Set in 8.5/10.5pt FrutigerLTStd-Light by Straive, Pondicherry, India

To the believers in the true essence of medicine: deep, soulful knowledge intertwined with humanity—in the midst of an increasingly regulated and automated world that, at times, feels soulless and Kafkaesque

To my mother Marie, my sister Eliana, and my beloved nephew Marc-Elias and nieces Clara and Elya, the true constants of my life

Contents

Preface, xix
Abbreviations, xx
About the Companion Website, xxiii

PART 1. **Coronary Artery Disease,** 1

1. **Non-ST-Segment Elevation Acute Coronary Syndrome,** 1

I. Definition, types of myocardial infarction, and pitfalls, 1
II. Clinical features, ECG, cardiac biomarkers, and echocardiography in ACS, 7
III. Initial approach to acute chest pain presentations and the use of high-sensitivity troponins, 9
IV. Management of NSTEMI, 11
V. General procedural management after coronary angiography: PCI (culprit and non-culprit), CABG, or medical therapy only, 15
VI. Discharge medications in NSTEMI, 16
VII. Prognosis, 19
Appendix 1. Multivessel obstructive (>50%) disease in NSTEMI: How to identify the culprit stenosis, 20
Appendix 2. Management according to the severity of angiographic stenosis in NSTEMI: How to manage intermediate stenoses (50–70%), 21
Appendix 3. Women and ACS, elderly patients and ACS, CKD, 22
Appendix 4. Bleeding, transfusion, patients on chronic warfarin or NOAC, gastrointestinal bleed, 23
Appendix 5. Antiplatelet and anticoagulant therapy, 24
Appendix 6. The 3 main types of plaque disruption: plaque rupture, plaque erosion, and eruptive calcified nodule, 27
Appendix 7. Spontaneous coronary artery dissection, 27
Appendix 8. Harmful effects of NSAIDs and cyclooxygenase-2 inhibitors in CAD, 30
Appendix 9. Additional ideas on the physiology of hs-troponin: Role of hs-troponin in primary prevention, 31
Questions and answers, 31

2. **ST-Segment Elevation Myocardial Infarction,** 45

1. Definition, reperfusion, and general management, 46
I. Definition, 46
II. Timing of reperfusion, 46
III. ECG phases of STEMI, 47
IV. STEMI diagnostic tips and clinical vignettes, 48
V. Subtle STEMI and occlusion MI, 49
VI. Specific case of new or presumably new LBBB, 51
VII. Reperfusion strategies: fibrinolytics, primary PCI, and combined fibrinolytics–PCI, 52
VIII. Late presenters: coronary angiography and PCI later than 24 hours after presentation, 56
IX. Angiographic findings, PCI, and cellular reperfusion; multivessel disease in STEMI, 58
X. Antithrombotic therapies in STEMI, 59
XI. Other acute therapies, 59
XII. Risk stratification, 60
XIII. LV remodeling and infarct expansion after MI, 61
XIV. Discharge, EF improvement, ICD, 61
2. STEMI complications, 62
I. Cardiogenic shock, 62
II. Mechanical complications, 65
III. Recurrent infarction and ischemia, 68
IV. Tachyarrhythmias, 68
V. Bradyarrhythmias, bundle branch blocks, fascicular blocks, 70
VI. LV aneurysm and LV pseudoaneurysm, 71
VII. Pericardial complications, 71
VIII. LV thrombus and thromboembolic complications, 73
IX. Early and late mortality after STEMI, 73
Appendix 1. Out-of-hospital cardiac arrest: role of early coronary angiography and therapeutic hypothermia, 73
Questions and answers, 77

3. **Stable Ischemic Heart Disease and Approach to Chronic Chest Pain,** 91

I. Causes of angina and pathophysiology of coronary flow, 91
II. Diagnostic approach, 92
III. Is there a role for screening asymptomatic patients and post-PCI patients?, 96
IV. Plaque burden vs. coronary stenosis. Management of asymptomatic high coronary calcium score, 97
V. Medical therapy: antithrombotic therapy, antianginal therapy and risk factor control, 97
VI. Indications for revascularization, 100
VII. CABG and CABG vs. medical therapy, 101
VIII. PCI and PCI vs. medical therapy, 101
IX. PCI vs. CABG in multivessel and left main disease, 102
X. High-surgical-risk patients, 104
XI. Role of complete functional revascularization, 104
XII. Hybrid CABG–PCI, 104
XIII. Enhanced external counterpulsation (EECP), 105
XIV. Mortality in CAD, 105
Appendix 1. Notes on various surgical grafts, 105
Appendix 2. Coronary vasospasm (variant angina, Prinzmetal angina), 107
Appendix 3. Microvascular endothelial dysfunction, 109
Appendix 4. Women with chest pain and normal coronary arteries, 110
Appendix 5. Diagnostic strategy for ischemia with non-obstructed coronary arteries (INOCA), 110
Appendix 6. Myocardial bridging, 111
Appendix 7. Coronary collaterals, chronic total occlusion, 111
Appendix 8. Hibernation, stunning, ischemic preconditioning, 112
Appendix 9. Coronary steal phenomenon, 112
Questions and answers, 113

PART 2. **Heart Failure (Chronic and Acute Heart Failure, Specific Cardiomyopathies, and Pathophysiology),** 125

4. **Heart Failure,** 125

Definition, Types, Causes, and Diagnosis of Heart Failure, 126
1. Definition and types of heart failure, 126
I. Heart failure is diagnosed clinically, not by echocardiography, 126
II. After HF is defined clinically, echocardiography is used to differentiate the three major types of HF, 127
III. Two additional types of HF, 129
2. Causes of heart failure, 129
I. Systolic HF or HF with reduced EF (HFrEF), 129
II. HF with preserved EF (HFpEF), 131
III. Right HF, 133
3. Diagnostic tests, 133
I. Echocardiography, 133
II. BNP, 134
III. ECG, 135
IV. Coronary angiography and other ischemic tests, 135
V. Diastolic stress testing, 136
VI. Endomyocardial biopsy, 136
VII. Cardiac MRI, 136

Chronic Treatment of Heart Failure, 136
1. Treatment of systolic heart failure, 136
I. Treat the underlying etiology: target BP and AF, 136
II. Value of revascularization in ischemic cardiomyopathy: STICH trial and REVIVED-BCIS-2 trial, 137
III. Limited value of viability testing, 138
IV. Drugs that affect survival in EF ≤40%, 138
V. Specifics of drugs that affect survival, 139
VI. Drugs that improve symptoms and morbidity, 144
VII. AF ablation and transcatheter mitral edge-to-edge repair (MitraClip) dramatically reduce mortality in HFrEF, 146
VIII. Devices, 147
IX. Other therapeutic measures, 148
X. Prognosis, 148
2. Treatment of HFpEF, 149
3. Treatment of HFmEF, 151

Acute Heart Failure, 151
I. Triggers of acute decompensation, their diagnosis and treatment, 152
II. Profiles of acute HF: congestion without low cardiac output, congestion with low cardiac output, 153
III. Treatment of acute HF: diuretics, cardiorenal syndrome, aggressive decongestion, ultrafiltration, 154
IV. Treatment of acute HF: vasodilators, 158
V. Treatment of acute HF: IV inotropic agents, 158
VI. In-hospital and pre-discharge use of ACE-I/ARB, angiotensin-neprilysin inhibition, β-blockers, mineralocorticoid antagonist, and SGLT-2 inhibitors, 160
VII. Treatment of acute HF: O_2, non-invasive ventilatory support (CPAP, BIPAP), intubation, 160
VIII. Summary: keys to the treatment of acute HF, 161
IX. Discharge, 161
X. Inability of severe HF to tolerate vasodilatation or hemodialysis, 161
XI. Outpatient monitoring of HF and prevention of hospitalization, 161
Appendix 1. Management of isolated or predominant RV failure, 162
Questions and answers, 164

5. **Additional Heart Failure Topics,** 184

1. Specific cardiomyopathies, 184
I. Arrhythmia-induced cardiomyopathy, 184
II. Viral myocarditis, 186
III. Acute eosinophilic myocarditis, 187
IV. HIV cardiomyopathy, 187
V. Chagas disease, 187
VI. Sarcoidosis, 188
VII. LV non-compaction, preferably called: Excessive LV trabeculation, 188
VIII. Takotsubo and other stress-related cardiomyopathies, 189
IX. Infiltrative restrictive cardiomyopathy: Amyloidosis, 189
X. Other infiltrative restrictive cardiomyopathies, 191
2. Advanced heart failure: heart transplant and ventricular assist devices (VADs), 192
I. Stages of HF, 192
II. Cardiac transplantation, 192
III. Left ventricular assist devices (LVADs), 194
3. Pathophysiology of heart failure and hemodynamic aspects, 196
I. LV diastolic pressure in normal conditions and in HF (whether systolic or diastolic), 196
II. Definition of afterload, 196
III. Cardiac output, relation to preload and afterload, 197
IV. LV pressure–volume relationship in systolic vs. diastolic failure: therapeutic implications, 198
V. Optimal heart rate in HF, 200
VI. Mechanisms of exercise intolerance in HF, 200
VII. Pressure–volume (PV) loops, 201
VIII. Additional features of HF with preserved EF, 201
IX. High-output HF, 202
X. Peripheral interplay of venous volume, arterial volume, interstitial volume, and lymphatic drainage in HF, 202
XI. "Hypervolemia and edema with intravascular volume depletion" is often an incorrect concept, 203
Questions and answers, 204

PART 3. **Valvular Disorders,** 213

6. **Valvular Disorders,** 213

1. Mitral regurgitation, 214
I. Mechanisms of mitral regurgitation, 214
II. Specifics of various causes of mitral regurgitation, 214
III. Assessment of MR severity, 220
IV. Natural history and pathophysiology of organic MR, 221
V. Treatment of organic (primary) MR, 221
VI. Treatment of secondary MR (ischemic and non-ischemic functional MR), 223
VII. Treatment of acute severe MR related to acute MI, 225
VIII. Percutaneous mitral valve repair technical ideas (transcatheter edge-to-edge repair), 225
2. Mitral stenosis, 225
I. Etiology and natural history, 225
II. Diagnosis, 226
III. Treatment, 230

3. Aortic insufficiency, 233
I. Etiology, 233
II. Pathophysiology and hemodynamics, 234
III. Diagnosis, 236
IV. Natural history and symptoms, 236
V. Treatment, 236
4. Aortic stenosis, 238
I. Etiology, 238
II. Echo and catheterization diagnosis, pitfalls, and hemodynamics, 239
III. Low-gradient AS with aortic valve area (AVA) ≤1 cm^2 and low EF <50%, 241
IV. Low-gradient AS with aortic valve area (AVA) ≤1 cm^2 but normal EF: paradoxical low-flow/ low-gradient severe AS *and* normal-flow/low-gradient severe AS, 242
V. Pressure recovery phenomenon, 243
VI. Symptoms, 244
VII. Natural history, 244
VIII. AS should be differentiated from subvalvular and supravalvular AS in children or young adults, 245
IX. Treatment, 245
5. Tricuspid regurgitation and stenosis, 248
I. Etiology of tricuspid regurgitation (TR), 248
II. Natural history of TR, 251
III. Treatment of TR, 251
IV. Tricuspid stenosis, 252
6. Pulmonic stenosis and regurgitation, 253
I. Pulmonic stenosis (PS), 253
II. Pulmonic regurgitation (PR), 253
7. Mixed valvular disease; radiation heart disease, 253
I. Mixed single-valve disease, 253
II. Multiple valvular involvement (combined stenosis or regurgitation of two different valves), 254
III. Radiation heart disease, 254
8. Prosthetic valves, 254
I. Bioprosthesis versus mechanical prosthesis, 254
II. Determinants of valve degeneration and valve thrombosis; anticoagulation guidelines, 256
III. Particular cases: women who wish to become pregnant and dialysis patients, 257
IV. Echocardiographic follow-up of prosthetic valves, 257
V. Complications, 257
9. Auscultation and summary ideas, 260
I. Auscultation and other physical findings, 260
II. General ideas and workup, 263
Questions and answers, 264

PART 4. **Hypertrophic Cardiomyopathy**, 283

7. **Hypertrophic Cardiomyopathy – Athlete's Heart,** 283

I. Definition and features of HCM, 283
II. Natural history and mortality, 285
III. Symptoms and ECG, 286
IV. Exam, 286
V. Invasive hemodynamic findings, 286
VI. Echocardiographic findings, 287
VII. Provocative maneuvers, 288
VIII. Genetic testing for diagnosis; screening of first-degree relatives, 288
IX. Differential diagnosis of LVOT obstruction, 289
X. Differential diagnosis of severe LV hypertrophy, 289
XI. Treatment of symptoms, 290
XII. Treatment: sudden cardiac death risk assessment and ICD therapy, 293
XIII. Apical HCM, mid-cavitary HCM, and mid-cavitary HCM with apical aneurysm, 293
XIV. Athlete's heart, 294
XV. Athlete's heart: Is athletic activity associated with increased cardiac risk or sudden death in young and middle-aged individuals?, 295
Appendix 1. Cases of mixed septal bulge and calcific aortic stenosis = mixed LVOT obstruction and aortic stenosis. How to figure out the main level of obstruction?, 295
Appendix 2. Common error: LVOT flow may be confused as MR on echo spectral Doppler (and vice versa), 298
Questions and answers, 299

PART 5. **Arrhythmias and Electrophysiology,** 305

8. **Approach to Narrow and Wide QRS Complex Tachyarrhythmias,** 305

I. The unstable patient (shock, acute pulmonary edema), 305
II. Initial approach to any tachycardia, 305
III. Approach to narrow QRS complex tachycardias, 306
IV. Approach to wide QRS complex tachycardias, 307
V. Features characteristic of VT, as opposed to SVT with aberrancy, 308
VI. Features characteristic of SVT with pre-excitation, 312
VII. Role of adenosine in establishing a diagnosis, 313
VIII. Differential diagnosis of a wide complex tachycardia on a 1-lead telemetry or Holter monitor strip, 314
IX. Various notes, 314
X. General management of SVT, 314
XI. Non-tachycardic wide complex rhythms, 315
XII. Practice ECGs of wide complex tachycardias, 315

9. **Ventricular Arrhythmias: Types and Management, Sudden Cardiac Death – Athlete Sports Participation,** 322

I. Premature ventricular complexes, 322
II. Ventricular tachycardia (VT), 324
III. Polymorphic ventricular tachycardia, 326
IV. Congenital long QT syndrome (LQT), 329
V. Indications for ICD implantation, 331
VI. VT with no obvious heart disease: VT related to subtle, overlooked cardiomyopathy, 332
VII. VT with no obvious heart disease: VT related to electrical disorders and channelopathies, 334
VIII. VT with no obvious heart disease: idiopathic outflow tract PVC or VT and idiopathic left fascicular PVC or VT, 336
IX. Sudden cardiac death and athlete's ECG screening, 336
X. Competitive high-intensity sports for athletes with various cardiovascular abnormalities, 338
Questions and answers, 339

10. **Atrial Fibrillation,** 345

I. Predisposing factors, 345
II. Types of AF, 346
III. General therapy of AF, 346
IV. Management of a patient who presents with acute, symptomatic AF, 349
V. Peri-cardioversion anticoagulation management, 350
VI. Antiarrhythmic management after the acute presentation, 350
VII. Decisions about long-term anticoagulation, including after bleeding events, 350
VIII. Special situation: atrial fibrillation and heart failure. Optimal heart rate in heart failure, 352
IX. Special situation: atrial fibrillation with hemodynamic compromise: special rate-control and rhythm-control considerations, 354
X. AF burden as a correlate and a driver of HF progression, 355
Appendix 1. Optimal heart rate and AF rate for optimal cardiac output, 355
Appendix 2. Antiarrhythmic drug therapy, 355
Appendix 3. Catheter ablation of atrial fibrillation, surgical ablation, AV nodal ablation, 357
Appendix 4. INR follow-up in patients receiving warfarin: Non-vitamin K oral anticoagulants, 359
Appendix 5. Bridging anticoagulation in patients undergoing procedures, 361
Appendix 6. Management of elevated INR values and active bleeding, 361
Appendix 7. Left atrial appendage surgical and percutaneous closure, 362
Appendix 8. A common situation: AF and symptomatic pauses or bradycardia, 362
Appendix 9. AF occurring post-cardiac surgery and AF related to acute transient triggers (trigger-induced AF), 363
Appendix 10. Brief asymptomatic runs of AF on device interrogation and association with stroke. Role of rhythm monitoring after cryptogenic stroke, 363
Appendix 11. Value of smartwatches and KardiaMobile in AF self-monitoring: AF detection and follow-up, 364
Appendix 12. Association of AF with cognitive decline/dementia, 365
Questions and answers, 365

11. **Atrial Flutter and Atrial Tachycardia,** 374

I. Atrial flutter, 374
II. Focal atrial tachycardia, 377
III. Multifocal atrial tachycardia (MAT) (or chaotic atrial tachycardia), 380
IV. Ectopic atrial rhythm, 381
Questions and answers, 381

12. **Atrioventricular Nodal Reentrant Tachycardia, Atrioventricular Reciprocating Tachycardia, Wolff–Parkinson–White Syndrome, and Junctional Rhythms,** 384

I. Inappropriate sinus tachycardia (IST) and postural orthostatic tachycardia syndrome (POTS), 384
II. Atrioventricular nodal reentrant tachycardia (AVNRT), 384
III. Atrioventricular reciprocating tachycardia (AVRT) and Wolff–Parkinson–White (WPW) syndrome, 387
IV. Junctional escape rhythm and accelerated junctional rhythm (or non-paroxysmal junctional tachycardia), 395
Questions and answers, 397

13. **Bradyarrhythmias,** 400

I. AV block, 400
II. Sinus node dysfunction, 409
III. Bundle branch blocks, bifascicular and trifascicular block, 412
Questions and answers, 415

14. **Permanent Pacemaker and Implantable Cardioverter Defibrillator,** 418

I. Indications for permanent pacemaker implantation, 418
II. Types of cardiac rhythm devices, 418
III. Pacemaker intervals, 423
IV. Leads, 426
V. Systematic PM/ICD interrogation using the programmer, 427
VI. Pacemaker troubleshooting, 428
VII. Perioperative management of PM and ICD (during any surgery), 432
VIII. Differential diagnosis and management of the patient who presents with ICD shock(s), 432
IX. Evidence and guidelines supporting various pacing devices, 433
Appendix. Cases of PM troubleshooting, 437
Questions and answers, 443

15. **Basic Electrophysiologic Study,** 447

I. General concepts; intracardiac electrograms, 447
II. AV conduction abnormalities, 447
III. Sinus node assessment, 449
IV. Ventricular vs. supraventricular tachycardia, 449
V. Dual AV nodal pathways, 449
VI. AVNRT, 451
VII. Accessory pathway, orthodromic AVRT, antidromic AVRT, 451
VIII. Atrial flutter, 453
IX. Inducible VT, 454
X. Mapping for ablation, 455
XI. 3D electro-anatomical mapping, 459

16. **Action Potential Features and Propagation: Mechanisms of Arrhythmias, Antiarrhythmic Drugs,** 461

I. Action potential, 461
II. Action potential propagation and mechanisms of arrhythmias, 461
III. General mechanism of action of antiarrhythmic agents, 464
IV. Modulated receptor hypothesis and use dependence, 466
V. Concept of concealed conduction, 467
VI. Specific examples of drugs, 467
VII. Amiodarone toxicity, 468
VIII. Effect on pacing thresholds and defibrillation thresholds, 468

PART 6. **Pericardial Disorders,** 469

17. **Pericardial Disorders,** 469

1. Acute pericarditis, 470
I. Causes of acute pericarditis, 470
II. History and physical findings, 470
III. ECG findings, 470
IV. Echocardiography, 471
V. Myopericarditis and perimyocarditis, 471
VI. Treatment, 471

2. Tamponade, 473
I. Definition, 473
II. Pathophysiology and hemodynamics, 473
III. Diagnosis: tamponade is a clinical diagnosis, not an echocardiographic diagnosis, 474
IV. Echocardiographic findings supporting the hemodynamic compromise of tamponade, 475
V. Role of hemodynamic evaluation, 475
VI. Special circumstances: low-pressure tamponade, tamponade with absent pulsus paradoxus, regional tamponade, 475
VII. Effusive–constrictive pericarditis, 476
VIII. Treatment of tamponade, 476
3. Pericardial effusion, 476
I. Causes of a pericardial effusion with or without tamponade, 477
II. Management of asymptomatic effusions and role of pericardiocentesis, 477
III. Note on postoperative pericardial effusions (after cardiac surgery), 480
IV. Note on uremic pericardial effusion, 480
4. Constrictive pericarditis, 480
I. Causes, 480
II. Pathophysiology and hemodynamics, 480
III. Hemodynamic findings in constrictive pericarditis and differential diagnosis of constrictive pericarditis: restrictive cardiomyopathy, decompensated RV failure, COPD, 482
IV. Practical performance of a hemodynamic study when constrictive pericarditis is suspected, 484
V. Echocardiographic features of constrictive pericarditis, and differentiation between constrictive pericarditis and restrictive cardiomyopathy, 485
VI. Physical exam, ECG findings, BNP, pericardial thickness (CT/MRI), 487
VII. Transient constrictive pericarditis, 488
VIII. Treatment, 488
IX. Hemodynamic cases analysis, 489
Questions and answers, 490

PART 7. **Congenital Heart Disease,** 497

18. **Congenital Heart Disease,** 497

1. Acyanotic congenital heart disease, 497
I. Atrial septal defect (ASD), 497
II. Patent foramen ovale (PFO), 501
III. Ventricular septal defect (VSD), 502
IV. Patent ductus arteriosus (PDA), 504
V. Coarctation of the aorta, 505
VI. Other anomalies, 505
2. Cyanotic congenital heart disease, 506
I. Pulmonary hypertension secondary to shunt, 506
II. Tetralogy of Fallot, 507
III. Ebstein anomaly, 509
3. More complex cyanotic congenital heart disease and shunt procedures, 510
I. Functionally single ventricle and Fontan procedure, 510
II. Transposition of great arteries (TGA), 512
III. Other anomalies, 514
IV. Isolated right-to-left shunting in adults (i.e., without left-to-right shunting): the 3 major forms, 514
Questions and answers, 515

PART 8. **Peripheral Arterial Disease,** 521

19. **Peripheral Arterial Disease,** 521

1. Lower extremity peripheral arterial disease, 521
I. Clinical tips, 522
II. Clinical classification of PAD – Critical limb ischemia, acute limb ischemia, atheroembolization, 523
III. Diagnosis of PAD, 525
IV. Medical therapy of PAD, 526
V. Revascularization for PAD, 526
VI. Notes on the technical aspects of surgical and percutaneous therapies, 528
VII. Management of acute limb ischemia, 530
VIII. Management of lower extremity ulcers, 530

2. Carotid disease, 530
I. Assessment of carotid stenosis, 530
II. Medical therapy of carotid stenosis, 531
III. Revascularization of asymptomatic carotid stenosis, 531
IV. Revascularization of symptomatic carotid stenosis, 531
V. Main risks of CEA and carotid stenting, 532
VI. CEA vs. carotid stenting, 532
VII. Carotid disease in a patient undergoing CABG, 532
VIII. Subtotal and total carotid occlusions, 533
3. Renal artery stenosis, 533
I. Forms of renal artery stenosis, 533
II. Screening and indications to revascularize renal artery stenosis, 533
III. Notes, 534
4. Superficial venous insufficiency, lymphedema, and phlebolymphedema, 534
Questions and answers, 535

20. **Aortic Diseases,** 541

I. Aortic dissection, 541
II. Thoracic aortic aneurysm, 546
III. Abdominal aortic aneurysm, 550

PART 9. **Other Cardiovascular Disease States,** 553

21. **Pulmonary Embolism and Deep Vein Thrombosis,** 553

1. Pulmonary embolism, 553
I. Presentation of pulmonary embolism (PE) and risk factors, 553
II. Probability of PE, 554
III. Initial workup, 554
IV. Specific PE workup, 554
V. Submassive or intermediate-high risk PE, pulmonary hypertension, and thrombolysis, 556
VI. PE and chronic pulmonary hypertension, 557
VII. Acute treatment of PE, 557
VIII. Duration of anticoagulation, 558
IX. Thrombophilias, 559
X. PE prognosis and long-term follow-up — CTEPH—CTED, 560
2. Deep vein thrombosis, 560
I. Types, 560
II. Diagnosis, 560
III. Treatment, 561
3. Immune heparin-induced thrombocytopenia, 561
I. Incidence, 561
II. Diagnosis, 561
III. Treatment, 561
Questions and answers, 562

22. **Septic Shock, Cardiogenic Shock, and Fluid Responsiveness,** 567

1. Shock in general and septic shock, 567
I. Shock definition and mechanisms, 567
II. Goals of shock treatment, 568
III. Sepsis and septic shock, 569
IV. Pitfalls in septic shock fluid management, 569
V. Immediate management of any shock, focused on septic shock, 570
2. Cardiogenic shock definition, stages, and management, 572
I. Definition, 572
II. SCAI stages, 572
III. Categories, 572
IV. Treatment, 574
V. Additional notes regarding Impella CP, timing of Impella insertion, IABP, and ECMO, 577
VI. How to wean and explant Impella and any MCS, 578
VII. Mixed septic-cardiogenic shock, 579
3. Fluid responsiveness, 579
Appendix. Hemodynamic equations, transfusion, and miscellaneous concepts, 581
Questions and answers, 583

23. **Hypertension,** 587

1. Hypertension, 587
I. Definition and key role of out-of-office BP measurements, 587
II. ACC and ESC targets of therapy and rationale, 588
III. Treatment of hypertension: timing, first-line drugs, compelling indications for specific drugs, 589
IV. Resistant hypertension, 590
V. Secondary hypertension, 591
VI. Peripheral vs. central aortic pressure: therapeutic implications, 592
VII. First-line antihypertensive drugs, 592
VIII. Second-line antihypertensive drugs, 595
IX. Orthostatic hypotension and extremely labile HTN, 597
2. Acute severe hypertension: hypertensive emergencies and urgencies, 598
I. Definitions, 598
II. Treatment of hypertensive emergencies, 598
III. Treatment of hypertensive urgencies, 600
IV. Specific situations, 600
3. Target resting heart rate in different cardiac conditions, 600
Questions and answers, 602

24. **Dyslipidemia,** 609

I. Indications for therapy, 609
II. Notes on LDL, HDL, and triglycerides, 610
III. Drugs: LDL-lowering drugs, 611
IV. Drugs: TG/HDL-treating drugs and lifestyle modification, 613
V. Metabolic syndrome, 613
VI. Diabetes and cardioprotective diabetic drugs, 613
VII. Elevated hs-CRP (high-sensitivity C-reactive protein test) ≥2 mg/L, 614
VIII. Chronic kidney disease, 614
IX. Causes of dyslipidemia to consider, 614
X. Side effects of specific drugs: muscle and liver intolerance with statins, 614
XI. Aspirin is ineffective in primary prevention, 615
Questions and answers, 615

25. **Pulmonary Hypertension,** 619

I. Definition, 619
II. Categories of PH, 619
III. Two tips in the evaluation of PH, 621
IV. Hypoxemia in patients with PH, and right-to-left shunting, 621
V. Diagnosis: echocardiography; right and left heart catheterization, 622
VI. Treatment, 623
Questions and answers, 625

26. **Syncope,** 630

I. Neurally mediated syncope (reflex syncope), 630
II. Orthostatic hypotension and postural orthostatic tachycardia syndrome, 631
III. Cardiac syncope, 632
IV. Other causes of syncope, 632
V. Syncope mimic: seizure, 633
VI. Clinical clues, 633
VII. Diagnostic evaluation of syncope, 633
VIII. Tilt table testing, 637
IX. Indications for hospitalization, 637
X. Treatment of vasovagal syncope, orthostatic hypotension, and POTS, 637
Questions and answers, 639

27. **Chest Pain, Dyspnea, Palpitations,** 644

1. Chest pain, 644
I. Causes, 644
II. Features, 645
III. Management of chronic chest pain, 646
IV. Management of acute chest pain, 646

2. Acute dyspnea, 648
I. Causes, 648
II. Notes, 649
III. Management, 649
3. Palpitations, 650
I. Causes, 650
II. Diagnosis, 651

28. **Infective Endocarditis and Cardiac Rhythm Device Infections,** 654

1. Infective endocarditis, 654
I. Clinical diagnosis, 654
II. Echocardiography: timing and indications, 654
III. Organisms, 655
IV. Morphology, 655
V. Anatomical complications, 655
VI. Additional diagnostic imaging: cardiac CTA and FDG-PET/CT may be considered in specific cases, 656
VII. Indications for valvular surgery and special situations, 657
2. Cardiac rhythm device infections, 659
I. Organisms and mechanisms of infection, 659
II. Diagnosis, 659
III. Diagnosis in patients with bacteremia but no local or TEE signs of infection, 659
IV. Management, 659

29. **Preoperative Cardiac Evaluation,** 662

I. Surgical risk: surgery's risk and patient's risk, 662
II. Steps in preoperative evaluation – Focus on the 4 cardiac systems, 663
III. CARP and DECREASE V trials, 664
IV. Only the unstable coronary patients require revascularization preoperatively, 665
V. Unplanned surgery that needs to be performed soon after stent placement, 665
VI. Preoperative β-blocker therapy and SGLT-2 inhibitor, 666
VII. Other interventions that improve outcomes, 666
VIII. Severe valvular disease, 666
IX. Perioperative hypertension and perioperative management of ACE inhibitor/ARB and other antihypertensives, 666
X. Preoperative management of patients with pacemakers or ICDs, 667
XI. Postoperative troponin rise: MI and MINS, 667
XII. Perioperative management of warfarin and NOACs, 667
XIII. Prior stroke or TIA, 667
Questions and answers, 667

30. **Miscellaneous Cardiac Topics: Cardiac Masses and Tumors, Pregnancy, HIV and Heart Disease, Cocaine and the Heart, Chest X-Ray,** 670

1. Cardiac masses, 671
I. Differential diagnosis of a cardiac mass, 671
II. Cardiac tumors; focus on atrial myxoma, 671
2. Pregnancy and heart disease, 673
I. High-risk cardiac conditions during which pregnancy is better avoided, 674
II. Cardiac conditions that are usually well tolerated during pregnancy, but in which careful cardiac evaluation and clinical and echo follow-up are warranted, 674
III. Cardiac indications for cesarean section, 675
IV. Mechanical prosthetic valves in pregnancy: anticoagulation management, 675
V. Peripartum cardiomyopathy (PPCM), 676
VI. Cardiovascular drugs during pregnancy, 676
VII. Arrhythmias during pregnancy, 677
VIII. MI and pregnancy, 677
IX. Hypertension and pregnancy, 677
3. HIV and heart disease, 678
I. Pericardial disease, 678
II. HIV cardiomyopathy, 678
III. Pulmonary hypertension (PH), 678
IV. CAD, 678
4. Cocaine and the heart, 678
I. Myocardial ischemia, 678
II. Other cardiac complications of cocaine, 679

5. Chest X-ray, 679
I. Chest X-ray in heart failure, 679
II. Various forms of cardiomegaly, 681
III. Left atrial enlargement; aortic dilatation, 681
IV. Lateral chest X-ray, 682
V. Chest X-ray in congenital heart disease, 682
Questions and answers, 683

31. **Cancer Therapy and the Heart,** 687

I. Overview of cancer drug therapies, particularly targeted therapy and immunotherapy, 687
II. Cancer therapy–related cardiac dysfunction (CTRCD), 689
III. Chemotherapy and the heart, 690
IV. Targeted therapy and the heart, 691
V. Androgen deprivation therapy for prostate cancer, 692
VI. Immune checkpoint inhibitors and the heart, 692
VII. CAR-T cell therapy, 693
VIII. Hematopoietic stem cell therapy, 693
IX. Radiation heart disease, 693
Questions and answers, 693

PART 10. **Cardiac Tests: Electrocardiography, Echocardiography, and Stress Testing,** 695

32. **Electrocardiography,** 695

I. Overview of ECG leads and QRS morphology, 695
II. Stepwise approach to ECG interpretation, 698
III. Rhythm and rate, 699
IV. QRS axis in the limb leads and normal QRS progression in the precordial leads, 701
V. P wave: analyze P wave in leads II and V1 for atrial enlargement, and analyze PR interval, 702
VI. Height of QRS: LVH, RVH, 704
VII. Width of QRS: Conduction abnormalities: bundle branch blocks, 706
VIII. Conduction abnormalities: fascicular blocks, 709
IX. Low QRS voltage and electrical alternans, 711
X. Assessment of ischemia and infarction: Q waves, 712
XI. Assessment of ischemia: ST-segment depression and T-wave inversion, 715
XII. Assessment of ischemia: differential diagnosis of ST-segment elevation, 725
XIII. Assessment of ischemia: large or tall T wave, 731
XIV. QT analysis and U wave, 732
XV. Electrolyte abnormalities, digitalis effect and digitalis toxicity, hypothermia, PE, poor precordial R-wave progression, 735
XVI. Approach to tachyarrhythmias, 740
XVII. Approach to bradyarrhythmias: AV block, 743
XVIII. Abnormal automatic rhythms that are not tachycardic, 745
XIX. Electrode misplacement, 746
Appendix 1. Supplement on STEMI and Q-wave MI: phases and localization, 747
Appendix 2. Spread of electrical depolarization in various disease states using vector illustration, 752
Questions and answers, 753

33. **Echocardiography,** 760

1. General echocardiography, 760
I. The 5 major echocardiographic views and the myocardial wall segments, 760
II. Global echo assessment of cardiac function and structure, 760
III. Doppler and assessment of valvular regurgitation and stenosis, 771
IV. Summary of features characterizing severe valvular regurgitation and stenosis, 782
V. M-mode echocardiography, 783
VI. Pericardial effusion, 785
VII. Echocardiographic determination of LV filling pressure and diastolic function, 787
VIII. Additional echocardiographic hemodynamics, 789
IX. Prosthetic valves, 794
X. Brief note on Doppler physics and echo artifacts, 798
2. Transesophageal echocardiography (TEE) views, 799
Appendix 1. Note on LV mechanics and myocardial tissue strain, 809
Appendix 2. Three-dimensional echocardiography basic tips and images, 811

34. **Stress Testing, Nuclear Imaging, Coronary CT Angiography, Cardiac MRI, Cardiopulmonary Exercise Testing, Viability Testing, Lung Ultrasound, JVP Assessment,** 812

I. Indications for stress testing, 812
II. Contraindications to all stress testing modalities, 813
III. Stress testing modalities, 813
IV. Diagnostic yields and pitfalls of stress ECG and stress imaging, 813
V. Mechanisms of various stress modalities, 819
VI. Nuclear stress imaging, 820
VII. Coronary CT angiography and coronary calcium scoring, 823
VIII. Role of CT imaging for coronary calcium scoring, 826
IX. Cardiac MRI: summary of applications and findings, 827
X. Cardiopulmonary exercise testing (CPET), 830
XI. Viability testing and limitations, 830
XII. Lung ultrasound and lung CT scan in heart failure, 832
XIII. Jugular venous pressure by physical exam and by ultrasound, 833

PART 11. **Cardiac Tests: Invasive Coronary and Cardiac Procedures,** 841

35. **Angiographic Views: Coronary Arteries and Grafts, Left Ventricle, Aorta, Coronary Anomalies, Peripheral Arteries, Carotid Arteries,** 841

I. Right coronary artery, 841
II. Left coronary artery, 842
III. Coronary angiography views. Recognize the angle of a view: LAO vs. RAO, cranial vs. caudal, 843
IV. Coronary angiography views. General ideas: cranial vs. caudal views, 845
V. Coronary angiography views. General ideas: foreshortening and identifying branches, 845
VI. Left coronary views, 846
VII. Right coronary views, 855
VIII. Improve the angiographic view in case of vessel overlap or foreshortening: effects of changing the angulation, effects of respiration, and vertical vs. horizontal heart, 858
IX. Saphenous venous graft views, 859
X. LIMA-to-LAD or LIMA-to-diagonal views, 861
XI. Left ventriculography, 861
XII. Aortography for assessment of aortic insufficiency, 865
XIII. Coronary anomalies, 865
XIV. Lower extremity angiography, 869
XV. Carotid angiography, 874
Questions and answers, 875

36. **Cardiac Catheterization Techniques, Tips, and Tricks,** 878

I. Design of the Judkins catheters, 879
II. Coronary cusps anatomy and view for the engagement of the native coronary arteries: LAO vs. RAO, 879
III. Difference in left coronary artery (LCA) catheter elongation between femoral and radial access, 880
IV. From any approach, how to switch a Judkins left (JL) catheter that is fully falling down below the LCA and a JL catheter that is elongated, 881
V. Additional, specific radial catheters and Amplatz catheters, 881
VI. Difference in RCA catheter elongation between femoral and radial access, 883
VII. Summary of diagnostic and guiding catheters used for left coronary and RCA engagement from femoral and radial accesses, 883

VIII. Steps in LCA engagement, tips and tricks (focused on transradial access), 883
IX. When JL tip falls below the LCA ostium after the cusp jump: techniques 3A, 3B, and beyond, 887
X. Case illustrations and 2 additional transradial and LCA engagement tips, 887
XI. Management of a JL catheter that is sub-selectively engaged in the LAD or LCx, 889

XII. Engagement of the RCA, 890
XIII. The 11 pitfalls of RCA engagement, 891
XIV. RCA pitfalls 1–3 management, 892
XV. RCA pitfall 4: elongated horizontal aorta. How to gauge the level of the RCA origin in relation to the aortic valve level, 893
XVI. RCA pitfall 5: RCA engagement attempts fail, and non-selective right cusp injections do not clearly show the ostium. What is the most likely diagnosis, and how to manage it?, 894
XVII. RCA pitfall 6: RCA engagement attempts fail, and non-selective right cusp injections do not clearly show the ostium. What is the second possibility, and how to manage it?, 896

XVIII. RCA pitfalls 7 and 8: unstable RCA engagement, 896
XIX. RCA pitfall 9: catheter is pointing up with pressure damping/ventricularization, 897
XX. RCA pitfall 10: severe aorto-innominate tortuosity and/or angulation (radial access) or severe aorto-iliofemoral tortuosity (femoral access), with inability to transmit the torque, 898
XXI. RCA pitfall 11: all RCA engagement attempts fail, and non-selective cusp injections in both LAO and RAO views do not show the ostium, 900

XXII. Selective engagement of SVGs: general tips, 901
XXIII. Specific torque maneuvers for engaging the SVGs, 902
XXIV. Appropriate catheters for engaging SVGs, 903
XXV. Engagement of the left internal mammary artery graft from a femoral access, 905
XXVI. Engagement of the left internal mammary artery graft from a left radial access, 906
XXVII. Engagement of the SVGs from a left or right radial access, 907
XXVIII. Major tips in native angiography that assist with graft mapping. How to report graft cases, 907

XXIX. Guiding catheters for left coronary engagement, 910
XXX. Maneuvering the EBU/XB/CLS guides and Ikari left guides for left coronary interventions, 912
XXXI. How to engage and maneuver Amplatz left catheter. Other guiding catheters for right coronary engagement: Ikari right and left, 914

XXXII. Damping and ventricularization of the aortic waveform upon coronary engagement, and role of side-hole catheters, 918
XXXIII. Coronary angiography in case of aorto-ostial stenosis, 920

XXXIV. Left ventricular catheterization, 921
XXXV. Radial approach issues at the radial or brachial level (radial loop, high-branching radial artery), 924
XXXVI. Right heart catheterization, 925

37. **Hemodynamics,** 928

I. Right heart catheter, 928
II. Overview of pressure tracings: differences between atrial, ventricular, and arterial tracings, 928
III. RA pressure abnormalities, 928
IV. Pulmonary capillary wedge pressure (PCWP) abnormalities, 928
V. LVEDP, 933
VI. Cardiac output and vascular resistances, 935
VII. Shunt evaluation, 936
VIII. Valvular disorders: overview of pressure gradients, 938
IX. Valvular disorders: valve area calculation, 943
X. Low-gradient aortic stenosis, 945
XI. Valve area vs. gradient for defining stenosis severity: differences between AS and MS, 945
XII. Aortic insufficiency, 946
XIII. Dynamic LVOT obstruction, 946
XIV. Pericardial disorders: tamponade and constrictive pericarditis, 949
XV. Exercise hemodynamics, 951
XVI. Additional hemodynamic caveats in AF, 952
Appendix 1. Advanced hemodynamic calculation: a case of shunt with pulmonary hypertension, 952
Questions and answers: Additional hemodynamic cases, 953

38. **Intracoronary Imaging,** 963

1. Intravascular ultrasound (IVUS), 963
I. Image basics, 963
II. Plaque types, 966
III. Basic IVUS measurements, 968
IV. Interpretation of how a severe stenosis may look mild angiographically, yet severe by IVUS; significance of lesion haziness, 970
V. Assessment of lesion significance by IVUS, 970
VI. Pre-stent IVUS or OCT sizing and calcium assessment. Post-stent IVUS or OCT assessment, 971
VII. Assessment of left main by IVUS, 972
2. Optical coherence tomography (OCT), 972

39. **Percutaneous Coronary Interventions and Complications, Intra-Aortic Balloon Pump, and Ventricular Assist Devices,** 976

I. Major coronary interventional devices, 976
II. Stent thrombosis, restenosis, and neoatherosclerosis, 979

III. Peri-PCI antithrombotic therapy, 981
IV. Sheath management, 982
V. Post-PCI mortality and coronary complications, 982
VI. Femoral access complications, 988
VII. Renal, stroke, and atheroembolic complications, 990
VIII. Intra-aortic balloon pump (IABP) or intra-aortic balloon counterpulsation, 991
IX. Percutaneous LV assist device: Impella mechanism, troubleshooting, and weaning, 994
X. Extracorporeal membrane oxygenation (ECMO), 999
Questions and answers, 1000

40. **Complex PCI Lesion Subsets—Fractional Flow Reserve,** 1006

1. Fractional flow reserve (FFR), 1006
2. Complex PCI lesion subsets, 1010
I. Bifurcation stenoses, 1010
II. Isolated ostial branch disease, ostial LAD, ostial LCx, 1014
III. In-stent restenosis management, 1016
IV. Long and diffuse disease, 1016
V. Chronic total occlusion (CTO), 1016
VI. Aorto-ostial stenting, 1017
VII. Severe coronary calcification, 1019
VIII. Balloon uncrossable lesions and how to improve guide support, 1021
IX. Brief on coronary guidewires, 1023
3. When to use LV support during complex PCI – Pre-planning left main PCI, 1025

Appendix: General review questions, 1030

1. Questions, 1030
I. NSTEMI and STEMI, 1030
II. Stable CAD, 1034
III. Heart failure and cardiomyopathies, 1037
IV. Valvular disorders, 1045
V. Arrhythmias, 1052
VI. Congenital heart disease, 1058
VII. Peripheral arterial disease—Pulmonary embolism—Pulmonary hypertension, 1061
VIII. Hypertension and syncope, 1063
IX. Pregnancy—Chemotherapy and heart disease—Miscellaneous, 1064
X. ECG, 1066
XI. Echocardiography, 1068
XII. Additional hemodynamics, 1071
XIII. Percutaneous coronary intervention and shock, 1074
XIV. Radiation in the cardiac catheterization laboratory, 1079
2. Answers, 1080

Index, 1110

Preface

Compassion is the chief and perhaps the only law of human existence

Fyodor Dostoevsky, The Idiot

There are those who give and know not pain in giving, nor do they seek joy,
nor give with mindfulness of virtue. Through the hands of such as these God speaks

Gibran, The Prophet

Practical Cardiovascular Medicine is designed to bridge the gap between pathophysiology, clinical evidence, and bedside patient care in a comprehensive yet practical manner. It addresses the entire spectrum of cardiovascular medicine, from fundamental principles to advanced concepts, and therefore serves experienced physicians as well as trainees. In fact, there is a particular emphasis on the knowledge gaps of cardiologists and cardiology fellows. Years of organizing fellowship conferences and working closely with cardiology and interventional cardiology fellows have helped me identify recurring misconceptions and devote particular attention to them.

Medicine cannot be mastered through guidelines, increasingly complex algorithms, or memorization alone. True clinical judgment emerges from understanding why diseases behave as they do, how evidence should be interpreted, and where physiology explains what algorithms cannot. This philosophy has guided every chapter of this book. My aim has been to strengthen the reader's grasp of cardiovascular pathophysiology, clinical trials, and hemodynamics, while presenting the material in a practical, illustrated, and easy-to-follow manner. To facilitate learning, bottom-line approaches are consistently provided throughout the 40 chapters. There is an extra emphasis on concepts that are frequently misunderstood by practitioners.

As in prior editions, I have sought to answer daily, practical questions that are often left unaddressed in standard texts. Even traditional topics, such as myocardial infarction, heart failure, arrhythmias, atrial fibrillation, cardiac catheterization, or electrocardiography are revisited from a different, fresh, and contemporary viewpoint. The book is wide-ranging, and many of its chapters are detailed enough to stand alone as separate books.

The third edition has been comprehensively updated with the newest data, expanded pathophysiological concepts, and current American and European guidelines. More specifically, 16 chapters have been rewritten, and the remainder have been extensively revised to include new clinical data, fresh clinical pearls, and a deeper exploration of disease mechanisms. Two new chapters have been added: an interventional cardiology chapter and a cardio-oncology chapter. Technical and procedural chapters have been substantially enhanced with additional concepts and illustrations, particularly the cardiac catheterization chapter (Chapter 36), which complements my YouTube catheterization videos, as well as the echocardiography, hemodynamics, and interventional cardiology chapters. Overall, more than 200 new figures have been added or have replaced older ones, bringing the total number of figures to over 920.

To reinforce learning, this edition continues to feature review questions at the end of most chapters. It also retains a dedicated self-assessment section at the end of the book, containing 259 board-style clinical questions with detailed answers. I have always believed that medicine is learned most effectively through clinical reasoning and real cases. Accordingly, most of these questions are derived from clinical cases or images I came across in my practice. This way, the book continues to fulfill one of its primary missions: to be multiple books condensed into a cohesive single volume, including a question book.

While primarily designed for cardiologists and cardiology fellows, this book will also prove highly valuable to internists, internal medicine residents, emergency physicians, and all healthcare professionals caring for patients with cardiovascular disease.

Cardiovascular medicine continues to evolve at an extraordinary pace, yet its greatest challenges remain thoughtful clinical reasoning, intellectual curiosity, and a deep understanding of disease. My hope is that this book will help cultivate those qualities. As in prior editions, I have written these pages in an effort to embrace the magic and evolving depths of cardiovascular diseases. It is written with love and the sincere hope of improving patients' outcomes.

Elias B. Hanna

Abbreviations

3D	three-dimensional
AAD	antiarrhythmic drug
AAA	abdominal aortic aneurysm
ABI	ankle–brachial index
ACC	American College of Cardiology
ACCP	American College of Chest Physicians
ACE-I	angiotensin converting enzyme inhibitor
ACS	acute coronary syndrome
ACT	activated clotting time
ADHF	acutely decompensated heart failure
ADP	adenosine diphosphate
AF	atrial fibrillation
Aflutter	atrial flutter
AHA	American Heart Association
AI	aortic insufficiency
AIVR	accelerated idioventricular rhythm
AKI	acute kidney injury
AL	Amplatz left
AM	acute marginal
ANA	antinuclear antibodies
Ao	aorta
AoV	aortic valve
AP	accessory pathway
AP	anteroposterior view
AR	Amplatz right
ARB	angiotensin-II receptor blocker
ARDS	acute respiratory distress syndrome
ARNI	angiotensin receptor-neprilysin inhibitor
ARVC	arrhythmogenic right ventricular cardiomyopathy
ARVD	arrhythmogenic right ventricular dysplasia
AS	aortic stenosis
ASD	atrial septal defect
ASE	American Society of Echocardiography
AT	anterior tibial artery
AT	atrial tachycardia
AT1 receptor	type 1 receptor of angiotensin 2
AT2 receptor	type 2 receptor of angiotensin 2
AT III	antithrombin IIII
AV	atrioventricular
AV block	atrioventricular block
AVA	aortic valve area
AVNRT	atrioventricular nodal reentrant tachycardia
AVR	aortic valve replacement
AVRT	atrioventricular reciprocating tachycardia
BBB	bundle branch block
BiPAP	bilevel positive airway pressure
BiV	biventricular
biVAD	biventricular assist device
BMS	bare-metal stent
BNP	brain natriuretic peptide
BP	blood pressure
bpm	beats per minutes
BSA	body surface area
BUN	blood urea nitrogen
Ca	calcium
CABG	coronary artery bypass grafting
CAD	coronary artery disease
Cath	catheterization
CBC	complete blood count
CCB	calcium channel blockers
CEA	carotid endarterectomy
CHF	congestive heart failure
CIA	common iliac artery
CK	creatine kinase
CK-MB	creatine kinase MB
CKD	chronic kidney disease
CO	cardiac output
COPD	chronic obstructive pulmonary disease
CPAP	continuous positive airway pressure
CRP	C-reactive protein
CRT	cardiac resynchronization therapy
CT	computed tomography
CTA	computed tomography angiography
CTI	cavotricuspid isthmus
CTO	chronic total occlusion
CTEPH	chronic thromboembolic pulmonary hypertension
CTRCD	cancer therapy-related cardiac dysfunction
CV	cardiovascular
CVP	central venous pressure
CW	continuous wave Doppler
CYP 450	cytochrome P450
CXR	chest X-ray
d	day
DAD	delayed afterdepolarization
DAPT	dual antiplatelet therapy
DBP	diastolic blood pressure
DCB	drug-coated balloon
DC cardioversion	R-wave synchronized direct-current cardioversion
DCM	dilated cardiomyopathy
DES	drug-eluting stent
Dg	diagonal branch
DHP	dihydropyridine (calcium channel blocker)
DI	dimensionless index (same as DVI)
dP/dt	delta pressure/delta time (sharpness of rise in pressure over time)
DTI	direct thrombin inhibitor
DTS	Duke treadmill score
DVI	Doppler velocity index
DVT	deep vein thrombosis
Ea	arterial elastance
EAD	early afterdepolarization
ECG	electrocardiogram
echo	echocardiogram
ECMO	extracorporeal membrane oxygenation
ED	emergency department
EDD	end-diastolic diameter
EEM	external elastic membrane
Ees	end-systolic elastance
EF	ejection fraction
EIA	external iliac artery
EP	electrophysiological

ERO	effective regurgitant orifice
ESC	European Society of Cardiology
ESD	end-systolic diameter
ESPVR	end-systolic pressure volume relationship
ESR	erythrocyte sedimentation rate
ESRD	end-stage renal disease
FDG	Fluorodeoxyglucose
FFR	fractional flow reserve
FiO_2	fraction of inspired oxygen
FMD	fibromuscular dysplasia
GFR	glomerular filtration rate
GI	gastrointestinal
GLP-1	glucagon-like peptide-1 receptor
GPI	glycoprotein IIb–IIIa inhibitor
Hb	hemoglobin
HbA1c	glycosylated hemoglobin
HCM	hypertrophic cardiomyopathy
HCTZ	hydrochlorothiazide
HDL	high-density lipoprotein
HF	heart failure
HFpEF	heart failure with preserved ejection fraction
HFrEF	heart failure with reduced ejection fraction
HIT	heparin-induced thrombocytopenia
HIV	human immunodeficiency virus
HOCM	hypertrophic obstructive cardiomyopathy
hr	hour
HR	heart rate
hs-CRP	high sensitivity C-reactive protein
HTN	hypertension
IABP	intra-aortic balloon pump
ICD	implantable cardioverter defibrillator
ICI	immune checkpoint inhibitor
ICU	intensive care unit
iFR	instantaneous wave-free ratio
IM	internal mammary
INR	international normalized ratio
IST	inappropriate sinus tachycardia
IV	intravenous or intravenously
IVC	inferior vena cava
IVC-	isovolumic contraction
IVCT	isovolumic contraction time
IVR	isovolumic relaxation
IVRT	isovolumic relaxation time
IVUS	intravascular ultrasound
JL	Judkins left
JR	Judkins right
JVD	jugular venous distension
JVP	jugular venous pressure
K	potassium
LA	left atrium
LAA	left atrial appendage
LAFB	left anterior fascicular block
LAD	left anterior descending artery
LAO	left anterior oblique
LBBB	left bundle branch block
LCA	left coronary artery
LCB	left coronary bypass catheter
LCC	left coronary cusp
LCx	left circumflex coronary artery
LDL	low-density lipoprotein
LGE	late gadolinium enhancement
LHC	left heart catheterization
LIMA	left internal mammary artery
LLSB	left lower sternal border
LM	left main coronary artery
LMNA	lamin A/C
LMWH	low-molecular-weight heparin
LPFB	left posterior fascicular block
L-R	left-to-right (for shunts)
LUSB	left upper sternal border
LV	left ventricle or left ventricular
LVAD	left ventricular assist device
LVEDD	left ventricular end-diastolic diameter
LVEDP	left ventricular end-diastolic pressure
LVEF	left ventricular ejection fraction
LVESD	left ventricular end-systolic diameter
LVH	left ventricular hypertrophy
LVOT	left ventricular outflow tract
MAP	mean arterial pressure
MAT	multifocal atrial tachycardia
MB	main branch
MCS	mechanical circulatory support
MET	metabolic equivalent of task
mph	miles per hour
MI	myocardial infarction
MP	multipurpose catheter
MR	mitral regurgitation
MRA	magnetic resonance angiography
MRI	magnetic resonance imaging
MS	mitral stenosis
MV	mitral valve
MV O_2	mixed venous oxygen saturation
MVA	mitral valve area
MVP	mitral valve prolapse
MVR	mitral valve replacement
Na	sodium
NC and NCC	non-coronary cusp
NO	nitric oxide
NSAID	non-steroidal anti-inflammatory drug
NSTEMI	non-ST-segment elevation myocardial infarction
NSVT	non-sustained ventricular tachycardia
NT pro-BNP	amino-terminal pro-brain natriuretic peptide
NTG	nitroglycerin
NYHA	New York Heart Association
OCT	optical coherence tomography
OM	obtuse marginal branch of the left circumflex
P	pressure
PA	pulmonary arterial or pulmonary artery
PA O_2	pulmonary arterial oxygen saturation
PAC	premature atrial complex
$PaCO_2$	partial pressure of carbon dioxide in arterial blood
PAD	peripheral arterial disease
PAH	pulmonary arterial hypertension
PAI	plasminogen activator inhibitor
PaO_2	arterial oxygen pressure
P_AO_2	alveolar oxygen pressure
PCI	percutaneous coronary intervention
PCSK9	Proprotein convertase subtilisin/kexin type 9
PCWP	pulmonary capillary wedge pressure
PDA	patent ductus arteriosus
PDA	posterior descending artery branch of the right coronary artery or left circumflex
PE	pulmonary embolism
PDE-5I	phosphodiesterase-5 inhibitor
PEA	pulseless electrical activity
PET	positron emission tomography
PFO	patent foramen ovale
PFT	pulmonary function testing

PH	pulmonary hypertension
PHT	pressure half-time
PISA	proximal isovelocity surface area
PJRT	permanent junctional reciprocating tachycardia
PLB or PLVB	posterolateral ventricular branches of the right coronary artery or left circumflex
PM	pacemaker
PMBV	percutaneous mitral balloon valvuloplasty
PMT	pacemaker-mediated tachycardia
PND	paroxysmal nocturnal dyspnea
POT	proximal optimization technique
POTS	postural orthostatic tachycardia syndrome
PPD	purified protein derivative for *Mycobacterium tuberculosis*
PPI	proton pump inhibitor
PPM	patient-prosthesis mismatch or permanent pacemaker
PR	pulmonic regurgitation
PS	pulmonic stenosis
PT	posterior tibial artery
PTT	partial thromboplastin time
PV loop	pressure–volume loop
PV O_2	pulmonary venous oxygen saturation
PVARP	post-ventricular atrial refractory period
PVC	premature ventricular complex
PVR	pulmonary vascular resistance
PW	pulsed wave Doppler
Qp	pulmonary blood flow
Qs	systemic blood flow
QTc	corrected QT interval
RA	right atrium or right atrial
RAAS	renin-angiotensin-aldosterone system
RAO	right anterior oblique
RAS	renal artery stenosis
RBBB	right bundle branch block
RCA	right coronary artery
RCB	right coronary bypass catheter
RCC	right coronary cusp
RHC	right heart catheterization
RIMA	right internal mammary artery
R-L	right-to-left (for shunts)
rPA	reteplase
rpm	revolutions per minute
r-tPA	recombinant tissue plasminogen activator (alteplase)
RUSB	right upper sternal border
RV	right ventricle/ventricular
RVAD	right ventricular assist device
RVEDP	right ventricular end-diastolic pressure
RVH	right ventricular hypertrophy
RVOT	right ventricular outflow tract SA sinoatrial
SA O_2	systemic arterial oxygen saturation
SAM	systolic anterior motion
SaO_2	systemic arterial oxygen saturation
SB	side branch
SBE	subacute bacterial endocarditis
SBP	systolic blood pressure
SCAD	spontaneous coronary artery dissection
SCD	sudden cardiac death
SGLT-2 inhibitor	sodium-glucose cotransporter-2 inhibitor
SIRS	systemic inflammatory response syndrome
SFA	superficial femoral artery
SNRT	sinus node reentrant tachycardia
SPECT	single photon emission computed tomography (nuclear imaging)
SQ	subcutaneously
STEMI	ST-segment elevation myocardial infarction
STS	Society of Thoracic Surgeons
SV	stroke volume
SVC	superior vena cava
SVG	saphenous venous graft
SvO_2	mixed venous oxygen saturation (also MV O_2)
SVR	systemic vascular resistance
SVT	supraventricular tachycardia
TAA	thoracic aortic aneurysm
TAP stenting	T and protrusion stenting
TdP	torsades de pointes
TEE	transesophageal echocardiogram
TGs	triglycerides
TGA	transposition of great arteries
TIA	transient ischemic attack
TID	transient ischemic dilatation
TKI	tyrosine kinase inhibitor
TLR	target lesion revascularization
TR	tricuspid regurgitation
TSH	thyroid-stimulating hormone
TTE	transthoracic echocardiogram
TVF	target vessel failure
UA	unstable angina
UFH	unfractionated heparin
VAD	ventricular assist device
VEGF	vascular endothelial growth factor
V/Q scan	lung ventilation/perfusion scan
VF	ventricular fibrillation
VLDL	very-low-density lipoprotein
Vp	velocity of propagation
VSD	ventricular septal defect
VSR	ventricular septal rupture
VT	ventricular tachycardia
VTI	velocity-time integral
WPW	Wolff–Parkinson–White

Part 1 CORONARY ARTERY DISEASE

1 Non-ST-Segment Elevation Acute Coronary Syndrome

I. Definition, types of myocardial infarction, and pitfalls 1
II. Clinical features, ECG, cardiac biomarkers, and echocardiography in ACS 7
III. Initial approach to acute chest pain presentations and the use of high-sensitivity troponins 9
IV. Management of NSTEMI 11
V. General procedural management after coronary angiography: PCI (culprit and non-culprit), CABG, or medical therapy only 15
VI. Discharge medications in NSTEMI 16
VII. Prognosis 19

Appendix 1. Multivessel obstructive (>50%) disease in NSTEMI: How to identify the culprit stenosis 20

Appendix 2. Management according to the severity of angiographic stenosis in NSTEMI: How to manage intermediate stenoses (50–70%) 21

Appendix 3. Women and ACS, elderly patients and ACS, CKD 22

Appendix 4. Bleeding, transfusion, patients on chronic warfarin or NOAC, gastrointestinal bleed 23

Appendix 5. Antiplatelet and anticoagulant therapy 24

Appendix 6. The 3 main types of plaque disruption: plaque rupture, plaque erosion, and eruptive calcified nodule 27

Appendix 7. Spontaneous coronary artery dissection 27

Appendix 8. Harmful effects of NSAIDs and cyclooxygenase-2 inhibitors in CAD 30

Appendix 9. Additional ideas on the physiology of hs-troponin: Role of hs-troponin in primary prevention 31

Questions and answers 31

I. Definition, types of myocardial infarction, and pitfalls

A rise in troponin, per se, is diagnostic of myocardial necrosis or injury but is not sufficient to define myocardial infarction (MI), which is myocardial necrosis secondary to myocardial ischemia. Additional clinical, ECG, or echocardiographic evidence of ischemia is needed to define MI (Figures 1.1, 1.2).

In fact, **MI** is defined as a *troponin elevation* above the 99th percentile of the reference limit (~14–50 ng/L, depending on the assay) *with a rise and/or fall pattern*, *along with any one of the following four features*: (i) angina; (ii) new or dynamic ST-T abnormalities not explained by LVH or LBBB, or new Q waves; (iii) new wall motion abnormality on imaging; (iv) intracoronary thrombus on angiography.[1,2]

Isolated myocardial necrosis is common in critically ill patients and manifests as a troponin rise, sometimes with a rise and fall pattern, but no clinical or ECG features of MI. This troponin rise is not called MI but is called "non-MI troponin elevation" or **"non-ischemic myocardial injury."**

A rise or fall in troponin is necessary to define MI. A mild, chronically elevated but stable troponin may be seen in chronic heart failure, severe left ventricular hypertrophy, or advanced kidney disease. While having a prognostic value, this stable troponin rise is not diagnostic of MI. A fluctuating troponin pattern may be seen in myocarditis. Different cutoffs have been used to define a relevant troponin change, but, in general, a troponin that rises above the 99th percentile with a rise or fall of >20% is characteristic of MI (50% cutoff is more applicable to low troponin levels below MI cutoff, e.g., high-sensitivity troponin [hs-troponin] T <14 ng/L).[3]

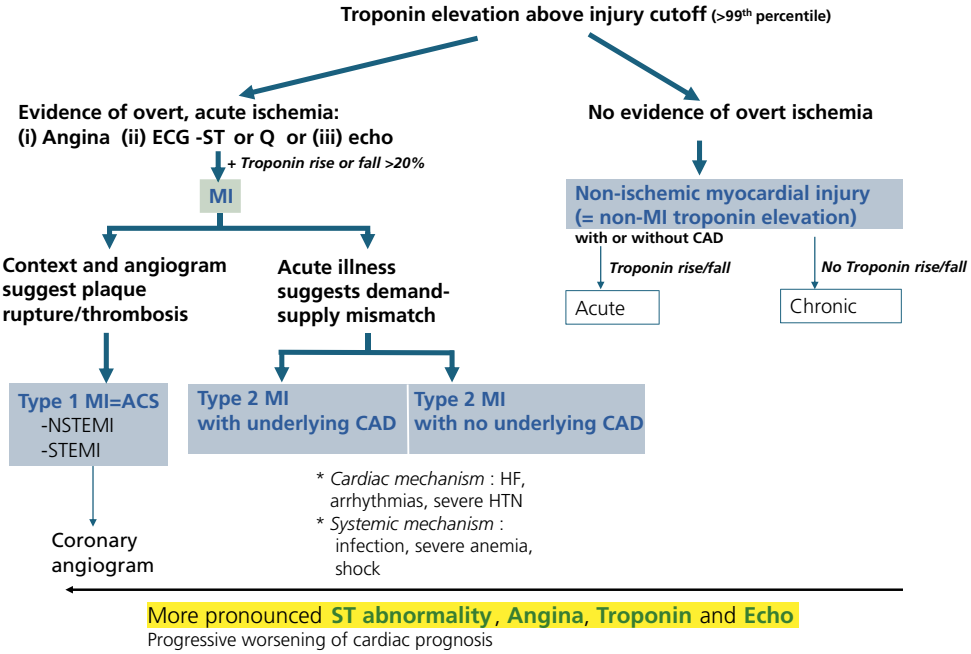

Figure 1.1 The four major types of myocardial injury. The more pronounced the troponin and ECG abnormalities, the greater the suspicion for type 1 MI, or type 2 MI with underlying CAD, with a graded worsening of both diagnosis and cardiac prognosis. At times, it may be difficult to differentiate type 2 MI on top of chronic CAD from type 1 MI, and the tendency is to treat those cases as type 1 MI.
Notes: To suggest acute MI, ST depression must be dynamic, and Q waves must be progressive and evolving. T inversion, even if dynamic, is not diagnostic of ischemia, unless it is profound >5 mm and evolving/dynamic, or has a Wellens morphology. Dyspnea and HF are less specific for ischemia than chest pain and may rather reflect separate non-ischemic primary processes. MI's pain typically occurs at rest or minimal exertion and lasts >20 min; it may be persistent (in STEMI + some NSTEMIs), or may wax and wane (most NSTEMIs).

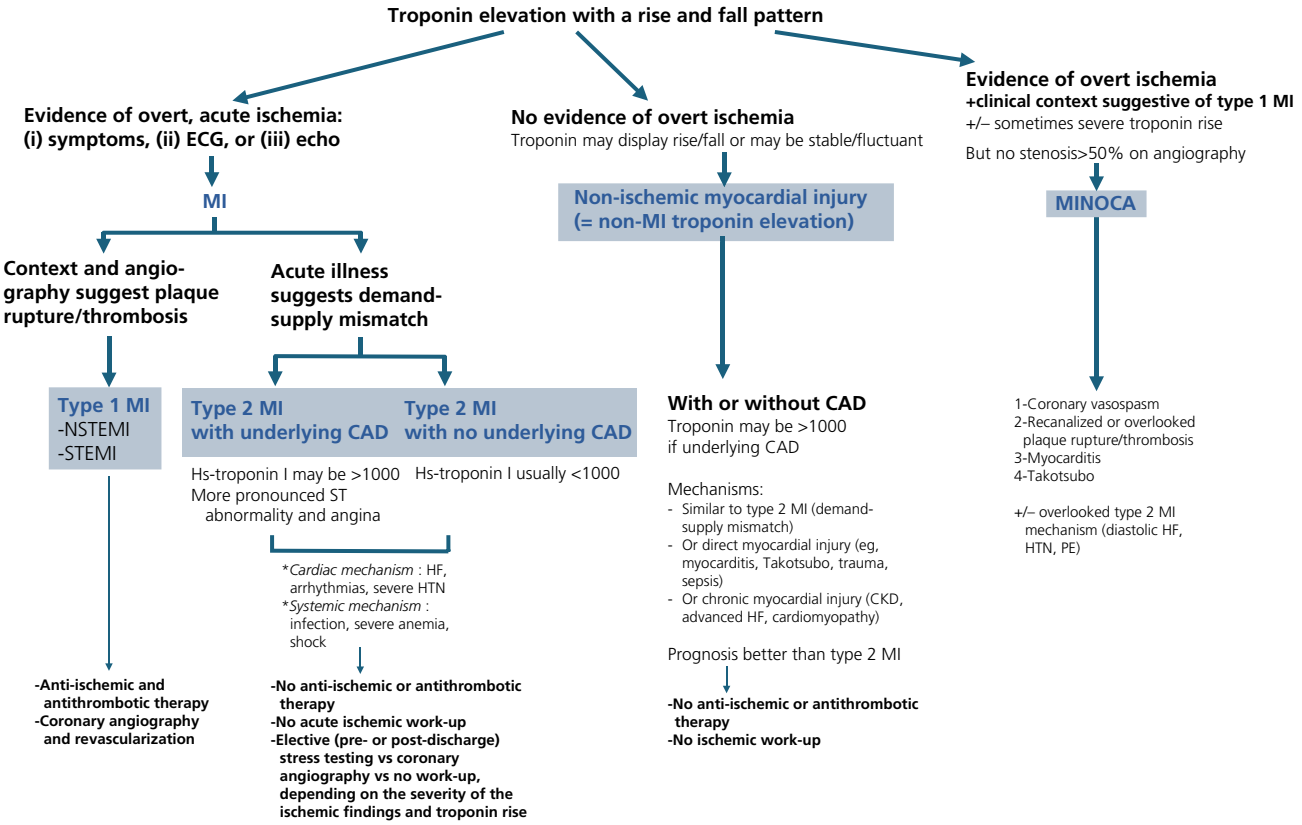

Figure 1.2 More detailed description of the types of myocardial injury. Note the fifth type of myocardial injury, MINOCA.

A. Type 1 MI (spontaneous MI) = True acute coronary syndrome (ACS)

Type 1 or spontaneous MI is usually due to plaque rupture or erosion that promotes platelet aggregation, thrombus formation and microembolization of platelet aggregates.

NSTEMI is a type 1 MI without persistent ST-segment elevation. **STEMI** is a type 1 MI with persistent (>20 min), ischemic ST-segment elevation.[1,4–6] For practical purposes, ischemic symptoms with ongoing ST-segment elevation of any duration are considered STEMI and treated as such. The diagnosis may be retrospectively changed to NSTEMI if ST elevation quickly resolves without reperfusion therapy, in <20 minutes.

In NSTEMI, the thrombus is most often a platelet-rich thrombus,~90% obstructive, sometimes <90% after spontaneous reopening or distal emboli. This contrasts with STEMI, which is due to an ~100% occlusive thrombus rich in platelets and fibrin. Also, NSTEMI usually has greater collateral flow to the infarct zone than STEMI.

As a result of the diffuse inflammation and alteration of platelet aggregability, multiple plaque ruptures are seen in ~30–80% of MIs, although only one is usually considered the culprit.[7] This shows the importance of medical therapy to "cool down" the diffuse process, and explains the high risk of MI recurrence within the following year even if the culprit plaque is stented.[7]

Occasionally, a ruptured plaque or, more commonly, an eroded plaque may lead to microembolization of platelets and thrombi and impaired coronary flow without any residual, angiographically significant lesion or thrombus.

B. Type 2 MI (secondary MI) with or without underlying CAD

In this case, ischemia is related to severely increased O_2 demands (demand/supply mismatch). The patient may have underlying CAD, but the coronary plaques are stable without acute rupture or thrombosis. Conversely, the patient may not have any underlying CAD, in which case troponin I usually remains <1000 ng/L and the ECG and echo are unlikely to show ischemia.[8–10] ***About half of patients with type 2 MI have underlying CAD.***

Cardiac mechanisms of type 2 MI include: severe hypertension, acute HF, arrhythmias, aortic stenosis/hypertrophic cardiomyopathy. Non-cardiac mechanisms of type 2 MI include: gastrointestinal bleed, severe anemia, sepsis, hypoxemia.

Type 1 MI and type 2 MI are differentiated by *the clinical context*. Type 1 MI (STEMI and NSTEMI) is generally the primary reason for a patient's presentation to the hospital with no evidence of acute noncardiac illness. Conversely, type 2 MI occurs in the setting of acute noncardiac illness. At times, a type 1 MI diagnosis is assumed, but the diagnosis is reconsidered after non-obstructive findings on coronary angiography; type 2 MI causes, such as elevated LVEDP and severe hypertension, are re-examined.

The degree of hs-troponin rise may also help distinguish various types of myocardial injury (Figure 1.3).[8–15] When ischemic imbalance occurs without underlying CAD, hs-troponin T usually remains <300 ng/L (hs-troponin I <1000 ng/L).[8–10,15] However, when ischemic imbalance occurs on top of underlying stable CAD, troponin T may rise to level >300 ng/L. Therefore, **a troponin T level >300 ng/L (or troponin I >1000 ng/L) suggests obstructive CAD, whether the primary insult is coronary (thrombotic, type 1 MI) or non-coronary (type 2 MI)**; the positive predictive value for CAD is high and approaches 90%, less so if renal dysfunction is present.[8] Conversely, any degree of troponin rise, even if very mild (e.g., troponin T 30 ng/L), in a patient with angina and without a context of secondary ischemia indicates type 1 MI until proven otherwise on angiography.

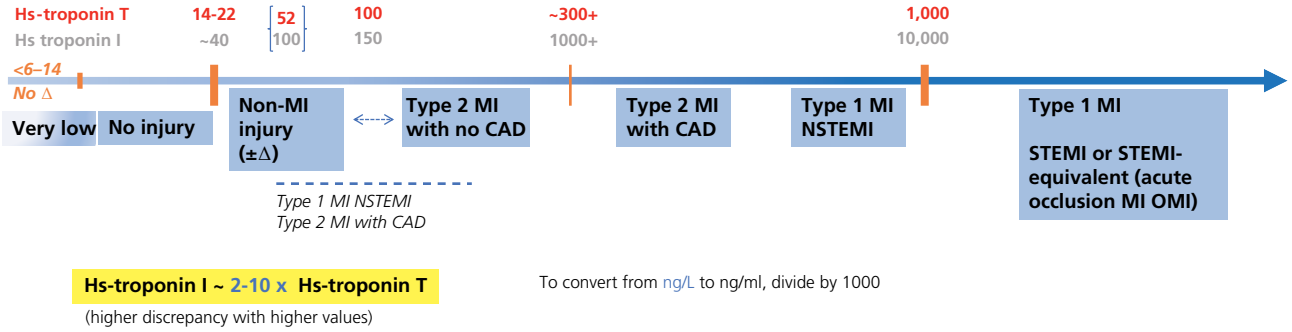

Figure 1.3 Correlation of hs-troponin levels with the type of myocardial injury. Note the difference between hs-troponin T and hs-troponin I (troponin I levels are 2–10 times higher and have higher cutoffs).

- Hs-troponin T <100 ng/L is frequently non-MI injury (≥50%).
- Hs-troponin T >300 (hs-troponin I >1000) frequently implies CAD, whether type 1 MI or type 2 MI with CAD.
- Hs-troponin T >1000 is overwhelmingly type 1 MI, frequently STEMI or occlusive MI.

This is a general guide suggested by the author with a lot of potential overlap in values. Notably, type 1 MI may be seen with low hs-troponin T of 22–100; however, non-MI injury and type 2 MI with no CAD do not usually lead to high hs-troponin T values >300 ng/L. Δ (delta)=significant troponin rise or fall.

In a type 2 MI setting, aside from the degree of troponin rise (troponin T >300 ng/L, troponin I >1000 ng/L), **pronounced angina, pronounced ST abnormality on the ECG, or wall motion abnormality signals underlying CAD and may compel a consideration of type 1 MI.** At times, it may be difficult to differentiate type 2 MI on top of chronic CAD vs. type 1 MI, and the tendency is to treat those cases as type 1 MI.

Case example: in a patient with septic shock, hs-troponin T of 400 ng/L with transient ST depression was initially considered type 2 MI with likely underlying CAD, but angiography showed acute thrombotic lesion; hence this was type 1 MI with plaque rupture from the stress of sepsis.

Acute bleed, severe anemia, or tachyarrhythmia destabilizes a stable angina. Treating the anemia or the arrhythmia is a first priority in these patients, taking precedence over treating CAD.

Acute HF often leads to troponin elevation because of microcirculatory compression by the high LVEDP and because of direct cardiomyocyte injury from wall stretch and neurohormones. Troponin I may even rise to >1000 ng/L in 6% of patients regardless of any underlying CAD.[16] Thus, an elevated troponin, by itself, does not establish the diagnosis of ACS in a patient presenting with HF.[1] In fact, most troponin elevations in HF are not even type 2 MI, but rather "non-MI troponin elevation." Yet, if CAD has not been addressed previously, coronary angiography is still warranted to address the underlying etiology of HF, after diuresis and preferably before discharge, with revascularization if appropriate.

Conversely, acute HF with *ischemic ST changes, new Q waves, severe troponin rise (hs-troponin T >300–400, hs-troponin I >1000–2000), or new segmental akinesis* may be considered type 1 MI or type 2 MI with CAD and treated as such. About 14% of acute HF presentations are triggered by ischemia.[17]

In acute HF, chest tightness is frequently a description of dyspnea, or ischemia from ↑ LVEDP, and does not equate with CAD. Crescendo exertional chest discomfort that precedes HF is more suggestive of CAD.

While acute severe hypertension may cause type 2 MI, it may also result from type 1 MI with severe angina (catecholamine surge). In type 1 MI, hypertension drastically improves with angina relief and nitroglycerin, whereas in malignant hypertension, hypertension is persistent and difficult to control despite multiple antihypertensive therapies, nitroglycerin only having a minor effect. Nitroglycerin has a mild and transient antihypertensive effect, and thus a sustained drop in BP with nitroglycerin often implies that hypertension was secondary to MI.

Management of type 2 MI: The primary therapy is directed towards the primary insult (e.g., sepsis, anemia, severe HTN, tachyarrhythmia). *Acute antithrombotic therapy and coronary angiography are not warranted. Ischemic workup, by means of stress testing or coronary angiography, may be electively performed, before or after discharge. This depends on the severity of the ischemic findings and troponin rise vs. the severity of the stressor*.

For example, in a patient with gastrointestinal (GI) bleed and angina, the primary treatment consists of transfusion and GI therapy, e.g., endoscopic cauterization. Antithrombotic drugs should be avoided for at least few days, and, if possible, weeks. Depending on the ECG, the echo findings, and the severity of anemia, coronary angiography may not be required. Accordingly, mild hs-troponin T rise of 100 ng/L without significant ECG abnormalities, occurring with acute and severe anemia or severe septic shock, may not require coronary angiography. On the other hand, hs-troponin T of 300–400 ng/L with ST depression in the setting of a nadir hemoglobin 8–9 g/dl or uncomplicated pneumonia often requires coronary angiography before discharge, particularly because it may be difficult to differentiate type 2 MI on top of chronic CAD from type 1 MI.

Importance of differentiating the two subtypes of type 2 MI: A large European registry distinguished between *type 2 MI with underlying CAD* (CAD history or new CAD diagnosis during admission), and *type 2 MI without underlying CAD*.[10] Half of patients with type 2 MI had no underlying CAD. From a cardiovascular standpoint, the prognosis was impressively benign in patients with type 2 MI without underlying CAD, whose mean age was 72: no cardiac mortality and 0.8% overall mortality at 3 months. Conversely, patients with type 2 MI and underlying CAD had a cardiac mortality comparable to type 1 MI at 3 months (~4% vs. 5%), and an overall mortality higher than type 1 MI (9% vs. 6%) (higher mortality related to older age [mean age 76], more comorbidities and higher BNP). Similar observations were made in other registries, except for the finding of a high non-cardiac mortality in all type 2 MIs.[18,19]

Thus, long-term management is dramatically different when underlying CAD is present and somewhat resembles the long-term management of type 1 MI (Table 1.1).

Table 1.1 Tips in MI definition.

- In the absence of clinical or ECG features of MI, the troponin rise is not even called MI (called injury).
- Most troponin elevations in HF are not even type 2 MI, but rather "non-MI troponin elevation."
- The term NSTEMI is reserved for type 1 MI. Type 2 MI is not called "type 2 NSTEMI."
- *Type 2 MI with underlying CAD* is managed differently than type 1 MI (no antithrombotic therapy, no acute revascularization). Yet, from the standpoints of cardiac prognosis and chronic management, type 2 MI with CAD is somewhat comparable to type 1 MI and dramatically different than type 2 MI with no CAD, which has a much better prognosis. This suggests the importance of eventual CAD workup after type 2 MI.
- A case may initially be considered type 1 MI, only to be later reconsidered type 2 MI once evidence of an acute noncardiac illness arises (e.g., fever, bacteremia) or once coronary angiography shows no acute disease. The reverse may also be true.
- ST depression is common during fast tachyarrhythmias and after their conversion to sinus rhythm (cardiac memory), even in the absence of ischemia. It is not specific for MI definition in this setting.

