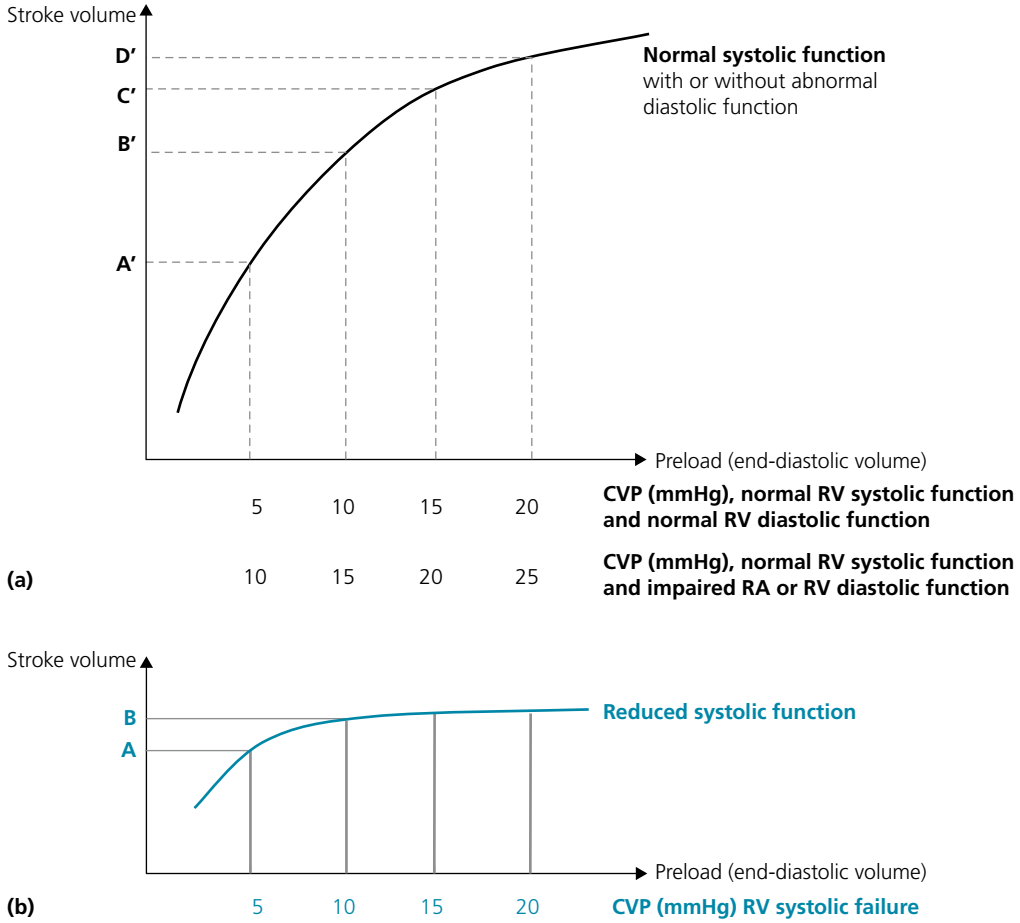

Figure 22.9 Relationship between stroke volume and CVP. A true Frank–Starling curve is the relationship between stroke volume and preload measured as volume rather than pressure. Preload volume and CVP do not linearly correlate, and their relationship depends on ventricular and atrial compliance. In fact, the same preload volume corresponds to a higher CVP value in patients with impaired ventricular or atrial compliance.

In patients with normal systolic function (*upper figure*), stroke volume continues to increase even when CVP rises from 10 to 15 and 20 mmHg, as the ventricle has a steeper Frank–Starling curve (*A*′ to *B*′ to *C*′ to *D*′); this is more marked if ventricular or atrial compliance is impaired. In patients with abnormal systolic function (*lower figure*), stroke volume does not significantly increase with a change in CVP from 5 to 10 or 20 mmHg (*A* to *B*), as the ventricle is already on a flat portion of the Frank–Starling curve.

Outside HF and cardiogenic shock, fluid responsiveness is better assessed using the dynamic response of stroke volume and systemic arterial waveform *to positive pressure ventilation* in mechanically ventilated patients or *to passive leg raising* in both mechanically ventilated and spontaneously breathing patients.

During mechanical ventilation, the positive intrathoracic pressure reduces cardiac output in patients who are fluid-responsive, and analysis of the respiratory change in stroke volume or systemic arterial waveform is very helpful in addressing fluid responsiveness.[6,39] If the ventricles are on the steep portion of the Frank–Starling curve, a reduction in venous return reduces stroke volume, and thus the respiratory changes in venous return lead to respiratory fluctuations of the stroke volume. If the stroke volume varies by >15% with respiration or if the pulse pressure varies by >13% with respiration, the RV and the LV are sensitive to volume changes and are, therefore, volume-responsive.* On echocardiography, LVOT or aortic valve VTI velocity may be used as a surrogate of stroke volume;[40,41] in fact, stroke volume = (LVOT VTI × LVOT area) or (aortic VTI × aortic valve area).

While the respiratory fluctuation in stroke volume and systolic arterial and pulse pressure may reflect hypovolemia (pulsus paradoxus), this is not sensitive or specific enough in patients who are **spontaneously breathing**, have an active effort on the ventilator, or have an irregular rhythm.[42,43] In such patients, rely on the clinical evidence of hypervolemia (peripheral edema), and assess the change in stroke volume or pulse pressure after 30–60 seconds of passive leg raising or after a small volume load (500 ml). Passive leg raising-induced change in stroke volume, cardiac output, or pulse pressure reliably predicts volume responsiveness, whatever the breathing conditions.[44–46] An increase in cardiac output or stroke volume of >15% or a change in pulse pressure of >10% with passive leg raising suggests volume responsiveness; echocardiographic aortic VTI may be used as a surrogate of stroke volume. A decrease in CVP during inspiration may also

*Positive pressure reduces RV preload and the eventual cardiac output; because of the pulmonary transit time, the RV flow change gets transmitted to the LV a few heartbeats later, at the next respiratory cycle; thus, the lower stroke volume and arterial pressure coincide with the negative pressure. The stroke volume variation may be analyzed via the arterial pressure waveform using the FloTrac system.

predict fluid responsiveness in patients who are breathing spontaneously but not deeply (in severe RV failure, CVP increases with inspiration or remains unchanged rather than decreases [Kussmaul's sign]).[47,48]

As described in the prior paragraphs, **echocardiography** may be used to assess volume responsiveness. An increase in aortic VTI >15% with passive leg raising, but also an IVC diameter <1.2 cm, predicts volume responsiveness in spontaneously breathing or mechanically ventilated patients.[46,49] Furthermore, a change in aortic valve VTI >15% between inspiration and expiration or IVC collapsibility >15% predicts volume responsiveness in mechanically ventilated patients.[18,50,51] Patients who are mechanically ventilated tend to have a larger IVC diameter and reduced IVC collapsibility because of the positive intrathoracic pressure that impedes venous return; that is why 15% collapsibility, as opposed to 50% in spontaneously breathing patients, is considered a sign of volume responsiveness.[6,50] In any patient, whether spontaneously breathing or mechanically ventilated, a hyperdynamic LV with systolic cavity collapse or a hyperdynamic LV with intracavitary LV pressure gradient and SAM of the mitral valve implies hypovolemia, particularly hypovolemia associated with excessive use of inotropes. However, a small LV cavity may also be seen in overloaded patients with restrictive cardiomyopathy.

In patients who do not have an arterial line, the pulse oximetry tracing may be used to predict volume responsiveness. The plethysmographic waveform of pulse oximeters is a qualitative indicator of blood volume changes at the fingertip. One study suggested a correlation between pulse waveform variation provided by pulse oximetry and the invasive one; thus, pulse waveform variation predicts volume responsiveness in mechanically ventilated patients.[52] However, the pulse oximetry tracing is not useful in hypotensive patients whose finger perfusion is reduced.

Appendix. Hemodynamic equations, transfusion, and miscellaneous concepts

A. Hemodynamic variables and equations

- O_2 arterial content (ml O_2/dl) = SaO_2 × Hb × capacity of 1 g Hb to carry O_2 (=1.36 ml of O_2 per g of Hb)
- O_2 venous content (ml O_2/dl) = SvO_2 × Hb × 1.36
- O_2 delivery (ml O_2/min) = O_2 arterial content × CO × 10
- O_2 consumption (ml O_2/min) = (O_2 arterial content – O_2 venous content) × CO × 10. This is the *Fick equation*.
- CVP = RA pressure: normal <8 mmHg
- RA pressure and RV diastolic pressure are generally equal (in the absence of tricuspid stenosis or regurgitation)
- Pulmonary capillary wedge pressure (PCWP) = pulmonary artery occlusive pressure: normal ≤15 mmHg
- PA pressure: normal <35/15 mmHg, with a mean pressure <25 mmHg. PA diastolic pressure is normally equal to PCWP, unless precapillary pulmonary hypertension exists (as in lung disease, pulmonary vascular disease, or pulmonary embolism). In these cases, pulmonary arterial disease or vasoconstriction leads to a diastolic PA pressure that exceeds PCWP by >7 mmHg
- Cardiac index: normal >2.2 L/min/m^2
- SVR = (mean BP – CVP) × 80/cardiac output. Normal SVR: 700–1500 dyn.s.cm^{-5}
- PVR = (mean PA pressure – PCWP)/cardiac output. Normal PVR <2 Wood units

B. Peripheral edema that occurs after resuscitation means hypervolemia and signals the need to back off fluid resuscitation

Contrary to common belief, **the concept of "hypervolemia with intravascular volume depletion" is often untrue**. An overhydrated interstitium quickly refills a depleted plasma volume, as the low intravascular hydrostatic pressure and high intravascular oncotic pressure create a pressure gradient toward the plasma. Therefore, edematous patients have excess of intravascular volume and are non-responsive to fluid administration. Occasional exceptions are seen, such as at the onset of septic or hemorrhagic shock in a patient who previously had peripheral edema; because of the acute onset, the intravascular volume has not had time to equilibrate with the interstitial volume, and these patients are initially fluid-responsive despite hypervolemia. This may also occur in acute abdominal illnesses, cirrhosis with ascites, or immediately after abdominal surgery (when fluids tend to accumulate in the abdominal cavity).

C. SvO_2 vs. $ScvO_2$

Mixed central venous O_2 saturation ($ScvO_2$) represents SVC O_2 saturation and is normally lower than IVC O_2 saturation, which receives the high venous O_2 content of the renal veins (low renal O_2 extraction). SVC O_2 is thus slightly lower than the overall mixed venous O_2 saturation, i.e., SvO_2. However, in shock, a reversal of this relation occurs and $ScvO_2$ becomes greater than SvO_2 (by 5–10%). Redistribution of blood away from the splenic, renal, and mesenteric blood (IVC territory) toward the cerebral circulation (SVC territory) leads to this phenomenon (more O_2 extraction in the IVC territory: SVC O_2 > IVC O_2 and PA O_2). In septic shock, the SvO_2 early goal is >65% while the $ScvO_2$ early goal is >70%.

D. Colloid fluids (Dextran, Hetastarch)

In sepsis, colloid fluids have not been shown to be superior to crystalloid fluids (such as normal saline). In fact, colloid fluids lead to more renal failure, coagulopathy, and mortality than crystalloids.[53]

E. Types of crystalloid fluids

In comparison to normal saline, balanced crystalloids such as lactated Ringer have lower sodium concentration (130 mEq/l) and more importantly, a lower chloride concentration (109 mEq/l). The high chloride content of normal saline is associated with hyperchloremic metabolic acidosis and a higher risk of kidney injury (from chloride-induced renal vasoconstriction). A trial comparing normal saline and balanced crystalloids in critically ill patients has shown a lower mortality with balanced crystalloids, particularly in patients with sepsis or those requiring large volumes of fluids (SMART-MED).[54]

F. Corticosteroids in septic shock

In a modern corticosteroid trial, the combination of hydrocortisone and fludrocortisone, given for 7 days, has reduced mortality in the sickest patients with septic shock, i.e., who have required vasopressors for >6 hours (norepinephrine >0.25 mcg/kg/min), and who have severe failure of at least 2 organs (49% vs. 43%).[55] In another modern trial that recruited less severe septic shock, steroids did not reduce mortality

but reduced shock duration, mechanical ventilation, and length of stay in the intensive care unit. Steroids have a vasoconstrictive and salt-retaining effect, and attenuate the inflammatory toxin-related organ injury, thereby accelerating organ recovery and the resolution of shock. The Surviving Sepsis guidelines suggest using corticosteroids whenever a second vasopressor is being added. The corticosteroid doses considered in septic shock are: hydrocortisone 50 mg IV Q6 hours and fludrocortisone 50 mcg/day at least until the cessation of vasopressors.

G. Intensive insulin therapy

Intensive insulin therapy given to achieve a glycemic control of 80–110 mg/dl reduced mortality in an old trial of surgical ICU patients. However, in medical ICU patients and in patients with sepsis, aggressive insulin therapy to achieve a glucose level of <110 mg/dl has not been beneficial and has led to severe episodes of hypoglycemia. A glucose level of ≤180 mg/dl is, however, desirable.[53]

H. Note about inotropes and vasopressors

The SOAP II trial randomized patients with septic or cardiogenic shock to dopamine vs. norepinephrine. There was no overall difference in mortality, but dopamine was associated with twice the risk of AF (~20% vs. 11%) and VT, and more sinus tachycardia. Also, in the subgroup of patients with cardiogenic shock, norepinephrine was associated with better survival than dopamine.[56]

A meta-analysis of 6 septic shock trials showed greater mortality with dopamine than with norepinephrine.[57] Thus, norepinephrine is the drug of choice in septic shock, and in cardiogenic shock with severe hypotension.

Vasopressin can reduce the need for a high norepinephrine dose and is suggested in patients requiring a norepinephrine dose >0.15 mcg/kg/min. It is safe and may be associated with a mortality reduction in vasodilatory shock.[58]

CATS trial compared epinephrine to norepinephrine + dobutamine in septic shock. No difference was noted in mortality, time to hemodynamic stabilization, or adverse effects, including arrhythmia or myocardial injury.[59] Another trial compared epinephrine to norepinephrine in cardiogenic shock: epinephrine was associated with more refractory shock, tachycardia, and lactic acidosis.[59] The CAPITAL trial compared milrinone with dobutamine in cardiogenic shock, mostly SCAI stage C. There was no difference in mortality, hospital course, lactic acid, renal outcomes, or arrhythmias between the 2 drugs.[60]

I. Indications for transfusion

Three classic randomized trials addressed transfusion in critically ill patients (TRICC trial: all-comers in the intensive care unit; TRISS trial: patients with septic shock; gastrointestinal bleeding trial: patients with acute gastrointestinal bleed but without shock).[23,24,61] All 3 trials showed that using a Hb transfusion cutoff <7 g/dl, rather than 9 g/dl, is safe, and it was associated with a significant mortality reduction in the gastrointestinal bleeding trial and a strong trend toward mortality reduction in the TRICC trial.

A restrictive strategy (transfusion for hemoglobin <7.5 g/dl) has also been shown to be safe and non-inferior to a liberal transfusion strategy (hemoglobin <9.5 g/dl) in the immediate post-cardiac surgery setting, regardless of underlying EF; moreover, the restrictive strategy was superior to the liberal strategy in the subgroup of patients older than 75 (TRICS III trial).[62]

Regarding patients with acute MI (type 1 or type 2): a randomized trial, REALITY, suggested that a restrictive transfusion strategy (transfusion for Hb ≤8 g/dl) is as safe as a more liberal strategy (transfusion for Hb ≤10 g/dl) in patients with MI, most of whom underwent an invasive strategy.[63] However, the larger MINT trial suggested that a liberal transfusion for Hb 8–10 g/dl trended toward better outcomes than a restrictive transfusion for Hb <8 g/dl in patients with type 1 or type 2 MI (death-recurrent MI at 30 days 14.5% vs 16.9%, $p = 0.07$); the liberal strategy significantly reduced death/MI in type 1 MI.[64] As such, in patients with MI, a transfusion cutoff of 8 g/dl may be used, but a higher cutoff of 8–10 g/dl is considered in patients with ongoing angina, tachycardia/hypotension, or with planned complex revascularization. Consider 2 units of blood for Hb <8 g/dl, and 1 unit of blood at a time for Hb 8–10 g/dl.

The above thresholds apply to most patients. However, higher cutoffs (~9 g/dl) may be used in patients with ongoing major bleed (e.g., hemorrhagic shock). Beware of transfusion above these cutoffs for a presumed "symptomatic anemia": dyspnea and fatigue are non-specific, and as such, they are not, per se, strong indications for transfusion.

Anemia is associated with worsened outcomes in all settings and exacerbates myocardial ischemia in patients with CAD or ACS. Yet transfusion, by itself, does not always reverse this ischemia and leads to its own untoward effects. It increases volume overload in HF. The transfused red cells are different from intrinsic red cells without as much capacity for O_2 carrying (the longer they are stored, the worse they get). Plus, transfused red cells have potential prothrombotic (ADP release) and proinflammatory effects. In fact, while normal red blood cells transport and dispense nitric oxide to the microvasculature, this function is disrupted in transfused red blood cells, which leads to impaired regional vasodilatation.

The general approach adopted by the author is presented in Table 22.5.

Table 22.5 General indications for transfusion in critically ill or ACS patients.

1. In any critical illness, septic shock, or hemodynamically stable gastrointestinal bleed, a cutoff of 7–7.5 g/dl is appropriate.
2. In patients with active bleed and hemodynamic instability from bleeding, transfusion may be considered at a higher cutoff (8–10 g/dl).
3. In patients with severe tachycardia, especially sinus tachycardia (>110–120 bpm) that can only be attributed to anemia, transfusion may be considered at a higher cutoff (8 g/dl).
4. In ACS managed conservatively or invasively, a Hb cutoff of 8 g/dl is appropriate, but a higher cutoff of 8–10 g/dl is reasonable in certain subsets, such as severe ongoing angina, tachycardia/hypotension, or planned complex revascularization.
5. In all patients, the cause of a new anemia should be sought and treated (bleeding, hemolysis). In ACS, this cause is sought before performing any PCI and before the administration of antithrombotic therapy. For example, in a patient with acute Hb 8 g/dl and severe angina: transfuse, perform endoscopy, start proton pump inhibitor, and ensure Hb stability for a few days before PCI.

QUESTIONS AND ANSWERS

Question 1. A 44-year-old man with a history of LAD stent and a previously preserved EF presents with 1 week of fever and progressive dyspnea. He is hypotensive (SBP 80 mmHg), tachycardic (120 bpm), with O_2 saturation of 75% on ambient air requiring high-flow O_2 therapy. Temperature is 39°C. ECG shows sinus tachycardia with mild diffuse ST elevation. Troponin = 6 ng/ml, BNP=1800 pg/ml, creatinine=1.8 mg/dl. Chest X-ray and chest CT show diffuse bilateral ground-glass consolidations. He progressively requires high doses of norepinephrine and vasopressin and is intubated yet continues to require FiO_2 of 100% to maintain arterial O_2 saturation of 90%. Echo shows severe biventricular failure, with LV EF of 20%, with thick LV and RV walls yet non-dilated cavities and thrombus at the LV apex. Right heart catheterization shows: PA pressure 45/30, PCWP 25 mmHg, RA pressure 25 mmHg, and cardiac index 1.5 L/min/m^2 with PA saturation of 47%. Coronary angiography shows a widely patent LAD stent and 80% OM1 disease. What is the next step?
A. PCI of OM1
B. ECMO
C. ECMO with Impella
D. ECMO with IABP
E. IABP
F. Impella

Question 2. A patient with severe myocarditis, biventricular failure, and LV thrombus with refractory shock undergoes VA-ECMO placement. A few hours after ECMO placement, PCWP increases to 35 mmHg, LV diastolic dimension increases on echo, and the aortic valve does not appear to open. What is the next step?
A. Continue current management
B. Initiate inotropes
C. Place IABP
D. Place Impella

Question 3. A patient with severe biventricular failure and shock receives femoral-femoral VA-ECMO and LV support device. He develops, the next day, right upper extremity cyanosis and hypoxemia. What is the next step?
A. Increase ventilator support and oxygenation
B. Change the modality of LV support
C. Discontinue LV support

Question 4. Which of the following is *incorrect* regarding the management of septic shock?
A. Aggressive crystalloid administration (30 ml/kg within 3 hours)
B. Corticosteroids are used in septic shock refractory to fluids and 1 vasopressor
C. Wait to start norepinephrine until 30 ml/kg of fluids has failed to achieve BP target
D. Ringer's lactate is preferred to normal saline
E. Monitoring clinical parameters of perfusion is as good as lactate clearance

Question 5. A 52-year-old man presents with fever, bilateral lung opacities, obtundation, and SBP of 80 mmHg. He is resuscitated with 2 L of lactated Ringer's within 1 hour, and norepinephrine is initiated. His arterial O_2 saturation is 95% on 3 L of O_2. His mean arterial pressure rises to 65 mmHg, but his urine output is limited and his legs are cold to the touch with a capillary refill of 5 seconds. He has no JVD. What is the next step?
A. Give 500 ml fluid boluses until perfusion improves
B. Give fluid boluses until CVP rises to 12 mmHg
C. Give fluid boluses based on dynamic measures of fluid responsiveness
D. Give fluid boluses until clinically replete (JVD, worsening pulse oximetry)
E. Use point-of-care IVC ultrasound and give fluid boluses if IVC small and collapsible

Question 6. The patient from the prior question receives fluids. His mean arterial pressure remains >65 mmHg, but he remains oliguric, cold to touch, and obtunded. What is the next step?
A. Obtain echo and initiate dobutamine if needed
B. Initiate dobutamine
C. Increase the vasopressor dose
D. Continue current management (same vasopressor dose, maintenance fluids)
E. Insert a Swan-Ganz catheter

Question 7. A 55-year-old man presents with cardiogenic shock and pulmonary edema 1 week after onset of chest pain. ECG shows anterior Q waves and ST elevation. He is intubated and norepinephrine is initiated. He has multiple runs of monomorphic VT requiring multiple cardioversions and amiodarone. Right heart catheterization shows: RA 13 mmHg, PA 45/27, PCWP 27 mmHg, cardiac output 3 L/min, systemic pressure 80/55 mmHg. Coronary angiography shows an occluded proximal LAD and 80% proximal RCA. What is his cardiac power output (CPO) and what is the next step?
A. CPO = 0.53 W. Place Impella and perform PCI of LAD and RCA
B. CPO = 0.41 W. Place Impella and perform PCI of LAD
C. CPO = 0.53 W. Place IABP first. PCI not indicated for MI >24 hours after MI onset
D. CPO = 0.41 W. Place IABP first. PCI not indicated for MI >24 hours or monomorphic VT
E. CPO = 0.41 W. Place left-sided and right-sided Impella, and perform PCI of LAD and RCA

Answer 1. D. This patient appears to have a severe viral illness with severe myocarditis and severe respiratory failure from acute lung injury and cardiogenic pulmonary edema. The OM disease is very disproportionate to this patient's dramatic HF and would likely only cause stable angina or small NSTEMI. Treating non-culprit CAD increased mortality in the CULPRIT-SHOCK trial. In this patient with profound shock, IABP is not enough and will minimally increase cardiac output. Impella CP or 5 may suffice for the LV, but that is likely to aggravate RV failure in this patient with high RA pressure (RA/PCWP = 1) and narrow PA pulsatility index (= PA pulse pressure/RA = 0.6 < 1). While one may try Impella and see if that indirectly improves RV failure, it is best to start with a biventricular support therapy with an oxygenator, such as ECMO. ECMO has one downside, it increases LV preload and afterload, and thus, LV must be unloaded during ECMO support, the so-called venting, using Impella or IABP. Impella is contraindicated if LV thrombus is present.

Answer 2. C. ECMO supports the systemic end-organ perfusion and oxygenation but increases LV afterload and preload. The LV continues to receive venous return from the bronchial and thebesian veins, and thus may overdistend in the absence of some intrinsic LV function. ECMO increases pressure afterload and may make it harder for the intrinsic LV to open the aortic valve and decompress. LV overdistension may lead to coronary compression, irreversible myocardial injury, pulmonary edema, and hemorrhage. This is evident by the rising PCWP and echo features in this patient. LV must be unloaded (or vented) and allowed to pump forward, using IABP, LA atrial septostomy, or Impella. Impella cannot be used here because of LV thrombus.

Answer 3. A. The meeting point between native LV flow and retrograde ECMO flow (watershed area) should either be proximal to the aortic arch, as in a patient with poor LV, or, if it is past it, there must be good gas exchange ability by the lungs to prevent brain hypoxemia from the native blood flow. Upper body hypoxemia (Harlequin syndrome) occurs when the native heart function is preserved or recovering or well supported (e.g., Impella, inotropes) but the lungs are poorly functioning. Therapeutic options include improving lung ventilation, converting to a central VA-ECMO into the aorta or right subclavian artery, or to a femoral veno-arterial-venous (VAV) ECMO. In VAV ECMO, an additional, smaller oxygenated blood return cannula is inserted into the right internal jugular vein with the tip in the superior vena cava at >15 cm distance from the inferior vena cava cannula to minimize recirculation. Here, part of the arterial outflow is directed toward the right atrium and to the pulmonary vasculature, thus oxygenating the coronary arteries and the upper body more efficiently.

Answer 4. C. Vasopressors are initiated early on, in the first hour, during rather than after fluid resuscitation, after 1–2 L have been administered. CENSER trial demonstrated that the early and systematic initiation of norepinephrine achieved superior shock control by 6 hours, with less pulmonary edema. Moreover, a restrictive fluid strategy with early vasopressor therapy after 1–2 L of fluids was safe in CLOVERS trial. SMART MED trial demonstrated that Ringer's lactate is associated with less mortality or renal dysfunction than normal saline, particularly in sepsis. In the ANDROMEDA trial, the use of lactate clearance in the management of septic shock resulted in more fluid administered and more vasopressors without any significant improvement in outcomes compared to the use of capillary refill.

Answer 5. C. Regarding fluid resuscitation after the first 1–2 L in septic shock, all the options A–E are correct. Process trial allowed fluid administration until signs of fluid overload occurred. Static CVP goal of 12 mmHg has been used in the first early goal-directed therapy trial. However, *beyond the initial 1-3 L of fluids, a more conservative fluid strategy may be used with reliance on dynamic measures of fluid responsiveness* (ANDROMEDA trial). *The best dynamic method assesses the change in aortic velocity (>15%) or invasive pulse pressure with passive leg raising*.

Answer 6. A. If the patient is not fluid responsive, yet still displays signs of low perfusion, one may aim to increase mean arterial pressure goal to 80–85 mmHg (Andromeda trial protocol). Alternatively, it is reasonable at this point to assess for RV or LV failure by echo, and selectively administer dobutamine in case of sepsis-induced cardiomyopathy with low EF.

Answer 7. B. CPO = CO × mean systemic BP = 0.41 W (<0.6 W, the critical value that indicates placement of a support device). PCI is not indicated >24 hours after MI onset based on the OAT trial, but this does not apply to cardiogenic shock. One may expect the benefit of PCI to be limited so late after MI, particularly in the setting of monomorphic VT, which already indicates scar formation. Monomorphic VT is unlikely to be improved by PCI. Yet, PCI is recommended in cardiogenic shock regardless of time delays. Only culprit artery PCI is performed in shock. Impella reduced mortality in progressive stage C or D STEMI-shock presenting within 24 hrs of symptom onset; the presentation is delayed here but Impella is still reasonable. RA/PCWP ratio is <0.65 and PA pulsatility index is >0.9, hence right VAD is not considered yet.

Questions and answers 602

1. HYPERTENSION

I. Definition and key role of out-of-office BP measurements

Hypertension (HTN) is defined as blood pressure ≥130/80 (ACC) or ≥140/90 (ESC) mmHg on 2 or more occasions, each one on a different clinic visit, or one in clinic and another one at home.[1,2] A truly normal BP is <120/80 mmHg, while a BP of 120–129/<80 is classified as elevated BP, but not HTN (ACC).

The cardiovascular risk is greater with increments in SBP than equivalent increments in DBP in patients >50 years; also, SBP is an independent predictor of cardiovascular events more consistently than DBP. Isolated diastolic HTN, even >90 mmHg, is not consistently associated with increased cardiovascular events in patients >50 years.[3–5] In patients <50 years, DBP is important, possibly as much as SBP, and precedes future onset of systolic HTN.[5–7]

Importantly, in patients older than 65 years or patients with CAD, a J curve is seen for drug-induced reductions of SBP and DBP: a low SBP <110 mmHg or DBP <70 mmHg is harmful and increases the risk of coronary events.[8–12] Younger patients have a hockeystick curve, wherein the risk remains flat, unchanged, at low DBP <70 mmHg.

The systemic arteries stiffen with increasing age, which leads to a sharp increase in pressure during systole and a sharp decline in pressure during diastole and upon standing, along with extreme salt sensitivity. Thus, with age, SBP and pulse pressure increase while DBP decreases and significant lability occurs; in some of these patients, achieving SBP goal <130 mmHg is unlikely to be tolerated. Chronic severe HTN begets more stiffening, more severe HTN peaks, and more HTN lability.

Studies have shown that **ambulatory BP is superior to the clinic's BP for the prediction of cardiovascular mortality**.[13–15] Thus, in order to confirm HTN diagnosis AND to guide drug titration, ACC and ESC guidelines recommend the **routine use of *home BP monitoring*** or ***24-hour ambulatory BP monitoring*** (class I recommendation for either modality). ESC guidelines clearly prefer home or ambulatory BP measurement over office BP, and state: "The diagnosis of hypertension requires confirmation using out-of-office measurements (home or ambulatory BP monitoring) or at least one additional subsequent office measurement . . . **Out-of-office measurement is the preferred method**." Specifically, adults with BP ≥130/80 (even ≥160/100 per ESC) are to be screened for white coat effect, while those with BP 120–129 are to be screened for masked HTN.[1,2]

The average measurements of home BP over 3–7 days should be <130/80. The average daytime ambulatory BP should be <130/80, while the average 24-hour ambulatory BP should be <125/75, with 10–20% nocturnal dip. Beware of the following 2 findings:

- The white coat effect, in which BP is high in the office and normal at home. This effect is suspected in patients who do not display any target end-organ damage and repeatedly show signs of overtreatment such as orthostatic hypotension. White coat effect increases with age, as arterial stiffness aggravates BP variability, and has a 13–35% prevalence in hypertensive populations (>50% in the very old). It has been associated with no or only slightly increased cardiovascular risk and mortality, and thus, therapy is not recommended (ACC and ESC guidelines).[1,2]
- Masked HTN, which is the reverse of white coat HTN. BP is high at home and normal at the office. This occurs in 10–30% of patients with HTN. Masked HTN is more prevalent in men, smokers, and diabetic and obese patients.[2] Masked HTN has a major, long-term adverse cardiovascular effect and needs to be treated.

Home BP monitoring consists of self-measuring BP every morning (after micturition and before food and drugs) and every evening before drug intake (ESC) or at bedtime (ACC). Obtain 2 readings each time, separated by 1–2 minutes, and average all measurements over 3–7 days. *Ambulatory BP* monitoring consists of wearing a BP cuff for 24 hours, with automatic BP measurements every 30 minutes. While more prognostic data are available for ambulatory BP than home BP, a review of cohort studies addressing both modalities suggested a similar prediction of cardiovascular events, and one prospective study showed superior correlation of home BP with LV mass compared to ambulatory BP.[16] Home BP monitoring has the advantage of monitoring over a long period, rather than just 24 hours.

BP is measured after >5 minutes of rest, in a sitting position, with both the back and feet supported. Use a proper BP cuff: the bladder length (the inflatable part) should be about 80% of the arm circumference. The Velcro should overlap by 25–50% (not barely touching, not completely overlapping). The cuff should wrap snugly around the upper arm (1–2 fingers may fit snugly under the cuff) and should be 2–3 cm above the antecubital fossa.

II. ACC and ESC targets of therapy and rationale

A. Targets of therapy

***ACC guidelines:**[1]

-Target BP <130/80 mmHg in all patients, ideally <120/80 mmHg.

-Medications are initiated for BP ≥130/80 in ~all cases (CAD, diabetes, HF, CKD, prior stroke).

-*Although they have a lower cardiovascular risk, younger patients are more likely to tolerate lower BP (less J curve) and have more longevity to benefit from this lower BP*. Hence even with a low 10-year risk <7.5%, ACC recommends initiating BP medications if BP remains ≥130/80 despite 3–6 months of lifestyle measures.

***ESC guidelines:**[2]

-Target BP <130/80 mmHg in all patients.

- Medications are initiated for BP ≥130/80 in most cases, except if 10-year cardiovascular risk is <5%, where medications are initiated for BP ≥ 140/90.
- Medications are also deferred until BP is ≥140/90 mmHg in: symptomatic orthostatic hypotension, age ≥85 years, moderate-to-severe frailty, and/or many comorbidities with limited predicted lifespan (<3 years).
- For patients with SBP at target <130 mmHg but elevated DBP >80 mmHg, or even >90 mmHg, the CV risk is low and evidence is less strong for specific DBP-targeted therapy, except in patients <50.[2–4] This scenario is typically seen in younger obese adults whose vascular compliance is not impaired, yet. ESC gives a class IIb recommendation for treatment in such scenario.

-The BP target with medications is 120–129/70–79 mmHg, 120 mmHg being the ideal on-treatment point. Medication-induced BP <120/70 mmHg is not recommended (unlike ACC). While SBP <120 mmHg is ideal, actively reducing BP to this level with drug therapy, particularly <110 mmHg, has increased cardiovascular events in many studies.[8–12] Though not mentioned in the guidelines, ***the only group where SBP <120 mmHg does not preclude medications is the heavily afterload-dependent systolic HF*** **(up to SBP of 90 mmHg).**

***Regarding heart rate: A tight rate control <70 bpm has proven beneficial in chronic sinus-rhythm HFrEF, but not in stable CAD, angina, HTN, HFpEF, or AF (even AF with HFrEF).**

B. Rationale for the guidelines (SPRINT trial is the driver of ACC guidelines)

In the HOT trial, which randomized patients to multiple DBP goals (<90 vs. <85 vs. <80), a DBP of 82 mmHg was associated with the lowest risk of cardiovascular events, with a J curve beyond that point. Diabetic patients derived further benefit from DBP <80 mmHg, with no evidence of a J curve. A similar lack of J curve in diabetes was seen in the UKPDS study.[12,17] While the **ACCORD trial of diabetic patients**

did not show a clear benefit of aggressive SBP control to <120 mmHg vs. <140 mmHg, the more recent Chinese **BPROAD trial** of diabetic patients showed that aggressive SBP control to <120 mmHg improved outcomes compared to a target of <140 mmHg (0.44% yearly reduction of cardiovascular events, 21% relative risk reduction; median SBP 118 vs. 135 mmHg, mean age 64, no mortality reduction).[18–20]

Concerning CKD, 3 trials and several meta-analyses addressed BP goals lower than 140/90 mmHg in CKD and did not find any statistically significant benefit on renal outcomes (AASK, MDRD, REIN-2 trials).[2,21–24] In the AASK trial of African-American patients, BP reduction to a mean of 128/78 mmHg did not improve renal outcomes in comparison with BP of 141/85 mmHg; conversely, the specific use of ACE-I improved renal outcomes compared to amlodipine.

Concerning **HFpEF**, the I-PRESERVE and PARAGON-HF trials have shown that ARB and sacubitril-ARB do not clearly improve outcomes in HFpEF with controlled HTN (BP 136/76 mmHg), indirectly suggesting that a SBP goal much lower than 140 mmHg may not be warranted in HFpEF.[25,26]

In **CAD** patients with normal EF and SBP of 130–140 mmHg who receive aggressive statin and revascularization therapy, the addition of ACE-I did not improve outcomes (55% had prior MI) (PEACE trial).[27] In the CAMELOT trial of stable CAD with baseline BP ~130/80, the addition of ACE-I or amlodipine did not improve death, MI, or stroke; amlodipine reduced angina and the need for coronary revascularization.

The **SPRINT trial** randomized *non-diabetic* patients with HTN and one additional cardiovascular risk factor to SBP goal <120 mmHg vs. <140 mmHg (28% of patients had CKD, 20% had coronary or vascular disease, mean age 68+/–9, and 28% were older than 75).[28] ***In contrast to some of the above data, intensive SBP control led to a reduction of total mortality, HF, and cardiac mortality.*** Note, however, that the mean SBP achieved in the intensive group was 121.4 mmHg, not <120 mmHg, and that office BP was measured in an unusual way (automatic unattended measurement) that resulted in lower office BP values. Also note that the absolute mortality reduction was small, 0.37% per year; side effects such as syncope and acute kidney injury were increased, and renal outcomes were not improved. Baseline HF, including symptomatic diastolic HF, was excluded. Patients with prior stroke were excluded and stroke risk was not reduced. Similar benefits of intensive BP control <130 mmHg were replicated in the Chinese STEP and ESPRIT trials (mortality reduction in the latter, mean age 65).

Concerning the very elderly ≥80 years of age, only 1 randomized trial addressed HTN in this age group and aimed for a target SBP of 150 mmHg (HYVET trial).[29] Thus, ***for patients ≥80–85 years, ESC recommends initiation of therapy only when SBP ≥140 mmHg.*** SBP of 150–160 mmHg may be accepted in elderly frail patients who develop orthostatic symptoms with drug therapy, even if <80 years of age.

The J curve between BP (SBP, and even more so DBP) and coronary events is particularly evident in patients with underlying CAD or LVH that impairs coronary flow autoregulation. Hence the importance of keeping DBP ≥70 mmHg (ESC).[2,30]

Isolated diastolic HTN is uncommon but sometimes seen in young adults with obesity and metabolic syndrome, whose arteries are still compliant (hence pulse pressure is narrow). It is likely associated with a slight increase in CV risk, but there is no clear evidence that HTN drug initiation or escalation has any benefit if SBP is <130 mmHg, especially <120 mmHg (as per ESC).

The improvement in cardiovascular and renal outcomes is related more to the BP achieved and the 24-hour hypertensive control than to a particular drug mechanism.

III. Treatment of hypertension: timing, first-line drugs, compelling indications for specific drugs

A. BP 130–159/80–99

For BP in this range, lifestyle modifications are initiated: sodium <2.3 g/d, ideally <1.5 g/d (ACC), exercise, and weight loss (10 mmHg SBP drop for every 20 pounds). Also, ***home BP is monitored***, and office BP is rechecked in 1 month.[1,2] If BP is still elevated, drug therapy is initiated.

Salt sensitivity ↑ with age and the chronicity of HTN as arteries gradually stiffen. The following patients are particularly susceptible to salt intake and may derive >20 mmHg reduction of SBP with low-salt diet: age >60–70 with non-compliant arteries, CKD, obese, and black patients.[31]

B. BP ≥ 160/100 mmHg

For BP in this range, confirm HTN with home BP monitoring for a few days only, then promptly initiate drug therapy in <1 month (ESC).[2] For BP > 180/110, confirm the measurement within 1 to a few days and commence therapy in <1 week.[2]

C. How and what to start

If BP ≥ 140/90, a combination therapy is initiated. One medication may be initiated with a slow stepwise titration in the following cases: BP of 130–139/80–89, orthostatic hypotension, age >80–85, or frailty.[2]

D. First-line drugs

In the absence of any compelling condition, any of the following 3 classes of agents can be used as a first-line therapy:

(a) Thiazide diuretic, ***(b)*** ACE-I or ARB, ***(c)*** CCB

In the ALLHAT trial, all 3 classes achieved similar reduction in mortality and MI. Thiazide diuretic was superior to ACE-I for stroke prevention and slightly superior to ACE-I and CCB for HF prevention.[32]

β-Blockers, especially atenolol given once daily, are less effective for HTN control, patient survival, and stroke/MI risk reduction and should not be used as a first-line therapy unless there is a compelling indication (HF, arrhythmias, angina).[33–37]

E. Follow-up

One or 2 drugs are started, then BP is rechecked 1 month later (oral agents work slowly and take 1–2 weeks to achieve the optimal effect).

a. If BP remains uncontrolled, the dosage of the drug(s) is optimized (the target being at least one-half of the maximal dose, which is usually an optimal dose). Subsequently, another first-line drug is added, then a third first-line drug is added if needed. If HTN persists in spite of drug A, doubling the dose of A achieves 5× less BP reduction than adding another drug.[38] In addition, maximizing the dose of 1 drug

increases side effects more than it improves BP control; therefore, in general, once a moderate dose of drug A is achieved, adding a new drug is preferred to maximizing the dose of drug A.

b. If not the first drug used, a thiazide diuretic is typically added as a second agent whenever a combination is needed. This is because hypervolemia is a common mechanism of HTN, *sometimes exacerbated by vasodilator-induced volume retention*. In fact, thiazide diuretics are synergistic with other antihypertensive drugs.

Conversely, the ACCOMPLISH trial suggests that when combination therapy is needed, the combination of ACE-I and amlodipine is superior to the combination of ACE-I and hydrochlorothiazide, with 20% more reduction of death, MI, and stroke.[39] This trial mainly recruited white patients without CKD, with a high prevalence of diabetes and CAD, and used a low HCTZ dose of 12.5–25 mg (mean 19 mg). The results may not apply to the standard HCTZ dose (25 mg), or to black patients or patients with obvious hypervolemia or CKD. **Diuretic therapy remains an appropriate second agent or, at least, third agent.**

c. Assess for signs of orthostatic hypotension or fatigue, which may occur with fast BP reduction, and dictate a slower titration as well as general measures to prevent orthostatic hypotension.

F. Compelling indications for specific antihypertensive drugs

1. CAD: β-blocker, ACE-I/ARB; aldosterone antagonist for LV dysfunction post-MI.

2. HF: β-blocker (carvedilol, metoprolol XL, bisoprolol), ACE-I/ARB, aldosterone antagonist, diuretic. The combination hydralazine–nitrates is a second-line therapy for persistent HF or refractory HTN despite the preceding regimen (especially for black patients).

3. CKD, proteinuria, or microalbuminuria: ACE-I/ARB. Volume overload, sometimes occult, is common in CKD and explains the antihypertensive efficacy of diuretics. SGLT-2 inhibitors, which have a modest BP-lowering effect, are indicated for CKD, with or without diabetes, as they slow CKD progression.

4. Diabetes or metabolic syndrome without nephropathy: the ALLHAT and VALUE trials suggest the lack of difference between ACE-I/ARB, CCB, and thiazide diuretic in terms of cardiovascular outcomes in the diabetic subgroup. Thus, any of the three first-line therapies may be initiated in diabetic patients. Yet ACE-I/ARB and CCB may be preferred, as they do not worsen diabetes control; in fact, ACE-I/ARB therapy potentially improves insulin sensitivity and reduces the risk of diabetes in patients with metabolic syndrome. β-Blockers and thiazide diuretics increase the risk of diabetes and may worsen the lipid profile.[2] ACE-I or ARB therapy is preferred in microalbuminuria.

5. Black patients do not respond well to ACE-I/ARB monotherapy when used for HTN control. Black patients are salt-sensitive, as they have a highly active distal tubular sodium channel (high renal sodium retention) and, consequently, low renin and angiotensin levels. Thiazides and CCBs are the most effective drugs for HTN in this population; aldosterone antagonists are also effective, as they reduce the amount of tubular sodium channels. However, ACE-I therapy is very effective in black patients with CKD or HF and remains first-line therapy in this context. ACE-I therapy is also an effective antihypertensive therapy in black patients already receiving CCB or diuretic therapy, both of which activate the renin–angiotensin system.[30] The AASK trial addressed ACE-Is in black patients with CKD and showed that ACE-Is are as effective as amlodipine in controlling HTN, and more effective in long-term GFR preservation.[22]

6. Supraventricular arrhythmias: β-blockers, non-DHP CCBs.

7. Ventricular arrhythmias: β-blockers.

IV. Resistant hypertension

Resistant HTN is HTN resistant to 3 drugs administered at an optimal dosage, including a diuretic, and confirmed by out-of-office measurements. Poor adherence to salt measures and medications, white coat effect, and inappropriate cuff size are called pseudo-resistant HTN and constitute up to 50% of resistant HTN.

A. Causes[40–42]

- *Non-compliance* with low-salt diet or drug therapy. Salt non-compliance may be assessed by measuring the 24-hour urinary sodium, which correlates with dietary sodium intake.
- *White coat HTN* (ambulatory or home BP measurements are mandatory in resistant HTN).
- Inappropriately small cuff size leads to BP overestimation in obese patients.
- *Obesity* increases renin–angiotensin activity, aldosterone synthesis, and thus extracellular volume. It also increases sympathetic activity. Every 10 kg of weight loss reduces BP by ~10 mmHg, and thus ***obesity itself is the most common cause of resistant HTN in morbidly obese patients, and weight loss is of critical importance in these patients***.
- NSAID, steroid therapy, cocaine, excessive alcohol use (>2 drinks/day for men or >1 drink/day for women).
- *Occult hypervolemia*: patients with resistant hypertension often have subclinical hypervolemia, which may be due to excessive salt intake, inadequate diuretic therapy, or a compensatory response to vasodilator therapy.
- *Secondary HTN*, particularly hyperaldosteronism (20% of resistant HTN), sleep apnea, and renal artery stenosis.
- *Pseudohypertension* of the elderly. In this case, the peripheral arteries are stiff and calcified and can hardly be compressed by the BP cuff, even if the intra-arterial pressure is normal. This results in a falsely elevated BP measurement. Hints to pseudohypertension:
  - "Severe HTN" is present without any end-organ damage, and small doses of antihypertensive drugs induce dizziness.
  - Radial or brachial arteries remain palpable, albeit pulseless, upon cuff inflation beyond the audible systolic BP.
  - The definitive diagnosis is established by performing intra-arterial measurements.

B. If HTN is truly resistant, second-line drugs may be added

- ***Spironolactone*** 25–50 mg daily or amiloride (a potassium-sparing diuretic) if GFR is ≥30 ml/min:[2] the addition of a small dose of spironolactone has been found to be very effective in treating drug-resistant HTN and decreases BP by ~20/10 mmHg in black or white patients (PATHWAY-2 trial and ASCOT substudy).[40,43,44] This may be particularly true in obese patients and in the frequently underdiagnosed primary hyperaldosteronism. The efficacy, however, appears independent of renin level or renin/aldosterone ratio.
- Consider ***increasing the dose of hydrochlorothiazide (HCTZ) or switching to chlorthalidone*** or a loop diuretic for better control of hypervolemia, including subclinical hypervolemia. Thiazide diuretics remain very effective in advanced CKD stage 4, with or without a

loop diuretic (Section VII.C.2); yet, a loop diuretic (+/– thiazide) is still suggested in CKD 4 with resistant HTN (ESC). According to the ESC and ACC guidelines, *increasing the diuretic dose and/or adding spironolactone is the immediate next step in resistant HTN management*.[1,2,33]

- ***β-Blockers***, especially nebivolol or the α/β-blocker carvedilol.
- ***α-Blockers***. In the PATHWAY-2 trial of resistant HTN, ***bisoprolol and extended-release doxazosin (4–8 mg) were significantly effective in resistant HTN compared with placebo, but 50% less effective than spironolactone***. Doxazosin was also effective in an ASCOT substudy.[45]
- ARNI (sacubitril-valsartan) reduced resistant HTN by up to 9 mmHg vs. ARB in the PARAGON trial.[46]
- Central sympathomimetics (clonidine: α_2-agonist).
- Direct vasodilators (hydralazine).
- The combination of ACE-I and ARB or renin inhibitor is neither useful nor recommended for patients with refractory HTN.

C. Consider the mechanism of the resistant HTN, and try to treat it accordingly[41] (volume, vascular tone, catecholamine tone)

- If the patient has CKD or volume overload on exam, consider increasing the diuretic therapy, or adding spironolactone if GFR ≥30 ml/min.
- If the patient's heart rate is >84 bpm, consider catecholamine excess as a cause of HTN or a result of diuretic and vasodilator therapy, and add or increase β-blocker therapy.
- In the absence of the above, try to increase vasodilator therapy. Alternatively, or later on, increase diuretic therapy for occult hypervolemia.
- In obese patients, hypervolemia (sometimes occult) is a key component of HTN and thus, weight loss, increasing diuretic therapy, and adding spironolactone are critical measures. CPAP only mildly improves BP control in resistant HTN (up to 7 mmHg reduction of SBP) (ACC class IIb).[47] In the large SAVE trial of patients with cardiovascular disease and moderate-to-severe obstructive sleep apnea, CPAP improved sleepiness and quality of life but did not reduce cardiovascular events.[48]

V. Secondary hypertension

Hypertension is primary (essential) in 90% and secondary in 10% of patients. Tables 23.1–23.4 list the features that suggest secondary HTN, the causes of secondary hypertension, and the workup of hypertension.

Table 23.1 Situations that warrant workup for secondary HTN.

A. Age <30 with systolic or diastolic HTN; age >60 with diastolic HTN
B. Resistant HTN (= resistant to 3 drugs at optimal doses, including a diuretic), **particularly if new or accelerated, or if "refractory"** (= resistant to 5 drugs, including a diuretic and spironolactone)
C. Acute HTN with DBP >110 mmHg, or malignant HTN
D. Laboratory findings (creatinine, K, urinalysis)
  1. ↓ K or metabolic alkalosis in the absence of diuretic therapy (→ RAS or hyperaldosteronism)
  2. ↑ Creatinine at baseline or with ACE-I (→ RAS or chronic renal failure): Abnormal urinalysis (glomerular hematuria, proteinuria)
  3. Unilateral small kidney (kidney size difference ≥1.5 cm suggests RAS)
E. History/exam features
  1. Abdominal bruit, peripheral arterial disease → RAS
  2. Paroxysmal headaches, palpitations, sweating, pallor → pheochromocytoma; HTN worsens with β-blockers → pheochromocytoma
  3. Orthostatic hypotension → stiff non-compliant arteries, autonomic dysfunction, or side effect of therapy; rarely pheochromocytoma

RAS, renal artery stenosis.

Table 23.2 Causes of secondary hypertension.

A. Primary hyperaldosteronism (bilateral adrenal hyperplasia, or adrenal adenoma [Conn's syndrome, 30% of cases]). This is the most common form of secondary HTN, is a common cause of resistant HTN, including severe HTN >180/110 mmHg, and is seen **in up to 5–10% of HTN and 20% of resistant HTN**.[40,49,50] K is often normal, as hypokalemia is only seen late in the disease process. ***Obesity and sleep apnea trigger a disproportionate increase in aldosterone (>renin), via both renin-dependent and independent pathways, sometimes mimicking primary hyperaldosteronism.***
B. Renal artery stenosis (RAS): ~2% of HTN (uni- or bilateral RAS)
C. Chronic kidney disease (CKD): CKD is the cause of HTN in ~2% of patients (diabetic nephropathy, glomerulonephritis, or polycystic kidney disease), but is more commonly a complication of essential HTN
D. Sleep apnea is present in 25–50% of hypertensives and is an aggravating factor, not usually the cause of HTN. CPAP therapy has not clearly improved cardiovascular events and only mildly improves BP control[47,48]
E. Drugs: contraceptive pills, NSAIDs, cocaine, steroid therapy, sympathomimetics (such as ADHD drugs and decongestants). Cancer drugs such as targeted therapies (especially anti-VEGF), and anti-androgen therapies
F. Cushing's syndrome, including its most common cause, steroid therapy
G. Pheochromocytoma: permanent HTN with paroxysmal spikes: ~50%; permanent HTN with no paroxysms: ~45%; purely paroxysmal HTN: ~5%
H. Hypercalcemia
I. Hyper- and hypothyroidism. Hypothyroidism causes hypervolemia and a predominantly diastolic hypertension, while hyperthyroidism usually causes isolated systolic hypertension
J. Coarctation of the aorta

These causes, especially RAS, generally lead to elevations of both systolic and diastolic BP, as both hypervolemia and vasoconstriction occur. Isolated systolic HTN is unlikely to be secondary to RAS.

Table 23.3 Basic workup for any HTN.

A. Creatinine, potassium, calcium; urinalysis (signs of glomerulopathy [proteinuria, hematuria])

B. Look for end-organ damage

1. *ECG (± echo when ECG is abnormal or HF is present)*: LVH voltage on ECG correlates with the left ventricular mass and with the risk of developing HF. LBBB or strain ST–T changes correlate with worse LVH and a higher risk of LV dysfunction
   - LVH voltage may regress with therapy. This correlates with a reduction of HF risk[51]
   - Echo may show diastolic dysfunction, which precedes LVH and is more prevalent than LVH
2. *Urinalysis*
   - Proteinuria hints at glomerular damage causing HTN or secondary to HTN
   - Microalbuminuria (ratio of urinary albumin/creatinine on a spot urine ≥ 30 mg/g): hints at early glomerular damage from diabetes or HTN
   - Decreasing albuminuria is a treatment goal and is associated with renoprotection and improved cardiovascular outcomes
3. *Funduscopic exam:* Arteriolar narrowing, hemorrhages, exudates, papilledema

Table 23.4 Specific workup when secondary HTN is suspected.

A. Doppler ultrasound of the renal arteries (or MRA or renal perfusion nuclear scan)

B. Aldosterone serum level and plasma renin activity (PRA). If aldosterone/PRA ratio >20, with aldosterone >6-10 ng/dl, primary hyperaldosteronism is suggested.[a] ACE inhibitors, aldosterone antagonists, and β-blockers affect this testing, but not enough to warrant drug interruption Aldosterone ↑ with aldosterone antagonists and ↓ with the other two. ACC recommends holding aldosterone antagonist for 4 weeks before testing, but ESC allows its continuation if needed in severe HTN or hypokalemia.

C. Serum-free metanephrines and normetanephrines, and 24-hour urinary metanephrines and normetanephrines (these two tests have the best yield for the diagnosis of pheochromocytoma)

D. TSH

E. Consider sleep study in the appropriate context

[a]A primary elevation in aldosterone level leads to a feedback decrease in PRA. Aldosterone is expressed in ng/dl while PRA is expressed in ng/ml/h.

VI. Peripheral vs. central aortic pressure: therapeutic implications

The systolic pressure increases in the peripheral arteries as a result of the pressure waves that are reflected from arterial bifurcation points and small peripheral vessels and that add to the systolic wave. After the age of 60, the reflected waves not only amplify the peripheral arterial pressure but also return to the central aorta quickly as a result of heightened arterial stiffness; this is called increased pulse wave velocity. Thus, these waves reach the aortic root in late systole, which leads to augmentation of the central aortic pressure as well as the peripheral pressure.[52–55] In fact, in the elderly, the systolic and pulse aortic pressures are increased because of: (1) ejection of the stroke volume into a stiff aorta; (2) increased pulse wave velocity that allows the reflected waves to return to the aorta in systole. In contrast, in the young patient, the reflected waves return to the central aorta in early diastole, which increases diastolic pressure and potentially coronary filling. The aortic systolic pressure is closer to the peripheral systolic pressure in the elderly than in the young.

β-Blockers, when used for hypertension, reduce the peripheral arterial pressure but less so the central arterial pressure (pseudo-antihypertensive effect).[53–55] This is because β-blockers exert less effect on arterial remodeling and stiffness than calcium channel blockers, ACE inhibitors, or diuretics. Furthermore, a reduction in heart rate prolongs the cardiac ejection phase and may allow the backward wave reflection to reach the central systolic pressure at its peak rather than late. Also, a reduction in heart rate may lead to the ejection of a higher stroke volume into a poorly compliant aorta. Consequently, the central aortic pressure may increase with heart rate reduction.[52–54] Vasodilators (ACE-Is, CCBs), diuretics, and aldosterone antagonists improve arterial compliance and delay reflected waves. Thus, these agents reduce peripheral pressure, but even more the central aortic pressure, and supplement diastolic coronary filling.

VII. First-line antihypertensive drugs

A. ACE-Is and ARBs

1. Mechanism of benefit in CKD

ACE-Is/ARBs are the preferred agents in CKD, including advanced CKD. ACE-I/ARBs vasodilate the efferent renal arterioles more than the afferent arterioles, which may reduce GFR and increase creatinine acutely. However, over the long term, the kidneys are protected from the high glomerular pressure that leads to scarring (Figure 23.1). ACE-Is/ARBs reduce the rate of decline of renal function and the incidence of end-stage renal disease by ~20–50% as compared to other antihypertensive agents, particularly CCBs, despite comparable BP reduction (AASK and IDNT trials).[21,22,56] This benefit is achieved with optimal to high doses and is accentuated in patients with proteinuria >1 g/d; in fact, ACE-Is/ARBs more effectively reduce proteinuria than any other agent.[22,56] The worse the proteinuria, the more striking the benefit. The benefit continues to be seen in advanced renal failure (up to a creatinine of 5 mg/dl).[53] It is also seen in black patients with CKD.[22] ACE-Is may not be more nephroprotective than CCBs or thiazide diuretics in patients with early nephropathy and no proteinuria (ALLHAT study).[32,57]

2. Contraindications and monitoring

ACE-I/ARB initiation is contraindicated in acute kidney injury and in bilateral RAS, in which cases kidney perfusion is dependent on angiotensin II.

Creatinine is checked 7–14 days after starting ACE-I/ARB. ***An increase in creatinine of up to 30% is tolerated, as these agents are beneficial over the long term.***[59] An acute increase ≥30% is associated with worse long-term renal outcomes compared to no acute increase (in most studies).[60,61] Yet even in the latter patients, the worsening of renal function may rather be a marker of adverse

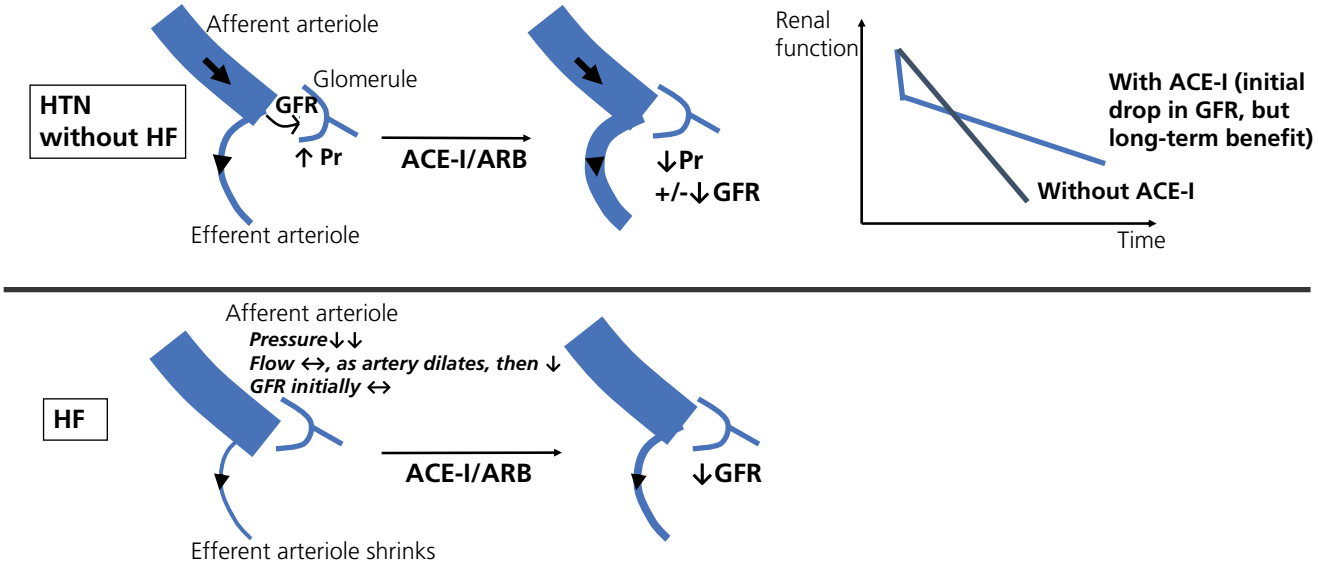

Figure 23.1 Effect of ACE-I/ARB on the renal flow and renal function. Angiotensin II constricts the afferent and more so, the efferent arteriole, which is smaller. The net result of ACE-I/ARB is efferent arteriolar vasodilatation.

1. In HTN and diabetes, there is glomerular hyperfiltration through the afferent arteriole with elevated glomerular pressure (Pr), which is damaging to the nephron over the long term. ACE-I reduces Pr and protects the nephron. It may reduce GFR in nephropathy, where total GFR is maintained by the compensatory rise of local GFR of in each remaining nephron (via angiotensin).
2. **In severe HF, the mechanism of renal benefit is indirect as Pr is already low (≠HTN).** *Background:* In severe HF, renal blood flow in the afferent arteriole (RBF) may be severely reduced, yet GFR is minimally reduced. This is related to: (i) afferent vasodilation, which ↓ renal resistance R and tries to maintain RBF (RBF = [afferent pressure – RA]/R); (ii) even if RBF declines up to 5×, GFR may minimally decline thanks to significant efferent vasoconstriction, which diverts a bigger proportion of the afferent flow into the glomerulus (=high filtered fraction >50%, the normal being ~20%). Thus, efferent artery vasodilation by ACE-I/ARB may particularly harm the renal function. *Yet, studies show that HF patients whose GFR declines with ACE-I/ARB derive the largest benefit from it, as those patients have the lowest cardiac output*.

   ACE-I/ARB has indirect renal benefits: (i) increased cardiac output increases RBF, by up to 60% in one study;[58] (ii) at high concentrations, angiotensin II constricts the afferent artery, thus paradoxically reducing GFR; vasodilatation of the clamped afferent artery by ACE-I/ARB overcomes the harm from efferent vasodilatation; (iii) sacubitril-valsartan increases natriuretic peptides, which have direct afferent dilatation (>efferent dilatation), further increasing RBF compared with ACE-I/ARB.

renal hemodynamics than harm from ACE-I, and continued ACE-I therapy seems to reduce long-term renal and cardiac events compared to no ACE-I therapy.[61,62] This has also been shown in HFrEF.[63] That said, it is prudent to withhold ACE-I when creatinine rises ≥30% (or ≥50% in HFrEF). The following 4 conditions most commonly explain a creatinine rise ≥30%: hypovolemia (overdiuresis), hypotension, severe HF, nephropathy with GFR dependence on the angiotensin system. While less common, bilateral RAS is also considered. Thus, if creatinine rises ≥30%:

- The patient is assessed for intermittent hypotension or orthostatic hypotension. A diuretic that was recently initiated may be withheld. In case of intermittent hypotension, ACE-I is interrupted temporarily then attempted later at a lower dose.
- In the absence of obvious hypovolemia, recent diuretic initiation, or intermittent hypotension, ACE-I is generally discontinued and RAS ruled out.

3. Differences between ACE-I and ARB

- Renin is released by the juxtaglomerular apparatus in response to low BP or low distal tubular Na. Renin converts angiotensinogen to angiotensin I, which is then converted to the active angiotensin II by the angiotensin converting enzyme, secreted by the vascular endothelium, especially in the lungs. Angiotensin II stimulates the adrenal secretion of aldosterone and acts as a vasoconstrictor. ACE-Is prevent the conversion of angiotensin I to the active angiotensin II and prevent the degradation of a vasodilator, bradykinin.
- ARBs block angiotensin-II type 1 receptor, which is the receptor involved in salt retention, vasoconstriction, tissue growth, and deleterious vascular and cardiac remodeling.
- The main advantage of ARB over ACE-I is the lower frequency of angioedema and the absence of cough (cough being a side effect of ACE-I-triggered bradykinin release, occurring in 10% of patients). A cross-reactive angioedema rarely occurs with ARB, in <5% of ACE-I reactive patients; ACE-I-related angioedema does not preclude the use of ARB in patients with a strong compelling indication, such as HF or CKD (close monitoring is warranted).

4. The combination of ACE-I and ARB should be avoided[1,2,21]

The combination ACE-I/ARB has not been shown to improve cardiovascular outcomes or HTN control, with a worsening of major renal outcomes (ONTARGET trial).[59]

B. CCBs

1. Types of CCBs and mechanisms of action

- Dihydropyridines (DHPs; e.g., nifedipine, amlodipine, felodipine) are vasodilators that have minimal to no negative chronotropic and inotropic effect. Felodipine has the least negative inotropic effect, and both amlodipine and felodipine have been studied in systolic HF and shown to be safe. Amlodipine is a very long-acting DHP, with sustained 24-hour BP reduction, which explains its clinical efficacy.
- Non-DHPs (diltiazem and verapamil) have negative inotropic and chronotropic effects, particularly prominent with verapamil. They also have a vasodilatory effect, slightly less prominent than that of DHPs.

A slight diuretic effect may be seen early on, via renal vasodilatation, sometimes followed by volume retention via activation of the renin-angiotensin system and via local edema from ↑ arterial capillary pressure. Both DHPs and non-DHPs are similarly effective in HTN. The combination of a DHP and a non-DHP is not generally used. This combination, however, may be used in patients with refractory HTN who cannot receive β-blockers because of asthma. If a patient can receive a β-blocker, DHP is better combined with a β-blocker than with a non-DHP.

2. Contraindications

- Non-DHPs are contraindicated in systolic HF, significant sinus bradyarrhythmia (rate <55–60 bpm) or second- or third-degree AV block. Non-DHPs are avoided in combination with β-blockers, except for the rate control of AF, where the combination β-blocker–diltiazem may be used.
- Long-acting DHPs are not contraindicated in compensated HF or in bradyarrhythmias. In general, the short-acting nifedipine is avoided in CAD as it leads to reflex tachycardia and subsequent myocardial ischemia, even though its direct effect is slightly rate slowing.

3. Other side effects

Headache, edema (mainly with DHPs), constipation (mainly with verapamil). *Peripheral edema* is related to CCB's preferential precapillary arterial dilatation, with less postcapillary venous dilatation, which increases the capillary hydrostatic pressure. It is dose dependent (5% with amlodipine 5 mg, 25% with 10 mg) and not responsive to diuretics unless a component of hypervolemia is present. It may be reduced with ACE-I/ARB, which has superior venodilating capacity. It is worse in obese or immobilized patients.

C. Diuretics (thiazide diuretics, loop diuretics, aldosterone antagonists)

1. Thiazide diuretics (hydrochlorothiazide, chlorthalidone)

Thiazide diuretics are weak diuretics that block sodium reabsorption in the distal tubule (Na-Cl transporter), where ~3–5% of sodium is reabsorbed. Loop diuretics block sodium reabsorption in the ascending loop of Henle, where ~25% of sodium is reabsorbed. Thiazide diuretics are the typical diuretics used in HTN. They are longer acting than loop diuretics, and induce less hypovolemia and hypokalemia than loop diuretics, but more hyponatremia. Chronic diuretic administration also produces mild vasodilation and improves arterial compliance by inhibiting sodium entry into smooth muscle cells.

At the dose of 12.5–25 mg, hydrochlorothiazide (HCTZ) reduces 24-hour ambulatory BP less than chlorthalidone 12.5–25 mg and other antihypertensives (ACE-I, CCBs), even though office BP may be similarly reduced.[64,65] Chlorthalidone is very long acting (2–3 days), longer acting than HCTZ (12–24 hours), and may provide greater 24-hour BP reduction, but may also be associated with a higher early risk of acute kidney injury and hypokalemia, warranting close monitoring. In the one large randomized trial comparing chlorthalidone ~12.5 mg with HCTZ ~25 mg daily, BP control and clinical outcomes were similar with both drugs; hypokalemia was more common with chlorthalidone.[66] As such, 25 mg of HCTZ is typically used, not 12.5 mg; HCTZ 50 mg, which achieves more optimal 24-hour BP reduction, is considered in refractory HTN.

Indapamide is a thiazide-like diuretic with a more pronounced vasodilatory effect.

a. Side effects of thiazides:

- Hypovolemia, hypokalemia, hypomagnesemia: mainly with HCTZ doses >25 mg/day or chlorthalidone. K drops by ~0.4 mEq/L with 25 mg of HCTZ, and ~0.7 mEq/L with 50 mg of HCTZ. Hypokalemia explains why thiazide diuretics were associated with an increased risk of sudden death in old studies. Potassium level should be closely monitored after thiazide initiation. *The combination of thiazide and a potassium-sparing diuretic counteracts the increased risk of sudden death*.[67] Creatinine and potassium are checked 7 days after diuretic initiation.
- Hyponatremia may be due to hypovolemia, but may also be due to the fact that the target of thiazide action, the distal tubule, is the *diluting segment of the nephron* (while the loop of Henle is the concentrating segment); thus, blocking it with thiazides creates a more concentrated, "saltier" urine, which gives a "SIADH-like" picture, especially in the elderly.
- Reduction of urinary calcium excretion may cause hypercalcemia, but on the positive side, may improve bone mineral density and reduce kidney stones (whereas loop diuretics enhance urinary calcium excretion and may aggravate osteoporosis).
- Other dose-dependent metabolic side effects: hyperuricemia, hyperglycemia (mostly related to hypokalemia and attenuated with K sparing diuretics), increased LDL.

b. Dose of chlorthalidone: 12.5–25.0 mg/day. Dose of HCTZ: 25 mg/day (~2:1 equivalence to chlorthalidone). HCTZ may be increased to 50 mg/day in resistant HTN. The 12.5 mg HCTZ dose has limited efficacy, except when combined with a potassium-sparing diuretic.

Rather than doubling the dose of a thiazide, combining it with the potassium-sparing diuretic amiloride improves BP control and eliminates the hyperglycemic and hypokalemic side effects (PATHWAY-3 trial: HCTZ 25 mg up-titrated to 50 mg vs. HCTZ 12.5 mg + amiloride 5 mg up-titrated to 25 mg + 10 mg).[68] It also counteracts the increased risk of sudden death.[67] This comes at the price of a small risk of hyperkalemia, especially in patients with CKD, acute prerenal renal failure, or diabetes, which mandates K monitoring early after therapy initiation and with any illness.

2. Loop diuretics (furosemide, bumetanide, torsemide)

Loop diuretics are mainly used in HF but may also be used for HTN when creatinine is >2.5 mg/dl or GFR is <30 ml/min, in which case the efficacy of thiazides may be reduced. In patients with GFR <30 ml/min, less sodium is filtered overall; in order to maintain appropriate natriuresis, relatively less sodium is reabsorbed from each of the remaining nephrons (compensatory mechanism). In those patients, less absolute and relative sodium can be eliminated by any diuretic, particularly a thiazide diuretic, since even normally, only ~3–5% of sodium is reabsorbed by the distal tubule. Thus, thiazide diuretics are thought to be less effective in patients with advanced renal failure, but, contrary to common belief, remain effective after cumulative dosing. All thiazide diuretics are renally eliminated, have a long half-life, especially chlorthalidone, and cumulate in renal failure, which further potentiates their effect after multiple dosing and explains their efficacy in hypertensive patients with advanced CKD, matching that of loop diuretics in multiple studies;[69,70] in fact, chlorthalidone may be "too" effective and lead to hypovolemia. ***In one randomized trial of patients with stage 4 CKD*** and resistant HTN—60% of whom were on loop diuretics— ***chlorthalidone 12.5–25 mg QD was highly effective*** for BP reduction (↓11/5 mmHg). This came at the cost of creatinine rise >25% in 45% of patients, *more so in patients receiving loop diuretics* at baseline.[70] With chlorthalidone discontinuation, creatinine changes reversed, but interestingly, some of the BP reduction was maintained (7 mmHg). ***Thus, the following diuretic regimens may be used for BP reduction in advanced CKD:*** chlorthalidone 12.5 mg every day or every other day, furosemide once or twice daily, torsemide once daily. Beware that the combination thiazide-loop diuretic increases the risk of kidney injury, and thus, keep the thiazide dose low (chlorthalidone ≤12.5 mg/day) and consider a lower loop diuretic dose during the combination.

The main problems with loop diuretics are: (i) short duration of action (4–6 hours), (ii) diuretic effect that is too potent for isolated HTN. Torsemide has a longer duration of action and may be preferred. In the absence of overt hypervolemia, HF, or advanced renal failure, thiazides are better antihypertensive agents than loop diuretics.

In case of hyponatremia during thiazide therapy, a loop diuretic is an option.

In case of sulfa allergy, thiazide diuretics and the typical loop diuretics cannot be used. Ethacrynic acid, a loop diuretic, may be used instead (available in both oral and IV forms).

3. Aldosterone receptor antagonists (spironolactone 25–50 mg/day, eplerenone)

Aldosterone induces the genomic synthesis of distal Na tubular channels and Na/K pumps that absorb Na and secrete K and H. The aldosterone antagonists block the aldosterone receptors and inhibit this synthesis rather than directly block Na/K pumps. They induce mild diuresis, which may be particularly prominent in patients with hyperactive distal tubular sodium channels or patients resistant to other diuretics. However, in many patients, this mild diuresis cannot account for all the antihypertensive benefit. Aldosterone has proliferative and fibrotic vascular and cardiac effects, and has vasoconstrictive effects through the vascular sodium ion, all of which are counteracted by spironolactone. In fact, spironolactone improves vascular compliance and tone, and increases nitric oxide release.[71] The benefit is seen in patients with or without high levels of aldosterone, with or without adjunctive diuretic therapy, implying that blocking even a slight, unnoticed excess of aldosterone provides clinical benefit. A spironolactone dose of up to 100 mg may be used in primary aldosteronism, if K allows.

Aldosterone antagonists and other potassium-sparing diuretics (triamterene or amiloride, direct distal sodium channel antagonists) are marginally effective for HTN as monotherapy but are very effective in combination therapy.[1] They may be used with thiazides to improve BP control and to counteract the risk of sudden death associated with hypokalemia.[67] The correction of hypokalemia has, by itself, vasodilatory and antihypertensive effects. Because the increased risk of diabetes associated with thiazides is related to hypokalemia, the addition of potassium-sparing diuretics to thiazides attenuates the risk of diabetes. Aldosterone antagonists and amiloride are excellent agents for refractory HTN in white or black patients, especially obese patients.[40,43,44]

The main side effect is hyperkalemia. Thus, aldosterone antagonists should be avoided if GFR <30 ml/min (ESC HTN guidelines), initiated with caution if K is 4.6–5 mEq/L, and potassium should be closely monitored at 3 and 7 days, then every 4 weeks for 3 months, then every 3 months.

VIII. Second-line antihypertensive drugs

A. β-Blockers

β-Blockers exert antihypertensive effects through a reduction of cardiac output but also through the blockade of juxtaglomerular β_1-receptors, which reduces renin release. Furthermore, lipophylic β-blockers may inhibit central sympathetic tone. However, β-blockers, particularly the hydrophilic β-blocker atenolol, appear inferior to first-line antihypertensive agents. In one meta-analysis, β-blockers reduced stroke and HF in comparison with placebo but were inferior to diuretics in regards to stroke and mortality.[35] In the LIFE trial, atenolol was inferior to losartan for stroke reduction.[36] In the ASCOT trial, an atenolol-based strategy was associated with more stroke, mortality, total cardiovascular events, and diabetes than an amlodipine-based strategy.[37] This inferiority of β-blockers may be related to atenolol itself, to an inappropriate once-daily use of atenolol, or to the fact that β-blockers are less effective in reducing central BP in poorly compliant arteries.[53]

While heart rate reduction is associated with improved outcomes in HFrEF, heart rate reduction with β-blockers in hypertensive trials has been linked to increased CV events, mainly when heart rate declines to <65 bpm. This probably occurs because a low heart rate may paradoxically increase stroke volume even when a β-blocker is used, with a resultant increase in pulse pressure and central aortic pressure.[72] **Not even in stable CAD or HFpEF is heart rate reduction clearly beneficial.**

On the other hand, data from the UKPDS study of diabetic patients showed that β-blockers were equivalent to ACE-Is in the reduction of cardiovascular events.[73] In younger patients with compliant arteries, β-blockers, in formulations other than atenolol, may remain effective.

1. *β-Blockers are contraindicated in:*[74]

- Decompensated HF (they are indicated for compensated systolic HF, where they should be titrated slowly, every 2 weeks).
- Symptomatic or severe sinus bradycardia or AV block (<55 bpm, PR interval >0.24 second, any second- or third-degree AV block).
- History of severe asthma or decompensated COPD. Patients with mild-to-moderate reactive airway disease or compensated COPD usually tolerate small-to-medium doses of β_1-blockers (e.g., metoprolol up to 100 mg/day).

Other side effects: fatigue, impotence (rarely). Fatigue may be due to a limitation of the cardiac output reserve or to a CNS effect.

Metabolic side effects: β-blockers may worsen hyperglycemia, hypoglycemia, and hypoglycemic unawareness. However, β-blockers are not contraindicated in diabetic patients if there is a compelling indication, and in fact β-blockers have a particular benefit in diabetic patients (UKPDS study). β-Blockers can increase triglycerides and reduce HDL.

2. *Cardioselective β_1-blockers* (atenolol, metoprolol, bisoprolol) have fewer metabolic effects, bronchospastic effects, and vasoconstrictive effects (better tolerated in PAD) than non-selective β-blockers but lose their cardioselectivity at high doses. Atenolol has a shorter duration of action than commonly thought, and, if used, should be given twice daily like metoprolol. Atenolol, unlike metoprolol, is renally cleared, and the dose should be reduced and given once daily in renal failure.

3. *Lipophilic β-blockers* are metabolized by the liver, leading to reduced bioavailability and a short half-life (metoprolol, propranolol: highly lipophilic; carvedilol, labetalol, bisoprolol: moderately lipophilic). Atenolol is a *hydrophilic β-blocker* but has a short half-life as well (6 hours). Lipophilic β-blockers have more CNS effects, such as fatigue, somnolence, and depression, but may also be more beneficial as a result of sympathetic neuromodulation. Besides the inappropriate once-daily dosing, hydrophilicity may explain why atenolol has not been clearly beneficial in HTN.[74] Yet, consider switching to atenolol if CNS side effects occur.

4. *Mixed α_1- and non-selective β-blockers* (labetalol, carvedilol) are more effective agents for BP reduction.[75] Carvedilol, in comparison with metoprolol, does not worsen glucose or lipid control, improves insulin resistance, provides better renal protection, and does not lead to weight gain;[75] it may also have a beneficial urological effect in patients with benign prostate hyperplasia.[76]

Labetalol—and to a lesser extent, carvedilol—lose significant α-blocking effect with long-term administration, while the β-blocking effect remains unchanged. Either way, the α-blocking effect is not as pronounced as with prazosin (carvedilol provides enough α-blockade to derive a benefit without the inherent harm).[77,78]

5. *Nebivolol* is the most cardioselective β_1-blocker. It also has direct vasodilatory effects mediated by nitric oxide potentiation. Nebivolol, like carvedilol, seems to have a more pronounced antihypertensive effect, without dyslipidemic and dysglycemic effects.

6. *Sudden β-blocker withdrawal* should be avoided, as it may lead to a withdrawal syndrome of tachycardia, HTN, and myocardial ischemia. Rather, they are slowly down-titrated over ~2 weeks.

B. α_1-Blockers

α_1-Blockers are used as third-line agents and are mainly indicated in patients who have HTN and benign prostate hyperplasia. α-Blockers reduce BP less effectively than first-line agents and are associated with a higher risk of HF and stroke as compared to first-line agents; this is related to a lesser antihypertensive efficacy but also to the reflex sympathetic stimulation.[79]

Beside the higher risk of HF, α-blockers are associated with the highest risk of orthostatic hypotension (especially with the first dose), which dictates their bedtime use. Extended-release doxazosin is less risky as it allows a more gradual release of the drug over 24 hours, eliminating the need for slow titration. This long-acting doxazosin was effective as a third-line agent in resistant HTN in PATHWAY-2 and ASCOT studies (up to 12/7 mmHg BP reduction, 50% less than spironolactone).

Prazosin is used for HTN, doxazosin and terazosin are used for both HTN and prostate hyperplasia, while tamsulosin is a more selective α_{1a}-blocker that is selective for urethral tissue.

C. Clonidine (centrally acting sympathomimetic, alpha-2 receptor agonist)

Clonidine leads to vasodilatation and negative ino- and chronotropism. It may worsen bradycardia (especially in combination with β-blockers) and HF.[30] In fact, clonidine is better avoided in HF, as a related central-acting sympathomimetic drug increased mortality in HF.[30]

Dose: 0.1–0.3 mg BID. Clonidine frequently leads to drowsiness. Acute withdrawal syndrome occurs on sudden withdrawal, hence clonidine must be tapered off slowly (e.g., 0.1 mg/day every 3–7 days). Clonidine is not an appropriate drug when compliance is uncertain. Because of this and *the CNS depressing effect, clonidine is a last-line choice*.

D. Hydralazine

Hydralazine is a direct-acting vasodilator that is mainly beneficial in black patients with HF, in combination with nitrates. It is also used as a third-line agent for refractory HTN.

Hydralazine is short-acting and has the following side effects:

- Reflex tachycardia and worsening of myocardial ischemia. Therefore, it must be used cautiously in CAD, along with nitrates and/or β-blockers.
- Fluid retention, as the abrupt drop in BP activates the renin-angiotensin system, which means that it *must be used with a diuretic*.
- Reversible drug-induced lupus (especially with high doses or in the case of renal failure).

Note that ACE-Is and long-acting DHPs are vasodilators that do not lead to reflex tachycardia. This is partly related to a slow-onset, sustained rather than abrupt effect. ACE-Is do not lead to reflex tachycardia because they reset the baroreceptor reactivity to lower levels of blood pressure.

E. Direct renin inhibitor

A direct renin inhibitor (aliskiren) is another blocker of the renin–angiotensin–aldosterone system and has the same antihypertensive effect as an ACE-I. It has renoprotective effects, reduces proteinuria, and is effective in combination with a CCB or a thiazide and seems better tolerated than an ACE-I. In combination with ACE-I or ARB, the additional antihypertensive effect is minimal.[80] Aliskiren is very long-acting – its effect lasts several days to weeks; this is an advantage of this drug.

No long-term outcome data are available, so an ACE-I or an ARB is preferred. In patients already taking ACE-I or ARB, aliskiren barely provides any additional antihypertensive effect. In the ATMOSPHERE trial of HFrEF, aliskiren was not non-inferior to ACE-I, and the combination with ACE-I was not superior to standalone ACE-I and led to more adverse events.[81] Thus, the role of aliskiren has yet to be defined.

IX. Orthostatic hypotension and extremely labile HTN

A. Orthostatic hypotension

Before starting therapy and during follow-up, check for orthostatic symptoms (dizziness) and check orthostatic changes in blood pressure. BP is checked during supine position then at 1 and 3 minutes of direct standing (the sitting position is skipped). Orthostatic hypotension is defined as SBP or DBP drop ≥20 or 10 mmHg, respectively. It is common, present in 10% of hypertensive patients. Patients may be hypertensive while recumbent but hypotensive while standing. **Orthostatic hypotension is often misattributed to hypovolemia but is rather due to HTN itself, which begets progressive arterial stiffness and BP lability over time.** In fact, orthostatic hypotension may be seen in volume overload states and is due to:

- Poor arterial compliance secondary to severe chronic HTN itself, age, or PAD. *Poor arterial compliance leads to a striking rise but also striking fall in BP upon small changes in arterial volume, as may happen during the change from a supine to an upright position. These patients may have severe supine hypertension yet severe orthostatic hypotension. HTN therapy may ↓ orthostatic hypotension over the long term by improving arterial compliance (ACC and ESC).*
- Autonomic dysfunction related to age, diabetes, B12 deficiency, renal disease, or amyloidosis. The reduced baroreceptor activity prevents the rise in heart rate and vascular tone upon orthostasis.
- Immobility, deconditioning, and prolonged recumbency create autonomic and cardiovascular deconditioning with insufficient rise in arterial tone and CO during upright posture.
- Hypovolemia, hypokalemia, psychotropic drugs.

Antihypertensive drugs tend to initially worsen orthostatic hypotension, regardless of its cause, as they further impede the compensatory mechanisms that occur during upright positioning, such as vasoconstriction, cardiac output increase, or baroreceptor activity. But drugs remain beneficial in hypertensive patients with asymptomatic orthostatic hypotension (SPRINT trial),[82] and may improve orthostatic hypotension over the long term.[1,2] Even without orthostatic hypotension, patients with severe HTN may experience reduced perfusion and dizziness upon initiating therapy. This is related to the autoregulation curve, which is shifted to the right (Figure 23.2). As the curve shifts back to the left over time, dizziness and any transient rise in creatinine typically resolve.

B. Extremely labile HTN

This is characterized by: (1) hypertensive crises mixed with (2) episodic hypotension, with and without an orthostatic component. This extreme lability is seen in severe arterial non-compliance and in autonomic failure; baroreceptors lose their control of the BP, which leads to an unbridled BP rise and fall with position, volume status, salt intake, and catecholamines (stress, profound white coat effect). It is also seen in other conditions:[83]

- Severe HTN, per se, can cause pressure diuresis and thus paradoxically facilitate hypotension and orthostatic lability
- HTN treated with short-acting medications, particularly clonidine, which causes hypotension followed by rebound HTN
- Tizanidine, a central muscular relaxant, with a central sympathomimetic effect similar to clonidine.
- Antidepressants and sedatives
- Neck radiation or surgery, directly affecting the baroreceptor function
- Conditions characterized by hyperadrenergic surges, such as POTS, panic attack, cocaine, or rarely pheochromocytoma. In the latter conditions, the pulse tracks BP, with tachycardia during HTN, and a paradoxical decline of pulse during hypotension. In autonomic dysfunction, the pulse is unaffected.

C. Treatment of patients with orthostatic hypotension or extreme BP lability[83,84]

Treatment of HTN peaks may paradoxically attenuate hypotensive episodes, particularly with continued therapy, as it reduces pressure diuresis and improves arterial compliance. The following **5 lifestyle measures** are key therapies:

- Sitting up during HTN crisis; lying down, handgrip or touching a cold surface during hypotension (pressor response).
- A 16-oz oral water bolus may be used before getting out of bed in the morning, and during hypotensive spells (pressor response).
- Waist-high compression stocking and abdominal binders.
- Sleep at 20–45 degrees, which prevents recumbent, nocturnal HTN. Also, upright sleep prevents pressure diuresis and may stimulate the renin–aldosterone system, preserving body fluid volume. This may be done by raising the head posts 6 inches (not just stacking pillows). *Abdominal heating pads* may also reduce supine HTN via vasodilatation.
- Deconditioning being a major perpetuator of orthostatic intolerance, exercise is key; seated biking, rowing, or water aerobics may be most tolerated. Strenuous exercise and raising core body temperature are avoided, as this may reduce BP.

Also, ensure proper hydration, avoid heat, avoid large meals high in carbohydrates, and avoid exertion after eating. Avoid diuretics, as BP is very sensitive to volume and sodium loss.

HTN drugs:[83–85]

- SBP of 160 mmHg may need to be accepted, and upright sleep may be sufficient treatment for this degree of supine HTN.[84,85] Only severe supine HTN > 160–180 mmHg necessitates BP medication(s). Start BP medications at low doses, one drug at a time. Several groups

recommend a short-acting BP medication at bedtime when HTN is predominantly supine or nocturnal (captopril, losartan, nifedipine, NTG patch 0.1 mg/hr during the night).[84,85]

- ***Avoid short-acting daytime BP medications, especially clonidine, and avoid chasing HTN spikes, which perpetuates a cycle of hypotension and rebound catecholamines and HTN***.[83]
- ACE-Is/ARBs are *least likely to worsen orthostatic hypotension*. Dihydropyridine CCBs are the second best option.
- Diuretics are avoided, as well as β-blockers and α_1-blockers preferably, as those drugs worsen orthostatic hypotension the most.
- HTN drugs are combined with lifestyle measures to prevent and treat hypotensive spells. ***Occasionally, nighttime HTN drugs are combined with daytime droxidopa or as needed midodrine*** to control severely symptomatic hypotensive spells; droxidopa is less likely to worsen supine HTN.

2. ACUTE SEVERE HYPERTENSION: HYPERTENSIVE EMERGENCIES AND URGENCIES

I. Definitions

A. Hypertensive emergency

Hypertensive emergency is severe HTN with acute end-organ damage. It is not defined by the level of BP but by its effect, which is related not only to the severity of HTN but to the acuteness of the rise. In general, **diastolic BP is >120 mmHg and/or SBP is >180 mmHg** in HTN emergency.[1] Truly "malignant" HTN leads to diffuse microvascular injury, similar to disseminated intravascular coagulation, with renal, cerebral, and cardiac ischemia. Acute damage to the following organs defines HTN emergency:

1. *Eye* (papilledema or retinal bleed): this is the most useful and specific definition of malignant HTN with acute microvascular injury.
2. *Acute encephalopathy* due to cerebral ischemia and edema: starts as headache/nausea/vomiting, followed by confusion.

Hypertensive encephalopathy must be differentiated from stroke. In both cases, severe HTN occurs and is associated with neurological changes. Unlike stroke, hypertensive encephalopathy is a non-focal neurological problem that progresses more insidiously than stroke and reverses when BP is controlled.

3. *Cardiovascular*: acute myocardial ischemia, pulmonary edema, aortic dissection.
4. *Renal*: acute kidney injury, called *malignant nephroangiosclerosis*, results from the acute microangiopathy. It is characterized by increased creatinine and hematuria or proteinuria on urinalysis. However, these renal findings are non-specific and may be chronic. Even if acute, it is possible that the renal failure is causing HTN rather than the reverse.

B. Hypertensive urgency

Hypertensive urgency is acute HTN (BP > 180/110–120) without acute end-organ damage.[1,2,86] Mild symptoms may be present, like headache, epistaxis, or mild dyspnea, but the majority of patients with severe HTN are asymptomatic; lowering BP is not an emergency in this case.[1,2,86,87]

C. Causes of acute severe HTN

Essential HTN is still the most common cause of malignant HTN.[86] In fact, over 75% of patients with hypertensive urgencies/emergencies are known to have chronic HTN, and non-compliance with medical therapy is the most common trigger. However, a small proportion of patients, particularly white patients, may have secondary hypertension, which should be sought if no clear precipitant is present or if HTN is resistant.

II. Treatment of hypertensive emergencies

A. Guidelines of treatment

Intravenous drugs, preferably short-acting and titratable drugs, are initially used, the goal being a reduction of mean blood pressure by ~25% within 30–60 minutes, then to 160/100–110 mmHg over 2–6 hours, then to normal over the next 48 hours (ACC).[1,2,86–90] The vascular beds are autoregulated and adapted to a high BP, which explains that a sharper BP drop will lead to myocardial, cerebral, and renal ischemia (Figure 23.2). A certain degree of quick BP reduction is necessary in hypertensive emergencies, as active organ damage is ongoing.

In 4 conditions, BP needs to be reduced further and faster to limit the ongoing damage (ACC and ESC):[88] aortic dissection (<120 mmHg in <20 minutes), ongoing myocardial ischemia or pulmonary edema (<140 mmHg in <60 minutes), or severe pre-eclampsia (<160/110 mmHg in <60 minutes). Beware that in myocardial ischemia and HF, BP may precipitously fall once ischemia and HF improve, as the catecholaminergic surge drops.

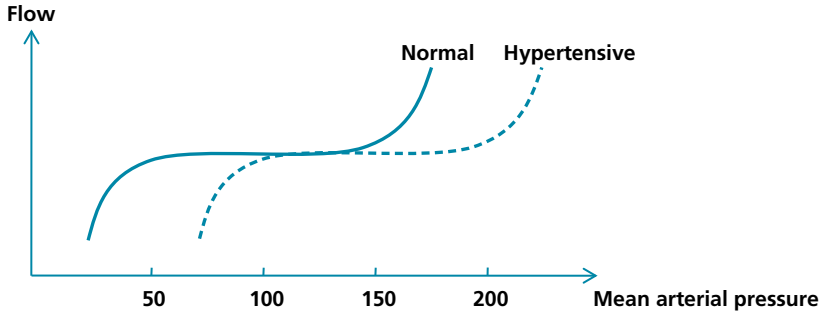

Figure 23.2 Autoregulation curve. Autoregulation of microvascular (mainly arteriolar) resistance allows the preservation of organ perfusion across a wide range of mean systemic pressures, between 50 and 150 mmHg. In severely hypertensive patients, this curve is shifted to the right (*dashed curve*), and systemic perfusion decreases when mean systemic pressure decreases below 100 mmHg (for example, when SBP decreases from 200 mmHg to 140 mmHg).

Two or 3 oral drugs may be introduced at 6–24 hours, after ensuring that BP does not excessively fall in the first few hours.[86] This is followed by tapering of the intravenous therapy. A normal BP is achieved over days. A patient who was supposed to receive multiple antihypertensive drugs chronically may not have been fully compliant with therapy; reintroduce those drugs gradually, e.g., 2 drugs at a time, rather than altogether.

B. Intravenous drugs

1. *Nitroprusside* drip (0.25–4 mcg/kg/min): nitroprusside is a NO donor with direct vasodilatory effect.
- Immediate onset of action, short duration of action (lasts 3–5 minutes on cessation), easy to titrate.
- Indicated in all hypertensive emergencies (including HF, myocardial ischemia, cerebrovascular events). Tachyphylaxis may occur.
- Risks: nitroprusside contains cyanide molecules, part of which is sulfurated by the liver to form thiocyanates. Cyanide toxicity is rare (liver failure). Thiocyanate toxicity is rare but may be seen in renal failure or when high doses are used for prolonged periods (>2–3 mcg/kg/min), as thiocyanate has a long half-life. Thiocyanate levels are checked after 5 days of therapy, and sooner (2 days) in high-risk patients.

Rarely, nitroprusside may worsen myocardial ischemia through coronary microvascular dilatation that is more pronounced across the healthier coronary territories: this diverts flow, via collaterals, away from the obstructed territories (coronary steal). Therefore, nitroprusside is better avoided the first 9 hours of an acute MI.[91]

2. *Labetalol* (α-, β-blocker; α/β ratio 1/7): labetalol is administered as IV bolus(es) (20–80 mg Q10 minutes until desired effect is achieved, up to a total of 300 mg), followed by scheduled boluses Q2–6 hours or an infusion (0.5–2.0 mg/min).
- Fast onset (minutes), but effect lasts 2–6 hours, which obviates the need for an infusion. Note that, if an infusion is used, the effect will last several hours after off-titration.
- May be used in most emergencies, except acute HF.

3. *Nicardipine* is a dihydropyridine CCB administered as a drip (2.5–15 mg/h):
- Fast onset, but effect lasts 1–4 hours.
- Caution is suggested in: (i) acute HF, as nicardipine has mild negative inotropic effects; (ii) acute coronary syndrome, as reflex tachycardia may occur (in the latter case, combine nicardipine with a β-blocker).

Nicardipine was more efficacious than labetalol in 2 studies.[86,92] Another dihydropyridine, *clevidipine*, has a fast onset and a fast offset and may be used as an IV infusion. It has the same pitfalls as nicardipine, except for the much shorter duration of action and the plasma metabolism (independent of hepatic or renal function); it is slightly more efficacious than nicardipine and is safe in HF.[93,94]

4. *Nitroglycerin* is indicated in acute HF and acute coronary ischemia. HTN being partly driven by HF and ischemia (catecholamine surge), nitroglycerin relieves HTN through its relief of ischemia and HF. Outside these 2 conditions, it is not very effective and tolerance to its effect develops rapidly, within 24 hours.

5. *Fenoldopam* drip (0.1–0.3 mcg/kg/min, max 1.6 mcg/kg/min): fenoldopam is a short-acting vasodilator that acts as an agonist of dopamine-1 and α_2 receptors. Unlike other intravenous antihypertensive agents, it may preserve or increase renal perfusion while it decreases BP, and is the preferred agent in patients with acute kidney injury.
- Onset in minutes; effect lasts 30 minutes.
- Can be used in all emergencies, particularly if renal function is impaired.
- Caution in glaucoma.

6. *Hydralazine*: in emergencies, hydralazine is administered as intravenous boluses of 10–20 mg Q2–4 hours.
- Onset of action is fast (10–20 minutes), but effect lasts 3–8 hours, more so in renal failure.
- Less effective and less predictable than other antihypertensive agents and may occasionally lead to profound and uncontrollable hypotension. It may also lead to reflex tachycardia and myocardial ischemia. Thus, hydralazine is preferably avoided in all hypertensive emergencies, particularly in acute myocardial ischemia.
- First-line agent in pre-eclampsia/eclampsia.

7. *Enalaprilat* is administered as intravenous boluses of 0.625–1.25 mg Q6 hours (max 5 mg IV Q6 hours). A 1.25 mg IV dose is equivalent to a 5 mg oral dose.
- Onset is fast (15 minutes); effect lasts 6 hours.
- Unpredictable and uncontrollable BP reduction, sometimes severe (especially in high renin states, such as renovascular HTN or renal failure).
- Also, avoid it in acute MI because of the risk of precipitous hypotension.

Severe HTN with myocardial ischemia (chest pain, ST changes):
- While acute malignant hypertension may lead to secondary myocardial ischemia and troponin rise, ACS per se may, on the flip side, lead to hypertension (catecholamine surge). In ACS, hypertension dramatically improves with angina relief and NTG, whereas in malignant hypertension, hypertension is persistent and difficult to control despite multiple antihypertensive therapies, NTG having only a minor effect on it.

Severe HTN with acute HF:
- While HTN may cause acute HF, acute HTN may at least be partially secondary to the acute pulmonary edema and the accompanying sympathetic surge. ***This explains the precipitous BP fall commonly seen during acute diuresis.*** Besides which, the impaired vascular compliance leads not only to sudden BP rise with slight volume change but also to sudden BP fall. While vasodilatation increases cardiac output of the failing heart, excessive vasodilatation, as is seen sometimes in patients who get sedated for intubation, may not be matched by enough rise in the limited cardiac output, which precipitates hypotension. Thus, the aggressive initiation of vasodilators (NTG, nitroprusside, nicardipine), sedative agents, or multiple antihypertensive agents should be avoided until diuresis has been initiated.

III. Treatment of hypertensive urgencies

BP is slowly reduced over 24–72 hours.[86,88] ***End-organ damage is not imminent, the short-term risk of adverse outcomes is low and not modified by acute BP reduction, and the main risk of hypertensive urgencies is over-treatment.***[86,87] **Hypertensive urgencies do not benefit from referral to the emergency department or hospitalization.** Place the patient in a quiet environment, treat pain/anxiety, recheck BP, and start oral medications. If the patient has withheld antihypertensive medications, restart them; this alone often allows HTN control.

Neither hospitalization nor immediate BP reduction is necessary. Prescribe 2 oral medications that will provide a long-term benefit and reduce BP over 24–72 hours, and discharge home with close follow-up within 1 week.

In hospitalized patients, "as needed" orders for hydralazine or labetalol are often inappropriate (ACC class III). These orders acutely and intermittently reduce severe, asymptomatic HTN, rather than address it in a sustained fashion. This practice was associated with prolonged hospital stays and 1.5-2 times higher risk of AKI and myocardial injury. This was seen even in matched analyses of patients with similarly high BP (>160 or >180 mmHg) who got treated vs. not treated.[95]

IV. Specific situations (see Table 23.5)

Table 23.5 Treatment in specific settings.

A. Ischemic stroke
- Tolerate BP up to 220/120 mmHg. In patients treated with thrombolytics or mechanical thrombectomy, BP should be lowered and maintained at ≤180/105 mmHg for ≥ 24 hours[1]
- Start treating HTN beyond the first 2 days; normalize it in 1–2 weeks. In the first 2 days, initiating or re-initiating therapy for BP < 220/120 does not improve mortality or dependency (CATIS and SCAST trials).[96,97]

B. Hemorrhagic stroke
- Control SBP to 140 mmHg or lower if the cerebral perfusion tolerates it. As BP is reduced, clinically monitor the mental status or invasively monitor the intracranial pressure and the cerebral perfusion pressure
- Labetalol or nitroprusside is the agent of choice

C. Aortic dissection
- Regimen should always include a β-blocker to reduce the aortic pulse pressure and sharpness of pressure rise (dP/dt). Vasodilators should not be administered alone, as they increase dP/dt
- Consider labetalol or the combination of nitroprusside and a β-blocker (e.g., esmolol)
- Aggressive BP control is indicated even if BP is normal; try to achieve a mean BP of ~70 mmHg (SBP ~90–100 mmHg)

D. Acute HTN with myocardial ischemia (ACS)

Give a combination of:
- NTG IV
- β-Blockers orally or IV in the absence of contraindications and risk factors for cardiogenic shock (see Chapter 2)
- Oral ACE-I, preferably oral captopril, which is the fastest and shortest-acting oral ACE-I; avoid the intravenous ACE-I enalaprilat
- Add nitroprusside IV or nicardipine IV if the preceding is not enough

E. Scleroderma crisis
- ACE-Is. In scleroderma, HTN results from severe activation of the renin–angiotensin system, and leads to acute, progressive microvascular injury and thrombotic microangiopathy, including renal injury. ACE-Is stabilize or improve renal function in most of those patients

F. Cocaine

First-line therapies:
- Benzodiazepine
- NTG

Second-line therapies for persistent HTN or persistent chest pain:
- Verapamil or diltiazem in the absence of HF, or long-acting dihydropyridine, orally (preferably) or intravenously
- Phentolamine (α-blocker)
- Avoid β-blockers acutely, even α- and β-blocker

G. Postoperative HTN
- Analgesics
- β-blockers, especially labetalol
- Post-cardiac surgery: NTG, β-blockers

H. Hypertensive pseudo-emergency
- HTN is related to a massive catecholaminergic surge from pain, anxiety, hypoxia, hypercapnia, postictal state, hypoglycemia. Treat the underlying cause

3. TARGET RESTING HEART RATE IN DIFFERENT CARDIAC CONDITIONS

A tight resting rate control <70 bpm has only proven beneficial in chronic sinus-rhythm HFrEF, not in HFpEF, AF (even AF with HFrEF), decompensated HFrEF, stable CAD, or HTN.

This is a **summary of the target resting heart rate in different conditions:**

1. Normal individual, maximal heart rate with exercise: 220 − age

2. HFrEF, chronically, at rest in sinus rhythm: <70
   HFrEF, decompensated or during exercise: 100–110s
3. HFpEF, chronically at rest: 75–100
   HFpEF, decompensated or mild/moderate exercise: likely 100–120s
4. AF chronically at rest: 75–100 (even if HFrEF)
   AF with decompensated HF or critical illness: 100–110s
5. AF rate that causes hemodynamic compromise and requires urgent cardioversion
   >150 bpm in the absence of HF
   >120–130 bpm in HFrEF
   >130 bpm in HFpEF

Data:

1. **In HFrEF**, the maximal CO seems to be achieved with a HR ~100–110s bpm at rest and with exertion, in sinus rhythm or AF (TREPPE and Bowditch revisited trials).[98–100] Beyond this rate, CO often does not rise. This is not because of reduced diastolic filling beyond a rate of 110s: in fact, as we see on the Starling curve, HFrEF is often not preload dependent and unless the patient is hypovolemic on the upslope of the Starling curve, a reduction in preload often does not affect CO in HFrEF. This suggests that a higher rate could benefit patients with HF. The fact that a rate higher than 120 was not beneficial reflects the loss of Bowditch phenomenon in the energy and metabolically depleted systolic HF, wherein contractility declines at higher rates.

Thus, the best CO and peak VO2 consumption in HFrEF are achieved at a rate of 100–110s bpm. This is an acceptable rate in exercise or decompensated HFrEF.

Yet, the resting heart rate goal is <70 bpm at the compensated stage of sinus-rhythm HFrEF.

Data from β-blockers trials suggest lower mortality with resting heart rate <70, and the SHIFT trial with ivabradine suggests fewer HF hospitalizations with the latter heart rate.[101,102]

2. Conversely, heart rate reduction has a questionable merit in **HFpEF** and in **AF**, where a rate of 80–100 bpm may be acceptable and even optimal.

In many HFpEF subsets, particularly those with the most restricted LV, the stiff and small LV cavity has limited capacity to raise its filling at slower heart rates, even in a compensated state, and may fully rely on heart rate to maintain cardiac output (Figure 23.3).

According to 2 trials, pure heart rate slowing with ivabradine was harmful in HFpEF.[103,104] One trial suggested that β-blocker withdrawal improves functional capacity and diastolic E/E' in HFpEF with resting heart rate <75 bpm and chronotropic incompetence (PRESERVE-HR trial).[105] Two other trials suggested that higher baseline pacing rate in HFpEF patients with pacemaker (~75-80 bpm vs. 60 bpm) improves quality of life and BNP, and reduces AF (myPACE trial).[106,107]

Moreover, *moderately* higher heart rates up to 120 bpm enhance LV contractility and *accelerate relaxation kinetics, particularly as the LV operates at a smaller volume and a more compliant portion of the P-V relationship*. This is not a lusitropic effect, as the pressure-volume relationship remains steep; it is just that this relationship is operating at lower volumes and pressures, the whole rectangle being shifted down and to the left, at a more favorable pressure-volume point.[106,108] Up to rates of 120 bpm, relaxation kinetics may accelerate and diastolic pressures decrease in HFpEF.[109,110] Beyond 120 bpm, lusitropy may get impaired.

Also, a higher heart rate over the long term, by reducing preload and central aortic pulse pressure and afterload, may induce eccentric LV remodeling with a reduction in ventricular wall thickness and a more favorable left ventricular mass-to-volume ratio and ventricular compliance.[111]

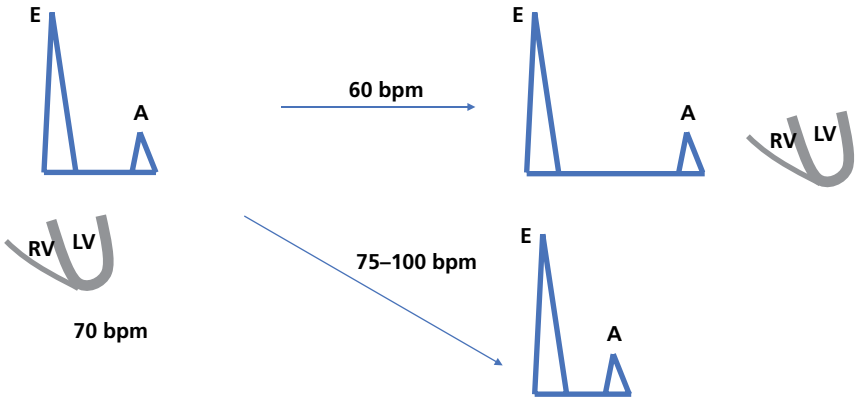

Figure 23.3 Effect of heart rate changes in HFpEF. HFpEF patients have limited capacity to use the Starling curve: if you give them more time to fill the LV, they may waste that time without dramatically increasing LV filling. Consider the diastolic filling of a severe restricted HFpEF at the baseline rate of 70 bpm (left image). If you slow the heart rate, the stiff LV does not improve its diastolic filling and LV diastolic volume may remain unchanged, as LV diastolic pressure quickly shoots up and prevents the LV from filling beyond this narrow E wave. As such, a dead phase is created in diastole where no filling happens; stroke volume is unchanged. In fact, a faster rate of 75–100 bpm allows more overall LV filling per minute and more cardiac output, via providing more cardiac cycles.

3. Specific case of AF – Atrial systole contributes to ~20–40% of LV filling and stroke volume (more so in stable HF, less so in decompensated HF). With loss of atrial systole, stroke volume ↓ and CO risks declining by up to 40% at a similar heart rate.

To maintain CO, heart rate must rise. For the same patient under the same conditions, when going from sinus rhythm to AF, the heart rate must rise to maintain CO. Hence aggressive rate control in AF (rate <80 bpm) has not been more beneficial than lenient rate control.

Even in HFrEF, AF rate control <80 bpm has not shown to be beneficial, based on β-blocker trials meta-analysis.[101,102]

The irregularity of AF further reduces CO when compared with a similar but regular rate, especially when RR intervals swing between rates <85 and >120 bpm. Some date suggest that the maximal CO in AF is achieved with AF rate of ~100–120s bpm (depending on preload) (Figure 23.4).[112–114]

4. A tight rate control <70 bpm using ivabradine failed to improve outcomes in stable CAD in the SIGNIFY trial.[115] Heart rate reduction <65 bpm with β-blockers in hypertensive trials was associated with increased event rate.[72]

Mild arm exercise

Mild arm exercise with isoproterenol

Figure 23.4 Simultaneous PCWP-LV recording in a 76-year-old woman with *AF and restrictive HFpEF.* The left image shows her PCWP during mild arm exercise: V wave rises dramatically to about 45 mmHg, as the stiff restricted LV and the noncompliant LA are overwhelmed by an even slight rise in venous return. Note that her rate is 88 bpm.

Conversely, on the right, isoproterenol infusion is given, and the same mild exercise is repeated. By allowing her AF rate to rise to 105–110 bpm, her PCWP dramatically improves. This reflects the improved CO and the overall increased LA emptying and LV filling via the increased number of emptying cycles.

QUESTIONS AND ANSWERS

Question 1. A 58-year-old obese man (BMI 40), diabetic, has refractory hypertension of 155/70 despite HCTZ, amlodipine 10 mg daily, and lisinopril 20 mg daily. Besides medical therapy, what are the 3 most important interventions that could improve his HTN?

Question 2. In the above patient, what is the best drug to be added for resistant hypertension?

A. Bisoprolol
B. Carvedilol
C. Clonidine
D. Spironolactone
E. Hydralazine

Question 3. A 55-year-old white man has HTN and is receiving lisinopril 20 mg daily. His BP on follow-up is 150/80 mmHg. He does not have any peripheral edema. What is the best treatment option, besides lifestyle measures?

A. Increase lisinopril to 40 mg then 80 mg daily
B. Add HCTZ 25 mg
C. Add amlodipine 5 mg
D. B or C

Question 4. A 60-year-old man presents with acute pulmonary edema. He has LVH on the ECG, and no ischemic abnormalities. BP is 210/100 mmHg. What is the next step?

A. Intravenous diuresis
B. Diuresis + nitroprusside, aiming for a reduction of mean arterial pressure ~25% at 30 minutes
C. Diuresis + nicardipine, aiming for a reduction of mean arterial pressure ~25% at 30 minutes
D. Diuresis + nitroglycerin

Question 5. Concerning the HTN autoregulation curve:
A. The x-axis is pressure, the y-axis is tissue flow
B. In HTN, the curve is shifted to the right
C. This curve explains why patients with chronic HTN do not tolerate an abrupt pressure drop to the normal level
D. The curve may shift back to the left with time, which explains that the symptoms and the slight creatinine rise sometimes seen upon initiation of antihypertensive drugs improve with time
E. All of the above

Question 6. A 52-year-old African-American man has HTN on several clinic visits, 150/95 mmHg. He is started on hydrochlorothiazide (HCTZ). Which statement is *incorrect*?
A. For better BP control and fewer metabolic effects, it is best to combine thiazide with amiloride or triamterene
B. Potassium and creatinine need to be checked 1 week after therapy initiation
C. A 12.5 mg dose of HCTZ is usually an effective starting dose
D. Thiazide diuretic is initially effective through volume reduction but is later effective through the reduction of vascular resistance

Question 7. In a patient with CKD, which statement is *incorrect*?
A. Aggressive BP control to a mean SBP of 128 mmHg did not clearly improve renal outcomes in comparison with SBP of 140 mmHg in the AASK trial
B. Diuretic therapy should be avoided
C. ACE-I improves renal outcomes in comparison to CCB despite similar BP control, mostly in patients with proteinuria (AASK and IDNT trials)
D. In the ALLHAT trial, analysis of patients with nephropathy showed that ACE-I was not superior to chlorthalidone or amlodipine in respect to renal outcomes (different result from AASK and IDNT)

Question 8. In a patient with diabetes and without CKD, which of the following is *incorrect*?
A. ACE-I or ARB is preferred, as it reduces the incidence of diabetic nephropathy compared to thiazides or CCBs
B. ACE-I is preferred to a thiazide diuretic, as the latter may worsen diabetes control. Yet both reduce cardiovascular and renal events to a similar degree (ALLHAT trial)
C. ACE-I/ARB may reduce the incidence of diabetes in patients with prediabetes according to the NAVIGATOR trial but not the DREAM trial

Question 9. Which statement is *incorrect*? β-Blocker therapy:
A. Has more LVH-reverting effect than losartan
B. Is less effective in reducing central aortic pressure than ACE-I, CCB, or diuretics
C. Is associated with a higher risk of stroke and mortality in comparison to thiazide diuretics or CCB

Question 10. Which of the following statements is *incorrect*?
A. In the ALLHAT trial, chlorthalidone, lisinopril, and amlodipine were associated with similar mortality and MI, but thiazide was superior for HF reduction, and superior to lisinopril for stroke reduction
B. In the VALUE trial, valsartan and amlodipine were associated with similar cardiac mortality and morbidity
C. In the ASCOT trial, atenolol and amlodipine were associated with similar stroke and mortality
D. HCTZ at the doses of 12.5–25 mg achieves less 24-hour BP reduction than chlorthalidone, ACE-I, or CCB
E. In black patients, ACE-I monotherapy has reduced efficacy, except in systolic HF or CKD

Question 11. A 68-year-old man with a history of stable CAD and normal LVEF has BP of 136/80 mmHg. Which statement is *incorrect*?
A. The PEACE trial suggests that the addition of ACE-I at this SBP range does not improve outcomes
B. The SPRINT trial suggests that intensive SBP control <130 mmHg would improve mortality in this patient
C. The HOT trial addressed various DBP goals and showed a J curve for a DBP <82 mmHg
D. The SPRINT trial suggests that SBP <130 mmHg improves renal outcomes, HF, and stroke

Question 12. How do you obtain orthostatic vital signs?
A. After lying down for 5 min, then standing up for 1 min and 3 min
B. After lying down for 5 min, then sitting up for 3 min, then standing up for 1 min and 3 min
C. After lying down for 3 min, then standing for 3 min and 5 min
D. After lying down for 3 min, then standing for 5 min and 10 min

Question 13. An 82-year-old patient with long-standing diabetes and CKD presents with frequent falls, injuries and mental fogging. His SBP is labile, and seems to vary from 200 mmHg, particularly when he is in bed in the morning, to 90 mmHg. He takes amlodipine for HTN, an antidepressant, and a benzodiazepine and an antihistamine for sleep. In clinic, his supine SBP is 200 mmHg (pulse 70 bpm) and drops to 100 mmHg after 1 min of standing (pulse 75 bpm). What is the next step?
A. Stop benzodiazepine and antihistamine. Stop amlodipine and replace it with bedtime losartan. Accept supine SBP of up to 160–180 mmHg
B. Stop benzodiazepine and antihistamine. Stop amlodipine and replace it with bedtime losartan. Target supine SBP of <150 mmHg
C. Stop benzodiazepine, antihistamine, and amlodipine. Avoid BP medications, just focus on head-up sleeping position and accept supine SBP of up to 160–180 mmHg
D. Stop benzodiazepine and antihistamine. Stop amlodipine, and replace it with bedtime carvedilol

Question 14. For the patient in question 13, all the following measures are recommended, except:
A. Head-up sleep position and avoidance of supine position at any time are the most important measures to control HTN
B. Counterpressure maneuvers
C. Compression stockings and abdominal binders
D. Avoid large meals and eat small frequent meals
E. Moderate seated exercise (e.g., stationary bike)
F. High water and salt intake, including upon awakening in the morning

Question 15. The patient in question 13 continues to experience falls and syncope despite lifestyle measures. He is still receiving one antihypertensive medication, and his supine BP is 160–170 mmHg. What is the next step?
A. Add a second antihypertensive medication
B. Stop his antihypertensive medication, and stay off antihypertensives
C. Keep his same antihypertensive medication, and add droxidopa during daytime
D. Keep his same antihypertensive medication, and add midodrine as needed during daytime
E. Add a second antihypertensive medication at night, and add midodrine as needed during daytime

Question 16. A 62-year-old-man, chronically hypertensive with CKD 4, presents with BP 161/80, pulse 67 bpm, BMI 34. His JVP is normal, and he has no peripheral edema. He takes lisinopril 5 mg QD, amlodipine 5 mg QD, furosemide 40 mg QD, and carvedilol 12.5 mg BID. Creatinine is 2.4 mg/dl, GFR 25 ml/min/m^2, K = 4.6 mEq/L. How do you ensure his HTN is truly resistant? Then once HTN is confirmed, what is the next step?
A. Increase lisinopril to 10 mg QD
B. Increase amlodipine to 10 mg QD
C. Add chlorthalidone 12.5 mg QD
D. Add spironolactone 12.5 mg QD
E. Perform sleep study and treat sleep apnea with CPAP

Question 17. A 60-year-old woman presents with HTN 165/95 mmHg. Home BP readings are in the 160s as well. BMI is 36. Creatinine is 1.4 mg/dl, K 3.1 mEq/L. She takes lisinopril 20 mg QD, amlodipine 7.5 mg QD, HCTZ 25 mg QD, carvedilol 12.5 mg BID, and spironolactone 25 mg QD. What is the next step?
A. Increase spironolactone to 50 mg QD
B. Serum-free metanephrines
C. Measure plasma renin activity and serum aldosterone
D. Stop spironolactone for 1 month and measure plasma renin activity and serum aldosterone

Answer 1. (1) Weight loss of 15–20 kg may fully control his HTN and is the most important intervention. (2) Low-salt diet. (3) Check for sleep apnea and treat it.

Answer 2. D. Spironolactone is the most efficacious drug in resistant HTN (PATHWAY-2 trial). Increasing the thiazide diuretic dose and adding carvedilol or nebivolol (especially if pulse >80 bpm) are also alternatives. Clonidine, hydralazine, and pure α-blockers are the last resort.

Answer 3. D. Adding a new drug is far more effective than increasing the dose of lisinopril, especially when lisinopril is already at an optimal dose. As shown in the ACCOMPLISH trial, the second drug does not have to be a diuretic, and the combination ACE-I–amlodipine was superior to ACE-I–thiazide in white patients without overt hypervolemia.

Answer 4. A. While HTN may cause acute HF, acute HTN may at least be partially secondary to the acute pulmonary edema and the accompanying sympathetic surge. This explains the precipitous BP fall commonly seen during acute diuresis. Thus, the aggressive initiation of vasodilators (NTG, nitroprusside, nicardipine), sedative agents, or multiple antihypertensive agents on admission should be avoided until diuresis has been initiated.

Answer 5. E.

Answer 6. C. A 25 mg dose of HCTZ is usually the effective starting dose.

Answer 7. B. Hypervolemia is frequently at the center of HTN in CKD. Diuretic therapy, usually with a thiazide, is a key antihypertensive therapy in CKD (usually initiated after ACE-I therapy).

Answer 8. A.

Answer 9. A. According to the LIFE trial, losartan has more LVH-reverting effect than atenolol.

Answer 10. C. In the ASCOT trial, atenolol-based therapy was associated with higher stroke and mortality than amlodipine-based therapy.

Answer 11. D. In the SPRINT trial, SBP goal <120 mmHg (SBP achieved = 121.4 mmHg) reduced mortality and HF, but not MI, stroke, or renal events. More acute kidney injury was seen with this intensive BP control.

Answer 12. A. The standard measurement is at 1 min and 3 min of standing, although it is also appropriate to extend measurement to 5 and 10 min. Although widely performed, measuring BP in the sitting position has no established value.

Answer 13. A. In the patient with supine HTN and profound neurogenic orthostatic hypotension, the best BP management consists of avoiding the supine position and sleeping in the upright position. Antihypertensive medications are preferably avoided, and supine SBP of

up to 160–180 mmHg may be accepted.[85] This patient's supine HTN is more severe, and stopping amlodipine will worsen it. He needs an antihypertensive, but one with less orthostatic hypotension risk: a short-acting bedtime medication with attenuated daytime effect is preferred. ACE-Is/ARBs are the least likely to aggravate orthostatic hypotension; bedtime NTG patch 0.1 mg/hr or nifedipine may be considered.[84]

Answer 14. F.

Answer 15. C. His HTN is in a range that must be accepted, considering the severity of his neurogenic orthostatic hypotension. His symptomatology is the result of orthostatic hypotension, so the addition of another antihypertensive agent is preferably avoided. Rather, one should focus on more aggressively managing orthostatic hypotension at this point. Since lifestyle measures have failed, the combination of nighttime antihypertensive drug with a daytime anti-hypotensive drug is suggested. Droxidopa activates the sympathetic synapses in the standing position predominantly and is less likely to cause supine HTN than midodrine; regardless, avoid droxidopa and midodrine within 5 hours before sleep.

Answer 16. C. In any resistant HTN, rule out pseudo-resistant HTN: (i) rule out a white coat effect with home BP measurements, (ii) ensure adherence to drugs and low salt, and (iii) ensure proper BP measurement/proper cuff. In advanced CKD, the most important mechanism of resistant HTN is hypervolemia, at times clinically occult as in this patient. Thus, it is most important to optimize the diuretic dose. Furosemide 40 mg may be insufficient for his degree of CKD, and a higher furosemide dose and/or the addition a thiazide is needed. Thiazides remain highly effective in CKD 4, alone or in combination with a loop diuretic,[70] but a loop diuretic (+/– thiazide) is believed to be necessary in CKD 4 with resistant HTN. Lisinopril is renally cleared; thus, 10 mg of lisinopril is equivalent to 20 mg in patient with no CKD, and raising this dose improves BP only marginally. Also, raising amlodipine from 5 to 10 mg only marginally improves BP, at the cost of a much higher risk of peripheral edema, especially in this patient with likely hypervolemia. Checking for sleep apnea and CPAP therapy are important general measures, but CPAP is only mildly effective for BP reduction (ACC) (although more so in CPAP-compliant patients with very severe sleep apnea and resistant HTN).