C. Non-ischemic myocardial injury (also called "non-MI troponin elevation")

In this case, myocardial injury occurs because of a demand-supply imbalance **similar to type 2 MI but less profound and with less CAD**, or because of a direct cardiomyocyte injury (trauma, myocarditis, rhabdomyolysis, cytokines and neurohormones in shock, stroke, or post-operative states). This injury may be chronic with steady, chronic troponin elevation (e.g., advanced kidney disease or cardiomyopathy).*

Therapy is directed towards the primary insult. The prognosis is *generally better than type 2 MI, as CAD is less likely*.[17] Ischemic workup is usually not needed or justified for non-MI injury (unlike some type 2 MIs). Antithrombotic therapy is not justified.

D. Coronary vasospasm and microvascular dysfunction

It was initially hypothesized by Prinzmetal and then demonstrated in a large series that coronary vasospasm and vasospastic angina most often occur in patients with significant CAD at the site of a significant and sometimes unstable atherosclerotic obstruction.[20–22] In fact, a ruptured plaque is commonly accompanied by vasospasm, as the activated platelets and leukocytes release vasoconstrictors.

Vasospasm also frequently occurs without obstructive coronary atherosclerosis and may lead to chronic vasospastic angina. In fact, in the current era, the term "coronary vasospasm" is mainly used to identify this "isolated coronary vasospasm" with no severe CAD. *Indeed, isolated vasospasm is frequently the underlying disease process in patients with typical angina or MI yet no significant CAD*.[23–27] The diagnosis is definitely made when: (i) vasospasm is angiographically reproduced with provocative testing, *along with* (ii) symptoms *and* (iii) ST changes during testing.

Endothelial dysfunction, which underlies isolated coronary vasospasm, may also occur at the microvascular level and manifest as diffuse microvascular constriction, not visible angiographically, or as insufficient microvascular dilatation during stress.

E. MI with non-obstructed coronary arteries (MINOCA)

About 6–10% of patients presenting with **a picture of type 1 MI** have normal coronary arteries or insignificant CAD (<50% obstructive; 50% being considered obstructive in MI, unlike the 70% cutoff in stable CAD). This prevalence is higher among women and younger patients; up to 15% of women presenting with a type 1 MI picture have no CAD.[26–35] The picture is mostly a NSTEMI picture, but up to a third of cases are STEMI, and half of the patients have completely normal angiographic appearance of the coronary arteries.[26,27] This phenomenon is coined MINOCA and may be due to any of the following processes:[26,27,31]

1. True type 1 infarction from:
   a. plaque rupture or plaque erosion that has embolized distally without leaving any significant stenosis; or thrombosed then recanalized with antithrombotic therapy (or spontaneously). As such, intracoronary imaging often needs to be performed to assess moderate or hazy irregular stenoses in ACS.
   b. overlooked occlusion of a branch vessel, such as a diagonal or OM, particularly when it is a flush occlusion
   c. coronary embolus (in patients with AF or severe LV dysfunction) or spontaneous coronary thrombosis from thrombophilia
2. Infarction from isolated coronary spasm or microvascular disease[24–27]
3. Myopericarditis
4. Takotsubo cardiomyopathy
5. Overlooked type 2 MI mechanisms:
   - Hypertension with diastolic dysfunction and elevated LVEDP
   - Pulmonary embolism
   - Tachyarrhythmia, or unsuspected hyperthyroidism

Troponin elevation is generally mild (hs-troponin T < 300 ng/L, troponin I < 1000 ng/L) in overlooked type 2 MI, but may be severe in the other processes 1–4.

Workup with cardiac MRI: Cardiac MRI is a central investigation in MINOCA. In an analysis of all comers with MINOCA, MRI established the diagnosis in most patients (***three main diagnoses: myocarditis 33%, infarction 24%, and takotsubo 16%***);[26,27] ~25% did not have significant MRI abnormality (myocardial injury too small, <1 gram?). In two studies of patients with severely elevated troponin

*A very small group of individuals have heterophile antibodies that agglutinate with the murine antibodies used in the troponin assay, causing the very rare "falsely positive troponin elevation." These patients have chronic troponin elevation, sometimes severe, discrepant with the stable clinical setting. An alternative troponin assay or a special heterophilic blocking reagent is used for confirmation.

(up to 27 ng/ml, mean 9 ng/ml) and unobstructed coronary arteries, cardiac MRI established the diagnosis in 90% of patients (myocarditis 60%, infarction 15%, and takotsubo ~14%).[34,35]**

Other workup: In a cohort of 145 women with MINOCA (median angiographic stenosis 30%), OCT showed plaque disruption in 46% of the cases, at times in an angiographically normal coronary segment and even in some patients with a fully normal coronary angiogram.[28] An even higher prevalence of plaque disruption, >50%, was seen in another OCT study of men and women with MINOCA whose MRI excluded myocarditis and takotsubo.[29] MRI showed an ischemic pattern in most (75%) but not all of these plaque disruption cases. Yet MRI detected an ischemic pattern in an additional 25% of patients, missed by OCT, coronary vasospasm being the likely culprit in this subset. Half the time, ischemic edema was seen with no LGE.

Regarding coronary artery vasospasm, one meta-analysis showed that vasospasm, macro- or microvascular, was inducible in 27% of patients with MINOCA, suggesting that it is a common pathogenetic mechanism in MINOCA.[26,27] In a contemporary study of MINOCA patients, coronary vasospasm was induced in 46% of them.[25]

Beware of microvascular dysfunction diagnosis in MINOCA: microvascular dysfunction may be a consequence of the myocardial injury, not the cause of it.

Thrombophilia was detected in 14% of MINOCA patients[26,27] (but beware that factor V Leiden and factor II mutation are also prevalent in normal white subjects, 5% and 2%, respectively).

PROMISE trial showed that a diagnostic strategy of systematic MRI, OCT, and acetylcholine provocation of vasospasm, followed by tailored treatment, improves angina status at 1 year; this is mainly driven by the diagnosis of vasospasm in 36% of patients.

Prognosis: Most studies suggest that MI patients without significant CAD have good long-term outcomes,[30–33] particularly if the coronary arteries are angiographically normal,[30,32] with a 6-month risk of death of <1% and death/MI of ~2%. One review suggests a more guarded prognosis, albeit better than MI with obstructive CAD with half of its 12-month mortality.[26,27] *The finding of plaque disruption on OCT does not dictate stenting if stenosis <50%, but rather aggressive antiplatelet and statin therapy.*

Consider the diagnosis of coronary embolus in patients with AF or severe LV dysfunction who present with a large troponin rise yet no obstructive CAD.

Beware of the misuse of the term MINOCA. The term MINOCA does not apply to patients with type 2 MI context or non-MI troponin elevation. It only applies to those with type 1 MI presentation who lack significant angiographic stenosis.

F. Unstable angina

Unstable angina is traditionally defined as any of the following clinical presentations, with or without ECG evidence of ischemia and with a normal troponin:

- Crescendo *exertional* angina: angina that increases in frequency, intensity, or duration, often requiring a more frequent use of nitroglycerin
- New-onset (<2 months) severe *exertional* angina, occurring during normal activities performed at a normal pace

True resting angina of ACS will generally result in a troponin rise. *In case of serially negative hs-troponin* (hs-troponin T < 14–22 ng/L), ***resting pain is not angina, ACS is very unlikely, and the 30-day risk of coronary events is <0.5%*.**[36–38] **In the current era of sensitive troponin, resting chest pain is generally either MI or non-cardiac pain (+/– vasospastic angina), not unstable angina.**

Unstable angina and NSTEMI are grouped together as non-ST-segment elevation ACS (NSTE-ACS). However, *it must be noted that unstable angina has a much better prognosis than NSTEMI,* particularly that many patients labeled as unstable angina do not actually have true angina, and if they do, the underlying CAD is stable CAD, sometimes severe, but not ACS.[4–6,39] **In fact, in the current era of highly sensitive troponin assays, a true ACS with coronary thrombosis and resting or prolonged (>20 min) pain is accompanied by a troponin rise. Resting unstable angina is, thus, a vanishing entity.[40]**

The patient either has non-cardiac pain, stable angina (sometimes severe), or true ACS with positive troponin. **The negative troponin, "unstable angina" is more in the realm of severe or progressive stable angina than unstable CAD with plaque rupture**.

G. Additional notes: definition of reinfarction, type 3 MI, post-PCI MI (type 4 MI), and post-CABG MI (type 5 MI)

In patients with a recent infarction (a few days earlier), the diagnosis of *reinfarction* relies on:

- CK or CK-MB re-elevation, as they normalize faster than troponin, or
- Change in the downward trend of troponin (re-increase *>20%* above the nadir)[1]

Type 3 MI is defined as sudden death with preceding clinical and ECG features suggestive of MI, such as VF.

In the *post-PCI context*, MI is diagnosed by a troponin elevation >5× normal, *along with* ischemic chest pain ≥20 minutes, ischemic ST changes or Q waves, new wall motion abnormality, or angiographic evidence of procedural complications.[1] In patients with elevated baseline cardiac markers that are stable or falling, post-PCI MI is diagnosed by *>20%* reincrease of the downward trending troponin to a value >5× normal, along with the other features (most studies use a 50% rather than a 20% cutoff in the post-PCI context). In patients

**Late gadolinium enhancement and/or edema on T2 may be seen with myocarditis or infarction. Only edema may be seen in takotsubo, not late gadolinium enhancement. The distribution of the anomaly distinguishes myocarditis from an ischemic pattern:[34]

- Distribution not consistent with an arterial territory + subepicardial or mid-wall predominance → myocarditis
- Distribution consistent with an arterial territory + subendocardial or transmural predominance → infarction

with elevated biomarkers that are on the rise, periprocedural MI is defined by an increase of the next troponin I by at least 50%, along with the other clinical/ECG/angiographic features (this is the definition used in trials, e.g., ACUITY, EARLY ACS, CHAMPION trials). Note that spontaneous NSTEMI carries a much stronger prognostic value than post-PCI NSTEMI, despite the often mild biomarker elevation in the former (threefold higher mortality).[41,42] In fact, in spontaneous NSTEMI, the adverse outcome is related not just to the minor myocardial injury but to the ruptured plaques that carry a high future risk of large infarctions. This is not the case in the controlled post-PCI MI. Along with data suggesting that only marked CK-MB elevation carries a prognostic value after PCI, an expert document has proposed the use of CK-MB ≥10× normal or troponin ≥70× normal to define post-PCI MI, rather than the mild troponin rise.[42]

In the *post-CABG context*, MI is diagnosed by a troponin elevation >10× normal, *associated with* new Q waves or new wall motion abnormality.[1]

Additional note: importance of LVEDP

The determination of LVEDP is critical in patients with ACS and insignificant CAD. Elevated LVEDP from acute diastolic dysfunction or severe HTN is a common cause of mild troponin elevation in patients with normal coronary arteries. Microvascular *coronary flow is driven by the gradient between diastolic blood pressure and LVEDP*; thus, microvascular flow is impeded by an elevated LVEDP. In fact, a gradient of 40 mmHg between diastolic blood pressure and CVP, or by extrapolation, LVEDP, is a zero-flow gradient, as at least 40 mmHg is required to overcome the microvascular resistance.[43]

II. Clinical features, ECG, cardiac biomarkers, and echocardiography in ACS

A. Assess the clinical features of chest pain (Table 1.2)

- The relief of chest pain with sublingual nitroglycerin does not reliably predict ACS. Similarly, the relief of chest pain with "GI cocktail" does not predict the absence of ACS.[44]
- Chest pain lasting over 30–60 minutes with consistently negative markers usually implies a low ACS likelihood. *A prolonged pain is usually 1 of 2 extremes, an infarct or a non-cardiac pain.*
- Older age and risk factors increase the general likelihood of future MI. They do not specifically predict that the current pain is MI (low acute predictive value).

B. ECG

The following ECG findings are diagnostic of non-ST elevation ischemia (Chapter 32, section IX):

- ST depression ≥ 0.5 mm, especially if transient, dynamic, not secondary to LVH, and occurring during the episode of chest pain.
- Deep T-wave inversion ≥ 5 mm (T inversion < 5 mm is non-specific); or dynamic, biphasic or inverted Wellens T waves in the precordial leads (in which case the ST segment is straight upsloping, followed by a sharp T-wave descent).
- Transient ST elevation (lasting < 20 minutes). This corresponds to a thrombus that occludes the lumen off and on, an unstable plaque with vasospasm, or, less commonly, a stable plaque with vasospasm.
- ST depression in ≥6 leads with ST elevation in aVR or V_1 suggests left main or 3-vessel CAD. This indicates high-risk NSTEMI but **is not STEMI**. It may also reflect, in up to 40% of the cases, global ischemia from profound demand-supply mismatch even with no major CAD (e.g., profound anemia, shock, ischemia post-cardiac arrest, prolonged hypoxemia).[45]

Table 1.2 Clinical features of chest pain.

Clinical features suggestive of angina
Typical angina is reproduced or worsened by exertion. In case of vasospasm or ACS, angina may occur only at rest or at night without an exertional component
Severe distress, deep fatigue, diaphoresis, jaw radiation, or severe nausea during pain is concerning for angina (the latter symptoms may occur without pain and are called "angina equivalents")
Prior history of CAD or MI with typical angina or symptoms mimicking prior MI[a]
New MR murmur[b]
Clinical features suggestive of a low angina likelihood (the 3 Ps)
Chest pain that is ***P***ositional or reproduced with certain chest/arm movements
Pleuritic pain (↑ with inspiration or cough: suggests pleural or pericardial pain, or costochondritis)
Palpable pain localized at a fingertip area and fully reproduced with palpation[c]
Pain >30–60 min with consistently negative troponin
Very brief pain <15 s

[a] **Traditional CAD risk factors are only weakly predictive of the likelihood of ACS during a given presentation**.[44] For example, shoulder pain that mainly occurs with shoulder movements is unlikely angina, even in a diabetic patient with prior MI. **Once ACS is otherwise diagnosed, diabetes and PAD do predict a higher ACS risk.**

[b] A new MR murmur in a patient with chest pain is considered ischemic MR until proven otherwise.

[c] True angina and PE pain may seem reproducible with palpation, as the chest wall is hypersensitive in those conditions. **A combination of multiple low-likelihood features** (e.g., reproducible pain that is also positional and sharp), rather than a sole reliance on pain reproducibility, better defines the low-likelihood group.[46,47]

On the other hand, LVH and bundle branch blocks are not specific for ischemia and make the ECG less interpretable. They cause discordant ST/T depression and ST/T elevation proportionate to the QRS size. ST/T changes may be slightly dynamic, depending on the heart and lead positions. If QRS is amplified, ST depression will amplify. They do predict an intermediate risk of in-hospital complications (vs. high risk for dynamic ST depression).[4–6,48] As per ESC guidelines: "hemodynamically stable patients presenting with chest pain and LBBB only have a slightly higher risk of MI compared to patients without LBBB."

Only 50% of patients with NSTEMI have an ischemic ECG,[49] and 20% of NSTEMIs have an absolutely normal ECG.[50,51] Yet, **patients with ischemic ECG are higher-risk patients** and more often have LAD or multivessel involvement.

ECG performed during active chest pain has a higher sensitivity and specificity for detection of ischemia. However, even when performed during active ischemia, the ECG may not be diagnostic, particularly in left circumflex ischemia. In fact, up to 50% of acute coronary occlusions fail to meet classic STEMI criteria.[52] These may show no significant ST-T abnormalities, or only subtle ST elevation or hyperacute T waves with subtle reciprocal ST depression (subtle STEMI), for various reasons: (i) the vessel may spontaneously recanalize and become subtotally occluded, or the vessel may occlude progressively, allowing the development of robust collaterals that prevent ST elevation or even ST depression upon coronary occlusion; (ii) the ischemic area is small or not well seen on the standard leads (especially the posterior or lateral area). ***In general, ~20–30% of NSTEMIs are due to acute coronary occlusion and may be, pathophysiologically, STEMI-equivalents missed by the ECG and potentially evolving into Q waves: they are better called occlusion MI (OMI)***, and have intermediate troponin values between STEMI and NSTEMI (closer to NSTEMI) and higher mortality than NSTEMI with non-occluded culprit artery.[52–54] ***Because they more commonly have some flow to the infarcted area compared to STEMI, they likely still benefit from late PCI >24 hours (they are on the overlap between STEMI and NSTEMI)***.

To improve the diagnostic yield of the ECG:

- In a patient with persistent typical angina and non-diagnostic ECG, record the ECG in leads V_7–V_9. ST elevation is seen in those leads in > 80% of LCx occlusions, many of which are missed on the 12-lead ECG.
- Repeat the ECG at 10–30-minute intervals in a patient with persistent typical angina.
- Perform urgent coronary angiography in a patient with persistent distress and a high suspicion of ACS, particularly if ECG has subtle, ischemic-looking ST elevation in some leads (Chapter 2, Part 1, Section V), even if troponin has not risen yet.
- *ECG should be repeated during each recurrence of pain, when the diagnostic yield is highest. ECG should also be repeated a few hours after pain resolution* (e.g., 3–9 hours) and next day, looking for post-ischemic T-wave inversion and Q waves, even if the initial ECG is non-diagnostic. The post-ischemic T waves may appear a few hours after chest pain resolution.

C. Cardiac Troponin I or T

Whereas troponin I and T are also present in skeletal muscles, the muscular configuration is different and is not detected by the cardiac troponin assays. Cardiac troponin I and T are highly specific for a myocardial injury. However, this myocardial injury may not be secondary to a coronary event but to other insults (e.g., critical illness, HF, hypoxemia, hypotension), without additional clinical, ECG, or echocardiographic features of MI.

Hs-troponin assays have a much lower *detection cutoff* than the conventional, sensitive troponin assays (e.g., *detection cutoff* = 0.005 ng/ml vs. 0.04 ng/ml); they detect troponin in ≥50% of healthy individuals, and in fact, some very-high-sensitivity assays can measure troponin in almost all individuals. This detection cutoff is not to be confused with *MI cutoff* of hs-troponin, which is close to that of conventional, sensitive troponin (~0.04 ng/ml). Yet, even MI cutoff is lower and more precise with hs-troponin, with precision at the third decimal; also, this fine precision allows MI cutoff to be lower in women than men, as women normally have smaller myocardial mass and troponin values.[55] Thus, **hs-troponin slightly increases the diagnosis of MI in comparison to sensitive troponin (by ~20%).**[4–6] **More importantly, it rises earlier and allows delineation of a very low level within the non-MI range, allowing patient stratification within this non-MI range (e.g., undetectable = very low risk).** *Note:* to avoid the confusion of decimals, hs-troponin is reported as a whole number in ng/L (e.g., detection cutoff 5 ng/L); this may be divided by 1000 to provide a conventional ng/ml value.

Kidney disease may be associated, per se, with a chronic mild elevation of troponin I. This is not related to reduced renal clearance of troponin, a marginal effect at best. It is rather due to the underlying myocardial hypertrophy, chronic CAD, and BP swings. This leads to a chronic ischemic imbalance, and, as a result, chronic myocardial damage.

Kinetics of troponin rise and decline: In MI, troponin rises above *MI cutoff* within *3 hours* of an episode of ischemia lasting >20–30 minutes. Hs-troponin rises above *detection cutoff* rapidly, usually within 1 hour of ischemia.[4–6] Troponin peaks at 24 hours and remains elevated for 10–14 days. However, in small MI, troponin usually normalizes within 2–3 days. Note that the troponin peak and downslope are much slower than the upslope; thus, patients presenting late after an infarct may have a plateau pattern of stable troponin (Figure 1.4).[1,2] In acutely reperfused infarcts (STEMI or NSTEMI), those markers peak earlier (e.g., 12–18 hours) and sometimes peak to higher values than if not reperfused, but decline faster. Hence, the total amount of biomarkers released, meaning the area under the curve, is much smaller, and the troponin elevation resolves more quickly (e.g., 4–5 days). The area under the curve, rather than the actual biomarker peak, correlates with the infarct size.

Note on CK-MB: CK-MB only rises with large MI, when troponin I exceeds ~1000 ng/L. CK-MB rises at 3–6 hours, peaks at 12–24 hours, and normalizes at 2–3 days. Overall, CK-MB testing has one potential application: in patients with marked troponin elevation and subacute symptom onset, CK-MB helps diagnose the age of the infarct (a normal or downtrending mild CK-MB implies that MI is several days old).

- Troponin will continue to rise until 24–36 hours after the event even if ischemia is alleviated: troponin peak reflects the past. A troponin that continues to rise does not imply, per se, ongoing ischemia. It reflects how big the initial event was many hours ago but does not imply it is still ongoing.
- A very high plateaued troponin (10,000s for hs-troponin I) with minimal delta (<20%) or with decline retrospectively supports late presentation of STEMI equivalent (OMI) >24 hours.

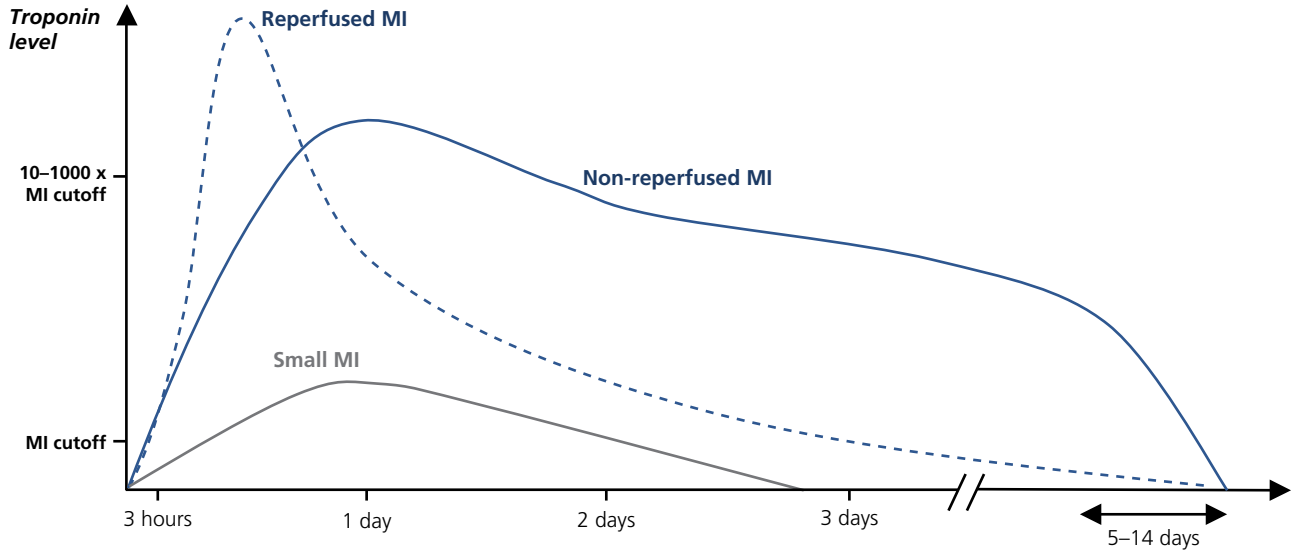

Figure 1.4 Kinetics of troponin release. Troponin rises above MI cutoff within 1–3 hours, then peaks and plateaus at ~24–36 hours. Note the slow decline that mimics a plateau pattern. Reperfused MI has a much narrower curve; the troponin area under the curve, rather than the peak, corresponds to the infarct size. An elevated troponin may be repeated every 8 hours until it trends down, to assess the area under the curve/infarct size.

D. Echocardiography and acute resting nuclear scan

The absence of wall motion abnormalities *during active chest pain* argues against marked ischemia. For optimal sensitivity, the patient must have active ischemia involving >20% of the myocardial thickness across a substantial territory while the test is performed. Wall motion abnormalities may persist after pain resolution in the case of stunning or subendocardial necrosis involving >20% of the inner myocardial thickness (<20% subendocardial necrosis or mild troponin rise may not lead to any discernible contractile abnormality).[56] Conversely, wall motion abnormalities, when present, are not very specific for acute ischemia and may reflect an old infarct. However, the patient is already in at least an intermediate risk category.

Strain echocardiography (global or regional) improves the sensitivity and negative predictive value of echo for ACS diagnosis in patients with normal initial troponin and non-diagnostic ECG (91%), even several hours after the chest pain episode, but is non-specific and has a poor positive predictive value (13% in one study).[46]

Acute resting nuclear scan, with the nuclear injection performed during active chest pain or within ~3 hours of the last chest pain episode, has an even higher sensitivity than echo in detecting ischemia. An abnormal resting scan, however, is not specific, as the defect may be an old infarct or an artifact.

III. Initial approach to acute chest pain presentations and the use of high-sensitivity troponins

Only ~15% of patients presenting with chest pain are eventually diagnosed with ACS.[57,58] Older age and **risk factors** increase the general risk of future MI but **are poor predictors of whether the current pain is MI** (limited acute predictive value).

A. Assess for other serious causes of chest pain at least clinically, by chest X-ray and by ECG. *Always consider decompensated HF (where dyspnea may be described as chest oppression), pulmonary embolism, aortic dissection, and pericarditis*.

B. Use hs-troponin for MI rule-in and rule-out

According to multiple large registries and meta-analyses, a single undetectable or very low hs-troponin (e.g., 6 ng/L) is associated with <0.3% risk of acute MI and nearly 0% risk of cardiac death at 30 days.[36–38,55,57–65] Even 1-year events were very low at 0.6% in several registries, with a cardiac death ≤0.1%.[36,57,61] This risk is further reduced in patients whose ECG is not suggestive of ischemia. Therefore, discharge is safe in those patients, at least as safe as in patients with negative stress tests, with no need for serial troponin measurement.

For patients acutely presenting with chest pain and no other critical illness, ESC and ACC suggest checking ***hs-troponin at presentation and at 1 or 2 hours after presentation*** (0/1 or 0/2 strategy) (Figure 1.5).[4–6,36–38,55,57–65] An undetectable hs-troponin, or a detectable hs-troponin with insignificant change at 1 or 2 hours rules out MI with >99.5% confidence. **However, the issue is that a substantial proportion of patients who rule in for MI have non-MI troponin elevation or type 2 MI, rather than type 1 MI.** ACS/type 1 MI is the diagnosis in 50–60% of the rule-in cases with hs-troponin T ≥ 52 ng/L, chest pain, and no other critical illness; this proportion is even lower in all comers with elevated troponin.

Note that the **MI cutoff of hs-troponin is close to that of conventional troponin**, but is slightly lower and more precise than conventional troponin, with precision at the third decimal, and the cutoff is lower in women than men with many assays.[55] Thus, **hs-troponin slightly increases the diagnosis of MI in comparison to conventional troponin (by 20%). More importantly, it allows delineation of a very low level and a very low risk population that cannot be delineated with conventional troponin** and allows early and safe discharge of these very low risk patients. Based on this strategy, over 60% of patients may be discharged at presentation or 1 to 2 hours later. In fact, up to 50% of patients presenting with chest pain have undetectable or very low hs-troponin (<5–6 ng/L).[61,62]

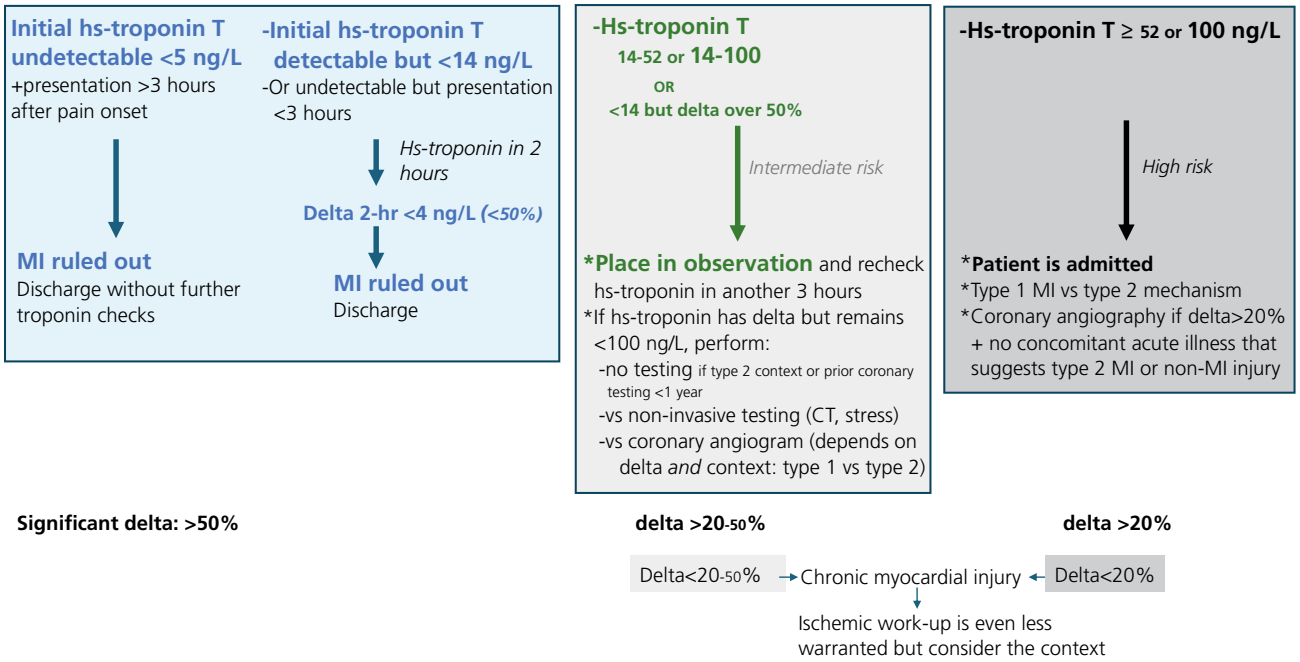

Figure 1.5 0/1-hour or 0/2-hour algorithm using hs-troponin in patients presenting to the emergency department with suspected ACS, inspired by ESC and ACC. This example uses the cutoff values specific for Roche Elecsys hs-troponin T assay. Of note, with this assay, *the 99th percentile threshold is 22 ng/L in men, 14 ng/L in women, and 30s ng/L* in the elderly (>60y), *yet 52 ng/L is chosen as the high-risk value*. As per ESC, this is done to improve the positive predictive value for type 1 MI, particularly that the 99th percentile threshold increases with age and the population studied and is not highly specific. Even the 52 ng/L cutoff has only a 50–60% positive predictive value for type 1 MI, and <50% in US studies, hence 100 ng/L is commonly used in the United States.

This algorithm may be applied to other hs-troponin assays using different cutoffs (Abbott hs-troponin I, high-risk rule-in value ~100–150).

Clinical scores (e.g., HEART) do not improve the safety of this algorithm and unnecessarily reduce the proportion of patients ruled out.[57,66]

Most patients who rule out with the hs-troponin strategy have non-cardiac pain. Hence, **further testing is not definitely required in patients who rule out with the hs-troponin strategy, particularly when hs-troponin is undetectable**. Yet some of the rule-out patients have true angina, especially those with exertional chest pain. CTA or stress imaging (>stress ECG, as per ESC) remains necessary in exertional chest pain and in patients with intermediate hs-troponin findings: a normal or low-risk stress imaging suggests no CAD, microvascular disease, or low-risk CAD for which medical therapy is appropriate. Medical therapy is tailored to how much the physician believes the chest pain is anginal, based on the *exertional component,* and is somewhat comparable to the management of chronic CAD.

Noteworthy case: A patient with persistent resting pain and negative serial troponin levels has a low likelihood of CAD and may be discharged, or may undergo stress testing while having the pain.

Rule-in patients frequently require coronary angiogram, in the absence of a concomitant type 2 MI setting.

C. Stratification of patients who rule in for MI

In patients with elevated troponin, the most important step is to distinguish type 1 MI from secondary myocardial injury (which does not dictate acute antithrombotic therapy or coronary angiography). In a patient presenting with chest pain and no other obvious cardiac or systemic insult (HF, critical illness), any troponin elevation, even if mild (e.g., hs-troponin T 40 ng/L), is a high-risk feature suggestive of type 1 MI and treated as such, with an initial invasive strategy. Yet, in all-comers with chest pain or suspected ACS, an hs-troponin T in the 14–52 ng/L range yields a limited positive predictive value for type 1 MI of <50%, and potentially <30%.[66,67] Even a higher cutoff of >52 ng/L has a modest positive predictive value for type 1 MI (~50–60%),[4–6] less so in US studies.[15,66,67] In the United States, a cutoff of >100 ng/L may be used to improve type 1 MI specificity. Thus, depending on the context, the 14–100 ng/L range may qualify for non-invasive coronary testing or no testing at all. ***Severe hypertension, elevated LVEDP from acute diastolic dysfunction, and vasospasm (micro- or macrovascular) are common causes of mild troponin elevation in patients with non-obstructed coronary arteries.***

Ischemic ST depression or more severe hs-troponin T rise >300 ng/L increases the probability of type 1 MI (rather than MI secondary to an overlooked type 2 MI setting, hypertension, or microvascular disease), and further justifies an initial invasive strategy.[68] ST changes also increase the probability of more extensive CAD. The author classifies hs-troponin levels as per Figure 1.3.

The TIMI, HEART and GRACE risk scores may be used in ACS once the diagnosis of ACS is established. **These scores should not be used for the diagnosis of ACS; they have a prognostic rather than a diagnostic utility.** They do not improve the safety of the hs-troponin algorithm and unnecessarily reduce the proportion of patients ruled out, causing more admissions and testing. They include baseline demographics (age, risk factors, history of CAD) and pain features that *do not specifically predict* whether the *current pain* is MI.[57] Also, an elevated troponin may be associated with a TIMI risk score of only 1, yet in the right setting, even a mild troponin rise (e.g., 40 ng/L) is a high-risk feature.

Unstable angina – Some patients qualify for an initial invasive strategy even if troponin is below MI cutoff, and may be placed under the category of *"unstable angina," although "severe" or "progressive angina" is a better nomenclature* (lower-risk ACS per ACC and ESC): typical angina at mild exertion, with a typical timing and duration of angina (chest discomfort occurs with exertion, is relieved with rest, and lasts a few minutes).

Hs-troponin is usually detectable in those patients, albeit below MI cutoff. This resembles the hs-troponin behavior after a stable angina episode or a positive exercise stress testing: hs-troponin rises to detectable levels but remains well below MI cutoff, even if *stress-induced ischemia is severe*. Ischemia must be *sustained* to induce a troponin rise above MI cutoff.[69]

Women with negative troponin do not generally qualify for an initial invasive strategy, as there is evidence of harm with this strategy in low-risk women; coronary angiography is generally reserved for high-risk findings on CTA or stress imaging.

Rest pain or *prolonged pain >20 min* with negative troponin is not usually ACS and does not qualify for initial coronary angiography. Conversely, *exertional pain* with negative troponin may reflect CAD, a stable CAD with no plaque rupture that may, nonetheless, be severe or extensive; when angina occurs on mild exertion, initial coronary angiography is justified.

IV. Management of NSTEMI

There are 4 lines of therapy for NSTEMI:

- Initial invasive strategy
- Antiplatelet therapy:
  1. Aspirin
  2. Platelet ADP-receptor antagonists (clopidogrel, prasugrel, ticagrelor)
  3. Glycoprotein IIb/IIIa antagonists
- Anticoagulants
- Anti-ischemic and other therapies
- No thrombolytics. Thrombolytics are only useful for STEMI. In NSTE-ACS, the thrombus is nonocclusive and thrombolytics may promote distal embolization, overall worsening myocardial perfusion.[70] Also, thrombolytics expose clot-bound thrombin, leading to platelet activation and potentially more thrombus formation in NSTE-ACS.

A. Initial invasive strategy

An initial invasive strategy implies that diagnostic coronary angiography and *possible* revascularization are performed within 72 hours of presentation, and within 24 hours in the highest risk subgroup. ***An initial or early invasive strategy does not equate with early PCI*. It rather equates with *early coronary angiography* for risk stratification and subsequent management by PCI, CABG, or medical therapy according to the angiographic findings. It is an early *intent* to revascularize.** In various clinical trials that managed ACS invasively, ~55% received PCI, ~20% received CABG, and 25% received medical therapy only.[71–73] The initial invasive strategy is contrasted with the initial conservative/selective invasive strategy, in which the patient is treated medically and risk-stratified with stress testing, then invasively managed in case of recurrent true angina or high-risk stress test result.

Three major trials (FRISC II, TACTICS-TIMI 18, RITA 3) established the benefit of an initial invasive strategy and showed that in high-risk ACS patients this strategy reduces the combined endpoint of death and MI in comparison to an initial conservative strategy, particularly in patients with positive troponin, ST-segment changes, or TIMI risk score ≥3 (50% reduction in death/MI in those subgroups in all three trials, with an absolute risk reduction of ~5% at 30 days and 1 year).[74–76] The mortality was reduced at 1-year follow-up in the overall FRISC II trial (by ~40%, more so in the highest risk groups), and at 5-year follow-up in the overall RITA 3 trial. Those beneficial results were seen despite the narrow difference in revascularization rates between the initial invasive and initial conservative strategy. For example, in TACTICS, 60% of patients in the initial invasive strategy vs. 35% of patients in the initial conservative strategy received revascularization at 30 days, this difference becoming narrower over the course of 6–12 months. ***These trials did not address revascularization vs. no revascularization in NSTEMI patients who angiographically qualify for revascularization, in which case revascularization is expected to show more striking benefits*.** These trials rather addressed the early intent to revascularize vs. the early intent to not revascularize. In trials where the difference in revascularization between groups was narrower, such as the ICTUS trial, the early invasive strategy could not show a benefit over the early conservative strategy (at 1 year, the revascularization rates were 79% vs. 54%).[77] The results of the ICTUS trial do not imply a lack of benefit from revascularization, but rather that an initial conservative strategy with a later invasive strategy if needed, sometimes weeks later, *may be* appropriate in initially stabilized patients who are free of angina, particularly if they have multiple comorbidities and are not ideal candidates for revascularization (class IIb in ACC guidelines; not recommended in ESC guidelines).

Timing of initial invasive strategy in NSTEMI: early invasive strategy ***<24 hours:*** The exact timing of the initial invasive strategy has been addressed in the TIMACS trial, where an "early" invasive strategy at <24 hours was compared to a "delayed early" invasive strategy at 36 hours to 5 days (mainly 48–72 hours).[73] The early invasive strategy did not reduce the rate of death/MI in the overall group but reduced it in the highest-risk group, with GRACE risk score >140. VERDICT trial reproduced similar findings.[78] Thus, an "early" invasive strategy <24 hours is reasonable in patients with a GRACE risk score >140, but also in all patients with elevated troponin or dynamic ST changes, per ACC and ESC guidelines (class IIa recommendation for <24 hours vs. a more delayed inpatient invasive strategy).[4–6]

Immediate invasive strategy ***<2 hours:*** Coronary angiography becomes "*urgent*" in the following very-high risk cases:

- ST depression of ischemic appearance is recurrent or ongoing, especially if ***also*** profound or extensive with ST elevation in V_1 or aVR (suggestive of left main disease). This indicates the importance of repeating the ECG during each pain recurrence or during persistent pain.
- Angina at rest or minimal exertion that is *refractory* or *recurrent* despite the initial anti-thrombotic and anti-ischemic therapies. In patients with negative ECG and troponin, the persistent chest pain is usually not angina, especially when troponin has been negative >3 hours after pain onset.
- Shock or severe HF or sustained VT attributed to ischemia ***with*** ongoing ***and*** profound ST depression.

Large-scale application of urgent coronary angiography (<2 hours) in all comers with NSTEMI did not improve death or MI (ABOARD and EARLY trials).[79,80]

Delayed initial invasive strategy ***<72 hours:*** This delay is acceptable in patients with negative troponin who nonetheless have typical exertional angina with unstable features (lower-risk ACS, paragraph III.C).[44]

Selective *invasive strategy* (to be done before hospital discharge) is applied to:

- Select patients with *intermediate hs-troponin* (troponin T 14–100 ng/L), mainly those with type 1 MI context or those who undergo CTA or stress imaging with high-risk result (gray zone of Figure 1.5)
- *Select* patients presumed to be *type 2 MI* but with high hs-troponin T >100 ng/L, or worse, >300 ng/L.
- *Select* patients with negative troponin but with typical exertional angina and high-risk CTA or stress imaging (small slice of blue zone in Figure 1.5).

Timing of invasive strategy in ***acute HF:*** In patients with evolving ischemic ST abnormality, new Q waves, or severe troponin rise (hs-troponin T > 300–400, hs-troponin I > 1000–2000), MI is presumed the cause of acute HF (type 1 MI) rather the result of it (type 2 MI). An invasive strategy is indicated and multivessel CAD is expected.

Yet, angiography and PCI are not usually warranted urgently, as they aggravate HF for the following 4 reasons: (i) supine positioning increases ventricular preload; (ii) contrast loading increases preload, LVEDP, and myocardial ischemia; (iii) procedural sedation blunts compensatory vasoconstriction and tachycardia in pre-shock patients; (iv) PCI causes intermittent myocardial flow impairment from balloon inflation, difficult stent delivery, no reflow, side branch loss, or reperfusion injury. This is particularly pronounced if the guiding catheter obstructs coronary flow with ventricularized pressure, and it will not be tolerated if LVEDP is elevated or BP is borderline.

These 4 factors may precipitate a downhill course of shock and massive pulmonary edema requiring emergent intubation in patients who were relatively stable. Thus, in somewhat stable patients, coronary angiography is usually performed 1–3 days later, once proper diuresis has been achieved.[81,82]

This is also the spirit of CULPRIT-SHOCK and NOTION-STEMI trials: in a tenuous patient, avoid treating what is not strictly necessary and rather wait until stabilization (with diuresis/pressors/anticoagulation) (Chapter 2, Section IX.B). **Only HF patients with STEMI or the following triple combination are treated with an immediate invasive strategy** within 2 hours:[4–6,81,82]

- ***Unstable HF***, such as shock or massive pulmonary edema already requiring mechanical ventilation ***AND***
- ***Ongoing AND profound ST depression***.

B. Antiplatelet therapy (Figure 1.6) (see Appendix 5 for a detailed discussion)

Typically, aspirin +/– one ADP-receptor antagonist (ticagrelor, clopidogrel) is started upon admission, upstream of catheterization.[44] In the current era of potent ADP-receptor antagonists and quick catheterization <24 hours, upstream therapy with those agents does not seem necessary, and initiation during catheterization appears sufficient (ACCOAST, ISAR-REACT-5 trials).[83,84] In fact, ESC guidelines recommend against routine pretreatment with an ADP-receptor antagonist when catheterization is planned <24 hours (class III), and both ESC and ACC guidelines give a weak class IIb recommendation for pretreatment when catheterization is planned at >24 hours. Upstream IIb/IIIa inhibitor therapy is not beneficial.[72,85,86]

C. Anticoagulant therapy (see Appendix 5 for a detailed discussion)

Four anticoagulants are considered in NSTE-ACS: (i) *unfractionated heparin (UFH)*, (ii) *enoxaparin*, (iii) *bivalirudin*, and (iv) *fondaparinux*. *Upon admission,* anticoagulation with any one of these four drugs should be initiated. UFH is given class I recommendation by ESC/ACC. Enoxaparin is accepted by ESC as alternative to UFH even if angiography is planned at <24 h (class IIa), but is only recommended by ACC when no invasive strategy is planned. *During PCI*, either UFH or bivalirudin is used (Figures 1.7, 1.8; Table 1.3).

- In NSTEMI, the anticoagulant is not usually withheld before the catheterization procedure.
- The dose of UFH used in NSTEMI is lower than the dose used in PE, with a PTT goal of 46–70 seconds. ***Moderate rather than high-level anticoagulation is appropriate for ischemic reduction in ACS*** and minimizes bleeding, which is a powerful prognostic marker in ACS.
- Anticoagulants are typically stopped after the performance of PCI. If catheterization shows a culprit coronary lesion but PCI is not performed, anticoagulants are typically administered for at least 48 hours (up to 8 days). Longer therapy reduces rebound ischemia, which mainly occurs with heparin.
- In patients undergoing catheterization, upstream enoxaparin therapy is associated with a higher bleeding risk than UFH. Moreover, *the switch between enoxaparin and UFH increases the bleeding risk and should be avoided*. If the patient is going for an invasive strategy and the operator prefers not to use enoxaparin during PCI, the patient should receive UFH on admission, not enoxaparin.
- During PCI, a switch from UFH to bivalirudin, or from fondaparinux to other anticoagulants has not shown harm.

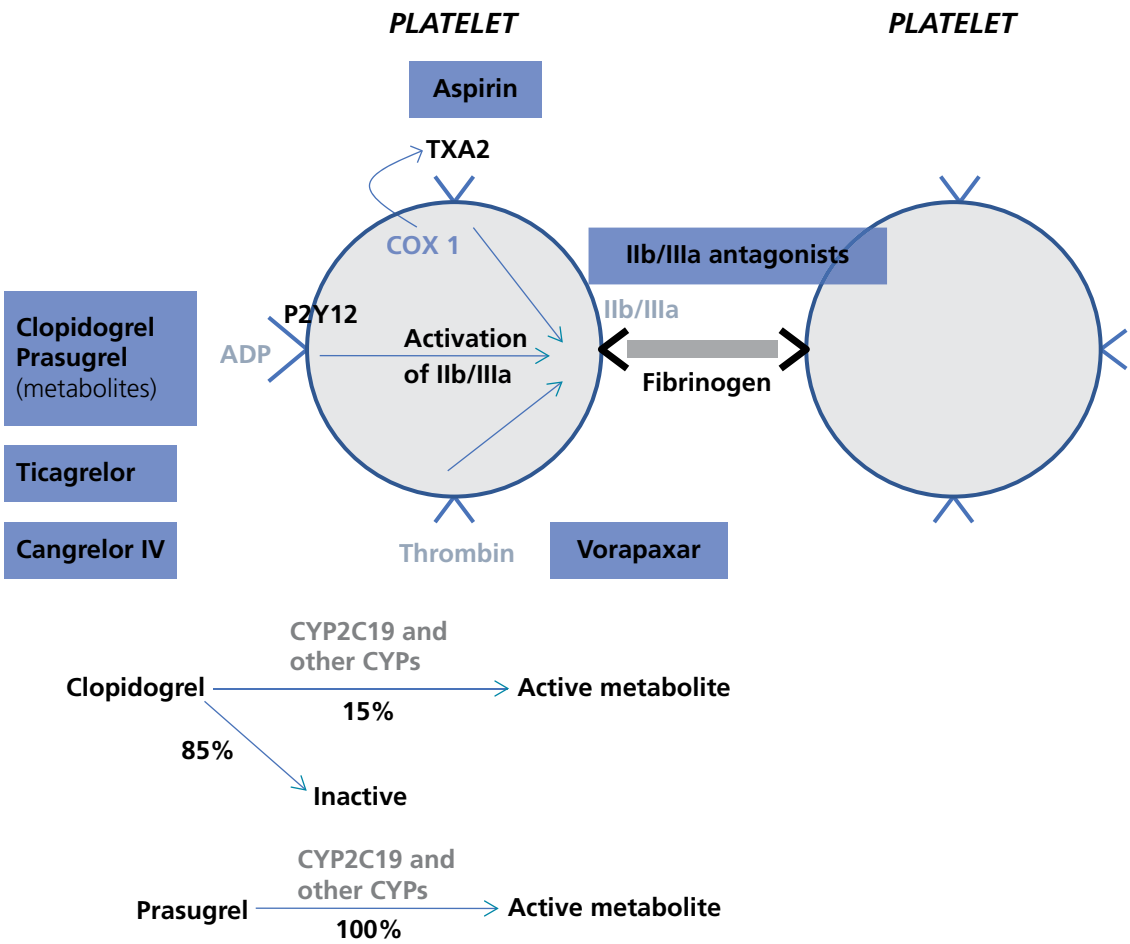

Figure 1.6 Platelet receptors and antiplatelet mechanisms of action.

Cyclooxygenase 1 *(COX-1)* allows the synthesis of thromboxane A2 (TXA2), which acts on its platelet receptor, eventually activating the IIb/IIIa receptor. Aspirin irreversibly acetylates COX-1. While the pharmacokinetic half-life of aspirin is only ~20 minutes to 2 hours, the pharmacodynamic effect of aspirin lasts the lifespan of the platelet (5–7 days).

The platelet ADP receptor eventually leads to conformational activation of the IIb/IIIa receptors. ***Clopidogrel and prasugrel*** (thienopyridines) are prodrugs that get metabolized into the same active metabolite. This active metabolite irreversibly binds to the P2Y12 ADP receptor, extending the pharmacodynamic effect of these drugs to 5–7 days despite a half-life of 6 hours. The prodrugs are metabolized by cytochromes (CYP), particularly CYP2C19; only 15% of clopidogrel vs. 100% of prasugrel is actively metabolized. This explains why prasugrel is a much more potent inhibitor of platelet aggregation (~75% vs. ~35% inhibition of platelet aggregation).

Some patients have a CYP2C19 mutation that slows clopidogrel metabolism and preferentially increases its inactivation by esterases, translating into a poor or no response to clopidogrel. Prasugrel, on the other hand, has only one metabolic pathway, and will be metabolized by cytochromes regardless of how slow the metabolism is.

Ticagrelor directly binds to the P2Y12 ADP receptor and reversibly inhibits it (the effect clears as the drug clears from plasma). Despite being a reversible ADP antagonist, the very potent ADP blockade and the long half-life translate into an antiplatelet effect that lasts 3–4 days (half-life ~15 hours). Since it directly acts on its receptor, the response to ticagrelor is consistent and potent (~75% platelet inhibition), including in clopidogrel non-responders.

Cangrelor is an intravenous ADP-receptor antagonist that directly and reversibly binds to the ADP receptor. It inhibits 90% of the platelet aggregation. In contrast to ticagrelor, it has a short half-life of 5 minutes, which, in addition to the reversible receptor binding, leads to a very quick onset and offset of action.

Thrombin is also a potent activator of platelet aggregation. ***Vorapaxar*** blocks the thrombin receptor.

Cyclic AMP, promoted by cilostazol, inhibits platelet aggregation.

The ***IIb/IIIa* receptor** is the final common pathway of platelet aggregation and allows linking of the platelets through fibrinogen molecules.

D. Anti-ischemic therapy and other therapies

1. ***β-Blocker***, such as oral metoprolol, is administered at a dose of 25 mg Q8–12 h and titrated to 50 mg Q8–12 h if tolerated. In the COMMIT-CCS trial, the initiation of β-blockers on the first day of MI (mainly STEMI) was associated with an increased risk of cardiogenic shock during that first day, the benefit from β-blockers on reinfarction and VF emerging gradually beyond the second day.[87] Overall, β-blockers significantly reduced the endpoint of death/MI/cardiac arrest between day 2 and day 15, but increased this endpoint in the first

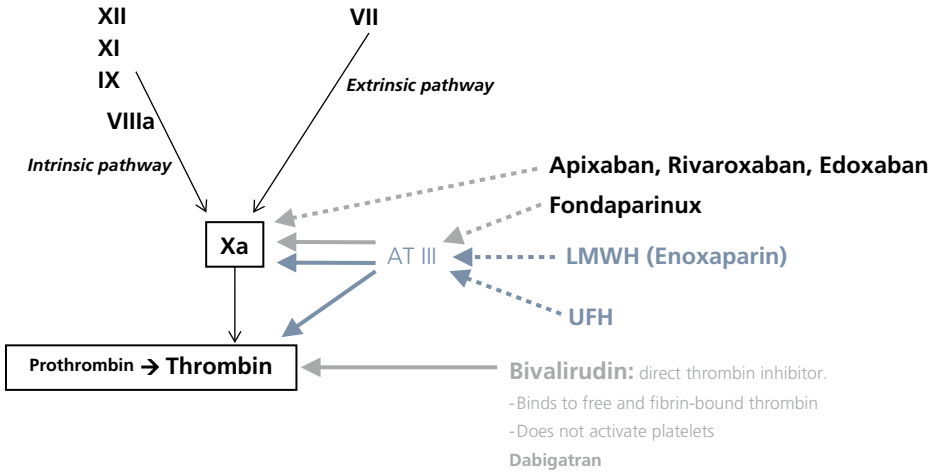

Figure 1.7 Specific effects of the four anticoagulants.

A heparin derivative induces a conformational change in antithrombin III (AT III), which, according to the size of the heparin–AT III complex, predominantly inactivates Xa or the active thrombin. UFH inactivates thrombin preferentially, while low-molecular-weight heparin (LMWH) inactivates Xa preferentially. The smaller fondaparinux molecule inactivates Xa exclusively. The inactivation of Xa eventually inhibits thrombin generation rather than thrombin activity. Heparin activates platelets directly by binding to them, which also triggers antiplatelet antibodies (HIT).

The oral direct thrombin inhibitor (dabigatran) and the oral Xa antagonists (apixaban, rivaroxaban) are used to treat AF, not ACS.

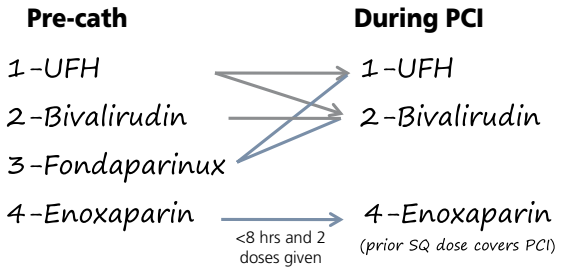

Figure 1.8 Summary of anticoagulant use in NSTE-ACS, before catheterization and during PCI.

Operators who are not comfortable with performing PCI solely under the coverage of a prior subcutaneous dose of enoxaparin should avoid starting enoxaparin on admission and should use any of the other 3 agents upfront.

Table 1.3 Summary of antithrombotic therapy in ACS.

Antiplatelet therapy

1. Aspirin 325 mg on admission to all, then 81 mg daily (after a 325 mg first dose)
2. Clopidogrel 300 mg or ticagrelor 180 mg *may be* used on admission, but in the era of expedite catheterization <24 hours, ADP receptor antagonists are best reserved for downstream use, during PCI
3. After coronary angiography, if PCI is to be performed:
   Add 300 mg of clopidogrel if 300 mg has already been given
   or load with 600 mg of clopidogrel in the lab if no clopidogrel has been given
   or load with prasugrel 60 mg (even if clopidogrel has been given)
   or load with ticagrelor 180 mg (even if clopidogrel has been given)
   or infuse IV cangrelor for 2 hours, *not if patient already received P2Y12-antagonist,* then load with oral P2Y12-antagonist as infusion finishes

   GPI if PCI complications or heavy thrombus burden (bailout use of GPI)

Anticoagulant therapy

UFH pre-catheterization and during PCI

or Fondaparinux 2.5 mg SQ once daily pre-catheterization, with standard-dose UFH during PCI. Valuable if catheterization >24 hours

or Enoxaparin pre-catheterization. If patient received 1 mg/kg SQ within 8 h of PCI and has already received 2 doses of enoxaparin, no additional anticoagulation is needed during PCI (if enoxaparin was used 8–12 h ago *or* only 1 SQ dose was given, add 0.3 mg/kg IV during PCI; if enoxaparin was used >12 hours ago, give 0.5–0.75 mg/kg IV bolus)

day and in patients at increased risk of cardiogenic shock, making the overall β-blocker effect neutral. Therefore, β-blockers are better avoided on the first day, particularly if there are any HF signs or features predictive of cardiogenic shock: SBP <120 mmHg, heart rate >110 bpm, or age >70 years.* Even without high-risk signs, the β-blocker effect was neutral the first day. Counterintuitively, β-blockers are avoided in sinus tachycardia, which is often a pre-shock state. Moreover, intravenous β-blockers are preferably avoided in all patients, as this was the formulation used in COMMIT-CCS on the first day, but may still be used in a patient with active ischemia and none of the previous features (IV metoprolol, 5 mg Q10 min up to 3 times).

2. ***ACE-Is or ARBs*** are recommended in MI with HF, LV dysfunction, or hypertension (class I indication). They may also be used for 6 weeks in MI patients without those features (ISIS-4 and GISSI-3 trials). They are avoided in acute renal failure or when SBP is <100 mmHg or 30 mmHg below baseline. Start slowly, lisinopril 2.5–5 mg QD or captopril 6.25 mgBID, then uptitrate lisinopril to 10 mg QD.

3. ***Statin therapy*** should be started during ACS hospitalization regardless of the baseline LDL. Statin's benefit is not usually immediate but may become evident within 1 month.[88] A more immediate benefit is seen in patients undergoing PCI, as high-dose statin reduces peri-PCI MI.[88] The high doses used in secondary prevention trials, such as atorvastatin 80 mg in the PROVE-IT trial, are preferred as they further reduce cardiovascular events (including death/MI) and peri-PCI MI, possibly through superior stabilization of vulnerable plaques. Note that, for patients receiving chronic statin therapy, the harm from statin withdrawal is immediate, with an early cardiac risk that is higher than that of statin non-users.[89]

4. ***Nitroglycerin (NTG)*** is administered sublingually for chest pain (as needed, Q5 min up to three times if tolerated). NTG should be avoided if SBP <100 mmHg or 30 mmHg below baseline, or bradycardia <50 bpm. Acutely in ACS, one can give NTG at a lower BP level than one can give β-blockers. Later on, in case of borderline BP, the priority is given to β-blocker administration.

IV NTG is indicated for frequently recurrent angina, ongoing angina, or ischemia associated with hypertension or HF. Angina that is not relieved by 400 mcg of sublingual NTG may not be relieved by the smaller infusion dose of IV NTG (10–200 mcg/min); the latter may however be tried, in conjunction with β-blockers and antithrombotic therapy. IV NTG is initiated at 10 mcg/min and increased by 10 mcg/min every 3–5 minutes until symptoms are relieved or a limiting reduction of SBP <100–110 mmHg occurs. Oral or topical nitrates (patch, paste) are acceptable alternatives in the absence of ongoing angina. After stabilization, IV NTG may be converted to an oral or topical nitrate, with a dosing that prevents tolerance and leaves a 12-hour nitrate-free interval (e.g., isosorbide dinitrate 10–40 mg or nitropaste 0.5–2 inches at 8 a.m., 2 p.m. and 8 p.m.).

5. ***Morphine*** may be given for angina that is refractory to the above after a decision is made as to whether emergent revascularization will be performed or not. **Thus, morphine should not be used to mask "refractory angina," and resolution of a true angina only after morphine administration should not defer the emergent performance of coronary angiography ± PCI**.

6. ***Calcium channel blockers***. Dihydropyridines (DHPs) are vasodilators (nifedipine, amlodipine). Non-dihydropyridines are vasodilators that also have negative ino- and chronotropic effects (verapamil, diltiazem). Short-acting DHPs, such as nifedipine, lead to reflex tachycardia and should be avoided in ACS; long-acting DHPs may be used in ACS in combination with β-blockers. Non-DHPs may be used in ACS if β-blockers are contraindicated and LV systolic function is normal; as opposed to DHPs, they should generally not be combined with β-blockers.

7. ***Aldosterone antagonist*** reduces short-term (30 days) and long-term mortality when initiated in MI patients with HF and EF < 40%, at 3–7 days (EPHESUS trial). However, its acute initiation the first 1–2 days in MI with EF > 40% or without HF was not beneficial (ALBATROSS trial [EF >40%] and CLEAR-SYNERGY trial [mostly STEMI, any EF, but no clinical HF]).[90,91]

V. General procedural management after coronary angiography: PCI (culprit and non-culprit), CABG, or medical therapy only

After coronary angiography, a decision is made for PCI vs. CABG vs. continuing medical therapy alone, as dictated by the coronary anatomy. If a decision is made to proceed with CABG, hold clopidogrel and ticagrelor for 5 days before surgery, if possible, and hold enoxaparin for 12–24 hours and eptifibatide for 4 hours before surgery.

A. CABG indications

- Left main disease
- Three-vessel CAD or complex 2-vessel CAD involving the LAD (especially proximal LAD), particularly if angiographic SYNTAX score ≥ 23 (SYNTAX trial) or diabetes (FREEDOM trial).[92]

B. PCI indications

- One- or 2-vessel disease (≥50%)
- PCI is an alternative to CABG in 3-vessel CAD or complex 2-vessel CAD involving the LAD with a SYNTAX score ≤22 and no diabetes.[76] Multivessel PCI (including proximal LAD PCI) compares favorably with CABG if the stenoses' morphology and location are technically amenable to PCI and if full functional revascularization can be achieved with PCI.[93] The presence of a chronic total occlusion, one or more technically difficult or long lesions, or diabetes, should favor CABG, especially because CABG provides a more complete revascularization.

* Also, always avoid β-blockers acutely and chronically in cases of second- or third-degree AV block, PR interval >240 ms, bradycardia <55 bpm, or active bronchospasm. Beyond the first day, SBP below 100 mmHg, rather than 120 mmHg, is the contraindication to β-blockers.

C. NSTEMI with multivessel CAD

1. If PCI is chosen, perform complete multivessel PCI rather than culprit-only PCI, based on FIRE, SLIM, and BIOVASC trials, and an extrapolation from STEMI trials (class I ACC). Treat all *major* arteries' stenoses that are ***angiographically >70%*** (based on NSTEMI invasive trials and BIOVASC trial) or ***50–70% with significant iFR/FFR***.[94–96] Even more than STEMI, when multiple complex lesions are seen in NSTEMI, the culprit artery may not be clearly identified and multivessel intervention is further justified. According to an MRI analysis, the culprit artery is misidentified by catheterization in 35% of patients.[97] FIRE trial showed that in elderly patients >75 with STEMI (35%) or NSTEMI (65%), PCI of non-culprit artery stenoses >50%, guided by FFR or iFR, in the same setting as culprit PCI (~2/3) or before discharge, reduces MI and even death at 1 year compared to culprit-only PCI (death, 9.2% vs. 12.8%).[95]

2. What is the timing of non-culprit PCI?

Biovasc trial randomized NSTEMI (~60%) and STEMI (~40%) patients with multivessel disease to immediate non-culprit PCI in the same setting as culprit PCI vs. non-culprit PCI later (within 6 weeks): immediate non-culprit PCI was associated with a significant ~3% reduction in recurrent MI in NSTEMI (where the culprit may be misidentified), particularly in the first 30 days. This is particularly true if the non-culprit(s) PCI is simple and quick, renal function is preserved, the contrast load is <220 ml, and the patient is not too sick to tolerate it.[94,98] Biovasc suggests a significant hazard of MI from non-culprit artery during the waiting period, hence the importance of *limiting the non-culprit PCI delay to less than a couple of weeks*. ACC allows flexible timing, whereas ESC gives a preference for non-culprit PCI in the same setting.

D. Among patients with high-risk ACS managed invasively, ~25–30% do not undergo any revascularization after coronary angiography

There are 2 types of patients within this group:

i. *About 10% of patients presenting with a picture of type 1 MI have normal coronary arteries or insignificant CAD (<50% obstructive),* this prevalence being higher among women and younger patients (15% of women) (MINOCA).[24–33] Half of these patients have a completely normal angiographic appearance of the coronary arteries. MINOCA may be due to: (a) overlooked or recanalized plaque rupture (even at an angiographically normal site), (b) vasospasm, (c) myocarditis or (d) takotsubo. In a meta-analysis of all comers with MINOCA, MRI established the diagnosis in most of the patients (***3 main diagnoses: myocarditis 38%, infarction from plaque rupture or vasospasm 24%, and takotsubo 16%***) (see Section I.E).[27,34,35] IVUS and provocative coronary testing (for vasospasm) may also be performed.[25,28] The long-term prognosis is generally good.

ii. *~15% have significant CAD but are not deemed candidates for revascularization*. These patients may have limited CAD in a small branch or a distal coronary segment that supplies a small territory, which is therefore not considered an appropriate revascularization target. The majority of these patients, however, have extensive and diffuse CAD, more extensive than patients undergoing PCI, along with more comorbidities (history of CABG, MI, PAD, stroke, CKD, anemia).[33,99] These patients are not considered candidates for PCI or CABG because of the diffuseness of the CAD, the small diameter of the involved vessels (<2 mm), the lack of appropriate distal targets for CABG, or the medical comorbidities. Their mortality is high, 3–4 times higher than the mortality of patients who are candidates for revascularization (~20% at 3–4 years).[33,99,100]

In patients with insignificant CAD <50% whose angiographic or IVUS/OCT appearance suggests stabilized plaque rupture (MINOCA), *stenting is not justified* but long-term aggressive medical therapy is indicated (including 1 year of clopidogrel or ticagrelor). This medical therapy also applies to the patients with significant CAD who do not get revascularized.

VI. Discharge medications in NSTEMI

A. Antiplatelet and anticoagulant therapy

1. *Aspirin* 81 mg/day. Chronically, the low dose is as effective as higher doses with a lower risk of GI bleed, even in patients who undergo coronary stenting.

2. *ADP-receptor antagonist* (clopidogrel 75 mg/day, prasugrel 10 mg/day, or ticagrelor 90 mg BID) (Figure 1.9).

Even if PCI is not performed, prescribe *clopidogrel* or *ticagrelor* for at least 1 month, and preferably 12 months. This applies to patients with significant CAD who are not revascularized, but also patients with insignificant CAD when moderate disease is present or plaque rupture is believed to be the underlying trigger.[85] In addition, clopidogrel is beneficial in patients who undergo CABG in the context of ACS, where clopidogrel may be started a few days after CABG.[101] In the absence of stenting, the ADP-receptor antagonist is more readily stopped if needed (bleeding, surgical procedure).

If PCI is performed, prescribe *clopidogrel*, *prasugrel*, or *ticagrelor* for 12 months, regardless of whether a bare-metal stent (BMS) or a drug-eluting stent (DES) is used. Prasugrel or ticagrelor is preferred by the ACC and ESC guidelines. De-escalation to clopidogrel may be done at 1 month if the bleeding risk is high (TOPIC and TALOS-AMI trials, ACC/ESC class IIb).

Does a longer duration of therapy (>12 months) provide extra benefit? (Table 1.4) According to the DAPT study, which included patients with MI (26%) or stable CAD undergoing DES placement, the continued administration of a thienopyridine between 1 year and 2.5 years reduced the MI risk in half during this time frame (from 4% to 2%). MI was reduced at the stent site (stent thrombosis) but also at distant lesions, where half of the events occur. This benefit was seen despite the short study duration (1.5 years) and despite the exclusion of patients who had a recurrent coronary event in the first year, the latter likely deriving an even larger benefit from continued thienopyridine administration.[105] A benefit of prolonged therapy was also seen in a separate DAPT study addressing BMS patients. Interestingly, even beyond 1 year, and even with BMS, there was a ~1% risk of stent thrombosis after thienopyridine interruption, similar to DES. The pitfall of this prolonged therapy was an increase in bleeding, cancer diagnoses, and overall deaths (related to cancer and bleeding). Thus, continued thienopyridine therapy seems reasonable in patients who have a low bleeding risk (e.g., age <75) and no suspicion of underlying

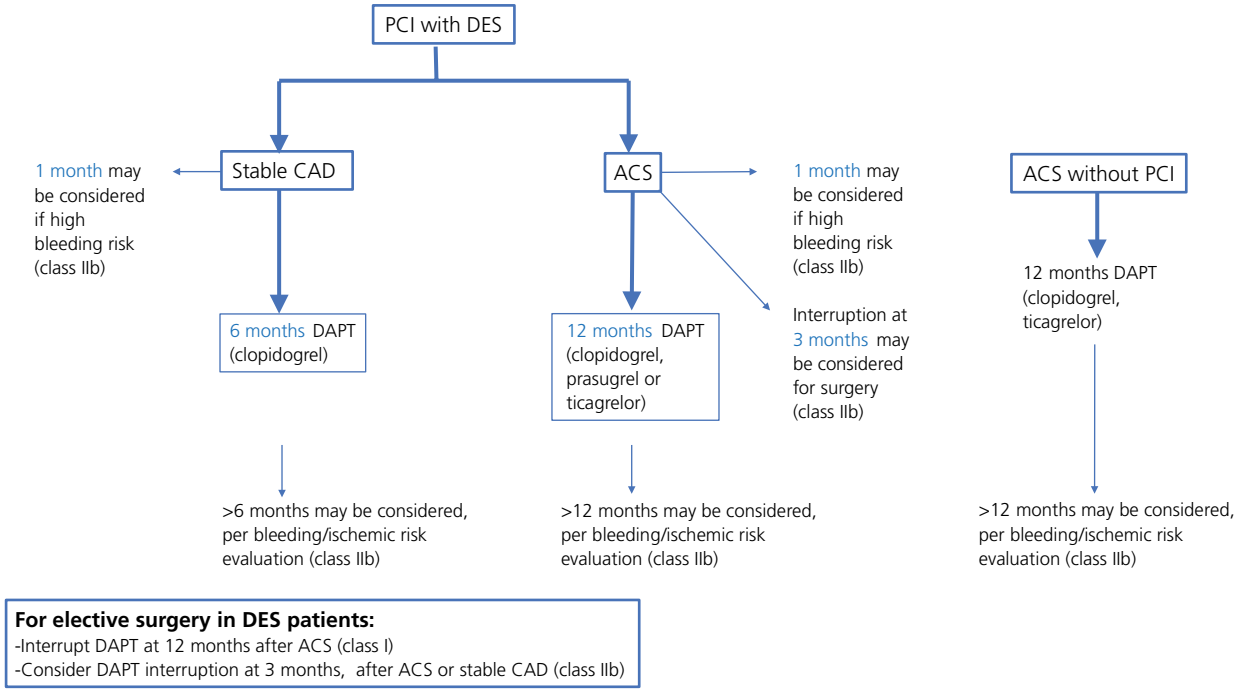

Figure 1.9 Duration of dual antiplatelet therapy (DAPT) according to both the ACC and ESC ACS guidelines. After DAPT is stopped, even at 1 month, guidelines allow the use of either aspirin or P2Y12 antagonist. Yet, in trials of 1-month DAPT, most patients received single clopidogrel rather than single aspirin (MASTER-DAPT, STOP-DAPT-2 trials). Even beyond 1 year, data support clopidogrel vs. aspirin (SMART-CHOICE-3 and HOST-EXAM trials, the former showing a mortality reduction with clopidogrel vs. aspirin). One additional ESC recommendation: for patients who are not at high ischemic risk, single antiplatelet therapy with clopidogrel may be considered at 3–6 months (class IIa).

Table 1.4 Long-term therapy >12 months may be considered based on the following:

i. ***DAPT score of mostly clinical variables (ischemic risk, long-term):***[102]
(1) age > 75: −2; 65–75: −1; <65: 0
(2) smoking: +1; (3) diabetes: +1;
(4) stent in the setting of MI: +1; (5) recurrent event (prior PCI or MI): +1;
(6) stent <3 mm: +1; (7) HF or EF < 30%: +2; (8) SVG stent: +2.

DAPT score ≥ +2 favors DAPT > 12 months, while age >75 argues against it.
PAD and CKD are additional markers of ischemic risk.[103]

ii. ***Anatomical complexity, i.e., any of the following, especially ≥ 3 (thrombotic risk, mostly early):***[104]
3 vessels treated, ≥3 stents implanted ≥3 lesions treated, stent length >60 mm,
bifurcation with 2 stents implanted, chronic total occlusion, left main, atherectomy

malignancy; it is expected to be particularly beneficial in the high ischemic risk groups, such as recurrent MI, multiple complex PCIs, combined CAD + PAD, ischemic HF, or ongoing uncontrolled risk factors, such as smoking or diabetes.[102,104] Another trial, CHARISMA, addressed prolonged dual antiplatelet therapy regardless of stenting and showed that patients with a prior MI, as opposed to stable CAD, benefited from extended dual antiplatelet therapy for up to 28 months, whether PCI was performed or not; the benefit was larger in patients with a prior MI and PAD.[106]

Conversely, is earlier interruption acceptable? The ADP-receptor antagonist may be safely interrupted at 3 months with DES in the stable CAD setting,[107–117] and at 6 months with DES in the ACS setting (DES registries and PRODIGY trial).[107,108,110–117] Upon interruption between 6 and 12 months, there is a small risk of MI that is, nonetheless, likely similar to the low and steady risk at >12 months' interruption, not higher.[104,108,111] For those patients deemed at high risk of stent thrombosis or recurrent MI, the interruption of the ADP-receptor antagonist is limited to <7–10 days. In fact, the median time from clopidogrel interruption to stent thrombosis, when it rarely happens in the 1–6-month time interval after stent implantation, is 13.5 days.[118,119]

Several studies suggest that ***1–3 months*** *of DAPT, followed by clopidogrel monotherapy (aspirin discontinuation)*, may be sufficient after DES in both stable or unstable CAD (MASTER-DAPT, STOP DAPT-2 and SMART-Choice trials with clopidogrel).[113–116] However, DAPT of 1 month followed by clopidogrel monotherapy led to increased ischemic events (by ~1%) in STOP-DAPT-2 ACS trial.[120] In HOST-BR trial of patients undergoing DES placement (ACS ~60%), 3-month DAPT was safer than 1-month DAPT followed by clopidogrel or aspirin monotherapy, even in patients with high bleeding risk (fewer ischemic events, no bleeding harm, clopidogrel monotherapy 68%). The 3-month DAPT was also

safer than 12-month DAPT even in patients with low bleeding risk (same ischemic events, less bleeding).[121] As such, 3 months of DAPT seemed the best choice even in clopidogrel-treated ACS patients and regardless of the bleeding risk. ***ACC and ESC give a weak recommendation for monotherapy with aspirin or clopidogrel at >1 month in stented ACS with high bleeding risk (class IIb), but data suggest 3 months to be safer, especially in ACS***. Conversely, monotherapy with ticagrelor beyond 1–3 months led to a similar ischemic protection as ticagrelor + aspirin even in ACS and complex anatomy, with about half the bleeding risk (TWILIGHT, TICO, and TARGET-first trials);[117] thus, ACC allows de-escalation to ticagrelor monotherapy at ≥1 month in all ACS patients undergoing PCI to reduce bleeding (class I).

In patients undergoing PCI who also need chronic anticoagulation (eg, AF):

↓

***Default strategy → Dual therapy immediately on discharge: NOAC + clopidogrel. No aspirin except during the procedure/hospitalization, for up to 1 week**

***High ischemic risk+ low bleeding risk → Triple therapy for 1 month: NOAC + clopidogrel+ aspirin. Then double therapy at >1 month**

***In all cases, stop clopidogrel and continue NOAC only (single therapy) beyond 12 months**

***Clopidogrel is the preferred ADP receptor antagonist in patients requiring anticoagulation. Rarely, ticagrelor may be used, but not prasugrel**

Figure 1.10 Antiplatelet therapy after PCI in patients who also require anticoagulation (AF, LV thrombus) (according to ESC and North American perspective 2021).[103] Warfarin replaces NOAC in mechanical valves or mitral stenosis.

3. *Oral anticoagulant* (Figure 1.10). In patients with AF or LV thrombus who undergo stent placement, the question is whether they need to receive a triple combination of aspirin, clopidogrel, and oral anticoagulant. The triple therapy has a 4× higher major bleeding risk than aspirin + warfarin (12% vs. 3–4% yearly bleeding risk).[122] According to WOEST (using warfarin), PIONEER-AF (rivaroxaban), RE-DUAL PCI (dabigatran), and AUGUSTUS (apixaban) trials, patients with AF undergoing PCI (mainly DES, ACS in 50–60% of patients) may be treated with the **dual combination of clopidogrel and one anticoagulant**, with no aspirin therapy beyond the first 3–7 days of PCI.[123–127] In fact, the dual combination clopidogrel-anticoagulant was much safer than the triple combination aspirin-clopidogrel-anticoagulant, used for 1–6 months, with a similar protection from MI and stent thrombosis, significant bleeding reduction in all trials, and mortality reduction in WOEST. The combined inhibition of the ADP pathway with clopidogrel and the thrombin pathway with anticoagulation may lessen the importance of cyclooxygenase inhibition with aspirin. As a result, after 3–7 days of triple therapy, **double therapy (clopidogrel + apixaban, rivaroxaban, edoxaban, dabigatran, or less favorably warfarin) is currently recommended and preferred over initial triple therapy in all patients**.[4–6,103] Triple therapy, for 1 month only, may be considered in patients who have a combined high ischemic risk/low bleeding risk (in AUGUSTUS trial, triple therapy reduced the 30-day ischemic risk by 0.9%, while increasing the bleeding risk by ~0.9%; beyond 1 month, triple therapy only caused increased bleeding, with no ischemic benefit).

Beyond 1 year of PCI or MI, single therapy with oral anticoagulant is recommended (no aspirin nor clopidogrel) and appears to reduce mortality, bleeding and cardiovascular events compared to anticoagulant+single antiplatelet agent (AFIRE trial with rivaroxaban, AQUATIC trial with mostly apixaban, and EPIC-CAD with edoxaban).[128,129]

B. Other therapies

1. *β-Blocker therapy:* in the pre-reperfusion era, high doses of β-blockers improved post-MI mortality.[130] In the reperfusion era, in STEMI or NSTEMI with EF >40% and without HF, some randomized trials showed a marginal benefit of long-term β-blocker therapy, whereas others did not: (i) in the REDUCE-AMI (EF >50%) and REBOOT (EF >40%) trials, β-blocker initiated in the hospital did not reduce death, MI, or HF at 3.5 years of follow-up.[131,132] (ii) Conversely, in the BETAMI-DANBLOCK trial, β-blocker initiated within 7 days of MI reduced reinfarction at 3.5 years of follow-up but only mildly (1.7% absolute reduction), and without a mortality effect.[133] In the ABYSS trial (EF > 40%), β-blocker interruption at >6 months post-MI was associated with a slightly increased angina risk.[134] One meta-analysis that included BETAMI and REBOOT showed a more marked benefit in the EF 40–50% subgroup (where death and HF tended to improve, beside reinfarction). Overall, the long-term use of β-blockers seems reasonable and mildly beneficial in post-MI patients with EF 40–50%, and *may* be considered in EF >50%. Take into account the patient's risk profile (e.g., more extensive CAD or CAD history), non-revascularized CAD, and the presence of angina or HTN, and keep in mind that low-to-medium doses are better tolerated and likely equally beneficial in this setting.[135] For example, in BETAMI, the β-blocker dose used was metoprolol ≤50 mg in >90% of patients. Also, consider acute therapy for 1 month, starting at ≥24 hours, to improve early LV remodeling and ventricular arrhythmias, as per the COMMIT-CCS trial.

β-Blockers improve long-term mortality in the EF ≤40% setting, wherein they are initiated after ≥2 days of hospitalization and titrated to high doses but slowly (e.g., carvedilol is started as 6.25 mg BID and doubled every 3–10 days) (CAPRICORN trial).[136] ***HF with low EF is the most harmed by β-blocker in the first day, but the most helped by it long term***.

2. *ACE-I:* while particularly indicated in hypertension or LV dysfunction, it is also useful for 6 weeks after any MI (ISIS-4 trial). In the stable phase beyond 6 weeks, if EF is normal and SBP is ≤130 mmHg, ACE-I therapy does not definitely improve outcomes (PEACE trial, prior MI subgroup).[137] In light of the SPRINT trial, the blood pressure goal is ≤130 mmHg.[138]

3. *High-intensity statin therapy* is administered regardless of LDL. The LDL goal after ACS is <55 mg/dl.[139] Other agents can be combined with high-intensity statin if needed (PCSK9 inhibitors, ezetimibe, bempedoic acid). If the patient was not on statin, high-intensity statin is initiated, lipids are rechecked at 4–8 weeks, and if LDL remains >55 mg/dl, especially >70 mg/dl, another agent is added. The initiation of both statin AND ezetimibe may be considered in statin-naive patients, as in IMPROVE-IT trial, particularly when LDL is far from target

(e.g., >160 mg/dl) (ACC class IIb). In patients with MI despite maximally tolerated statin with LDL >55, nonstatin drug should be added upon discharge (ACC).[4–6] The decision between ezetimibe and PCSK9 inhibitors depends on how far LDL is from goal.

4. ***Aldosterone antagonist*** reduces short- and long-term mortality of acute MI patients with EF <40% associated with any degree of clinical HF or diabetes; creatinine must be <2 mg/dl.[140] The routine use of spironolactone in all MI patients without HF was not beneficial (CLEAR SYNERGY trial, mostly STEMI).[141]

5. ***Sacubitril-valsartan did not reduce mortality or HF vs. ACE-I in post-acute MI*** patients with EF ≤40% or clinical congestion (PARADISE-MI trial, 76% STEMI, 53% congestion, EF 36 ± 9%).[142] ARNI failed because post-MI mortality and HF progression are lower than in chronic HF, and hypotension tolerance is worse.

6. ***SGLT-2 inhibitors did not reduce mortality in post-acute MI*** patients with EF <45% or clinical congestion (EMPACT-MI, DAPA-MI trials, ~75% STEMI, 57% congestion, EF mostly 35–45%). Empagliflozin reduced post-MI HF hospitalizations; hence it may be selectively considered in post-MI patients with severe HF (EMPACT-MI trial).[143]

7. No clear value of colchicine. The initial COLCOT trial of MI patients suggested a colchicine benefit on the soft outcome of angina-driven revascularizations (not MI or death). The larger CLEAR-SYNERGY did not show any benefit of colchicine post-MI.[141]

8. ***Proton pump inhibitors (PPIs)*** may inhibit CYP2C19 and thus reduce the conversion of clopidogrel to its active metabolite. PPIs were associated with increased cardiovascular events in some retrospective analyses of clopidogrel therapy. Yet, the only randomized trial that compared PPI to placebo in patients requiring clopidogrel therapy showed a reduction of GI events with omeprazole without any increase in cardiac events.[144] Thus, patients who definitely need a PPI, such as patients with an established history of peptic ulcer disease, esophagitis, or GI bleed, or patients receiving a triple antithrombotic combination, are appropriately treated with a PPI. Patients with dyspepsia or reflux symptoms should not receive a PPI.

In summary, post-MI patients routinely receive on discharge:
- Aspirin, P2Y12 antagonist, statin.
- β-Blocker if low EF <40%, started at day 2 or beyond, after proper diuresis. It is important to attain high doses in low EF. β-Blocker may be considered for 1 month in normal EF patients (even longer if not revascularized).
- ACE-I/ARB for ≥6 weeks. Benefit is more marked and more sustained over the long term in case of low EF or anterior MI, in which case treatment is extended >6 weeks.
- Spironolactone if EF <40% with HF or diabetes.

Contrary to chronic HFrEF, there is no clear value of routine sacubitril/valsartan or SGLT-2 inhibitor.

NSAIDs should be avoided for their known risks of renal failure, fluid retention, HTN, and GI bleed, especially in combination with aspirin and clopidogrel. Acetaminophen, local remedies (e.g., lidocaine cream), or, if needed, a short course of tramadol may be tried for osteoarthritic pain. If an NSAID is absolutely necessary, use the lowest possible dose and *administer aspirin 2 hours before the NSAID*.

9. ***Return to regular activities***, including sexual activities, 1–2 weeks after NSTEMI. Patients with a large infarct and new LV dysfunction should avoid strenuous activities for 4 weeks (high arrhythmic risk during this period).

VII. Prognosis (Table 1.5)

In-hospital mortality of NSTEMI is lower than STEMI.[145] However, short-term (30 days) and long-term mortality of NSTEMI approximates STEMI mortality (~3% at 30 days, ~5% at 1 year).[72,74,85,145] Short-term mortality of unstable angina without positive markers or ST changes is much lower (≤1.7%).[39,145] The risk of death or MI is 5–10% at 30 days and ~10–15% at 1 year.[71,72,74,76] The risk is much lower beyond the first year (~2% per year).[77,90,146,147] **Half of these events are recurrences at the site of the culprit lesion, while the remaining events are related to non-culprit lesions, mostly <50% stenosed.** Adverse IVUS features (thin cap, heavy atheroma with positive remodeling, small luminal area) predict the progression of a moderate non-culprit lesion, yet the predictive value is low (~20% progression of this lesion over 3 years with <1% death/MI risk).[147]

Table 1.5 Prognosis of NSTEMI.

	30 days	1 year	5 years
Death	3%	**4–5%**	10% *(1% per year past the first year)*
Death or MI	5% (early invasive) 10–14% (early conservative)	**10%** (early invasive) 15% (early conservative)	20% *(2% per year past the first year)*
Death, MI, or revascularization		15–20%	30% *(3–5% per year past the first year)*

The most important numbers to remember are 5% death and 10% death/MI at 1 year despite PCI and optimal therapy. The rates herein provided are derived from clinical trial data. Real-world patients tend to be older with more comorbidities and more extensive disease, and thus have higher event rates.

Appendix 1. Multivessel obstructive (>50%) disease in NSTEMI: How to identify the culprit stenosis

Multivessel disease is common in NSTEMI (Table 1.6). **Multiple obstructive plaques (stenosis > 50%) with complex features are seen angiographically in up to 40% of MI patients,** specifically STEMI patients (based on Goldstein et al.),[148,149] and by extrapolation, NSTEMI. The **culprit lesion is unclear or misidentified in 30–40% of NSTEMI**, based on an MRI study.[97] Also, NSTEMI may not only have multiple complex plaques in 40%, but also multiple culprit lesions in 10% of patients.[150] As such, with this difficulty in identifying the culprit in NSTEMI, multivessel PCI of multiple obstructive stenoses is particularly justified in NSTEMI.

How to identify the culprit stenosis?

1. Angiographically. A complex plaque, i.e., a ruptured unstable plaque, is identified angiographically by being *≥50% obstructive, along with 2 or more of the following features (Figure 1.11):*[4–6,148,149]

i. Thrombus: round intraluminal filling defect *or* contrast stain, i.e., persistence of contrast over a focal area even after it clears from the rest of the vessel. Alternatively, a thrombotic vessel cutoff with squared or bulging edges may be present.
ii. Plaque ulceration: contrast seeping beyond the lumen into the plaque or vessel wall (with hazy lesion contours)
iii. Irregular plaque with irregular margins or overhanging edges
iv. Impaired flow

However, as stated earlier, multiple such plaques are present in up to 40% of MI.

2. ECG

In NSTEMI, the ECG frequently cannot localize ischemia, even when ST depression occurs. This is because ST depression, unlike ST elevation, does not localize ischemia. However, the following ECG features may help localize ischemia, likely in less than half of NSTEMI:

- The extent and the magnitude of ST depression correlate with the extent and the severity of ischemia. As such, more extensive and deep ST depression suggests left main or LAD or multivessel ischemia (e.g., diffuse ST ↓ [>6 leads] with ST ↑ in aVR and V1)
- Wellens T abnormality in the precordial leads indicates LAD ischemia (biphasic T wave or deep T inversion preceded by upsloping ST segment in the precordial leads)
- Subtle ST elevation localizes ischemia (subtle STEMI, on the overlap between NSTEMI and STEMI)

Table 1.6 Angiographic findings in NSTEMI and rates of revascularization.[71–73]

Angiographic findings	Revascularization
Insignificant disease or normal coronaries ~10%	PCI in ~60%
One-vessel CAD ~30%	CABG in ~15–20%
Two-vessel CAD ~30%	No revascularization in ~25%
Three-vessel CAD ~30%	
Left main disease ~10%	

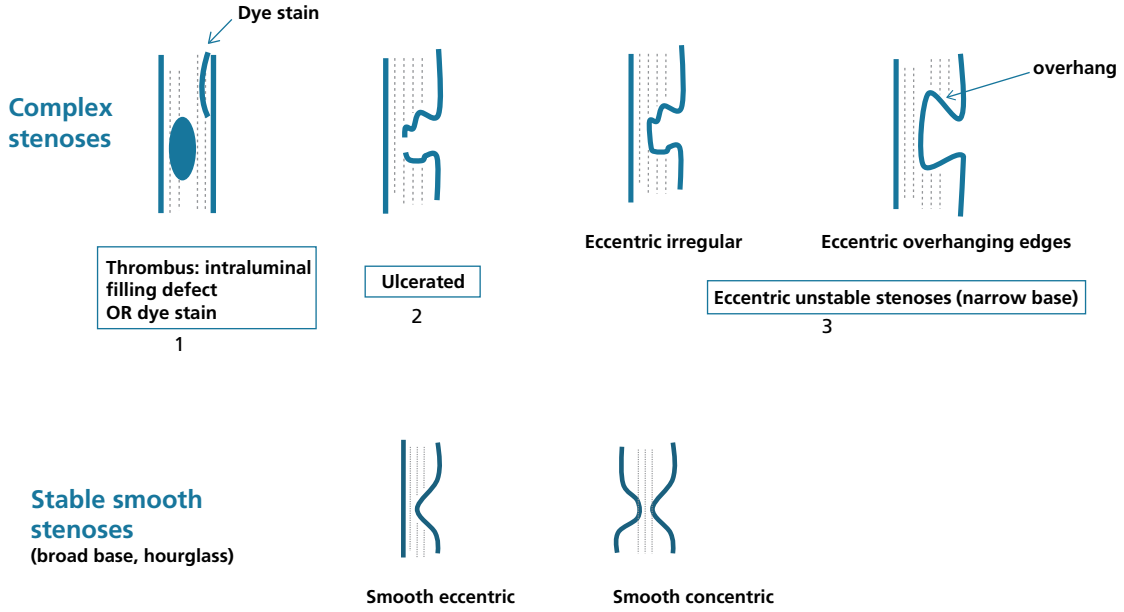

Figure 1.11 The 3 types of complex coronary stenoses vs. stable stenoses. The concentric and eccentric lesions with smooth borders are predominantly seen in stable CAD, while the lesions with irregular or overhanging borders are predominantly seen in ACS.

Note: Haziness may be caused by an unstable fissured plaque, with contrast faintly seeping through the fissures of the plaque beyond the true lumen; it may also be a result of concentric calcium surrounding the lumen and does not necessarily imply instability.

3. Wall motion abnormalities on echo or left ventriculography
Most NSTEMIs do not have localizing wall motion abnormality. The latter is mainly seen with ongoing severe ischemia (>20% of transmural thickness over a large territory), or prolonged and extensive preceding ischemia with a persistent degree of stunning or necrosis after ischemia resolves.

4. IVUS/OCT intracoronary imaging (plaque erosion, rupture, erosive calcified nodule, SCAD). Again, multiple complex plaques may be identified.

5. Cardiac MRI is best. The region of LGE or acute edema localizes the infarct, but MRI is not widely available in a timely manner, especially in relatively unstable patients.

Appendix 2. Management according to the severity of angiographic stenosis in NSTEMI: How to manage intermediate stenoses (50–70%)

In NSTEMI:

1. Stenosis >70% angiographically supplying a major coronary territory → perform PCI (based on NSTEMI early invasive trials).

2. Stenosis <50% → do not perform PCI. Consider **IVUS/OCT** to define the true severity of the stenosis, especially if the stenosis is hazy (Figure 1.12), and only stent if:

- Diameter stenosis proven to be >70% compared to the reference proximal/distal lumen
- Diameter stenosis >50% with plaque disruption
- Or potentially if: lumen area <3 mm^2
- Or potentially if: lumen area <4 mm^2 with plaque disruption or with plaque burden >70%.

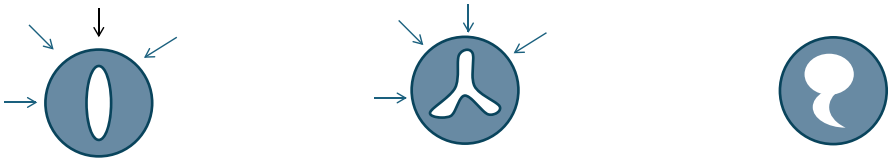
The last 2 criteria were used in PREVENT, FLAVOUR, and ISCHEMIA trials for stenting intermediate stenoses in mostly stable CAD; those criteria are potentially extrapolated to unstable CAD (ISCHEMIA used <4 mm^2 + plaque burden >60%).[151,152]

Do not stent solely because plaque disruption is seen on IVUS/OCT. The luminal narrowing criteria must be present, otherwise the MI is considered **MINOCA-plaque disruption subtype** and treated medically. The landmark invasive trials in NSTEMI only treated lesions >50–70% obstructive (TACTICS-TIMI, FRISC II, RITA 3). The same applies for STEMI trials addressing PCI after thrombolysis (e.g., CARESS AMI, TRANSFER AMI). PCI of MI lesions with high-risk IVUS features but <50% narrowing has not been studied on a large scale and is not recommended; several small-scale studies question the value of PCI in such a setting (EROSION I and III, PROSPECT ABSORB trials).[153–155]

3. Stenosis 50–70% angiographically. In MI setting, it may be best to assess those stenoses by **IVUS/OCT**, and stent if the IVUS/OCT criteria under (2) are met.

How about iFR/FFR for those intermediate stenoses? iFR/FFR is less validated in MI than CAD setting, especially for the culprit stenosis. Some data suggest it is acceptable in MI:

- FAMOUS-NSTEMI trial: PCI vs. FFR-guided PCI of all lesions in NSTEMI (culprit or not) → same MACE at 1 year[156]
- PRIME-FFR registry: systematic FFR measurement led to a change in the management strategy in 38% of NSTEMI cases, without an adverse impact on death/MI or angina symptoms at 1 year compared to the non-reclassified[157–159]
- Trials using FFR for non-culprit stenoses in NSTEMI, particularly for 50–70% stenoses (FIRE, BIOVASC, SLIM, FRAME-AMI). Because distinguishing the culprit vs. non-culprit stenoses is difficult in NSTEMI, those trials indirectly suggest a validity of iFR/FFR for all moderate NSTEMI stenoses, culprit or not.



(a) Eccentric lesion with most angiographic views missing the stenosis (except for the *black arrow* angle)

(b) Serpiginous lesion with mild contrast filling in all directions → stenosis looks mild angiographically from all angles

(c) Ulcer is not a functional lumen, but it fills with contrast and may make the angiographic stenosis appear mild

Figure 1.12 Examples of hazy irregular lesions that appear <50% obstructive angiographically but are, in fact, more severe. The lesions do not look tight angiographically but are hazy. *Arrows* are angiographic angles; the narrow lumen is *white* and falsely projects as a large lumen:

(a) and (b): eccentric stenoses with no angiographic view orthogonal to the narrow lumen
(c): ruptured plaque

Note, however, that haziness may also be a result of a concentric shell of calcium without underlying severe stenosis.

Intracoronary imaging with OCT or IVUS is valuable for moderate NSTEMI lesions. In fact, in NSTEMI, the question is not only whether the lesion is functionally significant but whether the lesion is anatomically significant and likely to acutely progress (e.g., plaque rupture, thrombus). The goal of therapy in NSTEMI is to reduce the high risk of recurrent infarction rather than just improve angina. A thrombotic lesion that is >50% but not functionally significant at one point in time may still progress within days or weeks. In addition, the true lumen of a ruptured or ulcerated plaque may be much narrower than its angiographic appearance (contrast seeps through the planes of the ruptured plaque beyond the true lumen, giving the impression of a large lumen that is, nonetheless, hazy) (Figure 1.12).

In summary, in NSTEMI:

- Perform PCI of all culprit and non-culprit lesions angiographically >70% (based on NSTEMI early invasive trials and BIOVASC and FIRE trials). Perform multivessel PCI in the same setting, or in separate settings preferably before hospital discharge.
- Perform PCI of all lesions 50–70% that have unstable features by IVUS/OCT, or that are significant by iFR/FFR (iFR/FFR based on FIRE, BIOVASC, and SLIM trials, keeping in mind the limitation of iFR/FFR for MI culprit lesions). ACC and ESC give only a class IIb for iFR/FFR of non-culprit arteries in NSTEMI.

Non-culprit stenoses <50% have a slow progression in both MI and stable CAD: the summation risk of angina progression from all lesions is ~6% at 1 year and ~10% at 3 years of follow-up, with only 1% death/MI from all these lesions at 3 years (PROSPECT trial).[147,160]

In stable CAD, the progression is slow even for stenoses >50% (<10% progression rate per lesion at 1.3 years with <2–3% ACS per lesion) (COURAGE trial, stenoses mostly in the 50–80% range).[161]

Appendix 3. Women and ACS, elderly patients and ACS, CKD

A. Women and ACS

In trials of initial invasive vs. initial conservative strategy, low-risk women without elevated troponin, ST changes, or high TIMI risk score had a higher risk of death/MI with an invasive strategy than a conservative strategy (significant in RITA 3, non-significant trend in FRISC II).[76,162] However, high-risk women derive a benefit from an initial invasive strategy (TACTICS, meta-analysis).[74,163] While an initial invasive strategy is not indicated in low-risk men either, a meta-analysis shows that an initial invasive strategy is not harmful to low-risk men but is harmful to low-risk women.[161] This is related to the fact that women have less extensive CAD than men in general, and that in these trials of NSTE-ACS, ~24% of women vs. 8% of men randomized to an invasive strategy had no significant CAD, and even among women with elevated troponin, 15–20% had no significant CAD.[163,164] In fact, women have a *higher burden of macro- or microvascular spasm*. Even among women with CAD, 3-vessel or left main disease is less common than among men. In addition, women have a higher bleeding risk, particularly at the vascular access site, which attenuates the benefit from an invasive strategy. Women also have a higher complication rate with CABG.[76]

Despite less extensive CAD, less positive troponin, and less common STEMI presentation relative to NSTE-ACS,[165] the mortality of women with ACS is equal to that of men, and may be higher on unadjusted analyses (GUSTO IIb analysis) or in the specific case of STEMI.[165] Women with ACS are older and have more comorbidities (diabetes, diastolic HF) than men. They have a higher BNP and a higher burden of dynamic ST changes on continuous ECG monitoring than men, indicative of a significant ischemic burden despite less CAD and less troponin rise (MERLIN-TIMI trial).[164] In fact, even among women without obstructive CAD, ~14% have dynamic ST changes on continuous ECG monitoring. *Ranolazine* may be of particular benefit in women with angina.[164]

B. Elderly patients and ACS

Patients >75 years old with ACS have double the mortality of younger patients. Elderly patients more frequently have atypical presentations with milder ST changes. While associated with a higher major bleeding risk in patients >75 years old, an early invasive strategy drastically reduced the absolute risk of death/MI by 10% at 6 months in those inherently high-risk patients (TACTICS-TIMI-18 trial).[166] This was further confirmed in a trial that randomized octogenarian ACS patients to an invasive vs. conservative strategy, using predominantly a radial access (AFTER EIGHTY, 13% absolute reduction of MI at 1.5 years).[167] However, this benefit may only apply to carefully selected elderly patients with limited comorbidities and bleeding risk, similar to the patients recruited in clinical trials.

In fact, SENIOR-RITA trial randomized NSTEMI patients > 75 years with high prevalence of frailty (32%), cognitive impairment (~60%), and comorbidities to an invasive strategy vs. conservative medical therapy without any stress testing. About half of the invasively managed patients received revascularization, mainly PCI.[168] At 4 years of follow-up, the risks of death and MI were similar in both groups. Invasive strategy was beneficial in some regards:

- Trend toward a reduction in the combined death/MI in the first year, but this trend abated by 2 years.
- Non-fatal MI was reduced at 4 years (~15% vs. 11.7%).
- Clinically driven future revascularizations were reduced (~14% vs. 4%).
- Invasive strategy was overall safe with minimal bleeding and procedural and renal complications <1%.

A careful access (radial) and antithrombotic strategy may maximize the benefit from an invasive strategy, and GPI should be avoided if possible.

C. CKD

Approximately 20–40% of patients presenting with NSTEMI have CKD. Although the bleeding risk is increased in renal failure regardless of the anticoagulant used, bivalirudin (in patients undergoing PCI) and fondaparinux (outside PCI) are associated with less bleeding than UFH or enoxaparin in patients with mild or moderate renal failure.[71] When GFR is <30 ml/min, UFH or dose-adjusted enoxaparin are approved for use; the bleeding risk is, however, higher with enoxaparin at any stage of renal failure, including GFR 30–60 ml/min, and UFH is preferred.[169] A GPI is best avoided in CKD; if used, the bolus and infusion doses of eptifibatide are reduced in half when GFR is <50 ml/min.

CKD patients are inherently high-risk patients. Despite the high prevalence of CKD, large randomized trials that have addressed the benefit of an invasive strategy in ACS have excluded patients with advanced CKD. Subgroup analyses of these trials suggest a benefit of an invasive strategy in patients with mild CKD, and observational data suggest that patients with mild or moderate CKD (GFR 30–60 ml/min) derive a benefit from an invasive strategy, which makes sense, considering the inherently high ischemic risk of these patients.[170,171] This benefit may extend to carefully selected high-risk patients with CKD stages 4 or 5, who, nonetheless, have a higher risk of bleeding and renal and HF complications peri-PCI.[171] One registry analysis suggests that an early invasive strategy is not beneficial in patients with GFR <45.[171]

Appendix 4. Bleeding, transfusion, patients on chronic warfarin or NOAC, gastrointestinal bleed

A. The negative impact of bleeding

In the context of ACS or PCI, the occurrence of major bleeding has at least the same prognostic impact as the occurrence of a new MI.[172,173] Compared with patients without bleeding, patients who experience bleeding have a much higher in-hospital but also late mortality (up to 5× higher). In fact, while bleeding is rarely fatal by itself, bleeding strikingly increases the risk of MI, coronary thrombosis, and ischemic events through the following concepts: (i) antithrombotic therapy may need to be temporarily withheld; (ii) bleeding is a very potent activator of the coagulation cascade; (iii) acute anemia may lead to demand ischemia; (iv) blood transfusion, sometimes necessary, leads to untoward proinflammatory and prothrombotic effects. One-half to two-thirds of major bleeding events are femoral access site bleeds, while the remaining events are gastrointestinal or genitourinary bleeds, a drop in hemoglobin without an overt source, or, rarely but fatally, an intracranial bleed.

Radial access drastically reduces bleeding and is associated with improved outcomes when performed by experienced operators. Appropriate antithrombotic therapy, with a limited use of GPI, reduces access and non-access bleeding and improves short- but also long-term outcomes.

B. Transfusion in ACS

Anemia may exacerbate myocardial ischemia in patients with CAD or ACS. Yet transfusion, by itself, does not necessarily reverse this ischemia and may be associated with worse clinical outcomes. This is linked to potential prothrombotic (ADP release) and proinflammatory effects of transfusion and to the impaired oxygen-carrying capacity of the transfused red blood cells.[172] In addition, while normal red blood cells transport and dispense nitric oxide to the microvasculature, this function is disrupted in transfused red blood cells, which leads to impaired regional vasodilatation. A *randomized trial*, REALITY, suggested that a restrictive transfusion strategy (transfusion for Hb ≤8 g/dl) is as safe as a more liberal strategy (transfusion for Hb ≤10 g/dl) in patients with MI, most of whom underwent an invasive strategy.[174] However, the larger MINT trial suggested that a liberal transfusion for Hb <10 g/dl had trends toward better outcomes than a restrictive transfusion (Hb <8 g/dl) in patients with type 1 or type 2 MI (death-recurrent MI at 30 days 14.5% vs. 16.9%, $p = 0.07$); the liberal strategy significantly reduced death/MI in type 1 MI.[175,176] Of note, in MINT, 1 unit of blood was transfused when needed (vs. 2 in REALITY), which made the restrictive strategy in MINT too strict, and its liberal strategy less liberal than REALITY. As such, in patients with MI, a transfusion cutoff of 8 g/dl may be used, but a higher cutoff of 8–10 g/dl is considered in patients with ongoing angina, tachycardia/hypotension, or with planned complex revascularization. *Consider 2 units of blood for Hb <8 g/dl, and 1 unit of blood at a time for Hb 8–10 g/dl*.

C. Patients on chronic anticoagulation who present with ACS

Warfarin, per se, is protective against coronary events.[177,178] If a conservative strategy is selected and the patient is appropriately anticoagulated, it may be reasonable to continue warfarin along with other therapies and withhold from adding any other anticoagulant. There is no reason to believe that combining 2 anticoagulants reduces ischemic events. In fact, overlapping 2 anticoagulants worsened the bleeding risk in the SYNERGY trial.

Warfarin management in transfemoral catheterization: Warfarin may be held for a few days before the coronary angiogram and a short-acting anticoagulant used instead of warfarin before and during the procedure. This way, the anticoagulation can be stopped after the procedure, reducing the bleeding complications and allowing for the removal of the arterial sheath. Heparin is started as soon as INR <2. The angiogram may be performed transfemorally when the INR is ≤1.6. Warfarin is restarted the evening of the procedure, and heparin may be restarted along with warfarin until INR is ≥2, because an early procoagulant effect occurs upon warfarin re-initiation and may not be tolerated post ACS. Anticoagulation with heparin at a low PTT target (~1.5× normal) may generally be resumed 12 hours after sheath removal. Avoid LMWH in those patients with a recent femoral access: LMWH is associated with a higher bleeding risk than controlled-dose heparin (SYNERGY trial), and should bleeding occur, the prolonged effect of LMWH makes it difficult to control.

Warfarin management in transradial catheterization: *Warfarin therapy is not interrupted (class IIa ESC)*, or only one dose is withheld. If PCI is performed, UFH is administered and adjusted according to ACT (UFH is mainly required if INR <2.5, per ESC).

NOAC management: *NOAC may be continued around a transradial procedure without any interruption (class IIa ESC)*, and UFH is administered during PCI. Alternatively, one dose may be held or catheterization may be performed at the nadir of the last dose. For transfemoral procedures, hold NOAC for 1–2 days.

D. Gastrointestinal (GI) bleed in patients receiving aspirin and clopidogrel after stent placement

In case of chronic blood loss and a recently placed stent, dual antiplatelet therapy should probably be continued as mandated, and, if indicated, endoscopic intervention performed while the patient is on dual antiplatelet therapy. PPI is administered and testing for *H. pylori* performed.[179]

In case of a major GI bleed, the cessation of one antiplatelet agent may be judged necessary, mainly when DES is >1 month old. Following successful endoscopic therapy of gastroduodenal ulcer combined with high-dose PPI therapy, it may be reasonable to reintroduce antiplatelet therapy 3–7 days later in those who remain free of recurrent bleeding. In case of lower GI bleed, the re-bleeding risk is higher and one may delay antiplatelet therapy for 7–10 days, depending on the colonic lesion size and the adequacy of endoscopic treatment.[127]

E. Management of elevated troponin in a patient with GI bleed

The elevated troponin often results from the combination of stable CAD and demand ischemia from anemia and tachycardia. Therefore, the treatment of anemia is the first and most important line of therapy. The patients should receive fluid resuscitation ± blood transfusion (particularly for Hb <8 g/dl, or for Hb 8–10 g/dl with shock, tachycardia, or persistent angina). PPI therapy is initiated, and endoscopy is performed if appropriate, usually before any coronary procedure. A coronary procedure, with the possible ensuing need for anticoagulation and antiplatelet therapy, is performed after stabilization and etiologic diagnosis of the GI bleed, typically several days later or, if possible, in an angina-free patient, weeks later.

Similarly, a patient with stable angina who has chronic anemia should undergo anemia workup before any potential coronary procedure.

A coronary procedure is performed more urgently and potentially before the GI procedure in some cases: (i) STEMI, (ii) ACS with ongoing angina despite transfusion, or (iii) major ST changes or severe troponin rise occurring with a rather mild or chronic anemia.

Appendix 5. Antiplatelet and anticoagulant therapy

A. Antiplatelet therapy (Table 1.7)

1. Aspirin is given as a 325 mg dose the first day (chewed for rapid absorption and effect), then 81 mg daily. On the second day and beyond, 81 mg is as effective as 325 mg with less bleeding risk, including in patients receiving coronary stents (CURRENT-OASIS trial).[180] In the case of aspirin allergy that consists of asthma or urticaria without anaphylaxis, perform aspirin desensitization, which may be performed urgently over less than 24 hours.

2. Clopidogrel is started as a 300 mg load, followed by 75 mg daily. In the CURE trial of NSTE-ACS patients managed invasively or conservatively, high or low risk, this clopidogrel regimen reduced the combined risk of death/MI by 2% at the cost of an increase in major bleeding risk by 1%; the life-threatening bleeding was not increased, and bleeding was overall attenuated when aspirin 81 mg, rather than 325 mg, was used.[85] The benefit was more marked in patients who were eventually managed invasively (~3% risk reduction) (PCI CURE).[181] The benefit was already significant by 24 hours of therapy and maximal within a few days.

Patients who undergo PCI should be loaded with 600 mg of clopidogrel, which has a more potent and faster onset of antiplatelet effect than 300 mg (2 hours for 600 mg vs. 6–24 hours for 300 mg). If the patient has already received 300 mg, an additional 300 mg is administered during PCI. If the patient requires CABG, clopidogrel is preferably withheld for 5 days to prevent an increase in bleeding risk (absolute risk increase = 4%).[85,182] Yet, in the highest-risk patients with critical CAD or ongoing ischemia, CABG may be performed sooner, as clopidogrel cessation for 3 days is often enough.[183,184] In addition, the peri-CABG use of clopidogrel does not adversely affect mortality.[182]

3. Prasugrel and ticagrelor are more potent than clopidogrel (75% vs. 35% inhibition of platelet aggregation) and have a faster onset of antiplatelet activity (30 minutes for onset, 2 hours for peak effect), without the interindividual response variability and the 30% hyporesponsiveness seen with clopidogrel. *These agents have only been studied in ACS (ACS receiving PCI for prasugrel, ACS receiving PCI or medical therapy for ticagrelor)*.[185,186] In comparison with clopidogrel, both have shown further reduction of combined death/MI at the expense of a higher major bleeding risk. Their superiority is particularly marked in the three highest-risk patient groups (STEMI, diabetes, and recurrent ACS).[187,188] On the other hand, 3 subsets of patients have a marked bleeding risk with prasugrel without any net benefit, and these are contraindications to prasugrel use: (i) history of stroke/TIA, (ii) age > 75, (iii) weight < 60 kg (the latter 2 are relative contraindications). *ESC guidelines give a class I preference to ticagrelor or prasugrel over clopidogrel in ACS*. Yet, one should consider the ischemic risk as well as the age; in patients older than 70, clopidogrel compared favorably to ticagrelor, with less bleeding and similar ischemic outcomes (POPular age trial).

Compared with prasugrel, ticagrelor has the following features: (i) reversible ADP-receptor binding that allows reversal of the antiplatelet effect at 3–4 days (vs. 5 days with clopidogrel and 7 days with prasugrel); (ii) ticagrelor increases the release of adenosine, which may improve coronary flow but may also increase the risk of bronchospasm or asymptomatic pauses; (iii) ticagrelor did not increase fatal bleeding and did not specifically harm patients with a prior stroke or patients older than 75, yet both ticagrelor and prasugrel should be used carefully, if at all, in patients deemed at a high bleeding risk; (iv) ticagrelor is indicated not only in patients managed with PCI but also in high-risk ACS patients managed conservatively or not deemed appropriate for revascularization. In the latter patients, ticagrelor reduced death/MI in comparison to clopidogrel; conversely, prasugrel has not shown any benefit in patients not receiving PCI (TRILOGY-ACS trial); (v) ticagrelor or clopidogrel may be administered on admission, upstream of coronary angiography, whereas prasugrel should only be administered after coronary angiography is performed and the need for CABG ruled out (in the event CABG is needed, its performance within 7 days of prasugrel therapy drastically increases the bleeding risk).[189]

Despite those features, one head-to-head ACS trial of upstream ticagrelor vs. downstream prasugrel, ISAR-REACT-5, showed superiority of downstream prasugrel on MI/death reduction; in a way, this also adds to the evidence that only downstream ADP-receptor antagonist therapy is needed.[83] Similarly, in TUXEDO-2 trial of diabetic patients, prasugrel was numerically superior to ticagrelor with less death/MI and bleeding.

4. Cangrelor is a very potent **intravenous ADP-receptor antagonist** (90% inhibition of platelet aggregation), reversible, and has a very short half-life. It is infused for the total duration of PCI (and for a total duration of at least 2 hours) and has a very short onset and offset of action (1 hour). It has been studied in stable and unstable CAD patients *who have not received clopidogrel upstream of PCI*, where it has allowed a quick and potent onset of an ADP antagonist effect during PCI.[190] It reduces acute stent thrombosis and intraprocedural complications, and increases minor but not major bleeding, with no overall mortality benefit (Champion trials). Clopidogrel or prasugrel must be started at the end of the infusion; if given during the infusion, cangrelor would prevent ADP-receptor binding of their short-lived metabolite, which would be eliminated by the end of the infusion. On the other hand, ticagrelor may be given during cangrelor infusion, as its plasma half-life is longer and it binds to the P2Y12 receptor at a site different from cangrelor and clopidogrel. Cangrelor is considered in *ADP-receptor antagonist-naïve* patients undergoing PCI, in the setting of ACS or stable CAD (class IIb).[4–6] It may be particularly useful in shock states, wherein the absorption of oral agents is limited, and in high-risk PCI. *For bail-out cases, no reflow, or high thrombus burden: GPI is the one proven beneficial by data and recommended in ESC guidelines, not cangrelor.*

5. Glycoprotein IIb-IIIa inhibitors (GPIs). GPIs are potent IV antiplatelet drugs that block the final common pathway of platelet aggregation (inhibit 95% of platelet aggregation). This comes at the expense of an absolute 2–4% increase in major bleeding risk.[47] In particular, GPI therapy upstream of coronary angiography was associated with an increase in bleeding without a significant reduction in ischemic

Table 1.7 Comparison of the three oral ADP-receptor antagonists.

	Clopidogrel	Prasugrel (60 mg load, 10 mg maintenance)	Ticagrelor (180 mg load, 90 mg BID maintenance)
Inhibition of platelet activation	35–40%	75%	75%
Activation	*Prodrug becomes active metabolite *Inefficient metabolization by CYP2C19 explains 30% clopidogrel hyporesponsiveness	*Prodrug becomes active metabolite *~Always efficiently metabolized by cytochromes	Active drug and active metabolite
Onset of action (i.e., time to 30% platelet inhibition)	600 mg: 2 h 300 mg: 6–24 h	30 min	30 min
Peak effect (hours)	600 mg: 6–8 h	2–4	2–4
Offset of action (days)[a]	5	7	3–4
Population studied and indications	Non-ST elevation or ST elevation ACS managed conservatively or invasively Any PCI (stable or unstable)	Non-ST elevation or ST elevation ACS managed by PCI (not conservatively) Not superior to clopidogrel in stable PCI	Non-ST elevation or ST elevation ACS managed conservatively or invasively
Absolute reduction of death/MI/stroke in comparison to clopidogrel (at 1 yr)	—	2%	2%
Mortality reduction in comparison to clopidogrel (at 1 yr)	—	None, except in the STEMI subgroup	1%
Stent thrombosis reduction in comparison to clopidogrel	—	1.3%	0.7%
Bleeding			
Absolute increase in TIMI major bleeding compared to clopidogrel (non-CABG related)		0.6%	0.6%
Increase in CABG-related bleeding		4 times	No
Increase in fatal bleeding		Yes	Possibly (increases intracranial bleeding)
High-risk subgroups where it should be avoided	—	Prior stroke/TIA (absolute contraindication) Weight <60 kg Age >75	No specific subgroups

[a] *Note that the duration of effect is related to both the pharmacokinetic half-life and the reversibility of receptor binding*. Aspirin, clopidogrel, and prasugrel have a relatively short half-life (<6 hrs) yet a very prolonged duration of action, as they irreversibly affect their target. Ticagrelor reversibly binds to ADP receptor but has a long half-life of ~15 hours, accounting for both ticagrelor and its metabolite, which translates into a duration of action of 3–4 days. Cangrelor reversibly binds to ADP receptor and has a very short half-life, translating into a duration of action of 1 hour.

events (EARLY ACS trial).[72] Thus, those drugs are typically used *during* PCI in *some* patients with elevated troponin, specifically those with heavy thrombus burden or thrombotic complications or no reflow (class IIa).[44,191] The bleeding risk associated with GPI drastically increases in patients older than 70, women, and patients with CKD. The half-lives of eptifibatide and tirofiban are 2–2.5 hours, and the infusion rate is halved when GFR <50.

Upstream ADP-receptor antagonist therapy, before coronary angiography, theoretically serves to: (i) reduce ischemic events pre-PCI (CURE trial), (ii) optimize PCI outcomes and reduce thrombotic complications during PCI and early afterwards. However, ACCOAST trial (using prasugrel), ISAR-REACT-5 trial, DUBIUS trial, and the large SCAAR registry have shown that this upstream initiation rather increases bleeding and does not reduce peri-PCI ischemic events, particularly when catheterization is performed within a few hours of presentation and a potent and fast ADP-receptor antagonist is used. In SCAAR, clopidogrel was used in half the patients and mean time to catheterization was 1.9 days, yet despite that, preloading was not beneficial. Based on those trials, aspirin and an anticoagulant appear sufficient before a timely PCI, and ESC guidelines recommend against upstream ADP-receptor antagonist (class III), while ACC gives it a weak class IIb when catheterization is anticipated >24 hours after admission.[83,84]

Upstream ADP-receptor antagonist is more readily avoided when extensive CAD requiring CABG seems probable, e.g., a man with elevated troponin and PAD, HF, or insulin-dependent diabetes; or a patient with extensive ST segment depressions in ≥6 leads or ST elevation in aVR.

B. Clopidogrel resistance is seen in ~30% of patients

Clopidogrel resistance is defined as <30% inhibition of ADP-induced platelet aggregation; or as an absolute platelet reactivity to ADP of <208–230 platelet reactivity units (using a quick point-of-care assay, VerifyNow assay). Clopidogrel resistance is related to impaired clopidogrel activation and is at least partly genetic, determined by mutations of the cytochrome genes (particularly CYP2C19). Other factors, such as ACS presentation, obesity, and CKD, may contribute.

Poor clopidogrel response is associated with an increased risk of coronary events and stent thrombosis. However, *in hyporesponsive patients undergoing PCI for stable CAD, the tailored use of prasugrel or a higher clopidogrel maintenance (150 mg) did not translate into a clinical benefit* (TRIGGER-PCI).[192] In fact, stable CAD PCI is associated with a low risk of stent thrombosis and adverse outcomes even in poor clopidogrel responders, reducing the benefit of more potent antiplatelet strategies. *Even in ACS PCI*, where poor clopidogrel response is particularly predictive of poor outcomes, tailored therapy was not superior to indiscriminate clopidogrel therapy.[193] TAILOR-PCI trial randomized PCI patients with ACS (~85% of patients) or stable CAD to clopidogrel or to escalating antiplatelet therapy based on genetic CYP2C19 testing (ticagrelor was given for mutation carriers, clopidogrel for non-carriers). Tailored therapy was not superior to clopidogrel, even among mutation carriers. Genetic testing may better serve to *de-escalate* from ticagrelor/prasugrel to clopidogrel in patients with good-function alleles (Popular genetics trial).

C. Anticoagulant therapy (Table 1.8)

IV UFH has been shown to reduce early ischemic events and MI in patients with NSTE-ACS.[194] The starting bolus (60 U/kg) and drip (12 U/kg/h) used in ACS are lower than what is used in pulmonary embolism, with a conservative PTT goal of 46–70 seconds or 1.5–2× normal (based on landmark heparin trials in ACS, such as SYNERGY). **Moderate rather than high-level anticoagulation is appropriate for ischemic reduction in ACS and minimizes the dreaded bleeding.** Per ESC, it is the preferred anticoagulant in patients managed invasively within 24 hours (class I).

SQ Enoxaparin. In NSTE-ACS managed medically, a therapeutic dose of SQ enoxaparin reduces ischemic events compared to UFH at the cost of more mild/moderate bleeding (1 mg/kg SQ twice daily, or once daily if GFR < 30).[195,196] In patients managed invasively, however, the SYNERGY trial failed to show any superiority of SQ enoxaparin over UFH, and there was a higher major bleeding risk with enoxaparin, particularly in patients who had crossover between heparin and enoxaparin.[197] A similar increase in bleeding risk with enoxaparin was seen in invasively treated patients in the A-to-Z trial.[198] Besides, if GFR < 60, bleeding risk increases more sharply with enoxaparin than with UFH.[199] Importantly, pharmacological studies have shown that the effect of SQ enoxaparin does not peak until a second dose is administered.[200] Thus, when 2 doses have already been administered, PCI may be performed within 8 hours of SQ enoxaparin without additional anticoagulation. However, when PCI is performed within a few hours of presentation, a single subcutaneous dose of enoxaparin does not provide appropriate

Table 1.8 Comparison of anticoagulants.

	Unfractionated heparin	Enoxaparin	Bivalirudin	Fondaparinux
Action	Binds to AT III in a way that inhibits thrombin > Xa	Is a small heparin derivative. Binds to AT III in a way that inhibits Xa > thrombin Inhibits thrombin generation	Direct thrombin inhibitor Inhibits both circulating and clot-bound thrombin[a]	Is a small heparin derivative. Binds to AT III in a way that inhibits Xa only
Effect on platelets	Potential activation	± Activation	Neutral	Neutral
Elimination	Reticulo-endothelial system	Renal	Renal	Renal
Half-life	1–1.5 h	4–7 h. Increases if renal failure	25 min. Increases to 1 hour if GFR < 30 ml/min	17–21 h. Increases if renal failure
Time to peak effect	Immediate after IV bolus; few hours after infusion without bolus	3–5 h after SQ dose	Immediate	2–3 h after SQ dose
Dose	ACS: 60 U/kg bolus then 12 U/kg/h IV drip DVT/PE: 80 U/kg bolus then 15–18 U/kg/h PTT goal in ACS: 46–70 s (less than PE)	ACS and PE: 1 mg/kg SQ BID[b]	During PCI: 0.75 mg/kg IV bolus then 1.75 mg/kg/h If started before PCI: 0.2 mg/kg/h	ACS: 2.5 mg SQ QD DVT/PE: 5–10 mg SQ QD (depending on weight)
Effect of renal failure on dosage	None	Change from 1 mg/kg BID to 1 mg/kg QD if GFR < 30 ml/min	Caution if GFR < 30 ml/min[a]	Avoid if GFR < 30 ml/min

[a] Only bivalirudin inhibits fibrin-bound thrombin. Heparin cannot act on fibrin-bound thrombin. Bivalirudin has not been studied in advanced renal failure (in ACUITY trial) but is not absolutely contraindicated.

[b] If only 1 SQ dose was provided before PCI, give additional 0.3 mg/kg IV during PCI. SQ enoxaparin is not well studied in patients > 150 kg, where the 1 mg/kg dose is associated with a marked increase in bleeding risk compared to patients with a normal body weight. AT III, antithrombin III.

anticoagulation for PCI and requires supplementation with 0.3 mg/kg of intravenous enoxaparin. The administration of a single SQ dose of enoxaparin is best avoided when PCI is planned in the next few hours; IV UFH is preferred in this case.

SQ Fondaparinux (2.5 mg SQ daily, half-life ~20 hours). This low dose of fondaparinux, equivalent to a DVT prophylaxis dose, has proven to be as effective as a standard dose of enoxaparin (1 mg/kg twice daily) in reducing MI/ischemic events in NSTE-ACS, with a large

IV UFH half-life increases with the dose used and is usually ~1.0–1.5 hours. SQ enoxaparin effect peaks at ~3–5 hours and is accelerated by the IV administration of enoxaparin 30 mg one-time dose in medically treated patients or 0.3 mg/kg in PCI. Its half-life is 4.5–7.0 hours, longer in renal failure. The short half-life of UFH may contribute to the "heparin rebound" phenomenon, wherein the abrupt cessation of UFH leads to a rebound increase in ischemia in the following 48 hours in medically treated patients (not PCI). Enoxaparin's antithrombotic effect wanes much more slowly than that of UFH, and enoxaparin inhibits thrombin generation in addition to thrombin action, which attenuates the heparin rebound effect and explains some of the anti-ischemic benefits of enoxaparin in medically treated patients (but not PCI).

reduction in major and fatal bleeding risk translating into a mortality reduction (OASIS 5 trial, where 40% of patients underwent PCI).[201] This again corroborates the concept that only moderate-level anticoagulation is required in ACS, less than that required in pulmonary embolism (except during PCI). Patients who are managed invasively after receiving fondaparinux should receive full anticoagulation with heparin or bivalirudin during PCI, as the small fondaparinux dose does not provide the level of anticoagulation required during PCI. In contrast to the harmful enoxaparin–UFH switch, the switch from fondaparinux to UFH during PCI does not attenuate the benefit of fondaparinux on bleeding.[202]

IV Bivalirudin. As opposed to UFH, bivalirudin does not activate platelets and inhibits both free and clot-bound thrombin. Bivalirudin is short-acting (half-life 25 min), which is both an advantage (bleeding reduction) but also an ischemic hazard, particularly in patients who have not received timely clopidogrel. Femoral-access studies suggested that bivalirudin is associated with less major bleeding than UFH (MATRIX), but this was partially due to higher GPI use in the UFH arm. A radial-access study with balanced and limited GPI use (VALIDATE-SWEDEHEART) showed an ischemic and bleeding risk identical to UFH.[203] Some studies have shown a higher risk of acute stent thrombosis with bivalirudin vs. UFH, which may be offset by extending the bivalirudin infusion 1–4 hours after PCI. Being an anticoagulant, bivalirudin is best compared to UFH, not the combination UFH + GPI. In fact, contrary to the design of older trials, the decision to add GPI should not be based on the anticoagulant used.[71]

Bivalirudin is administered as an intravenous infusion during PCI. On admission, patients may receive UFH with a switch to bivalirudin during PCI. The switch to bivalirudin is safe.[204]

Appendix 6. The 3 main types of plaque disruption: plaque rupture, plaque erosion, and eruptive calcified nodule

A vulnerable plaque is characterized by a lipid-rich necrotic core that is surrounded by a thin fibrous cap and infiltrated by inflammatory cells, especially metalloproteinase-rich macrophages (called *thin-cap fibroatheroma*). The thin cap ruptures, especially at the shoulders/margins of the plaque where the stress is highest, and leads to thrombus formation. *Plaque rupture is, thus, characterized by a ruptured cap and a thrombus in continuity with a necrotic core*. The ruptured cap is identified as a flap on IVUS or OCT (Figure 1.13). *Most plaque ruptures are non-occlusive and silent* contributing to a stair-step progression of coronary stenosis. *Stable CAD stenoses are frequently multiple layers of healed plaque ruptures:* healed plaque ruptures are present in up to 73% of stenoses >50% without a prior clinical MI. Approximately 75% of plaque ruptures in acute MIs occur on top of prior subclinical plaque ruptures, while 25% of plaque ruptures causing acute MI are virgin ruptures.[205,206] On IVUS, heavy atherosclerosis and compensatory vessel expansion (positive remodeling) often indicate prior episodes of plaque rupture and a vessel that has expanded to its limit, risking a more symptomatic rupture (the plaque is also running out of energy supply).

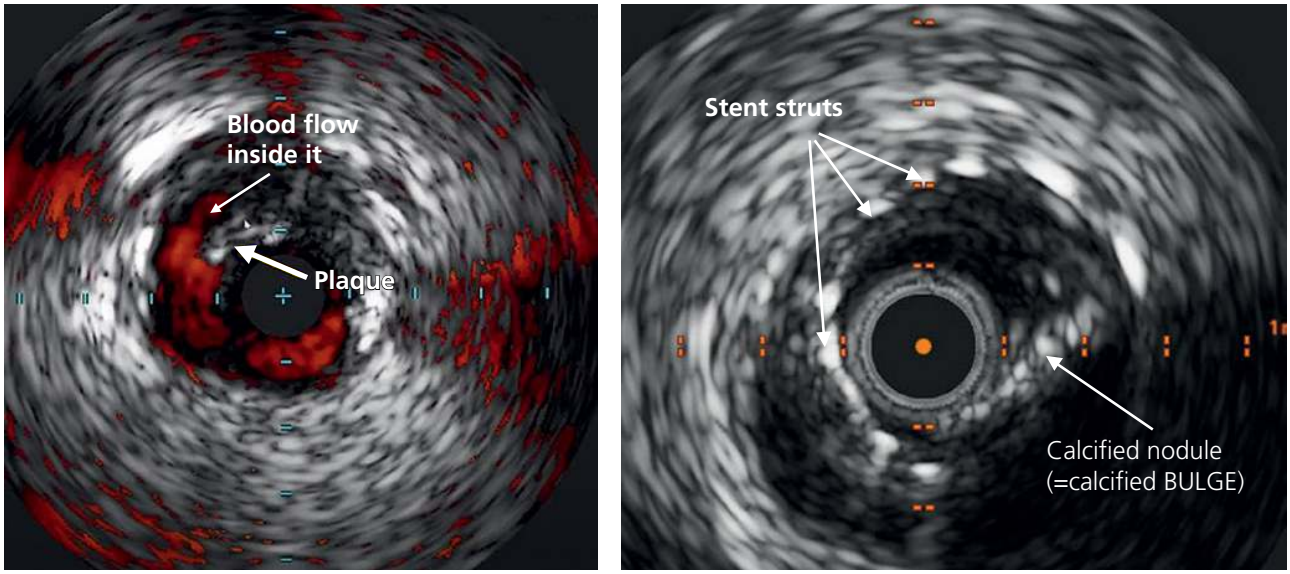
Plaque erosion, on the other hand, is characterized by thrombus formation over a plaque with thick cap that has not ruptured. The thick cap if formed of smooth muscle cells and collagen. There may be a deep lipid or necrotic core inside the plaque, but the thick cap is covering it and the thrombus does not communicate with the lipid core.[207–209] Plaque erosion results from denudation of thin endothelial cells overlying the cap, without cap rupture. It may be triggered by inflammation or flow perturbations. Plaque erosion is responsible for ~25% of MIs, more so in women, especially young female smokers (<50 years old). Compared with plaque rupture, plaque erosion occurs, on average, on less stenotic lesions.

Plaque rupture leads to the complex eccentric morphology and overhanging borders on angiography. Conversely, plaque erosion has an uncomplicated angiographic morphology with smooth borders.

A calcified nodule is an eccentric piece of calcium **protruding** into the lumen. As opposed to calcified sheets or plate, the key defining feature is the **bulge** into the lumen, likely from fracture of the calcium sheets, hence it is more likely to occur at hinge points and in the RCA (Figure 1.13). *An eruptive calcified nodule is a calcified nodule that, in addition, ruptures the cap, and often causes thrombus* formation and ACS. A calcified nodule accounts for 4–8% of MI culprit lesions, but is much more prevalent in heavily calcified lesions with >180–270° arc of calcium or lesions considered for calcium modification therapies (40s%).

Appendix 7. Spontaneous coronary artery dissection

Spontaneous coronary artery dissection (SCAD) is a split of a coronary artery wall without atheroma, resulting from either a bleeding inside the media or an intimal tear. SCAD is the cause of up to 4% of MIs; however, it is underdiagnosed and may be the cause of up to 35% of MIs in women ≤50 years of age. It most frequently involves the *media*, leading to a long smooth stenosis > 30 mm (average 46 mm) without a flap or stain, mimicking the smooth appearance of vasospasm or plaque erosion (this is called intramural hematoma or SCAD type 2, ~70% of SCADs). Less frequently, it involves the *intima*, in which case a flap or stain is seen angiographically (called SCAD type 1, ~30% of SCADs). Rarely, SCAD manifests as a focal stenosis (SCAD type 3, ~5%). The intimal flap being absent in 70% of patients, spontaneous



Plaque rupture with blood flowing inside the plaque

Calcified neoatheroma inside a stent with calcified nodule BULGING into the lumen

Figure 1.13 IVUS images of plaque rupture and calcified nodule.

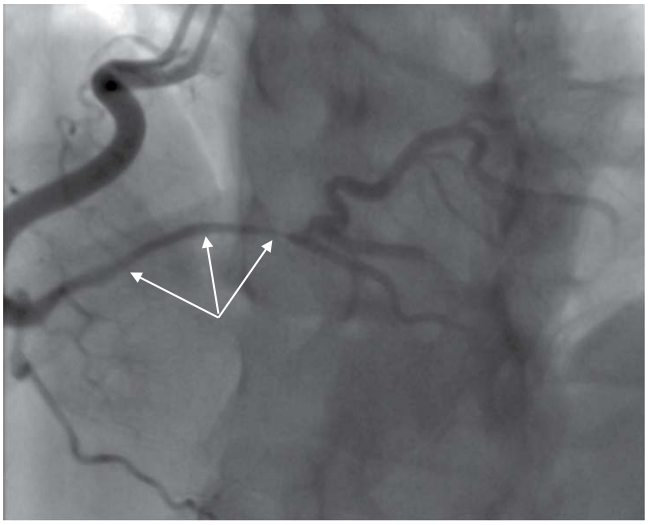


Figure 1.14 NSTEMI in a healthy 47-year-old woman. Chest pain started during kick boxing. Several features suggest SCAD type 2 and argue against performing PCI: (1) long smooth disease >30 mm with no calcification (*arrows*), (2) tortuous, elongated coronary arteries, (3) distal disease, (4) woman <60 years. The flow was TIMI 2 and she was not having ongoing angina, so conservative management was adopted. Intravascular imaging was avoided.

coronary dissection is suspected in a woman with a smooth, long lesion non-responsive to NTG and non-calcified, mimicking a "long refractory vasospasm" (Figures 1.14–1.16). IVUS or OCT may be used to confirm the diagnosis by showing a large "blood-speckled" hypodense (dark) *mass* behind the intima, pushing the intact and relatively thin intima into the lumen; yet, IVUS or OCT is not routinely recommended as any coronary manipulation may propagate the dissection.[210] SCAD has the following additional features:[210–214]

- Typically involves the mid-to-distal coronary segments, most commonly the LAD, and may involve multiple coronary arteries (~10–20%). Proximal or left main involvement is rare (~8%), hence shock is rare.
- Occurs overwhelmingly in women (95%), mainly young and middle-age women (like coronary erosion), but is also seen in women >50, with one large registry suggesting that the mean age of women affected by SCAD is 61;[211] it may rarely be seen in men.
- Presents as NSTEMI (~60%) or STEMI (~40%).
- Is highly associated with coronary tortuosity (78%), including corkscrew coronary arteries with substantial angiographic overlap, and peripheral fibromuscular dysplasia. The same collagen fragility that predisposes to wall disruption also facilitates coronary elongation.
- Is often initiated by intense exercise (especially isometric), heavy lifting, or intense Valsalva (including vomiting). Intense emotional stress may also be a trigger.
- Non-calcified coronary arteries (usually), sometimes with a history of calcium score of 0.

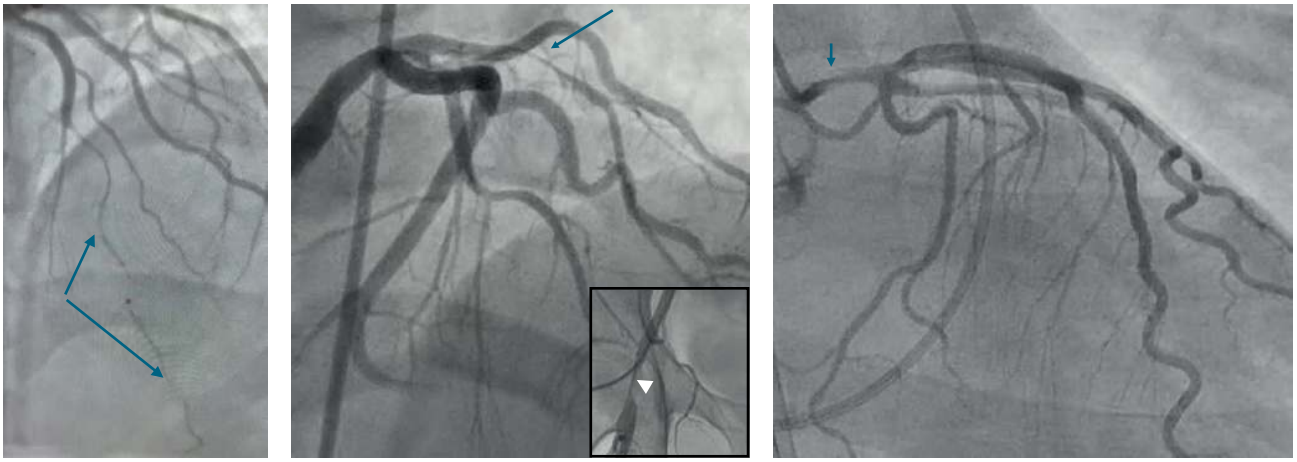

Figure 1.15 **(a)** Long diffuse distal LAD disease, extending all the way to the tip (*arrows*): coronary vasospasm vs. SCAB type 2B. Being refractory to intracoronary NTG and verapamil, the diagnosis is SCAD type 2B. SCAD type 2B means SCAD extends all the way to the end of the vessel, vs. type 2A: long diffuse intramural hematoma that does not extend to the vessel tip. **(b)** SCAD type 2A of a diagonal branch (long smooth narrowing, *arrow*). Notice the heavy overlap of vessels. This tends to be a characteristic of SCAD: ***long redundant tortuous vessels with a lot of overlap***. Also, peripheral angiography further corroborates the diagnosis by showing femoral FMD (*arrowhead*). **(c)** Left main type 1 SCAD in a 37-year-old post-partum woman with shock. Notice the split lumen of the LM, characteristic of SCAD type 1 (*arrow*), along with contrast stain. Pregnancy SCAD more often involves proximal vessels and the left main.

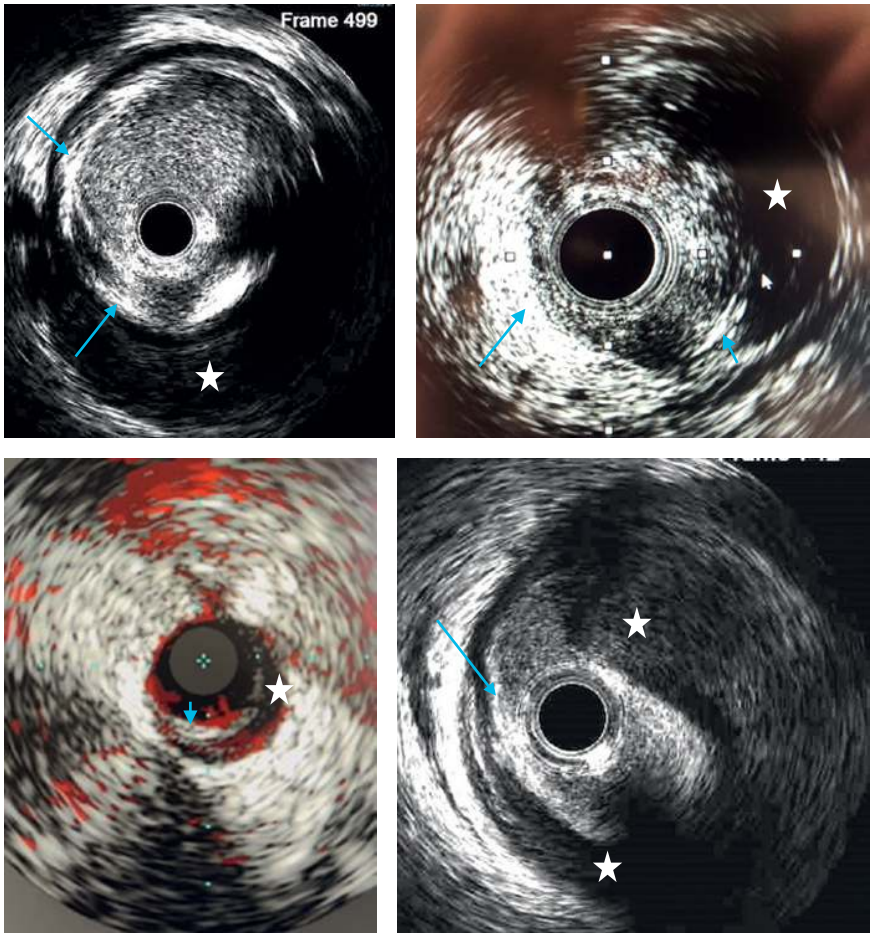

Figure 1.16 IVUS features of SCAD (*stars*). The intima is the white structure (*arrows*). The intramural subintimal hematoma manifests as (*stars*):

- Crescent or banana shape, well demarcated
- Somewhat homogeneous and dark (± white speckles).
- SCAD may have multiple "bananas," as shown on the *right lower* image (*stars*), or may be fully circumferential.

Treatment: PCI vs. conservative management: Spontaneous coronary dissection has a relatively high complication rate during PCI, which results from wiring the false lumen or balloon-induced hematoma propagation distally or proximally toward the left main coronary artery. In fact, *PCI failure or complications are seen in 50–70% of the cases* and emergency CABG is required for complications in 13% of the cases![210–215] Even coronary engagement and contrast injections are associated with a risk of ostial or left main dissection, including hydraulic dissection. Indeed, dissection complicates 3.4% of diagnostic angiographies and up to 8% of intracoronary imaging studies. As opposed to plaque rupture or erosion, ***the overwhelming majority of spontaneous coronary dissections spontaneously heal on follow-up angiography ≥35 days (70–97%), justifying conservative management in patients without active ischemia, without total occlusion, and with TIMI 2 or 3 flow.*** Some may recanalize acutely if the intramural hematoma bursts and communicates with the true lumen.

The diagnosis being solely based on angiographic lesion morphology and context, some operators may feel uneasy observing tight stenoses without definite diagnostic confirmation; as such, IVUS may be used in equivocal cases, the patient is closely monitored for 5–7 days, peripheral CTA is done looking for carotid/renal/iliofemoral FMD which further corroborates the diagnosis, and the diagnosis is eventually confirmed retrospectively by repeating coronary imaging at 6 weeks to show healing (typically CT). IVUS/OCT was done in only ~8% of SCAD cases in the Canadian registry, further implying that the diagnosis is overwhelmingly made based on context and angiographic recognition, and IVUS/OCT is reserved for ambiguous cases.

Conservative treatment consists of aspirin, clopidogrel, and β-blocker therapy, along with 5–7 days of inpatient monitoring. Some degree of antithrombotic therapy is required to prevent thrombosis of the compressed true lumen. Too much antithrombotic therapy, however, risks extending the false lumen hematoma; hence, only antiplatelet therapy is typically used, not anticoagulation.[213,214]

In patients with ongoing STEMI, total occlusion, or hemodynamic compromise, PCI is justified: low-pressure, undersized balloon dilatation may be tried as a stand-alone strategy to re-establish flow, avoiding long stenting in a pathology that will heal on its own. The main goal of PCI is to re-establish flow, not to eliminate the stenosis. As such, balloon angioplasty often suffices as it creates tears in the intima, allowing the intramural hematoma to decompress. Conversely, stenting may "squeeze" the intramural hematoma longitudinally and cause it to propagate, worsening the flow. Also, once the hematoma heals, the stent may become grossly malapposed (floating in the lumen). CABG is an option in left main or multivessel SCAD; CABG is hampered by distal vessel involvement and by a high rate of graft closure (70%) on long-term follow-up, as native disease regresses.[215]

In the case of total occlusion, the immediate diagnosis of SCAD is less relevant, as PCI often needs to be attempted anyway, unless the occlusion is very distal. After wiring, if extensive SCAD features are seen, one may choose to re-establish flow solely via undersized balloon angioplasty.

Progression and follow-up:

- SCAD almost always heals, yet acute extension may be seen in ~5–15% of cases *in the first week*, before eventual healing; thus, ECG signs of ongoing or recurrent ischemia may justify repeat coronary angiography or CT. Note that persistent pain, by itself, does not necessarily imply ischemia, as the dissection process may be painful by itself.
- Instead of repeating coronary angiography, coronary CT may be used to document SCAD healing 6 weeks later; it may also be used in patients with recurrent ischemia, to rule out proximal SCAD extension that would warrant intervention. CT is not a great initial diagnostic modality as it is insensitive for distal SCAD of small vessels <2.5 mm. CTA often does not show hematoma features and does not distinguish dissection vs. atheromatous stenosis, but is still relevant for SCAD diagnosis as: (i) it shows very low atherosclerotic and calcium burden, which corroborates the diagnosis in retrospect; (ii) it assesses resolution of luminal stenosis at 6 weeks, which retrospectively suggests SCAD.
- In-hospital and long-term survival are very favorable in non-pregnancy SCAD (0–2% in-hospital mortality, 0% mortality in the Canadian SCAD registry).[215] Yet, one series suggests a high mortality, higher than traditional MI, mainly when PCI is attempted or in women older than 60.[211] Also, there is a 10–30% risk of recurrence at 1–3 years, and 30% at 5 years. Recurrence is reduced with: β-blockers (2/3 reduction), avoidance of emotional and physical triggers, such as heavy lifting >30–50 lbs, Valsalva, and hormonal therapy.
- SCAD is associated with a high prevalence of peripheral fibromuscular dysplasia (renal ~70%, iliac ~50%, carotid ~50%) and intracranial aneurysms (~15%). Therefore, screening with abdominal CT and carotid-cerebral CT angiography is often warranted.
- Peripartum SCAD is more severe clinically than non-pregnancy SCAD and more frequently proximal (40% proximal coronary involvement, 24% left main, 20–45% multivessel), with consequently more cardiogenic shock (up to 24%) and death (~4%).[216–219] It typically occurs in the first month postpartum. SCAD, even non-pregnancy SCAD, generally contraindicates future pregnancies (8% risk of recurrent SCAD in one registry).[216]

Appendix 8. Harmful effects of NSAIDs and cyclooxygenase-2 inhibitors in CAD

There are 2 types of cyclooxygenases (COX): COX-1 and COX-2. COX-1, found in the normal epithelium and in platelets, is responsible for the homeostatic prostaglandins but also for the generation of thromboxane A2 and platelet activation. Conversely, COX-2, found in inflammatory cells, generates inflammatory prostanoids but also the protective prostacyclin (vasodilatory and antiplatelet effects). The low aspirin dose predominantly inhibits COX-1 with less effect on COX-2.

NSAIDs are harmful in several ways: (i) NSAIDs bind to COX-1, the site of action of aspirin, yet, as opposed to aspirin, they bind in a reversible manner and do not have a sustained antiplatelet effect; (ii) NSAIDs inhibit COX-2 and thus, prostacyclin production. Predominant or selective COX- 2 inhibitors are potentially worse from a platelet standpoint, as they block prostacyclin without any reduction of COX-1's thromboxane and are more detrimental to the prostacyclin–thromboxane balance.

Moreover, if aspirin is administered after NSAID, the COX-1 site will be blocked by the NSAID, which prevents aspirin from binding to it; since the plasma half-life of aspirin is only 20 minutes, aspirin will be eliminated before it gets an opportunity to act.

Appendix 9. Additional ideas on the physiology of hs-troponin: Role of hs-troponin in primary prevention

While troponin release above MI cutoff reflects myocardial cell necrosis, low but detectable hs-troponin typically represent physiological levels of troponin release, or ischemia without necrosis. This may be due to expulsion of the cytosolic pool of troponin without cell death (most of the troponin is in the myofibrils and degrades over 12–24 hours after cell death, but ~8% is cytosolic and may be released physiologically or pathologically without cell death). For example, myocardial stretching, ischemia, or fast heart rate may increase cell membrane permeability without necrosis.[219] This may explain why, following rapid atrial pacing for a few minutes, hs-troponin levels rise, and sometimes double or triple (without exceeding MI cutoff) even in patients without CAD and sometimes even without ischemia (as evidenced by a lack of lactate release in the coronary sinus).[219] This also explains why, after a positive stress test, hs-troponin slightly rises, even while remaining well below MI cutoff, and is associated, in this case, with the presence and severity of perfusion defects.[220] As such, physiological demands or transient provoked ischemia can release troponin in the absence of necrosis. The change is so small that it cannot be detected with conventional troponin, and *troponin level does not usually rise above MI cutoff even if stress-induced ischemia is severe.* ***Ischemia or injury must be sustained to raise troponin above MI cutoff.***

Hs-troponin is more likely to be chronically detectable in patients with underlying CAD and in patients with comorbidities such as hypertension or diabetes.[219,221] In fact, even in the outpatient setting, an undetectable hs-troponin, or a detectable troponin that is in the lower tertile of detection, is associated with a very low risk of long-term events (even lower than that of a normal stress test), and a low probability of obstructive CAD.[222,223] In another study that screened asymptomatic outpatients with a mean age of 62, an undetectable troponin (<0.003 ng/ml) predicated a very low risk of cardiac events, 0.5% per year, similar to the risk of patients with a calcium score of 0.[224] In fact, hs-troponin is complementary to coronary calcium scoring for risk stratification of asymptomatic patients: the lowest risk is in patients with a calcium score of 0+ undetectable hs-troponin.[225]

The only circumstance wherein troponin may exceed MI cutoff physiologically, without necrosis, is marathon exercise among non-highly trained individuals. After marathon, ~50% of nonelite participants have a rise in troponin above MI cutoff (>0.03, up to 0.8 ng/ml), along with transient LV diastolic dysfunction and RV dilatation.[226] Yet troponin rise is brief and normalizes within a few hours, and there is no evidence of late gadolinium enhancement on MRI (troponin leak from myocardial stretch rather than cell necrosis?).[227]

QUESTIONS AND ANSWERS

Question 1. A 72-year-old man is admitted with fever, severe bilateral pneumonia, and sepsis. His exam does not suggest volume overload. During his first hospitalization day, his ECG shows transient deep ST depression in the lateral leads. His troponin I peaks at 1.2 ng/ml, with a rise and fall pattern; BNP = 65. He has acute renal failure with creatinine of 1.7 mg/dl. He does not complain of chest pain. His echo shows a hyperdynamic LV. What is the next step?

A. His troponin rise is due to ischemic imbalance. He does not fulfill the definition of MI. No need for further cardiac workup
B. His troponin is partly due to ischemic imbalance. He fulfills the definition of MI. Perform stress testing before discharge
C. His troponin is partly due to ischemic imbalance. He fulfills the definition of MI. Perform coronary angiography after stabilization of infectious state and renal function

Question 2. A 72-year-old man is admitted with fever, severe bilateral pneumonia, and sepsis. His exam does not suggest volume overload. His ECG shows mild lateral T inversion. His troponin I peaks at 0.8 ng/ml, with a rise and fall pattern; BNP = 65. He has acute renal failure with creatinine of 1.7 mg/dl. He does not complain of chest pain. His echo shows a hyperdynamic LV. What is the next step?

A. His troponin rise is due to ischemic imbalance. He does not fulfill the definition of MI. No need for further cardiac workup at this point
B. His troponin is partly due to ischemic imbalance. He fulfills the definition of MI. Perform stress testing before discharge
C. His troponin is partly due to ischemic imbalance. He fulfills the definition of MI. Perform coronary angiography after stabilization of his infectious state and renal function

Question 3. A 72-year-old man is admitted with melena and severe anemia (hemoglobin 6.5 g/dl). He is tachycardic but not in shock. His ECG shows diffuse 1.5 mm ST depression that has resolved after transfusion. His troponin I peaks at 3 ng/ml, with a rise and fall pattern. He does not complain of chest pain. His echo shows severe anterior hypokinesis. What is the next step?

A. Transfuse and treat with proton pump inhibitors (PPI). No need for coronary angiography. Perform outpatient stress testing
B. Transfuse and treat with PPI. No need for any cardiac workup unless angina occurs despite hemoglobin stabilization
C. Transfuse, treat with PPI, and perform gastroscopy. Perform coronary angiography once bleeding has stabilized for 1–2 weeks
D. Transfuse, treat with PPI, and perform gastroscopy. Administer β-blockers and nitrates. Perform coronary angiography once bleeding has stabilized for 1–2 weeks

Question 4. A 62-year-old man has a history of heart failure with LVEF of 25%. Coronary angiography performed a year previously showed mild, non-obstructive plaques. He presents with acutely decompensated HF, volume overload, and chest tightness. His troponin I peaks at 1 ng/ml with a rise and fall pattern (his baseline troponin is 0.05 ng/ml). His ECG shows LVH with a strain pattern; no Q waves are seen. What is the next step?

A. Diuresis and vasodilator therapy. Initiate antithrombotic therapy. Once proper diuresis is achieved, perform coronary angiography
B. Diuresis and vasodilator therapy. No need to repeat coronary angiography

Question 5. A 62-year-old man presents with progressive dyspnea and chest tightness for the last week. Exam and X-ray are diagnostic of pulmonary edema and severe HF. Echo shows LVEF 25% with global hypokinesis. Troponin I peaks at 0.5 ng/ml with a rise and fall pattern. ECG shows LVH with strain. Creatinine is 1.7 mg/dl. What is the next step?

A. Diuresis, vasodilator therapy, and antithrombotic therapy. Once proper diuresis is achieved, perform coronary angiography during this hospitalization
B. Diuresis and vasodilator therapy. Once proper diuresis is achieved, perform coronary angiography during this hospitalization
C. Diuresis and vasodilator therapy. Once proper diuresis is achieved, perform stress testing for ischemic evaluation
D. Diuresis and vasodilator therapy. Perform elective coronary angiography in the outpatient setting

Question 6. A 62-year-old man presents with progressive dyspnea and chest tightness for the last week. Exam and X-ray are diagnostic of pulmonary edema and severe HF. Echo shows LVEF 25% with global hypokinesis and inferior akinesis. Troponin I peaks at 0.5 ng/ml with a rise and fall pattern. ECG shows diffuse ST depression and inferior Q waves. Creatinine is 1.7 mg/dl. What is the next step?

A. Diuresis, vasodilator therapy, and antithrombotic therapy. Once proper diuresis is achieved, perform coronary angiography during this hospitalization
B. Diuresis and vasodilator therapy. Once proper diuresis is achieved, perform coronary angiography during this hospitalization
C. Diuresis and vasodilator therapy. Once proper diuresis is achieved, perform stress testing for ischemic evaluation
D. Diuresis and vasodilator therapy. Perform elective coronary angiography in the outpatient setting

Question 7. A 56-year-old man, with no cardiac history, presents with one severe episode of chest pain that started after pushing some furniture. The pain lasted 20 minutes and did not recur. His admission BP is 160/95 mmHg, and no murmur or rub is heard. His ECG is normal. His initial troponin I is 0.02 ng/ml, and peaks at 0.05 ng/ml (99th percentile < 0.04 ng/ml). Renal function is normal. What is the next step?

A. Initiate antithrombotic therapy. Coronary angiography within 24 hours.
B. Initiate antithrombotic therapy. Coronary angiography within 72 hours.
C. Stress testing before discharge for risk stratification.

Question 8. A 47-year-old man, smoker, diabetic, presents to the emergency department with sharp chest pain that has been occurring intermittently at rest for the last 2 days. It does not prevent him from performing his daily activities. On exam, his BP is 145/92 mmHg, heart rate 85 bpm. He has no HF or murmur. ECG shows inferior T-wave inversion of 1 mm, and the admission hs-troponin I is undetectable (< 0.005 ng/ml). What is the next step?

A. Perform inpatient stress testing. Home discharge followed by outpatient stress testing is not acceptable
B. Perform inpatient stress testing. Home discharge followed by outpatient stress testing (within 72 hours) is acceptable
C. Perform coronary angiography
D. Discharge home and arrange for clinic follow-up within a week. Further workup depends on progression of symptoms

Question 9. A 56-year-old woman has a history of RCA PCI 8 months previously. She presents with one episode of chest pain that felt similar to her prior angina. It occurred once at rest, 2 days ago, lasted 20 minutes and did not recur. ECG shows LVH with strain and inferior Q waves. Serial troponin levels are <0.04 ng/ml. Creatinine is normal. What is the next step?

A. Coronary angiography within 72 hours
B. Coronary angiography within 24 hours
C. Stress testing 3–6 hours after presentation

Question 10. In comparison with men, women with ACS (multiple answers)

A. Have a higher in-hospital mortality
B. Are less likely to benefit from an early invasive strategy
C. Have fewer underlying comorbidities
D. Have a higher proportion of non-obstructive CAD and less extensive CAD
E. Have a higher bleeding risk
F. Have a higher ischemic burden despite a lower prevalence and extent of CAD

Question 11. A 56-year-old woman presents with severe chest pressure that lasted 2 hours. Her ECG shows deep T-wave inversion across the precordial leads. BP was 190/105 mmHg on presentation. Troponin rises to 2.5 ng/ml. A coronary angiography is performed and only shows minimal plaques <25%. What is the differential diagnosis at this point (multiple answers)?

A. Stabilized plaque rupture
B. Coronary vasospasm
C. Takotsubo cardiomyopathy
D. Myopericarditis
E. Pulmonary embolism
F. Hypertensive crisis with elevated LVEDP and ischemic imbalance
G. Demand/supply mismatch from anemia or tachyarrhythmia

Question 12. For the patient in Question 11, what additional testing *best* helps establish a diagnosis?