Answer 17. D. This patient not only has resistant HTN, but refractory HTN, which is HTN resistant to 5 drugs, including a good diuretic dose and spironolactone. It is best to work up secondary HTN before raising the dose of spironolactone, the most common being hyperaldosteronism. ACC guidelines recommend holding spironolactone for 1 month before measuring renin and aldosterone (answer D). However, this may not be safe in a patient with such severe HTN and hypokalemia, and ESC allows making the measurements without spironolactone interruption in such a patient, as "the accuracy of testing under this treatment is only marginally impacted, particularly in the presence of florid primary aldosteronism" (answer C).

Questions and answers 615

I. Indications for therapy

Evidence supports the following 2 concepts:

- Statin drugs have pleiotropic effects (improvement of endothelial function, anti-inflammatory effects) and reduce mortality in patients with CAD by >30% regardless of the baseline LDL level, even if it is below 70 mg/dl (or even 40 mg/dl).[1–3] Statins stabilize plaque volume and even slightly reduce it, and favorably modify plaque composition: they reduce lipid core content, increase fibrous cap thickness, and reduce macrophage content and inflammation, which reduces plaque rupture.[4] *Higher-intensity statins provide ~20% further reduction in MI and stroke, and ~20% trend toward lower CV mortality* compared to lower-intensity dosing (PROVE-IT and TNT trials; LDL 90s–100 in the lower-intensity arms, 60s–70s in the higher-intensity arms).
- The lower the LDL achieved in CAD patients (even levels well below 70 mg/dl), the greater the benefit (PROVE-IT and TNT trials).[5–7] In the TNT trial of stable CAD, patients with the lowest achieved LDL <64 mg/dl had the lowest risk of cardiovascular events, and there was no evidence of harm with very low LDL levels.[1,2,8] In the IMPROVE-IT trial, a lower LDL (53 mg/dl) achieved with a statin + ezetimibe combination translated into a lower MI and stroke risk than statin alone (LDL 69 mg/ dl).[9]

  In FOURIER (stable CAD or PAD) and ODYSSEY OUTCOMES (ACS patients) trials, the addition of anti-PCSK9 to statin therapy reduced cardiovascular events by 15% in both trials; in both trials, LDL was reduced from ~90 mg/dl to ~30–40 mg/dl with anti-PCSK9.[10,11] Despite this massive LDL drop, CV mortality was not clearly reduced with anti-PCSK-9. This attests to the ***distinct efficacy of statins, the only lipid agents clearly proven to reduce mortality— by ~30%,*** in both secondary and even primary prevention, in both high or low baseline LDL.

Conversely, 2 trials suggest that the addition of niacin or fibrate to statin therapy does not improve outcomes in high-risk patients (AIM-HIGH and ACCORD trials).[12,13] In these 2 trials, LDL was not significantly reduced by the addition of niacin or fibrate.

In light of the importance of both statin therapy and attainment of very low LDL levels, ACC/AHA recommends the use of statin in 4 high-risk groups regardless of lipid levels.[14,15] The **4 major statin benefit groups** are:

a. *Patients with established CAD or vascular disease* (→ prescribe high-intensity statin in most patients; consider moderate-intensity statin in patients >75 years old or those at a high risk of intolerance)
b. *Diabetic patients* (→ prescribe moderate or high-intensity statin)
c. *Patients with LDL ≥190 mg/dl* (→ prescribe high-intensity statin)
d. *Patients 30–79 years old without vascular disease or diabetes, whose LDL is 70–189 mg/dl, and whose estimated 10-year risk of cardiovascular events is 5–10% (intermediate) or ≥10% (high)*, using PREVENT risk calculator. The clinical risk calculator accounts for age/sex, diabetes, BMI, smoking, HTN and its control, GFR, HDL and total cholesterol. PREVENT score of 5–10% ~ corresponds to 7.5–20% on ASCVD and SCORE-2 equations.

In intermediate risk and in borderline risk (3–5%), statin is beneficial, but the absolute risk reduction is small on a yearly basis *A 10-year CV risk of 10% drops to ~7% with statins, whereas a 3% risk drops only to 2.1% or by ~0.1% per year, which may seem negligible to the patient.* ***While the relative CV risk reduction is ~constant at ~30%, the absolute reduction scales with baseline risk.*** Young patients have lower baseline risk and lower absolute yearly gains, but a longer time span to accumulate the benefit, which may justify statin treatment. Overall, statin is more readily prescribed in borderline-risk and even intermediate-risk patients if 1 of the following *enhancing risk factors* is present: LDL 160–190 mg/dl, additional elevation of triglycerides and non-HDL cholesterol, metabolic syndrome, high Lp(a), CKD, family history of premature CAD, CRP ≥ 2 mg/L. Moderate-intensity statin is recommended if the risk is 5–10%, and high intensity is recommended for a risk>10%.

CT calcium scoring may also be used in borderline-risk and intermediate-risk patients, and statin is prescribed if calcium score is >0, and particularly if it is ≥100 or 75th percentile for age/sex. Calcium scoring is the strongest prognostic marker in primary prevention. Specifically, a calcium score of 0 implies a very low risk of death/MI (<0.5% per year for 5–10 years) and a low prevalence of obstructive CAD (<6%).[16] Even in patients with LDL > 190 mg/dl, a calcium score of 0 indicates a low risk of CV events at 5–10 years (0.7%/yr).[17] However, risk accumulates over time, especially in a young person, since atherosclerosis may simply not be calcified yet. The CV risk in individuals with a calcium score of 0 and LDL > 190 mg/dL is low at <1% per year but is up to twice as high as low LDL, especially over >5–10 years.[18] Moreover, *in young patients <40–50 years old, the 5-year warranty of a zero calcium score is less relevant* as long-term, >10-year prognosis is the primary target. Hence, guidelines recommend statin for LDL > 190 mg/dl regardless of calcium score. Guidelines even suggest statin for LDL 160–189 mg/dl or PREVENT 30-yr score ≥10% in younger, low-risk adults aged 30–50s.

Non-statin drugs, particularly PCSK9 inhibitors, **have been robustly studied only *in patients with established cardiovascular disease* or *familial hypercholesterolemia or diabetes***. *Hence, they are primarily considered in these 3 patient populations when* LDL does not decline >50% and to <55–70 mg/dl with statin, or when they cannot tolerate any statin → add anti-PCSK9 or bempedoic acid or ezetimibe. If LDL is far from its goal, anti-PCSK9 is added; if LDL is close to its goal, bempedoic acid or ezetimibe may be tried first. Patients whose triglyceride levels remain markedly abnormal (>500 mg/dl) under statin therapy are considered for fenofibrate or omega-3 fatty acids (particularly icosapent ethyl).

LDL goals (the **non-HDL goal**, which is the 2nd key target, is set by adding **+30 mg/dl** to the LDL goal)**:**

- **<55 mg/dl** in patients with cardiovascular disease, with a particular emphasis on the highest risk group (e.g., post-ACS, multiple coronary or vascular events, combined CAD-PAD, combined CAD-diabetes), as in ODYSSEY OUTCOMES trials.[11] This is recommended by both ACC and ESC guidelines.[14,15,19]
- **<100 mg/dl** in diabetes without CAD. **<70 mg/dl** if long duration (>10 yrs), insulin dependency, microvascular disease, or multiple risk factors.
- <100 mg/dl in severe hypercholesterolemia (LDL≥190 mg/dl or ApoB ≥140 mg/dl) without CAD. <70 mg/dl in genetically-confirmed familial hypercholesterolemia.
- <100 mg/dl in primary prevention if risk score is 5–10%, and <70 mg/dl if risk score is >10% (ACC and ESC).

Target LDL may also be fine-tuned by calcium score. An elevated calcium score not only warrants statin therapy, but the degree of elevation correlates with CV risk and with how aggressive LDL goal should be (ACC): Score 1–99--> LDL<100// Score >100, or >75th percentile, or >300--> LDL <70// Score>1000 --> consider LDL <55.

Note: ***the aggressive primary prevention LDL targets in ACC and ESC guidelines have been criticized for the following reasons:***

- The aggressive LDL goal <70 mg/dl has been achieved mainly in secondary prevention trials (post-MI or at least stable vascular disease) (PROVE-IT, TNT, FOURIER, ODYSSEY, IMPROVE-IT trials).
- Non-statin drugs, which may be needed to achieve those low targets, have been studied mainly in secondary prevention.
- Non-statin drugs have improved CV events, but never reduced all-cause and CV mortality in a definitive fashion in any trial, not even in secondary prevention.

II. Notes on LDL, HDL, and triglycerides

A. LDL

The atherogenic risk of a lipoprotein is not only related to its cholesterol content, but to its size. LDL particles, and more particularly the small and dense LDL particles, are more likely to penetrate the endothelium and initiate atherosclerosis than VLDL particles. For a given LDL cholesterol level, small LDL particles or a high number of LDL particles (LDL-p) are more atherogenic than large or less numerous LDL particles, because they lead to more endothelial penetration and injury.[8] In fact, cholesterol is only a portion of any given liproprotein (LDL, HDL, or VLDL), which also contains proteins (Apo B), triglycerides, and phospholipids. *In patients with low LDL who continue to have recurrent events, a high number of small LDL particles is suspected, and is indirectly reflected by a low HDL level and high triglyceride, VLDL, and non-HDL cholesterol levels*. LDL-p has not been studied independently at a large scale, and thus this measurement is not routinely performed, especially in primary prevention. Apo B is the protein found in all atherogenic particles, such as LDL, VLDL, and Lp(a). Apo B levels correlate with the number of LDL particles and may predict cardiovascular outcomes as well as or better than LDL, especially in patients with low LDL levels. ApoB targets in mg/dl approximate those of LDL. Apo A is the central protein of HDL, and low Apo A levels may be associated with impaired outcomes.

Hepatic lipoprotein synthesis (VLDL, LDL) is driven by fatty acid intake and by excessive fructose and glucose intake that the liver metabolizes into fatty acids. The liver circulates fatty acids via lipoproteins, and as such, increases its cholesterol synthesis to accompany these fatty acids in lipoproteins. *Dietary cholesterol intake has much less of an effect on cholesterol levels than liver cholesterol synthesis, which is driven by sugar and fatty acid intake*. In fact, most intestinal cholesterol (~80%) is biliary, produced by the liver: high dietary intake may be counteracted by reducing the absorption of biliary cholesterol.

Triglycerides and large VLDL undergo lipolysis and evolve into the highly atherogenic small and dense LDL. Some fats cause the formation of a VLDL that breaks into large LDL, which is less atherogenic, while sugar causes the formation of a VLDL that breaks into the atherogenic small LDL. That is why the WHI trial has shown that a lower-fat diet, while reducing LDL, does not reduce CV events.[20] Also, that is why in the PURE cohort study, higher fat intake was associated with lower mortality vs. lower fat, whereas higher sugar intake was associated with higher mortality vs. lower sugar.[21] Sugar-induced changes in lipid particles—high VLDL and small LDL—may precede insulin resistance and diabetes.

Saturated fat from butter, red meat, and animal products increases atherogenic LDL.[22] Omega-6 seed oils reduce LDL levels but cause the formation of small dense LDL. Moreover, the omega-6 fatty acids in LDL are more prone to oxidation in the body or even before ingestion during cooking (oxidized LDL), oxidation being at a center of atheroma formation. Omega-6 fatty acids also increase inflammation. Hence multiple studies and meta-analyses showed that omega-6 fatty acids increase CAD risk, platelet activity, plaque inflammation, and instability.[23,24] Within LDL, it is not only the cholesterol amount but the particle small size and the fatty acid composition and oxidation that affect atherogenesis.

Monounstaurated fats (olive oil) may reduce LDL but mostly improve the quality of LDL and reduce its oxidation; they also reduce VLDL and raise HDL. Omega-3 fatty acids do not reduce LDL but improve LDL size and oxidation, reduce TGs, and raise HDL.

B. Non-HDL cholesterol

Non-HDL cholesterol = total cholesterol – HDL = LDL + VLDL + VLDL remnants. It is a strong predictor of adverse outcomes and **should be targeted to <100 mg/dl in the high-risk categories (along with LDL < 70 mg/dl).** The targeting of non-HDL is **particularly relevant in patients with high TGs (and thus high VLDL), whose atherogenic particles and risk may not be fully represented by LDL.** While LDL calculation may not be possible in patients with TG >300 mg/dl, it remains possible and important to calculate and target non-HDL.

C. HDL

HDL scavenges "bad" cholesterol from the endothelium and lipid-laden macrophages (cholesterol efflux), then empties it onto VLDL through the cholesteryl ester transfer protein (CETP). VLDL is then taken up by the liver and eliminated in the bile (reverse transport mechanism). A *spontaneously* high HDL is protective against CAD as it indicates that "bad" cholesterol has been scavenged and will be eliminated through the CETP enzyme. High VLDL and TGs prevent HDL scavenging and hence reduce cholesterol movement toward HDL, which reduces HDL cholesterol. Drugs that increase HDL by inhibiting CETP may saturate HDL and inhibit its capacity to scavenge cholesterol (dysfunctional HDL). This may paradoxically increase cardiovascular events.[25] In fact, the HDL process is complex: (i) a pharmacological increase in HDL may not improve outcomes, and (ii) **spontaneously very high HDL >80 mg/dl in men or >90 in women,** seen in ~2–5% of the population, **is associated with >70% increased total and cardiovascular mortality.**[26,27] The latter risk may be fine-tuned using calcium scoring.

Furthermore, **HDL may cease to predict cardiovascular outcomes in patients receiving statin who have an adequately controlled LDL** (substudies of JUPITER and CETP inhibitor trials).[25,28,29]

D. Triglycerides (TGs)

TGs, when >500 mg/dl, warrant therapy because of the marked risk of pancreatitis. TGs are associated with some increase in the risk of cardiovascular events, through their association with a high level of atherogenic lipoproteins, rather than a direct TG effect. In fact, a high TG level is associated with high levels of VLDL and VLDL remnants; large VLDLs may not be atherogenic, but the smaller VLDLs and their remnants are small enough to penetrate the endothelium. Besides, VLDL breaks down into the atherogenic small LDL. Also, high VLDL precludes cholesterol elimination from HDL, which affects the efficacy of HDL scavenging. Thus, **a high TG level reflects a high level of atherogenic lipoproteins, and primarily mandates a calculation of non-HDL cholesterol and a reduction of non-HDL cholesterol rather than TG per se.**

Note: LDL is not directly measured but calculated as: total cholesterol-HDL-TG/5. This equation is inaccurate with *high TGs>150, especially* ***>300, in which case ApoB or non-HDL cholesterol is preferred over LDL to guide therapy*** (ACC).

E. Lipoprotein (a) is an atherogenic small and dense LDL-like particle bound to apolipoprotein (a). Levels are mainly determined genetically and remain stable throughout life; thus, it should be measured once. Levels >50 and >100 mg/dl correlate with 1.4x and 2x higher CV risk, respectively. While no drug directly lowers Lp(a), an elevated level warrants more aggressive LDL reduction. Anti-PCSK9 may reduce Lp(a) by up to 25% (FOURIER trial).

III. Drugs: LDL-lowering drugs

A. Statins

Statins inhibit HMG-CoA reductase, the enzyme that synthesizes intracellular cholesterol. This leads to an increase in LDL receptors and LDL uptake by cells. Statins lower LDL by 30–60%, TG by 15–25%, and increase HDL by 5–10%. Statins are the best agents for lowering non-HDL cholesterol as well.

a. The most potent statins are rosuvastatin (5–40 mg/day) and atorvastatin (10–80 mg) (LDL ↓ 40–60%), followed by simvastatin 10–40 mg (LDL ↓ 35–45%) and pravastatin (LDL ↓ 30%). Rosuvastatin is the most effective statin for raising HDL, while atorvastatin is the most effective statin for reducing TGs.

b. Doubling the statin dose lowers LDL by 6% more, but is associated with a more significant increase in myopathy.

c. Increasing the dose of atorvastatin to 80 mg reduces LDL by 60% vs. 40% reduction with a dose of 10 mg.

d. Dosing:
- **i.** In high-risk patients with established vascular disease, high statin doses proven to be the best in clinical trials are used (atorvastatin 40–80 mg; rosuvastatin 20–40 mg). These doses reduce LDL by ≥50% and are particularly important in ACS, where statins may directly stabilize active plaques.
- **ii.** If the patient is a lower-risk patient, or if there is a concern about side effects (e.g., elderly patients >75, renal failure, or possibility of drug interactions), use a moderate-intensity statin dose, which reduces LDL by 30–50% (simvastatin 20 mg, atorvastatin 10 mg, pitavastatin 1–4 mg, pravastatin 40 mg). Ezetimibe may be added for further LDL reduction.
- **iii.** Low-intensity statin is only tried in patients with statin intolerance.

B. Ezetimibe

Ezetimibe inhibits cholesterol absorption and reduces LDL by ~20% even in patients already receiving a statin. It mainly reduces the recirculation and absorption of biliary cholesterol synthesized by the liver. It also reduces non-HDL cholesterol. In the IMPROVE-IT trial, patients with a recent ACS (mainly MI) and a baseline LDL of 95 mg/dl were randomized to simvastatin 40 mg vs. simvastatin 40 mg + ezetimibe. The statin group achieved LDL of 69 mg/dl, while the combined group achieved LDL of 53 mg/dl, which translated into a 10% reduction of MI and 20% reduction of stroke. Lower LDL was better in this high-risk ACS population, even when a non-statin drug was added.[9]

C. Anti-PCSK9 antibodies (alirocumab, evolocumab)

PCSK9 is an enzyme that destroys LDL receptors. Blocking this enzyme increases LDL receptors and dramatically reduces LDL by over 50% even in patients already receiving a statin ("double negative effect on LDL receptor"). Genetic studies have shown that individuals with loss of function of the PCSK9 gene have low LDL and cardiovascular events. This led to the development of fully human, monoclonal antibodies inhibiting PCSK9. These drugs are administered subcutaneously, once every 2 weeks. They have been associated with a reduction of cardiovascular events in 3 groups of patients and are used mainly in these 3 groups:

- **Patients with established cardiovascular disease whose LDL remains >70 mg/dl** with statin (FOURIER and ODYSSEY OUTCOMES trials, mean LDL 90 mg/dl).[10,11] Cardiovascular events are reduced by ~15%, but without a clear CV mortality reduction; the benefit is more striking in patients whose baseline LDL is >100 mg/dl or those who do not tolerate any statin (risk reduction >25%).[11]
- **Patients with familial hypercholesterolemia whose LDL remains >100 mg/dl** with statin therapy.
- Patients with diabetes that is long standing (>10 yrs), insulin dependent, or with microvascular disease. Absolute CV reduction is however small, 1.8%/5 yrs (VESALIUS trial).

D. Inclisiran

Inclisiran also blocks the PCSK9 system, but via a different mechanism. It is an oligonucleotide that inhibits PCSK9 translation by interfering with the PCSK9 RNA, promoting its degradation. It is long-acting and given as subcutaneous injection Q6 months, reducing LDL by 40–50%.

E. Bempedoic acid

Like statins, bempedoic acid inhibits hepatic cholesterol synthesis, which causes an upregulation of LDL receptors. It inhibits ATP citrate lyase, an enzyme in the cholesterol synthesis pathway upstream of HMG-CoA reductase. Unlike statins, bempedoic acid is a prodrug that can only be activated in the liver and can only inhibit the HMG-CoA pathway in the liver. Conversely, statins inhibit the HMG-CoA pathway in both the liver and the muscle. In the muscle, this pathway enables the local synthesis of cholesterol and affects the synthesis of other molecules necessary for muscular function, such as coenzyme Q, which explains why statins may lead to muscular symptoms.

Bempedoic acid reduces LDL by only ~20%. In statin-intolerant patients, the combination of bempedoic acid + ezetimibe reduces LDL by ~35–40%.

Bempedoic acid improved cardiovascular outcomes by ~15% in the CLEAR Outcomes trial, with no effect on mortality (mean baseline LDL 139 mg/dl, 70% of patients had prior cardiovascular event, and 22% were taking a small statin dose). Patients enrolled in this trial were either intolerant of statins or only able to tolerate the lowest dose of statins. Notably, even on top of high-intensity statin, bempedoic acid reduced LDL by ~20% in the CLEAR-harmony trial.[30]

F. Bile acid sequestrants (cholestyramine, colestipol)

These agents reduce bile acid reabsorption, which reduces the cholesterol available to synthesize LDL (LDL ↓ 15–30% but TG may ↑). These agents raise TG and are avoided if TG >300 mg/dl.

The LDL level in neonates is only ~40 mg/dl, and it appears that human cells only require an LDL plasma level of 25 mg/dl. Wild mammalian species have LDL ~40 mg/dl and rarely develop atherosclerosis (monkey, horse, elephant). Human hunter–gatherer societies, which carry on the Paleolithic lifestyle, and rural Chinese have LDL cholesterol in that range as well and show no evidence of atherosclerosis, even late in life. The same applies to many patients with genetic loss-of-function of PCSK9. All this led to the suggestion that LDL is at the center of atherosclerosis, and a very low LDL may prevent the initiation of atherosclerosis.[31,32] This also suggests that a very low LDL is safe. Data from PCSK9 trials concur that a very low LDL, even <25 mg/dl, is safe (ODYSSEY long-term trial).[33] A very low LDL level, however, may not fully prevent the progression of a pre-existing atherosclerosis.

Of note, the cholesterol in brain cell membranes and myelin does not depend on circulating cholesterol, as the latter cannot cross the blood–brain barrier. Brain cells cholesterol is rather synthesized by the brain cells, particularly during childhood, and recycled throughout life with a lower level synthesis in adulthood. Brain cholesterol is insulated from changes in circulating cholesterol.[34,35] Statins may, however, cross the blood-brain barrier (BBB) and affect the low-level brain cholestrol synthesis (marginal effect typically).[36] The other 3 drugs do not affect brain cholesterol synthesis and have no CNS effect: PCSK-9 inhibitors do not cross the BBB, exetimibe only works on GI absorption, and bempedoic acid cannot get enzymatically activated in the brain.[37]

IV. Drugs: TG/HDL-treating drugs and lifestyle modification

A. Fibrates

Fibrates increase lipoprotein lipase activity, which degrades VLDL into VLDL remnants and buoyant LDLs that are readily taken up by the liver. Fibrates also have other effects, such as reducing VLDL synthesis in the liver and increasing Apo A1 synthesis (HDL protein). Thus, fibrates lower TG 20–50%, increase HDL 10–20%, ± lower LDL 10–15% (especially fenofibrate).

Aside from the potent Olezarsen, fibrates are the most effective conventional agents for lowering TGs. They reduced CV events, but not mortality, in old trials of patients not on statins.[38,39] In a modern trial of diabetic patients already receiving statins, fenofibrate failed to provide any benefit, regardless of baseline CAD (ACCORD trial).[12]

Fibrates, when used in renal failure or in combination with statins, are associated with an increased risk of myositis. In statin-treated patients who continue to have a markedly high TG>500 mg/dl, fenofibrate is the safest fibrate to combine with a statin.[40] Gemfibrozil is best avoided in combination with a statin.[12]

B. Omega-3 fatty acids

Omega-3 fatty acids reduce TG by ~30–40%. While other fatty acids typically promote TG synthesis in the liver, omega-3s rather block hepatic TG and VLDL synthesis and enhance their utilization in the periphery. Omega-3s have shown benefit in some trials but not in most primary or secondary prevention trials.[41-43] This may be related to the formulation and its purity: 1 gram of fish oil only contains ~350–800 mg of omega-3 fatty acids; ≥1 gram of omega-3 (>>1 gram of fish oil) is required for benefit. Purified prescription omega-3s are preferred over supplements and have been *beneficial in specific trials, independent of their lipid effect* (e.g. Lovaza 1 g, which contains 850 mg of highly-purified EPA and DHA): (i) in GISSI-Prevenzione (recent MI ≤3 months), omega-3s (Lovaza 1 g/day) reduced the risk of cardiovascular events, likely via improved endothelial function and oxidative stress.[41] (ii) In GISSI-HF, omega-3s slightly reduced mortality in HFrEF.[42] (iii) In the PISCES trial of *patients on hemodialysis, omega-3s at a dose 2.4 g/d markedly reduced CV mortality*, MI, and CV events by ~45% (NEJM 2026). (iv) In ***REDUCE-IT***, ***a high dose of purified EPA, icosapent ethyl*** (2 g twice daily) added to statin in patients with CAD or diabetes and triglycerides >135 mg/dl, reduced cardiovascular events by 25% and cardiovascular mortality by 20%, despite a well-controlled LDL of ~75 mg/dl at baseline.[44] However, REDUCE-IT used a potentially harmful mineral oil placebo that may have exaggerated the benefit of icosapent ethyl (hence its class IIb status). Moreover, AF risk was increased by 31%, consistent with meta-analyses of high-dose omega-3s, which highlights this arrhythmic dichotomy: omega-3s may reduce sudden death but increase AF.

C. Tight glycemic control

Tight glycemic control is one of the most effective means of achieving the TG/HDL goal in diabetic patients.

D. Lifestyle modification

Diet and exercise are indicated in all patients. These are moderately effective in reducing LDL (usually a 20% reduction, possibly more with a stricter diet). A diet very high in saturated fat, like some ketogenic diets, may dramatically raise LDL more than 2-fold to over 200 mg/dl; in this case, altering fat intake may reduce LDL more markedly, even >50% (Am J Prev Cardiol. 2023;14:100495) The most effective diets are the Mediterranean diet (fruits, vegetables, whole grains, fish, nuts, and olive oil), the vegan diet, diets high in fiber, and a diet switch from saturated to monounsaturated fat (olive oil) and omega-3 fat.

Lifestyle modification, particularly the reduction of simple and refined sugars, is quite effective in reducing TG and raising HDL, more so than it is effective in reducing LDL.

Smoking cessation raises HDL. Mild alcohol consumption (1 drink/day) raises HDL but should be avoided if TG >200 mg/dl.

V. Metabolic syndrome

A. Diagnosis

Three of 5 criteria are needed for the diagnosis (AHA):[45]

1. Obesity (male: waist >40 inches; female: waist >35 inches). Lower cut-points are used in Asian populations; **2.** TG level >150 mg/dl; **3.** HDL <40 mg/dl in men, <50 mg/dl in women; **4.** HTN >130/80 mmHg; **5.** Fasting blood glucose >100 mg/dl or HbA1c 5.7–6.4%

B. Treatment

1. Diet, exercise, and weight loss. Statin therapy is indicated in most of these patients, based on their 10-year cardiovascular risk.
2. HTN: ACE-I/ARB may reduce glucose levels and lower the risk of diabetes.[45,46]
3. Glucose intolerance and risk of diabetes: metformin is effective in decreasing the risk of diabetes by 31% in pre-diabetic patients. However, therapeutic lifestyle changes are the most effective means of reducing this risk (58%, DPP trial).[47,48] *Semaglutide,* a GLP-1 agonist, given at a once weekly SQ dose higher than the diabetic dose, dramatically reduces weight by ~15% and improves the metabolic profile.[47,48]

VI. Diabetes and cardioprotective diabetic drugs

A. Statin therapy

All diabetic patients older than 40 years of age derive a reduction of cardiovascular events, stroke, and mortality with statin therapy, even in the absence of established CAD and regardless of LDL levels (even if <100 mg/dl) (HPS and CARDS trials).[49,50] Not infrequently, patients with diabetes have low yet atherogenic levels of LDL.

B. SGLT-2 inhibitors (gliflozins) and GLP-1 receptor agonists ("-glutides") are first-line options in diabetes

Sodium-glucose cotransporter 2 (SGLT-2) inhibitors inhibit glucose and Na reabsorption in the proximal tubule. In randomized trials of patients with or without cardiac disease, they consistently and strikingly reduced ***HF events*** (by ~35–40%). They also reduced ***mortality*** of patients with diabetes and cardiovascular disease (EMPA-REG trial with empagliflozin, mainly CAD at baseline, 32% relative risk reduction);[51] and patients with HFrEF with or without diabetes (DAPA-HF trial with dapagliflozin).[52] They do not clearly reduce MI.

Even without diabetes, SGLT-2 inhibitors dramatically reduce mortality and HF hospitalizations in HFrEF (DAPA-HF, EMPEROR-reduced), reduce HF hospitalizations in HFpEF (EMPEROR-preserved, DELIVER), and dramatically reduce mortality and the risk of renal deterioration by 40% in CKD patients with GFR 25–75 ml/min (DAPA-CKD). Thus, they are recommended in HF (class I) and CKD, regardless of diabetes.

Glucagon-like peptide 1 (GLP-1) is normally a gut hormone secreted during eating, as a response to oral glucose; it works on the pancreas to increase insulin and reduce glucagon secretion; it also controls appetite as: (i) it slows gastric emptying and causes satiety; (ii) it reduces cravings (brain effect). ***GLP-1 receptor agonists*** mimic GLP-1 and are mostly administered subcutaneously. In randomized trials that predominantly recruited patients with cardiovascular disease, they reduced cardiovascular events, mainly ***MI*** (liraglutide, dulaglutide, and semaglutide, which is the only GLP-1 agonist also available orally).[53,54] In LEADERS trial, liraglutide reduced ***mortality*** by 15%.

The GLP-1 agonists semaglutide (weekly SQ dose of 2.4 mg) and tirzepatide (GLP-1/GIP agonist, weekly SQ dose) dramatically reduced weight by 15% and 20%, respectively, in specific obesity trials.[47,48] They are FDA approved for weight loss in obese patients, even without diabetes. ***Specific semaglutide trials:*** *(i) SELECT trial- In overweight patients with BMI>27 (mean 33+/-5) and CV disease* but no diabetes, weekly SQ semaglutide 2.4 mg ↓ CV events (death/MI/stroke) by 20%, HF by 19%, and all-cause mortality by 19%. *(ii) In diabetic patients with CV disease or CKD*, oral or low-dose SQ semaglutide (~1 mg) ↓ CV events by ~25% and major kidney events by 20s% (SUSTAIN-6, Pioneer-6, and Flow trials, mortality reduction >20% in the latter 2).

SGLT-2 inhibitors mainly reduce HF events (+/- mortality), while GLP-1 agonists mainly reduce MI events and weight, +/- mortality. GLP-1 agonists also ↓ HF in obese patients. Both attenuate long-term severe renal deterioration (by ~40% and ~20%, respectively), and reduce BP, TGs, and VLDL. SGLT-2 inhibitors are less effective on HbA1c control (~0.5% vs. 1+% with liraglutide, 1.5+% with semglutide, and 2+% with tirzepatide).

Distinguish those agents from dipeptidyl peptidase-4 inhibitors (gliptins). The latter are oral drugs that inhibit the degradation of GLP-1 but are less potent activators of GLP-1, are less effective than GLP-1 agonists for glycemic control, and mostly have a neutral cardiovascular effect.

VII. Elevated hs-CRP (high-sensitivity C-reactive protein test) ≥2 mg/L

The JUPITER trial has shown that in patients with low LDL levels (~100 mg/dl), age >50 (men) or 60 (women), and no CAD equivalent but hs-CRP >2 mg/L, statin therapy reduces 5-year cardiovascular events by ~47% and mortality by 20%, even in a seemingly low-risk primary prevention setting.[55] The addition of CRP to lipid screening may select seemingly low-risk patients with low LDL and no history of CAD who would benefit from statin therapy.

VIII. Chronic kidney disease

In patients aged ≥50 years, CKD (GFR <60 ml/min/1.73 m^2 or albuminuria) is associated with a 10-year risk of cardiovascular events >20%, and thus CKD should be considered a CAD equivalent and treated with a statin, regardless of LDL level and regardless of the presence of CAD (Kidney society guidelines).[56] Paradoxically, at the extreme of CKD, patients with end-stage renal disease did not derive a benefit from statin therapy in one randomized trial; this does not apply to patients with end-stage renal disease and established CAD.[57]

IX. Causes of dyslipidemia to consider

A. Markedly elevated LDL (>190 mg/dl) suggests familial hypercholesterolemia, in which case *LDL receptor* is underproduced or dysfunctional. These LDL levels may, however, be seen with diets very high in saturated fat, such as some keto diets. Panel-based genetic testing is recommended (ACC).

B. Markedly elevated TG level (>500 mg/dl) suggests familial hypertriglyceridemia

C. Consider secondary causes of dyslipidemia in the proper setting

Hypothyroidism (↑ LDL), nephrotic syndrome (↑ LDL), uremia (↑ TG), alcohol abuse (↑ TG), and medications: β-blockers (↑ TG, ↓ HDL), thiazides (↑ LDL), contraceptive pills (↑ TG).

X. Side effects of specific drugs: muscle and liver intolerance with statins

With all lipid-lowering drugs, baseline liver profile is obtained and the patient is monitored for muscular symptoms. Follow-up liver profile is not routinely indicated with statin therapy but is indicated if toxicity is clinically suspected (6–8 weeks after starting therapy or after changing dose, then every 6 months). Baseline CK may be measured in those at risk of adverse muscle events; CK is obtained during therapy only in those who develop muscular symptoms. Lipid profile is checked 1.5–3.0 months after therapy initiation to ensure compliance and appropriate LDL reduction.

A. Statins

Adverse effects:

i. *Myopathy*. Statins inhbit the HMG-CoA reductase pathway in both the liver and the muscle, where HMG-CoA reductase allows the synthesis of cholesterol and other molecules necessary for muscular function. Muscle symptoms with or without elevated CK are reported in up to 10–15% of real-world, registry patients, and usually occur within 4–6 weeks of statin initiation (<12 weeks, median of 1 month).[58] Statin toxicity may manifest as cramping, heaviness, or weakness, particularly with exertion. Myopathy is typically bilateral and involves large muscle groups. Active patients, especially athletes, are more likely to manifest muscular symptoms. Myopathy may be related to pharmacokinetics (high dose or drug interactions) or to an underlying metabolic disorder that is unveiled by statin therapy.[59] The latter patients typically cannot tolerate any statin. Three degrees of muscular effects occur with statin:[60]

a. Myalgia: muscular symptoms without CK elevation
b. Myositis: muscular symptoms with CK elevation

c. Rhabdomyolysis: muscular symptoms with CK elevation over 10× upper limit of normal. It is often accompanied by acute renal failure. Rhabdomyolysis occurs in <0.1% of patients.

Many patients with mild muscle aches have improvement of symptoms within 2 weeks of continued use, and thus immediate discontinuation may not be warranted. CK elevation 3–10× normal without significant symptoms does not warrant discontinuation either.[58,59] Statin is discontinued if CK >10× normal or the patient experiences severe muscle aches. Muscle aches usually disappear within a few days to 2 weeks of discontinuation. *The persistence of symptoms longer than 2 weeks after discontinuation* implies that they are not related to statin; the original statin may be resumed. If the patient has severe muscle aches or myositis without rhabdomyolysis, he may tolerate another statin, which should be started once symptoms resolve. Based on the PRIMO study, ***fluvastatin XL has the least muscle toxicity, followed by pravastatin.***[48] Some data suggest ***pitavastatin is one of the safest statins***.[61,62] Among the potent statins, rosuvastatin may be the safest, especially when administered at a low dose, such as 5 mg, on alternate days.[59]
The risk of myositis increases with age; renal failure; combined therapy with fibrate (~1%) and, less so, niacin; and combined therapy with CYP450 inhibitors (diltiazem, amiodarone, macrolides, HIV protease inhibitors, azole, grapefruit juice).

Remember the following ideas in a patient with statin-associated myopathy: (1) look for drug interactions (e.g., diltiazem), underlying hypothyroidism, or 25-hydroxy-vitamin D deficiency as common predisposing factors; (2) consider switching to pitavastatin, fluvastatin XL, or to alternate-day rosuvastatin 5 mg. CoQ 10 reduced muscle symptoms in one meta-analysis.[63]

ii. *Hepatitis*. Mildly elevated transaminases, 1–2× normal, do not contraindicate the initiation or continuation of statin therapy. A rise in transaminases to >3× normal usually dictates statin discontinuation (~0.5% risk; ~1% risk in the case of statin + niacin combination). Liver profile should return to normal within 2 weeks of discontinuation. A lower dose of the same statin or another statin may be tried.
iii. Except for pravastatin and pitavastatin, all statins are metabolized by the cytochrome P450 system. Pravastatin and pitavastatin, but also rosuvastatin and fluvastatin, are less subject to cytochrome P450 drug interactions than other statins. Pravastatin and rosuvastatin are hydrophilic, which may explain the lower frequency of muscular symptoms with these agents.
iv. Very small, but significant increase in HbA1c and the risk of diabetes, particularly in patients with pre-diabetes. This risk is more pronounced with high-intensity statin therapy and is not seen with pravastatin or pitavastatin.[64] Conversely, bempedoic acid has a positive effect on glucose metabolism.

B. PCSK9 inhibitors

PCSK9 inhibitors appear to be well tolerated in patients who are intolerant to statins. In such patients, the rate of discontinuation of PCSK9 inhibitors for muscular symptoms is low (<5%), lower than the rate of discontinuation with ezetimibe.[65] In fact, in most studies, muscular symptoms occurred with similar frequency in patients receiving PCSK9 inhibitors and placebo.[66]

C. Fibrates

Adverse effects: gallstones (gemfibrozil), hepatitis, myositis. Gemfibrozil interacts with warfarin (↑ INR). Gemfibrozil is contraindicated in conjunction with statin. Fenofibrate is contraindicated if GFR <30 ml/min/1.73 m^2, and the dose should not exceed 54 mg/day if GFR is 30–60 ml/min/1.73 m^2.

XI. Aspirin is ineffective in primary prevention

Aspirin is not indicated in patients with no prior cardiovascular event or revascularization. It does not provide any net benefit even in patients with increased cardiovascular risk (diabetes, age >55 with multiple risk factors, or subclinical vascular disease).

In the old Physician Health study, aspirin significantly reduced the risk of MI by ~0.2% per year (from ~0.4% to ~0.2%), but increased GI bleeding risk by 0.2% per year and the risk of intracranial hemorrhage by 0.1% over 5 years.

In the more modern ARRIVE trial of patients >55 with multiple risk factors or with subclinical disease (low ABI, carotid stenosis), aspirin did not reduce at all the risk of cardiovascular events at 5 years and was associated with increased GI bleed.[67] In the modern ASCEND trial of diabetic patients >65, aspirin was associated with a significant reduction of cardiovascular events of only 0.15% per year (from 1.3% to 1.15%, relative reduction of 12%), at the price of a nearly similar increase of major bleeding events.[68] Similar findings were seen in another diabetes trial.[69] Also, in asymptomatic patients with low ABI (0.7–0.95), aspirin did not reduce cardiovascular events at all after 8 years of follow-up.[70] In patients older than 70 with no cardiovascular disease, aspirin significantly increased mortality (ASPREE trial).[71]

In a large meta-analysis, aspirin was associated with a significant increase in intracranial hemorrhage (0.1%) and major bleeds (0.5%), with only a slight reduction of non-fatal MI and ischemic strokes (0.4% at a median follow-up of 5 years), and no effect on mortality, fatal MI, or total stroke.[72]

Patients with a coronary calcium score >400 have a risk of coronary events similar to patients with obstructive CAD or prior coronary events, and this risk exceeds 3% per year.[73,74] As such, aspirin may be considered in those patients, mainly if they are young (<70) with a low bleeding risk.

QUESTIONS AND ANSWERS

Question 1. A 60-year-old diabetic man presents with NSTEMI and undergoes stenting of the mid-LAD. He has a history of stroke 2 years prior. His LDL is 190 mg/dl, HDL 35 mg/dl, and triglycerides 300 mg/dl. He used a statin in the past but stopped it because of hip pain. What is the best treatment strategy?
A. Ezetimibe and niacin
B. Ezetimibe and PCSK9 inhibitor

C. Niacin and PCSK9 inhibitor
D. Reintroduce statin along with ezetimibe

Question 2. A 45-year-old woman is obese, smokes, and has prediabetes and controlled HTN. She has premature CAD in first-degree relatives at the age of 50. LDL is 118 mg/dl, HDL is 45 mg/dl. Her 10-year PREVENT cardiovascular risk score is 4%. Which of the following indicates statin therapy in this patient, according to the ACC guidelines?
A. The family history of premature CAD
B. Metabolic syndrome
C. CT calcium score of 25
D. HIV
E. Any of the above
F. None of the above

Question 3. A patient had a recent ACS and AF and was placed on atorvastatin 80 mg. He is also on diltiazem, amiodarone, aspirin, and clopidogrel. On his follow-up clinic visit, he notes significant proximal myalgias. Which of the following is *incorrect*?
A. Diltiazem and amiodarone are inhibitors of cytochrome P450 3A4 and increase the level and toxicity of atorvastatin
B. Simvastatin can be used, as it is not a substrate of cytochrome P450 3A4
C. Pravastatin is not metabolized by any cytochrome, while rosuvastatin and fluvastatin are metabolized by different cytochromes (2C9 rather than 3A4). The latter 2 can be used with diltiazem or amiodarone.
D. PCSK9 inhibitors can be used, and are associated with a low discontinuation rate in patients intolerant to statin

Question 4. A patient with PAD and diabetes had a recent MI. He was already on atorvastatin 40 mg with LDL of 60 mg/dl, TGs of 300, total cholesterol 155 mg/dl, and HDL of 35 mg/dl. What is the next step?
A. Add PCSK9 inhibitor
B. Add ezetimibe
C. Add icosapentyl omega-3 fatty acid
D. Add fenofibrate
E. Continue same regimen

Question 5. A 55-year-old obese man has diabetes, HTN, and HFpEF. He is receiving metformin and wants to learn about newer anti-diabetic agents. Which of the following is *incorrect*?
A. SGLT-2 inhibitors reduce the occurrence of new HF in diabetic patients
B. Dapagliflozin (SGLT-2 inhibitor) has reduced mortality in patients with HFrEF, regardless of the presence of diabetes
C. Empagliflozin (SGLT-2 inhibitor) has reduced mortality in patients with diabetes and cardiovascular disease
D. GLP-1 agonists reduce cardiovascular events but not mortality or CKD progression
E. The combination of GLP-1 agonists and dipeptidyl-peptidate-4 inhibitors is not beneficial

Answer 1. D. Frequently, muscular symptoms are not solely related to statin, and may be related to low vitamin D, thyroid disorder, or drug interaction. The patient may tolerate statin, especially a different statin, upon re-initiation. Rosuvastatin may be tried, starting at low dose every other day, then up-titrated if possible. Pitavastatin is another alternative. Recheck lipids 6 weeks later; if LDL still >70, or if the patient cannot tolerate statin, add PCSK9 inhibitor. Two objectives should be achieved: (1) provide statin therapy and (2) reduce LDL <55–70 mg/dl. The focus should be on LDL-lowering drugs.

Answer 2. E. A PREVENT risk score of 3–5% has a class IIa recommendation for statin therapy. Risk enhancers strongly push for statin therapy, like they do for patients with a risk of 5–10%, which is nonetheless a class I recommendation for statin therapy. B through E are risk enhancers. Of note, the calcium score is normally 0 at the age of 45 (man or woman); although 25 is low in absolute value, it is above the 75th percentile and this compels statin therapy (in fact, this calcium score is above the 90th percentile for age).

Answer 3. B. Simvastatin and lovastatin are extensively metabolized by cytochrome P450 3A4, which is inhibited by diltiazem, amiodarone, macrolides, grapefruit juice, and protease inhibitors; atorvastatin is moderately metabolized by this cytochrome. Rosuvastatin is metabolized by another cytochrome and does not have these drug interactions. PCSK9 inhibitors do not have any known drug interaction.

Answer 4. A. This patient has a very high cardiovascular risk and continues to have cardiovascular events despite an LDL of 60 mg/dl. This is because his other atherogenic particles, e.g., VLDL, remain significant elevated. Also, with high TGs of 300, LDL is undercalculated and is probably higher. The elevated non-HDL cholesterol reflects this fact. Non-HDL cholesterol measures 120 mg/dl, significantly higher than the target of <100 mg/dl**. Even if the LDL goal is achieved (<70), ezetimibe or a PCSK9 inhibitor must be added when non-HDL goal is not achieved (ACC guidelines).** Considering this patient's risk and the better data with anti-PCSK9 therapy, the latter is preferred. Also, LDL may be targeted to below 50–55, as in anti-PCSk9 trials and ESC guidelines. Icosapent ethyl fatty acid may be considered, but only after LDL and non-HDL goals have been achieved.

Answer 5. D. GLP-1 agonists ↓ weight and MI. They ↓ HF in obese patients. They reduced mortality in multiple trials of diabetes (LEADERS with liraglutide, Pioneer-6 and Flow with semaglutide), and in a trial of obesity without diabetes (SELECT with semaglutide). Answer E is correct: while the combination may further boost GLP-1 levels, the GLP-1 effect is already maximized with GLP-1 agonists. B is correct (DAPA-HF trial) and C is correct (Empa-reg trial).

Questions and answers 625

I. Definition

Pulmonary hypertension (PH) is defined as a mean PA pressure ≥25 mmHg at rest (≥21 mmHg is adopted by the 2022 ESC guidelines to improve sensitivity).[1–4]

In patients with normal resting PA pressure, an absolute mean PA pressure >30 mmHg with exercise was used previously as a diagnostic feature of PH but is less specific, particularly in patients >50 years old who may normally increase their mean PA up to 40 mmHg and systolic PA up to 50 mmHg with exercise. Yet, the 2022 ESC guidelines do recognize exercise PH as (delta mean PA)/(delta CO) >3 mmHg/L/min (the ratio of the change between rest and peak exercise values).

The classification of PH is shown in Table 25.1.

II. Categories of PH

There are 2 major categories of pulmonary hypertension (Figure 25.1).

A. PH secondary to left heart disease (also called pulmonary venous hypertension or postcapillary PH)

Left-sided ventricular or valvular diseases may produce an increase in LA pressure with passive backward transmission of pressure to the pulmonary circulation. As a result, PA pressure rises. In this case:[3,4]

- PCWP is elevated (mean >15 mmHg).
- Diastolic PA pressure is passively increased and is equal to PCWP or is <7 mmHg higher than PCWP: diastolic pressure gradient (DPG) = (diastolic PA pressure – PCWP) < 7 mmHg.
- Pulmonary vascular resistance (PVR) is <3 Wood units. The transpulmonary gradient, i.e., mean PA pressure – PCWP, is <12 mmHg (some investigators use a cutoff of 20 mmHg).[1] Note that the transpulmonary gradient is the numerator in PVR calculation: PVR = transpulmonary gradient/cardiac output.

Left heart failure is the most common cause of PH. HF may be obvious in some patients, but may be occult in others, especially when isolated LV diastolic dysfunction is present.[5] Furthermore, with chronic postcapillary PH, pulmonary arteries may undergo reactive changes and PH may become a ***combined pre- and postcapillary PH,*** in which case PCWP is elevated but diastolic PA pressure is ≥7 mmHg higher than PCWP and PVR is ≥3 Wood units.[4,6] In fact, a precapillary component accompanies PH in 20–35% of patients with advanced left HFrEF, 20–38% of HFpEF (even if not advanced), and, commonly, mitral stenosis.[6–10] In addition, this situation may be seen in patients with mixed disorders, such as left HF and COPD. The active, precapillary PH component resolves after treatment of HF, but may take weeks or months to fully resolve.[3]

PVR is most important for defining a precapillary component of PH per ESC. DPG is not used in ESC PH classification, as its prognostic value in left heart-related PH has been questioned in multiple registries and is inferior to that of PVR. This is partly related to the technical pitfalls of DPG measurement: to be done properly, the DPG is the gradient between diastolic PA and end-diastolic PCWP (midway through the X descent), not mean PCWP. Mean PCWP is used in PH classification and PVR calculation, but not in DPG calculation. As such, in case of a large V wave, mean PCWP is much higher than end-diastolic PCWP, and DPG will be falsely low if one uses mean PCWP.

Special case of precapillary PH with occult postcapillary PH – Resting PCWP may be normal despite LV failure, especially in patients appropriately treated with diuretics. The improvement of pulmonary pressure lags behind the improvement of PCWP, and these patients may have a normal PCWP with elevated PA pressure, simulating precapillary PH, except for a PVR that is only mildly increased. Table 25.1 Classification of severity of pulmonary hypertension.

	Systolic PA pressure	Mean PA pressure
Mild PH	35–50 mmHg	25–35 mmHg
Moderate PH	50–70 mmHg	35–45 mmHg
Severe PH	>70 mmHg	>45 mmHg or PVR >5–7 Wood units

WHO classification: WHO group 1 is PAH; WHO group 2 is left heart disease-related PH; WHO group 3 is PH secondary to lung disease or hypoxemia; WHO group 4 is chronic thromboembolic PH.

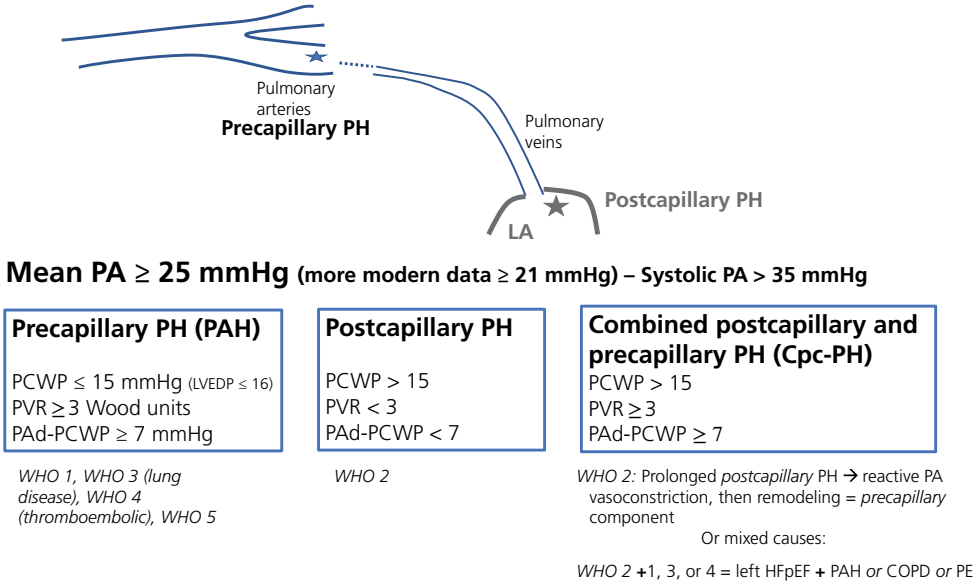

Figure 25.1 Hemodynamic classification of pulmonary hypertension.

testing, volume loading, or pulmonary vasodilator challenge are appropriate strategies that increase PCWP in occult LV dysfunction and thus unveil the diagnosis of postcapillary PH: they are recommended in cases of high clinical or echo pre-test probability of left HFpEF. Vasodilator therapy is still considered if PVR >5 Wood and resting PCWP is normal, but more carefully (ESC class IIa).[11] These patients, like patients with florid combined pre- and postcapillary PH, have a worse survival compared to patients with pure HFpEF or pure precapillary PH.[12] Patients who are suspected of having left heart disease-associated PH or mixed postcapillary PH and precapillary PH are approached as in Figure 25.2.

B. Precapillary PH

Precapillary PH is characterized by mean PCWP and LVEDP ≤ 15 mmHg, and PVR ≥ 3 Wood units (ESC guidelines 2022 use >2 Wood units as cutoff).[1,2,4,13]

There are 3 major categories of precapillary PH:

1. ***Pulmonary arterial hypertension (PAH)***, which is related to a pulmonary vascular disease affecting the pulmonary arterioles. PAH may be idiopathic, familial, or related to connective tissue disease, toxins (amphetamines, anorexigen), cirrhosis (portopulmonary hypertension), HIV, or Eisenmenger syndrome. Idiopathic PAH may be seen at any age or sex but is more common in female patients (female/male ratio 3:1; age 36 ± 15 years). Plexiform lesion is seen on pathology: intimal and medial proliferation occluding the lumen, with multiple small holes inside this occlusion, trying to create some flow.

In congenital heart disease with a large left-to-right shunt (e.g., VSD, PDA, or less often ASD), PA pressure initially increases as a result of the increase in right-sided flow, PVR remaining initially low (pressure = flow × resistance; an increase in flow leads to an increase in pressure). This "dynamic" PH resolves with shunt closure. Over time, the increased pulmonary flow induces progressive pulmonary vascular disease and severe increase in PVR to a point that PVR approaches SVR, PA pressure approaches systemic pressure, and the shunt reverses and becomes directed right-to-left or bidirectional. This is Eisenmenger syndrome and, except in ASD, is usually established in infancy or childhood. It is unusual for VSD or PDA to be diagnosed as a cause of PH in an adult. Note that ***small defects (VSD <1 cm, ASD <2 cm) do not usually account for PVR elevation; when found in a patient with PAH, they are incidental and should not be closed.***[4]

Pulmonary veno-occlusive disease is characterized by primary venular abnormalities similar to the arteriolar abnormalities seen in idiopathic PAH and may be idiopathic or associated with scleroderma. Similar to PAH, true pulmonary arterial wedging is difficult during catheterization, but, if successful, it still creates a column of stagnant blood between the catheter and the LA; thus, the truly wedged PCWP approximates the LA pressure, albeit damped through the venular obstruction, and is normal in value. The wedged PA pressure, i.e., LA pressure, is normal, but the pulmonary capillary pressure is increased and pulmonary edema may be seen. The diagnosis is suggested by the triple combination

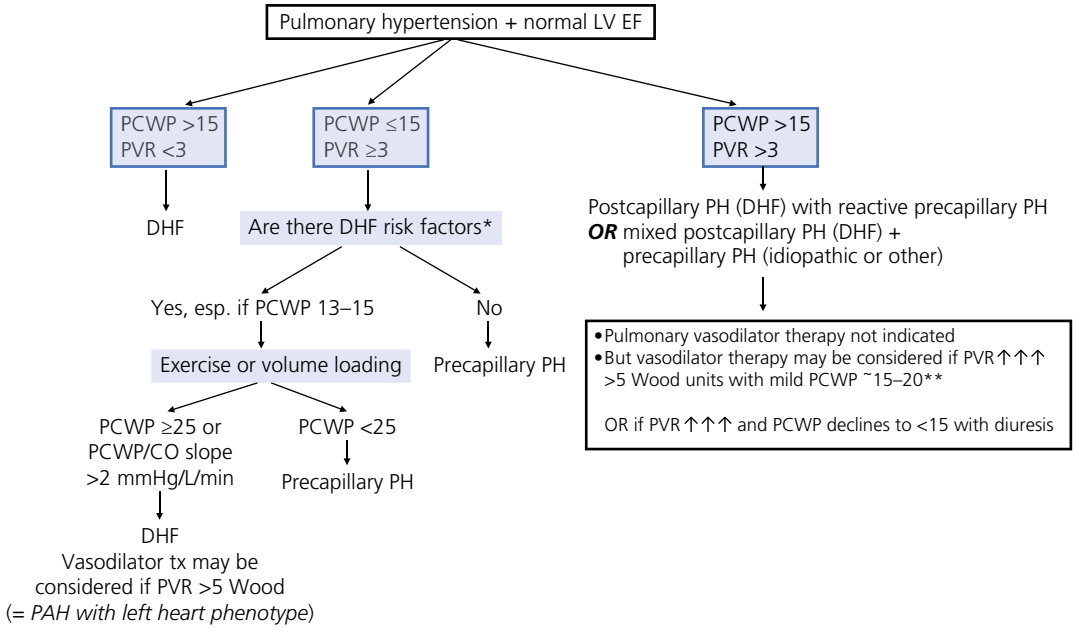

Figure 25.2 Diagnostic approach to distinguish between precapillary PH (pulmonary arterial hypertension) and postcapillary PH related to diastolic heart failure (DHF).

*HTN, age >65, obesity, LVH, left atrial enlargement, atrial fibrillation, low E′, E/E′ >15. With exercise, PCWP may normally rise up to 20–25 mmHg. Provocation PCWP is abnormal if it rises to ≥25 mmHg with exercise, or to ≥19 mmHg with passive leg raise, saline challenge, or vasodilator testing.

**If PCWP does not further rise with vasodilator challenge and PVR is severely disproportionate to PCWP, pulmonary vasodilators may be considered (off label).

of severe pulmonary hypertension, normal PCWP, and radiographic pulmonary edema/ground-glass opacities, as well as the lack of response to vasodilator therapy (or the deterioration with this therapy).

Portopulmonary PAH is driven by portal hypertension rather than synthetic liver function. Patients may have preserved synthetic liver function but significant portal hypertension, which causes an inability to clear some substances through the liver. Portal hypertension may also cause AVMs, which result in right-to-left shunting. While AVMs are unrelated to PAH, they do nonetheless provide an escape mechanism from the high PA pressure.

2. *PH secondary to thromboembolic disease*. Approximately 4% of patients who develop acute PE do not fully resolve their thrombus burden and go on to develop chronic PH. This often occurs after single PE episodes. Most often, the thrombus involves the main lobar pulmonary artery or the proximal arteries (80%), with small-vessel arteriopathy and thrombosis that subsequently occur and contribute to disease progression. In a smaller category of cases, the thromboembolic process is purely distal, involving the small distal pulmonary arteries (the distal type is less likely to benefit from surgical thromboendarterectomy).

3. *PH secondary to hypoxic lung disease*. Mild PH is common in patients with COPD, but severe PH is very unusual. In fact, moderate and severe PH are only seen in 5–10% and 2% of severe COPD cases, respectively.[14,15] Also, sleep apnea does not usually lead to more than mild PH. Conversely, severe PH may be seen with advanced-stage fibrotic lung disease that obliterates the pulmonary capillaries, sarcoidosis, or obesity–hypoventilation syndrome.

III. Two tips in the evaluation of PH

The following 2 ideas are essential to the evaluation of PH:

1. In chronic severe PH, the PA pressure number may start declining into the mild range as the RV develops severe failure and becomes unable to generate high PA pressure. PVR, on the other hand, remains severely elevated.

2. In acute PH (e.g., pulmonary embolism), the RV is not able to generate a systolic PA pressure higher than 45–50 mmHg. Therefore, in a case of acute pulmonary embolism, a systolic PA pressure higher than 40 mmHg implies severe pulmonary hypertension.[13] A systolic PA pressure higher than 50 mmHg suggests a subacute or chronic process.

In both cases, the PA pressure number underestimates the true severity of the pulmonary vascular abnormality. The presence of severe RV dysfunction, a severely elevated RA pressure, and a severely elevated PVR >5–7 Wood units is diagnostic of severe PH. In fact, in patients with severe PH that is evidenced by elevated PVR and RV failure, a high systolic PA pressure predicts recovery of RV function with therapy and better outcomes than a low systolic PA pressure. A higher systolic PA pressure corresponds to a better RV function.[16]

IV. Hypoxemia in patients with PH, and right-to-left shunting

Hypoxemia may be related to the cause of PH, such as pulmonary edema (left heart disease), lung disease, or hypoventilation syndrome. On the other hand, PAH may, by itself, lead to hypoxemia, mainly in patients with patent foramen ovale. In those patients, the increased RA pressure "opens" the PFO, leading to a secondary right-to-left shunt (this shunt is the result rather than the cause of PAH). Also, *a degree of arteriovenous shunting may occur at the pulmonary level, as a diversion from the "plugged" pulmonary microvascular flow*. Right-to-left shunt worsens with exercise (increased right venous return).

When asked to "look for right-to-left (R-L) shunt" in a patient with PAH and hypoxemia, the answer is often: **R-L shunt is inherently present, but this shunt is the result of PH and a compensatory, pop-off mechanism, not the cause of PH.** A causal shunt with Eisenmenger syndrome is very rarely diagnosed de novo in an adult: in such cases, a large defect is usually obvious on echocardiography, and a concomitant L-R shunt is often present (bidirectional shunt; hence the importance of seeking an L-R shunt in the workup of PH). Even when an ASD or VSD is detected, it does not account for severe PAH unless the defect is large (>2 cm and >1 cm, respectively). **Hypoxemia of PAH improves with vasodilator therapy**, as forward RV output improves and R-L shunt declines.

V. Diagnosis: echocardiography; right and left heart catheterization

A. Echocardiography and chest CT

PH is often initially suggested by echocardiography. Echocardiography estimates PA pressure, and:

1. Suggests a left-sided etiology. In addition to valvular function and LV systolic function, echocardiography assesses LA pressure, LV diastolic function, and left atrial size.
2. Looks for signs of severity of PH: RV and RA dilatation, severe TR, and abnormal interventricular septal motion (the high, right-sided pressure or volume makes the septum bow to the left). Low RV S' <10 cm/s, low TAPSE <18 mm, and low RV/PA coupling: TAPSE/sPA pressure <0.35.
3. Frequently, PA pressure cannot be directly measured by echo. Analysis of the RVOT ejection waveform may help establish PAH: 94% of patients with PAH have midsystolic notching of the pulsed RVOT envelope; the high PA pressure opposes RV ejection and causes mid-systolic slowing of ejection (mainly correlates with high PVR). This may also manifest as mid-systolic closure of the pulmonic valve on M mode ("flying W" shape).[17] Also, PH is indicated by quick peaking of this RVOT velocity in <90 ms (= acceleration time = time to first peak).

On chest CT, PA ≥30 mm or PA larger than aortic root, and RV/LV ratio ≥1 are predictive of PH.

B. Catheterization

Catheterization is needed to confirm the diagnosis and the etiology of PH, particularly in cases of moderate-to-severe PH without a clear cause. Patients with a clear clinical and echo diagnosis of left HF do not require cardiac catheterization for PH assessment. Also, patients with an acute PE diagnosis do not require cardiac catheterization (this may, however, be required for chronic thromboembolic PH). The goals of catheterization are:

1. Confirm the diagnosis of PH by measuring PA pressure and calculating PVR (PVR = [mean PA – PCWP]/cardiac output). The spectral Doppler profile of TR is too weak or insufficient to measure the PA pressure in approximately 25–55% of patients referred for PA pressure evaluation; TR may not be present even when PH is severe.[18] The echocardiographic diagnosis of PH is falsely positive in up to 50% of patients, and, overall, the PA pressure value differs from the catheterization value by >10 mmHg in 50% of patients. Echocardiography may under- or overestimate PA pressure in various PH etiologies.[18,19]
2. Assess PCWP to determine if PH is secondary to left HF. **This is the single most important measurement in PH.** Yet, the assessment of PCWP may be difficult in patients with severe PH:[20–22] (i) segmental PA branches are dilated, which makes them difficult to wedge; thus, a hybrid PCWP–PA pressure tracing may be obtained and lead to overestimation of the true PCWP; (ii) on the other hand, the true PCWP waveform may be flattened without distinct waves, as the retrograde transmission of LA pressure through the constricted pulmonary vasculature is damped. Moreover, wedging a PA catheter in a patient with PH is associated with an increased risk of PA rupture. Try to confirm the appropriateness of PCWP by measuring a wedged O_2 saturation, which should be within 5% of the systemic arterial O_2 saturation.

In the absence of an appropriate PCWP tracing, LVEDP needs to be measured. ***Not only can PCWP overestimate LVEDP***, but according to a large analysis of 4000 heart catheterizations in patients with PH, ***PCWP underestimates LVEDP in over 50% of patients*** and misclassifies postcapillary PH as precapillary PH. This is related to the fact that LVEDP is larger than PCWP in patients with compensated LV dysfunction (Chapter 37, Figures 37.10, 37.11).[23] Assess mean PCWP in end expiration, or, in patients breathing heavily with respiratory swings, take the average PCWP through multiple cycles. However, when mean PCWP is normal, especially in the 13–15 mmHg range, account for the height of V wave and A wave, which may indicate occult LV dysfunction, and assess the end-diastolic PCWP at the end of A wave, which corresponds to LVEDP.

Patients with normal LVEDP and PCWP may still have left HF, sometimes masked by diuretics (which improve PCWP but the precapillary PA component lags behind). ***If suspected clinically, give a volume load or perform exercise testing or vasodilator challenge and see if PCWP or LVEDP increases, unveiling left HF as a component of PH*** (≥25 mmHg with exercise, ≥19 mmHg with passive leg raise, saline challenge, or vasodilator testing). Exercise testing for normal resting PCWP is only given class IIb in ESC guidelines, and patients with isolated exertional rise in PCWP may still be treated with pulmonary vasodilators.[11]

3. Assess for a left-to-right shunt (oximetry screen of SVC, IVC, and PA). Right-to-left shunt, on the other hand, is suspected when hypoxemia is present at rest and does not quickly improve with deep breathing or O_2 therapy. Right-to-left shunt is most commonly secondary to PH, i.e., a compensatory decompression shunt, rather than a cause of PH.
4. Perform acute vasoreactivity testing if PAH is diagnosed. Vasodilator challenge should not be performed in overt left HF with marked PCWP elevation, as it may increase pulmonary blood flow and thus PCWP, which leads to pulmonary edema. It is not typically performed in case of PH secondary to severe lung disease, as vasodilators worsen V/Q mismatch and hypoxemia. It may, however, be performed when *severe* PH is concomitant with lung disease, as severe PH often implies a primary pulmonary vascular disease independent of lung disease.

Only 10% of patients with PAH have a positive response to vasodilator challenge. ***Since non-responders still respond well to the chronic administration of potent pulmonary vasodilators (prostacyclin, bosentan, sildenafil), one may wonder what the rationale for vasodilator challenge is. The rationale for vasodilator challenge is 3-fold:*** (1) positive responders to vasodilator challenge may respond to chronic calcium channel blocker therapy; (2) positive responders have a better long-term prognosis; (3) the hemodynamic tolerance to vasodilator therapy is assessed. One should ensure that PCWP does not increase and cardiac output and systemic pressure do not decrease with vasodilators. **In fact, a vasodilator challenge may be used as a form of left heart stress testing, unveiling occult left HF.**

An acute response to vasodilator testing is defined by the ACC and pulmonary societies as a drop of mean PA pressure by >10 mmHg to <40 mmHg without a decrease in cardiac output. Other investigators have defined a positive response as a decrease in PA pressure and PVR by ≥20%.[20] Some patients have a decrease in PVR and an increase in cardiac output with vasodilators, such that PA pressure (cardiac output × PVR) remains unchanged. Thus, the sole reliance on PA pressure to assess vasoreactivity has its limitation, yet it more specifically predicts a response to CCB. Beside the assessment of PA pressure and PVR during testing, it is also important to assess:

a. *Cardiac output* generally increases with vasodilator therapy, except in severe RV failure with lack of contractile reserve.
b. *PCWP*: an increase in PCWP unveils an overlooked left heart failure and predicts intolerance to vasodilator therapy.
c. *O_2 saturation* may drop in patients with lung disease.
d. *RA pressure*: vasodilators increase venous return, which may not be tolerated in a patient with severe RV failure.
e. *Systemic blood pressure*.

Acute vasodilator testing is performed using 1 of the 3 following agents: IV epoprostenol, IV adenosine (starting at 50 mcg/kg/min, and titrated by 50–100 mcg/kg/min every 2 minutes, to a maximum of 250 mcg/kg/min), and inhaled nitric oxide. These agents are titrated up until the maximal dose is reached, systemic intolerance occurs (dyspnea, nausea), or 1 of the 5 negative endpoints occurs (hypotension, ↓ CO, ↑ PCWP, ↑ RA pressure, ↓ O_2 saturation).

Additional note: Vasoreactivity testing is useful in 2 more situations. Patients with left-to-right shunt (ASD, VSD, PDA) who have PH with a PVR >1/3 SVR or >5 Wood units need to have vasoreactivity testing or a trial of vasodilator therapy before shunt correction to ensure that PH is reversible; otherwise shunt closure may precipitate right heart failure. Patients with advanced left HF who are considered for cardiac transplantation and who have PH with high PVR require vasoreactivity testing to assess the reversibility of PH and their operability. In this case, however, the use of prostanoids may increase PCWP and is poorly tolerated. Nitroprusside and milrinone are the vasodilators of choice, as they reduce PVR in reactive PH but also reduce LV afterload, which prevents the increase in PCWP.

C. Other tests

Depending on the context, these tests are performed before or after confirmation of PH:

1. Chest CTA or better, V/Q scan for the diagnosis of thromboembolic PH. These studies do not usually miss the proximal form of thromboembolic PH, which is the most common form and the treatable form of thromboembolic PH. To definitely rule out PE and diagnose multiple distal PEs missed by the above, a pulmonary angiogram may need to be performed if the clinical suspicion is high. A CT mosaic pattern is characteristic of thromboembolic PH: one PA branch is occluded, so one lung segment receives very little flow, while another lung segment receives a compensatory high flow.
2. Chest X-ray, arterial blood gases, pulmonary function testing with diffusion capacity, ± high-resolution CT scan of the chest for the diagnosis of lung diseases. Remember, however, that lung diseases do not usually lead to severe PH.

On chest X-ray, look for pulmonary edema or parenchymal lung disease. Pulmonary hypertension, per se, leads to enlarged central pulmonary arteries, i.e., enlarged hila, with marked tapering of the peripheral arteries and oligemia of the lung fields. This is opposed to the diffuse vascular engorgement seen with pulmonary edema.

3. Sleep study in most patients.
4. HIV, liver function testing, antinuclear antibodies, TSH, BNP.

VI. Treatment

A. PH secondary to left heart failure, pulmonary thromboembolic disease, or lung disease: treat the underlying cause

1. Treat LV failure, aggressively treat hypertension, and perform valvular surgery in case of severe valvular disease. PH is expected to be reversible, but the process may be slow, and temporary support with pulmonary vasodilators may be needed perioperatively.
2. Pulmonary thromboendarterectomy in thromboembolic PH with proximal thromboembolic disease.
3. Bronchodilators and O_2 in the case of lung disease.

B. Role of pulmonary vasodilators in PH secondary to lung disease: Pulmonary vasodilators are generally not recommended and may be harmful

Pulmonary vasodilators may worsen V/Q mismatch by vasodilating the hypoventilated areas of the lungs, which worsens hypoxemia. However, severe PAH in a patient with lung disease is usually a coexistent pulmonary vascular disease, as lung disease, even if severe with severe hypoxemia, rarely causes severe PH. Hence *PDE-5i* may be considered for *severe PAH* (PVR > 5 Wood units) in patients with lung disease and is supported by one small trial (ESC class IIb): this is the so-called "pulmonary vascular disease phenotype" of lung disease, in which the bronchial obstruction is typically only moderate on spirometry but hypoxemia is relatively severe.[24] PDE-5i is *avoided in non-severe PAH* from lung disease. Better than PDE-5i, inhaled treprostinil showed benefit in PAH of all severities associated with idiopathic pulmonary fibrosis, in which case it is given a class IIb ESC recommendation;[25] an inhaled vasodilator is inherently safer because it mainly vasodilates the well-ventilated areas of the lung, hence it does not worsen V/Q mismatch.

C. PH associated with left heart disease: Pulmonary vasodilators are generally not recommended and may be harmful

Pulmonary vasodilators may increase pulmonary blood flow and LV preload, thus leading to pulmonary edema in the case of LV dysfunction.

Sildenafil acts on the cGMP pathway, which plays a role in myocardial relaxation; however, 2 trials of sildenafil in HFpEF, including HFpEF with pulmonary hypertension (predominantly postcapillary +/– mild precapillary component), have not shown any beneficial effect of sildenafil on symptoms, peak VO2, and hemodynamics, even in patients with elevated PA pressure, RV dysfunction, and impaired RV/PA coupling.[26] Also, sildenafil has not proven beneficial in patients with corrected valvular heart disease and residual pulmonary hypertension. In fact, it worsened clinical status and increased the risk of hospitalization (SIOVAC trial).[27] Also, 2 small studies of bosentan and macitentan in HFpEF with combined pre- and postcapillary PH failed to show efficacy.[28,29]

However, none of the prior trials focused on severe precapillary PH associated with left HF. Pulmonary vasodilator therapy may be considered in 3 specific cases of combined pre- and postcapillary PH (Cpc PH):

i. In Cpc PH with only mild PCWP rise of 15–20 mmHg but severe PVR > 5 Wood units and predominant RV failure—the so-called RV phenotype of HFpEF—PDE-5i may be considered according to just 1 trial by Guazzi et al.[30] and 2 retrospective analyses.[31,32] Although this

has a questionable value, the 2022 ESC guidelines do not contraindicate PDE-5i in postcapillary PH combined with severe precapillary PH and a PVR > 5 Wood units, and recommend "an individualized approach to treatment." *Sotatercept is a promising option* in CpcPH: it improved PVR, PA pressure, PCWP and walking distance in phase 2 CADENCE trial (PVR ≥ 4 [4–7.5], PCWP ~18–26).

ii. In Cpc PH patients whose elevated PCWP declines to <15 mmHg with therapy, mainly if PVR remains >5 Wood units.

iii. In patients with PH and normal resting PCWP who nonetheless have HFpEF features and abnormal PCWP with exercise or fluid challenge or vasodilator challenge. Vasodilator therapy is started slowly as monotherapy and with close monitoring (ESC class IIa for vasodilator monotherapy in PAH with left heart phenotype).[11] Those patients are considered to have a combination of WHO 1 and 2 PH, i.e., idiopathic PAH with postcapillary PH. They have a worse prognosis than isolated precapillary PH and a lower tolerance of vasodilator therapy.[11,12]

D. Pulmonary arterial hypertension

Without specific therapy, idiopathic PAH has a poor prognosis with a median survival of 2.8 years. PAH related to Eisenmenger syndrome has a better prognosis, as the right-to-left shunt relieves the RV overload. Conversely, PAH associated with connective tissue disease (scleroderma) or HIV has a worse prognosis.[33] Several high-risk features imply a poor prognosis:[4]

- NYHA class IV; syncope (implies a severe reduction of the cardiac output reserve)
- 6-minute walking distance <165 m (165–440 m is intermediate risk)
- Clinical signs of RV failure or severe RV or RA dilatation on echo, or TAPSE/systolic PA <0.19 mm/mmHg
- Elevated RA pressure >14 mmHg (8–14 mmHg is intermediate risk), low cardiac index <2 L/min/m^2, SvO2 < 60% (2–2.5 L/min/m^2 and 60–65% are intermediate risks)
- Pericardial effusion
- BNP >800 ng/L or NT-proBNP >1100
- The severity of PA pressure rise, per se, is not an indicator of poor prognosis. In fact, a declining PA pressure in the face of a severely increased PVR is a marker of reduced cardiac output and RV failure (poor prognosis).

Pulmonary vasodilator therapy improves symptoms and survival very significantly (meta-analysis).[34] It is targeted to patients with pulmonary arterial hypertension and NYHA classes II–IV (Figure 25.3). Calcium channel blockers (CCBs) are associated with a dramatic improvement in survival of the few patients who acutely respond to vasodilator testing and achieve a sustained clinical response; thus, those select patients (5%) are initially treated with CCBs.[22,35]

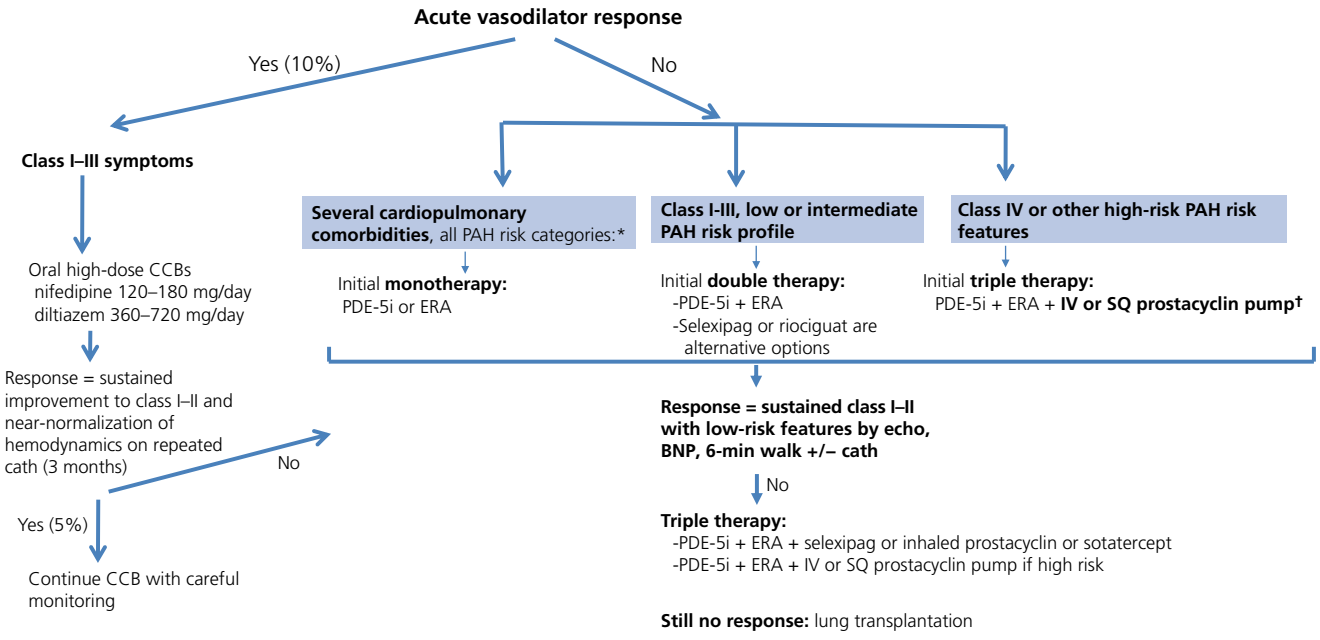

Figure 25.3 Treatment algorithm for patients with idiopathic, heritable, or drug-associated PAH. Connective tissue disease-associated PAH and HIV-PAH are not responsive to CCB, hence vasodilator challenge should not be done for the purpose of CCB therapy. This algorithm is cautiously extrapolated to Eisenmenger syndrome, and to thromboembolic PAH that cannot be treated surgically or that persists after surgical therapy. This algorithm is adapted from recommendations from references 4 and 35.

*Even if PH is precapillary, the presence of multiple HFpEF risk factors (e.g., AF, age > 65–70, obesity, HTN, or echo features of diastolic dysfunction) increases the risk of left HFpEF and side effects with pulmonary vasodilator therapy, as in AMBITION trial analysis; hence monotherapy is initiated at first. The same applies to patients with underlying lung disease.

†In class IV, intravenous epoprostenol is preferred because it is the therapy that has shown a mortality reduction in a randomized fashion, and is the therapy most widely studied in class IV.[38]

CCB, calcium channel blocker; ERA, endothelin-receptor antagonist; PDE-5i, phosphodiesterase-5 inhibitors.

Non-responders to vasodilator testing are treated with 1 of the 4 categories of selective pulmonary vasodilators:[36] (i) prostacyclin (IV epoprostenol pump, IV or SQ treprostinil pump, inhaled iloprost or treprostinil), and selexipag, an oral prostacyclin receptor agonist; (ii) endothelin-receptor antagonists (ERA) (bosentan, ambrisentan, macitentan); (iii) phosphodiesterase-5 inhibitors (sildenafil and tadalafil), which reduce the degradation of the vasodilator cGMP; (iv) stimulator of guanylate cyclase (riociguat), which enhances cGMP production. A newer, fifth type of PAH therapy, sotatercept, administered SQ every 3 weeks, inhibits the TGF-β pathway, which reduces arterial wall growth and promotes reverse remodeling. It improves outcomes when added to double or triple therapy.

PDE-5i and riociguat are related, as they both act on the cGMP system, i.e., the downstream nitric oxide system. In fact, nitric oxide binds to the intracellular guanylate cyclase and activates it, generating cGMP. Riociguat should not be combined with phosphodiesterase inhibitors, as they both act on the cGMP system (risk of hypotension without much benefit). Nitrates increase cGMP in the systemic but not pulmonary arteries and are not effective in PAH.

Even in the absence of a positive vasodilator response upon testing, these potent pulmonary vasodilators reduce PVR over the long term, and, more importantly, prevent arterial remodeling, scarring, and the further increase in PA pressure. They have an antiproliferative effect and, for some, an antiplatelet effect (NO and prostacyclin). Therapy needs to be started as soon as possible, as it dramatically reduces mortality over the short-term follow-up (14 weeks in a meta-analysis).[34] Clinical non-responders to pulmonary-specific vasodilators, i.e., those who do not improve to a functional class I or II, may be treated with combined therapies. Initial combination therapy with tadalafil and ambrisentan, vs. initial therapy with either one of them, is associated with a 50% reduction in clinical events and twice the increase in walking distance (AMBITION trial).

Note that, except for the rare dramatic responder to CCB, PAH therapies only mildly reduce PA pressure (by ~10%), and thus PA pressure is not used as a therapeutic endpoint. PAH therapies improve PVR, RV function and size on echo, RA pressure, and cardiac output without much of an effect on PA pressure.[1,37,38] Along with the reduction in PVR, cardiac output increases, which may mask any PA pressure improvement (PA pressure ~ PVR × cardiac output). ***While PA pressure may not change, its quality changes: it is driven by high CO rather than PVR.*** Thus, therapy targets clinical improvement (sustained class I–II, improved 6-minute walking distance), and normalization of echo parameters and BNP. Invasive assessment is repeated in patients who do not become low risk, and may be systematically considered in high-risk patients at 3–6 months of therapy.

Chronic anticoagulation (warfarin) was associated with improved survival in old retrospective analyses of idiopathic or familial PAH.[27,34] Anticoagulation may prevent the progressive, thrombotic pulmonary arteriopathy that occurs in PAH. The strength of anticoagulant recommendation has lessened over the years, as contemporary data are inconclusive (COMPERA registry shows benefit, while REVEAL does not; no benefit in scleroderma-PAH in either registry) (ESC does not recommend for or against anticoagulation).

Supportive measures are frequently used: O_2 for severe hypoxemia and diuretics for RV volume overload. Diuretics are useful for symptom relief and are usually well tolerated, as the dilated RV is not preload-dependent.

QUESTIONS AND ANSWERS

Question 1. Among elderly patients referred for the evaluation of pulmonary hypertension, what is the most commonly missed diagnosis?
A. Sleep apnea
B. Chronic lung disease
C. HFpEF
D. PE

Question 2. A 57-year-old obese woman has dyspnea on exertion, NYHA III. She has a history of hypertension. Her BP is currently 136/85 mmHg. No clinical signs of HF are present. Her echo shows a systolic PA pressure of 75 mmHg with RV pressure overload pattern, mild concentric LV remodeling, and mild LA enlargement with normal LA pressure. What is the next step?
A. Prescribe a diuretic and reassess PA pressure
B. Sleep study
C. Right and left heart catheterization with vasoreactivity and exercise testing
D. Prescribe sildenafil

Question 3. A patient with exertional dyspnea undergoes cardiac catheterization that shows severe PH: PA pressure 75/35, mean 45 mmHg; PCWP and LVEDP 13 mmHg at rest and 19 mmHg with exercise; no significant drop of PA pressure with adenosine testing. A chest X-ray and a lung perfusion scan are normal. She is placed on bosentan and selexipag therapy. Three months later, her functional capacity and dyspnea have improved significantly (NYHA II). No signs of right HF are present on exam. An echo is performed and still shows severe PH, PA pressure 75 mmHg. What is the next step?
A. Switch selexipag to sildenafil
B. Switch selexipag to SQ treprostinil
C. Add sildenafil
D. Continue the same therapy

Question 4. Vasodilator therapy is initiated in a patient with severe PAH, elevated RA pressure, and severe RV dilatation on echo. All of the following parameters are endpoints of therapy, *except for which one*?
A. Improving functional class to NYHA I–II
B. Reducing RA pressure to <8 mmHg
C. Increasing 6-minute walking distance to >380–440 m (or more in young patients)
D. Reducing PA pressure by 20%
E. Reducing RV dilation to normal or near-normal
F. Increasing cardiac index to >2.5–3 L/min/m^2
G. Normal BNP

Question 5. A 55-year-old woman presents with class III dyspnea. She is diagnosed with PAH. Based on recent data, which therapy is the best first-line therapy?

A. Sildenafil
B. Ambrisentan
C. IV epoprostenol
D. Combination tadalafil–ambrisentan

Question 6. A 49-year-old man has a history of thromboembolic PH with RV failure. A year ago, his cardiac catheterization demonstrated RA pressure 25 mmHg, PA pressure 95/55 mmHg, PCWP 20–22 mmHg, and PVR 11 Wood units. He is placed on bosentan and sildenafil. More recently, due to progressive symptoms, subcutaneous treprostinil is added. However, his symptoms continue to worsen. A right heart catheterization is repeated, revealing the PA and PCWP shown in Figure 25.4. His RA pressure is 14 mmHg and his cardiac output is 8 L/min by thermodilution. What is the next step?

A. The patient's PH is refractory. Up-titrate the dose of treprostinil
B. Continue the current regimen. RA pressure, CO, and PVR have improved
C. Reduce the dose of vasodilator therapy and consider adding furosemide

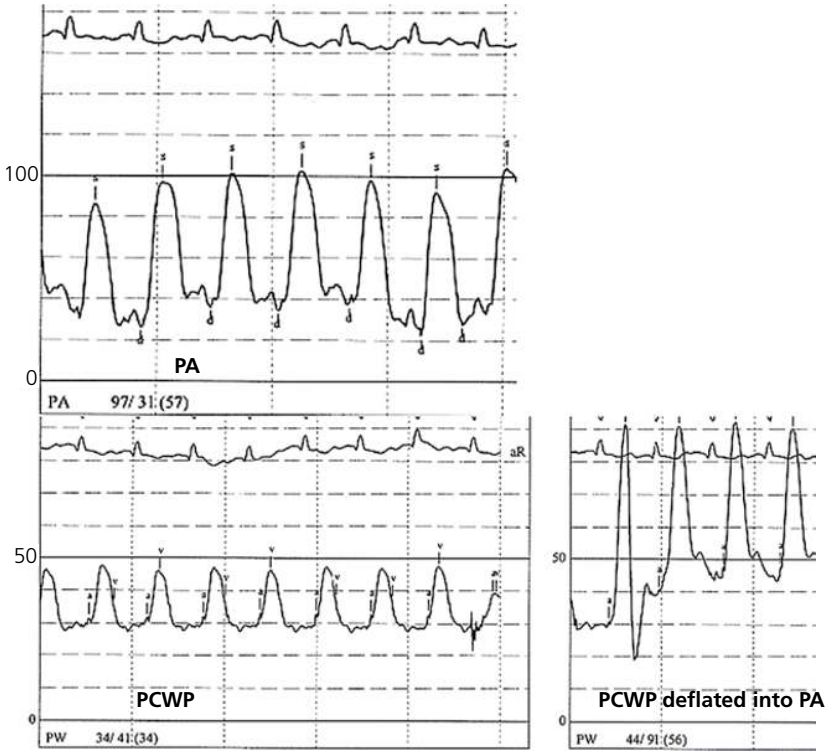

Figure 25.4

Question 7. A 35-year-old woman presents with class III dyspnea. She is found to have severe PAH with PA pressure 100 mmHg and PVR 9 Wood units. Echo shows ASD of 1 cm with right-to-left shunt across it. The RV is mildly dilated, and it mostly displays signs of pressure overload. What is the diagnosis and next management?

A. Eisenmenger syndrome. ASD closure is contraindicated at this point
B. Idiopathic PAH. ASD is an incidental finding and should not be closed
C. PAH secondary to ASD, but not a definite Eisenmenger. Perform RHC and attempt vasodilator testing: if PVR declines and the shunt converts from right-to-left to left-to-right with testing, ASD may be closed.

Question 8. Of the following PAH medications, select the one that has the most liver toxicity (10%), the one that has most been associated with peripheral edema, the one that has most interactions with cytochrome P450 3A4 and 2C9, and the one that reduces the blood levels of oral contraceptives:

A. Sildenafil
B. Bosentan
C. Ambrisentan
D. Macitentan

Question 9. An obese, hypertensive 71-year-old man presents with dyspnea and peripheral edema, for which the family physician prescribed furosemide. Echo shows normal EF, with moderate LVH and LA enlargement, and PA systolic pressure of 65 mmHg. Right heart catheterization confirms PA pressure of 60/32 (mean 41 mmHg) and PCWP of 14 mmHg. What is the next step?

A. Vasoreactivity challenge for PAH
B. Initiate sildenafil and ambrisentan
C. Administer 500 ml of saline over 5 minutes and recheck PCWP
D. Measure LVEDP

Question 10. A 41-year-old woman presents with dyspnea on exertion, elevated JVP, and a loud split S2. Echo shows a dilated RV with severe TR. Right heart catheterization shows: RA pressure 15 mmHg, mean PA pressure 43 mmHg, PCWP 19 mmHg, and thermodilution cardiac output 5.4 L/min. Classify her pulmonary hypertension:

A. Precapillary PH
B. Postcapillary PH
C. Combined pre- and postcapillary PH
D. Cannot properly measure PVR. Indirect Fick method is superior to thermodilution cardiac output in severe TR

Answer 1. C.

Answer 2. C. The patient's PH may be precapillary (PAH) or may be related to left heart diastolic dysfunction. In the absence of overt hypervolemia or HTN, and without proof that PCWP is elevated, adding a diuretic is not appropriate. A diuretic would be an appropriate first step in a patient with florid left HF/pulmonary edema. Sildenafil is not prescribed before a right heart catheterization confirms the diagnosis of PH and the precapillary origin of PH. Right and left heart catheterization is the next step: resting pressures are obtained, then, if PCWP and LVEDP are normal or borderline at rest, exercise testing is performed to unveil LV diastolic dysfunction, especially in a patient with LA enlargement and concentric LV remodeling. Vasoreactivity testing is also a left heart stressor that may increase PCWP/LVEDP and unveil LV diastolic dysfunction. A sleep study needs to be performed and sleep apnea treated; however, this is not the most important next step, especially because sleep apnea does not usually explain severe PH. In fact, sleep apnea may aggravate LV diastolic failure.

Answer 3. D. Except for a rare dramatic response seen in patients who have a positive response to vasoreactivity testing, PAH therapies only mildly reduce PA pressure (by ~10%), if at all, and thus PA pressure is not used as a therapeutic endpoint. The improvement in functional class to I–II and the improvement of RV failure and RA pressure are endpoints of therapy. Vasodilators reduce PVR and increase cardiac output, both of which are desirable effects that correlate with clinical improvement. However, PA pressure, which is ~ PVR × cardiac output, remains unchanged. The 75 mmHg value that follows therapy is different from the initial 75 mmHg value, as the underlying components (CO × PVR) have favorably changed.

Answer 4. D.

Answer 5. D. Initial combination therapy was superior to initial monotherapy in the AMBITION trial. Prostanoids are first-line therapy in patients with NYHA class IV or other high-risk, RV failure features (Section VI.D), not this patient.

Answer 6. C. Initially (a year ago), the patient had severe pulmonary arterial (precapillary) hypertension, with RV failure and severely elevated RA pressure. PCWP was mildly elevated as a result of RV failure and the inherent equalization of left and right diastolic pressures (with RA pressure remaining slightly higher than PCWP). The elevation of PCWP did not match the severity of PVR elevation.

On the current study, note the very wide PA pulse pressure and the near-ventricularization of the PA pressure waveform. This may imply either (i) severe pulmonic valve insufficiency or (ii) high-cardiac-output state. The high cardiac output obtained by thermodilution suggests the latter. In pulmonary insufficiency, the thermodilution injectate keeps recirculating away from the PA sensor and a low cardiac output is obtained, or sometimes no CO can be obtained.

PCWP is very elevated (mean ~35 mmHg) with a very large V wave that approximates 50 mmHg. This implies severe LV failure. In fact, PCWP > >RA pressure, definitely implying that LV failure is the primary process at this point. Moreover, PVR is calculated at ~2.5 Wood units (PVR = [mean PA – PCWP]/CO). Thus, at this point, the severe pulmonary hypertension is secondary to both LV failure and the high-output state, rather than elevated PVR (PA pressure being proportional to CO × PVR, a high cardiac output may lead to a high PA pressure, even if PVR is reduced). LV failure, by itself, is secondary to the excessive vasodilator therapy that floods the left heart with a high preload (high-output HF).

Answer 7. B. When a small defect is found in an adult with severe PH and severe PVR elevation (usually VSD <1 cm or ASD <2 cm), the defect is likely an incidental finding rather than a cause of PAH (ESC guidelines); the defect allows decompression of the right chambers and should not be closed. In the current case, the severity of PVR elevation is disproportionate to the size of the ASD. ASD rarely causes Eisenmenger, and when it does, the defect is usually large (>2 cm) and has already caused RV failure for some time before Eisenmenger develops. Answer C would be an appropriate management strategy if the defect was large.

Answer 8. All endothelin-receptor antagonists may cause peripheral edema (in up to 20%). The drug with the most liver toxicity is bosentan; the one with the most peripheral edema is ambrisentan; the one with the most cytochrome drug interactions is bosentan (sildenafil also has cytochrome drug interactions); and the one that reduces the effect of oral contraception is bosentan. Macitentan has no reported liver toxicity and less peripheral edema than ambrisentan, but a 4% risk of severe anemia with Hb < 8 g/dl.

Answer 9. C. Clinically, this patient has a high suspicion of HFpEF (age, obesity, HTN, LVH, LA enlargement). His PCWP may be low at rest, partly because of furosemide, but exercise or volume challenge would unveil an excessive PCWP rise. A PCWP rise to >18 mmHg with 500 ml

saline challenge or >25 mmHg with exercise, such as supine biking on the catheterization table, indicates left HF. LVEDP is frequently higher than PCWP in occult LV failure and may diagnose HFpEF, but measuring LVEDP is not the highest yield measure. Measuring LVEDP is more relevant in patients with elevated PCWP whose clinical context suggests PAH and whose PCWP waveform may rather be a damped PA waveform.

Answer 10. C. Measure PVR: (mean PA-PCWP)/CO ~4.5 Wood units. PCWP is >15 mmHg (= postcapillary component), and PVR is ≥3 Wood units (precapillary component). Thus, this is combined pre- and postcapillary PH. While traditionally considered less accurate in severe TR, thermodilution remains superior to the indirect Fick method even in severe TR, and continues to have a good correlation with the direct Fick method.

Questions and answers 639

Syncope is a transient loss of consciousness *and* postural tone followed by spontaneous, complete recovery. *Lightheadedness* and *dizziness*, on the other hand, are terms that may imply any 1 of the following 4 conditions: (i) near-syncope or pre-syncope, i.e., the feeling of impending faint; (ii) vertigo, i.e., an illusion of motion, usually from an inner ear disorder; (iii) disequilibrium (ataxia) from peripheral neuropathy or cerebellar disorder; (iv) non-specific lightheadedness from anxiety.
There are 3 major types of syncope: neurally mediated syncope, orthostatic hypotension, and cardiac syncope.

I. Neurally mediated syncope (reflex syncope)

Neurally mediated syncope is the most common type of syncope, accounting for two-thirds of the cases.[1–3] It results from an inappropriate response of autonomic reflexes, leading to vasodilatation and bradycardia. It is usually preceded by premonitory symptoms (lightheadedness, diaphoresis, nausea, malaise, abdominal discomfort, tunnel vision). However, this may not be the case in a third of patients, more so elderly patients who may not recognize or remember the warning. *Palpitations* are frequently reported with reflex syncope and do not necessarily imply an arrhythmic syncope.[4,5] This syncope does not usually occur in a supine position,[4,5] but may occur in a seated position.[6] Subtypes of neurally mediated syncope are as follows:

A. Vasovagal syncope (neurocardiogenic syncope)

This syncope is usually triggered by sudden emotional stress, prolonged sitting or standing, dehydration, or a warm environment, but may also occur without any trigger. It is the most common syncope in young patients (female > male) and, contrary to a common misconception, may occur in the elderly as well.[7] Usually, it is not only preceded but followed by nausea, malaise, fatigue, or diaphoresis;[4,5,8] the patient's full revival may be slow and malaise may persist for hours. When the syncope is prolonged >30–60 seconds, clonic movements and loss of bladder control are common.[9]

Mechanism. Vasovagal syncope is initiated by anything that leads to strong myocardial contractions on an "empty" heart. Emotional stress, reduced venous return (from dehydration or prolonged standing), or vasodilatation (hot environment) stimulates the sympathetic system and reduces the LV cavity size, which leads to strong hyperdynamic contractions in a relatively empty heart. This hyperdynamic cavity obliteration activates the myocardial mechanoreceptors C, initiating a paradoxical *vagal reflex with vasodilatation and relative bradycardia*.[10] Vasodilatation is usually the predominant mechanism (*vasodepressor response*), particularly in older patients. Hypotension usually precedes bradycardia, hence the limited role of bradycardia in this process; but severe and long asystolic pauses may play a more pronounced role (cardioinhibitory response).[7] ***Diuretic and vasodilator therapies increase the predisposition to vasovagal syncope, particularly in the elderly***.

On tilt table testing, vasovagal syncope is characterized by hypotension and a relative bradycardia, sometimes severe.[10]

B. Situational syncope

This syncope is caused by a reflex triggered in specific circumstances such as micturition, defecation, coughing, weightlifting, laughing, or deglutition. The reflex may be initiated by a receptor on the visceral wall (e.g., bladder wall) or by the strain that reduces venous return.

C. Carotid sinus hypersensitivity

Carotid sinus hypersensitivity (CSH) is an abnormal response to carotid massage that is predominantly found in patients over 50 years of age. *Spontaneous carotid sinus syndrome* is a form of CSH where syncope clearly occurs in a situation that stimulates the carotid sinus (***head rotation***, head extension, shaving, tight collar); this is a rare cause of syncope (~1% of syncope cases). Conversely, *induced carotid sinus syndrome* is much more common and represents CSH in a patient with unexplained syncope and without obvious triggers; the abnormal response is *induced* during carotid massage rather than spontaneously. In induced carotid sinus syndrome, carotid sinus hypersensitivity is a marker of a diseased sinus node or AV node that cannot withstand any inhibition; this diseased node is the true cause of syncope rather than CSH per se, and carotid massage is a "stress test" that unveils conduction disease.

Thus, carotid sinus massage is indicated in unexplained syncope regardless of circumstantial triggers. It consists of applying firm pressure over each carotid bifurcation (just below the angle of the jaw) consecutively for 10 seconds. It is performed at the bedside, and may be performed in both supine and erect positions during tilt table testing; erect positioning increases the sensitivity of carotid massage.

An abnormal response to carotid sinus massage is defined as any of the following:[11–13]

i. Vasodepressor response: systolic blood pressure (SBP) decreases by ≥50 mmHg
ii. Cardioinhibitory response: pause ≥3 seconds (sinus pause or AV block)
iii. Mixed vasodepressor and cardioinhibitory response

Overall, a cardioinhibitory component is present in ~2/3 of CSH cases. CSH is found in 25–50% of patients over 50 years of age with unexplained syncope or fall, and is almost equally seen in men and women.[11] One study correlated CSH with the later occurrence of asystolic syncope during prolonged internal loop monitoring; subsequent pacemaker therapy reduced the burden of syncope.[12] Another study, in patients >50 years old with unexplained falls, found that 16% of them had cardioinhibitory CSH; pacemaker placement reduced falls and syncope by 70% compared with no pacemaker therapy in these patients.[13] On the other hand, CSH is seen in 39% of elderly patients who do not have a history of syncope or fall, and thus it is important to rule out other causes of syncope before attributing it to CSH.

D. Post-exertional syncope

While exertional syncope is alarming for a malignant cardiac or arrhythmic cause, post-exertional syncope is usually a form of vasovagal syncope. Upon exercise cessation, venous blood stops getting pumped back to the heart through the peripheral muscular contraction, yet the heart is still exposed to the catecholamine surge and hypercontracts on an empty cavity. This low preload reduces cardiac output and may trigger a vagal reflex.

Post-exertional syncope may also be seen in hypertrophic obstructive cardiomyopathy (HOCM) and aortic stenosis (AS), where the small left ventricular cavity is less likely to tolerate the reduced preload after exercise and is more likely to obliterate.

II. Orthostatic hypotension and postural orthostatic tachycardia syndrome

A. Orthostatic hypotension

Orthostatic hypotension accounts for ~10% of cases of syncope.[1–3] Normally, after the *first few minutes* of standing, ~25–30% of blood pools in the veins of the pelvis and the lower extremities, strikingly reducing venous return and stroke volume. Upon prolonged standing, additional blood volume extravasates in the extravascular space, further reducing venous return. This normally leads to a reflex increase of sympathetic tone, peripheral and splanchnic vasoconstriction, *and* an increase in heart rate of 5–20 bpm. Overall, cardiac output (CO) is reduced while blood pressure (BP) is maintained (BP = CO × vascular resistance: vascular resistance ↑, CO ↓).

Orthostatic hypotension is characterized by *autonomic failure*, with a lack of compensatory increase in vascular resistance or heart rate upon standing; or by significant *hypovolemia* that cannot be overcome by sympathetic mechanisms. It is defined as a drop of SBP ≥20 mmHg or DBP ≥10 mmHg after 30 seconds to 3 minutes of orthostasis. BP is checked immediately upon standing and at 3 (+/– 5) minutes of orthostasis; this may be done at the bedside or during tilt table testing.[2,4] Some patients may have an immediate BP drop of >40 mmHg upon standing, with a quick return to normal within 30 seconds. This "initial orthostatic hypotension" may be common in elderly patients receiving antihypertensive drugs and may elude detection upon standard BP measurement.[2] Other patients with milder orthostatic hypotension may develop a more delayed hypotension later than 3 minutes (10–15 minutes), as more blood pools in the periphery.[14]

In some ways, vasovagal syncope is a form of orthostatic hypotension, more delayed and abrupt, with additional vagal involvement.

Along with the BP drop, a failure to increase heart rate (<15 bpm) identifies autonomic dysfunction. On the other hand, an excessive increase in heart rate >20–30 bpm may signify a hypovolemic state even if BP is maintained, the lack of BP drop being related to the excessive heart rate increase. "*Coat-hanger pain*" of the neck, shoulders and suboccipital muscles is characteristic of autonomic dysfunction and the ensuing chronic malperfusion of postural muscles.

Orthostatic hypotension is the most common cause of syncope in the elderly and may be due to: (i) autonomic dysfunction = *neurogenic orthostatic hypotension* (age, diabetes, CKD, TTR amyloidosis, paraneoplastic syndrome, Parkinson disease), (ii) volume depletion, (iii) drugs that block autonomic effects or cause hypovolemia (vasodilators, β-blockers, diuretics, neuropsychiatric medications, alcohol).

Since digestion leads to peripheral vasodilatation and splanchnic blood pooling, syncope that occurs within 1 hour postprandially has a similar mechanism to orthostatic syncope.

Supine HTN with orthostatic hypotension – Some patients with severe autonomic dysfunction or ***severely non-compliant arteries*** are unable to regulate vascular tone. They display striking rise but also striking fall in BP upon small changes in arterial volume. Hence, they develop severe HTN when supine, as venous blood returns to the heart and the arterial circulation, and significant hypotension when upright.

B. Postural orthostatic tachycardia syndrome (POTS)

POTS is another form of orthostatic failure that occurs most frequently in young women (<50 years old, 86% women). POTS is defined as a striking increase in rate of ≥30 bpm within 5–10 minutes of standing, often to an absolute heart rate >120 bpm, with no significant drop in BP (<20 mmHg). Unlike in orthostatic hypotension, BP and cardiac output are maintained through this increase in heart rate, yet

the patient still develops symptoms of severe fatigue or near-syncope, because of flow maldistribution and reduced cerebral flow.[2] While POTS, per se, does not induce syncope,[2] it may be associated with a vasovagal form of syncope that occurs beyond the first 10 minutes of standing in up to 38% of these patients.[15] *Autonomic dysfunction* is prevalent in POTS, but the universal finding is ***cardiovascular deconditioning (orthostatic deconditioning)***. In fact, a period of bedrest following either surgery or a viral illness is frequently the trigger of POTS, often in individuals who are normally very active. Cardiovascular deconditioning can occur rapidly, with as little as 20 hours of bedrest in predisposed patients, hence POTS frequently has an acute onset and a vicious circle of further bedrest and cardiac deconditioning. POTS physiology is similar to the orthostatic intolerance of astronauts returning to Earth.[16] Cardiac unloading in space or after bedrest leads to: (a) physiological cardiac atrophy (the converse of athletic hypertrophy) with reduced stroke volume; (b) ***volume dysregulation*** (reduced renin-angiotensin), which reduces blood volume; and (c) ***peripheral autonomic denervation***, which does not affect the heart, but affects the peripheral vascular resistance, preventing its rise with orthostatic stress. To maintain cardiac output, heart rate rises at rest and more so with orthostasis.

In a second form of POTS called **hyperadrenergic POTS** (30–50% of POTSs), the sympathetic system gets overly activated with orthostasis (SBP rises ≥10 mmHg with standing).[10,17] Excessive sympathetic tone drives tachycardia and symptoms here, more than volume or autonomic impairment. The dominant symptom here is *palpitation*, while *dizziness* predominates in the first form of POTS.

POTS is diagnosed at the bedside, via orthostatic assessment of BP/pulse (3, 5, 10 minutes), and *does not require tilt table testing*. Hyperadrenergic POTS is specifically diagnosed by measuring norepinephrine levels after 5–10 minutes of standing (≥600 pg/ml). The supine pulse is normal in POTS, unlike IST, which is characterized by a more persistent sinus tachycardia, including supine nocturnal tachycardia.

III. Cardiac syncope

Accounting for ~10–20% of cases of syncope, a cardiac etiology is the main concern in patients presenting with syncope, and ***the main predictor of mortality and sudden death***.[1,2,8,18,19] Syncope often occurs suddenly without any warning signs (sudden syncope is also called *malignant syncope*). As opposed to neurally mediated syncope, the post-recovery period is not usually marked by lingering malaise.

There are 3 forms of cardiac syncope:

1. ***Structural heart disease with cardiac obstruction***: AS, HOCM, severe pulmonary arterial hypertension. Peripheral vasodilatation occurs *during* exercise, but CO cannot increase because of the fixed or dynamic obstruction to the ventricular outflow. Since BP = CO × peripheral vascular resistance, BP drops with the reduction in vascular resistance. Syncope may also occur *after* exercise. In addition, exertional ventricular arrhythmias may occur.
2. ***Ventricular tachycardia (VT)*** secondary to:
   - **i.** Underlying structural heart disease, with or without reduced LVEF, such as coronary arterial disease, hypertrophic cardiomyopathy, hypertensive cardiomyopathy, or valvular disease.
   - **ii.** Primary electrical disease (long QT syndrome, Wolff–Parkinson–White syndrome, Brugada syndrome, arrhythmogenic right ventricular dysplasia, sarcoidosis).

   MI/CAD causes syncope only when complicated by arrhythmias or by a shock.

   Occasionally, *fast supraventricular tachycardia* causes syncope at its onset, before vascular compensation develops, or at its offset (post-conversion sinus pause). This may occur in patients without major heart disease and usually causes near-syncope, not full syncope.[2]
3. ***Bradyarrhythmias***, with or without underlying structural heart disease. Bradyarrhythmias are most often related to degeneration of the conduction system or to medications, rather than cardiomyopathies.

When a patient with a history of heart failure presents with syncope, VT and bradyarrhythmias are top considerations. Nevertheless, about 50–60% of cases of syncope in cardiac patients have a non-cardiac cause,[18] including the hypotensive or bradycardic side effect of drugs.

IV. Other causes of syncope

Acute medical or cardiovascular illnesses may cause syncope and are sought in the appropriate clinical context: (1) severe hypovolemia or gastrointestinal bleed; (2) large pulmonary embolus with hemodynamic compromise; (3) tamponade; (4) aortic dissection; (5) hypoglycemia.

Bilateral critical carotid disease or severe vertebrobasilar disease very rarely causes syncope, and, when it does, it is associated with focal neurological deficits.[2] Vertebrobasilar disease may cause "drop attacks," i.e., a loss of muscular tone with fall but without loss of consciousness.[20]

Severe proximal subclavian disease leads to reversal of the flow in the ipsilateral vertebral artery as blood is shunted toward the upper extremity. It manifests as dizziness and syncope during the ipsilateral upper extremity activity, usually with focal neurological signs (subclavian steal syndrome).[2]

Psychogenic pseudosyncope is characterized by a high frequency of attacks that typically last longer than a true syncope and occur multiple times per day or week, sometimes with a loss of motor tone.[2] It occurs in patients with anxiety or somatization disorders.

Note

Reflex syncope is the most frequent *etiology* of syncope. However, long asystolic pauses due to sinus or AV nodal block are the most frequent *mechanism* of unexplained syncope and are seen in >50% of syncope cases on prolonged rhythm monitoring.[1,21] **These pauses may be related to intrinsic sinus or AV nodal disease or, more commonly, to extrinsic effects, such as a vasovagal mechanism.** Some European experts favor classifying and treating syncope based on the mechanism rather than the etiology, but this is not universally accepted.[1,22]

V. Syncope mimic: seizure (see Table 26.1)

Table 26.1 Features that suggest seizure rather than syncope.

- Unconsciousness often lasts longer than 5 minutes
- Postictal confusion or paralysis
- Prolonged tonic–clonic movements. Clonic movements may be seen with any prolonged syncope (>30 seconds), but in a more localized and brief form (<15 seconds), without the tonic arching of the back
- Tongue biting strongly suggests seizure

Urinary incontinence is not helpful, as it frequently occurs with syncope as well as seizure

VI. Clinical clues (see Table 26.2)

Table 26.2 Clinical clues to the diagnosis of syncope.[2–5,8]

Position during syncope
- Supine → reflex syncope is unlikely
- Sitting or standing position → any cause is possible
- Within a few minutes of standing → orthostatic hypotension
- Prolonged sitting or standing → vasovagal

Situation during syncope
- Exertion (strenuous activity, not just walking) → cardiac syncope (cardiac obstacle, ventricular arrhythmias)
- Post-exertion → vasovagal
- Postprandial → orthostatic hypotension
- Sudden fear, pain, unpleasant sight, hot environment → vasovagal
- Strain situation (micturition) → reflex syncope
- Head turning, shaving, tight collar → carotid sinus syndrome

Prodromes (abdominal discomfort, malaise, palpitations, nausea, blurry vision)
- Yes and >5 seconds → reflex syncope
- No or <5 seconds → reflex or cardiac syncope. *Reflex or orthostatic syncope may be associated with prodromes <5 seconds or no prodrome in 33–50% of patients, more so in the elderly*

How consciousness is regained after syncope
- Promptly → cardiac syncope
- Prolonged fatigue or nausea after syncope → reflex syncope
- Confusion → seizure

Color during syncope
- Pale, diaphoresis → reflex syncope, orthostatic syncope
- Blue → arrhythmia, seizure

Duration
- >5 minutes → seizure, hypoglycemia; not syncope (except occasionally aortic stenosis)

Underlying heart disease, chest pain → cardiac syncope

Multiple neuropsychiatric or blood pressure medications → reflex or orthostatic syncope

The presence or the lack of injury does not help differentiate cardiac from reflex syncope

Multiple syncopal recurrences (≥3) suggest a reflex or orthostatic syncope (one is less likely to survive 3 spells of cardiac syncope). This is particularly true if the interval between spells is >4 years[8]

VII. Diagnostic evaluation of syncope (Figure 26.1)

Underlying structural heart disease is the most important predictor of ventricular arrhythmias and death.[18,23–25] Thus, the primary goal of syncope evaluation is to rule out structural heart disease by history, examination, ECG, and echocardiography.

A. Basic initial strategy

The etiology of syncope is determined by history and physical examination alone in up to 50% of cases, mainly vasovagal syncope, orthostatic syncope, or seizure.[2,3,17] Always check blood pressure both lying and standing and in both arms, and obtain an ECG. Perform carotid massage in all patients older than 50 years if syncope is not clearly vasovagal or orthostatic and if cardiac syncope is not likely. Carotid massage is contraindicated if the patient has a carotid bruit or any history of stroke.

ECG establishes or suggests a diagnosis in 10% of patients (Table 26.3).[2,8,18,26] A normal ECG, or mild non-specific ST–T abnormality, suggests a low likelihood of cardiac syncope and is associated with an excellent prognosis. The ECG is abnormal in 90% of cases of cardiac syncope and only 6% of cases of neurally mediated syncope.[27] In one study of syncope patients with a normal ECG and a negative cardiac history, none had an abnormal echocardiogram.[28]

B. If the heart is normal clinically and by ECG

If the history suggests neurally mediated syncope or orthostatic hypotension, and the history, examination, and ECG are not suggestive of CAD or any other cardiac disease, the workup is stopped.

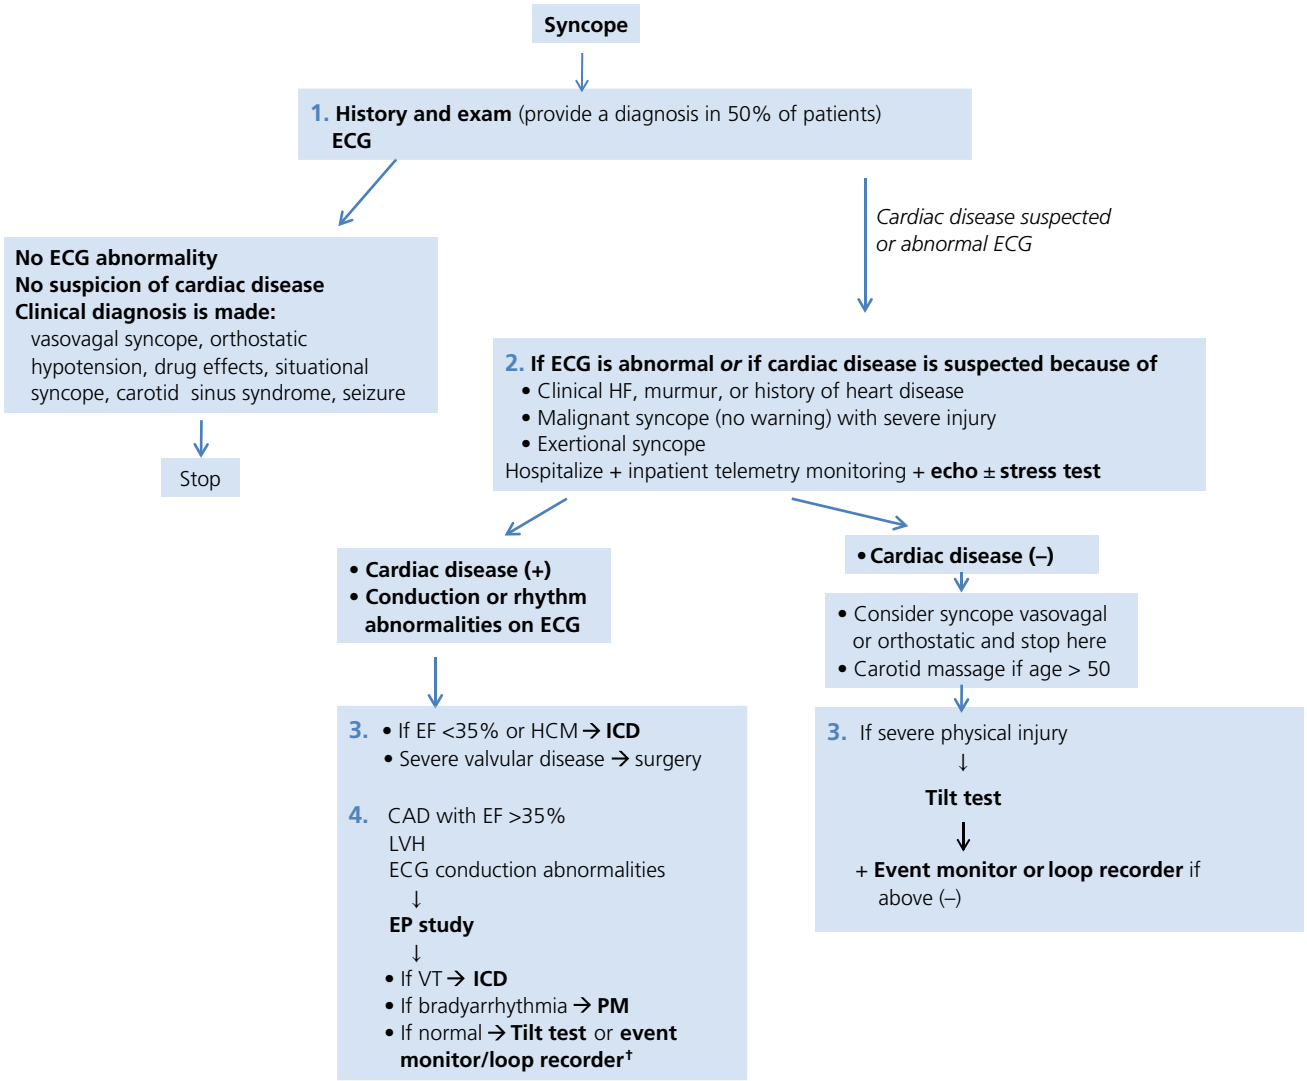

Figure 26.1 Management of syncope. Also, consider severe hypovolemia, bleeding, pulmonary embolism, and tamponade and rule them out clinically. Carotid Doppler and head CT scan are not indicated, especially given that carotid stenoses, per se, very rarely lead to syncope.

†EP study may have missed bradyarrhythmias and some forms of VT.

CAD, coronary arterial disease; EF, ejection fraction; EP, electrophysiological; HCM, hypertrophic cardiomyopathy; ICD, implantable cardioverter defibrillator; LVH, left ventricular hypertrophy; PM, pacemaker.

Table 26.3 ECG or rhythm monitor findings suggestive of cardiac syncope.

1. **Bradyarrhythmia-related syncope is *established* with any of the following:**
   - Sinus bradycardia <40 bpm or sinus pauses >3 s while awake, ***unless in a setting of high vagal tone or vasovagal mechanism***
   - Mobitz II or complete AV block (except complete nodal AV block *in a setting of high vagal tone or vasovagal mechanism*)
   - Alternating LBBB or RBBB (on the same ECG or on ECGs obtained on separate occasions)
2. **Bradyarrhythmia-related syncope is *suggested* with:**
   - Isolated RBBB or LBBB (VT also possible, depending on the underlying cardiac disease)
   - Mobitz type I AV block
3. **Tachyarrhythmia-related syncope is *established* with:**
   - Sustained VT or fast SVT (>160 bpm)
4. **Underlying heart disease and VT are *suggested* with:**
   - AF
   - Q waves
   - LBBB, RBBB, QRS >0.11 s
   - LVH, RVH, large R wave in V1
5. **Primary electrical disorders are *suggested* with:**
   - Long QTc, pre-excitation, RBBB with Brugada pattern, or T-wave inversion in V_1–V_3 or epsilon waves (ARVD)
6. **Acute ST–T abnormalities**

C. If the patient has signs or symptoms of heart disease

If the patient has signs or symptoms of heart disease (angina, dyspnea, clinical signs of HF, murmur), a history of heart disease, or exertional or malignant features, *heart disease should be sought,* and the following performed:

- *Echocardiography* to assess LV function, severe valvular disease, and LV hypertrophy.
- *Stress test* (possibly) in case of exertional syncope or associated angina. However, the overall yield of stress testing in syncope is low (<5%).[29]

D. If no heart disease is suggested by ECG and echocardiography

Often, the workup may be stopped, and syncope considered neurally mediated. ***The likelihood of cardiac syncope is very low in patients with normal ECG and echocardiography, and several studies have shown that patients with syncope who have no structural heart disease have a normal long-term survival***.[19,25,30] Yet, SVT or fast AF may be seen in patients with no clear underlying heart disease and may cause near syncope, or rarely, full syncope (particularly when a *pause occurs at the conversion of AF into sinus rhythm*). The following workup may be ordered if syncope has no clear trigger or prodrome and is associated with physical injury (especially if recurrent):[2,3,18]

- ***Carotid sinus massage*** in patients >50 years old, if not already performed. Up to 50% of these patients with unexplained syncope have CSH.[11]
- ***Tilt table testing*** to diagnose vasovagal syncope. It is positive for a vasovagal response in up to 66% of patients with unexplained syncope.[1,17] Patients with heart disease taking vasodilators or β-blockers may have abnormal baroreflexes; therefore, a positive tilt test is not necessarily indicative of vasovagal syncope in patients with heart disease (tilt testing is less specific in these patients).
- If the etiology remains unclear, particularly in patients with prolonged episodes of *palpitations + weakness rather than syncope* (suspicious for AF), an ***event monitor*** (4 weeks of external rhythm monitoring) or an ***implantable loop recorder*** (implanted subcutaneously in the prepectoral area for 1–2 years) is placed (Figure 26.2). Those monitors record the rhythm when the rate is lower or higher than predefined cutoffs or when the rhythm is irregular, regardless of symptoms. The patient or an observer may also activate the event monitor during or after an event, which freezes the recording of the 2–5 minutes preceding the activation and the 1 minute following it. A significant arrhythmia may be detected; on the other hand, syncope or dizziness may occur without any arrhythmia, ruling out arrhythmia as a cause of the symptoms.[31] Since syncope does not occur daily, the diagnostic yield of a 24-hour Holter monitoring is low (1–2%)[1,2] and is not improved with 72-hour monitoring; thus, ***prolonged rhythm monitoring is used in syncope, not Holter***.[31]

  Beware that pauses and high-grade AV block may be due to a vasovagal mechanism (Figure 26.3). The finding of non-sustained VT on monitoring increases the suspicion of VT as a cause of syncope, but does not prove it or dictate an ICD, per se.
- Electrophysiological (EP) study has a low yield in patients with normal ECG and echocardiography (bradycardia indices are detected in 10%).[31]

Carotid Doppler and head CT are not indicated, especially because carotid stenoses, per se, almost never lead to syncope. Head CT is performed whenever a seizure is suggested clinically.