A. Cardiac MRI
B. IVUS
C. Echo

Question 13. A 62-year-old man presents with angina and a troponin of 0.12 ng/ml. ECG shows 1 mm dynamic lateral ST depression. He is started on antithrombotic therapy. Coronary angiography is performed and reveals a 40% hazy lesion in the mid RCA with TIMI grade 3 flow. It is eccentric with overhanging edges (Figures 1.11, 1.12, Appendices 1, 2). There is minimal disease otherwise. What is the next step?
A. PCI of the hazy lesion
B. FFR of the RCA
C. IVUS of the RCA
D. Medical therapy since lesion is <50%

Question 14. A 66-year-old woman presents with severe chest pain that started 2 hours ago. The pain is ongoing, unrelieved with NTG, with severe distress, diaphoresis, and severe nausea. BP = 165/90, heart rate 90 bpm, O_2 saturation 100% on ambient air. Exam does not reveal signs of HF. No rub is heard, and BP is equal in both arms. The abdomen is soft and non-tender. ECG is normal. Initial troponin is detectable but below MI cutoff. What is the next step?
A. The pain is unlikely cardiac, as ECG is normal during ongoing pain. ACS likelihood is low. Obtain serial troponin levels then perform stress testing
B. The pain is likely cardiac by clinical features. Give morphine, metoprolol, and anticoagulation, then perform coronary angiography within 24 hours
C. The pain is likely cardiac. Perform chest X-ray. Perform urgent coronary angiography

Question 15. A 70-year-old man who has insulin-dependent diabetes presents with chest pain and inferior ST-segment depression (dynamic). His troponin I is 0.55 ng/ml. He is currently chest pain free. He is tachycardic (sinus tachycardia 105 bpm) with BP of 110/75 mmHg. What is the appropriate therapy?
A. Aspirin, clopidogrel load, GPI, and UFH. Perform coronary angiography within 24 hours
B. Aspirin and UFH. Perform coronary angiography within 72 hours
C. Aspirin and UFH. Perform coronary angiography within 24 hours
D. Aspirin, clopidogrel load, and UFH. Perform coronary angiography within 24 hours
E. Aspirin, clopidogrel load, metoprolol, and UFH. Perform coronary angiography within 24 hours

Question 16. A 70-year-old woman presents with NSTEMI. Her coronary angiogram shows multiple moderate lesions in the LAD and RCA. The physician decides to treat her medically. What is the best long-term antiplatelet regimen?
A. Aspirin only, as no PCI was performed
B. Aspirin and clopidogrel for 1 year
C. Aspirin and ticagrelor for 1 year
D. Aspirin and prasugrel for 1 year

Question 17. A 52-year-old woman presents with chest pain and is found to have 2-mm T inversion in the lateral leads and troponin I of 0.14 ng/ml. She is given clopidogrel 300 mg, aspirin 325 mg, heparin 4000 units and drip on admission. She undergoes coronary angiography next day and is found to have 95% mid RCA stenosis. What PCI pharmacotherapy is associated with the best outcomes during and after PCI?
A. Heparin
B. Bivalirudin
C. Heparin and GPI
D. Heparin or bivalirudin and start ticagrelor instead of clopidogrel
E. Bivalirudin and start ticagrelor instead of clopidogrel

Question 18.
I. Should the patient in Question 16 receive anticoagulation after coronary angiography? Yes/No
II. Should the patient in Question 17 receive anticoagulation after PCI? Yes/No

Question 19. Choose the correct answer(s) (multiple answers possible):
A. Ticagrelor reduces mortality in invasively and non-invasively managed ACS
B. Ticagrelor may be administered before coronary angiography
C. Ticagrelor is a reversible ADP receptor antagonist, but because of a 15-hour half-life, its effect lasts ~3–4 days
D. Ticagrelor has a higher non-CABG bleeding risk than clopidogrel, but this bleeding hazard is not clearly accentuated in older patients or those with prior stroke
E. Prasugrel is only used in patients managed with PCI, and is loaded after coronary angiography (may be loaded before angiography in STEMI)
F. Prasugrel reduces MI but does not reduce mortality, except in STEMI patients (also, a mortality reduction trend is seen in diabetics)
G. Prasugrel showed excessive bleeding hazard in older patients or those with prior stroke

Question 20. Concerning prasugrel and ticagrelor:
A. Ticagrelor and prasugrel are preferred over clopidogrel in all ACS patients (all ACS for ticagrelor, ACS managed with PCI for prasugrel) (class I recommendation in ESC)
B. Prasugrel and ticagrelor are particularly beneficial in high-risk conditions (STEMI, diabetes, recurrent events, and complex PCI)
C. Consider the bleeding risk, particularly age >75 and prior stroke with both agents, especially prasugrel
D. Even in the absence of the high-risk conditions (STEMI, diabetes, recurrent events), prasugrel and ticagrelor are warranted in ACS
E. A head-to-head trial of prasugrel vs. ticagrelor showed superiority of prasugrel on ischemic outcomes, with a similar bleeding risk

Question 21. A 56-year-old man has NSTEMI and undergoes BMS placement in the mid-RCA. He does not have any prior bleeding history. His EF is normal. Besides lifelong aspirin, which antiplatelet and β-blocker therapies should he receive (multiple answers possible)?
A. Clopidogrel for 1 month
B. Clopidogrel or ticagrelor for 1 year
C. Clopidogrel, prasugrel or ticagrelor for 1 year.
D. Consider chronic clopidogrel therapy beyond 1 year if his bleeding risk is deemed low
E. Lifelong metoprolol (medium or high doses)
F. 1 year of metoprolol (medium doses)

Question 22. A 42-year-old woman with a smoking history presents with a severe episode of resting angina. ECG shows diffuse T inversion. Troponin I peaks at 2 ng/ml. Coronary angiography shows a long (~35 mm), smooth, non-calcified 70% stenosis of the mid-RCA. Her coronary arteries are tortuous. What is the likely mechanism?
A. Vasospasm
B. Plaque rupture
C. Plaque erosion
D. Spontaneous coronary artery dissection

Question 23. What is the next step for the patient of Question 22?
A. Direct stenting
B. NTG followed by direct stenting
C. NTG followed by conservative management
D. NTG, followed by OCT then direct stenting

Question 24. A 55-year-old man has a history of untreated HTN. He presents with chest pain and dyspnea. He has severe HTN upon presentation, 220/120 mmHg. His pain and HTN do not improve with NTG and he requires a 24-hour intravenous drip of nicardipine and multiple agents to control HTN. ECG shows LVH with a strain pattern. Initial troponin I is 0.08 and it peaks at 0.6 ng/ml. Creatinine is 1.5 mg/dl. Echo shows LVH with mild LV systolic dysfunction and elevated LA pressure. What is the diagnosis and the next step?
A. Type 1 MI from plaque rupture. Must perform early invasive strategy
B. Type 2 MI from severe HTN. HTN control is the initial measure. Perform stress testing once HTN is controlled and chest pain resolves

Question 25. A 55-year-old man has a history of untreated HTN. He presents with chest pain and dyspnea. He has severe HTN upon presentation, 190/110 mmHg. After the administration of two NTG tablets, chest pain resolves and BP declines to 145/85 mmHg. Troponin I is 0.04 ng/ml and peaks at 0.15 ng/ml. What is the diagnosis and the next step?
A. Type 1 MI from plaque rupture. Must perform early invasive strategy
B. Type 2 MI from severe HTN. HTN control is the initial measure

Answer 1. C. He fulfills the MI definition as he has an elevated troponin with a rise and fall pattern, *along with* ST changes. The degree of troponin I rise (>1 ng/ml) as well as the ST changes are concerning for underlying CAD, whether type 1 MI (plaque rupture initiated by the infectious status) or severe ischemic imbalance on top of underlying CAD. In the absence of contraindication, coronary angiography may be performed after his infection and renal function stabilize.

Answer 2. A. He does not fulfill the MI definition as he has an elevated troponin with a rise and fall pattern, but *without associated chest pain, ST changes, or wall motion abnormality*. The severe non-cardiac illness along with the mild degree of troponin rise (<1 ng/ml) is consistent with ischemic imbalance and does not necessarily imply underlying CAD. There is no definite need for antithrombotic therapy, and a later, elective evaluation with stress testing may be performed.

Answer 3. C. The patient has a rise and fall in troponin along with ST changes and wall motion abnormality. This is a type 2 MI, related to ischemic imbalance in the context of severe, acute anemia. However, the extensive ST changes, the severity of troponin rise (>0.5–1 ng/ml), and the wall motion abnormality are concerning for severe underlying CAD, which was probably stable and was unveiled by the stress of anemia/tachycardia. CAD needs to be addressed. Stress testing is unlikely to provide additional information, as the patient already shows severe myocardial ischemia and ST depression with the stress of anemia. Coronary angiography, followed by possible revascularization (PCI or CABG), is warranted. However, in a patient with active or recent bleeding, PCI or CABG is not advised, as peri-PCI or peri-CABG anticoagulation and dual antiplatelet therapy may not be tolerated. Wait 1–2 weeks (preferably) after hemoglobin has stabilized and proper gastrointestinal therapy is performed (PPI, endoscopic cauterization). This allows a safer performance of revascularization if needed. β-Blockers should not be administered acutely, as the patient is in a pre-shock state and tachycardia is compensatory; they may be administered 24–48 hours later.

Answer 4. B. The mild rise in troponin is secondary to the ischemic imbalance of HF (LV dilatation increases wall stress/afterload; LVEDP elevation reduces coronary flow). Similarly, the chest tightness that occurs in decompensated HF is commonly secondary to ischemic imbalance. In fact, troponin rise in HF is a prognostic marker that correlates more with the severity of HF decompensation than the coronary status and does not necessarily imply ACS. The fact that a coronary angiography performed in the last 2–3 years did not reveal obstructive CAD strongly argues against ACS.

Answer 5. B. The mild troponin rise is at least partly secondary to the ischemic imbalance of HF. Yet, any HF, particularly acute or systolic HF, warrants evaluation for an underlying ischemic etiology (chronic CAD) using coronary angiography. Antithrombotic therapy does not

appear warranted, as the ECG does not suggest acute ischemia. Elevated troponin alone does not establish the diagnosis of ACS in a patient presenting with HF. While the underlying CAD is often stable, ischemic evaluation is preferably performed before discharge. CAD, if present, is likely extensive with an increased risk of recurrent HF or MI.

Answer 6. A. The Q waves suggest an ischemic etiology of HF. The Q-wave infarct may be recent, coinciding with his onset of symptoms. Moreover, global ischemia is suggested by the extensive ST depression and the wall motion abnormality that extends beyond the infarcted territory. Thus, unlike Question 5, ECG implies that HF is secondary to a recent infarction and acute ischemia. He should be treated as type 1 MI with antithrombotic therapy and he should undergo coronary angiography once he has received proper diuresis. In acute HF, in the absence of acute ST elevation, angiography and PCI are not warranted urgently, as supine positioning, sedation, and contrast loading are likely to aggravate HF and myocardial ischemia. His Q-wave MI is >24 hours old (by history), without persistent ST elevation.

Answer 7. A. Any increase in troponin above the 99th percentile with a rise and fall pattern, in the context of angina presentation, and in the absence of severe non-cardiac illness (sepsis, anemia, HF, tachyarrhythmia) is diagnostic of primary NSTEMI (ACS). This patient is managed with antithrombotic therapy and an initial invasive strategy rather than stress testing. His GRACE risk score is <140 (age <70, no ST depression, HF, hypotension, tachycardia); thus, coronary angiography may be performed at 24–72 hours per TIMACS and VERDICT trials. However, ESC and ACC guidelines favor early invasive strategy <24 hours in all NSTEMIs.

Answer 8. D. Traditional risk factors, like smoking and diabetes, increase the general probability of CAD but only weakly increase the likelihood of ACS in a patient with acute chest pain syndrome. Other factors, such as pain timing/duration, troponin, and ECG should be taken into account: (1) the undetectable troponin makes ACS very unlikely; (2) T-wave inversion < 3 mm is non-diagnostic and does not significantly increase the likelihood of ACS or worsen its prognosis; (3) chest pain occurrence and timing are atypical. In this patient with undetectable hs-troponin, early discharge is appropriate. Early stress testing at 6–12 hours after admission or post-discharge stress testing are appropriate (A or B), but not necessary in the setting of undetectable troponin and atypical symptoms.

Answer 9. C. While the pain is concerning, it does not have a typical exertional pattern, and it is resting pain with negative troponin. Considering her troponin and non-specific ECG, the ACS likelihood is not high. In women with negative troponin, no ST changes, and low TIMI risk score, an initial invasive strategy is associated with increased risk of death/MI, and thus initial stress testing is preferably performed.

Answer 10. A, B, D, E, F.

Answer 11. A, B, C, D (see explication under Answer 12).

Answer 12. A. About 10% of patients with NSTEMI, particularly women, are not found to have any significant CAD. In those cases, reasons A through G can explain the troponin rise. Demand/supply mismatch without underlying CAD usually causes a troponin rise <1 ng/ml, and thus is not likely to explain the patient's troponin (causes F and G). Similarly, in pulmonary embolism, troponin does not usually rise beyond 1 ng/ml.

In the absence of obstructive CAD, a myocardial process, such as myocarditis or takotsubo cardiomyopathy, must be considered. Transient severe myocardial ischemia is also possible (vasospasm or stabilized plaque rupture). The deep T inversion is consistent with takotsubo cardiomyopathy, but also myocarditis and a post-ischemic state. In all those cases, the distribution of the echocardiographic wall motion abnormality helps establish a diagnosis. MRI is most helpful: late gadolinium enhancement rules out takotsubo cardiomyopathy and is only seen with infarction or myocarditis. The distribution of late gadolinium enhancement distinguishes myocarditis from an ischemic pattern:[62]

- Distribution not consistent with an arterial territory + subepicardial or mid-wall predominance → myocarditis
- Distribution consistent with an arterial territory + subendocardial or transmural predominance → infarction

In all 3 cases (myocarditis, infarction, takotsubo), edema may be seen on T2-weighed images if the process is acute. The distribution of edema also distinguishes myocarditis from infarction. IVUS and OCT may be done and may detect plaque disruption, even in some cases where MRI is unrevealing; they may obviate the need for MRI.

Answer 13. C. In ACS, it is important to ascertain that a seemingly non-obstructive plaque is truly non-obstructive. For example, a 40–50% hazy stenosis with irregular or overhanging borders is possibly unstable and may be anatomically significant by IVUS (more obstructive and ulcerated than the angiography suggests).

Answer 14. C. About 40–45% of acute LCx occlusions do not show any significant ST-T abnormality. **In fact, ~20% of NSTEMIs have acute coronary occlusion, mostly LCx or RCA, and may be STEMI-equivalents that lack ST elevation and sometimes ST depression. LCx and RCA occlusions represent 2/3 of these "occluded" NSTEMIs.** Besides the unremarkable ECG, the first troponin may be negative in these patients, which explains the diagnostic delay. Hints to a true ACS: (i) ongoing, unexplained severe distress/pain (rule out clinically and by X-ray aortic dissection, perforated peptic ulcer, and abdominal catastrophe); (ii) posterior-lead ECG; (iii) ECG abnormality may emerge when ECG is repeated every 10 min. Even if the posterior-lead ECG is normal, treat the patient as acute coronary occlusion and perform urgent catheterization. Perform chest X-ray to rule out pneumothorax and any suggestion of aortic dissection or perforated peptic ulcer (subdiaphragmatic air). Morphine should not be used, as it masks an ongoing angina and provides false reassurance.

Answer 15. C. Upstream GPI (before PCI) is not justified, whether upstream clopidogrel is administered or not. On admission, the patient may receive dual antiplatelet therapy with aspirin and clopidogrel or ticagrelor. However, in 2 trials using potent ADP-receptor antagonists (prasugrel in ACCOAST, and prasugrel and ticagrelor in ISAR-REACT 5), and in the large SCAAR registry, their upstream administration pre-catheterization did not improve outcomes; if PCI is to be performed, the ADP-receptor antagonist is administered during PCI. Upstream

administration may particularly delay the care of patients who eventually need CABG, such as, potentially, this insulin-dependent diabetic man. The patient has a very high-risk NSTEMI, with a high GRACE score > 140 (in light of the age ≥ 70, tachycardia, SBP < 120, and both troponin rise and ST changes). An early invasive strategy <24 hours is preferred. Since coronary angiography will be performed in less than 12–24 hours, heparin is preferred over enoxaparin. He has tachycardia and SBP < 120 mmHg, hence he is in a pre-shock state and should not receive metoprolol in the first 24 hours.

Answer 16. C (B is an acceptable option). The patient likely had plaque rupture of one of her moderate lesions, leading to thrombus and microembolization. Her plaques stabilized with antithrombotic therapy. Clopidogrel (CURE trial) and ticagrelor (PLATO) are therapies that have shown benefit in medically treated ACS patients, ticagrelor being the superior agent (ticagrelor showed mortality and MI reductions in this subgroup of medically treated patients). Prasugrel is only studied in ACS patients treated with PCI; it failed to show superiority in medically treated ACS (TRILOGY ACS trial).

Answer 17. D. The downstream use of GPI (during PCI) is not clearly beneficial, except in bail-out situations. Ticagrelor reduces ischemic events and mortality more than clopidogrel after ACS. Heparin has been shown to be as safe and efficacious as bivalirudin in a large study with balanced GPI use and radial access.[203]

Answer 18. (i) yes, (ii) no. Anticoagulation for at least 48 hours is warranted in NSTEMI patients managed without PCI. Low-dose UFH, with no bolus, may be started 8–12 hours after coronary angiography and continued for a total of 48 hours. Fondaparinux may be used for 2–8 days. Enoxaparin may also be used but is associated with a higher bleeding risk after catheterization.

In patients who undergo PCI, the anticoagulant is stopped after PCI. Only bivalirudin may be infused for 1–4 hours after PCI. In patients who receive GPI during PCI, GPI may be continued for up to 24 hours.

Answer 19. All are correct.

Answer 20. All are correct.

Answer 21. C, D, and F. Regardless of the stent type, NSTEMI patients should receive 1 year of ADP-receptor antagonist. Beyond 1 year, DAPT trial suggests a benefit of dual antiplatelet therapy in patients who have not bled in the first year, especially the MI subset. If EF is normal, β-blocker does not have a clear benefit beyond 1 year after MI.

Answer 22. D. The smooth angiographic appearance and the age and sex of the patient suggest vasospasm, plaque erosion, or spontaneous coronary dissection. The latter is the most likely diagnosis here: (i) the length of the stenosis is concerning for dissection; (ii) a tortuous or corkscrew coronary artery further supports spontaneous coronary dissection.

Answer 23. C. OCT helps show features of plaque erosion and SCAD. Plaque erosion is characterized by thrombus with an intact intimal cap or a fibrointimal plaque. However, when SCAD is suspected, it is best to avoid any coronary manipulation, including OCT, as each manipulation increases the risk of intramural hematoma propagation. When the flow is preserved and the disease is not critical, SCAD is best treated conservatively with no PCI. The majority of SCADs (70–97%) will heal by 1–2 months.

Answer 24. B. Patients with true ACS/type 1 MI may have HTN secondary to the distress of angina. However, in the case presented here, the persistence of HTN and its requirement for multiple agents implies that malignant HTN is the primary process responsible for the patient's pain and troponin rise. The severe LVH, seen on echo, accentuates ischemic demands and is a marker of uncontrolled HTN. The degree of troponin rise (<1 ng/ml) is consistent with ischemic imbalance. Ischemic workup, possibly stress testing, may be performed once HTN is controlled and chest pain resolves.

Answer 25. A. Compare this case to Question 24. The quick resolution of HTN with NTG implies that HTN was secondary to myocardial ischemia (catecholamine surge), rather than a cause of ischemia. Even the milder troponin rise, in context, is worrisome for true ACS and plaque rupture.

63. Badertscher P, Boeddinghaus J, Twerenbold R, et al. Direct comparison of the 0/1h and 0/3h algorithms for early rule-out of acute myocardial infarction. Circulation 2018; 137:2536–2538*: 0/1 hour is superior to old protocol (using MI cutoff). High negative predictive value of 99.8%*.
64. Sandoval Y, Nowak R, deFellipi CR, et al. Myocardial infarction risk stratification with a single measurement of troponin I. J Am Coll Cardiol 2019; 74:271–282: *A single very low hs-troponin I has a 30-day negative predictive value of 99.8% for MI/death, using troponin I US assays (very low defined as <0.005 ng/ml, the detection cutoff being 0.002). It seems <0.005 ng/ml is a good rule-out cutoff in all hs-troponin assays; hs troponin does not have to be undetectable, as assays are becoming more sensitive*.
65. Twerenbold R, Costabel JP, Nestelberger T, et al. Outcome of applying the ESC 0/1-hour algorithm in patients with suspected myocardial infarction. J Am Coll Cardiol 2019; 74:483–494. *Very low cardiovascular death 0.1% at 30 days in the rule-out group*.

66. Allen BR, Christenson RH, Cohen SA, et al. Diagnostic performance of high-sensitivity cardiac troponin T strategies and clinical variables in a multisite US cohort. Circulation 2021; 143(17): 1659–672. *Patients with hs-troponin T >52 had PPV for MI (type 1 or 2) of 55% only. The PPV for type 1 MI was only 26.8%. 30-day MACE risk in the hs-troponin rule-out zone was ~2.8% (NPV 97.2%), with the risk of MI/death 1.6% (NPV 98.4%). However, most of the MACE events were revascularization, not MI, and most MI events were type 2 MI, not type 1 MI. The numbers of type 1 MI and cardiac death at 30 days were 3 and 1, respectively, among 826 ruled-out patients (1,430 total cohort); 10 were type 2 MI, 9 were revascularization. Low Heart score (≤3) marginally improved the NPV by 1%, at the cost dramatic reduction of rule out/discharge from 58% to 31% and a reduction of the PPV to <50%*.

1. DEFINITION, REPERFUSION, AND GENERAL MANAGEMENT

I. Definition

STEMI is a clinical syndrome of angina or angina equivalent along with:[1–3]

- ST-segment elevation ≥2 mm in men or ≥1.5 mm in women in leads V_2–V_3, or ≥1 mm in 2 other contiguous chest or limb leads, *with a shape consistent with ischemic ST elevation*. The shape must be distinguished from early repolarization, pericarditis, or ST-segment elevation secondary to LVH or LBBB; emergent echo or coronary angiography may be performed in case of doubt.

or:

- Isolated or most prominent ST-segment depression in leads V_1–V_3 ≥ 0.5 mm, which is reciprocal to posterior ST elevation in leads V_7–V_9 (true posterior STEMI). In leads V_7–V_9, the ST-segment elevation cutoff is only 0.5 mm, as the distant location of these leads behind the heart minimizes ST-segment elevation.

ST-segment elevation below these cut-points may still imply myocardial injury when the clinical setting or the ST-segment morphology suggests ischemia. Emergent reperfusion may still be indicated in these patients, generally with PCI (thrombolysis is not an established therapy for mild degrees of ST elevation, <1 mm).

Conversely, ST-segment elevation that exceeds these cut-points may not represent STEMI. Careful attention to the morphology of the ST segment and the associated features (Q wave, inverted or ample T wave) is critical.

STEMI usually evolves into electrocardiographic Q waves (Q-wave MI) and is usually a transmural and large MI. NSTEMI usually evolves into a non-Q-wave MI and is usually a subendocardial, smaller MI. However, there is some overlap. STEMI may not generate Q waves in case of early reperfusion: Q waves occur in 23–58% of PCI-treated STEMIs, and even when they occur, Q waves regress in 40% of cases.[4] Conversely, NSTEMI may generate Q waves if it is large or if it is, in fact, a subtle STEMI.

Since it takes up to 3 hours for troponin to rise after the onset of infarction, it should not be relied upon for the diagnosis or initiation of emergent therapies.

Approximately 12.5% of MIs are totally silent and ~12.5% have a mild, atypical presentation (e.g., dyspnea, malaise, nausea).[5] These cases go unrecognized, and patients may present with HF days or months after acute MI. Atypical presentation is more common in diabetic, female, and elderly patients. *Contrary to common belief, there is no evidence that fully silent MI is more common in these 3 subgroups*.[5] In ORBITA-2 trial, ischemic symptoms were not different in these subgroups.

~60–80% of first MIs are not preceded by any angina (or angina for few days only), and MI is their first cardiac presentation. This is because most MIs arise from non-obstructive plaques (see Appendix, Questions II.5 and 21)

II. Timing of reperfusion

a. Emergent reperfusion with PCI or fibrinolytics is indicated in patients who present *within 12 (24) hours of symptom onset* and who have *persistent* ST elevation in two or more contiguous leads or ST depression that is isolated or most prominent in V_1–V_3 (class I recommendation for PCI or fibrinolytics at ≤12 hours, class IIa for PCI at 12–24 hours).[1] This applies even if ischemic symptoms have resolved, as long as ST elevation is persistent and the onset of ischemic symptoms is ≤24 hours.

PCI is the preferred strategy, and it should be performed with a door-to-balloon time (DTB) of ≤90 minutes in patients presenting to PCI-capable hospitals, and ≤120 minutes in patients transferred from non-PCI-capable to PCI-capable hospitals. If PCI cannot be performed with a DTB of ≤120 minutes, fibrinolytics should be given to patients presenting within 12 hours of symptom onset (initiated ≤10 minutes from diagnosis).* ***Regardless of the setting, the DTB that mitigates PCI's benefit over fibrinolysis is 120 minutes*** (ESC).

b. Patients presenting *>24 hours after symptom onset (or 48 hours per ESC)* generally do not have an indication for emergent PCI. *Emergent PCI (not fibrinolysis) is selectively indicated* in some of these patients, such as patients with persistent ischemic symptoms, cardiogenic shock, acute severe HF with massive pulmonary edema, or when the onset of STEMI is not clearly >24 hours.

Non-urgent PCI is indicated in patients presenting >24 hours with:

- recurrent chest pain at rest or mild activities
- severe ischemia on exercise testing, mainly chest pain in stage 1, or ≥2 mm ST depression, or large reversible defect within or around the infarct.

Non-urgent coronary angiography may be done in all patients presenting >24 hours, even if asymptomatic at this point (class IIa ESC). However, do not recanalize a totally occluded artery >24–48 hours (OAT trial). Coronary angiography remains useful as it may show: (i) non-totally occluded culprit artery (up to 45% of patients), which may be considered for PCI; (ii) extensive non-culprit CAD, which qualifies for non-culprit PCI or CABG. For example, a patient with RCA infarct who also has left main or LAD disease may benefit from PCI or CABG.

While a timely primary PCI is favored over fibrinolysis in all STEMI patients, it is more heavily favored in the following circumstances, where the efficacy of fibrinolysis is reduced:

- Cardiogenic shock or severe HF attributed to STEMI should undergo emergent PCI regardless of the delay to presentation (even if >24 hours). Fibrinolytics should not be a standalone therapy for cardiogenic shock but may be used en route to PCI in early presenters, when delays are expected.
- Late presenters, 3–12 hours.

---

* ACC defines DTB as the time from first medical contact (FMC) to first establishment of reperfusion with an interventional device; the preferred term is *"FMC-to-device time."* FMC is the time of on-scene arrival of emergency medical service, or the time of hospital arrival in case the patient transports himself. First establishment of reperfusion corresponds to the first balloon inflation or thrombectomy that successfully re-establishes coronary flow. Note that the term DTB is not used in ESC guidelines: *"STEMI diagnosis-to-wire crossing"* is used instead.

- Age >75 years.
- History of CABG with suspicion of SVG thrombosis. Both PCI and fibrinolytics have reduced efficacy in this high-risk subset, but PCI remains more effective than fibrinolytics. PCI re-establishes TIMI 3 flow in 50–70% of SVG MIs, vs. 25–50% with fibrinolytics.
- ECG is not definite for STEMI, or STEMI is subtle with ischemic ST elevation<1 mm, or time of onset of symptoms is unclear (may be >12 hours).

Myocardial effect of reperfusion therapy according to ***ischemic time:***

- *1 hour:* Golden hour, most myocardium is saved with reperfusion. Thrombolysis is very effective for recanalizing this fresh thrombus, nearly as effective as PCI.
- *1–3 hours:* High percentage of ischemic myocardium is saved with reperfusion. Thrombolysis (+/− rescue PCI) is as effective as a timely PCI for survival (CAPTIM, STREAM trials).
- *3–12 hours:*
  - Significant myocardial necrosis already occurred.
  - **Thrombolysis is moderately effective; PCI is much more effective for recanalization and mortality.**
  - Reperfusion treats peri-infarct ischemia, ↓ deleterious remodeling, improves scar turgor, and ↓ mortality (absolute mortality reduction 2–3%).
  - Reperfusion may save large amount of myocardium, mainly in cases of partial recanalization of the culprit artery or pre-existing collaterals.
- *12–24 (48) hours:* Most myocardial necrosis already occurred. Thrombolysis is ineffective; PCI remains somewhat effective.

At 3–12 hours and at 12–48 hours, reperfusion may still reduce the extent of LV necrosis, mainly in patients with pre-infarct angina, or if the artery partially recanalized spontaneously, or in case of pre-existing collaterals. Pre-infarct ischemia is beneficial and is associated with a smaller infarct size, compared with abrupt MI with no preceding ischemia, as it promotes 2 processes: collaterals and cellular ischemic pre-conditioning. Also note that:

- 25% of acutely occluded arteries partially recanalize by 2-4 hours, and ~40–45% partially recanalize by 24 hours.[6–8]
- 50% of acute MIs develop collateral flow in the first 6 hours (mostly weak collaterals, grade 1), while almost all patients develop collaterals within 24 hours to a few days (grade 2 or 3 collaterals in >50%).[9]

III. ECG phases of STEMI (Figures 2.1, 2.2)

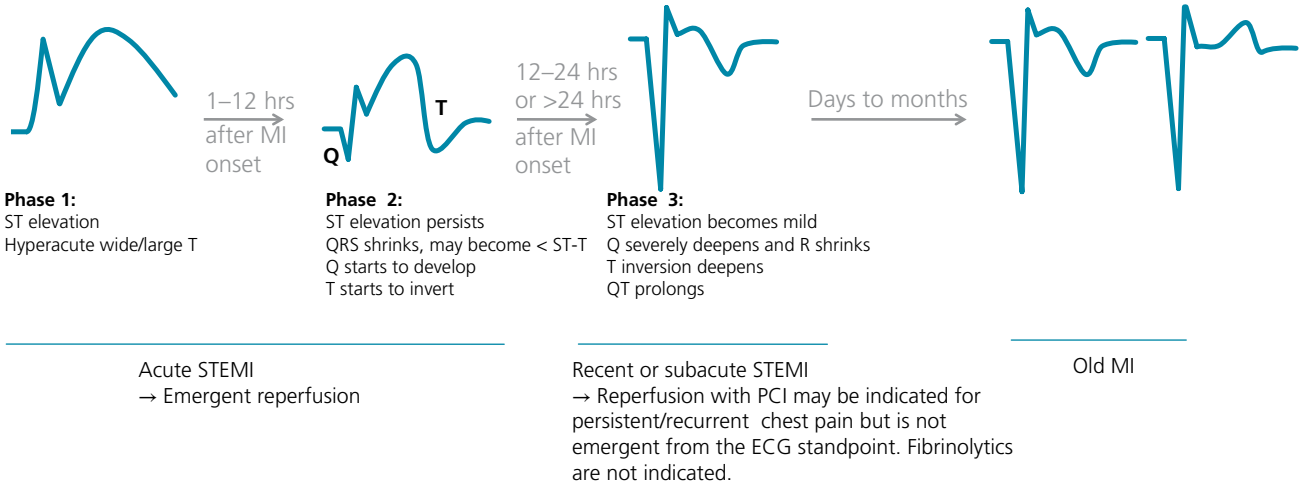

Figure 2.1 Phases of STEMI.

ST elevation may persist for days, weeks, or chronically >3 weeks in patients with a dyskinetic or aneurysmal myocardium. Let's take the case of a patient who had chest discomfort several days previously and currently has HF without angina; if his ECG shows deep Qs and mild ST elevation (phase 3), his STEMI is likely >24 hours old and the persistent ST elevation likely reflects dyskinesia. An echocardiogram showing a dilated LV with a truly thin wall in diastole confirms this suspicion.

Q waves frequently regress in recanalized MI, weeks or months later. The inverted T waves may persist for days, weeks, months, or even years. Patients with LV dyskinesia and persistent ST-segment elevation may have chronic T-wave inversion as well.

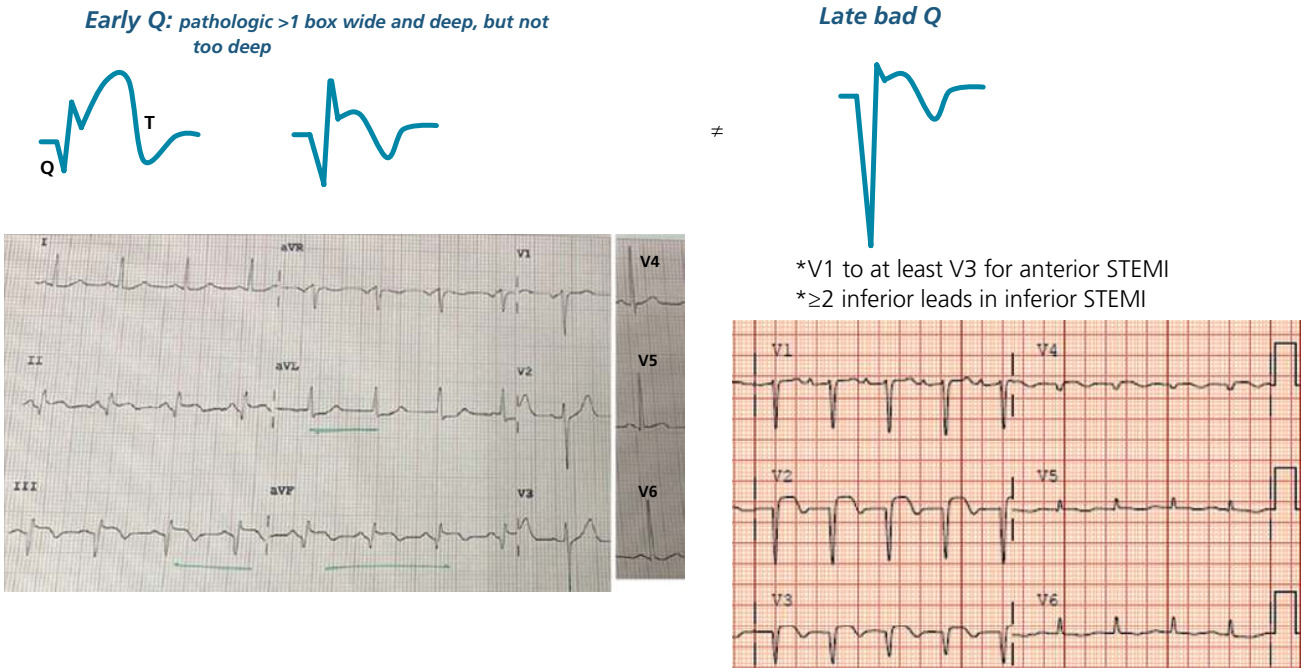

Figure 2.2 Compare the **early Q waves** (*left images*) with the **late deep Q waves** (*right images*): (i) the early Q waves are wide and pathologic, but there is still a significant R wave with significant R:Q ratio and ST:Q ratio; (ii) the "bad" Q waves are deep with minimal residual R waves and relatively mild residual ST elevation; they must be seen in multiple leads to be worrisome for late presentation. On the *left* ECG, a deep Q wave with minimal R is seen in lead III, but not in leads II and aVF, where Q has the appearance of an early Q wave; as such, this ECG is overall suggestive of an early MI presentation and is consistent with the patient's chest pain description of 3 hours.

Even the "bad" Q waves with minimal residual ST elevation may occasionally be seen in earlier STEMI <24 hours with spontaneous recanalization. Thus, the "bad" Q waves do not preclude PCI if pain started <24 hours and especially if pain is ongoing, or if the artery is not totally occluded. In these cases, the bad Q waves may regress with reperfusion.[4,10–13]

IV. STEMI diagnostic tips and clinical vignettes

1. A patient presents with one episode of chest pain that lasted 10 minutes. He does not have any pain currently. He reports a prior history of a large MI 2 years previously. His ECG shows 1.5 mm ST elevation in the anterior leads with Q waves and T-wave inversion. Should he undergo emergent reperfusion?

Emergent reperfusion is probably not warranted. It is important to seek old ECGs and urgently obtain an echocardiogram. In fact, ST elevation may represent an old STEMI with a chronic dyskinetic myocardium and a chronic, persistent ST elevation with Q waves; T waves may be inverted or upright, but not ample. Deep Q waves with minimal residual R waves and ST elevation (Q much larger than R and ST elevation in multiple leads), a history of an old MI, an old ECG (if available), or a quick bedside echocardiogram may allow the diagnosis. Echocardiography shows a myocardium that is thin, not just in systole but in diastole, bright (scarred) and possibly aneurysmal in case of an old infarct, whereas in acute STEMI the myocardium is neither thin nor scarred yet. *If the patient does not report a history of MI, if T wave is ample, or if he is having ongoing chest discomfort, ST elevation is generally considered acute STEMI*.

2. A patient presents with ongoing chest pain for the last 8 hours. His ECG shows inferior ST elevation of 1 mm with deep Q waves. Should he undergo emergent reperfusion?

Q waves often develop at 1–14 hours after STEMI onset, while the ST segment is still elevated. While Q waves are associated with a more delayed presentation, larger MI, less myocardial salvage, and worse short-term prognosis, they are not synonymous with irreversible myocardial damage and do not preclude reperfusion therapy; significant myocardial salvage is achieved in the overwhelming majority of those patients (>50% myocardial salvage of the area at risk and >1/3 reduction of the infarcted mass).[4,10–13] Q waves regress in 40% of patients, and persistent Q waves at >1 month have a stronger prognostic value than acute Q waves.

Note that the particular pattern of deep Q waves with minimal residual R waves and relatively mild residual ST elevation in multiple leads is more worrisome and suggests MI older than 12–24 hours (Figure 2.2), but PCI reperfusion is still warranted for persistent chest pain. Even those "bad" Q waves may regress with reperfusion, in which case the prognosis improves.[4,10–13]

3. A patient presents with intermittent chest pain for the last 3 days. He had an episode of pain 2 hours previously but is currently free of any pain. His ECG shows anterolateral ST elevation. Should he undergo emergent reperfusion?

Some patients have episodes of unstable angina for hours or days before STEMI. Presume that the onset of STEMI is the onset of the last episode of prolonged chest pain. Thus, this patient qualifies for emergent reperfusion.

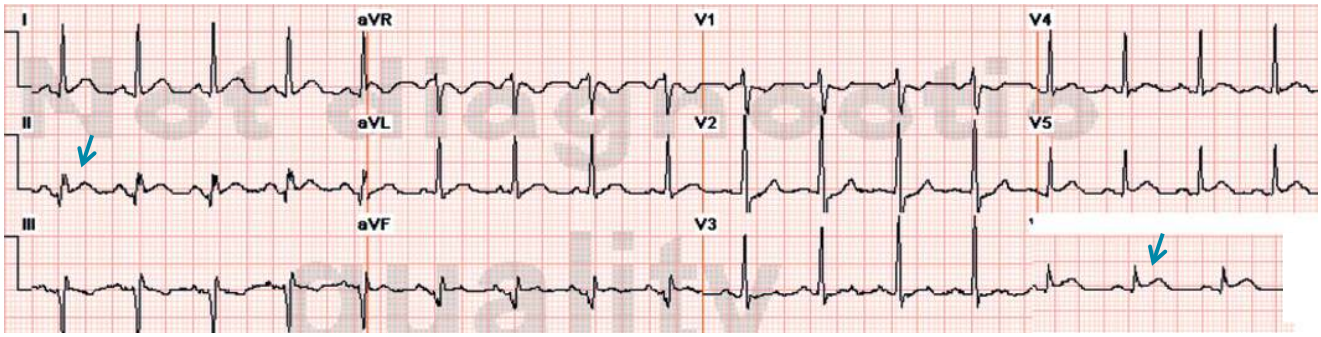

Figure 2.3 The patient presents with chest discomfort that has lasted 3 hours and resolved 2 hours ago. Subtle ST elevation is seen in leads II and aVF, and in leads V_5 and V_6, with subtle ST depression in V_1–V_2. Three features suggest that this mild ST elevation is actually STEMI: (i) Q waves; (ii) ST depression in reciprocal leads (V_1–V_2); (iii) wide T-wave morphology and fused ST-T segments in leads I, II, V_5, and V_6 (*arrows*). This patient qualifies for emergent catheterization since his discomfort occurred in the last 24 hours. He is found to have an acutely occluded large obtuse marginal branch.

4. A patient presents with chest pain that started 4 hours previously and inferior ST elevation. His pain has just resolved with aspirin and nitroglycerin, but ST elevation is persistent. Should he undergo emergent reperfusion?

Some patients have resolution of chest pain with nitroglycerin or antithrombotic therapies *but ST elevation persists*. These patients should still undergo emergent reperfusion therapy, as long as they present within 24 hours of pain onset.

5. A patient presents with chest pain that started 4 hours previously and inferior ST elevation. Both his pain and ST elevation resolve after aspirin and nitroglycerin administration. Should he undergo emergent reperfusion?

Chest pain and ST elevation *may both resolve spontaneously* or with the acute therapies (*transient or self-aborted STEMI*). This often indicates spontaneous thrombolysis and occurs in ~15% of STEMIs, leading to a much lower mortality and a smaller infarct size.[14,15] Occasionally, this may represent resolution of a coronary spasm. Coronary angiography may be performed emergently, but this is not mandatory: delayed angiography (mean 23 hours) was associated with a similarly low event rate and infarct size in TRANSIENT-STEMI trial.[15] Full ACS therapy and early coronary angiography, within the next day, are indicated.

6. A patient presents with chest pain that lasted 2–3 hours earlier today and has now resolved. His ECG shows subtle ST elevation (<1 mm) in leads II, aVF, V_5, and V_6 (Figure 2.3). Should he undergo emergent reperfusion?

Yes, he should. This patient has mild ST elevation (<1 mm) with a morphology that is, nonetheless, consistent with STEMI. Q waves are also present. This patient does not qualify for fibrinolytics, as ST elevation is <1 mm, but qualifies for emergent PCI. STEMI likely recanalized partially, but ST elevation has not fully resolved.

7. A patient presents with chest pain that has lasted 2–3 hours earlier today and has now resolved. His ECG shows inferior Q waves and T-wave inversion, without any significant ST elevation. Should he undergo emergent reperfusion?

Coronary angiography may be performed emergently, but this is not obligatory. Resolution of ST elevation with appearance of Q waves may occur after a brief ischemia, e.g., 1–2 hours, with spontaneous recanalization (as in this case).

In general, a patient qualifies for emergent PCI with either of the following two conditions: (i) persistent ST elevation with a presentation less than 24 hours after pain onset (even if pain is not persistent); (ii) persistent pain, even if the patient presents later than 24 hours after pain onset and even if ST elevation has resolved.

V. Subtle STEMI and occlusion MI

Approximately 20–30% of NSTEMIs have acute total coronary occlusion and are STEMI-equivalents. The below 4 ECG findings are ***subtle STEMI* or *STEMI-equivalents*** that indicate acute occlusion and dictate emergent catheterization (Figures 2.4–2.6).[16,17] Subtle STEMI does not usually qualify for thrombolysis, as major thrombolytic trials, such as GISSI-1 and GUSTO-1, recruited more definite ST elevation >1–2 mm. Both obvious STEMIs and those subtle STEMIs are grouped under the term **"occlusion MI" (OMI)**.

1. **Subtle ST elevation** <1 mm, sometimes in only 1 or 2 leads, but **morphology** is consistent with STEMI, along with any of the following:
   - glaring or subtle reciprocal ST depression or T inversion
   - evolving Q waves
   - ***shrinking QRS with a relatively large T wave, so much that T approximates QRS size*** or ST approximates 50% of QRS, typically in ≥2 of the infarct leads (Birnbaum. JACC 1996;27:1128). QRS shrinks on its way to becoming Q wave.
   - upward pull of the S wave, lifting it above the baseline (=terminal QRS distortion)

There are 2 additional well-described subtle ST elevation patterns of OMI: (i) ST elevation in noncontiguous leads V_2 and aVL, with inferior reciprocal ST depression → diagonal occlusion (South African flag pattern); (ii) mild ST elevation in III with diffuse ST depression, especially in the lateral leads → *possible* inferior OMI with critical LAD disease (Aslanger pattern, ~25% have acute LCx or RCA occlusion).

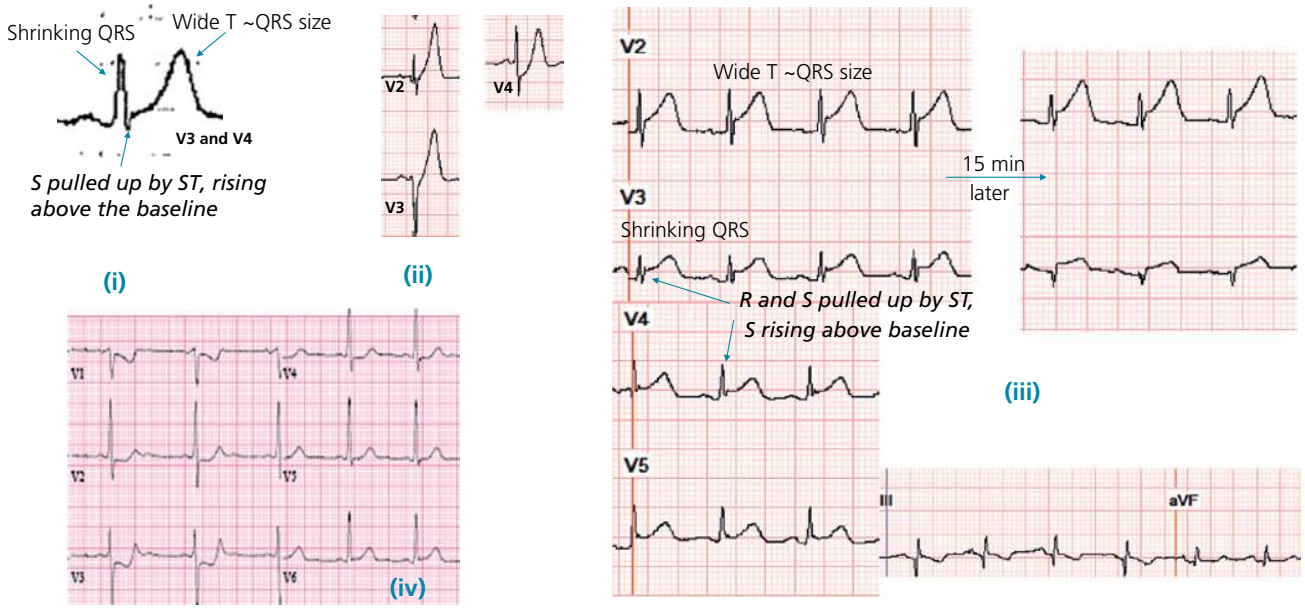

Figure 2.4 Illustrations of "occlusion MI" or subtle STEMI cases, in patients with ongoing or intermittent chest pain, all found to have occluded arteries (LAD occlusion in i, ii, and iii, and LCx occlusion in iv).

i. Hyperacute T wave, not very tall but approximating QRS height
+ shrinking QRS height, which further shrinks on subsequent ECGs or progresses to Q wave
+ beside getting shrunk, QRS is uplifted, so much that S is lifted above the baseline. This morphology of S lifting above the baseline with sharp J point (not J wave) in both leads V_3+V_4, called terminal QRS distortion, is not seen in early repolarization and suggests MI.

ii. deWinter hyperacute T waves with upsloping depressed ST segment.

iii. ECG showing many subtle STEMI features: subtle anterior ST elevation with shrinking QRS, especially in V_3; T wave about the size of QRS; S pulled above the baseline (terminal QRS distortion); and subtle inferior ST depression. On subsequent ECG, QRS further shrinks in V_2 and evolves to Q wave in V_3.

iv. Isolated ST depression in V_1–V_4 with upright T wave, and tall R wave in V_2, indicating posterior STEMI.

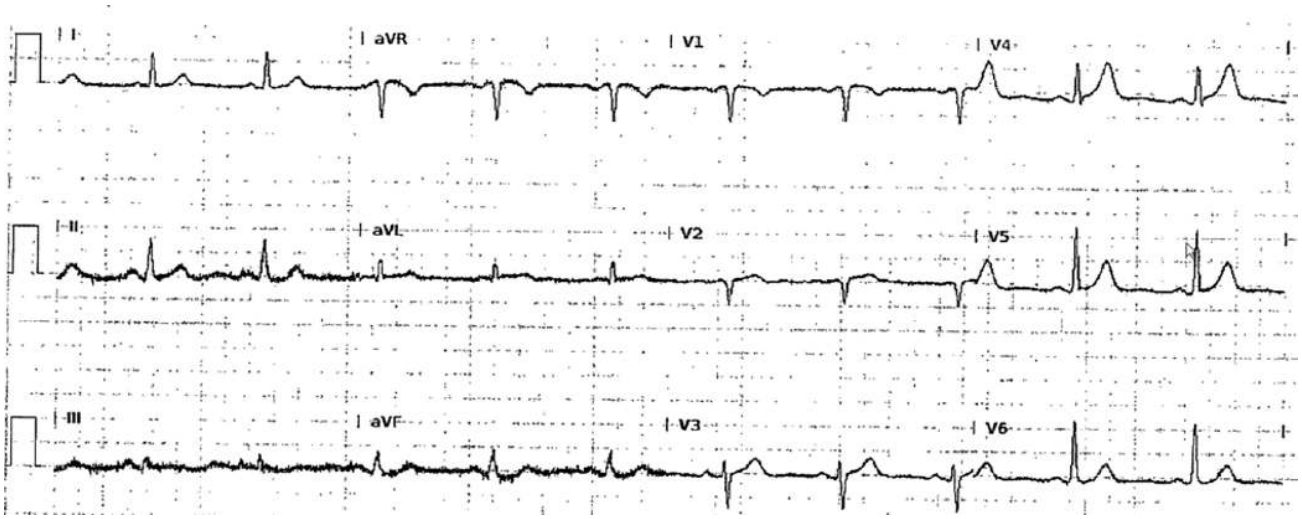

Figure 2.5 ECG of a 61-year-old woman presenting with chest pain and diaphoresis that started 1 hour previously. It shows septal Q waves in V_1–V_2, subtle ST depression in the inferior leads, subtle ST elevation in V_4–V_5 and in aVL, and wide T wave in V_4 that approximates the size of a shrinking QRS. Also, in V_4, S is pulled up above the baseline by the ST segment without J wave.

This ECG may be read as normal in an asymptomatic patient, but with her ongoing distress, the elevated troponin, and the constellation of subtle ECG findings, this indicates subtle STEMI. Indeed, coronary angiography showed a totally occluded proximal LAD. The LAD had grade 3 well-developed collaterals and was heavily calcified, indicating a degree of chronicity; the collaterals likely attenuated the severity of ST changes.

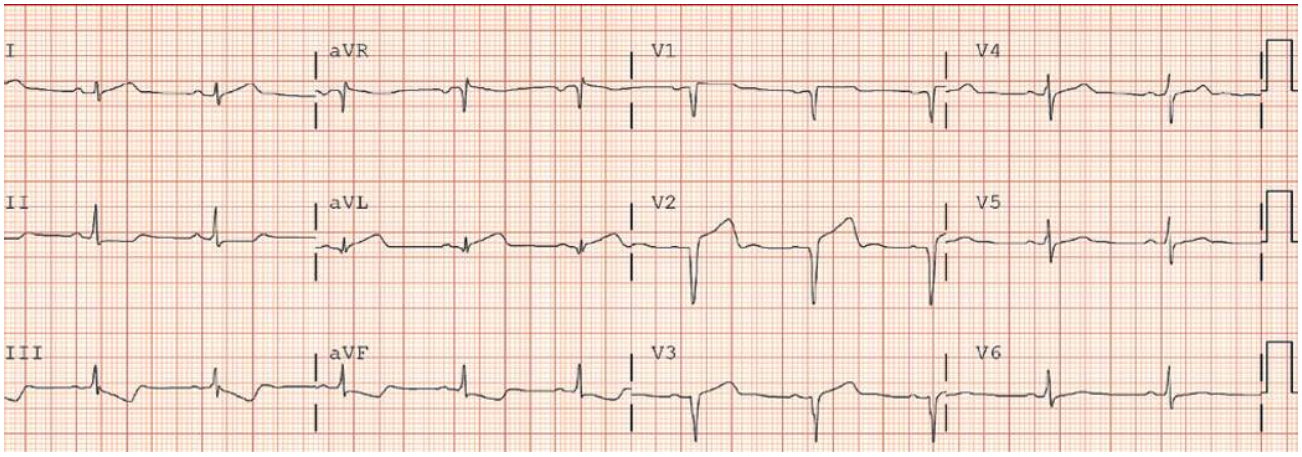

Figure 2.6 ECG of a 41-year-old female presenting after near syncope. Deep Q waves and mild residual ST elevation in V_1–V_3 may indicate either:
i. late presentation >24 hours or
ii. earlier presentation but spontaneous recanalization (+/– on top of pre-existing collaterals) insomuch that ST attenuates. This is a less likely scenario considering the depth of Q and the minimal or no residual R. Delays to coronary angiography are acceptable if presentation >24 hours *and* no ongoing chest pain.

2. Hyperacute large and wide T waves, almost the size of the QRS, especially if associated with a shrinking QRS, subtle ST elevation, or subtle reciprocal ST depression. T wave may not be tall, just wide and tall relatively to a shrinking QRS. One subtype, DeWinter hyperacute T waves, is characterized by upsloping ST depression in leads V_1 through V_6 followed by tall upright T waves; unlike the typical hyperacute T waves, they do not progress to ST elevation.
3. ST depression that is maximal in V_1–V_4 (indicates posterior occlusion MI).
4. LBBB or ventricular pacing with discordant ST elevation >25% of QRS height, or with concordant ST elevation.
Note: Diffuse ST depression >6 leads with *ST elevation in aVR* and V_1 suggests left main ischemia, particularly when aVR's ST elevation is >1.5 mm and >V_1, but may also be seen in any major demand-supply mismatch, such as profound shock or profound anemia: in one study, 40% of such ECGs purely reflected demand-supply mismatch with no CAD. This is *NOT a STEMI*, but if ST changes are deep AND persistent, it is treated as urgent NSTEMI.

Why is ST elevation mild in subtle STEMI? The top 2 explanations are:
1. Pre-existence of good collateral flow (occlusion on top of chronic severe disease) OR early spontaneous recanalization OR subtotal rather than total occlusion OR ischemic preconditioning (Figure 2.5). Hence in subtle STEMI studies, troponin does not often rise to classic STEMI levels and is closer to NSTEMI levels (albeit higher), and angiographic occlusion is less common than in classic STEMI (~30%).[18,19] Hence ***these patients are on the overlap between STEMI and NSTEMI and may benefit from late PCI >24 hours***.
2. Late STEMI presentation, in which case there are often deep Q waves with minimal residual R waves and relatively mild ST ↑ (Figure 2.6).

Other explanations include:
- MI area not well "seen" by ECG 12 leads, e.g., posterior or lateral MI.
- Small MI territory not well "seen" by ECG.
- Concomitant STEMI in 1 territory (e.g., inferior) and diffuse ST depression from NSTEMI of another territory that attenuates the focal ST elevation, as in the Aslanger pattern. But BEWARE that this pattern may also reflect severe LM or 3-vessel ischemia along with CTO of RCA or LCx: when LM is critically stenosed, the RCA territory, which is fed by collaterals from the LAD, suffers the most and gets so ischemic that it develops mild ST elevation in 1–2 leads. This is not primary RCA STEMI. In fact, at least half of Aslanger patterns do not have acute occlusion and 25% have CTO.[19] Careful analysis of the angiogram is necessary before PCI.

VI. Specific case of new or presumably new LBBB

Normally, LBBB is associated with ST-segment deviation that is discordant to QRS, i.e., directed opposite to QRS. If a patient has an ischemic presentation and LBBB on the ECG, one cannot tell whether ST elevation is purely secondary to LBBB, if an ischemic injury is partially contributing to the ST elevation, or if there is ischemic ST depression masked by the ST elevation. STEMI is definite if ST abnormality is concordant to QRS, but STEMI or non-ST elevation ischemia is still possible if ST changes are discordant to QRS. This would be the case of a patient with a true anterior injury in V_1–V_4 or inferior injury, where LBBB's QRS is negative and where ischemic ST elevation would inherently appear discordant. RBBB, on the other hand, is not associated with significant ST abnormality, and thus ST changes in a patient with RBBB are diagnostic of ischemia. Early thrombolytic trials and their meta-analysis have shown a striking benefit from thrombolytic therapy in patients with any bundle branch block, particularly that a new bundle branch block in STEMI indicates a high-risk STEMI.[20] Both types of bundle branch blocks, if secondary to STEMI, represent high-risk categories, but since *only LBBB poses a diagnostic challenge*, a new or presumably new LBBB has been considered a STEMI-equivalent in old ACC guidelines, in order not to miss a high-risk STEMI.

However, STEMI rarely causes left bundle branch infarction, because the left bundle is supplied by both the LAD and RCA and is only affected in extensive infarction. In the GUSTO-1 trial, only ~1% of STEMIs had LBBB on presentation. In fact, a **new LBBB often results from a chronic cardiomyopathy, ischemic or non-ischemic, with a dilated or hypertrophied myocardium, rather than an extensive acute infarction, and may be first diagnosed in the setting of HF presentation or uncontrolled HTN.**[21] A new LBBB may also be rate-related and may have been unveiled by an increase in heart rate.

Evidence has shown that only ~10% of patients with an ischemic presentation and a new LBBB have a STEMI-equivalent (acute coronary occlusion on angiography), and <40% have any MI, most commonly NSTEMI.[22–25] *STEMI is even far less likely when all comers with new LBBB, both atypical or typical presentations, are included (<5%).*[24] Therefore, in order to make the diagnosis of STEMI, an ischemic presentation is required (ongoing angina, flash pulmonary edema) along with additional ECG features (Chapter 32, Figures 32.54–56):

- Concordant ST-segment depression or elevation of ≥1 mm is >95% specific for the diagnosis of STEMI, but has a limited sensitivity of 20% (Sgarbossa's concordance). If present, STEMI diagnosis is definite, and emergent reperfusion with fibrinolytics or PCI should be achieved.
- Concordant negative T wave or biphasic T wave in multiple leads increases the likelihood of STEMI.
- Extreme discordance increases the likelihood of STEMI but has a reduced specificity: discordant ST elevation that exceeds 25% of the QRS height; or upright T wave that exceeds 50% of the QRS height. This discordance ratio is more sensitive and specific than an absolute ST discordance >5 mm, initially suggested by Sgarbossa, but may still be seen in 9% of control patients without MI.[26]

In the absence of these features, it is reasonable to urgently perform bedside echocardiography, keeping in mind that abnormal septal motion is universal with LBBB but the anterior and apical contraction is preserved; therefore, anterior and apical akinesis without severe thinning implies ischemia. Fibrinolytics are preferably avoided since many of these patients have NSTEMI rather than STEMI, and transfer for angiography is preferred even if delays are expected to exceed 120 minutes.[22] Global hypokinesis often implies ischemic or non-ischemic cardiomyopathy, such as hypertensive cardiomyopathy, rather than acute ischemia;[21] angiography may be needed eventually but is not urgent.

Thus, the 2013 STEMI guidelines state that **"new or presumably new LBBB should not be considered diagnostic of acute myocardial infarction (MI) in isolation."**[1] The 2020 ESC ACS guidelines state: **"hemodynamically stable patients presenting with chest pain and LBBB only have a slightly higher risk of having MI compared to patients without LBBB."**

VII. Reperfusion strategies: fibrinolytics, primary PCI, and combined fibrinolytics–PCI

A. Fibrinolytics (also called thrombolytics): mortality benefit

In the GISSI-1 and ISIS-2 trials and a large meta-analysis, fibrinolytics (mainly streptokinase) have shown:[20, 27–29]

- A striking 6.5% absolute mortality reduction and 50% relative mortality reduction in the first hour after STEMI onset, called the golden hour
- A 4% absolute mortality reduction in the second hour
- A plateau 3% mortality reduction between 3 and 6 hours (relative mortality reduction ~25%)
- Absolute mortality reduction of ~2% between 6 and 12 hours. Beyond that, between 12 and 24 hours, the benefit is marginal and questionable.

This time-dependent benefit is due to the fact that very early reperfusion of the occluded coronary artery may lead to full recovery of the ischemic tissue and thus prevent necrosis. In addition, fibrinolytic therapy in the first 2–3 hours is highly efficacious in lysing a fresh thrombus.

The benefit is more striking in high-risk subgroups, such as anterior STEMI, STEMI with bundle branch block, or high STEMI risk score (tachycardia, hypotension). *The elderly subgroup is the only high-risk subgroup that, paradoxically, only derives a marginal benefit from fibrinolysis;* this is partly because of the high bleeding risk but also because of the more extensive CAD that makes it less likely for fibrinolysis to re-establish perfusion; a half-dose of TNK is recommended in patients ≥75 (ESC class IIa).

The mortality benefit is also more striking with the fibrin-specific fibrinolytics (~1% additional mortality reduction).

B. Fibrinolytics: limitations, contraindications, definition of successful response, and definition of TIMI flow (Table 2.1)[1,20,30,31]

In addition to the classic contraindications, fibrinolysis is contraindicated in a patient with an expected intracranial bleeding risk of >4% (e.g., an elderly [>75] small woman with HTN).[30]

Consider fibrinolytic therapy successful if: chest pain resolves *and* initial ST-segment elevation decreases by ≥50% (preferably 70%) in the anterior leads, and ≥70% in the inferior leads at 60–90 minutes after therapy initiation. % ST resolution is measured either in the lead with maximal baseline ST elevation or as a sum of ST deviation (elevation + depression) across all leads (ACC).[1] Also, the occurrence of an accelerated idioventricular rhythm (AIVR) *in conjunction* with the preceding features is highly specific for reperfusion. In the absence of a response (persistent ischemic symptoms, ST elevation, or both), plan for emergent *rescue PCI*. It is best to start transferring the patient to a PCI-capable hospital as soon as fibrinolytic therapy is started, so that, if no response is seen at 60 minutes, cardiac catheterization is readily available.

A successful fibrinolysis correlates with TIMI 3 flow on coronary angiography. *TIMI grade 0 flow* implies the absence of any flow. *TIMI 1* flow implies the presence of some flow beyond the obstruction but without full distal perfusion. *TIMI 2* flow means that the vessel is fully perfused but the flow is slow compared with a normal artery and/or the contrast material clears more slowly than in a normal artery; TIMI 2 flow is related to a residual mechanical obstruction or to microvascular obstruction from microvascular emboli. *TIMI 3* flow means full perfusion of the vessel with normal flow. In fibrinolytic trials, TIMI 3 flow has been shown to be associated with the lowest mortality. TIMI 2 flow is associated with an intermediate mortality, while TIMI 0–1 flow is associated with the highest mortality.[32,33] The outcome is improved in patients whose TIMI 2 flow eventually improves to TIMI 3 flow within a few days (this happens two-thirds of the time).[34] In a patent artery, TIMI 2 and 3 flow patterns are associated with divergent outcomes and should not be grouped together.

Following PCI and in the absence of any residual mechanical obstruction, the flow may still be TIMI 0–2 flow because of microvascular embolization, spasm, or edema; this is called *no reflow*, i.e., TIMI 0–2 flow without any residual epicardial stenosis. *The term "no reflow" is used only with PCI, not with fibrinolysis*.

Table 2.1 Limitations and contraindications of fibrinolysis.

Limitations

- Patency of the infarct-related artery (TIMI 2 or 3 flow) is achieved in ~70–75%, likely >90% the first hour. TIMI 3 flow is achieved in 55–60%[a]
- Intracranial hemorrhage: 0.5–1.5%
- Major bleeding: ~5%
- Early recurrent ischemia or MI: 10–20% (within hours or days)

Most important absolute contraindications

- Any prior intracranial hemorrhage
- Ischemic stroke <3 months. Ischemic stroke >3 months is a relative contraindication
- Severe acute hypertension unresponsive to acute therapy
- Active bleeding (except menses)
- Cranial or spinal surgery <2 months
- Closed head or facial trauma <1 month, even without a documented bleed (e.g., recent fall with head trauma)

Most important relative contraindications

- Ischemic stroke >3 months
- Severe acute HTN (SBP >180 or DBP >110) responsive to acute therapy
- Chronic severe hypertension
- Recent major surgery or internal bleed <2–4 weeks. Proliferative retinopathy is not a contraindication
- Oral anticoagulant therapy, including warfarin with INR >2 (strong relative contraindication)

[a] Full patency with <50% residual disease is achieved in only 15–20%.

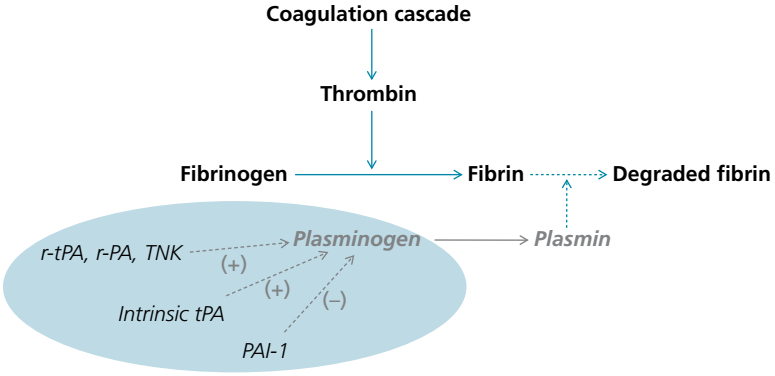

Figure 2.7 Fibrinolysis cascade and mechanism of action of fibrinolytics. Fibrinolytics activate plasminogen into plasmin, which degrades fibrin. PAI-1, plasminogen activator inhibitor (~ tPA inhibitor); r-PA, reteplase; r-tPA, alteplase; TNK, tenecteplase; tPA, tissue plasminogen activator.

C. Fibrinolytics: various agents

Fibrinolytics bind to the clot-bound plasminogen and convert it to plasmin, which promotes the degradation of fibrin (Figure 2.7). The old fibrinolytic *streptokinase* also binds to free plasminogen; thus, in addition to lysing fibrin, it depletes systemic, free fibrinogen and affects systemic coagulation for 12–24 hours.

Alteplase (recombinant tissue plasminogen activator [r-tPA]) binds to the plasminogen entrapped in a thrombus and thus mainly degrades fibrin of a thrombus, rather than systemic fibrinogen (fibrin-specific fibrinolytic). Being more concentrated at the thrombus level, it is a more effective lytic than streptokinase. It generally does not affect the systemic fibrinogen and has a short half-life of only 6 minutes; thus, after the infusion is discontinued and the drug eliminated (~30 minutes), there is no significant residual effect on systemic coagulation. Therefore, the performance of PCI soon after r-tPA administration is not necessarily associated with a significant increase in bleeding. On the other hand, this short half-life and the lack of residual effect on the systemic coagulation explain the high risk of recurrent thrombosis and the need to *start heparin infusion immediately* at the end of r-tPA infusion in MI.

In the GUSTO trial of r-tPA vs. streptokinase, r-tPA further reduced mortality by 1% and reduced major bleeding in general, but increased intracranial hemorrhage by 0.25% in comparison with streptokinase.[31]

Reteplase (r-PA) is a mutation variant of r-tPA. It is slightly less fibrin-specific than r-tPA and has a longer half-life (~15 minutes), allowing its administration in two boluses rather than an infusion. It has the same mortality benefit and bleeding risk as r-tPA.

Tenecteplase (TNK) is also a mutation variant of r-tPA that is 14 times more fibrin-specific than r-tPA and less likely to be degraded by tPA inhibitors. Thus, TNK is slightly more effective, which explains the higher TIMI 3 flow rate achieved with TNK vs. r-tPA (~65% vs. 60%). It also has a longer half-life than r-tPA, with a duration of effect of ~120 minutes. In the ASSENT-2 trial, TNK was associated with the same overall mortality as r-tPA, but a reduction in major non-cerebral bleeding and a reduction in mortality of patients presenting >4 hours after symptom onset.[35]

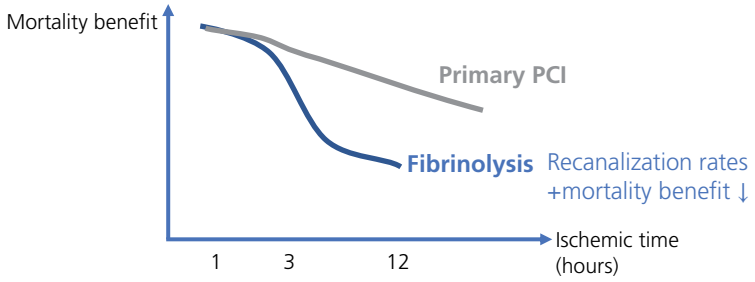

Figure 2.8 The benefit from fibrinolytic therapy strikingly drops beyond 3 hours of ischemic time, whereas PCI has a less pronounced drop in benefit. The superiority of PCI over fibrinolysis widens as the presentation is more delayed >3 hours. Long DTB >120 minutes may not compromise the equipoise with fibrinolytics beyond 3 hours of pain onset.

D. Primary PCI is superior to fibrinolytic therapy; importance of time of presentation, door-to-balloon time, and PCI delay

In comparison with fibrinolytic therapy, primary PCI is more effective in re-establishing TIMI 3 flow (95%), and thus reduces 30-day mortality by 2% (7% vs. 9%), recurrent MI by 4% (3% vs. 7%), and stroke by 1%.[36–38] However, this superiority of PCI depends on a DTB <120 minutes and PCI-related delay <60 minutes (delay between the expected time of fibrinolytic therapy and the expected time of balloon inflation). In fact, ***the "90-minute" and "120-minute" cutoffs of DTB have been established in terms of PCI delays beyond which PCI loses its advantage over fibrinolysis (120-minute DTB corresponds to equipoise between PCI and fibrinolysis)*.**

DTB is particularly important if the patient presents early, <3 hours after symptom onset, *or* if the patient is high-risk (anterior MI, tachycardia, SBP <100 mmHg, Killip class ≥II, age ≥65), as those patients derive the greatest benefit from fibrinolytics and are most harmed by reperfusion delays. In CAPTIM, PRAGUE-2, and the modern STREAM trial, fibrinolytic therapy resulted in the same mortality reduction as primary PCI in patients presenting <2–3 hours after symptom onset (granted that rescue PCI is done if needed, and routine early PCI <24 hours is carried in all patients, as in STREAM).[39–41] Conversely, *in low-risk patients presenting late*, DTB is less important and, in a large MI registry, PCI-related delays of 100 minutes did not negate the survival advantage of primary PCI over fibrinolytic therapy in those patients.[42] In fact**, the superiority of PCI over fibrinolysis widens as the presentation is more delayed; while the benefit from fibrinolysis strikingly drops beyond 3 hours, PCI has a less pronounced drop in benefit (Figure 2.8)**.[43] In two retrospective analyses that only assessed PCI patients, DTB >90–120 minutes did not impair outcomes vs. DTB <120 minutes in patients presenting late, >3 hours, especially if they are low risk.[44,45] Yet in all patients, systems should strive for as small a DTB as possible.

In high-risk patients presenting early, any DTB delay, even within the 90-minute window, is associated with increased mortality compared to a shorter DTB (mortality difference of 0.5–1% for every 30-minute DTB delay, e.g., between DTB of 30 minutes and 60 minutes).[46] ***This is the rationale behind the ESC recommendations, which go beyond DTB <90 minutes. ESC recommends a STEMI diagnosis-to-wire crossing time <60 minutes in patients self-presenting to PCI centers and <90 minutes in patients transported by paramedics or from non-PCI centers*.** While this is valuable in early presenters with definite STEMI, keep in mind that aggressive reduction of DTB in all comers on a system level has not been consistently associated with improvement of outcomes,[44,45,47,48] particularly in registries comparing the modern DTB era with a previous era of longer DTB. Overzealous reduction of DTB should not preclude proper clinical and ECG assessment and should not lead to a rushed procedure in a patient whose clinical and ECG picture is not definite for STEMI.

Elderly patients (age >75) – In fibrinolytic trials, the benefit from fibrinolytic therapy was much less striking in the elderly than in the young.[20,49] Conversely, primary PCI remains effective in the elderly, with more absolute mortality reduction in the elderly than in young patients. This makes fibrinolytic therapy, whether standalone or combined with PCI, a less attractive alternative to primary PCI in the elderly. Studies of combined fibrinolytic therapy and PCI included very few patients over the age 75.[50] In the modern STREAM trial of fibrinolysis vs. PCI, the dose of TNK was reduced by 50% in the elderly midway through the trial, which attenuated intracranial hemorrhage without reducing TNK efficacy.[51] Hence, ESC guidelines suggest a half-dose of TNK in the elderly ≥75 (class IIa).[2]

E. Combination of PCI and fibrinolytic therapy

Three different combinations of PCI and fibrinolytics have been studied in STEMI (Figure 2.9):[50]

- **Facilitated PCI** is a strategy of emergent PCI with a planned door-to-balloon time of <120 minutes. Fibrinolytic therapy is administered "on the way" to a timely PCI.[52,53]
- **Pharmacoinvasive therapy** means that fibrinolytic therapy is administered at a non-PCI facility, then the patient is promptly and systematically transferred to a PCI facility, where PCI is performed 2–24 hours after the start of fibrinolytic therapy, regardless of whether fibrinolysis results in successful reperfusion. Thus, the time to PCI is longer than with facilitated PCI. *Facilitated PCI addresses patients primarily treated with a timely PCI*, and looks at the value of pre-treatment with fibrinolytics or glycoprotein IIb/IIIa inhibitors (GPI), whereas *pharmacoinvasive therapy addresses patients who are primarily treated with fibrinolytics*, as they cannot undergo a timely PCI, and looks at the value of routine early PCI after fibrinolysis.[54–56]
- **Rescue PCI** refers to PCI that is performed urgently *if* fibrinolysis fails, failure being defined as persistent hemodynamic or electrical instability, persistent ischemic symptoms, or failure to achieve at least a 50–70% resolution of the maximal ST-segment elevation 90 minutes after fibrinolysis is started.[57] Approximately 35% of patients treated with fibrinolysis require rescue PCI.[40,54,55]

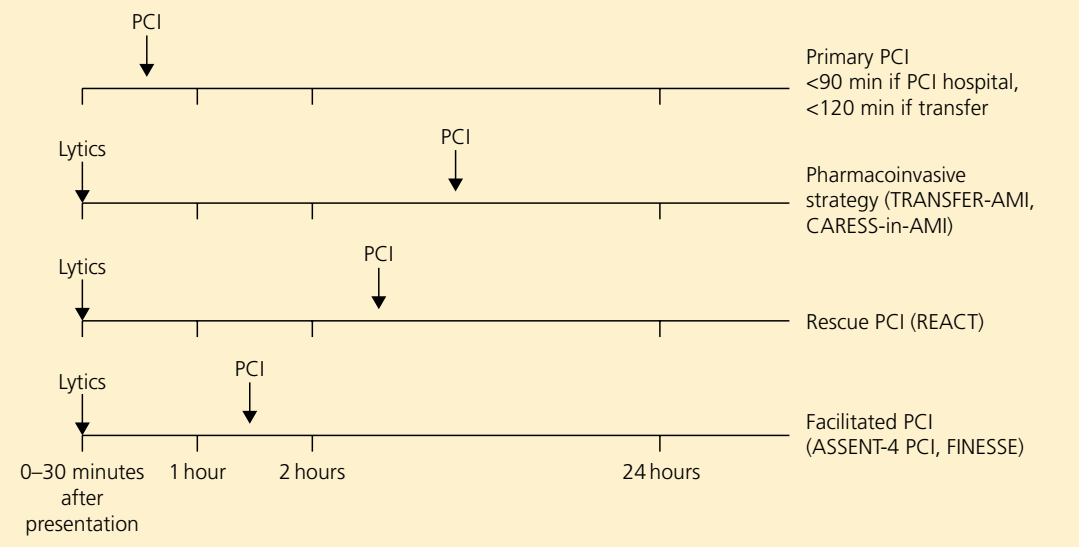

Figure 2.9 The timing of PCI in relation to thrombolysis in the pharmacoinvasive strategy, rescue PCI strategy, and facilitated PCI strategy, with the clinical trials that addressed and defined these strategies.

Facilitated PCI has been associated with worse outcomes than primary PCI, probably because the administration of fibrinolytics before a timely PCI cannot offer any ischemic advantage yet increases the bleeding risk. Also, fibrinoytics expose clot-bound thrombin, a potent platelet activator, which heightens platelet activation and aggregation. PCI facilitated with fibrinolytics is associated with increased mortality, ischemic complications, HF, and bleeding (ASSENT-4 trial). Even PCI facilitation with a brief upstream GPI therapy leads to increased bleeding without any ischemic benefit (FINESSE trial).[52,53] Conversely, *pharmacoinvasive therapy*, also called *routine early PCI* 2–24 hours after fibrinolytics, has been shown to improve outcomes, mainly recurrent MI and recurrent ischemia in high-risk STEMI, without increasing the bleeding risk (despite the use of femoral access in the trials). Patients who achieve successful reperfusion with fibrinolytics are actually left with severe residual disease of the culprit artery in ~85% of the cases, and benefit from early PCI. However, there is no evidence of PCI benefit in patients with <50% residual stenosis (as per the protocol of primary PCI trials and pharmacoinvasive trials).

F. Putting it all together: management of patients presenting to non-PCI-capable hospitals

1. If there is a pre-established transfer system with a predicted DTB <120 minutes, a transfer for primary PCI is the best strategy and is superior to fibrinolysis (DANAMI-2 and PRAGUE trials).[37] This usually implies a distance <60 miles, often with a helicopter transfer, a door-in door-out time <30 minutes, direct activation of the outside PCI team through a central pager, and direct transfer to the outside cath lab.[58]

2. When DTB is expected to be >120 minutes, administer primary fibrinolytic therapy and immediately transfer the patient to allow the performance of *routine early PCI* 2–24 hours later, or to allow immediate rescue PCI if no response to fibrinolysis. Several registries suggest that timely fibrinolysis followed by semiurgent transfer for PCI offers a benefit similar to that seen in patients presenting to a PCI hospital and undergoing a timely primary PCI.[58,59]

Besides fibrinolytics, the patient should receive aspirin, heparin bolus and infusion, and 300 mg of clopidogrel. Prasugrel, ticagrelor, or 600 mg of clopidogrel have not been studied as an immediate adjunct to fibrinolytic therapy. Subcutaneous enoxaparin is not appropriate in patients undergoing early PCI. Glycoprotein IIb/IIa inhibitors may be used during PCI (rather than upstream of PCI).[54]

3. When DTB is expected to be >120 minutes but the patient is presenting >3 hours after symptom onset and has a non-anterior MI with low-risk clinical features (Killip class I, heart rate <100 bpm, SBP >100 mmHg), a transfer for primary PCI without preceding fibrinolytic therapy may be reasonable in individual cases, although not clearly expressed in the guidelines.

A combination of 2 of the following 3 features favors transfer for primary PCI without preceding fibrinolytic therapy: presentation >3 hours, non-anterior low-risk MI, and age >75 years.

4. Subtle STEMI with true but mild ST elevation <1 mm favors transfer without fibrinolysis: it often implies some flow to the infarcted territory (recanalization or collaterals), or delayed presentation.

5. If fibrinolytic therapy is contraindicated, immediately transfer for primary PCI regardless of the expected DTB.

6. For cardiogenic shock or acute severe HF (Killip class III or IV), administer fibrinolytic therapy if DTB is expected to be >120 minutes, and immediately transfer for PCI.

7. In patients presenting early, prehospital fibrinolytic therapy delivered by paramedics and followed by early transfer to a PCI facility has been associated with further reduction in mortality compared with in-hospital fibrinolytic therapy according to a meta-analysis of randomized trials and a mortality comparable to that of primary PCI (STREAM, CAPTIM trial).[40,60] This is the preferred strategy in patients unable to undergo timely PCI, in regions where such a system can be implemented, as per ESC guidelines.[59]

To prevent the dilemma of non-PCI hospitals, emergency medical systems are encouraged to triage STEMI patients to a PCI center and to bypass non-PCI hospitals, even if a non-PCI hospital is closer (class I ACC and ESC guidelines). In a statewide registry, bypassing a closer non-PCI hospital in favor of a PCI hospital led to an additional 16-minute drive, yet was associated with significant reduction of time to reperfusion (31 minutes) and lower mortality. In fact, only 35% of patients brought to non-PCI hospitals received fibrinolytics; the majority were transferred for primary PCI, resulting in much longer time to reperfusion.[61] Nonetheless, to meet the DTB guidelines, the drive to the PCI hospital should not exceed 45–60 minutes.

Also, consider bypassing the emergency department and taking the patient directly to the catheterization laboratory when the diagnosis is certain, as this results in a 20-minute or a third reduction of DTB.[62]

VIII. Late presenters: coronary angiography and PCI later than 24 hours after presentation

In the OAT trial, patients with MI older than 24 hours (1–28 days old specifically, mainly STEMI/Q-wave MI) who were selected based on the following features did not benefit from PCI and had a trend toward more frequent reinfarctions:[63–65]

- Totally occluded infarct-related artery (TIMI 0 or 1 flow)
- Akinetic or dyskinetic infarcted wall
- One- or two-vessel CAD
- No recurrent rest or low-threshold angina
- No severe ischemia on stress test. Stress test was only done in patients whose infarct zone was not akinetic (27% of the total cohort)
- No shock and no persistent functional class III–IV HF

Further analysis showed that PCI was not beneficial even among patients enrolled 1–3 days after MI onset.[66] Thus, late PCI of an occluded infarct artery is only indicated in patients with persistent ischemic symptoms, massive HF/shock, or severe ischemia on stress testing.

On the other hand, data suggest that an infarct artery *that is not totally occluded* (TIMI 2–3 flow) may benefit from late revascularization (>24 hours) to the same extent that it may benefit from early revascularization, as a patent infarct artery with good collaterals is associated with a more limited MI size and a significant amount of viable myocardium that can be salvaged with revascularization.[7,8,67] Approximately 40% of totally occluded infarct-related arteries spontaneously recanalize in the first 24 hours and may qualify for late revascularization.

Therefore, patients who did not receive emergent reperfusion (late presenters >24 hours) or patients who received fibrinolytics, with or without response, but did not undergo angiography in the first 24 hours after symptom onset should, preferably, still undergo angiography even later than 24 hours (ESC):

- A non-occluded infarct-related artery may be treated with PCI (class IIb).
- Left main disease or three-vessel CAD that *largely* extends beyond the occluded artery should receive revascularization, typically surgical revascularization, after a post-MI waiting period of at least 3–7 days.
- A totally occluded artery should not be treated with PCI unless the patient has a low-threshold angina or severe ischemia on stress testing (class I). Stress test may be performed *if the infarct wall is not akinetic*, as per OAT trial, and the patient may be brought back for PCI once severe ischemia is documented.
- If one is unsure that the MI is >24 hours old, PCI may still be performed. While not beneficial, late PCI in the OAT trial was not significantly harmful either, which may justify its use when timing is unclear. Note that ESC uses 48 hours cutoff for avoidance of routine PCI based on BRAVE-2 trial.

Table 2.2 summarizes the PCI timelines. Questions 2, 9,10, and 14 at the end of this chapter illustrate these concepts.

As an alternative to coronary angiography, patients who have not been managed invasively in the first 24 hours of STEMI, and who are stable without angina, may ***undergo stress testing rather than angiography***, although this is an uncommon practice that is no longer discussed in the 2025 ACC guidelines and is only briefly mentioned in the ESC guidelines. In those stable patients, a submaximal stress test (modified Bruce protocol) may be performed 4 days after STEMI onset, and a maximal stress test (symptom-limited Bruce protocol) may be performed 5–14 days later. Severe ischemia or angina on stress testing dictates coronary angiography and revascularization. If no significant residual ischemia is detected, only medical therapy is provided. Severe ischemia is defined by OAT as extensive ST depressions ≥2 mm, or quick-onset chest pain at <3–4 METs, or large area of reversibility involving ≥20% of the LV within or around the infarct.[63–65]

As opposed to NSTEMI, where stress testing is avoided even in patients who become free of angina, stress testing may be performed in stable post-STEMI patients free of angina. In NSTEMI, the amount of myocardial necrosis is usually minor and revascularization is needed to salvage a large area of ischemic but non-infarcted myocardium. In non-reperfused STEMI, the myocardium is already largely infarcted and unlikely to benefit from revascularization, unless residual angina or ischemia is shown.

Table 2.2 Revascularization timelines in STEMI.

<12 hr after STEMI onset: Emergent primary PCI or fibrinolytic therapy (class I, level of evidence A)
12–24 hr: Emergent primary PCI (class IIa). ESC uses 48-hr cutoff
>24 hr: Delayed, non-urgent PCI for: (i) recurrent angina, (ii) severe ischemia on stress testing (class I).
>24 hr: Delayed, non-urgent *coronary angiography*, even if patient is asymptomatic at this point (as per ESC), but do not open an occluded artery >24–48 hr.

After fibrinolytic therapy
- Delayed routine PCI 2–24 hr later (class I ACC and ESC)
- Rescue PCI for fibrinolytic failure (class I)

If PCI was not performed in the first 24 hr, coronary angiography is still recommended at >24 hr, even without persistent pain. This applies whether the patient received fibrinolytic therapy or not. Stress testing is an alternative to coronary angiography. Coronary angiography and late revascularization have the following recommendations:
- Coronary angiography >24 hr after STEMI onset: class IIa
- PCI of a stenotic but not totally occluded artery: class IIb
- Avoid PCI of a totally occluded artery >24 hr (OAT trial, class III), except in cases of *recurrent angina, high-risk stress test, or uncertain timing*. ESC uses 48-hr cutoff
- CABG if left main or 3-vessel CAD extending *largely* beyond the infarct artery

Cardiogenic shock *or* acute severe HF (massive pulmonary edema = Killip III): emergent PCI regardless of time (class I)

Ischemia and viability are 2 different entities, ischemia being the one most definitely improved with revascularization (SWISSI-2 trial). *Viability* implies that at rest, the infarcted territory can uptake significant nuclear agent. Conversely, *ischemia* implies that at stress, the nuclear defect in the infarcted or peri-infarct territory is markedly more intense and more extensive than at rest; or significant/extensive ST-segment depressions ≥2 mm or early chest pain occur. **A territory may be partially viable but non-ischemic,** meaning it is already receiving enough perfusion, in which case the benefit of revascularization is less clear. In a substudy of OAT patients who received viability testing, viability did not predict a benefit from late PCI.[68] Conversely, in the SWISSI-2 trial, asymptomatic patients who had a STEMI or a NSTEMI within the preceding 3 months, documented ischemia on stress testing, and 1- or 2-vessel CAD derived a 70% reduction of cardiovascular events, including cardiac death, with PCI.[69]

The OAT trial does not apply to a coronary chronic total occlusion (CTO) that has not led to a large transmural infarct, in which case the myocardial contractility is fairly preserved because of the collateral network. A progressive occlusion that allows for an adequate collateral network to develop may not present as MI. It typically presents as chronic angina or a small NSTEMI, not STEMI. Opening a CTO has a beneficial effect on symptoms and, possibly, LV function.

How to recognize late presenters in STEMI or Q-wave MI

Persistent ST elevation does not necessarily signify that the infarct is acute, <24 hours; in fact, ST elevation commonly persists several days, as per OAT trial (in OAT, 68% of patients still had ST elevation several days after STEMI, at a median of 8 days). On the other hand, Q waves do not signify that the infarct is too late and are not synonymous with irreversible myocardial damage; Qs may reflect stunning and significant myocardial salvage is achieved in the majority of Q-wave patients. However, **deep Q waves with minimal residual R waves and relatively mild ST elevation in *several leads* suggest MI older than 12–24 hours, especially in the absence of ongoing pain** (Figure 2.2).

Incorporate the patient's pain description with the ECG and account for the following 3 features to call STEMI/Q-wave MI late:

1. ECG pattern of deep Q waves with minimal residual R and relatively mild ST ↑
2. Patient description of pain onset >24 hours
3. No ongoing significant chest pain and distress. Mild lingering "bruising" discomfort may be seen after an infarct and does not always equate with ongoing angina. Mainly account for persistent significant distress.

If all 3 features are present → STEMI/Q-wave MI is late. PCI is not indicated if the culprit artery is occluded, even if ST ↑ persists (OAT). Coronary angiography is still warranted for late STEMI: (i) PCI is performed if culprit artery is not totally occluded, (ii) PCI or CABG may be performed for extensive multivessel disease outside the occluded artery.

If 2 of the 3 features are present → STEMI/Q-wave MI is possibly late. Ongoing significant pain is the one that pushes for PCI regardless of the other 2. If the patient has no ongoing pain and pain onset was >24 hours ago, MI is likely late STEMI even if ECG has no Q waves, as long as there is evidence of some ST elevation to call the infarct STEMI; in fact, 33% of late patients in OAT trial did not have Q waves. Deep "bad" Q waves are concerning, but the lack of Q waves is not always reassuring (Figure 2.12 of Section 2.II). *Those time delays do not apply to NSTEMI, which benefits from revascularization even several days or weeks later*.

IX. Angiographic findings, PCI, and cellular reperfusion; multivessel disease in STEMI

A. PCI: microvascular and cellular reperfusion

Approximately 25–30% of occluded arteries acutely recanalize before the PCI procedure, in the first 4 hours, and achieve TIMI 2 or 3 flow (from spontaneous or antithrombotic-induced lysis).[6,70,71] This STEMI is called "transient STEMI" if ST elevation spontaneously resolves, and may also be called "aborted STEMI" if cardiac biomarkers only rise minimally (CK-MB <2× normal).[15] Residual stenosis usually persists.[6,70,71]

During PCI, the lesion is dilated with balloon angioplasty then stented. In comparison with standalone balloon angioplasty, stenting reduces the early risk of reocclusion/reinfarction by 50% (to <2%) and the late risk of restenosis, without affecting mortality.[70] Drug-eluting stents are used, as they do not increase late stent thrombosis and significantly reduce restenosis.[71] A routine initial use of aspiration thrombectomy has not shown superiority to balloon angioplasty in 2 large trials.[72]

Following primary PCI, ~95% of patients achieve TIMI 3 flow, while 5% achieve TIMI 0–2 flow despite wide macrovascular patency, also called "no reflow." *The term "no reflow" implies poor microvascular flow and is only used after treating all significant epicardial stenoses*. TIMI flow <3 is a predictor of poor outcomes, but TIMI 3 flow does not necessarily imply appropriate microvascular flow. In fact, only ~60% of patients with TIMI 3 flow achieve significant ST-segment resolution (= cellular reperfusion), and only 70% achieve appropriate myocardial blush (= microvascular reperfusion).[72,73] "Appropriate myocardial blush," also called "myocardial blush grade 2 or 3," is used to describe brisk contrast staining of the myocardium followed by contrast clearance and no residual myocardial stain by the next injection. Impaired coronary flow, impaired myocardial blush, or the lack of ST resolution implies: (i) distal microembolization, (ii) microvascular spasm, or (iii) myocyte injury and swelling from ischemia or reperfusion injury, especially late reperfusion, sometimes irreversible. The best long-term outcomes (survival and LV function) are seen in patients with ST-segment resolution and good myocardial blush, while intermediate outcomes are seen in patients with discordant findings.[74]

Persistent ST elevation after successful primary or rescue PCI implies microvascular obstruction or cellular injury, and thus worse long-term prognosis. The patient may have mild persistent chest pain. Unlike persistent ST elevation after thrombolysis, persistent ST elevation after a successful PCI does not dictate any further procedure, unless the patient has severe residual pain or angiographic no reflow.

Patients with no reflow are treated with (i) intracoronary vasodilators, (ii) GPI, or (iii) IABP. After treatment of the epicardial stenosis, IABP improves coronary microvascular flow and relieves ongoing ischemia.

When angiography is performed in patients who have been successfully reperfused with fibrinolytics, data from the pharmacoinvasive trials suggests that ~15–20% of the infarct-related arteries have a residual stenosis <50% that does not require PCI.[40,53,75,76] While most plaques that lead to MI are <50% at baseline, fibrinolytics often partially dissolve the thrombus, not fully, hence the frequent residual obstruction.

B. Multivessel disease in STEMI

Approximately 50–60% of patients presenting with STEMI have multivessel CAD, and up to 40% have multiple complex plaques.[55,70,77]

Stable patients without any degree of HF (Killip class 1) may safely undergo non-culprit PCI acutely, while cardiogenic shock patients with a clear culprit artery have a dramatic 8% absolute increase in mortality if non-culprit PCI is performed acutely (CULPRIT-SHOCK trial, STEMI or NSTEMI).[78] Non-culprit PCI increases procedural time and contrast load, leading to more LV volume overload and renal injury and is hazardous in the hemodynamically compromised patient. Also, non-culprit PCI may induce peri-PCI myocardial injury, distal embolization or side branch compromise, unlikely to be tolerated in the tenuous patient.

Outside cardiogenic shock, complete revascularization of non-culprit arteries with stenoses >70%, regardless of the presence of residual symptoms or ischemia, was beneficial and reduced the 3-year risk of future MI, mainly NSTEMI, in comparison to culprit-only PCI, according to the large COMPLETE trial (5.4% vs. 7.9%); of note, mortality was not reduced. Non-culprit PCI was performed during a procedure separate from culprit PCI, within the same hospitalization or up to 45 days after discharge.[79] Another trial, FIRE, showed that in elderly patients >75 years with STEMI (35%) or NSTEMI, PCI of non-culprit artery stenoses >50%, guided by FFR or iFR, in the same initial procedure (~2/3) or before discharge, reduces MI and even death at 1-year follow-up (9.2% vs. 12.8%). *PCI is preferably guided by angiographic severity >70% (COMPLETE trial, ESC guidelines); alternatively, iFR or FFR may be used for a stenosis of 50–70% (FIRE)*.

What is the timing of non-culprit PCI? Based on combination of data from OPTION-STEMI and BIOVASC trials, it seems best, in the case of STEMI, to *perform non-culprit PCI in a staged separate procedure few days later, before hospital discharge*. Immediate non-culprit PCI (in the same setting as primary PCI) may be considered if the lesion(s) is simple and quick, renal function is preserved, the contrast load is <220 ml, and the patient is not too sick to tolerate it. In OPTION-STEMI, the immediate performance of non-culprit PCI was associated with more cardiogenic shock and numerically more deaths than staged PCI performed few days later; this was driven by the ~33% of patients who had acute HF with Killip class 2 or 3 and who were significantly harmed by immediate PCI, as those patients do not tolerate any unnecessary additional procedural or ischemic time.[80] On the other hand, in the BIOVASC trial, immediate non-culprit PCI was as safe as staged PCI <6 weeks later (~15 days) and was associated with numerically less recurrent MI.[81] While OPTION-STEMI highlighted the risks of immediate non-culprit PCI, especially in HF, BIOVASC and MULTISTARS-AMI demonstrated that long delays to staged PCI increase interim non-culprit MI.

CABG is rarely required acutely in STEMI (~0.2–1%). If staged CABG is judged necessary for full revascularization of non-culprit arteries after culprit PCI, it is preferred to wait at least 24 hours, and preferably 3–7 days. CABG mortality is increased in the first 3 days after a large MI.[82] In patients who developed RV infarct and were not successfully reperfused in the first 6 hours, it is better to delay CABG 4 weeks to let the RV heal (otherwise, there may be severe, intractable RV dilatation upon opening the pericardium during CABG). In a patient with left main or 3-vessel disease and RCA-related MI, consider the following 3 scenarios:

- If left CAD is not critical, the RCA is stented and CABG performed 1 month later.
- If left CAD is critical (e.g., >80% left main stenosis), one may recanalize the RCA with balloon angioplasty +/– IIb/IIIa antagonist or cangrelor and perform CABG sooner, 1–7 days later.
- If left CAD is critical but RCA stent is needed (poor angioplasty result), IV cangrelor may be used and CABG performed a few days later. Expect the fresh RCA stent to thrombose during or after CABG, because of hypotension and P2Y12 blockade interruption, hence SVG-RCA is needed during CABG.

X. Antithrombotic therapies in STEMI

A. Antithrombotic therapies in conjunction with primary PCI

1. ***Aspirin*** 325 mg upon presentation.
2. ***ADP-receptor antagonist*** is loaded at the time of PCI, or in the emergency room before catheterization if STEMI diagnosis is certain.[83] Even prasugrel may be loaded before catheterization in STEMI. Yet, ATLANTIC trial failed to show a benefit of pre-cath loading (with ticagrelor) vs. loading during PCI.[84]
   Ticagrelor and *prasugrel* are preferred as they further reduce ischemic events compared to *clopidogrel*, particularly in STEMI.
3. ***Upstream unfractionated heparin*** (UFH) in the ED (60 units/kg, up to a maximum dose of 4000 units). Upstream UFH increases the likelihood of partial recanalization before PCI (~23% vs. 17%) and may reduce HF and coronary events at 30 days (HELP-PCI trial).[85]
4. ***During PCI:***
   - ***UFH***. IV enoxaparin is less favored but may be used (class IIb, ATOLL trial, 0.5–0.75 mg/Kg IV)
   - ***Bivalirudin vs. UFH:*** initial studies suggested lower bleeding with bivalirudin, but these studies were flawed by an unbalanced GPI use with UFH. A radial-access study with balanced and limited GPI use (SWEDEHEART) showed an ischemic and bleeding risk identical to UFH.[86] Also, bivalirudin may be associated with a higher risk of acute stent thrombosis than UFH, which is reduced by 1–4 hours of high-dose bivalirudin post-PCI.
     Except for this optional brief infusion of bivalirudin, anticoagulants are stopped after PCI.
   - GPI, in conjunction with either UFH or bivalirudin, is reserved for bailout use during PCI (large thrombus burden, thrombotic complications, or no reflow) (class IIa).[87] In contemporary trials, ~15% of STEMI patients require the use of GPI.

B. Antithrombotic therapies in patients treated with fibrinolytics (started upon presentation)

1. ***Aspirin*** 325 mg.
2. ***Clopidogrel*** 300 mg load if patient is <75 years old, or 75 mg if >75 years old (300 mg rather than 600 mg is the dose studied with fibrinolytics, even in pharmacoinvasive trials; 75 mg is the only dose studied with fibrinolytics in elderly patients).[88,89]
3. ***UFH*** IV bolus 60 units/kg (not more than 4000 units), followed *immediately* by heparin drip 12 units/kg/h, adjusted Q6h to keep the PTT 1.5–2.0× the control.

If PCI is not expected in the next 24 hours, ***enoxaparin*** SQ or ***fondaparinux*** SQ may be used instead of UFH. In the patient receiving primary fibrinolytic reperfusion, enoxaparin and fondaparinux have a more favorable effect on reinfarction risk than UFH, with less major bleeding with fondaparinux, vs. more major bleeding with enoxaparin.[90,91] Patients undergoing standalone fibrinolytic therapy should receive anticoagulants for at least 48 hours and preferably for the duration of the hospitalization.

- Dosage of enoxaparin: initial 30 mg IV dose, followed 15 minutes later by 1 mg/kg SQ Q12h
  - For patients >75 years old, avoid IV dose and administer 0.75 mg/kg Q12h
  - If GFR <30 ml/min, administer 1 mg/kg SQ Q24h
- Dosage of fondaparinux: 2.5 mg IV initially, then 2.5 mg SQ Qday. Avoid if GFR <30 ml/min.

For PCI within 24 hours of fibrinolytics, clopidogrel is the agent of choice. While 300 mg is the dose used in pharmacoinvasive trials,[54–56] clopidogrel 600 mg dose or ticagrelor load is likely safe as well, particularly several hours after fibrinolysis in patients <75 years (based on the TREAT trial, ~5–18 hours after fibrinolysis).[92] Also, GPI may be used if needed during early PCI.[54–56] Avoid prasugrel within 24 hours of fibrinolysis.

XI. Other acute therapies

1. ***β-Blockers*** (e.g., metoprolol orally 25 mg Q8–12h, titrated to 50 mg Q8–12h). In the COMMIT-CCS trial, the use of β-blockers beyond the first 24–48 hours after MI was beneficial and significantly reduced the risk of recurrent MI and VF at 15 days.[93] However, the earlier administration of β-blockers, especially IV β-blockers, increased the risk of cardiogenic shock, particularly in high-risk subgroups, where a net adverse effect was seen. Even without high-risk signs, β-blocker therapy was neutral the first day. Thus, β-blockers are better avoided the first day, especially in these subgroups:

- Killip class ≥ II (any degree of HF); age >70 years.
- Sinus tachycardia >110 bpm: The more tachycardic the patient, the less likely he is to acutely benefit from β-blockers. In general, tachycardia reflects a large MI and compensates for a low stroke volume (pre-shock state). Slowing the heart rate precipitates shock.

- SBP <120 mmHg or 30 mmHg lower than baseline, or evidence of low output. However, beyond the first 24–48 hours, SBP <90–100 mmHg, rather than 120 mmHg, is the contraindication to β-blocker use.
- Also, avoid β-blockers in other classic contraindications: Sinus bradycardia <60 bpm, PR >0.24 seconds, any second- or third-degree AV block, history of severe asthma, or active bronchospasm.

In patients with LVEF <40% or patients who developed HF but are now stable, β-blockers are started slowly, later than 24 hours, then titrated in the outpatient setting (e.g., carvedilol is started as 6.25 mg BID in the hospital, 3 days after MI, and uptitrated every 3–10 days, as in the CAPRICORN trial; this regimen reduced late mortality in patients with low EF, with or without HF).[94]

In patients with normal EF of ≥50% who get revascularized, long-term β-blocker initiated in the hospital does not reduce death or MI at 3.5-year follow-up (REDUCE-AMI trial).[95,96] β-blocker may still be considered for 1 month, as in the COMMIT-CCS trial, or 1 year, and may be considered in non-reperfused patients. If started, low-to-medium doses are as effective as higher doses, and the interruption should take into account HTN and angina (ABYSS trial).[97,98]

2. *Oral ACE-Is (or ARBs if cough or angioedema occurs with ACE-I).* Wait a few hours before starting an ACE-I to ensure the patient is stable and not evolving into cardiogenic shock. Try to start an ACE-I early, in the first 24 hours. In landmark trials of ACE-inhibition in acute MI, ACE-I was initiated in the first 24 hours of all types of MI, whether anterior or inferior, accompanied by HF or not, and improved early mortality (survival curves start to diverge at day 1 and become significant at 1 week and 6 weeks).[99,100] ACE-I therapy is particularly beneficial in LV dysfunction, anterior MI or HF (SAVE trial).[101] The benefit is less marked when ACE-I is used unselectively in all MI patients, including those with inferior MI and without HF, but ACE-I is still reasonable for a duration of 6 weeks, as in those trials. ACE-I is avoided in acute renal failure or when SBP <100 mmHg or 30 mmHg below baseline; intravenous ACE-I is avoided in all patients because of the risk of hypotension. A low-dose, short-acting ACE-I may be used in the acute setting in order to verify tolerability. ***Sacubitril-valsartan did not prove superior*** to ACE-I in acute MI with EF ≤40% or clinical congestion (PARADISE-MI trial). Examples of ACE-I dosing:

- Captopril 6.25 mg TID, to be doubled with each subsequent dosage, until 50 mg TID
- *or* Lisinopril 5 mg Qday, to be increased to 20–40 mg Qday

3. Aldosterone antagonists reduce short- and long-term mortality of acute MI patients with EF <40% associated with either clinical HF or diabetes (EPHESUS trial). Their routine use in all STEMI patients was not beneficial (CLEAR SYNERGY trial).

4. SGLT-2 inhibitors did not reduce mortality in post-acute MI patients with EF <45% or clinical congestion. Empagliflozin reduced post-MI HF hospitalizations and may be selectively considered in post-MI patients with severe HF (EMPACT-MI trial).

5. *Nitroglycerin.* Administer 0.4 mg of sublingual NTG up to 3 times during active angina, then start IV drip if tolerated hemodynamically. NTG is useful for chest pain, HTN, or HF concomitant to MI. It may lead to hypotension or vagal shock and should be avoided if SBP <100 mmHg, bradycardia <50 bpm, tachycardia >100 bpm, or if RV infarct is suspected with inferior MI (even if RV infarct is clinically silent).

6. *Morphine.* Administer morphine if the pain is severe and uncontrolled despite NTG, provided that reperfusion therapy is underway.

7. *High statin dose* (atorvastatin 80 mg, rosuvastatin 20 mg)

8. *Glucose control.* In hyperglycemia, with or without prior diabetes, insulin (IV or SQ) is administered to maintain blood glucose ≤180 mg/dl during acute MI. Afterwards, when the patient is less ill, try to achieve normoglycemia.[102]

9. *Monitoring.* The patient is monitored in a coronary care unit for 12–24 hours, then transferred to a step-down unit in the absence of complications. In general, an uncomplicated STEMI is safely discharged after 72 hours of hospitalization (PAMI-II trial), or even 48 hours according to modern data.[103–105] Patients qualify for early discharge if they undergo a successful reperfusion with primary PCI, have one- or 2-vessel CAD, are younger than 70 years of age without major comorbidities, and have no arrhythmias or pump failure.

10. *Echo.* Echo should be performed before hospital discharge in all patients, and should be performed or repeated urgently in a patient with shock or suspected mechanical complication.

XII. Risk stratification

A. Killip classification uses clinical features upon *presentation* to assess STEMI prognosis.

- Class I: no HF (30-day mortality = 3%)[106]
- Class II: crackles up to one-third of the lung fields or S3 (= HF, mortality = 13%)
- Class III: pulmonary edema (mortality = 27%)
- Class IV: cardiogenic shock (mortality = 50–60%)

Note that Killip classification is only applied at presentation. It also has a prognostic value in NSTE-ACS.

B. TIMI risk score for STEMI

Depending on the STEMI TIMI risk score (Table 2.3), the 30-day mortality of fibrinolytic-treated STEMI patients ranges from 1% to 35%.[107] The benefit of reperfusion is highest in the higher risk groups.

C. Troponin I peaks at a level of 50–300 ng/ml (at ~24 hours), CK typically peaks at 2500–5000 units/L (at 18–24 hours). Reperfusion therapy makes these biomarkers peak earlier and often at higher levels; however, the total volume of CK or troponin released is smaller, i.e., the distribution curves over time are narrower and the decline is faster (3–4 days for troponin I). The CK or troponin mass, rather than the CK or troponin peak, correlates with the infarct size and the prognosis. ***Aborted STEMI***, whether aborted spontaneously or with very early reperfusion, is characterized by a biomarker rise that is usually mild (CK-MB <2× normal).

Table 2.3 STEMI TIMI risk score.

Variable	Score
Age ≥65 yr / ≥75 yr	2 for ≥65; 3 for ≥75
SBP <100 mmHg	3
Sinus tachycardia >100 bpm	2
Killip class ≥ II	2
Anterior location of MI or LBBB	1
Prior history of diabetes, HTN, or angina	1
Time to treatment >4 h after symptom onset	1
Weight <67 kg (higher bleeding with fibrinolytics)	1

30-d mortality according to the score: score ≤2 → <2.2%; score 3–4 → 4–7%; score ≥5→ >12%.

XIII. LV remodeling and infarct expansion after MI (see Figure 2.10)

XIV. Discharge, EF improvement, ICD

A. Discharge medications

See Chapter 1, Section VI.

B. EF improves 1–3 months after discharge and justifies follow-up echocardiography for risk assessment. There are 2 explanations for EF improvement:

- LV dysfunction that occurs immediately after MI is partly due to post-ischemic stunning rather than necrosis. When an artery occludes transiently, necrosis occurs in part of the myocardium, while dysfunction without necrosis, called stunning, occurs in other parts. The stunned myocardium recovers over the course of days to weeks after arterial recanalization.
- ACE-Is, β-blockers, and aldosterone antagonists reduce LV remodeling and LV size, allowing an increase in EF for the same amount of necrotic myocardium (Figure 2.10). Each one of these drugs allows an EF improvement of up to 5%.

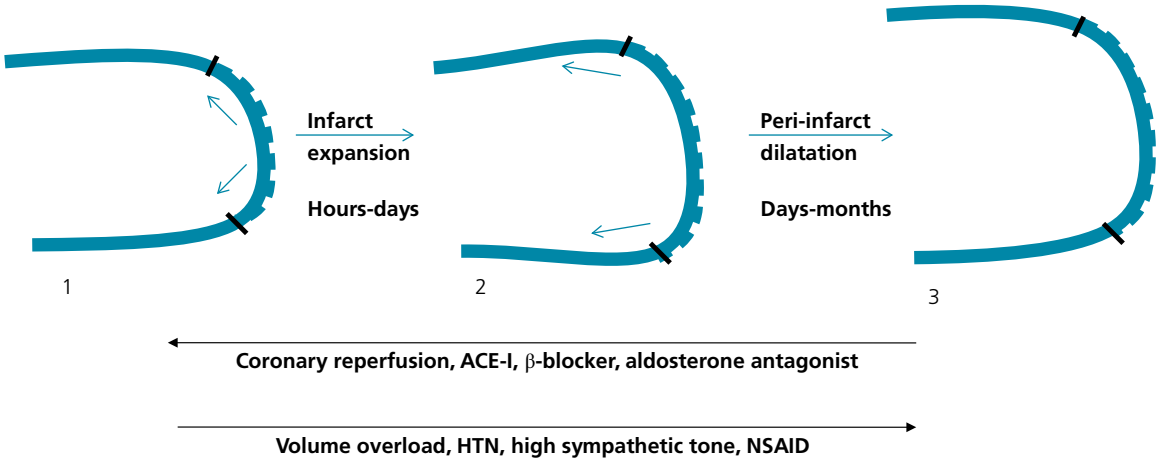

Figure 2.10 Stages of negative LV remodeling post-MI, also called infarct expansion.

For the same amount of necrosis, the dashed infarcted area thins and stretches out *(from 1 to 2)*. Then, this stretched infarcted area increases tension at its edges *(arrows)*, which eventually leads to progressive dilatation of the normal, non-necrotic myocardium *(from 2 to 3)*. The dilatation occurs as a compensatory attempt to increase stroke volume, albeit counterproductive and maladaptive. The LV loses its normal elliptical shape and becomes a sphere, which further increases wall stress and reduces the efficiency of the non-infarcted myocardium.

Thus, *for the same amount of tissue necrosis*, the infarcted area and the EF vary largely, depending on:

(a) Loading conditions.

(b) Opening of the occluded artery, even at a time when necrosis has already occurred (e.g., 3–24 hours). Reperfusion accelerates myocardial scar formation and turgor and reduces the thinning of the necrotic area, even if it does not salvage myocardium beyond 3–6 hours.

(c) Medical therapy: ACE-Is reduce afterload and exert a direct myocardial effect that reduces LV dilatation and reduces fibrosis in peri-infarct areas. Aldosterone antagonists also exert a direct myocardial effect that reduces LV dilatation and fibrosis. β-Blockers reduce the high wall stress induced by the sympathetic tone. Diuretics reduce preload and afterload.

C. ICD

The risk of sudden death is highest in the first 30 days after MI (1.2%) and increases with HF and severe LV dysfunction (~3%).[108] However, placing an ICD in the first 40 days after MI has not been shown to reduce the overall mortality; it reduces sudden-death mortality by 50%, but the patients prone to early sudden death are typically high-risk patients also prone to dying from pump failure or recurrent MI.[109,110] Early ICD placement only changes the mode of death of these patients, from sudden death to pump-failure death (conversion hypothesis). Also, early LV dysfunction/stunning may improve and some patients may turn out to be at a lower long-term risk than expected, and thus would not require an ICD. *Therefore, ICD is indicated for primary prevention of VT/VF if EF is ≤35% at 40 days post-MI*.

On the other hand, ICD is indicated early on, before hospital discharge, for the patient who develops sustained VT or VF anytime beyond the first 2 days after MI.

2. STEMI COMPLICATIONS

I. Cardiogenic shock

A. Differential diagnosis (see Table 2.4)

Clinically, RV-related shock leads to a high JVP and clear lungs, whereas LV-related shock leads to a high JVP with pulmonary edema. PCWP is frequently increased in RV shock, with a mean PCWP of 23 mmHg, because of concomitant LV failure and RV/LV interdependence.[111]

When a patient with inferior MI develops cardiogenic shock, consider the following:

- RV shock
- Relative sinus bradycardia or AV block or vagal response (likely most common transient hypotension in inferior MI)
- Mechanical complication
- Prior MI or LV dysfunction
- Superdominant RCA with apical, posterior, or lateral involvement

In the SHOCK trial and registry, ~60% of patients with predominant LV shock had anterior MI, while 34% had inferior MI without predominant RV failure and without any acute anterior involvement.[112,113] Concerning the latter 34% of patients, 14% had prior MI and 11% had concomitant apical, posterior or lateral involvement, while only 9% had isolated, new inferior MI.[112] In any shock, particularly inferior MI shock, perform emergent echo or left ventriculogram during PCI to rule out mechanical complications (MR, VSR).

B. Pathophysiology of LV-related cardiogenic shock and failure in acute MI

In the SHOCK trial, LVEF was ~30 ± 12%, implying that at least half the patients only had a moderate LV insult and a moderate reduction of LV systolic function.[113] Also, ~40% of patients had non-anterior MI, mainly inferior MI.[112,113] Thus, an EF that is well tolerated in chronic HF may be associated with cardiogenic shock in acute MI. In a way, this is similar to tolerating chronic MR or AI vs. developing shock with acute MR or AI. Besides systolic dysfunction, several mechanisms explain cardiogenic shock in acute MI:

- While the progressive LV dilatation that occurs chronically raises afterload and is maladaptive, some early degree of LV dilatation is adaptive and increases stroke volume at a given LV contractility. Also, some degree of LA dilatation is adaptive and lessens the rise in backward pressure. This is similar to the chronic LV adaptation to MR or AI. In fact, half of patients with cardiogenic shock have a small or normal-size LV, which represents failure of the mechanism of acute LV dilatation.[114,115]

Table 2.4 Differential diagnosis of shock in MI.

1. **LV-related cardiogenic shock:** anterior MI, MI with a prior history of MI or LV dysfunction, or MI in a patient with multivessel CAD. Cardiogenic shock occurs in 4–7% of STEMI (vs. 2.5% of NSTEMI). It is occasionally present on admission, and more typically develops soon after admission, at a median of 5.5 hours after MI onset (vs. a later shock development, at ~3 days, in NSTEMI with three-vessel disease).
2. **RV infarct:** RV-related shock should be considered **whenever hypotension occurs in inferior MI**. RV infarct occurs in 30% of inferior MIs, mainly with proximal RCA occlusion. Only one-half of RV infarcts produce clinical RV failure.
3. **Mechanical complications** (mitral regurgitation, ventricular septal rupture, free wall rupture) or **tamponade**.
4. **Arrhythmias** (inappropriate bradycardia, advanced AV block, VT).
5. **Vagal stimulation and vagal shock** in inferior MI. It manifests as bradycardia with clear lungs and low JVP. It is treated with atropine and fluid administration.
6. **Hypovolemic hypotension:** hypotension with clear lungs, low JVP, and no bradycardia. May attempt small fluid challenge in this situation.

During or after PCI, shock may develop from the use of sedative and vasodilatory drugs in a patient with limited cardiac output reserve, or from ischemia that accompanies PCI manipulations, guide ventricularization, distal embolization/no reflow, or myocardial reperfusion injury. Coronary reocclusion, coronary perforation with tamponade, and bleeding complications are also considered.

- For a given LV contractility, the more severe impairment of LV compliance in acute MI leads to a more severe rise of LV filling pressure, which further reduces coronary perfusion pressure.
- Transient hypotension (drugs, arrhythmia, sedation) in an initially stable patient may transiently reduce coronary blood flow and thus initiate a vicious circle of progressive myocardial ischemia that sustains the hypotension. Furthermore, since the pulmonary edema of MI results from volume redistribution rather than volume overload, aggressive diuresis may precipitate shock in MI. ***Also, β-blockers, ACE-Is, and other vasodilators, including sedatives administered during PCI or during intubation, may precipitate shock in a pre-shock patient who depends on the compensatory vasoconstriction and tachycardia.*** This partly explains why cardiogenic shock often develops after hospital admission.

While mild hypotension unloads the LV and may be tolerated in chronic LV failure, it is not well tolerated in a patient with acute ischemia and unstable CAD or in a patient with RV failure.

- In over 25% of MI-associated cardiogenic shock, SVR is inappropriately low or normal rather than elevated, despite the use of vasopressors (SVR ≤1000 dyn.s.cm^{-5}).[116] *This mismatch between myocardial depression and inappropriate vasodilatation (or lack of compensatory vasoconstriction) may result in cardiogenic shock*. Also, 18% of patients, mainly those with a low initial SVR, go on to develop a clinical picture of sepsis with fever or leukocytosis 2–4 days later, mostly with positive bacterial cultures. Thus, inappropriate vasodilatation is initiated by a systemic inflammatory response syndrome (SIRS) secondary to MI early on, then a septic process later on, and contributes to shock in a substantial proportion of patients. This implies a role for vasopressors in this subset of patients. High levels of cytokines and *inducible* nitric oxide synthase, beyond the healthy levels of *endothelial* nitric oxide synthase, precipitate vasodilatation and further myocardial depression. The initial vasodilatation, per se, is associated with an increased risk of later sepsis (bacterial translocation?).[116]

Some patients with a pre-shock state before PCI develop a full-blown shock after PCI. PCI may induce distal microemboli and a reperfusion injury with further activation of inducible nitric oxide synthase, and thus vasodilatation and myocardial depression. This is a temporary phenomenon, as the benefit from PCI eventually takes over. Also, sedatives and supine positioning may precipitate shock during PCI.

C. Management of LV-related cardiogenic shock

A shock is defined as sustained SBP <90 mmHg for at least 30 minutes, *with* signs of low perfusion (increased lactate >2 mmol/l, oliguria <30 ml/h, cold/clammy extremities, impaired mentation).[113] LV-related cardiogenic shock is characterized by additional features suggestive of increased left-sided filling pressure, such as clinical or radiographic pulmonary edema. Supportive hemodynamic features consist of a cardiac index ≤2.2 L/min and PCWP ≥15 mmHg, but right heart catheterization was not absolutely required in the SHOCK trial when pulmonary congestion was evident in a patient with anterior MI. Echo may be used to assess left-sided filling pressures and confirm the diagnosis, in addition to ruling out mechanical complications.

In the SHOCK trial, patients with cardiogenic shock and STEMI or Q-wave MI of less than 36 hours' duration were randomized to emergent revascularization vs. medical therapy. The median time from the onset of MI to shock was 5.6 hours, from MI to PCI 11 hours, and from MI to CABG 19 hours. Approximately 65% of patients had 3-vessel disease and ~20% had left main disease. Revascularization with PCI or CABG, as appropriate, reduced the absolute 6-month mortality by a drastic 13% (30-day mortality 46% vs. 56%, with a lower mortality of 38% if successful PCI was performed; 6-month mortality 50% vs. 63%). Patients who survive the acute phase of cardiogenic shock have a good long-term survival, two-thirds being alive at 6 years.[117,118]

Notably, fibrinolytics were administered to 63% of the SHOCK trial patients managed medically and were associated with a marked and significant 40% mortality reduction in comparison to no fibrinolytic therapy.[119] In addition, fibrinolytics were administered to ~50% of patients managed with revascularization, as half of SHOCK trial patients presented to non-PCI-capable hospitals; the mortality benefit of fibrinolytics in this subgroup was less clear. In the SHOCK registry, fibrinolytic therapy was associated with a mortality reduction even in those who eventually underwent revascularization.[109] Yet, the impaired systemic perfusion may impede lytic delivery.

In the SHOCK trial, 37% of patients received emergent CABG rather than PCI, and CABG was performed briskly, at a median of 2.7 hours after randomization. CABG was associated with the same survival as PCI, despite the higher prevalence of extensive CAD.[121] However, this quick CABG is not feasible at many institutions and the CABG rate in the community is lower.

IABP was recommended in all SHOCK trial patients, including medically treated patients and those initially presenting to a non-PCI hospital, and was used in 86% of patients. In the SHOCK registry, IABP was associated with reduced mortality.[120] However, randomized trials such as CRISP-AMI failed to show a benefit of IABP in STEMI patients with LV failure,[122] and the IABP-SHOCK II trial failed to show a benefit of IABP even in MI patients with cardiogenic shock.[123] The failure of the IABP-SHOCK II trial may be due to the heterogeneity of cardiogenic shock and the inclusion of patients whose shock was not purely related to LV dysfunction (median EF was 35%, 33% of patients had NSTEMI), or whose organ failure was advanced (45% had post-cardiac arrest shock). Nonetheless, the *routine* use of IABP in MI-shock is a class III in the ESC and ACC ACS guidelines.

The following strategy is recommended in cardiogenic shock:

a. *Emergent revascularization* of the infarct-related artery *only*, irrespective of the time of presentation (even >24 hours after MI onset). *Ongoing* ischemia and necrosis are typical of the vicious cycle that characterizes shock, even late shock. Non-culprit artery PCI is preferably avoided as it adds contrast load, supine time, and potential ischemia of the non-culprit territory during coronary manipulations, and therefore worsens LV volume overload and possibly myocardial injury (CULPRIT-SHOCK trial, STEMI [62%] or NSTEMI, and OPTION-STEMI trial).[69] Even patients with RCA culprit and severe LAD non-culprit do not appear to benefit from non-culprit PCI. No trial specifically addressed revascularization in NSTEMI or type 2 MI with cardiogenic shock, in which case emergent revascularization is likely best reserved for shock

with persistent AND profound diffuse ST depression. Absent that, in NSTEMI, the indirect message from CULPRIT-SHOCK and OPTION-STEMI is to avoid treating what is not strictly necessary in a tenuous patient, and rather await stabilization (with diuretics/pressors/support devices as needed).

b. In patients presenting to non-PCI-capable hospitals within 12 hours of MI onset, administer ***fibrinolytics*** whenever transfer delays are expected. Also, IABP may be placed before transfer. Augmentation of blood pressure with IABP or vasopressors may increase coronary flow and facilitate fibrinolysis.

c. ***In patients with multivessel CAD*** on angiography:

- Severe 3-vessel CAD (>90%) or critical left main disease dictates immediate CABG if possible. Alternatively, PCI of only the infarct-related artery is performed. Balloon angioplasty of the culprit artery followed by early CABG is another alternative.

d. ***Impella CP*** dramatically improves mortality in very select STEMI-related cardiogenic shock. This is based on DanGer shock trial, where Impella CP was placed in STEMI with cardiogenic shock that is progressive stage C or early stage D or E, within a few hours of MI and shock (<24 hours, median 4 hours), and with the exclusion of comatose post-cardiac arrest patients (median lactate 4.6, age 67 [58–76] years, EF 25%, anterior MI 71%, 6-month mortality 45% vs. 58%).[124] As such, Impella CP is placed in **STEMI-shock that is recent *and* severe, *not mild* and stabilizing on low inopressor dose, not *late and severe* stage D or E >24 hours, and not comatose** (U-shape concept). Caveats: no benefit seen in women; no benefit noted in patients >77 years with a trend toward raising mortality;[125] Impella CP increased survival at the cost of a high complication rate among patients it saved (much more bleeding, limb ischemia, and need for acute dialysis in the Impella group).

Timing of Impella CP insertion: For a shock that is deteriorating and requiring more than medium inopressor doses, it is reasonable to place Impella CP before PCI as an early measure to stabilize the patient, unload the LV, and better tolerate PCI's coronary flow interruptions. For a shock stabilizing on low inopressor doses, Impella may be placed after PCI, or not at all if hemodynamics continue to improve.

e. ***Mechanical ventilation*** is often necessary to reduce the respiratory work, improve oxygenation, and reduce LV preload and afterload.

f. ***Inotropic support:*** dobutamine is used in patients whose SBP is >80 mmHg, while norepinephrine is required in patients with SBP <80 mmHg or inappropriately low or normal SVR. While vasoconstriction may be harmful, the maintenance of an appropriate systemic perfusion pressure, including coronary perfusion pressure, is a priority and justifies the use of norepinephrine in severely hypotensive patients; in fact, *afterload remains low in hypotensive patients, even if vasopressors are used*. Also, norepinephrine stimulates the myocardial release of local coronary vasodilators that counteract its direct α_1-constrictive effect. Patients whose shock has been precipitated by vasodilators or sedation may also be temporarily treated with vasopressors, until the effect of the drugs wears off.

g. ***Temporary pacing,*** usually at a rate over 80–100 bpm, is required if the heart rate is inappropriately low or even "normal" (60–70 bpm).

h. ***PA catheter*** is generally placed to support the diagnosis and guide management, unless the patient quickly improves with revascularization; the finding of a low SVR may dictate the use of vasopressors.

Echo should be done to rule out mechanical complications and to assess left-sided filling pressures.

Alternatively, *LV pressure measurement and LV angiography* are performed during the emergent cardiac catheterization.

i. ***Mechanical circulatory support*** (MCS) in MI-cardiogenic shock: (1) IABP failed to improve outcomes in IABP-SHOCK II trial; (2) ECMO failed to improve outcomes in ECLS-SHOCK;[126] (3) Impella CP reduced mortality in STEMI shock (DanGer trial) but was associated with dramatic increase in bleeding and vascular complications, no clear benefit in women, and possible harm in patients > 77 years. These pitfalls prevent MCS from being first-line therapy, but MCS, particularly Impella CP, remains indicated *early on*, within 24 hours of both STEMI and shock (mainly 6–12 hours), if low or medium inopressor dose fails and the patient has favorable survival features.[124]

D. Management of severe acute left heart failure without shock

In acute MI, pulmonary edema results from volume redistribution to the lungs without overt volume overload and sometimes without LV dilatation. Treatment consists of small doses of furosemide (e.g., 20–40 mg IV), along with a low dose of intravenous NTG to reduce preload. *Excessive preload or afterload reduction may, however, precipitate shock*.

Severe HF (Killip class III), i.e., massive pulmonary edema that frequently requires mechanical ventilation, is an indication for primary PCI of the culprit artery irrespective of the delay to presentation (approach similar to cardiogenic shock).[1,2] ***Unless HF quickly improves with IV furosemide, intubate the patient before PCI to avoid full-blown decompensation during PCI.***

Conversely, *less severe HF with late presentation (>24 hours) and no residual angina does not dictate urgent PCI*. Coronary angiography is performed after diuresis, non-urgently, with adherence to the OAT trial concept, i.e., a totally occluded culprit artery is not recanalized.

E. RV-related cardiogenic shock: characteristics and management

If the patient survives the acute phase of RV MI, RV function usually improves spontaneously within 1 month, as RV ischemia is usually reversible and does not lead to chronic RV failure, even if the RV is not reperfused.[127] In fact, the long-term survival is excellent in survivors of the acute phase and RV "infarction" is a misnomer, as irreversible RV necrosis and chronic RV failure are very rare even in those without successful reperfusion, and MRI follow-up shows no RV LGE or, rarely, minimal LGE.[128] RV is thin (less O_2 demands), is able to increase its transcoronary O_2 extraction (which is 50% at baseline vs. 75% for the LV), is perfused in both systole and diastole, easily recruits collaterals because of its lower coronary microvascular resistance, and may derive O_2 from the RV cavity through the deep trabeculations; thus, RV usually recovers all of its contractile function. Acutely, however, RV shock is associated with a very high mortality, almost similar to LV shock (~50%), despite a younger age, a higher LVEF, and a much lower likelihood of three-vessel CAD.[111] Similarly to LV shock, RV shock benefits from emergent reperfusion with PCI or CABG. In fact, reperfusion promptly improves RV function within 1 hour and normalizes it within 3–5 days, dramatically and quickly improving the survival and the clinical status.[127] Non-reperfused patients continue to have a poor RV function and poor hemodynamics at 3–5 days; RV function eventually normalizes at 1 month, which may be too late.

In the SHOCK registry, PCWP was equally elevated in RV shock as in LV shock (23 ± 11 mmHg), and was equalized with RA pressure.[111] This is mainly related to the RV–LV interdependence. The dilated RV pushes the septum, forcing the LV diastolic pressure to equalize with the RV diastolic pressure and reducing LV output. The LV is underfilled, yet LA and LV diastolic pressures are elevated. LV systole is also impaired: the paradoxical rightward septal motion in systole reduces LV ejection (loss of septal contribution), but paradoxically improves RV output. RV is thin, intolerant to the increased afterload, and thus intolerant to RV dilatation, which begets more dilatation.

The usual culprit of RV shock is RCA in 96% of the cases, usually proximal RCA affecting flow to the acute marginal branches (RV free wall) and the PDA (inferior septum). An even more proximal RCA occlusion affects RA branches and causes a *more pronounced shock from the combined RA and RV infarctions*. The left coronary is responsible for only 4% of RV MIs. The anterior RV is partly supplied by LAD branches, more so in case of RCA CTO; hence, during LAD MI, up to a third of the RV free wall becomes ischemic, but this RV involvement is usually inconsequential.[128]

Treatment: Emergent reperfusion leads to rapid and complete recovery of RV function within hours, even after prolonged occlusion, much faster than recovery of LV function.[129] Beware, however, that ***a large thrombotic RCA with extensive clot burden is prone to no-reflow and transient worsening of RV perfusion after stenting, along with abrupt bradycardia and hypotension***. Anticipate this brief yet sometimes profoundly destabilizing phenomenon and have a transvenous pacemaker and vasopressors readily available.

a. *Fluid administration.* In patients without significant pulmonary hypertension, one may increase the RA pressure to passively force flow through the PA and therefore increase the cardiac output. However, this is only effective as long as the RV does not dilate. Once the RV dilates, fluid administration worsens ventricular interdependence, further reduces LV output, and increases TR. Thus, 500 ml fluid boluses are provided while carefully assessing the hemodynamic response to each bolus, and preferably the RV size on echo. Boluses are stopped if RV is significantly dilated *or* if no improvement in SBP and pulse pressure is noted.

While RA pressure may not correlate with volume responsiveness of the stiff RV, a study has suggested that in RV MI, the best stroke volume is seen when RA pressure is 10–14 mmHg (13–18 cmH_2O), beyond which the stroke volume declines.[130]

b. *Inotropes/vasopressors.* After RV preload has been optimized, the patient with persistent hypotension is treated with inotropes/vasopressors. Since at least half of the RV coronary flow occurs in systole, RV coronary flow depends on the driving gradient between SBP and RV systolic pressure. Thus, the RV is very sensitive to decreased SBP, more so than the LV, which may thrive with a slightly reduced SBP.

Inotropes used in RV MI should be able to increase SBP, and thus norepinephrine is often the agent of choice.[131]

c. *Maintenance of AV synchrony* is critical in acute RV failure, as the RV but also the underfilled LV are dependent on the extra-filling provided by the atrial contraction, *more so than a failing, overfilled LV*.[132] In fact, a large RA A wave is helpful and pushes blood in the PA: this is lost in atrial arrhythmia but also in atrial infarction from very proximal RCA occlusion. AF may need to be DC cardioverted. Patients with AV block or AV dissociation from an accelerated junctional rhythm need to have atrial and ventricular sequential pacing. Transvenous atrial and ventricular leads are placed through separate venous accesses (e.g., bilateral femoral accesses).

As in any shock, a "normal" heart rate of 60–70 bpm is inappropriate and dictates pacing to a rate >80 bpm.

d. *Hypoxemia* should be aggressively treated with mechanical ventilation if necessary, as hypoxemia increases pulmonary vascular resist- ance and RV afterload.

e. *IABP* may be useful to increase RV perfusion through the reperfused RCA, lessening RV ischemia. It also enhances the LV septal contraction and its contribution to RV output. It is reserved for RV shock refractory to inotropes, or concomitant LV failure (pulmonary edema). It serves as a bridge to RV recovery, which is quick after reperfusion (hours to 1 day)

f. *Inhaled NO* may be used in refractory RV shock and has been shown to reduce RA pressure and pulmonary vascular resistance, and increase stroke volume, in RV MI.[133]

g. *More advanced MCS for refractory RV shock* (right-sided Impella RP, Protek Duo Tandem heart, VA-ECMO).

Beware of 2 processes that may mimic RV infarct: pulmonary embolism and tamponade.

II. Mechanical complications

Mechanical complications occur within the first 14 days of STEMI and have two peaks (24 hours and 3–5 days). They are responsible for 12% of cases of cardiogenic shock (severe mitral regurgitation, 7%; ventricular septal rupture, 3.9%).[112] The myocardial rupture responsible for all 3 mechanical complications usually results from the shear stress at the border between the live hypercontractile area and the infarcted area. In the reperfusion era, myocardial rupture is most frequently seen in the first 24 hours (SHOCK registry).[134,135] It may occur at 3–5 days, particularly in non-reperfused patients, when the forming scar thins, expands, and exerts excessive tension at the border; this late remodeling is unlikely in reperfused MI, which explains why rupture is relatively more common in the first 24 hours in reperfused MI, particularly the reperfused late presenter, and may even be favored by reperfusion injury and myocardial hemorrhage in the late presenter. In the second week, the rupture may involve the thin necrotic area itself.

A. Severe mitral regurgitation (MR)

- *Posterior leaflet tethering* – A degree of ischemic MR is seen in ~30% of acute MI, and is severe in ~1-2% of acute MI.[136] *Inferior MI* with localized inferior/posterior akinesis pulls the posterior papillary muscle posterolaterally, with subsequent tethering of the posterior mitral leaflet (predominantly). This tethering may lead to severe MR, a dynamic form of MR that may be mild at rest and severe with increased ventricular loading. *Tethering may also occur with anterior MI and is usually a posterior tethering as well*. In anterior MI, posterior tethering is secondary to global LV dilatation. This MR improves in >50% of patients after PCI.[136]

- *Papillary muscle rupture* – Severe MR may result from rupture of a papillary muscle head, usually the posterior papillary muscle in the context of an *inferior or posterior MI* (which was the culprit in 2/3 of papillary ruptures in the SHOCK registry).[134] The posterior papillary muscle is supplied by one artery, the PDA (from a dominant RCA or LCx), whereas the anterolateral muscle has a dual blood supply from the LAD (usually first diagonal) and the LCx. Papillary muscle rupture occurs in ~1% of MIs (~0.2% of reperfused MIs), and, unlike ventricular septal rupture, the infarct is relatively small in 50% of the cases. Rupture may be partial, involving one of the heads of a papillary muscle, or may be complete involving its full thickness with more profound shock. Each papillary muscle extends chordae to both leaflets, and therefore flailing of *either or both leaflets* may occur with rupture of *either papillary muscle*.

Echo distinguishes papillary muscle rupture (treated surgically) from leaflet tethering (initially treated with revascularization and supportive measures). In the former, the leaflet(s) are flail, prolapsed, with flailing of chordae and flailing of an echogenic piece of papillary muscle; in the latter, the posterior leaflet is restricted and the jet is usually posterior.

B. Ventricular septal rupture (VSR) occurs in ~1% of MIs (only 0.2% of reperfused MIs). Anterior MI (LAD) and inferior MI (mainly RCA) were equally common causes of VSR in the SHOCK registry, while other registries suggest that anterior MI is slightly more common.[135] Patients with a wrap-around LAD have less septal collaterals and are at a higher risk of septal rupture with anterior MI. The location is apical septal in anterior MI and basal inferior in inferior MI. VSR leads to a severe left-to-right shunting with severe hypotension and LV volume overload, as the shunted blood recirculates back to the LA and LV (almost like acute regurgitation).

C. Free wall rupture occurs in ~2% of MIs and is the most common and most underdiagnosed mechanical complication (≤1.5% of patients treated with PCI, 3% of patients treated with thrombolysis, 6% of patients not reperfused).[137,138] The most common location is anterior MI (LAD culprit); the second most common location is lateral MI (LCx culprit).[139]

Free wall rupture often leads to tamponade and a bradycardic pulseless electrical activity. It commonly has one of the following prodromes: chest pain, re-elevation of ST segments, bradycardia, or syncope from a vagal shock.[138] In ~30% of the cases, the rupture may be temporarily sealed by the pericardium, causing the formation of LV pseudo-aneurysm or pericardial effusion.[138]

Risk factors for all mechanical complications: late presentation, female sex, older age, first MI, absence of collaterals, history of HTN. Also, the use of NSAIDs or steroids increases the risk of rupture. Anticoagulants do not clearly increase the risk of rupture.

Reperfusion with thrombolysis or PCI reduces the incidence of all mechanical complications. While early thrombolysis reduces the risk of free wall rupture, late thrombolysis >12 hours, particularly in elderly patients, may increase the risk of free wall rupture according to a meta-analysis of thrombolytic trials.[140,141]

The majority of patients with VSR have multivessel disease, while patients with papillary muscle or free wall rupture usually have a single-vessel disease with good LV function.

D. Clinical manifestations

Patients with either MR or VSR present with cardiogenic shock and pulmonary edema.

- Pulmonary edema is less marked with VSR than with MR and may occasionally be mild in VSR.
- The murmur may be faint or absent with acute MR, because of the near-equalization of LV and LA pressures. The murmur is usually loud in VSR and is associated with a thrill at the left lower sternal border.

E. Diagnosis

a. ***Transthoracic echo*** (TTE) is the initial test. TTE shows a left-to-right shunt in VSR. It may miss severe acute MR because of the narrowing of the pressure difference between the LV and the LA, leading to attenuation of the regurgitant color flow. TTE may show a pericardial effusion with layered echodensities, corresponding to blood, in free wall rupture; however, it may miss a sealed rupture (an effusion is not seen in 25% of sealed ruptures).[139]

b. If the severity/mechanism of MR is unclear on TTE in a patient with shock, perform ***transesophageal echocardiography***.

c. ***MRI*** is needed when a sealed free wall rupture is suspected but not well delineated by echo.

d. ***Right heart catheterization*** may also be useful to diagnose VSR and MR:

- In VSR, there is O_2 saturation step-up ≥7% between RA and RV.
- In MR, PCWP tracing has a giant V wave; however, a large V wave is also seen with VSR or severe LV failure. In both MR and VSR, PCWP is higher than LVEDP.

e. ***Left ventriculography*** may be performed during PCI in a patient with cardiogenic shock. It allows the diagnosis of severe MR, VSR, or free wall rupture.

F. Case illustrations

Case 1. A 55-year-old man presents with shock and severe pulmonary edema. His wife notes that he complained of chest pressure for several hours 4 days previously. ECG shows inferior Q waves and 1 mm ST elevation. No murmur is heard on exam. Echo shows inferior akinesis with mild MR. What is the next step: PCI vs. TEE vs. Impella CP?

The answer is TEE. It is unlikely for an inferior MI, per se, to lead to such severe hemodynamic compromise. The patient likely has severe acute MR from papillary muscle rupture, with *eccentric* jet and *brief (cutoff) MR doppler* missed by TTE. LA V-wave and LV pressures nearly equalize in late systole, which attenuates the Doppler color velocity and the murmur on exam (Figure 2.11). TEE should be followed by IABP, coronary angiography, and emergent surgical MV replacement.

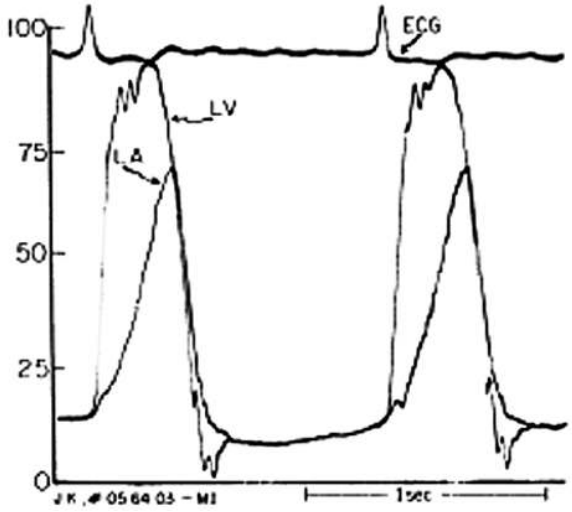

Figure 2.11 Massive LA V wave in systole, in acute papillary muscle rupture. Attenuation of LV-LA pressure gradient, particularly in late systole, attenuates the murmur and the MR jet on Doppler.

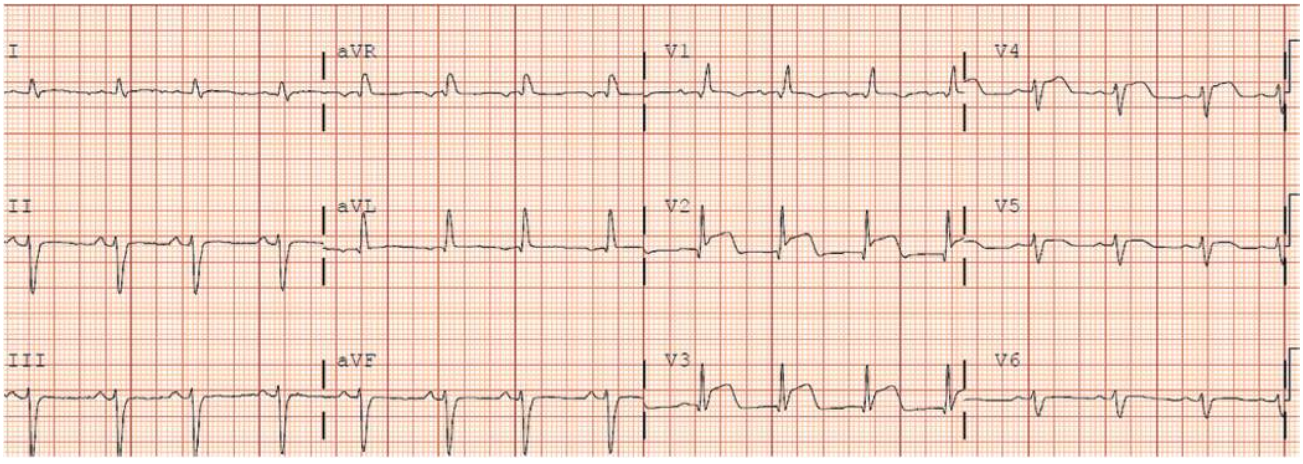

Figure 2.12 ECG pre- and post-PCI. Anterior STEMI with ischemic RBBB (anterior qR pattern), and no definite wide Q waves.

Case 2. An 80-year-old woman presents with chest pain that started 48 hours ago. She has no residual pain. ECG is shown (Figure 2.12). She undergoes primary PCI, but ECG remains unchanged. Twelve hours later, she develops pre-syncope while getting up to the restroom, with SBP 75 mmHg, pulse 40 bpm, and worsening of ST ↑ on telemetry. BP improves with lying down and a fluid bolus, and she goes back to sleep. What is the next step?

The answer is emergent echo. This is likely contained free wall rupture in an elderly woman with late reperfusion and persistent ST ↑ (poor cellular perfusion, reperfusion injury). Free wall rupture often leads to tamponade and a bradycardic PEA, and commonly has one of the following prodromes: chest pain, re-elevation of ST segments (local pericardial irritation), bradycardia, or syncope from a vagal effect. It is important to recognize the prodromes, particularly that sealed cases are salvageable. *Note:* She did not develop Q waves, but persistent ST elevation is worse prognostically than Q waves. In the OAT trial, 33% of late presenters did not have Q waves; the lack of Q waves is not always reassuring.

G. Treatment of severe MR

Papillary muscle rupture dictates emergent valvular surgery + CABG. Place IABP preoperatively and administer IV vasodilators (nitroprusside) as in all cases of acute severe MR. Mitral valve replacement is most often performed as it is more expeditious than repair, and it is difficult to sew necrotic tissue. Emergent surgery reduces mortality from 90–100% to 20–40%.[134] In high-risk patients, MitraClip may be implanted, and high success rates have been reported (improvement of MR in 87% of patients, hospital mortality 30%).

When severe acute MR is secondary to acute mitral leaflet tethering, the patient may be treated with percutaneous revascularization, vasodilators and temporary IABP support. It is expected that leaflet tethering improves once the function of the reperfused territory improves.[142–144] This is not the case in chronic leaflet tethering seen with chronic infarction. Surgery or Mitraclip should be considered a second-line therapy for those patients who do not improve with medical therapy.

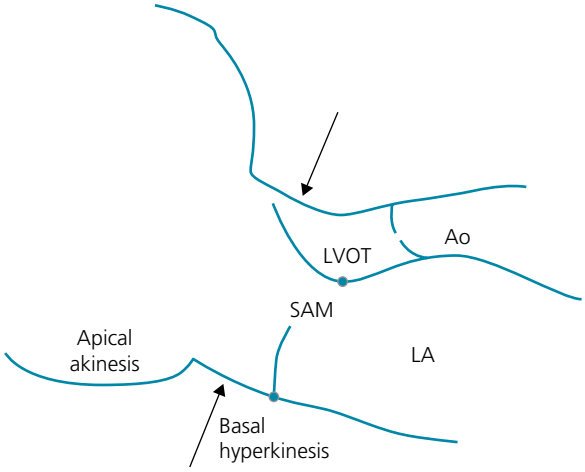

Figure 2.13 Dynamic left ventricular outflow tract obstruction in apical infarction.

H. Treatment of VSR

Surgery is the definitive treatment of VSR, even small VSR as the tear may progress rapidly and unpredictably. The mortality of unoperated VSR is 94% at 30 days.[145,146] However, it is difficult to sew VSR early on, as the margins are necrotic, friable, and "mushy." The same limitation applies to percutaneous closure. Hence ***surgical or percutaneous mortality improves with waiting >7 days and, if possible, >3 weeks*** (operative mortality 60% the first day vs. 30% at >7 days and 10% at >3 weeks). Note that this is partly related to the survival bias, i.e., patients surviving >7 days are less ill and more likely to survive. Thus, try to stabilize hemodynamics with IABP or Impella, and try to wait 7 days before surgical or percutaneous repair. Patients with severe shock may require emergent surgery vs. more aggressive stabilization with ECMO + Impella, although their mortality is likely very high regardless of surgery.

Impella 5.5 appears to be the device with the most reduction of L-R shunting and PCWP. ECMO achieves the most improvement of systemic flow and BP, but increases L-R shunt flow and PCWP; ECMO + Impella is a good strategy.[147]

Mortality is highest in basal-inferior VSR, because the latter is more serpiginous and often associated with RV infarct.

The long-term survival of patients who survive any of the 3 mechanical complications is good.

I. Another mechanical complication: dynamic left ventricular outflow tract obstruction

This complication occurs in 1–2% of MIs and up to 12% of anterior MIs in women. It is due to anteroapical akinesis associated with a compensatory hyperkinesis of the LV base. This narrows the LVOT and leads to drawing of the mitral valve to the septum and systolic anterior motion (SAM) of the mitral valve, similar to HOCM (Figure 2.13).[148]

Hypotension and pulmonary edema may subsequently occur. Clinically, a new, dynamic systolic murmur, similar to HOCM murmur, is heard. MR murmur (SAM) may also be heard.

As opposed to the treatment of cardiogenic shock, inotropes, diuretics, and IABP should be avoided, as they worsen the basal hyperkinesis and LVOT narrowing. β-Blockers are used to reduce the LVOT hyperkinesis. α-Agonists may be used in case of hypotension.

III. Recurrent infarction and ischemia

Within 30 days, recurrent infarction or ischemia occurs in ~10–15% of patients treated with fibrinolytic therapy, vs. <4% of patients treated with PCI (less so with stenting, ~2%).[36,54,55] Recurrent infarction is usually due to reocclusion and is also called "infarct extension," which is different from "infarct expansion" (LV remodeling).

It is diagnosed based on clinical grounds, ECG, and a reincrease of a downtrending troponin by >20%.

Treatment – Escalate β-blockers, NTG, and readminister anticoagulants. Emergent PCI is indicated in STEMI or hemodynamic instability. Otherwise, a non-urgent coronary angiogram is usually performed. For recurrent ST elevation, the fibrin-specific fibrinolytics may be (re-) administered if PCI cannot be performed in a timely fashion.

IV. Tachyarrhythmias

A. Ventricular tachyarrhythmias: VF and sudden death

Improvements in reperfusion therapy have reduced the 30-day mortality of a STEMI patient presenting to the hospital from 15% to 5–6%. Yet, out-of-hospital mortality remains very high, and is responsible for most MI fatalities, mainly in the first hour after MI onset. In fact, the risk of out-of-hospital cardiac arrest in STEMI is ~15–20%,[149,150] mainly in the first hour after STEMI onset, when over half of all VF episodes occur;[151] and between hours 1 and 4, where most of the remaining VF events occur.

Conversely, for patients who make it to the hospital without cardiac arrest, the risk of primary VF within 48 hours is ~4%, mostly in the first 4 hours after symptom onset, and the risk of VT and/or VF is ~10%.[152]

B. Ventricular tachyarrhythmias: VF

In the reperfusion era, sustained VF occurs in 4% of patients hospitalized with acute STEMI. There are 3 types of VF, mostly character- ized in fibrinolytic trials:

- *Primary VF* is defined as VF occurring in the first 48 hours after MI without an associated shock or severe HF. It occurs because of rapid potassium fluxes with increased automaticity and dispersion of repolarization, or increased sympathetic or vagal tone. It mostly occurs in the first 4 hours. Primary VF, whether in the first 4 hours or at 4–48 hours, is associated with a 2–4 times increased in-hospital mortality, from the VF episode itself, VF recurrence, or the larger ischemic burden. However, VF does not affect long-term mortality in survivors, even on unadjusted analyses.[152–154] *In fact, primary VF correlates with the extent of initial ischemia and is much more commonly seen in STEMI than NSTEMI, but does not correlate with the eventual infarct size and is at least as frequently seen in inferior as in anterior MI* (GISSI-2, Apex-AMI analyses). Sinus bradycardia or pauses may precipitate VF in patients with inferior MI.

  Even after primary PCI, a small but significant proportion of patients have VT/VF at 24–48 hours (~1.5% of patients).[155,156] This post-PCI VT/VF carries an increase in short-term,[156] but not long-term, mortality.

Post-PCI VF may reflect stent thrombosis and warrants thorough clinical and ECG investigation.

- *Secondary VF* is defined as VF occurring in association with HF or shock (<48 hours or >48 hours) and portends a poor early and long-term survival, mainly from a downhill HF course.[153,154]
- *Late VF* is defined as VF occurring after 48 hours without an associated HF or shock. It is secondary to the myocardial scar and correlates with pump failure, extensive myocardial damage, and increased long-term mortality.[152]

C. Ventricular tachyarrhythmias: sustained VT

There are 2 types of VT:

- *Polymorphic VT* is usually an ischemic rhythm that occurs in the first 48 hours of MI or during ischemic recurrences.[157] In contrast to torsades de pointes, this polymorphic VT is usually associated with a normal or a minimally prolonged QT interval. Similar to primary VF, it is associated with increased short-term but not long-term mortality.[158]
- *Monomorphic VT*, whether occurring early (in the first 48 hours) or late (>48 hours), is a sign of extensive myocardial damage and portends a strikingly increased in-hospital but also long-term mortality, even when it is not accompanied by HF or shock (GUSTO-1 data).[152,159,160] It is rarely seen, in ~2% of MI.

Polymorphic VT usually corresponds to active ischemia, many times without underlying anatomic substrate/scar or with less underlying anatomic substrate and higher EF than monomorphic VT.[161] Monomorphic VT, on the other hand, usually reflects the presence of an often large scar and originates in the border zone between viable and infarcted tissue.[152]

D. Ventricular tachyarrhythmias: non-sustained VT (NSVT)

Early NSVT (<48 hours) is not associated with any impairment of short- or long-term survival.[158] Late NSVT (≥4 beats) is associated with impaired long-term survival.[162] NSVT does not require any specific therapy; provide general MI therapy and, more specifically, a β-blocker if possible.

E. Accelerated idioventricular rhythm = slow VT = slow wide ventricular rhythm at a rate of 60–100 (120) bpm. Its incidence is 20% in the first 48 hours, mostly after successful reperfusion. Its occurrence immediately after fibrinolytic therapy may signal reperfusion; however, since it frequently occurs without reperfusion, it cannot be used as a standalone reperfusion marker. In any case, it is benign and resolves spontaneously; no specific treatment is required.

F. Acute therapy of sustained VT/VF

- DC cardioversion and IV amiodarone (first choice), procainamide, or lidocaine for 6–24 hours. Use procainamide cautiously in HF, as it has a negative inotropic effect.
- Revascularization
- β-Blockers if possible
- Keep K levels >4.0–4.5 mEq/L and Mg >2 mg/dl
- Consider repeating the coronary angiogram in case of recurrent VT or VF despite earlier reperfusion therapy
- Primary VT prophylaxis with antiarrhythmic drugs (e.g., lidocaine) is not indicated and does not improve outcomes

G. Atrial fibrillation, atrial flutter

In the reperfusion era, the incidence of new AF or atrial flutter in acute MI, usually paroxysmal AF/atrial flutter, is ~10%. This incidence is increased in patients with HF, large MI (including RV MI), pericarditis, or older age. AF is associated with an increased in-hospital as well as long-term mortality, which is partly related to the associated pump failure and the late VT/VF.[163] Post-MI AF has been associated with a striking increase in the risk of in-hospital but also long-term stroke across multiple studies, even when AF is only transient.[163] In the GUSTO-1 trial, the in-hospital stroke risk was 3.1% with AF vs. 1.3% without AF.[164] Another study addressed patients with inferior MI and preserved EF who had transient AF, i.e., AF that spontaneously reverted to sinus rhythm before hospital discharge; these patients had a much higher risk of AF at 1 year than patients without transient AF (22% vs. 1.3%) and a high risk of stroke under aspirin therapy (~10% vs. 2%), despite a normal EF. This suggests that AF occurring during MI is not a transient phenomenon, but rather a chronic process with a high stroke risk.[165]

This high risk of stroke supports anticoagulation for peri-MI AF and is further supported by another registry analysis.[166] However, in the era of PCI and routine dual antiplatelet therapy, the role of anticoagulation for transient, peri-MI AF is unclear. The in-hospital use of unfractionated heparin is encouraged to reduce the in-hospital stroke risk, and chronic NOAC therapy is considered along with clopidogrel in patients with a low bleeding risk, while keeping aspirin therapy short (1 week to 1 month).

β-Blockers are used for rate control, but are not appropriate in patients with acute HF. In ill patients with acute HF, some degree of tachycardia may be tolerated to prevent a shock state (heart rate of 100–110 bpm). Anti-congestive measures and afterload reduction improve the AF rate; if needed, digoxin and IV amiodarone may be added for rate control.

H. Accelerated junctional rhythm (also called non-paroxysmal junctional tachycardia)

The accelerated junctional rhythm is an automatic rhythm originating from the AV node at a rate of 70–130 bpm, often ~80 bpm. The junctional rhythm is faster than the sinus rhythm, which leads to AV dissociation. Sometimes, the junctional and sinus rhythms compete at close rates, leading to isorhythmic AV dissociation, i.e., some beats may be sinus beats preceded by sinus P waves, while the other beats may be junctional beats dissociated from P waves and showing up at any deceleration of the sinus P rate (see Chapter 13, Figure 13.9). The QRS is narrow, except in patients with a baseline bundle branch block. This rhythm may occur with inferior MI, is benign and transient, and does not generally require any specific therapy unless the patient is in shock. In shock, atrial pacing at a rate faster than the junctional rhythm may be performed to promote AV synchrony and a more appropriate rate for shock.

Persistent sinus tachycardia is a strong negative prognostic marker; it often signifies pump failure from a large MI. Do not necessarily attempt to slow it down, and avoid β-blockers in the first 24 hours if the heart rate exceeds 110 bpm. One may attempt to slow it down in young patients with hyperdynamic circulation and limited-size MI. Sinus tachycardia may improve with anticongestive measures and afterload reduction.

V. Bradyarrhythmias, bundle branch blocks, fascicular blocks

A. Inferior MI

The sinus nodal artery originates from the proximal RCA (60%) or the LCx (40%). The AV nodal artery originates from the AV groove continuation of a dominant RCA (90%) or a dominant LCx (10%).

In inferior MI, sinus bradycardia and AV blocks may develop in the first 24 hours, at which time they are usually brief and result from the increased vagal tone that accompanies inferior MI. Beyond 24 hours, the AV block is due to ischemia and edema of the AV node and is more persistent, but eventually resolves within a few days (<1 week). The AV node is resistant to ischemia, and therefore it almost never infarcts. When AV block is seen along with a fast P-wave rate, the block is due to nodal ischemia or edema, rather than a high vagal tone.

The AV block being at the nodal level, it may manifest as first-degree AV block, second-degree type I AV block, or complete AV block with a junctional rhythm (rate 40–100). Those blocks are usually well tolerated, develop gradually (first-degree to second-degree then third-degree AV block), and resolve gradually. Complete AV block is seen in ~4-5% of inferior MIs, mostly on the first day.[167,168]

Complete AV block is associated with a larger MI, more RV MI, and a 2-fold higher in-hospital mortality.[167,168] Patients who survive to hospital discharge, however, do not have an increase in long-term mortality in some,[169] but not all studies.[167]

Treatment – AV block that occurs in the first 24 hours responds to atropine, which should be used in case of hemodynamic instability. Since it is not driven by a high vagal tone, later AV block (>24 hours) does not typically respond to atropine but may respond to *aminophylline* (adenosine-receptor blocker) (ACC); being usually well tolerated with a good escape, ***complete AV block does not require pacing*. It only requires temporary transvenous ventricular pacing in case of shock, HF, or low-output signs.**

Symptomatic sinus bradycardia or pauses are initially treated with up to 2 mg of atropine. Transcutaneous or transvenous pacing may be used if symptomatic bradycardia persists.

B. Anterior MI

The bundle branches and fascicles are, at least partially, supplied by the LAD. Anterior MI may lead to bundle branch blocks and AV block. The AV block is Hisian or infra-Hisian and is usually preceded by bundle branch blocks. A high-degree AV block is seen in ~1–2% of anterior MIs and portends a very high mortality related to pump failure (3–4 times increase in mortality; mortality was >50% in the pre-reperfusion era).[169,170] The anterior MI's AV block often resolves but may recur in a minority of patients.[170]

Transvenous pacing, while indicated for any high-grade second- or third-degree AV block occurring with anterior MI, even if asymptomatic, does not improve the grim overall prognosis that is dictated by the pump function. Permanent pacing is indicated for persistent, infranodal second- or third-degree AV block.

C. Bundle branch and fascicular blocks

Approximately 2–8% of STEMI patients develop some form of new intraventricular block, LAFB being the most common block. Note the following arterial supply:[171]

- The right bundle mainly has a single arterial supply from the LAD (first septal branch).
- The left anterior fascicle has a single arterial supply from the LAD (first septal branch).
- The His bundle, the main left bundle, and the posterior fascicle have a dual supply from the LAD septal branches and the AV nodal artery. Thus, the composite of the anterior and posterior fascicles, the branching left bundle, usually has a dual supply. This explains why it is difficult to infarct the left bundle and why most new LBBBs are non-ischemic in nature.

RBBB or LAFB is most commonly seen in anterior MI,[172] but may also be seen in inferior MI if the LAD has severe disease and is dependent on the RCA for collaterals. LBBB may result from either anterior or inferior MI, and is more likely seen when both RCA and LAD are

compromised, with one acutely occluded and the other chronically obstructed (in the GUSTO trial, LBBB was associated with an RCA culprit at least as much as an LAD culprit).[20,173]

The conduction system is more resistant to ischemia than the myocardium, as the myocardial cells require much more O_2 for their continuous mechanical work than the electrical cells, which also frequently receive dual or collateral supply. This explains why conduction blocks are frequently due to edema or ischemia rather than necrosis and are frequently reversible (25–75% of the cases).[172,173] If not reversible, and if secondary to MI rather than degenerative disease, the myocardial injury is usually quite extensive (e.g., persistent RBBB or LBBB).

While a chronic bundle branch block (BBB) has a very low risk of progression to complete AV block, 20% of acute BBBs progress to complete AV block, and 25–40% of acute bifascicular blocks progress to complete AV block.