E. If heart disease is diagnosed by echocardiography or if significant ECG abnormalities are found

Perform the following:

1. ***Pacemaker placement for these ECG abnormalities***:[1,2,18]
   - Mobitz II AV block or infranodal high-grade AV block
   - High-grade AV block, sinus pause >3 seconds or bradycardia <40 bpm while awake, except if vasovagal mechanism
   - Alternating left bundle branch block (LBBB) and right bundle branch block (RBBB) on the same ECG or separate ECGs
2. ***Inpatient telemetry monitoring***
3. ***Electrophysiological (EP) study*** is mainly valuable for patients with structural heart disease, including EF 36–49%, CAD, AF, or LV hypertrophy with normal EF.[26] Overall, in patients with structural heart disease and unexplained syncope, the yield is 55% (inducible VT in 21%, abnormal indices of bradycardia in 34%).[31]

   Limitations. The yield of EP study is low in bradyarrhythmias and in patients with EF ≤35%.[32] In the latter case, the syncope is often arrhythmia-related and the patient often has an indication for an ICD regardless of EP study results, especially if the low EF has been persistent despite medical therapy.[26]
4. If the above tests are negative, the differential diagnosis still includes arrhythmia, as the yield of EP study is low for bradyarrhythmias and some VTs, but also, at this point, neurally mediated syncope. The next step may be ***prolonged rhythm monitoring or tilt table testing***. The yield of the 30-day *event monitor* is highest in patients with frequently recurring syncope, where it reaches a yield of up to 40% (10–20% will have a positive diagnosis of arrhythmia, while 15–20% will have symptoms with a normal rhythm).[31,33] The *implantable loop recorder* has a high diagnostic yield overall and is used in patients with infrequent syncopal episodes (yield up to 50%).[1,21,34]

In brief, there are *2 diagnostic approaches to unexplained syncope:* the monitoring approach (loop recorder) and the testing approach (tilt table testing). A combination of both strategies is frequently required in patients with unexplained syncope, and, according to some investigators, a loop recorder may be implanted early on.[21]

Beware that the most frequent cause of sinus bradycardia, AV nodal block, or long asystolic pause (even 15–20 seconds) during syncope is vasovagal mechanism, not sinus or AV nodal disease.[1,21,35] In fact, in one study of patients with unexplained syncope receiving a loop recorder, 33% had recurrence of syncope at 1 year, half of which being asystolic reflex syncope with a median pause of 11.5 seconds (6–18.5 seconds) related to a vasovagal mechanism.[21] In the ISSUE-3 trial of vasovagal syncope, the mean asystolic pause was 11 ± 4 seconds (3–44 seconds).[22] In these studies, patients were older (~65 ± 14), and asystolic pauses were detected twice as often on loop recording as on tilt table testing. Tilt testing is more likely to detect asystole in younger patients with reflex syncope than older patients >60–70 years old. A vasovagal pause does not dictate pacemaker therapy, although a pacemaker is considered for recurrent vasovagal syncope along with age >40 (Figure 26.3). Autonomic symptoms (nausea, diaphoresis, feeling warm) suggest vasovagal mechanism.

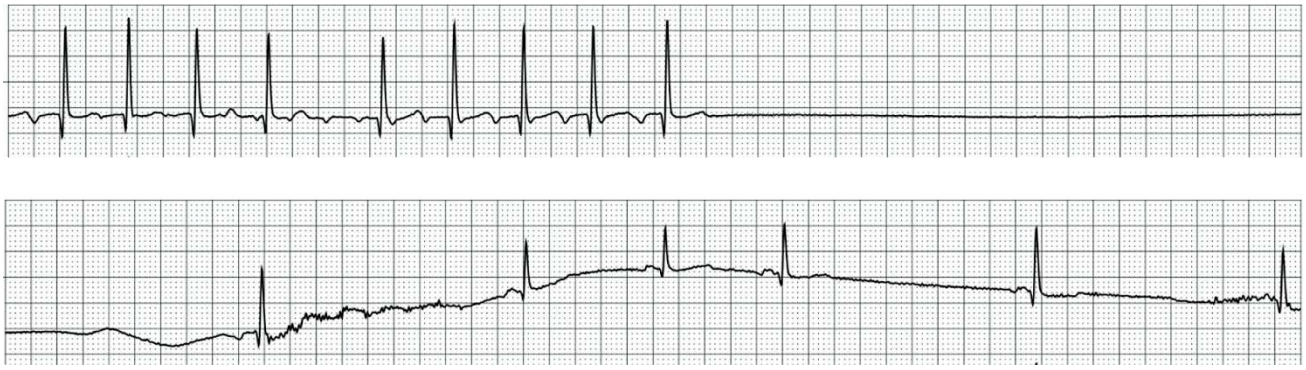

Figure 26.2 Rhythm monitoring in a 63-year-old patient with episodic prolonged palpitations and occasional near-syncope. Baseline ECG is normal and echo shows mild abnormality (left atrial enlargement). The rhythm monitor shows paroxysmal AF that spontaneously converts to sinus rhythm, with a long sinus pause at the point of transition from AF (*top row*) to sinus rhythm (*bottom row*). This pause is the most common cause of syncope in patients with tachy-brady syndrome (pause at every AF conversion) and may be seen in patients with no obvious heart disease.

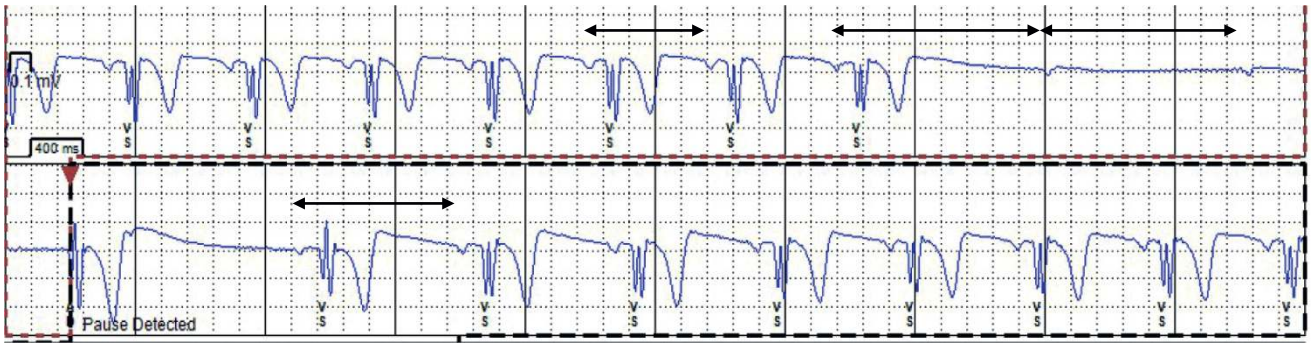

Figure 26.3 Episode of complete AV block on loop recorder, with 3 non-conducted P waves, leading to a pause of 4 seconds and 1 junctional escape beat (next to the *dashed line*). This occurred during wakefulness, in a patient with prior syncope. One is inclined to think that AV block with long pause is the cause of the patient's syncope. **However, always assess whether the AV block is vagally mediated.** The sinus P rate significantly slows down during the pause, with increased P-P interval, then progressively accelerates after the pause (*arrows*) → this indicates that a high vagal tone caused the AV block. If AV block was intrinsic, sinus P rate would accelerate during the pause rather than decelerate. Thus, the AV block is vagal in nature, and the syncope is due to the vasovagal process rather than AV block per se; pacemaker therapy is not definitely indicated and may not affect syncope recurrence, as syncope is mostly driven by the vasoplegia that precedes the AV block. Yet, pacemaker may be reasonable in patients with recurrent vasovagal syncope and long pauses (ESC class I, ACC class IIb).

F. Heart disease with LV dysfunction and EF ≤ 35%

ICD can be placed without the need for an EP study. ICD is needed anyway in these patients for the prevention of sudden death even if the cause of syncope is not an arrhythmia. Patients with a low EF and a history of syncope are at a high risk of sudden cardiac death.[26] Yet, in some patients with newly diagnosed cardiomyopathy, LV function may improve with medical therapy (myocarditis, hypertensive cardiomyopathy); the arrhythmic risk being essentially high during the period of ventricular dysfunction, a wearable external defibrillator may be placed while the decision about ICD is finalized within the ensuing months.

In patients with hypertrophic cardiomyopathy, place ICD after any unexplained syncope.

If ischemic heart disease is suspected, coronary angiography is performed, with revascularization as appropriate. If revascularization is carried out, an ICD should still be placed when syncope is suspected to result from VT (i.e., LV scar on ECG or echo with EF ≤ 35%, or inducible VT on EP study). Except in a large acute myocardial infarction, the substrate for VT is not ameliorated with revascularization.[26,36]

G. Note on LBBB and RBBB

Patients with RBBB or LBBB and unexplained syncope (not clearly vasovagal or orthostatic) likely have syncope related to intermittent high-grade AV block.[37] One study monitored these patients with an implanted loop recorder and showed that ~40% of them had recurrence of syncope within 48 days, often concordantly to complete AV block; ~55% had major events (syncope or high-grade AV block).[38] Many of the patients had a positive tilt test; thus, tilt testing is not specific for vasovagal syncope in these patients and should not be used to exclude a bradyarrhythmic syncope. Also, patients selected for this study had undergone carotid sinus massage and EP study with a negative result. In another analysis, EP study detected a proportion of the bradyarrhythmias, but more importantly, induced VT in 14% of patients with RBBB or LBBB; while not sensitive enough for bradyarrhythmia, EP study was highly specific and fairly sensitive for the emergence of VT upon follow-up.[37] Thus, unexplained syncope in a patient with RBBB or LBBB warrants carotid sinus massage, then EP study to assess HV interval and rule out VT, followed by placement of a ***loop recorder*** (ESC class I). Alternatively, after a negative EP study, a ***pacemaker*** may be directly placed (ACC class IIa, ESC IIb);[2,3] this is supported by the randomized PRESS trial, wherein permanent pacing

reduced cardiac events, mainly pre-syncope, by ~60% in patients with syncope and bifascicular block.[39] The drawback of indiscriminate pacing is that nearly 30–50% of patients rather have reflex syncope. This is further supported by the SPRITELY study, where patients with bifascicular block and syncope were randomized to permanent pacing vs. loop recorder; pacemaker reduced cardiac events, mainly near-syncope and symptomatic and asymptomatic bradycardic events warranting pacing (35% vs. 76% at a median of 33 months); yet syncope was not reduced and occurred in 29% of the pacing group, likely as a result of vasodepressor vasovagal syncope (only ~1% VT).[40]

VIII. Tilt table testing (see Table 26.4)[10,41]

Tilt testing consists of strapping the patient to a table that is subsequently inclined to 60–80° for 30–45 minutes. It is a form of orthostatic stress that simulates prolonged standing and is actually more stressful than standing, as the patient is deprived of the skeletal muscle pumping that normally occurs with standing. The patient may be further stressed by infusing isoproterenol or administering sublingual nitroglycerin, which increases the likelihood of syncope during testing, but this is a very nonspecific response and test medications are no longer recommended.[16]

The specificity of tilt table testing for vasovagal syncope is up to 90%, and the false positive rate is ~10% (the specificity is reduced with pharmacological facilitation). The sensitivity is ~80%, and it is positive in up to 66% of patients with unexplained syncope.[10,42] The false-positive rate is higher in patients with structural heart disease, LBBB, or RBBB; in fact, tilt table testing elicits syncope in up to 25% of patients with arrhythmic syncope and abnormal EP study. The yield of tilt testing is highest in patients with an intermediate pre-test probability of vasovagal syncope, such as *patients without structural heart disease who have an unexplained malignant or recurrent syncope, elderly patients with unexplained syncope or fall, or patients with structural heart disease (e.g., treated CAD, LV hypertrophy) but normal or only mildly reduced EF and normal EP study*. Patients with a high or low pre-test probability of vasovagal syncope have the lowest yield from tilt testing.

IX. Indications for hospitalization

Patients should be hospitalized if they have severe hypovolemia or bleeding, or if there is any suspicion of heart disease by history, examination, or electrocardiography, including:

- History of HF, low EF, or CAD
- ECG suggestive of arrhythmias (Table 26.3)
- Family history of sudden death
- Lack of prodromes, physical injury, exertional syncope, or syncope associated with dyspnea or chest pain[2,43]

In these situations, there is concern about arrhythmia, structural heart disease, or acute myocardial ischemia. The patient is admitted for *immediate telemetry monitoring*; *echocardiography* and sometimes stress testing are performed. Then the patient is discharged within 24 hours if this initial workup does not suggest underlying heart disease. Alternatively, EP study is performed or a device is placed in patients found to have structural heart disease. Prolonged rhythm monitoring or tilt table testing may be performed when syncope with underlying heart disease or worrisome features remains unexplained.

Several web-based interactive algorithms have been used to determine the indication for hospitalization. They incorporate the above clinical and ECG features and, sometimes, echocardiographic features.[2,23,24,43–45]

Among high-risk patients, the risk of sudden death, a major cardiovascular event, or significant arrhythmia is high in the first few days after the index syncopal episode, justifying the hospitalization and inpatient rhythm monitoring and workup in the presence of the above criteria.[23,43,45]

X. Treatment of vasovagal syncope, orthostatic hypotension, and POTS

A. Treatment of vasovagal syncope

Vasovagal therapy essentially consists of the lifestyle measures described under POTS, particularly the 5 essential ideas (Section X.B). Also, tilt training may help and consists of two 30-minute sessions of upright standing against a vertical wall every day.

- If syncope recurs despite non-pharmacological measures, consider:
  - Midodrine (α-agonist) (class IIa) or fludrocortisone (mineralocorticoid) (class IIb).
  - While β-blockers have been used, one randomized trial has shown that β-blocker therapy is not more effective than placebo.[46]

Table 26.4 Types of response to tilt table testing.

1. **Vasodepressor syncope:** abrupt, rapid hypotension without a significant drop in heart rate (<10% drop)
2. **Cardioinhibitory syncope:** hypotension with a drop in heart rate to <40 bpm or a pause >3 seconds. A mixed response is characterized by a significant drop in heart rate that remains, nonetheless, > 40 bpm without a prolonged pause. In all forms of vasovagal syncope, except some cardioinhibitory forms, BP falls before the heart rate falls. BP falls suddenly
3. **Orthostatic hypotension:** hypotension within 10 minutes of tilt, without bradycardia (a slight increase in heart rate is expected). The drop in blood pressure is more gradual in orthostatic hypotension than in vasovagal syncope
4. **POTS:** significant increase in heart rate during the first 10 minutes of tilt (an increase of ≥30 bpm, often to >120 bpm). Significant hypotension does not occur (blood pressure is normal or low normal)
5. **Cerebral syncope:** no significant hemodynamic change, but intense cerebral vasoconstriction on transcranial Doppler
6. **Psychogenic syncope:** syncope without hemodynamic or transcranial Doppler change

To be considered positive for vasovagal syncope, hypotension (with or without bradycardia) needs to occur *along with reproduction of syncope or near-syncope*. A hemodynamic effect without symptoms is not considered an abnormal tilt test result.

- Intracerebral serotonin appears to facilitate the sympathetic withdrawal that occurs in vasovagal syncope. Selective serotonin reuptake inhibitors have reduced the occurrence of vasovagal syncope in several studies (one randomized trial with paroxetine) (class IIb).[47]

- Role of pacing. In the ISSUE-3 trial, patients ≥ 40 years old with vasovagal syncope and ≥3 recurrences underwent loop recorder implantation. About one-third of these patients had a recurrence of syncope during recording, with asystole (≥3 seconds, mean 11 ± 4 seconds) in half of them. In this subgroup with cardioinhibitory recurrence, pacemaker therapy, compared with sham pacing, reduced the 2-year recurrence from 57% to 25%.[22] This study supports the paradigm of treating syncope based on the mechanism rather than the etiology (according to these investigators, asystole secondary to a vasovagal mechanism is treated similarly to asystole secondary to AV nodal disease). Two other trials, SPAIN and BioSync-CLS, showed similar benefit from pacing in patients with recurrent reflex syncope (>5 episodes, including 2 in the last year) and asystolic tilt table response. The 2-year syncope recurrence was reduced from 68% to 22%.[48] Other studies have shown that pacemaker therapy is highly effective when asystole is documented at the time of syncope, regardless of the etiology.[21] Thus, pacing *may be* considered in recurrent vasovagal syncope with asystolic pauses (3-second cutoff for pauses coinciding with symptoms, 6 seconds for asymptomatic pauses, 3 seconds for symptomatic tilt pauses, along with age ≥40). This is provided a class I recommendation in ESC guidelines and IIb in ACC guidelines.
- Some patients have reflex syncope with no triggers and no prodromes. A subtype is *adenosine-sensitive syncope*, characterized by abrupt AV block or sinus arrest with an otherwise normal heart, no conduction disease on ECG/EP, and often negative tilt test. They have very low plasma adenosine levels and a high induction rate of pauses >6 seconds when injected with adenosine or ATP. The cardiovascular actions of adenosine and acetylcholine are similar, and vasovagal syncope is facilitated by susceptibility to adenosine. This syncope may qualify for pacing (class IIb ESC), but it is best to document pauses on loop recorder, which eventually happen in ~50% of the cases.
- Cardioneuroablation (CNA) has emerged as an effective procedure for cardioinhibitory recurrent vasovagal syncope (>3 seconds asystole on tilt table or loop recorder). Branches of the vagal nerve that innervate the myocardium and the AV/SA nodes synapse onto ganglionated plexi located in the epicardial fat pads. Those plexi are concentrated around the pulmonary veins, and one is on the superior RA surface between the SVC and right upper pulmonary vein. RA and/or LA plexi are ablated via an endocardial catheter approach, using anatomical guidance as well as EGM guidance (plexi have highly fractionated EGMs). Multiple non-randomized studies and one small randomized trial showed 70–90% syncope resolution with CNA.[49]

B. Carotid sinus hypersensitivity

Carotid sinus syndrome, which is a syncope clearly occurring in a circumstance wherein the carotid sinus is manipulated, along with a cardioinhibitory response to carotid sinus massage, is an indication for dual-chamber pacing.

Unexplained syncope with a cardioinhibitory carotid sinus hypersensitivity is a class IIa indication for dual-chamber pacing.

C. Orthostatic hypotension and POTS

- Treat hypovolemia, hypokalemia, and maintain good fluid intake (>3 L/day) and salt intake (>3 g/day; >5–10 g/day in young POTS patients). Avoid large meals high in fat and complex carbohydrates, and avoid exertion after eating; eat small frequent meals.
- Diuretics and other antihypertensives may need to be withheld. In elderly patients with the difficult combination of orthostatic hypotension and supine HTN, supine position is best avoided (even during sleep), short-acting antihypertensive drugs are initiated slowly at bedtime, diuretics are avoided, and some degree of supine HTN may be accepted (160–180 mmHg in the most severe cases).[50] ACE-I/ARBs are least likely to cause orthostatic hypotension. Avoid short-acting antihypertensives during daytime, particularly clonidine, and avoid chasing HTN spikes, which perpetuates a cycle of hypotension and rebound catecholamines and HTN.

In addition, the following **5 ideas** are essential to treatment:[16,50,51]

- Sleeping in an upright position attenuates supine HTN (as BP drops in the upright position) and decreases renal pressure, thereby reducing pressure diuresis and increasing the extracellular volume. This may be achieved by elevating the bed's head posts 5–6 inches.
- Waist-high compression stockings and abdominal binders.
- Drink 16 oz of water in the morning before getting out of bed or before prolonged standing.
- Use counter-pressure maneuvers to raise BP and abort a spell, or 8–16-oz tap water bolus (which causes a pressor response), or lie down. Examples of counter-pressure maneuvers: handgrip, arm tensing (lock both hands together and try to pull away with both arms), leg crossing and tensing.
- Both POTS and orthostatic hypotension are often related to cardiovascular deconditioning. Regular, progressive exercise training over a period of 3 months leads to remission of POTS in the majority of patients. To be tolerated, upright exercises may initially be avoided, with a focus on swimming, water aerobics, seated biking, or rowing.

If the above fails, 1 of **4 medications** may be used temporarily until the benefit from the exercise program kicks in: fludrocortisone (may worsen supine HTN), midodrine (may worsen supine HTN, avoid it after 6 PM), droxidopa, and cholinesterase inhibitor (pyridostigmine). Droxidopa gets metabolized into norepinephrine at the sympathetic ganglions. Such effect is particularly expected during periods of sympathetic activation, such as the upright position, hence droxidopa is much less likely to cause supine hypertension than midodrine, according to one meta-analysis.[52] Pyridostigmine works on cholinergic sympathetic ganglionic transmission, also during sympathetic activation, and is less likely to cause supine hypertension; its effect is relatively small, and it is mostly used as an adjunctive drug. Droxidopa is only approved for neurogenic orthostatic hypotension (class IIa) and may conversely aggravate the sympathetic activation in POTS. The other 3 drugs may be used in both POTS and orthostatic hypotension, but are less valuable in POTS (class IIa in orthostatic hypotension, HRS class IIb in POTS).[16,51]

Specific to hyperadrenergic POTS, diagnosed by elevated norepinephrine levels in a standing position, a small propranolol dose (10–20 mg TID) (HRS class IIb) or ivabradine may be used; long-acting propranolol or higher doses may worsen POTS symptoms.[53,54]

D. Syncope and driving

In survivors of VT/VF, the highest risk of arrhythmic events and syncope recurrence is in the first 6–12 months.[55] Thus, patients with cardiac syncope or possible cardiac syncope better refrain from driving for at least 6 months, even if ICD is implanted.

In general, the risk of recurrence after a vasovagal syncope is ~10–30% and is highest in patients with multiple prior recurrences.[6] A study showed that the most common cause of syncope while driving is vasovagal syncope. The risk of another syncope was relatively higher in the first 6 months after the event, with a 12% recurrence rate during this period. However, ~50% of all recurrences occurred >6 months later, with a 12% recurrence rate between 6 months and 4–5 years.[6] Despite this recurrence risk that persists for several years, the recurrence during driving was unusual in appropriately diagnosed and treated patients (up to 7% per 8 years), and, importantly, patients who had syncope while driving and no underlying structural heart disease had the same long-term survival as the general population. Long drives increase the risk of recurrence by increasing the peripheral venous pooling; also, recurrence of syncope during driving is more likely and more dangerous for commercial drivers who spend a significant proportion of their time driving.

In general, patients with syncope should be prohibited from driving for at least a period of time (e.g., 6 months), during which the risk of recurrence is highest and serious cardiac disease or arrhythmia, if present, would emerge. It is relatively safe to resume driving beyond 6 months, particularly short drives with proper hydration, after appropriate cardiac evaluation. Commercial driving may need to be permanently prohibited.

QUESTIONS AND ANSWERS

Question 1. A 62-year-old man presents with syncope while working in his yard (standing position). He did not have any prodrome and sustained a head bruise. He does not report any recent chest discomfort or dyspnea. He has a history of myocardial infarction 5 years previously, and he takes aspirin, metoprolol, lisinopril, thiazide diuretic, and atorvastatin. His electrocardiogram shows inferior Q waves, but no ischemic ST–T abnormalities and no conduction abnormality. His echocardiogram shows inferior hypokinesis with an overall LVEF of 45%. His troponin I level is normal. What is the next best step?

A. Coronary angiography
B. Admit for telemetry monitoring then discharge home next day if no arrhythmia is seen, with a diagnosis of vasovagal syncope
C. Place a 30-day event monitor
D. Place an implantable loop recorder
E. Tilt table testing
F. Telemetry and electrophysiological (EP) study

Question 2. A 66-year-old man presents with syncope. It occurred while he was walking his dog. He has a facial laceration and does not recall any premonitory symptom. A similar episode occurred 8 months previously. He has no known cardiac history and takes a thiazide diuretic for hypertension. His exam is overall unremarkable and shows a blood pressure of 135/80 without any orthostatic hypotension. An ECG shows non-specific low T-wave voltage and an echocardiogram is normal. Telemetry monitoring for 24 hours did not reveal any significant arrhythmia. What is the next management step?

A. Reassurance, no further workup
B. Tilt table testing
C. Carotid sinus massage followed by tilt table testing
D. 30-day event monitor
E. Stress testing
F. Electrophysiological study

Question 3. A 30-year-old man who grew up in Mexico, and who has no prior medical problems, presents with syncope while playing basketball. He had very brief premonitory dizziness. He is admitted to the hospital. Telemetry monitoring does not show any arrhythmia. ECG and echo are normal. What is the next step?

A. Reassurance
B. Exercise stress test
C. Event monitoring
D. Tilt table testing

Question 4. A 33-year-old man has exertional syncope. He undergoes stress testing, which shows monomorphic VT at peak exercise, along with dyspnea and no syncope. This VT appears to be originating from the LV inferolateral wall. Coronary angiography shows normal coronary arteries. What is the next step?

A. Ablation for idiopathic LV VT
B. Cardiac MRI

Question 5. A 66-year-old woman has a history of permanent AF that is rate-controlled without any AV nodal blocking agent. She has a history of obesity and mild LVH. Her medications consist of warfarin and amlodipine. She had syncope upon standing up after eating a large meal. Another episode of near-syncope occurred while driving for 10 minutes, 3 months later. ECG shows AF, rate 55 bpm, LAFB, and incomplete RBBB. Telemetry monitoring shows AF pauses of up to 2.6 seconds during sleep. Echo shows normal LVEF with LVH. What is the next step?

A. Reassurance (vasovagal syncope)
B. Tilt table testing
C. Pacemaker placement
D. EP study

Question 6. A 28-year-old woman presents with symptoms of palpitations and dizziness. She is slim and used to run routinely, but over the last few months, after a minor viral illness, she has not been able to perform any physical exertion. She gets palpitations within a few minutes of walking, along with near syncope and mental fog. Her pulse goes up to 140 bpm, based on her smartwatch; it seems to then decline slowly. This mainly occurs with mild activity. She is constantly exhausted. In clinic, her baseline pulse (sitting) is 90 bpm, with BP of 105/75 mmHg. Pulse went up to 130 bpm after 5 minutes of standing, and BP became 96/76 mmHg. What is the diagnosis and how to confirm?

A. POTS. No further workup is needed
B. POTS. Perform tilt table testing to confirm
C. POTS. Perform Holter monitoring to confirm
D. Vasovagal near-syncope. Perform tilt table testing
E. Combined POTS and vasovagal mechanism. Perform tilt table testing

Question 7. In the patient from Question 6, what is the most effective therapy?

A. Lifestyle measures, focused on hydration, exercise training, high compression stockings
B. Midodrine
C. Fludrocortisone
D. Propranolol or ivabradine

Question 8. An 81-year-old man has severe HTN, with SBP up to 210 mmHg. He also has severe dizziness upon walking with several syncopal spells and falls. He takes HCTZ for HTN, and he was taking amlodipine and lisinopril, but those were stopped. In clinic, his supine SBP is 210 mmHg, and it declines to 100 mmHg with standing. How to best manage this patient (one answer is *incorrect*)?

A. Avoid supine position if possible, sleep upright
B. Treat HTN with upright positioning
C. ACE-Is/ARBs are the antihypertensive drugs that are least likely to cause orthostatic hypotension
D. Stop HCTZ. Diuretics are the antihypertensive drugs with the highest risk of orthostatic hypotension
E. If HTN is predominantly nocturnal and supine, consider short-acting ACE-I/ARB or NTG patch at night
F. May use short-acting clonidine for HTN spikes
G. Treat hypotensive spells using counterpressure maneuvers, oral water bolus and prevent them with compression stockings
H. In refractory cases, consider clamping HTN with higher doses of clonidine patch and ACE-I, and treat hypotensive episodes with daytime droxidopa or rescue midodrine

Question 9. Which of the following recommendations for vasovagal syncope is *incorrect*?

A. Lifestyle measures (class I)
B. Counterpressure maneuvers to abort a spell (class IIa)
C. Tilt training (class IIb)
D. Midodrine class IIa, fludrocortisone class IIb
E. Selective serotonin reuptake inhibitors class IIb
F. Droxidopa (class IIb)
G. Metoprolol (class III ESC)
H. Pacemaker for recurrent vasovagal syncope, age ≥40, and long spontaneous pauses (>3 sec, or >6 sec if asymptomatic) (class IIb; class I in ESC)

Question 10. Which of the following tests has the highest diagnostic value when evaluating syncope?

A. ECG
B. 72-hour Holter monitor
C. Head CT scan
D. Orthostatic vital signs
E. Stress testing

Question 11. Which of the following is not consistent with neurogenic orthostatic hypotension?

A. Postprandial syncope
B. Coat hanger pain
C. Pulse rises 15 bpm at 3 min of standing
D. Mental fogging

Question 12. What is the best therapy of neurogenic orthostatic hypotension?

A. Lifestyle nonpharmacological measures
B. Droxidopa
C. Midodrine

Answer 1. F. An acute coronary event is not likely in the absence of cardiac complaints surrounding the syncope and in the absence of acute electrocardiographic or troponin abnormalities. Coronary angiography has a low yield in this context. While vasovagal syncope is possible (syncope in a hot environment, vasodilatory and diuretic medications), the first diagnosis to eliminate is cardiac syncope secondary to ventricular tachycardia from a myocardial scar, especially when the syncope is sudden and has an exertional trigger. An EP study is the next step in a patient with structural heart disease and EF >35%. If EP study does not induce a tachyarrhythmia or does not detect a conduction abnormality, it is reasonable to proceed with either tilt table testing (vasovagal syncope) or implantable loop recorder (arrhythmia undetected by EP study).

Answer 2. C. In light of the benign ECG and echocardiogram, it is unlikely that this patient has a cardiac or arrhythmic syncope. However, considering the syncope recurrence, the abruptness (no premonitory symptom), and the physical injury, further workup is necessary to establish a definite cause and treat it. Carotid sinus massage is necessary in any unexplained syncope over the age of 50. If carotid massage is negative, and in the absence of structural heart disease, tilt table testing is an appropriate next step. Vasovagal syncope of the elderly is a likely diagnosis. An alternative strategy would be implanting a loop recorder for long-term rhythm monitoring. The yield of EP study is low when the ECG and echocardiogram are normal. The yield of a 30-day event monitor is low in patients with infrequent syncope recurrences. In the absence of angina, the yield of stress testing is low.

Answer 3. B. The syncope occurrence during exercise is suggestive of arrhythmia or heart disease. Even if ECG and echo are normal, stress testing is warranted.

Answer 4. B. The normal ECG and echo suggest that VT may be idiopathic, but the occurrence of syncope and the inferolateral origin make idiopathic VT less likely. In this case, cardiac MRI is performed and shows a large inferolateral scar. The patient should receive an ICD. However, he declines it and develops a complete RBBB on his ECG a few months later. Cardiac sarcoidosis or Chagas disease is the most likely diagnosis.

Answer 5. D. *The following sequence of tests is suggested in this patient: carotid sinus massage, followed by EP study, followed by tilt table testing then implantable loop recording*. The patient's syncope, especially the first episode, may be suggestive of vasovagal syncope. However, the conduction abnormality present on the ECG (AF with slow conduction) is suggestive of AV conduction disease. This is further suggested by LAFB and incomplete RBBB. In this context, syncope is likely due to AV block, manifesting as a long AF pause. However, a pacemaker is not indicated as none of the findings, per se, is diagnostic of AV block and syncope could still be vasovagal. EP study should be performed, seeking a long HV interval or an infra-His block (with procainamide, which is used instead of incremental A pacing in AF). EP also seeks VT in a patient with underlying cardiac abnormality. This is followed by implanting a loop recorder, then a pacemaker if a long pause (>3 seconds) is documented during wakefulness. Tilt table testing may also be performed, even in a patient with structural heart disease, as long as EF is >35% and EP study has not suggested any arrhythmia (case where the likelihood of vasovagal syncope is not low).

Answer 6. A. POTS is a simple clinical diagnosis that is confirmed in clinic (sinus rate rises >30 bpm within 10 min of standing). Tilt table testing may diagnose POTS, but this is not necessary. Holter monitoring is not needed, as the patient's timing of palpitations (activity) and pattern (slow decline, not abrupt) is consistent with POTS's sinus tachycardia rather than arrhythmia.

Answer 7. A. Lifestyle measures are far more effective than medical therapy in POTS. Midodrine or fludrocortisone may occasionally be used, temporarily, to allow a refractory patient to tolerate exercise training. They are eventually stopped, after cardiovascular conditioning improves. In POTS, sinus tachycardia compensates for the low stroke volume and the lack of adaptive vasoconstriction in the upright position, thus maintaining cardiac output and BP; attenuating the sinus rate with metoprolol or ivabradine may reduce palpitations but lead to syncope. Low-dose propranolol or ivabradine may be used in hyperadrenergic POTS, proven by norepinephrine levels.

Answer 8. F. This situation is treated as follows: (i) avoidance of supine position (to avoid HTN peaks); (ii) low dose of ACE-I/ARB or NTG patch at bedtime, with acceptance of SBP 160 mmHg; and (iii) lifestyle measures to prevent and abort hypotensive spells, which will continue to occur. Only in cases with refractory hypotensive symptoms (rather than just hypotensive numbers), droxidopa or as needed midodrine may be considered. Chasing HTN with short-acting daytime clonidine should be avoided, as this results in abrupt hypotension followed by rebound HTN peak.

Answer 9. F. Droxidopa is given a class IIa in orthostatic hypotension but is not recommended in vasovagal syncope or POTS. Answer H is based on ISSUE-3 and SPAIN trials, which showed a benefit from pacing in select patients with recurrent vasovagal syncope.

Answer 10. D. Orthostatic vital signs determine the cause of syncope in up to 21% of patients and affect the management of up to 30% of patients. ECG has a diagnostic yield of up 10%, while Holter and CT head have a diagnostic yield of <2%.[56]

Answer 11. C. In neurogenic orthostatic hypotension, the pulse rises insufficiently with standing, <15 bpm, vs. ≥15 bpm in non-neurogenic orthostatic hypotension. Also, one may compare the orthostatic change of the pulse to that of SBP: delta pulse-to-delta SBP ratio of <0.5 strongly suggests neurogenic orthostatic hypotension.[57] Coat hanger pain is pain in the shoulders and suboccipital area, indicative of low perfusion of the large neck muscles, and is characteristic of dysautonomia. Mental fogging also results from low perfusion.

Answer 12. A. Droxidopa is likely the best second-line option, if lifestyle measures fail.

27 Chest Pain, Dyspnea, Palpitations

1. Chest pain
I. Causes 644
II. Features 645
III. Management of chronic chest pain 646
IV. Management of acute chest pain 646

2. Acute dyspnea
I. Causes 648
II. Notes 649
III. Management 649

3. Palpitations
I. Causes 650
II. Diagnosis 651

1. CHEST PAIN

I. Causes (see Table 27.1)

Table 27.1 Causes of chest pain.

A. Cardiac
1. CAD: stable angina, ACS
2. Aortic dissection
3. Acute pericarditis
4. Secondary ischemia from cardiac causes: acute HF,[a] acute HTN, AS, HOCM
5. Secondary ischemia from non-cardiac causes: tachyarrhythmia, anemia

B. Pulmonary
1. Pneumothorax
2. Pneumonia
3. Exudative pleural effusion
4. Pulmonary embolism
5. Pulmonary hypertension (→ chest pain + dyspnea + syncope on exertion)

C. Gastrointestinal
1. Esophageal spasm or reflux
2. Esophageal ulceration after vomiting (Mallory–Weiss syndrome)
3. Peptic ulcer disease
4. Acute pancreatitis, cholecystitis, biliary colic

D. Chest wall
1. Strain of muscles or ligaments
2. Costochondritis ("Tietze's syndrome" is a costochondritis with swollen red costochondral joints)
3. Shoulder or cervical joint problem (pain is exacerbated by a particular movement of neck/shoulder rather than exertion)

E. Psychogenic

[a]The increase in LVEDP reduces the pressure gradient between aortic diastolic pressure and LVEDP, i.e., the coronary perfusing pressure in diastole, and thus reduces coronary flow even in the absence of CAD. Also, elevated LVEDP increases microvascular resistance.

Only 10–15% of patients presenting to the ED with chest pain have true ACS. However, ACS should be the first consideration and should always be ruled out. Also, consider other emergencies like aortic dissection, PE, pericarditis, and gastrointestinal urgencies (pancreatitis, complicated peptic ulcer), and rule them out at least clinically and by chest X-ray and ECG. Keep in mind that **acute HF is a common cause of chest pain and troponin rise and should be considered in a patient with congestive signs on exam/CXR/BNP**.[1] In acute HF, chest tightness is frequently a description of dyspnea or myocardial O2 demand-supply mismatch and does not equate with CAD. Only with extensive ST abnormalities or severe troponin rise should MI be considered the cause of the acute HF.

II. Features

A. Angina and acute coronary syndrome

- Typical angina occurs with exertion and is relieved with rest. It is precipitated by walking uphill, in the cold, or after a meal. *Chest pain that occurs at rest* and is not reproduced with exertion is unlikely to be angina, the exception being vasospastic angina. *Postprandial angina* is often a marker of severe, sometimes multivessel CAD; as opposed to biliary colic or peptic ulcer disease, angina occurs immediately after the meal and is exacerbated by postprandial physical activity. *Nocturnal angina* may imply severe CAD or vasospasm on top of fixed CAD; the increased venous return in the recumbent position increases O_2 demands and triggers ischemia in patients with critical, sometimes multivessel, CAD.
- The duration of angina is typically a few minutes. If chest pain lasts over 20–30 minutes, the cardiac markers should be positive; otherwise, angina is an unlikely diagnosis. If chest pain lasts <15 seconds, angina is also very unlikely (likely musculoskeletal pain).
- Severe distress or profuse diaphoresis could mean ACS or another serious illness (aortic dissection). Nausea and vomiting may be seen with severe angina but are not specific. Eructation could mean angina or gastroesophageal disease.
- *Dyspnea* may be an angina equivalent and may indicate extensive CAD with a secondary increase in ventricular stiffness and LVEDP. Consider angina in the differential diagnosis of *dyspnea with no objective findings* (no hypoxemia, wheezes, or pulmonary edema). On the other hand, dyspnea is often unrelated to CAD, and dyspnea by itself may cause a subjective feeling of chest pressure, unrelated to CAD (e.g., acute HF).
- Indigestion, deep fatigue, or pain in the arms, neck, or jaw are other atypical presentations for which ACS should be considered.

- Atypical pain location or isolated malaise, nausea, indigestion, or diaphoresis is more common in the elderly, female, and diabetic patients.
- A positive response to nitroglycerin is defined as chest pain relief within less than 5 minutes of sublingual nitroglycerin. The relief of chest pain with sublingual nitroglycerin does not reliably predict ACS; similarly, the relief of chest pain with a GI cocktail does not predict the absence of ACS.
- S_4 is commonly heard during active angina. S_3 and MR murmur often imply HF (ischemic or non-ischemic).
- On ECG, ischemia is suggested by ST elevation or depression of ischemic morphology, not secondary to LVH/LBBB, and typically dynamic. ECG may be normal or non-diagnostic in 50% of ACS cases. Ischemia related to circumflex distribution may be silent, since the posterolateral wall is underrepresented on the 12-lead ECG. Also, some patients have baseline ECG abnormalities, such as LBBB, LVH, or a paced rhythm that affects ECG interpretation. Yet, as per ESC guidelines: "hemodynamically stable patients presenting with chest pain and LBBB only have a slightly higher risk of MI compared to patients without LBBB."

True angina and PE pain may seem reproducible with palpation, as the chest wall is frequently hypersensitive in these conditions. ***A combination of multiple low-likelihood features*** (***P***ositional pain, ***P***leuritic stabbing pain, or ***P***alpable localized pain), rather than reliance solely on pain reproducibility, better defines the low-likelihood group.[2]

B. Aortic dissection

Three clinical features point to the possibility of aortic dissection:[3]

- Predisposing condition: aortic valve disease, known aortic aneurysm, Marfan, or family history of aortic dissection.
- Suggestive symptoms: chest, back, or abdominal pain that is either very abrupt (within seconds), severe, or tearing. Note, however, that the pain of aortic dissection is commonly sharp rather than tearing, and ~10% of dissections are painless and present with syncope, dyspnea, or ischemic complications..
- Suggestive exam findings: AI murmur (in 25–45%), pulse deficit or blood pressure differential between arms (~20%), neurological deficit concomitant with chest pain (5%).

The presence of 2 or 3 features makes aortic dissection highly probable. The probability is intermediate when 1 feature is present; aortic imaging is warranted in the latter case if symptoms are not clearly explained by chest X-ray (CXR) or ECG. Up to 5% of aortic dissections have none of the features but may be suspected by a widened mediastinum on CXR.

Aortic dissection should be suspected in any patient with chest pain and concomitant stroke, mental status changes, or peripheral ischemia.

In addition to the classic hypertension, hypotension may be seen with complicated aortic dissection (AI, tamponade). Hypotension may also be a pseudohypotension resulting from the obstruction of flow to one limb. Measuring blood pressure in all limbs may unveil this phenomenon.

C. Pulmonary embolism (PE)

1. Clinical features

- Dyspnea and tachypnea are the most common findings; however, they may not be seen at rest and may be purely exertional.
- Tachycardia is common and is occasionally an isolated finding. Frequently, however, tachycardia is either *transient* or *relative* (80–90 bpm).
- Chest pain is usually a pleuritic pain in patients with distal emboli; angina-like pain may be seen in patients with large central emboli and secondary RV ischemia. Hemoptysis is seen with pulmonary infarction, often resulting from small distal emboli.
- Hypotension, syncope, and RV failure with increased JVP/RV heave/right-sided S_3 are seen with a large PE and imply reduced hemodynamic reserve.
- Lower extremity edema or tenderness on palpation is seen in 50% of DVTs.

2. The clinical probability of PE is assessed using the Wells criteria, which essentially give weight to 3 features

- No alternative diagnosis for the patient's presentation, whether it is dyspnea, hypoxemia <95%, chest pain, or tachycardia
- Clinical signs of DVT or hemoptysis
- Major risk factors for DVT/PE

The probability is high when 2 or 3 features are present, intermediate when only 1 feature is present, and low when none is present.

3. Initial workup

- A negative D-dimer rules out PE in low or intermediate probability cases, with an age-adjusted cutoff (age/100, in mg/L). D-dimer has, however, a very low specificity <30%.
- Arterial blood gas usually shows hypoxia, hypocapnia, and a high A–a gradient (>10 mmHg on ambient air, >50 mmHg on high-dose O_2). O_2 saturation and A–a gradient are, however, normal in up to 20% of patients. A–a gradient increases in most pulmonary pathologies as a result of V/Q mismatch, and thus is not specific for PE. Hypercapnia is rare, and only a massive PE with a massive increase in dead space can cause hypercapnia, per se.
- Chest X-ray is grossly normal.
- ECG shows sinus tachycardia or relative tachycardia (80–100 bpm). In large PE, it shows more pronounced tachycardia and signs of RV strain in up to 85% of patients: T inversion in the anterior leads V_1–V_3, RVH/right-axis deviation/RBBB, $S_1Q_3T_3$, and P pulmonale. Atrial arrhythmias may also be seen. *Look at the admission ECG, as tachycardia may be transient*.

D. Acute pericarditis

Pericarditis is characterized by pleuritic chest pain that increases with recumbency and movements and improves with leaning forward. It typically radiates to the trapezius. It has a rapid onset.

- On exam, a pericardial friction rub with a systolic and a diastolic component is heard.
- ECG shows diffuse ST elevation and/or PR depression in 90% of patients. These changes may resolve after one to several days.
- CRP is highly sensitive for the diagnosis of acute pericarditis.
- In addition to pericarditic pain, **the diagnosis of pericarditis requires 2 of the following 4 features**:

(1) high CRP; (2) rub; (3) typical ECG findings (widespread ST-segment elevation and/or PR depression); (4) pericardial effusion (which is only present in 50–60% of pericarditis cases and is usually small). CRP is elevated in 85-90% of pericarditis cases.

E. Pneumonia, pleural effusion, pneumothorax

Pleural and pulmonary illnesses are characterized by dyspnea, cough, and pleuritic chest pain, i.e., sharp pain that increases with deep inspiration, cough, or movement.

III. Management of chronic chest pain

See Chapter 3, Section II and Figures 3.1 and 3.2.

IV. Management of acute chest pain (see Chapter 1, Sections II and III)

A. ECG

If the ECG shows ST elevation consistent with STEMI, perform emergent reperfusion with primary PCI or fibrinolysis.

If the ECG shows ST depression or deep T inversion consistent with ischemia, especially if dynamic, consider the diagnosis of non-ST elevation ACS, but keep in mind the possibility of aortic dissection, PE, or pericarditis if clinically plausible.

B. CXR ± bedside echo during active pain

In ACS, a bedside echo performed during active chest pain reveals a wall motion abnormality if ischemia involves >20% of the myocardial thickness across a substantial territory. In fact, a normal echo *during active chest pain* reduces the likelihood of ACS. Echo is less sensitive if performed after pain resolution. Conversely, echo is not very specific for ACS, as a wall motion abnormality may correspond to an old infarct. Strain echocardiography (global or regional) improves the sensitivity and negative predictive value of echo for ACS in patients with normal initial troponin and non-diagnostic ECG (91%), but it is non-specific and has a poor positive predictive value (13% in one study).[4] Echo may suggest type A aortic dissection if scanning focuses on the tubular aorta and on indirect signs, such as aortic dilatation or significant AI. In *PE*, echo may show RV or PASP abnormalities only when PE is large and at least Stage C2.

C. If any clinical, X-ray, or ECG feature suggests aortic dissection, PE, pericarditis, or a pulmonary cause of chest pain, proceed to the appropriate workup and therapy. Avoid anticoagulation if the clinical or radiographic likelihood of aortic dissection is more than low. Before starting anticoagulation, verify the lack of mediastinal enlargement on CXR.
If aortic dissection is suggested, perform aortic CT or emergent TEE and start aggressive BP control and intravenous β-blockers.

If PE is suggested (clinical probability high, or intermediate with + D-dimer), perform chest CT angiography, PE protocol. The same CT and contrast injection are usually appropriate for the diagnosis of aortic dissection as well (but not vice versa). V/Q scan may be performed instead of CT in renal failure with no severe CXR abnormalities; CXR abnormalities decrease the specificity and the diagnostic yield of the V/Q scan. Anticoagulation is started early on, before the workup, if PE is probable and the bleeding risk is low.

If pericarditis is suggested, the diagnosis will be established by clinical, ECG, and CRP features.

If a pulmonary cause is suggested, the diagnosis will be established by CXR and chest CT if needed.

If cholecystitis or acute pancreatitis is suggested, the diagnosis will be established by a liver function panel, amylase/lipase and abdominal ultrasound.

D. In the absence of aortic dissection, PE, pericarditis, or pulmonary features, use conventional troponin or hs-troponin for MI rule-in and rule-out. A single undetectable or very low hs-troponin (eg, <5 ng/L) is associated with <0.5% risk of acute MI and nearly 0% risk of cardiac death at 30 days.[5–14] This risk is further reduced in patients whose ECG is not suggestive of ischemia. Therefore, home discharge is safe in those patients.
ESC and multiple European investigators suggest checking ***hs-troponin at presentation and at 1 or 2 hours after presentation*** (0/1 or 0/2 strategy). An undetectable hs-troponin, or a detectable hs-troponin with insignificant change at 1 or 2 hours rules out MI with >99.5% confidence (Figure 27.1).[5–14]

Most patients who rule out have non-cardiac chest pain, particularly if ruled out with the hs-troponin strategy. **Non-invasive testing with CTA or stress testing** may be performed after the second negative troponin; **it is not definitely required in patients who rule out with the hs-troponin strategy**. Yet some of the latter patients have true angina, especially those with exertional chest pain. CTA or stress testing remains necessary in patients with exertional chest pain: a normal or low-risk stress test result suggests no CAD, microvascular disease, or low-risk CAD for which medical therapy is appropriate. Medical therapy is tailored to how much the physician believes the chest pain is anginal based on clinical grounds and is somewhat comparable to the management of chronic CAD; as such, coronary angiography is performed in those patients with significant angina on mild exertion.

In patients with elevated troponin, the most important step is to distinguish type 1 MI from secondary myocardial injury, guided primarily by the clinical context. ≥ 50% of patients with mild troponin rise (hs-troponin T 14–100 ng/L) have type 2 MI or injury, rather than type 1 MI.[5] ST depression on ECG or more severe troponin elevation (hs-troponin T >300, hs-troponin I >1000) increases the likelihood of CAD and type 1 MI (Figure 27.2).

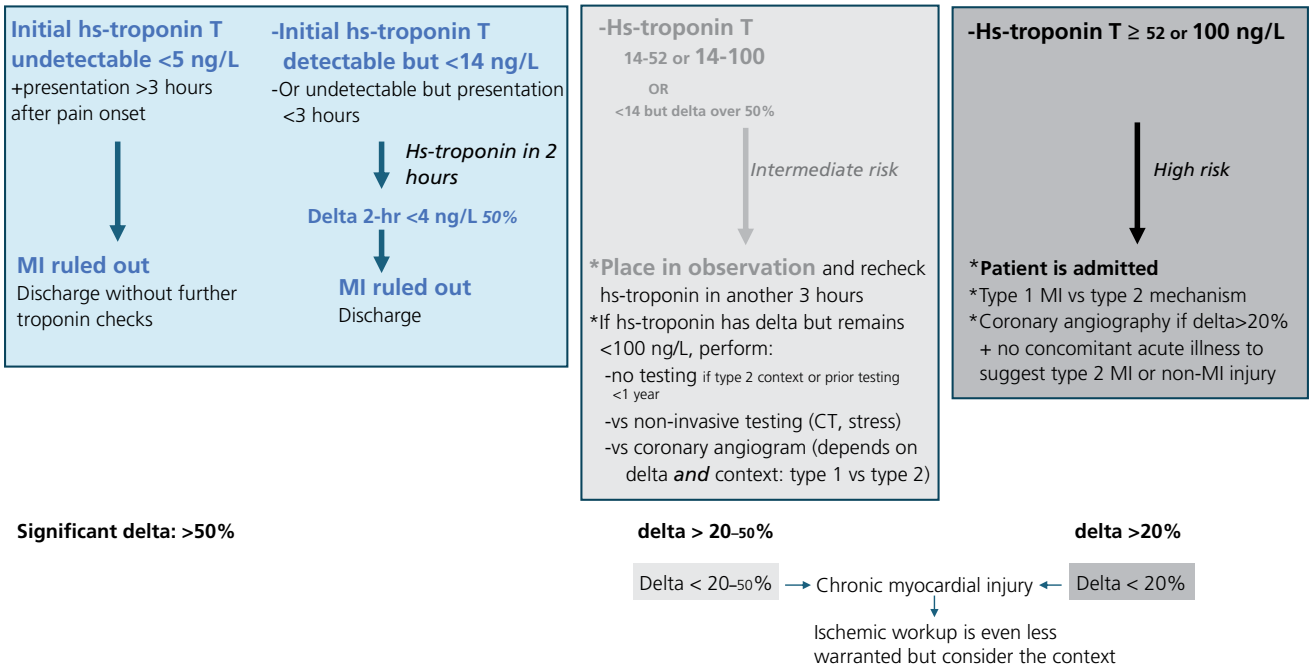

Figure 27.1 0/2-hour ESC algorithm using hs-troponin in patients presenting to the emergency department with suspected ACS. This example uses the cutoff values specific for hs-troponin T. Of note, with this assay, *the 99th percentile threshold is 14 ng/l in ♀ and 22 ng/l in ♂, yet 52 or 100 ng/L is chosen as the high-risk value*. Even the 52 ng/L cutoff only has a 50–60% positive predictive value for type 1 MI, and <50% in US studies, hence 100 ng/L is commonly used in the US.

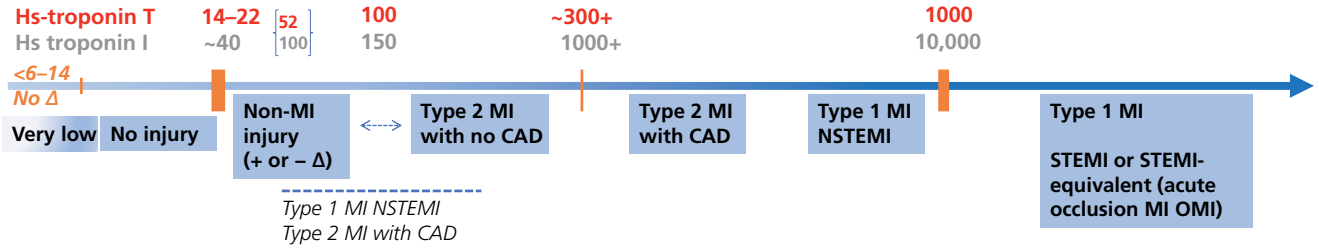
Delta is the absolute or relative change in troponin value between 0 and 1 or 2 hours. Detection cutoff, MI cutoff, and delta cutoffs depend on the hs-troponin assay. This example uses the cutoff values specific for Roche hs-troponin T assay. It may be applied to other hs-troponin assays using different cutoffs (e.g., Abbott hs-troponin I, high-risk value ~100–150). Clinical scores (e.g., HEART) do not improve the safety of this algorithm and unnecessarily reduce the proportion of patients ruled out.



Hs troponin I ~2–10 × hs-troponin T
(higher discrepancy with higher values)

To convert from ng/L to ng/ml, divide by 1000

Figure 27.2 Correlation of hs-troponin levels with the type of myocardial injury. Note the difference between hs-troponin T and hs-troponin I (troponin I levels are 2–10 times higher and have higher cutoffs).

- Hs-troponin T <100 ng/L is frequently non-MI injury (≥50%).
- Hs-troponin T >300 (hs-troponin I >1000) frequently implies CAD, whether type 1 MI or type 2 MI with CAD.
- Hs-troponin T >1000 is overwhelmingly type 1 MI, frequently STEMI or occlusive MI.

This is a general guide with a lot of potential overlap in values. Notably, type 1 MI may be seen with low hs-troponin T of 14–100; however, non-MI injury and type 2 MI with no CAD do not usually lead to high hs-troponin T values >300.

2. ACUTE DYSPNEA

I. Causes (see Table 27.2)

Notes:

Besides HF, there are 2 additional causes of *nocturnal dyspnea*:[15]

- Patients with COPD may have mucous hypersecretion, so that, after a few hours of sleep, secretions accumulate and produce dyspnea and wheezing, which are relieved by cough and sputum expectoration.
- Patients with asthma may have their most severe bronchospasm between 2 a.m. and 4 a.m. and wake up with severe dyspnea and wheezing. Inhaled bronchodilators usually improve symptoms quickly.

In HF, paroxysmal nocturnal dyspnea (PND) usually develops 2–4 hours after sleep and improves after 15–30 minutes of sitting upright or walking. Dyspnea is often accompanied by cough (dry or productive of frothy sputum), wheezing, and diaphoresis.

Table 27.2 Causes of acute dyspnea.

A. Cardiac

1. Acute pulmonary edema due to acutely decompensated HF, or to acute new-onset HF (acute MI, acute hypertension, acute valvular insufficiency, AF)
   Diagnosis: history (orthopnea, paroxysmal nocturnal dyspnea, recent quick weight gain, and past cardiac history), exam (↑ JVP, loud P2 manifesting as S2>S1 at the apex, S_3, ± S_4, crackles, peripheral edema), elevated BNP, chest X-ray
2. Tamponade (↑ JVP, pulsus paradoxus)
3. Always remember that *dyspnea with no objective lung findings or hypoxemia could be an angina equivalent*

B. Pulmonary embolism

Diagnosed by the following three features: (i) PE/DVT risk factors; (ii) DVT signs; and (iii) absence of other causes of dyspnea (no gross abnormalities on chest X-ray)

C. Pulmonary

1. Pneumonia
2. Asthma attack or COPD exacerbation: asthma may occasionally lead to cough and/or dyspnea in the absence of wheezes on examination (cough-variant asthma or atypical asthma). Wheezing may be uncovered with maximal forced expiration. Also, severe asthma exacerbation may not produce wheezes (airways are so narrow that there is total interruption of airflow and decrease in breath sounds)
3. Pneumothorax or large pleural effusion
4. ARDS in the context of pneumonia, aspiration, septic shock, or trauma

D. Shock of any cause leads to hyperventilation and tachypnea

+Laryngeal causes (laryngospasm, laryngeal edema [anaphylaxis]) lead to an inspiratory stridor ± urticaria

+Metabolic causes: Metabolic acidosis (such as diabetic ketoacidosis), hypocalcemia, dyskalemia, severe acute anemia, hyperthyroid storm

Orthopnea is mainly seen in HF but may also be seen with pericardial diseases, advanced asthma/COPD with diaphragmatic flattening and weakness, bilateral diaphragmatic paralysis, severe obesity and severe ascites, all cases where the diaphragm tends be pushed up in a supine position.

Platypnea is dyspnea that worsens in the upright position. Platypnea is seen with pulmonary right-to-left shunts such as pulmonary AV fistulas (including hepatopulmonary syndrome), or the rare case of PFO that allows right-to-left shunting in the upright position.

Trepopnea is orthopnea that mainly occurs in one lateral decubitus position. Patients with HF are typically more comfortable in the right lateral decubitus position, as this position raises the level of the heart (especially the left ventricle), which slows venous return. This position may partly explain the predominance of right pleural effusion in HF.[16] Patients with unilateral lung disease are most comfortable lying over the side of the healthy lung, to improve its perfusion and the V/Q matching.

Note that nocturnal or exertional cough, rather than dyspnea, may be the primary complaint of patients with HF, as well as those with cough-variant asthma.

II. Notes

A. Differential diagnosis of shock + respiratory distress

Any shock leads to tachypnea (the patient hyperventilates in order to improve O_2 supply). Think specifically of:

- Cardiogenic shock with pulmonary edema
- Septic shock due to pneumonia or septic shock with ARDS
- Tamponade
- Massive PE
- Anaphylactic shock with bronchospasm, laryngeal edema, urticaria

B. Wheezing

Wheezing may indicate COPD/asthma but may also indicate pulmonary edema ("cardiac asthma"), PE, or pneumonia. In cardiac asthma, cyanosis and diaphoresis occur more often than in bronchial asthma, and adventitious breath sounds are more common (crackles, rhonchi). True asthma has more musical, pure wheezes.[15]

C. Pulmonary shunt and pulmonary shunt effect

Most of the disorders listed in Table 27.2, A–C, lead to a *pulmonary shunt effect* in which pulmonary blood is not oxygenated because of obstruction of the airways, or to a *true pulmonary shunt* in which the alveoli, per se, are obstructed and filled with fluid. A pulmonary shunt or shunt effect initially leads to hypocapnia, hypoxemia, or normoxemia (pO_2 may be normal early on), and elevated A–a gradient. A–a gradient increases in most pulmonary pathologies; it implies V/Q mismatch but does not identify it. The more severe the process, the higher the A–a gradient rises.

$$\begin{aligned} \text{A–a gradient} &= \text{alveolar } PO_2 - \text{arterial } PO_2 \\ &= (FiO_2 \times [\text{atmospheric pressure} - 47] - PaCO_2/0.8) - PaO_2 \\ &= (\sim 150 \text{ mmHg on ambient air, sea level} - PaCO_2/0.8) - PaO_2 \end{aligned}$$

Normal <10–15 mmHg on ambient air, <50–75 mmHg on high-flow O_2. A–a gradient normally increases by 5–7 mmHg with each 10% increase in FiO_2.

As the illness progresses, the patient gets tired and starts hypoventilating, which leads to a worsening of the hypoxemia and development of hypercapnia. **Hypercapnia occurs sooner in pulmonary edema and COPD than in asthma and pneumonia and is rare in PE**. A patient with COPD may have chronic hypercapnia that worsens during exacerbations.

D. Cyanosis

Cyanosis corresponds to a deoxygenated Hb concentration of >5 g/dl. There are 2 forms of cyanosis: (i) central cyanosis related to severe hypoxemia (respiratory issue or cardiac right-to-left shunt); (ii) peripheral cyanosis related to a shock state where arterial O_2 saturation is normal but peripheral tissue hypoxia occurs from hypoperfusion. There is tongue cyanosis in the former, not the latter.

Cyanosis manifests less easily in anemic patients.

Respiratory distress without gross abnormalities on CXR:
- PE
- Acutely decompensated chronic HF, where CXR findings are frequently subtle (exam and BNP findings help with the diagnosis)
- Bronchospasm, COPD exacerbation
- Severe sepsis, shock states, or metabolic acidosis
- Also, myocardial ischemia or systolic or diastolic LV dysfunction can increase the pulmonary capillary pressure and the pulmonary engorgement on exertion without leading to frank pulmonary edema.

III. Management

The hemodynamics and the volume status are quickly assessed clinically. The following is obtained: ECG (seeking ischemia and arrhythmias), CXR, arterial blood gas, basic lab tests including cardiac markers and BNP. BNP helps differentiate a cardiac from a pulmonary origin of dyspnea in the acute setting: BNP < 100 pg/ml makes left HF a very unlikely cause of acute dyspnea, while BNP over 500 pg/ml makes left HF a likely cause of dyspnea (corresponding NT-proBNP cutoffs are <300 and >1200).

A. Quick and specific therapies are instituted

When pulmonary edema is suspected, furosemide (40–80 mg IV) and/or vasodilator therapy (e.g., IV nitroglycerin) is administered. The administration of furosemide may await CXR if the diagnosis is uncertain and the patient is stable. ACS should be considered and treated in the case of ischemic, dynamic ST abnormality *or* marked troponin rise. Echocardiography is performed.

If pneumonia is suspected, broad-spectrum antibiotics are administered, and blood and sputum cultures are obtained.

A hypoxemia that is severe and out of proportion to lung findings on exam and CXR is suggestive of PE. When the probability of PE is intermediate or high, anticoagulation is initiated, then a CT PE protocol or a V/Q scan is performed.

Wheezes secondary to a true asthma are treated with albuterol nebulization. Conversely, wheezes secondary to HF should not be aggressively treated with albuterol, as it worsens myocardial ischemia and tachyarrhythmias with no clear benefit.

For sizeable pleural effusions (~1–1.5 L) secondary to HF and occupying <2/3 of the hemithorax, thoracentesis may not improve mortality, length of stay, symptoms, or weight loss vs standard therapy (TAP-IT trial). Focus instead on aggressive decongestion.

B. Intubation and non-invasive ventilation

Consider intubation in the following cases:

1. Respiratory distress with a respiratory rate > 35/min, not improving quickly with furosemide, O_2, and nebulizer therapy regardless of O_2 saturation (the patient is getting more tired, breathing is getting shallower with accessory muscle use and paradoxical respiration).
2. Hypoxemia not responding to maximal O_2 therapy (O_2 saturation <88% despite the administration of 100% O_2 via a face mask).
3. Acute hypercapnia or worsening of chronic hypercapnia with pH < 7.2.
4. Any shock associated with respiratory distress.
5. Alteration of mental status with inability to maintain proper ventilation and open airway (tongue, pharyngeal collapse).

In COPD and in acute pulmonary edema, while waiting for the initial measures to take effect, non-invasive ventilation may be tried (CPAP, BiPAP). Non-invasive ventilation is particularly helpful for:

- Decompensated COPD with ventilatory failure and hypercapnia, where non-invasive ventilation reduces the need for intubation and, probably, mortality.[17] The expiratory flow limitation in COPD causes insufficient lung emptying and as a result, auto-PEEP (positive end-expiratory pressure), which is difficult to overcome in inspiration: inspiratory muscles must generate more negative pleural pressure to initiate a breath. Extrinsic, applied PEEP (CPAP) decreases the pressure gradient between the alveoli and the mouth in end-expiration, which reduces airway resistance (it stretches airways, and recruits normal lung units collapsed by emphysematous areas). This facilitates expiration via less airway resistance, and facilitates inspiration via reducing the waterfall pressure to overcome in inspiration (mouth minus alveoli). However, too much PEEP (>10 cmH_2O) rather impedes expiration and aggravates hyperinflation.
- HF, where the positive thoracic pressure reduces the preload and the afterload. In HF, non-invasive ventilation with either CPAP or BiPAP improves dyspnea and oxygenation more quickly than standard therapy, with a reduction in the need for intubation and, possibly, hospital mortality.[18]

Non-invasive ventilation is not useful in patients with ARDS, where severe alveolar filling rather than hypoventilation is the main issue.[19] Regardless of the underlying illness, if no improvement is seen within the first 30 minutes of non-invasive ventilation and initial measures, or if there are mental status changes, severe acidosis (pH <7.2), or hemodynamic compromise, proceed with immediate intubation.

A prolonged ineffective use of CPAP or BiPAP may paradoxically increase *expiratory work,* gastric distension and aspiration, and may prolong hypoxemia and delay a salutary intubation. *All this leads to increased mortality in patients who are intubated after a prolonged and ineffective non-invasive ventilation*.[20,21]

3. PALPITATIONS

I. Causes

A. Benign premature beats: 20–30% of palpitations are secondary to PACs or PVCs.

B. Sustained cardiac arrhythmia, consisting of one of the following (10–20% of palpitations):[22–24]

1. *Benign arrhythmia* that is nonetheless sustained and sometimes poorly tolerated: AVNRT/AVRT, atrial tachycardia, inappropriate sinus tachycardia.
2. *Serious but non-malignant arrhythmia*: AF, atrial flutter, pacemaker syndrome in patients with a single-lead VVI pacemaker.
3. *Malignant arrhythmia*: VT.

The malignant arrhythmias typically occur in patients with underlying structural heart disease. The serious and benign arrhythmias may occur without any underlying heart disease.

C. Perception of normal sinus rhythm or sinus tachycardia, related to a psychiatric issue (anxiety, somatization) or obesity and deconditioning (30–40% of palpitations): in these cases, **palpitations coincide with sinus rhythm or sinus tachycardia.** Obesity and deconditioning may lead to disproportionate sinus tachycardia and amplified myocardial contraction with mild activity. Anxiety is a common cause of palpitations, yet occasionally anxiety may be triggered by a true arrhythmia; in one study, two-thirds of patients who were eventually diagnosed with SVT were falsely diagnosed with panic disorder early on.[25]

Serious causes of sinus rhythm perception: HF and AI. HF can lead to sinus tachycardia and palpitations on mild exertion, i.e., palpitations disproportionate to the degree of exertion. In severe aortic insufficiency, the augmented stroke volume may be felt as palpitation.

D. Orthostatic sinus tachycardia (POTS) in young patients <50. See Chapter 12, Section 12.I and Chapter 26, Section 26.II for a discussion of POTS.

E. Metabolic/drugs (10% of palpitations): hyperthyroidism, anemia, pheochromocytoma, and drugs: decongestants, anticholinergic drugs, albuterol, hydralazine (reflex tachycardia), withdrawal of β-blockers or clonidine, others (caffeine, cocaine, alcohol withdrawal).

II. Diagnosis

A. The diagnosis mainly relies on the history and examination (see Table 27.3)

B. Workup of palpitations (see Table 27.4)

In most patients with palpitations, the cause is benign, and the history, physical exam, and basic workup suggest a cause and rule out malignant arrhythmias. ***A normal or non-specific ECG and a normal echo almost exclude a malignant arrhythmia (VT secondary to myocardial disease) and reduce the likelihood of serious arrhythmias.*** A normal pulse rate <100 bpm during the arrhythmia, using any mobile device, makes serious arrhythmia unlikely (only AF remains possible). Brief or occasional palpitations with normal ECG, echo, and basic blood work are likely secondary to premature beats or anxiety and do not warrant any further workup.

When palpitations are ***sustained and poorly tolerated***, an event monitor is used to diagnose paroxysmal AF or SVT. A 2- to 4-week **event monitor** provides a high yield for the diagnosis of palpitations when a sustained arrhythmia is suspected (up to 80% yield), much higher than the diagnostic yield of a Holter monitor (~30% yield).[23,26,27] This is true when the palpitations are frequent, more than once a month. In the assessment of palpitations, most events are detected in the first 2 weeks.[26] Syncope, on the other hand, may require more prolonged monitoring, including an implantable loop recorder for recurrent unexplained syncope. Current event monitors consist of a waterproof adhesive ECG patch, applied to the left pectoral area, and connected wirelessly to a dedicated phone device. It provides continuous single-lead ECG monitoring, and automated algorithms record all perceived anomalies (based on rate, irregularities, and P-wave analysis).

When palpitations *are prolonged and poorly tolerated but infrequent* (less than monthly), event monitoring may not detect any arrhythmia; **mobile technologies** may be used to record the rhythm during the occasional palpitations. ***Kardia Mobile*** device allows single-lead 30-second ECG recording between the right and left fingers. Kardia records lead I between the right and left fingers, yet other leads may be configured, e.g., lead II between the right finger and left knee, lead III between the left finger and left knee, and pseudo-precordial leads by placing the device over the chest at various angles. In fact, the Kardia 6-lead device records all limb leads by combining 3 electrodes touching the R and L fingers and the left knee.

Table 27.3 Diagnostic features of palpitations (duration, onset/offset, regularity, relation to exertion).

a. Palpitations lasting a second; "flip-flopping" in the chest or skipped beats lasting an instant → premature beats (PACs/PVCs)
b. Sustained, fast palpitations → sustained arrhythmia (SVT, AF, VT). Ask if regular or irregular
c. Abrupt onset/offset → sustained arrhythmia
Gradual onset/offset → sinus tachycardia
d. *Poorly tolerated sustained palpitations* → sustained arrhythmia (SVT, AF, VT)
Syncope → VT, or palpitations associated with reflex syncope
e. Pounding in the neck means that the atria and ventricles contract at the same time → PVC, VT (AV dissociation), or AVNRT (simultaneous A and V)
f. Steady heart rate → arrhythmia. Variable heart rate → sinus tachycardia
g. Palpitations on mild exertion disproportionate to the degree of exertion → POTS, exaggerated sinus tachycardia (obesity/deconditioning, HF, anemia, hyperthyroidism), or persistent AF
h. Palpitations on standing → POTS, postural hypotension
i. Palpitations accompanied by a regular and normal heart rate → anxiety

Table 27.4 Workup of palpitations.

Basic workup

1. **ECG:** look for signs of underlying heart disease, suggesting the possibility of arrhythmias:
   - Q wave, ischemic ST–T abnormalities
   - LVH, bundle branch blocks
   - ↑ QT, WPW
2. **TSH, blood count**
3. **Echo:** look for structural heart disease (large LA, low EF, valvular disease, severe LVH)

Selective workup

1. **Stress test** is indicated for exertional chest pain, exertional palpitations, or poorly tolerated palpitations (rule out an angina equivalent)
2. **14- to-30-day adhesive ECG patch (event monitor)** is indicated for:
   - *Sustained and poorly tolerated* palpitations that occur more than monthly. Sustained and poorly tolerated palpitations suggest sustained arrhythmia even in patients with no heart disease (SVT, AF, or idiopathic VT may occur without any structural heart disease).
3. **Mobile technologies** (Kardia, Apple watch): allow an "as needed" self-recording of cardiac rhythm, particularly in sustained and poorly tolerated palpitations that are infrequent (less than monthly).

Smartwatches (Apple and Fitbit) provide 2 valuable tools to detect AF:

- They allow 30-second ECG recording of lead I between the electrode at the digital crown and the one at the back of the watch.
- Apple watch and Fitbit use PPG (photoplethysmography) to: (1) monitor the pulse rate (during rest and exertion), and (2) detect rhythm irregularities during rest. They use proprietary algorithms to detect irregularities while the patient is stationary. Apple algorithm analyzes 1 minute of pulse (called tachogram) every 2 hours then every 15 minutes if irregularity is found; Fitbit analyzes 5 minutes of pulse in an overlapping fashion for 30 minutes. If multiple tachograms (>5–11) show irregularities, an AF alert is sent, at which point the patient should self-record an ECG using the smartwatch to document AF. Smartwatch algorithms have 84-98% specificity for AF: >84% of patients receiving AF PPG notification while wearing an ECG monitor had concurrent AF on the ECG (84% for Apple watch, 98% for Fitbit).[28,29]
- The watch also sends an alert for a pulse >120 minutes while resting, but this notification is separate from the irregular pulse (AF) notification.

Kardia Mobile and smartwatches increase the detection of arrhythmias, or, conversely, the confirmation that palpitations are benign and associated with sinus rhythm, sinus tachycardia, or ectopy. Mobile technologies are particularly useful in sustained palpitations that are poorly tolerated with pre-syncope, or those associated with a fast pulse (IPED study).[30]

II. Diagnosis 659
III. Diagnosis in patients with bacteremia but no local or TEE signs of infection 659
IV. Management 659

1. INFECTIVE ENDOCARDITIS

I. Clinical diagnosis

The diagnosis of infective endocarditis (IE) is based on the Duke criteria, which consist of 2 major and 5 minor criteria.[1]

In brief, the 2 major criteria are: (i) 2 positive blood cultures for a typical IE organism; (ii) echo finding of a vegetation, leaflet perforation, abscess, or a new valvular regurgitation (worsening of a prior regurgitation or murmur is not enough). Cardiac CTA or FDG/PET may alternatively be used for the imaging diagnosis when echo is inconclusive (ESC).

The 5 minor criteria are: (i) fever; (ii) predisposing valvular condition or intravenous drug use; (iii) immunological phenomenon, such as Osler nodes or glomerulopnephritis; (iv) vascular embolism, major (e.g., stroke, pulmonary embolism) or minor (e.g., Janeway lesions, conjunctival hemorrhage); (v) only 1 positive blood culture, or positive blood culture for an organism that is not a usual IE organism (such as Gram-negative bacilli or coagulase-negative staphylococci in suspected native valve endocarditis: they require 3 positive blood cultures to be a major criterion). The diagnosis is made in the presence of 2 major criteria, or 1 major and 3 minor criteria, or all 5 minor criteria.

II. Echocardiography: timing and indications

When IE is suspected, TTE and TEE are often both required. TTE is the recommended initial imaging modality and may be sufficient in patients with a low clinical suspicion, good quality images, and negative valvular findings.[2]

TEE is recommended in patients with a high clinical suspicion of IE and normal TTE. In fact, the sensitivity of TTE for the diagnosis of TEE-confirmed endocarditis is ~55–60%, both for aortic and for mitral endocarditis.[3,4] TEE should also be performed in the majority of patients with positive TTE, in order to diagnose local abscess complications that will dictate urgent surgery. On both TTE and TEE, vegetations but also destructive valvular lesions and local infectious complications should be sought.

TEE may miss vegetations in 5–10% of patients, particularly in the following cases:[2,3] (1) very early stage; (2) very small vegetation <3 mm; (3) pre-existing, severe valvular lesion (myxomatous mitral valve, calcified AS, prosthetic valve). If the clinical suspicion remains high, TEE should be repeated 3–5 days after the initial examination (e.g., *Staphylococcus aureus* bacteremia in a patient with prosthetic valve and negative initial TEE).[2,5] The diagnostic yield of a third examination is low.

Several abnormalities may mimic a vegetation and may warrant cardiac CTA to assist with the diagnosis:

a. Mitral valve abnormalities, such as myxomatous mitral leaflet thickening, prolapsed mitral cusp, or flail mitral chordae. In addition, a tumor may mimic a vegetation (e.g., papillary fibroelastoma that originates from the valve, or myxoma that originates from interatrial septum and extends toward the valve).
b. Aortic valve abnormalities, such as Lambl excrescence or prolapsed aortic cusp.

Also, a healed endocarditis may be hard to differentiate from active endocarditis. As compared to a recent vegetation, an old vegetation tends to be more echogenic or even calcified, but this cannot be reliably used to exclude acute IE.

For right-sided endocarditis, TTE and TEE may have a similar diagnostic yield.[6] However, TEE is superior for the assessment of vegetations on pacemaker leads or indwelling catheters, and thus is required in those cases. It is also required when concomitant left-sided involvement or abscess complications need to be addressed.

A particular diagnostic case is *S. aureus* bacteremia. Regardless of whether the source of bacteremia is known (osteomyelitis, cellulitis, central catheter infection, pneumonia), ~25% of all patients with *S. aureus* bacteremia and 23% of those with central catheter infection as the primary focus have evidence of endocarditis by TEE, without clinical or transthoracic echocardiographic findings.[7] Contrary to a common misconception, IE most commonly involves the *left-sided valves*, in 65% of these patients. Thus, it seems warranted and cost-effective for all patients with *S. aureus* bacteremia to undergo TEE.[7,8] *S. aureus* is virulent and can even cause endocarditis of a normal native valve.

III. Organisms

The most common organisms responsible for IE are: streptococci (viridians streptococci and *Streptococcus bovis*: 40–60%), enterococci (5–15%), *S. aureus* (30–40%), HACEK organisms (5–10%, *Haemophilus*, *Aggregatibacter*, *Cardiobacterium*, *Eikenella*, and *Kingella* Gram-negative bacilli: those require a special milieu for culture and grow slowly), and coagulase-negative staphylococci (5%).[2] Streptococci and enterococci involve left-sided, abnormal valves and lead to subacute IE that progresses over weeks to months. *S. aureus* involves the right- or left-sided valves, and has a predilection to seed normal as well as abnormal valves; *S. aureus* IE is rapidly invasive and destructive and leads to acute IE that progresses over days to weeks. Coagulase-negative *Staphylococcus* infection of native valves may be seen in patients with a central line or intracardiac device, and is often aggressive and complicated. Occasionally, *Coxiella* endocarditis may be seen in farmers, and *Bartonella* endocarditis in cat owners. Of note, positive *Coxiella* or *Bartonella* titers >1:800, or a positive blood PCR for these organisms or for *Tropheryma whipplei* are now major Duke diagnostic criteria.

Intravenous drug users are prone to *S. aureus* IE (~70%), which in this case more commonly involves the tricuspid valve (~60%) rather than the left-sided valves (~40%), many of which are previously normal valves. This is in contradistinction to patients with focal *S. aureus* infections, such as osteomyelitis or catheter infections, who tend to be older with intrinsic left valvular disease, in whom *S. aureus* more frequently seeds the abnormal, left-sided valves. IV drug users with abnormal left-sided valves may have streptococcal and enteroccoccal infection of these left-sided valves. *Pseudomonas aeruginosa* and fungi may also be seen in intravenous drug users.

Prosthetic valves may be infected early postoperatively (<60 days to 1 year) or late (>1 year). Early infections are usually surgical infections, predominantly caused by *Staphylococcus* coagulase-negative (~25–30%) and positive (~25–30%); enterococci and Gram-negative bacilli are second in frequency. With TAVR, *Enterococcus* (from the moist femoral area) and *S. aureus* are the most common organisms. Late infections are caused by the same organisms as native valve endocarditis: streptococci (viridians, *S. bovis*) are the most common, followed by staphylococci and enteroccoci. Coagulase-negative staphylococci may still be seen, especially with central line or device placement.

IV. Morphology

Vegetations are typically located on the upstream side of the valve, in the path of a regurgitant jet, but may be located anywhere on the components of the valvular or subvalvular apparatus, as well as the mural endocardium of the cardiac chambers (LA, LV) or ascending aorta. Large vegetations are almost always associated with significant valvular regurgitation or, less often, valvular stenosis. Regurgitation results from the bulk of the vegetation impeding valvular closure, from valvular perforation/tear, or from rupture of an infected chorda. In fact, a large mass without valvular regurgitation argues against vegetation (in this case, other cardiac masses should be considered). Smaller vegetations, on the other hand, may not be associated with any significant regurgitation in up to 25% of cases.[3]

V. Anatomical complications

Periannular extension is common, occurring in 10–40% of all native valve endocarditis, more commonly aortic endocarditis than mitral or tricuspid endocarditis. Periannular infection is even more common with prosthetic valve endocarditis, occurring in 56–100% of cases, and leading to prosthetic dehiscence and paraprosthetic regurgitation.[2] Perivalvular abscesses are common with prosthetic valves because the annulus, rather than the leaflet, is usually the primary site of infection.[2]

Aortic valve vegetation can extend to the aortic annulus and lead to aortic abscess. The infection tends to spread through the weakest annular structure, the membranous septum, which lies in between the non-coronary (+/– right) aortic cusp, the anterior mitral annulus (mitro-aortic fibrosa), and the septal tricuspid leaflet (Figures 28.1, 28.2, and 6.24). The membranous septum has atrial and ventricular portions, which hold the AV node and His bundle, respectively.[9] This explains why AV block is common with perivalvular abscess. This abscess may communicate with the aortic lumen and lead to pseudoaneurysm formation. An abscess or pseudoaneurysm may rupture and communicate with the pericardium surrounding the base of the aorta (full-blown rupture or microperforation), leading to a hemorrhagic pericardial effusion. It may communicate with a cardiac chamber such as LV, leading to paravalvular AI; LA, leading to severe pulmonary edema; or RA or RV, leading to a massive left-to-right shunt and severe left ± right failure (Figures 28.1, 28.2). The annular abscess may lead to dehiscence of a prosthetic valve with perivalvular regurgitation. Therefore, worsening HF, persistent infection, new murmur, pericardial effusion, or new AV block in a patient with IE is a hint to abscess formation and warrants repeating TEE. AV block (including a new first-degree AV block or bundle branch block) has a high positive predictive value for abscess formation (88%) but low sensitivity (45%).[2,9]

A narrow fibrous space, called the mitral–aortic intervalvular fibrosa (or interannular fibrosa), separates the aortic root and mitral annulus. Aortic root abscess or mitral annular abscess may extend into this space and lead to pseudoaneurysm of this space, with subsequent seeding of the mitral valve from the aortic valve (or vice versa) and extension throughout the cardiac cytoskeleton (Figure 28.1).

Aortic root abscess manifests initially as aortic root wall thickening. If only slight thickening is visualized, TEE may need to be repeated a few days later, at which time a clear aortic free space, with or without fistulization on color Doppler, confirms the diagnosis.

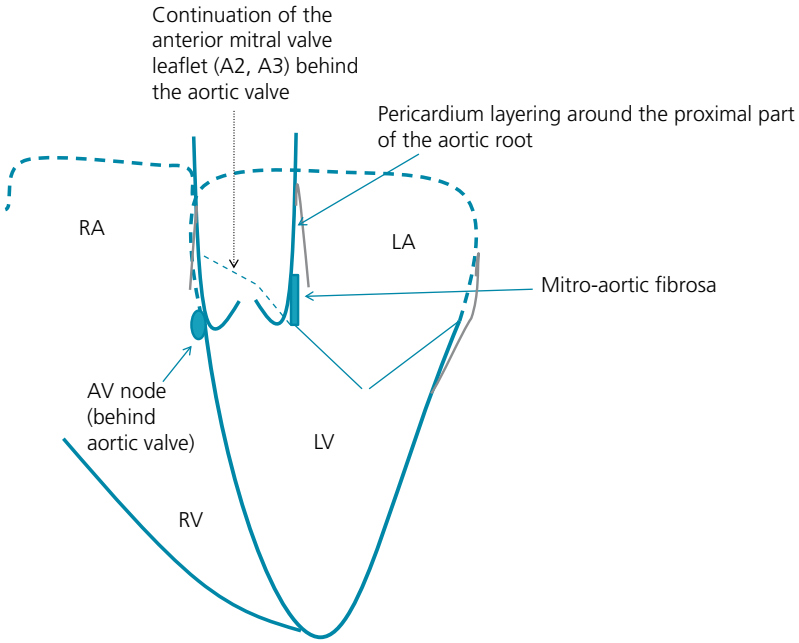

Figure 28.1 Aortic or mitral endocarditis can extend into the valvular annulus then into each 1 of these 3 structures: mitral–aortic interannular fibrosa, AV node, or pericardial space. Fistulization into a cardiac cavity (LA, LV, RA, RV) may also occur.

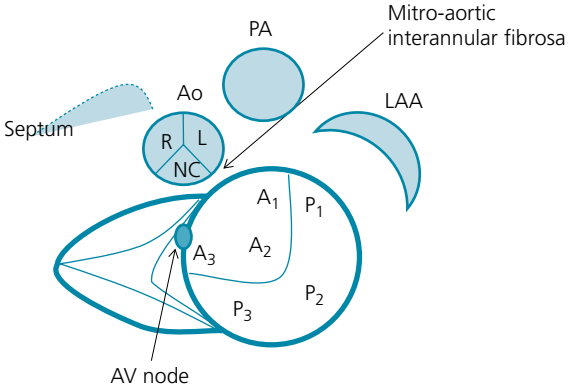

Figure 28.2 The AV node, and particularly the His bundle coming off the AV node, are anterior structures, located anterior to the ostium of the coronary sinus at the distal interatrial septum (AV node) and membranous ventricular septum (His). Two-thirds of the circumference of the aortic valve is connected to the muscular ventricular septum, while the remaining one-third is in fibrous continuity with the anterior mitral leaflet (interannular fibrosa, close to the non-coronary cusp). At one point posteriorly, the aortic valve is in continuity with the His bundle and the interatrial septum.

VI. Additional diagnostic imaging: cardiac CTA and FDG-PET/CT may be considered in specific cases

1. For native valve endocarditis: Cardiac CTA has a slightly lower sensitivity than TEE for the diagnosis of valvular vegetation, especially <1 cm, but the combination TEE + CTA is superior to TEE for the diagnosis of endocarditis in inconclusive TEE cases, and for defining local abscess complications and periannular extension.[10] CTA is also valuable for preoperative coronary assessment, particularly in aortic valve endocarditis where invasive angiography may dislodge a vegetation and is preferably avoided.

In cases where the diagnosis of endocarditis is questionable by TEE and Duke criteria, cardiac CTA should be considered (e.g., heavily calcified aortic valve or heavy mitral MAC with a mass that may represent calcium vs. vegetation).

FDG-PET has a low sensitivity of only 31% for native valve endocarditis but may still be valuable to identify septic emboli. FDG-PET does not usually detect valvular vegetation; it needs more pronounced inflammatory response to detect FDG uptake. As such, prosthetic valve endocarditis or paravalvular involvement must be present to cause inflammation severe enough for detection by PET.[10]

2. For prosthetic valve endocarditis (where the diagnostic sensitivity of TEE is 90%):[10]

- *When TEE is non-diagnostic or equivocal, but the probability of endocarditis is ≥ moderate:* either cardiac CTA or FDG-PET/CT may be used to establish the diagnosis. FDG-PET detects prosthetic endocarditis earlier than TEE with a sensitivity of 91–100% and a specificity of 84%. FDG-PET assesses the avid glucose uptake of inflammatory cells and is combined with low-dose non-contrast CT for attenuation correction and anatomical colocalization of the exact site of high uptake. It is performed in a fasting state, preceded by

high-fat/low-carbohydrate diet, to suppress the normal myocardial glucose uptake. A whole-body PET/CT is generally performed to additionally localize the source of infection as well as septic emboli.[10,11]

Cardiac CTA has a global sensitivity and specificity similar to TEE in prosthetic endocarditis: it is slightly inferior for small vegetations and leaflet perforations, but superior for paravalvular abscess and for anatomic surgical planning.[11]

- *When TEE establishes the diagnosis:*
  - CTA often remains necessary for defining periannular extension.
  - FDG-PET may still be used in specific cases to look for septic emboli and to find the source of infection.

3. For cardiac electronic device infection or LVAD infection (driveline or pump):

If the diagnosis is not established by TTE/TEE: Cardiac CTA is limited because of metallic artifacts. FDG-PET/CT is the next imaging modality.

Rarely, for prosthetic valves and cardiac devices, if FDG-PET result is equivocal, radiolabeled WBC scan may be used (lower sensitivity than FDG-PET, but higher specificity for infection vs. inflammation).

VII. Indications for valvular surgery and special situations

A. Indications for valvular surgery in left-sided endocarditis

Valvular surgery is definitely indicated in the following cases (class I indications):[2,12]

1. Severe valvular regurgitation or obstruction with cardiogenic shock or refractory pulmonary edema (emergent), or with any degree of heart failure (urgent, within 3–5 days per ESC). Delaying surgery to allow extended antibiotic therapy carries the risk of permanent ventricular dysfunction and progressive chamber enlargement and should be discouraged. In fact, even mild congestive heart failure at initial presentation may progress insidiously despite appropriate antibiotic therapy. Early mitral closure in acute AI, rapidly decelerating MR signal on spectral Doppler of MR (V-wave cutoff), or pulmonary hypertension are signs of poor hemodynamic tolerance of the valvular insufficiency that indicate the need for surgery. HF is the most frequent and serious complication of IE.

2. Local infectious complications (abscess, pseudoaneurysm, fistula) indicate urgent surgery, within 3 days. Delaying surgery carries the risk of abscess extension.

3. Refractory or relapsing bacteremia (>7 days) despite appropriate antibiotic therapy, often indicative of a local complication. This situation is more common with aggressive organisms, including *S. aureus*, and when vegetations are bulky and resistant to antibiotic penetration. Persistent bacteremia is frequently due to perivalvular abscess or to distant abscesses from embolization (splenic, cerebral, vertebra, renal). Distant abscesses should be ruled out before assuming that persistent bacteremia is due to the valvular infection.

4. Certain organisms:

- Left-sided *S. aureus* endocarditis is difficult to control, highly destructive, and is likely to require urgent surgery. It is, per se, a relative indication for early surgery in native or prosthetic valve endocarditis, unless an immediate response is obtained with antibiotic therapy.
- The same *S. aureus* description applies to non-HACEK Gram-negative bacilli.
- Fungal endocarditis.

Note: Surgery is not mandatory in all prosthetic valve infections. For example, uncomplicated streptococcal prosthetic endocarditis or *S. aureus* endocarditis that quickly responds to antibiotic treatment with no HF may be managed medically.[11,12]

B. Case of a large vegetation >1 cm or prior embolization

Systemic embolization occurs in 20–40% of patients with IE and most frequently involves the brain (65% of the cases), then the spleen and kidneys; some emboli are asymptomatic and diagnosed by CT. The risk of embolization is dramatically reduced after 2 weeks of antibiotic therapy. Per ESC, embolic risk is highest the day after antibiotic initiation, then it continuously declines over the subsequent 1-2 weeks. Besides the timing, vegetation >10 mm in size, hypermobile vegetation, *S. aureus* or fungal infection, or IE of the anterior mitral leaflet are risk factors for embolization.[13] In fact, the risk of embolization of aortic IE (10%) is lower than that of mitral IE (25%) or anterior leaflet mitral IE (37%). Also, one study has shown that vegetation length >10 mm or >15 mm is associated with a 60% or 83% risk of embolization, respectively.[13] Therefore:

- Surgery is recommended (class I ESC guidelines) in patients who have clinical evidence of embolization *despite several days of antibiotic therapy* and have a persistently large vegetation ≥1 cm (urgent surgery within 3 days).
- Surgery may be performed in patients with vegetation ≥ 10 mm without prior embolization, when the regurgitation is severe (class I ESC guidelines). If surgery is considered for this indication, it should be done urgently within 3 days, at the time the risk of embolization is highest. This indication is supported by one randomized trial.[14]
- Since most patients with severe valvular regurgitation eventually need surgery sooner or later, the *early performance of surgery appears to be the preferred strategy if a large vegetation is associated with severe valvular regurgitation*.[14] Seventy-six patients with a vegetation >1 cm in diameter and severe valvular disease were randomized to early surgery (within 48 hours of randomization) or conventional treatment with surgery as needed, later on (77% eventually underwent surgery, mostly during hospitalization). Patients with classic indications for early surgery (HF, abscess) and patients without severe valvular disease were excluded. Patients with major stroke were also excluded. Patients with smaller strokes, TIA, or renal/splenic embolism were included, and ~45% of randomized patients had a prior embolism (~28% cerebral). Early surgery dramatically reduced the risk of symptomatic recurrent events (8 cases [21% vs. 0%], 7 of which occurred between 2 and 9 days after randomization, especially at 2–5 days, and included 5 major strokes, 1 anterior MI, 1 limb ischemia).

Surgery in patients with a large vegetation but without severe valvular disease and without clinical emboli while on antibiotics is more controversial (class IIb in ESC guidelines, if surgical risk low). *The clearest indication is the patient with a large vegetation, severe valvular disease, and peripheral embolism or cerebral embolism not associated with a major stroke*.

The problem is, however, that when patients have already had a cerebral embolization, early surgery within the first 2 weeks after a stroke is associated with a high risk of neurological deterioration. Neurological deterioration may result from hemorrhagic transformation during cardiopulmonary bypass/anticoagulation, or exacerbation or expansion of ischemia from perioperative hypotension. These factors make a recent large embolic stroke a relative contraindication to valvular surgery in infective endocarditis (STS guidelines).[15] In fact, after an ischemic stroke, the risk of deterioration with surgery is 20% in the first 3 days, 20–50% between 4 and 14 days, 6–10% between 15 and 28 days, and <1% after 28 days. Two other series suggest, however, that surgery performed at a median of 4 days after a stroke did not compromise neurological recovery.[16,17] Thus, surgery is likely safe after a "small stroke" with no or mild residual clinical deficit and small infarct on imaging. Also, surgery is probably safe within the first 4 days after an ischemic event (especially a small or silent infarct or a transient ischemic attack).[18] Cardiac surgery may need to be delayed 2 weeks after a large cerebral infarction, but may be performed earlier, especially in the first 4 days, in case of recurrent embolization, increased vegetation size despite appropriate antibiotic therapy, refractory infection, or HF.[16,17] Surgery needs to be delayed at least 4 weeks after a hemorrhagic stroke.

Hemorrhagic transformation is common following cerebral embolization, with rates as high as 50% in some studies. Less common is the formation of an abscess within the infarct cavity over the days or weeks following the infarct. Intracranial hemorrhage may also result from infected intracranial aneurysms, which are best diagnosed by digital substraction angiography, or alternatively, when >5 mm, by CTA or MRA. These aneurysms should be sought before surgery, and endovascular treatment is recommended for large or ruptured infected aneurysms.

Management of anticoagulation – Because of this risk of hemorrhagic transformation, anticoagulation of patients with mechanical prostheses is discontinued for 2 weeks after a symptomatic cerebral embolism.[2] CT or MRI is not routinely indicated for the detection of subclinical cerebral emboli. In asymptomatic patients, brain MRI frequently detects silent lesions such as microbleeds, and these have not been associated with parenchymal hemorrhage or postoperative neurological complications (ESC). However, some centers perform brain imaging in asymptomatic patients with mechanical valves and large mobile vegetations to decide about anticoagulation: if silent infarcts are detected, anticoagulation is held. Also, warfarin may be held on admission in patients with mechanical valve endocarditis, even without neurological symptoms, and replaced with IV UFH. This switch is maintained until the early course becomes clearer (stroke occurrence) and until a decision is made regarding surgery.

C. Types of valvular surgery

Valvular surgery often consists of valve replacement, but valvular repair with vegetectomy and patch repair may be performed, particularly for the mitral valve (class I recommendation for mitral valve repair when technically feasible, STS guidelines).[15] Repair rates range from 33% to 94% in published series (STS guidelines). In the previously described study, ~50% of mitral surgeries consisted of valvular repair.[14] In the case of aortic endocarditis with periannular extension, drainage of abscess cavities, excision of necrotic tissue, and closure of fistulous tracts often accompany valve replacement surgery. Aortic valve homograft and root homograft, when available, may be preferred because they are associated with a low incidence of sewing-ring infection and mural endocarditis, possibly related to the improved antibiotic penetration.

D. Indications for tricuspid valve surgery

Two different populations get right-sided endocarditis, mainly tricuspid endocarditis: (i) IV drug users, (ii) chronically ill patients with indwelling catheters (e.g., cancer patients), device leads, or immunocompromise. Group (ii) has the worst prognosis. Tricuspid endocarditis in IV drug users has a benign short-term prognosis with a low in-hospital mortality; it can be medically managed in ~90% of patients. However, IV drug users have a high rate of recurrent endocarditis and poor long-term prognosis related to ongoing drug use. A conservative approach is appropriate for the large majority of patients with tricuspid and pulmonic valve endocarditis.[19] When PA pressure is normal, TR and RV volume overload are usually well tolerated without an imminent risk of RV failure.

Surgical indications:[12,20]

- Refractory bacteremia despite 1–2 weeks of antibiotic therapy, in the absence of a pulmonary abscess (otherwise, pulmonary abscess may explain the persistence of infection).[12] This is the main indication for tricuspid endocarditis surgery.
- Massive TR with deteriorating RV dilatation refractory to diuretics.[20]
- Recurrent pulmonary emboli are a surgical indication only if the patient has severe respiratory failure requiring ventilatory support or a residual large vegetation >2 cm after the recurrent emboli (ESC 2023).[12]

Surgical options include:[19,20] (i) debridement and vegetation excision with valve repair if the vegetation/destruction does not involve more than half of the tricuspid apparatus, or (ii) total valvectomy with prosthetic valve replacement. Vegetectomy with valve repair is preferred whenever possible. Total excision of the tricuspid valve without immediate replacement may be tolerated by some patients.[20,21] RV dysfunction does not usually occur for several months after valvular excision, unless the patient has pulmonary hypertension secondary to multiple pulmonary emboli; a bioprosthetic valve may be inserted 6–9 months later, after infection control.

Percutaneous mechanical apsiration of the vegetation, using the AngioVac system, is highly successful in removing right-sided vegetation on the valves or leads. AngioVac removes venous blood via one large-bore venous access (e.g., jugular) and re-infuses it via another large venous access after filtering, using extracorporeal pump. It is suggested for patients with refractory bacteremia, persistent large vegetation >2 cm, or recurrent septic emboli, and has shown high clinical success of ~90% in those indications (CLEAR-IE registry). It does not improve TR that is due to valvular destruction, and may even worsen it (unless TR is due to the bulk of a large vegetation).

E. Role of partial oral antibiotic treatment

One Danish trial randomized stable endocarditis patients (*Streptococcus*, *Staphylococcus*, or *Enterococcus*) who have received IV antibiotics for ≥10 days, and ≥7 days after surgery if performed (38%), to continuing IV antibiotics vs. switching to an oral regimen of 2 antibiotics (mostly ampicillin, dicloxacillin, or linezolid, with rifampin, for 2–4 weeks). The partial oral regimen was equally safe and effective and dramatically shortened hospitalization.[22] These select patients must have no abscess on a recent TEE, and must be afebrile with declining CRP and white count.

2. CARDIAC RHYTHM DEVICE INFECTIONS

I. Organisms and mechanisms of infection

Cardiac device infection is often caused by *Staphylococcus* species, most commonly coagulase-negative staphylococci (45%) or *S. aureus* (29%). The pocket may become infected at the time of implantation, either endogenously from the skin of the patient or exogenously.[23] It may also get infected if the generator or leads erode through the skin; note that device erosion, per se, may result from an underlying infection.

On the other hand, the generator or leads may become infected as a result of hematogenous seeding during bacteremia or fungemia secondary to a distantly infected focus. This characteristically occurs with *S. aureus* bacteremia and is unlikely with Gram-negative bacteremia. The prevalence of device infection secondary to *S. aureus* bacteremia is difficult to determine, as it is not easy to differentiate this mechanism of device infection from intraoperative contamination at the time of device placement.

Device infection may track along the intravascular portion of the lead and result in lead or valvular vegetation in up to one-fourth of cases.

II. Diagnosis

A. Clinical

Most often (~70%), local inflammatory changes of the generator/pocket site are present, or cutaneous erosion with percutaneous exposure of the generator and/or leads is seen. A device that erodes through the skin is definitely infected.

Fever or increased white count may not be seen. Infrequently, device infection manifests as fever of undefined origin without local inflammatory changes at the generator/pocket site.

Among all-comers with *S. aureus* bacteremia and an implanted cardiac rhythm device, ~45% had confirmed device infection by echocardiography (vegetations) or upon explantation. Only 40% of confirmed device infections had local signs of infection. Also, only 40% of device infections had the device as a source of infection, the remaining patients having a central catheter or a soft tissue infection as a distant source of bacteremia.[24] The device was more likely the source of infection in case of early *S. aureus* bacteremia (<1 year post-implantation).

B. Echocardiography

In the above study, one-third of patients with confirmed device infection did not have any vegetation on TEE.[24] Thus, in case of *S. aureus* bacteremia, the clinician should have a high index of suspicion that the implant is infected, even if local signs of generator pocket infection are absent and no generator, wire, or valvular vegetations are detected by TEE.

While TEE may not be superior to TTE in demonstrating tricuspid valve endocarditis, it is superior in demonstrating lead endocarditis (RA, SVC vegetations) and is a valuable diagnostic tool when a device infection is suspected, particularly in case of bacteremia, more so *S. aureus* bacteremia.

On the other hand, lead masses are frequently seen on TEE in patients without any infectious concern. In one study, masses were seen on the leads of 5% of pacemakers and were considered thrombus rather than vegetation.[25] In another report, lead masses were seen in 13/132 patients (10%) in whom TEE was performed for an indication other than ruling out endocarditis, and only one of those patients was clinically adjudicated to have an infected device.[26] Thus, it is important to take the clinical context into account, and an unsuspected lead mass on TTE or TEE is often a thrombus.

III. Diagnosis in patients with bacteremia but no local or TEE signs of infection

Although bloodstream infection can be associated with device infection, it can occur without device infection in ~55% of the cases. The device is more likely to be infected if the patient has *S. aureus* or coagulase-negative *Staphylococcus* bacteremia with any one of the following: (1) no clear source of bacteremia can be identified; (2) persistent bacteremia despite antibiotic therapy and removal of a culprit central catheter; (3) the patient develops recurrent bacteremia; (4) bacteremia within the first 3 months of device placement. Cardiac devices may sometimes be retained in patients with an identifiable source of *Staphylococcus* infection (e.g., infected intravascular catheter) and no clear involvement of the leads or device by TEE or physical examination. Such patients, however, require careful follow-up to detect relapsing infection, which would generally occur within 12 weeks after discontinuation of antibiotic therapy if the prosthetic device was seeded at the time of the initial *Staphylococcus* bacteremia. Patients found to have relapsing infection should undergo complete device extraction.[23,24,27] Combined PET-CT imaging may be used in these equivocal cases, and identifies a pocket or lead nuclear uptake in case of infection.[28]

Device infection is unlikely in patients with Gram-negative bacteremia and no other signs of infection; thus, device removal is not recommended in this setting. This also applies, to some degree, to *Streptococcus* and *Enterococcus* bacteremias.[23,27] However, a relapsing or refractory Gram-negative bacteremia despite appropriate antibiotic therapy and despite the absence of a defined source of infection should trigger device removal.

Candidemia is handled similarly to *Staphylococcus* bacteremia.[27]

IV. Management

The whole system (generator and leads) should be removed in all patients with device infection, including patients with only localized pocket infection and no sign of systemic infection.[27–29] The only exception is superficial infection of the wound or incision site (e.g., stitch abscess, superficial cellulitis) early after implantation that can be managed by conservative oral antibiotic therapy (7–10 days) without removing the device.

Complete removal of hardware is needed because the relapse rate from retained hardware is high. Device infections are associated with a high mortality, particularly in patients with a confirmed device-related endocarditis and in those treated without device removal. The in-hospital mortality varies between 7% and 14%. Leads may be extracted percutaneously with <1% procedure-related mortality.[29]

After extraction, 2 decisions have to be made: duration of antibiotic therapy and timing of reimplantation (Figure 28.3). Antibiotic therapy is generally continued for 2 weeks after device explantation, longer if there is evidence of endocarditis. Also, before reimplanting a device, one should assess *whether* the patient still needs one. Studies indicate that up to 30% of patients may no longer require a cardiac device.[29] If an ICD is still needed, consider implantation of a subcutaneous ICD, which is associated with fewer systemic infections.

In patients with pacemaker who are pacemaker dependent, a temporary pacemaker is placed at the time of explant, followed by permanent pacemaker reimplantation most often at 72 hours if blood cultures obtained post-explant are negative at 72 hours. Alternatively, a leadless permanent pacemaker may be implanted in the RV at the time of explant, particularly in patients who are not frequently paced; a leadless pacemaker has a very low risk of infection.

Questions and answers 667

Up to 60% of patients undergoing vascular surgery have significant CAD. Two major mechanisms underlie perioperative myocardial infarction:

1. Catecholamine surge, tachycardia, and hypertension increase coronary shear stress, which triggers plaque rupture. This is more likely to happen in plaques with a large atherosclerotic burden even if non-obstructive.[1,2]

Surgery-induced procoagulant state may lead to coronary thrombosis over a ruptured or even a non-ruptured lesion, particularly if the stenosis is tight with a low-flow state.

2. Prolonged periods of demand/supply mismatch in patients with severe but previously stable CAD, without any plaque rupture.

Overall, each one of the 2 mechanisms is primarily responsible for ~50% of postoperative MIs.[1] A combination is likely responsible for MI in a substantial proportion of patients. Most events occur in the first 24–48 hours postoperatively, the period of highest sympathetic tone. The infarct is most commonly NSTEMI/non-Q-wave MI. In a series of 21 patients who underwent preoperative coronary angiography and developed postoperative MI after vascular surgery, slightly over half of the infarcts corresponded to the territory of a totally occluded coronary artery, in which collaterals could not provide enough supply during a period of high stress; additionally, those patients had severe multivessel disease, potentially impairing collateral flow.[3] The remaining infarcts occurred in the territory of a non-significant lesion, in patients who nonetheless had extensive atherosclerosis. This highlights not only the frequency of demand/supply mismatch, but also the fact that plaque rupture may very well occur at non-obstructive sites. The overall extent of CAD correlates with the risk of events and plaque rupture; however, the infarct does not necessarily occur at the actual site of severe stenosis. In fact, a non-obstructive lesion may be vulnerable (high plaque burden, thin cap). This explains why revascularization does not prevent postoperative MI.

I. Surgical risk: surgery's risk and patient's risk

A. Classification of the surgery's risk

The surgery risk is related to its duration, amount of blood loss, and the degree of fluid shifts and BP fluctuations. The surgery is classified into 1 of 3 risk categories (ESC):[4,5]

- High risk: aortic or major peripheral vascular surgery; pancreatic surgery; esophagectomy; liver resection; lung resection; liver or lung transplant; repair of perforated bowel

Practical Cardiovascular Medicine, Third Edition. Elias B. Hanna.

© 2027 John Wiley & Sons Ltd. All rights reserved, including rights for text and data mining and training of artificial intelligence technologies or similar technologies. Published 2027 by John Wiley & Sons Ltd.

Companion website: www.wiley.com/go/hanna/cardiomedicine3e

- Intermediate risk: simpler intraperitoneal surgery (e.g., cholecystectomy, splenectomy), carotid endarterectomy, common femoral endarterectomy, percutaneous AAA repair, percutaneous arterial procedures, head and neck surgery, major orthopedic surgery (e.g., spine or hip surgery), prostate surgery, renal transplant, major urological or gynecological surgery, VATS lung resection
- Low risk: endoscopic procedures, breast surgery, cataract surgery, dental surgery, ambulatory surgery (e.g., meniscectomy), prostate transurethral resection

The risk of perioperative major cardiac events (death or MI) is generally ≤1% with low-risk surgery, regardless of the underlying patient's risk; and is generally 1–5% with intermediate-risk surgery and >5% with high-risk surgery, although the actual risk of intermediate- and high-risk surgeries also depends on the patient's intrinsic risk (Lee risk score). For example, a low-risk patient undergoing major vascular surgery has <2–5% risk of major cardiac events.

B. Classification of the patient's overall risk (integrates the surgery's risk with the patient's risk factors)

In the presence of an active cardiac condition (Section IIB, below), the patient is a high-risk patient.

In the absence of an active cardiac condition, operative risk scores may be used, such as NSQIP or the revised cardiac risk index (Lee risk score). Those risk scores refine the surgery's general risk and classify the risk of major cardiac events as low (<1%), elevated (1–5%), or high (>5%). The problem is that these risk scores, particularly ACS-NSQIP and AUB-HAS2, generally assess the combined risk of coronary and non-coronary cardiac events but also total mortality, part of which is non-cardiac (e.g., bleeding, infection, etc.). Lee risk score consists of the following 6 factors: (i) history of CAD, (ii) compensated or prior HF, (iii) diabetes requiring insulin, (iv) renal insufficiency with creatinine >2 mg/dl, (v) cerebrovascular disease, (vi) high-risk surgery (suprainguinal vascular, intraperitoneal, intrathoracic).

A Lee risk score ≥3 identifies high-risk stable patients, a score of 2 identifies intermediate-risk patients, while a score of 0 or 1 identifies low-risk patients. The risk of postoperative major adverse cardiac events (MACEs) (MI, VF or primary cardiac arrest, or definite pulmonary edema) in high-, intermediate-, and low-risk patients is ≥9%, 4–5%, and 0.5–1.3%, respectively.[6]

C. Risk of MACE according to stress testing results

A high-risk stress test result (stress echo or nuclear stress test) is associated with a 10–25% risk of perioperative death or MI, while a normal stress test result is associated with a 0–4% (~2%) risk of death or MI.[4,5] Therefore, a low-risk stress test steps down the risk in a patient with a high Lee index, but the absolute risk may remain significant.

II. Steps in preoperative evaluation – Focus on the 4 cardiac systems

A. First step: if the surgery is emergent, no cardiac workup is performed preoperatively

B. Second step: assess for instability of any of the 4 major cardiac systems:[4,5]

- Active, unstable coronary syndrome, or anginal chest pain on mild activity
- Severe unstable arrhythmia
- Decompensated HF
- Severely symptomatic valvular heart disease

These patients need to have their cardiac condition treated before surgery, depending on the urgency of the surgery (PCI for ACS, medical therapy for HF, surgical therapy for symptomatic, severe valvular disease).

In case of an emergent surgery, proceed to the high-risk surgery after initiating diuresis for HF and rate control for AF (potentially with amiodarone if the patient is unstable). Strictly monitor the patient's hemodynamics during surgery, and aim to prevent BP fluctuations and limit blood loss.

C. Third step: assess the 4 major cardiac systems for stable disease or less severe decompensation

Clinicians excessively focus on evaluating patients for CAD, which is not usually a modifiable procedural risk as coronary outcomes do not improve with revascularization. Rather, at least as big of a focus should be placed on the assessment of HF status and volume status, as most postoperative cardiac complications are related to HF and HF is a modifiable risk, i.e., postoperative HF may be reduced by preoperative optimization of volume status and initiation of the pillars of HF therapy.

The following 4 cardiac systems are evaluated:

1. **HF:** clinical evaluation: JVP, edema, dyspnea, hypoxemia, lie the patient flat for 1 minute and check for orthopnea. Consider, as needed: echo, BNP, and CXR.
2. **Valvular disease:** clinical evaluation (murmurs) and, if needed, echo.
3. **Arrhythmia,** particularly rate-uncontrolled AF: focus on rate control, and if time allows, in the case of a recent-onset AF, attempt rhythm control.
4. **CAD:** only typical exertional chest pain that is frequent (~daily or more) and that consistently occurs on mild effort may require further assessment via hs-troponin and stress testing, CTA, or coronary angiography.

In terms of CAD evaluation, be restrictive in ordering tests and performing PCI as revascularization of stable CAD, including symptomatic stable single- or multivessel CAD with stable angina, does not generally improve postoperative MI or cardiac death based on CARP trial (outside left main or possibly complex 3-vessel CAD). Moreover, it may cause harm by delaying a necessary surgery and subjecting, unnecessarily, cancer patients or high-bleeding-risk patients to antiplatelet therapy. Hence, ACC recommends against routine preoperative revascularization of stable non-LM CAD (class III).

Although operative risk scores, such as NSQIP or the revised cardiac risk index, may be used, the issue is that they are not cardiac specific and do not assess the sole risk of coronary or even combined cardiac events; rather, they incorporate total mortality, part of which is non-cardiac. The following is recommended, based on the ACC and ESC guidelines:[4,5]

1. **Echo** for pathological murmurs, or clinical HF or severe dyspnea, or elevated BNP, or severely abnormal ECG (Q, LVH, BBB).

2. In patients with a history of cardiovascular disease, or age ≥ 65, or symptoms suggestive of HF or CAD undergoing elevated-risk surgery, obtain:

- baseline **BNP** (class IIa ACC and ESC)
- preoperative and 24-hour and 48-hour postoperative **hs-troponin** (class I ESC, class IIb ACC)

Multiple studies have shown that elevated preoperative hs-troponin T > 14 ng/L is a strong predictor of perioperative cardiac complications (mortality of 6.9% vs. 1.2% for hs-troponin < 14). An elevated troponin dictates more careful cardiac monitoring and medical management (e.g., statin, antianginal drugs, avoidance of BP swings and excessive fluid administration, rate control), *rather than coronary imaging*.

An elevated BNP (>100) or NT-pro-BNP (>300) dictates more careful HF assessment, a lower threshold for HF diuresis, and prompt therapy pre- and postoperatively (note that BNP cutoff is higher in older age, renal dysfunction, and AF).

3. Outside symptomatic patients with typical chest pain on mild exertion, **stress imaging or coronary CTA is generally avoided** and may only be considered in **very select patients**, such as patients with the following triple combination, where it is **given only an ACC class IIb recommendation**:

- high-risk surgery
- *and* poor functional capacity < 4 METs
- *and* ≥1 clinical risk factor according to Lee risk score (Lee score ≥2)

ACC does not give a class I or IIa recommendation for preoperative stress testing in any patient. If the functional capacity is ≥4 METs, especially ≥7 METs, stress testing is further avoided even if Lee risk score is high (class III). Four METs corresponds to climbing 2 flights of stairs, walking up a hill, walking fast at ground level (3 mph), dancing, or performing heavy housework or yardwork (pushing a power mower, scrubbing floors, carrying heavy groceries). Sexual intercourse corresponds to 3–5 METs.

Coronary testing, when occasionally done, aims to further risk-stratify the patient and assess whether surgery should be altered or avoided, if possible, or, at least, operative monitoring intensified. ***It should not aim to revascularize patients with no angina or non-severe angina because: (i) this is largely non-beneficial (CARP Trial),*** outside MI or critical LM disease; there is no evidence that PCI or CABG for single- or multivessel disease improves perioperative outcomes; a stent or a graft does not eliminate the risk of MI from the diffuse plaque burden and even from the stenotic lesion, as the surgical milieu potentiates stent or graft thrombosis; ***(ii)*** revascularization is harmful in patients with active cancer or bleeding risk who are not candidates for dual antiplatelet therapy; ***(iii)*** further harm is caused by delaying a lifesaving cancer surgery. ***Preoperative coronary testing is much less useful in patients who require a necessary, vital surgery that cannot be delayed, the so-called time-sensitive surgery <6–12 weeks (e.g., cancer surgery) vs. elective surgery.***

***Illustration of difficult case scenarios:**

1. A patient with mild angina is found to have high-risk ischemia on stress testing, then 3-vessel CAD on preoperative coronary angiography (in the 50–90% range). He needs to undergo a necessary high-risk cancer surgery. How to proceed?

This 3-vessel CAD does not dictate preoperative revascularization outside MI or critical angina. Rather consider: statin, β-blocker started >1 week before surgery, careful attention to hemodynamics/BP swings during surgery (maintain SBP > 90–100), and arterial line. Reduce blood loss and readily transfuse. Both the surgeon and anesthesiologist must maintain a higher level of alertness and monitoring during surgery and afterward.

Readily perform catheterization for postoperative MI with ischemic ECG. Postoperative bailout stenting is potentially safer than preoperative pre-emptive revascularization, which has proven hazard and no proven benefit. The bleeding risk and the ability to tolerate an antithrombotic regimen are likely better after the surgery, even soon after it, than during it. Also, the risk of stent thrombosis is likely lower when stenting is done postoperatively than if a fresh stent is present during surgery (peak inflammatory, hemodynamic, and prothrombotic stress).

2. In a patient with necessary cancer surgery that cannot be significantly delayed, *preoperative revascularization is performed only for:* **(i)** *active MI (along with critical disease of a major territory on angiography), or* **(ii)** *severe angina on mild effort, or* **(iii)** *critical left main disease*. In those cases, stenting is typically done and surgery is delayed for 4–5 weeks only, at which time clopidogrel is possibly interrupted and resumed 1–2 days postoperatively.

III. CARP and DECREASE V trials

The CARP and DECREASE V trials have shown that patients with established but stable CAD, including multivessel/triple-vessel CAD, who are undergoing high-risk vascular surgery, do not benefit from revascularization preoperatively.

The CARP trial enrolled 509 intermediate- to high-risk patients (by Lee risk score or stress testing) undergoing vascular surgery (33% AAA) and found to have obstructive CAD (>70%) on coronary angiography. They were randomized to medical therapy or coronary revascularization (59% CABG, 41% PCI). Surgery was delayed a median of 6 weeks after revascularization. The postoperative risk of death was ~3% in both groups, and MI rate was ~8% (high MACE risk not modified by revascularization).[7] Of note, 35% of patients had 3-vessel CAD, and left main disease was excluded.

In the DECREASE V trial of patients with extensive baseline ischemia (≥5/17 segments), the MACE risk was high but unchanged with revascularization. This is related to the fact that postoperative MI in a CAD patient may result from a plaque rupture occurring at the site of an obstructive lesion but also frequently a non-obstructive one. Moreover, preoperative revascularization does not eliminate the risk of MI from an obstructive lesion, as the prothrombotic and hemodynamic milieu of surgery heightens the risk of stent or graft thrombosis. This is besides the long-term restenosis risk of a lesion that may have remained stable. Therefore, the usefulness of preoperative coronary revascularization in patients not having active ACS is not established, even in high-risk subgroups with strongly positive stress tests.[8]

Preoperative coronary testing may be useful to show the general prognosis of the patient. A high surgical risk based on preoperative stress testing may lead to a change in management but not necessarily revascularization. It should lead to a risk/benefit discussion with the patient, with a potential cancellation of non-vital surgery and consideration of percutaneous angioplasty for PAD or endovascular repair of abdominal aortic aneurysm, even if the result is expected to be inferior to surgery. Preoperative coronary testing is much less useful in patients who require a vital surgery, such as cancer surgery.

Patients with high-risk stable CAD (left main or triple-vessel CAD) are expected to have long-term improvement with revascularization and have an indication for revascularization to improve their long-term outcome rather than their immediate postoperative outcome.

These patients require revascularization regardless of surgery, and if possible this may be performed before surgery. Conversely, finding 1- or multi-vessel stable disease does not dictate preoperative revascularization per se, since, again, this revascularization does not improve perioperative outcomes.

IV. Only the unstable coronary patients require revascularization preoperatively

The unstable coronary patients are those with acute MI or severe and frequent typical exertional angina. Stenting, however, is associated with several pitfalls:

1. Dual antiplatelet therapy after stenting increases the surgical bleeding risk.
2. The prothrombotic milieu created by surgery and the intermittent hypotension increase the risk of stent thrombosis.

Surgery soon after stenting (2 weeks) may lead to catastrophic results, with a high risk of death and MI. In one analysis, death (mostly secondary to stent thrombosis, and partly secondary to bleeding) occurred in 32% of patients who underwent surgery <2 weeks after stenting, and in 4 out of 5 patients who underwent surgery 1 day after stenting.[9] One or both antiplatelet agents were only briefly interrupted before surgery (~1 day), and interruption of antiplatelet therapy may therefore not have been solely responsible for this high rate of stent thrombosis. Bleeding was also very common, and early post-PCI bleeding is known to be associated with MI and stent thrombosis.

If percutaneous revascularization needs to be performed preoperatively, dual antiplatelet therapy is given and ***surgery is postponed for at least 3 months after drug-eluting stent (DES) for ACS*** (class IIb for clopidogrel interruption at 3 months, per ACC and ESC). ***After non-ACS*** non-high-risk PCI, ESC allows clopidogrel interruption at 1 month with a class IIa. Several trials suggest the safety of discontinuing 1 antiplatelet at 1 month (e.g., MASTER-DAPT trial), but less so if PCI was done for ACS (STOP-DAPT-2 ACS); 3 months appears safer (HOST-BR trial) (Chapter 1, Section VI). ADP-receptor antagonist should be resumed as soon as possible, typically within 48 hours after surgery at a loading dose (ESC) (within 24 hours per ACCP).

If surgery is needed more urgently (<4 weeks) and the patient is having acute large MI, balloon angioplasty is performed without any stenting if possible, and stenting is only done as a bailout for complicated angioplasty. Surgery can be performed 2–4 weeks after balloon angioplasty; there is a risk of acute vessel thrombosis with earlier surgery.