Besides the risk of progressing to complete AV block, ***a new BBB is independently associated with a 2- to 3-fold increase in in-hospital mortality, HF, and VF, particularly because it correlates with a more extensive infarction*** (mortality 18% vs. 11% in GUSTO-I trial; 35–50% in the pre-reperfusion era).[173] Up to 75% of these blocks are transient, and transient blocks do not portend any increase in mortality.[172,173] Old BBBs do not portend any increase in mortality either. ***Both RBBB and LBBB are associated with the same increase in mortality.***[172,173]

A standby temporary transcutaneous *or* transvenous pacemaker is indicated for a new BBB or bifascicular block occurring in anterior MI.

VI. LV aneurysm and LV pseudoaneurysm

A. LV aneurysm

Dyskinesis signifies that a non-contractile myocardial segment moves out during myocardial contraction and moves in during relaxation (paradoxical motion). **LV aneurysm** is an extreme form of dyskinesis and consists of a *thin* area of infarcted, dyskinetic myocardium that forms a myocardial pocket. Dyskinesis without an aneurysm implies that the myocardium protrudes only during systole, whereas an *aneurysm protrudes in both systole and diastole, forming a separate chamber, and always has thin walls*. LV aneurysm usually reflects the presence of extensive transmural necrosis; contrarily, dyskinesis may be seen with acute reversible ischemia, post-ischemic stunning, or takotsubo cardiomyopathy without any necrosis, in which case the myocardial wall is not thin (it may appear thin in systole from the lack of thickening, but it is not thin in diastole). Dyskinesis without an aneurysm is much more common than a true aneurysm.

LV aneurysm is a form of adverse LV remodeling and dilatation of the necrotic area. Approximately 50% develop acutely in the first 48 hours, from early dilatation of the necrotic, expansile myocardium, and the remainder usually appear within 2 weeks.[174] The mature, thick scar appears several weeks later, followed by calcifications. The early use of ACE-I, β-blocker, and aggressive blood pressure control prevents LV aneurysm from appearing or expanding.

An aneurysm leads to increased preload and afterload, and a double mortality for the same EF.[175] LV aneurysm occurs in 5% of STEMI cases, mainly anteroapical STEMI (80% of LV aneurysms are anteroapical; the rest are inferoposterior). LV aneurysm may initiate or worsen: (i) HF, (ii) angina (from the adverse loading conditions), (iii) VT, and (iv) mural thrombosis.

The diagnosis is made by echo. ST elevation that persists >3 weeks suggests LV aneurysm, but may also be seen with a dyskinetic, often non-viable wall.

Treatment consists of standard HF therapy that aims to reverse LV remodeling. Aneurysmectomy is indicated for refractory HF or refractory VT, mainly in conjunction with CABG. Operative mortality is <10%.

B. LV pseudoaneurysm

Pseudoaneurysm is a myocardial rupture that has been sealed by pericardium, organized thrombus and fibrosis. Unlike a true LV aneurysm, the LV pseudoaneurysmal wall does not contain any myocardium. Note that thrombus is layered inside both the LV aneurysm and LV pseudoaneurysm. A pseudoaneurysm may also be seen after trauma or cardiac surgery (especially mitral surgery, at the posterobasal level) (Figure 2.14).

A pseudoaneurysm has a 40–50% risk of progressing to a full rupture, and thus warrants urgent surgical suturing. Rupture often occurs in the first week,[176] but rupture of chronic pseudoaneurysms, even small pseudoaneurysms, has been described.[177] Conversely, a true aneurysm does not rupture (it may, rarely, rupture in the first 2 weeks of MI, but does not rupture later on, once it is fully fibrosed).

The distinction between a true LV aneurysm and a pseudoaneurysm is made by echo: a pseudoaneurysm has a narrow neck with a neck-to-internal diameter ratio <0.5,[178] although occasionally in large cases, it can be 0.5–1.[176] Doppler may also support the diagnosis of pseudoaneurysm by showing a to-and-fro turbulent flow through the narrow neck, which corresponds to a murmur on exam. However, echo-Doppler does not always allow this distinction. MRI may be used in equivocal cases and shows loss of epicardial fat across the pseudoaneurysm.

Left ventriculography is also highly accurate in distinguishing an aneurysm from a pseudoaneurysm.[176] In case of a pseudoaneurysm, it shows a pocket with a contrast stain that persists over multiple beats. Moreover, in contrast with a true aneurysm, the coronary arteries do not extend over the pseudoaneurysmal wall.

VII. Pericardial complications

A. Acute post-infarction pericarditis

In the reperfusion era, inflammatory pericarditis occurs in ~5% of STEMIs, usually large or anterior STEMIs (it was more common in the pre-reperfusion era, ~10–20%). Less commonly, it may occur in large NSTEMIs. The incidence is higher if only pericarditic chest pain is used to define post-infarction pericarditis, without mandating a rub.[179] On the other hand, asymptomatic rubs are also common in the first 48 hours of MI. Pericarditis, including asymptomatic rub, correlates with a larger MI size, and thus carries a worse prognosis despite being innocuous per se.

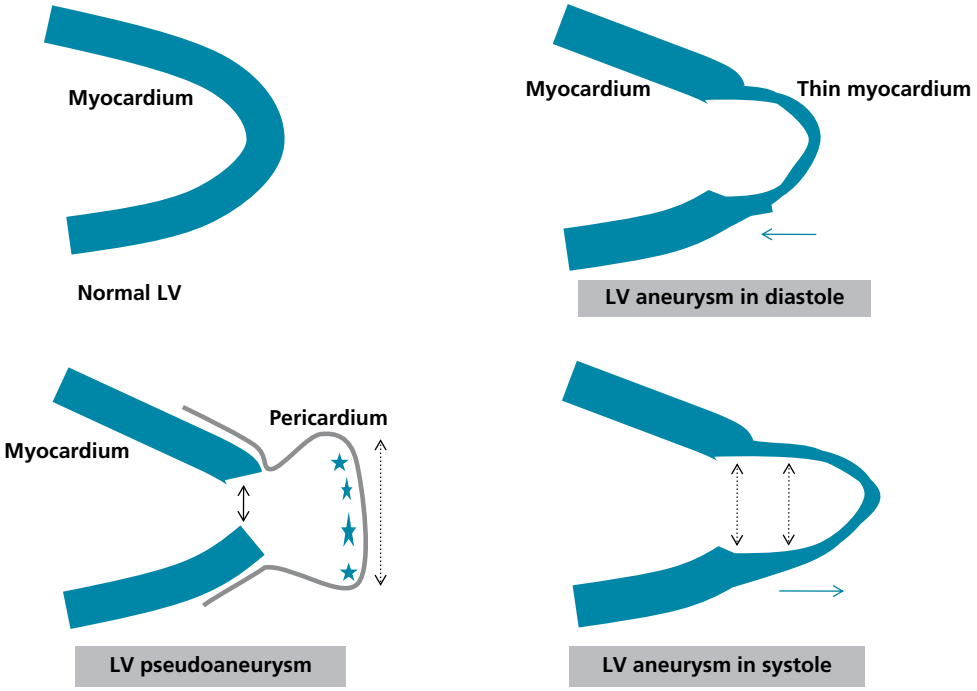

Figure 2.14 LV aneurysm and LV pseudoaneurysm.

In comparison with the normal LV, note the bulging pocket seen in LV aneurysm and LV pseudoaneurysm. The aneurysmal wall consists of thin scarred myocardium ± clot, whereas the pseudoaneurysmal wall consists of adherent pericardium and clot (*stars*). The neck of the LV pseudoaneurysm is narrow; the neck/internal diameter ratio is <0.5 in pseudoaneurysm vs. >0.5, usually 0.8–1, in aneurysm (ratio of *double arrows*). The dyskinetic motion of the aneurysm is indicated by the *horizontal arrows*.

A minimal or small pericardial effusion is seen in up to a third of patients with MI.[180] *Pericarditis and pericardial effusion do not necessarily coincide*. Over half of pericarditis cases are not associated with any effusion; similarly, half of pericardial effusions are not inflammatory (no rub), and rather result from pump failure and transudation.[180]

1. *Diagnosis* – Pericarditis develops in the first few days of MI, most commonly the first or second day, and usually lasts a few days only. The pain is typically pleuritic, and radiation to the trapezius is characteristic. A fleeting rub may be heard. On ECG, a pattern of diffuse pericarditis with diffuse ST elevation is rare (<20%);[179] rather, pericarditis is localized to the infarcted area with ECG findings of localized ST elevation. The latter may simulate reinfarction or may be overshadowed by the pre-existing ST elevation. *The persistence of upright T waves or the reversal from inverted T waves to upright T waves very early after MI* is 100% sensitive for the diagnosis of pericarditis, but may also be seen with ischemia (normally, inverted T waves are seen a few hours after MI onset, and persist several days at least).[181]

2. *Treatment* – NSAIDs should not be used post-MI because of the risk of adverse LV remodeling and free wall rupture. High-dose aspirin (325–650 mg Q 6–8 h) may be used; alternatively, acetaminophen or colchicine may be used for this transient process.

The risk of hemorrhagic transformation of acute post-MI pericarditis is theoretical and very rarely reported. Thus, pericarditis should not alter the antiplatelet regimen and anticoagulation may be continued in patients who need it, with close monitoring. However, in the presence of a moderate or large effusion, anticoagulants are preferably discontinued (antiplatelet agents are usually continued).

B. Pericardial effusion

Small pericardial effusions (5–9 mm) are seen in 5% of STEMIs, usually appearing during the first 5 days and slowly resolving over several weeks.[182,183] A small pericardial effusion may be secondary to pericarditis or to pump failure and may be associated with an increase in long-term mortality. It is not usually associated with a free wall rupture unless it progresses to a moderate effusion, which happens in a minority of patients.[183] Echo surveillance is warranted even for a small effusion.

Moderate or large pericardial effusions (≥10 mm) were seen in 5% of STEMIs before the reperfusion era, and are probably less common in the PCI era. A moderate pericardial effusion, even if asymptomatic, is associated with an 8% risk of death from free wall rupture, which tends to occur over a week late.[183] While it may result from pump failure or pericarditis in some patients, a moderate pericardial effusion represents a sealed, subacute myocardial rupture with self-limited bleeding in a substantial proportion of patients. A large effusion with tamponade or pulseless electrical activity is usually due to free wall rupture and warrants emergent surgical repair. A moderate effusion, if diagnosed on a pre-discharge echo or in a symptomatic patient, warrants at least more prolonged monitoring, close echo surveillance, and potentially a cardiac MRI to diagnose impending rupture. Anticoagulation should be discontinued.

C. Dressler syndrome or post-cardiac injury syndrome

This nowadays rare syndrome is an inflammatory and likely autoimmune process related to anti-cardiac antibodies. It occurs 1–8 weeks after MI, and leads to fever, pericarditis, but also pericardial and pleural effusions. It is treated similarly to early post-MI pericarditis.

VIII. LV thrombus and thromboembolic complications

LV thrombus is most common in patients with anteroapical MI, with a 30–40% incidence in the pre-reperfusion era, down to 10% in the thrombolytic era and 5–10% in the PCI era.[184,185] It usually forms 3–6 days after MI, with at least 25% of thrombi forming in the first 24 hours;[185,186] however, a few thrombi form 1–2 weeks later. In addition to akinesis, the hypercoagulable state of STEMI promotes the formation of LV thrombi, particularly early LV thrombi. Severe global LV dysfunction is not a prerequisite for LV thrombus formation. LV thrombus may rarely form over a large inferoposterior MI.

In the absence of anticoagulation, LV thrombus is associated with a ~10–15% embolization risk (contrast this risk with the 1% stroke risk in STEMI patients without AF or LV thrombus).[187] In 2 old landmark analyses, nearly all embolic events occurred within 3 months of MI. Beyond this period, as LV aneurysm becomes chronic, the thrombus becomes organized and unlikely to embolize.[188–190] Some studies suggest that a mobile or a pedunculated thrombus bulging in the LV has a higher risk of embolization than a laminated, mural thrombus.[188–190] More importantly than the pedunculated morphology, AF, severe HF, severe LV dysfunction, and older age are associated with higher embolization rates.[184] Interestingly, the risk of late embolization beyond 3 months from a LV thrombus seemed greater with dilated cardiomyopathy than segmental apical aneurysm, likely because in the latter the segment adjacent to the thrombus is static and unlikely to dislodge the thrombus.

Echo is usually used for diagnosis. However, echo may give a false positive diagnosis because of side lobe artifacts or reverberations from the ribs. On the other hand, MRI studies have shown that echo frequently misses apical thrombi, in up to 50% of the cases, particularly when the thrombus is laminated/flat or when the echo plane does not cut through the true apex. Echo contrast improves the echo sensitivity to 64%. Delayed-enhancement MRI or cardiac CTA allows an accurate diagnosis and allows the distinction between thrombus and the underlying myocardial scar.[191]

Treatment – Warfarin anticoagulation almost abolishes the embolization risk.[185,187,191] In addition, warfarin allows intrinsic lysis of the thrombus or, at least, organization and endothelialization. In fact, ~60–80% of LV thrombi resolve within 6–12 months of anticoagulation, while the rest organize and become laminated. It is believed that an organized thrombus actually has beneficial effects, as it adheres to the dyskinetic apex preventing further infarct expansion and reducing the paradoxical myocardial motion by a plugging effect.

Thus, ACC guidelines recommend the use of warfarin for at least 3 months in patients with LV thrombus, as most emboli occur within 3 months of MI.[188–190]

Data and expert reviews suggest the following approach:[192–194]

i. Perform echo with contrast within 72 hours of an infarct; if the echo is negative but the patient has high-risk features (large apical akinesis/dyskinesis), echo with contrast is repeated at 2 weeks, and MRI/CTA is considered.
ii. If LV thrombus is found, warfarin or NOAC is given for 3 months, then echo is repeated at 3 months.
iii. Anticoagulation is continued beyond 3 months if bleeding risk is acceptable and: (a) LV thrombus persists and is mobile or pedunculated/protruding; or (b) severe apical dysfunction or HF persists, even if LV thrombus resolves. Otherwise anticoagulation is stopped at 3 months, then echo is repeated within 3 months later to detect LV thrombus recurrence, which occurs in ~15%.[192]

It is unclear whether dual antiplatelet therapy has any effect on LV thrombus, and thus, anticoagulation seems warranted on top of antiplatelet therapy, particularly for the first 3 months. NOACs have been used and have been found to be comparable to warfarin in several retrospective studies and over 3 small randomized trials, and are an acceptable alternative to warfarin in the ESC guidelines.[192,194–196]

IX. Early and late mortality after STEMI

Over half of the STEMI fatalities occur suddenly outside the hospital (VF). For patients who present to the hospital, the short-term mortality (30 days) is, on average, 4–5% for patients treated with primary PCI, 6–7% for patients treated with fibrinolytics, and ~11–12% for patients not treated with reperfusion therapy. This varies according to the risk criteria listed in Section 1.XII (Killip class and TIMI risk score), the ST-segment response to reperfusion therapy, and the coronary microvascular perfusion achieved with reperfusion therapy.

Afterward, the yearly mortality is 2–6% depending on the degree of LV dysfunction, the presence of HF, and the presence and extent of residual severe CAD.

The risk of sudden death is highest in the first 30 days after MI (1.2%), followed by a 1.2% sudden death risk per year.[108] The risk is higher in patients with HF or severe LV dysfunction (2.5–3%).

Note that NSTEMI has the same short- and long-term mortality as STEMI (but lower in-hospital mortality).[197]

Appendix 1. Out-of-hospital cardiac arrest: role of early coronary angiography and therapeutic hypothermia

Of 100 patients suffering out-of-hospital cardiac arrest (OHCA), ~30–40 are successfully resuscitated in the field with return of spontaneous circulation and reach the hospital. Of those 30–40, ~5–10 survive to hospital discharge (5–10% overall survival).[198] A better survival is seen in patients whose initial rhythm is VF/VT (22% survival to discharge). In patients with VF, the survival decreases by 7–10% for each minute of delay to defibrillation. The prognosis is very poor in patients with non-shockable rhythm: survival to hospital discharge 10% for PEA and 2% for asystole. Some patients with non-shockable rhythm develop VT/VF during the course of resuscitation, but they should still be considered as non-shockable rhythm for the purposes of prognosis and therapy.[199] Withholding resuscitation can be recommended in unwitnessed asystole cases (excluding hypothermia and near-drowning), but unwitnessed PEA may still be resuscitated, especially if EMS response time is <10 minutes.

Note about PEA: Primary PEA arrest (PEA as truly initial cardiac arrest rhythm) is sometimes caused by reversible metabolic causes/PE/tamponade/massive bleed (5H and 5T), in which case the PEA rhythm usually progresses from sinus tachycardia to bradycardia. But the most common cause is severe primary cardiac failure, whether from advanced HF or massive global primary myocardial ischemia (e.g., MI on top of prior LV dysfunction), cases in which the outcome is very poor.[200] Hence PEA is a common mode of death in patients with ICD,

whether primary PEA or post-shock PEA. The second most common PEA cause is likely a hypoxemia/respiratory event.[201] PEA may occur after VF shock, with a rhythm that is often wide and slow, and has a prognosis at least as bad as initial PEA (manifestation of end-stage pump failure after VT/VF has been terminated by a shock).

Prolonged VF progresses into asystole, not PEA. It may progress into PEA after shock, not spontaneously.[200]

A. Decision to perform immediate coronary angiography and role of post-resuscitation ECG

The large COACT trial randomized comatose patients with resuscitated OHCA, whose initial rhythm was VT/VF, and whose post-arrest ECG did not show STEMI (~70% of OHCA), to immediate coronary angiography vs. coronary angiography delayed until neurological recovery. The 90-day survival was similar in both groups (~60%).[202] There was no benefit of immediate coronary angiography, even though the trial selected patients with favorable features for neurological recovery, except for a Glasgow coma scale of 3 (mostly witnessed arrest, with only 2 minutes from arrest to basic life support, and 15 minutes to return of spontaneous circulation, pH 7.2). Importantly, while most patients had CAD (~65%), most of this CAD was chronic stable CAD (CTO 37% prior PCI or CABG in ~35%) and VT/VF was related to ischemic cardiomyopathy and old scars/infarcts rather than active ischemia; only ~5% of patients had acute thrombotic occlusion and ~15% had unstable coronary lesions. Another large trial, TOMAHAWK, confirmed this lack of benefit from immediate coronary angiography, which was conversely associated with a trend toward more death and severe neurological deficit; a culprit coronary lesion was identified in 39% of patients (Figure 2.15).[203–205]

In those 2 trials, immediate angiography failed to improve outcomes for 2 reasons: (i) CAD, when present, was mostly stable CAD, with only 5% acute occlusions; (ii) deaths were mostly related to anoxic brain injury (~65%) or multiorgan failure/sepsis (~12%), while cardiogenic shock and arrhythmias were responsible for only ~17% of deaths.

The initial neurological status, upon return of spontaneous circulation, is a strong determinant of survival. In patients who regain consciousness early on or who display response to pain or stimuli, the survival to hospital discharge with good neurological status is >90%.[205,206] ***Conversely, the prognosis is poor in patients who are totally unresponsive***, although up to 50% may recover if there are no other bad features, as in COACT/TOMAWK. ***The prognosis is very poor in patients who are missing multiple brainstem reflexes, or who display early generalized status myoclonus*** (or undifferentiated myoclonic jerks, albeit less specific for poor outcome than generalized myoclonus per ACLS guidelines).

In addition, **older age (>75–80), initial non-shockable rhythm, unwitnessed arrest or delayed initiation of cardiac compressions (>10 minutes), prolonged resuscitation before return of spontaneous circulation (>20 minutes, >3 doses of epinephrine required), and low pH < 7.2 indicate a poor likelihood of neurological recovery** and argue against immediate coronary angiography, particularly in the absence of ST elevation (ESC).[2,207] Proper cardiac compressions only provide ~20% of the normal cardiac output.

Overall, immediate coronary angiography is indicated in the following cases (ESC, SCAI 2020):[2,199]

- **Post-resuscitation ECG consistent with STEMI**. along with **3 features:** (i) patient maintains a stable BP on stable doses of pressors >20 minutes, with no recurrent cardiac arrests as soon as epinephrine wears off, as in TTM and TTM-2 trials; (ii) *persistence of ST elevation at >8–33 minutes after arrest* (not just ST elevation on the first post-arrest ECG); (iii) not many poor neurological predictors. *If multiple unfavorable predictors are present in a comatose patient, treatment is individualized, and coronary angiography may be deferred* (SCAI).

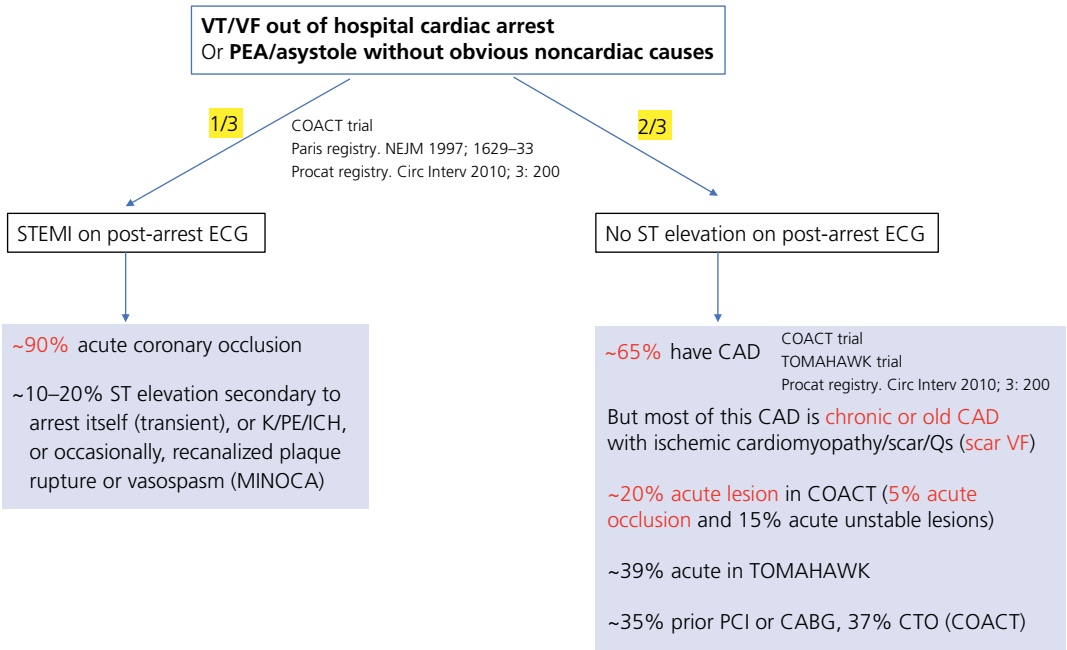

Figure 2.15 Prevalence of ST elevation, acute coronary occlusion, and CAD in patients with cardiac arrest and no obvious non-cardiac cause. ICH, intracranial hemorrhage.

- **In the absence of ST elevation**, quickly evaluate for non-cardiac causes (intracranial hemorrhage, respiratory failure, PE, sepsis), take into consideration Q waves (old scar?) and persistent pronounced ST depression (active ischemia?), and consider urgent echocardiography. **Coronary angiography does not need to be performed immediately**. It may rarely be considered in case of (a) profound and persistent ST depression with (b) persistent shock and (c) no poor neurological predictors.
- Consider urgent angiography in patients who are **awake and responsive** after cardiac arrest, even if there is no ST elevation. COACT and TOMAHAWK only randomized deeply comatose patients.

Note that, when indicated, immediate coronary angiography is performed in patients who are successfully resuscitated and whose systemic pressure is maintained on reasonable and stable doses of vasopressors. The performance of PCI in patients with no return of spontaneous circulation who are actively receiving chest compressions, using LUCAS external compression device, did not improve the grim mortality in several case series and was not recommended in an expert viewpoint.[198,208]

Note: 5–20% of patients with ST elevation on the immediate ECG after return of spontaneous circulation do not have acute coronary occlusion.[203–205] In those cases, ST elevation is related to a myocardial injury from the cardiac arrest itself, hyperkalemia, PE, or intracranial hemorrhage. One study has shown that ECG performed <8 minutes after return of circulation has 18.5% false positive rate (i.e., ST elevation with no obstructive CAD).[209] In this case, ST elevation is frequently transient and related to the global myocardial ischemia caused by the cardiac arrest, rather than causing the cardiac arrest. Performing the ECG at ≥8 and 33 minutes reduces the false positive rate to 7% and 5.8%, respectively.

B. Role of post-resuscitation echocardiography

Echo often shows LV dysfunction that is non-specific, as it may be secondary to acute ischemia but also post-cardiac arrest myocardial stunning or chronic cardiomyopathy. Echo may be more specific in some settings, particularly when segmental dysfunction is present: (i) segmental akinesis of a thin myocardium with Q waves and no ST elevation suggests an old infarct and a scar-related VF, rather than acute ischemia VF; (ii) segmental akinesis without Q waves suggests acute ischemia; (iii) preserved LV function with akinetic or dilated RV suggests massive PE; (iv) preserved cardiac function suggests non-cardiac cause of arrest, or, in a young patient, channelopathy.

C. Role of extra-corporeal membrane oxygenation (ECMO) in ongoing VF arrest

PCI is futile in patients who are actively undergoing cardiac compressions, but a select group of these patients with refractory VF arrest may qualify for emergent ECMO placement to provide organ and cerebral perfusion (in the emergency room or the catheterization suite), followed by PCI. This is considered in patients with: (1) witnessed VF arrest that is refractory to 3 shocks and amiodarone (may have evolved to PEA/asystole), (2) usually witnessed arrest with near immediate initiation of bystander resuscitation, (3) resuscitation ongoing for <45 minutes and estimated transfer from field to cath lab <30 minutes, and (4) young age (<75).[199]

D. No role for thrombolysis during the resuscitation of cardiac arrest

In patients undergoing cardiopulmonary resuscitation for an arrest of presumed cardiac origin, the administration of tenecteplase during resuscitation did not improve the 30-day survival, the return of spontaneous circulation, or the neurological outcome, and increased intracranial hemorrhage. During cardiac arrest, the poor systemic perfusion may preclude the delivery of the fibrinolytic agent to its target, explaining the lack of efficacy; also, frequently, there is no acute coronary thrombosis, or thrombosis is not totally occlusive. Bleeding, including intracranial hemorrhage, may be a cause of arrest in a small proportion of patients and is aggravated by thrombolysis.[210] However, after the return of spontaneous circulation in a patient with STEMI, fibrinolytics may be appropriate, as suggested by a small analysis.[211]

E. No clear role for Impella or other mechanical circulatory support in comatose post-cardiac arrest patients with shock (failure of IABP-shock and ECLS-shock trials). Impella may be considered in post-cardiac arrest patients with STEMI who are awake and responsive.

F. Temperature control or mild therapeutic hypothermia

Two old landmark trials of resuscitated post-cardiac arrest patients have shown that mild therapeutic hypothermia drastically improves survival with appropriate neurological recovery (49% vs. 26% in one trial, 55% vs. 39% in the other trial).[212,213] In the control group of these trials, the post-arrest temperature was close to 38 °C. Two later studies (TTM and TTM-2) demonstrated that the mere prevention of this post-arrest hyperthermia with a low normal temperature of 36 °C (TTM) or <37.5 °C (TTM-2) is as effective as a temperature goal of 33 °C, which was used in the 2 early trials.[214,215] Notably, even to achieve a temperature <37.5 °C, ~50% of patients required a cooling device in TTM-2.

Unconscious patients (Glascow coma scale <8) post-VT/VF arrest but also post-PEA and asystole qualify for temperature control, as in the TTM trials. They should have temperature control initiated as soon as possible after arrival to the emergency department, with a *temperature goal of 32–37.5 °C within 6 hours after return of spontaneous circulation*. The temperature is reduced by 0.5–1 °C per hour. In one of the trials, hypothermia was initiated as late as several hours after restoration of circulation, and the goal temperature was achieved at a mean of 8 hours (interquartile range, 4–16 hours).[213] However, hypothermia should not be initiated later than 6 hours, as there is probably no benefit beyond this point.

Hypothermia is achieved using ice packs, cold intravenous saline, or a cooling blanket with adjustable settings. The patient may be given paralytic agents to prevent the counterproductive shivering during induction of hypothermia. Paralytic agents are not usually necessary once the goal temperature is reached. Sedation is also administered. Hypothermia is maintained for 24 hours, then the patient is rewarmed very slowly, at a rate no faster than 0.5 °C per hour. Since the patient is sedated, the neurologic prognosis of patients undergoing hypothermia may not be properly assessed until 72 hours after rewarming.

During hypothermia, the patient is monitored for the following side effects:[216]

- Metabolic: hypokalemia (resulting from intracellular K shift), hyperglycemia, mild reduction of GFR, cold-induced diuresis. Hypokalemia should not be aggressively replaced, as severe hyperkalemia may occur during rewarming.
- Bradyarrhythmia, VT. Arrhythmias were more prevalent with hypothermia vs. normothermia in TTM-2.

The early initiation of hypothermia does not preclude the early performance of coronary angiography and PCI. The induction of hypothermia prior to or on arrival to the catheterization laboratory has been shown to be safe in several studies.[198] In fact, PCI should be performed urgently, and hypothermia started as soon as possible, preferably before the initiation of PCI (international consensus recommendation).[217] Antithrombotic therapies may also be used and have not significantly increased bleeding risk in hypothermic patients, but the patient should still be carefully monitored for bleeding.[216]

G. Hemodynamic status post cardiac arrest

Hemodynamic instability after a cardiac arrest may be secondary to myocardial infarction, myocardial stunning that results from the arrest itself, or post-cardiac arrest syndrome, which is a form of systemic inflammatory response syndrome (SIRS) with systemic vasodilatation similar to sepsis. Post-cardiac arrest syndrome is managed similarly to sepsis with an early goal-directed therapy. The SBP goal is usually >90 mmHg; one study has shown that targeting a higher mean BP of 77 mmHg vs. 63 mmHg after cardiac arrest did not improve mortality or neurologic recovery (BOX trial). Also, targeting a higher PaO2 (100 mmHg) vs. a lower PaO2 (70 mmhg) resulted in similar outcomes.[218] Initially, 1–2 liters of isotonic fluid is administered, followed by dopamine or norepinephrine.

H. Long-term ICD placement in survivors of VT/VF cardiac arrest, depending on post-arrest ECG and coronary angiographic findings (Figure 2.16)

Consider the following 3 possibilities:

1. Post-arrest ECG shows STEMI, and coronary angiogram shows acute coronary occlusion that gets recanalized: no indication for ICD.
2. Post-arrest ECG does not show ST elevation, while coronary angiography shows significant CAD that is >70% stenotic (this is the case of ~65% of VT/VF with no ST elevation): ICD is generally indicated, as VF is usually a scar-related VF rather than acute ischemia-VF.

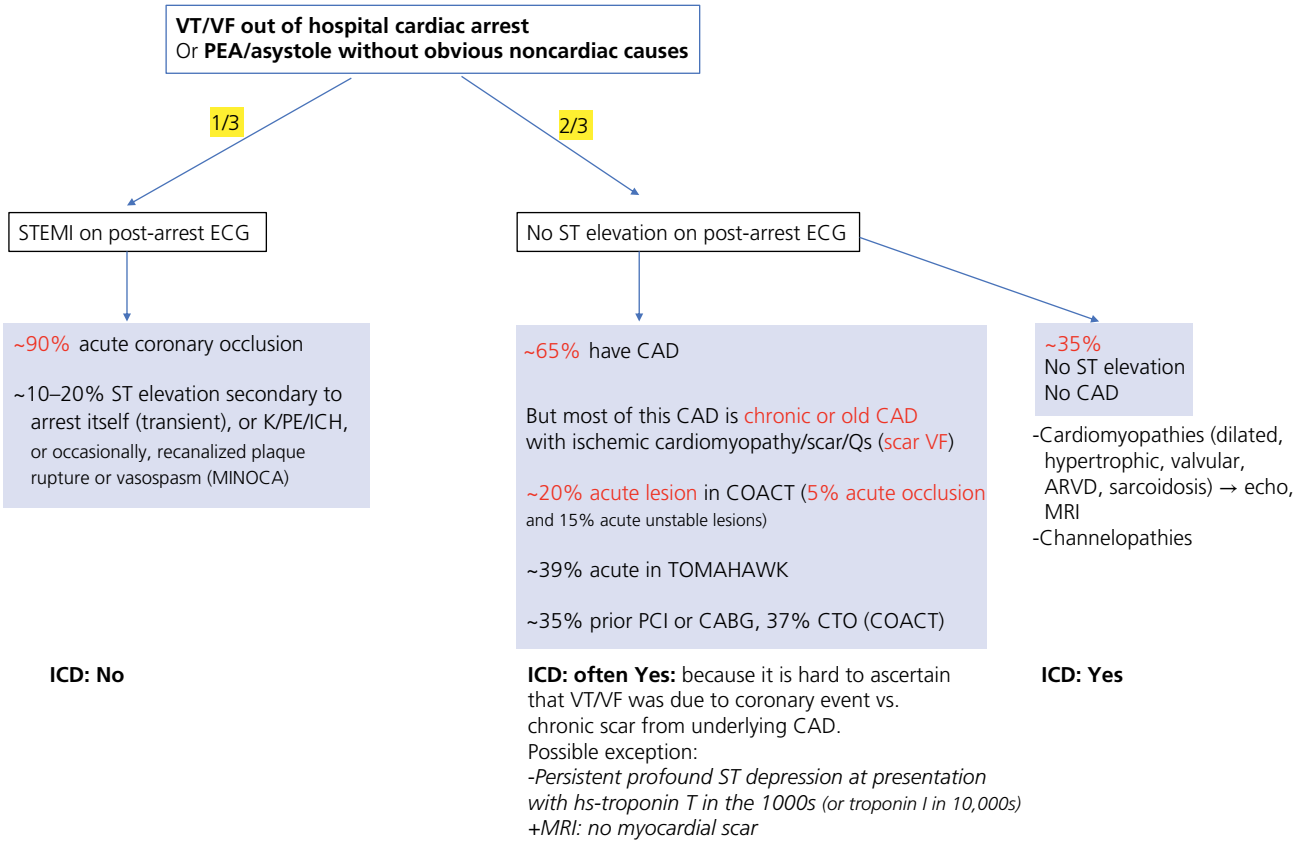

Figure 2.16 Long-term ICD placement in survivors of VT/VF cardiac arrest, depending on post-arrest ECG and coronary angiographic findings.

This is more readily the case if the patient has prior MI/scar with Q waves *or* if no acute total occlusion or acute thrombotic complex stenosis is found, including by IVUS. However, even if a coronary stenosis is deemed unstable and stented, it is hard to ascertain—in the absence of ST elevation—that VT/VF was due to acute coronary event vs. chronic scar from underlying CAD. Only the following combination may suggest that indeed an acute coronary event caused VT/VF and that ICD may not be needed (if CAD is properly revascularized):

- *Post-arrest ECG showed persistent profound ST depression along with hs-troponin T in the 1000s*.
- *Complex culprit stenosis (by angiogram or IVUS) is identified and treated*.
- *MRI does not show myocardial scar*.

3. Post-arrest ECG does not show ST elevation, and coronary angiography shows no significant CAD: VT/VF in this case is due to either: (i) chronic cardiomyopathy (dilated, hypertrophic, or valvular cardiomyopathy, or ischemic cardiomyopathy that has been previously revascularized, or ARVD, sarcoidosis); (ii) channelopathies. Either way, ICD is warranted in this case.

QUESTIONS AND ANSWERS

Question 1. A 52-year-old man presents to a non-PCI hospital with 2 hours of chest pain. His ECG shows anterior ST-segment elevation. His blood pressure is 109/67 and his heart rate is 105. He has no known contraindication to thrombolysis. The closest PCI hospital is 90 miles away and no community transfer system is in place. The best reperfusion strategy for this patient is:

A. No administration of thrombolysis. Transfer for primary PCI
B. Immediate thrombolysis and immediate transfer to a PCI hospital for consideration of routine early PCI within 24 hours of presentation or for rescue PCI if thrombolysis fails
C. Immediate thrombolysis. Transfer to the PCI center only if thrombolysis fails at 90 minutes after starting therapy
D. Administer aspirin, heparin and clopidogrel 300 mg before transfer
E. B and D
F. C and D

Question 2. A 49-year-old man presents with progressive dyspnea over the last week. He recalls having 2 hours of mild chest discomfort and nausea 10 days ago. No chest pain is currently reported. His ECG shows anterior Q waves with 1 mm ST elevation and T inversion. The exam and X-ray suggest pulmonary edema. The echo shows anteroapical akinesis and thinning. Besides diuresis and medical therapy, what is the appropriate management?

A. Coronary angiography emergently
B. Coronary angiography is not urgent but should be performed before discharge. Attempt to open an occluded LAD
C. Perform stress SPECT before discharge, then perform coronary angiography if there is evidence of severe ischemia
D. Test for viability of anterior wall. If viable, perform coronary angiography and attempt to open an occluded LAD

Question 3. A 76-year-old female presents with 2 hours of chest pain to a non-PCI hospital. The closest PCI hospital is 100 miles away. ECG shows anterior ST-segment elevation. BP = 170/85, weight 62 kg. She has not had any recent bleed, surgery, fall, or history of stroke. A recent hemoglobin is 12 g/dl. What is the next step?

A. Administer fibrinolytics then transfer for routine early PCI
B. Do not administer fibrinolytics, transfer for primary PCI

Question 4. A 72-year-old man presents with 3–4 hours of chest pain and respiratory distress. BP = 80/60, heart rate = 120. He is intubated by paramedics and transferred to a non-PCI-capable hospital. ECG shows 5 mm ST elevation anterior leads. The closest cath lab is 3 hours away. What is the next step?

A. Emergent transfer for PCI; thrombolysis is not helpful in cardiogenic shock
B. Thrombolysis and emergent transfer for PCI
C. IABP and emergent transfer
D. Thrombolysis, IABP, and emergent transfer for PCI

Question 5. The patient in Question 4 arrives to the cath lab. He still has ST elevation and is in shock. He is found to have thrombotic 100% proximal LAD, CTO of mid RCA, and 80% stenosis of mid LCx. What is the next step?

A. PCI of LAD only
B. PCI of LAD and LCx
C. PCI of LAD initially. If no hemodynamic improvement, proceed with PCI of LCx
D. Emergent CABG

Question 6. A 68-year-old man presents with inferior and lateral STEMI. He undergoes primary PCI of a large, thrombotic, codominant proximal LCx. While he has been doing well, he suddenly develops near syncope on day 2. BP 70/40, pulse 35, and no murmur is heard. ECG shows sinus bradycardia with re-elevation of ST segments in the inferior leads. What is the most important next step?

A. Immediate coronary angiography ± PCI
B. Immediate echocardiography
C. Immediate placement of a transvenous pacemaker

Question 7. A 57-year-old man presented with anterior STEMI and received primary PCI of the proximal LAD at 16 hours after pain onset. At day 3, the patient is doing well, ambulating without angina and no HF on exam. He had an asymptomatic 14-beat run of NSVT. At day 4, a pre-discharge echo is performed and shows a large area of anterior akinesis with LVEF 25%, mild MR, and moderate size (1 cm) pericardial effusion. What is the next step?

A. Discharge home on ACE-I, carvedilol, spironolactone, statin, aspirin/plavix, and check echo in 40 days. If EF <35% → ICD
B. Discharge home on ACE-I, carvedilol, statin, aspirin and plavix, and check echo in 40 days. If EF <35% → ICD
C. Monitor the patient in the hospital for a longer period of time, repeat echo next day and obtain cardiac MRI.
D. Discharge home on ACE-I, carvedilol, statin, aspirin/plavix. Place a LifeVest and then ICD at 40 days if EF <35%

Question 8. A 64-year-old man presents with anterior STEMI, BP 105/75, pulse 110, and bibasilar crackles. He is found to have occluded LAD and mid RCA 80%. What is the next step?

A. Perform multivessel PCI at the time of primary PCI
B. Perform culprit PCI only. Plan for elective PCI of RCA only if the patient has residual angina
C. Perform LAD PCI, then plan for elective RCA PCI before home discharge, regardless of symptoms
D. Perform LAD PCI, then plan for elective RCA angiography before home discharge, then RCA PCI if appropriate, regardless of symptoms

Question 9. A 70-year-old female had chest pain 3 days previously. The chest pain resolved after 8 hours. She has syncope on the day of presentation and is currently dizzy and dyspneic. BP 80/60, pulse 30 bpm. ECG shows complete AV block with ventricular escape rhythm, and ST elevation concordant with the wide QRS in the anterolateral leads. She has bibasilar crackles and is hypoxic. What is her 30-day mortality?

A. <10%
B. 20%
C. 50%

Question 10. For the patient in Question 9, a temporary pacemaker is placed. Her BP improves to 110/70, and she is not dizzy anymore. She is dyspneic at rest with bibasilar crackles on exam. What is the next step, besides starting diuretics?

A. Take urgently to the cath lab for PCI of LAD
B. Perform coronary angiography after HF improves
C. Perform stress testing after HF improves, to assess for residual ischemia

Question 11. A 66-year-old man presents with chest pain that has lasted 3 hours earlier today and has now resolved. His ECG shows subtle ST elevation (<1 mm) in leads II, aVF and in leads V_5 and V_6, and inferior Q waves. Should he undergo emergent reperfusion?

A. No emergent reperfusion
B. Emergent reperfusion with PCI
C. Emergent reperfusion with thrombolysis
D. B or C

Question 12. A 50-year-old woman presents with a persistent, mild chest pain for the last 6 hours. Chest pain fully resolves after nitroglycerin administration. The ECG performed after pain resolution is shown (Figure 2.17). What is the next step?

A. Perform coronary angiography/PCI next day (not urgent anymore)
B. Perform emergent reperfusion, whether with thrombolysis or PCI
C. Obtain serial troponin levels, as the ECG is not definite for MI

Figure 2.17

Figure 2.18

Question 13. A 72-year-old man presents with waxing and waning episodes of resting chest pain for the last 10 hours. Chest pain is reproducible with palpation and the patient does not appear to be in distress. He is not actively having chest pain. The first troponin is 0.03 ng/ml. ECG is shown (Figure 2.18). What is the next step?

A. Emergent reperfusion with PCI
B. Emergent reperfusion with thrombolysis
C. Follow serial cardiac markers (ECG non-diagnostic)
D. Initiate antiplatelet therapy, heparin, and NTG and perform non-urgent coronary angiography (next day)

Question 14. A 66-year-old woman presents with anterior STEMI. She receives thrombolysis at a non-PCI hospital, with resolution of chest pain and >50% resolution of ST elevation. She had a mild degree of pulmonary edema on admission, which quickly responded to diuresis. Echo shows severe anterior hypokinesis with LVEF of 35%. Three days later, she is able to ambulate without chest pain and with a mild degree of dyspnea. What is the next step?

A. Coronary angiography
B. Treadmill nuclear imaging (modified Bruce protocol)
C. Pharmacological nuclear imaging
D. Continue medical therapy without any further intervention

Question 15. A 67-year-old man presents with chest pain that started 45 minutes ago. His ECG shows 5 mm anterior ST elevation with ample T waves and no Q waves. His BP is 130/75, pulse is 105 bpm. He can be transferred for PCI with a DTB <90 minutes. Which reperfusion strategy achieves the lowest mortality?

A. Primary PCI
B. Thrombolysis
C. Thrombolysis followed by routine PCI 3–24 hours later
D. Any of the above

Question 16. A patient presents with chest pain. ECG shows a new LBBB, severe discordant ST elevation in the anterior leads (>25% of S wave) and concordant ST elevation in the lateral leads. Which statement is incorrect?

A. The left bundle receives dual arterial supply, hence LBBB rarely occurs in STEMI
B. LBBB implies a high-risk STEMI with extensive infarction and extensive CAD
C. LBBB is associated with 3–4 times higher mortality and a more drastic benefit from reperfusion
D. LBBB is associated with increased mortality only when persistent
E. A new LBBB is associated with a higher mortality than a new RBBB
F. A new RBBB is usually seen with LAD-related infarct

Question 17. Which statement is incorrect?

A. LV pseudoaneurysm has a neck to internal diameter ratio <0.5 (vs. >0.5 in LV aneurysm)
B. LV pseudoaneurysm may be characterized by to-and-fro flow on Doppler and a murmur on exam (not present with aneurysm)
C. MRI may help differentiate pseudoaneurysm from aneurysm in equivocal cases
D. Left ventriculogram does not help differentiate pseudoaneurysm from aneurysm
E. Post-MI pericarditis often occurs in the 1st or 2nd day and implies a large MI
F. A persistently upright T wave (lack of T inversion) or a reversal of T wave from an inverted to an upright position is 100% sensitive for post-MI pericarditis

Question 18. A 68-year-old man presents with chest pain. He is dizzy and weak. Blood pressure is 80/55 and pulse is 55 bpm. JVP is 5 cmH_2O and lungs are clear. ECG shows sinus rhythm with 2:1 AV block and a ventricular rate of 55 bpm, along with inferior ST elevation. What is the immediate next step?
A. IV fluids
B. IV fluids + dopamine
C. IV fluids + atropine
D. Atropine + transvenous pacing + IV fluids
E. Primary PCI
F. IABP followed by primary PCI

Question 19. The patient in Question 18 receives atropine and a fluid bolus. AV conduction improves and heart rate is 100 bpm. He remains hypotensive and dizzy. Peripheral O_2 saturation is 94% on ambient air. No murmur or thrill is present. What is the most likely diagnosis?
A. RV MI shock
B. Mechanical complication (papillary muscle rupture or ventricular septal rupture)
C. LV shock from an isolated inferior MI
D. LV shock from inferior MI extending to the lateral wall or inferior MI associated with an old anterior MI

Question 20. The patient in Question 18 now has a JVP of 11 cmH_2O. What is the next step?
A. Norepinephrine
B. Administer another 500 ml IV fluid bolus. If he remains hypotensive, add norepinephrine
C. Primary PCI
D. IABP followed by primary PCI
E. A + C
F. B + C
G. A + D

Question 21. With the administration of more fluids, the patient in Question 18 now develops arterial desaturation (85%), which is minimally responsive to supplemental O_2. His lungs are still clear and no murmur is heard. What is the most likely cause?
A. Ventricular septal rupture
B. Patent foramen ovale
C. Severe MR
D. LV failure

Question 22. A 67-year-old woman had severe nausea 2 days ago. This was followed by dyspnea and cough. On presentation, she is hypotensive (90/45 mmHg) and has respiratory distress with lung crackles and orthopnea. A holosystolic mumur is heard with S3 and without a thrill. ECG shows lateral ST elevation of 1 mm in leads I and aVL. She later develops fever. What is the most likely diagnosis?
A. Cardiogenic shock from extensive infarction
B. RV shock
C. Posterior papillary muscle rupture
D. Anterior papillary muscle rupture
E. Septic shock
F. C + E
G. D + E

Question 23. A 65-year-old man had anterior STEMI 4 months ago. He received primary PCI. EF was 25% with apical akinesis and LV thrombus. He was placed on warfarin + clopidogrel. Repeat echo shows EF 45% and improvement of apical function (it is now hypokinetic). LV thrombus has resolved. Will you stop his anticoagulation (Yes/No)? Was NOAC an alternative to warfarin (Yes/No)?

Question 24. A 67-year-old man presents with generalized malaise and chest discomfort for ~16 hours. ECG shows inferior ST elevation with no significant Q waves. He undergoes PCI of an occluded RCA; post-PCI ECG is unchanged. ~36 hours after PCI, he develops the rhythm shown in Figure 2.19. After successful defibrillation, the repeat ECG remains unchanged, with unchanged ST segments. The patient denies any chest pain or dyspnea. Echo shows inferolateral akinesis with EF ~40%. Besides amiodarone, how should this patient be treated on discharge?
A. No ICD or LifeVest or repeat coronary angiography
B. Urgent coronary angiography. Long-term treatment depends on findings
C. LifeVest
D. ICD
E. VT ablation

Answer 1. E. The patient has an expected DTB >120 minutes, which justifies thrombolysis. This is even more paramount when the patient is presenting within 3 hours, or has high-risk features: anterior STEMI, tachycardia >100 bpm, SBP <100, Killip ≥2 (crackles). The current standard of care for every STEMI patient receiving thrombolysis is to immediately transfer for rescue PCI (if thrombolysis fails) or for systematic coronary angiography and PCI 3–24 hours later (even if thrombolysis succeeds, the so-called pharmacoinvasive strategy).

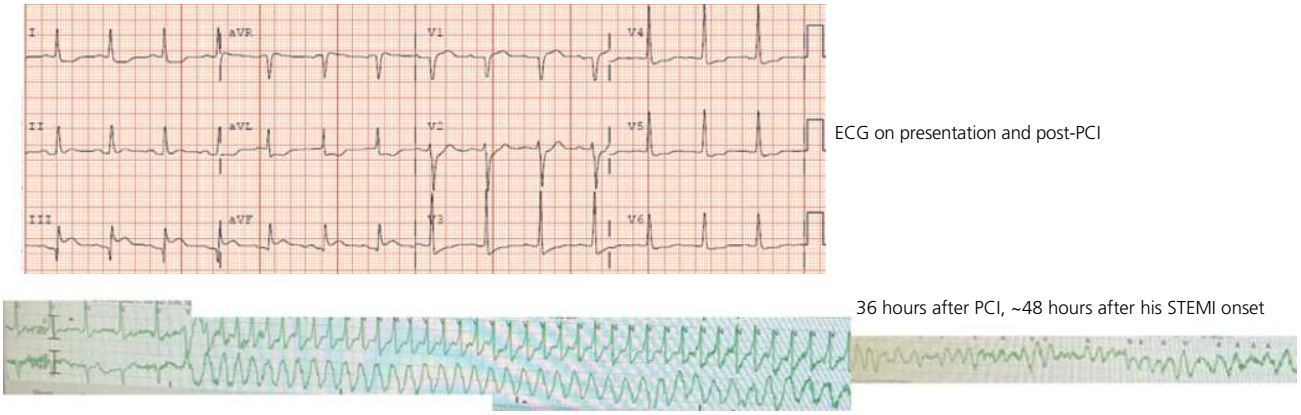

Figure 2.19

Answer 2. C. This is a patient presenting with Q-wave MI >24 hours after MI onset without residual angina. Stress test may be performed and followed by angiography ± revascularization in the presence of severe residual ischemia in the infarcted territory. Alternatively, angiography may be performed first (class II): (i) if left main or 3-vessel CAD is found, CABG may be considered on a non-urgent basis (>3–7 days after MI); (ii) if the culprit is not totally occluded, PCI may be performed (class IIb); (iii) if the culprit is totally occluded, PCI should not be immediately performed. In the latter case, stress testing may be performed *if the infarct wall is not akinetic*, and the patient brought back for PCI if severe ischemia is present. Viability is different from ischemia. It is important to document that the wall is ischemic with stress, not just viable. A moderate viability without documented ischemia is not a clear indication to revascularize. Ischemia is documented clinically (angina), by ECG (ST depression), or by reduction of nuclear uptake at stress.

Answer 3. B. This patient has a combination of 4 features (elderly small woman with HTN). The combination predicts >4% risk of intracranial hemorrhage with fibrinolytics.

Answer 4. D. Thrombolysis improved survival in the medically treated arm of the SHOCK trial and in all arms of the SHOCK registry. The insertion of IABP was part of the protocol of the SHOCK trial and was associated with better outcomes in the SHOCK registry (although recent data question its benefit).

Answer 5. A or D. In the SHOCK trial, patients with complex multivessel CAD more frequently underwent CABG than PCI. CABG was associated with the same survival as PCI, despite the higher prevalence of extensive CAD. PCI is reasonable at institutions where CABG cannot be promptly performed, which is commonly the case. Culprit-only PCI is performed; multivessel acute PCI is not advised in cardiogenic shock (CULPRIT SHOCK trial).

Answer 6. B. The presentation is consistent with free wall rupture. Stent thrombosis is a second possibility. Echocardiography is immediately followed by pericardiocentesis and surgical correction if the diagnosis of myocardial rupture/tamponade is confirmed.

Answer 7. C. A moderate pericardial effusion is concerning for a sealed cardiac rupture (in at least 8% of the cases) and warrants further observation and MRI if possible. Late NSVT, while carrying a worse prognosis, does not, per se, change management and does not dictate earlier ICD or LifeVest placement.

Answer 8. D. Non-culprit lesions are revascularized even in the absence of angina. They are revascularized before discharge or within 45 days, as per COMPLETE trial; pre-discharge PCI is preferred in patients with critical disease or angina at mild exertion. Non-critical lesions may improve on subsequent angiograms as the vasospastic component improves (J Am Coll Cardiol 2002; 40: 911–16); thus, before elective revascularization of these lesions in asymptomatic patients, the lesion is reassessed on repeat angiography and non-culprit FFR may be performed.

Answer 9. C. In anterior MI, AV block indicates extensive anterior infarction. The patient likely has multivessel disease preventing collateral supply to the left bundle. In the pre-reperfusion era, the mortality of complete AV block in anterior MI was ≥50%. Also, a shock that persists with pacing (Killip IV) portends a mortality of ≥50%.

Answer 10. B. Cardiogenic shock or massive HF qualifies for emergent reperfusion regardless of the time of presentation, as long as it is not purely secondary to bradyarrhythmia (a purely bradycardic shock was excluded from the SHOCK trial). Massive HF is defined as Killip class III, i.e., massive pulmonary edema frequently requiring mechanical ventilation. Since the patient's shock resolved with pacing and since she does not have massive HF, there is no indication for emergent PCI >24 hours after the infarct. However, as in any late STEMI >24 hours, she qualifies for coronary angiography after diuresis and stabilization (non-urgently, e.g., after 24 hours of diuresis) (ESC): a total occlusion does not benefit from late PCI, later than 24–48 hours (OAT trial), but a subtotal occlusion or extensive 3-vessel or left main disease may benefit from late revascularization.

Answer 11. B. STEMI may be over 12–24 hours old, at a stage where ST-segment elevation is resolving but has not fully resolved yet (close to phase 3). Alternatively, STEMI may be more recent with ongoing or resolving ischemia. This patient does not qualify for fibrinolytics, as ST elevation is <1 mm and the occlusion duration is questionable, but qualifies for primary PCI if the discomfort is ongoing, or if the discomfort occurred within the last 24 hours, even if it is not ongoing.

Answer 12. B. The ECG shows persistent ST elevation in leads V_1–V_4. ST elevation is barely 2 mm, but the morphology is typical of STEMI (terminal T inversion, reciprocal ST depression in I–aVL, and lack of alternative explanation of the mild ST elevation in V_1–V_3, i.e., no LVH/LBBB). Even if chest pain resolves, a persistent ST elevation along with a presentation <12 hours qualifies the patient for primary PCI or thrombolysis.

Answer 13. A. The ECG shows subtle signs of inferior, lateral, and posterior ST elevation injury. In fact, the isolated ST depression in leads V_1–V_3 implies posterior ST elevation. The ST segment is minimally elevated in the inferior leads and in leads V_5 and V_6 (~0.5 mm), but has a strikingly convex morphology with a wide hyperacute T wave, particularly evident on the aberrant beat. Also, reciprocal ST depression is seen in lead aVL. All this confirms that the ECG, while subtle, is definitely consistent with ST elevation injury. Being <1 mm, thrombolysis is not justified. Emergent PCI is warranted even if pain resolved (presentation within 24 hours). In reality, this patient was not emergently reperfused, his troponin ended up peaking at 76 ng/ml, and he was found to have subtotal OM occlusion.

Answer 14. A. The patient would have best been treated with early coronary angiography and PCI at 3–24 hours after thrombolysis. Beyond 24 hours, coronary angiography may still be performed (class IIa), even in the absence of recurrent pain or massive HF (the patient only had transient HF on admission). Stress testing is an alternative that is not mentioned in the ACC guidelines and is only briefly mentioned as an alternative to coronary angiography in the 2017 ESC guidelines; exercise testing would be preferred.

Answer 15. D. In the first 3 hours of STEMI, especially the first hour, and in the absence of shock, the mortality reduction with thrombolysis is likely equivalent to that of primary PCI, provided that rescue PCI is performed if needed (CAPTIM, PRAGUE [<3 hours subgroup], STREAM trials). If thrombolysis is used as a primary revascularization strategy, outcomes are improved when thrombolysis is followed by routine early PCI (further reduction of recurrent MI in comparison to thrombolysis alone).

Answer 16. E. Both new LBBB and RBBB are associated with a similarly increased mortality. A transient LBBB or RBBB is not associated with increased mortality.

Answer 17. D.

Answer 18. C. The patient is in shock, which is aggravated by the inappropriate heart rate. In shock, compensatory tachycardia is expected, but the 2:1 AV block is cutting the patient's ventricular rate in half. In the first 24 hours of inferior MI, AV block is responsive to atropine. In the context of inferior MI, hypotension with clear lungs suggests hypovolemia or RV shock, so fluid administration is appropriate. Those simple measures are performed while PCI is being arranged.

Answer 19. A. The patient has shock with clear lungs and no hypoxia, which suggests RV shock. Inferior MI does not usually lead to LV shock, unless a mechanical complication occurs or the inferior MI is associated with posterolateral extension or an old anterior MI. The exam does not suggest LV failure or mechanical complication.

Answer 20. F. The most definitive therapy of RV shock is primary PCI. Simultaneously, IV fluids are administered. In acute RV failure, the RV is small and non-compliant, in a way that JVP of 10–14 mmHg (13–18 cmH_2O) was associated with the best stroke volume in one study. Stroke volume universally declined when RA pressure exceeded 14 mmHg. If JVP is elevated and the patient is unresponsive to a fluid challenge, norepinephrine therapy is appropriate (preferred to dopamine). In RV shock, IABP is warranted if high-dose pressors are required despite reperfusion or if LV failure is concomitantly present.

Answer 21. B. Clinically, the patient does not appear to have pulmonary edema. His hypoxemia is likely due to an underlying, previously innocent PFO. With RV failure and fluid resuscitation, the RA pressure rises and causes exaggerated flow through the PFO and a right-to-left shunt with hypoxemia refractory to O_2.

Answer 22. G. The patient's nausea represents the true onset of MI (angina-equivalent). Her shock 2 days later is due to a papillary muscle rupture. It is likely that the anterior papillary muscle is ruptured in this patient with non-inferior MI (likely LCx-related MI). The anterior papillary muscle is supplied by both the LCx and the LAD (usually first diagonal); an LCx-related MI may lead to papillary muscle rupture if the LAD also has an underlying stenosis. The infarct associated with papillary muscle rupture may be small, as in this case. The wide pulse pressure and the fever suggest an associated vasodilatory or septic shock, which is seen in 25% of post-MI cardiogenic shock. In this patient, echo is subsequently performed and shows rupture of the anterolateral papillary muscle (echodense mass attached to the leaflets) with flailing of both leaflets and both a central and a posterior jet. SVR is low (~600–700) and cardiac index relatively high, despite MR (~4 L/min/m^2), confirming an associated vasodilatory/septic shock.

Answer 23. Yes, it is reasonable to stop anticoagulation. The risk of embolization, even with persistent LV thrombus, is low after 3 months. Anticoagulation is suggested beyond 3 months if: (a) LV thrombus persists and is mobile or protruding, or (b) severe apical dysfunction or HF persists, regardless of persistent LV thrombus. NOAC could have been used instead of warfarin, based on several retrospective studies and small randomized trials.

Answer 24. A. The patient has persistent ST elevation after PCI (<50% resolution). Even though he has not developed Q waves in II and aVF, the recovery of his inferior wall is unlikely in light of the persistent ST elevation. Persistent ST elevation after PCI is at least as bad and likely worse than Q waves; usually Q waves are present as well, but not always (33% of OAT late presenters did not have Q waves). He developed monomorphic VT ~48 hours after MI, which degenerated into VF. **Monomorphic VT typically results from a scar and is not due to acute ischemia** (ACC guidelines). Conversely, **direct VF after PVC or polymorphic VT may reflect either acute ischemia *or* a scar: acute ischemia would be suggested by profound ST abnormality on the ECG or a timing <48 hours post-STEMI.**

His late presentation, the persistent ST elevation, and the monomorphic VT morphology suggest early scar formation in the inferior wall. He does not display signs of acute ischemia: ECG ST elevation is unchanged, no angina, and troponin continues to trend down. Repeat angiography is not mandatory. He requires long-term ICD placement for late, monomorphic scar VT. VT ablation is an adjunctive therapy for scar VT that continues to recur despite amiodarone (VANISH-2 trial, Chapter 9).

Questions and answers 113

I. Causes of angina and pathophysiology of coronary flow

A. Angina caused by fixed coronary obstruction

Coronary blood flow constitutes ~5% of the total cardiac output and may increase up to 5 times with exercise. Normally, the coronary microcirculatory resistance constitutes the only resistance to myocardial flow; the epicardial vessels are just conductance vessels that offer no resistance to myocardial flow. In the presence of a functionally significant stenosis, classically a 70% diameter stenosis, the trans-stenotic flow drops during exertion; at a 90% diameter stenosis, the trans-stenotic flow drops at rest. During exercise or adenosine infusion, extensive microvascular dilatation occurs, requiring an extensive increase in flow to fill the dilated circulation; since the flow cannot increase across a flow-limiting stenosis, ischemia occurs.[1] Ischemia is driven by the combined severity of both: *(i) coronary stenosis, and (ii) microcirculatory impairment*. For a given stenosis, a more dilated, expansile microcirculation maximizes achievable flow and *attenuates angina*.

Supply ischemia is typically caused by ≥50% diameter stenosis of the left main coronary artery or ≥70–80% diameter stenosis of the major epicardial vessels. However, a 50–80% stenosis may be functionally significant, i.e., may impede maximal coronary flow during stress. The functional significance of a fixed lesion depends not only on the luminal narrowing, but also on:[1]

- The size of the territory supplied by the vessel: a 50% proximal LAD stenosis is more likely to be significant than a 50% diagonal or distal LAD stenosis. A larger flow translates into a larger percentage of flow drop across the stenosis.
- Lesion length, as resistance across a stenosis correlates with (viscosity × length)/radius^4 (Poiseuille law).
- Impaired microvascular dilation, which worsens ischemia but lessens the relative contribution of the stenosis to ischemia.
- Degree of coronary distensibility at the lesion site. As such, for the same luminal stenosis, a large necrotic core or positive remodeling increases the functional significance.[2]

Therefore, stress imaging may be useful to assess the functional significance of a borderline lesion. Also, in the cath lab, fractional flow reserve (FFR), i.e., the relative drop in flow across a lesion, may be invasively measured. FFR consists of assessing the pressure drop across a lesion using a coronary pressure wire; this pressure drop corresponds to a flow drop in patients with maximal microcirculatory hyperemia that exhausts autoregulation (flow = pressure/microvascular resistance). A flow drop ≥20%, i.e., FFR flow ratio ≤0.80, implies functional significance. In the FAME trial of multivessel PCI, 35% of 50–70% stenoses, 80% of 70–90% stenoses, and almost all stenoses >90% were functionally significant (FFR ≤0.80).[3] This highlights the limitations of angiography even for stenoses of 70–90%. ISCHEMIA trial used **≥80% cutoff** for stenting a lesion without the use of FFR or ischemia on stress imaging; it mandated functional significance by FFR or stress imaging for stenting lesions **50–80%**.

B. Vasospastic angina (Prinzmetal angina) or dynamic coronary obstruction

It was initially hypothesized by Prinzmetal and then demonstrated in an old series that vasospasm and vasospastic angina often occur *at the site of a significant atherosclerotic obstruction in patients with significant CAD*.[4,5] CAD was not only significant but frequently unstable.[5] Later reports suggest that ***vasospasm is also a common diagnosis in patients with angina and no significant CAD***, men or women.[6] Even in patients with normal or near-normal coronary arteries, atherosclerosis is documented at the site of vasospasm, and, in fact, vasospasm correlates with the burden of atherosclerosis and lipid-rich plaque at this site.[7,8] Vasospasm may be related to vasoconstrictors released by platelets and leukocytes at the atherosclerotic site, or endothelial dysfunction and abnormal vasomotor response induced by atherosclerosis.[7] Paradoxical vasoconstriction may occur during exercise, adrenergic stimulation (stress), or cold exposure. Approximately 40–50% of patients only have symptoms at rest without exertional limitation, sometimes in a cyclic nocturnal pattern.[5] On the other hand, many patients have exertional angina, whether from the CAD itself or from the exertional vasospasm, and some patients only have exertional angina.[6] Vasospastic angina is classically more severe than fixed-threshold angina, as the episodic obstruction is totally or subtotally occlusive, with more frequent arrhythmia, high-grade AV block, or syncope during the episodes. While characteristically more common in women, some series suggest that vasospasm is as common in men.[9,10]

C. Angina secondary to severely increased demands

This is seen with severe LV hypertrophy, severe HTN, valvular heart disease, HF, marked tachycardia, or metabolic disorders (anemia or hyperthyroidism). Some of these patients have underlying significant CAD, but many do not, angina being completely explained by the severely increased demands.

Note on coronary flow physiology

Because of systolic compression of the microcirculation, the LV receives blood mainly during diastole (>80% of the left coronary flow occurs in diastole). Tachycardia, in addition to increasing O_2 demands, reduces myocardial O_2 supply by reducing diastolic time.

As opposed to the LV, the RV is thin and does not compress its microcirculation as much in systole, which explains why its flow is not as affected by systole. Approximately 50% of the right coronary-to-RV flow occurs in systole.

The LV coronary blood flow is directly related to the pressure gradient between DBP and LVEDP (coronary perfusion pressure) and inversely related to the microvascular resistance; the latter depends on myocardial stiffness, and, thus, on LVEDP as well (flow = delta pressure/microvascular resistance). An increase in LVEDP reduces coronary flow, even in the absence of a coronary stenosis.

Since the RV receives significant flow during systole, the coronary blood flow of the RV is partly related to the gradient between SBP and RV systolic pressure, not just DBP and RVEDP.

II. Diagnostic approach

A. Clinical features of typical angina

Typical angina is characterized by three features (Rose angina and ORBITA-2 trial):

1. Retrosternal or epigastric discomfort; neck/jaw/arm pain.
2. Occurrence with physical exertion (ROSE mandates effort as the stressor).
3. Quick relief by rest or nitroglycerin (within 30 seconds to 5 minutes). A prolonged pain (>20 minutes), or a delay to relief with rest or nitroglycerin (>10 minutes) usually implies 1 of 2 extremes: acute MI or non-cardiac pain.

Angina is precipitated by walking uphill, in the cold, or after a meal.* Nausea or diaphoresis during pain increases the likelihood of angina. *Postprandial angina* is often a marker of severe, sometimes multivessel CAD. As opposed to biliary colic or peptic ulcer disease, angina occurs immediately after the meal and is *exacerbated by postprandial physical activity*. *Nocturnal angina* may imply severe CAD vs. vasospasm; the increased venous return in the recumbent position increases O_2 demands and triggers ischemia in patients with critical, sometimes multivessel, CAD. *Chronic resting chest pain* without an exertional component is not usually angina, but may occasionally be

*Cold leads to vasoconstriction (afterload increase) and shivering, increasing O_2 demands. The severity of angina is classified using the Canadian Cardiovascular Society grading (CCS). CCS IV is angina with minimal activities, CCS III is angina at a low level of activity, such as walking 1 flight of stairs or 1–2 flat blocks at a normal pace, CCS II is angina with walking more or at a faster pace, and does not usually occur daily, and CCS I is angina with strenuous lifting or running.

vasospastic angina, with or without underlying CAD (although many of the latter patients also have exertional angina). *"Warm-up" angina* is angina that starts with the onset of activity and improves with further exertion (e.g., in the morning); it suggests a very severe stenosis, with collaterals that get recruited during exertion and a myocardium that adapts to ischemia (ischemic preconditioning).

Dyspnea may be an angina-equivalent in case of extensive CAD; however, **dyspnea is very non-specific compared to chest pain. The pretest probability of CAD with exertional dyspnea approximates that of atypical chest pain** (5–25%, low to intermediate CAD probability). Dyspnea is, thus, a poor angina-equivalent. **Even if CAD is found, standalone dyspnea is frequently unrelated to CAD and unlikely to be relieved by PCI** (ORBITA-2 substudy). If dyspnea is due to CAD, the **CAD must be severe or extensive enough** to elevate LVEDP during ischemic spells, not single-vessel mid-RCA. Typically, multivessel severe disease is present and the stress test shows extensive ischemia, not low-risk localized or mild ischemia. As such, when dyspnea is reflective of CAD, it usually has ***2 features:*** (i) recent and rapidly progressive, and (ii) forces the patient to fully avoid mild activities (e.g., patient can no longer go up 2 flights of stairs or carry groceries and comes to a complete stop, as opposed to still doing these activities with breathlessness).

Typical angina is defined by its relation to exertion, not by pain descriptors. **Non-exertional chest pain or any pain not fulfilling the 3 features is overwhelmingly unrelated to CAD even if severe or extensive CAD is found, and is unlikely to improve with PCI or anti-anginal therapies.** In fact, in the ORBITA-2 trial, 60% of patients continued to experience symptoms after PCI, and PCI mainly relieved symptoms of patients with typical exertional chest pain.[11–13] It is even unlikely that atypical pain can be attributed to microvascular dysfunction, as a similar proportion of patients in the ORBITA-1 trial, 60%, did not improve with maximal anti-anginal therapy. While there is a widely held belief that women, individuals with diabetes, and older adults tend to have atypical symptoms, there is no evidence that this is true, per ORBITA-2 trial, or that dyspnea or non-exertional pain improves with PCI in those populations. Angina in women manifests as typical discomfort that is exertional and relieved with rest, but may be associated with more nausea, diaphoresis, malaise, or jaw or arm pain (VIRGO study).[14]

Symptom descriptors, such as tightness, sharpness, and radiation, are poorly predictive of angina per se (ORBITA-2 substudy). Per ORBITA-2, the only patients with atypical symptoms who *may* derive a symptomatic relief from PCI are those with *severe* ischemia on stress testing or FFR (extremely ↓ FFR <0.60 or iFR <0.76), albeit less than patients with Rose angina. In other words, severe ischemia may validate a correlation between CAD and symptoms (including dyspnea/atypical pain), albeit less than Rose angina.[15,16]

B. Pre-test clinical probability of significant CAD

The presence of all three Rose features defines typical angina, while two features define atypical chest pain or possible cardiac pain (e.g., pain is exertional but prolonged and not relieved with rest), and chest pain without any additional feature defines non-anginal non-cardiac chest pain. The combination of (1) angina features, (2) age and sex, and (3) risk factors establishes the probability of obstructive CAD (ESC's prediction model, using Winther et al. and Juarez-Orosco et al.; Figure 3.1).[17–20] This probability is improved by incorporating: (4) calcium score. Note that **typical angina is defined by its relation to exertion, not by a description of "chest heaviness" or arm radiation.**

In addition, the following features increase the probability of CAD in exertional chest pain: Q waves or ST-T changes on the resting ECG, PAD, and LV segmental dysfunction (ESC).

Contemporary data suggest that the pretest probability of CAD is far lower than the old prediction tables. As per ESC guidelines, a pooled analysis of several contemporary study cohorts indicates that the pretest probability based on symptoms, age, sex, and risk factors is approximately one-third of old models (e.g., Diamond-Forrester).[18–20] **Exertional chest pain is necessary to have an intermediate**

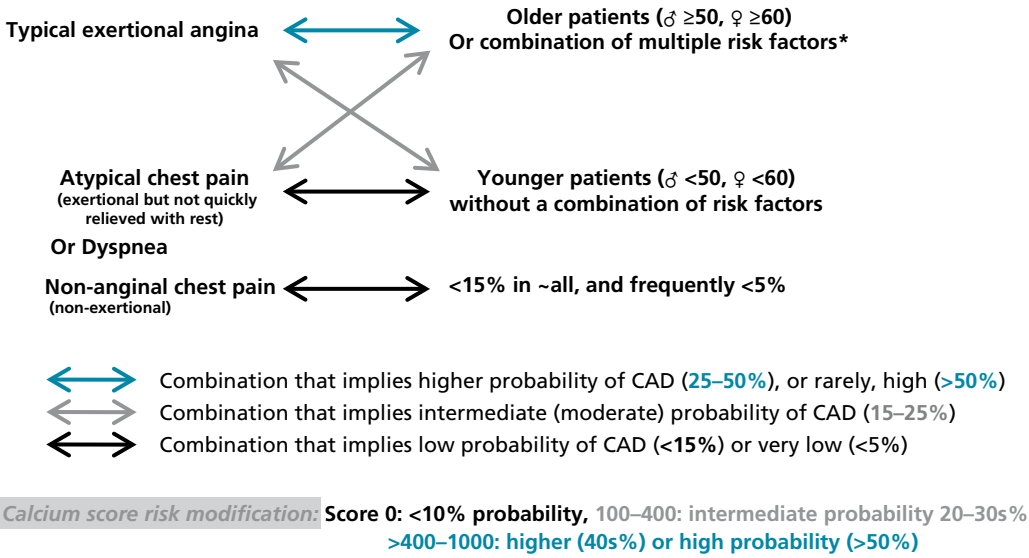

Figure 3.1 Clinical probability of CAD using risk factor weighed clinical likelihood of CAD (RF-CL). The pre-test probability of CAD is far lower than the old prediction tables and may be adjusted with calcium scoring. **Exertional chest pain is necessary to have an intermediate pre-test probability of obstructive CAD and to warrant coronary testing. Chronic non-exertional chest pain is not angina and does not justify coronary testing.** *Even if severe CAD is found, non-exertional pain is overwhelmingly unrelated to CAD and is unlikely to improve with PCI.* Thus, in these patients, the probability of CAD that is responsible for symptoms is even lower than the listed <15% probability of CAD.
*Combination of diabetes, smoking, hyperlipidemia (LDL >160–190 mg/dl), HTN, or premature family history, especially when 3–5 are present.[21] PAD, segmental LV dysfunction, or Qs or resting ST-T changes further ↑ CAD probability.

Table 3.1 Cases where stress imaging is preferred over coronary CTA.

Cases where heavy calcium is expected, making it difficult to assess luminal stenosis by CTA:*
• Age > 70 years with multiple uncontrolled risk factors
• Uncontrolled diabetes or long-standing smoking or severe PAD
• Heavy MAC
CKD (GFR < 60, especially <45)
Heavy and diffuse coronary atheroma expected: stress testing is more helpful for determining whether disease is functionally significant/obstructive and causing angina*
Severe obesity
Persistent AF; or fast sinus rate and inability to take β-blockers

* Although less desired by ACC and ESC CAD guidelines, CTA may be considered even when heavy diffuse coronary atheroma is expected, as the goal is not comprehensive assessment of stenoses, but rather exclusion of very *proximal* disease. Hence ESC valve guidelines allow the omission of coronary angiography in elderly TAVR candidates when CTA excludes relevant proximal CAD (class IIa). A large analysis showed a great correlation between pre-TAVR CTA and invasive angiography for *proximal stenoses* >70%, with a positive predictive value of 83%, in elderly patients with calcified disease (age 79 ± 8.5).[27]

pretest probability of CAD and to warrant coronary testing, but even typical exertional chest pain is not highly predictive of CAD (only 10–50%): less than 25% of women and less than 50% of men with typical exertional chest pain have CAD (ESC).[18–20,22] **Also, dyspnea is a poor angina equivalent** with CAD probability of 10–25% at most.

The *CAD probability may be refined by incorporating coronary calcium scoring with chest pain/age/risk factors*: a high calcium score >400, or worse, >1000, in conjunction with typical exertional chest pain, increases the pretest probability to >50%, whereas a calcium score of 0 reduces this probability to <5–10%, even with typical chest pain.[20,23]

All the above explains the low diagnostic yield of invasive and noninvasive testing and the high rate of non-obstructive coronary angiography (>50–60%) even in patients with seemingly high pretest probability, particularly women, and why **coronary testing should be avoided in patients with non-exertional chest pain**. *Even if severe CAD is found, non-exertional pain is overwhelmingly unrelated to CAD and is unlikely to improve with PCI, hence the probability of finding a "responsible" CAD is far less than the listed <15%*.

Notably, half of patients with typical angina but without obstructive CAD have macrovascular spasm or microvascular dysfunction with an intermediate ~9% risk of death/MI at 4 years.[24]

C. Testing modalities (diagnostic and prognostic purposes):[18,22]

- ***Higher (25–50%) or high (>50%)*** *pre-test probability* (typical exertional angina at an older age or with many risk factors, or with calcium score >400 or worse, >1000):
  - Coronary angiography is rarely directly performed, only if probability is high >50% and typical exertional angina occurs on mild effort and is frequent, requiring revascularization.
  - CTA is performed if typical angina is not severe. It confirms CAD, excludes left main disease and allows conservative CAD management, as per ISCHEMIA trial.[25]
  - As an alternative to CTA in typical angina that is not severe, stress testing may be performed, especially in CKD: a low-risk result implies conservative management, but even a high-risk result may be managed conservatively in the absence of severe exertional angina (ISCHEMIA trials, ACC class I).[25,26] Besides CKD, features that favor stress testing over CTA are shown in Table 3.1.
- ***Intermediate*** *pre-test probability* (typical exertional angina in a woman or young man): stress testing or CTA is performed for diagnosis and prognosis. CTA is also indicated after a high- or intermediate-risk stress test or a negative stress test yet persistent symptoms. SCOT-Heart trial showed that routine CTA on top of functional testing reduces the 5-year MI risk in patients with chest pain, typical or atypical, compared to functional testing alone, not via more revascularizations but via assessing plaque burden and dictating aggressive risk factor control.[28]

  Before CTA or stress testing, calcium scoring may be used as initial test to further delineate the pretest probability of obstructive CAD and has proven valuable even in symptomatic patients: <100: low; 100–400: intermediate; >400–1000: higher or high probability (~30s% if low clinical likelihood, up to 60–70% if high clinical likelihood).[20]
- ***Low*** *pretest probability <15%* (non-exertional pain): stress testing is not recommended. Even if the stress test is positive, the probability of CAD increases from <10% up to 20%, i.e., the stress test is likely falsely positive (Bayes theorem). Thus, avoid stress testing in low-probability patients, especially nuclear testing, as it has a high false-positive rate in this population and a radiation hazard.

D. Risk stratification with stress testing

Treadmill stress ECG, more specifically the Duke Treadmill Score (DTS), is a powerful risk stratifier. A high-risk DTS implies an increased cardiac mortality and a 75% probability of left main or 3-vessel CAD, regardless of imaging results. A low-risk DTS often implies a low mortality; however, ~10% of patients with a low-risk DTS have severe 3-vessel or left main disease with a high mortality, and another 10% have 2-vessel or proximal LAD disease, and thus, 20% of symptomatic patients with normal stress ECG have significant, high-risk CAD (particularly men).[29] These patients are likely to be picked up by stress imaging.[30,31] *In fact, a high-risk result on nuclear or echo stress imaging overrules a low- or intermediate-risk result on stress ECG*.[30,31] Thus, stress imaging is preferred to stress ECG in patients with a higher or high probability of CAD or with prior coronary revascularization even if ECG is interpretable, while stress ECG is preferred in patients with an intermediate probability who are able to walk and have an interpretable baseline ECG (Table 3.2).[22]

A high-risk DTS, on the other hand, implies a high risk regardless of imaging results, with a 75% probability of left main or 3-vessel CAD and >90% probability of any significant CAD.[29] Because of balanced ischemia, some patients with extensive disease have normal or mildly abnormal perfusion imaging but are picked up by ECG variables, DTS, severe angina during testing, and post-stress LV dysfunction. Table 3.3 stratifies the risk according to stress testing.