V. Unplanned surgery that needs to be performed soon after stent placement

- If a time-sensitive surgery needs to be performed earlier than 3 months after DES placement, especially 1 month, try to perform the surgery while the patient is still on dual antiplatelet therapy.
- Dual antiplatelet therapy does not usually need to be held before dental procedures.
- Except for aortobifemoral bypass surgery, peripheral vascular surgery (femoropopliteal bypass, CEA) may be performed under a dual antiplatelet regimen.
- Gastrointestinal endoscopic procedures:
  - Gastroscopy, colonoscopy with biopsies, and ERCP with endoprosthesis placement may be performed under dual antiplatelet regimen.
  - Polypectomy or ERCP with sphincterotomy may be done under aspirin monotherapy.
  - Endoscopic gastrostomy tube may require holding both antiplatelet agents.
- Aspirin monotherapy increases major surgical bleeding, but only mildly (<1%). The risk is more dramatic during certain surgeries, such as intracranial surgery and posterior chamber ophthalmic surgery, where it definitely needs to be withheld, and during transurethral prostatectomy, where some protocols suggest it may nonetheless be continued.

The perioperative risk of MACE is highest in the first 30–45 days after BMS or DES stenting (10–20%), then is reduced to ≤5% (~3%) beyond 45 days for both BMS and DES, with ~1.5% risk of stent thrombosis (low in absolute numbers, but much higher than the natural incidence of stent thrombosis during this post-PCI period).[10–13] With second-generation DES, data suggest that the risk of stent thrombosis with clopidogrel discontinuation 6 months after PCI is very low, likely even 1 month, especially if DES was implanted for stable CAD rather than ACS (stenting of STEMI carries the highest risk of stent thrombosis).[14] Surgery 1–6 months after DES placement carries an increased but not dramatic risk of MACE (~4–5% MACE, with 2% stent thrombosis, despite the interruption of clopidogrel in the majority of patients reported).[10,11]

If clopidogrel is discontinued perioperatively within 1–6 months after DES placement, resume it as soon as possible after surgery, using a 300 mg load. In fact, when clopidogrel is interrupted beyond the first month after PCI, stent thrombosis typically occurs >7 days after interruption, if at all.[14–16] Therefore, brief interruption of clopidogrel beyond the first month after DES placement, when inevitable, is usually safe.

Always ensure that at least 1 antiplatelet agent is continued throughout surgery, regardless of the type of stent used and even if surgery is performed >6 months after PCI. There is a lifetime risk of stent thrombosis upon discontinuation of both antiplatelet agents.

Bridging with IV glycoprotein IIb/IIIa inhibitor (GPI) or cangrelor has been suggested, starting 2 days after clopidogrel discontinuation until 12 hours before surgery. However, no evidence supports this strategy. Since GPI or cangrelor is not used during surgery and postoperatively, i.e., during the highest-risk period, the risk of stent thrombosis may not be reduced. Moreover, the bleeding risk makes it unfavorable in most situations. This strategy may be reserved for individual high-risk situations (ESC and ACC class IIb).

VI. Preoperative β-blocker therapy and SGLT-2 inhibitor

In the POISE trial, the initiation of a high β-blocker dose in the immediate preoperative period (<24 hours) without proper titration increased the risk of hypotension, stroke, and mortality, even in high-cardiac-risk patients with CAD or PAD, despite the reduction of postoperative MI.[17] As such, ACC guidelines do not recommend the routine initiation of β-blocker in any risk group preoperatively. If needed for a new indication such as AF or angina, it should be slowly initiated far enough from surgery (optimally >7 days). Only patients who are on a chronic β-blocker are given a class I recommendation to continue it.

ESC guidelines allow the initiation of a β-blocker in patients undergoing high-risk surgery with high Lee risk score, or patients with CAD or high-risk stress tests, as long as it is initiated and titrated slowly >1 week preoperatively with a target heart rate 60–70 bpm (class IIb).[18]

SGLT-2 inhibitors should be stopped 3–4 days before planned surgery to reduce the risk of perioperative metabolic acidosis.

VII. Other interventions that improve outcomes

A. Statin therapy

In addition to improving long-term outcomes, the perioperative use of statins decreases the immediate postoperative cardiovascular events. High-risk patients who initiated statin therapy at a median of 37 days before vascular surgery had >50% reduction of their postoperative cardiovascular events, including death and MI.[19] A meta-analysis of randomized trials that initiated statin preoperatively, often for ≥2 weeks, showed a similar benefit (class I in patients at high surgical risk or high 10-year CV risk).[19]

B. Aspirin

In the POISE-2 trial, aspirin provided a reduction of thrombotic events in patients with prior PCI, but not in all-comers with high-risk features, such as diabetes, CKD, PAD, vascular surgery, stroke, or stable CAD with no prior PCI (carotid endarterectomy was excluded from POISE-2).[20,21] Aspirin caused a 25% relative increase in bleeding risk (~0.8% absolute increase).

C. Optimize the volume status of patients with HF

Always look for S_3, high JVP, and pulmonary edema, and treat any volume overload preoperatively.

HF patients are at a particularly high risk of developing pulmonary edema during the ***stress of extubation***. Positive-pressure ventilation reduces both LV preload and afterload, providing optimal loading conditions. Conversely, extubation is a major stressor associated with a sudden rise of both preload and afterload, and a risk of myocardial ischemia or HF decompensation.

VIII. Severe valvular disease

Patients with severe, symptomatic valvular disease should generally undergo valvular surgery before elective non-cardiac surgery. The perioperative risk is highest with symptomatic AS.

In asymptomatic severe MR, AI, or MS not meeting surgical indications, elective non-cardiac surgery may be performed with attention to volume and rate control (avoid tachycardia with MS and bradycardia with AI) (class IIa recommendation).

In asymptomatic severe AS, elective surgery may be performed without a significant increase in the risk of death or MI (class IIa). In one series, the perioperative rates of death and MI were 0% and 3%, respectively. These patients frequently developed intraoperative hypotension and required vasopressors.[22]

Patients with severe symptomatic AS who cannot undergo valvular surgery – because of comorbidities or patient refusal – can undergo non-cardiac surgery with an acceptable risk. In the combined results of 2 series, 2 of 36 patients with severe and mostly symptomatic AS died late postoperatively (aortic valve area ~0.6 cm^2, EF mostly normal). No death occurred intraoperatively. Careful volume control, aggressive BP monitoring, often with an intra-arterial line, and prompt therapy of hypotension with vasopressors are required.[23,24] Reduction of preload and systemic vascular resistance should be avoided. The severe fixed obstruction prevents an increase in cardiac output should systemic vasodilatation occur, which precipitates severe hypotension.

On a similar note, patients with symptomatic HOCM do well with non-cardiac surgery, with a very low mortality risk, but have an increased risk of postoperative HF.[25] BP should be carefully monitored and afterload and excessive preload reduction avoided. This implies appropriate volume control and the use of phenyleprine as needed.

IX. Perioperative hypertension and perioperative management of ACE inhibitor/ARB and other antihypertensives

Appropriate HTN control is necessary to prevent perioperative myocardial ischemia. Patients with severe HTN are more prone to intraoperative hypotension than normotensive patients; this may be related to the heightened vascular resistance that suddenly drops with anesthesia, or to the impaired vascular compliance, which makes the systemic pressure quickly rise up but also quickly fall with volume fluctuations. Perioperative ACE-I/ARB may exaggerate this intraoperative hypotension. ACE-I/ARB may be withheld the morning of surgery or the prior evening then resumed as soon as possible postoperatively if the patient is hemodynamically stable. However, the POISE-3 trial randomized hypertensive patients to hold ACE-I/ARB +/– other drugs the night before or morning of surgery vs. continue those drugs perioperatively (intraoperative mean BP goal ≥80 mmHg vs. ≥60 mmHg, respectively). Major vascular complications were similar between both groups. STOP-or-not trial showed that ACE-I interruption reduces intraprocedural hypotension, but major clinical outcomes were similar in the interruption vs. no interruption groups. Thus, holding ACE-I/ARB did not translate into improvement of cardiovascular or renal outcomes in trials. As such, ACE-I/ARB may be held in patients whose BP is tightly controlled on preoperative assessment (e.g., SBP <110–120 mmHg), AND who either (i) are undergoing higher-risk surgery, where BP swings are expected, OR (ii) have a high cardiac risk where hypotension would be poorly tolerated (e.g., AS, severe CAD). In HFrEF, continuation of ACE-I/ARB is favored.

Thiazide diuretics are typically held the day of surgery (ESC) and resumed 1 or 2 days later. In HF patients, loop diuretics may be continued throughout surgery to reduce the risk of postoperative HF, unless HF is very well compensated with no recent HF hospitalization.

X. Preoperative management of patients with pacemakers or ICDs

See Chapter 14, Section VII.

XI. Postoperative troponin rise: MI and MINS

Among higher-risk patients who get troponin checked at baseline and postoperatively, an isolated rise in troponin is called MINS (myocardial injury after non-cardiac surgery) and is associated with increased 30-day cardiac events. However, it does not dictate any cardiac workup or therapy, except statin and risk factor control. +/– Consider dabigatran, class IIb, based on the MANAGE trial, where dabigatran started 5–7 days postoperatively reduced thromboembolic events in MINS, with no effect on mortality. Alternatively, antiplatelet therapy may be considered.

Postoperative MI, defined as troponin rise along with clinical MI features (pronounced chest pain, dynamic ST segment shifts, segmental echo abnormalities) may be type 2 MI or type 1 NSTEMI. The severity and persistence of the clinical features, as well as the severity of hs-troponin rise (e.g., troponin T > 300–400 ng/L), suggest postoperative type 1 MI or type 2 MI with underlying CAD. The latter 2 are difficult to distinguish in the postoperative setting and are often managed similarly. Coronary angiography *may be* considered in patients with: (i) severe or persistent/recurrent chest pain, or (ii) severe or recurrent ST depression, or (iii) new, large wall motion abnormality, (iv) after addressing the bleeding risk (class IIa).

XII. Perioperative management of warfarin and NOACs

See Chapter 10, Appendix 5.

XIII. Prior stroke or TIA

In patients with a history of stroke or transient ischemic attack, try to delay elective surgery for >3 months after the most recent cerebrovascular event to reduce the risk of recurrent stroke (ACC class IIa).

QUESTIONS AND ANSWERS

Question 1. A 65-year-old diabetic patient is planning to undergo elective cholecystectomy for recurrent postprandial pain. He has mild dyspnea on exertion (>4 METs) but no chest pain. He undergoes preoperative testing with a nuclear SPECT, which shows severe inferior ischemia and preserved LVEF. Coronary angiography shows 80% mid-RCA stenosis. What is the next step?

A. Aggressive medical regimen. Revascularization is not indicated. His surgical risk is intermediate but revascularization will not improve his surgical risk
B. Aggressive medical regimen. Revascularization is not indicated. His surgical risk is low
C. Aggressive medical regimen and PCI of the RCA with BMS
D. Aggressive medical regimen and PCI of the RCA with DES

Question 2. A 70-year-old diabetic man is found to have colon cancer and will need to undergo colon resection. He has been weak and minimally active for the last few months (<4 METs). He does not have angina or prior HF; he has HTN and CKD. What is the next step?

A. Considering his low METs and his Lee risk score, he needs preoperative stress testing
B. Proceed with surgery with optimal statin and β-blocker therapy

Question 3. The patient of Question 3 underwent stress testing, which showed moderate anterior ischemia. Coronary angiography is performed and shows 70% mid-LAD stenosis. What is the next step?

A. PCI of LAD with BMS and colon surgery in 6 weeks
B. Proceed with surgery with optimal statin and β-blocker therapy, and careful perioperative monitoring

Question 4. A 70-year-old patient has a history of mid-LAD DES (everolimus stent) placed 6 weeks previously for stable angina. His angina has resolved. He now develops abdominal pain and is found to have cholecystitis with abscess formation. The surgeon wants to perform cholecystectomy during this hospital stay and wants to discontinue clopidogrel. What is your recommendation?

A. Try to postpone surgery until 3 months after the PCI date
B. Perform surgery under dual antiplatelet therapy
C. May interrupt clopidogrel for 5–7 days, then resume it the second day postoperatively

Question 5. A patient had a TIA yesterday, manifesting as aphasia. His carotid ultrasound and CT show 80% left internal carotid stenosis. CEA is planned. He has a history of exertional chest pain for the last 6 months. His troponin I is negative. What is the best strategy?

A. Proceed with CEA as soon as possible, without any cardiac workup
B. Perform preoperative stress testing
C. Perform preoperative coronary angiography

Question 6. A patient had a TIA, manifesting as aphasia, yesterday. His carotid ultrasound and CT show 80% left internal carotid stenosis. He also experienced resting chest pain and had a mild troponin rise. Coronary angiography is performed and shows 80% proximal LAD and 80% mid-RCA stenoses. What is the best strategy?

A. Proceed with CEA without coronary revascularization
B. Simultaneous CEA–CABG
C. Coronary stenting followed by CEA within the same hospital stay
D. Coronary stenting followed by CEA in 1 month
E. Coronary stenting and carotid stenting within the same hospital stay

Question 7. A 65-year-old patient, smoker, has severe bilateral claudication with non-healing ulcer and rest pain of the left foot. He does not report any angina, but his activity is limited. Angiography shows occlusion of both common and external iliacs (TASC D lesions). He is

referred for aortobifemoral bypass grafting. A preoperative nuclear stress test shows anterior ischemia, and a subsequent coronary angiography shows 80% mid-LAD stenosis. Rank these 3 management strategies in order of preference:

A. Stent the LAD with BMS, then perform aortofemoral bypass surgery in 4 weeks
B. Proceed with aortofemoral bypass surgery without any LAD stenting
C. Reconsider the percutaneous treatment option for iliac disease, even it was deemed anatomically unfavorable

Answer 1. A. The patient does not have a clear angina. The inferior ischemia implies that the patient has an increased surgical risk, including a risk of functional ischemia/infarction of the RCA territory during surgery. However, except for active MI, left main disease or extensive 3-vessel CAD, preoperative revascularization does not change postoperative cardiac complications. Medical therapy with a statin and a β-blocker, initiated more than a week before surgery, and careful perioperative monitoring are the strategies that improve outcomes. If PCI is performed, surgery will have to be postponed >1 month.

Answer 2. B. The patient has a Lee risk score of 3 and a functional status <4 METs, which may seem to qualify him for preoperative stress testing. However, this recommendation is only class IIb and preferably avoided, and testing is only performed if it will change management, i.e., if surgery can be deferred and if preoperative revascularization is feasible. Preoperative testing is much less useful in a patient who requires a necessary, vital surgery, where delays are unacceptable and where the potential peri-PCI antithrombotic therapy will make the active cancer bleed.

Answer 3. B.

Answer 4. C. The patient has an active condition that may not allow a 3-month surgical delay. Since the bleeding risk is increased with dual antiplatelet therapy and may not be accepted by the surgeon, and since PCI is over 1 month old, clopidogrel may be interrupted and resumed soon after surgery. With second-generation DES, the risk of stent thrombosis with brief clopidogrel interruption (<10 days) beyond 1 month of PCI is low, and does not seem different from the risk with BMS (based on 3 trials).

Answer 5. A. Stress testing soon after a stroke or TIA may not be safe, particularly in light of the BP swings that accompany stress testing. The stroke risk is high in the early period after TIA, implying a prompt need for surgery. Coronary revascularization at this time is not indicated. More specifically, coronary stenting followed by surgery within the ensuing 2–4 weeks may lead to catastrophic outcomes. It is best to proceed with CEA without the delays of cardiac workup or revascularization.

Answer 6. E. The patient has 2 active conditions: ACS and cerebrovascular event. Surgery for one may worsen the other. Stenting for both conditions, if anatomically feasible, likely presents less risk than surgery. Simultaneous CEA–CABG is associated with a high risk of stroke and mortality, in comparison with sequential CEA–CABG, and should be avoided if possible.

Answer 7. C > B > A. While TASC D iliac lesions are preferably treated surgically, they often can be treated percutaneously by experienced operators, in a high-surgical-risk patient. In this patient, percutaneous therapy is the safest strategy from a cardiac standpoint. If percutaneous therapy fails or is deemed impossible, bypass surgery should be performed as soon as possible in this patient with critical limb ischemia. As per CARP trial, stenting does not improve perioperative outcomes and only delays surgery. Yet, as per CARP trial and registry analyses, the highest-risk patients, probably left main or 3-vessel disease patients, may benefit from preoperative revascularization. Hence, if the patient only had claudication and surgery could be delayed, stenting the LAD with BMS or DES and waiting 1 or 3 months, respectively, might be acceptable.

1. CARDIAC MASSES

I. Differential diagnosis of a cardiac mass

The differential diagnosis of a cardiac mass includes 4 entities: (1) echo artifact or normal variant; (2) thrombus; (3) vegetation; (4) cardiac tumor (Table 30.1).

A *thrombus* usually occurs at specific cardiac locations in association with specific cardiac conditions (LV apex in patients with apical akinesis, right-sided chambers in patients with pacemaker leads). A *vegetation* arises from the free edge of a valve, on the side of the upstream chamber, and may occasionally involve the subvalvular apparatus; when large and visible, it is usually associated with a significant valvular regurgitation. A *myxoma* usually originates from the interatrial septum through a stalk, while a *fibroelastoma* often originates from the free edge of a valve, on the side of the downstream chamber.

II. Cardiac tumors; focus on atrial myxoma

A. General features

About 85% of primary cardiac tumors are benign, and of those, myxoma is the most common subtype. The relative frequency of *myxoma* in pathological and surgical series is 50% of all primary tumors (~50–75% of benign tumors).[1,2] The second most common cardiac tumor is *papillary fibroelastoma* (involves the mitral or aortic valve). Other benign cardiac tumors include lipomas, rhabdomyoma, and hemangiomas. Most valvular tumors are papillary fibroelastomas. Primary malignant cardiac tumors are very rare and include angiosarcoma, the most common type, and rhabdomyosarcoma.

Secondary metastatic malignancies are 20 times more common than primary cardiac tumors. However, these malignancies often involve the pericardium leading to effusions, less commonly involve the myocardium, and least commonly involve the endocardium.[3] In fact, a cavitary or endocardial mass is usually a primary cardiac tumor rather than a metastatic malignancy. Renal cell carcinoma is an exception that masquerades as a right-sided endocardial mass.

Cardiac myxomas, more specifically, are characterized by polygonal cells in an extracellular matrix of acid-mucopolysaccharides. They are thought to arise from remnants of subendocardial primitive mesenchymal cells in the fossa ovalis and endocardium.[4] Anatomically, myxomas typically originate from the interatrial septum (fossa ovalis) and extend into the LA (75%) or RA (15%) (Figures 30.1, 30.2).[5,6] About 3–4% of myxomas arise from the LV or RV wall. Rarely, atrial myxomas may arise from the mitral valve or the atrial wall. Myxomas are present at multiple locations in 5% of patients, more so in familial cases.

Table 30.1 Echocardiographic features allowing the differential diagnosis of a cardiac mass.

1. **Variants or artifacts**
   - RA: Eustachian valve, Chiari network, crista terminalis
   - LA: calcified aortic valve projecting inside the LA (beam width artifact)
   - Aortic valve: nodules of Arantius, Lambl excrescences[a]
   - Mitral valve: thick myxomatous valve, elongated chordae, flail chordae
   - RV: moderator band (between apex and septum)
   - Interatrial septum: lipomatous hypertrophy of the septum secundum sparing the fossa ovalis (dumbbell-shaped)
2. **Features favoring cardiac thrombus**

   Thrombus occurs in association with specific cardiac conditions at the following locations:
   - LA appendage in atrial fibrillation
   - LA appendage ± main LA in mitral stenosis
   - LV in case of apical akinesis
   - Prosthetic valve
   - Right-sided pacemaker leads or indwelling catheters
   - Right heart in case of venous thrombus in transition
3. **Features favoring a vegetation**
   - Originates from a valve, usually the free edge of a valve, on the upstream side (LA in mitral endocarditis, LV in aortic endocarditis). May rarely come off the chordae, or the LA wall if underlying MR is present
   - Significant valvular regurgitation is usually present with a large vegetation
   - Abnormal valvular structure (abnormal baseline structure ± valvular perforation or distortion related to the infectious process)
   - Morphology: irregularly shaped, highly mobile. Motion chaotic, does not track the leaflet motion (sometimes opposite)
4. **Features favoring a cardiac tumor**
   - ***Myxoma*** originates from the interatrial septum through a narrow stalk and extends into LA (75%) or RA (15%). Myxoma may also originate from RV or LV

     Morphology: myxoma is mobile, irregularly shaped ("grape cluster" appearance) with lucencies ± calcifications. This morphology may simulate vegetation. Unlike vegetation, myxoma may also be round and smooth-surfaced
   - ***Fibroelastoma*** originates from the aortic or mitral valve, mitral chordae, or papillary muscles. It is most often on the downstream side of the valve without significant regurgitation (≠ vegetation). At the aortic level, it may simulate Lambl excrescence but is larger (0.5–2 cm)

[a]Nodules of Arantius are small fibrous thickenings of the aortic leaflets edges, at the points where the leaflets abut. Lambl excrescences are small fibrous fibers arising from the edges of the aortic valve leaflets, mostly seen in patients older than 40 years.

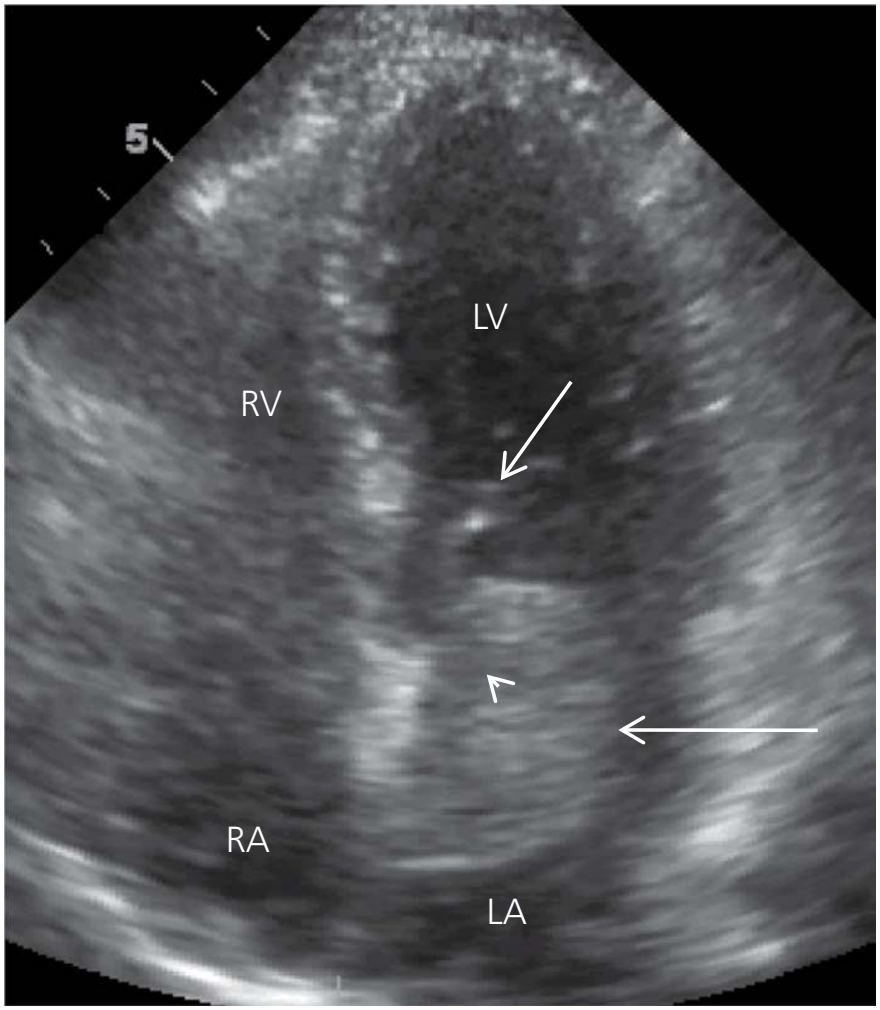

Figure 30.1 Apical 4-chamber view showing a large left atrial mass (*horizontal arrow*). The mass does not seem to originate from the mitral valve (*oblique arrow*). It is round, smooth-surfaced with areas of lucencies (*arrowhead*). This is consistent with left atrial myxoma rather than vegetation.

Figure 30.2 3D echocardiography of the aortic valve showing: (i) on the left: Lambl excrescence of the left coronary cusp, which has the appearance of a thin fibril or filament at the edge of the cusp (*arrow*); (ii) on the right: fibroelastoma of the RCC, which has the appearance of a round nodule (*arrow*).

B. Clinical presentation and diagnosis of myxoma

The median age at the time of diagnosis is 50–60 years, with an age range of 15–80 years and a slight female predominance.[5] Most patients are symptomatic at the time of diagnosis (85%). Three types of symptoms are encountered:

I. Obstructive signs and symptoms that result from the tumor obstructing the mitral inflow (70% of patients). This leads to paroxysmal dyspnea or syncope that may occur with specific body positions. A diastolic tumor plop may be heard, simulating S_3.
II. Peripheral embolization of the friable myxoma (in 30% of patients, cerebral in two-thirds of them). This is more common with lobulated than round tumors. One study found more emboli with smaller tumors.[5]
III. Constitutional symptoms, such as fever, rash, or weight loss (in 30% of patients, related to interleukin-6 release by the myxoma).

On echo, myxoma is characterized by an irregular shape with a "grape cluster" appearance, but it may also be round, smooth-surfaced. It is non-homogeneous, with areas of lucency (corresponding to hemorrhage) and sometimes calcifications.

The diagnosis is usually established by the typical location and echocardiographic features (Figure 30.1). TEE helps confirm the diagnosis, as it shows the narrow stalk originating from the fossa ovalis, defines whether there is valvular invasion, and excludes multiple masses, which is important for surgical planning. MRI may also be used for that purpose; in light of its high extracellular water content, myxoma has a high intensity on T2 images.

C. Treatment

Treatment of cardiac *myxomas* is surgical. Despite being a benign tumor, a myxoma is potentially lethal because of intracavitary or valvular obstruction, embolization, and induction of conduction and rhythm disturbances, all of which may occur while awaiting surgical correction. Therefore, surgery is usually performed promptly, or urgently in some series, after the diagnosis is made. Recurrence may occur in case of incomplete resection, intraoperative dissemination, or growth from a new focus, and is seen in 1–3% of sporadic cases (~20% of familial cases), mostly in the first 4 years after resection.[7]

Valvular *fibroelastomas* also appear to have a significant embolization risk, and warrant removal in case of a prior embolic event, large size ≥ 1 cm, or mobility. Furthermore, aortic fibroelastoma may prolapse across the left main and obstruct it, causing sudden death.

Rhabdomyoma is the most common pediatric cardiac tumor. It may occur sporadically or in conjunction with tuberous sclerosis. It generally arises from the ventricular myocardium and regresses spontaneously (very good prognosis).

2. PREGNANCY AND HEART DISEASE

Pregnancy is associated with a 50% increase in blood volume and with reduced systemic and pulmonary vascular resistances. Preload is increased while afterload is reduced, which leads to increased stroke volume. In addition, heart rate increases by 20%. All this increases cardiac output by 40–50%. The increase in blood volume and cardiac output peaks in the second trimester (24 weeks) then plateaus.[8] Cardiac output decreases with supine position (caval compression) and increases with lateral position. Both SBP and DBP decline, reaching a nadir in mid-pregnancy, with a more marked drop of DBP (from the reduced vascular resistance). Systemic vascular resistance starts to rise in the third trimester, at which time BP slightly rises, although it remains lower than pre-conception, and cardiac output stops increasing.

Cardiac output further increases during labor and delivery and in the postpartum (60–80%), partly because of the high adrenergic tone, and partly because each uterine contraction pumps blood into the intravascular space. More specifically, depending on the stage of labor:

- *1st stage of labor:* pain and uterine contractions raise cardiac output. Specifically, **uterine contractions empty uterine blood in the systemic circulation and raise preload.** Epidural analgesia reduces pain and attenuates the rise in CO, which nonetheless continues to rise from uterine contractions.
- *2nd stage of labor (delivery):* the greatest hemodynamic changes of vaginal birth occur during this stage, when the patient is pushing to deliver the infant. CO, BP, and afterload ↑ with the pushing effort and the uterine contractions, and preload also ↑ with uterine contractions. Valsalva may have a countereffect reducing preload and CO, creating hemodynamic fluctuations (however, the Valsalva effect is likely not pronounced). Assisted second stage (e.g., forceps) attenuates those fluctuations.
- *After delivery:* **preload further increases** as IVC compression is relieved and as **blood leaves the congested uterus over the next 1–3 days ("autotransfusion")**. Thus, cardiac output continues to rise after delivery. Preload may also transiently decrease with bleeding, and this is more likely to occur with cesarean delivery as it incurs more blood loss (1000 ml vs. 500 ml). The eventual increase in preload explains how pulmonary edema may occur in the first few days after delivery. **Hemodynamic changes mostly resolve within 2 weeks after delivery**, but may take up to 2–3 months for full normalization, hence close monitoring is needed during this period.

Overall, vaginal delivery causes and requires a higher CO because of the effort and the pain. Conversely, **cesarian delivery does not require the effort and rise in CO. It tends to drop BP/afterload** because of the more robust and higher neuraxial anesthesia (→ vasoplegia) **and to drop preload** because of more blood loss (→ less preload). Cesarian delivery, with its inherent drop in afterload and preload and more limited CO rise, is likely more tolerated in decompensated HF with florid preload and limited CO reserve, while vaginal delivery is more tolerated in compensated cardiac conditions, especially preload-dependent stable conditions such as severe AS without active HF.

A loud S_1, an S_3, and a mild midsystolic murmur (2 or 3/6) may be normally heard. A mild RV heave and a displaced apical impulse may be felt.

A persistently split S_2, an S_4, a loud systolic murmur, or any diastolic murmur are abnormal.

BNP and NT-pro-BNP levels do not significantly change in pregnancy, except for a slight rise in the immediate postpartum, and remain reliable markers of HF or cardiac dysfunction.[8]

I. High-risk cardiac conditions during which pregnancy is better avoided[9]

A. Eisenmenger syndrome, or primary or secondary severe pulmonary hypertension

Severe pulmonary hypertension is associated with a 30–50% maternal mortality and is an absolute contraindication to pregnancy.[9,10]

B. Severe AS, even if asymptomatic

During pregnancy, the increased preload may lead to pulmonary edema, while the striking afterload reduction in a patient with fixed obstruction and fixed cardiac output may lead to hypotension and collapse.[11] This may even be more prominent around delivery, when a sudden increase in preload may occur. In patients planning to conceive, severe AS should be corrected before pregnancy, even if asymptomatic (class IIa); patients with non-calcified AS may be treated with percutaneous valvuloplasty to avoid the hazard of prosthetic valves. If AS is discovered during pregnancy, percutaneous valvuloplasty may need to be performed in patients who develop severe symptoms.

Pregnancy is risky even in asymptomatic patients. Yet, a subset of asymptomatic severe AS patients may have a low mortality during pregnancy without the need for valve intervention; this subset consists of patients who are asymptomatic on stress testing with good functional capacity and BP response, and normal BNP. Pregnancy may be considered in these patients (class IIb).[9]

C. Severe MS, even if asymptomatic

The increased preload and tachycardia associated with pregnancy exaggerate the transmitral gradient, particularly in the third trimester and during delivery.[11] In patients planning to conceive, MS should be corrected before pregnancy, even if asymptomatic with no standard indication for PMBV (class IIa). Otherwise, if pregnancy occurs before correction, β-blockers and judicious doses of diuretics are used during pregnancy. PMBV may need to be performed in pregnant patients with uncontrolled symptoms.

D. Any cardiomyopathy or valvular disease with EF <30% or NYHA III/IV

In one study, patients with dilated cardiomyopathy (mostly idiopathic) and moderate or severe LV dysfunction or NYHA class III/IV had a 70–80% risk of cardiac events during pregnancy or postpartum. These consisted mainly of HF decompensations, arrhythmias (AF, atrial flutter), and 1 transient ischemic attack (among 18 patients). These complications were managed medically and no maternal death occurred; 1 fetal death occurred during maternal pulmonary edema.[12,13] Pregnancy also appeared to increase HF events over the next year (vs. matched non-pregnant women). Another DCM registry similarly showed a high rate of maternal complications during pregnancy, with no maternal death during pregnancy but with 10% fetal loss and 10% late maternal mortality 2–12 months later (from HF).[12] Pregnancy is preferably avoided in these patients, but some patients may want to proceed in light of the limited mortality risk. Those who proceed with pregnancy may continue β-blocker therapy, hydralazine, digoxin, and low-dose diuretic; ACE-I and aldosterone antagonists are stopped.

E. Aortic root dilatation ≥ 45 mm (surgery before pregnancy is generally recommended)

F. Complex cyanotic congenital heart disease (tetralogy of Fallot, Ebstein, Fontan circulation)

Cyanosis, by itself, reduces fetal growth, particularly when arterial O_2 saturation is <85% at rest or stress. In the absence of HF or ventricular dysfunction, the maternal risk may be low, but the fetal risk is always high when O_2 saturation <85%. In fact, fetal survival is only 12% in the latter case. In corrected tetralogy of Fallot, carefully assess for any residual defect before giving advice about the safety of pregnancy. In the absence of significant VSD, pulmonic stenosis, or pulmonic regurgitation, and in the case of a normal PA pressure and RV function, pregnancy is well tolerated. In a Fontan patient with normal ventricular function, no cyanosis, and no significant valvular regurgitation, pregnancy may be possible.

Patients with any of the above conditions (A–F) should be counseled against pregnancy, unless the condition is a valvular condition (MS or AS) that is corrected before conception. On the other hand, if an unplanned pregnancy occurs, early termination is considered in some, but not all of these conditions. Early termination is most definitely considered in patients with severe pulmonary hypertension, severe LV dysfunction that is also severely symptomatic, cyanosis with hypoxemia <85%, or prior peripartum cardiomyopathy with persistent LV dysfunction. Conversely, severe AS, severe MS, or compensated LV dysfunction may be managed at a tertiary center without termination, with close follow-ups and medical therapy (+ procedural therapy, if needed for AS and MS); termination may be considered if severe symptoms develop early on, in the first trimester.

II. Cardiac conditions that are usually well tolerated during pregnancy, but in which careful cardiac evaluation and clinical and echo follow-up are warranted[9]

A. ASD, even if a large left-to-right shunt is present with RA and RV enlargement.[14] In pregnancy, the systemic resistance decreases more than the pulmonary resistance, which may reduce the left-to-right shunt. Closure before pregnancy is preferred, but pregnancy should be allowed to continue if a large ASD is diagnosed during pregnancy, as complications are uncommon.[14,15]

B. Small VSD; small PDA.

C. Severe asymptomatic TR, even if RV and RA are mildly dilated, as long as RV function is preserved.

D. Severe MR and AI are usually well tolerated when LV function is normal and the patient is asymptomatic. This is because pregnancy is associated with reduced afterload and increased heart rate (reduces AI symptoms). The increased preload may, however, accelerate LV dilatation and warrants careful monitoring. Exercise testing is recommended before pregnancy to confirm the asymptomatic state.[9] While mitral valve repair is appropriate in asymptomatic severe MR due to posterior leaflet prolapse, the decision is more nuanced in the asymptomatic woman planning pregnancy. In such case, the surgical intervention may be deferred, as any intraoperative failure of repair would necessitate mitral valve replacement, with its inherent pregnancy risks.

E. Mild or moderate asymptomatic AS.

F. Severe pulmonic stenosis. In the absence of RV dysfunction, pulmonic stenosis is usually well tolerated during pregnancy.

G. Hypertrophic obstructive cardiomyopathy. While afterload reduction may increase the LVOT gradient, the increase in preload counteracts it, and pregnancy is usually well tolerated in HOCM with very low maternal mortality. Symptoms, if present, are controlled with β-blockers. ESC and WHO consider HOCM with LVOT gradient >50 mmHg a high-risk condition during pregnancy. However, data and ACC HCM guidelines demonstrate that pregnancy is generally safe in HOCM, with very low maternal mortality (0–0.2%) and extremely low risk of sudden death. ~25% of patients have controllable cardiac events during pregnancy, such as worsening of symptoms, HF, or arrhythmia (AF ~4%), with no difference between those with or without LVOT obstruction.[16,17]

H. Marfan syndrome with aortic root <4 cm. Two studies showed no fatality during these patients' pregnancy and no significant acceleration of aortic dilatation.[18,19] β-blockers are administered during pregnancy to reduce aortic growth, and frequent ultrasound surveillance is performed (Q1–2 months). Patients with aortic size of 4–4.4 cm have a significant aortic growth during pregnancy, occasionally a striking growth with a risk of dissection.

I. Milder LV dysfunction (EF 30–45%, or better, >45%) with mild NYHA I–II symptomatology.

J. Long QT syndrome. Pregnancy does not seem to increase arrhythmic events during pregnancy, but it increases them during the 12 months postpartum, especially in LQT2.[9] Consistent β-blockade with nadolol or propranolol reduces this risk.

Note: Antibiotic prophylaxis is not recommended in women with native valvular disease undergoing vaginal delivery, except for a prior history of endocarditis.

III. Cardiac indications for cesarean section

Cesarean delivery attenuates the rise in cardiac output at the price of more blood loss and a decline in afterload compared to vaginal delivery. In fact, a more complete neuraxial analgesia is required for cesarean delivery than labor analgesia because the nerve block must be higher and more dense. Neuraxial analgesia causes sympathectomy, and thus, vasodilatation and BP drop. For cesarean delivery, spinal anesthesia is usually used as it provides a denser and more reliable block, but causes more rapid sympathectomy than a slowly titrated epidural block, although the 2 are sometimes sequentially combined to reduce the dose of intrathecal anesthesia (phenylephrine may be administered during block onset).[20] Also, the larger blood loss causes further hemodynamic compromise. Overall, vaginal delivery causes and requires a higher CO because of the effort and the pain. Conversely, cesarean delivery tends to drop aferload/BP and preload because of the more robust and higher neuraxial anesthesia (→ vasoplegia) and blood loss (a drop in preload is more tolerated in decompensated HF with florid preload). Also, cesarean delivery increases the risk of venous thrombosis. Thus, vaginal delivery with assisted second stage is preferred in the majority of patients; epidural anesthesia is advised to limit the increase in cardiac output in the first stage (unless the patient is anticoagulated). Cesarean delivery is indicated for obstetric reasons and in the following 3 cardiac conditions:[15]

- Unstable aorta >4.5 cm (vaginal delivery is generally recommended for aortas of 4–4.4 cm)
- Warfarin anticoagulation around delivery time (vaginal delivery is associated with a high risk of neonatal intracranial hemorrhage)
- Severe HF or severe AS with active HF and life-threatening symptoms, wherein the limited cardiac output reserve cannot provide the high output required for vaginal delivery and wherein the drop in preload and afterload with cesarean delivery is more readily tolerated

IV. Mechanical prosthetic valves in pregnancy: anticoagulation management

Patients with mechanical prosthetic valves have a strikingly increased risk of valve thrombosis and thromboembolism during pregnancy. One large meta-analysis has shown that even when adequately anticoagulated with warfarin throughout pregnancy, the thromboembolic risk is ~3–4%. *The risk drastically increases when heparin is substituted for warfarin between weeks 6 and 12* (*the risk increases from 3–4% to 6–9%*, even if heparin is only used for 6 weeks), with a doubling of the maternal mortality risk (from 2% to 4%).[21] The thromboembolic risk is much higher if adjusted-dose unfractionated heparin is used throughout pregnancy (25%). Those risks are seen even in modern registries using modern valves and proper heparin and LMWH dosing.[22,23]

Conversely, while warfarin is a much more effective anticoagulant in pregnancy than heparin, it traverses the placental barrier and is associated with a fetopathy risk (mainly bone and facial hypoplasia, sometimes mental retardation) and a risk of spontaneous abortion. This risk mostly results from warfarin administration between 6 and 12 weeks, especially if the required dose is >5 mg/day (risk >30%). The same meta-analysis has shown that when unfractionated heparin is substituted at or before 6 weeks of gestation, the risk of fetopathy is dramatically reduced, at the price of a drastic increase in maternal thromboembolism. The thrombotic risk may be lower with LMWH vs. UFH, when LMWH is adjusted according to anti-Xa levels, but remains high at 4–8% even with adequate anti-Xa levels.[22,23] Heparin is a large molecule that does not traverse the placental barrier, and it is safe from the fetal standpoint.

Thus, continuous intravenous UFH (rather than subcutaneous heparin) or preferably, subcutaneous LMWH with anti-Xa monitoring may be substituted for warfarin as soon as pregnancy is recognized, ideally before 6 weeks, and administered until 12 weeks (both agents receive a class IIa recommendation if the required warfarin dose is >5 mg/day, class IIb if the required warfarin dose is ≤5 mg/day). Warfarin is resumed after 12 weeks, until 36 weeks. Alternatively, when the risk of valve thrombosis is high and the warfarin dose is ≤5 mg, continuous warfarin therapy throughout 36 weeks may be considered and discussed with the patient (class IIa recommendation). The risk of embryopathy is reduced (<3%) when warfarin dose is ≤5 mg, but not eliminated; in these patients, the combined maternal plus fetal risk is lowest with continuous warfarin therapy.

LMWH or IV heparin is started at 36 weeks, at least 1–2 weeks before the anticipated delivery, to prevent the fetal intracranial hemorrhage associated with warfarin (the latter has a longer half-life in the fetus, where it inhibits hepatic vitamin K reactivation). If LMWH is utilized, it is further converted to IV UFH at least 36 hours before planned delivery. The UFH infusion is then stopped 4–6 hours before delivery (ACC valve guidelines). If labor begins or urgent delivery is needed while on warfarin, C-section is done after reversal of maternal anticoagulation (which does not reliably reverse the fetal warfarin effect).

When UFH is used in the substitution period, PTT should be monitored and kept over twice the control. When LMWH is used, anti-Xa activity should be measured 4–6 hours post-injection at least once weekly and kept at 0.8–1.2 units/ml. With warfarin, the INR goal is 2.5–3.5. The addition of aspirin is not specifically indicated for mechanical valve prophylaxis, but it may be warranted for another indication (e.g., pre-eclampsia prevention).

Both warfarin and heparin are compatible with ***breastfeeding***, as none of them is secreted in breast milk (or only in negligible amounts).[24]

V. Peripartum cardiomyopathy (PPCM)

PPCM is LV systolic dysfunction with EF < 45% that develops in the last month of pregnancy or within 5 months postpartum, most commonly the first month postpartum, without any prior heart disease. Hypertension frequently coexists with PPCM and is a risk factor for PPCM. Older age, African American race, multiparity, and multifetal pregnancies are other risk factors. Depending on its severity, hypertension does not necessarily imply a diagnosis of hypertensive cardiomyopathy and is consistent with PPCM.[24,25] In fact, severe acute HTN usually causes pulmonary edema through acute diastolic rather than systolic dysfunction; acute HTN does not usually reduce EF in the absence of a chronic process, hence a low EF suggests PPCM.[26] The pathogenesis of PPCM is multifactorial, involving genetic susceptibility or autoimmune triggers exacerbated by the peak hemodynamic stress of pregnancy. A leading hypothesis implicates the abnormal cleavage of prolactin into a cardiotoxic fragment. Genetic cardiomyopathy testing should be considered.

A. Prognosis, LV recovery

LV function fully recovers in ~50–55% of PPCM cases within 6 months of the diagnosis. Before recovery, however, PPCM is associated with a significant risk of complications, including a mortality of 3–10% (sudden death or HF death, mainly within 6 months of the diagnosis), severe progressive HF requiring heart transplantation in 6%, and thromboembolic complications.[24,25] PPCM may be associated with a higher risk of LV thrombus than other forms of dilated cardiomyopathy, and potentially a higher risk of embolization. This higher thromboembolic risk may be due to the hypercoagulable state of pregnancy and the first 2 postpartum months.

B. Treatment

Similarly to any systolic HF, standard HF therapy is used, even if it is unclear whether this therapy specifically increases the recovery of PPCM. ACE inhibitors are contraindicated during pregnancy but are generally safe during lactation. PPCM is thus treated with β-blockers, hydralazine, digoxin, and loop diuretics during pregnancy, and, additionally, ACE-I and spironolactone in the postpartum, including in breastfeeding women. Since PPCM is associated with a high thromboembolic risk, an expert review suggests anticoagulation therapy until EF improves to over 35%.[24] If PPCM recovers, the sequential tapering and discontinuation of these drugs may be safe >1 year after sustained LV recovery, provided there is no evidence of genetic cardiomyopathy or a positive family history. Afterwards, close monitoring is required, as late deterioration of LV function has been described.[27]

PPCM is associated with a high early risk of sudden death before LV function eventually recovers. Since this risk of sudden death is only transient in patients who eventually recover, a wearable defibrillator vest rather than an ICD is considered in severe cases until LV recovery (class IIb). ICD is indicated in patients who do not recover their LV function within 6 months of medical therapy.

Bromocriptine, which suppresses prolactin production, showed benefit in 11 small studies and their meta-analysis, showing greater EF improvement than standard HF therapy (mean difference 10%) and a trend toward lower MACE and mortality (ESC class IIb). It is given for 1–8 weeks, in conjunction with at least prophylactic-dose LMWH to mitigate its prothrombotic risk.

Breastfeeding is generally avoided in severe cases to reduce metabolic demands and to allow bromocriptine therapy..

Subsequent pregnancies should be avoided in patients with PPCM, particularly in those who do not recover their LV function. In one report, pregnancy was associated with a 20% mortality and 50% risk of worsening of LV function in patients with persistent LV dysfunction; in those who recovered LV function, pregnancy was safer, with no fatality, but a 20% risk of relapse.[28]

VI. Cardiovascular drugs during pregnancy (see Table 30.2)[29]

Table 30.2 Cardiovascular drugs and pregnancy.

- ACE-I, ARB, ARNI, aldosterone antagonists: contraindicated during pregnancy
- Adenosine: safe
- Aspirin 81 mg is safe (higher doses should be avoided as they cause premature PDA closure)
- β-Blockers (labetolol, metoprolol) have been extensively and safely used in pregnancy, but may rarely cause intrauterine growth retardation or neonatal hypoglycemia. Atenolol may be teratogenic and should be avoided. Limited data available for carvedilol
- Calcium channel blockers: less studied than β-blockers, but appear safe. β-Blockers are preferred for arrhythmias. Most experience exists with verapamil and nifedipine
- Colchicine: safe
- Digoxin: safe
- Diuretics: may be used to treat HF. Avoid the aggressive use of diuretics, as they may reduce placental flow
- Amiodarone: crosses the placenta and may cause neonatal goiter. May be used if necessary
- Sotalol, flecainide: relatively safe
- Hydralazine, methyldopa: safe
- Nitrates: may be used in HF, but preferably avoided
- Clopidogrel: probably safe, may be used after stenting, but limited data
- PCSK-9 inhibitors, ezetimibe: contraindicated
- Statins: used to be contraindicated (possible ↑ risk of miscarriage). However, evidence points to the absence of excess teratogenic risk, and statins may be used in high-risk vascular patients per ESC and FDA
- SGLT-2 inhibitor: not safe, contraindicated.
- NOACs: no safety data, contraindicated
- Mavacamtem in HOCM: contraindicated

Lactation: Furosemide and 3 of the 4 main HF drugs (ACE-Is, ß-blockers, and spironolactone) are generally safe during lactation. More specifically, ACE-I is secreted in breast milk in a very small amount, hence it may be used during lactation (captopril, benazepril, enalapril) with close follow-up of the child's weight. β-Blockers (labetolol, metoprolol), digoxin, and hydralazine are only secreted in a small amount in milk, and may be used during lactation. There are no data regarding ARB, ARNI, SGLT-2 inhibitors, and NOAC, hence they should be avoided.

VII. Arrhythmias during pregnancy

Pregnancy is associated with an increased risk of arrhythmias, whether structural heart disease is present or not. There is a significant increase in the risk of SVT, especially in the third trimester (AVNRT, AVRT, incessant atrial tachycardia). AF and atrial flutter are rare during pregnancy and are usually associated with cardiomyopathies, valvular or congenital heart disease, or hyperthyroidism. AF may rarely be seen in healthy pregnancies (lone AF).

Carotid sinus massage is safe in pregnancy. Adenosine, β-blockers, or calcium channel blockers may be used for SVT. DC cardioversion is also safe and may be used, if needed, for hemodynamic instability.

VIII. MI and pregnancy

The risk of MI increases 3- to 4-fold during pregnancy, especially during the third trimester and the first 6 weeks postpartum. The MI is most commonly a STEMI (75%) and usually occurs in patients older than 30. It is associated with a high mortality of 7–11%. In case series where angiography or autopsy was performed, the following processes were found:[30,31]

i. Coronary atherosclerosis with or without thrombosis in 40% of the cases
ii. Coronary artery dissection in 27% of the cases, frequently involving multiple coronary arteries (~50%), and most commonly involving the left main or LAD
iii. Coronary thrombosis without underlying atherosclerosis in ~15%
iv. Normal coronary arteries in 13% (likely coronary spasm)

In a more modern series, coronary artery dissection was the most common cause of pregnancy-related MI (43%).[31] Coronary dissection (SCAD) is relatively more frequent in the postpartum than the antepartum period. *SCAD peaks in the first postpartum month, like PPCM.* Patients with coronary artery dissection have an increased risk of iatrogenic coronary dissection during diagnostic angiography and contrast injections, and a risk of further propagating the dissection during PCI; thus, PCI may be reserved for severe obstruction/occlusion of proximal segments with impaired flow and active ischemia.[31] Also, fibrinolytic therapy is contraindicated in coronary dissection. A history of SCAD, even non-pregnancy SCAD, usually contraindicates future pregnancies because of the high risk of recurrence (Chapter 1, Appendix 7).

IX. Hypertension and pregnancy

A. Types

- Chronic HTN, present before pregnancy or new but arising before 20 weeks of pregnancy. It persists >6 weeks postpartum.
- Gestational HTN: new HTN arising beyond 20 weeks of pregnancy, without proteinuria. It usually resolves within 6 weeks postpartum.
- Pre-eclampsia: new HTN or worsening of a chronic HTN beyond 20 weeks of pregnancy, associated with proteinuria >0.3 g/24 hours or other end-organ damage. Pre-eclampsia, particularly before 34 weeks, is due to endothelial dysfunction and abnormal uteroplacental and systemic vasoconstriction (instead of the normal vasodilatation), which causes placental malperfusion and a reduction of cardiac output. Pre-eclampsia beyond 34 weeks, and especially postpartum, may rather be due to increased cardiac output and hypervolemia, along with vasodilation, a phenotype more commonly associated with obesity, normal fetal growth, and better maternal and fetal outcomes.[32] Risk factors: chronic HTN, prior pre-eclampsia, older age, diabetes, obesity, multifetal gestation, first pregnancy at an older age (*unlike PPCM and SCAD*, where older age but also multiparity are risk factors). The risk is further predicted by low levels of PlGF (placental growth factor).
- Pre-eclampsia with severe features: new HTN or worsening of chronic HTN with one of the following features: BP ≥160/110, thrombocytopenia, HELLP, liver injury, acute kidney injury, seizures/eclampsia.
- Postpartum hypertension or pre-eclampsia: occurs within days to 6–12 weeks postpartum. Prevalence may be as high as 8% in women without antepartum hypertension. It is related to the postpartum autotransfusion (hypervolemia, responsive to furosemide) or the endothelial dysfunction and vasoconstriction that underlies pre-eclampsia.

The large CHAP trial randomized pregnant women with chronic HTN to BP treatment with a target <140/90 vs. treatment initiation only when BP ≥160/105. Treatment was initiated early in pregnancy (~15 weeks). The lower BP target reduced the risk of severe pre-eclampsia without adverse effect on neonatal weight.[33] As such, drug therapy initiation for BP ≥140/90 is reasonable in chronic HTN and is likely reasonable in all hypertensive disorders of pregnancy, including pre-eclampsia (the acute HTN of pre-eclampsia is at least as likely to tolerate BP reduction as chronic HTN). This is given a class I recommendation by ESC HTN guidelines, for both chronic and gestational HTN. But beware of too aggressive BP reduction, as the placenta does not autoregulate blood flow, and thus, acute maternal BP reduction with therapy may cause fetal hypoperfusion.

On the other hand, a 5–10 mmHg physiological reduction of mean BP is seen in the second trimester; thus, in chronic HTN, a dose reduction may be needed in the second trimester.

B. Treatment

Three first-line therapies: methyldopa, β-blockers (especially labetalol), nifedipine. Methyldopa is stopped after delivery as it increases postpartum depression (ESC). Aspirin may be used to *prevent* pre-eclampsia in high-risk patients, such as patients with gestational hypertension or prior pre-eclampsia, or multiple risk factors with low levels of PlGF; it is started at 12 weeks and continued until delivery.

Pre-eclampsia *with severe features* warrants IV magnesium, IV drugs to lower BP <160/110 within 60 minutes (labetalol or nicardipine), and immediate delivery. In pregnancies <34 weeks where BP>160/110 is the sole high-risk feature and the maternofetal condition remains stable, delivery may be delayed 2 days to allow steroid therapy. In pre-eclampsia *without severe features*, ESC recommends delivery at 37 weeks; magnesium *may* also be considered. In gestational HTN, delivery is recommended at 39 weeks.

C. Pre-eclampsia and HF

About 10% of patients with pre-eclampsia develop pulmonary edema, particularly the late hypervolemic phenotype. ***Yet pre-eclampsia, per se, does not induce LV systolic dysfunction, even when assessed by echo strain imaging. Instead, it primarily induces LV diastolic dysfunction and may induce acute diastolic HF*** with elevated LA pressure, RV failure, and elevated BNP in ~10% of cases.[34]

3. HIV AND HEART DISEASE

I. Pericardial disease

Pericardial effusion is the most common cardiac manifestation of HIV infection, with an incidence of 11% per year in patients with CD4 count <200 not receiving antiretroviral therapy. It is usually asymptomatic and small but is seen with lower CD4 counts, which implies a more advanced disease and a 2.2× increase in adjusted mortality despite the usually small size.[35] Patients with a moderate or large effusion may have a high risk of progression to tamponade. Also, a large or symptomatic effusion frequently, in over 50% of the cases, has a specific diagnosis: infectious (tuberculosis, purulent, opportunistic infection) or malignant (especially lymphoma or Kaposi sarcoma).[36]

II. HIV cardiomyopathy

See Chapter 5.

III. Pulmonary hypertension (PH)

The prevalence of pulmonary arterial hypertension (PAH) in HIV is ~0.5%. PH may also be due to lung disease or left HF, which increases the overall prevalence of any PH in HIV, particularly mild PH, up to 30%.[37] As opposed to myocardial and pericardial processes, PAH does not appear to correlate with CD4 count, and was described in patients with CD4 count over 900.[38] Pathologically, lesions are similar to idiopathic PAH (plexiform arteriopathy). PAH results from circulating cytokines or circulating HIV antigens activating endothelial cells. Antiretroviral therapy improves survival but does not clearly have a direct effect on PAH. Epoprostenol and bosentan were effective in small studies.[39]

IV. CAD

Patients with HIV have accelerated atherosclerosis and an almost doubled risk of MI, particularly HIV patients older than 50.[40] The risk of MI is further increased by protease inhibitors, which increase triglycerides and the number of small LDL particles, and reduce HDL. Truncal fat redistribution (lipodystrophy) may occur with HIV regardless of the type of therapy and may lead to metabolic syndrome.

4. COCAINE AND THE HEART

I. Myocardial ischemia

A. Causes

Cocaine induces myocardial ischemia through several mechanisms:

1. α+effect leads to coronary vasoconstriction.
2. Severe HTN and tachycardia increase myocardial O2 demands.
3. Cocaine promotes platelet aggregation and thrombus formation through increased plasminogen activator inhibitor (PAI).
4. Chronic cocaine use promotes atherosclerosis.

All of these effects are strongly promoted by concomitant cigarette or alcohol use (alcohol is synergistic with cocaine). Fifty percent of patients with cocaine-related MI have normal coronaries.

B. Presentation

Chest pain mainly occurs within 1 hour of cocaine use, but can occur up to several hours later (up to 36–96 hours later), because the concentration of active metabolites increases hours later and may lead to delayed vasoconstriction. Between 7% and 20% of patients presenting with chest pain to urban emergency units have a positive cocaine screen.[41]

C. Diagnosis

Approximately 6% of patients with cocaine-associated chest pain have MI (as manifested by elevated CK or troponin), half of whom have normal coronary arteries.[41] The remaining patients have ischemia that is not sustained enough to lead to MI, or non-cardiac pleuritic pain.

MI is difficult to diagnose by ECG, because many cocaine users have an abnormal baseline ECG with ST elevation (early repolarization, LVH). On the other hand, ST elevation can be related to spasm rather than thrombotic occlusion. Thus, ST elevation is sensitive but not very specific in cocaine users.

Cocaine use is diagnosed by a urinary screen of both cocaine and its metabolites. Cocaine half-life is 60–90 minutes, but its metabolites persist 24–72 hours. In chronic high-dose users, cocaine metabolites may be found for up to 2 weeks.

Always think of aortic dissection and rule it out at least clinically and by chest X-ray.

D. Treatment of cocaine-related MI or ischemia

1. Medical therapy

The following 3 treatments are first-line, class I therapies that should be administered to most patients with cocaine-induced chest pain:[42]

1. Aspirin.
2. Nitroglycerin, which reduces vasospasm and hypertension.
3. Benzodiazepines, which reduce the central sympathetic stimulatory effects of cocaine, and thus reduce tachycardia and hypertension.

The following therapies are class IIb therapies that may be used selectively in patients with persistent hypertension or chest pain despite the first-line therapies:

4. Verapamil or diltiazem in the absence of HF, or long-acting dihydropyridine, orally (preferably) or intravenously.
5. Phentolamine (α-blocker) may also be used as a second-line agent for persistent ischemia or hypertension.

Avoid β-blockers acutely. β-Blockers increase vasospasm, as they lead to unopposed α activation. While combined α- and β-blockers may seem safe, labetalol was associated with an increased risk of seizure and death in animal studies, probably because it is much more a β-blocker than an α-blocker; thus, even α/β-blockers should be avoided acutely. Most cocaine users continue to use cocaine after discharge, and chronic β-blocker therapy should therefore be avoided in most patients, except in case of a strong compelling reason, such as LV systolic dysfunction.

2. Role of invasive management and thrombolysis
If chest pain persists despite the first 4 treatments listed above, and ECG shows persistent ST elevation, emergent coronary angiography ± PCI should be performed. Thrombolytics are preferably avoided in cocaine users because of the concomitant hypertension that contraindicates their use, and because ST elevation may be a persistent spasm rather than a thrombus. Yet, as per AHA guidelines, thombolytics may be used in persistent ischemia with a clear-cut ischemic ST elevation despite nitroglycerin, benzodiazepines, and calcium channel blockers, if a coronary angiogram is not available.

3. Role of stress testing
If chest pain resolves with the initial measures and cardiac enzymes are negative, the patient may be discharged after ~3–6 hours (a stress test is optional).

II. Other cardiac complications of cocaine

A. LV dysfunction is seen in 7% of chronic cocaine users. LV dysfunction results from ischemia and/or catecholamine toxicity (contraction band necrosis, tachycardia-mediated cardiomyopathy).
B. Supraventricular or ventricular arrhythmias. Arrhythmias mainly occur in patients with cocaine-induced myocardial ischemia or LV dysfunction.
C. Aortic dissection.
D. Hypertensive crisis. Hypertension may be treated with nitroglycerin, nitroprusside, nicardipine, or phentolamine.
E. Brugada pattern on ECG (RBBB with ST elevation in V_1–V_2).
F. Endocarditis with intravenous cocaine use. The intravenous use of cocaine is associated with a higher risk of endocarditis than the intravenous use of other drugs. Unlike the endocarditis associated with other drugs, the endocarditis of cocaine users more often involves the left-sided cardiac valves than the right-sided valves. This is because cocaine-induced severe HTN and hemodynamic stress impose mechanical injury and endothelial damage on the aortic and mitral valves, priming them for bacterial seeding.

5. CHEST X-RAY

I. Chest X-ray in heart failure (see Figures 30.3, 30.4)

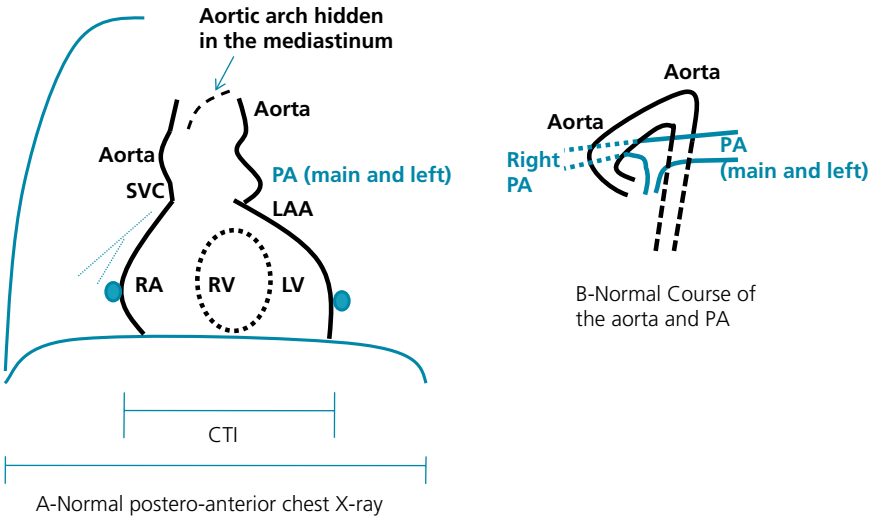

Figure 30.3 (a) Normal posteroanterior chest X-ray. Note that the RV does not have a shadow, and LA does not have a shadow (except for LA appendage [LAA]). The lung vessels are seen in the lower lung fields and do not extend to the outer third of the lungs. The cardiothoracic index (CTI) measures the width of the cardiac silhouette from the outermost right point to the outermost left point (*dots*), and divides it by the widest thoracic cage diameter (usually at the costophrenic angles). **(b) Normal course of the PA and aorta**, explaining how they project on chest X-ray posteroanterior view. The right hilum is slightly lower than the left.

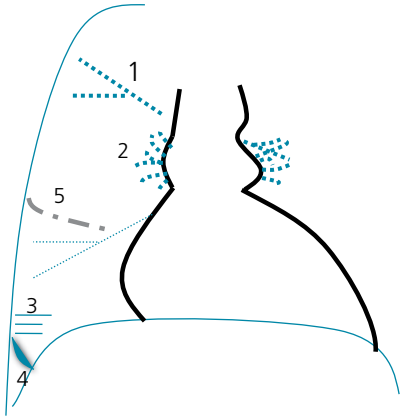

Figure 30.4 Chest X-ray in HF. (1) Cephalization and vessel extension to the outer third of the lung fields; (2) perihilar haziness and peribronchial cuffing; (3) Kerley B lines; (4) right pleural effusion; (5) minor fissure effusion.

A. Early signs of LV failure

a. *Cardiomegaly* (cardiothoracic index >0.5)

b. *Cephalization of pulmonary vessels*. Normally, the pulmonary capillary pressure is low at the upper lobe (~0 mmHg), allowing the alveolar pressure to collapse those capillaries and prevent flow (zone 1); thus, the lower lobe vessels are wider than the upper lobe vessels. In addition, pulmonary vessels do not normally extend to the outer third of the lungs. When the LA pressure increases, the high pulmonary capillary pressure prevents capillary collapse at the upper lobes while creating a leak into the interstitium of the lower lobes. This leak compresses the lower lobe vessels and diverts blood to the upper lobes, which explains why *the upper lobe vessels become at least as wide as the lower lobe vessels*.

c. *Vessels extend toward the outer third of the lung fields and are hazy*. Beware that an underpenetrated CXR may exaggerate pulmonary vascular findings.

B. At a later stage, interstitial pulmonary edema occurs and manifests as:

a. *Perihilar haziness, perivascular haziness, and peribronchial cuffing:* the bronchi, as well as both the hilar and peripheral pulmonary arteries, lose their sharpness and become hazy and "fluffy" from the interstitial edema. The thick bronchial walls may lead to "doughnut-like" densities throughout the lung fields.

b. *Kerley B lines:* represent edema in the interlobular septa and manifest as 1–2 cm horizontal, pleural-based lines, at the lower lungs ("stepladder").

c. *Pleural effusions*, frequently bilateral (60–70%) with a right-sided predominance. Unilateral effusions are more commonly isolated to the right (~20s%) than the left (~10s%).

Normally, the minor fissure, a right-sided fissure, may be seen on the frontal chest X-ray (CXR) view. The oblique fissures are not seen on the frontal view, as the frontal view is parallel to the oblique fissures rather than orthogonal to them. Both fissures may be seen on the lateral view. During HF, edema may be seen in the minor fissure and may collect as a round opacity that simulates a tumor ("pseudotumor") but resolves with diuresis.

C. At the latest stage, alveolar pulmonary edema is seen and manifests as "white" patches, predominantly over the perihilar area ("batwing" appearance).

Note that all of these signs may be absent in patients with chronically elevated PCWP, in whom the lymphatic drainage prevents the occurrence of any edema. Even the heart size may be normal in patients with diastolic HF (LV hypertrophy, restrictive cardiomyopathy). On the other hand, in patients with acute HF, many or all of these signs are present.

The absence of cardiomegaly in patients with radiographic HF implies three possibilities: (i) de novo acute HF (acute MI, myocarditis, acute MR/AI); (ii) diastolic HF (no LV dilatation); (iii) non-cardiogenic pulmonary edema.

The presence of interstitial and/or alveolar edema with sharp costophrenic angles, i.e., without any pleural effusion, argues against HF and favors the diagnosis of non-cardiogenic pulmonary edema or severe bilateral pneumonia.

A radiographic delay of 1–2 days may be seen between normalization of pulmonary capillary pressure and resolution of pulmonary edema. Pleural effusions may take a long time to resolve.

In pulmonary arterial hypertension, the hila are enlarged as in HF, but as opposed to HF, there is constriction and pruning of the peripheral vessels.

II. Various forms of cardiomegaly (see Figure 30.5)

A. False impression of cardiomegaly

CXR is normally taken in full inspiration, in which case the right hemidiaphragm normally projects over the ninth posterior rib or sixth anterior rib. Expiration or supine position makes the heart more horizontal and exaggerates the cardiac silhouette. Also, the cardiac silhouette is exaggerated in anteroposterior imaging (portable CXR), as the source is closer to the heart than in posteroanterior imaging. Supine positioning, anteroposterior imaging, and expiration exaggerate the cardiac silhouette and the vascular markings, including cephalization.

B. Enlarged RV

An enlarged RV expands to the left heart contour and makes the apex look up ("boot-shape"); however, the majority of adults have biventricular enlargement rather than isolated RV enlargement, and in that case this shape is uncommon.

C. Enlarged LV

In LV enlargement, the LV contour is displaced downward, sometimes even without an increase in cardiothoracic index. Conversely, anteroapical akinesis or aneurysm is characterized by a horizontal LV contour.

Generalized cardiac enlargement with a globular or water-bottle shape may indicate pericardial effusion but also cardiomyopathy.

In the absence of LV dilatation, LV hypertrophy may be associated with a normal cardiac silhouette or a slightly prominent apex, depending on whether the hypertrophy extends inward or outward.

III. Left atrial enlargement; aortic dilatation

Left atrial enlargement is recognized on the posteroanterior view as: (i) convex bulging of the shadow of the LA appendage (rather than straight line); (ii) widening of the carinal angle (>100°), with the left main bronchus becoming horizontal; (iii) double density over the RA shadow, implying that the LA is extending toward the RA (Figure 30.5). It is also recognized on the lateral view by a local posterior bulge of the upper cardiac silhouette (toward the spine).

Aortic dilatation is characterized by widening of the ascending aorta (on the right) or the descending aorta (left aortic knob fills the space between the aorta and the PA) (Figure 30.6). The widening of the ascending aortic shadow may also indicate elongated rather than dilated aorta.

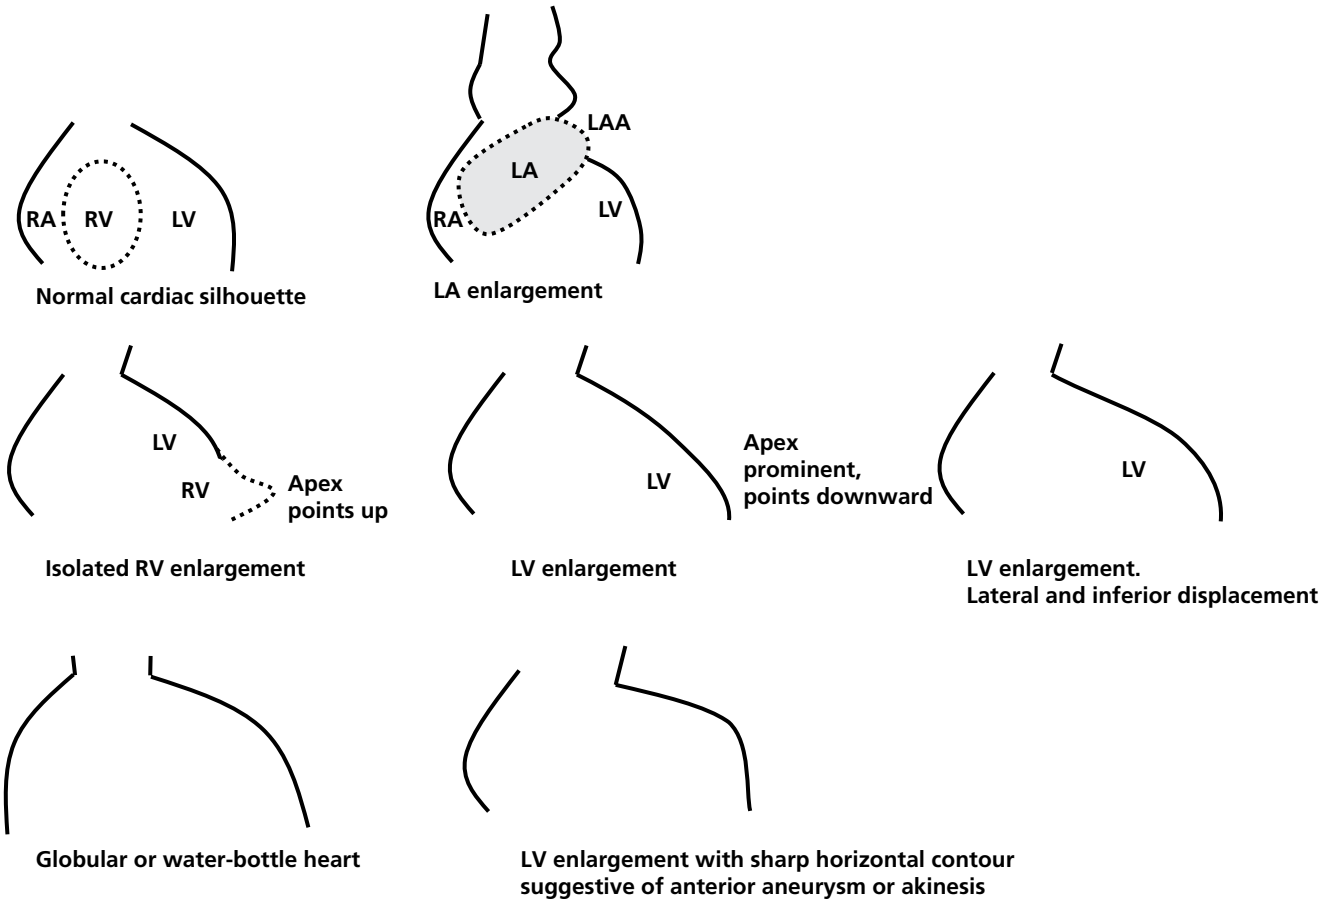

Figure 30.5 Various morphologies of cardiomegaly. LA enlargement is characterized by convex bulging of the LAA, and double density over the RA contour.

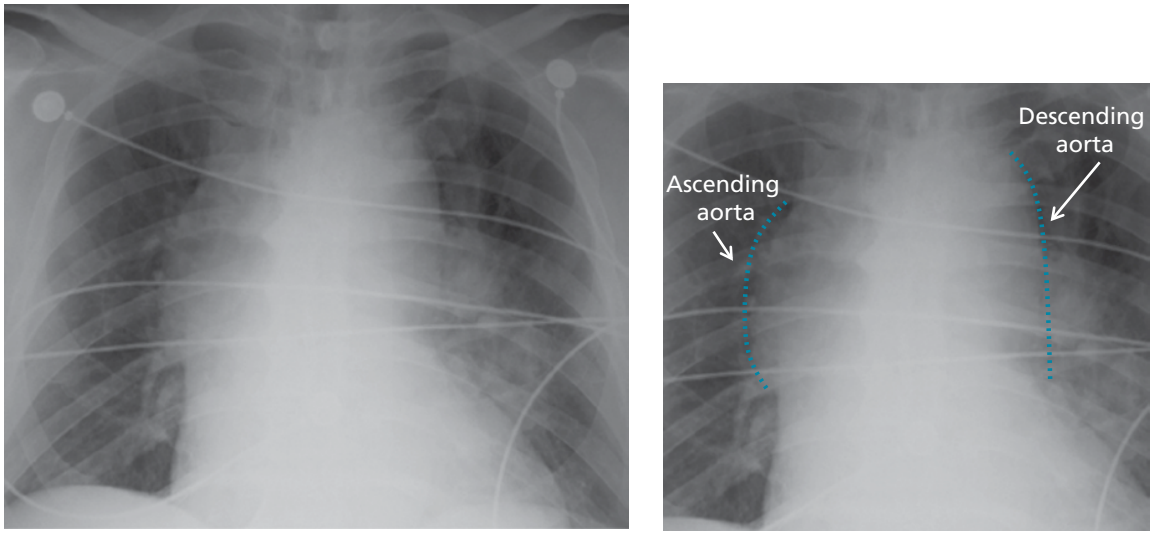

(a) (b)

Figure 30.6 The same X-ray is shown **(a)** without and **(b)** with annotations. Prominent ascending aorta is seen on the right mediastinum, and descending aorta on the left mediastinum, as indicated by the interrupted lines. This indicates ascending and descending aortic dilatation, dissection, or simply elongation (uncoiling). This patient had ascending and descending aortic dissection.

IV. Lateral chest X-ray

Note the features of LV, RV, and LA dilatation on the lateral CXR (Figure 30.7).

V. Chest X-ray in congenital heart disease

See Chapter 18, Figure 18.10.

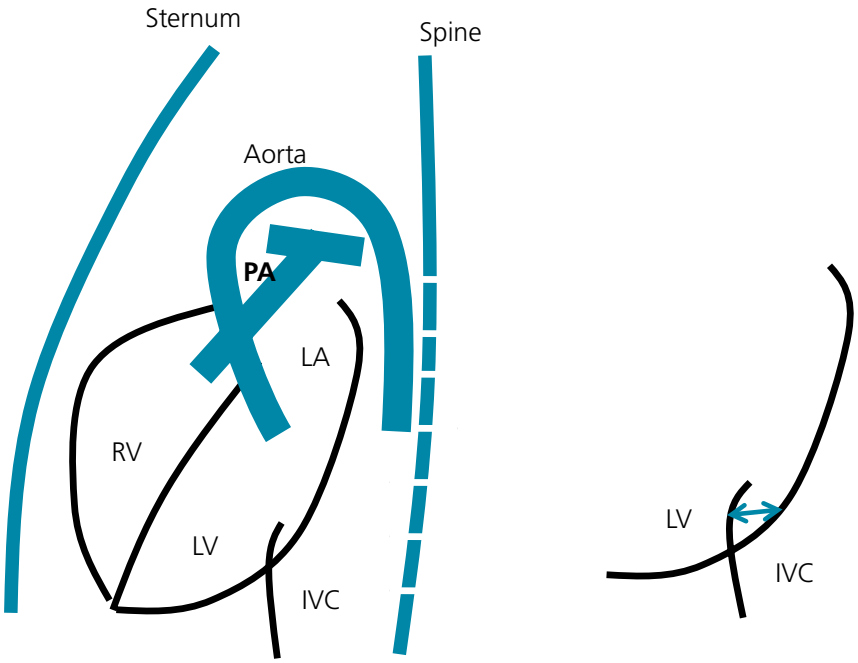

Figure 30.7 Lateral chest X-ray. Note that the LA shadow is surrounded by the aortic and PA shadows.

- When RV is enlarged, it expands superiorly and fills the retrosternal space for over a third of the sternal length, i.e., the distance from the top of the sternal notch to the xyphoid.
- When LV is enlarged, it bulges posteriorly toward the spine but also inferiorly below the shadow of the diaphragm. LV enlargement is suggested when the distance between the LV border and the IVC border becomes >17 mm (*double arrow*, right image).
- When LA enlarges, it causes a focal, round bulge of the upper cardiac silhouette toward the spine.
- Dilatation or elongation of the ascending or descending aorta may be seen. A dilated ascending aorta fills the anterior mediastinal space.

QUESTIONS AND ANSWERS

Question 1. A 29-year-old woman of Columbian origin is at 30 weeks of gestation. She presents with cough productive of blood-tinged sputum, severe dyspnea, and hypoxia (O_2 saturation 80% on ambient air). On exam, BP = 150/90, pulse = 125 bpm, JVP is elevated, P_2 is loud, and diffuse crackles are heard. The differential diagnosis includes (multiple answers possible):
A. Peripartum cardiomyopathy
B. Pre-existing dilated cardiomyopathy
C. Chagas disease
D. Myocardial infarction from coronary dissection
E. Mitral stenosis from rheumatic heart disease
F. Severe HTN/pre-eclampsia with pulmonary edema

Question 2. The ECG of the patient in Question 1 shows sinus tachycardia at 125 bpm and P mitrale. She remains hypoxic despite high-flow O_2 therapy. Echo confirms severe mitral stenosis with a valvular gradient of 20 mmHg (heart rate 125 bpm), a valve area of 1.2 cm^2, and systolic PA pressure of 80 mmHg. What is the next step?
A. Intravenous metoprolol
B. Intravenous furosemide
C. Immediate sedation and intubation
D. All of the above

Question 3. The patient's pulmonary edema improved with furosemide and heart rate reduction to 75 bpm (maximally tolerated dose of metoprolol [50 mg BID]). She is extubated and ambulates with mild dyspnea. What is the next step?
A. Continue conservative management
B. Mitral valvuloplasty

Question 4. All the following antihypertensive drug(s) are used in pregnancy, *except*?
A. Methyldopa
B. Hydralazine
C. Labetalol
D. Nifedipine
E. Atenolol

Question 5. In which of the following conditions is pregnancy contraindicated? (multiple answers)
A. Severe pulmonary hypertension of any origin
B. Severe asymptomatic AS with normal EF and exercise test
C. Severe symptomatic AS
D. Severe asymptomatic MS
E. Severe asymptomatic MR with normal EF
F. HOCM
G. Large ASD with large left-to-right shunt
H. Cyanotic congenital heart disease with O_2 saturation <85% (rest or stress)
I. Dilated cardiomyopathy with LVEF 25% and persistent NYHA class III–IV

Question 6. Should pregnancy occur anyway, in which of the conditions of Question 5 may termination of pregnancy be considered?

Question 7. Concerning HIV and heart disease, all of the following is true *except*:
A. Pericardial effusion is the most common cardiac manifestation of HIV
B. Pericardial effusion is usually small but associated with increased mortality
C. A large HIV-related effusion has a low risk of progression to tamponade and is rarely due to coinfections
D. HIV cardiomyopathy is often seen in patients with CD4 counts <400 and is associated with a high mortality risk (may approximate 50% at 2 years)
E. Endomyocardial biopsy may be needed in an HIV patient with progressive HF (to rule out opportunistic myocardial infections)

Question 8. A 33-year-old woman, 36 weeks pregnant, presents with severe dyspnea and hypoxemia. She has pulmonary edema by exam and X-ray. BP is 170/105, pulse is 110 bpm. ECG shows diffuse ST depression. Echo shows a non-dilated LV with global hypokinesis and EF of 25%, with no MS. What is the *least likely* mechanism of her cardiac presentation?
A. Peripartum cardiomyopathy
B. Acute MI of pregnancy (NSTEMI)
C. Acute myocarditis
D. Pre-eclampsia

Question 9. A 29-year-old woman has severe MR from an anterior mitral leaflet prolapse. She is asymptomatic with normal LV dimension and EF of 65%. She is able to perform 11 minutes on treadmill Bruce protocol with exertional PA pressure <50 mmHg. She wants to conceive. What is the best advice?
A. She has a relatively low cardiac risk during pregnancy, overall favoring pregnancy now rather than pregnancy following mitral valve replacement. She should conceive now with close monitoring

B. Perform bioprosthetic mitral replacement, followed by pregnancy
C. Perform mechanical mitral replacement, followed by pregnancy

Question 10. A 26-year-old woman is pregnant at 12 weeks. She is asymptomatic. A murmur is heard during routine exam with split S_2. Echo shows a large ASD with L–R shunt, RV enlargement, and normal PA pressure. What is the next step?
A. Recommend pregnancy termination, considering the high maternal cardiac risk
B. Pursue the pregnancy with clinical cardiac follow-up
C. Close the ASD during pregnancy

Question 11. A 26-year-old woman is pregnant at 12 weeks. She is asymptomatic. A continuous murmur is heard at the left upper sternal border. Echo shows a PDA with L–R shunt, Qp/Qs of 1.3, mild LV enlargement, and normal PA pressure. What is the next step?
A. Recommend pregnancy termination, considering the high maternal cardiac risk
B. Pursue the pregnancy with clinical cardiac follow-up
C. Close the PDA during pregnancy

Question 12. A 34-year-old pregnant woman (33 weeks) develops severe chest pain that has been ongoing for the last 2 hours. ECG shows anterior ST elevation. She receives aspirin, clopidogrel, heparin, NTG, and metoprolol. Chest pain resolves and ST elevation dramatically improves. Coronary angiography is performed and shows a 35-mm-long smooth 70% stenosis in the mid-LAD without impaired distal flow. What is the next step?
A. Low-pressure balloon dilatation
B. Low-pressure stenting
C. Conservative management with no intervention

Question 13. When to initiate HTN treatment in a pregnant woman with chronic or gestational HTN?
A. >130/80
B. >140/90
C. >150/95

Question 14. A woman has a mechanical mitral valve and is therapeutic on 4 mg warfarin. She has a positive pregnancy test. What is the preferred anticoagulation regimen during her pregnancy?
A. Warfarin throughout pregnancy, except for LMWH the last week and IV UFH 36 hours before delivery
B. Start LMWH for the first trimester, then switch to warfarin
C. Give LMWH throughout pregnancy

Answer 1. B, C, D, and E. The presentation is too early for peripartum cardiomyopathy. HTN is relatively mild and rather secondary to the patient's distress and pulmonary edema.

Answer 2. D. MS is 1 of 2 conditions that respond to immediate β-blocker therapy during active pulmonary edema (the other condition being HOCM). In a non-pregnant, mildly hypoxic patient, one may administer medical therapy and await 15 minutes before proceeding with intubation. In a pregnant woman, hypoxemia or acidemia of any degree or duration should not be tolerated. Fetal oxygenation requires a maternal PaO_2 >70 mmHg (O_2 saturation >95%) and a pH >7.3.

Answer 3. A. In most pregnant women with severe MS, stability can be achieved with medical therapy. Only if the patient has recurrent or refractory pulmonary edema or hypoxia would mitral valvuloplasty be performed during pregnancy.

Answer 4. E.

Answer 5. A, C, D, H, I.

Answer 6. A, H, I.

Answer 7. C. A large HIV-related effusion has a high risk of progression to tamponade, which warrants pericardiocentesis. Also, frequently (>50%), this effusion is due to associated infections or cancers.

Answer 8. D. A non-dilated LV with severe dysfunction is consistent with acute-onset cardiomyopathy. In the absence of pre-existing cardiomyopathy, severe acute HTN is unlikely to cause acute systolic LV dysfunction. In the absence of quick stabilization with diuretic therapy ± NTG and intubation, coronary angiography is warranted.

Answer 9. A.

Answer 10. B. Pregnancy is usually well tolerated in patients with ASD and no clinical HF, especially given that right–left shunting may decrease during pregnancy.

Answer 11. B. A small PDA without significant LV failure or pulmonary hypertension is usually well tolerated during pregnancy. The LV enlargement is likely secondary to the pregnancy itself, rather than the PDA.

Answer 12. C. The smooth, long morphology suggests dissection of the media (intramural hematoma). Commonly, an intimal flap is not seen in spontaneous coronary dissection. Considering the high risk of propagating the dissection during PCI, conservative management is appropriate in a patient with non-critical disease and no ongoing ischemia. As opposed to plaque rupture or erosion, the majority of spontaneous coronary dissections spontaneously heal on follow-up angiography (≥1 month).

Answer 13. B. Based on the CHAP trial, initiating BP treatment for BP ≥ 140/90 vs. treatment initiation only when BP ≥160/105 reduced the risk of severe pre-eclampsia without adverse effect on neonatal weight. However, an even more aggressive BP control in pregnancy is not clearly safe for the fetus and placental circulation (CHIPS trial).

Answer 14. A. Warfarin throughout pregnancy gives the best maternal outcomes with the lowest maternal mortality and thromboembolic risk. However, it is associated with a high risk of fetal abnormalities and fetal loss predominantly in the first trimester, particularly when the warfarin dose is ≥5 mg. The fetal risk is lower with warfarin dose <5 mg in the first trimester and is dramatically reduced with a switch to heparin in that first trimester.

Questions and answers 693

I. Overview of cancer drug therapies, particularly targeted therapy and immunotherapy

There are 4 types of systemic cancer therapies:

1. *Chemotherapy*
2. *Hormonal therapy*: In breast cancer and prostate cancer (androgen deprivation therapy such as GnRH agonist leuprolide and GnRH antagonists).
3. *Targeted therapy*: This therapy targets growth factor receptors on the cancer cell membrane *OR* signal transduction pathways inside the cell that regulate the cancer cell cycle. Unlike chemotherapy, this therapy tries to target abnormal proteins specifically expressed by cancer cells rather than normal cells.
4. *Immunotherapy*: It mainly consists of immune checkpoint inhibitors, CAR-T cell therapy (chimeric antigen receptor T-cell therapy), immunomodulators in multiple myeloma, and high-dose interleukin-2.

Regarding (3), there are grossly 2 common types of targeted therapy (Figure 31.1):[1]

a. *Monoclonal antibodies*. They target ***(i) cancer cell-surface receptors*** such as growth factors receptors (or CD receptors in lymphoma and myeloma), or ***(ii) cancer arteries surface angiogenesis receptors*.** Examples of targets: HER 2-epidermal growth factor receptor (EGFR) of breast cancer, EGFR of other cancers, FGFR, VEGFR, PDGFR, and CD20. Their names end in ***-mab*** and they are given ***intravenously***. Examples: rituximab (CD20 on lymphoma cells), trastuzumab (HER-2 target), bevacizumab, panitumumab, and pertuzumab. ***Bevacizumab*** binds to VEGFR and inhibits the growth of tumor blood vessels in colon cancer and many other cancers. Panitumumab, another monoclonal antibody, targets EGFR in colon cancer. Daratumumab targets CD38 on myeloma cells. The antibodies may be further linked to a chemotherapy drug or radiolabeled agent for further cell destruction (e.g., brentuximab for lymphomas).
b. *Small molecule drugs*. Owing to their low weight, they penetrate the cancer cell membrane and damage ***intracellular signaling molecules***, mainly various kinases frequently linked to growth factor receptors (e.g., tyrosine kinase of VEGF and EGF receptors, JAK, MEK, ERK). These targeted kinases, like the surface receptors, are overexpressed in specific cancers and promote cellular growth, metabolism, and angiogenesis while inhibiting apoptosis, hence their inhibition causes cancer cell death. Their names end in ***-nib*** (or occasionally *-lib)* for kinase inhibitors, or *-mib* for proteasome inhibitors, and they are given ***orally***. Examples:

- EGFR tyrosine-kinase inhibitors (e.g., osimertinib, gefitinib, erlotinib) target EGFR mutation–positive non-small cell lung cancer
- ALK inhibitor in non-small cell lung carcinoma
- VEGFR-tyrosine kinase inhibitors (e.g., sunitinib, sorafenib, axitinib) are used to treat renal, colorectal, thyroid, neuroendocrine, and hepatocellular cancers
- Imatinib targets the tyrosine kinase protein resulting from BCR-ABL fusion gene (Philadelphia chromosome in chronic myelogenous leukemia)
- RAF and MEK inhibitors are used in metastatic melanoma
- Bruton tyrosine-kinase inhibitors (e.g., ibrutinib) are used to treat chronic lymphocytic leukemia and some B-cell lymphomas

Companion website: www.wiley.com/go/hanna/cardiomedicine3e

- CDK 4/6 kinase inhibitors (palbociclib, ribociclib) are used in metastatic breast cancer that is hormone+/HER-2−.
- Proteasome inhibitors (e.g., bortezomib) are used in multiple myeloma.

All targeted therapies, particularly VEGF receptor antibodies and kinase inhibitors, may cause 5 major toxicities (Figure 31.2):
- Hypertension (>20%)
- HF (1–10%, over 10% with VEGF targeted therapy)
- Arterial thrombosis/MI (1–10%) (particularly therapies that target vasculature, such as VEGF targeted therapy)
- Venous thrombosis (1–10%)
- AF and QTc prolongation

This is besides impaired wound healing. Also, EGFR antibodies and inhibitors commonly cause skin papular or papulopustular rashes.

Regarding (4), immune checkpoint inhibitors (ICIs) are antibodies that block physiological immune "brakes," thus purposefully activating the immune system. Those brakes include the PD1 receptor on T cells, which binds to the PD-L1 ligand on cancer cells, and the CTLA-4 system. They may cause autoimmune reaction affecting, most commonly, and to various degrees of severity, the following 4 systems: skin, gastrointestinal tract (diarrhea, hematochezia), the endocrine system (thyroid or pituitary), or the liver. They are frequently well tolerated, and side effects are relatively mild. ***About 10–20% experience more severe side effects in the 4 systems***, or more rarely, in severe cases, in the lungs (pneumonitis), the neurological system (e.g., Guillain-Barre or aseptic meningitis), the muscles, or the heart (myocarditis, ~1–2%). Myocarditis is unlikely to occur in the absence of other, more common autoimmune manifestations, such as myositis, dermatitis, and colitis. There is some correlation between cancer response and side effects, and patients who experience severe side effects generally have a better cancer response. Severe side effects, including myocarditis, warrant treatment interruption, but the drug remains at its target for several months and its immunological efficacy persists even after interruption, partly through immune memory. Corticosteroids are used to treat severe side effects and do not seem to diminish the cancer response.

Being antibodies, ICIs names end in ***-mab*** and they are administered ***intravenously***. Examples of immune checkpoint inhibitors: ***pembrolizumab*** (Keytruda, targets PD-1), ***nivolumab*** (PD-1), ipilimumab (CTLA-4), durvalumab and atezolizumab (PD-L1). They are mainly used in unresectable or metastatic melanoma, non-small cell lung cancer, renal cell and urothelial carcinomas, head and neck cancers, various metastatic GI malignancies (esophageal, colon), lymphoma, and hepatocellular carcinoma. Their use has recently been extended to resectable tumors as adjuvant or neoadjuvant therapy (e.g., non-small cell lung cancer, urothelial carcinoma, melanoma).

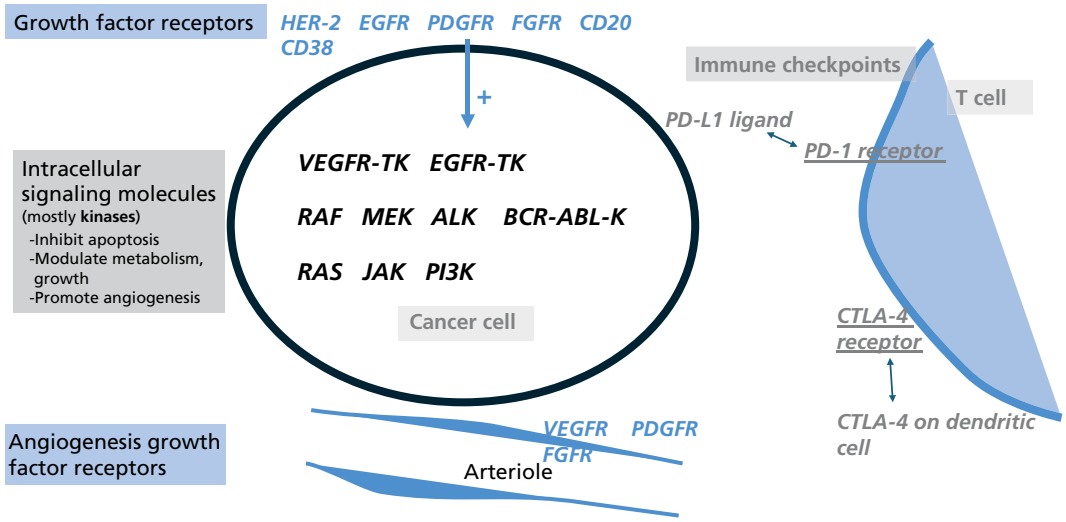

Figure 31.1 Targets of targeted therapy and immune checkpoint therapy. K in abbreviations stands for "kinase"; TK, tyrosine kinase.

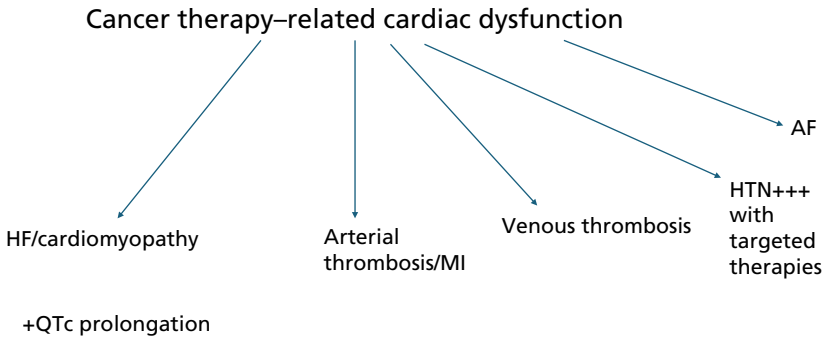

Figure 31.2 Types of cancer-related cardiac dysfunction. Any of the 5 types may be seen, to a variable degree, with targeted therapies.

In CAR-T cell therapy, the patient's own T cells are removed via apheresis, then modified in vitro to express receptors that bind to a cancer cell antigen, leading to cancer cell destruction. Those cells are grown to large numbers then infused to the patient. The most common antigen targeted by CAR-T cells engineering is CD-19 for lymphomas and BCMA for myeloma. This therapy is currently used in non-Hodgkin B-cell lymphoma, acute lymphoblastic leukemia, and myeloma. CAR-T may cause immune activation with cytokine release syndrome in 56% of patients, decreased LVEF (10–28%), decompensated HF (3–10%), arrhythmias (3–4%), and cardiovascular death (4%).[2,3] Cardiomyopathy mainly develops in older patients with high-grade cytokine release syndrome.

II. Cancer therapy–related cardiac dysfunction (CTRCD)

A. Definitions of baseline cardiac risk and stages of CTRCD (Figures 31.3, 31.4)

With all cancer therapies, particularly the ones known to cause LV dysfunction, cancer therapy is considered **high risk** if the patient has: clinical HF, severe valvular disease, baseline EF < 50%, or prior MI/PCI/CABG. Cancer therapy is **moderate risk** if: EF 50–54%, low global longitudinal strain (GLS), elevated baseline troponin or BNP, or prior AF. **A high risk does not preclude cancer therapy but warrants HF optimization, CAD risk factors and symptom optimization, and closer surveillance with ECG, echo, and biomarkers during therapy** (ESC). Even a baseline EF of 30–50% is not generally prohibitive of initiating cardiotoxic therapies under close surveillance, including anthracyclines.[4,5] EF <30% is prohibitive of anthracycline therapy;[5] EF <30% may be prohibitive of HER-2 inhibitors and other targeted therapies such as VEGF inhibitors, but not as strictly as with anthracyclines, particularly if no other cancer treatment is possible.[4] Prior CAD history (type 1 MI/PCI/CABG) or CAD symptoms are considered high risk mainly for cancer therapies associated with vascular toxicity (e.g., fluoropyrimidines such as 5-FU, and targeted therapies such as VEGF inhibitors and BCR-ABL inhibitors) (ESC).

With all cancer therapies, including chemotherapy and targeted therapies, ESC defines significant cardiac toxicity as the following:[6]

1. Severe CTRCD:
   - Clinically severe HF requiring hospitalization, or shock, usually with EF decline to <40%
   - *OR* asymptomatic EF reduction to <40%
2. Moderate CTRCD:
   - Clinical HF requiring outpatient diuretic and HF therapies
   - *OR* EF decline ≥10% to an EF of 40–49%
   - *OR* EF decline by <10% to an EF of 40–49% *AND* either new relative decline in GLS by >15% from baseline *OR* new rise in cardiac biomarkers (troponin or BNP)
3. Mild CTRCD:
   - Isolated decline of echo GLS by >15% from baseline, and/or rise in cardiac biomarkers, without a decline of EF to <50% and without new or worsening HF.

On the other hand, ASE defines significant CTRCD as EF decline by ≥10% to <53%.[5,7]

Generally, severe and moderate CTRCDs dictate the interruption of the cancer drug until HF and EF recover (usually after ≥1 month), whereas mild CTRCD does not dictate interruption but warrants the initiation of ACE-I and β-blocker therapy, along with close echo surveillance***. In severe and moderate CTRCDs, the drug may eventually be re-initiated if EF normalizes and clinical HF resolves,*** even if EF severely declined to <40% at one point (one exception: if severe clinical HF occurred with anthracycline → permanent discontinuation). The drug may even be continued without interruption during moderate asymptomatic CTRCD (EF 40–49% without HF), especially with trastuzumab and targeted therapies: this is called permissive cardiotoxicity.[6,8,9]

Besides EF, ***GLS*** has emerged as a valuable tool in LV assessment *before* chemotherapy and detection of subclinical myocardial dysfunction *during* chemotherapy: a decline of GLS of >15% from baseline is significant and predicts future HF. This applies to both anthracycline and trastuzumab therapy. **If EF remains >50%, GLS, per se, does not prompt halting or changing chemotherapy** but warrants closer monitoring of EF and consideration of β-blocker and ACE-I/ARB therapy. The same applies to the measurement ***of hs-troponin and BNP*** before and during cancer therapy. Of note, the prognostic value of hs-troponin is not consistent across studies; as such, the cutoff of biomarkers needs to account for age and baseline CKD.

Note that CTRCD is more prevalent in women.

Cancer therapy is considered **high-risk** if at baseline:
-Clinical HF
-or severe valvular disease
-or baseline EF <50%
-or prior major CAD history (type 1 MI/PCI/CABG)

Cancer therapy is **moderate-risk** if:
-EF 50–54%
-low GLS, or elevated baseline troponin or BNP
-or AF

→

1. **A high risk does not preclude cancer therapy but warrants cardiac HF optimization, CAD risk factors and symptom optimization, and closer surveillance during therapy**
2. Baseline EF of 30–50% is generally not prohibitive of initiating cardiotoxic therapies under close surveillance.
3. EF <30% is prohibitive of anthracycline therapy. EF <30% may be prohibitive of HER-2 inhibitors and other targeted therapies such as VEGF inhibitors, but not always, particularly if no other cancer treatment is possible.

Figure 31.3 Pre-cancer therapy high and moderate cardiac risks, and how to manage.

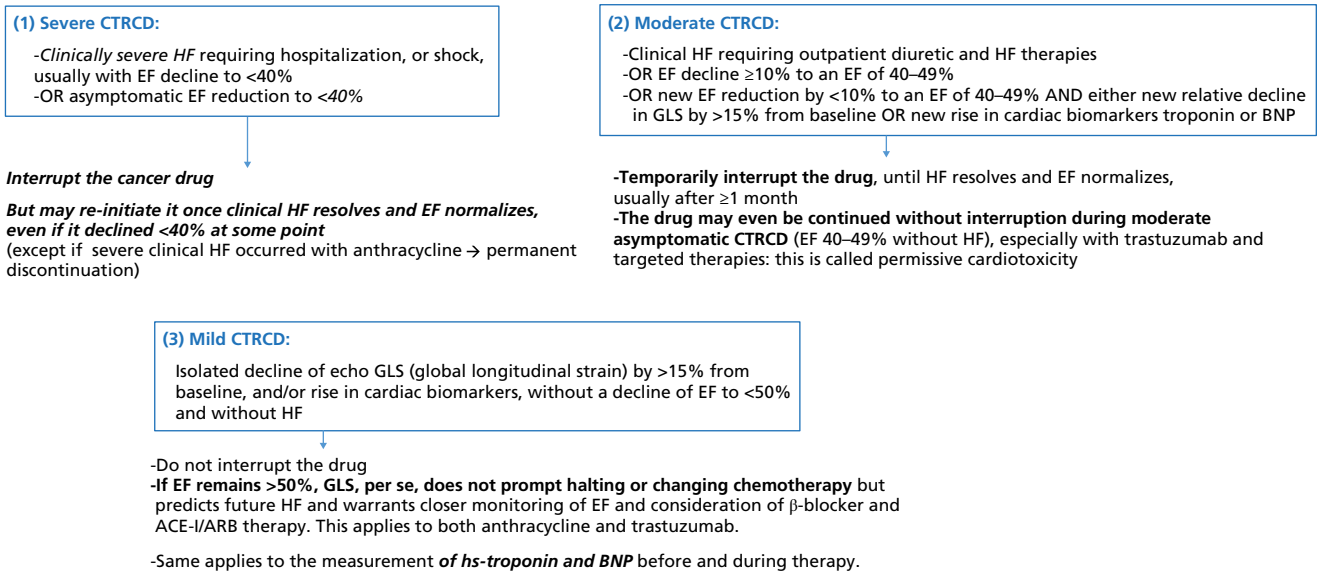

Figure 31.4 Summary of CTRCD stages and how to manage them, including when to interrupt and re-initiate cancer drug.

B. Role of ACE-I/ARB/sacubitril-valsartan and β-blocker therapy in preventing severe CTRCD

Most of the data addressed patients receiving anthracyclines. ACE-I and carvedilol have both shown, in small randomized trials, a reduction of anthracycline toxicity (EF decline) in patients receiving high doses of an anthracycline or those with a rise in troponin after chemotherapy.[7,10–12] In the OVERCOME trial, the combination ARB + carvedilol significantly attenuated EF decline and clinical events in anthracycline-treated patients.[13] In the larger CECCY randomized trial, carvedilol failed to reduce doxorubicin cardiotoxicity, defined as EF reduction >10%; it did attenuate troponin rise and diastolic dysfunction.[14] In the SARAH trial, sacubitril-valsartan attenuated GLS and EF decline in anthracycline-treated patients with high post-therapy troponin. In a large meta-analysis of randomized trials involving 1,035 patients treated with anthracyclines, cardioprotection with ACE-I and/or β-blockers was associated with a smaller decline in LVEF, but not with a reduced risk of overt heart failure.[15] Per ESC, full HF therapy is recommended for patients who develop moderate or severe CTRCD, whether symptomatic or not. Outside that, preventive ACE-I/ARB and β-blockers should be considered for:

- Primary prevention in high-risk patients (e.g., underlying HF, EF < 50%, or CAD) receiving anthracyclines and/or anti-HER2 therapies and/or targeted therapies with HF risk (class IIa)
- Patients who develop mild CTRCD, i.e., decline of GLS >15% or rise in troponin or BNP, with EF remaining >50% (class IIa)

Also, statins should be considered for primary prevention in adult patients with cancer at high and very high CAD toxicity risk.

III. Chemotherapy and the heart

A. Anthracyclines

Cardiomyopathy typically occurs *early on*, i.e., during therapy or within a year of completion of therapy,[16] or may develop *late*, i.e., over a year after therapy, sometimes even decades later. In fact, the prevalence of anthracycline toxicity increases with time, especially in children.[7,8,10] However, this late occurrence is rather a progressive worsening of early cardiotoxicity that was not promptly detected. The risk is 3–26%, is dose dependent, and increases after a cumulative doxorubicin dose of 250 mg/m^2, and particularly a dose of 550 mg/m^2 (26% frequency at this dose). ACE-I and carvedilol prevent some of the EF decline with therapy: in a large meta-analysis of randomized trials involving 1,035 patients treated with anthracyclines, cardioprotection with ACE-I and/or β-blockers was associated with a smaller decline in LVEF, but not with a reduced risk of heart failure.[15] An intracellular chelator, dexrazoxane, *and* liposomal anthracyclines should be considered in patients receiving cumulative doses >250 mg/m^2 or patients at high risk for CTRCD (ESC).

Rarely, acute immediate cardiotoxicity occurs during infusion; this is usually transient.

Anthracyclines cause myocardial free radical formation with subsequent myocardial necrosis and progressive myocardial injury. While traditionally considered irreversible, modern studies show that, if treated early with HF therapies less than 2 months after the end of chemotherapy, EF fully recovers in 64% of patients and improves—at least partially—in 82% of patients overall; beyond 12 months, even partial EF improvement cannot be achieved.[16,17] Thus, anthracycline toxicity is not irreversible, and reversibility is rather a function of early diagnosis and immediate treatment.

Surveillance – Echo/EF should be performed before therapy initiation and after a cumulative dosing of 250 mg/m^2. In high-risk patients with underlying HF, cardiomyopathy, severe valvular disease, or CAD, echo is also repeated every 2 cycles and within 3 months of therapy completion, and troponin and BNP are measured at baseline and before every cycle; troponin and BNP surveillance may also be considered in lower-risk patients (ESC).[6]

Treatment – Anthracycline therapy should be avoided in patients with EF < 30%, and preferably avoided in patients with EF 30–50%.[5] After initiation, therapy is interrupted in cases of severe CTRCD (severe HF or EF decline to <40%), or moderate CTRCD (moderate outpatient HF, or EF declines ≥10% to 40–49%, or EF decline by <10% to 40–49% along with a drop in GLS >15%) (ESC).[6] ***However, in the***

absence of severe clinical CTRCD, i.e., HF warranting hospitalization, anthracycline therapy may be restarted after recovery of HF and LV function under HF treatment. This applies even if moderate HF had occurred or EF had declined to <40% at one point, provided there is a compelling reason to continue anthracycline chemotherapy. Liposomal anthracyclines and dexrazoxane are recommended upon therapy re-initiation.

An increase in troponin or BNP, a decline in GLS, or a new diastolic dysfunction may precede systolic dysfunction and indicate early cardiotoxicity, but do not mandate treatment interruption when not accompanied by EF decline or HF. They warrant consideration of β-blocker and ACE-I/ARB therapy.

B. Cyclophosphamide

Cyclophosphamide, when used in high individual doses, may induce acute cardiac toxicity consisting of myopericarditis and pericardial effusion within 10 days of therapy. This acute toxicity lasts less than a week, without long-term sequelae or cumulative effect in patients who survive the acute cardiomyopathy.[18] Unfortunately, the acute cardiomyopathy has a significant mortality of up to 12% when very high doses are used.

C. Agents causing myocardial ischemia and MI

1. **5-Fluorouracil (5-FU) and its oral prodrug capecitabine.** These antimetabolites may cause coronary macro- or microvascular spasm, within 2–5 days of drug administration and lasting up to 48 hours, sometimes occurring after cessation of therapy. Vasospasm affects 3–20% of patients, with a likely comparable risk between 5-FU and capecitabine.[7,10] High doses and continuous 5-FU infusions have higher cardiotoxicity than bolus 5-FU administration. Coronary thrombosis may also occur, particularly after prolonged or refractory vasospasm. The risk is higher in patients with underlying CAD. It is treated, sometimes pre-emptively, with CCB and nitrates.
2. **Paclitaxel and docetaxel** may cause myocardial ischemia and infarction during and up to 14 days after therapy, in up to 1.5% of patients.[7,19] Paclitaxel may also cause bradycardia and ventricular arrhythmias, and it may increase the risk of anthracycline-induced cardiomyopathy.
3. **Cisplatin and carboplatin** may cause vasospasm or vascular injury leading to myocardial ischemia. Hypertension is also a common side effect.
4. **Targeted therapies** may cause arterial thrombosis and MI, particularly **VEGF** antibodies and VEGF-tyrosine kinase inhibitors.
5. **Multiple myeloma therapies,** particularly the immunomodulatory drug lenalidomide and the proteasome inhibitors, increase the risk of arterial thrombosis and MI.
6. **Androgen-deprivation therapies in prostate cancer** increase the risk of arterial thrombosis and MI.

IV. Targeted therapy and the heart

A. Toxicity of targeted therapies

VEGF antibodies (e.g., bevacizumab) and VEGF tyrosine-kinase inhibitors cause ***HTN*** (>20%, up to 80%), ***cardiomyopathy (10–28%)***,[8] and arterial and venous thrombosis through endothelial injury. They are associated with 1–10% risk of acute MI.[6–8]

HTN is highly prevalent with most targeted therapies (>10%). All targeted therapies, including those involving targets other than VEGF, may cause cardiomyopathy (2–10%; more so, >10%, with VEGF targeted therapy). Cardiomyopathy usually occurs early on during therapy, after the first cycle or the first few cycles, and is secondary to: (i) direct myocardial toxicity: blocking growth factors and intracellular kinases may cause contractile dysfunction and cellular apoptosis, given their normally pro-metabolism and antiapoptosis functions; (ii) HTN, (iii) coronary macro- and microvascular toxicity. Cardiomyopathy is usually ***reversible*** with drug interruption. They may also cause ***arterial thrombosis (MI)*** (1–10%), ***venous thromboembolism*** (1–10%, and even >10% with bevacizumab, an anti-VEGF antibody), ***AF*** (up to 5–10% with some kinase inhibitors), and ***QT prolongation***. AF is particularly prevalent with Bruton tyrosine kinase inhibitor used in CLL and lymphomas (e.g., ibrutinib), some BCR-ABL kinase inhibitors, some VEGF inhibitors, and multiple myeloma targeted therapies.

In general, most of these therapies require baseline echo, ECG and +/– cardiac markers, and repeating the latter studies at 6–8 weeks then every 3 months, especially in high-risk patients (ESC).

B. Specific toxicity of trastuzumab (HER-2 receptor antagonist used in breast cancer)

Trastuzumab inhibits EGF, and thus reduces normal myocardial growth, repair, and survival. The incidence of trastuzumab-induced cardiotoxicity is 15–20%, and this increases up to 27% when it is combined with other cardiotoxic agents. It is mostly asymptomatic LV dysfunction, which progresses to clinical HF if missed early on. The cardiotoxicity is usually reversible after cessation of therapy in 80% of the cases, after a mean of 1.5 months.

Surveillance – Baseline echo is performed and repeated every 3 months during therapy, and 3 and 12 months after therapy completion. Cardiac biomarkers are measured at baseline and every 3 months (ESC).

Treatment – If EF declines to <40%, or by >10% to <50%, or if HF develops, trastuzumab or other targeted therapy is held for 1 month and EF reassessed afterward. ***Trastuzumab or other targeted therapy may be restarted if EF normalizes and clinical HF resolves***, even if severe HF has occurred at one point (unlike the case of anthracycline-induced cardiotoxicity, which is less reversible and where severe HF dictates permanent discontinuation of the drug) (ESC). Trastuzumab or other targeted therapy may even be continued for moderate asymptomatic CTRCD with EF 40–49% (ESC class IIa).

In 1 large trial, lisinopril and carvedilol failed to reduce the cardiotoxicity of trastuzumab therapy, but each one of them reduced the cardiotoxicity of the combination trastuzumab + doxorubicin.[20] *Overall, neurohormonal therapies are more studied and established for anthracycline than trastuzumab therapy, and a large meta-analysis confirmed their attenuation of EF decline.*[21]

C. Multiple myeloma therapies

In multiple myeloma, the following 4 classes of drugs may be used: (1) alkylating chemotherapy; (2) immunomodulatory drugs (e.g., thalidomide, lenalidomide); (3) proteasome inhibitors (e.g., bortezomib); (4) targeted monoclonal antibodies (especially anti-CD38, such as daratumumab).

(2) to (4) are associated with HTN (>10%) and elevated risks (1–10%) of HF/cardiomyopathy, AF, arterial thrombosis/MI, and venous thrombosis, particularly the immunomodulatory drugs and the proteasome inhibitors.

D. Atrial fibrillation and cancer

AF is common in cancer patients and is partly due to cancer-induced inflammation and stress, metabolic abnormalities, but also some of the drugs:

- Chemotherapy: cisplatin, 5-FU, anthracyclines
- Some small-molecule kinase inhibitors, such as Bruton kinase inhibitors and some BCR-ABL kinase inhibitors (AF in 5–10% of treated patients), and some VEGF tyrosine-kinase inhibitors (e.g., sunitinib, sorafenib)
- Multiple myeloma therapy: >10% risk with melphalan chemotherapy and ~1–10% risk with each of: targeted monoclonal antibodies, proteasome inhibitors, and immunomodulatory drugs
- Abiraterone used in prostate cancer

E. QT prolongation

Prolonged QT is particularly prevalent with VEGFR antibodies and inhibitors and BCR-ABL inhibitors (1–10% risk).

V. Androgen deprivation therapy for prostate cancer

This therapy is used in multiple disease stages of prostate cancer, including metastatic cancer, localized prostate cancer as adjuvant to radiation, and high-risk biochemical recurrence after definitive prostate cancer therapy. Therapy may consist of: **(i)** GnRH agonist (e.g., goserelin SQ implant or leuprolide, IM injection or SQ implant, which initially causes a surge of LH followed by suppression), **(ii)** androgen receptor inhibitors (*-mide*, such as apalutamide, oral drugs), **(iii)** androgen synthesis inhibitor (abiraterone, oral, for resistant metastatic prostate cancer), or **(iv)** GnRH antagonist. GnRH antagonist causes more complete and rapid androgen suppression without the initial surge (e.g., degare*lix* SQ). All these agents are associated with increased risks of HTN (>10% with some of them), adiposity, sarcopenia, hyperglycemia, HF (1–10%), and MI (1–10%). Abiraterone also increases AF risk and fluid retention. The risk with GnRH antagonist is lower, hence GnRH antagonist is suggested in higher-cardiac-risk patients.[6]

VI. Immune checkpoint inhibitors and the heart

ICI-associated myocarditis has variable presentations ranging from: (i) asymptomatic troponin elevation *with* abnormal ECG, to (ii) non-fulminant myocarditis (ACS-like chest pain *or* mild HF *or* LV dysfunction), to (iii) fulminant myocarditis with severe HF, cardiogenic shock, ventricular arrhythmias/AV block, or sudden death.[6,22] Early ECG abnormalities consist of early conduction disease, such as PR prolongation or BBB, frequent PVCs, or ST depression or elevation or diffuse T inversions. More advanced AV blocks and sustained ventricular or atrial arrhythmias may then occur.[22] Of note, concomitant pericardial effusion may be present.

ICI myocarditis is rare (prevalence up to 1.4%) but more common with ICIs combinations (double the risk) or with underlying cardiomyopathy. Also, subclinical cases may be more common. At least half of patients with ICI-associated myocarditis have a normal EF on presentation; a reduction of GLS is more sensitive for the diagnosis of ICI-myocarditis, but the specificity is reduced if other cardiotoxic drugs have been used. It is frequently associated with other autoimmune manifestations, including myositis and myasthenia gravis–like syndrome in ~30%. It develops at a median of 30 days after ICI initiation (<12 weeks) and has a high mortality of 17–30%.[8,23,24]

Surveillance – It has been suggested that ICI-treated patients undergo baseline ECG and troponin measurement before treatment, followed by surveillance with regular troponin measurement every 1–2 weeks,[23] or before doses 2, 3, and 4 (ESC). If troponin rises, ECG and echo are performed, but in the absence of a major ECG or echo abnormality, particularly EF or GLS decline or arrhythmias, treatment is continued with close surveillance. In one study, >10% of patients exhibited elevated cardiac troponin levels, yet only 1.4% were ultimately diagnosed with myocarditis.[8] Furthermore, if the patient develops chest pain or dyspnea, but without a significant troponin change from baseline, myocarditis is unlikely.

If troponin is elevated along with any of the following, the myocarditis pathway is initiated:

- Chest pain/dyspnea
- *or* EF +/– GLS decline
- *or* ECG abnormalities (ST depression or elevation or diffuse T inversions; early conduction disease, such as PR prolongation or BBB; frequent PVCs; more advanced AV blocks and sustained ventricular or atrial arrhythmias)

Myocarditis pathway (diagnosis and treatment) – If troponin is markedly increased, along with chest pain/dyspnea, EF +/– GLS decline, or ECG abnormalities, myocarditis is suspected, and cardiac MRI is performed.[23] The diagnosis is based on cardiac MRI Lake Louise criteria and is further corroborated if other immune phenomena, particularly myositis, are present (elevated CK and acetylcholine receptor antibodies). If MRI is unavailable, the diagnosis relies on troponin rise and a combination of 2 of the following 4:

- Clinical syndrome (chest pain, dyspnea, or overt HF)
- Suggestive ECG (particularly arrhythmia or new conduction disturbance)
- LV systolic dysfunction, with or without segmental dysfunction in a non-Takotsubo pattern
- Other immune phenomena (especially myositis, myasthenia gravis, or colitis) (ESC)

Some of the cases are early asymptomatic myocarditis (e.g., troponin elevation with early ECG abnormalities and early LV dysfunction or another immune phenomenon).

Treatment consists of holding ICIs, initiating methylprednisolone 1 gram IV daily for 3 days, with daily troponin measurement to assess response. If the troponin does not reduce significantly (>50% reduction from peak within 24–72 hours), and/or AV block, ventricular arrhythmias, or LV dysfunction do not improve despite 3 days of methylprednisolone plus HF treatment, then steroid-resistant ICI myocarditis is diagnosed and second-line immunosuppression should be considered, particularly IV abatacept every ~1 week (abatacept is a CTLA-4 agonist, CTLA-4 being one of the immune checkpoints attacked by ICIs) (ESC). In responsive patients (clinically and troponin levels), oral prednisone is initiated (~1 mg/kg/day) and tapered over 4–6 weeks (10 mg/week initially). During the taper, continue clinical and troponin monitoring, as ICIs have long half-lives (21–25 days), increasing the potential for recurrent myocarditis. Advanced AV block is expected to recover but warrants temporary pacemaker implantation.[22]

Future ICI treatment – ICI remains at its target for several months, and its immunological efficacy persists even after interruption, partly through immune memory. Corticosteroids do not seem to diminish the cancer response.

ICI rechallenge is associated with a significant risk of myocarditis recurrence but may be considered in the case of asymptomatic myocarditis, after its complete recovery. Regarding more significant cases, the decision to restart ICI treatment after complete myocarditis recovery (normal troponin and EF even after discontinuation of immunosuppression and weaning of oral steroid therapy) depends on various factors. These include the severity of the ICI-associated myocarditis (fulminant with shock vs. non-fulminant vs. asymptomatic), alternative cancer treatment options, metastatic vs. adjuvant/neoadjuvant indication, and the feasibility of switching to ICI monotherapy if the toxicity was initially induced by combination ICI therapy.

VII. CAR-T cell therapy

CAR-T may cause immune activation with cytokine release syndrome in 56% of patients, decreased LVEF (10–28%), decompensated HF (3–10%), arrhythmias (3–4%), and cardiovascular death (4%).[2,3] Cardiomyopathy mainly develops in older patients with high-grade cytokine release syndrome.

VIII. Hematopoietic stem cell therapy

Stem cell therapy is associated with increased cardiac risk, more so with allogenic stem cell transplant than autologous stem cell transplant. The risk is mainly related to fluid administration/resuscitation, sepsis, and thrombotic microangiopathy occurring through the process, all of which aggravate underlying diastolic dysfunction and HTN or induce a high-output HF. Moreover, the heart may be compromised by the direct cardiotoxic effects of anticancer therapies received before and during stem cell transplant (anthracycline-combined induction regimen, mediastinal radiation, total body irradiation, or cyclophosphamide-based conditioning regimen). The most frequent complications early on (<100 days) are AF and HF. In addition, with allogenic transplant, various degrees of GVHD (graft versus host disease) may occur. As per ESC: "acute GVHD is associated with thrombosis and inflammatory myocardial damage (myocarditis, HF, conduction abnormalities, arrhythmias, and pericardial effusions), and chronic GVHD has been linked with increasing risk of hypertension, diabetes, and dyslipidemia." Baseline ECG, echo, and cardiac markers are warranted, and are repeated at 3 and 12 months in high-risk patients.

IX. Radiation heart disease (see Chapter 6, Section 7)

Radiation heart disease typically develops more than 10 years after exposure and may affect: (i) pericardium (constrictive pericarditis); (ii) valves: aortic (AS/AI) > mitral (MR) > tricuspid; (iii) fibrous cardiac skeleton, valvular annuli, and mitro-aortic intervalvular fibrosa; (iv) coronary arteries, mainly the left main, ostial RCA, or mid-LAD (anterior); (v) myocardium (RCM); (vi) conduction system. Patients at risk are generally screened by TTE 10 years after exposure, then every 5 years. The risk increases with high cumulative heart dosing >25 Gy (= total radiation dose × percent of heart exposure), radiation of the left or anterior chest, concomitant anthracycline therapy, and young age <50 with long time span since radiotherapy. Cardiac toxicity may be limited by: (i) deep-breath hold, which pushes the heart posteriorly, away from the left breast radiation field, and (ii) image-guided precision radiotherapy that maximizes dose delivery to the tumor and reduces the exposure of adjacent tissues.

QUESTIONS AND ANSWERS

Question 1. A 65-year-old man with no known CAD with esophageal cancer is receiving an intravenous infusion of chemotherapy. He develops chest pain with diffuse ST-segment elevation. Pain and ST elevation resolve with sublingual nitroglycerin, but keep re-occurring. What chemotherapy is he receiving?

A. Pembrolizumab with myopericarditis
B. 5-Fluorouracil
C. Doxorubicin
D. Bevacizumab
E. Cisplatin

Question 2. A 56-year-old woman is undergoing chemotherapy for metastatic breast cancer, with a regimen containing doxorubicin. She has no cardiac history and her baseline LV EF is 60%. At 3 months of therapy, her EF declined to 38% and she developed dyspnea with mild HF on CXR that responded well to outpatient furosemide. Doxorubicin is stopped, and carvedilol and lisinopril are initiated, besides dapagliflozin and furosemide 20 mg daily. Two months later, her EF normalized. She has limited therapeutic options for her cancer, and another doxorubicin cycle would be helpful. Which of the following is true?

A. Considering the prior severe doxorubicin toxicity, she has an absolute contraindication to doxorubicin re-initiation
B. Doxorubicin toxicity is irreversible and her EF will likely decline again, with or without rechallenge
C. Doxorubicin may be re-initiated
D. Doxorubicin may be re-initiated, preferably in the form of liposomal doxorubicin with dexrazoxane

Question 3. All of the following therapies are associated with increased risk of MI (1–10%), *except:*

A. VEGF inhibitors
B. Proteasome inhibitors and immunomodulator drugs in multiple myeloma
C. Trastuzumab
D. Androgen deprivation therapy in prostate cancer, including abiraterone

Question 4. A patient with breast cancer needs to receive trastuzumab. She has a history of prior LAD PCI and EF is 48%. She has no clinical HF. Which of the following is true?

A. The risk of CTRCD is high. Trastuzumab is contraindicated
B. The risk of CTRCD is high, but trastuzumab may be used along with ACE-I, carvedilol, statin, and HF volume optimization
C. The risk of CTRCD is moderate. Trastuzumab may be used along with ACE-I, carvedilol, statin, and HF volume optimization

Question 5. The patient of Question 4 develops EF decline to 40% during trastuzumab therapy, without any HF. What is the next step?

A. Discontinue trastuzumab, optimize HF regimen, and reassess EF in 1 month. Consider re-initiating trastuzumab if absolutely necessary

B. If trastuzumab is the main choice for cancer therapy, continue it without interruption, up-titrate ACE-I/carvedilol, and closely monitor the patient clinically + echo + BNP

Answer 1. B. The clinical picture is suggestive of coronary vasospasm, which is common with 5-fluorouracil (5-FU) infusion (5–20% prevalence). Coronary thrombosis may be seen with 5-FU, especially after prolonged untreated vasospasm. It is best treated, sometimes preemptively, with a combination of CCB (e.g., diltiazem IV) and nitrates. Cisplatin may further increase the risk of vasospasm in combination with 5-FU. Bevacizumab may cause coronary thrombosis, but the intermittent ischemia is more suggestive of vasospasm.

Answer 2. D. In the absence of severe clinical CTRCD, i.e., HF warranting hospitalization, anthracycline therapy may be restarted after recovery of HF and LV function under HF treatment. This applies even if moderate HF had occurred or EF had declined to <40% at one point, provided there is a compelling reason to continue anthracycline chemotherapy. Liposomal anthracyclines and dexrazoxane are recommended upon therapy re-initiation. Although traditionally considered irreversible, modern studies show that, if treated early with HF therapies less than 2 months after the end of chemotherapy, EF fully recovers or improves, at least partially, in 82% of patients.

Answer 3. C.

Answer 4. B (see Section II.A and Figure 31.3).

Answer 5. B. *In severe and moderate CTRCDs, the drug is usually interrupted but may be re-initiated if EF normalizes and clinical HF resolves,* even if EF severely declined to <40% at one point. If necessary, the drug may even be continued without interruption during moderate asymptomatic CTRCD (EF 40–49% without HF), especially with trastuzumab and targeted therapies: this is called permissive cardiotoxicity.

Questions and answers 753

I. Overview of ECG leads and QRS morphology

An ECG lead consists of 2 poles (a positive pole and a negative pole). It captures the cardiac electrical potential spreading between these 2 poles (Figures 32.1, 32.2). If a wave spreads toward the negative pole then turns toward the positive pole, a negative deflection is initially seen, followed by a positive deflection. If the vector of the propagating wave is parallel to the line formed by the 2 poles, the amplitude of the deflection will be largest; if it is orthogonal, the deflection will be small and almost isoelectric. The electrodes that are positioned on the limbs and the precordium are the poles, whereas the axis formed between 2 poles is called a lead. Leads I, II, and III are bipolar leads that register the electrical spread between 2 limb poles. Limb leads aVR, aVL, and aVF register the electrical spread between a central pole and 1 limb pole; the central pole is the center of the 2 other limb poles (Figures 32.3, 32.4).

Precordial leads V_1–V_6 register the electrical spread between a central pole and 1 chest pole; the central pole is the center of all limb poles, located in the center of the chest (Figures 32.5, 32.6). The limb leads aVR, aVL, and aVF, and the precordial leads, are called unipolar leads because they mainly depend on the position of 1 pole.

Precordial leads V_5–V_6 and limb leads I and aVL point to the left and are left lateral leads, leads I and aVL being high lateral leads. Precordial leads V_1–V_2 are right-sided leads but also septal leads; they overlie the right heart but also the interventricular septum. V_1–V_3 are anteroseptal leads. Limb leads II, III, and aVF point inferiorly, and are thus inferior leads.

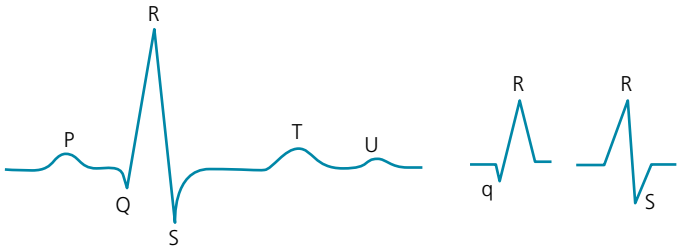

Figure 32.1 P–QRS–T complex. P wave represents the atrial depolarization and includes a part of the AV nodal conduction. PR interval consists of P wave and AV conduction. AV conduction consists of AV nodal conduction, His conduction, and infra-Hisian conduction (bundle branches before the myocardium); most of the AV conduction time is consumed by conduction through the AV node. The PR segment also includes the atrial repolarization; in normal states, the PR segment is isoelectric or slightly depressed < 0.8 mm (as a result of atrial repolarization).

QRS complex represents ventricular depolarization. ST–T segments represent ventricular repolarization. ST segment = phase 2 of the action potential or plateau phase of repolarization. T wave = phase 3 of the action potential. TP segment = phase 4 of the action potential. The normal U wave is a diastolic wave related to the mechanical stretch of the myocardium in phase 4 (diastole).

Normal calibration:

- Height of 1 small box = 1 mm = 0.1 mV. One big box = 5 small boxes = 0.5 mV.
- Width of 1 small box = 1 mm = 0.04 second. One big box = 5 small boxes = 0.2 second (sweep speed: 25 mm/s).

Watch for half-standardization, especially when comparing ECGs.

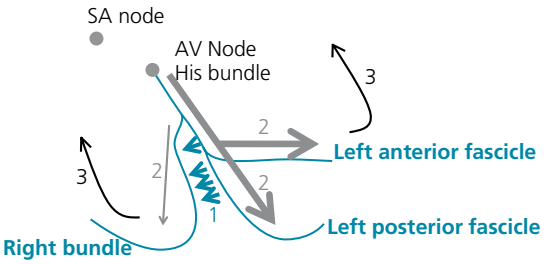

Figure 32.2 Arrows show the spread of the electrical depolarization. Ventricular depolarization starts at the left-sided septum, then spreads to the whole septum from left to right (through the left bundle, *blue arrows 1*). It then spreads to each ventricle through the left and right bundles (*gray arrows 2*). The apex of each ventricle is depolarized first, followed by the lateral wall and the basal region, including the basal lateral wall and the basal septal muscle close to His (apical-to-basal spread of depolarization bilaterally, *black arrows 3*). Note that *septal depolarization occurs from left to right*. The basal septum muscle depolarizes late, like the basal lateral wall, as it gets depolarized retrogradely via muscular cells, not directly via His-Purkinje (fast conduction through His-Purkinje, slow conduction through myocardial cells).

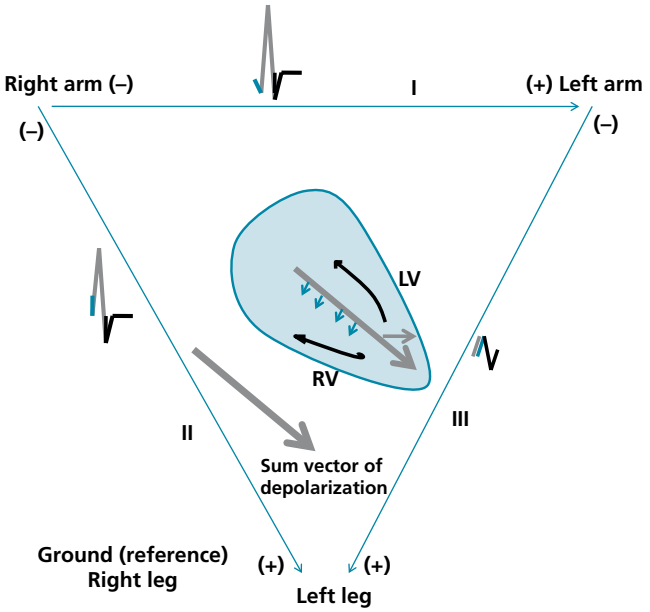

Figure 32.3 Illustration of how the electrical depolarization spreads in the heart (frontal plane, bipolar limb leads). The *blue arrows* represent the left-to-right septal depolarization. The *gray arrow* is the main axis of depolarization along the septum toward the LV and apex. The *black arrows* represent the late depolarization spreading towards the base. The QRS deflections that correspond to each one of these depolarizations are colored likewise.

The QRS complex in each lead represents how the electrical activity is spreading in relation to the lead. The **septal depolarization** (*blue*) **explains the normal small q wave** seen in normal individuals in lead I, other limb leads (sometimes), and left precordial leads. The basal depolarization explains the late "s" wave in those leads. The main deflection (big R or big S) is explained by the main depolarization spread. One can imagine how the amplitude of a deflection changes with a slight change in the way depolarization spreads.

To grossly conceive how QRS appears in a lead (amplitude, positive vs. negative direction), contrast the sum vector of depolarization with the axis of the lead.

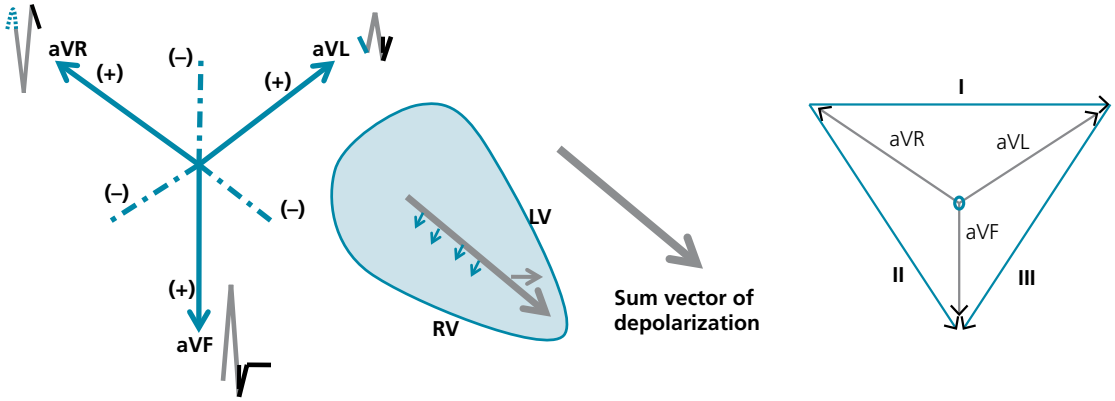

Figure 32.4 Illustration of how electrical depolarization spreads in the heart (frontal plane, unipolar limb leads).
In order to catch cardiac activity, the axis of the lead should traverse near the heart; as such, no cardiac activity is detected when both poles are placed on the legs. The limb leads' poles are best placed at the mid or distal portions of the limbs. If placed more proximally, on the torso, the amplitude of some QRS waveforms is magnified, especially with proximal positioning of left arm pole.

One can imagine a myriad of non-standard ECG leads. For telemetry monitoring, one bipolar lead consists of right chest pole and left shoulder pole (called middle chest lead MCL, with a recording somewhat similar to the unipolar V_1). For long-term rhythm monitoring, a 2-pole patch is positioned on the left upper chest, parallel to the cardiac axis.

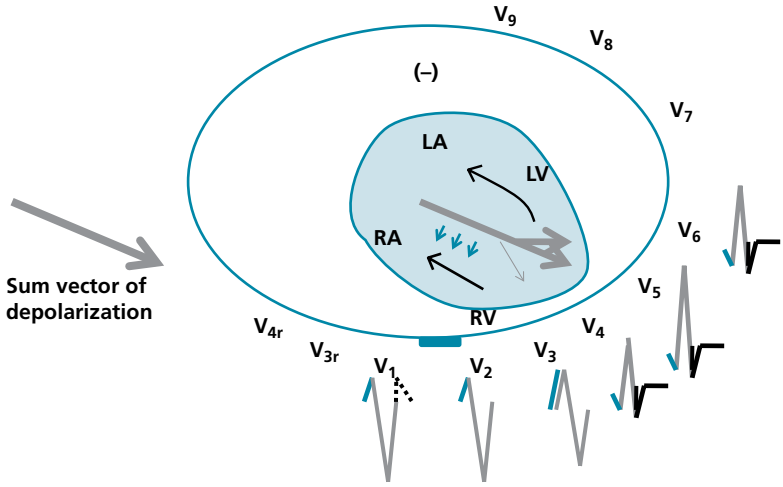

Figure 32.5 Illustration of how electrical depolarization spreads in the heart (horizontal plane, unipolar precordial leads). **V_1 and V_2** overlie the **right** heart and the septum, whereas **V_4 through V_6** overlie the **apex and the LV**. The QRS complex starts as rS in leads V_1–V_3 and progresses to qRs in the left leads. The small r in V_1–V_2 and the small q past the transition zone (V_4–V_6) represent septal depolarization. At the transition zone (e.g., V_3 in this picture), the R wave represents septal depolarization and part of the main axis of depolarization. The amplitude of R or S in each lead depends on how parallel the sum vector of depolarization is to the axis of the lead.

Since leads V_1 and V_2 overlie the right heart, any abnormality that makes electrical forces go toward the right heart makes QRS positive in V_1 or V_2; this is the case in RBBB and RVH. Conversely, any abnormality that makes electrical forces go toward the left makes QRS positive in V_5 or V_6; this is the case in LBBB and LVH.

$V_1 \rightarrow$ 4th intercostal space, right sternal border. $V_2 \rightarrow$ 4th intercostal space, left sternal border. $V_4 \rightarrow$ 5th intercostal space, midclavicular level. $V_3 \rightarrow$ between V_2 and V_4. $V_5 \rightarrow$ 5th space, anterior axillary line. $V_6 \rightarrow$ 5th space, midaxillary line. $V_7 \rightarrow$ posterior axillary line, $V_9 \rightarrow$ paraspinal line; $V_8 \rightarrow$ between V_7 and V_9 (~ below the scapula)

Appendix 2 provides an illustration of cardiac depolarization and the QRS morphology in the limb and precordial leads in various disease states.

The electrical spread of ventricular depolarization (QRS) and ventricular repolarization (ST–T) is captured by the ECG leads. Ventricular repolarization (phases 2 and 3 of the action potential) has an opposite polarity to ventricular depolarization (phase 0 of the action potential), yet the T wave has the same polarity as QRS. In fact, ventricular depolarization spreads from the endocardium to the epicardium; however, the epicardium has a shorter action potential than the endocardium, and although it is activated later, repolarization starts earlier in the epicardium and spreads to the endocardium. Therefore, in normal individuals, the electrical vectors of repolarization and depolarization have the same direction. QRS and ST–T are concordant, with the ST segment being isoelectric as all myocardial cells reach the same phase 2 plateau level without any intramyocardial gradient.

In disease states where some myocardial areas are activated very late, such as bundle branch block or ventricular dilatation or hypertrophy, the late areas are repolarized very late as well, so that the difference in action potential duration between epicardium and endocardium

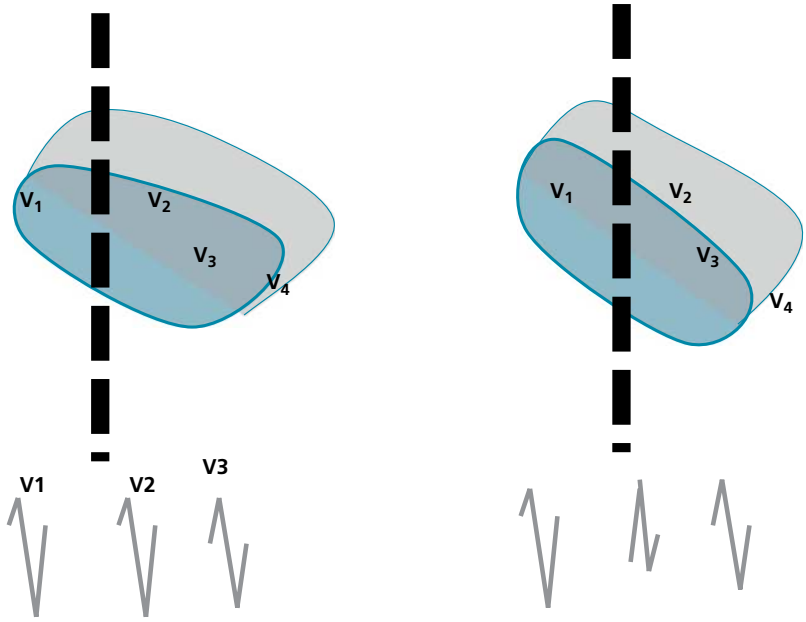

Figure 32.6 Frontal view of the precordial leads. Normally, R wave progressively increases in height between V_1 and V_3, V_1 and V_2 overlying the right heart. Occasionally, depending on the heart orientation, the electrode V_2 may be on the left of the septum, while V_3 may be on the right of the septum. R wave may be large in V_2 but becomes small again in V_3. This is more likely to happen if V_3 is placed at the same vertical level as V_2.

is unable to restore the polarity of repolarization. For example, in LBBB, both the endocardium and epicardium that depolarize late repolarize late as well; in severe concentric LVH, the epicardium depolarizes so late that it repolarizes late as well. In these patients, the electrical vectors of depolarization and repolarization have opposite polarity and directions (QRS and ST–T are discordant), and different parts of the myocardium reach phase 2 (ST segment) at different times, which creates an oblique deviation of the ST segment. This is particularly true in patients with the most delayed depolarization (severe ventricular hypertrophy or enlargement, LBBB).

On the other hand, the length of the QT corresponds to how dispersed the repolarization is across various myocardial areas, regardless of which areas are repolarized first and last.

II. Stepwise approach to ECG interpretation

The following steps are followed in ECG interpretation:[1]

1. Rhythm: look at QRS regularity and rate.
- Then look for P waves, and assess the P–QRS relationship.
- Determine if the rhythm is sinus (P [+] in I and II and [–] in aVR).

2. Determine QRS axis in the frontal plane (leads I, II, and aVF). Also assess R-wave progression in V_1–V_6 (normal vs. poor progression vs. early transition).

Then start analyzing each ECG segment:

3. Analyze P wave in leads II and V_1–V_2 (left or right atrial enlargement).

4. Analyze PR interval.

5. Analyze *QRS width*: if ≥120 ms, look at the QRS morphology in the right leads V_1–V_2 and the left leads V_5–V_6, and characterize it as RBBB (wide upright QRS on the right, V_1–V_2), LBBB (wide upright QRS on the left, V_5–V_6), non-specific conduction delay, or pre-excitation (WPW).

Look for LAFB features.

Analyze *QRS amplitude*: look for big R wave on the right (RVH) or big R wave on the left (LVH), and use the hypertrophy criteria.

6. Look for abnormal Q waves.

7. Analyze ST–T segments. Are they depressed or elevated? In which leads and which family?
- In case of ST depression, does the abnormality appear secondary to LVH/LBBB/RVH/RBBB and is it opposite to the QRS direction? Or does it appear ischemic?
- In case of ST elevation, does the abnormality appear secondary to LVH/LBBB and is it opposite to QRS direction? Is it concave upward without reciprocal changes or Q waves (this may suggest pericarditis or secondary ST elevation)? Is PR segment depressed?

8. Assess QT segment. Look for patterns of electrolyte abnormalities.

III. Rhythm and rate

A. Look at the rhythm strip and survey for the following:

1. Assess the regularity of QRS complexes. Then look for P waves and assess the P and QRS relationship, i.e., look for an association between P and QRS, and look for hidden P waves manifesting as notches over the QRS or the ST–T segment. P wave is often best seen in lead II, which is often parallel to the P-wave axis.

Examples of cardiac rhythms:

a. ***Sinus rhythm or tachycardia***: one sinus-looking P wave before each QRS (Figure 32.7).

b. ***Atrial tachycardia, atrial flutter***: one or more P waves are seen before each QRS with consistent P–QRS association. R–R intervals are equal or, if not equal, there is a consistent repetition of the same pattern of R–R intervals.
   - Example: 2:1 conduction, meaning that every second P wave gets conducted, so there is 1 QRS for every 2 P waves with regular P–P intervals and R–R intervals.
   - Or 4:1 or 1:1 conduction.
   - Or variable conduction (2:1, mixed with 3:1, 4:1). In this case, R–R intervals are irregular, but there is repetition of the same R–R intervals.

c. ***Atrial fibrillation***: irregularly irregular rhythm or tachycardia (total chaos; no repetition of the same R–R intervals; Figure 32.8). Another irregularly irregular rhythm is MAT. Unlike AF, in MAT, polymorphic P waves are seen and conduct in a 1:1 fashion.

d. ***AVNRT/AVRT***: regular, narrow complex tachycardia. P waves are not seen or are seen just after or within ST–T, with a 1:1 QRS–P association (Figure 32.9).

e. ***Ventricular tachycardia***: wide complex tachycardia with no relation between P waves and QRS complexes (AV dissociation) *and/or* more QRS complexes than P waves (Figure 32.10).

f. ***Bradycardia with regular P waves and regular QRS complexes, unrelated to each other***: complete AV block (Figures 32.11, 32.12).

g. ***Bradycardia without any P wave***: sinus arrest with junctional escape rhythm, AF with complete AV block and junctional escape rhythm, or hyperkalemia.

2. Premature ventricular or atrial complexes (PVCs or PACs). *PVC* is wide with ST–T directed opposite to QRS. *PAC* is narrow, but may be wide in case of aberrancy (Figure 32.13).

3. Irregular rhythm with some pattern or regularity, meaning that R–R intervals are not all equal, but some of them are:
- Atrial tachycardia or atrial flutter with variable AV conduction (e.g., conduction changes from 2:1 to 3:1, then 2:1 again). The rhythm is irregular, but there is a pattern to it (Figure 32.14).
- PVCs or PACs (PVCs and PACs are usually followed by a pause).
- Sinus arrhythmia (P–P interval varies cyclically, PR distance remains constant).

4. Groups of beats separated by pauses:
- Second-degree AV block (Figure 32.15)
- Frequent PACs, PVCs, or non-conducted premature Ps, each followed by a pause (Figure 32.13)

5. Look for **pacemaker spikes** (small vertical lines before P or QRS or both P and QRS).

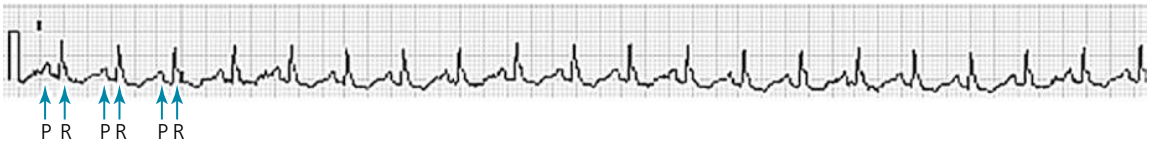

Figure 32.7 Regular QRS rhythm with a P wave before each QRS complex: sinus tachycardia or atrial tachycardia. Analyze P morphology in leads I, aVR, and II to determine if the rhythm is sinus or ectopic atrial.

Figure 32.8 Irregular tachycardia with no repetition of any R–R pattern. No clear P wave is seen; rather, waves that vary greatly in shape are seen. This is AF with fibrillatory atrial waves.

Figure 32.9 Narrow complex tachycardia with a pseudo-r′ in lead V_1 that represents a retrograde P wave (*arrows*). This is a narrow complex tachycardia with a very short interval between QRS and the retrograde P wave → AVNRT.

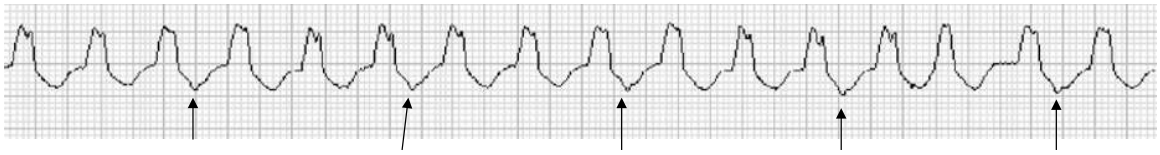

Figure 32.10 Wide complex tachycardia: VT vs. SVT with bundle branch block. Look for P waves on top of the ST–T segments: one can identify deflections that have a consistent *morphology* and *timing* and that can be marched out. They occur after every third QRS. Since the number of QRS complexes > number of P waves, this is VT. The P waves are retrograde P waves.

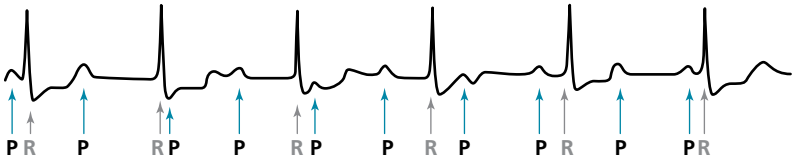

Figure 32.11 Bradycardia with regular P waves and regular QRS complexes, unrelated to each other. Some P waves fall on top of the ST–T segments and manifest as notches. This is a third-degree AV block. If P wave occasionally conducts, the QRS rhythm would have some irregularity.

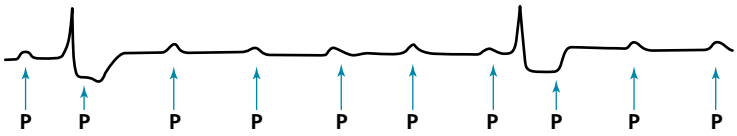

Figure 32.12 Severe bradycardia with regular P waves and regular QRS complexes, unrelated to each other: third-degree AV block.

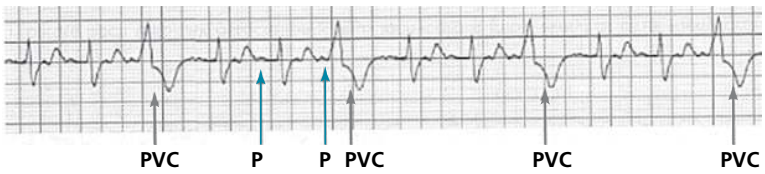

Figure 32.13 Irregularity with a pattern. Wide premature complexes with ST–T changes opposite to QRS are seen; these occur in a trigeminal pattern. A wide premature beat is typically a PVC, but could be a PAC with bundle branch block (aberrancy). In this case, the premature beat falls after a normally occurring, non-premature P wave (*blue arrows)* with a shorter PR interval than the sinus beat: this is typical of a PVC. **A PVC does not affect the sinus P wave, which keeps marching through it, sometimes falling before it at a short PR interval.** A PAC, on the other hand, should be preceded by a non-sinus premature P wave that does not march out with the preceding sinus P waves; the premature P may fall prematurely into the preceding T wave and deform it. *A deformed T wave is a clue to a PAC.*

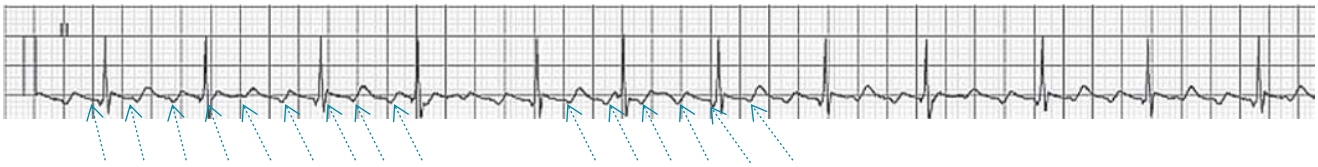

Figure 32.14 Atrial flutter with variable conduction (3:1, 4:1). The sawtooth flutter waves are marked by the *arrows*. R–R intervals are not equal, but there is some repetition of the same R–R intervals.

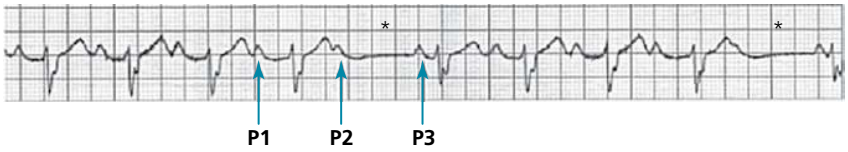

Figure 32.15 There are 2 groups of beats followed by pauses (*asterisks*), which raises the suspicion of second-degree AV block (e.g., Wenckebach). P2 is not conducted: this could be AV block or a very premature PAC that gets blocked. The fact that P2 is not premature rules out a blocked PAC. The clue to AV Wenckebach is the progressive PR prolongation, especially manifest when comparing P3R to P1R (P3R < P1R); also, the progressive R–R shortening before the block is a feature of Wenckebach.

B. Calculate the ventricular rate

The ventricular rate is equal to 300 divided by the number of big boxes between 2 QRS complexes. If the rhythm is irregular (e.g., AF), count the number of QRS complexes in 3 seconds (15 large boxes), then multiply this number by 20; or count the number of QRS complexes on the standard 12-lead ECG run (10 seconds) and multiply it by 6.

C. The rhythm is sinus if P wave is upright in leads I, II, and aVF and inverted in lead aVR, corresponding to a P-wave axis of 0–75°. Also, a sinus P wave is typically biphasic (positive then negative) in V_1, though it may be entirely positive or entirely negative in V_1. While it may also be biphasic in V_2, the sinus P wave is always upright in V_3–V_6.

A different P-wave morphology means ectopic atrial rhythm/tachycardia, accelerated junctional rhythm with retrograde P wave, or AVNRT/AVRT with retrograde P wave. ***A retrograde P wave*** is negative in the inferior leads II, III, and aVF and is usually seen shortly after the QRS. If P waves have 3 different morphologies, the rhythm is a wandering atrial pacemaker (rate < 100 bpm) or a wandering atrial tachycardia (rate > 100 bpm, also called *MAT*) and is irregular.

IV. QRS axis in the limb leads and normal QRS progression in the precordial leads

A. Determine the frontal QRS axis by looking at the net QRS voltage (upward minus downward deflection) in leads I, II, and aVF (see Figure 32.16)

The normal QRS axis is between –30° and +90°. To determine QRS axis, start by looking at leads I and aVF. If the net QRS is negative in lead aVF, the axis is < 0°; one must look at lead II to determine if the axis is < –30°, which defines left-axis deviation.

1. *If the net QRS is negative in lead I and upright in lead aVF,* ***right-axis deviation*** *is present.* Six causes (the first 4 are abnormal):
   - RVH (including pulmonary embolism)
   - Lung disease even without RVH
   - Left posterior fascicular block (LPFB) (usually associated with right bundle branch block [RBBB])
   - Lateral MI: Q wave is seen in lead I. Instead of a Q wave, a diminutive small r wave (rS pattern) sometimes appears in leads I–aVL. In this case, the Q waves in leads V_5–V_6 and the frequently seen T-wave inversion in I–aVL allow the diagnosis (≠ RVH)
   - Normal variant: vertical heart with a 90–100° axis in young individuals
   - Arm electrodes misplacement: P wave will also be negative in lead I, and upright in lead aVR

If right-axis deviation is present, evaluate for RVH by looking for a tall R wave in $V_1 \pm V_2$ (R wave > 7 mm or R wave > S wave) or a deep S wave in V_6.

> Note that isolated RBBB does not lead to right-axis deviation (think of an associated RVH or LPFB when right axis accompanies RBBB).

2. *If the net QRS is upright in lead I but negative in leads II and aVF,* ***left-axis deviation*** *is present.* Four causes:
   - LVH
   - Left anterior fascicular block (LAFB)
   - Left bundle branch block (LBBB)
   - Inferior MI

The QRS axis progressively shifts more leftward with obesity, which pushes the diaphragm up, and with age, but does not normally exceed –30°. Conversely, thin individuals tend to have a more vertical heart. ***Inspiration and upright position make the heart more vertical and may explain a change in axis without intervening disease.***

3. *If the net QRS is negative in leads I and aVF, the* ***axis is in the northwest quadrant*** *(extreme right or left deviation).* The northwest axis may occur in various right or left pathologies.

If QRS is equiphasic in all limb leads, the axis is perpendicular to the frontal plane and is called *indeterminate*. This may be a normal variant or may occur with right ventricular pathology. One variant, $S_1S_2S_3$, signifies that S ≥ R in leads I, II, and III, and implies an indeterminate axis (S = R) or northwest axis (S > R). It may be a normal variant when the axis is indeterminate.

> To fine-tune the axis, look at the lead where QRS is closest to equiphasic, i.e., the lead where R = S with a neutral net force. The axis is close to + or –90° from this lead (Figure 32.16). If QRS is closest to equiphasic in 2 leads, the axis is in between the perpendicular lines to these 2 leads, in the appropriate quadrant.

B. Look at the normal QRS progression across V_1–V_6

Normally, QRS is negative in V_1–V_2 (rS) and becomes progressively positive in V_5–V_6 (Rs). Note: rS denotes small R, big S. Rs denotes big R, small S.

1. *If QRS starts positive in V_1–V_2 (**early transition**), consider 6 causes, the first 2 being "Right problems":*
   - RVH (which also leads to right-axis deviation).
   - RBBB.
   - Posterior wall infarction: large, and more importantly, wide R wave in V_1, reciprocal of a posterior Q wave. Often, Q waves are present in V_7–V_9 and in the inferior leads.
   - WPW: short PR and delta wave are present.

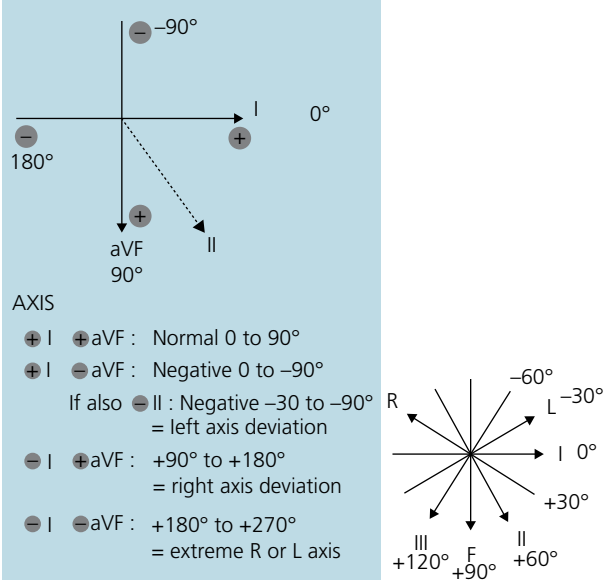

Figure 32.16 Start by looking at leads I and aVF. If QRS is negative in lead aVF, the axis is <0°; one must look at lead II to determine if the axis is <–30°, which defines left-axis deviation. In all other cases, looking at leads I and aVF is enough to grossly define the type of axis deviation. Reproduced with permission of Scrub Hill Press from Hanna et al. (2009).[1]

- Septal hypertrophic cardiomyopathy (thick septum, thicker than the lateral wall, projects as big R in V_1–V_2 and big Q in the lateral leads); or Duchenne muscular dystrophy (posterior wall fibrosis).
- However, the most common cause of early transition is a normal variant. It is more common in the stocky/obese or the young, where the heart is swung more anteriorly than older individuals. A low malposition of electrodes V_1–V_2 is also a common cause of early transition.

2. *Poor precordial R-wave progression* *means that the R-wave height remains <3 mm (=0.3 mV, 3 small boxes) in lead V_3, and more specifically ≤1.5 mm, with failure of the R/S height ratio to increase.*

It may be an equivalent of Q wave and may signify an anterior MI, particularly if 1 of the following 2 features coexists: (i) T inversion in V_1–V_3; (ii) R wave in lead I < 4 mm. The small R wave in lead I suggests diminution from a lateral MI, although it may also be secondary to COPD. Conversely, the following 2 features argue against MI: (i) improvement of R-wave progression with lower placement of the chest electrodes; (ii) sudden R-wave transition in V_4 or V_5, which suggests a high misplacement of electrodes V_1–V_2 and a normal placement of electrodes V_3–V_6, as in patients with large breasts. In MI, R wave remains small in V_4–V_5 and transitions slowly, yet a slow transition does not necessarily imply MI and may be seen with LAFB, LVH, or COPD, which swing cardiac depolarization posteriorly. Even when poor R progression results from an anterior MI, the MI is nontransmural in 92% of cases and is "better" than an MI with Q waves in V_1–V_3 (Zema et al. Chest 1981). Reverse R progression, which means that R wave not only progresses poorly but gets smaller between V_1 and V_2 or V_2 and V_3, slightly increases the likelihood of MI.

However, poor R progression is most often related to the following causes, the first 3 being "left problems" (Figure 32.17):

- LAFB.
- LVH.
- LBBB.
- High misplacement of electrodes V_1–V_2 or low heart/low diaphragm position (thin and tall individuals); or heart swung posteriorly, away from V_1–V_2, as in older patients where the elongated unfolded aorta rotates the heart posteriorly. Normal R-wave progression may be seen when the chest leads are placed 1 interspace lower.
- COPD, in which case the heart is pushed down and posteriorly, away from the precordium: COPD leads to poor R-wave progression with right-axis deviation. Poor R-wave progression with right-axis deviation may also be seen when anterior MI is associated with a high lateral MI. The overall size of the QRS allows the distinction between COPD and anterior MI (QRS voltage is often reduced in COPD). Also, in COPD, recording the chest leads 1 interspace lower often corrects R-wave progression, at least partially.

V. P wave: analyze P wave in leads II and V_1 for atrial enlargement, and analyze PR interval (see Figures 32.18, 32.19)

A. Lead V_1 (and/or V_2)

- Left atrial enlargement = terminal negative P-wave deflection > 1 box wide (40 ms) and 1 box deep (0.1 mV).
- Right atrial enlargement = initial positive P-wave deflection ≥ 1.5 small boxes high.

B. Lead II (and I, III)

P waves should be <2.5 small boxes high (0.25 mV high) and <3 small boxes wide (120 ms wide).

- Left atrial enlargement = P wave ≥120 ms and notched
  P may have a negative terminal deflection in leads III and aVF, i.e., left P-axis deviation. While an abnormal P-wave axis suggests ectopic atrial origin, in context, it may rather imply atrial enlargement.

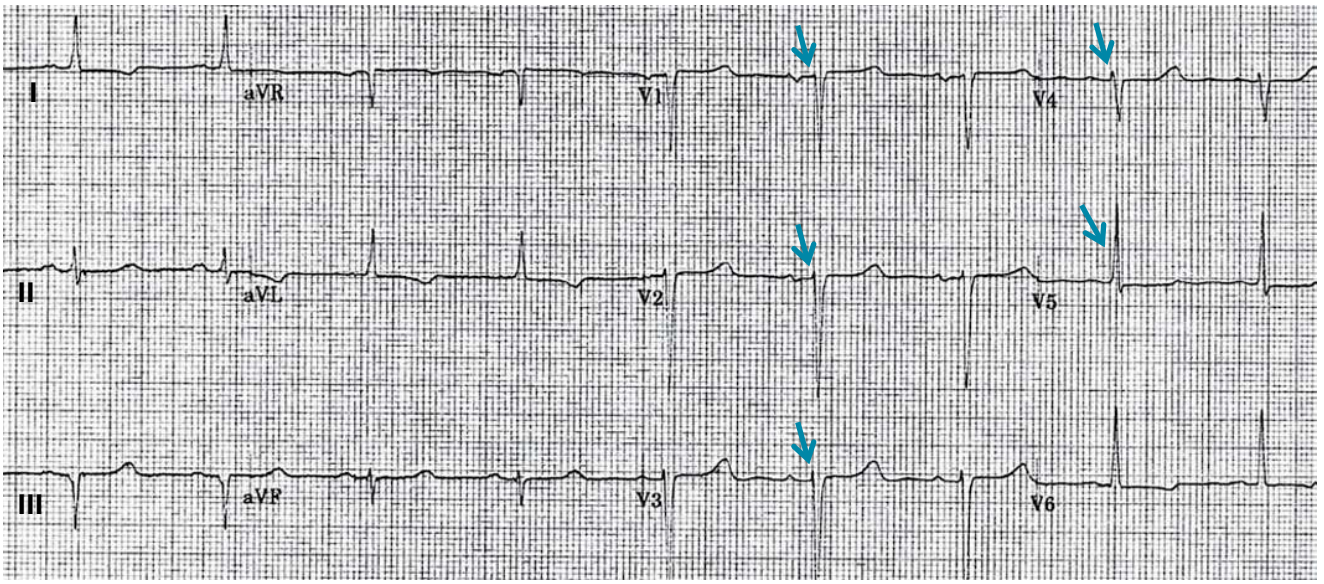

Figure 32.17 Poor R-wave progression probably secondary to LVH with a sudden transition in V_5 (*arrows*). Sudden transition is a good indicator of the absence of anterior MI. The lack of T-wave inversion in the anterior leads and the normal-size R wave in lead I also make MI unlikely.

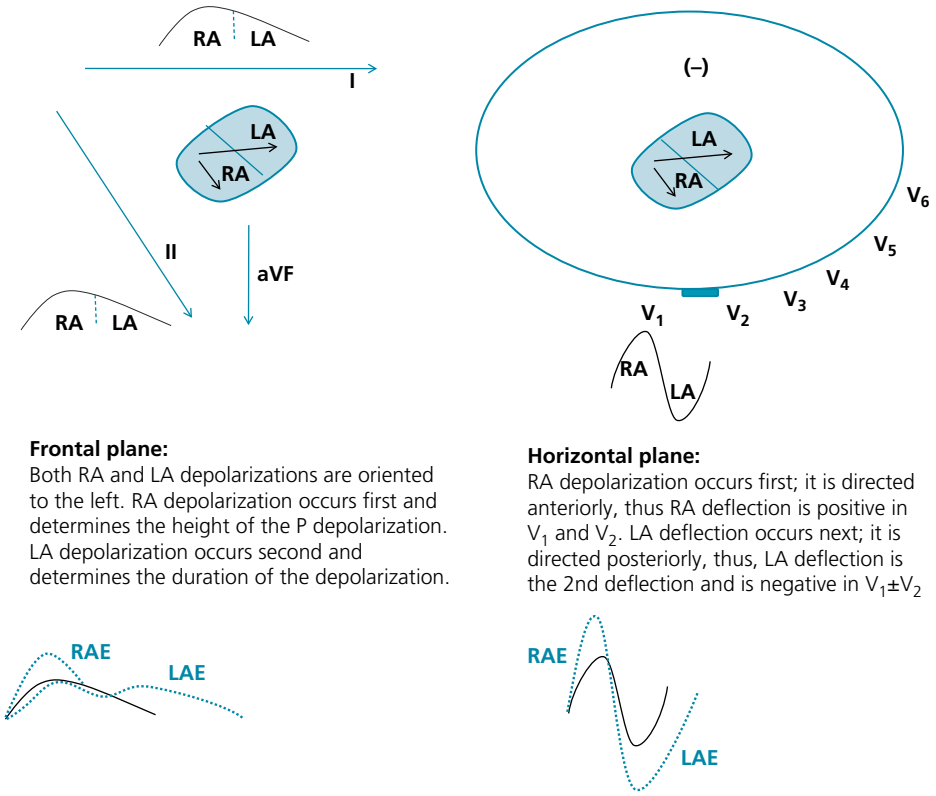

Figure 32.18 Normal and abnormal RA and LA deflections. Atrial depolarization starts from the sinus node, at the junction of SVC–RA, and spreads in a radial fashion to depolarize the RA, interatrial septum, and LA.

RA enlargement (RAE) is characterized by increased voltage of the first atrial deflection in lead II and in leads V_1–V_2. LA enlargement (LAE) is characterized by prolongation of P duration in lead II with a double hump, the second hump corresponding to LA depolarization. Depending on the severity of LAE and on the heart orientation, the P wave may peak high and relatively early in lead II, simulating RAE (e.g., vertical heart). Also, it may have a positive component in lead V_1. Thus, anatomical LAE may mimic RAE electrocardiographically; up to 30% of cases of electrocardiographic RAE are actually LAE.

Moreover, depending on the severity of RAE, the duration of P wave may be increased and a negative component may be seen in lead V_1. Thus, anatomical RAE may simulate LAE electrocardiographically.

P-wave amplitude normally increases during sinus tachycardia or exercise, while the P-wave duration decreases; this is due to a more synchronized RA and LA depolarization. Thus, RAE criteria are less valid in sinus tachycardia, but LAE criteria remain valid. In fact, an increase in P duration with exercise suggests left HF with LA volume overload unveiled by exercise.

RAE and LAE may be seen on ECG as a result of increased atrial pressure or atrial ischemia, even in the absence of true enlargement. RAE may be seen in patients with lung disease (vertical heart) even in the absence of true enlargement. Thus, the ECG terms RAE and LAE are better replaced with RA abnormality and LA abnormality, respectively.

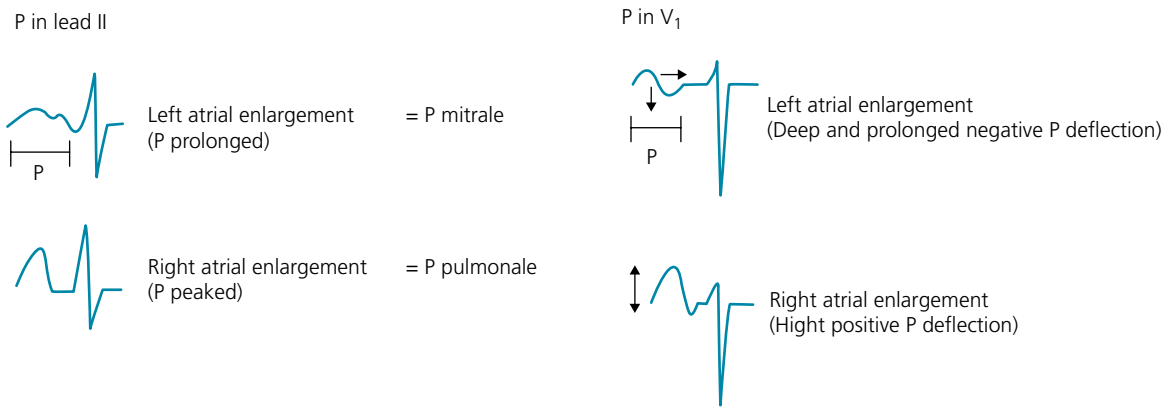

Figure 32.19 Right atrial enlargement and left atrial enlargement. Reproduced with permission of Scrub Hill Press from Hanna et al. (2009).[1]

- Right atrial enlargement = P wave is peaked ≥ 0.25 mV
  P axis may be rightward > +75°, and P may become flat in lead I and inverted in aVL. This could suggest a non-sinus P wave. However, in the presence of other signs of right heart pathology (i.e., right-axis deviation of QRS), the P wave is rather a sinus P wave with a right P-axis deviation.

C. Normal PR interval

Normal PR interval is 120–200 ms (3–5 small boxes; assess it in multiple leads and take the longest).

- PR < 3 small boxes: pre-excitation (WPW pattern), but may just be a fast-conducting AV node. Look for delta waves.
- PR > 5 small boxes: first-degree AV block.
- PR interval includes AV conduction but also atrial repolarization. Atrial enlargement, atrial infarction, or sinus tachycardia with increased P-wave amplitude may depress the PR interval; also, atrial repolarization may prolong and extend over the ST segment, causing ST depression.

VI. Height of QRS: LVH, RVH

Grossly, look at the height and the width of QRS in leads V_1, V_6, and I–aVL.

A. Look for LVH (see Figure 32.20)

LVH can be identified using any of the following criteria (assuming standard calibration):

- In lead I, R wave > 14 mm, or R wave in lead I + S wave in lead III > 25 mm.
- In lead aVL, R wave > 11 mm or > 13 mm in case of LAFB (very specific criterion).
- S wave in V_3 + R wave in aVL ≥ 28 mm in men or ≥ 20 mm in women. This is Cornell criterion, the most sensitive and specific classic LVH criterion. A novel marker proved more sensitive (Peguero-Lo Presti): Deepest S in any lead +S in V_4 ≥ 28 mm ♂, 23 mm ♀
- In the precordial leads: **big R on the left** (V_5–V_6) and big S on the right (V_1–V_2) translate into:
  - S wave in V_1 + R wave in V_5 or V_6 ≥ 35 mm
  - Any S wave (V_1–V_3) + any R wave (V_4–V_6) ≥ 45 mm
  - R wave in V_6 > R wave in V_5
  - R wave in V_5 or V_6 > 26 mm
- Notes:
  - LVH may be associated with delayed precordial QRS transition, as the vector of depolarization is turned leftward. Left-axis deviation <–30° may be seen but is infrequent; a leftward axis (0 to –30°) is more common.
  - LAFB shifts the electrical depolarization superiorly and posteriorly; thus, R wave is increased in the limb leads I and aVL, and S wave is deepened across the precordial leads. This reduces the specificity of Cornell and aVL criteria.

- LVH should not be formally diagnosed in the presence of complete LBBB. For practical purposes, however, 80% of patients with LBBB have LVH.
- A strain repolarization pattern may be present. Strain means the ST segment and T wave are directed opposite to QRS. A strain pattern correlates with a more severe LVH.
- Electrocardiographic LVH correlates with LV mass but also LV volume, and may imply LV dilatation rather than thickening.
- QRS voltage is high in the young and declines with age due to pericardial fat deposition and insulation. Hence, precordial voltage criteria are less specific for LVH in those < 35 (esp. if slim/athletic). Cornell and limb criteria remain specific, and the probability of true LVH ↑ with concomitant findings: leftward axis, LAE, strain pattern, or QRS ~110 ms.

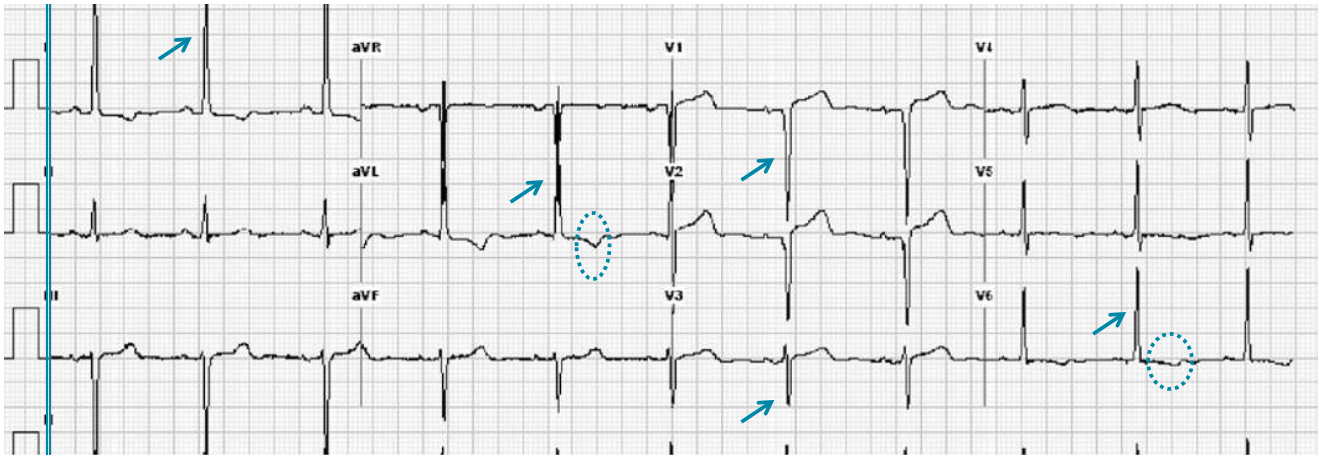

Figure 32.20 LVH with secondary ST–T depression in the left lateral leads, directed opposite to the QRS complex, called *strain pattern* (marked by the *circles*). The following LVH criteria are met (as indicated by the arrows):

- R aVL + S $V_3 \geq 28$ mm (5.5 big boxes)
- R aVL > 11 mm (>2.2 big boxes)
- R in I ≥ 15 mm (3 boxes); R in I + S in III > 25 mm
- S in V_1 + R in V_5 or $V_6 \geq 35$ mm; R in $V_5 > 26$ mm

B. Look for RVH (Figure 32.21)

RVH is characterized by:

1. Right-axis deviation (net QRS [–] in lead I, [+] in lead aVF)
   and
2. **Big R** wave in the **right** lead V_1 (≥7 mm), or big S wave in the left leads V_5–V_6 (≥7 mm)
   Or big R > S in V_1, big S > R in V_6, or small S in $V_1 \leq 2$ mm
   Or R in V_1 + S in V_6 > 10.5 mm

RVH from *volume overload* may cause an rsR′ pattern in V_1 with R′>S + Right axis. The rsR′ may be <110 ms, or 110–119 ms (incomplete RBBB), or ≥120 ms (complete RBBB), as RV further dilates. Yet, specificity for RVH declines as QRS widens, as most RBBB is not RVH-related (unlike on the left). Conversely, a monophasic R wave in V_1 or a qR pattern in V_1 signifies severe RV *pressure overload* (RV pressure higher than systemic pressure in the case of qR pattern).

RVH differential diagnosis and coexisting patterns

- ***Posterior MI*** may lead to a prominent R wave in V_1. In posterior MI, R wave is not only high but is also wide > 1 mm (≠ RVH), T wave is positive in V_1–V_2 (vs. inverted in RVH), the axis is not right, and there are often Q waves in V_7–V_9 and in the inferior or lateral leads.
- ***An incomplete RBBB pattern*** with RSR′ may be seen along with RVH. ***How to diagnose RVH when there is RBBB?*** Most incomplete RBBBs and complete RBBBs are benign and not related to RVH. On the other hand, most RVHs from volume overload have some degree of incomplete RBBB, so incomplete RBBB may be worrisome if some features are associated: R′>10 mm + right axis.
  RVH diagnosis is less specific in complete RBBB.
- ***Lung disease, such as COPD***, is characterized by: (1) right-axis deviation in the frontal plane as the heart is pushed down and made more vertical; (2) deep S wave in all precordial leads, V_1 through V_6, as the heart rotates posteriorly; (3) reduced overall QRS voltage in all leads, especially limb leads, because of increased chest air; while dominant, S wave is not particularly deep in the precordial leads. This chronic lung disease pattern simulates an old anterolateral MI, wherein R is diminished across all precordial leads and in the lateral leads I and aVL (rS pattern throughout all those leads).
  The presence of true RVH in conjunction with lung disease is characterized by one of the following: large R or small S in V_1 (≤2 mm), RSR′ pattern, or T-wave inversion in V_1–V_2. P pulmonale may be seen with lung disease even without RVH.

Additional notes

- Right-axis deviation may be less evident in patients with an associated LVH or LAFB.
- Higher voltage and more strain pattern is seen with pressure overload (pulmonary hypertension) than with volume overload (ASD). ASD is often only characterized by rSR′ pattern, and rarely leads to tall monophasic R waves.
- Left atrial enlargement supports the diagnosis of LVH, and right atrial enlargement supports the diagnosis of RVH in cases of borderline voltage criteria. LVH with right atrial enlargement or RVH with left atrial enlargement suggests biventricular hypertrophy, unless MS is present (MS may lead to left atrial enlargement + RVH).

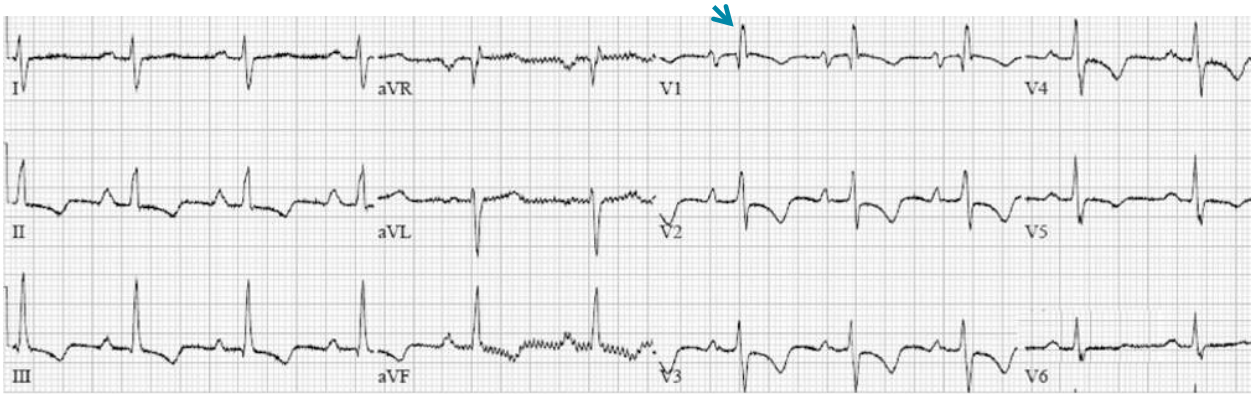

Figure 32.21 QRS is (–) in lead I and (+) in lead aVF, implying a right-axis deviation. The smallest net QRS is in leads I and aVR. QRS axis is thus between perpendicular to I (+90°) and aVR (+120°). Axis is ~ +105°. RVH is diagnosed by the fact that axis is right and R > S in V_1. In fact, there is a qR pattern in V_1 (S = 0) (*arrow*), signifying severely increased RV pressure. P pulmonale and secondary T inversion are also seen.

C. Biventricular enlargement

Biventricular enlargement is characterized by any one of the following:

1. Voltage criteria for both LVH and RVH. This usually implies tall R waves in V_5–V_6 (LVH) with a small S wave in V_1, or R > S in V_1 (R is not usually large in V_1, but is larger than S).
2. LVH with right-axis deviation.
3. LVH with right atrial or biatrial enlargement.
4. LVH with T inversion in V_1–V_2 (T going in the same direction as QRS). This T inversion can be secondary to RV strain or anterior ischemia.
5. Tall R wave and tall S wave in the mid-precordial leads V_3–V_4 (Katz–Wachtel sign).

VII. Width of QRS: Conduction abnormalities: bundle branch blocks

The normal QRS duration is < 110 ms. In complete bundle branch block, the QRS is wide (≥120 ms or 3 small boxes). In incomplete bundle branch block, the QRS is 110–119 ms.

Look at the QRS complex in lead V_1. **Is the net QRS complex upright (i.e., positive)?**

- If yes, consider RBBB.
- If no (negative QRS in lead V_1), consider LBBB. *A conduction block makes the QRS vector look toward it: RBBB makes the QRS vector look toward the right, leading to an upright wide QRS in the right leads* (Figures 32.22–32.26).

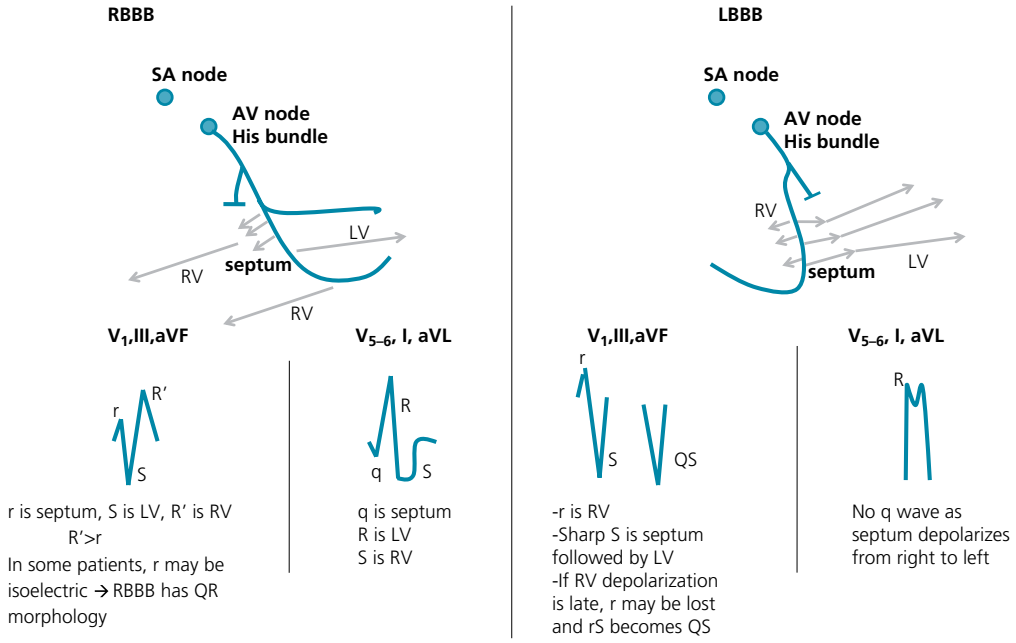

Figure 32.22 In RBBB, the vector of depolarization spreads from the left septum to the right and left ventricles. RSR' is seen in V_1, R being septal depolarization, S being LV depolarization, and R' being the late RV depolarization. RS is seen in V_6, R being LV depolarization, and the wide S being the slow RV depolarization.

In LBBB, the vector of depolarization spreads from the right septum to the left septum and the left ventricle. The vector looks toward V_6 and away from V_1. Thus, in LBBB, QRS is positive in V_5–V_6 and widely negative in V_1. The septal q wave that is normally seen in the left lateral leads is lost, as the septum depolarizes from the right to the left. The presence of any q wave in leads V_5–V_6 or lead I is not typical of LBBB and suggests an old MI. Only rarely, a q wave may be seen in lead aVL.

In both RBBB and LBBB, QRS starts narrow and normal, then widens later.

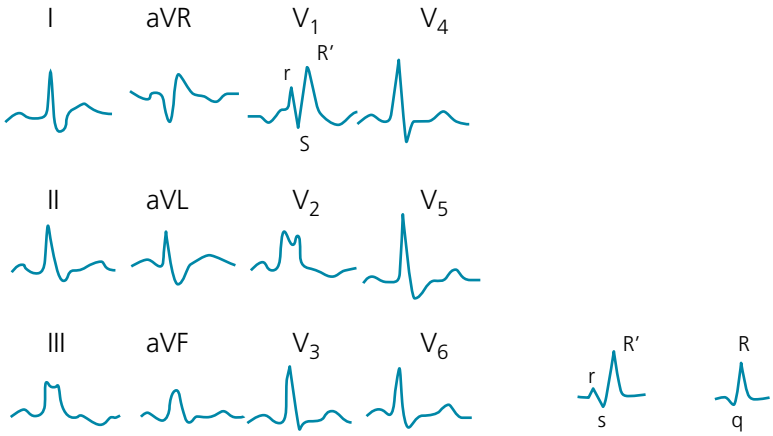

Figure 32.23 RBBB. rSR' is seen in V_1, notched R wave is seen in V_2, and rsR' and qR patterns are shown on the right (rsR' means small R, small S, big R'). Any of those patterns is consistent with RBBB in V_1–V_2. S wave is wide and slurred in leads I, aVL, and V_5–V_6. In all leads, QRS starts sharp and widens later.

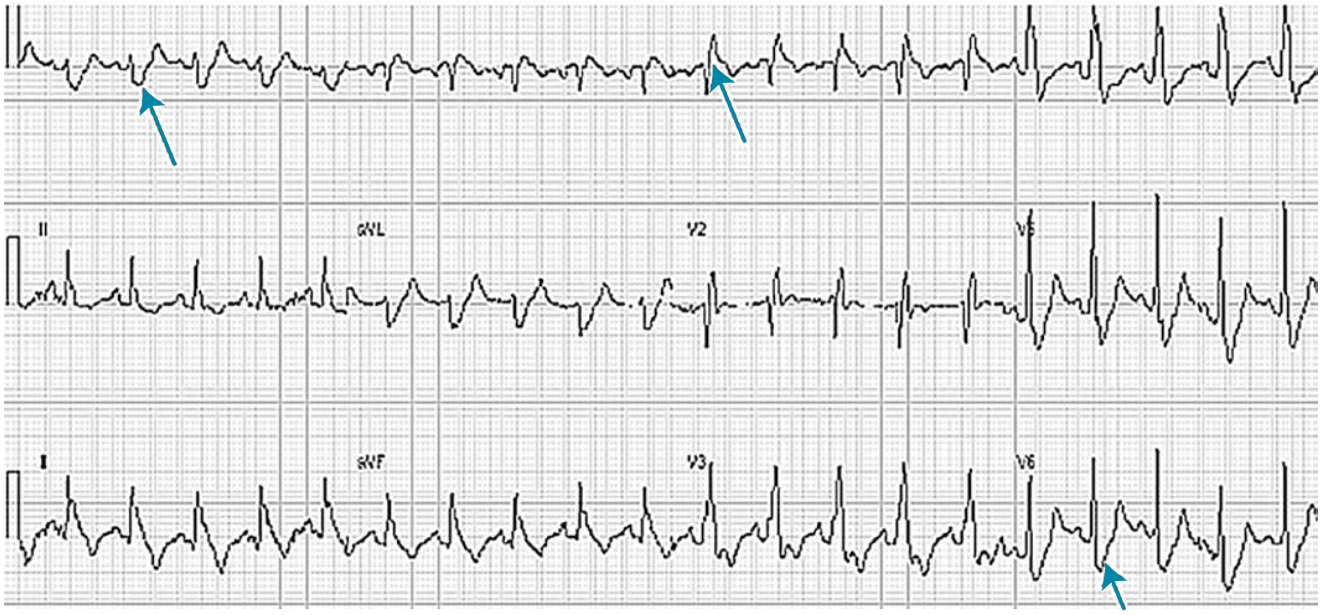

Figure 32.24 Sinus tachycardia with RBBB (rSR' in V_1–V_2, wide and slurred S in V_5–V_6 and I–aVL, *arrows*). Right-axis deviation (QRS [–] in lead I, [+] in lead aVF) signifies an associated RVH (most commonly) or LPFB. T-wave inversion in V_1–V_3 and II/III/aVF is secondary to RBBB and RVH. The patient is diagnosed with PE. Reproduced with permission of Scrub Hill Press from Hanna et al. (2009).[1]

A. RBBB

In **RBBB**, QRS has a slurred positivity in the **right** leads. Besides QRS ≥ 120 ms, *both* the following two criteria are required to make the diagnosis of RBBB:

- rSR', rsR', or rsr' pattern in the **right** leads V_1 and/or V_2. R' is usually wider and taller than the initial R wave. A qR pattern may replace rSR' in lead V_1 when the initial r wave is isoelectric. A single wide R wave, often notched, may be seen instead of rSR'.
- A *wide* S wave in the left leads I and V_6. *S wave must be wider than R wave or wider than 40 ms.*

In addition, T-wave inversion in V_1–V_2 is common but not mandatory (T directed in an opposite direction to QRS).

B. LBBB

In **LBBB,** QRS has a slurred positivity in the **left** leads. The first 4 criteria are required to make the diagnosis of LBBB:

1. Wide notched R wave in leads I, aVL, and V_5–V_6 (M-shaped or slurred, plateaued R wave).
2. QRS is negative in leads V_1, V_2, V_3 with an rS or QS pattern.
   QS pattern may also occur in leads III and aVF, simulating an inferior MI, but not in lead II.
   QR pattern does not occur with LBBB and always implies an associated MI.

3. The septal q wave should be absent in the left leads I and V_5–V_6. A narrow q wave may be seen in aVL.
4. The ST segment and T wave should be directed opposite to QRS. Unlike LVH, RBBB, and RVH, secondary ST–T changes are mandatory in LBBB.
5. Two less usual features may be seen in LBBB and do not preclude the diagnosis of LBBB:
- q wave in aVL.
- RS pattern (rather than a plateaued R pattern) in leads V_5–V_6. This occurs in patients with delayed QRS transition, such as patients with enlarged LV or LV depolarization that spreads from apex to base; the frontal QRS axis is leftward in both of these cases.

An incomplete RBBB or LBBB, also called bundle branch delay, is characterized by a QRS of 110–119 ms with QRS features of the respective bundle branch block in V_1, V_6, and I. Similarly to a complete block, an incomplete block is accompanied by the secondary repolarization abnormalities.

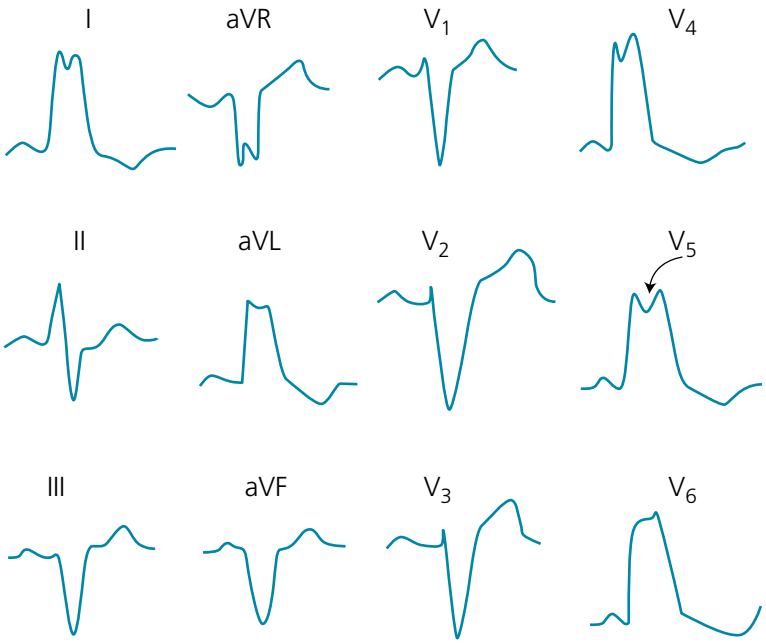

Figure 32.25 LBBB. In the lateral leads, there may be an "M-shaped" R wave (as seen here in I and V_5) or a broad slurred R wave (as seen in V_6), with delayed R-wave peak time > 60 ms, measured from QRS onset to the second R notch or the end of the R plateau. When the LV is enlarged or the depolarization is turned further leftward, the transition zone and the wide R wave may not be reached in lead V_6, and an RS pattern is seen in leads V_5–V_6. The wide, M-shaped R wave will still be seen in leads I–aVL and will also be seen more laterally in leads V_7–V_9. Note that, in all leads, QRS starts sharp and widens later. Reproduced with permission of Scrub Hill Press from Hanna et al. (2009).[1]

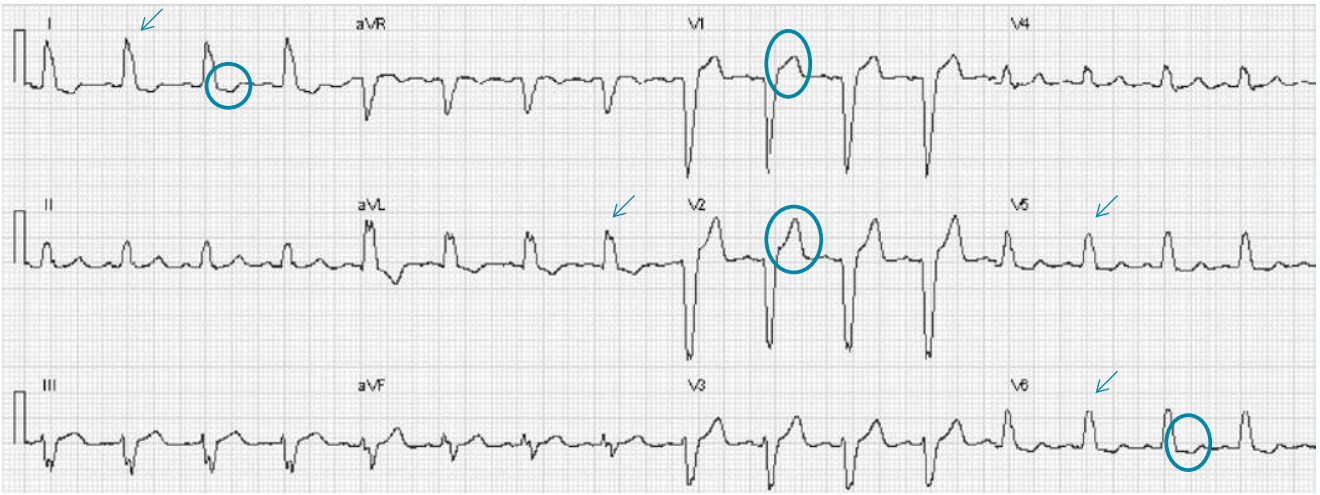

Figure 32.26 LBBB (slurred R wave in the left leads: V_5–V_6 and I–aVL) (*arrows*). ST depression in V_5–V_6, I, and aVL, and ST elevation in V_1–V_3, directed opposite to QRS, are secondary to LBBB (*circles*).

- rSR′ or rSr′ patterns in V_1–V_2 may be normal variants if QRS is <110 ms and r and r′ are small (r′ < 5 mm) and smaller than S wave, without right-axis deviation, right atrial enlargement, or T-wave inversion.
- Posterior MI may simulate rSR′ in V_1. As opposed to RBBB, r is usually wide.
- RVH may lead to rSR′ pattern in V_1 with incomplete or complete RBBB. In those cases, RVH is diagnosed if the axis is right, as determined by the net voltage of the initial, unblocked 80 ms of QRS in the limb leads, *along with* a suggestive clinical context or R′ >10 mm in V_1. In fact, right axis in a RBBB is most commonly due to RVH, more so when RBBB is *incomplete*. Incomplete RBBB may reflect a prolonged depolarization of a large RV rather than a histological abnormality of the right bundle.

LVH cannot be formally diagnosed in the presence of complete LBBB, but can be diagnosed in the presence of incomplete LBBB. In fact, *LVH with QRS 110–119 ms and with loss of septal q waves and delayed R peak in leads I and V_5–V_6 (>60 ms) is a combined LVH + incomplete LBBB*. Conversely, in LVH without LBBB, septal q waves are prominent and may be of pathological dimension. In some patients, LBBB is due to a block across the left bundle, but in many other patients, LBBB is due to diffuse slowing across a diseased, enlarged LV. In the latter patients, such as those with hypertensive heart disease, *there is a progression from (i) LVH, to (ii) LVH with strain, to (iii) incomplete LBBB then (iv) complete LBBB then (v) wider complete LBBB (>150 ms then >180 ms). This progression occurs over months to years, as cardiomyopathy progresses. Also, LBBB will develop progressively more left-axis deviation.* The wider the LBBB (>150 ms, especially >180 ms), and the more fragmented and notched, the more likely it is that LBBB reflects LVH or LV dilatation/low EF, including low EF induced or aggravated by LBBB.

A wide QRS ("complete block" ≥120 ms) typically has either RBBB or LBBB pattern. A mildly widened QRS (110–119 ms) may be an incomplete block (RBBB or LBBB pattern), or a widened QRS accompanying LVH, RVH, or fascicular block.

A widened QRS that does not meet criteria for typical RBBB or LBBB may signify:

- Pre-excitation (WPW). In that case, the wide QRS starts with a "slur" (= delta wave = slow QRS upslope). This slur is riding the P wave (= short PR). ***Unlike bundle branch block, where QRS has a steep initial portion and a slow terminal portion, the QRS complex of WPW is widened at its initial uptake*** (Figure 32.27).
- Non-specific intraventricular conduction delay.
- A form of RBBB + LAFB, or RBBB with masked LBBB (Section VIII.C)
- Hyperkalemia-Drugs (class Ic antiarrhythmic drugs, tricyclics, phenothiazines).

In contrast to bundle branch block and WPW, the wide QRS of hyperkalemia is characterized by being wide both in its initial portion (≠ bundle branch block) and in its terminal portion (≠ WPW). A very wide QRS (>180–200 ms) should always suggest hyperkalemia or WPW pattern or advanced cardiomyopathy with severe ventricular dilatation.

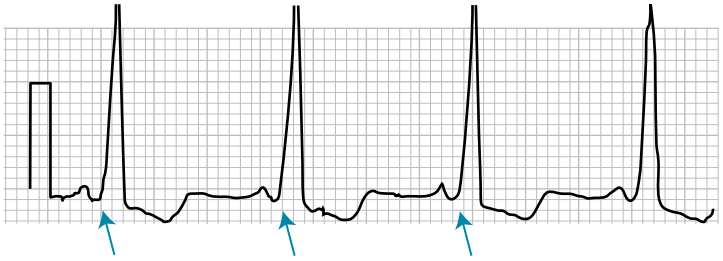

Figure 32.27 WPW with short PR segment and slurred R wave. The upslope of R wave is slow (≠ LBBB).

VIII. Conduction abnormalities: fascicular blocks

The left bundle divides into the left anterior and the left posterior fascicles. In fascicular blocks, unlike bundle branch blocks, QRS must not be very wide and must be <120 ms; usually, QRS is 80–100 ms wide (Figures 32.28–32.30).

A. Left anterior fascicular block (LAFB)

- LAFB is defined as "*an unexplained left-axis deviation*" with QRS axis between –45° and –90°. In other words, LAFB manifests as left-axis deviation beyond –45° without LBBB or inferior MI.
- A qR pattern is seen in lead I and particularly lead aVL, while rS pattern is typically seen in the inferior leads II, III, and aVF (net QRS is negative in the latter leads). Beside being positive in I and negative in aVF, the net QRS is larger in aVF than in I, which defines axis ≤ –45°.
- Additional notes:
  - LVH does not preclude LAFB diagnosis. In fact, LVH with left-axis deviation over –45° usually implies LVH + LAFB.
  - Inferior MI makes LAFB diagnosis more difficult. Inferior MI may lead to a QS pattern in leads II, III, and aVF and a left axis over –45°, whether LAFB coexists or not. If LAFB coexists, R wave will peak in aVL earlier than in aVR.
  - LAFB does not, by itself, produce QS waves in leads III and aVF and should not mimic inferior MI.
  - While the ACC guidelines mandate the presence of a small septal q wave in lead aVL for the definition of LAFB, a study has suggested that up to 27% of patients with LAFB do not have a q wave in leads I and/or aVL. These may be patients who have a horizontal heart, in whom the septal depolarization is orthogonal to lead I ± aVL, or patients who have a degree of septal conduction block.
  - LAFB is common with and without underlying heart disease and does not portend an independent prognostic significance. LAFB does not lead to secondary ST–T abnormalities.

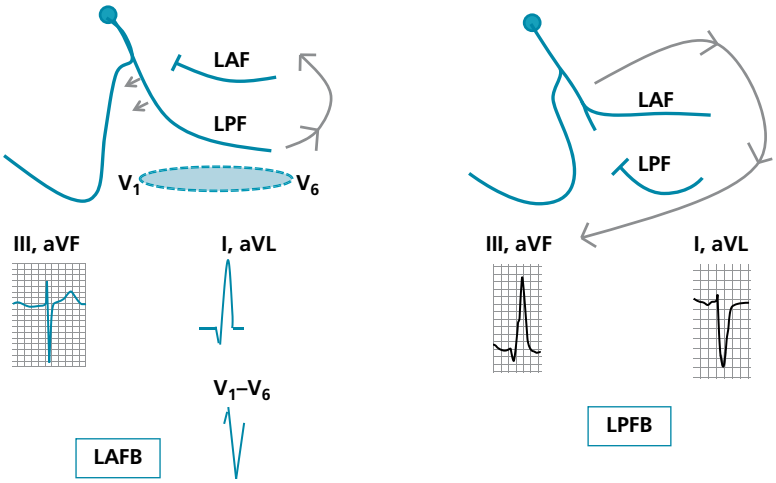

Figure 32.28 **In LAFB**, the vector of depolarization spreads from the posterior fascicle *superiorly* and *to the left* in a counterclockwise fashion. The superior spread in the *frontal plane* explains the left-axis deviation and the fact that R wave peaks earlier in lead aVL (*left*) than aVR (*right*). Also, the R wave amplitude is increased in leads I and aVL. Unlike LBBB, septal depolarization is still left-to-right, hence the septal q wave in leads I and aVL is not usually lost. The q wave may be lost in lead I if the septal depolarization is orthogonal to lead I, but not usually in lead aVL. Regarding the inferior leads, there is an r wave (no QS wave), because the initial depolarization is directed inferiorly before it shifts superiorly: hence, LAFB does not mimic inferior MI, but it may mask it by creating these r waves.

The superior spread away from the *precordial plane* explains the deep S waves across all of the precordial leads V_1–V_6 and the delayed R-wave progression. The small "r" corresponds to the initial, inferiorly directed septal and LV depolarization. Occasionally, if the leads are moved up, away from this initial depolarization, the initial "r" is lost, which produces a QS pattern in V_1–V_2 mimicking anterior MI. Moreover, a tiny initial q wave may appear before "r" in V_1–V_3 (qrS pattern), further mimicking MI. The resolution of Q wave by moving the leads one intercostal space down argues against MI.

In LPFB, the depolarization spreads left/up through the anterior fascicle then down and to the right. This initial upward spread explains the q waves in leads III and aVF, while the inferior spread explains the prominent R wave in those leads, the right-axis deviation, and the deep S wave in leads I and aVL. LAF, left anterior fascicle; LPF, left posterior fascicle.

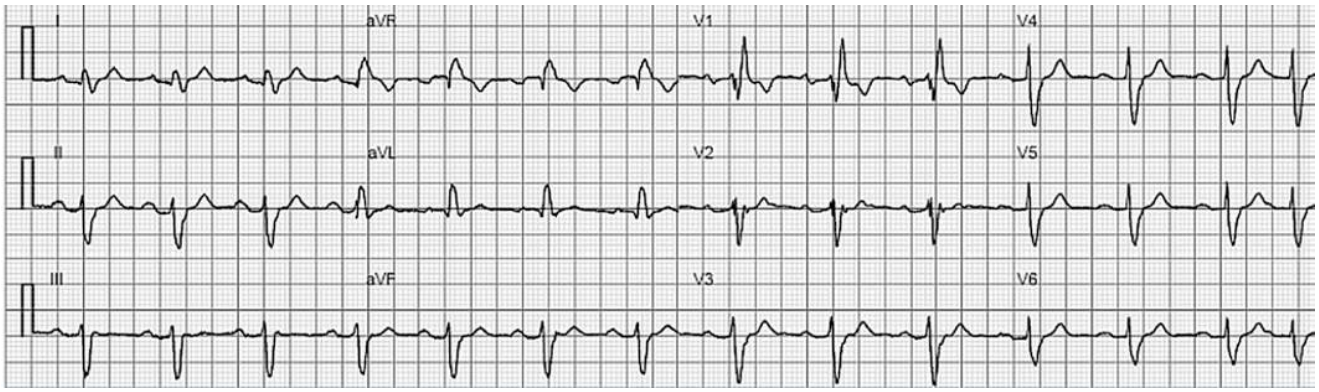

Figure 32.29 LAFB + RBBB.

- QRS is wide > 120 ms with rSR′ in V_1 and a wide S in V_5–V_6 = RBBB.
- The net QRS is (–) in lead aVF and equiphasic in lead I, implying a left axis of ~ –90°. In the absence of LBBB, this is diagnostic of LAFB. Also, a q wave is seen in lead aVL, which is often necessary to define LAFB.

Reproduced with permission of Scrub Hill Press from Hanna et al. (2009).[1]

A combination of RBBB and left-axis deviation suggests the presence of LAFB in addition to the RBBB (= bifascicular block). This is a common conduction abnormality.

B. LPFB

- LPFB is uncommon and typically occurs in conjunction with RBBB.
- LPFB is defined as "*an unexplained right-axis deviation*" (more than +90°) = right-axis deviation without RVH, COPD, or lateral MI (R wave in V_1 and S wave in V_6 are not large). A qR pattern is seen in the inferior leads III/aVF. LPFB does not lead to ST–T abnormalities.

C. Bifascicular and trifascicular blocks

A bifascicular block is a block in 2 of the 3 conduction fascicles (right bundle, left anterior fascicle, and left posterior fascicle). It can take 1 of the following forms: (i) LBBB; (ii) RBBB + LAFB = RBBB with left-axis deviation; (iii) RBBB + LPFB = RBBB with right-axis deviation (which could also be RBBB + RVH).

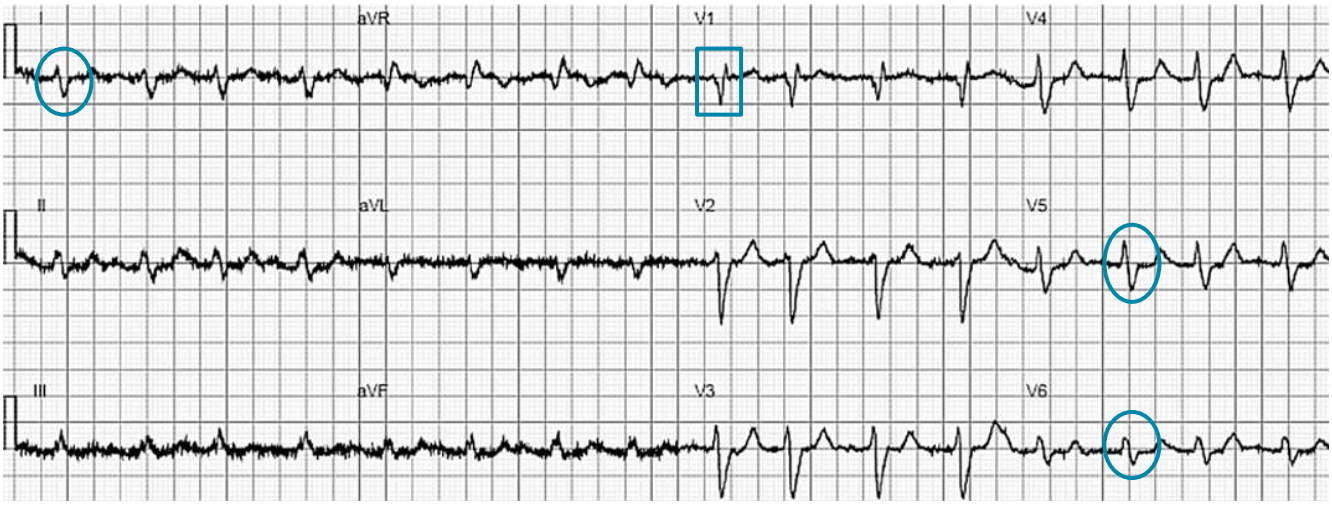

Figure 32.30 RBBB + LPFB. Since QRS is wide > 120 ms, look in V_1 and in V_6 to determine if the morphology fits more with LBBB or RBBB. In this case, QR morphology is seen in V_1 (*box*), with a wide slurred S wave in V_5–V_6 and I, aVL (*circles*): this is RBBB. The axis is right (net QRS is negative in I and positive in aVF). Exact axis: QRS is closest to equiphasic in lead II → axis perpendicular to +60° → +150°. The cause of right axis could be RVH or LPFB. Because there are no RVH criteria (R′ < S in V_1, S not larger than R in V_6), LPFB is the probable diagnosis. Reproduced with permission of Scrub Hill Press from Hanna et al. (2009).[1]

A trifascicular block implies that all 3 fascicles have a conduction block. The block is incomplete in at least 1 fascicle, otherwise complete AV block would be present. Trifascicular block may manifest as:

- Bifascicular block + increased PR interval: this is often a trifascicular block (may also be bifascicular block with first-degree AV block)
- Alternating RBBB + LBBB, i.e., RBBB and LBBB alternate on the same ECG or on different ECGs obtained up to several years apart
- RBBB with alternating LAFB and LPFB
- RBBB > 150–180 ms may reflect cardiomyopathy and may be associated with delayed conduction in the left bundle as well, the ECG showing RBBB because of a longer right bundle delay. This is called "masked LBBB" and is characterized by a wide RBBB > 150 ms with a broad, slurred, sometimes notched R in I and aVL (ESC 2021, pacing guidelines).

D. Wide QRS 110–119 ms or ≥120 ms that does not fulfill the typical LBBB or RBBB morphology
For example, one bundle branch block morphology is seen in the precordial leads and the contralateral bundle branch block morphology is seen in the limb leads. This wide QRS may be:

- A form of RBBB + LAFB or RBBB with masked LBBB as described in Section VIII.C
- Non-specific intraventricular conduction delay, especially in a patient with cardiomyopathy and diffuse conduction slowing
- Pre-excitation, hyperkalemia, or drugs (class I antiarrhythmics, tricyclics)

Note that QRS notching with a normal QRS duration < 110 ms does not imply a conduction delay and is often normal. It is related to the way the vector of depolarization spreads around the lead.

Always think of hyperkalemia in any patient with atypical bundle branch block.

IX. Low QRS voltage and electrical alternans

Low QRS voltage is defined as an **absolute sum of R and S waves < 5 mm in every limb lead and < 10 mm in every precordial lead.** Also, a decrease in voltage in the limbs and/or precordial leads in comparison to an old ECG may be indicative of disease, even if it does not fulfill the listed criteria. A patient with baseline LVH may have a relatively reduced QRS voltage without fulfilling the low-voltage definition.

A. Differential diagnosis of small QRS voltage

- Pericardial effusion. Electrical alternans may also be seen.
- Any "shield" around the heart: COPD, obesity, large pleural effusion, and notably hypothyroidism ("low" and "slow").
- Constrictive pericarditis; some restrictive infiltrative cardiomyopathies (such as amyloidosis and hemochromatosis, but not Fabry disease).

B. High QRS voltage in the precordial leads with low QRS voltage in the limb leads is relatively specific for a dilated LV with low EF (Goldberger pattern). The heart expands posteriorly as it dilates, becoming somewhat orthogonal to the frontal plane of the limb leads, which attenuates QRS voltage in these leads. Also, soft tissue edema attenuates limb leads' voltage.

C. Electrical alternans is an every-other-beat alternation of 2 different but *equally wide* and *equidistant* QRS complexes
Electrical alternans may also involve the P and T waves, in which case it is called total alternans and is very specific for pericardial effusion (Figure 32.31).

Figure 32.31 **(a)** Electrical alternans. Note the alternation between 2 main QRS morphologies every other beat (*arrows* and *arrowheads*). This is different from the cyclical QRS changes seen in patients breathing deeply and rapidly. The 2 QRS complexes have approximately the same width.

(b) Atrial flutter. Negative flutter waves are seen in lead II (*vertical arrows*). Note the alternation of 2 QRS morphologies, both equally wide and equidistant (*oblique arrows*). The larger QRS in V_1 is a typical RBBB, the smaller QRS is an atypical RBBB with RSR'S' pattern. This is electrical alternans secondary to tachyarrhythmia, wherein the ventricular conduction alternately follows a slightly different path.

(c) Alternation between a narrow QRS and an equidistant wide QRS with LBBB morphology (*arrowheads*). Ventricular bigeminy is unlikely, as the wide QRS is equidistant from the narrow one. This is not electrical alternans either, as QRS width is changing significantly. This is an intermittent, alternating LBBB.

(d) Alternation of a narrow and an equidistant wide QRS. PR interval shortens and a delta wave is seen on the wider QRS complexes (*arrows*). This is intermittent pre-excitation. One QRS is antegradely conducted over an accessory pathway with a short PR and a delta wave (WPW). The next beat proceeds down the AV node rather than the accessory pathway, the accessory pathway being in a refractory period.

QRS amplitude may vary with respiration, particularly in patients who are breathing heavily. In this case, the heart position, and more particularly the septal position, varies with respiration; this may be seen in tamponade, but also in severe COPD or any respiratory distress. This cyclic change of QRS morphology and axis is not electrical alternans and correlates more with pulsus paradoxus ("electrical paradoxus"). Conversely, electrical alternans implies every-other-beat alternation of 2 distinct QRS morphologies and corresponds to a swinging heart in a patient with pericardial efffusion. Electrical alternans may also be seen with:

- Severe HF, where it is mechanically induced by an alternate change in cardiac contraction (like pulsus alternans).
- SVT, especially AVRT or any fast SVT, wherein a slight variation in ventricular conduction occurs alternately.
- Acute myocardial ischemia or PE, where again there is a conduction alternans.
- Intermittent pre-excitation or intermittent conduction block, such as LAFB or bundle branch block, occurring in an alternating fashion. This is rather a mimic than a true electrical alternans.

A slight change in QRS morphology may normally be seen between the beats of an irregular rhythm, making the diagnosis of true electrical alternans more difficult (e.g., AF).

X. Assessment of ischemia and infarction: Q waves

Normally, a small Q wave (q) may be seen in all leads except the right precordial leads before the R/S transition zone, which usually corresponds to leads V_1, V_2, and V_3. An abnormal Q wave signifies an old MI, a recent MI, or an acute evolving STEMI (in the latter, concomitant ST elevation would be present in the same leads) (Figures 32.32–32.35).

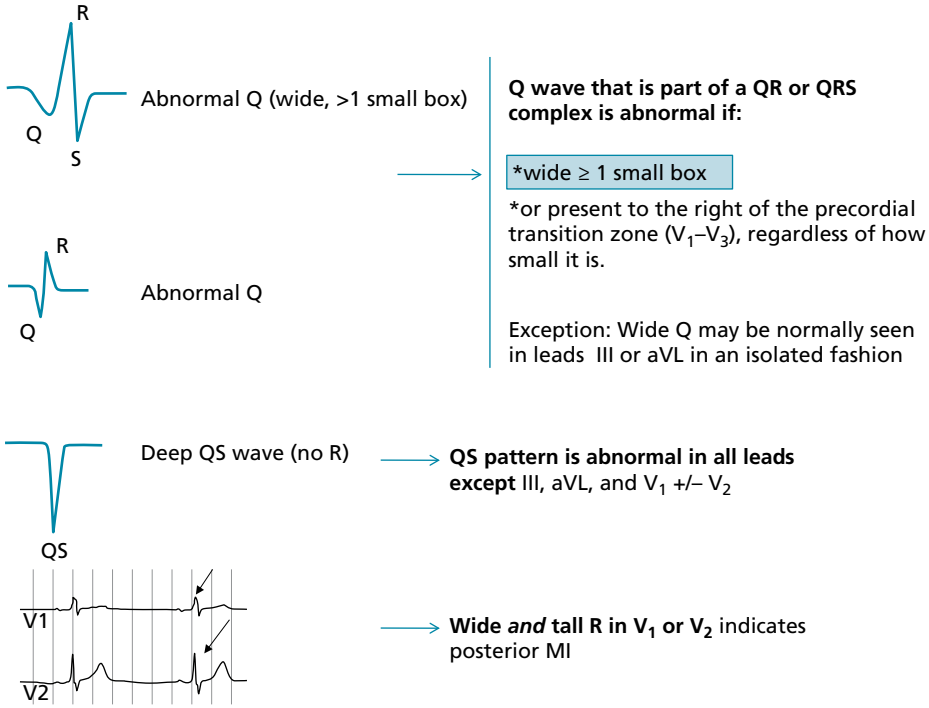

Figure 32.32 Wide Q wave (QS or QR) may be normally seen in lead III of a horizontal heart looking away from lead III. QS or QR pattern may normally be seen in lead aVL in a patient with a vertical heart that looks away from lead aVL.

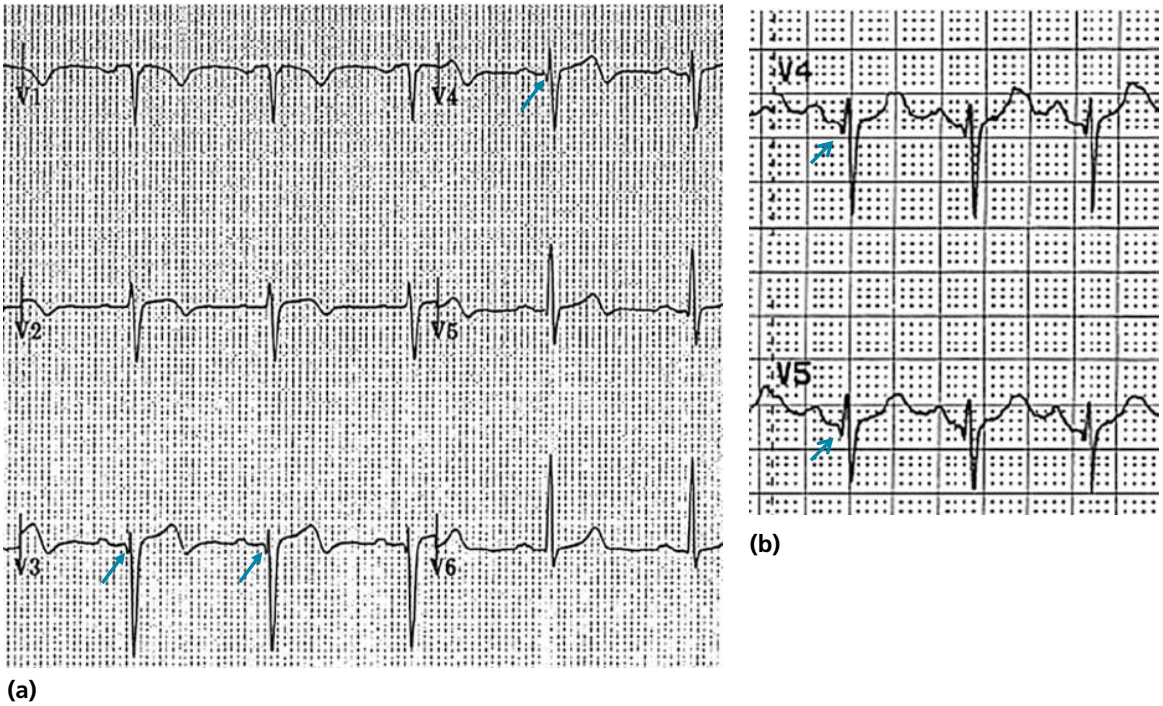

Figure 32.33 Examples of an abnormal Q wave. **(a)** ECG shows minimal ST elevation with narrow small q waves in leads V_3–V_4 and post-ischemic terminal T-wave inversion (not a Wellens syndrome since Q waves are present). **Q of any size, when seen in the precordial leads before the transition zone as part of a qrS complex, is abnormal and is almost 100% indicative of MI** (the rare exception being the tiny q wave sometimes seen with LAFB). This ECG is a late STEMI, at a time when Q waves/T inversion have appeared and ST elevation is resolving. **(b)** Small q waves in leads V_4–V_5 where QRS is still overall negative. Thus, these q waves occur before the transition zone and imply MI, even if very small.

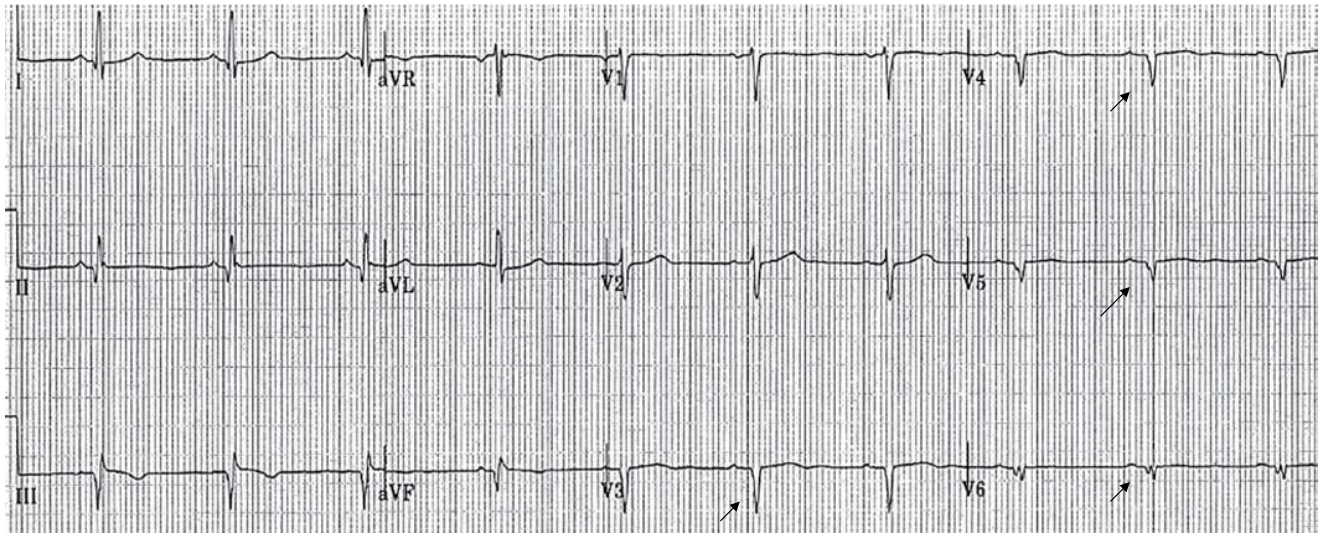

Figure 32.34 Inferior Q waves and anterolateral QS waves (QS waves are wide monophasic Q waves, *arrows*). QS waves may be normal in leads V_1–V_2, but not in leads V_3–V_6.

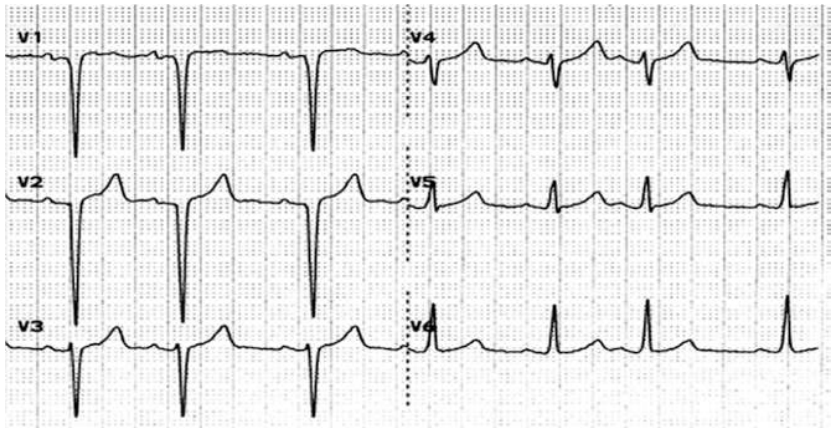

Figure 32.35 QS pattern is seen in leads V_1–V_2, small R wave is seen in leads V_3–V_4. As opposed to QS pattern extending to V_3 or beyond, QS pattern limited to V_1 or V_2 is not definitely an anterior MI. Only 20% of patients with a QS pattern in leads V_1–V_2, without other abnormalities on the ECG, have an anterior MI. The differential diagnosis of a QS pattern in leads V_1–V_2 is similar to the differential diagnosis of delayed R-wave progression.

Q wave is abnormal when it is:

- ≥0.03 second wide (~1 small box) and ≥0.1 mV deep (1 mm)
  or
- whenever any q wave is seen before the precordial transition zone as part of a QRS pattern, no matter how small it is (= any q wave in leads V_1–V_3 is abnormal when QRS is still overall negative in V_1–V_3).

A wide Q wave ≥1 box that is also ≥¼ of R height, not just ≥1 mm, is more specific for MI and implies a worse prognosis than a 1-mm deep Q wave, reflecting a larger infarct size and lower EF.[2]

A wide *and* tall R wave in leads V_1 or V_2 is a mirror image of a posterior Q wave and implies posterior MI (R≥0.04 second in width and R>S in height). As opposed to RVH, R wave is not just tall but wide, T wave is upright rather than inverted, and Q waves are often present in the inferior or lateral leads, and in leads V_7–V_9.

Differential diagnosis of pathological Q waves

- A QRS that consists of only 1 deep negative deflection is, in fact, a monophasic deep Q wave. Since there is no intervening R wave, this negative wave is a Q wave rather than an S wave, but is sometimes called a QS wave.
- QS in V_1–V_2 may represent an anterior MI in 20% of the cases, but often does not. Similarly to poor R-wave progression, it often results from LBBB, LAFB, LVH shifting the heart leftward and posteriorly, COPD pushing the heart down and posteriorly, or, frequently, low heart/low diaphragm with high lead placement away from the heart. Moving the precordial leads below the standard position may correct Q waves in many of the latter cases (COPD, low heart, LAFB). QS that extends to V_3 is often an anterior MI, while QS extending to V_4 is definitely an anterior MI. **Importantly, as opposed to QS, qrS in V_1–V_3 always signifies anterior MI, regardless how small the q wave is** (rarely, anterior qrS may be seen with LAFB). While infrequently suggestive of anterior MI, poor R-wave progression may be the only sequela of ~25% of anterior MIs.

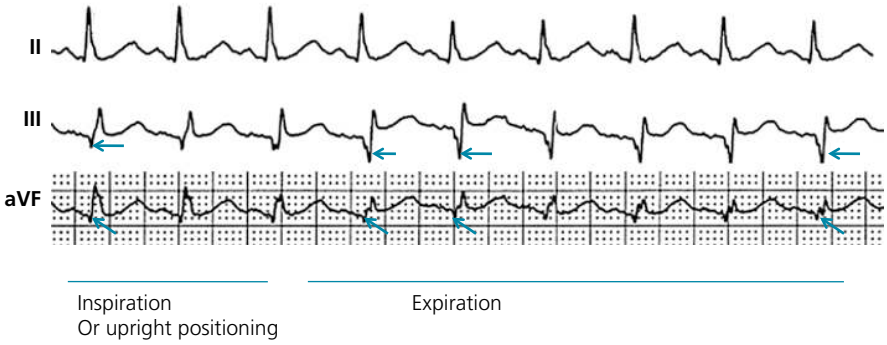

Figure 32.36 In expiration, Q wave is wide and deep in leads III and aVF (*arrows*); no Q wave is seen in lead II at any time (Q wave in lead II makes inferior MI definite). During inspiration or upright position, the Q wave becomes smaller and narrower in both leads III and aVF, implying that this Q wave is most likely related to a horizontal heart position during expiration. This lessens the probability of inferior MI but does not rule it out.

- QS or QR in the inferior leads III and aVF may indicate an MI, but it may be a normal variant in up to 2/3 of the cases, particularly in obese/stocky individuals with horizontal hearts or left QRS axis directed away from the inferior leads. A deep breath or standing up verticalizes the heart and minimizes these Q waves (Figure 32.36). An associated q wave in lead II that is either wide >0.03 second *or* narrow but >25% of R wave indicates inferior MI with close to 100% sensitivity and specificity.[3]

  QS in leads III and aVF, but not in lead II and not QR, may also occur with LBBB and LVH, cases where the depolarization vector looks away from the inferior leads.

  QR in leads III and aVF may be seen with RVH or PE, wherein the LV is pushed up and the RV expands down. The up-looking LV depolarization explains the inferior Q waves.

  Note, however, that a wide Q in the inferior lead II almost always implies MI, and a QrS pattern, even when limited to leads III and aVF, usually implies MI and is not seen with obesity or conduction abnormalities. Also, the presence of a wide R wave in lead aVR increases the likelihood of a true inferior MI.
- QS or QR may normally occur in lead aVL in patients with vertical hearts, or in cases of chest deformity or left pneumothorax. Severe septal hypertrophy (HCM) may produce deep/wide Q waves in the lateral leads (QR pattern in leads I, aVL, V_5–V_6), and sometimes the inferior leads, ± prominent R waves in the right precordial leads V_1–V_2 (all correspond to the septal forces).
- The negative delta wave of pre-excitation may simulate a wide and pathological Q wave. It may be seen in the inferior, lateral, or anterior leads.
- Any cardiomyopathy, especially infiltrative cardiomyopathy (e.g., amyloidosis), may lead to Q waves as a result of fibrosis or myocardial replacement with the infiltrative process. Myocarditis occasionally leads to Q waves.
- Takotsubo cardiomyopathy, which leads to anterior ST-segment elevation and T-wave inversion, may also lead to transient anterior Q waves.

XI. Assessment of ischemia: ST-segment depression and T-wave inversion

Abnormalities of the ST segment and T wave represent abnormalities of ventricular repolarization. The ST segment corresponds to the plateau phase of ventricular repolarization (phase 2), while the T wave corresponds to the phase of rapid ventricular repolarization (phase 3). ST-segment or T-wave changes may be secondary to abnormalities of depolarization, i.e., pre-excitation or abnormalities of QRS voltage or duration. On the other hand, ST-segment and T-wave abnormalities may be unrelated to any QRS abnormality, in which case they are called primary repolarization abnormalities. They are caused by ischemia, pericarditis, myocarditis, drugs (digoxin, antiarrhythmic drugs), and electrolyte abnormalities, particularly potassium abnormalities.[4]

ST-segment deviation is usually measured at its junction with the end of the QRS complex, i.e., the J point, and is referenced against the TP or PR segment.[5] Some authors, however, prefer measuring the magnitude of the ST segment deviation 40–80 ms after the J point, when all myocardial fibers are expected to have reached the same level of membrane potential and to form an isoelectric ST segment; at the very onset of repolarization, small differences in membrane potential may normally be seen and may cause deviation of the J point and of the early portion of the ST segment.[6] A diagnosis of ST-segment elevation myocardial infarction (STEMI) that mandates emergent reperfusion therapy requires ST-segment elevation equaling or exceeding the following cut-points, in at least 2 contiguous leads (using the standard of 1.0 mV = 10 mm):[7]

- 1 mm in all standard leads other than leads V_2–V_3.
- 2.5 mm in leads V_2 and V_3 in men younger than age 40, 2 mm in leads V_2 and V_3 in men older than age 40, and 1.5 mm in these leads in women.
- 0.5 mm in the posterior chest leads V_7–V_9. ST-segment elevation is attenuated in the posterior leads because of their greater distance from the heart, explaining the lower cut-point.

Concerning ST-segment depression, a depression of up to 0.5 mm in leads V_2 and V_3 and 1 mm in the other leads may be normal.[5]

While ST-segment deviation that falls below these cut-points may be a normal variant, any ST-segment elevation or depression (≥0.5 mm) may be abnormal, particularly when the clinical setting or the ST-segment morphology suggests ischemia, or when other ischemic signs such as

T-wave abnormalities, Q waves, or reciprocal ST-segment changes are concomitantly present. Conversely, ST-segment elevation that exceeds these cut-points may not represent STEMI. In an analysis of chest pain patients manifesting ST-segment elevation, only 15% were eventually diagnosed with STEMI. Besides size, careful attention to the morphology of the ST segment and the associated features is critical.

In adults, the T wave is normally inverted in lead aVR; is upright or inverted in leads aVL, III, and V_1; and is upright in the remaining leads. The T wave is considered inverted when it is deeper than 1 mm and is considered flat when its peak amplitude is between 1 mm and –1 mm.[5]

A. Secondary ST-segment and/or T-wave abnormalities

In secondary ST-segment or T-wave abnormalities, QRS criteria for ventricular hypertrophy (LVH or RVH), bundle branch block (LBBB or RBBB), or pre-excitation are usually present, and the ST segment and T wave have *all of* the following morphological features (Figure 32.37a):

i. The ST segment and T wave are directed opposite to the QRS: this is called discordance between the QRS complex and the ST–T abnormalities. In the case of RBBB, the ST and T are directed opposite to the terminal portion of the QRS, i.e., the part of the QRS deformed by the conduction abnormality.
ii. The ST segment and T wave are both abnormal and deviate in the same direction, i.e., the ST segment is downsloping and the T wave is inverted in leads with an upright QRS complex, which gives the ST–T complex a "reverse checkmark" asymmetric morphology.
iii. The ST and T abnormalities are not dynamic, i.e., they do not change in the course of several hours to several days.

Thus, in LVH or LBBB, since the QRS complex is upright in the left lateral leads I, aVL, V_5, and V_6, the ST segment is characteristically depressed and T wave inverted in these leads (Figure 32.38). In RVH or RBBB, T waves are characteristically inverted in the right precordial leads V_1–V_3. LBBB is always associated with secondary ST–T abnormalities, the absence of which suggests associated ischemia. LVH, RVH, and RBBB, on the other hand, are not always associated with ST–T abnormalities, but when present, they correlate with more severe hypertrophy or ventricular systolic dysfunction,[8] and have been called *strain pattern*. In addition, while these morphological features are consistent with secondary abnormalities, they do not rule out ischemia in a patient with angina.

There are **some exceptions** to these typical morphological features:

- In LVH/LBBB, the transition of QRS from negative to positive may occur in a different lead than the transition of T wave from positive to negative. Thus, in 1 lead, the QRS and T wave may both be upright, or the QRS and T wave may both be negative. This, however, is usually limited to 1 lead.
- RVH and RBBB may be associated with isolated T-wave inversion without ST-segment depression in the precordial leads V_1–V_3. In fact, RBBB and RVH are usually associated with only mild degrees of ST-segment depression in comparison to their left counterparts (the R wave and myocardial mass are smaller with RVH/RBBB than LVH/LBBB).
- LVH may be associated with symmetric T-wave inversion without ST-segment depression or with a horizontally depressed ST segment. This may be the case in up to one-third of ST–T abnormalities secondary to LVH and is seen in hypertrophic cardiomyopathy in leads V_3–V_6 (this pattern is classically seen with the apical variant but is common with any variant).[9]

B. Ischemic ST-segment depression and/or T-wave inversion

ST-segment depression or T-wave inversion that adopts *any* of the features shown in Figure 32.37b–e is consistent with ischemia:

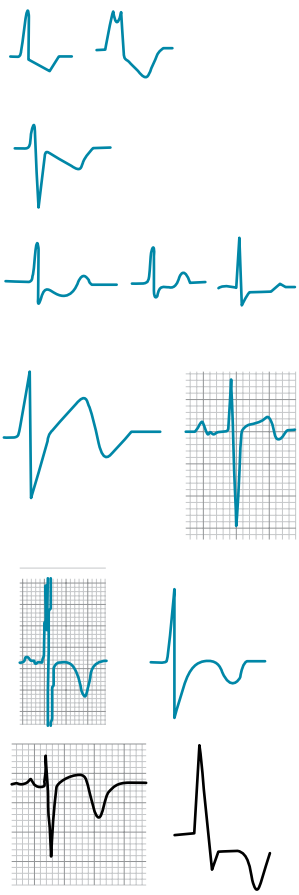
i. The ST-segment depression *or* T-wave inversion is directed in the same direction as the QRS complex: this is called concordance between the QRS complex and the ST or T abnormality (Figure 32.37b).
ii. The ST segment is depressed, but the T wave is upright (Figure 32.37c).
iii. The T wave has a positive–negative biphasic pattern (Figure 32.37d).
iv. The T wave is symmetrically inverted and has a pointed configuration, while the ST segment is not deviated or is upwardly bowed (coved) or horizontally depressed (Figure 32.37e).
v. The magnitude of ST-segment depression progresses or regresses on serial tracings, or ST-segment depression progresses to T-wave abnormality during ischemia-free intervals (dynamic ST-segment depression).

Unlike ST-segment elevation, ST-segment depression does not localize ischemia.[10] However, the extent and the magnitude of ST-segment depression correlate with the extent and the severity of ischemia. In fact, ST-segment depression in eight or more leads, combined with ST-segment elevation in leads aVR and V_1 and occurring during ischemic pain, is associated with a 75% predictive accuracy of left main or 3-vessel disease (Figure 32.39).[11,12] This finding may also be seen in cases of tight proximal left anterior descending stenosis.[13] It implies diffuse subendocardial ischemia, with reciprocal ST-segment elevation in the 2 leads that look away from the normal myocardial repolarization. Also, injury of the basal septum, seen with left main or proximal LAD, causes ST elevation in aVR and V_1. ST-segment elevation that is more prominent in aVR than V_1, particularly >1.5 mm, often implies critical left main coronary disease, while ST elevation that is equal or more pronounced in V_1 than aVR suggests proximal LAD or 3-vessel ischemia. A critical LM causes counterbalanced ischemia of the proximal LAD and the LCx, i.e., posterior wall, which attenuates the ST elevation anteriorly in V_1 (aVR > V_1); this is not the case in proximal LAD or multivessel disease.[13]

When ST-segment elevation occurs in 2 contiguous leads while ST-segment depression occurs in other leads, and when the ST–T abnormalities are ischemic rather than secondary to LVH or LBBB, ST-segment elevation is considered the primary ischemic abnormality, whereas ST-segment depression is often considered a reciprocal "mirror image" change in opposite leads. ST-segment elevation is reciprocal to ST-segment depression only when ST depression is diffuse and ST elevation is limited to the 2 non-contiguous leads, V_1 and aVR, implying an extensive subendocardial ischemia.

Note: T-wave inversion and Wellens syndrome

Either the positive–negative biphasic T waves of the type shown in Figure 32.37d or the deeply inverted (≥5 mm) T waves that often follow them, when occurring in the precordial leads V_2 and V_3, with or without similar changes in V_1, V_4, V_5, are virtually pathognomonic for very recent severe ischemia or injury in the distribution of the left anterior descending artery (LAD) and characterize what is known as Wellens syndrome (Figure 32.40).[14–17] Wellens et al. showed that 75% of patients who developed these T-wave abnormalities and who were treated



(a) ST-segment depression and asymmetric T-wave inversion secondary to left ventricular hypertrophy (left) and left bundle branch block (right).

(b) ST-segment depression and T-wave inversion concordant to QRS, suggestive of ischemia.

(c) ST-segment depression with an upright or biphasic negative-positive T wave, suggestive of ischemia.

(d) Positive-negative biphasic T wave with a minimally elevated J point and an angle of 60 to 90 degrees between the initial ascending portion and the descending portion of the T wave (Wellens-type T-wave abnormality, usually seen in precordial leads V_1–V_4). This finding is very specific for ischemia.

(e) Symmetric and pointed deep T-wave inversion with an isoelectric or a slightly up-sloping or horizontally depressed ST segment (isoelectric: top 2 panels; slightly up-sloping: third panel; horizontally depressed: fourth panel); often follows the biphasic T waves seen in D by hours to days. As the T-wave changes subsequently regress, the positive-negative biphasic T-waves are again seen before repolarization returns to normal.

Figure 32.37 ST-segment and T-wave morphologies in cases of **(a)** secondary abnormalities and **(b–e)** ischemic abnormalities. Modified with permission of Scrub Hill Press from Hanna et al. (2009).