Table 3.2 Indications for stress imaging, as opposed to plain treadmill stress ECG.

Treadmill stress imaging (nuclear or echo) >Treadmill stress ECG
- Baseline ST depression >1 mm[a]
- High pre-test probability of CAD
- Prior coronary revascularization (stress imaging allows localization of ischemia and has a higher sensitivity in detecting single-vessel ischemia)
- Prior stress ECG with intermediate result

Pharmacological stress imaging (nuclear or echo)
- Unable to walk
- ± Able to walk but baseline ECG has LBBB or ventricular paced rhythm (classically, pharmacological nuclear imaging is performed)[b]

[a] LVH without ST depression is appropriately tested with stress ECG.
[b] Exercise and dobutamine may exaggerate the septal motion abnormality and septal defect present in LBBB, falsely suggesting ischemia, but have shown an appropriate yield when the apical motion or perfusion is analyzed, rather than the septum.[32]

Table 3.3 Risk stratification with stress testing.

Severe ischemia: yearly cardiac mortality >3%, yearly cardiac events >5%
- DTS ≤–11[a]
- Reversible, large *or* severe perfusion defect (summed difference score [stress-rest] >+8, corresponding to ischemia involving >10% of the myocardium)
- Stress-induced drop in EF ≥10% or TID
- On stress echo: ischemia of ≥3 segments (out of 17), or >1 coronary distribution, especially if it occurs at a low rate <120 bpm or a low dose of dobutamine (≤10 mcg/kg/min)

Moderate ischemia: yearly cardiac mortality 1–3%, cardiac events 1–5%
- DTS –10 to +4
- Summed difference score 4–8

Mild or no ischemia: yearly cardiac mortality and cardiac events <1% (~0.5% with stress imaging)
- DTS ≥+5 (≥ +8 is very low risk)
- No perfusion defect or small perfusion defect with a summed difference score <4

[a] Duke Treadmill Score (DTS) = prognostic score for treadmill stress testing
= Exercise time on Bruce protocol – 5 × (the deepest ST depression on ECG) – 4 × (angina score) (Angina score: 0 = no angina, 1 = non-limiting angina, 2 = exercise-limiting angina)

In patients who have undergone PCI: (i) chest pain relief followed by recurrence months later is typical of in-stent restenosis, or progression of moderate disease outside the stented area (especially in patients who initially presented with ACS); (ii) a persistent chest pain without a pattern of relief and recurrence suggests either non-cardiac pain or residual, non-revascularized disease. The same applies to patients with prior CABG (graft disease instead of in-stent restenosis). Intensify antianginal therapy for typical angina, and repeat the coronary angiogram only if typical angina occurs on mild exertion and is refractory. Otherwise, stick to medical therapy even without further imaging. Consider CTA or stress imaging to rule out new high-risk disease, such as left main disease, in a *select subset* whose prior anatomy is concerning for such progression.

Of note, CTA remains valuable in CABG patients for assessing SVG and LIMA patency (class IIa). Even in CABG patients with planned invasive angiography, pre-planning with CTA eliminates engagement efforts of occluded grafts and reduces procedural time, complications, peri-procedural MI, and even the overall contrast volume (BYPASS-CTCA trial).[33]

When should testing be repeated in patients with prior negative studies who present with chest pain? After a normal stress test, the risk of cardiovascular events is low for 1–2 years (<1% per year)—although this is less defined for pharmacological testing, older age (>70–80), CAD history, or uncontrolled risk factors.[34] During this time, repeat coronary testing is unnecessary unless there is objective evidence of new CAD, such as ACS with positive biomarkers or ischemic ST changes, or new severe exertional angina.

When a coronary angiogram or CTA shows normal coronary arteries or minimal disease, the risk of coronary events is low for 5 years, and unless there is evidence of MI, the angiogram is not usually repeated within the next 2 years (ACC). As per the CASS registry, the 7-year survival is 96% for patients with normal EF and normal coronaries and 92% for patients with mild coronary disease <50% (much better prognosis than obstructive CAD).[35]

How about patients who had a coronary angiogram showing single- or multivessel moderate disease (30–70%), or showing severe disease (>70%) in a small branch where PCI is not beneficial? If they present with recurrent or persistent chest pain a

few months or 1–2 years later, the coronary angiogram may not need to be repeated unless there is an ischemic ST abnormality, a positive troponin, or a dramatic change in the severity of a typical, exertional angina. *Also, the true functional significance of moderate stenoses (50–70%) is worth assessing with stress imaging or FFR.*

Patients with moderate stenoses that are insignificant by FFR have a very low risk of MI from each individual stenosis, yet the summation risk of MI from all nonsignificant lesions is not negligible, ~1.5% per year (FAME 2 trial).[36]

A normal stress test carries lower individual MI risk than an abnormal one, yet on a population level, most MIs arise from non-obstructive plaques in patients who would have had a recent insignificant stress test or angiography. This is because these non-obstructive plaques are vastly more prevalent. Hence, there is no true "warranty period".

E. Putting it together: diagnostic approach and management of chronic chest pain (Figure 3.2)

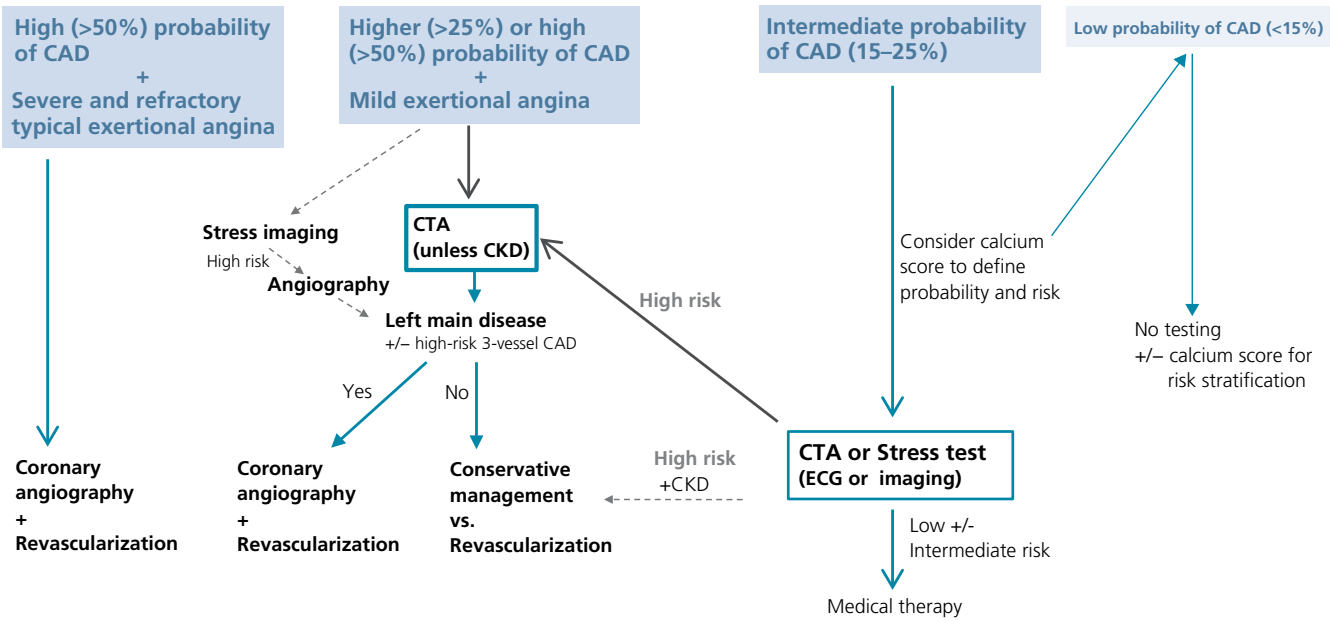

Figure 3.2 Proposed diagnostic approach to chronic chest pain (*solid arrows* indicate the preferred strategy). **Exertional chest pain is necessary to consider the patient at high or even intermediate CAD probability and to perform any diagnostic testing**. Note that CTA has gained a central role in high CAD probability and high-risk patients, including high-risk stress test, thanks to ISCHEMIA trial. The main goal of CTA in high-risk patients is to rule out left main and proximal 3-vessel disease. If absent, conservative management is acceptable. CTA is less favored in 2 instances: CKD *and* cases where heavy calcium is expected (age >70 and/or multiple uncontrolled risk factors), wherein stress imaging is preferred for diagnosis. Notably, even a high-risk stress test is appropriately managed conservatively with no angiographic assessment at all if angina is controlled, as per ACC (class I) and ISCHEMIA trials-CKD subgroups.[22] CTA may be considered even when heavy diffuse coronary atheroma and calcium is expected, as the goal is not comprehensive assessment of stenoses, but rather exclusion of very proximal disease.

III. Is there a role for screening asymptomatic patients and post-PCI patients?

A totally silent severe myocardial ischemia is uncommon (10–15% of CAD). The more common form of silent myocardial ischemia consists of silent ischemia interspersed with symptomatic ischemia, such as angina or prior MI.[37]

Revascularization does not generally modify the prognosis of asymptomatic patients, and screening asymptomatic patients based solely on risk factors is not indicated, nor is screening of post-PCI patients indicated. In the DIAD study, asymptomatic diabetic patients, who constitute a relatively high-risk population, were screened for CAD with nuclear stress imaging. These asymptomatic patients actually had a low risk of cardiac events (0.6% per year), and while this risk was higher in the small subgroup of patients with moderate or severe ischemia (2.5% per year), 70% of events eventually occurred in patients with normal testing. In fact, a 0.6% event rate in 90% of the population leads to more total events than a 2.5% event rate in 10% of the population. Even if revascularization reduces the risk of late MI in this small subgroup, the benefit is nullified by the periprocedural risk of MI and by the risk of unnecessary diagnostic angiograms in patients with false positive stress tests. This explains why the event rate was similar in the screened and non-screened diabetic populations. Thus, stress testing is not generally useful in asymptomatic patients, even those at seemingly high risk (as in the DIAD study).[38] These findings were corroborated by another study, wherein asymptomatic diabetic patients were randomized to coronary CTA screening vs. routine care. Coronary CTA found significant CAD (>70% stenosis) in 11% of patients and resulted in a 6% revascularization rate, which did not translate into any reduction of death, MI, or unstable angina (FACTOR-64 study).[39] *While obstructive plaques have higher individual risk of MI (2–3%) than non-obstructive plaques (<0.5%), the latter are much more common throughout the coronary tree of the patient and, more so, across the larger population without obstructive CAD*. Hence, most MIs arise from non-obstructive plaques and are not preceded by chronic angina (esp. first MIs). Moreover, the following 3 ideas argue against testing and stenting asymptomatic patients:

-**~75% of MIs arise from a plaque that was not obstructive (<50%) on a recent CT or coronary angiography (within the last couple of years)**.[40] This is particularly true if the patient is asymptomatic, even more so if asymptomatic despite being active.
-Atherosclerotic burden, as assessed by CT calcium scoring, is at least as good a predictor of coronary events as the presence of obstructive CAD. Stenting does not modify this major driver of outcomes, i.e., plaque burden.[41]
-Occlusion of a stenosis >70% is far less likely to cause a large MI than occlusion of mild disease (30% vs. 75% likelihood), and far more likely to be preceded by angina as first presentation (70%). This is because chronic collaterals reduce infarct size in the former. Thus, seeking stenoses >70% is seeking the less deadly disease.[42]

The only valuable test in asymptomatic patients is CT calcium scoring, a powerful risk stratifier that, when moderate or high, **dictates more aggressive risk factor modification, not revascularization**. Conversely, a calcium score of 0 implies a very low risk of death/MI (<0.5% per year for 5–10 years) and a low prevalence of obstructive CAD (<6% even in symptomatic patients); this is the "*power of zero*."[41,43] A calcium-score centered screening protocol emphasizing medical therapy, not catheterization, reduced mortality and MI/stroke in the *DANCAVAS trials* (esp. age <70).

If stress testing is done in asymptomatic patients, the detection of severe ischemia would lead to revascularization only in extensive CAD, mainly left main disease.

Silent ischemia 6 months after PCI, even if severe, is not clearly associated with increased death or MI. *In-stent restenosis is asymptomatic ~50% of the time, in which case the prognosis is very good*; **routine stress testing or angiographic follow-up and routine PCI of asymptomatic in-stent restenosis do not improve outcomes compared to angina-driven PCI (registry data and large POST-PCI trial).[44,45]**

IV. Plaque burden vs. coronary stenosis. Management of asymptomatic high coronary calcium score

- **Coronary stenosis (+ischemia and FFR) → determines angina**, more than MI/death. ***Revascularization of stenosis reduces angina, not MI/death.*** It is assessed by coronary angiography, CTA, or stress testing.
- **Plaque burden and calcium score → determine MI + death,** regardless of stenosis and its severity.[41] It is not modifiable by revascularization and is assessed by CTA or calcium score. Plaque burden has only a moderate correlation with the presence of obstructive CAD: depending on symptoms, ~30–70% of patients with high calcium score >400–1000 have obstructive CAD. Yet, regardless, with or without coronary obstruction, the risk of MI is similarly high and may be underestimated by the degree of coronary obstruction.[41] On the other hand, *even if obstructive CAD is present, a calcium score of 0 still predicts a low death/MI event rate of ~0.7% per year*.[41,43]

A high calcium score >400 or even >1000 in an asymptomatic patient does not dictate coronary angiography or CTA/stress testing, as: (i) calcium score strongly predicts coronary events but is less strongly predictive of obstructive CAD; (ii) obstructive CAD is better predicted by the combination of exertional chest pain with high calcium score; (iii) high calcium score is a powerful predictor of coronary events regardless of the presence of obstructive CAD (3–5% per year); seeking and treating obstructive CAD does not clearly alter the prognosis, which is driven by plaque burden, and a lack of obstructive CAD is not reassuring (high event rate regardless); (iv) seeking and revascularizing obstructive CAD in asymptomatic patients has not proven beneficial (except for left main disease): it is rather ***risk factor control and statin that improve outcomes,*** and aspirin may be considered in young patients < 70 years with low bleeding risk. **The same applies to severe coronary calcium incidentally found on a non-dedicated chest CT.**

V. Medical therapy: antithrombotic therapy, antianginal therapy and risk factor control

A. Antithrombotic therapy

While the combination of aspirin and clopidogrel is beneficial for up to 1 year after MI or stent placement, this combination has not shown superiority to aspirin monotherapy in stable CAD and peripheral vascular disease (CHARISMA trial). However, in a substudy of CHARISMA, patients with prior MI appeared to derive a benefit from prolonged combination therapy for up to 28 months, especially if they had disease in multiple vascular locations (e.g., MI and PAD).[46] In monotherapy, clopidogrel is an alternative to aspirin and is, in fact, superior in reducing coronary and cerebrovascular events with a lower risk of GI bleed (CAPRIE trial);[47] this is also the case 6–12 months after stenting (HOST-EXAM and SMART-CHOICE-3 trials, the latter showing a mortality reduction with long-term clopidogrel vs. aspirin).[48,49]

Patients with CAD who also have an indication for anticoagulation (AF or a history of DVT) are best treated with standalone anticoagulation beyond 1 year of MI or coronary stenting (warfarin or NOAC). Anticoagulation, per se, effectively reduces coronary events, as in old post-MI trials using warfarin, modern trials using rivaroxaban and edoxaban, and AQUATIC trial using any anticoagulant, mainly apixaban.[50–53] In the AQUATIC trial, patients who underwent stenting for ACS or complex CAD >6 months previously and who had a high residual ischemic risk derived dramatic mortality reduction with single anticoagulant vs. anticoagulant + aspirin (8.4% vs. 13.4% at 1.7 years) and a dramatic, >3-fold reduction of major bleeding. A similar mortality reduction was seen with single rivaroxaban vs. rivaroxaban + antiplatelet in the AFIRE trial.

B. Four antianginal drugs: β-Blockers, calcium channel blockers, nitrates, and ranolazine

Myocardial oxygen demands are related to the following ***four factors***: inotropism, chronotropism, afterload, and preload. Each antianginal agent targets some of these factors. Nitrates and vasodilatory calcium channel blockers reduce ischemia by reducing preload and afterload, and, except in vasospastic angina, the coronary vasodilatory effect is a less important effect.

C. β-Blockers

a. In patients with established CAD and angina, β-blockers are first-line therapy as they reduce mortality after MI with EF <50% (class I). However, ***in stable CAD with EF ≥50%, there is no evidence of mortality reduction and the main benefit is angina relief***.[54,55] Without angina or low EF, the recommendation for β-blocker therapy is weak (class IIb).

b. ***A tight rate control <70 bpm has proven beneficial in chronic compensated HFrEF, but not in stable CAD, angina, HTN, AF, or HFpEF***.[56,57] In fact, in the SIMPLIFY trial, stable CAD patients with baseline pulse >70 bpm (most of whom had MI >3 months prior) did not derive a benefit from slowing the sinus rate with ivabradine, even when angina CCS was ≥II. Thus, tight heart rate control <70 bpm may not need to be pursued in stable CAD with normal EF, except possibly in severe angina.

c. Myocardial β_1-receptors have a positive inotropic and chronotropic effect, thus increasing myocardial O_2 demands. β_2-receptors mainly have vasodilatory and bronchodilatory effects, with a limited inotropic and chronotropic effect at baseline. However, the latter effect is exaggerated when β_1-receptors are blocked. Thus, β_2-blockade may be useful in patients requiring a comprehensive blockade of all myocardial adrenergic receptors, such as HF (carvedilol), but may induce harmful vasoconstrictive and bronchospastic effects.

d. Four types of β-blockers:

- **i.** Non-selective β_1- and β_2-blockers (e.g., propranolol).
- **ii.** Selective β_1-blockers (e.g., metoprolol, atenolol, bisoprolol). Selectivity is lost at high doses.
- **iii.** β-Blockers with intrinsic sympathomimetic activity – β-blockade does not occur at rest, and rather occurs during catecholamine surges; these agents do not decrease mortality and are preferably avoided.
- **iv.** β-Blockers with combined α- and non-selective β-blocker activity (carvedilol, labetalol) have a vasodilatory effect and, thus, a more pronounced antihypertensive effect. However, the α-blocking effect gets attenuated with time, particularly with labetalol.[58]

e. Contraindications

- **i.** Bradycardia <55 bpm or symptomatic bradycardia-PR interval >0.24 seconds, or any second- or third-degree AV block.
- **ii.** Decompensated HF (start β-blockers once HF is compensated).
- **iii.** History of clinically severe asthma, even if the patient is currently stable, or actively decompensated COPD with wheezes. A low or moderate dose of a selective β-blocker, such as metoprolol 100 mg/day, may be used in stable, mild/moderate asthma.
- **iv.** Use caution in diabetic patients with hypoglycemic episodes.

f. Doses:

- Metoprolol tartrate 25 mg BID titrated every 3–7 days to a target dose of 50–100 mg BID if tolerated (maximum 200 mg BID). Metoprolol succinate (Toprol XL): the once-daily dose of Toprol XL is almost equivalent to the total daily dose of metoprolol tartrate.
- Atenolol 12.5–25 mg BID (Qday in renal failure), titrated to 50 mg BID. Carvedilol: 3.125–25 mg BID; labetalol 100–400 mg BID.

Notes

Severe PAD was considered a relative contraindication to non-selective β-blockers, because of an initial β_2-blocker vasoconstrictive effect. However, this is no longer a contraindication to β-blockers, as they proved safe in PAD.[59] Also, PAD patients often die of CAD, and thus, β-blockers are valuable in the PAD setting. Individual responses may vary, so be aware of a potential worsening of severe rest symptoms.

In diabetic patients, metoprolol appears to slightly worsen diabetes control (HbA1c). This is not the case with carvedilol and nebivolol, which should be the preferred β-blockers in diabetic patients (GEMINI trial).[60]

D. Nitrates

a. Nitrates are venodilators and thus reduce ischemia primarily by reducing preload. They also improve coronary flow by reducing intramyocardial diastolic tension, i.e., LVEDP. They are also, to a lesser extent, arterial vasodilators and thus reduce afterload.

The dilatation of epicardial coronary arteries is a less important anti-ischemic mechanism than preload reduction, but dilatation of collaterals may be particularly useful. Unlike CCBs, nitrates do not drastically dilate the coronary microcirculation and thus, do not directly increase the coronary flow.

b. While sublingual nitroglycerin (NTG) is used as needed (during angina or before exertion) and has a short effect <5 min, long-acting formulations are used as adjunct to background β-blocker or calcium channel blocker therapy:

- Isosorbide dinitrate (ISDN) 10–40 mg TID, isosorbide mononitrate (ISMN) 30–240 mg Qday, NTG paste 0.5–2 inches TID, NTG patch 0.2–0.6 mg/h Q24h.

c. Tolerance to nitrates develops quickly, within 24 hours of therapy. It is minimized by providing nitrate-free intervals (e.g., administer ISDN at 8 a.m., 2 p.m., and 8 p.m., with 10–14 hours free interval; administer ISMN once daily; or place NTG patch for 12 out of 24 hours every day). However, rebound ischemia may occur during the nitrate-free intervals.

d. Nitrates are metabolized into NO by large arteries. NO promotes the release of cGMP, a smooth muscle relaxant. ***In contrast to large arteries, arterioles cannot metabolize nitrates into NO.***

Nitrate tolerance occurs as the beneficial NO eventually gets metabolized into reactive oxygen species, which reduce NO generation and NO effect and increase the vascular sensitivity to vasoconstrictors; nitrates may, in fact, impair endothelial function.[61] Neurohormonal activation may also contribute to nitrate tolerance. The same phenomenon leads to vasoconstriction and rebound ischemia in the first 4 hours after nitrate withdrawal in a tolerant patient. Several studies have shown that statin, ACE-I (and possibly ARB), hydralazine, and carvedilol reduce nitrate tolerance as they reduce the production of reactive oxygen species and counteract the neurohormonal activation.[61–64] Thus, with the contemporary drug regimens, nitrate tolerance and rebound are minimized.

E. Calcium channel blockers (CCBs)

a. Non-dihydropyridines (non-DHPs) decrease cardiac inotropism and chronotropism and have a vasodilatory effect (afterload reduction). Also, they dilate the coronary arteries and, more importantly for stable angina, the coronary microcirculation.

i. Examples: diltiazem and verapamil. Verapamil has more negative inotropic effect and slightly more AV and SA nodal depressant effect than diltiazem.
ii. Non-DHPs are contraindicated in bradycardia or systolic HF. Avoid non-DHPs, particularly verapamil, in combination with a β-blocker. Diltiazem may be combined with a β-blocker in rate-uncontrolled AF.
iii. Doses: diltiazem 30–90 mg TID–QID, diltiazem ER 120–480 mg Qday; verapamil 80–120 mg TID–QID, verapamil ER 180–480 mg/d.

b. Dihydropyridines (DHPs) are more pure and powerful vasodilators than non-DHPs, with minimal ino- and chronotropic effects.
i. Only the long-acting formulations are used. Short-acting DHPs may cause reflex tachycardia, which leads to ischemia.
ii. DHPs are not contraindicated in bradycardia or HF, except for nifedipine, which has some negative inotropic effect and is preferably avoided in HF; other DHPs have minimal to no negative inotropic effects.
iii. In contrast to non-DHPs, DHPs are preferably combined with a β-blocker to counteract any potential reflex tachycardia.
iv. DHPs are the first-choice antianginal therapy in patients with bradycardia and the second choice in patients already on β-blockers.
v. Examples are amlodipine 2.5–10 mg Qday, felodipine 2.5–10 mg Qday, and nifedipine XL 30–90 mg Qday.

F. Choice of antianginal drugs

If heart rate>70 bpm, β-blockers are first-line agents. If β-blockers are contraindicated because of bronchospasm, use a non-DHP. ***If heart rate <60 bpm*** or if significant AV conduction disease, use a DHP. A long-acting nitrate or ranolazine is used as a second- or third-line agent. The combination DHP + nitrates may be used but is less favored, particularly if baseline heart rate is >70, as both agents are vasodilators and their combination may lead to reflex tachycardia.

If one agent does not greatly relieve angina, use a combination of 2 to 4 agents (β-blocker + DHP +/– nitrate +/– ranolazine).

In HF patients with angina, β-blockers are started slowly. Nitrates may be added for angina, or the combination of nitrates + hydralazine may be used for HF. DHP or ranolazine may be added if needed (amlodipine or felodipine may be slowly added, only if HF is compensated).

G. Ranolazine

Ranolazine blocks the late current of the inward sodium channel (I_{Na}), a channel that is particularly active in ischemia or HF. This reduces intracellular sodium and, subsequently, intracellular calcium through the sodium–calcium sarcoplasmic exchange (***opposite to digoxin effect***). The main effect of ranolazine is the reduction of diastolic calcium overload, which reduces O_2 consumption and improves LV relaxation. Moreover, the improvement of LV relaxation reduces LVEDP and the coronary compression, which improves microvascular function and coronary flow.

Ranolazine has been shown to reduce angina burden, increase exercise duration, and reduce ischemic burden on nuclear imaging, particularly in patients with the most severe or frequent angina, whether used in monotherapy or in combination with other antianginal drugs.[65,66]

In the MERLIN-TIMI 36 trial of NSTE-ACS patients, ranolazine added to standard therapy reduced the endpoint of recurrent ischemia or worsening angina. The benefit was most striking in *women* and in patients with *elevated BNP*.[67–69] Ranolazine has not shown any effect on mortality.

Ranolazine only slightly prolongs QT from I_K blockade (by 2–6 ms) and does not increase the risk of arrhythmia. The blockade of I_{Na} serves to shorten the action potential, similarly to the effect of lidocaine, and counteracts the I_K blockade. In fact, in the MERLIN trial, ranolazine significantly reduced the risk of VT, SVT, and AF. *In addition, ranolazine appeared to reduce the risk of sudden death in patients with VT lasting over 8 beats in the setting of NSTE-ACS*.[70] However, ranolazine should only be used cautiously in patients with prolonged QT or patients receiving QT-prolonging drugs.

Thus, ranolazine has the advantages of:

- Reduction of ischemia *without affecting the systemic pressure or heart rat*e. It is particularly valuable when systemic pressure or heart rate limits the use of other antianginal agents.
- Improvement of LV diastolic function.
- Reduction of arrhythmias.
- Reduction of HbA1c of ~1% in patients with HbA1c ≥8% (MERLIN analysis).

Ranolazine may be used as *initial therapy* in patients who do not tolerate β-blockers (alternative to CCB and nitrates), or as *additional therapy* in patients with persistent angina despite standard therapy.

H. Role of ACE inhibitors/ARBs in stable CAD, lack of antianginal effect vs. CCB

ACE inhibitors (ACE-Is) have failed to reduce exertional angina in multiple studies from the 1980s–1990s. They may reduce angina in severely hypertensive patients via BP control, but unlike CCBs, they have no specific anti-anginal effect in normotensive patients.[71] In the CAMELOT trial of amlodipine vs. ACE-I vs. placebo in normotensive stable CAD, only amlodipine improved coronary events, mainly angina and the need for revascularization, despite similar BP reduction.[72] It is unclear why ACE-Is do not have a specific anti-anginal effect, even though they not only reduce afterload but also preload via venodilatation and they have a sympatholytic effect. Also, ACE-Is reduce afterload, i.e., wall stress, more potently than CCBs by reducing LV size and aldosterone release, beyond their vasodilatory effect. Conversely, CCBs have no venodilatory preload effect and reduce LV afterload less comprehensively than ACE-Is.[73] Yet, CCBs more effectively relieve angina. This may be related to the fact that CCBs are more potent direct vasodilators, producing more coronary microvascular dilatation

and more increase in myocardial blood flow than ACE-Is, vs. more coronary steal phenomenon with ACE-Is.[71,74] ACE-Is reduce BP without much coronary microvascular dilatation → reduction of coronary perfusion pressure + reduction of flow in obstructed areas where the already dilated microvessels—via autoregulation—are difficult to further dilate, especially with ACE-Is (but somewhat dilate with CCBs). Furthermore, coronary collateral flow drops as BP drops.

Regarding reduction of death and MI in stable CAD with normal EF and with or without prior MI, ACE-I proved beneficial in 2 trials (HOPE and EUROPA),[75] but not in the PEACE trial of normotensive CAD with SBP 130–140 mmHg,[76] and not in the CAMELOT trial. Thus, in stable CAD, ACE-I is mainly valuable in case of low EF, HTN, or CKD: those are the only ESC class I indications for ACE-I in stable CAD.

In the early post-CABG setting (≤7 days) with normal EF and BP, ACE-I initiation did not improve outcomes and was associated with more adverse events in the first 3 months, likely because of the hypotensive propensity of early post-CABG patients (IMAGINE trial).[77]

I. Control of risk factors

1. Statin, regardless of LDL. If needed, ezetimibe or PCSK-9 inhibitor may be added to achieve LDL <55–70 mg/dl.
2. HTN is controlled to <130/80 mmHg (ACC and SPRINT trial).[78]
3. Control of diabetes to a HbA1c ≤7%.
4. Smoking cessation leads to a 50% reduction of the excessive risk of MI and stroke within 1 year (mostly within 2 months). At 3–5 years, the risk approaches that of never-smokers.

VI. Indications for revascularization

The first step is to determine if the patient requires coronary angiography (Figure 3.2). The *second step* is to determine if the patient requires revascularization. The *third step* is to determine whether CABG or PCI is appropriate. The need for coronary angiography does not imply a need for revascularization once CAD is found. In fact, medical therapy is frequently appropriate in a patient with significant, even multivessel CAD (with no left main disease). *Coronary angiography serves as a risk stratification tool that helps determine whether medical therapy alone is appropriate*. Based on ISCHEMIA trial, coronary CTA may replace coronary angiography and may be used to exclude left main disease and proceed with conservative management even in patients with multivessel disease.

In order to benefit from revascularization, 1 of the following 2 features excluded from ISCHEMIA trial must be present: (1) severe refractory angina, or (2) severe left main disease, regardless of angina.[25,26] Extensive 3-vessel CAD or 2-vessel CAD with proximal LAD may also benefit from CABG, but less strongly (mainly MI reduction, not death).[18,79] Refractory angina is defined as frequent angina (multiple times weekly) that persists despite the use of at least two antianginal medications (or less in case of intolerance or a baseline low BP and heart rate).

Old retrospective analyses suggested that revascularization in the setting of extensive ischemia involving ≥10% of the LV was associated with a reduction of mortality; this suggested a role for ischemia assessment in guiding revascularization.[80] However, the large randomized trial ISCHEMIA disproved this hypothesis. ***Analyses from both ISCHEMIA and COURAGE suggest that the anatomic burden of disease is a far superior predictor of death and cardiac outcomes than ischemia, even though neither one predicts a benefit from revascularization.***[81,82] Ruling out left main disease via CTA or angiography appears more important than functional ischemia evaluation. *Ischemic testing and FFR's main value is to link symptoms to stenosis*, mainly when symptoms are atypical or stenosis is moderate.

Even in the setting of low EF <35% with multivessel stable CAD, multivessel PCI was not beneficial (REVIVED trial), and CABG provided only a marginal and late benefit (STICH trial).

In chronic stable CAD, revascularization of single or even multivessel CAD mainly has a symptomatic value, particularly in patients with refractory angina, with no effect on survival or MI prevention.

While a significant stenosis has a higher individual risk of plaque rupture and MI (~2–3% per year) than a non-significant plaque (<0.5%) (COURAGE, ISCHEMIA, FAME trials),[25,83–85] non-significant plaques are much more common throughout the coronary vasculature than significant plaques; therefore, **MI or ACS often occurs over a lesion that is <50% stenotic: these lesions were responsible for 2/3 of ACS events upon long-term follow-up in PROSPECT trial and coronary CT studies.**[40,41,86] In FAME-2 trial, patients with insignificant FFR had a very low risk of MI from individual plaques, but the summation MI risk was still ~2% at 8 months and 8% at 5 years.[36,85] While stenting reduces the risk of spontaneous events arising from a significant plaque, the benefit is negated by periprocedural myocardial infarction (~2.5%), stent thrombosis and severe restenosis, which explains why stenting stable CAD does not reduce the overall MI risk.[85] Moreover, a larger number of events continues to arise from non-significant plaques.

In stable CAD, ***the natural progression of a stenosis that is significant but non-critical (50–80%) is likely slower than the progression of in-stent processes.***[83] ***This suggests avoiding PCI of moderate disease, even if functionally significant, unless angina is severe + refractory:***

- Natural progression of a stenosis >50%: <10% risk of angiographic progression over 1.5–2 years per COURAGE trial, with <2–3% individual risk of MI (at least as many events arise from non-significant plaques).[83]
- Within stents:[87–89]
  - At 1 year: ~10% in-stent restenosis with ~1% stent thrombosis and 1–2% stent-related MI.
  - Beyond 1 year: ~1–2% severe in-stent tissue growth per year with up to 0.5% stent thrombosis per year.

VII. CABG and CABG vs. medical therapy

CABG is the only revascularization modality shown to improve survival in the high-risk subsets of stable CAD. In a meta-analysis that included the 3 classic trials of CABG vs. medical therapy, the Coronary Artery Surgery Study (CASS), the European Coronary Surgery Study (ECSS), and the VA study, CABG reduced mortality by 40–50% in the following groups:[90]

- Left main disease (mortality reduction of ~75%).
- Three-vessel CAD, or 1- or 2-vessel CAD involving the proximal LAD. CABG is beneficial in these patients irrespective of LV function, but more so in the case of mild LV dysfunction with EF 35–50% or evidence of moderate/severe ischemia on stress testing (i.e., make sure CAD is functionally significant).

CABG was beneficial in the classic trials despite a 25% crossover to CABG in the medical therapy arm at 5 years, implying that the absolute CABG benefit is even higher. This CABG benefit was seen irrespective of symptom status and extended to asymptomatic patients. *Note that the survival benefit in stable CAD does not emerge until 2 years after CABG, partly because of the early surgical hazard*; thus, CABG is an appropriate therapy in patients who are otherwise likely to have a good longevity. CABG is expected to be beneficial sooner in patients with unstable CAD. Those trials were done in the 1970s, at a time when medical therapy was suboptimal (mainly consisting of β-blockers, with very limited use of aspirin and no statin). In fact, in the CABG stratum of the modern **BARI 2D trial**, initial CABG did not reduce the mortality of diabetic patients with multivessel, non-left main disease (vs. initial medical therapy). The same results were replicated in **ISCHEMIA trial**. **Thus, the only absolute indication for CABG in the stable CAD setting is left main disease, not 3-vessel or proximal LAD disease. Yet, CABG remains valuable in the latter subgroups** (ACC class IIb, ESC class I): MI, but not death, was reduced by CABG in the BARI 2D trial of diabetic patients, mainly in multivessel disease with high SYNTAX score >22.[91] MI, but not death, was reduced by revascularization in the extensive CAD subgroup of ISCHEMIA trial (3-vessel >70% or 2-vessel >70% with proximal LAD).[82,91]

The above trials excluded patients with severe LV dysfunction (EF <35%). In patients with severe ischemic LV dysfunction (EF <35%), no or mild angina, and mostly NYHA II–III HF, CABG reduced death and cardiovascular hospitalizations at 10 years in the STICH trial.[92,93] However, the benefit appeared late, >5 years after CABG, and was *not dramatic* (7% mortality reduction at 10 years). Despite the marginal benefit, CABG is provided as a class I recommendation for multivessel CAD with EF ≤35% by both ACC and ESC CAD guidelines, if the operative risk is acceptable.[18,79]

CABG may also be performed for single- or 2-vessel CAD not involving the LAD, if PCI is not technically feasible and the patient has refractory, severe angina. The value of a single- or 2-vessel CABG to a non-LAD vessel is mainly symptomatic.

The well-known benefit of CABG in diabetic patients is seen in CABG vs. PCI trials, rather than in the above trials of CABG vs. medical therapy.

VIII. PCI and PCI vs. medical therapy

General PCI indications and pitfalls – Consider the following 3 settings:[18,79]

- PCI is a first-line consideration for 1- or 2-vessel CAD, along with severe angina.
- PCI is an alternative to CABG in 3-vessel CAD, or 2-vessel CAD involving the proximal LAD, with an angiographic SYNTAX score ≤22 and no diabetes.
- In 3-vessel CAD, or complex 2-vessel disease involving the LAD (especially proximal LAD), with *either diabetes or SYNTAX score >22*, CABG significantly improves survival in comparison with PCI (SYNTAX and FREEDOM trials).

By today's standards, in order to perform PCI, not only severe angina needs to be present, but the **stenosis needs to be >80%, or, if only 50–80% obstructive, objective significance needs to be documented by stress imaging or FFR** (as per the ISCHEMIA trial). PCI is flawed by a risk of restenosis of ~10% at 1 year, and >1–2% per year thereafter. At the 5-year follow-up of PCI populations without extensive CAD, 20–25% of patients had recurrent events, mainly recurrent symptoms with a need for revascularization. Approximately 50% of these events occur in the target vessel, mainly the target stented lesion, while 50% occur in remote vessels (non-culprit disease progression).[86,94] Those events would be more common in patients with diffuse and complex CAD, who not only have a higher risk of restenosis but also a higher risk of progression of non-target lesions/vessels, as PCI only addresses the focal disease.

PCI vs. medical therapy (6 trials) – The **COURAGE trial** evaluated patients with stable, rather mild angina, normal EF, and a good functional status (mean stress test exercise time = 7 minutes).[95] It included a large population of patients with multivessel CAD (~70%, including 30% 3-vessel CAD) and patients with proximal LAD disease (~35%). *Initial* PCI did not improve death or MI outcomes as compared to *initial* medical therapy ± delayed PCI (PCI was eventually performed in 31% of patients in the medical therapy arm). COURAGE results, however, do not dismiss the value of PCI in highly symptomatic patients with frequent anginal episodes (i.e., daily), those with severely limiting angina, or those with persistent angina despite medical therapy, patients in whom PCI has strong effects on quality of life and functional status, according to the COURAGE quality-of-life substudy.[96]

Similar results were replicated in the **BARI 2D trial**.[97] In diabetic patients with mild angina, *initial* revascularization did not reduce death or MI in comparison to *initial* medical therapy, although 40% of patients eventually crossed over from medical therapy to revascularization over 5 years. More specifically, in patients with 1- or 2-vessel CAD, initial revascularization with PCI did not reduce death or MI in comparison with medical therapy (PCI stratum). In patients with extensive CAD randomized to initial CABG vs. medical therapy (CABG stratum), initial CABG reduced MI (14.6% vs. 7.4% at 5 years), but not death, in comparison with medical therapy.

The **FAME 2 trial** randomized patients who mainly had 1- or 2-vessel CAD (65% proximal/mid-LAD) to FFR-guided PCI vs. medical therapy. FAME-2 trial differs from the COURAGE trial mainly in the use of FFR guidance. PCI strikingly reduced the risk of urgent revascularization at 8 months and 5 years (6% vs. 21%), as well as all future revascularizations (13% vs. 51%), more so in lesions with

FFR ≤ 0.65.[85] Yet PCI failed to show any mortality or MI reduction even at 5 years.[36] While *PCI significantly reduced the risk of late spontaneous MI, which occurred in 10% of medically managed patients vs. 6.5% of PCI patients at 5 years*, it was associated with a risk of periprocedural MI (2%) and stent thrombosis (1%), which, beside non-target lesion progression, negated the overall MI benefit. Moreover, late STEMI was not reduced by PCI and was similarly low in both arms (1.6% at 5 years). It was speculated that long-term mortality rates might diverge in favor of PCI, as spontaneous MI has a larger impact on long-term mortality than periprocedural MI,[98] but this was not seen at 5 years (not even a trend).

The **ISCHEMIA trial** selected stable patients with moderate or severe ischemia on stress testing (≥10% of the LV). Those patients were subjected to *coronary CTA to confirm CAD diagnosis (≥50% in a major epicardial vessel) and to rule out left main disease*; ~5% of screened patients had left main disease and were excluded. Patients with CAD were randomized to medical therapy vs. cardiac catheterization followed by revascularization; patients in the medical therapy arm only received CTA at baseline, not cardiac catheterization.[22] ***Unlike COURAGE and BARI 2D, this trial randomized patients before any catheterization was done. In a way, this study did not just question the value of revascularization, but also the value of invasive coronary angiography after a severely abnormal stress test.*** At baseline, in both groups, 45% of patients had 3-vessel CAD on CTA, 31% had 2-vessel CAD, 47% had proximal LAD disease, and 42% had diabetes. In the invasive arm, only 13% did not have significant CAD on catheterization, and thus most patients underwent revascularization, of whom 76% received PCI and 24% received CABG. At 4 years of follow-up, invasive strategy and revascularization did not affect mortality (~6.5% in both arms), MI, or the combined endpoint of MI/mortality (11.7% for invasive vs. 13.9% for conservative). Invasive strategy increased MI by ~2% in the first 6 months (large periprocedural MI) and reduced it by 4% between 6 months and 5 years (spontaneous MI), with a nearly neutral overall effect. This lack of benefit was consistent across all subgroups, including 3-vessel CAD, proximal LAD, and diabetic subgroups, and was not affected by ischemia or anatomic severity.[82] Of note, EF was >35% and mostly normal (median 60%). The biggest pitfall is that >95% of patients had CCS 0-II angina and most patients had infrequent angina, monthly or less. Eventually, crossover revascularization was performed in 21% of the medical therapy arm at 4 years. At a longer follow-up of up to 7 years (median 5.7 years), the invasive strategy was associated with ~2% lower cardiovascular mortality but a higher non-cardiovascular mortality, with an overall null mortality effect.[99]

In sum, ISCHEMIA trial shifts 2 paradigms in stable CAD:

i. **Revascularization: in stable CAD, revascularization does not reduce mortality or MI even in extensive CAD and severe ischemia** (the only exclusion being left main disease).
ii. **Diagnostic strategy:** this trial questions the value of functional stress testing in the management of stable CAD and rather emphasizes the value of anatomical rule-out of left main disease via CTA. Even invasive coronary angiography is not routinely necessary after a severely abnormal stress test, which is a paradigm shift. *CTA takes a more central role*.

ISCHEMIA-CKD trial and CKD subgroup of ISCHEMIA trial – Only patients with CKD did not undergo CTA (GFR 30–60 ml/min/1.73 m^2 in main ISCHEMIA trial, and GFR <30 ml/min/1.73 m^2 or dialysis in ISCHEMIA-CKD trial).[25] ***CKD patients were randomized to a conservative strategy straight after moderate/high-risk stress testing, without any coronary imaging to rule out left main disease***, yet they had a similar death/MI outcome vs. invasive strategy. Invasive strategy increased stroke (~4 times!) and requirement for dialysis in ISCHEMIA-CKD trial and appeared particularly harmful in stage 4 CKD, wherein it trended to increase death.[100] Despite their very high risk, ISCHEMIA-CKD patients did not benefit from revascularization (mortality ~27% at 2.2 years and 40% at 5 years). Approximately 70% of mortality is cardiovascular, mostly sudden cardiac death, not necessarily from MI, but from altered myocardial substrate and rapid BP, volume, and electrolyte changes.[101,102]

All the above 5 trials (COURAGE, FAME 2, BARI 2D, ISCHEMIA and ISCHEMIA-CKD) included patients with ***stable symptoms that are reasonably controlled with medical therapy, not ACS, not daily angina (~excluded in ISCHEMIA), and not angina on short walks.*** In those patients, **revascularization does not improve death or MI even if ischemia is severe or CAD is multivessel.** Severe, refractory symptoms and ACS remain appropriate indications for coronary angiography and revascularization. PCI is superior for angina relief and is particularly helpful in patients with severe functional limitation, and in patients with angina and a combination of low heart rate/low blood pressure, whose myocardial demands are inherently low (low rate-pressure product) and whose angina is mainly driven by the severe stenosis rather than hemodynamic variables.[96,103]

REVIVED-BCIS-2 trial selected multivessel stable CAD with EF <35%. Even in severe LV dysfunction, multivessel PCI did not provide a mortality or HF benefit (review Chapter 4).

Furthermore, it is unclear if PCI improves survival in patients with left main or extensive multivessel disease who would derive a survival benefit from CABG, but who are not candidates for CABG or whose SYNTAX score is ≤22. By extrapolating the results of CABG vs. PCI trials, PCI is presumed to improve survival in those patients (PCI and CABG are associated with equivalent survival in select patients with multivessel or left main CAD); this has not been directly proven.

IX. PCI vs. CABG in multivessel and left main disease

CABG outcome is less dependent on the complexity and diffuseness of lesions than PCI, and when a graft is placed, the whole proximal 6–8 cm of the coronary artery is protected from MI induced by plaque rupture (Table 3.4). Keep in mind that plaque ruptures and acute coronary occlusions occur overwhelmingly in the proximal third of the coronary arteries, a segment protected by CABG (80–90% of acute LAD and LCX plaque ruptures are in the proximal 5 cm).[104] Hence, CABG is consistently associated with a lower risk of MI and angina

Table 3.4 Reasons for superiority of CABG vs. PCI.

i.	CABG success is much less affected by the anatomical complexity (e.g., CTO) and the diffuseness of CAD
ii.	While PCI treats focal disease, a graft improves flow to the whole coronary territory, including segments with moderate diffuse disease, and protects against MI resulting from occlusion of the proximal 6–8 cm coronary segment. Plaque ruptures and acute coronary occlusions occur overwhelmingly in the proximal 5 cm of coronary arteries
iii.	Very long longevity of LIMA graft
iv.	More complete revascularization with CABG (vessels with CTO are sometimes left untreated in a multivessel PCI strategy)

recurrence than PCI. Even when MI occurs after CABG, it is less likely to be fatal and more likely a small MI, as compared with patients receiving medical therapy or PCI (CASS registry, BARI trial, and SYNTAX trial).[105]

Isolated proximal LAD disease – A meta-analysis of randomized trials of CABG vs. PCI for isolated proximal LAD disease suggests the lack of mortality difference, although repeat revascularizations were much lower with CABG (pre-DES era).[106]

SYNTAX trial – In the DES era, the *SYNTAX trial* randomized patients with 3-vessel and/or left main disease to CABG vs. PCI with DES. This trial included patients with extensive, complex CAD, and graded the angiographic severity of CAD using the SYNTAX score. In the overall trial, at 5 years of follow-up, CABG was associated with a significant reduction in MI (~10% vs. 4%), a marked reduction in the need for repeat revascularizations (26% vs. 14%), but no mortality difference (13.9% vs. 11.4%). CABG significantly reduced mortality by an absolute 8% in the high SYNTAX scores (>32).[107,108] Conversely, patients with a low SYNTAX score (≤22) had comparable death and MI rates with CABG and PCI, whether they had 3-vessel or left main disease, yet more repeat revascularizations with PCI. ***Regarding 5- and 10-year mortality, CABG and PCI were equipoise for the left main subset (=left main +1-, 2-, or 3-vessel CAD), but CABG reduced mortality in 3-vessel CAD without left main***. Interestingly, *CABG outcomes were not affected by SYNTAX score, i.e., CABG success and post-CABG survival were not affected by angiographic complexity, in contradistinction with PCI*. The only pitfall of CABG was the higher early risk of stroke (2.2% vs. 0.6% at 1 year).

The SYNTAX score assigns a number for the location of each stenosis (e.g., left main 5, proximal LAD 3.5, proximal LCx 1.5, OM 1, RCA 1), and multiplies this number by 2 in case of a 50–99% stenosis, and 5 in case of a CTO. Additional points are added at every lesion for tri- or bifurcation, long disease, calcium, and CTO complexity. Overall, the score emphasizes proximal stenoses (especially LAD) and angiographic complexity, especially CTO.

FREEDOM trial – Diabetic patients with 2- or 3-vessel CAD involving the LAD were randomized to CABG vs. PCI with DES.[109] At 5 years of follow-up, CABG significantly reduced mortality vs. PCI, almost as much as in the high SYNTAX group of SYNTAX trial (16.3% vs. 10.9%). It reduced MI (~14% vs. 6%) at the price of an increase in postoperative stroke and a higher early postoperative mortality. The benefit in these diabetic patients was consistent across all SYNTAX score groups, including the low SYNTAX group.

FAME 3 trial – This trial randomized 3-vessel CAD without left main involvement and with a mean SYNTAX score of 26 to FFR-guided PCI vs. CABG (diabetes 28%). Unlike the SYNTAX trial, the difference in death/MI/stroke between PCI and CABG narrowed over time and was insignificant at 5 years. PCI events were much lower than in the SYNTAX trial (16% with PCI vs. 14% with CABG in FAME 3, 22% with PCI vs. 14% with CABG in SYNTAX 3-vessel group). Unlike the SYNTAX 3-vessel group, mortality was similar with PCI vs. CABG in FAME 3. MI (8% vs. 5%) and repeat revascularization (16% vs. 8%) were mildly improved with CABG vs. PCI. FAME 3 is the most favorable PCI trial in 3-vessel CAD and partly reflects PCI improvements (radial access, better stents, FFR guidance).[110,111]

EXCEL and NOBLE trials of left main disease – Both EXCEL and NOBLE trials specifically randomized patients with left main disease and mainly low or intermediate SYNTAX score (≤32, 21 ± 6) to CABG vs. PCI; 81% of patients had distal left main disease, and 15–29% had diabetes. In both trials, CABG was slightly superior to PCI at 5 years of follow-up.[112,113] In EXCEL, the 5-year composite death/MI/stroke was not different, but CABG slightly yet significantly reduced mortality (13 vs. 9.9%), nonprocedural MI (6.8 vs. 3.5%), and repeat revascularizations (target and non-target, 16.9 vs. 10%). In the CABG group, the composite outcome was increased in the first 30 days but reduced beyond 30 days (survival curves crossed at 1 year). In NOBLE, CABG significantly reduced the primary outcome, which included repeat revascularizations (28.9% vs. 19%), and reduced nonprocedural MI, but did not reduce mortality.

For 3-vessel CAD – SYNTAX and FREEDOM trials, and to a lesser degree, FAME-3 trial, support CABG. PCI is an option in patients with a low SYNTAX score ≤22 and no diabetes (ESC class I as alternative to CABG).

For left main disease – Both EXCEL and NOBLE trials support PCI as an alternative to CABG, including in complex distal left main. In fact, **PCI seems a more viable option in left main disease than complex 3-vessel CAD, as per SYNTAX left main analysis.** PCI is associated with lower early stroke and periprocedural MI, but higher late MI and revascularizations. As such, ESC guidelines allow PCI as an alternative to CABG in left main disease, including distal left main disease, with a SYNTAX score ≤22 and no complex multivessel disease (class I as alternative to CABG).[18]

Note some of the features of the SYNTAX, FREEDOM, NOBLE and EXCEL trials:

- LVEF was normal or >40% in almost all patients. Very few patients had HF (4% in SYNTAX trial).
- Patients with acute MI were included in the stable phase, beyond the initial few days: up to 30s% of patients in those trials had recent ACS. Also, CABG accounted for ~20% of revascularizations in NSTEMI invasive trials (e.g., TACTICS).
- While the CABG benefit on repeat revascularization emerges early within the first year, the survival and MI benefit only starts to emerge beyond 2 years of follow-up, after an early perioperative hazard (in all trials). This benefit appeared sooner in the high SYNTAX score group in SYNTAX trial. Overall, this implies that CABG mainly applies to patients who are expected to have a long longevity (e.g., > 3–4 years).

- Near consistent increase in the risk of stroke with CABG (by an absolute ~2%).
- Patients with prior stroke were essentially excluded from these trials. In fact, very few patients had carotid disease. Yet, despite this, CABG led to a higher risk of stroke than PCI, which is expected to be even higher in patients with prior stroke or carotid disease.
- Randomized patients were relatively young (median age ~65).

Thus, these trials do not necessarily prove the superiority of CABG in a sicker population: older patients, higher prevalence of stroke, lower expected longevity, severe LV dysfunction or HF. In SYNTAX trial, **elderly patients** (>70) had similar 5- and 10-year mortality with CABG and PCI, and even similar combined cardiovascular events, despite a high mean SYNTAX score of 30, while patients <70 had a reduction in mortality and events with CABG.[114,115] Similarly, when an older but also sicker population was randomized to CABG vs. PCI in the VA-AWESOME trial, the 6-month survival was better with PCI, and the 5-year survival was equivalent with both strategies.[116] In the VA-AWESOME trial, patients had at least one of the following: age >70 (50%), MI <7 days (33%), EF ≤35% (20%), prior CABG (33%). Thus, PCI still has a role in ill patients with multivessel CAD and comorbidities who are deemed at a high surgical risk.

X. High-surgical-risk patients

In a patient with multivessel disease where CABG or PCI is considered, 2 risk scores are used: (i) SYNTAX score to determine PCI outcomes, and (ii) STS score or EuroSCORE to assess surgical mortality (Table 3.5).[117,118] The average CABG mortality is 1.5–2%, but increases to >5% with the combination of several risk factors, especially combined CABG and valve surgery, redo CABG, age >80, prior disabling stroke, severe lung disease, acute MI, HF or hemodynamic compromise. Patients who are at a high surgical risk, much higher than the 2% seen in randomized trials (e.g., >5%), may be better served with PCI (class IIa for low-SYNTAX left main disease, IIb for low-SYNTAX 3-vessel CAD). *Thus, in the era of an aging population with comorbidities, multivessel complex PCI still has a role*. A heart team discussion is warranted for these patients.

In addition to high-surgical-risk patients, patients with small vessels and diffuse distal disease that is severe or calcified may not have appropriate distal targets for CABG and may not be CABG candidates, especially when the LAD cannot be grafted. They may undergo PCI of focal, critical, proximal disease. A third reason that may preclude CABG is the lack of conduits, in particular venous conduits in patients with large varicose veins and venous insufficiency.

The use of LIMA necessitates surgical dissection through the pleural cavity, with a high risk of pleural effusion and deterioration of pulmonary function in patients with severe lung disease.

XI. Role of complete functional revascularization

Complete revascularization is defined as revascularization of all functionally significant stenoses in vessels ≥1.5 mm supplying viable territories. However, this has been defined differently across studies, and some based it on angiographic disease >50–70% rather than on functionally significant disease, or on achieving revascularization of the 3 major epicardial vessels (as opposed to all branches).[119] CABG generally achieves more complete revascularization than PCI, as it is less affected by lesion complexity (e.g., CTO) (63% vs. 43% in SYNTAX trial).[120] *In most registries and post hoc analyses, incomplete revascularization was associated with impaired outcomes only after PCI, not CABG* (New York and ARTS registries and SYNTAX trial analysis).[120–122] This adverse outcome may be related to the residual disease itself, or more so, to the fact that residual disease is a marker of more extensive and aggressive atherosclerosis even across the revascularized arteries, which explains why incomplete revascularization is more unfavorable after PCI, which only treats focal disease, than after CABG. In fact, the intense pursuit of complete revascularization may not, by itself, improve outcomes. In 2 analyses of CABG patients, incomplete revascularization of a small/poor target RCA or LCx in patients receiving LIMA-to-LAD graft did not adversely affect long-term outcomes; in fact, too aggressive revascularization of >1 non-LAD vessel may be associated with worse outcomes.[123,124] This is called "reasonable" incomplete revascularization. This *reasonable revascularization* concept fits with the *functional revascularization* concept where *only large and ischemic* territories are revascularized. Incomplete revascularization usually has a worse connotation with PCI than with CABG, as (i) PCI is a suboptimal therapy for extensive disease, and (ii) PCI more frequently omits large, otherwise graftable vessels because of a technical challenge, such as CTO.

XII. Hybrid CABG–PCI

The superiority of CABG mainly results from the longevity of the LIMA-to-LAD graft. DES stenting of non-LAD vessels, when feasible (e.g., no CTO, no heavily calcified disease), is likely associated with equal or superior results to placement of venous grafts, ~20% of which occlude by the first year. The so-called hybrid strategy consists of performing LIMA–LAD using off-pump CABG (beating heart), followed

Table 3.5 Variables analyzed in surgical risk scores (STS and EuroSCORE).

1.	**Underlying patient-related factors and comorbidities** (i) age (the risk doubles with every 10 yrs >60); (ii) women (~50% higher risk than men); (iii) moderate or severe COPD; (iv) severe CKD; (v) prior disabling stroke or neurological illness; (vi) carotid disease, PAD
2.	**Underlying EF–HF** (i) EF (<50%: mild score; <30%: severe score); (ii) HF functional class IV
3.	**Prior cardiac surgery, especially redo CABG**
4.	**Isolated CABG < isolated valve surgery < CABG + valve surgery**
5.	**Current cardiac status** (i) recent MI; (ii) unstable vs. stable angina; (iii) hemodynamic or electrical instability and requirements for IABP and/or inotropes

by DES PCI of the remaining stenoses during the same hospitalization (hours or days later, with clopidogrel loading after CABG). Occasionally, in patients with critical non-LAD disease, non-LAD disease is stented first, followed by performance of off-pump CABG under clopidogrel therapy.

The off-pump LIMA-to-LAD surgery offers the advantage of avoiding aortic manipulation, which is necessary during on-pump CABG or during SVG grafting (whether off- or on-pump). Also, the shorter surgical time, the lower blood loss, and the avoidance of cardioplegia and cardiopulmonary bypass are advantages.

Currently, the hybrid approach is particularly applicable to: (i) patients with heavily calcified, porcelain aorta in whom aortic manipulation needs to be avoided; and (ii) patients with good LAD target but poor LCx and RCA targets that, nonetheless, have severe proximal disease amenable to PCI.

XIII. Enhanced external counterpulsation (EECP)

This therapy consists of inflating cuffs around the lower extremities during diastole, and deflating them in systole, creating an effect similar to IABP. The systolic cuff depression reduces LV afterload and O_2 demands. It may also have a sustained effect on endothelial function, collateral function, and oxidative stress, explaining the sustained benefit. EECP consists of 35 one-hour sessions. Non-randomized and limited randomized data suggest a reduction of angina and a reduction of ECG and nuclear ischemia with this therapy (class IIb for refractory angina).[18,20]

XIV. Mortality in CAD (Table 3.6)

Note on left main disease – Medical therapy has not been addressed as a standalone therapy for left main disease in any contemporary trial. Old studies such as the VA-CABG trial and the CASS registry have shown that the mortality of medically treated left main disease, whether symptomatic or asymptomatic, is ~10% per year, with a dramatic reduction to 2% per year after CABG, the largest mortality benefit of CABG in any subgroup of patients.[127,128]

Appendix 1. Notes on various surgical grafts

A. SVG

1. *General SVG outcomes*

SVG grafts occlude at the following rates: ~10% in the first month, 15–25% in the first year, and 2–4% per year beyond the first year. Thus, the fastest occlusion rate occurs in the first year, and at 10 years, 50% of SVGs are occluded (Table 3.7). In addition, 20–40% of patients have native disease progression in non-grafted vessels or in grafted vessels distal to the anastomoses at 5–10 years of follow-up.

Table 3.6 CAD mortality.

Older data of medically treated CAD patients (CASS registry)[125,126]
One- or two-vessel CAD: 1.5–2% mortality per yr
Three-vessel CAD with normal EF: 4.5% mortality per yr
Multivessel CAD with EF <35%: 10% mortality per yr
Contemporary data in non-extensive single or multivessel CAD, treated with PCI or medical therapy (COURAGE, BARI 2D PCI group)
1.5% mortality per yr
8–10% cardiovascular event rate in first yr, then 2% per yr
Contemporary data in patients with multivessel CAD and normal EF undergoing CABG or PCI (SYNTAX, FREEDOM, BARI 2D CABG group)
2–3% mortality per yr (after a higher 1st-yr mortality of 3.5%)
12.5% overall death or cardiovascular event rate in first yr, then ~3% per yr (27% for CABG vs. ~37% for PCI at 5 years in complex patients)
Contemporary data in multivessel CAD with EF <35% but no or mild HF (STICH)
~7% mortality per yr with CABG, 8% mortality per yr with medical therapy (mortality would be higher with worse HF status)

Mortality is higher in patients with ACS, low EF, symptomatic HF, or comorbidities.

Table 3.7 Causes and histology of SVG failure.

<1 month
Graft thrombosis, often before hospital discharge, sometimes related to distal native disease past the anastomosis or to technical issues (anastomotic stenosis from the suture, SVG kinking or stretching)
1 month to 1–3 years
Fibrointimal hyperplasia leads to peri-anastomotic or mid-graft stenosis: exposure of the vein to the arterial pressure leads to endothelial injury with formation of a hard neointima, called fibrointimal hyperplasia
>1–3 years
Atherosclerosis starts to develop at >1–3 years, with similar risk factors to native atherosclerosis
As compared with native atherosclerosis, SVG atherosclerosis is more extensive, friable, with more foam cells and no fibrous cap, and may be mixed with thrombi. Aggressive lipid lowering slows down this process

CABG patients who present with ACS often have an SVG culprit. However, <50% of SVG occlusions lead to MI (STEMI or NSTEMI), the remainder being either silent or leading to stable angina;[107] this depends on the status of the native vessel and the presence of collaterals. Overall, MI occurs at a rate of ~1–2% per year, and additional revascularization is required in ~15–20% of patients at 5 years (CASS, SYNTAX trials).[108]

2. *Factors determining SVG patency*

Early and late SVG patency is dependent on a good flow through the graft and requires: (i) good distal runoff and good size of the recipient artery (>1.5–2.0 mm) without distal disease; (ii) significant proximal disease in the recipient artery (otherwise, the flow through the recipient artery prevents appropriate flow through the graft); (iii) well-matched size of the graft and recipient artery.[129–131] This dependency on size and flow explains that SVG graft to LAD has higher patency than SVG to RCA or LCx, and that SVG to a diagonal or to a small vessel has the lowest patency. Of note, FFR-guided CABG, wherein only vessels with significant FFR are grafted, did not significantly improve clinical outcomes or graft failure compared to angiography-guided CABG (FARGO trial) (unlike the benefit of FFR-guided PCI);[132] moreover, the disease progressed quickly after CABG, within 6 months, in vessels with insignificant FFR (from a mean of 0.89 to 0.81, with 40% of vessels progressing from insignificant to significant FFR). Also, in a patient who already needs CABG, adding a graft to a moderately obstructed territory may still protect it from infarcts.

3. *Treatment of SVG failure*

**In the first 30 days*, ST elevation is often the result of venous graft thrombosis with distal embolization, which worsens the perfusion of a previously stable territory subtended by a stenotic artery or by collaterals. Since the main issue is distal embolization, angiography is not necessarily performed for every post-CABG ST elevation. If there is a clinical, arrhythmic (VT), or hemodynamic manifestation of ischemia, the patient often needs to be revascularized. Emergent post-CABG angiography is performed, even the first day, to identify the problem and potentially treat native distal disease, or less often, graft anastomotic disease, with PCI.[133,134] If a thrombotic SVG occlusion is found, PCI of the native artery may be attempted if possible. Urgent redo-CABG is also considered. A review of the preoperative anatomy is critical: e.g., an expected occlusion of a graft supplying a small distal RCA may not have any revascularization option when the native RCA has a CTO. In large registries, ~4% of patients require urgent angiography within 24 hours of CABG for suspected graft failure, ~1.5% undergo PCI (mainly of a native artery), and ~2–3% undergo redo-CABG.[135]

**Beyond the first 30 days*, when SVG disease develops, either the SVG or the native artery may be targeted for PCI. SVG PCI is often preferred initially, particularly if native artery PCI is complex (e.g., long calcified CTO) (PROCTOR trial). Conversely, native PCI is more strongly considered for recurrent SVG disease or total SVG occlusion; conservative medical therapy is reasonable in complex cases. *Location and timing* of the disease determine long-term success. Distal SVG stenosis has the best long-term success rate with PCI, especially when it occurs within the first few years after CABG, in which case it is due to intimal hyperplasia without atherosclerosis (20% restenosis after plain angioplasty). Mid-shaft disease has an intermediate long-term success rate, while proximal disease has the lowest success rate.

Regarding timing, disease occurring at <1–3 years without significant atherosclerosis has the best long-term success.[136,137] In fact, the extent of atherosclerosis >1–3 years after CABG is a major determinant of long-term success. Treating the focal lesion, particularly a proximal lesion, does not prevent the eventual progression of the diffuse atherosclerotic disease and the eventual *~30–50% failure rate of the treated SVG at 2 years* (DIVA trial, 37% SVG failure at 2.7 yrs).[138] While DES may prevent the focal restenosis, it does not eliminate this aggressive disease progression outside the stented area and the long-term occlusion risk of diffusely diseased grafts. Degenerated SVGs with diffuse atherosclerosis have a high adverse event rate at 2 years (up to 45%), even if SVG stenosis is only moderate.[138]

Patients with multiple failing SVGs and no patent graft to the LAD have an indication for redo CABG, unless the operative risk is prohibitively high.

4. *Role of DAPT*

After CABG, 1-year *DAPT with ticagrelor* reduced SVG occlusion compared to aspirin monotherapy in DACAB trial and a subsequent meta-analysis (~50% reduction), including in patients with stable CAD or MI at baseline.[139] However, in the large TACSI trial that recruited ACS patients undergoing CABG, DAPT with ticagrelor did not improve clinical outcomes and rather increased bleeding.[140]

DAPT with clopidogrel also reduced SVG occlusion in the meta-analysis (by ~40%), but the clopidogrel trials were small, and only 2 small trials showed, by themselves, a significant reduction of SVG occlusion.[141]

B. LIMA

LIMA graft is usually used as an in-situ graft: the distal part of the LIMA is connected directly to the LAD, while the proximal LIMA is not touched and remains connected to the subclavian artery. LIMA atherosclerosis is extremely uncommon, hence the excellent long-term patency of 90% at 10 years; *a LIMA that is patent beyond the first few months post-CABG usually remains patent for life*. LIMA has an intact internal elastic membrane that prevents smooth muscle migration and atherosclerosis. Early LIMA failure is possible, however, and is related to anastomotic fibrointimal hyperplasia or to poor LIMA development. LIMA may not develop or may regress because of a subclavian stenosis, poor distal LAD flow, or insignificant proximal LAD stenosis. Significant native proximal disease is necessary to allow SVG and, more particularly, LIMA and radial grafts to remain patent; a good native flow may impede SVG or LIMA flow, leading to thrombosis of the SVG or spasm of an arterial graft. In fact, bypassing a LAD that has <50–60% stenosis leads to disuse atrophy of the LIMA or "string sign" in up to 80% of patients.

Always attempt to use LIMA to the LAD, except in emergent cases with hemodynamic instability, where SVG-to-LAD may be preferred, because SVG has a higher and more expeditious flow initially.[130] Also, LIMA is occasionally avoided in patients with severe lung disease in order to avoid pleural dissection and the subsequent left pleural effusion.

While LIMA does not develop atherosclerotic disease, ischemia of the LIMA territory may be caused by:

1. Subclavian stenosis (this is the most common cause of LIMA ischemia). The assessment of BP in both arms is critically important in CABG patients presenting with angina.
2. Atresia of the LIMA graft related to insignificant proximal LAD disease, poor distal LAD runoff, or subclavian stenosis. It is usually seen early after CABG.
3. Stenosis of the LIMA-to-LAD anastomosis, which often occurs in the first 3–6 months and results from intimal hyperplasia. Since it is not due to an atherosclerotic process, plain angioplasty provides good long-term patency (as good as BMS). Stenting may be reserved for a suboptimal result but is more systematically used in the DES era.
4. Progression of native LAD disease distal to the anastomosis.
5. If the LIMA's intercostal and lateral thoracic branches are not clipped, the flow may be directed away from the LAD (steal phenomenon). However, this is an unlikely cause of myocardial ischemia, as the coronary flow is mainly diastolic, while the flow into the intercostal branches is mainly systolic. Multiple studies failed to show any hemodynamic significance of LIMA side branches, with no effect on coronary flow reserve during exercise or adenosine infusion.[142,143]

C. Other arterial grafts

Radial grafts have similar 1-year patency to SVGs, but very low attrition rate beyond the first year and better long-term patency (85% at 5 years).[144,145] Radial grafts are very prone to spasm and more prone than any other graft to early failure if the underlying native stenosis is not severe or the target artery is not large. They are probably best used when stenosis is >90% and the recipient artery is very large.[145] Moreover, radial grafts are more susceptible to atherosclerosis than mammary arteries.

RIMA may also be used, as in-situ or free graft, mainly for RCA or LCx. It may be used as a free rather than in-situ graft to the distal RCA and sometimes LCx branches, because RIMA may be too short to reach these branches. RIMA has a better patency than radial and SVG grafts but may be technically more challenging with a risk of sternal wound infection, especially in patients with diabetes.[146]

The gastroepiploic artery may be used as a free or in-situ graft.

A classical CABG surgery involves grafting a LIMA to the LAD, one or several SVGs to diagonal(s), obtuse marginal branch(es), and distal RCA (or its PDA or PLB branch). Instead of SVGs, radial or free RIMA grafts may be used.

In distal left main disease, both the LAD and one of the obtuse marginal branches are bypassed.

D. Grafts with multiple distal anastomoses (see Chapter 34, Figure 34.41)

Some grafts connect to 2 or multiple distal targets. A ***sequential graft*** (or jump graft) connects to one branch, e.g., OM1, in a side-to- side anastomosis, then continues and connects to another branch, e.g., OM2, in an end-to-side anastomosis. A ***split graft*** (or Y graft) consists of a graft A that connects to one branch and a second graft B that is anastomosed to graft A and that separately connects to another branch. Sequential and split grafts reduce the number of aortic anastomoses and may improve patency in light of the higher flow across the graft. However, when the runoff is good, grafts with single targets have a higher patency than sequential grafts.[130,131] Sequential grafting is useful in patients with poor runoff or patients with limited venous conduits (e.g., varicose veins). The best sequential graft patency is obtained by placing the last distal anastomosis onto the coronary branch with the greatest runoff, while the smaller coronary branch is anastomosed more proximally in a side-to-side fashion (e.g., graft to diagonal and LAD, LAD being the last anastomosis); this allows an increase in flow throughout the whole graft.[131]

E. Off-pump CABG

During on-pump CABG, the aorta is cannulated and cross-clamped, and a cardiopulmonary bypass (heart–lung pump) is used between the venae cavae and the aorta. Cardioplegia is then induced, and the pulmonary ventilation is turned off. The arrested heart is not perfused and is thus ischemic: this is reduced by rapid and cold cardioplegia, and limiting "pump time." *Off-pump CABG* is performed on a beating heart without cardioplegia and aortic cannulation, although partial aortic cross-clamping is still needed if SVG anastomoses are performed.

Off-pump CABG has the advantage of less bleeding/less requirement for transfusion, less renal failure, less respiratory complications, and probably less stroke as aortic manipulation is limited.[147,148] In fact, in patients with heavy aortic calcifications or atherosclerosis, off-pump CABG with only LIMA or LIMA and RIMA grafting is particularly valuable, as it avoids aortic manipulation. Another advantage is in severe HF: off-pump CABG with partial femoral pump support may reduce cardiac ischemic time and post-op shock compared to on-pump CABG. Off-pump CABG is, however, associated with less complete revascularization and a higher risk of early ischemia and graft failure.[147] **MIDCAB (minimally invasive direct CABG)** is a form of off-pump CABG performed through a mini-thoracotomy between 2 ribs, and mainly consists of single-vessel grafting of the LIMA to the LAD. Off-pump LIMA–LAD may be used as part of a hybrid strategy, where non-LAD disease is treated with PCI.

Appendix 2. Coronary vasospasm (variant angina, Prinzmetal angina)

A. Underlying CAD: patterns of vasospasm

While Prinzmetal angina was initially described in patients who had underlying obstructive CAD, sometimes unstable CAD,[4,5,149,150] later reports suggest that vasospasm is also commonly diagnosed in patients with typical angina and no obstructive CAD.[6] Even when the coronary arteries appear angiographically normal, IVUS imaging demonstrates that the sites of vasospasm exhibit underlying atherosclerosis. Atherosclerosis induces endothelial dysfunction and dysregulation of nitric oxide production, which leads to local vascular hyperreactivity.[7]

Vasospasm may be ***epicardial and focal***, i.e., involving one coronary segment, or ***epicardial and diffuse***, involving 2 or more coronary segments. It may also occur solely at the ***microvascular level***.

Additional features of vasospasm are:

- Epicardial vasospasm often involves one site and *recurs at the same atherosclerotic site*; less commonly, it may involve multiple sites, sometimes two separate coronaries, or occur at separate sites at different times (~15% of cases).[151]
- The LAD and RCA are most involved. The proximal and distal segments have been variously involved in different reports.
- In the absence of CAD, spontaneous remissions within 6–12 months of follow-up or remissions with CCBs are common (up to 83% of patients). Yet up to a third of these patients may experience recurrences.[150–153]
- Vasospasm that occurs without significant CAD is more commonly seen in women,[6,154,155] although some series suggest it is more common in men.[149,150,153] It is generally described in patients >40 years of age, with a mean age of 55–65, and is more prevalent among Asian populations. Smoking and chronic alcohol or cocaine use increase the risk of vasospasm.

B. ECG, arrhythmias, and clinical manifestations

Vasospasm usually leads to a more severe ischemia than fixed stenosis and is occlusive or subtotally occlusive, particularly when it occurs on top of obstructive, fixed stenosis. It typically leads to transient ST elevation, reflecting transmural ischemia, but it may also lead to ST-segment depression when the spasm is not totally occlusive. Post-ischemic T-wave inversion may be seen. Since ischemia may be severe, serious arrhythmias (VT, VF, AV block), syncope, sudden death, or MI may be seen. The combined risk of the latter complications is ~20% at several years of follow-up, even in the absence of CAD;[150–153] yet, spontaneous remissions (~40%) or remissions with CCBs (83%) are common, and the course is often, but not always, benign. Vasospasm may cause MI directly but may also lead to coronary thrombosis or intraplaque hemorrhage, creating an acute fixed obstruction.

Angina is commonly (~40%) a rest angina without exertional limitation, even in patients with CAD (angina manifests when the dynamic component exaggerates the fixed stenosis).[5,151,152] It may also be a mixed rest/exertional angina, or a purely exertional angina.[6,153–155] The rest angina typically follows a cyclic, often nocturnal pattern, and is more prolonged and more severe than classic angina; emotional stress is a common trigger.

Exercise ECG testing is frequently positive in these patients (50–70%),[5,6] partly from the underlying CAD and partly from exercise-induced vasospasm.

C. Diagnosis of vasospasm

Epicardial (macrovascular) vasospasm is definitely diagnosed on coronary angiography when the following 3 features occur, spontaneously or with provocation:[6,154–156]

- Focal or diffuse vasospasm leading to ≥75% dynamic luminal reduction. One study used a 90% cutoff[156]
- ST-segment elevation or depression
- Reproduction of the patient's symptoms

Microvascular vasospasm is diagnosed when ST-segment changes and symptoms occur with provocation, without any visualized spasm.[6] An additional feature of microvascular spasm is a slow coronary flow (delayed TIMI frame count) without epicardial obstruction.

When present spontaneously, vasospasm is frequently confused with a true fixed obstruction; the diagnosis of vasospasm is made when the stenosis improves to <50% with intracoronary NTG administration. While it is reasonable to administer NTG whenever any coronary stenosis is seen, to rule out a dynamic component before any PCI, vasospasm is particularly suspected when the stenosis is concentric with smooth borders. *Conversely, ostial spasm occurring at the catheter tip does not have a diagnostic value*. The dose of intracoronary NTG is 50–200 mcg—studies suggest no further coronary dilatation with doses beyond 200 mcg (Kern MJ. Am Heart J 1986;111:845–52).

Vasospasm may be provoked with intracoronary ergonovine, or safer yet, slow intracoronary acetylcholine boluses (very quick offset). Angiographic vasospasm without symptoms or ECG changes is suspicious but not diagnostic of vasospastic angina.

Although acetylcholine provocation is safe, it is not routinely performed at many institutions. The diagnosis of coronary vasomotion abnormality is presumptive in a patient with the following triple combination: (i) effort chest pain; or resting chest pain with significant distress, especially if nocturnal/early morning or induced by emotional stress and responsive to NTG; (ii) no angiographic CAD; and (iii) documentation of transient ST changes on stress ECG or true perfusion defect. Comprehensive invasive measurements, including acetylcholine testing, are preferably performed (Appendix 5).[156]

In vessels with normal endothelial function, acetylcholine induces the synthesis of NO and coronary vasodilatation. In vessels with endothelial dysfunction, the endothelium cannot generate NO, hence acetylcholine directly acts as a vasoconstrictor.

D. Frequency of vasospasm in patients with exertional chest pain and no significant CAD

The ACOVA study assessed patients (age 63 ± 10) with a predominantly exertional chest pain and unobstructed coronary arteries (<20%) on angiography. Among patients who underwent a stress ECG before angiography, half had ischemic ECG changes. Upon provocative testing with acetylcholine, 62% of all patients developed macrovascular or microvascular spasm (28% macrovascular, 34% microvascular). Macrovascular spasm was often diffuse and distal, and involved 1 or 2 vessels (1 vessel 67%).[6,155] Most of these patients were women.

Thus, macrovascular vasospasm, and more so, microvascular dysfunction, not only cause rest angina but are also a common cause of exertional angina in patients without CAD.[154–156] The stimulation of adrenergic α-receptors may induce macro- or microvascular spasm. Alternatively, the macro- or microvascular spasm induced by acetylcholine testing may be a marker of abnormal coronary vascular tone that prevents appropriate macro- and microvascular dilatation with exercise.

E. Treatment and prognosis of macrovascular vasospasm

An underlying significant CAD is treated with PCI or CABG as appropriate. Beware that, sometimes, the lesion is only moderate and not hemodynamically significant, but becomes significant when vasospasm aggravates it; in those cases, revascularization is not indicated and good results are obtained with CCBs.

In the absence of severe CAD, CCBs are first-line therapy. CCBs are very effective (control of symptoms in 83% of patients),[157] and spontaneous remission is also very common.[150–152] Nitrates may also be used, but are less effective (31%).[157] β-Blockers may exaggerate vasospasm through blocking the β_2-receptor, but may be beneficial in patients with a fixed stenosis and exertional symptoms. In comparison with CCB monotherapy, the combination of CCB and statin has been shown to dramatically reduce vasospasm in one trial.[158]

The long-term risk of cardiac events is intermediate and is partly related to the extent of underlying CAD.[4,5] In 5 series, patients without CAD had a lower, but still significant, risk of MI (up to 15%),[5,149,152,153,157] VT (25%),[5,152,157] syncope from arrhythmia (20%), and particularly cardiac arrest (2.5%)[149,153] at several years of follow-up; these patients, for the most part, were not receiving CCB. In fact, vasospasm has been well documented as a cause of cardiac arrest in 5 patients without significant CAD; CCB prevented ergonovine-induced spasm and arrhythmias in these patients.[159] The severity of vasospasm, as evidenced by the severity and extent of ST elevation, correlates with adverse events and ventricular arrhythmias regardless of the underlying CAD.[149,153] Similarly, prior MI or cardiac arrest is a strong predictor of future events.[153]

Patients receiving CCBs have a much more benign course with much less angina, much less unstable angina (6% at 3 years), and 10× lower risk of MI and cardiac death (<3% at 3 years), which suggests the great efficacy of CCBs.[149,151,153,156] However, in patients who have already had a cardiac arrest, CCB therapy does not fully eliminate the risk of VF, and ICD may be justified (in one series, 15% of patients receiving ICD had appropriate shocks despite CCB therapy; in another series, >50% had VT/VF or ICD shock despite CCB therapy).[153,160] Abstinence from smoking and alcohol is also associated with a reduction of events.