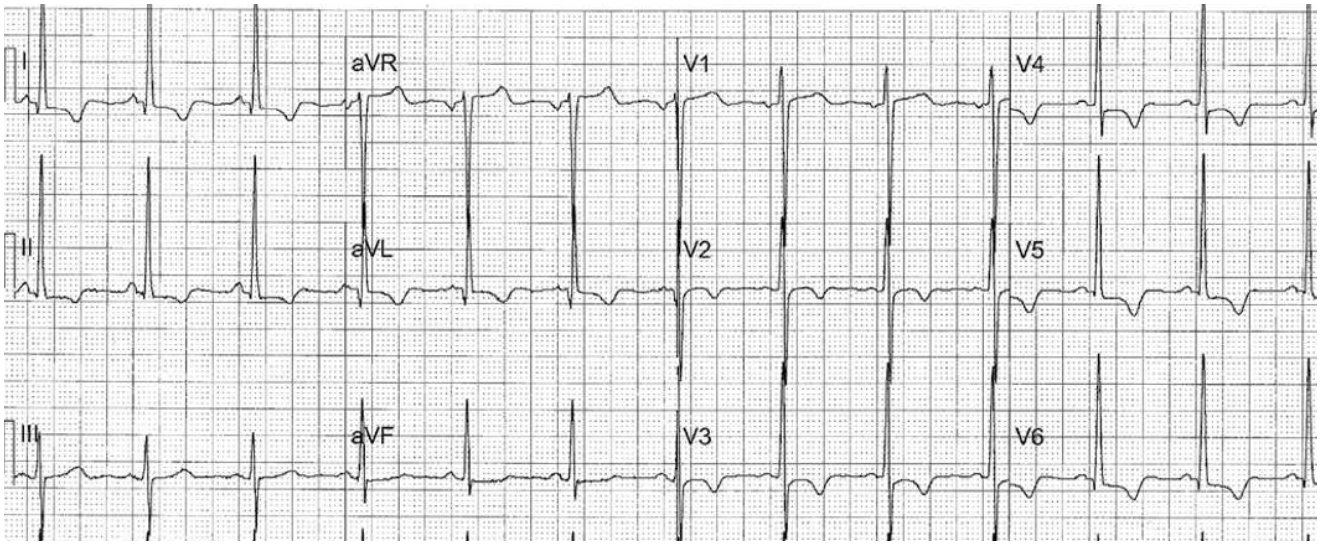


Figure 32.38 Example of left ventricular hypertrophy with typical secondary ST–T abnormalities in leads I, II, aVL, V_4–V_6. The QRS complex is upright in these leads while the ST segment and T wave are directed in the opposite direction, i.e., the QRS and the ST–T complexes are discordant. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

medically without angiographic investigation went on to develop extensive anterior wall myocardial infarction within a mean of 8.5 days.[14] In a later investigation of 1260 patients presenting with unstable angina, 180 patients (14%) had this characteristic T-wave pattern.[15] All of the latter patients had stenosis of 50% or more in the LAD (proximal to the second septal branch), and 18% had total LAD occlusion. Thus, although medical management may provide symptomatic improvement at first, early coronary angiography and revascularization should be strongly considered in anyone with Wellens syndrome because it usually predicts impending anterior myocardial infarction.

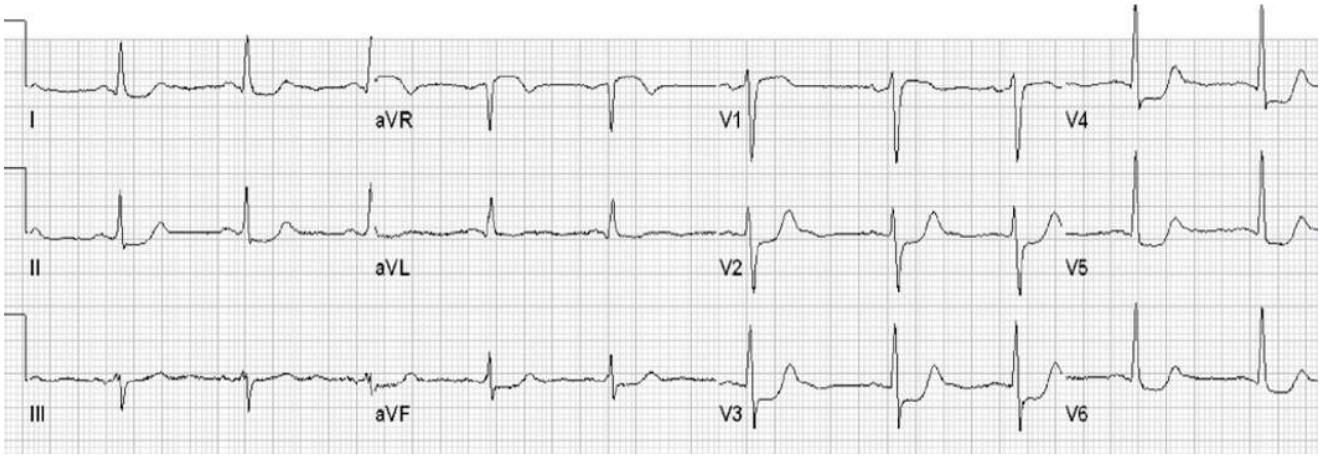

Figure 32.39 Electrocardiogram of a patient with angina at rest and elevated cardiac biomarkers. ST-segment depression in 9 leads with elevation in leads aVR and V_1 suggested subendocardial ischemia related to 3-vessel or left main coronary artery disease. He had severe left main and 3-vessel disease on coronary arteriography. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

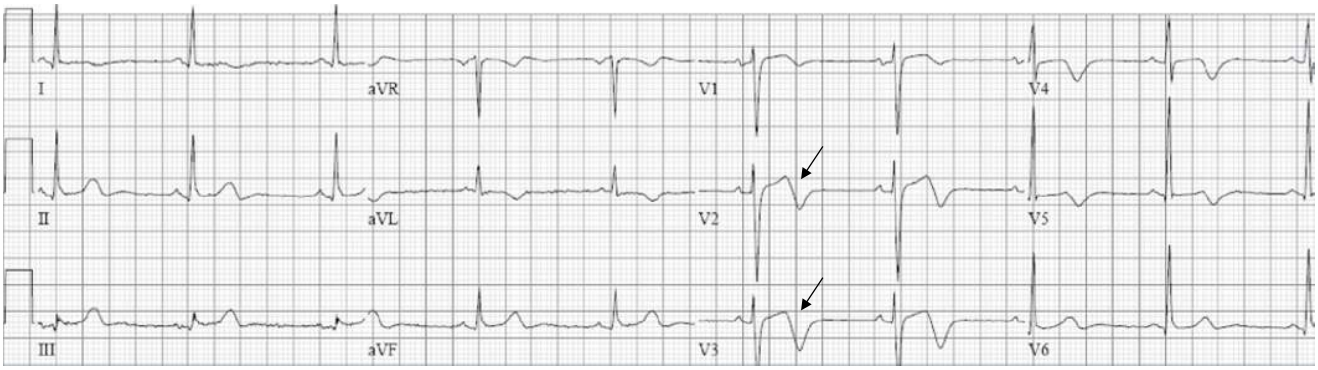
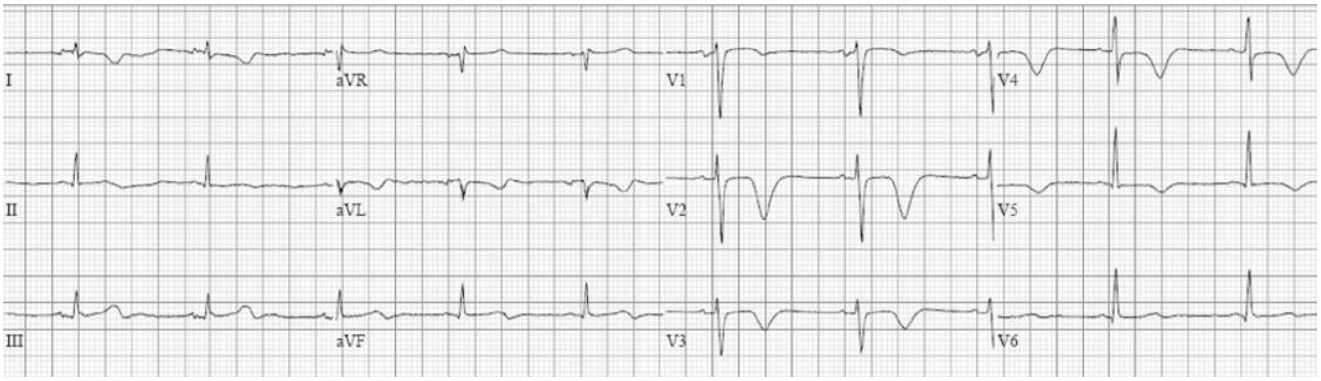


(a)



(b)

Figure 32.40 Examples of Wellens-type T-wave abnormalities. **(a)** Wellens-type biphasic T wave in leads V_2 and V_3 *(arrows)* and deep T-wave inversion in lead V_4, with a straight or convex ST segment. **(b)** Wellens-type deep T-wave inversion in leads V_2–V_4. Each patient had a 90% proximal left anterior descending stenosis at coronary arteriography. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

Wellens syndrome is characterized by 2 patterns of T-wave changes. In 75% of the cases, T waves are deeply (≥5 mm) and symmetrically inverted in leads V_2 through V_4. In 25% of the cases, the T wave has a characteristic positive–negative biphasic morphology in leads V_2 through V_4 (Figure 32.37d).[14] In both patterns, the ST segment is straight or convex, but is not significantly elevated (<1 mm); the downslope of the T wave is sharp (60–90°); and the QT interval is often prolonged. This abnormality is characteristically seen hours to days after the ischemic chest pain resolves. In fact, the ischemic episode is usually associated with transient ST-segment elevation or depression that progresses to the T-wave abnormality after the pain subsides.[15] In Wellens' original description, only 12% of patients had small increases in the creatine kinase level. Therefore, the ECG may be the only indication of an impending large anterior infarction in a chest-pain-free patient.[16]

No Q wave is seen and the ST segment is not significantly elevated. The same T-wave morphology may be seen with Q-wave MI or STEMI, but is not called Wellens syndrome in those instances. Rather, it is part of the ECG progression of Q-wave MI (Figure 32.33).

T waves that are symmetrically but less deeply inverted than Wellens-type T waves may still represent ischemia. However, this finding is less specific for ischemia and is associated with better outcomes than Wellens syndrome or ST-segment deviation, particularly when the T wave is less than 3 mm deep.[18] In fact, one prospective cohort study found that isolated mild T-wave inversion in patients presenting with ACS is associated with a favorable long-term outcome, similar to patients with no ECG changes.[19] Similarly to Wellens syndrome, U-wave inversion in leads V_1–V_3, a subtle finding, often implies anterior ischemia.

Biphasic T waves may be seen in the precordial leads outside Wellens syndrome (Figure 32.41).

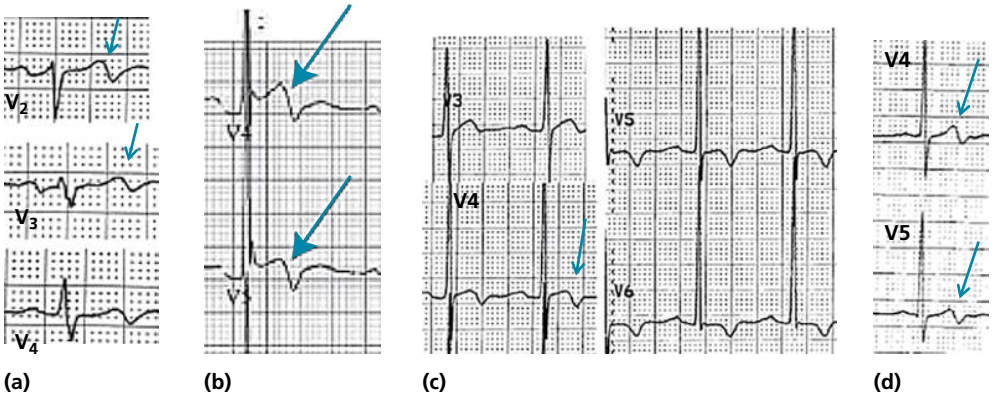


Figure 32.41 Non-Wellens biphasic T waves. **(a)** Biphasic T wave in leads V_2–V_3, not absolutely typical of Wellens syndrome as the ST segment is concave and T-wave downslope is not very steep. However, this patient had 95% proximal LAD stenosis. **(b)** Normal variant T-wave inversion in an asymptomatic young black male, with prominent, early repolarization-type ST elevation (seen here in leads V_4–V_5, but may be seen in V_2–V_3). **(c)** Biphasic T wave in lead V_4 in a patient with LVH; T wave is transitioning to an inverted pattern in lead V_4, while ST segment is transitioning to depression in lead V_6. This early T-wave transition gives a biphasic shape in lead V_4. **(d)** Normal variant biphasic T wave in leads V_4–V_5 in a 50-year-old white man with negative cardiac markers and normal coronary angiography. This pattern was transient; ECGs performed the same day, before and after this ECG, were normal. Unlike Wellens, the ST segment is not straight and the downslope of the T wave is not very steep. A pattern of biphasic T waves may also be seen in pericarditis before T waves fully invert.

C. Frequently missed diagnoses manifesting as ST-segment depression or T-wave inversion

1. True posterior ST-segment elevation myocardial infarction (STEMI)

When accompanied by inferior STEMI, posterior infarction is easily recognized, but it can be difficult to diagnose when it occurs alone, the so-called true posterior STEMI. ST-segment depression that is most prominent in leads V_1 through V_3 often indicates posterior STEMI rather than non-ST-segment elevation ischemia and indicates the need for emergent revascularization. ***In fact, in the setting of posterior infarction, leads V_1–V_3 predominate as the areas of maximum depression, whereas greater ST-segment depression in the lateral precordial leads (V_4 through V_6) or inferior leads (II, III, aVF) is more indicative of non-occlusive and non-regional subendocardial ischemia*** (Figure 32.42A–B).[12,20–22] In most or all of the cases of posterior infarction, the posterior chest leads V_7–V_9 reveal ST-segment elevation.[23] One study has found that ST-segment depression in the anterior precordial leads is as sensitive as ST-segment elevation in leads V_7 through V_9 in identifying posterior myocardial infarction (sensitivity 80%),[24] while other studies revealed that ST-segment deviation on the standard 12-lead ECG has a lower sensitivity (~60%) in identifying posterior infarction.[22,25] The posterior leads are far from the myocardium, which explains how ST elevation may be minimized and missed in these leads; to improve the sensitivity, 0.5 mm of ST elevation is considered significant in those leads (ACC guidelines).[5]

Tall *and* wide (≥0.04 second) R waves in leads V_1 or V_2, particularly when associated with upright T waves, suggest posterior infarction and may further corroborate this diagnosis, but this finding may take up to 24 hours to manifest and is only seen in about 50% of patients with posterior infarction.[25]

Studies have shown that ST-segment elevation on the standard 12-lead ECG is found in fewer than 50% of patients with acute left circumflex occlusion and inferoposterior infarction,[22] yet these are cases of "missed" STEMI that indeed benefit from emergent angiography and reperfusion. In addition, studies of non-ST-segment elevation ACS consistently identify patients who have acute vessel occlusion (~20–30% of cases),[22] yet their initial angiography is usually delayed for hours or days after the initial presentation.[26] Recognizing that ST-segment depression that is greatest in leads V_1, V_2, or V_3 represents posterior infarction helps identify a portion of the missed STEMIs in a timely fashion. In addition, in cases of anterior ST-segment depression and in cases of chest pain with non-diagnostic ECG, the recording of ST elevation in leads V_7–V_9 is highly sensitive for detecting a true posterior injury.

2. Acute pulmonary embolism

An anterior ischemic pattern of symmetric T-wave inversion in the precordial leads V_1 through V_4 may also be a sign of acute or chronic right ventricular strain, particularly acute PE. Sinus tachycardia is usually present, but other ECG signs of pulmonary embolism, such as RVH and RBBB, may be absent. In fact, T-wave inversion in leads V_1–V_4 is noted in 19% of patients with non-massive PE and in 85% of patients

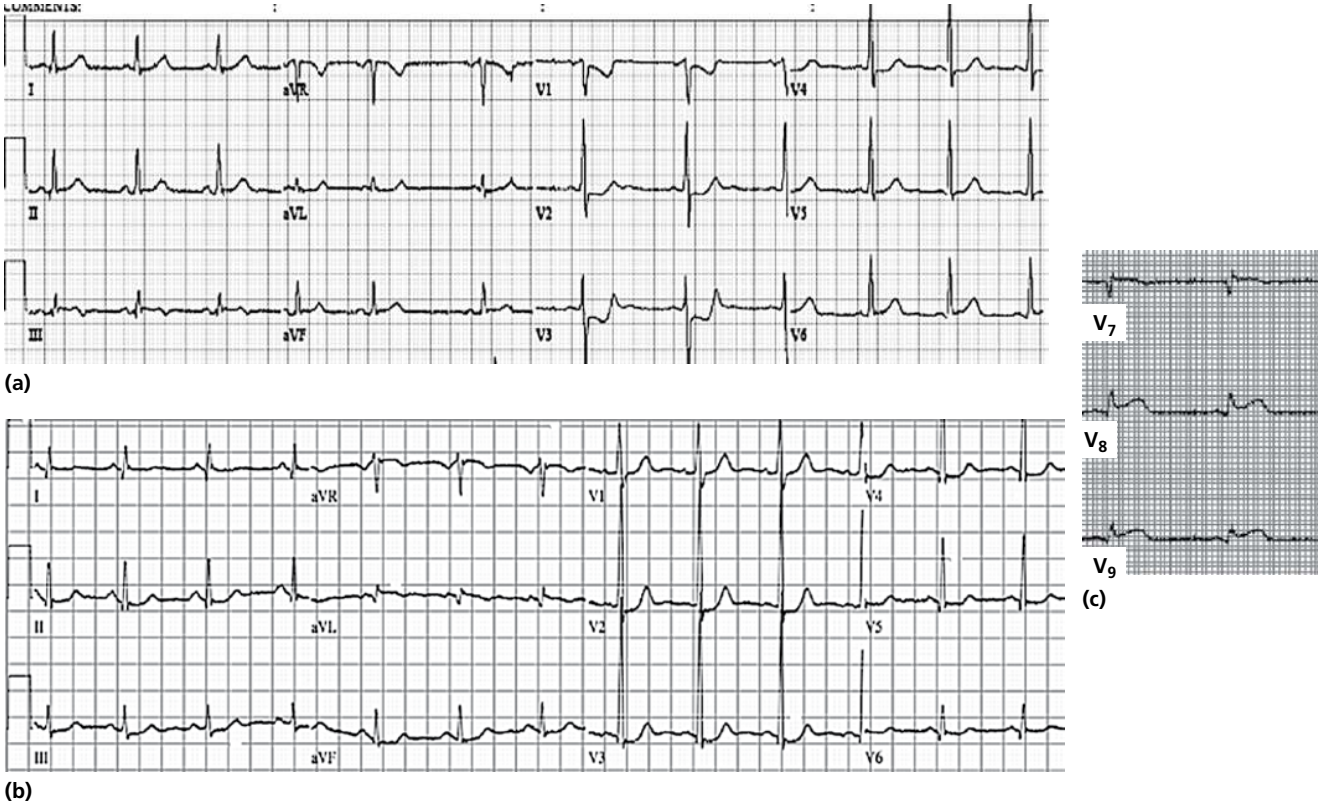

Figure 32.42 Examples of posterior infarction. **(a)** ST-segment depression in the precordial leads V_1–V_4, with a maximal depression in lead V_3, in a patient with severe ongoing chest pain for the preceding 3 hours. This suggests a true posterior ST-segment elevation myocardial infarction. There is also a subtle ST-segment elevation in lead III, which further points to the diagnosis of inferoposterior infarction. Emergency coronary arteriography shows a totally occluded mid-left circumflex coronary artery.

(b) The ST segment is depressed in leads V_1–V_6 and leads II, III, aVF, with a maximal depression in leads V_2 and V_3. In addition, tall R waves are seen in leads V_1 and V_2, and Q waves are seen in the lateral leads I and aVL. In a patient with severe persistent chest pain, this suggests a posterolateral infarct. Coronary arteriography shows a totally occluded second obtuse marginal branch.

(c) In both (a) and (b), ST elevation and wide Q waves are seen in the posterior leads V_7–V_9. ST elevation is barely 1 mm, as the posterior leads are further away from the heart than the anterior leads, which makes posterior ST changes subtle (0.5 mm of ST elevation in those leads is significant). ST elevation appears pronounced when compared to the size of the QRS.

Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

with massive PE, and is the most sensitive and specific ECG finding in massive PE.[27] In addition, acute PE may be associated with T-wave inversion in leads III and aVF,[28] and changes of concomitant anterior and inferior ischemia should always raise the suspicion of this diagnosis.[29] Rapid regression of these changes on serial tracings favors PE rather than MI.

Top 2 differential diagnoses for anterior ST-segment depression (V_1–V_3) (***0.5 mm ST↓*** is significant in V_1–V_3, as these normally have slight ST↑):

- Posterior STEMI if ST depression predominates in the anterior leads.
- Anterior ischemia if ST depression is diffuse rather than predominant in the anterior leads

Top 2 differential diagnoses for anterior T-wave inversion (V_1–V_3):

- Anterior ischemia (may be Wellens syndrome)
- PE

3. ST-segment depression reciprocal to a subtle ST-segment elevation

Reciprocal ST-segment depression is present in all patients with inferior MI and in 70% of patients with anterior MI.[30] This "reciprocal" change might also represent remote ischemia in a distant territory in patients with multivessel coronary disease.[31,32] However, it is important to recognize that the magnitude of ST-segment elevation and reciprocal ST-segment depression is affected by the distance of the leads recording these changes from the ischemic region and their angle of deviation from the ischemic region.[33] This explains why occasionally – and particularly when the overall amplitude of the QRS complex is low – the magnitude of ST-segment elevation is small, whereas the reciprocal ST-segment depression is more prominent. In fact, in the absence of LVH or LBBB, the reciprocal ST-segment depression should always be sought. It is of great utility in patients with acute cardiac symptoms and mild elevation of ST segments of 1–1.5 mm in 2 contiguous leads, as it strongly suggests the diagnosis of STEMI rather than other causes of mild ST-segment elevation (1–1.5 mm) (Figure 32.43).[34] The less-pronounced ST-segment elevation is often overlooked, and the patient is erroneously diagnosed with non-ST-segment

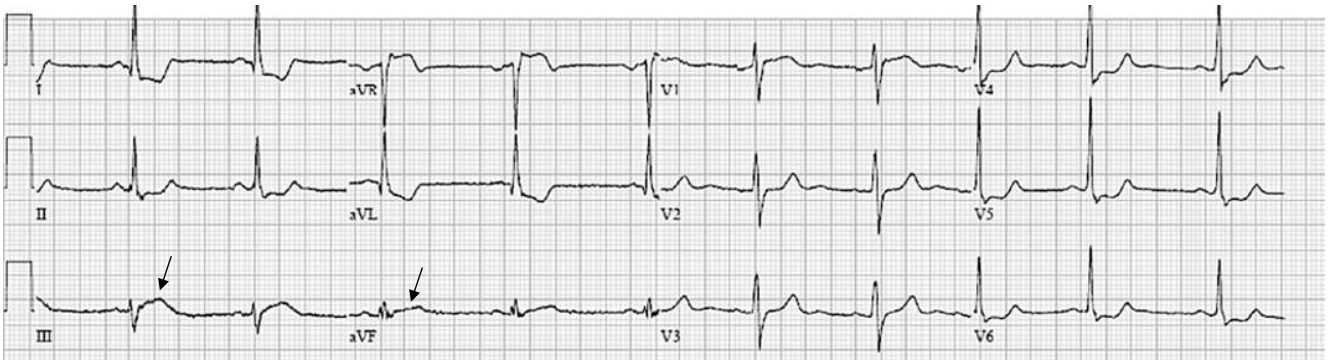

Figure 32.43 Example of subtle ST-segment elevation in two contiguous leads with a prominent ST-segment depression in other leads. The ST segment is depressed in leads I and aVL and V_4–V_6. There is a subtle ST-segment elevation with a broad dome-shaped T wave in leads III and aVF *(arrows)*, suggesting that the primary abnormality is actually an acute inferior injury. Coronary arteriography shows a totally occluded right coronary artery in its mid-segment and severe left circumflex disease. The ST-segment depression is partly reciprocal to the inferior injury and partly a reflection of left circumflex-related ischemia. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

elevation ACS rather than STEMI. This has a marked impact on the patient's management, as STEMI requires emergent revascularization, while non-ST-segment elevation ischemia requires early (but not emergency) coronary angiography.

4. Hypokalemia and digitalis effect

ST-segment depression, T-wave flattening, and prominent U waves are the hallmarks of hypokalemia and can be mistaken for ischemic changes, including ischemic lengthening of the QT interval (Figure 32.44).[35–38] Digitalis also produces ST-segment depression, low or inverted T waves, and prominent U waves, but the U waves rarely are of the giant variety seen with severe hypokalemia, and the ST-segment depression has a sagging shape. In addition, digitalis shortens the QT interval.

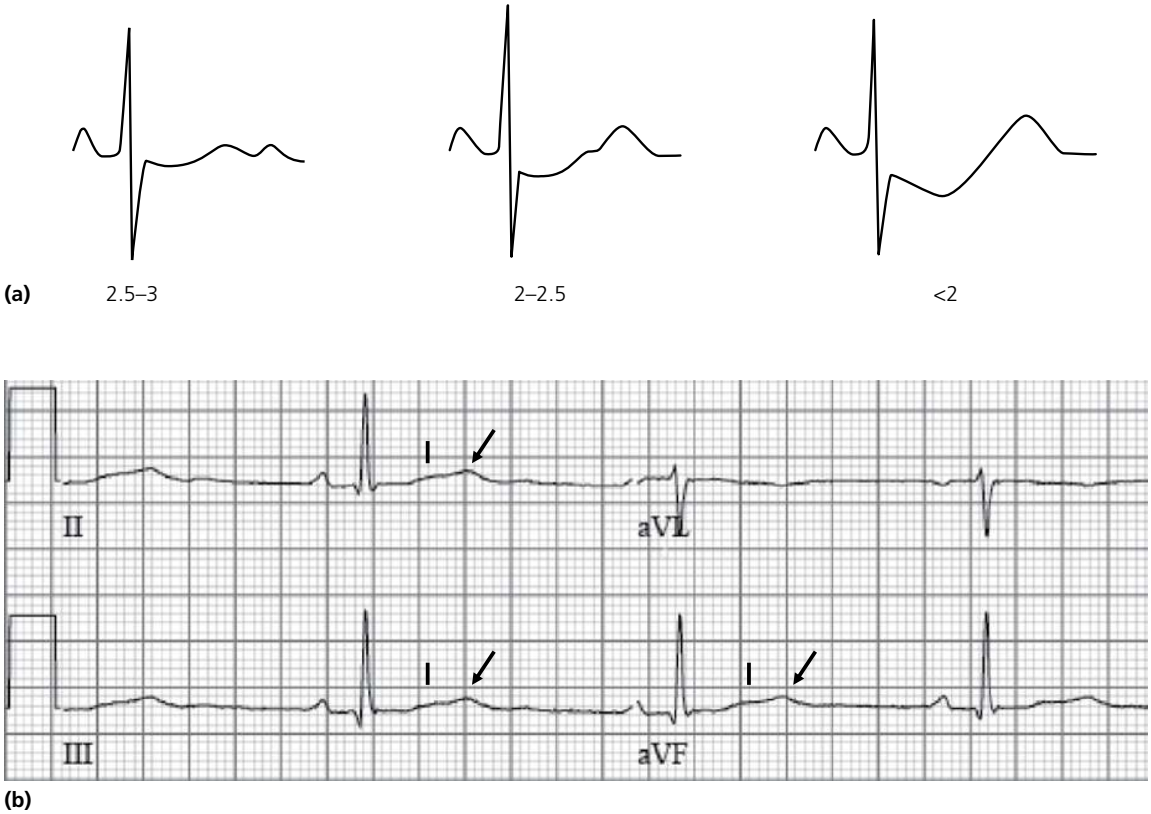

Figure 32.44 Hypokalemia and electrocardiographic abnormalities. **(a)** Note the progressive flattening of T wave, increase in U-wave amplitude, and depression of ST segment with progressive levels of hypokalemia (potassium levels are expressed in mEq/L). **(b)** Electrocardiogram of a patient with potassium level of 2.8 mEq/L. Note the flattened T waves *(bars)* and the prominent U waves *(arrows)*. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

5. Memory T waves

RV pacing, LBBB, frequent PVCs, VT, or even SVT are associated with secondary ST-segment and T-wave abnormalities. When these events are intermittent, T waves may remain inverted for hours to weeks after resolution of the event, and these are called memory T waves.[39,40] The ST segment may also get depressed. "Memory T wave" is a misnomer in that the repolarization abnormality does not necessarily have the same morphology as the provoking event and does not necessarily occur in the leads where the T wave was inverted during the provoking event; in fact, ST–T may have been normal during tachycardia.

D. Diffuse (global) T-wave inversion

This term is applied when the T wave is inverted in most of the standard ECG leads except aVR, which shows a reciprocal upright T wave. The QT interval is often prolonged, and T-wave inversion is often symmetric and "giant" (>10 mm) (Figure 32.45).[5,41] Walder and Spodick have found this pattern to be caused most often by either *myocardial ischemia* or *neurological events*, particularly intracranial hemorrhage, and it seems more prevalent in women.[42] Two other mechanisms can cause this pattern: *hypertrophic cardiomyopathy* and *high catecholamine state* (takotsubo cardiomyopathy, cocaine abuse). Less commonly, global T inversion may be due to pericarditis, PE, and advanced or complete AV block.[42,43] The prognosis in patients with global T-wave inversion is determined by the underlying disease, and the striking T-wave changes per se do not imply a poor prognosis.[44] This pattern may suggest ischemia, yet, unlike Wellens sign, and in spite of the more extensive T inversion, it is not pathognomonic for ischemia.

On a particular note, takotsubo cardiomyopathy is characterized by ECG changes that mimic ischemia, especially anterior STEMI, and is often impossible to differentiate from myocardial ischemia related to a coronary event without performing coronary arteriography. The most common abnormality on the admission ECG is ST-segment elevation (~80% of patients), typically seen in the precordial leads. Within 24–48 hours of presentation, almost all patients also develop post-ischemic diffuse T-wave inversion and prolongation of the QT interval. New Q waves may be seen in 6–31% of the patients and are usually transient.[45,46] Inferior ST-segment elevation may be seen but is unusual. ST elevation is usually less marked than STEMI.

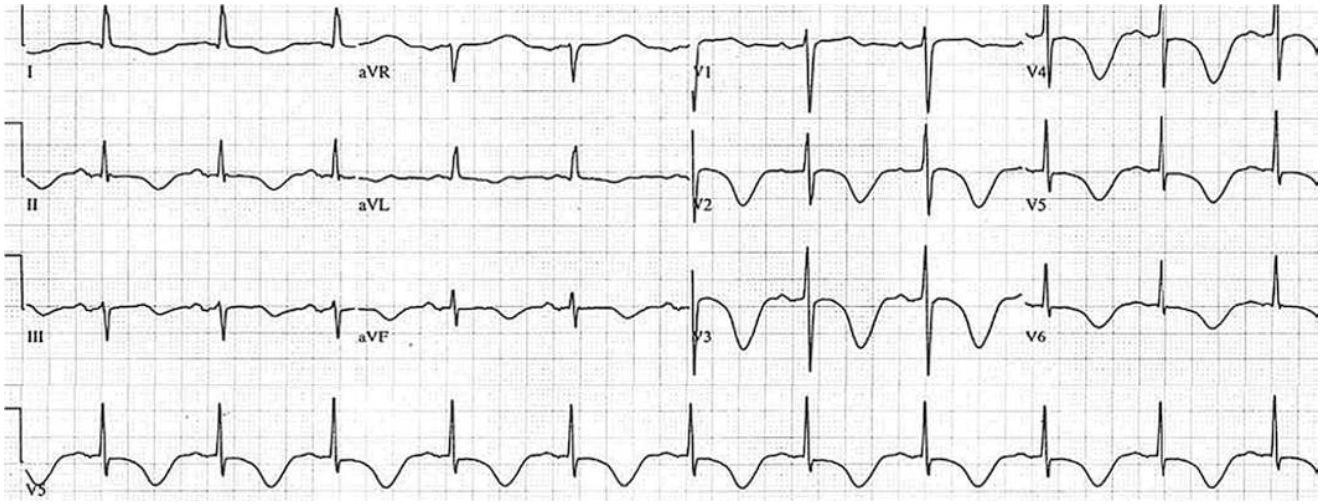

Figure 32.45 Global T-wave inversion with marked QT prolongation in a 77-year-old woman presenting with dyspnea and elevated cardiac biomarkers. **In contrast to Wellens T wave, T wave is not biphasic in any lead, T inversion extends beyond the precordial leads, and the ST segment does not have an upwardly coved shape with a sharp T descent.** Her coronary arteriography showed a 90% distal left main stenosis. Reproduced with permission of Baylor University Medical Center from Glancy et al. (2009).[41]

E. Other causes of T-wave inversion or ST-segment depression

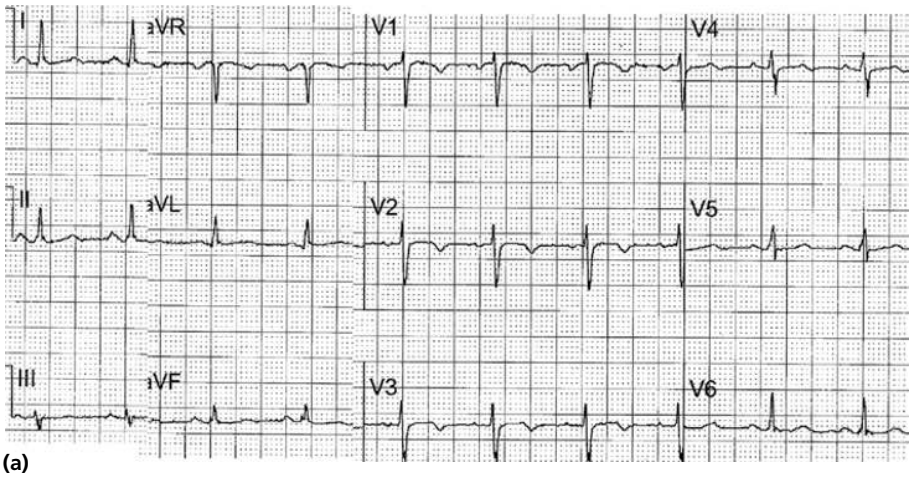
Various other entities may cause T-wave inversion, notably acute pericarditis or myocarditis,[47,48] and normal variants of repolarization (Table 32.1, Figure 32.46).[49] Additionally, a non-pathological junctional ST-segment depression may be seen in tachycardia (Figure 32.47). When baseline ST-segment depression is present, the occurrence of any tachycardia will accentuate ST-segment depression regardless of ischemia.

The term non-specific ST–T changes applies to mild changes, especially ST-segment depression < 1 mm and T-wave inversion < 3 mm. A non-specific T-wave inversion and sometimes a mild ST-segment depression may occur with upright posture, high catecholamine tone, fear, tachycardia, or after a meal, and are partly explained by a *direct effect of catecholamines or tachycardia on myocardial repolarization*. Hyperventilation may produce T-wave inversion but also ST-segment depression; this may create false-positive stress test results. Conversely, a baseline T-wave inversion may normalize with those same processes or with exercise. This normalization is commonly a true normalization of a benign abnormality; however, in a patient with ischemic symptoms, the upright change may represent an ischemic response ("pseudo-normalization" of T-wave inversion).

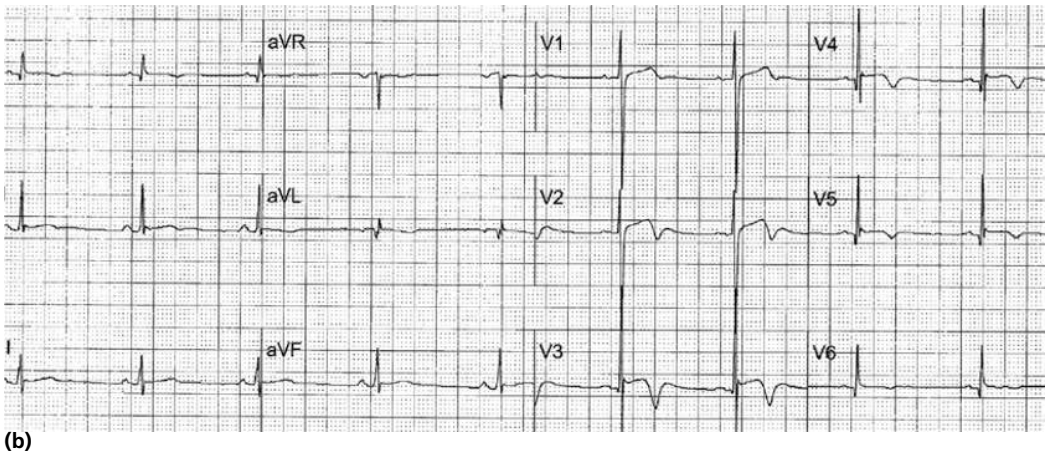
Table 32.1 Differential diagnosis of ST-segment depression and/or T-wave inversion.

Condition	Features
Secondary repolarization abnormalities	• ST segment and T wave move in the same direction, discordant with QRS
Ischemic ST-segment or T-wave abnormalities[a]	• ST segment or T wave may be concordant with QRS • ST segment and T wave may go in opposite directions • Symmetric and pointed T-wave inversion • Positive–negative biphasic T wave
Wellens syndrome	• Symmetric and deeply inverted T waves *OR* Positive–negative biphasic T wave in leads V_2 and V_3, occasionally V_1, V_4, V_5, and V_6 *PLUS* • Isoelectric or minimally elevated (<1 mm) ST segment • No precordial Q waves • Prolonged QT interval • History of recent chest pain in the last hours to days • Pattern present in pain-free state • Normal or slightly elevated cardiac serum markers
True posterior STEMI	• Maximal ST-segment depression in V_1–V_3 • ST-segment elevation in V_7–V_9
ST-segment elevation reciprocal to a subtle ST-segment depression	• Subtle ST-segment elevation concomitant to a more marked ST-segment depression in the reciprocal leads
Pulmonary embolism	• T-wave inversion in the anterior and/or inferior leads • Sinus tachycardia, rSR' in V_1–V_2, right ventricular hypertrophy, "P pulmonale" • Rapid regression of abnormalities on serial tracings favors PE rather than MI
Hypokalemia	• ST-segment depression • T-wave flattening • Prominent U wave (with the flattened T wave, may mimic a wide and notched upright T wave) • Prolonged QTU interval
Digitalis effect	• Similar to hypokalemia, except that ST-segment depression is typically sagging, T–U wave separation is more distinct, and QT interval is shortened
Takotsubo cardiomyopathy	• ST-segment elevation in the precordial leads or more diffusely • Diffuse T-wave inversion • Prolonged QT
Acute pericarditis	• Diffusely inverted or biphasic T waves • ST-segment elevation has often resolved at this stage
Memory inverted T waves	• Appear after pacing, transient LBBB, or transient tachycardia (VT or SVT)
Mild rapidly reversible T-wave abnormalities	• T-wave inversion occurs with standing, hyperventilation, exercise, or after a meal. May improve with exercise. ST depression may also be seen, especially with hyperventilation
Persistent juvenile T-wave pattern	• T-wave inversion in V_1–V_3 • Decrements between V_1 and V_3 • Young female (<40 years old) • No other ECG or clinical abnormality
Global T-wave inversion	• T-wave inversion in most leads except aVR. • T wave sometimes giant (>10 mm) • May be seen with ischemia, intracranial processes, hypertrophic cardiomyopathy, cocaine use, takotsubo cardiomyopathy. • Less often: pericarditis/myocarditis, PE, advanced AV block

[a] Any one of these features suggests ischemia.

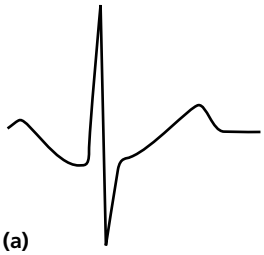


(a)

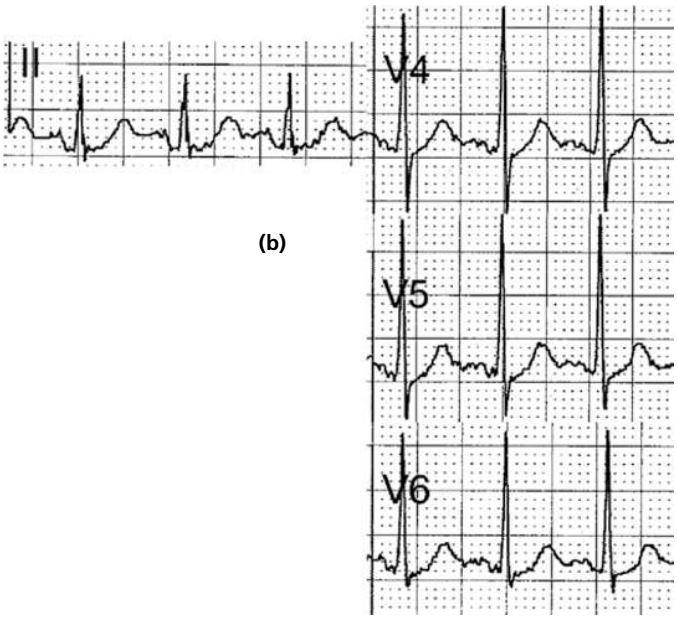


(b)

Figure 32.46 Examples of normal variants of repolarization. **(a)** Persistent juvenile T-wave pattern in a 40-year-old female with T-wave inversion extending from lead V_1 to lead V_4. The depth of the inverted T waves decrements between V_1 and V_4. Also, T wave progressively becomes less deeply inverted as the patient ages. **(b)** Normal variant terminal T-wave inversion with ST-segment elevation in leads V_2 through V_5 in a 21-year-old black man. This pattern is most often seen in young black men, a few of whom at other times manifest the typical early repolarization pattern. The age and clinical presentation distinguish this pattern from ARVD or Wellens. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]



(a)



(b)

Figure 32.47 **(a)** Upsloping ST-segment depression in sinus tachycardia. During tachycardia, the amplitudes of the P wave and the negative atrial repolarization wave increase. This exaggerated atrial repolarization extends over the PR and ST segments, and depresses the PR segment and the initial portion of the ST segment. Here, the ST segment is better referenced to the PR segment than the TP segment, as the PR segment is depressed to the same extent by atrial repolarization. **(b)** ECG of a patient with sinus tachycardia and junctional ST-segment depression in leads II and V_4 through V_6. It has no pathological significance. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

XII. Assessment of ischemia: differential diagnosis of ST-segment elevation

The differential diagnosis of ST-segment elevation on the ECG includes **4 major processes**: ST-segment elevation myocardial infarction (STEMI), early repolarization, pericarditis, and ST-segment elevation secondary to a QRS abnormality (left bundle branch block, left ventricular hypertrophy, or pre-excitation). Additional processes, such as hyperkalemia, pulmonary embolism, and Brugada syndrome, may be associated with ST-segment elevation. The clinical setting, as well as careful attention to the ST–T configuration, often allow an etiological diagnosis (Table 32.2, Figure 32.48).[50]

A. STEMI (acute subepicardial injury pattern)

In STEMI, the ST-segment elevation is typically a convex or a straight oblique line, blending with a wide T wave to form a dome.[51] ST-segment elevation may, however, be concave, in up to 40% of anterior STEMIs, particularly in the early stage.[51–53] The non-concave morphology is highly specific but not sensitive for the diagnosis of anterior STEMI.[51–54]

Four other features characteristic of STEMI may be present (Figures 32.49, 32.50):

- Concomitant T-wave abnormalities (wide, ample, or inverted T wave).
- Q waves. QRS initially *shrinks* with the loss of active myocardium, then evolves into Q waves as the myocardium becomes fully inert.
- ST depression in the reciprocal leads. Reciprocal ST depression is seen in all inferior STEMIs and in 70% of anterior STEMIs.[55,56] *Diffuse ST elevation mimicking pericarditis may be seen with mid-vessel occlusion of a LAD that wraps around the apex* and supplies part of the inferior wall.
- ST- or T-wave amplitude may approximate or exceed the QRS amplitude in at least 1 lead.[51,57,58] This finding is characteristic of STEMI, wherein the QRS complex "shrinks" as the infarcted area becomes electrically neutral, whereas the ST–T segments become ample.[51,57] In fact, early STEMI may be characterized by a small R wave that seems to be pulled up by the elevated ST segment. A small or absent R wave, along with an ample, convex ST segment that fuses with the T wave and exceeds the height of the remaining R wave is called "tombstoning."

Note that ST elevation may not be acute STEMI but an old STEMI with a chronically dysfunctional myocardium (dyskinetic or aneurysmal myocardium). In fact, an old STEMI may manifest as a chronic, persistent ST elevation along with Q waves; T waves may be inverted or upright, but not ample.[58] A history of an old myocardial infarction, old ECGs, if available, and a quick bedside echo may allow the diagnosis. In the case of an old dyskinetic infarct, echocardiography shows a thin, bright (scarred) and possibly aneurysmal myocardium, whereas in acute STEMI the myocardium is neither thin nor scarred yet. If the patient does not report a history of myocardial infarction, if the T wave is ample (>75% the size of QRS), or if the patient presents with a typical ongoing angina, presume it is acute STEMI.

B. Early repolarization

Early repolarization is a normal variant of ST-segment elevation ≥ 1 mm (measured at the J point). It is highly prevalent in individuals under age 40 and remains prevalent in a middle-aged population. Two distinct and sometimes coexistent forms of early repolarization have been described: (i) ST elevation in the anterior leads V_1–V_3;[59–62] (ii) ST elevation in the lateral leads (V_4–V_6, I, aVL) or inferior leads.[61–65] The prevalence of the first form, i.e., ST elevation ≥ 1 mm in any of the leads V_1 through V_3, is 60–90% in men < 45 years of age, 20–40% in men > 45 years of age, and ~10% in women of any age.[59] Thus, this form of early repolarization is called "normal male pattern."

Even early repolarization that involves the lateral or inferior leads is common, with a prevalence of ~15% in individuals 30–40 years of age and ~5–10% in those 40–65 years of age.[63–66] It is 2–4 times more prevalent in men and 3 times more prevalent in African-Americans. It is also highly prevalent in athletes younger than 25 (~30–40%).[65]

Either way, early repolarization closely resembles the ST-segment elevation of pericarditis and has the following features (Figure 32.51):

- The ST segment is concave upward. The J point is well demarcated and may be *notched* or *slurred* (Figure 32.48).
- The ST elevation is usually ≤ 3 mm.
- The ST elevation may be limited to the anterior leads or, in many instances, may extend to the inferior leads, lateral leads, or both. *Early repolarization is very rarely limited to the limb leads, and involvement of some precordial leads is the rule.*[61,62] The ST segment is depressed in lead aVR in 50% of patients.
- The T wave is usually ample and may exceed 10 mm in the precordial leads in one-third of patients.[60] As opposed to the ample T wave of STEMI, the T wave is not broad and remains smaller than the QRS complex. The ample T wave distinguishes early repolarization from pericarditis, and explains the low ST–T ratio in lead V_6. In up to 10% of young black men, T wave has a terminal inversion in leads V_3 to V_5, and occasionally leads V_1 and V_2, mimicking infarction, ARVD, or Wellens pattern (Figures 32.46, 32.52).
- The QRS complex tends to have a prominent precordial voltage, in sharp contrast with STEMI where QRS "shrinks."[51,60,65]

The early repolarization pattern may be intermittent and may vary between serial ECGs. It typically decreases with a rise in sympathetic tone, as observed during exercise, and increases with a rise in vagal tone.[61,62,67,68] While it is usually a benign finding, the early repolarization pattern in leads other than V_1–V_3 has been associated with an increased risk of sudden death, particularly when the ST-segment elevation is horizontal/descending rather than upsloping, and possibly, when early repolarization involves the inferior leads with a J point that is notched and wide (≥1 mm) or elevated ≥2 mm.[63,65] The absolute increase in the risk of sudden death, however, is very small (0.07% per year).[69]

Table 32.2 Differential diagnosis of ST-segment elevation.

STEMI[a]	Early repolarization	Pericarditis	LVH, LBBB, pre-excitation	Hyperkalemia
1. ST elevation straight or convex upward, blends with T to form a dome **2. Wide upright T *or* inverted T** **3. Q waves or, preceding that, QRS shrinkage** **4. ST elevation or T wave may approximate or exceed QRS height, a shrinking QRS** **5. Reciprocal ST depression**	• Notched J point • ST elevation ≤ 3 mm	• PR depression > 1 mm[b] • ST elevation < 5 mm	• Both ST and T are directed opposite to QRS • ST elevation < 25% of QRS height (and ST elevation < 2.5 mm in LVH) • Delta wave, short PR, and pseudo-Q waves are seen in pre-excitation	• Narrow-based, peaked T wave pulling the ST segment

[a] **The presence of just 1 of the first 4 STEMI features makes the diagnosis of STEMI. Conversely, the lack of all STEMI features does not necessarily rule out STEMI.** The fifth STEMI feature, reciprocal ST depression, may be seen with LBBB and LVH, where ST depression in the lateral leads usually accompanies the anterior ST elevation. Typical reciprocal ST depression is not seen in pericarditis and early repolarization (except for the ST depression in leads aVR and V_1 in pericarditis, and in lead aVR in early repolarization). **While the QTc may be prolonged in STEMI, it is normal in pericarditis and early repolarization.**
[b] PR depression < 1 mm may be seen in early repolarization, and PR depression of any degree may be seen with the atrial injury coinciding with STEMI.

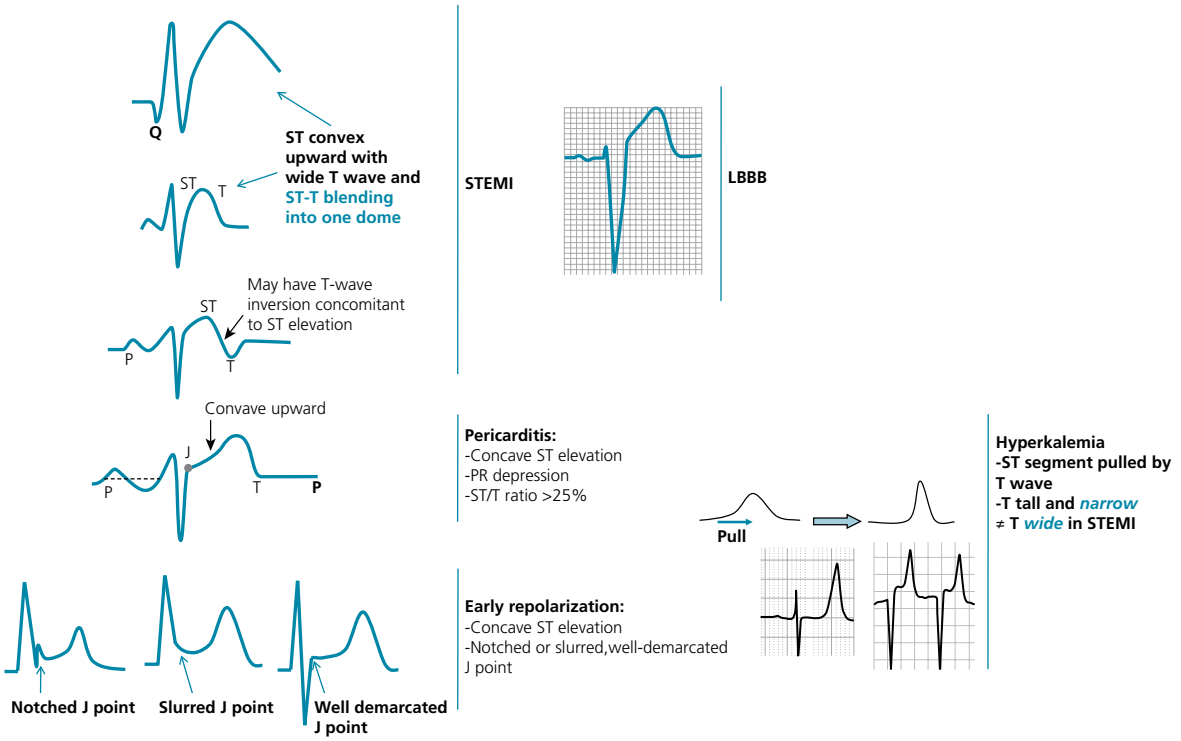


Figure 32.48 Various patterns of ST-segment elevation. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2011).[4]

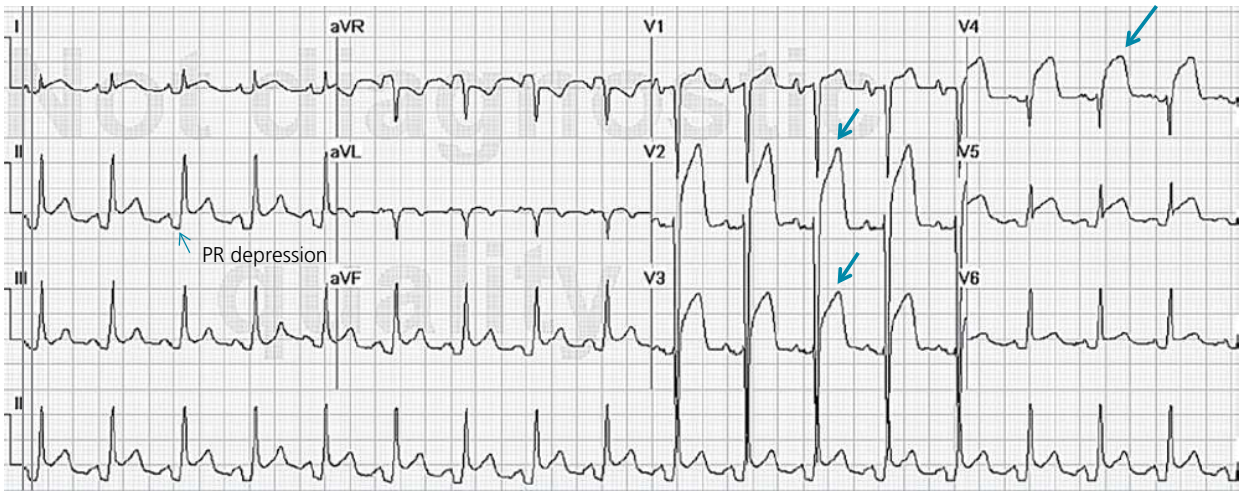

Figure 32.49 Diffuse ST elevation in ~all leads and ST depression in lead aVR. This initially suggests pericarditis. PR depression in leads II, aVF, V_5, and V_6 further suggests pericarditis. However, having pericarditis features does not necessarily rule out STEMI. One should search for the 5 STEMI features and make sure none of them is present. In this case, the ST-segment morphology and the abnormally wide T wave are STEMI features. The ST elevation has an upwardly convex shape with a wide and high T wave fused with the ST segment, very typical of STEMI (leads V_2–V_4, *arrows*). Also, the size of the ST elevation (i.e., >5 mm in V_2–V_4, and larger than the QRS complex in V_4, a feature called "tombstoning") is more consistent with STEMI than with pericarditis. PR depression may be seen in STEMI as a result of atrial infarction (atrial injury leads to atrial repolarization abnormality). The LAD is found to be occluded on coronary arteriography. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

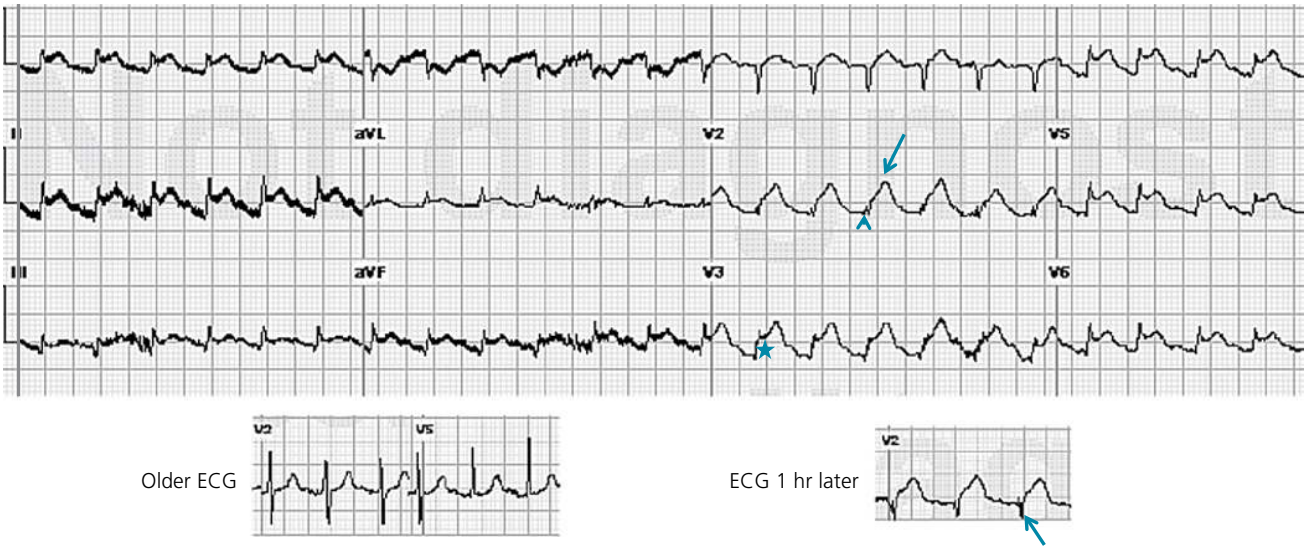

Figure 32.50 ECG of a patient who has lung cancer. Sinus tachycardia with diffuse ST elevation is seen, along with ST depression in aVR. The QRS voltage is low, particularly when compared to the ECG performed a few days earlier (*left lower panel*). PR depression is seen in lead II. This could be pericarditis with pericardial effusion. However, go through the STEMI checklist before calling this pericarditis. The ST–T morphology in lead V_2, where the ST and T are blended to form one dome, is characteristic of STEMI (*top arrow*). Moreover, the ST elevation and T wave in leads V_2–V_4 are larger than the QRS, the QRS voltage is "shrinking" (*arrowhead*), and the R wave is pulled up by the ST segment (*star*); this is called "tombstoning." All these features are characteristic of STEMI, wherein the R wave and the QRS complex shrink before forming a deep Q wave. In fact, an ECG recorded 1 hour later shows a fully developed Q wave in lead V_2 (right lower panel, *arrow*). Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

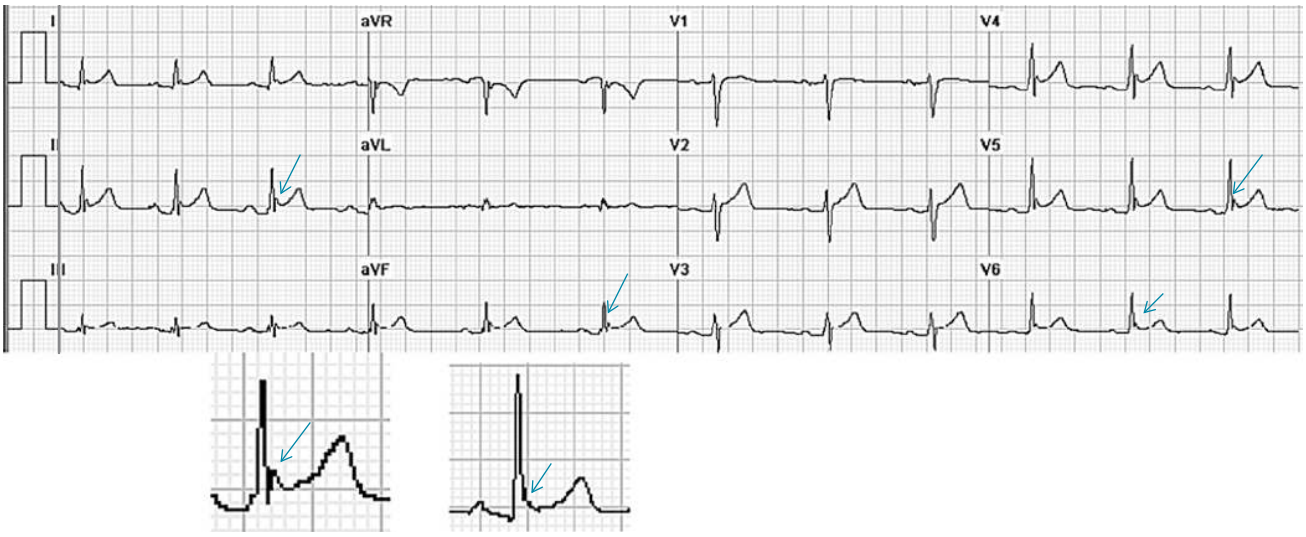

Figure 32.51 Early repolarization with ST-segment elevation in the inferior leads and in the anterolateral leads V_2–V_6. ST elevation is most prominent in leads V_4 and II, with a concavely upward ST morphology and a notch at the J point (*arrows* and *left magnified image*). In half of early repolarization cases, the J point is well demarcated but smooth (*right magnified image*). Note the 1-mm PR depression in leads II and V_5. Slight PR depression may be seen in normal individuals and corresponds to the normal atrial repolarization. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

Figure 32.52 Early repolarization with a normal variant T-wave inversion in a 33-year-old black man. The ST segment is elevated with a prominent J-point notch in leads V_3–V_5 (*arrows*). T wave is inverted in leads V_4–V_5. Depending on the autonomic tone, the T waves may at times become upright. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

C. Pericarditis (Figure 32.53)

In pericarditis, ST elevation is concave upward and is widespread to more than 1 region without reciprocal ST depression, except for the frequent ST depression in leads aVR and V_1 (64%);[70] ST elevation is seldom greater than 4–5 mm.[70,71] The subepicardial injury being diffuse in pericarditis, the axis of the ST segment follows the anatomic axis of the heart and is generally +45° in the frontal plane. Thus, ST depression is seen in leads aVR and V_1, ST elevation is highest in leads II, V_5 and V_6, and is less in leads III and aVL, where the ST segment may occasionally be depressed.[72] The ST segment is elevated at some stage in > 90% of patients, and normalizes within 1–7 days.

Transient PR depression > 1 mm is often seen and may be the earliest change. It is most frequent in leads II, aVF, and V_4–V_6, and represents atrial subepicardial injury. PR depression in those leads is always associated with PR elevation in lead aVR and sometimes V_1. PR changes often coexist with ST changes, but may be isolated and may precede ST changes.[73] PR depression is characteristic of pericarditis but may be seen in early repolarization, where it is less marked than in pericarditis (<0.8 mm) and implies early repolarization of the atrial tissue;[74] and in MI, where it implies atrial infarction with atrial injury pattern.

Classically, it is said that in pericarditis, unlike in STEMI, the T wave does not invert until the ST elevation subsides. In reality, up to 40% of patients develop a notched or biphasic positive–negative T wave before full return of the ST segment to the baseline, mimicking ischemia.[70,75] Also, if T-wave inversion antedates pericarditis, concomitant ST elevation and T inversion may be seen once pericarditis develops. However, the T wave inverts less deeply and less completely than in STEMI, and the QTc interval remains normal even when the T wave inverts.

Three criteria distinguish pericarditis from early repolarization (*but not from STEMI*):

a. PR depression > 1 mm.
b. ST-segment depression in lead V_1.
c. Ratio of ST-segment height to T-wave height ≥ 25% in lead V_6, V_5, or V_4. This feature allows the distinction between pericarditis and early repolarization with a very high sensitivity and specificity. In pericarditis, the T waves have normal or reduced amplitude, and the ST/T ratio is therefore high.[76] In early repolarization, T waves are tall, and thus the ST/T ratio is < 25%.

Widespread ST elevation may be seen with both pericarditis and early repolarization. ST elevation limited to the anterior leads is more likely to be early repolarization than pericarditis. Crucially, *widespread ST elevation is also seen in ~30% of anterior STEMIs*.

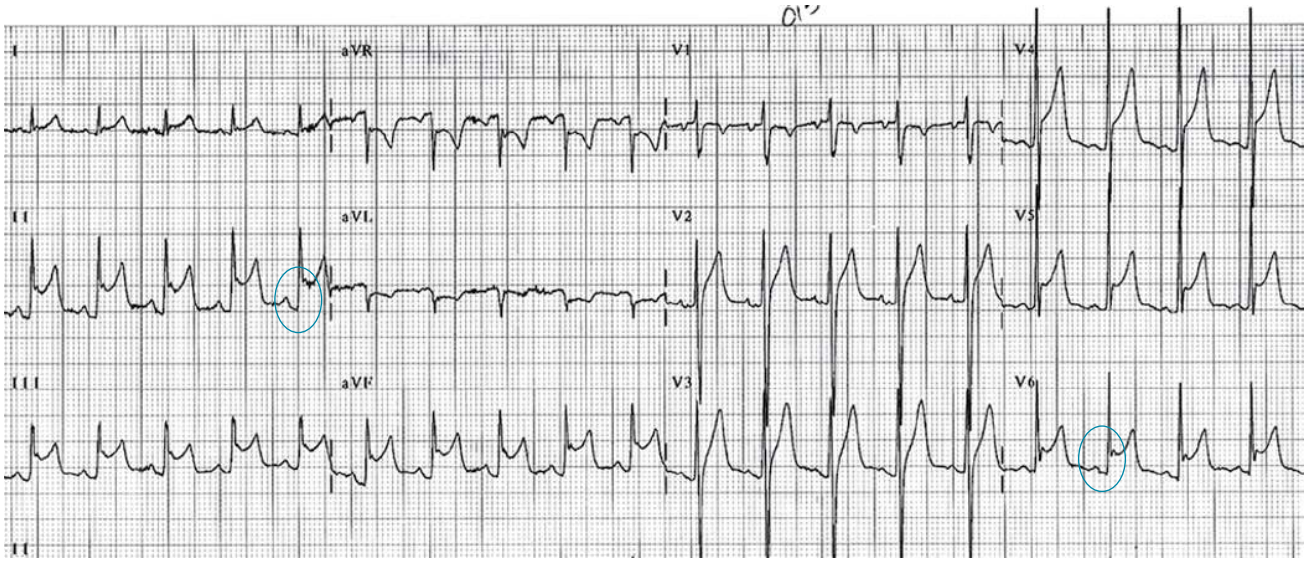

Figure 32.53 Diffuse ST elevation in most leads, with ST depression in lead aVR and an isoelectric ST segment in V_1. None of the STEMI features is present: ST elevation is concave upward, no reciprocal ST depression is seen except in lead aVR, T wave is not wide, inverted, or ample (in relation to QRS), and no Q wave is seen. Furthermore, ST elevation does not exceed 5 mm, ST and T heights are smaller than QRS height, and PR depression is present (*circled areas*). This is consistent with pericarditis, and the hospital course of this patient confirmed this diagnosis.

Early repolarization may lead to a similarly concave ST elevation. However, in early repolarization: (i) ST elevation is ≤3mm; (ii) ST elevation is often limited to the anterior and lateral or inferior leads, but rarely extends to all of them; (iii) there is no deep PR depression; and (iv) the T wave in lead V_6 is high with an ST–T ratio < 25%, which is not the case here.

D. Left ventricular hypertrophy (LVH) and left bundle branch block (LBBB) (see Figures 32.54–32.56)

A deep S wave is seen in leads V_1–V_3 and sometimes in the inferior leads, with ST elevation and T waves that are discordant with the QRS complex, i.e., directed opposite to the QRS. The ST elevation is typically concave upward.[53,77] Occasionally, in LBBB or, less so, LVH, ST elevation may be straight or convex, mimicking the dome of STEMI. In the lateral leads, the discordant ST segment is depressed, mimicking a reciprocal ST change.

The following findings imply myocardial infarction:

a. *ST elevation or depression that is concordant with the QRS complex*. Moreover, since ST deviation is mandatory with LBBB, *a "normal-looking" ST segment* implies ischemia.

b. *Inverted T waves* concordant with the QRS in more than 1 lead*, or biphasic T waves* in more than 1 lead (e.g., V_1–V_3). Across the precordial leads, T wave may transition from positive to negative 1 lead earlier or later than the QRS and ST transition (negative T-wave concordance in 1 lead).

c. In addition to concordance, a *discordant ST segment or T wave that is very large* may imply ischemia. Whether in LBBB or LVH, *discordant ST elevation ≥ 25% of the QRS height or upright T wave ≥ 50% of the QRS height often implies ischemia.*

In the particular case of LVH, ST elevation is usually <2.5 mm in leads V_1–V_3 and is rarely seen in the inferior leads, where it would be <1 mm.[77]

Unlike LVH, ST elevation that accompanies LBBB can be ample; thus, absolute ST elevation cutoffs are less helpful in LBBB. For the diagnosis of STEMI in LBBB, a discordant ST elevation ≥ 5 mm has been suggested by Sgarbossa et al.; however, this feature is seen in 10% of control patients with LBBB and no STEMI, and is therefore poorly specific but also poorly sensitive, frequently missing STEMI.[78,79] A discordant ST elevation ≥ 25% of the QRS height has been suggested as a far more sensitive and accurate feature.[80,81]

On another note, ***RVH and RBBB may lead to ST depression and T inversion, but not ST elevation. Thus, ST elevation occurring with RBBB or RVH implies STEMI***. While only LBBB poses a diagnostic challenge, both types of bundle branch blocks, if secondary to STEMI, represent equally high-risk categories.[82]

RV pacing leads to discordant ST elevation, similar to LBBB; the same criteria may be used to diagnose MI in the setting of RV pacing.

Note concerning Q waves

The septum normally depolarizes left-to-right through the left bundle. Thus, RBBB does not change septal depolarization and only affects the late part of the QRS complex; therefore, it does not create Q waves. LBBB, on the other hand, changes the septal depolarization and may create QS waves in leads V_1–V_3 and III–aVF, mimicking MI. However, LBBB does not typically create any q in the lateral leads or lead II, nor QR anywhere (the latter findings suggest MI). Also, a notch on the *upslope of S* wave in leads V_3–V_5, or the *upslope of R* wave in leads I, aVL, or V6 may signify old MI and scarring (Cabrera's sign). In fact, any excessive *fragmentation* and notching of a wide QRS (multiple notches in the R or S wave) is indicative of scarring.

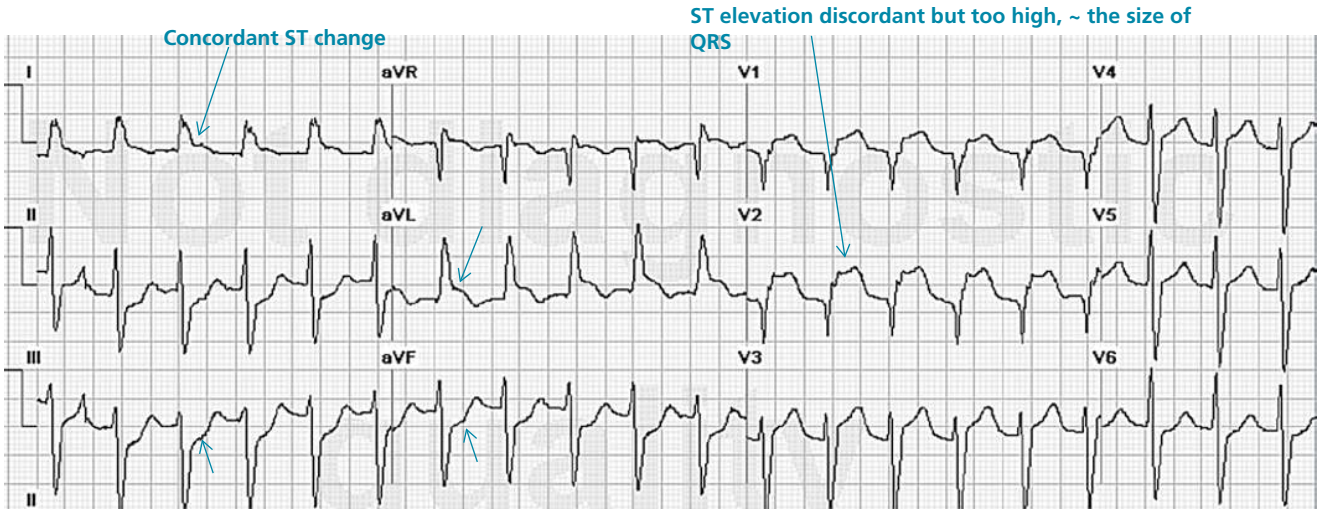

Figure 32.54 SVT with a typical LBBB in leads I and aVL. Concordant ST elevation is seen in leads I and aVL, while concordant ST depression is seen in the inferior leads (*arrows*). The ST elevation in lead V_2 is discordant but is disproportionately high in relation to the QRS (well above 25% of the QRS height). All these features are diagnostic of STEMI. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

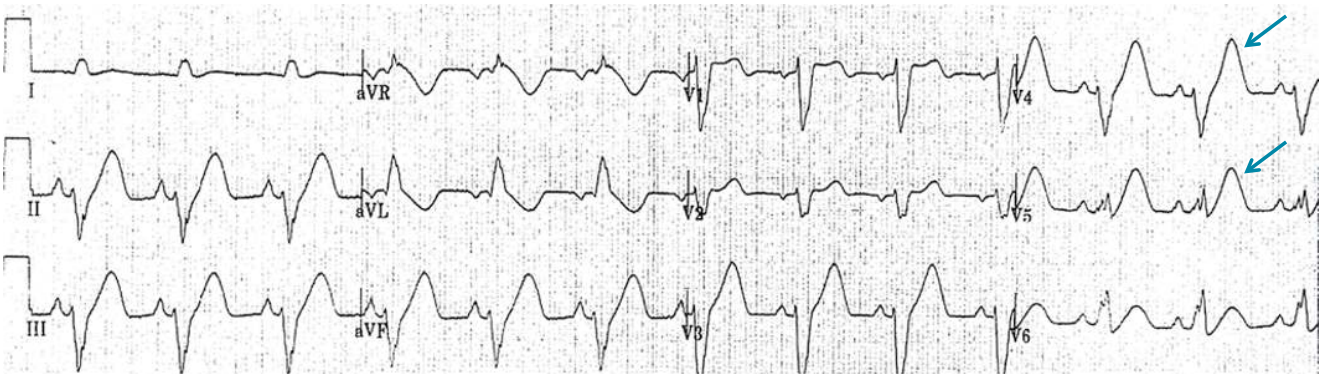

Figure 32.55 LBBB with discordant ST-segment changes. However, the T wave is wide and fused with the ST segment in a domed morphology, and the T wave is larger than the QRS in leads V_4, V_5, and II (*arrows*). This implies a diagnosis of STEMI with hyperacute T waves. This patient had an occluded left anterior descending coronary artery. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

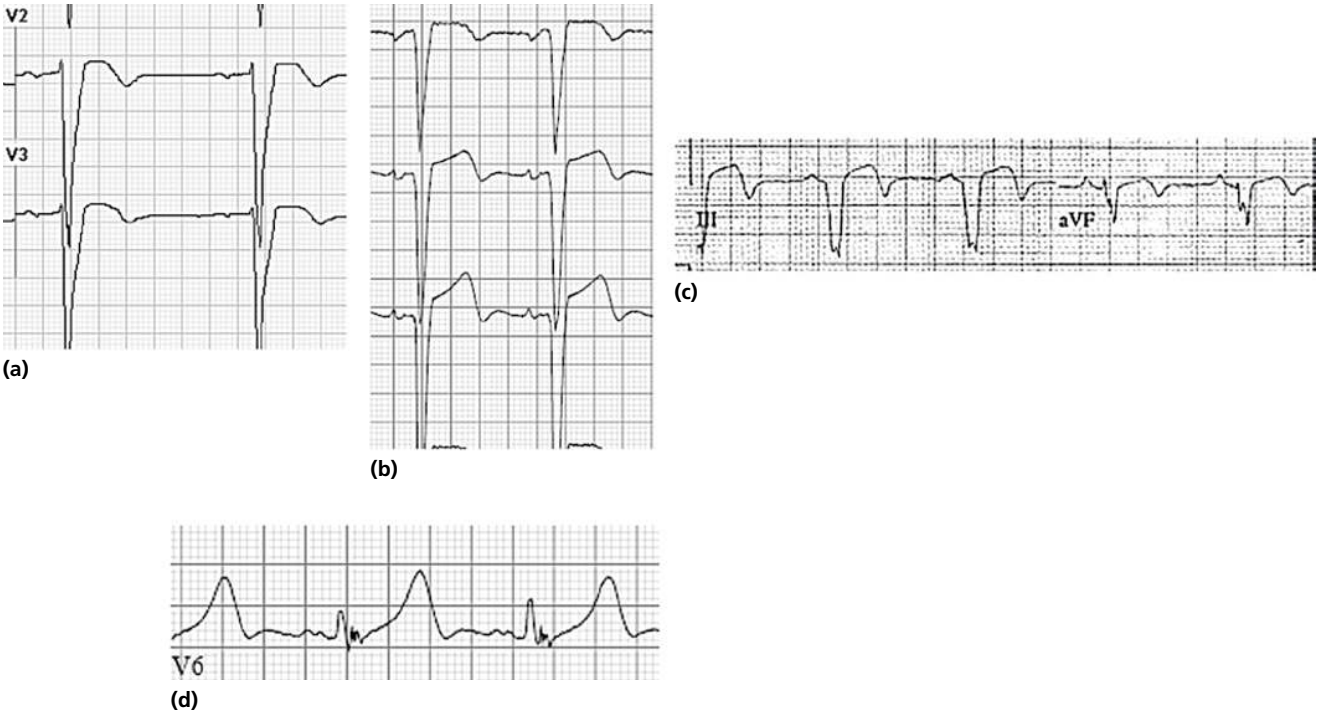

Figure 32.56 LBBB with abnormal T waves. **(a, b)** Discordant ST elevation in V_1–V_3 but concordant T-wave inversion **(a)** or biphasic T wave **(b)**. This is consistent with an anterior injury pattern. **(c)** Concordant T-wave inversion in the inferior leads, consistent with inferior injury. **(d)** A large upright T wave in lead V_6, larger than the QRS, consistent with injury. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

E. Pre-excitation (Figure 32.57)

Pre-excitation may be associated with negative delta waves that mimic Q waves, and with ST elevation in the leads where the negative delta waves are seen, i.e., ST elevation discordant with the delta wave. The QRS morphology and the delta wave allow the distinction from STEMI.

F. Hyperkalemia (Figure 32.58)

The most common finding in hyperkalemia is a peaked, narrow-based T wave that is usually, albeit not necessarily, tall. ST elevation may be evident in leads V_1–V_3. In contrast to hyperkalemia, the T wave of STEMI is typically wide.

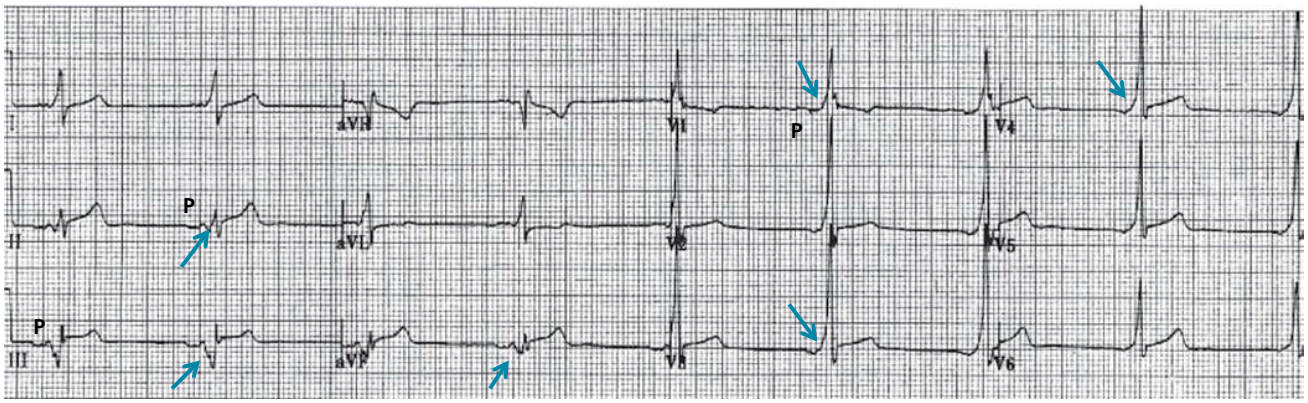

Figure 32.57 At first glance, it seems there is ST elevation in the inferior leads II, III, and aVF, with a wide Q wave. Moreover, there is a wide and tall R wave in lead V_1 with ST-segment depression, suggesting an associated posterior infarct. An ECG performed a few days previously did not show any Q wave or ST-segment elevation. All of this is consistent with an acute inferoposterior STEMI. On further analysis, however, a slur is seen on the upslope of QRS in leads V_1–V_6 (*arrows*), and P wave is "riding" this slur. In the inferior leads, P wave is "riding" the Q wave, which is in fact a negative delta wave. Thus, this ECG represents pre-excitation. The ST deviations are secondary to the pre-excitation and have an orientation opposite to the delta wave. The degree of pre-excitation depends on how fast the AV node is conducting, and thus often varies between ECGs. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

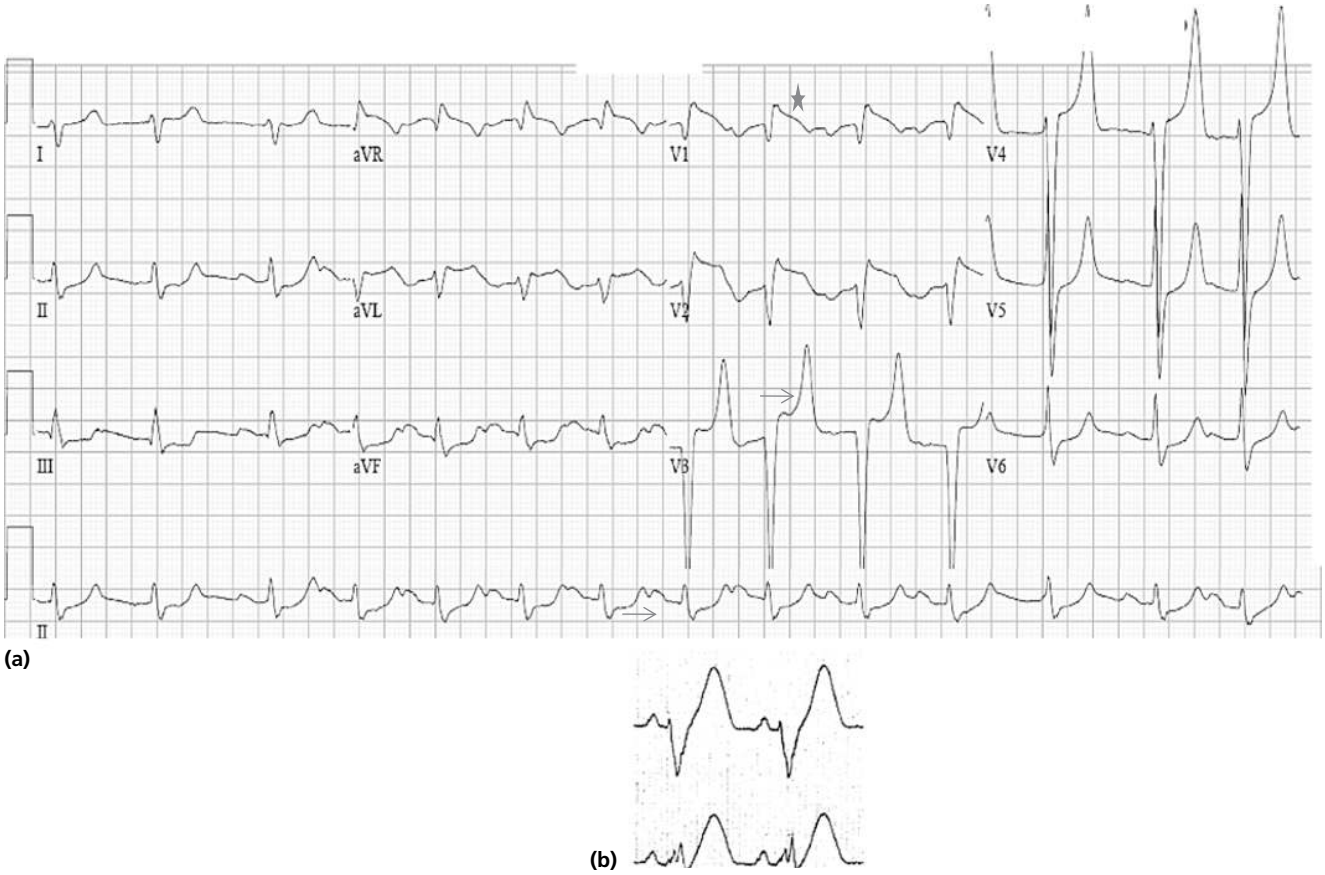

Figure 32.58 **(a)** There are ST elevations in leads V_1–V_4, ST depressions in the inferior leads, and peaked T waves in leads V_3–V_5. These T waves have a narrow base and seem to "pull" the ST segment, creating ST elevation in the anterior leads and ST depression in the inferior leads (*arrows*); this shape is consistent with hyperkalemia. In addition, the dowsloping ST elevation seen in V_1–V_2 is consistent with hyperkalemia (*star*). Occasionally, STEMI may have a similar ST–T shape. An RBBB pattern is seen in V_1–V_2 (rSR'); this is consistent with STEMI but also with hyperkalemia, where conduction blocks are common. The serum K level was 7.4 mmol/L and coronary angiography revealed normal coronary arteries.

(b) Hyperacute T wave of STEMI. Note that it is wide and it blends with the ST segment to form 1 wave. The QRS is shrinking and T wave may become larger than the QRS, a finding characteristic of STEMI.

Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

G. Other causes of ST-segment elevation

- ***Takotsubo cardiomyopathy*** mimics all ECG features of anteroapical STEMI. ST elevation may extend to the inferior leads but cannot be isolated in the inferior leads.[83] As in apical STEMI, reciprocal ST depression is uncommon. Within 24–48 hours, ST elevation evolves into deep anterior T-wave inversion and prolonged QT interval. Transient Q waves may be seen.
- ***Myocarditis*** may have 1 of the following 2 ECG patterns: (i) pericarditis pattern; or (ii) typical STEMI pattern with Q waves, sometimes localized to one area.
- ***Atrial flutter waves***, particularly of 2:1 atrial flutter, may deform the ST segment in such a manner as to mimic an injury pattern on the ECG. Flutter waves may mimic ST elevation or ST depression (Figures 32.59, 32.60).
- ***A large pulmonary embolism*** may be associated with T-wave inversion in the anterior leads and/or the inferior leads, reflective of cor pulmonale. Less commonly, ST elevation in the anterior or inferior leads is seen, and is most typically isolated to the "right" leads V_1–V_2.[28,84]
- ***Brugada syndrome*** is characterized by ST elevation *and* an RBBB or a pseudo-RBBB pattern in at least 2 of the leads V_1–V_3. In pseudo-RBBB, the QRS adopts an rSR' morphology in the anterior leads but is normal in the lateral leads. Type 1 Brugada pattern, the pattern that is most specifically associated with sudden death, is characterized by a coved, downsloping ST elevation ≥2 mm with T-wave inversion (Figure 32.61).[85] The Brugada pattern can be transient, triggered by fever, cocaine, or class I antiarrhythmic drugs.

Hyperkalemia, Brugada syndrome, and sometimes pulmonary embolism are characterized by an ST elevation that slopes down (Figures 32.58, 32.61), which contrasts with the upsloping, convex ST elevation of STEMI.

XIII. Assessment of ischemia: large or tall T wave

A. Differential diagnosis of a tall upright T wave

Grossly, a T wave is considered tall upright if it is >10 mm in a precordial lead or >6 mm in a limb leads. Yet a T wave may be larger than 10 mm in leads V_2–V_3 in normal young men. It is therefore important to also consider the height of the T wave in relation to the QRS. A T

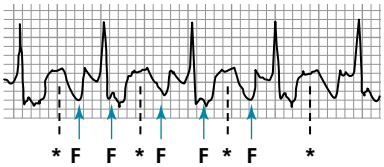

Figure 32.59 Atrial flutter that simulates ST-segment elevation. "F" indicates the negative flutter wave; asterisk (*) indicates the upslope of the flutter wave that gets superimposed on the ST segment, mimicking ST elevation. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

Figure 32.60 Atrial flutter that simulates ST-segment depression. The undulations of the baseline are flutter waves (*arrows*).

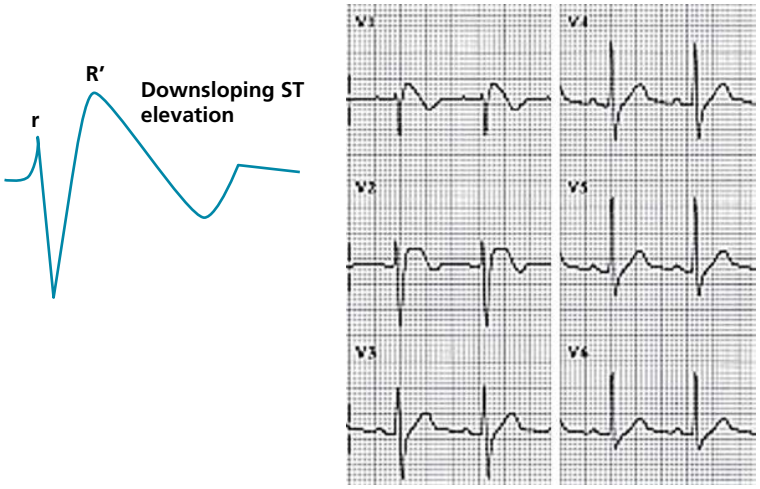

Figure 32.61 Type 1 Brugada pattern in V_1 and V_2, with a downsloping ST elevation that creates a pseudo-R' wave (pseudo-RBBB). The QRS does not have RBBB morphology in leads V_5 and V_6. Reproduced with permission of the Cleveland Clinic Foundation from Hanna and Glancy (2015).[50]

wave that is taller than the dominant QRS waveform (R or S) is abnormal, except in a transition zone precordial lead where the QRS is nearly isoelectric. A T wave that is >75% of this waveform is often abnormal.

1. **Hyperacute T wave in acute STEMI:** T wave is ample and, more importantly, *wide* and coalesced with the ST segment into one dome. It frequently exceeds QRS height in at least 1 lead. It precedes and/or coincides with ST-segment elevation.
2. **Hyperkalemia:** T wave is peaked and narrow.
3. **Ample T wave in leads V_1–V_3 secondary to LVH/LBBB:** the ample T wave is directed opposite to the ample, negative QRS complex.
4. **Normal variant:** a normal-variant ample T wave is particularly seen in association with early repolarization and high QRS voltage. The normal-variant ample T wave is mostly seen in young men in leads V_2–V_4, where it may exceed 10 mm.

B. deWinter complex, "shark fin" pattern, and spiked helmet sign

deWinter complex is characterized by an upsloping ST depression in leads V_1 through V_6 followed by a tall upright T wave, which may be narrow or wide (Figure 32.62).[86] It is similar to the hyperacute T-wave pattern; however, while hyperacute T waves quickly progress to a typical ST elevation pattern within a few minutes, deWinter complex does not progress to ST elevation and remains static. The morphology mimics hyperkalemia. deWinter complex is associated with an acute LAD occlusion, and is thus equivalent to an acute anterior STEMI and should warrant emergent catheterization. For unclear reasons (mutation of I_{K-ATP}?), these patients are unable to generate ST-segment elevation. ~2% of anterior STEMIs manifest this deWinter's pattern of static hyperacute T waves.

The "shark fin" pattern and the spiked helmet sign are ST-elevation variants, sometimes seen in non-cardiac critical illness.

XIV. QT analysis and U wave

A. QT interval measurement

QT interval is best measured in the lead that shows a distinct T-wave termination, with the best separation of T and U waves. The QT interval may be artificially shortened in some leads, because the beginning of the QRS complex or the end of the T wave may be isoelectric in those

leads. On the other hand, QT is often longest in leads V_2–V_3, but those leads have the largest U waves, show the least T–U separation, and may, therefore, overestimate the length of the QT interval. Leads I, aVR, and aVL do not have the diastolic U wave but do not always show a distinct T wave. Thus, QT interval is often best measured in leads II and V_5 or V_6 (Figure 32.63).

QT interval shortens with increasing heart rate. The corrected QT (QTc) at a particular heart rate corresponds to the patient's predicted QT interval had the heart rate been 60 bpm. If the patient's rate is 60 bpm, QTc equals absolute QT. The normal QTc is >350 ms, and <460 ms in women and <450 ms in men.

QTc may be calculated using Bazett's formula:

$$QTc = QT/\sqrt{R\text{–}R \text{ interval in seconds}}$$

Bazett is acceptable for rates 50–100 bpm. It falsely prolongs the QTc when the rate is >100 bpm and falsely reduces it when the rate is <50 bpm. Hodges' formula is a linear equation that is simpler and more accurate than Bazett's formula at both high and low rates:

$$QTc = QT + 1.75\ (\text{rate} - 60)$$

This means that normally, QT decreases by 17.5 ms for every 10-beat increase in heart rate, and increases 17.5 ms for every 10-beat decrease in heart rate. If a patient has a QT of 400 ms at a rate of 100 bpm, the QT at a rate of 60 bpm would be $(400 + 17.5 \times 4) = 470$ ms. Bazett would yield a QTc of 515 ms ($400/\sqrt{0.6}$ s). Another quick rule is that for heart rates < 100 bpm, QT interval should be shorter than 1/2 the R–R interval. However, for rates > 100 bpm, the QT interval is normally > 1/2 R–R interval; for rates < 60 bpm, a QT interval < 1/2 R–R interval does not guarantee a normal QTc.

In case of a prolonged QRS, as in bundle branch block, use a higher upper limit of normal for QTc (500 ms), or use the JT interval instead of QT to assess repolarization (normal JTc < 360 ms). In AF, QT interval varies from beat to beat due to R–R interval changes. One may measure the QT intervals that follow the longest and shortest R–R intervals, then divide each by the square root of the preceding R–R interval (QTc1 and QTc2). The average of these 2 values is QTc.

Figure 32.62 STEMI ECG variants. *Right image: DeWinter complex* in V_1-V_6.

Middle image: Shark fin pattern: QRS and ST-T merge together into one triangular waveform. This may be an ominous STEMI, but is also seen in non-cardiac critical illness. *Contrast the tombstone and shark fin patterns:* in the *tombstone* pattern, ST and T are indiscernable and merged into one dome. In the *shark fin pattern*, QRS, ST and T are indiscernable and merged into one wave. *Left image: Spiked helmet sign:* QRS-ST-T is domed with a spike on top and with no isoelectric line. This pattern has been mostly described in non-cardiac critical illness, and is attributed to repolarization effects of the adrenergic tone.

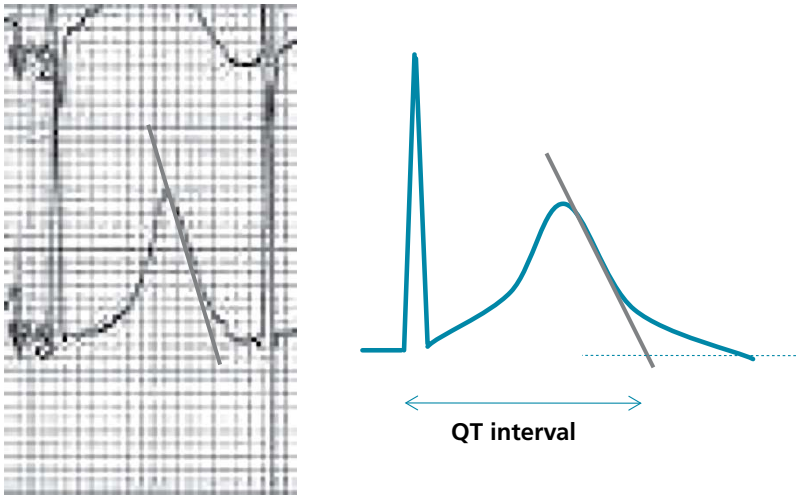

Figure 32.63 QT is not measured using the end of the T wave. Instead, a line is drawn across the maximal T-wave downslope, using the last T-wave peak. The intersection of this line with the baseline is used to calculate QT interval; otherwise, the QT interval may be overestimated.

B. U wave

The normal U wave is a diastolic wave related to the mechanical stretch of the myocardium in phase 4 (diastole). The abnormal U wave could be part of phase 4 (delayed afterdepolarization [DAD]), or part of phase 3 in patients with prolonged repolarization (early afterdepolarization [EAD] seen in patients with prolonged QT).

The U wave of phase 3 is a repolarization wave and is actually a part of the T wave, called T2 wave, that gives the T wave a notched or biphasic shape; it may be seen in leads I/aVL/aVR and should be measured as part of the QT interval. This T2 wave is seen with hypokalemia and QT-prolonging drugs. ***In practice, a U wave that is prominent* and *that merges with the T wave or gives a "bifid" T-wave appearance should be included in the measurement of the QT interval and predicts TdP (ominous TU wave).*** Conversely, a normal U wave (<25% of T wave), or a prominent U wave that is distant from the T wave (>150 ms peak-to-peak distance, as with digoxin), is a phase 4 U wave and should not be counted as part of the QT interval. Thus, leads V_2–V_3 are best avoided for QT measurement.

The normal U wave is particularly visible in leads V_2–V_3 at heart rates < 65 bpm, and is not usually seen at rates > 100 bpm; bradycardia makes U waves more visible but also more ample. The U wave is normally a positive wave, with an amplitude < 25% the T-wave amplitude and < 1.5 mm. An abnormal U wave is an upright U wave that is ≥25% of the T wave or ≥1.5 mm. A negative U wave is always abnormal but is very rare.

C. Differential diagnosis of a prolonged QTc (Figures 32.64, 32.65)

There are 5 major causes of a prolonged QTc:

1. Ischemia or post-ischemic evolution
2. Hypokalemia (also gives a prominent U wave), hypocalcemia
3. QT-prolonging drugs (also give a prominent U wave)
4. Congenital long QT syndrome (LQT)
5. Miscellaneous causes: hypothyroidism, hypothermia, cerebrovascular event with large upright or deeply inverted T waves, and any cardiomyopathy (hypertrophic, dilated)

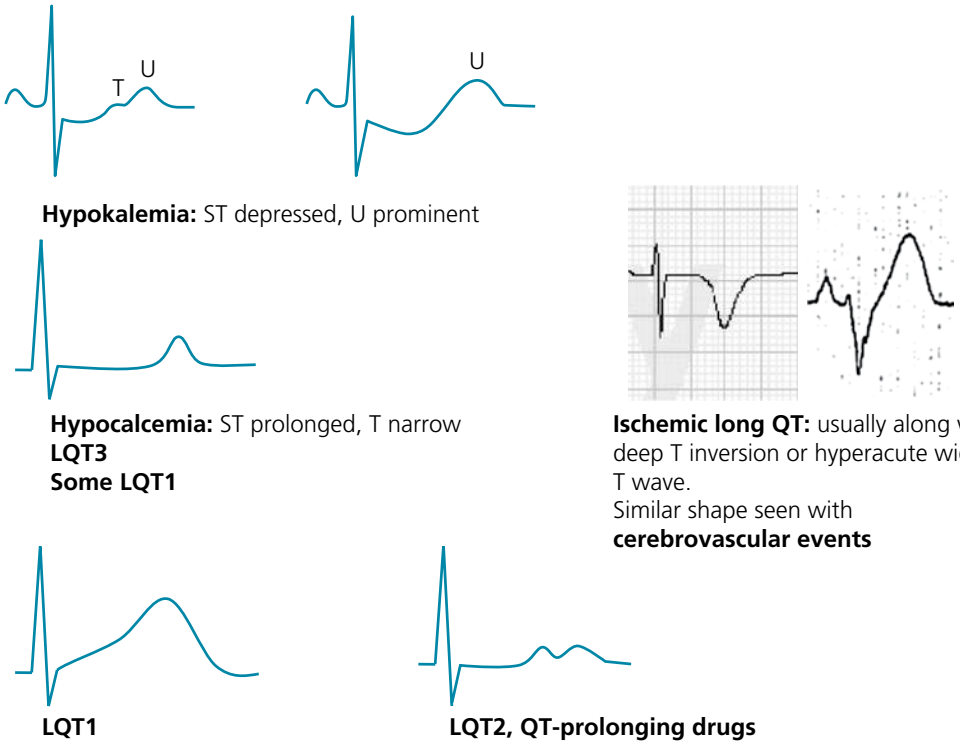

Figure 32.64 Typical ST–T morphologies in hypokalemia, hypocalcemia, congenital long QT syndromes, and ischemic QT prolongation.

- In hypokalemia, the ST segment is depressed and U wave is large while T wave is flattened.
- In hypocalcemia and LQT3, QT interval is prolonged as a result of the ST-segment prolongation. As opposed to other congenital long QT syndromes or QT prolongation secondary to drugs, T wave is not significantly widened.
- In LQT1, T wave is wide and ample without ST-segment depression, but may also take the shape of LQT3. In LQT2 and in many drug-induced long QT cases, T wave is wide and notched (double hump) and may simulate hypokalemia.

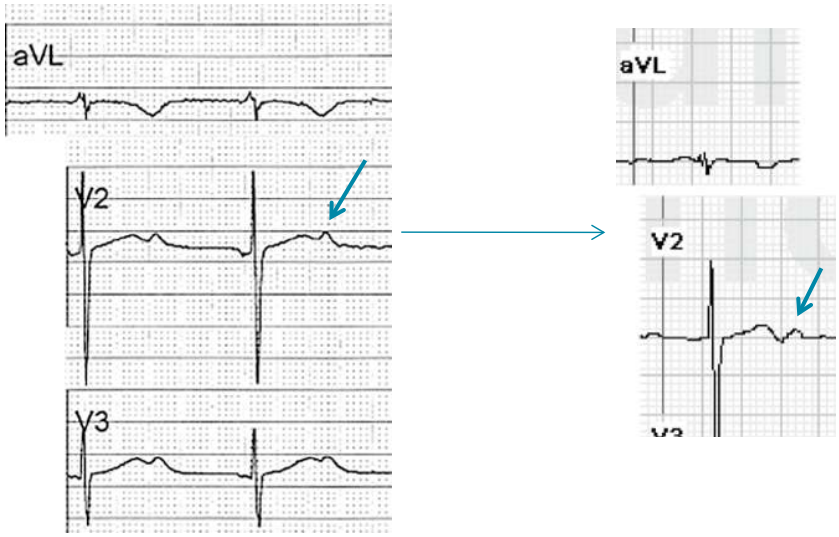

Figure 32.65 *On the left*, markedly prolonged QT with a notched T wave is seen (QTc ~600 ms). Note that the second T peak is part of the T wave rather than a U wave (*arrow*), as QT is as prolonged in lead aVL, which does not usually show U wave. This patient was receiving amiodarone. *On the right*, after amiodarone cessation, QT is reduced to normal (QTc 440 ms). Note that lead V_2 now shows a U wave rather than a T wave (*arrow*), as evidenced by the fact that the dip between the two peaks reaches the baseline, and that this wave is not seen in lead aVL.

Note the morphology of a prolonged QT induced by hypokalemia (Figure 32.64). A prolonged QT with a wide ample T wave and no ST depression is not hypokalemia; a deep negative T wave is not hypokalemia either. Consider other causes of long QT in this case, such as congenital long QT syndrome, drugs, or ischemia.

Most of the causes of prolonged QT are related to a prolonged T-wave duration. Three causes are characterized by a prolonged ST segment with a normal T-wave duration: hypocalcemia, hypothermia, LQT3 and sometimes LQT1.

D. Differential diagnosis of an abnormal U wave

1. *Negative U wave*
   - Ischemia
   - LVH
   - Regurgitant valvular disease with volume overload
2. *Prominent upright U wave*
   - Digoxin (DAD), catecholamines (DAD)
   - Antiarrhythmic drugs (actually T2 wave rather than U wave)
   - Hypokalemia (actually T2 wave rather than U wave)
   - Bradycardia
   - LVH
   - Other: hypercalcemia (DAD), cerebrovascular event

Ischemia does not typically cause a tall upright U wave. Digoxin and hypercalcemia are causes of U wave that are associated with a shortened QT interval.

XV. Electrolyte abnormalities, digitalis effect and digitalis toxicity, hypothermia, PE, poor precordial R-wave progression

A. Electrolyte abnormalities

Hypokalemia initially produces diffusely flattened T wave. With severe hypokalemia < 3 mEq/L, the ST–T pattern may mimic an ischemic pattern of ST-segment depression with a wide upright T wave and a prolonged QT interval (Figures 32.66, 32.67). Hypokalemia may lead to PACs/PVCs, polymorphic VT, or, similarly to digoxin, AT with block. Hypokalemia increases vagal sensitivity, and thus may be associated with bradyarrhythmias.

In patients hospitalized for any surgical or medical illness, a hypokalemia pattern is very common on ECG and is commonly mistaken for ischemia.

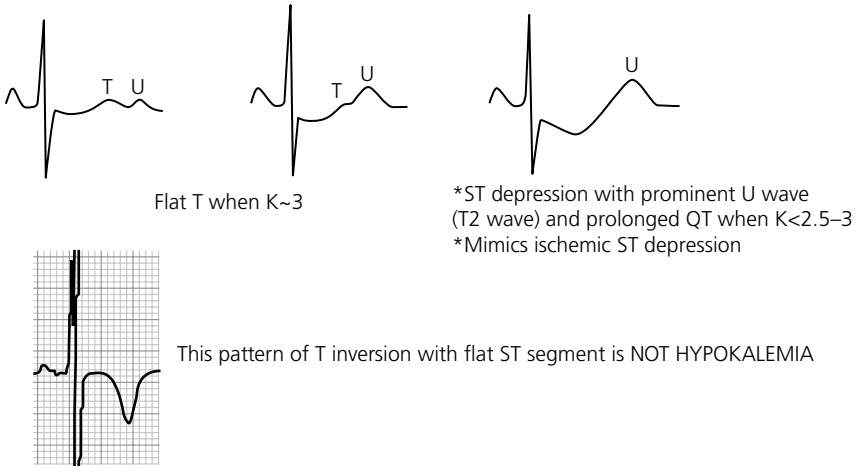

Figure 32.66 Hypokalemia and a pattern that should not be confused with hypokalemia are shown.

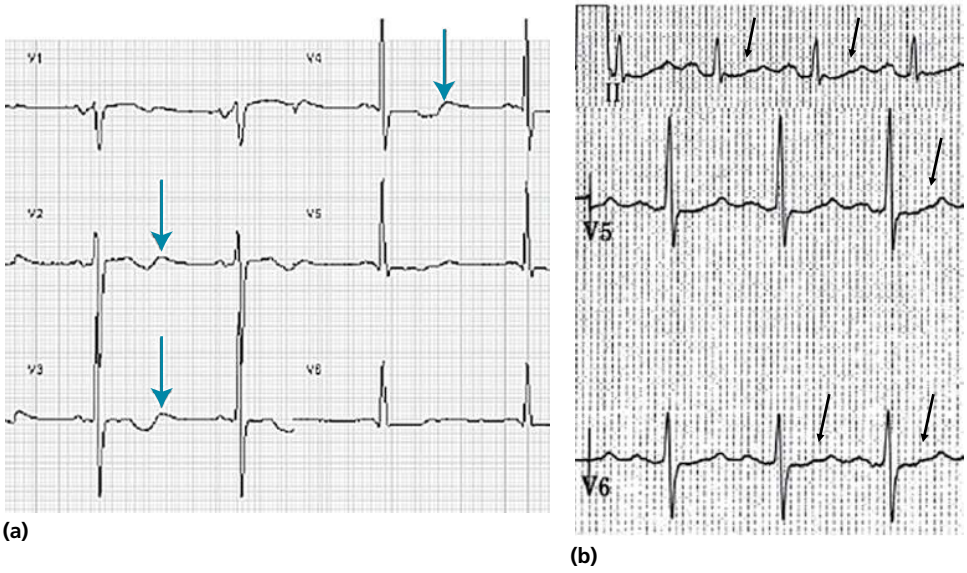

Figure 32.67 Two ECG examples of hypokalemia. **(a)** Prolonged QT (QT ~600 ms, QTc 550 ms) with diffuse ST depression and prominent, positive U waves (well seen in V_2–V_5; *arrows)* (K = 2.5 mEq/L). The abnormal U wave merging with T wave is included in QT measurement. **(b)** ST depression with upright "T" wave. On further examination, a notch on the upslope of the ST segment is seen in multiple leads, suggesting that the "T" wave is actually a prominent U wave and the notch is a flattened true T wave (*arrows*).

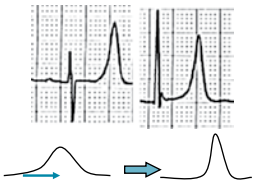
Hyperkalemia is characterized by the following (Figures 32.58, 32.68, 32.69):

- Potassium 5.5–6 mEq/L: narrow, peaked T waves that are usually, but not necessarily, tall. T wave pulls and tents the ST segment.
- Potassium > 6 or 6.5 mEq/L:
  - Conduction abnormalities and wide QRS complex: RBBB, LBBB, LAFB. The wide QRS of hyperkalemia is not usually a typical RBBB or LBBB. With hyperkalemia, the whole QRS is wide, including the initial portion, whereas with a typical bundle branch block, the initial portion is narrow.
  - PR segment prolongs and P wave progressively flattens then becomes absent. The rhythm becomes an accelerated junctional (narrow QRS) or idioventricular (wide QRS) rhythm, sometimes due to a sinoventricular conduction with a total lack of atrial activity.
  - ST-segment elevation that slopes down and/or ST-segment depression.
  - The QRS becomes progressively wider, evolving into a sine wave pattern, then VT/VF. ***A very wide QRS > 200 ms is always suggestive of hyperkalemia.***

Hypocalcemia and ***hypercalcemia*** only affect the length of the ST segment (Figure 32.70).

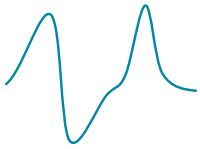
B. Digitalis effect and digitalis toxicity (Figure 32.71)

Digitalis effect pertains to the ECG changes associated with therapeutic digoxin dosing. Digitalis effect is similar to hypokalemia, i.e., ST-segment depression, T-wave flattening, and prominent U wave. Unlike hypokalemia, the ST segment has a "scooping" shape (like a spoon) and QT is shortened. Atypical changes may be seen, such as inverted T wave or reverse-checkmark shape of ST–T, particularly when LVH is also present.



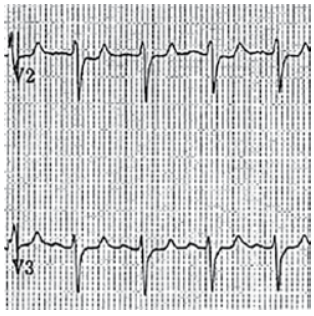
Pull

Absent P wave + wide QRS (typical or atypical bundle branch block). Both the initial and late QRS portions are wide

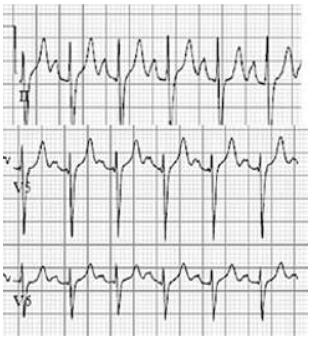


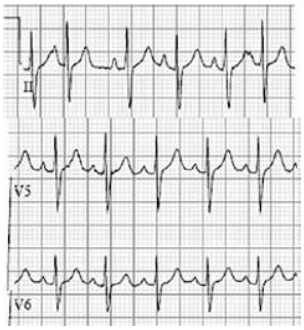
Progressively more QRS widening leading to a sine wave shape

Figure 32.68 Stages of hyperkalemia.



(a)

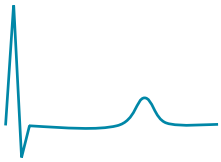


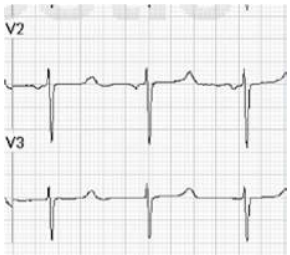


(b)

K= 6.5 K= 5.5

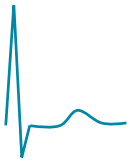
Figure 32.69 **(a)** Hyperkalemia of 6.1 mEq/L. Note that T waves are not tall, but are narrow and peaked with ST-segment tenting. **(b)** Hyperkalemia with peaked T waves that are not tall but narrow. Note the improvement after appropriate therapy.





Hypocalcemia:

Long QT that is due to a long ST segment, which is different from long QT secondary to drugs or hypokalemia. T wave is not wide, there is no T wave abnormality.



Hypercalcemia: short QTc <390 ms. No significant ST or T wave abnormality

Figure 32.70 Hypocalcemia and hypercalcemia.

Figure 32.71 Digitalis effect in a patient with AF. Note the prominent U wave (*arrows*), well separated from T wave. ST is depressed and the overall ST–U shape mimics hypokalemia, except for the relatively short QT and the better T–U separation (QT ~380–400 ms, at an overall heart rate of 65 bpm).

Digitalis toxicity pertains to the occurrence of arrhythmias with digoxin therapy. *The 3 most characteristic arrhythmias are*: (i) AT with block, (ii) accelerated junctional rhythm, (iii) slow or regular ventricular response in AF (implying complete AV block with a junctional escape or accelerated junctional rhythm). Other arrhythmias include frequent PVCs (*the most common and earliest arrhythmia*), VT, bidirectional VT or bidirectional wide SVT, AIVR, and AV block. Digitalis toxicity is exacerbated by hypokalemia, hypomagnesemia, and hypercalcemia.

C. Hypothermia (see Figure 32.72)

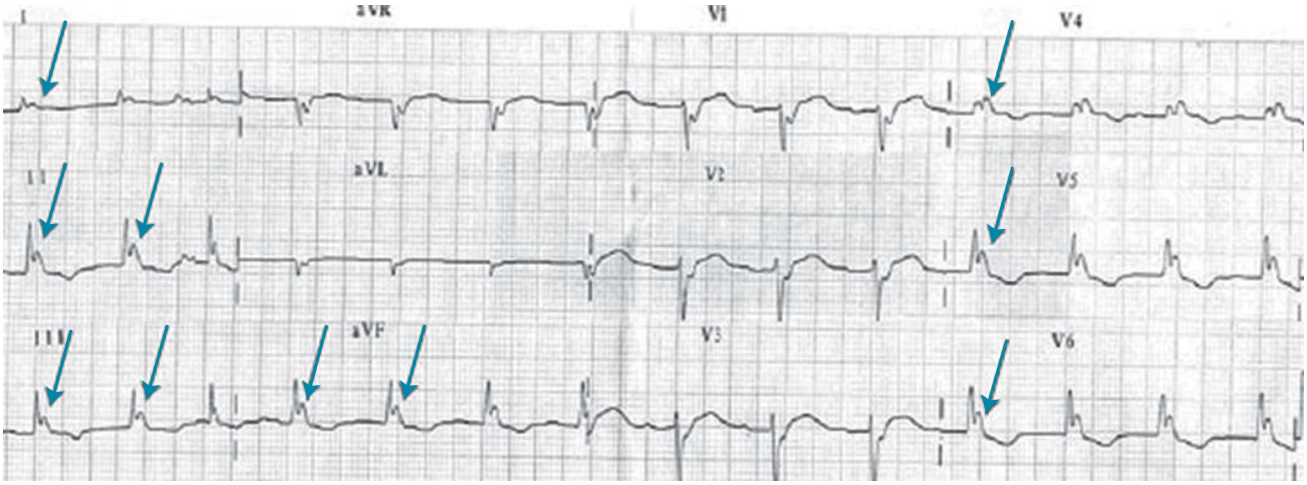


Figure 32.72 Hypothermia. QRS is prolonged>120 ms. It is not a typical LBBB, as QRS is negative in aVL, and it is not a typical RBBB. Characteristic "dome" waves are seen at the end of QRS in multiple leads (*arrows*): these are Osborne or J waves in a patient with hypothermia. Hypothermia slows impulse conduction throughout all the cardiac tissue, resulting in prolongation of PR, QRS, and QT. It also causes AV block, AF with slow ventricular response, and accelerated junctional rhythm. The height of the Osborne wave is proportional to the degree of hypothermia.

D. Pulmonary embolism (see Figure 32.73, Table 32.1)

E. Poor precordial R-wave progression in COPD and anterior MI (see Figures 32.74, 32.75)

F. ASD and Ebstein anomaly

Secundum ASD is characterized by RV volume overload pattern:

- Incomplete RBBB. RBBB may occasionally be complete (in 5–20% of the cases).
- Right-axis deviation. A severe RVH picture with tall R' or monophasic R wave is not usually seen in volume overload patterns.
- P pulmonale in one-third of the cases.
- R-wave notching near its peak is frequently seen in the inferior leads (~73%) and is called "crochetage." Notching of a normal QRS may, however, be seen in 7% of normal individuals. Also, notching may be seen with other congenital or acquired heart disease. It is mostly specific for ASD when seen in multiple inferior leads and when accompanied by incomplete RBBB.

Primum ASD is characterized by:

- Incomplete RBBB
- Left-axis deviation, as opposed to the right-axis deviation seen with secundum ASD. This is secondary to a distortion of the left bundle with early excitation of the posterior wall. The effect on the conduction system also explains a higher prevalence of prolonged PR interval.

Sinus venosus ASD has ECG findings similar to secundum ASD. Additionally, an ectopic atrial rhythm frequently replaces the sinus rhythm.

Ebstein anomaly is characterized by:

- Right atrial enlargement with very tall P waves ("Himalayan" P waves)
- RBBB that is frequently atypical with a RSR'S' pattern. The latter may occasionally be seen with ASD.
- Prominent Q waves in the inferior leads, which may also be seen with any RVH or PE.

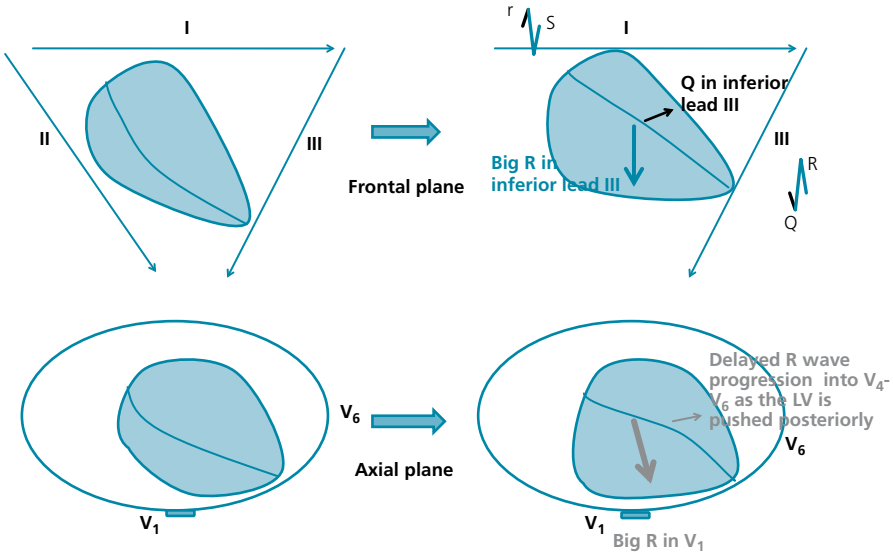

Figure 32.73 Change of vector of depolarization between a normal heart and pulmonary embolism. ***In the frontal plane*** (*top figures*), the LV is pushed up while the RV expands down and to the right, explaining the right axis (S in I, QR in III and aVF); inferior Q wave is explained by the LV being pushed up away from those leads. ***In the axial plane*** (*bottom figures*), the LV is pushed posteriorly while the RV expands to the right. The size of the R wave in V_1 may not be large if the RV is strained without being enlarged, and delayed R-wave progression may be the only finding. T inversion in the anterior and inferior leads reflects RV strain and is the most common finding in massive PE.

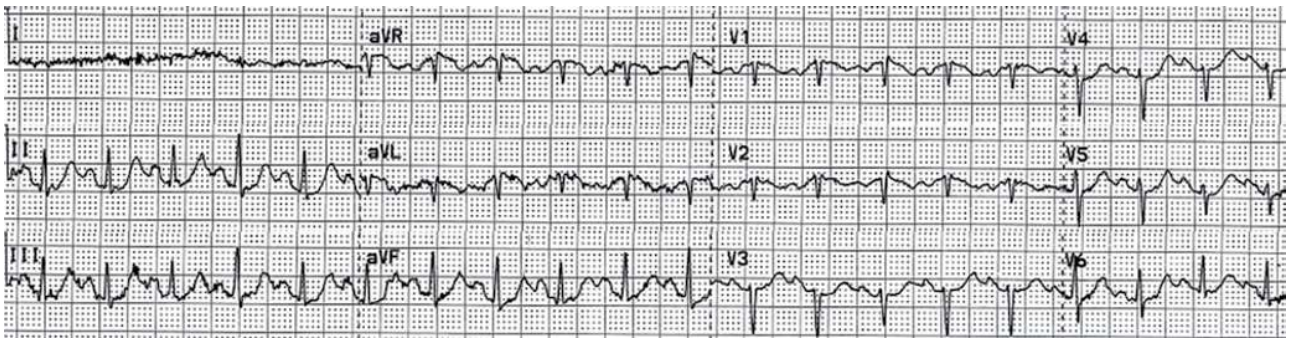

Figure 32.74 Poor precordial R-wave progression with a very small R wave < 1.5 mm in leads V_1–V_4. The axis is rightward with Q wave in lead aVL. This could be: (1) anterior MI with lateral MI explaining the right-axis deviation; or (2) severe lung disease pattern with prominent posterior forces across the precordial leads. The small QRS voltage in all leads, including the precordial leads, where S is dominant but not particularly deep, suggests lung disease pattern but may be seen with extensive infarction. This patient has severe lung disease with significant hypoxemia at rest and normal LV function.

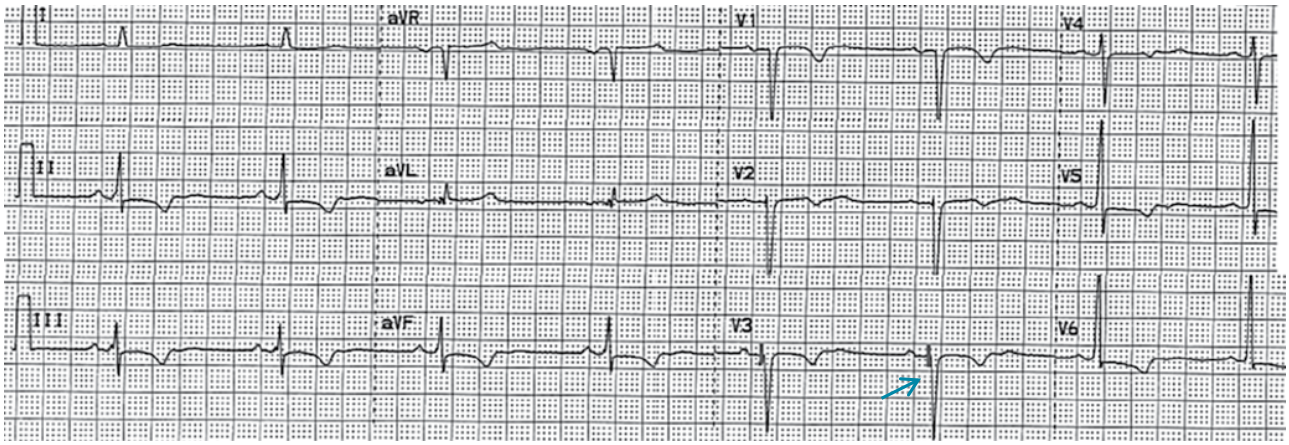

Figure 32.75 Poor precordial R-wave progression with a monophasic Q (QS) in V_1 and a small R wave in V_2 and V_3 (~1 mm). The T-wave inversion in V_1–V_3 and the small QRS in lead I (~4 mm) are supportive of an anterior MI. As opposed to the ECG shown in Figure 32.74, note that the QRS voltage is not reduced and a deep S wave is seen in V_2–V_3 (*arrow*). A large voltage is against COPD, while a small voltage may be seen in both COPD or MI.

XVI. Approach to tachyarrhythmias

(See also Chapter 8)

When analyzing a tachycardia, start by looking at 3 features:

1. Narrow QRS vs. wide QRS (≥120 ms) (choose the lead where QRS is widest).
2. Regular vs. irregular ventricular rate.
3. Look for P waves and their relationship with QRS complexes. P waves are usually seen as notches or deflections that fall over the ST–T segments and have a *consistent morphology* and *timing,* i.e., those deflections are regularly placed and can be marched out. Try to confirm that these deflections are P waves, rather than artifacts or parts of T wave, by analyzing multiple leads. Once P waves are found, their relationship with QRS complexes is analyzed. In wide QRS tachycardia, analyze: (i) AV dissociation, and (ii) the number of P waves compared to the number of QRS complexes. In narrow QRS tachycardia, assess the length of the RP interval.

A. Approach to narrow QRS-complex tachycardias (Figures 32.76–32.79)

Note the Ashman phenomenon (Figure 32.79).

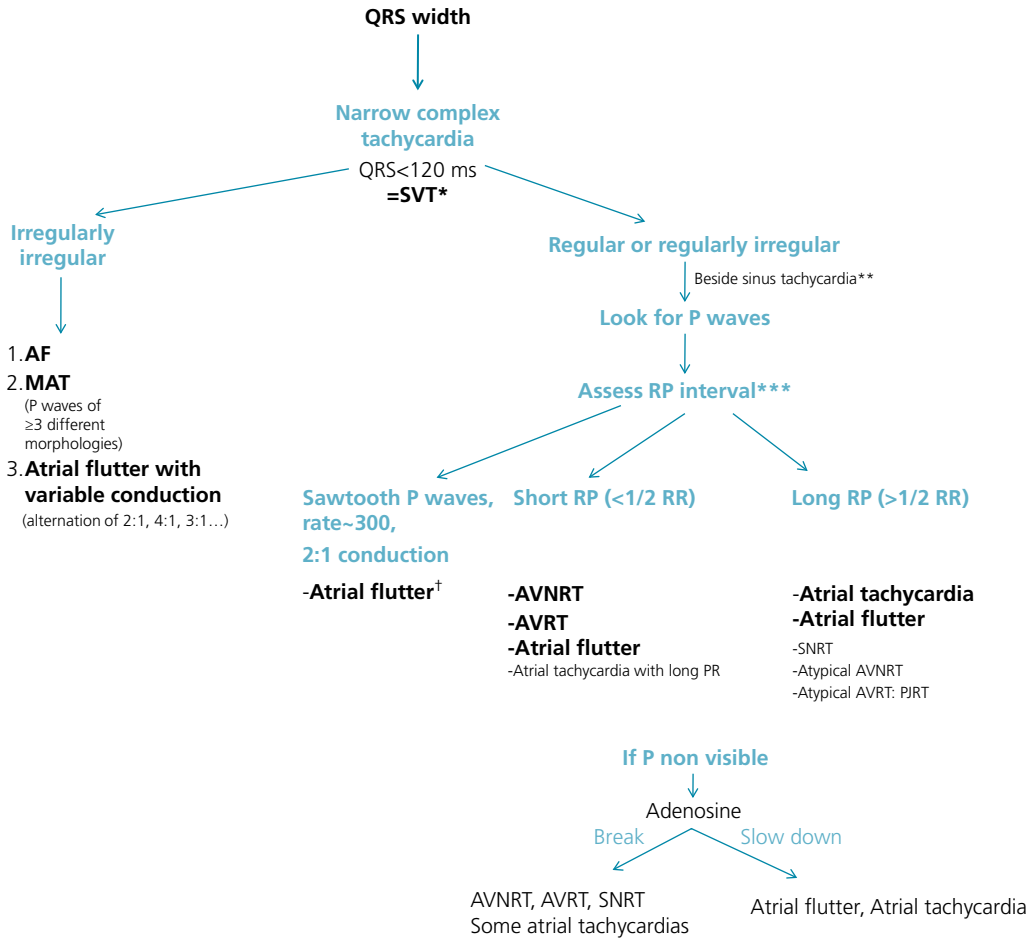

Figure 32.76 Approach to narrow complex tachycardias.
*A narrow QRS tachycardia may occasionally be VT. If QRS is relatively narrow (~110–120 ms) but different in morphology from the baseline QRS, consider it VT or SVT with aberrancy.
As opposed to other tachycardias, sinus tachycardia has a gradual onset and termination and does not have a fixed rate. **Tachyarrhythmias typically have a sudden onset and offset and a very fixed rate, although they may have a quick warm-up at the beginning. For example, a tachycardia with a fixed rate of 122 bpm on a telemetry monitor suggests arrhythmia. In particular, the P wave of atrial tachycardia or SNRT may have a sinus P morphology, but the abrupt onset and the steady rate help differentiate the arrhythmia from sinus tachycardia.
***RP interval is the interval between onset of QRS and onset of the following P wave (retrograde P wave in AVNRT or AVRT). If this interval is<1/2 of the R–R interval, the tachycardia is a short RP tachycardia.
†**Atrial flutter** may mimic short RP tachycardia if only the flutter wave following the QRS is seen, or may mimic long RP tachycardia/atrial tachycardia if only the flutter wave preceding the QRS is seen. ***Atrial tachycardia with negative P waves preceding the QRS complexes in the inferior leads may, in fact, be atrial flutter.*** Look carefully for flutter waves to make the diagnosis.

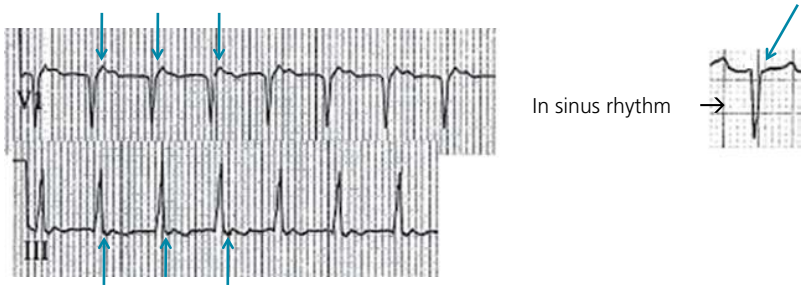

Figure 32.77 Narrow complex tachycardia. A deflection is seen at the end of QRS in leads V_1 and III; this deflection is seen in multiple leads and likely represents P wave. RP interval is very short (~1.5 small boxes, <90 ms), thus implying AVNRT. Also, the P wave falls so close within the QRS, giving a pseudo-r′ shape in V_1 and a pseudo-S shape in lead III, typical of AVNRT (*arrows*). The QRS morphology in sinus rhythm does not show r′ (*arrow, right panel*) and thus confirms that the r′ seen during tachycardia is a P wave rather than a true r′ wave.

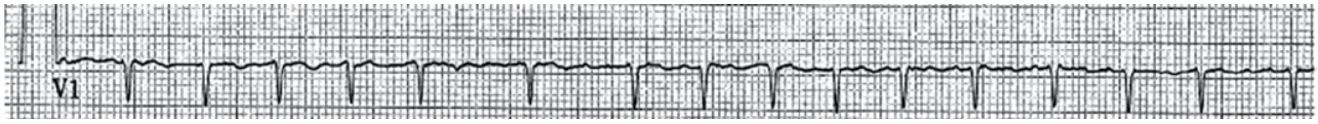

Figure 32.78 Narrow complex tachycardia, irregular. Differential diagnosis:

1. AF.
2. MAT: in MAT, a well-formed P wave is seen before every QRS complex, yet P waves have various morphologies (≥3) and various PR intervals. The rate is usually 100–150 bpm.
3. Atrial flutter with variable conduction (alternation of 2:1, 4:1, 3:1, …).
4. Sinus tachycardia with frequent PACs, including several PACs in a row.

AF is the diagnosis in this case. The small "blips" seen over the baseline are atrial fibrillatory waves rather than real P waves. They do not have a consistent *morphology* or *timing*.

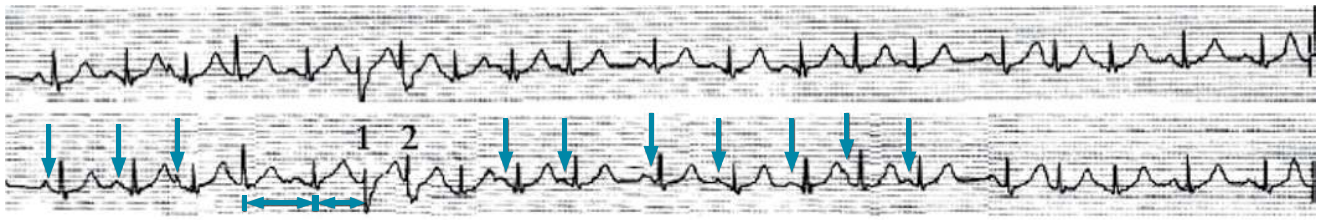

Figure 32.79 The rhythm is irregular. Look for P waves: P waves are present, have more than 3 different morphologies (*arrows*), with varying PR intervals; this is diagnostic of MAT. Some of the P waves of MAT are of sinus origin, the rest originate from multiple atrial foci.

How about the 2 wide complexes (*1* and *2*)? Are these PVCs or aberrant complexes, i.e., complexes with functional bundle branch block? In the context of an irregular rhythm (e.g., AF, sinus rhythm with PACs), complexes occurring at a short R–R interval may be aberrant, especially if the short R–R is preceded by a long R–R interval (**long–short sequence**): this is the **Ashman phenomenon**. This is related to the fact that one of the bundles, often the right bundle, is still in a refractory period when the supraventricular stimulus hits early. A long R–R interval further prolongs the bundles' refractory period and makes a QRS that falls shortly after it aberrant (*long–short sequence*). The right bundle normally has a longer refractory period than the left bundle and is more likely to become aberrant. The R–R interval preceding complex 1 (*short caliper*) is short, shorter than any non-aberrant R–R interval, and is preceded by a relatively long R–R interval (*longer caliper*). This is typical of aberrancy. Finding shorter R–R interval(s) not followed by aberrancy argues against aberrancy but may be seen, because aberrancy also depends on the length of the "long" part of the long–short sequence. Complex 2 is preceded by a shorter R–R interval than complex 1, leading to a wider aberrancy. Both complexes 1 and 2 have RBBB morphology, which is the most common pattern in functional aberrancy.

B. Approach to wide QRS-complex tachycardias

A wide QRS-complex tachycardia could be:

1. VT.
2. SVT (including AF) with aberrancy. Aberrancy signifies the occurrence of a functional RBBB, LBBB, or RBBB + LAFB during supraventricular tachycardia, leading to a wide complex morphology simulating VT. Aberrancy occurs when the refractory period of one of the bundles or fascicles is surpassed during tachycardia. In addition, the bundle branch block may be a pre-existing bundle branch block, in which case the QRS morphology during tachycardia is similar to the QRS morphology during sinus rhythm, sometimes slightly wider.
3. SVT (especially AF) with pre-excitation. This means that the SVT is conducted antegradely over an accessory pathway that connects one atrium to one ventricle, short-circuiting the AV node.
4. Other diagnoses: hyperkalemia; drug toxicity (class I antiarrhythmic agents, tricyclic drugs); ventricular pacemaker tracking an atrial arrhythmia (lack of mode switch), or pacemaker-mediated tachycardia.

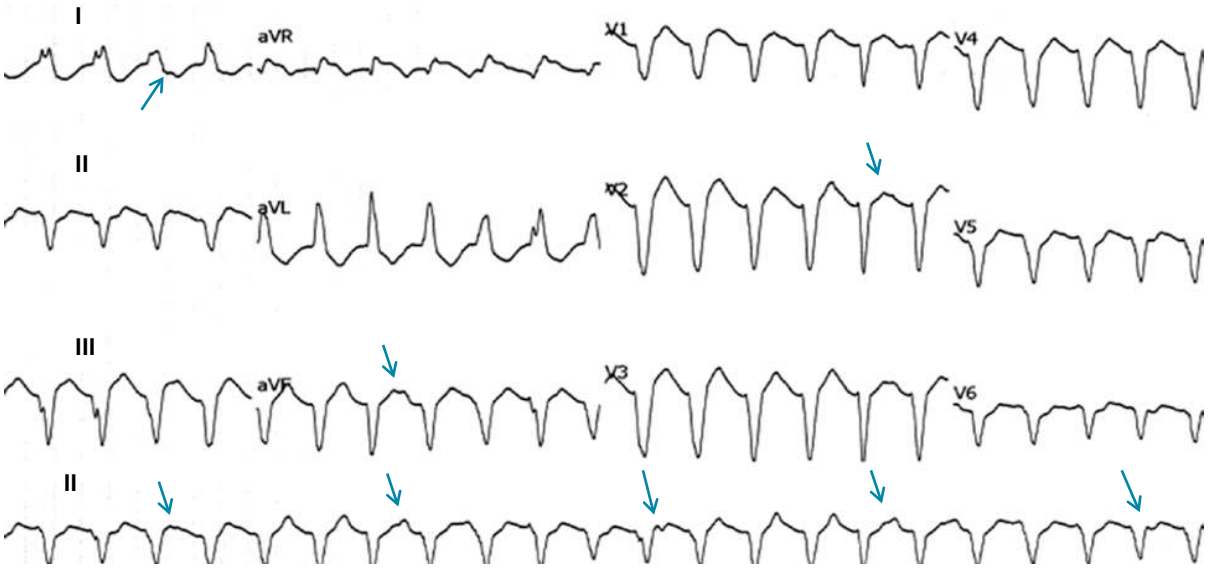

Figure 32.80 Regular wide complex tachycardia. SVT vs.VT?

1. Look for P waves, i.e., look for "blips" or notches that: (a) have a consistent morphology and timing, and (b) can be marched out. P waves are usually best seen in lead II and in the lead with the smallest T and QRS. On this ECG, blips are seen in lead II (*arrows*). These blips can be marched out and have a consistent morphology; they are not part of the T wave, as they are not seen after every QRS and they disfigure T wave variably, depending on where they fall. They are also seen in other leads (leads V_2, I, and aVF: *arrows*), further corroborating that these are P waves, not artifacts or parts of T wave. They do not have a consistent relationship with QRS complexes, and some of them fall inside QRS complexes and are not seen; in fact, an additional P wave is probably hidden between every 2 evident P waves. Thus, P waves are dissociated from QRS and are less numerous than QRS complexes → VT.

   The variable T-wave morphology is usually a hint to the presence of P waves that are dissociated from QRS/T and falling variably over some T waves.
2. QRS morphology. QRS has a monophasic, negative QS morphology in V_1–V_6. A monophosic negative or positive QRS in all precordial leads is not consistent with RBBB or LBBB and implies VT. This is called QRS concordance (e.g., QS pattern or monophasic R-wave pattern throughout V_1–V_6). QRS being negative in all precordial leads, this VT looks away from the precordium and thus originates from the apex.

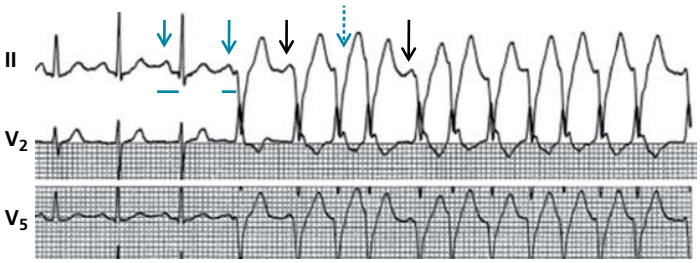

Figure 32.81 Run of irregular wide complex tachycardia. The irregularity does not necessarily imply AF. During a short run of VT or at the initiation of VT, the rhythm may be irregular. Analyze the following:

1. How the tachycardia starts. The tachycardia starts after a regularly occurring sinus P wave (*blue arrows*), ***at a shorter PR interval*** (compare *bars*). This implies that it starts with a PVC, without interrupting the regularly occurring sinus P waves. The tachycardia has the same morphology as this PVC, thus, this is VT.
2. Look for P waves. Two P waves are seen within the tachycardia (*black arrows*). The first P wave has a morphology similar to the sinus P wave and comes at an interval that is equal to the sinus P–P interval. The second P wave falls at an interval that is a multiple of the sinus P–P interval; there is another P wave preceding it and hidden in the QRS complex (*dashed arrow*). Those P waves fall around the QRS and ST–T segments at their own rate and are dissociated from QRS.
3. QRS morphology. The QRS has a ***QS morphology in V_5***, which is not seen with LBBB or RBBB, and is pathognomonic of VT. Final diagnosis: VT.

A wide complex tachycardia that is very grossly irregular is AF: AF with aberrancy, AF with pre-excitation, or AF with class I antiarrhythmic drug therapy. Polymorphic VT is a distant second possibility. On the other hand, a slightly irregular tachycardia, with only slight variations of R–R interval, may be seen with VT or any SVT at its onset (the first 20 beats).

Summarized approach to wide QRS-complex tachycardias (Figures 32.80, 32.81):

1. ~80% of wide complex tachycardias are VT (95% if CAD or HF). Thus, if one is unsure of the diagnosis, it is safer to consider the arrhythmia VT than SVT and treat it as such. However, it is best to look for features characteristic of VT and establish a definitive diagnosis. **Features that further support VT**:
   - P waves are seen scattered between QRS complexes and unrelated to QRS complexes (**AV dissociation**), and/or number of P waves < number of QRS complexes.
   - Morphology of QRS is not consistent with a typical LBBB or a typical RBBB. In patients with a wide baseline QRS, a wide QRS tachycardia that is narrower than baseline is VT.

- Tachycardia starts with a PVC rather than a PAC, and has a morphology similar to the PVC. *How to distinguish a PVC from an aberrant PAC?* A PVC falls on the top of a normally occurring sinus P wave (the regularly occurring sinus P wave appears as a "blip" within the PVC or just before it, at a short PR interval). On the other hand, an aberrantly conducted PAC starts after a premature, non-sinus P wave that may fall within the preceding T wave and deform it. *A deformation of the T wave preceding the premature complex is a hint to a PAC.*

2. SVT with aberrancy: this diagnosis is most confidently made if a baseline bundle branch block is present and the tachycardia has the same morphology as the baseline bundle branch block. Otherwise, the lack of any VT feature supports the diagnosis of SVT.

3. AF with pre-excitation: tachycardia is irregular, polymorphic, bizarre-looking, with a morphology that is wide but not consistent with aberrancy (not a typical RBBB or LBBB).

XVII. Approach to bradyarrhythmias: AV block

(See also Chapter 13)

Identify the **type** but also the **location** of the block (nodal vs. infranodal block) (Figures 32.82–32.87):

1. ***First-degree AV block*** = PR interval > 200 ms (may be as long as 1000 ms).

2. ***Second-degree AV block***

i. Mobitz type I (Wenckebach type): PR progressively prolongs until QRS drops, i.e., a P wave occurring at the intrinsic atrial rate is not followed by a QRS complex. To make the diagnosis, compare PR that follows the blocked P (the shortest PR) with the one that immediately precedes the blocked P (the longest PR). While PR lengthens, R–R progressively shortens before the pause.

ii. Mobitz type II: QRS suddenly drops without a preceding PR change. *The baseline QRS is usually wide*. It may present as intermittently non-conducted P waves or as 1 non-conducted P wave that is not preceded by progressive PR prolongation and not followed by PR shortening. It is more ominous than Mobitz I and is almost always a distal infranodal AV block. It progresses to a complete infranodal AV block commonly and suddenly.

iii. 2:1 AV block (alternative drop of 1 QRS complex) could be equivalent to Mobitz I or Mobitz II AV block. If QRS is wide, the block is likely infranodal and is thus a Mobitz II equivalent. If QRS is narrow, the block is likely a Mobitz I equivalent. More specifically, a PR interval > 250 ms with a narrow QRS complex implies a nodal AV block, while a PR interval < 200–250 ms implies that the block is unlikely to be at the nodal level. Also, look for periods of 3:2 conduction on a long rhythm strip; the PR-segment pattern on the long strip helps elucidate the diagnosis.

3. ***Third-degree or complete AV block***

No P wave is conducted and a junctional or ventricular escape rhythm takes over. The ventricular rate is regular and unrelated to P waves (AV dissociation). **The PR distance is variable yet the R–R interval is regular**, providing evidence that none of the P waves is conducted. If the AV block is infranodal, the escape is ventricular, wide, at a rate of 20–40 bpm usually. If the AV block is nodal, the escape is junctional, narrow, at a rate of 40–60 bpm (Figures 32.84, 32.85). A wide-complex escape may be considered junctional if a similar bundle branch block is present on the baseline ECG; otherwise, the wide escape is considered ventricular. Both cases, when symptomatic, are urgently treated with a temporary pacemaker followed by permanent pacemaker placement, but infranodal AV block is a real emergency with an imminent risk of cardiac arrest regardless of symptoms.

High-grade AV block means that most P waves are not conducted and an escape rhythm is seen, but some P waves are conducted. The regular escape rhythm is interrupted by some irregularities (Figure 32.86).

Notes

3:2 AV block means that 2 consecutive P waves conduct while the third P wave gets blocked (i.e., three P waves with 2 QRS complexes). 4:3 block means 3 consecutive P waves conduct while the fourth P wave gets blocked. This could be Mobitz I or II depending on the occurrence of progressive PR prolongation. 3:1 block means that only 1 of 3 P waves is conducted (3 P waves with one QRS). This is also called high-grade AV block or advanced second-degree AV block and has the same negative implication as complete AV block.

Second-degree AV block is characterized by group beating, in which a group of QRS complexes is followed by a pause, then the cycle repeats. The cycle length may be variable (2:1 AV block alternating with 3:2, 4:3, 8:7, etc.). Think of second-degree AV block whenever there is a repetition of groups of beats. Clue to Wenckebach: compare the PR immediately after the pause (the shortest) to the one immediately before it (the longest). Also, R–R progressively shortens before the pause and the duration of the pause is less than twice the R–R interval preceding the pause.

A pause on a rhythm strip may be: (1) a sinus pause; (2) a blocked P wave secondary to AV block; (3) a blocked P wave of a very premature PAC that falls in the ventricular refractory period and does not get conducted. As opposed to AV block, the blocked P wave of a PAC does not march out with the sinus P waves.

Group beating on ECG may be a second-degree AV or SA block, or frequent PVCs or PACs, blocked or conducted, followed by pauses.

One particular type of group beating, *bigeminal rhythm*, is characterized by a repetition of 2 beats followed by a pause. It is caused by: 3:2 AV or SA block, PACs/PVCs occurring in a bigeminal pattern, or atrial flutter with alternation of 4:1 and 2:1 AV conduction.

Look carefully for 2:1 AV block in any case of sinus bradycardia. 2:1 AV block may mimic sinus bradycardia when the blocked P waves fall on the preceding T waves and go unnoticed or are mistaken for U waves. Conversely, in sinus bradycardia, U waves may be misinterpreted as blocked P waves, causing a false diagnosis of 2:1 AV block. Blocked P waves are distinguished from U waves by the fact that they march out almost equidistantly with the P waves that precede the QRS complexes and have the same shape/amplitude as those P waves, whereas U waves have a different shape and are often less peaked than P waves (Figure 32.87).

AV dissociation is present in all cases of AV block, but AV dissociation does not imply AV block. A competing accelerated junctional or ventricular rhythm that is equal in rate to the sinus rhythm, or faster than it, leads to AV dissociation. It is a competing form of AV dissociation, rather than an AV-block form of AV dissociation. One form of competing AV dissociation is isorhythmic AV dissociation, in which the junctional or ventricular rhythm almost has the same rate as the sinus rhythm, allowing intermittent conduction of sinus P waves that are falling far enough from the QRS complexes (e.g., AIVR, accelerated junctional rhythm). One beat may be a sinus beat preceded by a P wave, the other may be a junctional beat dissociated from the P wave and showing up at any deceleration of the sinus rate (Figure 32.88). ***A P wave that falls far enough from the QRS complex yet does not get conducted implies AV block***. In some cases, the junctional rhythm may lead to retrograde P waves that reset the sinus node and inhibit sinus P-wave formation.

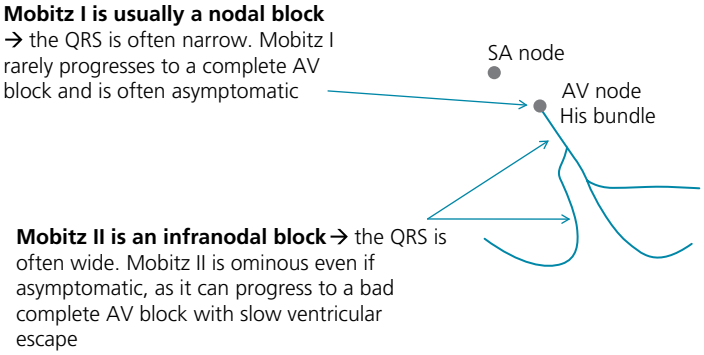

Figure 32.82 Location of the AV block.

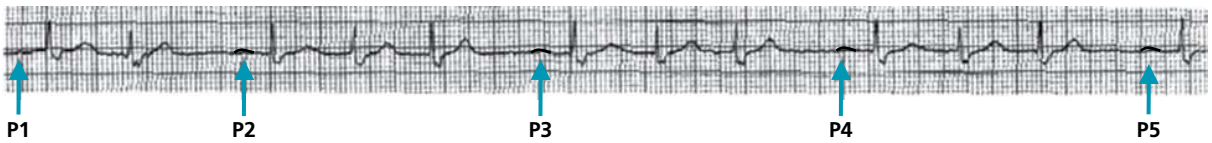

Figure 32.83 Repetition of groups of beats separated by a pause. Think of second-degree AV block. P waves are not seen between P1–P2–P3–P4–P5. However, a slight R–R shortening is progressively seen before each pause, and the pause is shorter than twice the smallest R–R interval: this is typical of the Wenckebach type of AV block. Outside the marked P waves, additional P waves are concealed with a very prolonged PR; P waves are falling onto the preceding T waves and deforming them, explaining why T waves appear to have different morphologies. PR is, therefore, progressively lengthening.

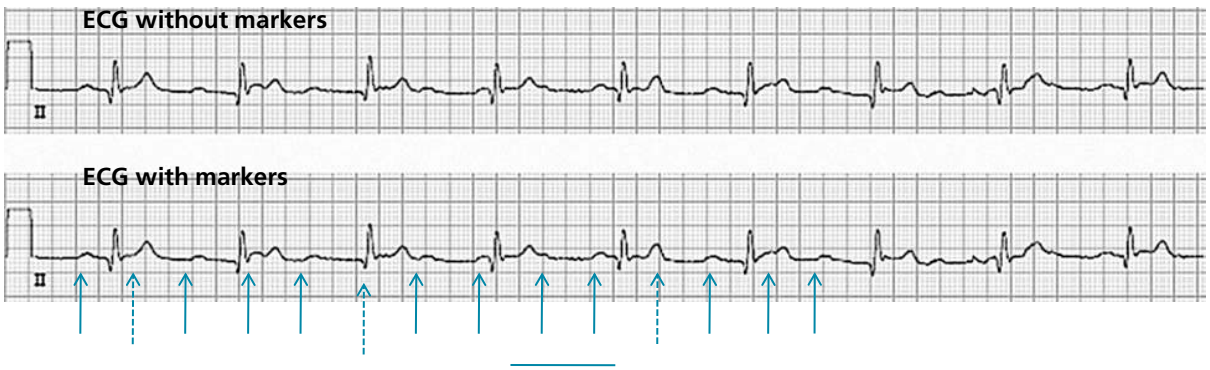

Figure 32.84 Regular, narrow complex rhythm, rate ~55 bpm. P waves are seen around the QRS complexes, falling onto the T waves or the QRS complexes (*arrows*). Some are not seen but expected to be present based on a consistent P–P interval (*dashed arrows*). None of them is conducted; this is evidenced by the fact that the **PR distance is variable yet the ventricular rate is regular**. The P waves are identified by their consistent shape as well as the consistent timing. Look for an R–R space where two P waves are clearly seen, such as the interval *underlined*, then start marching out P waves using this P–P interval. Final diagnosis: sinus tachycardia ~125 bpm with complete AV block and junctional escape rhythm.

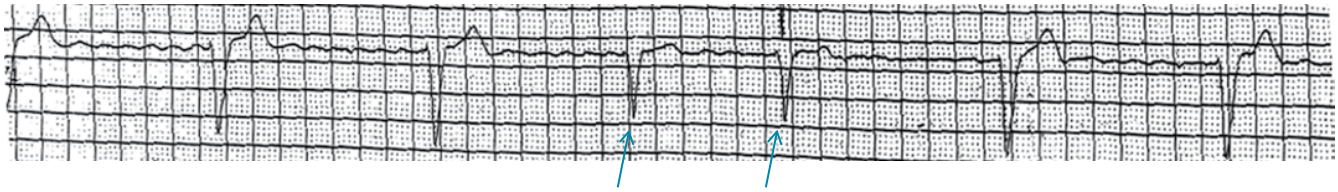

Figure 32.85 AF with a ventricular rate that is slow and mostly regular. This is AF with an almost complete AV block and a wide, regular escape rhythm, likely ventricular. Two QRS complexes occur at a shorter R–R distance and signify occasional AV conduction (*arrows*). Those supraventricular complexes are narrower than the escape rhythm. This is a high-grade rather than a complete AV block.

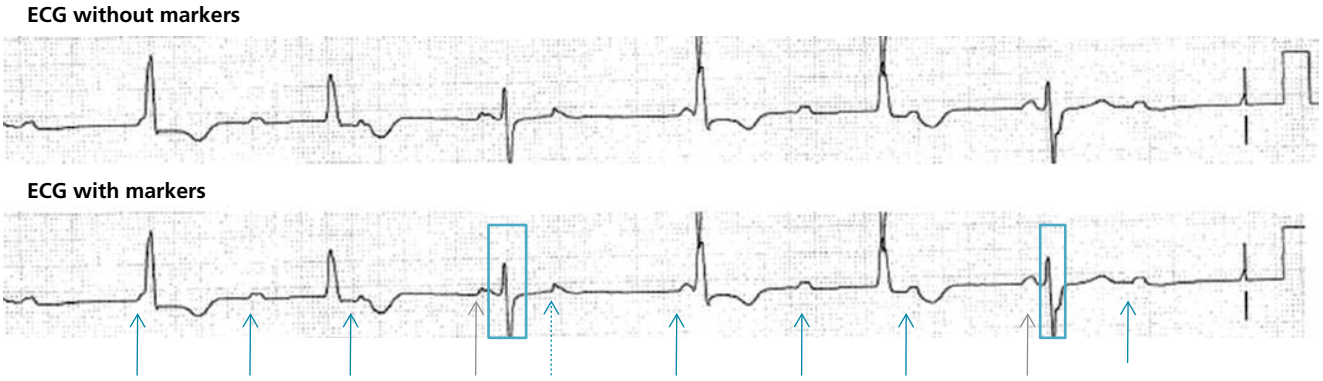

Figure 32.86 Regular wide complex rhythm interrupted by narrower complexes that occur at shorter R–R intervals (*rectangles*). P waves are seen and are grossly regular (*blue and gray arrows*). They are mostly non-conducted, with the exception of the P waves that lead to the shorter R–R intervals and the narrower QRS complexes (*gray arrows*). Besides the wide escape, the short PR interval of the conducted P waves implies an infranodal AV block.

Note a slight irregularity of the P waves. In fact, the P–P interval containing a QRS is shorter than the P–P interval not containing a QRS (ventriculophasic sinus arrhythmia). There is also one PAC (*dashed arrow*). Final diagnosis: high-grade infranodal AV block with ventricular escape rhythm and incomplete AV dissociation (2 P waves are conducted).

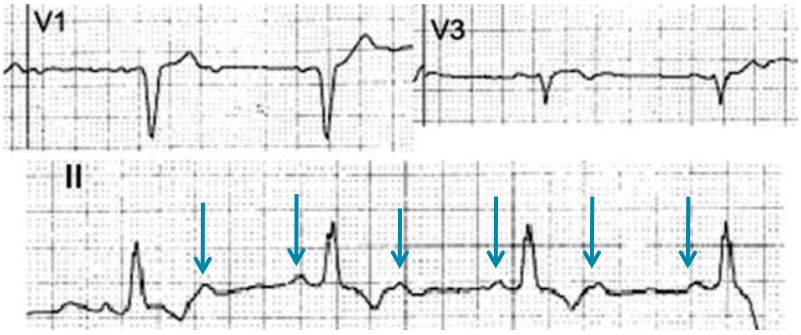

Figure 32.87 2:1 AV block that can be easily mistaken for sinus bradycardia, especially as the non-conducted P waves fall too close to the T waves. The non-conducted P waves are recognized by the fact that they have the same shape and peak as the conducted P waves, implying that they are P waves rather than U waves. Confirm their presence in multiple leads: besides lead II, they are subtly seen in V_1 and V_3 and consistently match the morphology of the conducted P waves. Also, they are negative in V_1, which reinforces they are Ps rather than Us (U is very rarely negative). The P waves do not perfectly march out, as the P–P interval containing a QRS complex is slightly shorter than the one not containing a QRS complex (*ventriculophasic sinus arrhythmia*). P waves are marked by *arrows*.

XVIII. Abnormal automatic rhythms that are not tachycardic

Three types of abnormal, non-tachycardic rhythms may be seen (Figures 32.89–32.91):

1. Ventricular escape rhythm (<60 bpm, usually < 40 bpm) or accelerated idioventricular rhythm (60–120 bpm)
2. Junctional escape rhythm (<60 bpm) or accelerated junctional rhythm (60–130 bpm)
3. Atrial escape rhythm (<60 bpm) or ectopic atrial rhythm (60–100 bpm)

The escape rhythms may be seen in patients with sinus bradyarrhythmia (all three types of escape) or AV block (first 2 types of escape). **Isorhythmic AV dissociation** may be seen when a junctional or a ventricular rhythm competes with the sinus rhythm at approximately the same rate (see Figure 32.88).

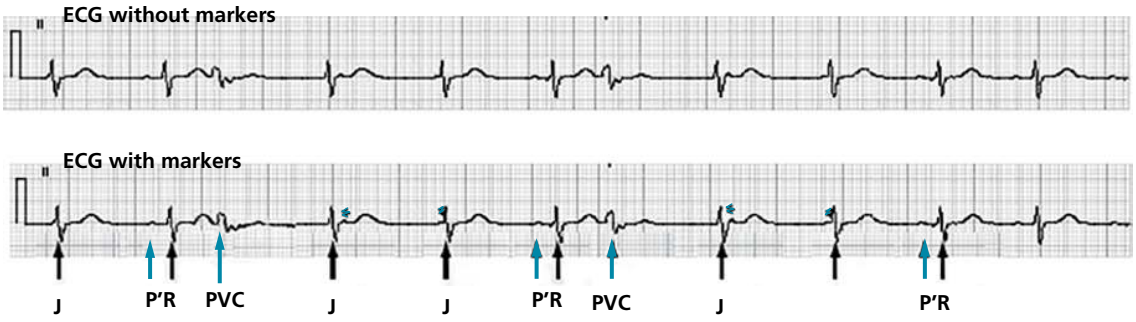

Figure 32.88 Outside the PVCs, the rhythm seems grossly regular. Analyze the P–QRS relationship: some QRS complexes seem to be preceded by P waves with a consistent PR relationship (conducted P, noted as *P')*. On the other hand, some QRS complexes are not preceded by any P wave (junctional QRS, noted as *J*). This suggests that a sinus rhythm and a junctional rhythm are competing at the same rate. After a post-PVC pause, or when the sinus rhythm slightly slows down, the junctional rhythm takes over. Note that during the junctional rhythm, sinus P waves keep occurring regularly, dissociated from QRS and falling around it, marked by asterisks (*). There is no AV block, as P wave gets conducted whenever it occurs long enough after the QRS and whenever the junctional rhythm does not kick in close to it (= isorhythmic AV dissociation).

Figure 32.89 Regular narrow complex rhythm without any P wave. This is a junctional rhythm (rate of ~60 bpm), likely a junctional escape rhythm. The cause is either: (i) complete sinus arrest with escape through the AV junction, or (ii) AF with complete AV nodal block and with small fibrillatory waves that are not well seen. Ensure it is not a sinus rhythm with marked PR prolongation, wherein Ps fall atop the preceding Ts and get overlooked.

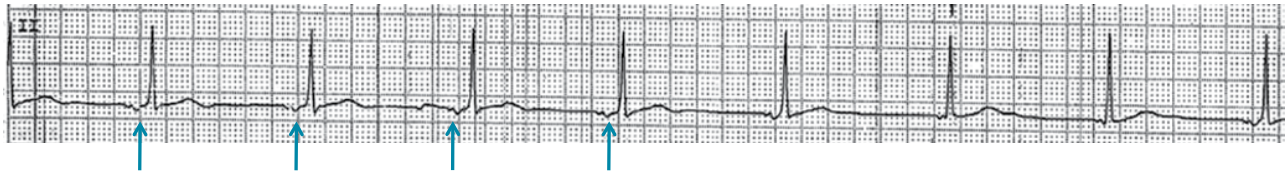

Figure 32.90 Regular narrow complex rhythm (~50 bpm). Negative P waves are seen in lead II, with a short PR interval of ~100 ms. This is either a low atrial rhythm or a junctional rhythm with retrograde P waves. Sinus arrest is not necessarily present; the sinus node may be suppressed by a faster atrial rhythm or by the retrograde P waves of the junctional rhythm.

Figure 32.91 Sinus rhythm is interrupted by a wide complex rhythm. The wide complex rhythm has a rate that approximates the sinus rate. P waves (*arrows*) keep occuring through the wide complex rhythm at a very short PR interval. Possible diagnoses:

a. Accelerated idioventricular rhythm (AIVR) that appears once the sinus rate slightly slows down. In fact P waves are falling too close to the QRS complexes and are not getting the opportunity to conduct (isorhythmic AV dissociation). Once the sinus rate increases again, the sinus P waves get conducted and suppress AIVR. Some fusion QRS complexes are seen (5th to 7th QRS, and last QRS of the wide complex run).

b. A less likely diagnosis is intermittent pre-excitation; the latter usually appears when the AV conduction decreases (e.g., more vagal tone), which is typically accompanied by slowing of the P rate.

XIX. Electrode misplacement

A switch of the right and left arm electrodes induces P, QRS, and T changes that follow the change in the axis of the leads. Lead I reverses 180°, and thus P and QRS invert in lead I. Leads II and III switch positions and thus switch their ECG complexes. Leads aVR and aVL switch position, and lead aVF remains the same. While an inverted QRS complex in lead I may suggest right-axis deviation, inverted P, QRS, and T waves often point to switched arm electrodes (Figure 32.92).

When the right arm electrode is switched with the *right leg* electrode (which is the neutral, ground electrode), the ground becomes at arm level, and lead II becomes a lead that runs between 2 legs, far away from the cardiac depolarization. The ECG of lead II becomes flat, i.e., P, QRS, and T are almost isoelectric. A similar phenomenon happens when the left arm electrode is switched with the right leg electrode, in which case lead III becomes flat. Any time the whole P–QRS–T is almost isoelectric in lead II or III, arm-to-right-leg electrode misplacement is suggested (Figures 32.93, 32.94).

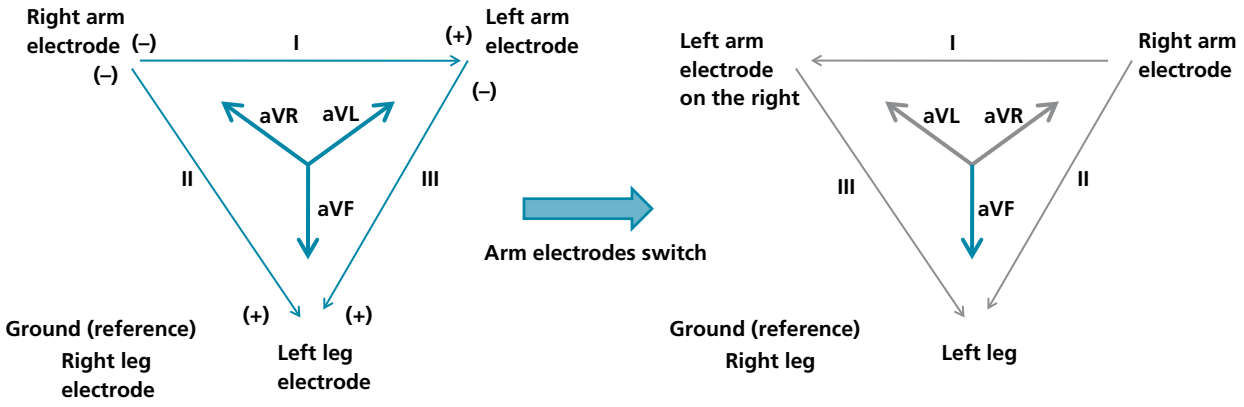

Figure 32.92 Right and left arm electrodes switched. The leads' axis changes are shown. The leads that have changed axis are colored in gray.

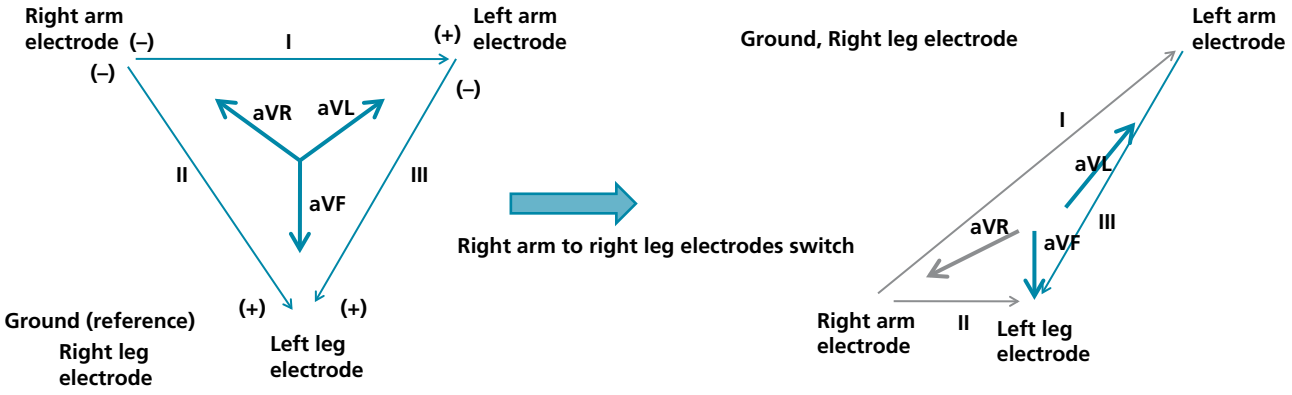

Figure 32.93 Right arm and right leg electrodes switched. The leads' axis changes are shown. The leads that have changed axis are colored in gray.

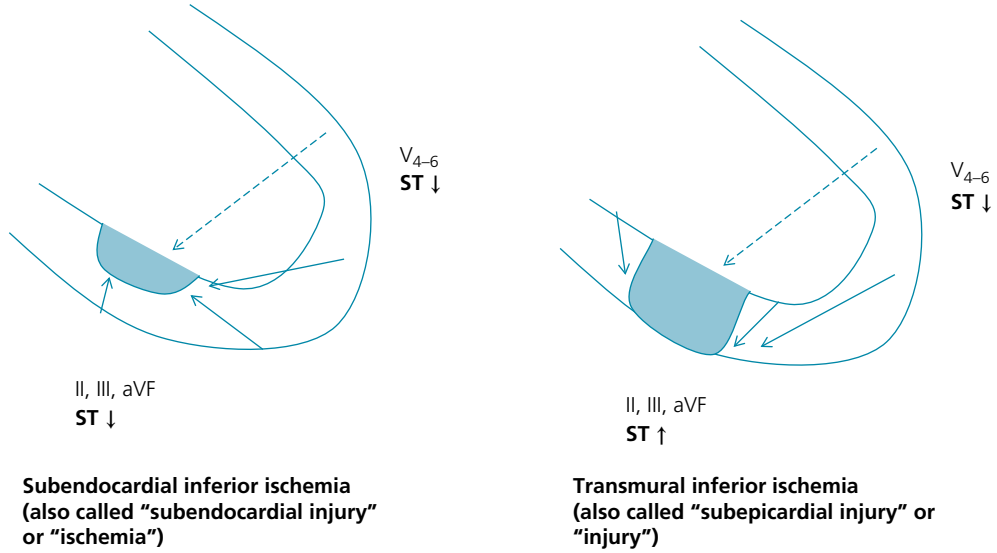
Figure 32.94 Right arm and right leg electrodes switched. Note how lead II is fully isoelectric. Leads aVL, aVF, and III continue to accurately display their respective QRS.

Appendix 1. Supplement on STEMI and Q-wave MI: phases and localization

A. Electrophysiology of the ST-segment changes

Through the opening of K_{ATP} channels, ischemia lowers the amplitude of the action potential, more specifically the plateau phase 2, in the ischemic area, which creates a systolic voltage gradient and a current during phase 2 (injury current) from the normal to the ischemic area (ST deviation); the resting potential of the injured area is less negative, which creates a diastolic injury current from the ischemic area to its surroundings (TP depression). In transmural ischemia, the gradient is between the surrounding areas and the ischemic area, with a resultant current directed toward the leads overlying the ischemic area, creating ST-segment elevation in those leads. In subendocardial ischemia, this current is directed from the subepicardium toward the subendocardium, away from the leads, creating ST-segment depression. This ST-segment depression is, however, non-localizing; the subepicardium wherein the current originates does not necessarily overlie the ischemic subendocardium. The LV and apex having the largest myocardial mass and repolarizing earlier than the rest of the LV (base), the current often originates from this area, leading to ST depression in V_4–V_6 even in inferior ischemia (Figure 32.95). A large area of ischemia creates a larger current and more diffuse and deep ST depression. Those injury currents can lead to triggered activity and can initiate multiple reentry wavelets and polymorphic arrhythmias.



Subendocardial inferior ischemia (also called "subendocardial injury" or "ischemia")

Transmural inferior ischemia (also called "subepicardial injury" or "injury")

Figure 32.95 Subendocardial ischemia (diffuse ST depression, not localized to the ischemic area) vs. transmural ischemia (ST elevation localized to the ischemic area).

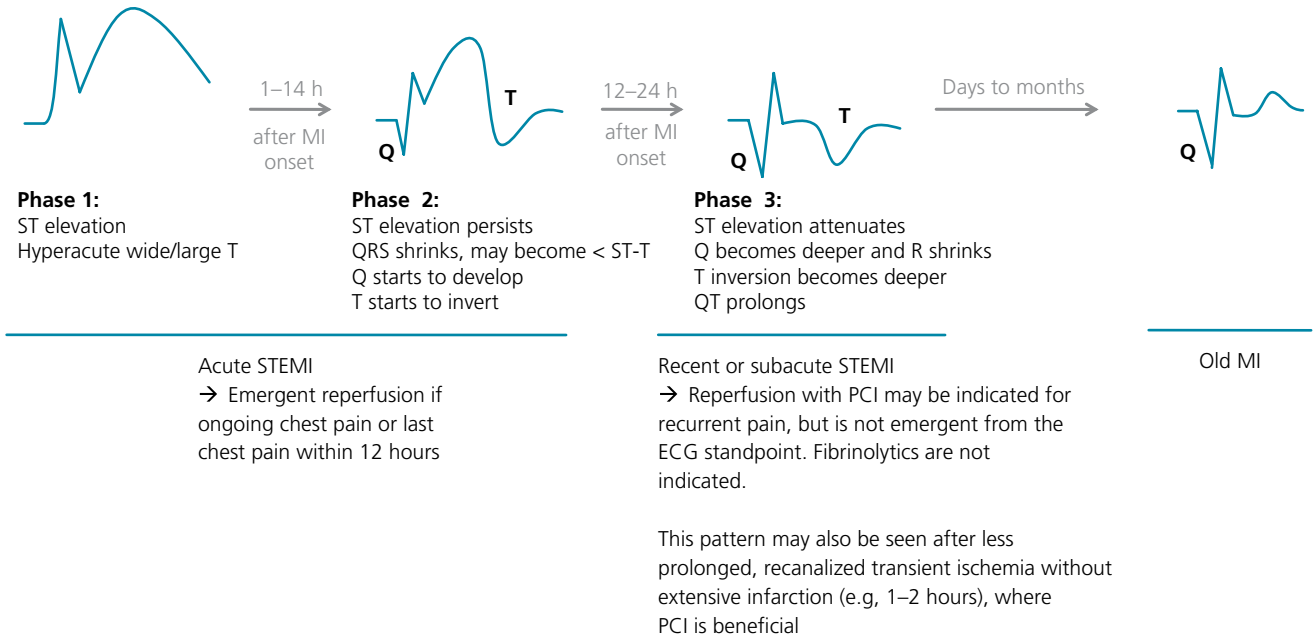


Figure 32.96 Phases of STEMI.

Q waves develop when a transmural area becomes electrically neutral, but not necessarily necrotic. The ventricular depolarization looks away from this neutral area, hence the negative Q deflection. Q waves are seen with transmural infarction, but also stunning or hibernation. They may also be seen with a large area of subendocardial infarction. Conversely, they may not be seen with a small or reperfused area of transmural infarction. Thus, Q-wave MI implies a *large* infarction that is often, but not always, *transmural*.

Q-wave MI is usually the result of a STEMI and is usually a transmural or large MI; non-Q-wave MI is usually NSTEMI and is typically a subendocardial smaller MI. However, some overlap exists. STEMI may lead to non-Q-wave MI, particularly when reperfused with recovery of most of the myocardium. NSTEMI may evolve into Q-wave MI if the non-transmural infarction is large or if it is, in fact, a subtle STEMI.

B. Phases of STEMI (see Figures 32.96, 32.97)

Note 1. T-wave inversion

T inversion usually starts while the ST segment is still elevated but is starting to subside. T-wave inversion progressively deepens and prolongs QT.

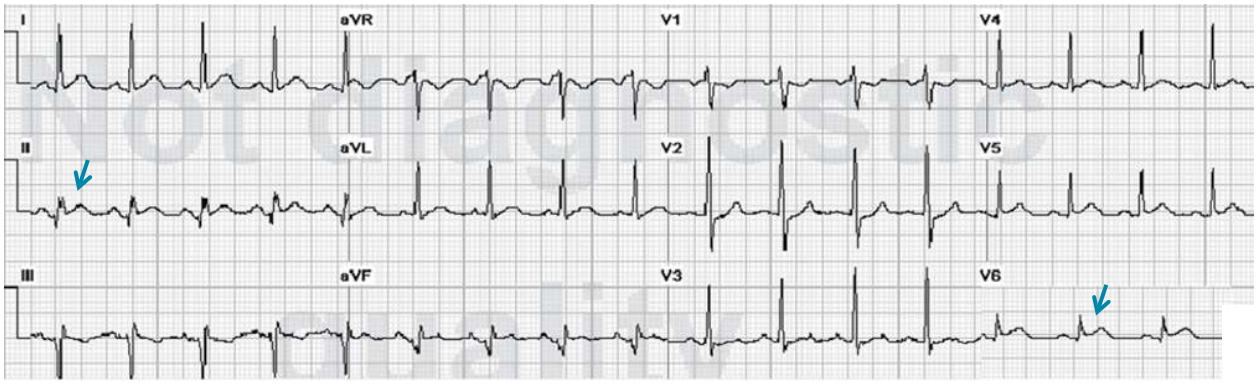

Figure 32.97 The patient presents with chest discomfort that has started 4 hours previously. Subtle ST elevation is seen in leads II, aVF, V_5 and V_6, with subtle ST depression in V_1–V_2. Three features suggest that this mild ST elevation is actually STEMI: (i) Q waves in leads II, III, aVF, and posteriorly (R wave in V_2); (ii) ST depression in reciprocal leads (V_1–V_2); (iii) wide T-wave morphology and fused ST–T segments in leads II, V_5 and V_6 (*arrows*), along with a "shrinking" R wave (R and T waves have ~ equal height). He is found to have an acutely occluded large OM branch.

a. T wave that inverts within 4 hours of reperfusion therapy is a sign of reperfusion.
b. T wave that spontaneously inverts within a few hours of symptom onset may imply spontaneous reperfusion.
c. T wave that inverts late, or > 4 hours after therapy, is part of the normal post-infarction evolution.
d. T-wave inversion should persist for at least a few days. *If it subsides quickly, in less than a few days, pericarditis or recurrent ischemia with T-wave pseudo-normalization should be suspected.*
e. T-wave inversion that persists > 3 weeks is an adverse prognostic sign, suggesting the absence of any functional recovery. T-wave inversion may persist for days, weeks, months, or even years.

Note 2. Hyperacute R waves

Hyperacute R waves, i.e., R waves of shrinking amplitude pulled up by the elevated ST segment, may be seen acutely (Figure 32.50).

Note 3. Q waves

Q waves develop at 1–14 hours (mean, 9 hours) after the onset of an acute MI, usually STEMI. Most often, they develop acutely while the Most often, they develop acutely while the ST is still elevated. In the pre-reperfusion era, Q waves developed and persisted indefinitely in 60-90% of patients.[87] In the PCI era, Q waves develop acutely in 23–58% of patients, depending on the definition used: 58% for Q waves ≥ 0.03 second and ≥1 mm deep, and 23% for Q waves ≥0.03 second and ≥1/4 of QRS. They regress in ~40% of patients.[2] Q waves do not necessarily mean subacute or old MI; Q waves concomitant with ST elevation usually signify an acute MI a few hours old (deep Q waves with relatively mild residual ST elevation may suggest late subacute MI). The appearance of Q waves early in the course of MI does not lessen the benefit of reperfusion and the reduction of the infarct size. Q waves are not synonymous with irreversible myocardial damage and may be seen with a severely ischemic or stunned, non-infarcted myocardium. Q waves may appear after an hour of transient ischemia or a prolonged coronary spasm. Outside STEMI, they may be seen with a viable but hibernating, chronically ischemic myocardium. Q waves may be absent if a reciprocal territory has an old infarction, leading to cancellation of electrical forces (e.g., anterior MI associated with an old posterior MI), or if the myocardium surrounding the scar is hypertrophied.

While the acute appearance of Q waves does not imply irreversible damage, their late persistence for several months implies some irreversible damage with worse LV dysfunction and more HF. In patients with similar baseline Q waves and similar extent of infarction, those who experience Q-wave regression at 1, 6, or 24 months have greater myocardial recovery and more striking EF improvement than those without Q-wave regression, greater improvement in regional wall thickening, and significant regression of infarct size (EF change: 9 ± 11% vs. 2 ± 8%). In fact, their EF and regional function become comparable to STEMI patients who did not develop Q waves.[2,88–90] Q waves are more likely to regress if the stunned myocardium is larger than the infarcted myocardium.

Q-wave regression is seen in ~40% of patients with anterior or inferior infarct and is generally defined as Q-wave disappearance with reappearance of R wave ≥ 1 mm in height in at least one lead; the regression is frequently partial, with persistent Q waves in some leads.[2,87] Other studies defined Q-wave regression as reclassification of the ECG from Q-wave MI to no MI.[88–90] Q-wave regression in leads I or aVL may manifest as rS pattern with persistent right-axis deviation and sometimes persistent Q waves in V_5–V_6. Q-wave regression in the inferior leads may manifest as a "shrinking" of Q wave to a non-significant width in ≥1 lead, or may manifest as rS complex with persistent left-axis deviation. Q-wave regression in leads V_1–V_3 may manifest as poor R-wave progression. In fact, while poor R-wave progression does not usually represent an old anterior MI, up to one-third of old anterior MIs have poor R-wave progression as their only sequela (better prognosis than persistent Q waves). Note that the regeneration of a very small and narrow R wave < 0.01 second, called embryonic R wave, does not imply Q-wave regression and is, for practical purposes, a form of persistent Q wave.

To summarize: although the depth and the extent of Q waves have a prognostic value in STEMI, and although a Q-wave MI is larger than a non-Q-wave MI and more likely transmural, with a worse short-term prognosis, the dynamics of the appearance, disappearance, or deepening of the Q waves early on are not as useful as the dynamics of ST-segment elevation and T-wave changes for the evaluation of MI reperfusion or viability. The late persistence of Q waves has a more definite prognostic value.

C. Localization of STEMI

1. MI territories

a. V_1–V_3 or V_2–V_4: anterior or anteroseptal MI, also involving the apex (LAD). ***Anterior or anteroseptal STEMI always has ST elevation in V_3. ST elevation in V_1–V_2 without V_3 is not usually an anterior STEMI.***

b. V_4–V_6: anterolateral or lateral MI. If ST elevation is present in V_3 → LAD. If ST elevation is isolated to V_4–V_6 → LAD or distal diagonal branch or LCx.

c. I–aVL: lateral or high lateral MI → high OM branch, high diagonal branch, or ramus intermedius.

d. II, III, aVF: inferior MI → RCA in 75% of the cases; or LCx, often a dominant LCx, in 25% of the cases. The LCx may be a non-dominant LCx with an OM branch that extends to the inferior wall distally.

e. V_7–V_9: posterior MI, with reciprocal ST depression in V_1–V_3 and wide *and* tall R waves in V_1 or V_2. Think of true posterior STEMI when ST depression is isolated or most prominent in V_1–V_3. ST elevation is usually seen in V_7–V_9, but not always; leads V_7–V_9 are distant from the heart, which sometimes minimizes the ST elevation. Posterior STEMI is often accompanied by some degree of ST elevation in the inferior or lateral leads. An isolated posterior STEMI is more likely due to LCx than RCA occlusion.

f. V_1, $\pm V_2$, right-sided V_4 (V_{4R}), ± right-sided V_3 (V_{3R}): RV infarct associated with an inferior infarct. Note that, besides, being a septal lead, V_1 ($\pm V_2$) is a right-sided lead that shows ST elevation in RV infarct.

2. Reciprocal changes

a. Anterior ST elevation from a proximal LAD occlusion that involves the high basal septal wall is associated with *inferior ST depression*. Anterior ST elevation from a mid-to-distal LAD occlusion is associated with *lateral ST depression (no inferior ST depression usually).*

b. Posterior injury and posterior Q waves lead to reciprocal ST-segment depression in V_1–V_3 and wide (≥1 mm), tall R waves in V_1 or V_2.

c. Inferior ST elevation may lead to a high lateral ST depression.

3. Exact location and extent (see Tables 32.3, 32.4; Figures 32.98, 32.99)

Table 32.3 Localization of anterior MI.

Anterior MI proximal to first septal	• ST depression in the inferior leads and in V_5 • ST elevation in V_1 > 2.5 mm • RBBB • ST elevation in aVR (similar to left main ischemia), and in I and aVL[a] • Inability to form Q waves in lateral leads, as these Q waves depend on septal depolarization
Anterior MI distal to first septal and proximal to first diagonal	• No ST depression in the inferior leads ± ST elevation if LAD wraps around the apex • ST elevation in the lateral leads I and aVL • **May have a pattern of diffuse ST elevation without any reciprocal change**
Anterior MI distal to both first septal and diagonal	• No ST depression in the inferior leads ± ST elevation if LAD wraps around the apex • ST depression in the lateral leads

[a] ST elevation in aVR indicates injury of the very proximal high septum, which looks toward the right shoulder. It may represent septal injury from *proximal LAD* occlusion or *left main subtotal occlusion*, or may be reciprocal to diffuse subendocardial ischemia in *left main disease*. Either way, it is a negative prognostic marker.

Table 32.4 Differentiate RCA from LCx in inferior MI.

The inferior RCA injury is looking rightward, while the inferior LCx injury is looking leftward. Features supportive of RCA:
i. Lateral ST depression in both leads I and aVL (vs. lack of ST depression or ST elevation in LCx MI). Discordant I and aVL findings are not helpful.
ii. ST elevation ≥ 0.5 mm in lead V_1 or V_{4R} (implies RV infarct, and thus, RCA). This is a very specific finding
iii. ST elevation in lead III > II (lead III is more parallel to the slightly rightward RCA current of injury, whereas lead II is parallel to the leftward LCx current of injury)
iv. No or minimal (<1 mm) ST depression in aVR implies RCA. The LCx current of injury is directly opposite to the right arm, thus LCx injury leads to ≥1 mm ST depression in aVR

LAD occlusion distal to the first septal branch and proximal to the first diagonal branch leads to anteroseptal ST elevation along with lateral and inferior ST elevation. Consequently, diffuse ST elevation without any reciprocal change is seen and may simulate pericarditis. This is alternatively explained by the fact that an apical infarction that does not involve the basal anterior wall is "seen" by all leads without any reciprocal change.

4. Conduction blocks and diagnostic dilemmas in LBBB and RBBB

See Section XII.D in this chapter, and Chapter 2, Sections 1.VI and 2.V.

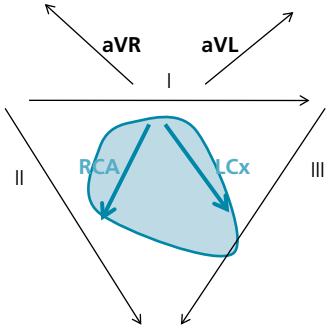

Figure 32.98 In inferior MI, the LCx current of injury looks to the left and has an axis of ~+45°, while the RCA current of injury looks to the right. RCA injury is parallel to lead III, while LCx injury is parallel to lead II. Thus,

1. ST elevation is more prominent in lead III with RCA injury and in lead II with LCx injury.
2. ST depression in lead I implies RCA injury (cannot be seen with LCx). ST elevation in lead aVL implies LCx injury (cannot be seen with RCA).
3. ST depression is seen in lead aVR with LCx injury, while ST elevation or more subtle ST depression is seen with RCA injury.

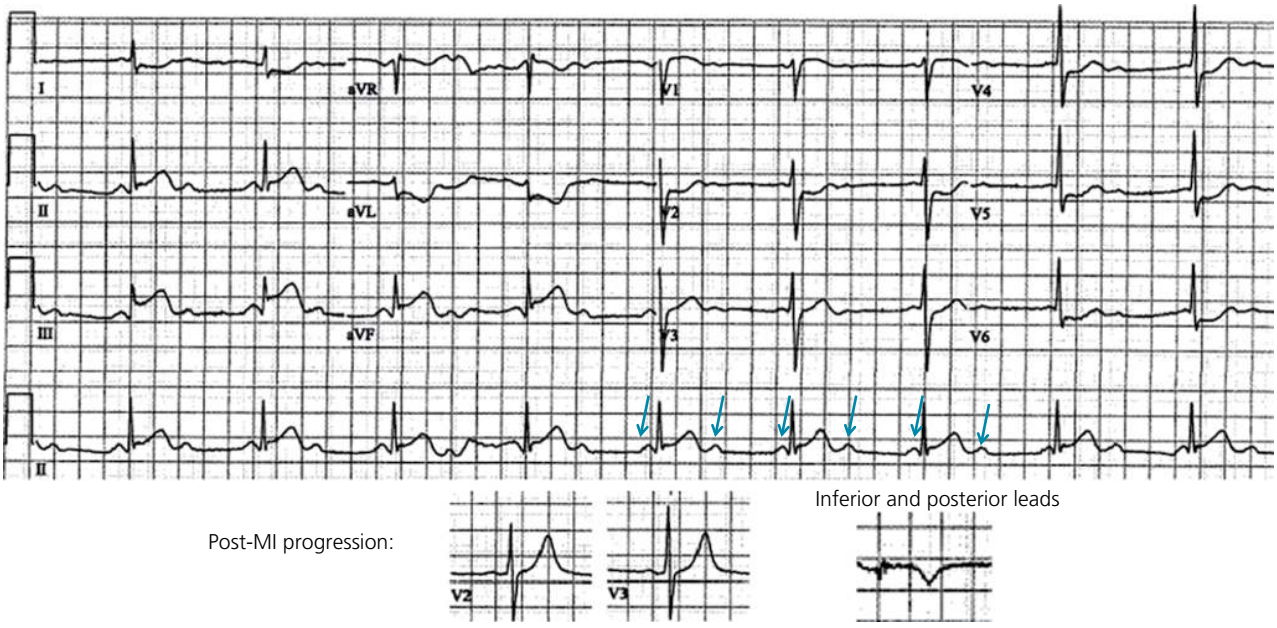

Figure 32.99 The rhythm initially appears to be sinus bradycardia (~55 bpm). On closer inspection, there is another P wave between QRS complexes; it is a P wave, rather than a U wave, by the fact that it marches out equidistantly with the P wave that precedes QRS and is as peaky as the P wave (*arrows*). It is also seen in leads I/aVL/aVR, which do not normally display U waves. Thus, the rhythm is sinus tachycardia with 2:1 AV block. QRS is narrow, so this 2:1 AV block is likely a Mobitz I equivalent. Sinus tachycardia implies that this AV block is not due to a high vagal tone, but rather to AV nodal ischemia/edema.

Inferior ST elevation with lateral ST depression is seen. ST depression is seen in V_2, which, in the setting of inferior STEMI, implies a posterior extension. 0.5 mm ST elevation is seen in V_1, which, in the setting of inferior STEMI, implies RV infarction. In fact, in a patient with posterior injury, the ST segment is expected to be depressed in V_1; an isoelectric ST segment in V_1 suggests RV infarction. Posterior MI leads to ST depression in V_1, while RV MI leads to ST elevation in V_1; the posterior LV is thicker than the RV but the RV is much closer to lead V_1, explaining how the RV injury overwhelms the posterior injury in lead V_1.

Is the culprit RCA or LCx? The following 4 findings suggest RCA: (1) reciprocal ST depression in lead I; (2) ST elevation in III>II; (3) RV infarction; and (4) the lack of ST depression in aVR.

During the post-MI evolution, T wave becomes inverted in the inferior leads. ***In the anterior leads, T wave becomes large and wide; this large T wave is, in fact, reciprocal to the deep posterior T wave.***

Appendix 2. Spread of electrical depolarization in various disease states using vector illustration (Figures 32.100–32.103)

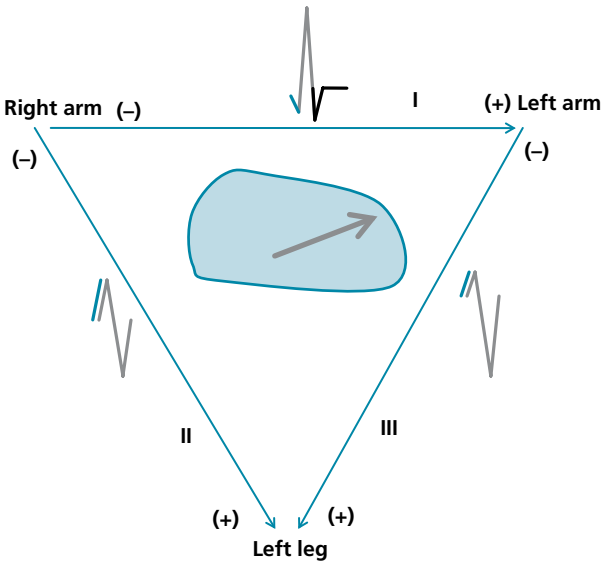

Figure 32.100 Frontal plane of left-axis deviation. This may be secondary to an anatomical shift of the heart, such as LV hypertrophy or enlargement, or to an electrical shift of the electrical depolarization, as in left anterior fascicular block, where the electrical depolarization spreads from down to up. A left-axis shift of a lesser degree is seen in patients with a horizontal heart, such as older or obese stocky patients.

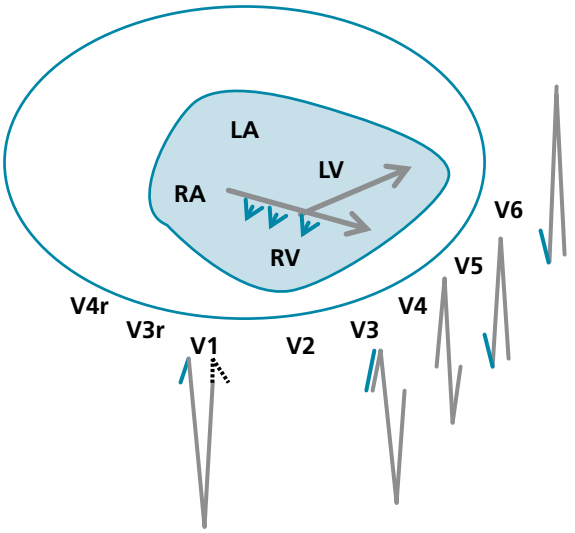

Figure 32.101 Horizontal plane of LV hypertrophy. The vector of depolarization is directed more leftward than normal; thus, R increases in height in V_5–V_6 and S deepens in V_1–V_2, with a later transition (V_4 or V_5 rather than V_3). The septum being thick, the blue septal depolarization is large, and thus the q wave in the lateral leads is deeper than normal; a lack of q wave in the lateral leads in patients with LVH implies incomplete LBBB.

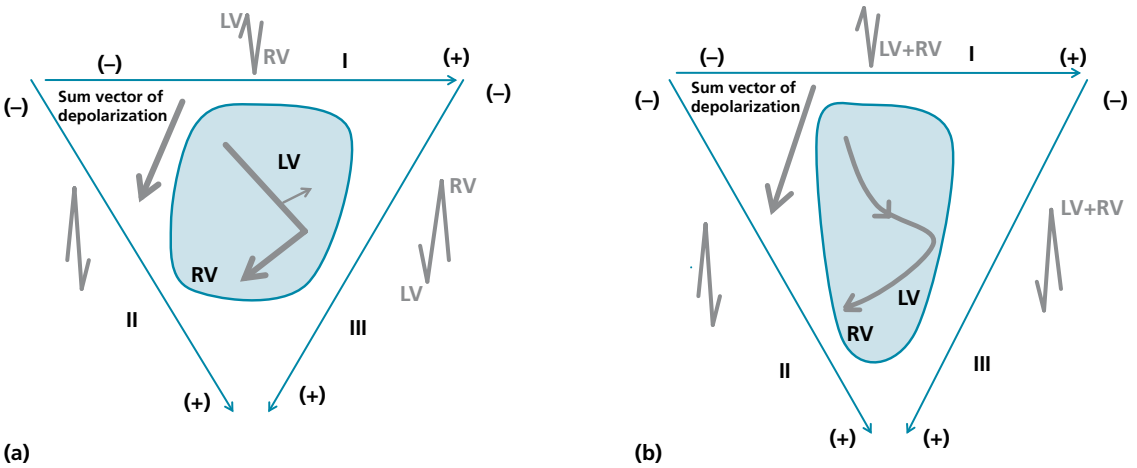

Figure 32.102 (a) Frontal plane of RV hypertrophy or RV strain such as PE. The RV extends to the right, while the LV is pushed up. The big RV explains the big S wave in lead I and the big R wave in the inferior leads, while the upwardly pushed LV depolarization explains the Q wave in leads III and aVF, but not usually in lead II (S_I Q_{III} Q_{aVF} pattern in PE). **(b) Frontal plane of right-axis deviation from upright posture, COPD, or left posterior fascicular block**.

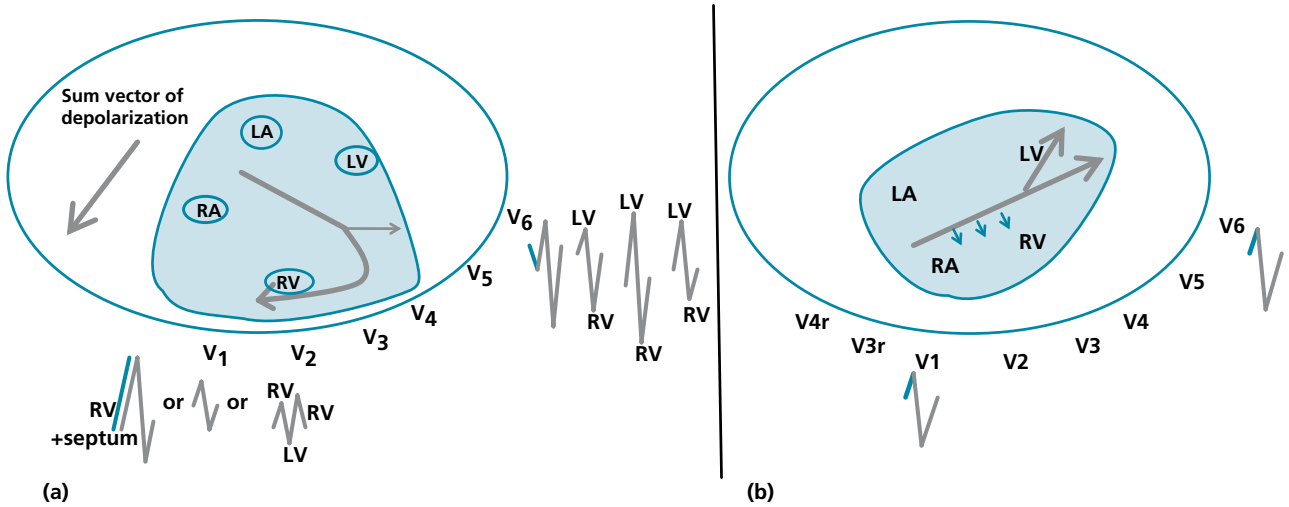

Figure 32.103 (a) Horizontal plane of RV hypertrophy. The sum vector of depolarization is rightward, and therefore R wave is large in V_1 and S wave is large in V_5–V_6, which is opposite to the normal QRS progression across the precordial leads. If the LV and RV depolarize simultaneously and the RV is not severely hypertrophied, the sum simultaneous electrical depolarization will be neutral, and thus R in V_1 will be small; the clue to RVH is that S is small as well. In dilated RV (volume overload), QRS may be wide because RV activity spread in time rather than height, explaining the incomplete RBBB pattern. In severe RV hypertrophy (pressure overload), a monophasic R pattern or a qR pattern may be seen in V_1 (the "q" in the qR pattern may be due to a loss of the normal left-to-right septal depolarization). **(b) Horizontal plane of COPD.** The heart is pushed posteriorly, which explains the deep S wave in both V_1 and V_6. While S wave is larger than R wave, the overall QRS voltage is reduced in all leads as a result of increased chest air.

QUESTIONS AND ANSWERS

Question 1. Analyze Figure 32.80. Is this VT or SVT?

Question 2. Analyze Figure 32.81. Is this VT or SVT?

Question 3. Analyze Figure 32.84. Is the rhythm 2:1 AV block, complete AV block, or Mobitz 1 AV block?

Question 4. Analyze Figure 32.86. Is the rhythm Mobitz 1 AV block, high-grade AV block, or complete AV block?

Question 5. A patient has occasional dizziness. ECG is performed (Figure 32.88):
A. ECG shows AV dissociation and AV block
B. ECG shows a competing form of AV dissociation without AV block

Question 6. Analyze Figure 32.91. What is the rhythm?

Question 7. Analyze Figure 13.18 (Chapter 13). Is there AV block or isorhythmic AV dissociation?

Question 8. Analyze Figure 8.9 (Chapter 8). Is this VT or SVT?

Question 9. An ECG shows a prominent R wave in lead V_1. What features differentiate RVH from posterior MI?

Question 10. An ECG shows right-axis deviation. What features differentiate isolated lung disease pattern from lung disease + RVH?

Question 11. A patient has RBBB. How to make a diagnosis of superimposed RVH?

Question 12. Is a QRS > 120 ms with rsR' pattern in V_1 enough to make a diagnosis of RBBB?

Question 13. An ECG has a QRS > 120 ms with a wide slurred R wave in leads I and V_5–V_6. A q wave is present in lead I. Is this LBBB?

Question 14. An ECG has a QRS > 120 ms with a wide slurred R wave in leads I and V_5–V_6. A q wave is present in lead aVL. Is this LBBB?

Question 15. Which of the following is consistent with LAFB?
A. QRS 100 ms, left axis –45°, with qR pattern in lead aVL and rS pattern in the inferior leads. LVH may be present
B. QRS 100 ms, left axis –45°, R pattern in aVL and I (no q)
C. QRS 100 ms, left axis –45°, qR pattern in aVL, and QS pattern in leads III and aVF

Question 16. Analyze Figure 32.33. Is Wellens syndrome present?

Question 17. Draw the morphology of ST depression secondary to LVH. Draw the 4 ST-depression morphologies suggestive of ischemic ST depression.

Question 18. A patient has ST depression concordant with QRS with upright T wave. Does this suggest ischemia?

Question 19. A patient has a flat ST segment with symmetrically inverted T wave. Does this suggest ischemia?

Question 20. Analyze Figures 32.40a, 32.45, and 32.46b. All show prominent biphasic or inverted T waves in the precordial leads. Which statement is *incorrect*?

A. Figure 32.40A is Wellens sign. Figure 32.45 is global T inversion. As opposed to Wellens sign, global T inversion is more widespread, the ST segment is not upwardly convex and T descent is not sharp.

B. Figure 32.46B is a form of early repolarization with precordial biphasic/inverted T wave. As opposed to Wellens sign, the patient is asymptomatic and young. The ST elevation is prominent (more than Wellens), with a notched J point consistent with early repolarization.

C. Global T inversion (Figure 32.45), with its deeper and more prominent T inversion, is more worrisome for ischemia than Wellens (Figure 32.40a).

Question 21. When ST elevation is present on ECG, any of the following characteristics implies STEMI, *except*:

A. ST elevation straight or convex upward, blends with T to form a dome

B. Wide upright T or inverted T

C. Q waves

D. ST elevation or T wave may approximate or exceed QRS height

E. Reciprocal ST depression

F. PR depression

Question 22. A patient presents with chest pain and is found to have the ECG shown in Figure 32.53. Is this STEMI, pericarditis, or early repolarization?

Question 23. A patient presents with chest pain and is found to have the ECG shown in Figure 32.57. An ECG performed a few weeks previously is grossly normal. What is the diagnosis?

Question 24. In a patient with LVH and discordant ST elevation, what absolute and relative ST elevation values suggest STEMI?

A. Discordant ST elevation ≥ 2.5 mm in V_1–V_3 in absolute terms, ST elevation ≥ 1 mm in the limb leads. Relative ST discordance > 25% of the QRS complex and relative T-wave discordance > 50%

B. Absolute ST discordance > 5 mm and relative ST discordance > 25%

Question 25. In a patient with LBBB and discordant ST elevation, what ST elevation values suggest STEMI?

A. Discordant ST elevation > 5 mm in V_1–V_3 in absolute terms

B. Relative ST discordance > 25% of the QRS complex and relative T-wave discordance > 50%

Question 26. Concerning the long QT morphology in various disease states, which of the following is *incorrect*?

A. Notched T wave in LQT2, hypokalemia, and drug-induced QT prolongation

B. ST depression with upright T-U wave in hypokalemia

C. Long ST segment with a narrow T wave in LQT3

D. Broad, prolonged T wave in LQT1

E. Broad, prolonged T wave in hypocalcemia

Question 27. Draw the ECG patterns of progressive hypokalemia.

Question 28. QT interval is longest in leads V_2–V_3. Yet QT is best measured in other leads. Which leads are best for measurement of QT and why?

Question 29. Define QTc and calculate QTc in a patient whose QT is 400 ms at a heart rate of 100 bpm.

Question 30. A patient has a long QT. Next to the T wave, there is another wave, fused with the T wave and measuring ~50% of the T height. Should QT calculation include this wave?

Question 31. A 55-year-old woman presents with off-and-on chest pain for the last 3 hours. Her ECG is shown in Figure 32.42b. What is the diagnosis?

A. Non-ST-segment elevation acute coronary syndrome. An invasive strategy is performed, but is not urgent

B. Pulmonary embolism

C. Hypokalemia

D. LVH with secondary repolarization abnormality

E. Posterior ST-segment elevation myocardial infarction. Record leads V_7–V_9 and perform emergent coronary angiography and percutaneous coronary intervention

Question 32. A 62-year-old woman with lung cancer presents with chest pain and near-sycope. She is hypotensive. The presenting ECG is shown in Figure 32.50. Which of the following is *incorrect*?

A. The PR depression in lead II, the diffuse ST elevation, and the ST depression in lead aVR are diagnostic of pericarditis. The low QRS voltage suggests an associated pericardial effusion.

B. The domed ST elevation that is fused with the T wave in lead V_2 is suggestive of STEMI
C. The ST elevation and the T wave approximate the QRS height in leads V_2 to V_4, which suggests STEMI
D. The shrinking QRS voltage with a "pulled-up" R wave suggests STEMI
E. Diffuse ST elevation may be seen with occlusion of the midportion of a wrap-around left anterior descending artery

Question 33. A 76-year-old woman presents with acute dyspnea and is found to have pulmonary edema. The presenting ECG is shown in Figure 32.54. A new LBBB is seen. In the context of the new LBBB, which of the following features is (or are) least specific for the diagnosis of STEMI on this ECG (multiple answers possible)?
A. ST elevation concordant with the QRS complex in leads I and aVL
B. ST depression concordant with the QRS complex in the inferior leads
C. Discordant ST elevation of 5 mm in lead V_2
D. Discordant ST elevation that exceeds 25% of the QRS height in lead V_2, especially one that approximates the whole QRS height
E. Discordant ST elevation that is convex in lead V_1

Question 34. A 46-year-old woman presents with dysphagia, vomiting, and atypical chest pain. ECG is performed (Figure 32.67a). Cardiac biomarkers remain negative. What is the most likely cause of the ECG abnormality?
A. Non-ST-segment elevation acute coronary syndrome
B. Pulmonary embolism
C. Takotsubo cardiomyopathy
D. Hypokalemia
E. Pericarditis

Question 35. Analyze Figure 32.71. What is the differential diagnosis?
A. Hypokalemia
B. LQT2
C. Digitalis effect

For questions referring to specific figures, detailed explanations are provided in the figure legends.

Answer 1. VT.

Answer 2. VT.

Answer 3. Complete AV block.

Answer 4. High-grade infranodal AV block with ventricular escape rhythm.

Answer 5. B. ECG shows a sinus rhythm and a junctional rhythm occurring at a close rate, with isorhythmic AV dissociation. There is no AV block.

Answer 6. Sinus rhythm and AIVR with isorhythmic AV dissociation.

Answer 7. High-grade AV block with a fast ventricular escape rhythm.

Answer 8. VT.

Answer 9. In posterior MI, R wave is not only high in V_1 but is also wide > 1 mm (≠ RVH), T wave is positive in V_1–V_2 (vs. inverted in RVH), the axis is not right, and there are often Q waves in V_7–V_9 and in the inferior or lateral leads (Section VI.B).

Answer 10. In isolated lung disease pattern, the QRS axis is deviated to the right, S is deep throughout all of the precordial leads, and QRS voltage is reduced, especially in the limb leads. Superimposed RVH is suggested by large R or small S in V_1 (≤2 mm), RSR' pattern, or T-wave inversion in V_1–V_2 (Sections VI.B, XV.E).

Answer 11. RVH is diagnosed if the axis is right, as determined by the net voltage of the initial, unblocked 80 ms of QRS in the limb leads, along with R' > S or R' > 10 mm in V_1, or S > R in V_6. R' > S or R' > 10 mm more strongly suggests RVH in incomplete RBBB than in complete RBBB.

Answer 12. No. A wide S wave, wider than R wave or wider than 40 ms, is also needed in the lateral leads to define RBBB.

Answer 13. No. A septal q wave should not be seen in the lateral leads in LBBB (except, occasionally, in lead aVL).

Answer 14. Yes (Section VII.B).

Answer 15. A. LAFB should have QRS < 120 ms, left axis –45° to –90°, and a small septal q wave in lead aVL. It does not lead to QS pattern in the inferior leads; the latter implies inferior MI rather than LAFB. LVH may coexist with LAFB and does not preclude LAFB diagnosis.

Answer 16. No, because Q waves are also present. In Wellens syndrome, neither Q waves nor prominent ST elevation is present (Wellens is a form of non-ST elevation/non-Q wave ischemia).

Answer 17. Figure 32.37.

Answer 18. Yes.

Answer 19. Yes.

Answer 20. C. Global T inversion is less specific for ischemia than Wellens.

Answer 21. F (see Table 32.2 and Figure 32.48). PR depression may be seen with STEMI (atrial injury), but is more characteristic of pericarditis. Reciprocal ST depression may be seen with LVH and LBBB, but outside the latter 2 settings, suggests STEMI. The remaining chracteristics suggest STEMI as well.

Answer 22. Pericarditis.

Answer 23. Pre-excitation, with negative delta waves mimicking Q waves, and secondary ST deviations mimicking STEMI.

Answer 24. A (Section XII.D).

Answer 25. B. For LBBB, absolute ST discordance > 5 mm is not very sensitive or specific for the diagnosis of STEMI. Relative discordance is more helpful.

Answer 26. E (Figures 32.64, 32.65).

Answer 27. See Figures 32.66 and 32.67. Hypokalemia leads to T flattening, then ST depression with prominent T-U wave.

Answer 28. Leads II, V_5–V_6 are the best leads for measurement of QT. Leads V_2–V_3 have the most prominent phase 4 U waves and may not show a good separation of T and U waves, leading to overestimation of QT interval. Leads II, V_5–V_6 show distinct T waves with good separation from U waves.

Answer 29. QTc corresponds to the patient's QT interval had the heart rate been 60 bpm. QT decreases by 17.5 ms for every 10-beat increase in heart rate, and increases 17.5 ms for every 10-beat decrease in heart rate. If a patient has a QT of 400 ms at a rate of 100 bpm, QTc would be $(400 + 17.5 \times 4) = 470$ ms.

Answer 30. Yes. This is a T2 wave, which some may call a repolarization U wave (not phase 4 U wave).This may be seen with hypokalemia or QT-prolonging drugs. This type of **U wave, when prominent in size *and* fused with T, should be included in the QT measurement** as it is a part of repolarization.

Answer 31. E. The ECG shows diffuse ST-segment depression that is most prominent in leads V_2–V_3. This should point toward true posterior STEMI rather than non-ST-elevation ischemia and lead to recording of the leads V_7–V_9 and emergent cardiac catheterization. T-wave inversion in the anterior and/or inferior leads, rather than ST-segment depression, may suggest pulmonary embolism in the right clinical context. Hypokalemia is unlikely as T wave is not flattened, no prominent U wave is seen and QT interval is not prolonged.

Answer 32. A. This ECG has a few features suggestive of pericarditis (PR depression and diffuse ST elevation). However, the ECG also shows features suggestive of STEMI. The presence of even 1 STEMI feature, any of the top 4 features described in Table 32.2, usually implies STEMI and outweighs other diagnoses. In addition, PR depression may be seen in STEMI (ischemic atrial injury). Diffuse ST elevation without reciprocal ST depression (except possibly in lead aVR) may be seen with occlusion of the mid-portion of the left anterior descending artery.

Answer 33. C and E. In LBBB, discordant ST elevation ≥ 25% of the QRS height (relative discordance) has good sensitivity and specificity for the diagnosis of STEMI, particularly when the size of ST elevation approximates the size of the QRS complex. Convex discordance or absolute discordance > 5 mm is less specific for STEMI.

Answer 34. D. There is diffuse ST depression with upright "T" wave. QT is prolonged, and on further inspection a notch on the upslope of the ST segment is seen in V_5, suggesting that the prominent wave is actually a U wave and the notch is a flattened T wave.

Answer 35. C. Prominent U wave is seen along with ST depression. The ECG may mimic hypokalemia, except that QT is not prolonged and the TU separation is more clear than in hypokalemia.

1. GENERAL ECHOCARDIOGRAPHY

I. The 5 major echocardiographic views and the myocardial wall segments

A. Parasternal short-axis view (Figures 33.1–33.5)
B. Parasternal long-axis view (Figures 33.6–33.8)
C. Apical 4-chamber view (Figure 33.9). Beware of an apical view that does not cut through the true apex, and thus may miss apical akinesis. A true apex is usually thinner than the septal and lateral walls, and, as opposed to the other walls, moves horizontally rather than longitudinally.
D. Apical 2-chamber view (Figure 33.10).
E. Subcostal 4-chamber view. This view is particularly useful in COPD patients and patients receiving ventilator support, in whom the previous views have a poor quality (Figures 33.11, 33.12).
Arterial distribution (Figures 33.2, 33.13). Note that LAD supplies the anterior two-thirds of the septum, while RCA supplies the inferior one-third of the septum.

II. Global echo assessment of cardiac function and structure

A. Global assessment of myocardial function

A normal wall motion is characterized by an appropriate inward endocardial movement but also appropriate myocardial thickening. A segment can be hypokinetic, akinetic, or dyskinetic. Dyskinesis is outward movement of a myocardial wall during systole, when the remaining walls have an inward movement. Dyskinesis is therefore myocardial outpouching in systole, whereas aneurysm is myocardial outpouching in *both* systole and diastole (see Chapter 2).

Views that are orthogonal to a structure allow better endocardial definition of that structure.

1. Overall assessment of LV function

- EF (measured using method of disks, as per Figure 33.13):
  - Normal: ≥52% in men, ≥54% in women
  - Mildly decreased: 40–50%
  - Moderately decreased: 30–40%
  - Severely decreased: <30%
- The loss of the inferior and posterior walls typically leads to an EF of 35–50%, while the loss of the anteroseptal and apical walls typically leads to an EF < 35–40%.

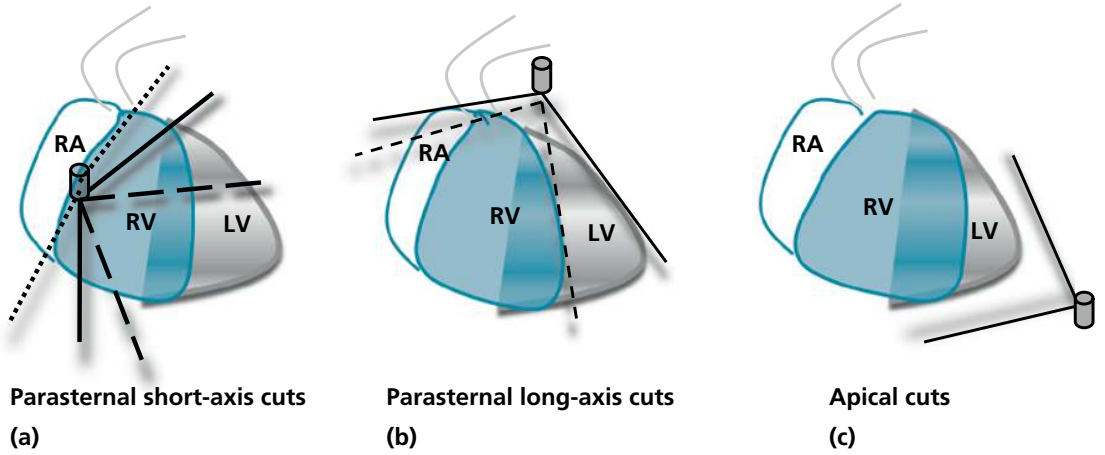

Figure 33.1 (a) Frontal view showing how the parasternal short-axis views cut through the heart (cross-sectional cuts). The first structure encountered is the right ventricle, which is actually the anterior ventricle; the base of the LV and the mitral valve are encountered more posteriorly. Angling the probe more superiorly allows visualization of the aortic valve, the RA and LA, as well as the RV inflow and outflow (aortic short-axis view, *dotted lines*). Angling the probe more inferiorly allows visualization of the LV body and apex (*dashed lines*).

(b) Parasternal long-axis cuts. The first structure encountered is the RV (more specifically, RVOT), which is actually the anterior ventricle. The LV, LA, and aortic base are encountered more posteriorly, and the interventricular septum is seen in between. Angling the probe more inferiorly (*dashed lines*) allows visualization of the inferior RV wall and the tricuspid valve, as well as the RA (RV inflow view). Angling the probe more superiorly allows visualization of the RVOT and pulmonic valve (RV outflow view).

(c) Apical 4-chamber cut. The first structures encountered are the apices of the LV and RV, while the atria are seen in the back. Superior angulation allows visualization of the aortic valve (5-chamber). A 90° rotation would focus on the LV–LA (2-chamber view). Further rotation opens the aortic valve (3-chamber view).

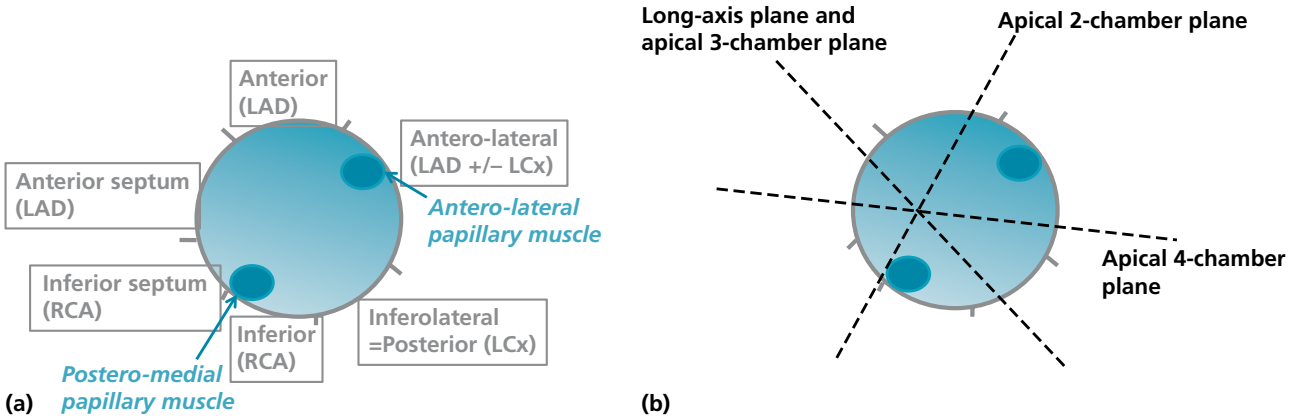

Figure 33.2 (a) Diagram of the **parasternal short-axis view** and various LV segments, with their corresponding arterial supply. **(b)** Orientation of various echo cuts.

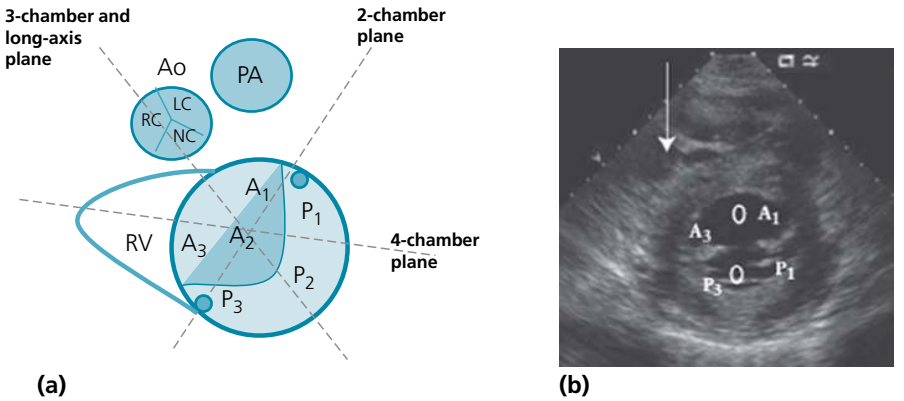

Figure 33.3 (a) Parasternal short-axis view at the level of the mitral valve (the aortic valve and PA are added to illustrate the anatomical relations). Each leaflet has three cusps (A_1–A_3 for the anterior leaflet, and P_1–P_3 for the posterior leaflet). A_3 and P_3 are medial, toward the RV; A_1 and P_1 are lateral. The orientations of various echo cuts through the mitral plane are shown. Note that the anterolateral and posteromedial papillary muscles (APM and PPM) are located between the 2 leaflets, underneath the commissures rather than underneath the corresponding leaflet. As such, *each papillary muscle provides chordae to both leaflets*: APM provides chordae to the adjacent A1 + P1, PPM provides chordae to A3 + P3, while A2 and P2 receive chordae from both papillary muscles. **(b)** Echocardiogram showing the parasternal short-axis view (anterior and posterior leaflets, *circles*). The triangular-shaped RV is partially seen (*arrow*).

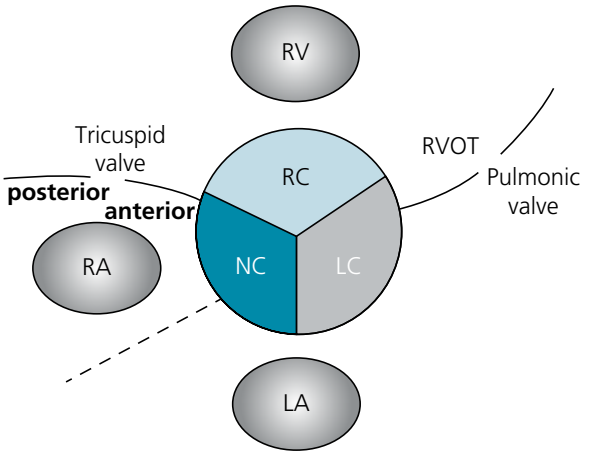

Figure 33.4 Diagram of the **parasternal short-axis view** at the level of the aortic valve (cut closer to the base than Figure 33.3, across the aortic valve, the LA/RA, and RVOT). The non-coronary or posterior cusp is always the cusp looking toward the interatrial septum. The anterior and posterior tricuspid leaflets are visualized (see Figure 33.8) (septal leaflet may replace anterior leaflet if the cut is at the LVOT below the aortic valve). LC, left coronary cusp; NC, non-coronary cusp; RC, right coronary cusp. Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

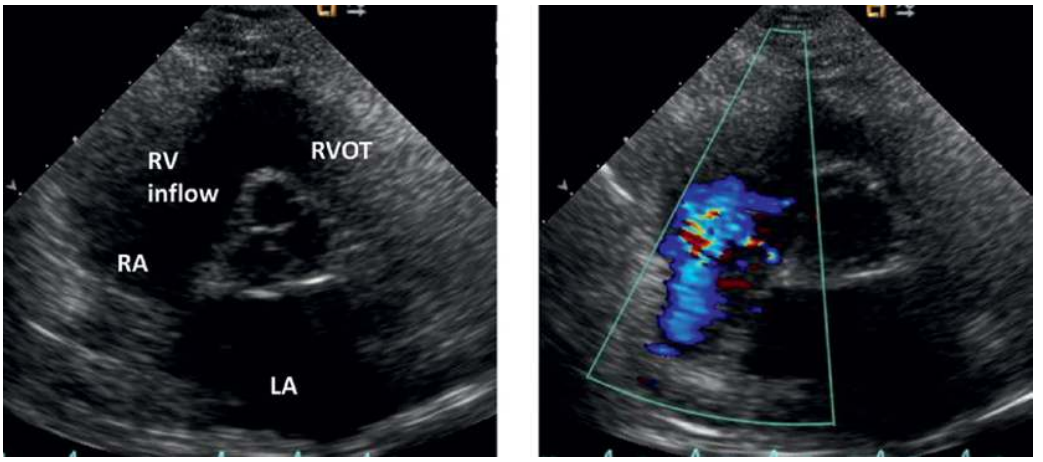

Figure 33.5 Parasternal short-axis view as described in Figure 33.4. A bicuspid aortic valve may be diagnosed on this view, by assessing how the valve opens in systole: a bicuspid valve opens in an oval rather than a "Y" fashion. In diastole, a bicuspid valve may look tricuspid because a fused raphe may be seen between the fused leaflets.

In severe AS, the aortic valve barely opens in this view; planimetry of the aortic valve area may be performed (especially by TEE). Rarely, however, the aortic valve may falsely look open if the cut is a bit below or above the valve level, masking severe AS.

The left image shows backward (= *blue*) blood flow across the tricuspid valve (= TR). Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

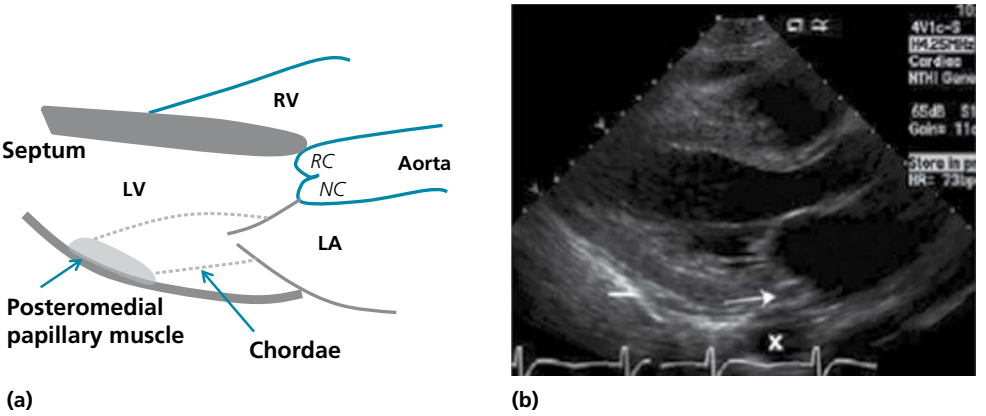

Figure 33.6 (a) Diagram of the **parasternal long-axis view**. Concerning the aortic valve cusps: the lower one, close to the LA, is the non-coronary cusp (NC); the upper one, close to RVOT, is the right coronary cusp (RC). The mitral leaflet close to the aorta is the anterior mitral leaflet (A_2 cusp); the mitral leaflet close to the posterior wall is the posterior leaflet (P_2 cusp). Note how the posteromedial papillary muscle gives chordae to both the posterior and anterior leaflets.

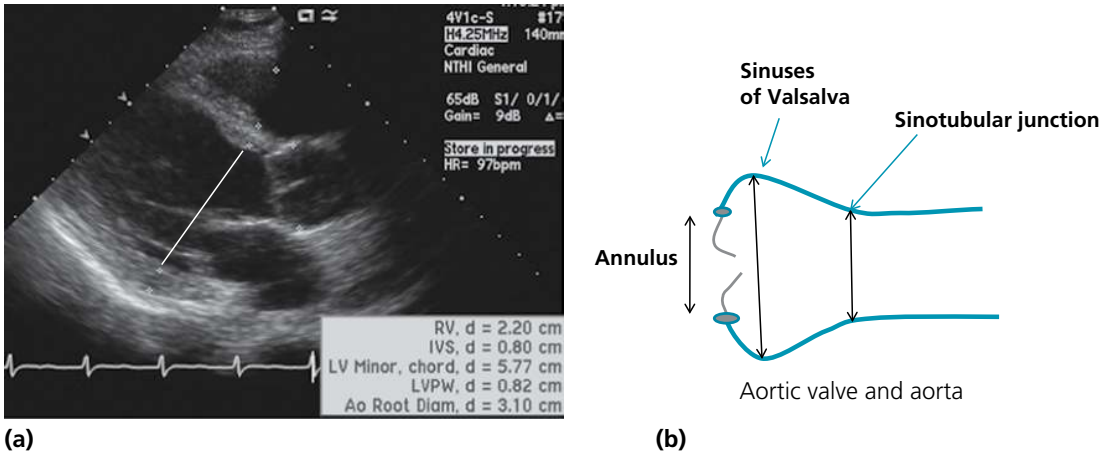
(b) Echocardiogram showing the parasternal long-axis view. Note the coronary sinus in the AV groove (*arrow*), and note the descending aorta behind it (*x*). The coronary sinus is anterior to the bright pericardium (*line*), whereas the descending aorta is posterior to it and is more rigid. ***From top to bottom, the following structures are seen around the pericardium: coronary sinus → pericardium/pericardial effusion → aorta → pleural effusion.*** The aorta separates pericardial from pleural effusion.

The coronary sinus goes on to drain in the RA. Coronary sinus may enlarge in case of RA dilatation/pulmonary hypertension or persistent left SVC; in the latter case, coronary sinus is severely enlarged>1 cm.



(a) (b)

Figure 33.7 (a) Parasternal long-axis view. Measurements are obtained from top to bottom, between delineated points, at an oblique line crossing the mitral leaflet tips and orthogonal to the axis of the LV (*line*).

(b) Aortic measurements. The annulus is formed by joining the basal hinges of the valve leaflets (leaflets' insertion on the LVOT, *dots*). It is a stable structure that is part of the ventricle/outflow tract and does not usually dilate. The aortic diameter at the level of the sinuses of Valsalva (i.e., the aortic dilatations that support the aortic cusps, also called *aortic root*) should not exceed any of the following 2 values: 4 cm and 2.1 cm/m² (ESC 2024). The diameter of the proximal ascending aorta and the sinotubular junction (junction of the ascending aorta with the sinuses of Valsalva) should not exceed 3.8 cm and 2 cm/m². Aortic dilatation may occur at the level of the ascending aorta and sinotubular junction (e.g., HTN), or may involve the sinuses of Valsalva in addition to the ascending aorta (bicuspid aortic valve, Marfan disease).

The normal aortic diameter is affected by age and body surface area. The aorta is smaller in patients under 40 years.

(a) **RV inflow view**

(b) **Orientation of various echo cuts through the RV and tricuspid leaflets**

Figure 33.8 (a) Parasternal RV inflow view, which is obtained by angling the probe inferiorly from the parasternal long-axis view. This view allows visualization of the RV (*horizontal bar*) and RA (*vertical bar*). The IVC entrance into the RA is seen, as well as the coronary sinus (CS) beneath it. A rigid Eustachian valve or a filamentous Chiari network separates the 2 (Eustachian valve is seen here). The RV walls are the anterior (*a*) and inferior (*b*) walls, and the 2 tricuspid leaflets are the anterior (*1*) and septal leaflets (*2*). (*2*) may be the posterior leaflet in some cases; this depends on whether the RV inflow cut, in **(b)**, goes through the septum and coronary sinus (→ septal leaflet) or not (→ posterior leaflet).

(b) The anterior tricuspid leaflet is the largest and is seen in most views, while the septal and posterior leaflets are smaller. Often, only one view shows the posterior leaflet, the aortic short-axis view (Figure 33.4). The RV inflow view may also show it if the cut is away from the CS. The other tricuspid valve views show the anterior and septal leaflets (4-chamber and subcostal views). Normally, the RV has one dominant anterior papillary muscle that gives chordae to both the anterior and posterior leaflets, and it is sometimes seen on the RV inflow view. The septal leaflet frequently gets its chordae directly from the septum. For a detailed analysis of TTE cuts through the tricuspid valve, see Appendix, Figure 64.

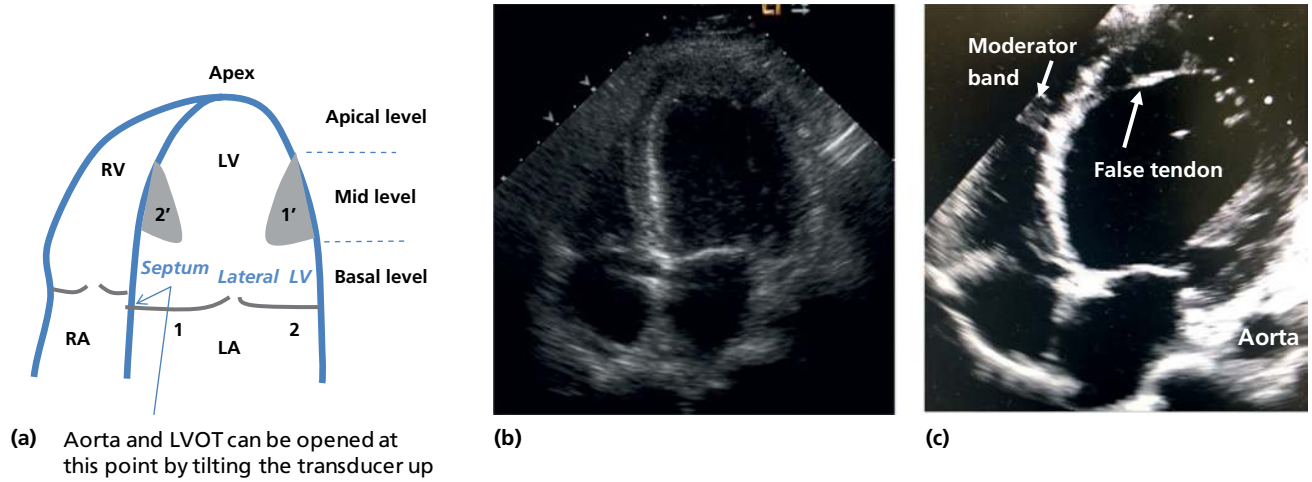

Figure 33.9 **(a)** Diagram and **(b)** echocardiogram of the **apical 4-chamber view**. Aorta and LVOT can be opened up by tilting the transducer up, creating the **5-chamber view**. The anterior leaflet is seen medially (*1*), the posterior leaflet is seen laterally (*2*), the anterior papillary muscle is lateral (*1′*), the posterior papillary muscle is medial (*2′*). ***Note that the valvular leaflets and their respective papillary muscles crisscross in this view.***

The tips of the papillary muscles define the separation between basal LV and mid-LV; the distal part of the papillary muscles separates mid-LV from apex.

Sometimes, *LV false tendon*, a fibrous/fibromuscular band, is seen extending distally from the septum to the lateral LV wall. The RV has coarse apical trabeculations, coarser than the LV, and one dominant anterior papillary muscle (+ smaller posterior +/– septal muscles). A muscular band where the right bundle is embedded, the *moderator band*, may sometimes be seen spanning from the septal to the lateral RV wall, similar to the false tendon on the left.

The tricuspid valve is more apical than the mitral valve. When both valves are at the same level, endocardial cushion defect is suspected.

Advanced note: The anterior cusp (*1*) is $A_2 \pm A_3$, the posterior cusp (*2*) is P_1, the most lateral one; see Figure 33.3 to understand how the cusps are cut and the relation between leaflets and papillary muscles.

(c) Apical 4-chamber view in dilated cardiomyopathy: LV changes from elliptical to spherical. Note the false tendon and the moderator band, and note the descending aorta behind the LA.

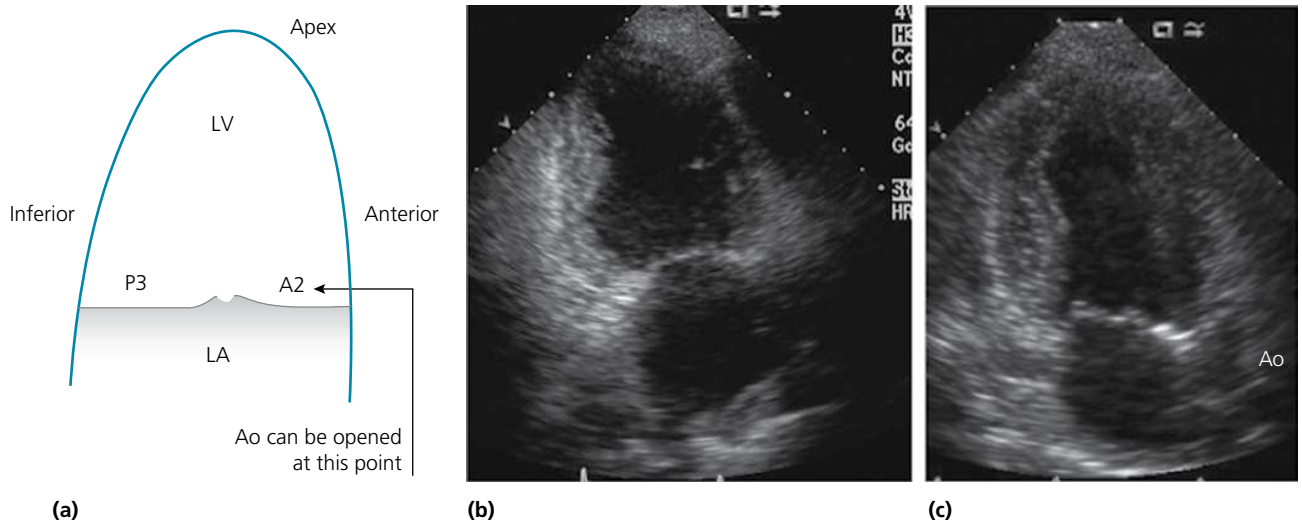

Figure 33.10 **(a)** Diagram and **(b)** echocardiogram of the **apical 2-chamber view**; and **(c)** echocardiogram of the **apical 3-chamber view**. By opening the aorta with a counterclockwise rotation, the apical 2-chamber view becomes the apical 3-chamber view, where the anterior and inferior walls are replaced by the septal and posterior walls, respectively. *The apical 3-chamber view, also called apical long-axis view, is similar to the parasternal long-axis view, except for a different heart orientation* (the beam is parallel to the aortic flow and the true apex is intercepted). Depending on the cut, 3 mitral cusps with 2 orifices may be seen on the 2-chamber view (P_3 next to the inferior wall, A_2 in the middle, and P_1 or A_1 next to the anterolateral wall). Use Figure 33.3 for guidance. Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

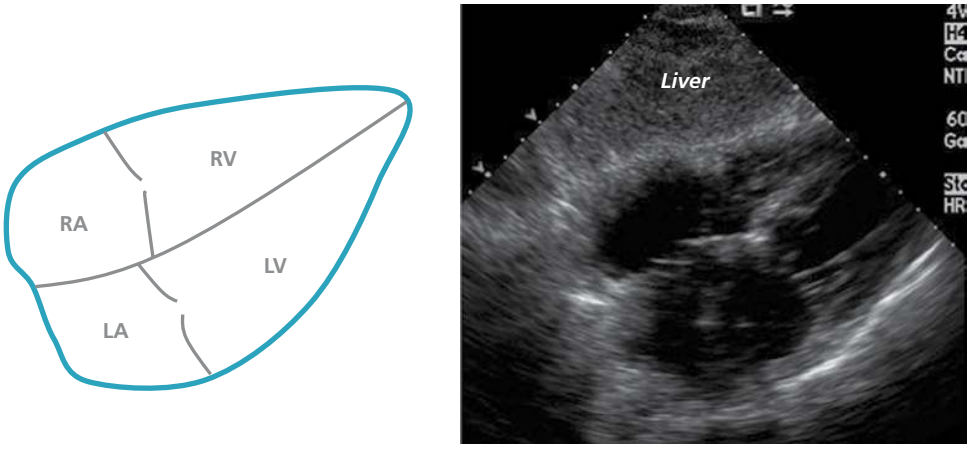

(a) (b)

Figure 33.11 (a) Diagram and **(b)** example of the **subcostal 4-chamber view**. Horizontal transducer orientation in the subcostal position displays this 4-chamber view.

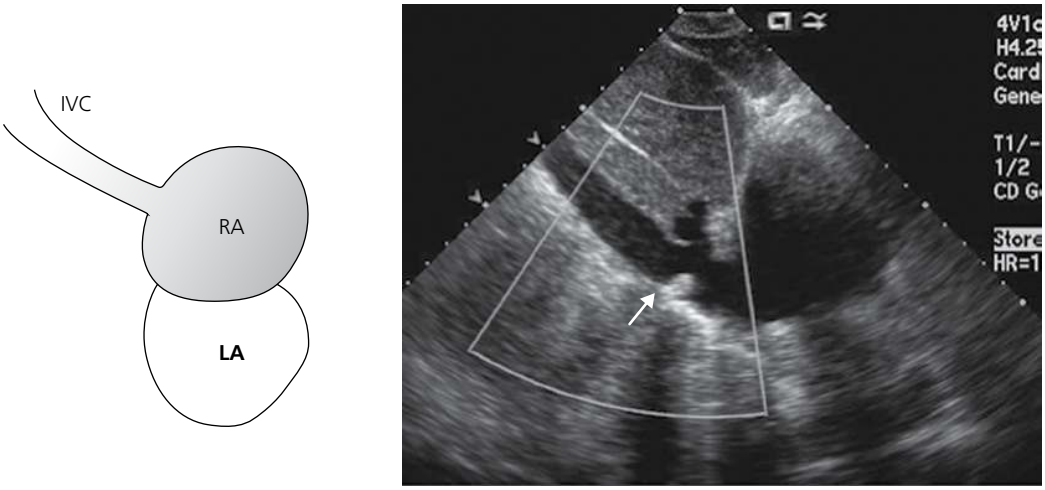

Figure 33.12 Subcostal view with a vertical tilt to visualize the IVC. A large IVC (>2.1 cm), as well as its lack of 50% collapse with inspiration or sniff, signals high RA pressure. The IVC is measured at a level just proximal (caudal) to its junction with the hepatic veins (1–2 cm proximal to the RA) (*arrow*). It is important to see the IVC joining the RA to ensure it is properly laid out during measurement, and to avoid oblique IVC cuts, which may alter IVC measurement (up or down) and create a false impression of IVC collapse.

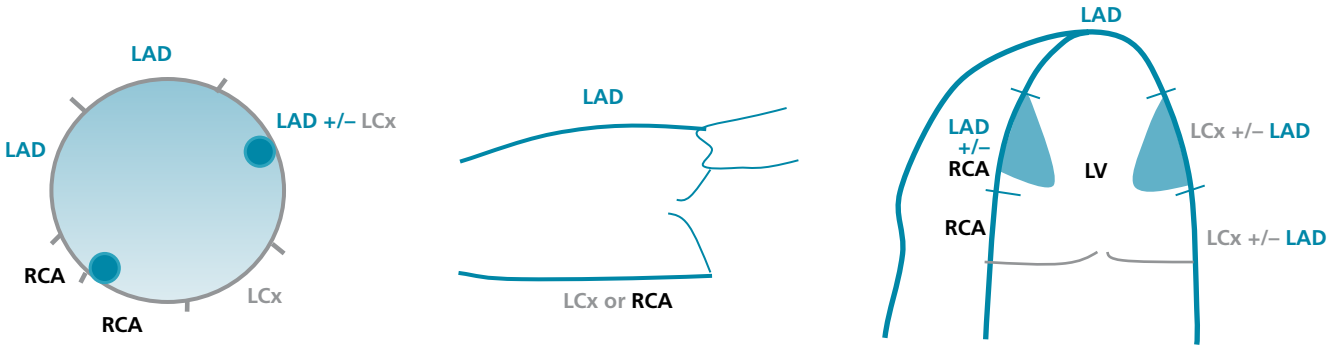
2. Assess for LV dilatation and RV dilatation, which are associated with LV and RV systolic dysfunction, respectively.

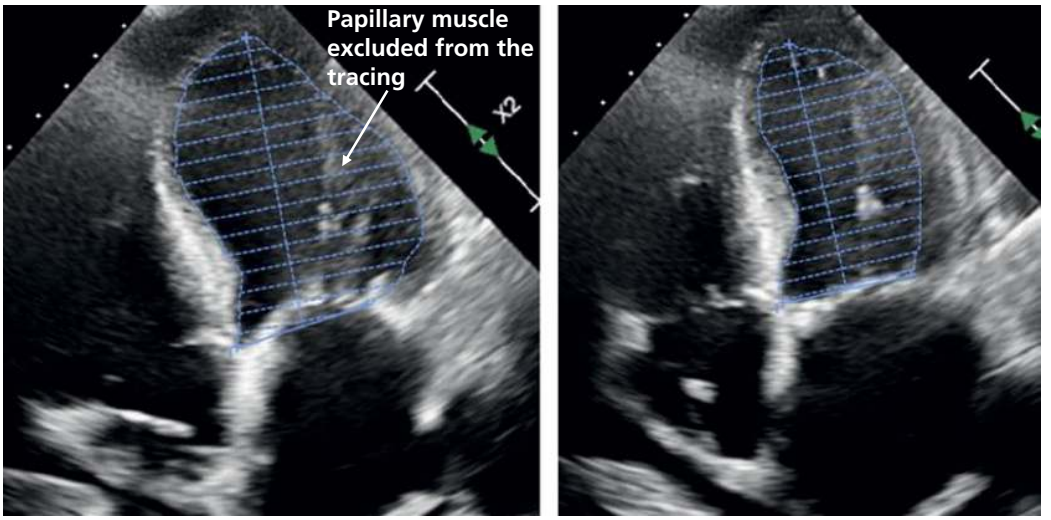
a. *LV dilatation* is characterized by LV diameter (obtained from the short- or long-axis view)>3.5 cm (women) or 4 cm (men) in systole; or >5.3 cm (women) or >5.8 cm (men) in diastole. Measurements are obtained at the level of the mitral leaflet tips, at the base of the LV. LV dilatation may be defined using *LV volumes*: LV end-diastolic volume >75 ml/m² in men or ~65 ml/m² in women.

b. *RV dilatation* (Figure 33.14) is characterized by:

- RV size larger than LV size on the apical 4-chamber view
- RV rounded rather than wedge-shaped on the parasternal long-axis view.
- RVOT diameter ≥ 3.0 cm or 3.2 cm on the long-axis view or the aortic short-axis view, respectively. RV diameter on the 4-chamber view >4.1 cm at the base and >3.5 cm at the mid-RV level. The RV base is located just below the tricuspid annulus and is slightly larger than the annulus. However, these measurements vary according to the way the RV is cut, particularly because the RV has a complex pyramidal shape, which limits their accuracy. They are done at end-diastole.
- *RV pressure overload pattern* associated with severe pulmonary hypertension: the RV compresses the LV in *systole* and leads to a straight vertical D-shaped septum in systole.
- *RV volume overload pattern*: the RV compresses the LV in *diastole* and leads to a paradoxical septal motion toward the RV in systole. In mixed RV volume and pressure overload pattern, the septum remains compressed toward the LV in both diastole and systole (Chapter 4, Figure 4.12).

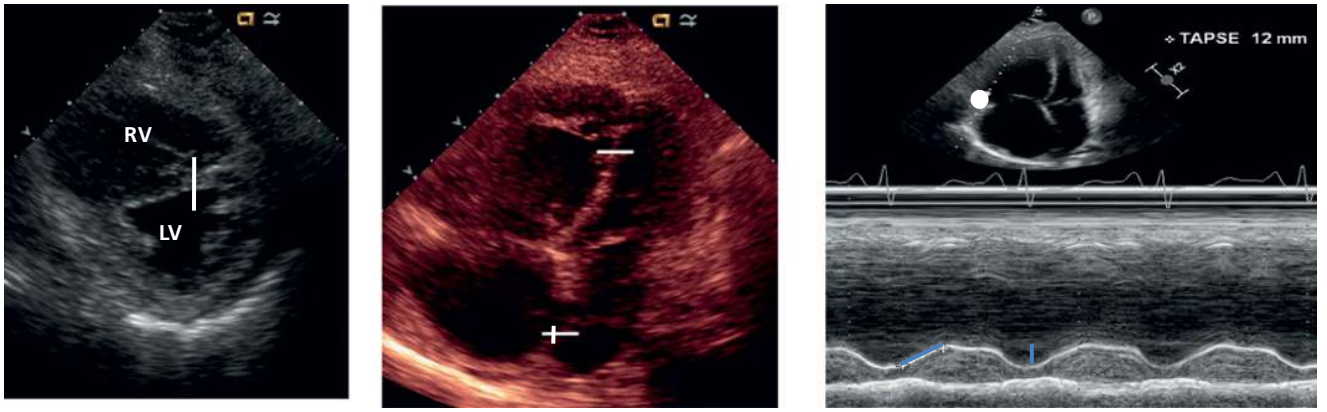


(a)



(b)

Figure 33.13 (a) Arterial distribution of various echo segments on the short-axis view, long-axis view, and apical four-chamber view. Note that the inferior septum (on the short-axis view) and the basal septum (on the 4-chamber view) are supplied by the RCA. If the 4-chamber cut is angled a bit posteriorly, some of the visualized mid-septum may be supplied by the RCA as well. **(b)** EF is measured using LV cavity volumes in end-diastole and end-systole in the 4-chamber and 2-chamber views (biplane method of disks or Simpson rule). The interface between the compacted myocardium and the LV cavity is traced. Papillary muscles are ignored while tracing (avoid tracking them). LV cavity is divided into ~16 disks, and the volume of each disk is measured based on its linear dimension. Volumes and EF are measured in both views then averaged. The validity of this method depends on viewing the apex fully, without foreshortening, and on proper delineation of the LV cavity–myocardium interface, which is greatly enhanced via echo contrast. Note that LA is frequently foreshortened when the apex is properly opened. EF may be derived from linear LV dimensions on PS long-axis view (LVEDD and LVESD, Teichholz method), but this is less accurate in the presence of regional—especially apical— LV dysfunction.



(a) (b)

Figure 33.14 (a) Example of **RV enlargement and RV volume overload** on the parasternal short-axis view and apical 4-chamber view. The interventricular septum is flattened and pushed toward the LV in diastole (*lines*). The interatrial septum is also bowing toward the LA (*cross*). **(b)** M mode across the lateral tricuspid annulus in 4-chamber view. The longitudinal excursion of this annulus over time is shown, and is called tricuspid annular plane systolic excursion (TAPSE). TAPSE reflects RV shortening/contraction, and is measured by any of the blue lines. It is reduced here (12 mm, normal ≥17 mm). The distance is the same whether the oblique or vertical blue line is used, as distances are only measured vertically on M mode (horizontal plane represents time).

- RA is enlarged if it is larger than LA on the 4-chamber view, or if the interatrial septum bows to the left, or if the septal-lateral diameter is >2.5 cm/m² of BSA (~4.4 cm). IVC is typically dilated in RA enlargement.

c. A left ventricular segment that is *bright and thin* (<6 mm) often implies necrotic, non-viable myocardium (due to an infarct or to irreversible non-ischemic cardiomyopathy).

3. Left ventricular hypertrophy (LVH) is characterized by an increased LV mass > 115 g/m² in men, or >95 g/m² in women. *Increased wall thickness*, which often underlies LVH, is characterized by an interventricular septal thickness or a posterior wall thickness ≥ 1.1 cm in men, or ≥1 cm in women. The wall thickness is severely increased if it is ≥1.7 cm in men, or ≥1.6 cm in women. LV mass is generally calculated via the cube formula, using the basal LV dimensions obtained on the parasternal long- or short-axis view (LVEDD, LVESD, LV thickness).

LVH is *concentric* when the walls are thick but the LV is not dilated. LVH is *eccentric* when the walls are thick and the LV is dilated. *Concentric LV remodeling* is characterized by thick walls without overall LVH; i.e., the LV mass is normal. Alternatively, relative wall thickness (RWT) may be calculated as: (2 × posterior wall thickness)/LVEDD. LVH with RWT >0.42 is concentric LVH, LVH with RWT ≤0.42 is eccentric LVH, while normal mass with RWT >0.42 is concentric remodeling.

4. Left atrial size is the "hemoglobin A1c" of the left heart; if LA size is normal, it is unlikely that there are any major systolic, diastolic, or left valvular issues.

A quick way of assessing LA size is by comparing it to the aorta on the long-axis view. LA is enlarged if it is >1.1× the aortic size. Normal LA anteroposterior diameter is <3.8 cm or 2.3 cm/m² on the parasternal long-axis view. It is measured perpendicular to the LA posterior wall, in end-systole (when LA is largest). LA enlargement is severe if LA diameter > 5 cm. LA volume is more important than LA diameter and is measured by tracing the LA on both the 4- and 2-chamber views (disk summation technique [like Figure 33.13 (b)] or area-length method). This is the preferred method for LA size assessment: LA volume is normally <34 ml/m² of BSA; LA is severely enlarged if LA volume is >48 ml/m². ***RA size*** is not well standardized but values similar to the LA my be applied: normal area and volume <20 cm² and <34 ml/m², respectively.

B. Paradoxical septal motion

Normally, the septum moves in toward the LV in systole, and relaxes toward the RV in diastole. Abnormal septal motion is characterized by a septum that moves out toward the RV in systole, or at least at one point of systole, leading to ineffective septal contraction; and moves in toward the LV in diastole, compressing the LV.

Five differential diagnoses (Figures 33.15–33.18):

1. LBBB and RV pacing. The abnormal septal motion of RV pacing is similar to LBBB, except that it involves the distal/apical septum (rather than the entirety of the septum).
2. RV dilatation with RV volume overload.
3. Pericardial processes (constrictive pericarditis, tamponade). Large respiratory swings (e.g., COPD) may simulate the abnormal septal motion of pericardial processes.
4. Abnormal septal motion post-cardiac surgery.
5. Septal akinesis in a patient with septal MI. Unlike all the other causes of septal motion abnormality, anterior and apical akinesis is also seen in this case.

As opposed to other diagnoses, *pericardial processes*, whether constriction or tamponade, *are characterized by an abnormal septal motion that increases with inspiration and thus varies between beats*, i.e., the septal collapse toward the LV in diastole varies with respiration. In other processes, the abnormal septal motion does not vary as much across beats. In addition, characteristic of constrictive pericarditis, a *septal bounce* may be seen during each diastole, representing an instantaneous change in the RV-to-LV push with instantaneous pressure changes.

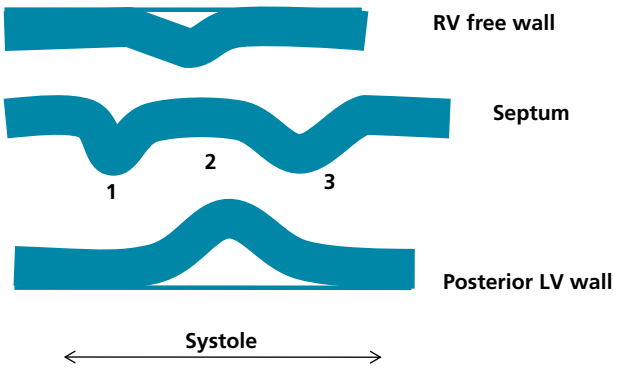


Figure 33.15 During systole, in **LBBB**: (*1*) the septum moves in toward the LV; (*2*) then the septum relaxes while the posterior wall moves in; (*3*) the septum moves in again at the end, not because it is contracting but because the RV is relaxing and pushing it. Thus, the septum moves in twice (*1* and *3*), while the posterior wall moves in during (2), when the septum is relaxed. The distance between the septal peak (*1*) and the posterior peak (*2*) is the septal-to-lateral M-mode delay, an index of dyssynchrony (>130 ms → significant).

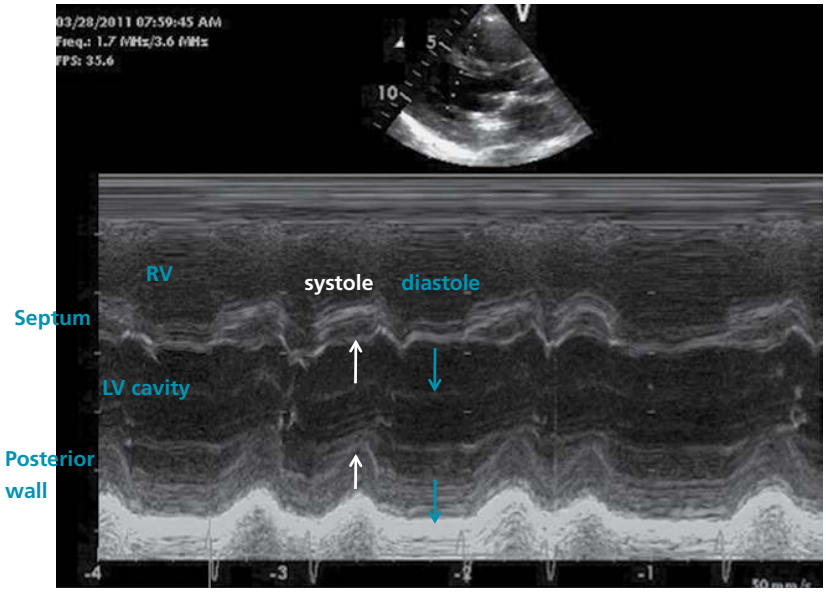

Figure 33.16 M-mode imaging shows **paradoxical septal motion of RV volume overload** (outward in systole, inward in diastole). This paradoxical motion is seen in both inspiration and expiration; it may be a bit more prominent in inspiration, but unlike constrictive pericarditis or tamponade, the respiratory change is not marked. M-mode allows a fine analysis of how various structures move during the cardiac cycle. QRS is used to time events.

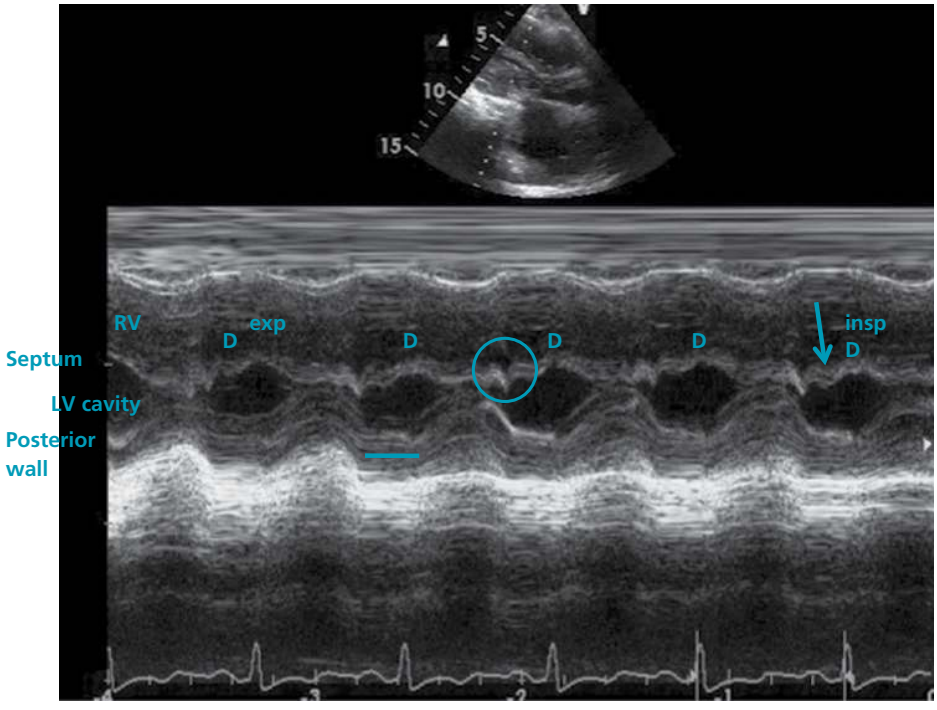

Figure 33.17 Constrictive pericarditis. Two septal abnormalities and one posterior wall abnormality are seen on M-mode (*D* corresponds to the septal position in diastole):

- Septum is pushed toward the LV in inspiration (*arrow*) and toward the RV in expiration (= respirophasic septal shift).
- The RV-to-LV diastolic push varies with instantaneous pressures (= septal bounce, *circle*).
- The posterior wall is stiff/horizontal in diastole after the initial brisk expansion (= plateau, *line*).

In RV volume overload, the RV pushes the septum toward the LV in all diastolic cycles with no marked respiratory variation: the abnormal motion is systolo-diastolic, not respiratory. Moreover, only 1 sharp septal motion toward the LV is seen in diastole.

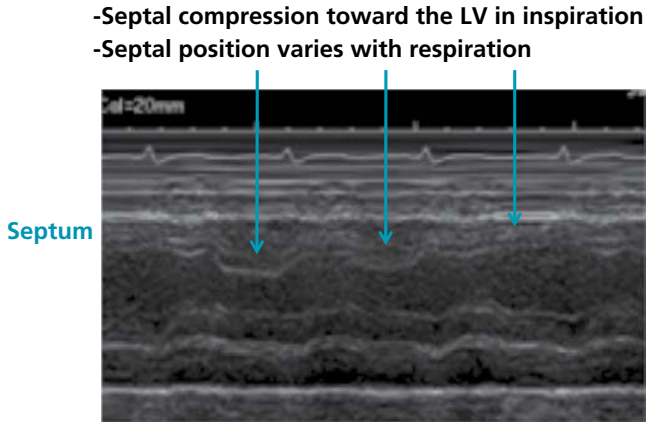

Figure 33.18 Pericardial processes are characterized by septal compression toward the LV in inspiration, and toward the RV in expiration.

A septal motion abnormality may also be seen in patients breathing deeply, wherein the RV pushes the septum toward the LV in deep inspiration. Like pericardial processes, this septal position varies with respiration, but septal bounce is not seen.

In a tachycardic patient, sorting out the respiratory effect may prove difficult. *M-mode imaging is particularly helpful because of its high frame rate.*

The abnormal postoperative septal motion is related to the fact that, after cardiac surgery, the heart is fixed anteriorly to the thorax (meaning, the RV is adherent to the sternum). During systole, the whole heart moves toward that fixation site, leading to what looks like septal motion abnormality. In fact, it is an abnormal anterior motion of the whole heart, including the posterolateral wall. The septal and posterior walls thicken synchronously.

C. Valvular structure assessment

1. Mitral valve (Figures 33.19–33.21)

- *Degenerative valve*: leaflet(s) are thick, elongated, ± prolapsed into the LA. If, in addition to the prolapse of the leaflet body, the free edge is overriding the other leaflet and turned toward the LA rather than the LV, the leaflet is called *flail leaflet*; this is usually secondary to chordal rupture (a piece of chorda is usually seen flopping in the LA).
- *Rheumatic valve*: thick, calcified valve with a stiff posterior leaflet and a stiff anterior leaflet tip. The anterior leaflet body is, however, mobile. The combination of a stiff anterior leaflet tip and a flexible body gives the anterior leaflet a hockeystick shape on the parasternal long-axis view. On the short-axis view, the commissures are fused and the valve only opens in its center ("fish mouth" mitral valve).

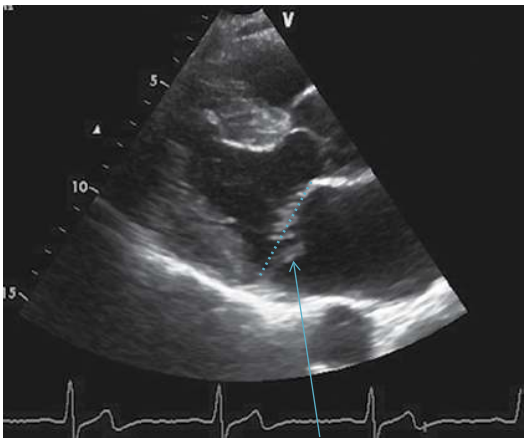

Figure 33.19 Posterior mitral leaflet prolapse. In systole, the leaflet prolapses posteriorly to the mitral annular plane (*blue line*). This leaflet is not just prolapsed but flail, as even its edge is tilted toward the LA. Severe MR is expected, and a torn, flopping chordae may be seen.

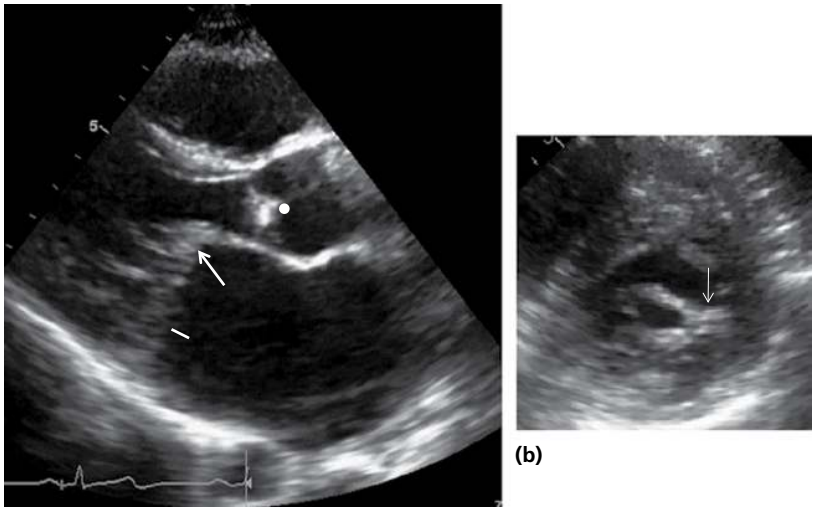

Figure 33.20 Rheumatic mitral valve. (a) Long-axis view in diastole. See the hockeystick shape of the anterior leaflet (*arrow*), the tip of which looks attached to the stiff posterior leaflet (*line*), with no diastolic opening. In fact, **both leaflets are tied together by the commissural fusion.** Note the severe LA enlargement, due to MS in this case. Also, note the aortic valve calcification (white aortic valve leaflet tips [*dot*]). Make sure the aortic calcification is not a false impression related to a high echo gain; the fact that the aortic walls appear bright may be a hint to the increased echo gain. **(b)** Short-axis view. Commissural fusion (*arrow*) explains the "fish mouth" opening.

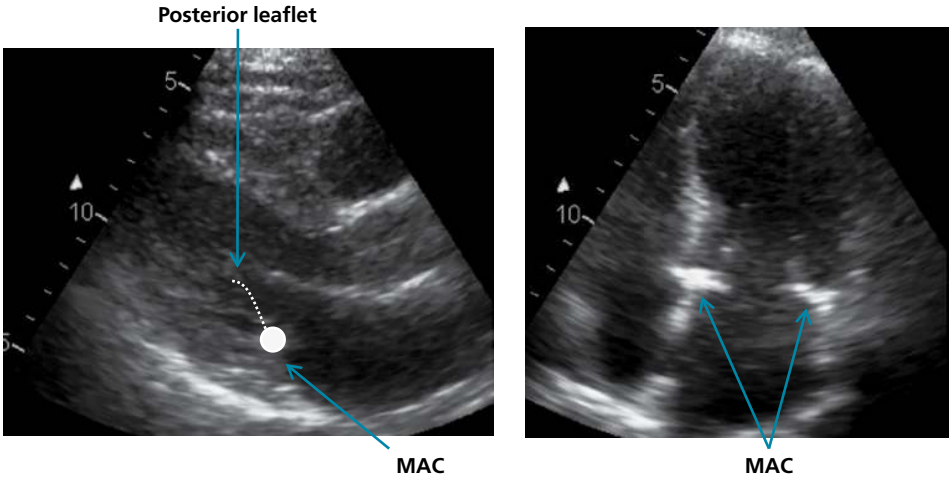

Figure 33.21 Posterior mitral annular calcifications (MAC) in the long-axis and 4-chamber views. These posterior calcifications project at the base of the posterior leaflet on the long-axis view and the base of both the posterior and anterior leaflets on the 4-chamber view. Anterior MAC in the long-axis view suggests radiation heart disease.

- *Mitral annular calcifications* involve the mitral annulus rather than the leaflets (in contrast to a rheumatic process). The annulus is calcified, but the leaflets' tips are free. Calcifications are mainly seen at the posterior aspect of the annulus and increase in incidence with age, high LV pressure (HTN, AS), and renal disease. *Only the posterior annulus, which is a muscular structure, calcifies; the anterior annulus is a fibrous structure that typically only calcifies in radiation heart disease.* Calcifications may, however, extend to the base of both the posterior and anterior leaflets on the 4-chamber view (not the leaflet tips, and not the anterior annulus on the long-axis view) (Chapter 6, Figure 6.9).

2. Aortic valve

- Aortic valve thickening (sclerosis) and calcification are precursors of AS. Also, aortic sclerosis and calcification are associated with coronary atherosclerosis

- A bicuspid aortic valve is characterized by fusion of 2 cusps, most commonly the right and left cusps (85%); a raphe is frequently seen between the 2 fused cusps, and this may create the false impression of a tricuspid valve. Therefore, on the aortic short-axis view, instead of analyzing how many cusps are seen when the valve is closed, it is best to analyze how the aortic valve opens. An elliptical rather than a triangular opening is a hint to a bicuspid valve (Figure 33.22).

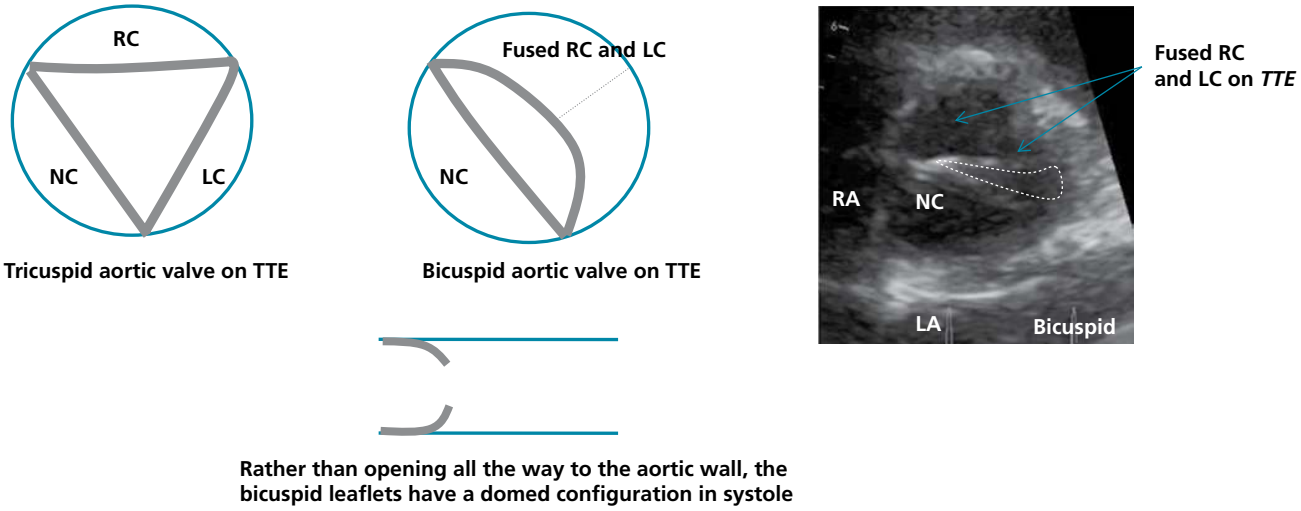

Figure 33.22 Difference in aortic orifice shape between the tricuspid and bicuspid aortic valves (short-axis view). Note that one cusp is larger than the other in bicuspid aortic valve, and hence the aortic opening/closure becomes eccentric; this is evident on the M-mode analysis of the aortic valve.

The leaflets open in a domed fashion on a longitudinal view (long-axis view), as they are restricted by the lack of a third commissure.

A severely stenotic bicuspid valve may appear to open well on the long-axis view. The stenosis being eccentric, it is 3-dimensionally more severe than it may appear on a 2-dimensional view. LC, left coronary cusp; NC, non-coronary cusp; RC, right coronary cusp.

III. Doppler and assessment of valvular regurgitation and stenosis

A. Types

1. *Color Doppler:* color Doppler assigns color to blood flow velocity and direction. The maximal Doppler velocity that can be sampled unambiguously and attributed a blue or red color is called the Nyquist or aliasing limit. Beyond this limit, the color becomes mosaic.

2. *Continuous-wave (CW) spectral Doppler:* CW Doppler traces the highest flow velocity *along one line* swept by the Doppler probe. Therefore, it captures the velocity across the narrowest point or obstruction. It continuously captures waves and is not dependent on the Nyquist limit.

3. *Pulsed-wave (PW) spectral Doppler:* PW Doppler traces the velocity *at one point along the line* swept by the cursor, rather than the whole line swept. It samples waves intermittently, at a specified sampling rate. Therefore, the maximal velocity that can be detected across this one point cannot exceed a certain limit, called the Nyquist limit.

B. Routine Doppler interrogations

1. Color Doppler is performed at the level of each valve to assess regurgitation (see Figures 33.23–33.33)

By "eyeballing" the view, regurgitation appears as a color going backward between chambers, opposite to the normal flow (e.g., any flow from LV to LA, RV to RA, or aorta to LV). It is *b*lue (*b*ackward) for the mitral and tricuspid valves on TTE. It usually has a higher velocity than the Nyquist limit, which leads to *color aliasing (= mixed, mosaic color).* Also, when severe, it is usually turbulent, with high *variance of velocities* (*turbulent flow*, coded as *green color*).

Reducing the Nyquist limit from 60 cm/s to 30 cm/s increases the area of regurgitant flow by Doppler. Increasing the color gain also increases the area of regurgitant flow. Therefore, an inappropriately low Nyquist limit or a high Doppler gain overestimates the regurgitation severity, while the opposite underestimates the regurgitation severity. Inappropriately low color gain is particularly common in patients with poor windows, wherein the color definition is reduced, similarly to the reduction in echo resolution. Increase the color gain until noise is seen and until color pixels appear within the cardiac tissue, then slightly reduce the gain just until the noise disappears; the latter gain corresponds to the appropriate color gain. For evaluation of regurgitation, the best Nyquist limit is 50–60 cm/s. Also, narrow the Doppler sector to focus on the valve of interest; a large sector reduces the color resolution across the valve of interest.

2. CW Doppler is performed at the level of each valve to assess forward-flow velocity, and, consequently, valvular stenosis (see Figures 33.34–33.36)

Normally, the forward peak velocity across each valve is 1 m/s. An increase in flow velocity corresponds to valvular stenosis.

The peak pressure gradient across a valve can be estimated using this equation (modified ***Bernoulli equation***):

$$\text{Peak gradient} = 4 \times V_{valve}^2$$

This is how gradient is estimated across the aortic valve and the severity of a stenosis is assessed. For spectral Doppler assessment, it is important to obtain a view parallel to the flow.

3. PW Doppler is used to see the velocity at one particular point, such as the mitral inflow (E/A), tricuspid inflow, pulmonary vein inflow (systolic, diastolic, atrial waves), and LVOT flow (Figures 33.37, 33.38)

PW has a limited capacity to measure high velocities that exceed twice the Nyquist limit (>2 m/s), particularly at greater depths.

Two types of velocities are analyzed on CW or PW Doppler: peak velocity and velocity–time integral (VTI). VTI corresponds to the area enclosed by the CW or PW Doppler velocity profile. It is measured in cm (velocity × time) and corresponds to the distance traveled by the blood column through the interrogated point during one cardiac cycle.

All Doppler modalities are ***angle-dependent*** and best measure the flow that is aligned with the ultrasound beam. For best assessment of stenosis or regurgitation and for velocity measurement, the ultrasound beam should be parallel to the flow (or within a 20° angle).

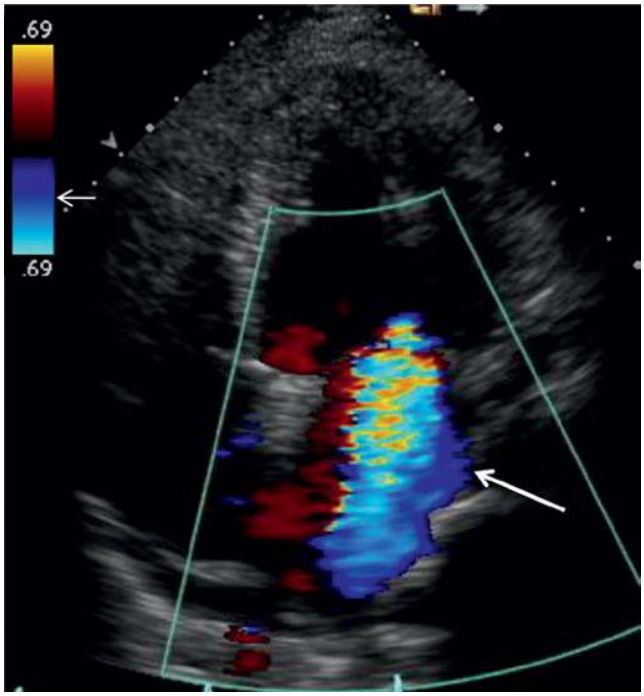

Figure 33.23 MR, 4-chamber view. The blue, backward flow between the LV and the LA is MR. The regurgitation can be graded by measuring the regurgitant (blue) area (*arrow)* and comparing it to the LA area. If the regurgitant area is > 40–50% LA area → severe MR (this also applies for TR). This provides a quick idea of the severity of MR, but is not very reliable. Increasing the color gain or lowering the Nyquist limit of the backward flow on the color scale (*horizontal arrow*) increases the regurgitant/turbulent area and makes the MR look more severe. The best Nyquist limit for regurgitation assessment is 50–60 cm/s. To obtain the best color gain, increase the gain until noise is seen in cardiac tissues, then slightly reduce it just until the noise disappears. Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

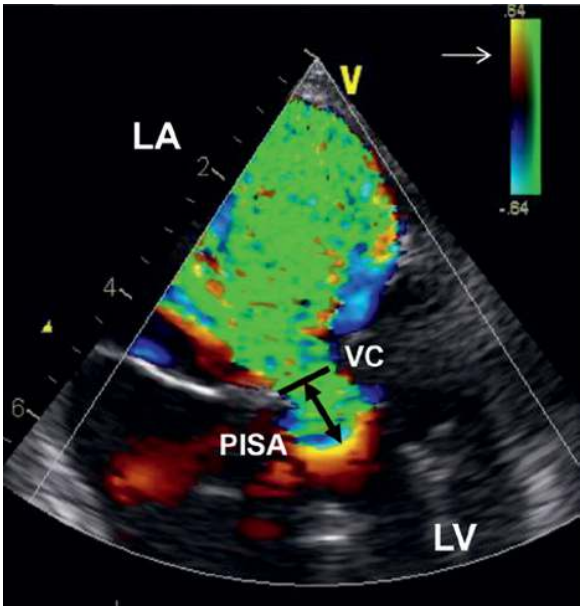

Figure 33.24 Severe MR on 4-chamber TEE view. **Severity criteria of MR:**

1. Look at the small spherical portion of the regurgitant jet that is on the side of the ventricle rather than the atrium. As the blood is flowing back from the LV to the LA, it goes through a narrow neck that corresponds to the vena contracta (VC) of the mitral orifice. The flow converging toward the mitral orifice forms hemispheres of increasing velocities, the areas of which are called *proximal isovelocity surface areas (PISA).* The hemisphere of interest is the one where aliasing occurs (*double arrow*). Thus, the radius of the PISA corresponds to the distance between the narrowest neck of flow and the outer aliasing line (*double arrow*). The larger this hemisphere (>0.9–1.0 cm), the more severe the MR. PISA allows calculation of the effective regurgitant orifice (ERO). If the backward aliasing limit is set at 40 cm/s on the regurgitant color bar (*arrow*), ERO is estimated as:

   $(\text{PISA radius})^2/2$

   If PISA radius is 0.9 cm, ERO is ~0.4 cm^2. MR is severe if ERO ≥ 0.4 cm^2. ERO can be used to calculate the regurgitant volume (= ERO × VTI of the regurgitant flow) and the regurgitant fraction. Regurgitant volume > 60 ml or regurgitant fraction > 50% signifies severe MR. PISA is affected by eccentricity of the jet, but less than MR jet area; another limitation is that the PISA should be a 180° hemisphere. The flattened, squashed PISA of functional MR has a wider base but a shorter diameter (shorter *double arrow*); the short diameter underestimates the PISA area as the calculation assumes PISA is round.
2. The diameter of the MR flow at its *vena contracta* neck, i.e., the narrowest part (mitral valve level), can be estimated. The larger the diameter, the more severe the MR *(≥7 mm → severe MR).*
3. A severe regurgitation should lead to enlargement of the backward chamber (LA in MR, RA in TR, LV in AI). In addition, the forward chamber often enlarges because of the volume overload. Except in acute cases, a normal-size backward chamber rules out severe regurgitation.
4. Other severity criteria of MR:
   - Increased forward flow and velocity across the mitral valve in diastole: **E velocity > 1.2 m/s**
   - Reversal of the systolic S flow of one or more pulmonary vein(s): specific for severe MR, but not sensitive, as LA compliance may prevent this flow reversal (compensated chronic MR). Moreover, if the jet is eccentric, reversal of flow may be seen in some but not all of the veins. Blunting of S flow, rather than reversal, is also consistent with severe MR but is not specific.

When MR seems severe but LA is not enlarged, make sure that MR is present throughout systole. What seems like severe MR by color or PISA is moderate if it only encompasses 50% of systole or end-systole (this may occur with mitral valve prolapse and with functional MR). The duration of MR is evaluated by CW Doppler or by color M-mode across the mitral valve.

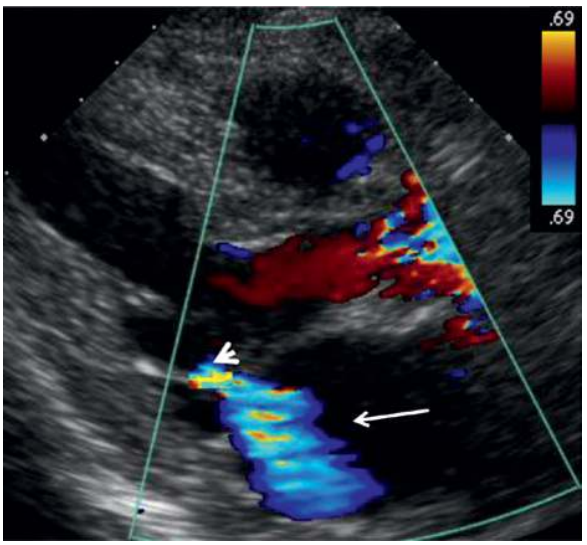

Figure 33.25 MR, long-axis view. The blue flow between LV and LA is MR (*arrow*). *It is eccentric, posteriorly* directed, and at least moderate in severity. Echo color correlates with velocity more than volume: MR volume may be high, but when eccentric, it hits the wall and its velocity and color may abate quickly. When MR is eccentric, consider it more severe than it appears (MR that appears mild is likely moderate). An eccentric jet that turns around the left atrial wall in a circular way is severe MR (Coanda effect). A well-visualized PISA hemisphere (*arrowhead*) despite a Nyquist limit of 69 cm/s is concerning for severe MR. A posteriorly directed MR usually implies either anterior leaflet prolapse or posterior leaflet tethering from inferior akinesis.

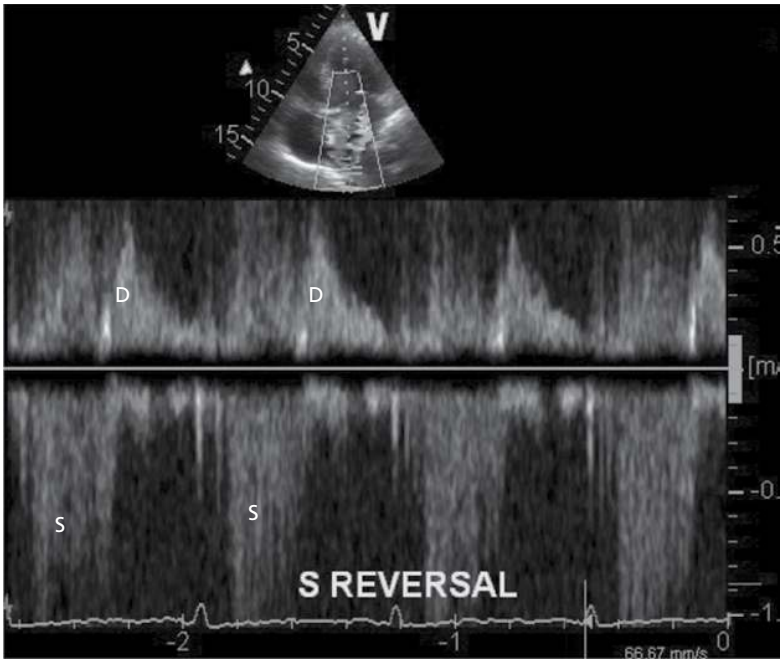

Figure 33.26 Systolic flow reversal of pulmonary venous flow in a patient with severe **MR**. Normally, S flow has the same direction as D flow.

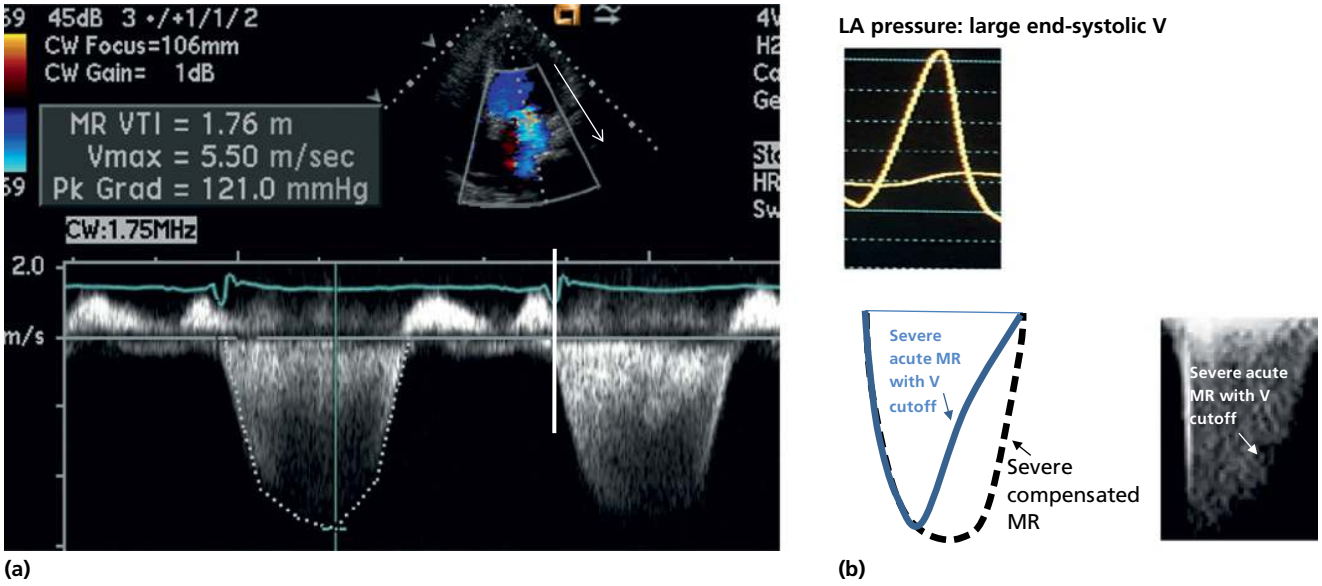

Figure 33.27 CW Doppler across the mitral valve on an apical 4-chamber view. The flow is directed backward (*arrow*) from the LV to the LA, and projects below the baseline on CW Doppler. **(a)** The backward jet is not as dense (not as white) as the forward jet, and thus MR is probably moderate. **(b)** Acute or decompensated severe MR may lead to a late indentation of the CW signal, related to a large V wave and decreased LV–LA pressure gradient at end-systole. This is called the *V-wave cutoff sign*, and leads to an early-peaking, triangular MR shape.

On the apical views, because of similarities in direction of AS and MR jets and because of beam width artifact, **AS Doppler interrogation may capture MR jet, creating the false impression of severe AS velocity.** Unlike AS, MR jet starts immediately at MV closure, immediately after the mitral inflow A wave, at the peak of R wave on the ECG (*white line*). The timing of the 2 jets and a back-and-forth sweeping of the transducer help differentiate the 2.

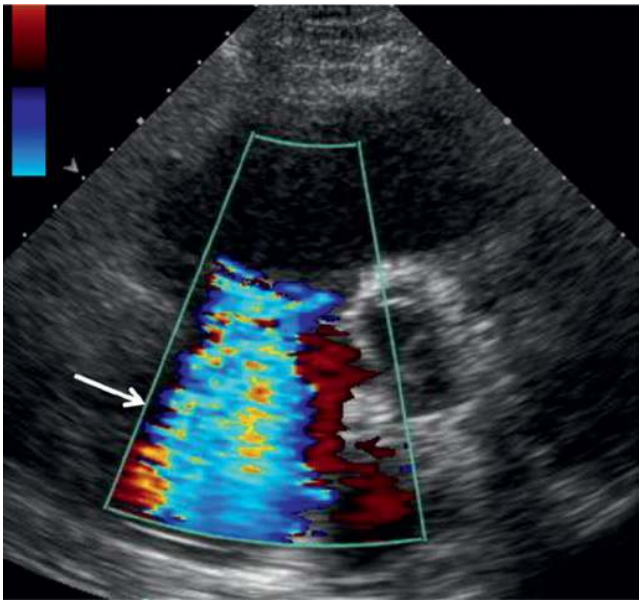

Figure 33.28 Severe TR seen from the short-axis view (aortic valve level) (*arrow*). To diagnose severe TR, use the same vena contracta, PISA radius, and ERO values as in MR (Figure 33.24), use jet area > 50% RA area, and look for hepatic vein flow reversal and RA enlargement. Annular dilatation ≥ 3.5 cm correlates with severe functional TR. The PISA radius cutoff of 0.9 cm best applies at a Nyquist limit of 28 cm/s. ERO is preferably calculated using the full equation: ERO = (PISA radius)^2 × aliasing velocity/peak regurgitant velocity. Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

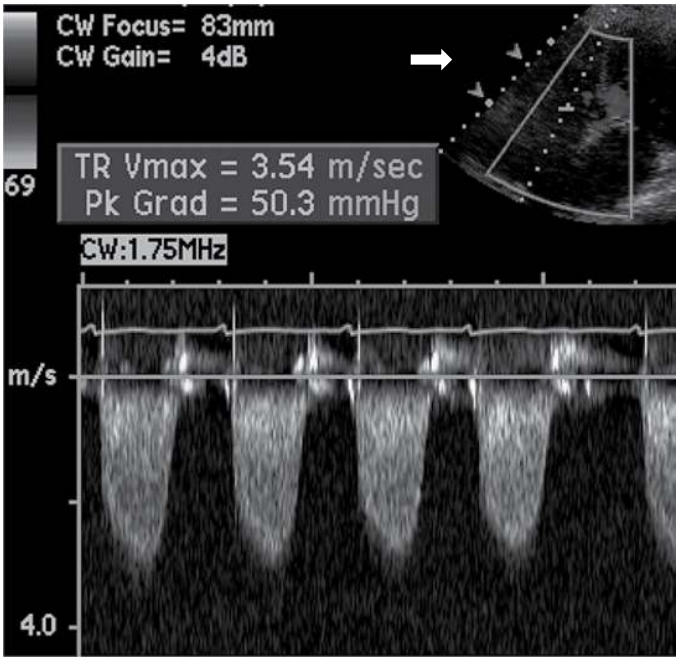

Figure 33.29 TR. CW Doppler across the tricuspid valve on a 4-chamber view (see that the line swept is on the right side, *arrow*). TR looks very dense (white) on CW Doppler, which often means large-volume moderate or severe regurgitation. A V-wave cutoff with a triangular jet would also indicate severe TR. Unlike the *density* of the regurgitation, the *peak velocity* does not correlate with the severity of the regurgitation. This peak velocity correlates with the pressure gradient between the 2 chambers (here: RV to RA), and hence PA pressure. Severe pulmonary hypertension may occur with mild, non-dense TR, yet the velocity would be high (>4 m/s); conversely, severe, dense TR may be seen with a low TR velocity when PA pressure is not elevated (e.g., primary TR).

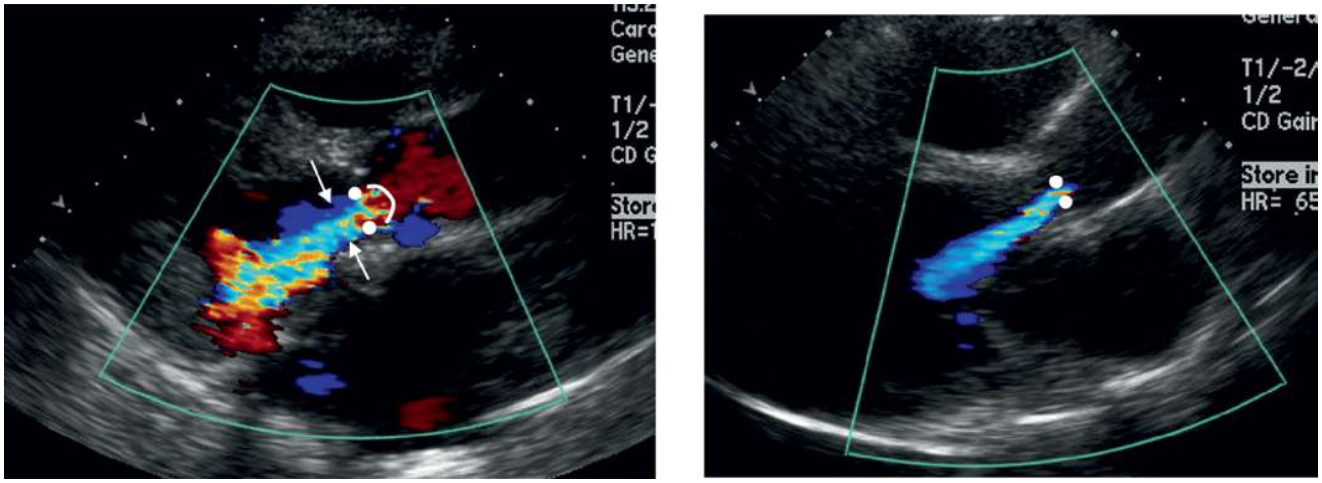

Figure 33.30 Aortic insufficiency (AI). Long-axis view shows blue–backward flow from the aorta to the LV, i.e., AI. Assess AI severity by looking at:

1. *Vena contracta*, which is the narrowest portion of the jet (between the *2 dots*, at the valve orifice). Vena contracta >6 mm implies severe AI.
2. *Width of the AI jet* just below the vena contracta, on the long-axis view (between the *2 arrows*). This is the AI size as the jet starts to expand, at the level of the leaflets' insertion site, i.e., the LVOT (within 1 cm of the vena contracta). If AI jet >60% of the LVOT diameter (which is the diameter between the 2 walls at the aortic leaflets insertion) → severe AI. AI jet width is better evaluated on the parasternal views than the apical views, which tend to falsely "widen" the AI jet.
3. *Pressure half-time* (on CW Doppler, Figure 33.33)
4. PISA in the aorta (*semi circle*). PISA radius ≥0.7 cm generally corresponds to severe AI. A Nyquist of 50–60 cm/s is used for vena contracta and jet width, while a Nyquist of 30–40 cm/s is used for PISA to enhance it.
5. *Holodiastolic reversal of flow* in the thoracic aorta (suprasternal view) or abdominal aorta (subcostal view), which is highly sensitive for severe AI (except acute AI where LV and aortic pressures equalize in end-diastole, and where, conversely, PHT becomes highly sensitive).

In **(a)**, AI is moderate; in **(b)**, AI is mild.

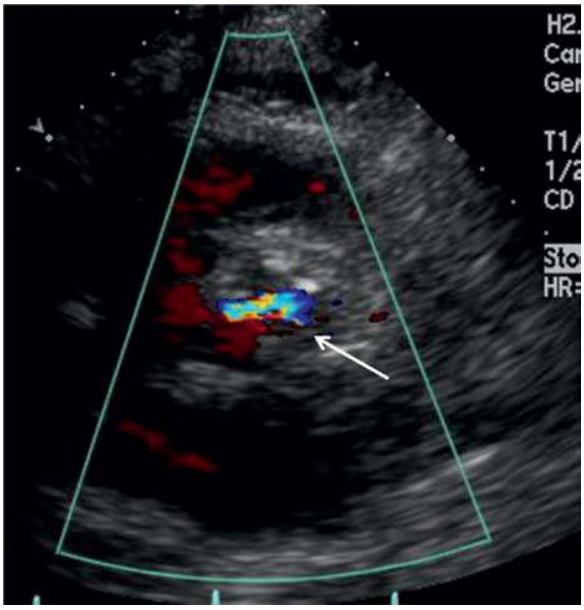

Figure 33.31 AI. The width of the AI jet may also be assessed on the aortic short-axis view. Here, look for a central blue or mixed-color "flame" in diastole (*arrow*), which corresponds to AI jet. AI jet area that is>60% of the whole aortic circle area implies severe AI. AI jet may look falsely enlarged if the cut is well below the regurgitant orifice, or falsely reduced if AI is eccentric. In order to obtain the accurate AI width, the transducer may be angled up until the AI flow is lost; the AI that is seen just before the flow is lost corresponds to the jet width. The latter maneuver is best performed on the TEE's aortic short-axis view. Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

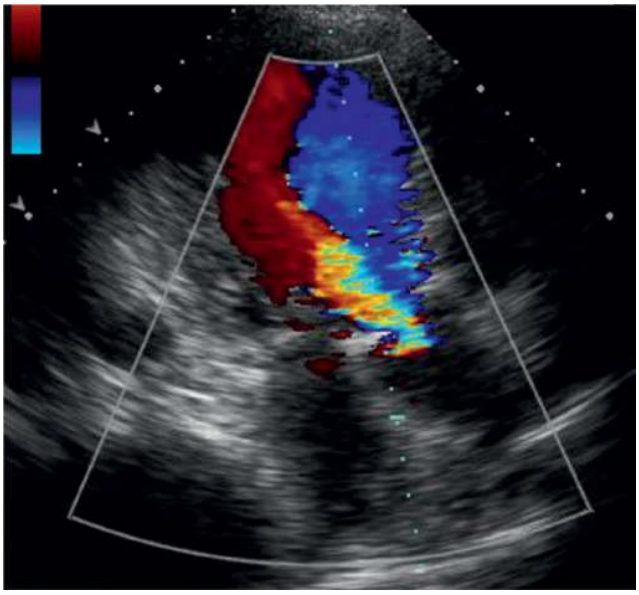

Figure 33.32 AI on 3-chamber apical view. This view is not accurate for measurement of the jet width and and is often less accurate than parasternal long axis for the vena contracta. Being parallel to the flow, it is excellent for recording of Doppler velocity and measurement of AS gradient or AI pressure half-time or AI PISA, but it is not accurate for width measurement. When assessing thickness of a structure or flow, it is best to be orthogonal to the structure or flow. Note AI's PISA, which is the spherical jet on the side of the aorta.

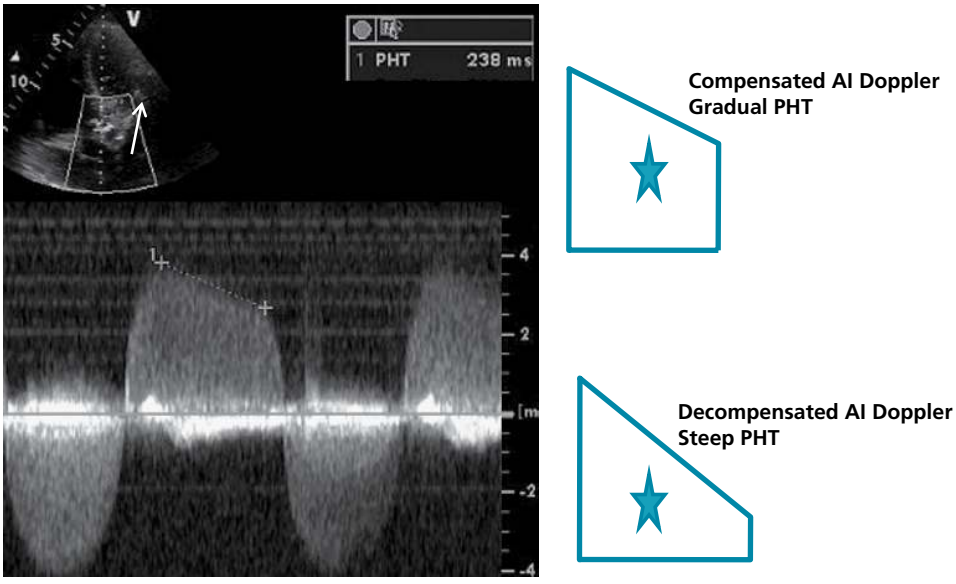

Figure 33.33 AI spectral Doppler assessment on an apical 5-chamber view. The flow between the aorta and the LV is directed upward (along the direction of the *arrow*). The slope of this regurgitant flow depends on how closely the LV and aortic pressures approximate during diastole, and thus how severe and acute AI is. The steeper the slope, the more severe and quick is the rise of LV diastolic pressure.

This is quantified by the *pressure half-time (PHT)*, which is the time needed for the pressure gradient to decrease in half. If PHT < 250 ms → steep slope → severe AI. Note, however, that a chronic severe but compensated AI with compensated LV may have PHT > 250 ms. PHT correlates more with acuity and decompensation of AI than its severity.

PHT of AI is different from PHT of MS, where a steeper slope implies less severe MS.

Also, the density of this regurgitant flow correlates with severity (the whiter it is in comparison to the forward flow, the larger the AI volume and the more severe the regurgitation).

In this case, note that the patient has severe AI with PHT < 250 ms but also significant AS, with a peak forward velocity of 4 m/s. AI exaggerates the AS velocity (increased stroke volume), while AS may exaggerate AI severity by the PHT method, as it impairs LV compliance.

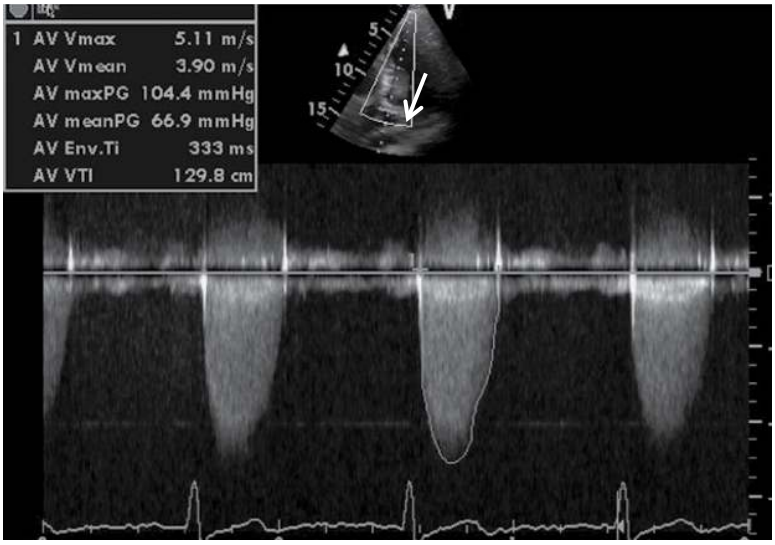

Figure 33.34 AS. CW Doppler across the aortic valve on the apical 5-chamber view. The flow directed down is the aortic flow in systole (along the direction of the *arrow*). The normal peak velocity is 1 m/s. Velocity > 2 m/s signals AS; velocity ≥ 4 m/s implies severe AS, which is the case here.

The *peak pressure gradient* may be calculated from peak velocity using the modified Bernoulli equation (= 4 V^2). The *mean pressure gradient* integrates all the gradients underneath the velocity envelope. Echo may underestimate the pressure gradient if the interrogation angle is not parallel to the flow, or if the jet envelope is incomplete (may need to increase the gain settings). Search for the best envelope and the highest gradient in multiple views (apical 5-chamber, apical 3-chamber, right parasternal, and suprasternal views).

Caution: increased CW velocity is not necessarily AS, because CW samples the highest velocity along the whole line swept and not only the aortic valve. It may be LVOT obstruction, where the velocity is increased across the LVOT rather than the aortic valve. In this case, the PW velocity is increased across the LVOT, whereas the localized aortic PW velocity is not increased (PW localizes the site of obstruction, even though it may not be able to record the exact velocity). Also, **in LVOT obstruction, the gradient peaks late and the CW velocity has a late-peaking dagger shape.**

In **low-output states,** the gradient may be low despite severe AS. Severe AS is diagnosed by using the dimensionless index (LVOT PW velocity divided by aortic valve CW velocity). Either VTI or peak velocity may be used. The index is normally ~1, and an index < 0.25 implies severe AS with AVA < 25% of normal and <25% of LVOT. DI is, in fact, a component of AVA calculation: AVA = LVOT area × DI. **If the index is >0.25, AS is likely non-severe, even if AVA measures <1 cm²** → false LVOT diameter measurement, or truly small AVA that is nonetheless >25% of the LVOT, meaning non-severe, despite being <1 cm^2.

In AF, AS velocity and gradient decrease after the shorter R–R cycles (unlike the gradient in MS). For AVA calculation, use LVOT VTI and aortic valve VTI obtained after the same R–R cycle lengths, or from a single CW aortic envelope that contains an LVOT envelope inside it. For peak/mean gradient estimation, control the rate; **since AF reduces cardiac output, AS severity is better gauged by the highest gradient (long R-R)** than by averaging down gradients.

AS gradient is often underestimated, not overestimated. AS gradient may rarely be overestimated in the case of pressure recovery, or when AS and MR jets are confused on the apical 5-chamber or 3-chamber view. MR jet starts exactly at the peak of R wave, whereas AS jet starts a bit later.

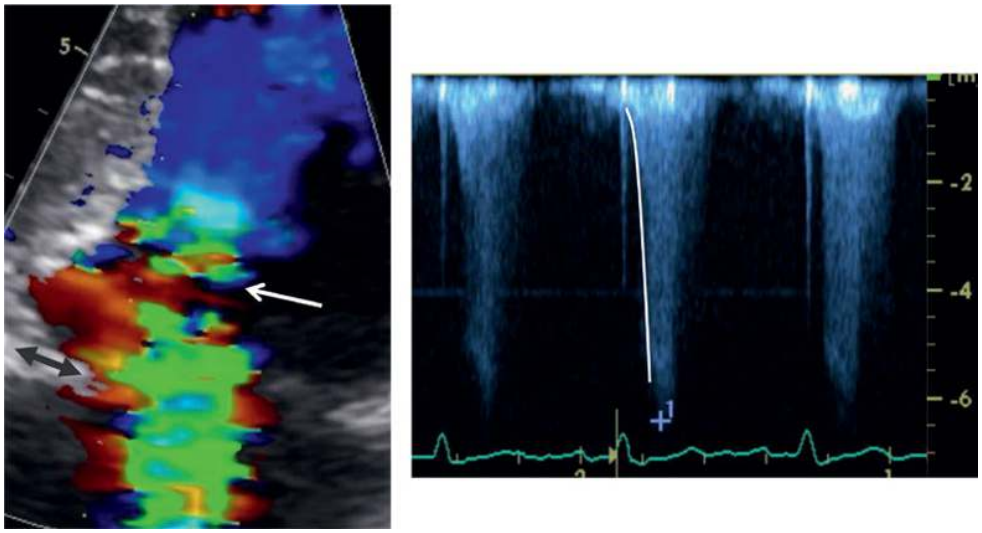

Figure 33.35 Severely increased velocity on aortic Doppler. Several features suggest LVOT obstruction rather than AS: (1) the velocity has a late-peaking dagger shape (*tilted line*), and is "skinnier" than the aortic velocity seen in Figure 33.34; (2) on color Doppler, the aliasing (*arrow*) occurs below the aortic valve level (*double arrow*). **To confirm LVOT obstruction, PW Doppler may be swept throughout the LVOT and the aortic valve. PW Doppler cannot record velocities over 1.5–2 m/s, but it will indicate that the velocity is increased across the LVOT rather than the aortic valve. Exact assessment of the velocity with CW ensues.**

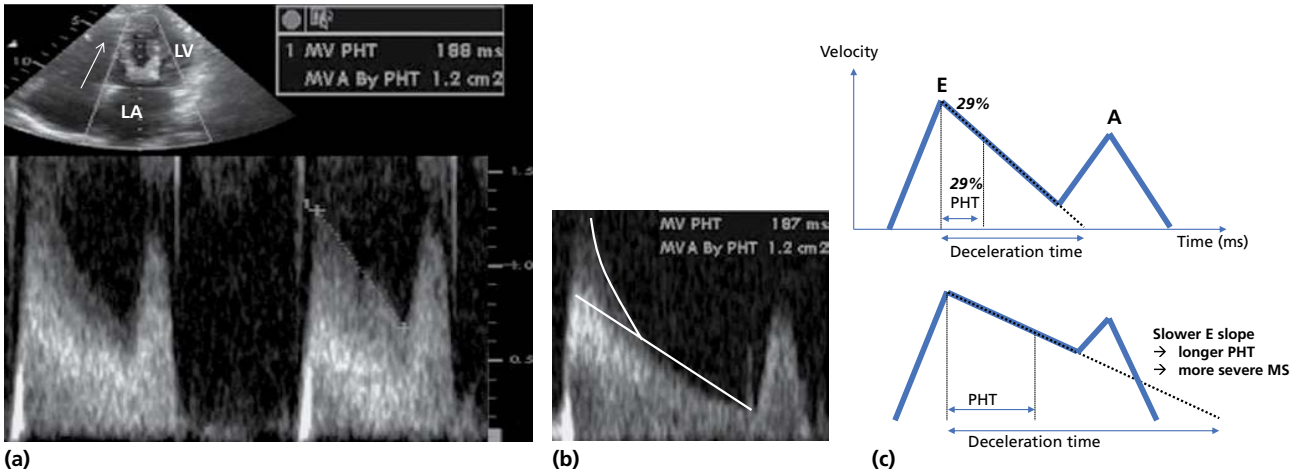

Figure 33.36 MS assessment.

(a) CW Doppler across the mitral valve (MV) on the apical four-chamber view. The flow is directed from the LA (which is down on this view) to the LV (up) along the direction of the *arrow.* A mean gradient >10 mmHg at rest, or 15 mmHg with exercise, corresponds to severe MS. ***Passive leg raising should be performed to assess stress gradient.*** *CW, not PW, should be used to capture the gradient.*

The downslope of the rapid diastolic filling (E wave, first wave) may be used to estimate MV area: a slow downslope that never touches the baseline means that LA pressure does not equalize with LV pressure even in late diastole (no diastasis), which corresponds to severe MS. The ***pressure half-time*** is the time it takes the pressure gradient to decrease in half [i.e., time it takes E velocity to decrease by 29%], and ***is long in severe MS***. MV area = 220 divided by pressure half-time. However, for the same valve area, LA and LV pressures more readily converge if LV diastolic pressure is elevated (AI, severe LVH): this makes the downslope look steeper → MV area will be seemingly larger and MS will be seemingly less severe. Even so, while the E downslope may be steeper, *it does not touch the baseline in severe MS* (diastasis is not reached).

High E wave may merely result from MR or HF and when MAC coincides, this high E may be falsely considered high gradient and MS. Unlike MS, E wave of the latter cases has a sharp downslope that touches the baseline (i.e., there is LA-LV diastasis).

(b) If E wave has a "ski slope" shape (i.e., initially steep then slow downslope), use the slow downslope portion to calculate the pressure half-time. When MS is associated with MR or high-output state, the early E velocity and the overall gradient increase, but the later E slope remains unchanged.

In AF, the pressure gradient varies between different beats (↑ with short R–R cycles, as LA emptying decreases), but the shape and slope of the CW envelope remain unchanged. Mean gradient increases as in any tachycardia (or exercise), but pressure half-time and MV area remain unchanged.

(c) Pressure half-time (PHT) is the time it takes peak pressure gradient to decline in half, which corresponds to the time it takes peak velocity to decline by 29%. It may be calculated as 0.29 × deceleration time, with deceleration time being the time it takes for the E velocity slope line to drop from peak to the extrapolated 0 on the *x* axis.

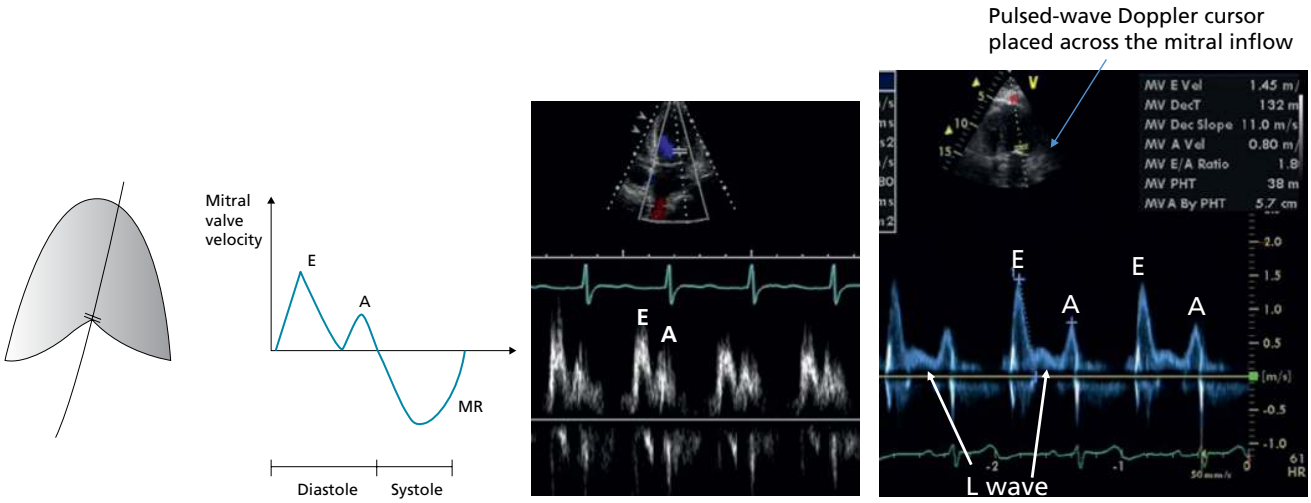

Figure 33.37 PW Doppler at the mitral leaflets' tips. During diastole, forward flow is recorded across the MV: E is the rapid diastolic filling, A is the filling related to atrial contraction. E occurs after T wave, while A occurs after P wave and almost coincides with QRS. E height positively correlates with LA pressure and with LV relaxation.

(*Right-most image*) Between E and A velocity waves, there is normally a phase of diastasis with minimal transmitral flow. On this image, however, a third wave called L-wave occurs between E and A, indicating severely increased LA pressure with continuous flow throughout diastole. The high E velocity >1.2 m/s, high E/A ratio >1.5–2, and narrow E (DT <160 ms) further suggest that.

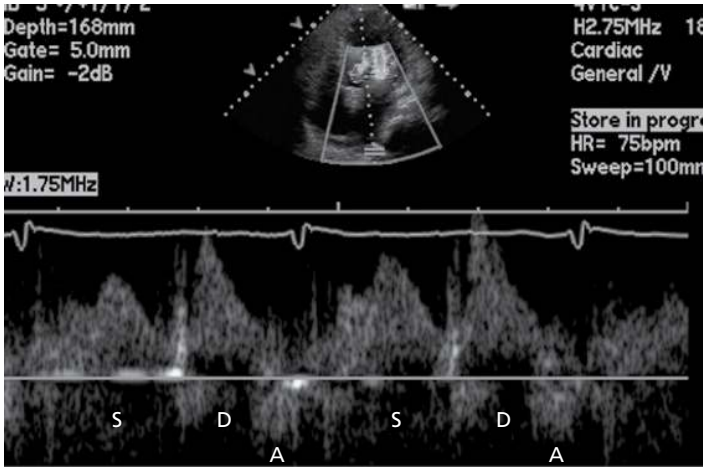

Figure 33.38 PW Doppler across the pulmonary veins on a 4-chamber view, these veins being behind the LA (*cursor*). S and D represent, as it is seen, forward systolic and diastolic flow toward the LA. A wave corresponds to atrial systole, when LA pressure increases and prevents forward pulmonary venous flow: A is a reversed flow wave. Normally, S is slightly > D or slightly < D. A severely reduced S wave implies elevated LA pressure.

The hepatic venous flow on the subcostal view looks similar to the pulmonary venous flow (S, D, A), except that S and D waves are below the baseline, whereas A wave is above the baseline.

4. Tissue Doppler assesses the movement of cardiac structures rather than blood flow (Figures 33.39, 33.40)

Tissue Doppler is useful to assess:

a. Mitral annular velocities during diastole (E′ and A′). E′ is the annular recoil toward the base during early diastolic filling; A′ is the annular recoil during atrial systole. Lateral E′ is normally ≥10 cm/s, medial E′ is ≥7 cm/s. The reduction of E′ indicates diastolic dysfunction or high left-sided filling pressures.

b. Dyssynchrony of various myocardial segments, manifested as different times from QRS onset to peak systolic velocity (or peak strain) between different walls. The assessment of mechanical dyssynchrony is particularly useful in patients with low EF and QRS 130–150 ms, as it may help identify the responders to biventricular pacing. In patients with HF and QRS < 130 ms, the use of echocardiographic dyssynchrony for identifying potential responders to biventricular pacing has not shown any value.

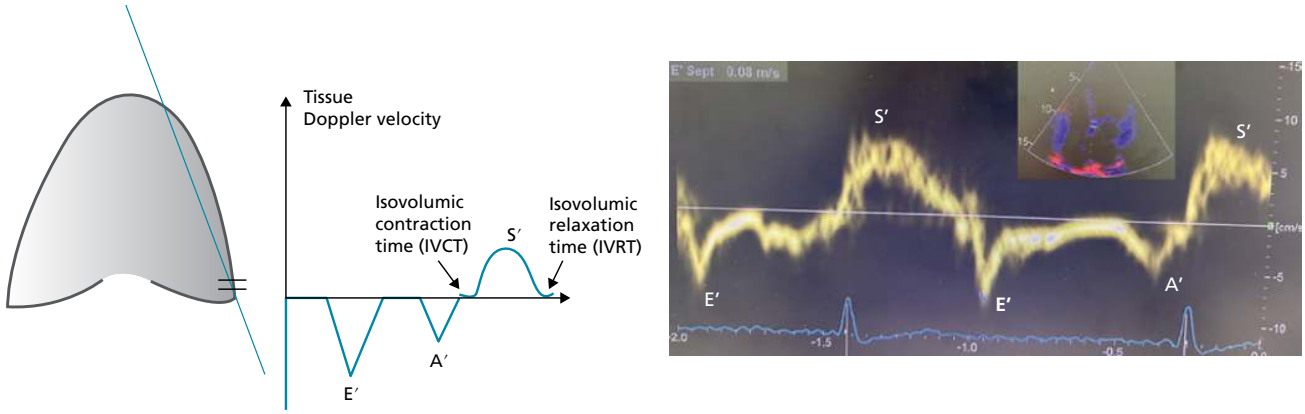

Figure 33.39 Myocardial tissue Doppler at the level of the mitral annulus. The cursor is placed on the myocardial lateral or medial annulus. E′ and A′ waves occur in diastole, on the downward negative side: E' corresponds to early diastolic LV recoil, and A' corresponds to LV recoil during the atrial kick (backward annular motion). Lateral E′ annular velocity is usually higher than medial E′. Measure both lateral and medial E′, and calculate E/E′ for each E′, and for the average E′.

The cursor should be positioned within 0.5 cm of the leaflet insertion site and should be parallel to the plane of cardiac motion.

E' declines with LV stiffening. A', like A, may rise or decline in LV diastolic dysfunction. A', like A, declines when LA pressure is elevated, as LV pre-A pressure would be elevated and LA cannot further empty in the LV. A', like A, may rise when pre-A LV pressure is normal but there is diastolic dysfunction.

In systole, a forward positive motion S' occurs: it is ≤ 7 cm/s in systolic dysfunction. Furthermore, in myocardial dysfunction (systolic or diastolic), IVCT and IVRT increase, leading to an increase of the following ratio: (IVCT + IVRT)/ejection time (ejection time corresponds to S′ time). This ratio, called myocardial performance index or Tei index, may be calculated using myocardial annular Doppler and is normally < 0.4.

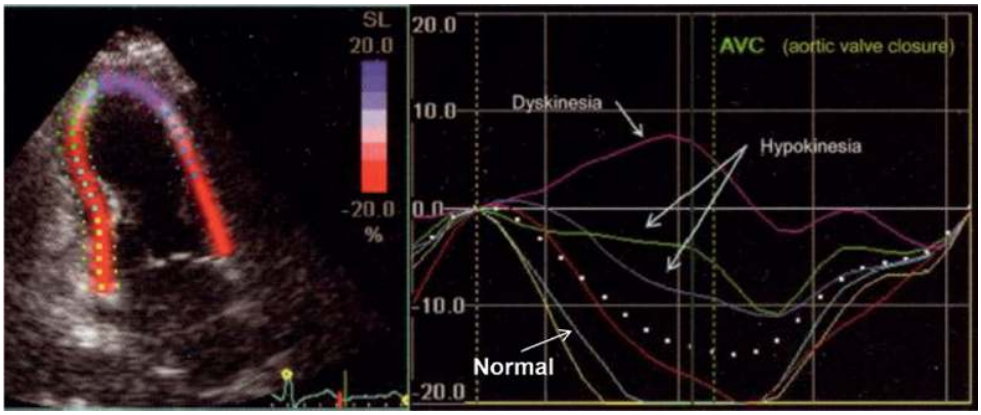

Figure 33.40 2D tissue strain imaging of the LV on a 2-chamber view. Strain between 2 myocardial points = % change in distance between the 2 points = ($\text{distance}_{\text{between these points in systole}} - \text{distance}_{\text{in diastole}}$)/$\text{distance}_{\text{in diastole}}$. Normal regional strain values are –20 to –12; abnormal values are –8 to +20. The red color corresponds to normal strain, while the blue/purple corresponds to abnormal strain. In this figure, the antero-apex is blue and therefore dysfunctional.

The time display (*right image*) shows the peak systolic strain of each segment and the strain curve throughout systole then diastole; the segment moving in the opposite direction to the baseline is a dyskinetic segment (apex). Courtesy of Carmen Ilie and Fred Helmcke, who provided this image.

c. Occult or manifest myocardial dysfunction. The *radial* myocardial *displacement*, *velocity*, and *strain* can be determined on the short-axis view; the *longitudinal* displacement, velocity and strain can be determined on the apical views. A dysfunctional segment may get pulled and displaced by a normal adjacent segment; therefore, a normal displacement or velocity of one myocardial segment does not necessarily imply normal function. Myocardial strain, on the other hand, assesses the percent change in distance between 2 points, i.e., myocardial deformation, and the strain rate assesses the change in velocity between 2 points. Myocardial strain allows an accurate determination of segmental function and may be determined using tissue Doppler or better yet today, automated ultrasound tissue imaging called speckle tracking (Appendix).

The global ventricular function may also be simply and routinely assessed using annular tissue Doppler. On the annular Doppler, S′ is the forward systolic movement of the annulus in systole (longitudinal fibers). S′ ≤ 7 cm/s correlates with LV systolic dysfunction. At the tricuspid annulus, S′ < 10 cm/s correlates with RV systolic dysfunction.

C. Routine Doppler calculations

1. Volume and flow calculations

Volume and flow can be derived from velocity using the ***continuity equation***, which states that blood volume that crosses a cardiac area during one cardiac cycle = area × VTI. Thus:

$$\text{Blood volume} = \pi r^2 \times \text{VTI} = 0.785 \times d^2 \times \text{VTI}\ (\text{r is radius, d is diameter})$$

Per second flow across a structure = blood volume crossing this structure per cardiac cycle *divided by* ejection duration, i.e., VTI duration

Stroke volume is equal to: $0.785 \times \text{LVOT } d^2 \times \text{LVOT VTI}$

Cardiac output is equal to: stroke volume × heart rate

2. Aortic valve area (AVA) calculation using the continuity equation

$$\text{AVA} \times \text{aortic velocity (aortic peak velocity or aortic VTI on CW Doppler)}$$
$$= \text{LVOT area} \times \text{LVOT velocity (LVOT peak velocity or LVOT VTI on PW Doppler)}$$

LVOT diameter should be measured at the insertion of the aortic valve leaflets (i.e., at the annulus, not below it), parallel to the leaflets' plane, in early systole (largest diameter). A falsely low LVOT measurement is a common cause of a falsely low AVA.

3. Calculation of the systolic PA pressure using the TR jet

Capture of TR jet by CW Doppler is necessary for the calculation of PA pressure. While many normal individuals have mild TR that allows this calculation, over 50% of patients, including some patients with severe pulmonary hypertension, do not have an adequate TR jet envelope.

According to the Bernoulli equation, the pressure difference between RV and RA in systole equals $4 \times V_{TR}^2$.

Thus, RV systolic pressure = $4 \times V_{TR}^2$ + RA pressure. In the absence of pulmonic stenosis, RV systolic pressure is equal to PA systolic pressure.

4. Assessment of RA pressure

RA pressure is assessed on the basis of IVC diameter and inspiratory collapse:

i. IVC ≤ 2.1 cm with >50% inspiratory collapse → RA pressure = 0–5 mmHg

ii. IVC ≤ 2.1 cm but <50% inspiratory collapse,
or IVC > 2.1 cm with >50% inspiratory collapse → RA pressure = 5–10 mmHg

iii. IVC > 2.1 cm with <50% collapse → RA pressure ≥15 mmHg, or ≥20 mmHg if 0% collapse. Also, even in the intermediate category (ii), if the collapse is ~0% or if the systolic flow of the hepatic veins is blunted, RA pressure is severely elevated.

IV. Summary of features characterizing severe valvular regurgitation and stenosis (see Tables 33.1, 33.2)

Table 33.1 Severe valvular regurgitation.

Mitral regurgitation

1. **Jet area > 50% of LA area *or* eccentric jet swirling around the LA wall (Coanda effect),** at a Nyquist limit of 50–60 cm/s and a proper color gain.
   Pros: area <20% makes severe MR very unlikely
   Cons: eccentricity reduces jet area; low color gain and high Nyquist falsely reduce the jet area. Conversely, inappropriately high color gain and low Nyquist limit falsely increase the jet area.
2. **Vena contracta ≥7 mm** at a Nyquist limit of 50–60 cm/s. Vena contracta is the narrowest part of the regurgitant flow, i.e., the neck at the origin of MR.
   Pros: accurate, even in eccentric MR. Vena contracta < 3 mm makes severe MR unlikely.
   Cons: does not reliably distinguish moderate from severe MR. Also, should be measured in a view orthogonal to the regurgitation (parasternal long-axis), not an apical view, which tends to falsely widen the vena contracta. It is not accurate if multiple jets are present.
3. **Flow convergence**
   - **PISA radius ≥ 0.9 cm** (regurgitant Nyquist limit set at 40 cm/s)
   - **ERO ≥ 0.4 cm²**. ERO = (PISA radius)² × aliasing velocity/peak regurgitant velocity
   - **Regurgitant volume ≥ 60 ml/beat** (regurgitant volume = ERO × MR VTI). May also be calculated using volumetric method
   - **Regurgitant fraction = regurgitant volume/(regurgitant volume + stroke volume at the LVOT) ≥ 50%**

   Cons: may underestimate MR if jet is eccentric (but better than jet area in this case), if multiple jets are present, or if PISA convergence is squashed rather than round (crescentic PISA), as in functional MR with dilated LV. Thus, 0.3 cm² is a better ERO cutoff in functional MR. It may overestimate MR if convergence is not a full hemisphere.
4. **Mitral E-wave velocity > 1.2 m/s**
   Pros: very sensitive, regardless of eccentricity. A lower E velocity or E/A reversal ~ excludes severe MR.
   Cons: not specific. E velocity increases with high LA pressure and AF.
5. **Pulmonary venous flow:** Blunted S is consistent with severe MR, reversed S is specific for severe MR
   Cons:
   - Blunted or reversed S may not be seen in compensated severe MR, where LA compliance absorbs the regurgitant flow and prevents pulmonary venous abnormalities
   - Blunted S may be seen with high LA pressure or AF, and is not specific for severe MR
   - All 4 pulmonary veins must be sampled on TEE (eccentric MR flow may enter and reverse the flow of 1 pulmonary vein only)
6. **CW MR Doppler as dense as the forward mitral flow; *or* dense and triangular with early peaking (V wave cutoff)**, indicative of decompensation. This supports severe MR, but dense flow may also be seen with moderate MR
7. **A flail leaflet** is highly specific for severe MR, regardless of color Doppler findings (**only feature that does not rely on Doppler**). A leaflet is flail when its *tip*, not just its body, is prolapsed in the LA with free motion.

Important supportive features

- LA enlargement is universal in all severe MR, except, occasionally, acute MR. A normal LA size ~ excludes severe MR except in the acute setting
- LV enlargement, particularly with normal EF, strongly supports severe MR (not as sensitive as LA enlargement, which occurs earlier)
- If MR appears severe yet LA is not enlarged, it is possible that MR is not holosystolic. A large MR jet with a large PISA is not severe MR if the regurgitation is brief, as seen sometimes with mitral valve prolapse (end-systolic) or functional MR from LV dyssynchrony (early systolic). PISA and ERO are large, but MR VTI and regurgitant volume are not. MR duration is evaluated by CW Doppler or by color M-mode across the mitral valve.

Aortic insufficiency

1. **Vena contracta width (narrowest neck at the origin of AI on the long-axis view) ≥ 7 mm**. Is a surrogate of **ERO** area (3D vena contracta area ~ ERO)
   AI jet width ≥ 60–65% of LVOT diameter (long-axis view)
   AI jet cross-sectional area ≥ 60% of LVOT area (short-axis view) at a Nyquist limit of 50–60 cm/s
   Note: AI jet size is different from vena contracta. AI jet size is the AI size just below the vena contracta, as the jet starts to expand (at the level of the LVOT, i.e., the leaflets' insertion site, within 1 cm of the vena contracta)
   Cons: eccentric AI, such as bicuspid AI, may be underestimated by jet width, because the jet abuts the mitral valve or the septum and shrinks in velocity (color). Color Doppler correlates with velocity more than volume; the regurgitant volume may be high, yet color may abate quickly. This is even more so when assessed in a 2D plane where it is narrowest (in the long-axis view). Conversely, AI may be overestimated when the measurement is performed too low below the vena contracta, or in the apical views
   Vena contracta remains accurate in eccentric jets, but must be measured perpendicular to the eccentric direction of AI rather than in line with the aortic valve, typically in the parasternal long-axis view.
2. **Flow convergence (PISA): ERO ≥ 0.3 cm² on parasternal or apical 3- or 5-chamber views. PISA radius ≥ 0.7 cm (Nyquist 40 cm/s)**
   Regurgitant volume ≥60 ml/beat using volumetric method (or less commonly ERO method)
   Regurgitant fraction ≥50%
   Cons: the rounded flow convergence is more difficult to measure in AI than in MR, as it is shadowed by the thick +/– calcified aortic leaflets. It may be used in eccentric AI in the parasternal view.
3. **CW Doppler pressure half-time (PHT) < 250 ms**
   Cons: depends on LV compliance and LVEDP. PHT may be >250 ms in chronic, compensated severe AI. PHT may be <250 ms in moderate AI with decompensated LV dysfunction and high LVEDP (e.g., severe HTN) or with stiff aorta causing rapid decay of aortic pressure. Also, vasodilators may reduce diastolic aortic pressure and thus, PHT.
   PHT > 500 ms ~ excludes severe AI
4. ***Holo*diastolic flow reversal in the descending aorta (suprasternal view) or, worse, in the abdominal aorta (subcostal view).** An end-diastolic velocity ≥20cm/s in the descending thoracic aorta is particularly specific. This is assessed by PW Doppler. Early to mid-diastolic reversal suggests moderate AI.
   Cons: reversal may attenuate (may no longer be holodiastolic) in acute severe AI and in high LVEDP, where, conversely, PHT is severe. Reversal may be exaggerated in non-compliant elderly aortas, in addition to AV fistula and high-output states, all being conditions that exaggerate the severity of AI PHT as well (any cause of wide pulse pressure and loss of dicrotic notch).
5. **Other features**
   - **CW Doppler signal as dense as the forward flow.** Cons: significant overlap between moderate and severe AI
   - **M-mode of the mitral valve shows leaflet fluttering or early closure**. This not only indicates severe AI but decompensated AI

Important supportive feature

- LV enlargement is universal in chronic severe AI. However, the LV may only be enlarged relative to the patient's baseline, or may only be mildly enlarged. LA enlargement is very common in severe AI

Table 33.1 (Continued)

Tricuspid regurgitation (same type of features and limitations as MR)

1. Large jet area >50% of RA or >10 cm² (Nyquist limit of 50–60 cm/s)
2. Vena contracta >7 mm (Nyquist limit 50–60 cm/s)
3. PISA radius >0.9 cm (at a Nyquist limit of 28 cm/s), with ERO ≥0.4 cm^2 and regurgitant volume ≥45 ml
4. TR jet dense ± triangular with early peaking (V-wave cutoff)
5. Hepatic venous S blunting, or, worse, reversal (reversal is specific for severe TR)

RA/IVC size is always increased in severe chronic TR. RV is dilated and elongated-elliptical in ventricular-functional TR, whereas the RV body is typically non-dilated and conical in atrial-functional TR; the tricuspid annulus is dilated >35-40 mm in both (Figure 6.26).

Severe TR is further subclassified into **massive TR** and **torrential TR** (vena contracta >14 and 21 mm, ERO >0.6 and 0.8 cm^2, and regurgitant volumes >60 and 75 ml, respectively) (Triluminate trial criteria).

Pulmonic regurgitation

- As opposed to AI, where the *jet width* below the neck determines severity, in PR, the *jet length* and the total jet area in the RV correlate with severity. In severe PR, the color jet goes deep into the RV, beyond the RVOT (use a large Doppler sector to visualize). In mild PR, the jet length is <1 cm
- CW Doppler: *dense* PR signal with *steep* deceleration and termination of PR flow in mid-diastole (severe PR leads to equalization of PA and RV diastolic pressures in mid-diastole). This early termination of PR flow may, however, be seen when milder PR is associated with severe RV failure and elevated RVEDP

RV is enlarged in chronic severe PR. In a patient with significant PR, RV enlargement without any other cause suggests severe PR

Meeting 4 criteria of severity establishes severe regurgitation, whereas 2–3 criteria usually imply severe regurgitation, although moderate regurgitation is possible (quantitative assessment with ERO area and regurgitant volume and fraction are particularly relevant in the latter case). In general, color Doppler criteria and vena contracta are assessed at a Nyquist of 50–60 cm/s, while flow convergence is measured at a lower Nyquist of 30–40 cm/s to magnify and visualize a rounded PISA and measure its radius.

Table 33.2 Severe valvular stenosis: severe AS, including low-gradient AS, and severe MS.

Aortic stenosis

Peak velocity ≥ 4 m/s, mean gradient ≥ 40 mmHg, and AVA ≤ 1 cm^2 by continuity equation[a]

Typically, in severe AS:

- Peak LVOT velocity is <1 m/s
- LVOT velocity/aortic valve velocity ≤ 0.25 (dimensionless index [DI]). DI is, in fact, a component of AVA calculation (AVA = LVOT area × DI). As opposed to AVA calculation, the dimensionless index is not subject to the bias of LVOT diameter measurement: DI ≤0.25 implies AVA ≤25% of normal

LVOT velocity may be >1 m/s when severe AS is associated with moderate AI or high-output states (anemia, fever), cases in which DI remains <0.25

Both LVOT velocity and DI may be falsely increased if the LVOT cursor is placed too close to the aortic valve, in the aliasing: this particularly occurs when severe AS is associated with significant septal bulge and subaortic obstruction, in which case LVOT velocity should be captured further away from the aortic valve and the septal bulge, before the flow acceleration.

Differential of paradoxical low-gradient AS with normal EF (AVA ≤ 1 cm^2 with low gradient < 40 mmHg):

- Echo mismeasurements (50%), particularly under-measurement of LVOT diameter or aortic velocity. A high DI (>0.3) generally rules out truly severe AS.
- Low-flow, low-gradient truly severe AS: hypertension and concentric LV hypertrophy explain the low output. AF also ↓ CO and gradient.
- Normal-flow, low-gradient truly severe AS: low gradient is related to misalignment of AVA and gradient cut-points in the guidelines (AVA of 1 cm^2 corresponds to a gradient of ~30 mmHg if CO = 5.5 L/min); or bradycardia

AS is likely severe if AVA ≤ 0.8 cm^2 with mean gradient >30 mmHg, or if DI ≤0.25.

Mitral stenosis (see Section VIII.C)

- Mild and moderate MS: MVA > 1.5 cm^2, gradient usually <5–10 mmHg at a normal heart rate (60–85 bpm)
- Severe MS: MVA 1.0–1.5 cm^2, gradient usually ≥10 mmHg at a normal heart rate. E downslope is ***slow*** and ***never touches the baseline*** (no LA-LV diastasis)
- Very severe MS: MVA < 1.0 cm^2, gradient usually >15 mmHg

Doppler assesses the transmitral gradient very accurately, as it is easy to align the cursor with the transmitral flow. Caveats:

(i) High E wave may merely result from MR or HF and be falsely interpreted as high gradient, and when MAC coincides, be falsely considered MS. The E wave of the latter cases has a sharp downslope and touches the baseline, which corresponds to LA-LV diastasis on catheterization.

(ii) A high gradient does not necessarily imply severe MS: **mild anatomic MS (MVA > 1.5 cm^2) may have a severe gradient in the presence of *tachycardia or high-output state***, but E downslope is unchanged and remains relatively steep. Thus, (i) **the shape of the E wave,** (ii) **the failure of E velocity to touch the baseline,** and (iii) **MVA** characterize the anatomic severity of MS better than the gradient.

The estimation of MVA using 1 of 4 methods (mitral inflow pressure half-time, continuity equation, PISA method, and planimetry) is subject to measurement errors. Pressure half-time may falsely ↓ and MVA may falsely ↑ in patients with LV dysfunction (HTN, elderly): nevertheless, E wave does not touch the baseline.

[a]AVA = (0.785 × LVOT diameter²) × LVOT velocity/aortic valve velocity.

LVOT is assumed to be circular, but it is in fact elliptical and underestimated. LVOT diameter should be measured at the insertion of the aortic valve leaflets (= annulus), rather than 5–10 mm below it (LVOT is largest and most circular at the annulus). LVOT is measured in the long-axis view, in early systole (largest diameter, inner edge to inner edge). In the presence of protruding annular calcification, LVOT measurement is extended beyond the outer edge of the calcification.

LVOT velocity is obtained by positioning the pulsed Doppler ~5 mm proximal to the stenotic valve (not too close to the valve). Avoid catching the high-velocity convergence proximal to the aortic valve. In case of septal bulge, place the cursor further down, away from the bulge. Either VTI or peak velocity may be used.

V. M-mode echocardiography

M-mode echocardiography is derived from 2D echo (see Figures 33.41–33.43; also Figures 33.15–33.18).

M-mode graphically displays the movement of cardiac structures along one line swept by the probe. It can assess valvular opening, chamber size, and subtle abnormalities of cardiac motion (such as RV compression by pericardial effusion). It has a very high temporal resolution and rapid sampling rate (1000 frames/s vs. 30/s for 2D) that allows recording of **subtle motion *and* timing of cardiac events.**

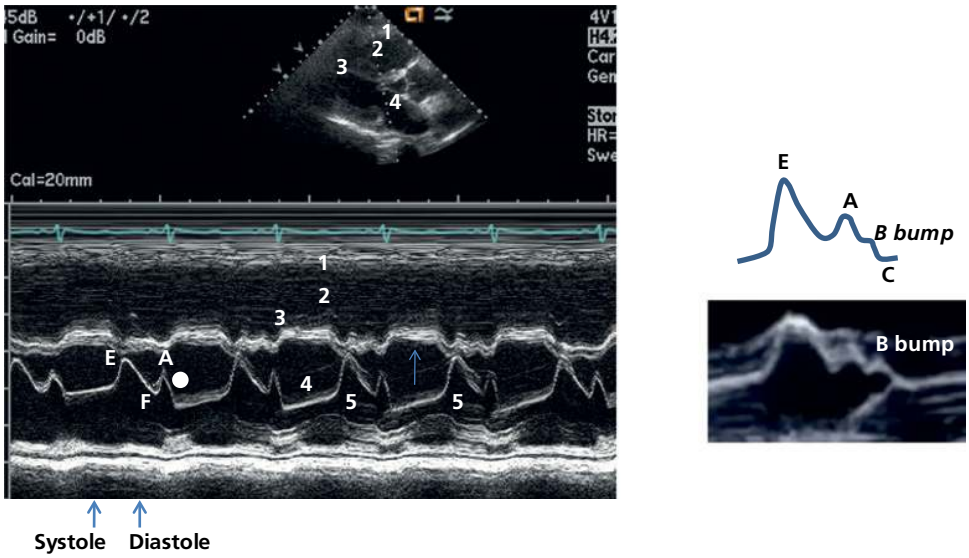

Figure 33.41 M-mode across the mitral valve on the parasternal long-axis view. The first structure intercepted, at the top, is the RVOT wall (white line); the second structure is the RV cavity (dark); the third structure is the septum; the fourth structure is the anterior leaflet of the MV (closes in systole and opens in diastole), and the fifth structure is the posterior mitral leaflet.

The anterior mitral leaflet has 2 waves in diastole: E (rapid filling) and A, similar to the mitral inflow Doppler. Examples of disease states:

- In MS, the E-wave downslope becomes flat horizontal (flat EF slope), and the posterior leaflet is drawn to the anterior leaflet.
- In high LVEDP, there will be a small extra wave (B bump) interrupting A emptying in the LV (at the location of the *dot*). B bump is shown on the *right images*.
- In SAM, the anterior leaflet will be drawn to the septum in end-systole or, worse, all systole (in the direction of the *arrow*).
- In severe AI, one may have early closure of the mitral valve or diastolic mitral fluttering.
- In tamponade, early diastolic inward indentation of the RVOT is seen.

By moving the interrogation line toward the mid LV, the systolic movement of the septum and the LV posterior wall can be assessed (see Figures 33.15–33.18).

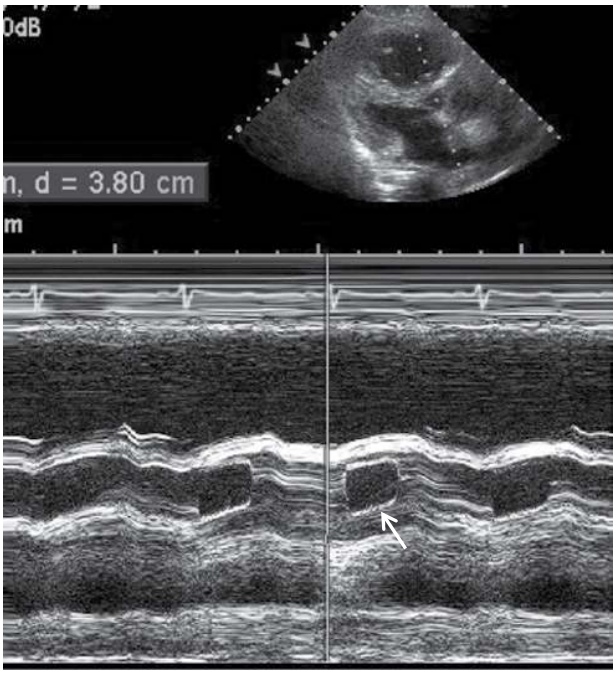

Figure 33.42 M-mode across the aortic valve on the long-axis view. The first structures encountered are the RVOT wall and cavity. Then the aortic walls (rather than LV walls) are encountered and, inside them, the aortic valve. The aortic valve opens well here (open box in systole [*arrow*]). Disease states:

- In severe AS, the box becomes flat. In bicuspid aortic valve, the line of closure in diastole is eccentric.
- In HOCM, there is mid-systolic notching (partial closure) of the box.
- In low cardiac output, there is early gradual closure of the aortic valve (the box becomes a triangle: >).
- In severe AI, the aortic valve may start opening in end-diastole, as LVEDP rises and equalizes with aortic diastolic pressure.

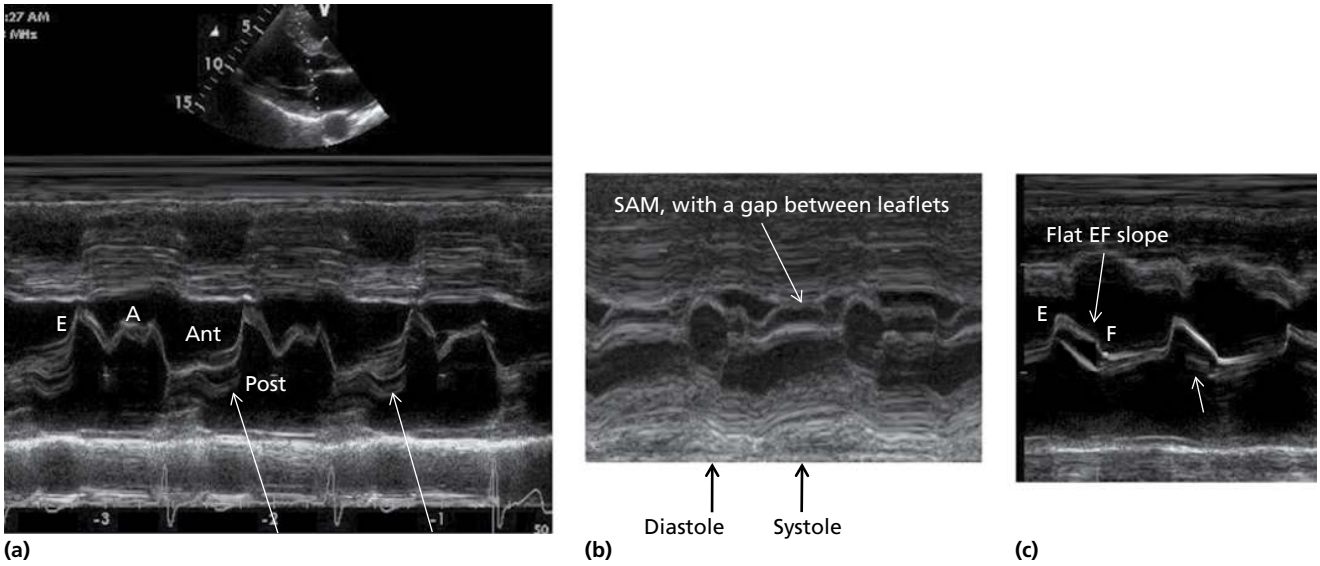

Figure 33.43 Examples of M-mode across the mitral valve. (a) Posterior mitral leaflet prolapse. See how the posterior leaflet moves posteriorly in mid-to-late systole, creating a "gap" in the mitral closure, and thus MR (*arrows*). **(b)** SAM of the anterior leaflet in HOCM, with the anterior leaflet touching the septum in systole, creating a gap away from the posterior leaflet. **(c)** Flat EF slope in diastole suggests MS (mitral valve is steadily open throughout diastole, with no diastasis). Also, the posterior leaflet is pulled toward the anterior leaflet (commissural fusion) (*arrow*). Ant, anterior mitral leaflet; Post, posterior mitral leaflet.

VI. Pericardial effusion

A. Size (see Figures 33.44, 33.45)

A pericardial effusion is small if <1 cm, moderate if 1–2 cm, and large if >2 cm. The effusion is measured as the summation of the anterior and posterior dimensions at end-diastole, i.e., when it appears *smallest*. A small effusion is usually localized posteriorly, while a large effusion is usually circumferential. A swinging heart, i.e., a heart that changes position in a phasic manner, may be seen with large effusions. An echo-free space that is present only anteriorly suggests an epicardial fat pad rather than a pericardial effusion; unless loculated, a pericardial effusion usually gravitates and predominates posteriorly in the supine position, or is circumferential.

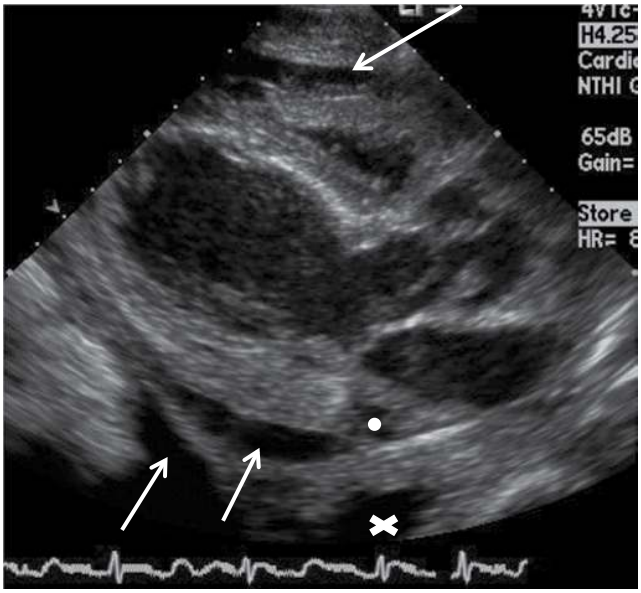

Figure 33.44 Diffuse pericardial effusion on long-axis view, identified as a black band above the RV (*upper arrow*) and a black band posterior to the LV. In this case, posterior to the LV, there are 2 black bands separated by the pericardium: pericardial effusion and pleural effusion (*lower arrows*). Differentiate pleural from pericardial effusion: the pericardial effusion is anterior to the descending aorta (*X*), whereas the pleural effusion extends behind the aorta. The coronary sinus is in the AV groove, anterior to the pericardium (*dot*). Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

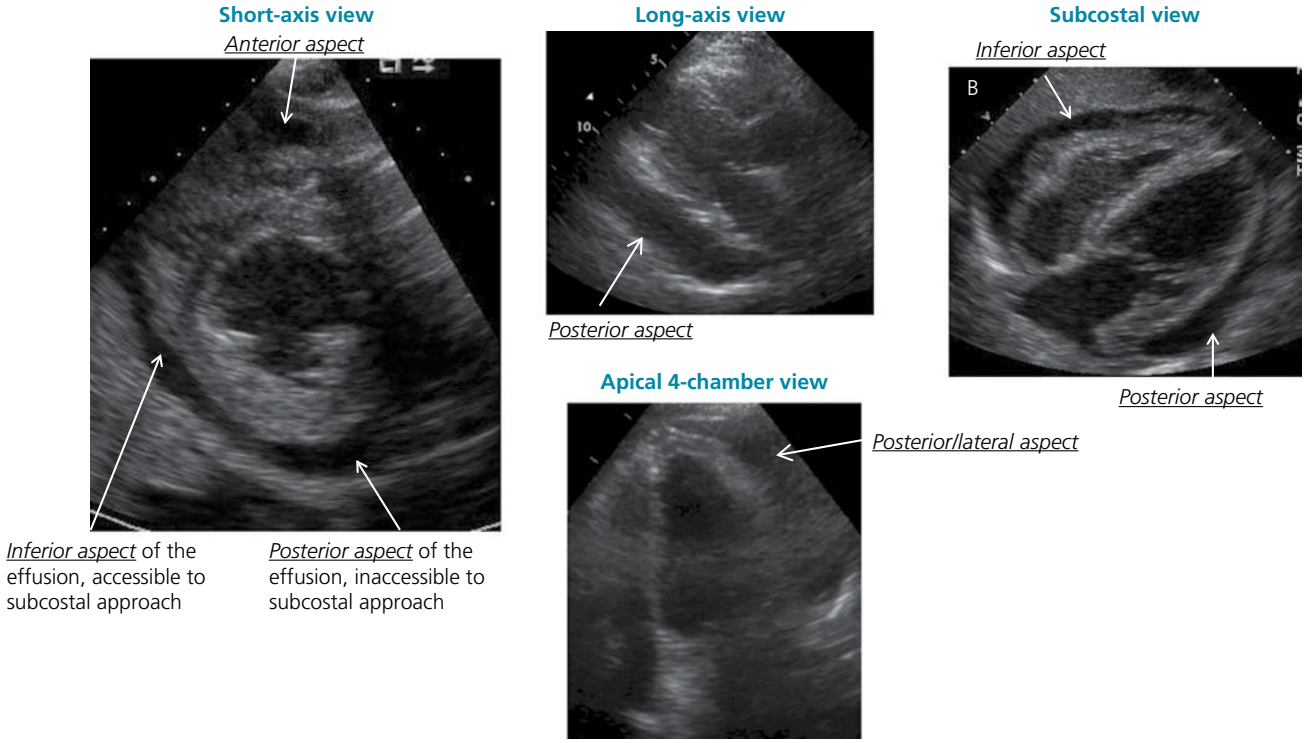

Figure 33.45 Pericardial effusion on multiple views. In a supine position, a free-flowing effusion gravitates and predominates over the posterior aspect of the LV. The posterior aspect is the one seen on the long-axis view (posterolateral aspect) and the 4-chamber view. This has to be distinguished from the effusion at the inferior/diaphragmatic aspect of the LV, which is more anterior and is the one seen on the subcostal view (used for subcostal pericardiocentesis).

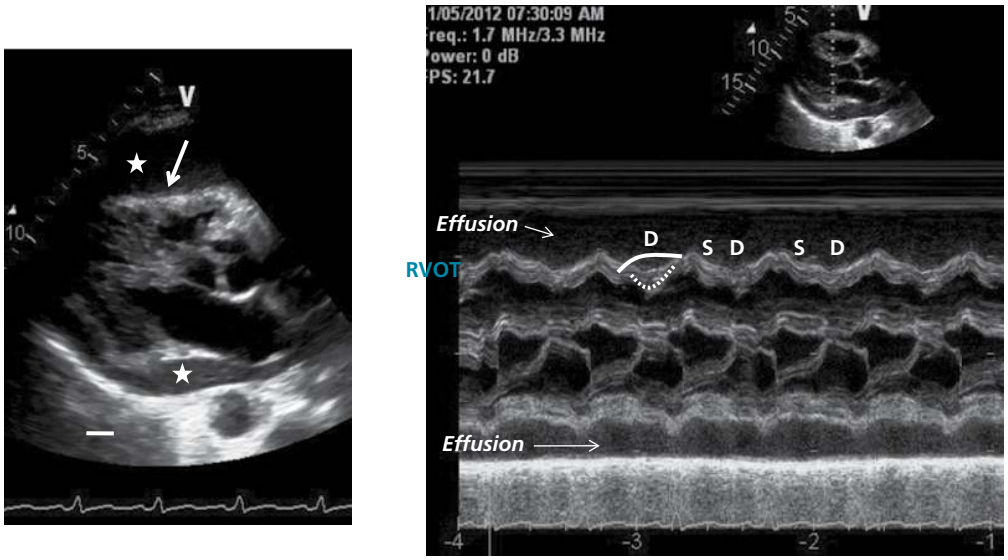

(a) **(b)**

Figure 33.46 (a) Pericardial effusion (*stars*) and pleural effusion (*bar*). The latter is behind the level of the descending aorta. RVOT is compressed in diastole, at a time when the mitral valve is open (RVOT diastolic indentation is marked by *arrow*).

(b) RVOT collapse in early diastole on M-mode. Always time events to the ECG; systole starts at the peak of R wave and occupies the ST–T segment, whereas diastole starts beyond the T wave. Events may also be timed to the mitral opening on M-mode. After the systolic dip, the RVOT should be expanding outward in diastole (as in the *solid line*), rather than pushed inward (*dashed line*). The presence of 2 dips, a systolic dip and a diastolic dip soon after the RV starts to expand out, is characteristic of tamponade. *For the diastolic dip to be diagnostic, the M-mode has to cut the RVOT in an orthogonal fashion*. D, diastole; S, systole.

B. IVC plethora

IVC plethora has a sensitivity of 97% for tamponade, but a specificity of only 40%, as it may occur with any right heart failure. On hepatic vein Doppler, ***a flat D wave*** (Y descent) —with expiratory reversal— corresponds to impeded right-sided diastolic filling and thus tamponade.

C. Pre-tamponade echocardiographic signs (see Figure 33.46)

- RV compression in early diastole. On M-mode, the RV continues to collapse after systole (inward indentation), while the LV is expanding. This is the most specific and latest tamponade sign. RVOT gets compressed earlier than the remaining RV walls.
- RA compression during ventricular systole. RA collapses excessively during atrial systole, then stays inward after atrial systole. RA collapse that persists for >1/3 of cardiac cycle is specific for tamponade.
- >25% inspiratory decrease of mitral inflow E velocity and aortic velocity (variation of 25% in reference to the highest E velocity, not the lowest). This is due to the LV compression by the RV. This Doppler finding is the corollary of pulsus paradoxus. *Make sure to track E wave, not A.*
- >40% expiratory decrease of tricuspid inflow E velocity.

Respiratory E variations are the earliest and least specific pre-tamponade findings, as they may be seen in any dyspnea with deep respiratory pressures. They are followed by progressive RA/RV collapse.

Tamponade is a clinical diagnosis. The echocardiographic signs appear earlier than clinical tamponade and pulsus paradoxus; they suggest hemodynamic abnormalities that are the substrate for tamponade, but on their own they do not establish the diagnosis of tamponade.

Tamponade may occur as a result of a localized effusion compressing one particular chamber, such as RV, LV, LA, RA, or pulmonary veins, as after cardiac surgery. This is more difficult to diagnose, and only some of the tamponade echocardiographic signs are seen. TEE may be more helpful in showing the localized effusion and cardiac chamber compression (e.g., isolated pulmonary venous compression).

VII. Echocardiographic determination of LV filling pressure and diastolic function

A. Main parameters

(see Chapter 5, Figure 5.2)

Diastolic E flow and E/A ratio-Diastolic E flow is affected by: (1) LA pressure, (2) LV relaxation, which is impaired in both diastolic dysfunction and systolic dysfunction, and (3) heart rate and PR interval. Impaired LV relaxation reduces E velocity; however, severe hypovolemia with low left-sided filling pressure may reduce E and E/A ratio even in the absence of a relaxation problem. Prolonged PR interval and sinus tachycardia reduce E and E/A ratio and may be associated with E–A fusion without any relaxation problem. On the other hand, high left-sided filling pressures but also high elastic recoil in normal young patients may elevate E velocity. In general, high E/A ratio ≥2 in patients older than 40 years indicates severely elevated LA pressure, except post-AF cardioversion when A is small from LA stunning.

One echocardiographic parameter correlates solely with LV relaxation and is thus reduced in any LV dysfunction, systolic or diastolic, regardless of filling pressure: mitral annular recoil velocity (E′). Therefore:

$$E / E' = (\text{LA filling pressure} \times \text{LV relaxation}) / \text{LV relaxation} = \text{LA filling pressure}$$

E/E′ ratio strongly correlates with LA pressure in both systolic and diastolic dysfunction. E/E′ ratio > 14 is strongly indicative of LV failure and high LA pressure. E/E′ and E deceleration time are still reliable in case of atrial fibrillation, where measurements should be averaged from 3 non-consecutive beats with cycle lengths within 20% of the average heart rate. E′ value may be obtained from the septal or lateral side of the mitral annulus on the 4-chamber view; septal E′ is normally lower than lateral E′, as the septal annulus is fibrous and tethered to the intervalvular fibrosa. Both values should be used and averaged and usually trend in the same direction. E/E' is calculated for septal and lateral E', and for average E' (the so-called average E/E'). E' and E/E′ have pitfalls in some contexts (Table 33.3). E' is reduced in all HF cases **except possibly the following 4**: AF, high-output HF, MR, and medial E' in constriction.

LA enlargement is a hallmark of diastolic dysfunction. It indicates that LA pressure is elevated *or* was elevated at some point, not necessarily now. LA remains enlarged for some time after normalization of a previously elevated LA pressure; this is similar to deflating a balloon that has been inflated for some time (it remains wrinkled and larger than baseline). Outside LV dysfunction, LA is enlarged in persistent AF, morbid obesity (high output state), and mitral disease. Conversely, LA size may be normal in mild, compensated diastolic dysfunction.

Table 33.3 Pitfalls of E' and E/E′ in the evaluation of LA pressure.

1. **Cases where E′ is inherently reduced and E/E′ does not correlate with LA pressure**
   - Mitral stenosis, prosthetic mitral valve, mitral ring, severe mitral annular calcification
2. **Case where E′ is inherently increased**
   - (i) AF, (ii) high-output HF, (iii) severe primary MR. E/E' may not correlate with LA pressure in severe MR with normal EF.
3. **Cases of discrepancy between medial and lateral E′**
   - Error in acquisition[a]
   - Constrictive pericarditis: increased septal E′, reduced lateral E′[b]
   - Severe pulmonary hypertension[c]

[a]Cursor should be positioned within 0.5 cm of the septal or lateral mitral leaflet insertion site and should be in line with the plane of annular motion, otherwise E' will be falsely reduced.
[b]In constrictive pericarditis, the LV lateral and anteroposterior expansion is constricted with a compensatory increase in septal expansion.
[c]Septal E′ is reduced regardless of LV failure because of reduced RV contribution to septal velocity. Lateral E′ and lateral E/E′ correlate with LV failure and should be used instead.

B. Other parameters that correlate with left-sided filling pressure

- *S and D on pulmonary venous flow.* The more depressed the systolic S wave, the higher the LA pressure. Patients with elevated LA pressure have a large V wave and a deep Y descent; X descent, on the other hand, is flattened and pulled up by the large V. This explains the large D wave (D = Y) and the flat S (S = X).
- *Isovolumic relaxation time (IVRT).* IVRT is prolonged (>110 ms) with stage 1 diastolic dysfunction, and reduced (<70 ms) with more advanced diastolic dysfunction and high LA pressure (in which case the intersection of LA and LV pressures occurs earlier). IVRT is calculated using 3- or 5-chamber CW across an LVOT line close to the aortic-mitral curtain that simultaneously displays the aortic ejection and the onset of mitral inflow (IVRT=interval between the end of aortic ejection and E onset).
- *E deceleration time (DT) (time it takes the E velocity to fall from peak to zero).* A reduced DT < 160 ms implies a high LA pressure that quickly equalizes with LV pressure.
- *B bump on M-mode.* B bump corresponds to a high LVEDP interrupting LA emptying in the LV during A wave (reverse motion of the mitral leaflets in end-diastole, Figure 33.41).
- L lump on the mitral inflow is a positive wave between E and A that implies very high LA pressure: E wave is narrow as LV quickly rises in pressure and stops accepting LA flow, but then restarts accepting LA flow as LA keeps filling and rising in pressure, particularly in bradycardia (Figure 33.37). A small L wave <40 cm/s may rarely be seen in normal individuals with bradycardia.
- *M-mode swept across the mitral valve in apical four-chamber view, with color Doppler recording (color M-mode).* Normally, the colored diastolic inflow looks, roughly, like a steep vertical line ("a flame"). A reduction of the steepness of this line with a velocity of propagation (Vp) < 45 cm/s signifies diastolic dysfunction (any grade). E/Vp > 2.5 correlates with increased LA pressure.
- All these parameters correlate with LA pressure. Only B bump and pulmonary vein A reversal amplitude and duration correlate with LVEDP: pulmonary vein A amplitude >35 cm/s and (pulmonary vein A duration) minus (mitral valve A duration) >30 ms correlate with elevated LVEDP even at a stage of normal LA pressure (compensated LV dysfunction). Rising LVEDP interrupts LV filling during A wave, hence mitral A duration is shortened, and retrograde A flow increases. This parameter is useful regardless of EF, mitral disease, or HCM.
- A and A' may rise or decline in LV diastolic dysfunction. A and A' decline when LA pressure is elevated, as LV pre-A pressure would be elevated as well and LA cannot further empty in the LV during A contraction. A and A' may rise in case of normal pre-A LV diastolic pressure with exclusive post-A LV elevation, i.e., exclusively high LVEDP.
- Strain may be applied to the LA myocardium. LA *reservoir strain* is LA strain during ventricular systole and is normally positive (as LA expands). The less positive it is (<18%), the more overwhelmed LA compliance is (preventing LA expansion), and the more LA pressure rises.
- In severe MR, E increases and E' recoil increases. E/E' still correlates with LA pressure if EF is reduced. Otherwise, IVRT and (pulmonary vein A duration) minus (mitral valve A duration) correlate with increased left pressures, regardless of EF.
- In AF, both E and E' increase to compensate for the loss of atrial kick, but E' rises more. Medial E/E' ratio of 11 instead of 15 correlates with elevated LA pressure, besides a low DT <160 ms or a low IVRT (average values from several cardiac cycles).
- In MAC, diastolic function is inherently impaired as MAC shares the same risk factors as diastolic dysfunction. E' is inherently low, but MAC precludes its accurate measurement and the use of E/E'. The measured E' is low but inaccurate. To assess LA pressure, it is best to use the E/A ratio (<0.8: normal, >1.8: high) or IVRT(<80 ms → high LA pressure)..

C. Putting it all together (Figures 33.47, 33.48)

When assessing LV function, a clinician is often faced with 2 problems: (1) In patients with normal EF, is there any LV diastolic dysfunction, whether compensated or not? (2) In patients with normal or abnormal EF, is LA pressure elevated, and does the patient have a diagnosis of heart failure as opposed to just LV dysfunction? Note that a high LA pressure establishes the diagnosis of diastolic dysfunction in patients with normal EF. Conversely, diastolic dysfunction is not always associated with increased LA pressure at rest.

D. Assess the volume status and cardiac output of critically ill patients

- The following findings suggest high left-sided filling pressures: high E/A ≥2, high E/E' with a small E', low/flat systolic wave on the pulmonary vein flow, high PA pressure.
- LV cavity collapse, with or without high LVOT velocity, suggests hypovolemia. However, this may be seen in patients with a stiff, restricted myocardium and volume overload.