Appendix 3. Microvascular endothelial dysfunction

Microvascular dysfunction has 2 forms, both reflective of endothelial dysfunction:

i. Microvascular spasm, which is part of the spectrum of coronary vasospasm
ii. Impaired capacity to vasodilate the microcirculation and increase myocardial flow during exercise (<2.5× increase)

It is diagnosed if any of the following is documented:

(1) Abnormal ST-segment and chest pain response to acetylcholine testing
(2) Demonstration of impaired coronary microvascular dilation and coronary flow reserve after adenosine (<2.5× increase in coronary flow, measured with a coronary flow wire).[6,161–163]

Other suggestive features include: (i) slow angiographic flow in the absence of CAD ("coronary slow flow phenomenon"); (ii) LVEDP is frequently elevated and may be the consequence or the cause of impaired coronary flow. Along those lines, microvascular dysfunction may be secondary to left ventricular hypertrophy.[163]

Coronary vasomotion abnormalities (microvascular dysfunction or epicardial vasospasm) are clinically suspected in a patient with the following, after coronary angiography or CTA rules out CAD:

1. Typical exertional chest pain (→ often microvascular dysfunction)
2. OR rest pain or mixed rest and exertional pain with significant distress, especially if nocturnal or induced by emotion and responsive to NTG (→ vasospasm or microvascular dysfunction)
3. AND chest pain persists after negative CTA/coronary angiography and after PPI
4. AND convincing perfusion defect or ST-segment abnormalities on stress testing

The pain in this case is true angina/ischemia with non-obstructed coronary arteries (INOCAs). ***While the stress test is sometimes considered falsely positive (e.g., artifact), patients with convincing angina and ischemic ECG or imaging defects most likely have microvascular dysfunction, or, less frequently, macrovascular spasm***. Indeed, one study has found a correlation between impaired coronary response to acetylcholine and ischemic defects on nuclear testing,[162] and another found an increased prevalence of abnormal stress testing (77%) in patients with abnormal vasomotion.[164] In a study of patients with no significant CAD but with angina—mostly typical exertional angina—ST depression on stress ECG was 100% specific for microvascular dysfunction, but insensitive (~40% sensitivity).[165] As such, ischemia on stress ECG, echo, or SPECT is strongly suggestive of abnormal vasomotion in the right setting, but is not very sensitive; ***stress imaging with PET or MRI*** is preferred to detect abnormal vasodilatory reserve. Unlike nuclear SPECT imaging, nuclear PET can quantify the absolute myocardial flow, both at rest and after stress, and their ratio (<2–2.5 is abnormal).

Microvascular dysfunction is mostly prevalent in women, while epicardial vasospasm is nearly as prevalent in men as in women.[154,155] In ACOVA and in 2 other large studies, ~20% of men with chest pain and unobstructed coronary arteries had microvascular dysfunction, and ~20% had macrovascular spasm; **~70% of women had abnormal vasomotor response** (microvascular dysfunction ~40%; macrovascular spasm ~30%).[6,154,155] The prevalence of microvascular dysfunction actually increases with age (mean age 58–64).

In macrovascular spasm, pain is predominantly a resting pain (40%) or mixed resting/exertional (30%), while in microvascular dysfunction, pain is predominantly exertional or mixed resting/exertional (70%).[154–156]

β-Blockers, CCBs, nitrates, and ranolazine have been used for this syndrome with a variable success rate. **Unlike in macrovascular spasm, β-blockers are recommended and were first-line treatment in CorMicA trial;[156]** they are efficacious via a reduction of exertional myocardial O2 demands, as in obstructive CAD, not via a direct microvascular effect. Nitrates are not microvascular dilators but lessen ischemia through preload reduction. Ranolazine appears to be particularly effective in reducing angina and improving myocardial flow, via improving diastolic relaxation.[166] In one study of microvascular dysfunction, L-arginine, a precursor of NO available as an over-the-counter supplement, significantly improved myocardial flow.[167] In the EDIT-CMD trial, diltiazem improved epicardial vasospasm, but not microvascular dysfunction or spasm.[168] In the WARRIOR trial, intensive statin and ACE-I therapy did not improve CV events or angina and quality of life.

Appendix 4. Women with chest pain and normal coronary arteries

Women with typical angina frequently (>50%) do not have any significant CAD. In the WISE study, ~60% of women with chest pain undergoing coronary angiography (median age, 58) did not have any significant CAD, despite an abnormal stress test in the majority of them;[169] ***~50% of women with chest pain and no obstructive CAD had microvascular dysfunction (as assessed by coronary flow reserve).***[170] Other studies showed a ***70%*** combined prevalence of vasomotor abnormalities in women with possible or typical angina and no CAD.[6,154–156] As such, 50% of women without CAD continue to have chest pain for over a year, with a significant risk of MI (5.5%), HF (7.5%), stroke, and combined cardiovascular events (20%) at 6-year follow-up, higher than patients without persistent chest pain, albeit far lower than patients with CAD.[169–171] Microvascular dysfunction may be present without any stress test abnormality.[170] Perfusion stress PET or MRI is preferred.

The high rate of events on follow-up may be directly related to the following:

- Ischemic events/MI triggered by coronary vasospasm.
- Endothelial dysfunction and abnormal response to acetylcholine predicts the future development of obstructive CAD,[171] and a 14% risk of cardiac events, including progressive CAD, at 3 years.[172]
- Since patients with spasm and endothelial dysfunction have underlying atherosclerosis, erosion of non-obstructive plaque is another potential mechanism of MI. A dysfunctional endothelium may contribute to plaque destabilization and erosion because of its reduced antioxidative potential.

The chicken or the egg dilemma: Diastolic dysfunction with elevated LVEDP may be the cause but also the consequence of microvascular dysfunction, especially in patients without significant LV concentric remodeling. This partly explains HF events in these patients.[173] Elevated LVEDP may suggest microvascular dysfunction in women without traditional risk factors for diastolic HF.

In sum, abnormalities of coronary flow may be due to obstructive CAD, coronary epicardial spasm, or microvascular spasm/dysfunction. While obstructive CAD is associated with the highest risk of events, abnormal vasomotion is associated with an intermediate risk of events, including MI, arrhythmias, and progressive CAD, higher than in patients with no CAD and normal vasomotion.

Appendix 5. Diagnostic strategy for ischemia with non-obstructed coronary arteries (INOCA)

In patients undergoing coronary angiography for typical angina who are found to have unobstructed coronary arteries, the following invasive strategy may be performed to diagnose "coronary vasomotion disorders":

- **Intracoronary acetylcholine assessment of the macro- and microcirculation.** When the endothelium is normal, acetylcholine vasodilates the coronary arteries at the macro- and microvascular levels. *Macrovascular endothelial dysfunction* is defined as a paradoxical, mild diffuse narrowing of the epicardial coronary arteries >20% with acetylcholine (less severe than vasospasm). *Microvascular endothelial dysfunction* is characterized by a coronary blood flow that declines or fails to increase adequately with acetylcholine (<50% increase). *Macrovascular spasm* is defined as >75–90% epicardial narrowing. *Microvascular spasm* is defined as chest pain and ST-segment changes with no epicardial spasm.[6,154–156] Low doses of acetylcholine are initially given to assess endothelial dysfunction and coronary flow (2 mcg then 20 mcg) followed by higher doses to induce macro- and microvascular coronary vasospasm (50–100 mcg, each over 60 s).
- **Intravenous adenosine assessment of the microcirculation via coronary flow reserve *OR* index of microvascular resistance**

  *Coronary blood flow may be calculated using a Doppler wire (flow = velocity × vessel area), but also a more widely available FFR pressure wire that has a temperature sensor. The wire is advanced midway in the coronary artery. Depending on the transit time of a 3-ml saline injection through the coronary guiding catheter, the thermodilution sensor estimates coronary flow at rest and during IV adenosine-induced hyperemia (flow = 1/transit time)

  *Coronary flow reserve (CFR) is the ratio of flow or velocity with adenosine vs. rest. CFR < 2.3 (2–2.5) is abnormal.

  *Index of microvascular resistance is calculated with the FFR wire at hyperemia (=distal coronary pressure/flow). An index ≥25 is indicative of microvascular dysfunction.

Acetylcholine causes vasodilatation if the endothelium is intact and able to generate NO, whereas *adenosine* vasodilates by directly acting on smooth muscle cells; thus, acetylcholine tests "NO- or endothelium-dependent" vascular function, whereas adenosine tests "endothelium-independent" function. Acetylcholine is administered in slow, incremental intracoronary boluses, over 60 sec for each, and adenosine is administered as IV infusion.

Albeit safe, the acetylcholine testing is skipped at some institutions. By adopting this protocol in patients with angina (mostly typical exertional) and unobstructed coronary arteries, macrovascular endothelial dysfunction is found in ~40%, microvascular dysfunction in 30–50%, and epicardial vasospasm in 20–30% of patients.[154–156,164,174,175] **Overall, abnormal vasomotion is found in ~70% of patients.** Preferably, microvascular dysfunction is assessed in each coronary artery, as microvascular dysfunction is frequently a localized process and patients most commonly have microvascular dysfunction in 1 vessel (nearly equal distribution among LAD and RCA, less likely in LCx).[174] For safety, most studies have only assessed 1 vessel, the LAD.[156,164,175]

Also, consider performing FFR if diffuse luminal irregularities are present (the mild diffuse epicardial disease may be significant in ~5% of the cases). If bridging is present, consider calculating diastolic FFR using dobutamine.

CorMicA trial showed that antianginal therapy tailored to the results of the above functional testing significantly improves angina severity and quality of life, compared to presumptive therapy.[156] **As such, patients with microvascular angina received: (first line) ß-blocker; (second line) CCB; (third line) ranolazine. Patients with epicardial vasospasm received CCB +/– nitrates.**

Non-invasive strategy: **Microvascular dysfunction may also be diagnosed non-invasively, after a negative coronary angiogram, via adenosine stress PET or adenosine MRI perfusion imaging. CorCMR trial** showed that in patients with angina but normal coronary angiography, stress MRI identifies microvascular dysfunction in 50% of patients and improves quality of life via tailored therapy (mainly higher CCB and nitrate use).

Unlike SPECT imaging, which qualitatively compares signal intensity of myocardial territories, PET perfusion imaging can accurately quantify myocardial blood flow, using the linear relationship between myocardial blood flow and the speed of radioisotope signal uptake during dynamic imaging. Cardiac MRI can assess myocardial perfusion based on the myocardial signal intensity of gadolinium upon first-pass imaging (not late gadolinium imaging); perfusion reserve is reflected by the change of this signal intensity with adenosine. Both modalities can calculate CFR non-invasively.

Appendix 6. Myocardial bridging

The coronary arteries normally take an epicardial course over the surface of the heart, but they occasionally have an intramyocardial segment that may get compressed in systole and cause symptomatic ischemia. This is called "myocardial bridging," and it is characterized by angiographic off-and-on narrowing of the intramyocardial segment by >70%, only *during systole* (milking effect). This phasic obstruction distinguishes bridging from spasm, which is present throughout the cardiac cycle. Bridging is seen in 2% of coronary angiograms and is almost always limited to the LAD. Intramyocardial coronary segments are even more commonly diagnosed on coronary CT, with a frequency of up to 25%.[176]

Since over 80% of the left coronary blood flow occurs during diastole, bridging does not usually cause ischemia and often does not explain chest pain.[177] During tachycardia, systolic coronary flow gains more importance as systole occupies a larger part of the cardiac cycle, while stronger inotropism leads to a stronger squeeze of the bridged LAD with a spillover into diastole, which may lead to exertional ischemia. This explains that up to 20% of patients with bridging may have ischemia on stress testing.[178] The combination of exertional angina, ischemia on stress testing, and bridging on angiography without obstructive CAD suggests the diagnosis of symptomatic myocardial bridging. Ischemia correlates with the severity of the narrowing and the intramyocardial depth of the bridge.

The hemodynamic significance of bridging may be assessed via a *modified FFR*, where dobutamine is used as the stressor (to exaggerate bridging severity), and the distal-to-proximal pressure ratio is calculated in diastole while ignoring systolic pressures (systolic pressure may falsely overshoot past the bridge, because of the direct compression effect). Non-invasively, stress echo may be used: a significant bridge often leads to a unique pattern of isolated mid-septal buckling that spares the apex. Unlike fixed LAD stenosis, a bridge results in ischemia that is mostly localized at the bridge level rather than distal to it.

Even when symptomatic, myocardial bridging is a benign condition with a very low risk of MI or arrhythmia,[179] yet the abnormal stress may cause atheroma 20–30 mm proximal to the bridge (usually not distal) and vasospasm within the bridge. Nitrates and diuretics aggravate bridging as they lead to reflex tachycardia and increased inotropism; the patient may improve enough upon their withdrawal. In fact, *NTG administration is a useful diagnostic test during angiography*, as it unveils the severity of bridging (opposite effect on vasospasm). β-blockers are the mainstay of therapy.

Appendix 7. Coronary collaterals, chronic total occlusion

In a patient with a coronary total occlusion, the presence of coronary collaterals does not imply that the occlusion is chronic. Underdeveloped intercoronary channels often pre-exist in normal individuals before the occurrence of the coronary occlusion; coronary occlusion or severe stenosis leads to widening of these channels within the first 24 hours, followed by progressive enlargement and maturation of the collateral wall. Mature collaterals that approximate the size of a side branch require ≥2 weeks to form, often ≥12 weeks for a large continuous connector channel.[180,181]

Basic collateral filling may be seen in acute MI. In fact, half of patients with acute MI develop collateral flow in the first 6 hours, while all patients develop collaterals within 24 hours.[181] More mature collaterals may be seen early in MI if it was preceded by a chronic, severe coronary stenosis (e.g., ≥90% chronic stenosis). Grade 3 CC2 collaterals suggest an occlusion that is at least several weeks old, but do not rule out the possibility of acute occlusion on top of a chronic, subtotally occlusive stenosis. Intercoronary collaterals are angiographically graded as follows (Rentrop classification): grade 1 = side branch filling of the recipient occluded artery, without visualization of the body of the recipient artery; grade 2 = partial, faint filling of the body of the recipient artery; and grade 3 (mature collaterals) = complete filling of the recipient artery. Collaterals grade 2–3 may be further classified by the size of the connector channel (CC classification): CC0, no continuous connection; CC1, continuous, threadlike connection ≤0.3 mm; and CC2, continuous, side branch–like size of the collateral ≥0.4 mm. Nitric oxide promotes collateral growth; traditional risk factors, *particularly diabetes*, may impede the development of collaterals.

Mature collateral flow may provide up to 50% of the native antegrade flow, and thus may drastically reduce ischemia.[182] Chronic total occlusions (CTOs) most often develop slowly, allowing collaterals to develop and allowing normal function of the subtended myocardium at rest. While a CTO is almost always associated with stress-induced ischemia, the degree of ischemia depends on the size of the territory and the maturity of collaterals.[183]

CTO is defined as a total occlusion that is >3 months old without any antegrade filling (*true CTO*), or with faint antegrade filling through microchannels (*functional CTO*). CTO is distinguished from an acute or recent occlusion by the clinical presentation and the ECG (stable angina in CTO, recent ACS or MI in recent occlusion). A small subset of CTOs may be the long-term remnant of an old, non-recanalized MI. The duration of the CTO is gauged by the date of worsening of angina or the date of an old MI. *Bridging collaterals*, which are fine collateral vessels that form a caput medusae around the CTO, usually imply an old occlusion >3 months old and a reduced PCI success rate. This fine bridging network is sometimes confused with intra-CTO microchannels (functional CTO), yet the 2 entities have radically opposite implications: the former implies a low PCI success rate, while the latter implies a high PCI success rate.

After successful PCI of a CTO, a considerable fraction (50%) of the collateral function is immediately lost through spasm and is non-recruitable should acute reocclusion occur, particularly when the collateral connection is small at baseline (CC0 or CC1).[181] The patient may have a stable CTO for years; however, if a CTO is recanalized with PCI then acutely reoccludes, an acute MI will ensue, even if reocclusion occurs as early as a few hours or days after recanalization. This is due to: (i) early loss of collateral flow (spasm early on, anatomic involution later on); (ii) distal embolization from the upstream thrombosis, which occludes the microcirculation and any patent collaterals (similar to early SVG thrombosis). Yet sometimes, when reocclusion occurs early in patients with baseline CC2 collaterals, collateral flow may be quickly recruited and may limit MI size.

Appendix 8. Hibernation, stunning, ischemic preconditioning

Hibernation is chronic impairment of the myocardial function that results from a severe, **persistent** coronary stenosis; the myocardium downregulates its function and its metabolism to survive and remains viable. Chronic ischemia may, however, lead to irreversible fibrosis. The myocardial segment has reduced nuclear uptake at rest and with stress, but unlike infarction, this nuclear uptake remains >50% at rest, metabolic uptake is preserved on PET imaging, and Q waves are absent.

Stunning is transient myocardial dysfunction occurring after a severe, **transient** episode of ischemia. Ischemia resolves and leaves a viable myocardium that will recover in time. This is seen in cases of acute MI recanalized via PCI or fibrinolytics, exertional ischemia that lingers for several minutes at rest, or ischemia induced by cardiac surgery or PCI. In the post-MI setting, some myocardium is necrotic already, some is stunned; only time will show. As opposed to hibernation, the artery is now open and there is no persistent ischemia. In the post-MI and post-cardiac surgery cases, temporary support with inotropes or IABP is sometimes needed until the myocardium recovers, provided there is no ongoing ischemia. Unlike hibernation, the *artery is open* and nuclear uptake is usually normal at rest. Repetitive stunning from a significant stenosis (exertional ischemia) can lead to persistent dysfunction and hibernation.

Recovery of function occurs 1–6 months after revascularization (faster with stunning, days to 1 month). See Chapter 4 for viability evaluation.

Ischemic preconditioning is the phenomenon whereby brief exposure to ischemia preconditions the heart and makes it more resilient to a later, prolonged and severe ischemia. In fact, ischemia stimulates protective myocyte receptors, such as adenosine receptors and G-protein receptors (protein kinase C). There are 2 windows of protection: the first starts within a few minutes of the brief ischemia and lasts a few hours; the second occurs at 24 hours and lasts 96 hours. This is partly why patients with pre-infarct angina suffer from smaller infarcts and have better outcomes. Also, patients with severe pre-existing disease have already formed mature collaterals, which attenuate the infarct size.

In a patient with active chest pain and severe CAD, the myocardial dysfunction is usually an actively ischemic dysfunction, rather than hibernation or stunning.

Appendix 9. Coronary steal phenomenon

Imagine a severely obstructed coronary artery receiving collateral flow from a healthier donor artery. In the severely obstructed coronary territory, microvessels are already significantly dilated via autoregulation and cannot dilate much more. As such, upon vasodilator administration, the healthier coronary territory microdilates and increases its flow much more than the severely obstructed one. If this healthier artery has any stenosis, it cannot increase its flow enough to match the microvascular dilatation, which causes a fall in its distal epicardial pressure. The severely obstructed territory shows little pressure drop, because it lacks further microvascular dilatation. Thus, the collateral pressure gradient drops, reducing collateral flow (note that collaterals originate at the epicardial level).[184] This is the coronary steal phenomenon, which is a misnomer, because it is a reduction of collateral flow, not a backward reversal of flow (Figure 3.3). It is characteristically seen with potent microvascular dilators such as adenosine, and less so with nitroprusside or short-acting DHPs. It may also be seen with drugs that drop BP without inducing any counteracting microdilatation in the obstructed territory, such as ACE-Is.[71,74]

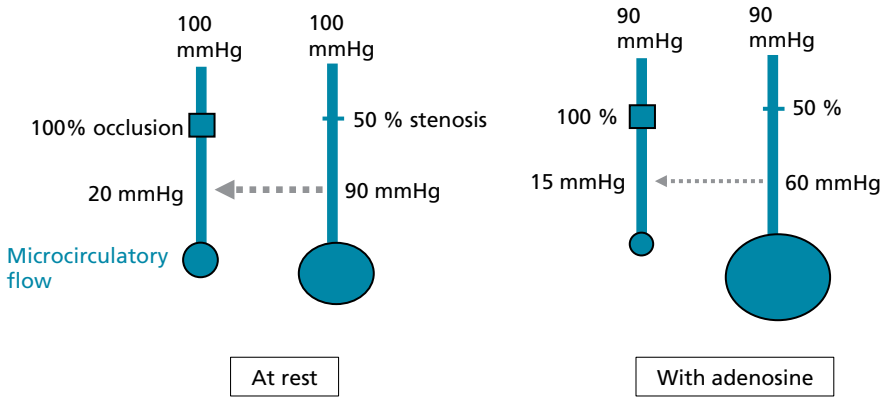

Figure 3.3 Coronary steal phenomenon. One coronary artery has 100% occlusion and is receiving collaterals (*gray interrupted arrow*) from the healthier artery with 50% stenosis. The microcirculatory flow (*circles*) is higher in the donor territory. At rest, the mean aortic pressure is 100 mmHg, and the distal epicardial pressure of the donor artery is 90 mmHg; the driving pressure gradient for the epicardial collaterals is 70 mmHg (90–20 mmHg). *With adenosine,* the microcirculation of the healthier territory vasodilates and causes a rise in flow. However, this rise in flow reduces the distal pressure of the healthier artery past the stenosis: ΔP across the stenosis = flow × resistance across the stenosis → more flow causes more pressure drop across the stenosis. Pressure drops less in the severely obstructed territory, because there is much less microvascular dilatation. Thus, the collateral pressure gradient drops, and collateral flow drops. *Note:* This may also happen without a discrete stenosis in the donor artery, as in cases of diffuse disease with diffuse pressure drop through the epicardial vessel, especially at very high flow and into distal collaterals.

QUESTIONS AND ANSWERS

Question 1. A 67-year-old man with a history of HTN and diabetes presents with exertional chest pain CCS III for 3–4 months. Chest pain is relieved with rest and with his wife's NTG. He has left lower extremity claudication. On exam, distal left lower extremity pulses are not palpable. ECG shows LVH with 0.5 mm ST-segment depression. What is the most appropriate next step?
A. Coronary angiography
B. Exercise stress ECG
C. Exercise stress SPECT
D. Adenosine SPECT

Question 2. A 67-year-old man with a history of LAD stent placed 2 years ago presents with mild angina on heavy exertion (CCS I). He is on atenolol, amlodipine, aspirin, and atorvastatin. BP 110/65, pulse 58 bpm. Exercise stress test result: 8 min on a Bruce protocol, mild angina occurred, DTS score +4. Nuclear perfusion shows a small area of apical–lateral ischemia, with a summed stress score of +3. Coronary angiography shows 60% proximal LCx stenosis, 30% mid-LAD, 40% mid-RCA. What is the next step?
A. PCI of LCx. No need for FFR since the lesion is angiographically significant
B. PCI of LCx. No need for FFR since the stress test is positive
C. FFR of LCx. Stent if FFR <0.80
D. Continue medical therapy, no PCI

Question 3. A 76-year-old man presents with chest pain on heavy activity. His home medications consist of aspirin and a statin. A nuclear stress test shows mild/moderate anterior ischemia, and coronary angiography shows 80% mid-LAD stenosis. What is the next step?
A. Medical therapy. There is no mortality difference between CABG, PCI, and medical therapy for this lesion
B. PCI
C. CABG, since it provides mortality benefit compared to PCI or medical therapy

Question 4. Same scenario as Question 3, except the patient has severe anterior ischemia and 80% proximal LAD stenosis.
A. Medical therapy.
B. PCI
C. CABG, since it provides mortality benefit compared to PCI or medical therapy

Question 5. A 76-year-old man presents with chest pain on heavy activity (walking >2 blocks). He receives aspirin and a statin. A nuclear stress test shows moderate anterior ischemia, and coronary angiography shows 80% proximal LAD stenosis and 75% mid-RCA and mid-LCx stenoses. What is the next step?
A. Medical therapy
B. PCI
C. CABG
D. A or C
E. B or C

Question 6. A 47-year-old executive man, asymptomatic, is starting an exercise program at the gym. He is asymptomatic during daily activities. A stress test is ordered by his family physician. He exercises for 5 minutes and develops 1.5 mm ST depression without chest pain. Nuclear images show a large anterior and anterolateral reversible defect, with a normal EF and no TID. What is the next step?

A. Just initiate medical therapy
B. Perform coronary angiography, but only revascularize if left main or 3-vessel CAD is present
C. CTA
D. B or C

Question 7. A 56-year-old man presents with angina walking up 1 flight of stairs or less (= CCS III). He is not receiving any antianginal therapy. His nuclear stress test shows severe inferior ischemia. His angiogram shows CTO of the RCA with features that make it favorable for PCI (non-calcified, ~2 cm long)

True or false: PCI is not appropriate, as the patient is not receiving maximal antianginal therapy

Question 8. A 50-year-old female, smoker, presents with chest pain that occurs with exertion, but not consistently, and sometimes occurs at rest. Each episode lasts ~45 minutes. BP = 160/95, HR = 78. She undergoes a treadmill nuclear stress testing. She exercises for 5 minutes, does not report any chest pain, and no ST abnormality is seen. Her nuclear images show a large reversible anterior defect with a summed stress score of +10. The patient prefers to try medical therapy first if deemed appropriate by the physician. What is her Duke Treadmill Score? What is the most appropriate next step?

A. Start aspirin, statin, β-blockers and amlodipine. Coronary angiography is indicated, as her risk of cardiac events is >5% per year
B. Start aspirin, statin, β-blockers and amlodipine. CTA is indicated, as her risk of cardiac events is >5% per year
C. No further test is indicated, as her risk of cardiac events is <1% per year
D. Start amlodipine, since the likely diagnosis is vasospasm

Question 9. A 65-year-old diabetic patient is planning to undergo elective cholecystectomy. He has mild dyspnea on exertion (>4 METs) but no angina. He undergoes preoperative testing with a nuclear SPECT, which shows severe inferior ischemia and preserved EF. Coronary angiography shows 80% mid-RCA stenosis. What is the next step?

A. Aggressive medical regimen. Revascularization is not indicated. His surgical risk is intermediate but revascularization will not improve it
B. Aggressive medical regimen. Revascularization is not indicated. His surgical risk is low and revascularization will not improve it
C. Aggressive medical regimen and PCI of the RCA with BMS
D. Aggressive medical regimen and PCI of the RCA with DES

Question 10. A 58-year-old woman has exertional chest pain (and some episodes of pain with mental stress). While undergoing treadmill stress ECG, she develops severe chest pain, inferior ST-segment elevation, and multiple runs of non-sustained VT. The pain and ST elevation resolve at 5 minutes of recovery. Coronary angiography is performed and shows a smooth 80% stenosis of the mid-RCA, which improves to a mild, 25% stenosis with NTG. What is the prognosis and what is the treatment?

A. Even in the absence of obstructive CAD, her risk of unstable angina/MI/VT is ~20% at several years of follow-up. She must be placed on amlodipine and statin
B. In the absence of obstructive CAD, her risk of unstable angina/MI/VT is low (<5%) at several years of follow-up. Provide CCB for symptomatic relief
C. Vasospasm frequently occurs on top of obstructive CAD. Perform IVUS to ensure that the residual stenosis is not a more severe stenosis or a ruptured plaque

Question 11. A 55-year-old woman, smoker, presents with exertional chest pain. A nuclear stress test shows a reversible anterior defect. Coronary angiography is performed and does not show any obstructive CAD. Moderate bridging of the mid-LAD (50% obstructive) is seen. What is the diagnosis?

A. Myocardial bridging
B. Coronary epicardial vasospasm
C. Microvascular dysfunction
D. Any of the above

Question 12. What diagnostic testing could help establish the diagnosis in the patient of Question 11?

A. Stress echo
B. Stress MRI
C. Intracoronary acetylcholine testing
D. Intracoronary or intravenous adenosine testing
E. Administer NTG during coronary angiography, even if no spasm is seen
F. B, C, D, and E
G. All of the above

Question 13. A 50-year-old man presents with resting chest pain and ST-segment elevation in the inferior leads. His coronary angiography shows a smooth 90% mid-RCA stenosis that is relieved with NTG. Which statement is *incorrect*?

A. Prinzmetal angina is twice more common in women than men
B. Microvascular dysfunction is more common than macrovascular spasm
C. Without CCB therapy, recurrent MI occurs in a substantial proportion of patients with Prinzmetal angina (~20%)

D. The definite diagnosis requires a concomitant documentation of the following 3 features: vasospasm on angiography, chest pain, and ST-segment changes
E. Among patients with exertional chest pain, abnormal stress testing, yet unobstructed coronary arteries, the incidence of coronary vasomotion abnormalities is 50–70% (macrovascular or microvascular)

Question 14. A 69-year-old man has chronic exertional angina, CCS III. He undergoes coronary angiography and is found to have 90% proximal RCA stenosis. Which statement is correct?
A. Initial PCI, as opposed to initial medical therapy only, reduces his risk of MI
B. Initial PCI reduces his cardiovascular mortality
C. Initial PCI reduces angina
D. Single-vessel CABG reduces his risk of death or MI

Question 15. A 59-year-old woman has occasional, atypical, non-exertional chest pain. She undergoes stress testing, which shows a large anterior defect. Coronary angiography shows 80% proximal LAD stenosis with FFR of 0.67. Which statement is correct (multiple possible answers)?
A. Initial PCI reduces her risk of MI
B. Initial PCI reduces her cardiovascular mortality
C. Initial PCI reduces angina
D. If the patient is undergoing non-cardiac surgery, PCI of LAD reduces her risk of perioperative MI
E. Single-vessel CABG may reduce her risk of death or MI

Question 16. After undergoing coronary revascularization, which statement is *incorrect*?
A. After 1- or 2-vessel PCI, the risk of repeat revascularization is ~20% at 5 years
B. After multivessel revascularization, the risk of recurrent events is ~27% with CABG and ~37% with PCI at 5 years
C. After high-risk PCI (e.g., complex proximal LAD PCI), stress testing is indicated routinely at 6–12 months

Question 17. A 70-year-old man has undergone PCI of the mid-LAD with one DES 1 year ago. He presents with recurrent mild angina. Coronary angiography shows 90% in-stent restenosis of the LAD. What is the next step?
A. Medical therapy
B. PCI
C. CABG
D. PCI or CABG

Question 18. A 51-year-old woman presents with exertional angina. She undergoes a standard treadmill ECG testing, where she exercises for 7 minutes and exhibits her typical angina without any ST change. What is the next step?
A. Risk factor modification, aspirin, statin, and antianginal therapy
B. Coronary angiography
C. CTA

Question 19. A coronary angiography is performed for the patient in Question 18 and does not reveal any significant CAD. What is the next step?
A. Reassure the patient that her pain is not of a cardiac origin. Consider gastroesophageal reflux therapy
B. The patient likely has coronary vasospasm. Prescribe amlodipine
C. Perform adenosine PET imaging. If the diagnosis is confirmed, add metoprolol and L-Arginine
D. Perform adenosine PET imaging. If the diagnosis is confirmed, add nitrates

Question 20. A 50-year-old diabetic man has exertional angina (2 flights of stairs, 4 blocks). On stress echo, he walks 7 minutes on Bruce protocol, develops mild pain, 2 mm of ST depression in leads V_4–V_6, and inferior hypokinesis. Coronary angiography shows 80% proximal RCA stenosis, with no disease in the LAD or LCx. What is the next step?
A. Optimize medical therapy
B. Perform RCA PCI
C. Perform RCA FFR, then PCI if appropriate

Question 21. In a diabetic patient with stable angina, which of the following is *incorrect*?
A. β-Blockers reduce mortality in patients with stable CAD and without prior MI
B. Metoprolol worsens HbA1c, while carvedilol does not affect HbA1c and improves insulin resistance
C. The higher the HbA1c, the more effective ranolazine is in reducing angina of diabetic patients
D. Ranolazine improves HbA1c by up to 1%

Question 22. A 60-year-old diabetic man has dyspnea on exertion and occasional episodes of rest chest discomfort. A resting ECG shows borderline inferior Q waves. On stress echo, he walked 8 minutes and had 1 mm of ST-segment depression in V_4–V_6, with dyspnea and no chest pain. His inferior wall is akinetic with EF 35–40% at rest and without worsening during exercise. Coronary angiography shows a totally occluded RCA in its mid-segment, and moderate, 50% disease in the proximal LAD. What is the next step?
A. Aggressive statin and antianginal therapy. No revascularization of RCA CTO
B. Revascularization of RCA CTO
C. Perform FFR of LAD. If significant, refer to CABG (LAD and RCA). If insignificant, perform PCI of RCA
D. Perform FFR of LAD. If significant, refer to CABG. If insignificant, perform medical therapy only
E. Perform FFR of LAD. If significant, perform LAD PCI (not RCA). If insignificant, perform medical therapy only

Question 23. In stable CAD, which two features guide the decision to revascularize?

Question 24. A 64-year-old man with no known CAD is found to incidentally have a heavy amount of coronary calcium on a chest CT done for lung cancer screening. The calcium is particularly heavy in the LAD. He is not very active and is limited by hip pain, but does not report any exertional chest pain or lifestyle-limiting dyspnea. What is the best management strategy?

A. Statin and risk factor control
B. A + coronary CTA
C. A + nuclear stress testing
D. A + coronary angiography

Answer 1. A The patient has >40% risk of severe CAD (age, sex, diabetes, typical angina).[18–20] Also, PAD predicts severe CAD. He has not only a high probability of CAD, but a high probability of severe CAD. The severity of his angina is another indicator of the need for invasive angiography with possible revascularization.

Answer 2. D. This is a typical COURAGE patient with mild angina, good functional capacity, and low-risk stress test. For this patient, medical therapy is as good as PCI + medical therapy. If angina is severe despite medical therapy, COURAGE functional substudies would support PCI (PCI would be superior to medical therapy for reduction of angina and reduction of ischemic burden). FFR is not necessary, since ischemia of the LCx territory has already been proven by nuclear imaging.

Answer 3. A. Except in left main disease, a patient with mild stable angina is appropriately treated with medical therapy only, regardless of ischemia severity. The MASS trial showed that for isolated LAD disease >80%, there was no difference in mortality between CABG vs. angioplasty vs. medical therapy, although angina was reduced with angioplasty and more so with CABG. The LAD disease addressed in the MASS trial was proximal LAD disease.

Answer 4. A. Again, a patient with mild angina and no severe functional limitation is appropriately treated with medical therapy only (typical COURAGE or ISCHEMIA patient). In the stable CAD setting, the value of revascularization is purely symptomatic and is questionable in a patient with no severe or refractory angina, even if proximal LAD (ISCHEMIA, COURAGE, MASS trial), severe ischemia (ISCHEMIA), or multivessel disease is present (ISCHEMIA, COURAGE, BARI 2D).

Answer 5. D. As opposed to Questions 3 and 4, the patient has 3-vessel CAD (>70%). Similarly to the previous questions, he does not necessarily need revascularization per ISCHEMIA and BARI 2D trials. CABG revascularization remains reasonable based on old CABG vs. medical therapy trials. Of note, the stress test may underestimate the true severity of ischemia. Nuclear defects being comparative to the best segment, the LCx and RCA may appear to be normally perfused when, in fact, they are ischemic but less ischemic than the LAD. If revascularization is chosen, FFR may be warranted since stress test is not high risk and will allow adequate assessment of RCA and LCx.

Answer 6. D. Asymptomatic patients qualify for revascularization only if left main disease is present (according to ISCHEMIA trial). Possibly, they may qualify for revascularization if 3-vessel CAD or 2-vessel CAD with proximal LAD is present (according to old CABG vs. medical therapy trials). CTA is an appropriate alternative to coronary angiography even after high-risk stress test, as per ISCHEMIA trial. While one may question the indication of stress test in this asymptomatic patient, it is reasonable to exclude left main disease once ischemia is found.

Answer 7. True. PCI of CTO is more technically challenging than standard PCI (2–3 times complication rates). Even more strictly than standard PCI, it is only indicated in patients who have severe and refractory angina, particularly with favorable PCI features (short <2 cm, not heavily calcified, good stump).

Answer 8. B. The patient has low-risk DTS of +5. A low-risk stress ECG/low-risk DTS does not necessarily rule out high-risk CAD. In fact, 10% of patients with low-risk DTS have left main or 3-vessel CAD. A high-risk stress imaging result overrules a low or intermediate DTS. This patient has a high-risk stress imaging result, but based on ISCHEMIA trial, this does not mandate an invasive strategy (coronary angiography +/– revascularization). A conservative strategy, preferably after left main rule-out by CTA, is appropriate.

Answer 9. A. The patient does not have a clear angina. Revascularization is only indicated if symptoms are severe or refractory. The patient has an increased surgical risk, including a risk of functional ischemia/infarction of the RCA territory during surgery. However, except for left main disease or extensive 3-vessel CAD, preoperative revascularization does not change postoperative cardiac complications. If surgery is necessary, medical therapy with a statin and a β-blocker, initiated more than a week before surgery, and careful perioperative monitoring are the strategies that improve outcomes.

Answer 10. A. Even in the absence of CAD, vasospastic angina is associated with a significant risk of cardiac events (~20% within a few years), especially when extensive or severe ST changes or arrhythmias have been demonstrated. With CCB, this risk is reduced to <1% (unstable angina may occur at a higher rate). Statin has additional benefit on top of CCB. IVUS is reasonable if the lesion is ≥50% obstructive on angiography or has worrisome angiographic features (overhanging borders, eccentric, hazy).

Answer 11. D. Even if coronary angiography does not show any obstruction, a convincing chest pain history along with a perfusion abnormality suggest that the chest discomfort is a true angina. ***Half of women whose symptoms are worrisome enough to warrant coronary angiography but who are not found to have CAD have, in fact, microvascular dysfunction or, less so, macrovascular spasm. This is particularly the case of patients with typical angina features and abnormal stress testing***. Myocardial bridging is usually incidental, even when severe; however, it may be considered the culprit in a patient with typical angina and anterior ischemia.

Answer 12. F. Stress MRI and stress PET are the best non-invasive modality for the diagnosis of microvascular dysfunction, followed by stress SPECT (which has the pitfall of a high false-positive rate in women). Stress echo and stress ECG have a lower yield. Invasively, there

are 2 aspects of microvascular dysfunction: (i) microvascular spasm, unveiled by acetylcholine; (ii) inability to vasodilate and increase coronary flow, unveiled by adenosine infusion. Concerning myocardial bridging, NTG administration may worsen it and further suggest it as a culprit.

Answer 13. A. Macrovascular spasm is only slightly more common in women than men. Microvascular dysfunction is 4 times more common in women than men.

Answer 14. C. In stable CAD, PCI only improves angina control. There is no demonstrated effect on MI or mortality, even if the lesion appears angiographically critical. It may improve unstable angina presentations (FAME 2 trial), but not MI. PCI is appropriate in a patient with severe angina, especially if it persists despite antianginal therapy. In the stable CAD setting, revascularization with CABG improves mortality of patients with left main disease and likely that of patients with 3-vessel disease or 2-vessel disease with proximal LAD (in multivessel disease without left main involvement, CABG may only reduce MI risk, not mortality, as per BARI 2D trial).

Answer 15. C. In stable CAD, PCI has not demonstrated a reduction of mortality or MI in comparison with medical therapy, even when the proximal LAD is treated (COURAGE, ISCHEMIA, MASS, MASS II trials). CABG may reduce mortality in single-vessel proximal LAD according to a meta-analysis of old CABG vs. medical therapy trials, but not according to more recent trials (MASS, BARI 2D, ISCHEMIA). Preoperative revascularization has not demonstrated an improvement of postoperative outcomes, except, possibly, in the case of left main or three-vessel CAD.

Answer 16. C. Asymptomatic restenosis is not clearly associated with adverse prognosis. Also, there is no evidence that PCI for recurrent, asymptomatic ischemia improves outcomes, and thus routine testing is not indicated. Concerning choice B, note that, after CABG, ~27% of patients have recurrent events at 5 years, yet each SVG has ~30% risk of occlusion at 5 years (most SVG occlusions are asymptomatic).

Answer 17. D. ISCHEMIA trial, wherein revascularization did not prove superior to conservative management in stable, high-risk CAD, excluded patients with PCI or CABG in the last year. COURAGE trial excluded patients with isolated in-stent restenosis. Symptomatic DES restenosis is often treated with repeat PCI: intracoronary imaging is performed to check for stent expansion, as stent underexpansion accounts for at least 50% of DES restenosis and is treated with high-pressure balloon inflation. If restenosis is mainly due to neointimal hyperplasia or if it is diffuse or extending outside the stent, repeated DES stenting is performed (stent inside a stent). CABG is an alternative therapy for LAD in-stent restenosis.

Answer 18. A. The stress test does not reveal high-risk findings and proves a good functional capacity. Thus, medical therapy for low-risk CAD vs. microvascular disease may be initiated. CTA or stress imaging may be performed for further risk stratification but is not necessary.

Answer 19. C. Half of women with typical angina have no significant CAD. The most likely cause of angina in this case is endothelial dysfunction, with inability of the microvasculature to dilate during stress. Macrovascular spasm is a second possibility, but it is less likely and more commonly presents as rest pain (vs. exertional pain in microvascular dysfunction). The diagnosis is made non-invasively by comparing the rest and post-adenosine myocardial perfusion using PET or MRI. Unlike macrovascular spasm, metoprolol is a first-line treatment for microvascular dysfunction (CorMica trial).

Answer 20. A. The patient has mild angina (CCS I) and mild functional limitation. This is a typical ISCHEMIA trial patient, where PCI does not improve survival or MI rates. To qualify for revascularization, his angina needs to be severe and persistent despite 2 antianginal drugs, or he needs to have left main disease (+/– 3-vessel CAD or 2-vessel with proximal LAD).

Answer 21. A

Answer 22. A. The patient does not clearly have angina, although dyspnea may be an angina equivalent (exertional dyspnea is commonly multifactorial and is not as specific as chest pain for CAD). Revascularization would only be appropriate for severe angina, or clinical HF caused by LV dysfunction. If dyspnea and LV dysfunction persist after medical therapy, PCI of RCA may be justified. If performed immediately, FFR of the LAD may be low but exaggerated as it supplies collaterals to the RCA (for the same lesion: larger territory → lower FFR). It is best to perform FFR of such a moderate LAD stenosis only after RCA recanalization, when such recanalization becomes indicated.

Answer 23. Decision to revascularize is guided by: (1) severity of angina, and (2) presence of left main disease (+/– other high-risk anatomical features, such as 3-vessel CAD or 2-vessel with proximal LAD). ISCHEMIA trial questioned the role of severe ischemia, which was previously used to guide revascularization.

Answer 24. A. Severe coronary calcifications in an asymptomatic patient do not dictate coronary angiography or CTA/stress testing, as: (i) high calcium score strongly predicts coronary events but is less strongly predictive of obstructive CAD; (ii) obstructive CAD is better predicted by the combination of exertional chest pain with high calcium score; (iii) high calcium score is a powerful predictor of events regardless of the presence of obstructive CAD, hence seeking obstructive CAD does not typically change prognosis and management; (iv) seeking and revascularizing obstructive CAD in asymptomatic patients has not proven beneficial (except for left main disease): it is rather risk factor control and statin that improve outcomes, and aspirin may be considered in young patients <70 years with low bleeding risk.

81. Mancini GB, Hartigan PM, Shaw LJ, et al. Predicting outcomes in the COURAGE trial: coronary anatomy versus ischemia. JACC Cardiovasc Interv 2014; 7: 195–201. *Only anatomic burden and EF are predictor of death and MI, not ischemic burden*. *PCI did not improve outcomes regardless of anatomic burden or ischemia.*
82. Reynolds HR, Shaw LJ, Min JK, et al. Outcomes in the ISCHEMIA trial based on coronary artery disease and ischemia severity. Circulation 2021; 144(13): 1024–38. *Anatomic burden of disease is a strong predictor of death and cardiac outcomes, while ischemia was not an independent predictor of death and only marginally predicted MI. Mortality and MI were similar with invasive vs. conservative strategy, regardless of the degree of ischemia severity or anatomic burden*.
83. Mancini GB, Hartigan PM, Bates ER, et al. Angiographic disease progression and residual risk of cardiovascular events while on optimal medical therapy. Observations from the COURAGE Trial. Circ Cardiovasc Interv 2011; 4: 545–52. *In the COURAGE trial, ~20% of patients undergoing medical therapy received a second coronary angiogram during follow-up, mostly for symptom progression rather than ACS/MI (~5% for ACS/MI) (mean follow-up 1.5 years, up to 4.6 years overall). By comparing the second angiogram to the first, it was noted that 21% of lesions >50% have become culprits and progressed angiographically by ~10%. Considering that 80% of patients remained stable and did not undergo a second angiogram up to a median follow-up of 4 years, the measured frequency of 21% overinflates the true progression by up to 5 times.*

Questions and answers 164

DEFINITION, TYPES, CAUSES, AND DIAGNOSIS OF HEART FAILURE

1. DEFINITION AND TYPES OF HEART FAILURE

I. Heart failure is diagnosed clinically, not by echocardiography

HF is defined as a ***clinical*** combination of congestive findings +/– low output findings, ***corroborated*** by objective evidence of cardiac dysfunction: echocardiographic systolic or diastolic dysfunction or severe valvular disease, ***or*** elevated LA or RA pressure by echo, cath, or BNP.

A. Congestive findings

- *Orthopnea and paroxysmal nocturnal dyspnea (PND)*, both relatively specific for HF. They result from the increase in venous return during recumbency and the subsequent increase in pulmonary capillary pressure. Many patients present with nocturnal cough or wheezes rather than nocturnal dyspnea; a dry cough during recumbency may be an orthopnea equivalent and should suggest HF. Wheezes result from congestion of the bronchial mucosa and the small airways.

  Orthopnea can be tested by asking the patient to lie supine for 1–2 minutes. Besides HF, *orthopnea* may be seen in obese patients or those with advanced lung disease and flattened diaphragm. Besides HF, *PND* may be seen in lung disease; whereas HF-related PND is relieved by upright posture, COPD-related PND results from mucous hypersecretion and is relieved by cough and albuterol, and asthma-related PND results from nocturnal bronchospasm and is relieved by albuterol.
- *Exertional dyspnea*. This may be a manifestation of a rise in pulmonary capillary pressure during exertion, even without overt pulmonary edema and without significant hypoxemia. The pulmonary venous engorgement stiffens the lungs and reduces vital capacity, leading to dyspnea. Dyspnea may also be a manifestation of an inappropriate rise in cardiac output during exertion, with subsequent peripheral and respiratory muscle fatigue and reduced pulmonary perfusion (increased pulmonary dead space). *Thus, outside florid edema, diuretics do not necessarily improve exertional dyspnea*. Dyspnea is frequently described as "chest pressure" and therefore, in HF, especially decompensated HF, chest pressure is not necessarily CAD.
- *Bendopnea*, i.e., dyspnea within 15 seconds of bending forward (e.g., dyspnea when putting on shoes), is highly specific for a baseline elevation of PCWP or RA pressure, with a further rise upon bending, particularly in the setting of low cardiac output.
- *Quick weight gain* (≥3 lb in <3 days) or quick weight loss in response to treatment implies volume overload.
- *Crackles/pulmonary edema/pleural effusions*. **Note that crackles are frequently (80%) absent in patients with decompensated chronic HF,** even when pulmonary capillary pressure is severely elevated. The increased lymphatic drainage of alveolar fluid prevents alveolar pulmonary edema.[1]
- *Increased JVP ≥ 9 cmH_2O*. JVP exam assesses the height of the *internal*, or sometimes external, jugular vein pulsations. JVP may also be assessed by ultrasound: the point of spontaneous collapse of the internal jugular vein corresponds to the height of RA pressure. In patients with a normal JVP, a hepatojugular reflux maneuver may be performed to unveil HF: a positive result is defined as a *sustained* rise of JVP of ≥3 cmH_2O following >10 seconds of pressure on the right upper quadrant during normal breathing (no Valsalva), or a fall of JVP of 4 cmH_2O upon release of pressure.[2–4]

  JVD means distension of the *external* jugular vein, which is the visible jugular vein, in an upright position, and usually implies an elevated JVP. When JVD is present, JVP may be assessed on the external jugular vein. **JVP and PCWP are proportional and concordant in ~80% of HF.** But 20–30% of decompensated left HF patients may have normal JVP, i.e., left HF without right HF.
- *S_3*: in patients > 40 years old, S_3 is highly specific (~90%) for an elevated PCWP, but insensitive.[5] *A loud P_2* implies significant pulmonary hypertension, suggestive of left HF in the right context. Normally, P_2 is soft and is only heard at the left upper sternal border, where it is split from A_2; ***a loud P_2 translates into a diffusely loud and sometimes split S_2,*** louder than S_1 at the lower sternal border and the apex. *S_4* is less specific for an elevated PCWP and may be seen with compensated LV dysfunction.
- *Peripheral edema ± ascites; congestive and sometimes painful hepatomegaly (pulsatile hepatomegaly if severe TR); and rarely, congestive splenomegaly in prolonged failure*. Over 4 liters of volume overload are required to see peripheral edema, as edema initially involves deep tissues. Also, venous dilatation may initially accommodate the excessive volume and prevent peripheral edema. Therefore, peripheral edema is an insensitive finding and may be absent in 60% of patients with elevated PCWP; moreover, in many cases, pulmonary edema results from volume redistribution to the lungs rather than florid volume overload.[2,6] Edema is, however, specific for HF in a dyspneic patient. Of note, the liver is atrophic in cirrhotic ascites, unlike HF and constrictive pericarditis.

The concept of **"hypervolemia and edema with intra-arterial volume depletion" is often untrue.** An overhydrated interstitium quickly refills a depleted plasma volume, as the lower intravascular hydrostatic pressure and higher intravascular oncotic pressure create a pressure gradient toward the plasma. Therefore, edematous patients usually have excess intravascular volume, especially if dyspneic. Even patients with marked hypoalbuminemia do not usually develop edema if their extracellular volume is normal (Chapter 5, Section 3.XI).

Yet, "edema with non-increased intra-arterial volume" may be seen in patients with local venous disease, such as lower-extremity venous insufficiency with locally impaired venous drainage. This venous blood does not "communicate" with the heart/arteries; hence the intra-arterial volume may not be high despite edema.

- *Congestion on X-ray*: similarly to the limitations of the pulmonary exam in chronic HF, the increased lymphatic drainage prevents the appearance of alveolar or even interstitial pulmonary edema in the majority of patients with chronically elevated PCWP. Pulmonary vascular cephalization, pleural effusion, and perihilar engorgement are the most sensitive findings, but overall, X-ray may not show any congestive finding in ~40% of patients with elevated PCWP.[1,2] CT scan is more helpful: *interlobular septal thickening* is a marker of interstitial pulmonary edema and is highly sensitive and specific for elevated PCWP.
- *B-lines on lung ultrasound*: the lung fields may be interrogated with an ultrasound probe running vertically across 2 ribs. *Lung fluid manifests as white vertical lines (like the beam of a flashlight);* this is highly sensitive and specific for pulmonary edema, more than chest X-ray, mainly when ≥ 3 lines are seen per view, bilaterally. ~4 to 6 regions are interrogated per lung (upper and lower lungs). The higher the number of lines and the more they are seen in the upper lungs, the more severe the pulmonary edema (see Chapter 34, Section XII).

In general, *1–2 congestive signs* along with at least *1 congestive symptom* are required for the clinical diagnosis of HF. The most reliable congestive findings are orthopnea, elevated JVP, S_3, diffusely loud S_2, and a recent, quick weight gain. In particular, elevated JVP at rest or with hepatojugular reflux is the most sensitive and specific finding (>80%) for the diagnosis of elevated right- but also left-sided filling pressures (PCWP).[2–4] Congestive signs may be absent in early stages of HF or in mild HF, especially HFpEF.

B. Low-output findings (also known as "cold" signs) correlate with a more advanced HF stage:

- Severe fatigue.
- Since ***the pulse pressure corresponds to stroke volume***, a narrow pulse pressure (<25% SBP) or a borderline systolic blood pressure implies a low stroke volume. In fact, *a narrow pulse pressure is the physical finding that most reliably predicts a low cardiac output* (>85% sensitivity and specificity).[1] Occasionally, severe arterial noncompliance prevents pulse pressure from narrowing.
- Compensatory sinus tachycardia.
- Pulsus alternans, which refers to an *every-other-beat variation in pulse intensity*. This is different from pulsus paradoxus, which is a more gradual variation in pulse intensity, seen in tamponade.
- Cold, clammy extremities.
- Oliguria, renal failure, hyponatremia, poor response to diuretics.
- At an advanced stage: impaired mentation, drowsiness, central hypoventilation with Cheyne–Stokes pattern (hyperpnea trigerred by pulmonary congestion and hypoxemia, alternating with hypopnea/apnea caused by the drop in PaCO2 and the poor central drive).
- Abdominal pain may result from functional bowel ischemia or from liver distension.

The functional capacity of HF patients is classified into 4 classes (NYHA class I: no limitation, can jog or carry >24 lb up a flight of stairs; class II: symptoms occur with heavy weight carrying or walking 2 blocks or 2 flights of stairs; IIIA: symptoms with walking 1 block; IIIB symptoms with mild activities, such as dressing, showering, short walking; IV: symptoms at rest). *This functional classification applies to patients at their most stable cardiac status, outside of HF exacerbations*. Frequent HF hospitalizations, however, usually imply a worse functional class and a poor prognosis.

II. After HF is defined clinically, echocardiography is used to differentiate the three major types of HF

A. HF secondary to LV systolic dysfunction, where EF is reduced ≤40% (HF with reduced EF, HFrEF)

In order to improve the stroke volume, the LV cavity dilates, but may be of normal size in acute systolic HF, resulting in more hemodynamic compromise (acute MI, acute valvular regurgitation, acute myocarditis).

B. HF secondary to LV diastolic dysfunction, where EF is normal (≥50%), sometimes supranormal, and LV is generally of normal or small size

LV is non-compliant, i.e., its diastolic pressure rises even at a normal preload volume. Diastolic HF is also called HF with preserved EF (HFpEF) and constitutes 40–50% of all HF presentations. HFpEF is diagnosed when the following 4 features are present (Figure 4.1):[7–10]

1. Clinical HF
2. Normal EF and normal or only mildly increased LV volume
3. No dynamic MR; and no transient, ischemic systolic dysfunction (particularly in acute, hospitalized HF)[11]
4. Invasive, echocardiographic, or BNP evidence of elevated LA pressure or diastolic dysfunction

HFpEF may be difficult to diagnose in dyspneic patients with no overt congestion. A combination of BNP and echo features is suggestive of the diagnosis but is insensitive and may miss HFpEF in 20–40% of the cases.[12] Even a normal BNP + normal LA size and E/e' do not exclude HFpEF. ***The gold standard for diagnosis is elevated mean PCWP at rest (>15 mmHg) or with exercise (≥25 mmHg)***, and right heart catheterization with exercise may be considered in select cases. Alternatively, the diagnosis is established via exertional echo measurement of E/E' and PA pressure, or assumed on clinical ground, such as the H2FPEF score (Figure 4.2).[10,12,13]

Patients with HF and EF of 41–49% constitute a specific group wherein the LV pressure–volume relationship may be as steep as in diastolic failure, and wherein the diastolic function is more severely impaired than systolic function. ***HF with EF 41–49% is predominantly a diastolic failure with mild systolic dysfunction:*** it behaves like HFpEF but its etiologies are closer to systolic HF, hence it is better called **HF with mildly reduced EF (HFmEF)**.[8]

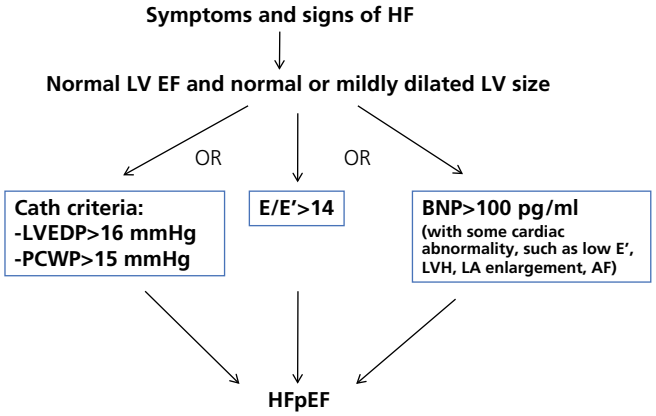

Figure 4.1 Diagnosis of HFpEF by catheterization, echo, or BNP features, according to older ESC criteria.[7] A normal or mildly dilated LV is defined as LV end-diastolic volume <75 ml/m^2 or 90 ml/m^2, respectively, in men (lower by 10 ml/m^2 in women).

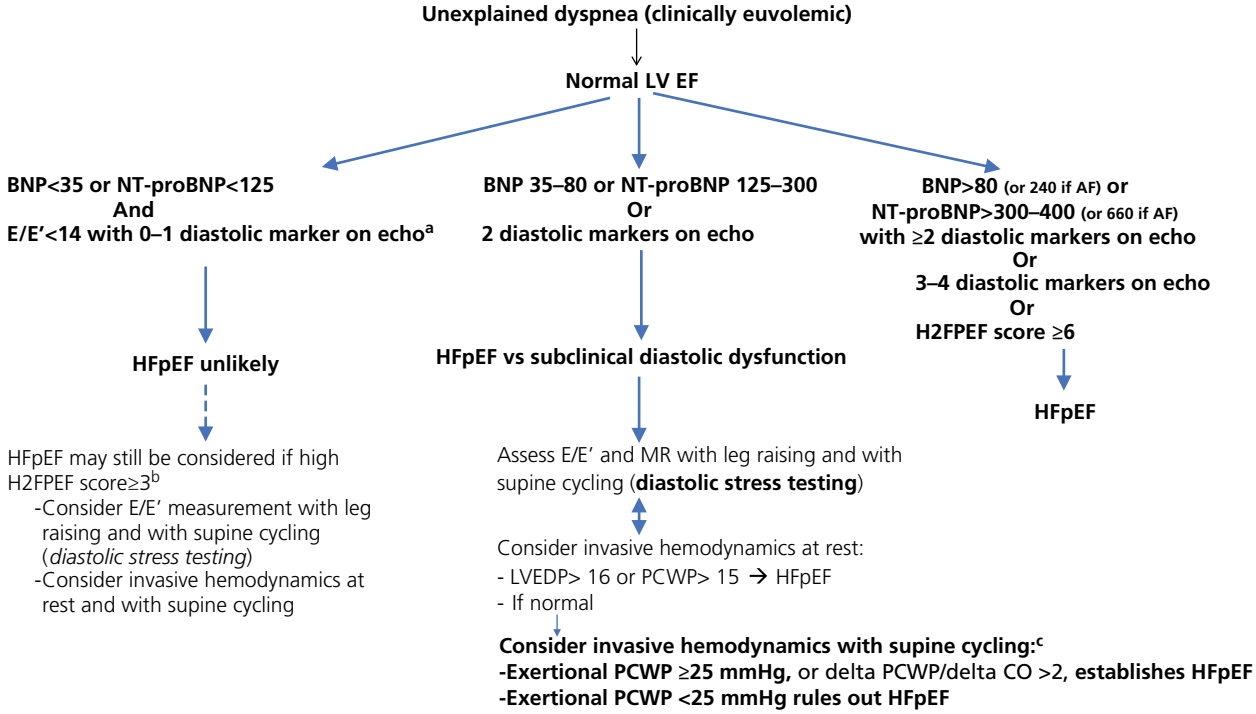

Figure 4.2 Diagnosis of HFpEF in subtle cases of dyspnea with no overt congestion.[8–10,12,13]
[a]The 4 major diastolic markers on echo are (ASE echo guidelines):
-Septal E'<6 cm/s or lateral E'<7–8 cm/s
-E/E'>14
-LA volume index >34 ml/m^2
-TR velocity >2.8 m/s (PA systolic pressure >35 mmHg)
-Consider the additional use of severe LVH, as per ESC (LV mass ≥149 g/m^2 in men, 122 g/m^2 in women)[10]
[b]H2FPEF score (a total score of 6 is >90% predictive of HFpEF; a score of 2–5, especially 3–5, suggests possible HFpEF, with a probability of 30–70%):
H (Heavy, BMI>30): score of 2 // H (Hypertensive requiring ≥2 drugs): score of 1 // F (atrial Fibrillation): score of 3
P (Pulmonary hypertension, systolic PA pressure>35 mmHg): score of 1 // E (Elderly>60): score of 1
F (Filling pressure with E/E'>9 on echo): score of 1
[c]Passive leg raise or saline challenge may be used for provocation: a rise of PCWP to ≥18 mmHg with those maneuvers suggests HFpEF.
Note: This approach is consistent with the European **HFA-PEFF score**, which integrates the ASE echo features and BNP.

Patients with EF < 40% usually have a variable degree of impairment of diastolic filling and diastolic properties. LV systolic dysfunction is, in fact, a combined systolic and diastolic dysfunction. However, by definition, to use the term diastolic HF, EF must be preserved.

C. HF due to severe valvular disease, in which the ventricular function is initially normal. Ultimately, with most left valvular disorders except MS, left ventricular systolic and diastolic dysfunction results.

Two forms of valvular disease are highly prevalent in HFrEF and HFpEF and are special because they are secondary to HF yet they perpetuate its progression and may become its primary drivers: ***functional MR and functional TR, secondary to ventricular dilatation (HFrEF) or atrial dilatation (HFpEF, the so-called atrial functional MR or TR***, particularly seen in elderly women with persistent AF). Importantly, they may also regress purely with HF and AF medical therapy.

Whether HF is due to systolic or to diastolic dysfunction, the same congestive and low-output manifestations are seen. Advanced low-output failure is mainly seen with LV systolic dysfunction but may be seen with restrictive cardiomyopathy (such as amyloidosis) or HFpEF with severe RV failure.

III. Two additional types of HF

A. High-output heart failure, particularly obesity-induced, which overlaps with the obese subtype of HFpEF (Chapter 5, 3.IX)

High-output HF is characterized by elevated left ± right filling pressures, yet a cardiac index that is at the upper limit of normal or elevated (>3.5–4 L/min/m^2) (e.g., morbid obesity, anemia, lung disease, cirrhosis). EF is often normal but may be mildly reduced. The high output is typically related to significant systemic vasodilatation or AV fistula or obesity. The systemic vasodilatation requires a high cardiac output to maintain the systemic pressure, which eventually leads to renal salt retention and a high venous return/preload. As a result of this severely increased preload, the left-and right-sided filling pressures increase. Even if LV compliance is normal, the LV diastolic pressure increases when LV diastolic volume exceeds 250–300 ml (Figures 5.5, 5.6). In many cases, these patients have a degree of ventricular dysfunction that further makes them sensitive to the rising preload. Also, chronically elevated preload and wall stress eventually lead to a decline of LV systolic function, similar to the pathophysiology of chronic MR, as the LV poorly tolerates volume overload conditions.

B. Predominant or isolated right heart failure

Left HF is often (~55–80%) associated with a secondary right systolic or diastolic failure, manifested as increased RA pressure. In fact, left HF is the most common cause of right HF; back-up pressure overload from the left side and loss of the septal contribution to RV contraction lead to biventricular failure. Therefore, an elevated JVP or an abnormal hepatojugular reflux suggests not only right but also left HF, and predicts an elevated PCWP.[1–4] JVP and PCWP are proportional and concordant in ~80% of the cases. ~20–30% of decompensated left HF patients may have normal JVP.

In some patients, the right HF becomes clinically more prominent than left HF as the lungs become underfilled, attenuating the pulmonary edema. Also, in non-ischemic cardiomyopathy, the RV may be directly involved by the myocardial process and may, in some cases, be more affected than the LV.

An overlooked LV diastolic failure is one of the most common and missed causes of what appears to be a predominant RV failure.

A truly isolated RV failure may be seen with *atrial functional TR*, ASD shunt, or pulmonary vascular disease. Atrial functional TR is a common modern cause of RV failure (e.g., elderly patient with persistent AF). Isolated RV failure is clinically characterized by peripheral edema and elevated JVP yet clear lungs, and invasively, *an elevated RA pressure with either a normal PCWP or a mildly increased PCWP that is equalized to the RA pressure*. Pleural effusions may be seen with isolated right HF as the parietal pleura drains in the venae cavae (visceral pleura drains in the pulmonary veins).

2. CAUSES OF HEART FAILURE

I. Systolic HF or HF with reduced EF (HFrEF)

A. CAD

CAD is the most common cause of systolic HF (~60%). Systolic HF that is secondary to CAD is called "ischemic cardiomyopathy." Two ischemic processes may explain LV dysfunction:

1. Large transmural Q-wave MI.
2. Hibernating myocardium. Severe coronary artery stenosis with chronic ischemia at rest or recurrent exertional ischemia may cause the myocardium to "shut down," i.e., hibernate without dying. Hibernation can be reversed with revascularization because the tissue usually remains viable.

LV dysfunction associated with single-vessel angiographic CAD, not involving the left main or the proximal LAD and without evidence of prior infarction, is disproportionate to the severity of CAD and implies a mortality that is similar to non-ischemic cardiomyopathy; this LV dysfunction is better classified as non-ischemic cardiomyopathy.[14] Ischemic cardiomyopathy, which has ~1.5-fold higher mortality than non-ischemic cardiomyopathy, requires one of the following: (1) history of a large MI; (2) ≥ two-vessel CAD (≥75% stenoses); or (3) single-vessel CAD that involves the left main or the proximal LAD. More extensive CAD is associated with further increase in mortality.[14] Some patients have mixed cardiomyopathies (e.g., LV dysfunction secondary to 2-vessel CAD and exaggerated by HTN).

In the modern era, classification of cardiomyopathy based on MRI may be more appropriate, as some patients with cardiomyopathy and CAD, including multivessel CAD, rather have non-ischemic or dual cardiomyopathy (~20% of them in a Minnesota study, and 12% of those screened for REVIVED study).[15] Patients with extensive CAD who also have a non-ischemic or dual cardiomyopathy have the worst prognosis, likely because of dual processes, and are unlikely to benefit from revascularization. On MRI, the non-ischemic component of the cardiomyopathy is determined by the LGE pattern (subepicardial or midmyocardial LGE, or subendocardial LGE in a non-coronary artery distribution) and/or by LV morphological features, such as severe LVH or severe LV dilatation outside the LGE zone (without CAD that could account for hibernating myocardium).

An ischemic etiology is often suspected by history (history of MI, coronary revascularization, or angina). Occasionally, HF is the first manifestation of CAD: among patients with unexplained cardiomyopathy and unsuspected ischemic etiology and no Q waves, only 7% are classified as ischemic cardiomyopathy after coronary angiography.[16]

B. Hypertension

Hypertension is the second most common cause of systolic HF. Chronic, severe hypertension leads to diastolic dysfunction initially, followed by systolic dysfunction. Acute blood pressure rise does not usually cause acute LV systolic dysfunction, unless myocardial disease or chronic hypertensive cardiomyopathy is present, as a normal LV tolerates acute pressure overload. Acute blood pressure rise more readily causes pulmonary edema through acute diastolic dysfunction.[11]

C. Arrhythmia-induced cardiomyopathy

Causes: AF (even if rate controlled), any persistent or frequently recurrent tachyarrhythmia, frequent PVCs, chronic progressive LBBB, or chronic RV pacing (see Chapter 5).

AF may induce a low EF through a fast ventricular rate. However, even when rate controlled, AF, per se, may induce LV systolic dysfunction. This is partly related to: (a) loss of atrial contribution to LV preload and stroke volume; (b) pronounced irregularity. For the same heart rate, an irregular rhythm generates lower cardiac output and creates significantly more calcium mishandling and overload than a regular rhythm. In fact, in patients with rate-controlled AF and HF, ***AF ablation improves EF by 10–18% and normalizes EF in 50–60% of patients*** (e.g., CAMERA-MRI trial). AF may also cause severe atrial functional MR or TR, driven by progressive atrial dilatation and potentially improving with rhythm control.

D. Residual effects of advanced left valvular disease that gets corrected late, at a stage when LV dysfunction may not correct postoperatively **(especially MR > AI > AS).**

E. Dilated cardiomyopathy (DCM) and non-dilated LV cardiomyopathy (NDLVC)

1. DCM and NDLVC are characterized by LV ± RV systolic dysfunction that is ***not fully explained by CAD, uncontrolled HTN or valvular disease***. The LV dysfunction is often global, but segmental wall motion abnormalities may be seen and do not necessarily imply ischemic cardiomyopathy. NDLVC represents an earlier stage in the spectrum of dilated cardiomyopathy, with largely the same underlying causes and mechanisms, often showing global or regional LV dysfunction but without significant LV dilatation (LVEDD <58 mm in men, <52 mm in women, and LVEDV <75 ml/m2). LV function may even be preserved, with only localized myocardial scarring, as in early-stage genetic cardiomyopathies.[17]

2. Causes (see Chapter 5, Section 1):

- *Viral myocarditis*: there are several forms of myocarditis: (i) subclinical myocarditis, usually self-limited, although a minority of these cases progress to chronic cardiomyopathy; (ii) mild clinical myocarditis with EF 45–50%, usually recovers within weeks or months; (iii) severe myocarditis, i.e., myocarditis manifesting as HF or significant LV dysfunction, fully reverses in one-third of the cases, improves in another 40%, but may rapidly progress in a minority.[18]
- *Idiopathic*: viral and idiopathic DCMs are the most common forms of DCM.
- *Toxic:* long-standing alcohol abuse with or without thiamine deficiency (reversible); cocaine use; radiation therapy; certain chemotherapy agents, such as doxorubicin (irreversible), cyclophosphamide and trastuzumab (reversible).
- *Genetic inheritance*: it is suggested if ≥1 first-degree relative has unexplained cardiomyopathy or unexplained sudden death. Familial DCM is the cause of ~20% of unexplained non-ischemic cardiomyopathies,[19] and is usually autosomal dominant with variable penetrance. Genetic testing may be considered in all unexplained non-ischemic cardiomyopathies and identifies a specific pathological gene in 37% of affected probands.[20] First-degree relatives of affected patients have ~20% lifetime risk of DCM and should be screened by routine ECGs + echos, and genetically if a specific gene is identified in a proband.[19]
- *HIV cardiomyopathy*.
- *Metabolic:* hyper- or hypothyroidism.
- *Infiltrative:* sarcoidosis, hemochromatosis.
- *Peripartum cardiomyopathy* develops in the last month of pregnancy or within 5 months of delivery, without any identifiable cause, and without pre-existing heart disease. 50–60% of the cases are reversible within 6 months.
- *Takotsubo cardiomyopathy*.

The worst prognosis is seen with the following 3 cardiomyopathies: HIV cardiomyopathy, amyloidosis, and doxorubicin-associated cardiomyopathy.[16]

3. Most cardiomyopathies may be reversible:

- Myocarditis.
- Alcoholic cardiomyopathy reverses if the alcohol abuse is stopped at an early stage ± thiamine supplemented.
- Hypertensive cardiomyopathy.
- Peripartum cardiomyopathy.
- All arrhythmia-mediated cardiomyopathy.
- Takotsubo cardiomyopathy.
- Other stress-related cardiomyopathies: sepsis or critical illness-associated cardiomyopathy, and neurogenic cardiomyopathy (following hemorrhagic or ischemic stroke). +Cardiomyopathy after transient global ischemia, such as cardiac arrest.
- Ischemic cardiomyopathy with hibernating or stunned myocardium.

On average, ~35% of recent-onset DCMs (<6 months) that are idiopathic or secondary to myocarditis resolve spontaneously or with medical therapy within 6 months. Another 40% have a significant improvement of EF (***HF-improved EF,*** *defined as EF improvement of ≥10% to >40%*).[18] This rate is higher for hypertensive, AF-induced, or other arrhythmia-induced cardiomyopathy and lower for genetic cardiomyopathy. Until they recover, these patients have an increased risk of arrhythmias and sudden death, well described with severe myocarditis. HF medical therapy should be continued over the long term, even after LV function normalizes.

Patients with ***HF-improved EF*** of any etiology, including ischemic, have a good long-term prognosis, much better than HF-reduced EF and HFpEF, but continue to have structural abnormalities, 1–2% cardiac mortality per year, >5% risk of HF hospitalization per year, BNP abnormality (frequently), and ***fluctuant "yoyo" EF***.[21] They need to continue HF medical regimen: in TRED-HF trial, a phased withdrawal of medical therapy in recovered HF resulted in a 44% recurrence rate at 6 months.[22] Three cardiomyopathies may be an exception, as they have a low risk of HF recurrence: peripartum cardiomyopathy, stress cardiomyopathy, and arrhythmia-induced cardiomyopathy. The latter includes AF-related HF that recovers with rhythm control and has no other cause (Withdraw-AF trial).

EF fluctuations are overwhelmingly related to alterations of loading conditions (increased preload or afterload, volume overload) or arrhythmias such as AF, **rather than ischemic events**, even in patients with CAD. Load alterations or arrhythmias readily lead to EF decline in a patient with underlying myocardial disease. Repeat coronary angiography is not necessary solely for EF decline.

II. HF with preserved EF (HFpEF)

A. Hypertension, obesity, and older age. Two major phenotypes: obese HFpEF vs. elderly HFpEF

Hypertension, obesity, and older age (>65 years) are the 3 most common risk factors for HFpEF. Diabetes and renal failure are other risk factors. One essential mechanism in HFpEF is impaired diastolic function, wherein (i) LV does not relax well (reduced active relaxation or tau index), and (ii) LV is not "elastic" enough to further distend after relaxation and accept the diastolic filling (increased diastolic stiffness or beta index). This results in a *stiff LV cavity with limited ability to accept preload* and, consequently, limited preload reserve, limited stroke volume reserve, and backward PCWP rise. Anatomically, LV hypertrophy is common in diastolic HF; yet, LV mass is normal in up to 50% of patients, and LV thickness is normal in up to 25% of patients.[23] Ventricular stiffening from increasing collagen and cytoskeletal proteins and abnormal calcium homeostasis is more prevalent than LV hypertrophy and may precede it.

Importantly, additional mechanisms are incriminated, hence HFpEF does not simply equate with diastolic HF. There are 2 major and sometimes overlapping phenotypes of HFpEF:

1. **Obese HFpEF** is characterized by (i) *increased extracellular volume and preload*, which causes mild RV/LV dilatation. Concurrently, obesity causes myocardial hypertrophy, as the LV supplies a larger body volume, and myocardial stiffening, which impairs LV compliance and heightens its sensitivity to this ↑ preload. (ii) This is further aggravated by *pericardial fat constraint in a subgroup of HFpEF*, creating functional constriction and RV/LV interdependence, even if the ventricles are only mildly dilated. (iii) *BNP deficiency* is seen in many obese patients, and up to 10% have full BNP deficiency with BNP <50 pg/ml even during HF hospitalization.[24] BNP has natriuretic, vasodilatory, and anti-fibrotic effects, hence BNP deficiency exaggerates hypervolemia.

   The full-blown *obese high-output HF* is part of the same spectrum but has a more dramatic rise in volume and cardiac output than obese HFpEF.
2. **Elderly HFpEF** and **severely hypertensive HFpEF** are characterized by a small and stiff LV with smaller cavity size and more severely impaired LV compliance than obese HFpEF, resulting in an inability to accommodate even normal preload.
3. **AF** frequently coexists with and aggravates both forms of HFpEF by further reducing LV filling and cardiac output (AF develops at some point in up to 2/3 of HFpEF). Even without AF, stiff LA syndrome may be present and may further raise LA pressure.

In addition, keep in mind **3 major mimickers of HFpEF:** (i) restrictive cardiomyopathy (amyloidosis, restrictive HCM); (ii) predominant RV failure, including from late-stage HFpEF or from atrial-functional TR in AF patients; and (iii) constrictive pericarditis.

Besides the 2 major phenotypes and the 3 mimickers, keep in mind the **progression of all phenotypes into more severe processes that may become dominant** and self-perpetuate: progressive AF, atrial functional MR and TR, and combined pre- and post-capillary PH. Eventually, HFpEF progresses into the dreaded **end-stage HFpEF: severe RV failure with self-perpetuating functional TR.**

Here are some **other HFpEF mechanisms**, commonly present in both obese and elderly HFpEF:

- Arterial and atrial stiffening (LA myopathy) besides LV stiffening. This makes LA pressure and SBP markedly increase with relatively minor volume overload. The arterial stiffness explains a very striking rise in SBP with exercise, a component of HFpEF in many patients.
- Impaired LV contractility. A normal EF does not necessarily imply normal contractility, as EF is affected by changes in loading conditions (smaller LV → higher EF). This may be unveiled by LV echo strain, which, for example, is severely abnormal in the small amyloid LV despite EF >60%.
- Chronotropic incompetence—from autonomic dysfunction—is seen in ~50% of patients and may contribute to exercise intolerance.
- Microvascular dysfunction +/– rarefaction, seen in up to 75% of HFpEF, is commonly the result of diastolic dysfunction but also an aggravating factor that is more prevalent with adiposity-induced inflammation. It may also be the cause of unexplained diastolic dysfunction in a substantial proportion of middle-aged women, particularly those without LV concentric remodeling.

B. CAD (ischemia without infarction)

Relaxation being an active process, CAD may contribute to diastolic dysfunction. In fact, in patients with CAD, a rise in LVEDP (diastolic stiffening) is an early hemodynamic manifestation of angina induced by pacing or exercise.[25]

As importantly, CAD may lead to transient LV systolic failure or dynamic ischemic MR that is mislabeled as diastolic failure. Thus, CAD, typically involving a large myocardial territory, needs to be considered in some acute heart failure cases that are labeled diastolic failure, particularly in the absence of diastolic HF risk factors.

Overall, CAD is a less common etiology of HFpEF than HF with reduced EF, but was still considered the underlying etiology of HFpEF in 25–45% of patients in large HFpEF trials (although some of it is coincidental CAD).[26,27] As with HF with reduced EF, significant, usually multivessel CAD must be present to be considered the underlying mechanism of HFpEF.

C. Restrictive cardiomyopathy (RCM)

RCM is characterized by:[28–31]

a. *LV is small and stiff with severe diastolic failure*. Unlike in dilated cardiomyopathy, the LV cavity is small. Systolic function is relatively preserved and becomes progressively impaired at an advanced stage, yet the LV remains small. The RV may also be stiff and small or may be dilated; *RV dilatation/RV systolic dysfunction is common* at an advanced stage and is a poor prognostic sign.[32]

b. As in any decompensated ventricular failure, *LA and RA are markedly dilated* and functional TR and MR, sometimes severe, may be seen.

c. The *myocardial thickness is increased ≥12–14 mm* in infiltrative restrictive cardiomyopathies, particularly amyloidosis, where it may reach levels seen with hypertrophic cardiomyopathy (>20 mm) and may occasionally be asymmetric. As opposed to hypertrophic or hypertensive cardiomyopathy, the increase in thickness is due to myocardial infiltration rather than myocardial hypertrophy, explaining the discrepancy between the low voltage on the ECG on the one hand and the thick myocardium on echocardiography on the other hand. As opposed to hypertensive cardiomyopathy, *the thickening frequently involves both ventricles, not just the LV*.

Moreover, amyloidosis has the following echo characteristics: a small pericardial effusion, valvular thickening, and a granular, "sparkling" myocardial texture. The sparkles are bright echo spots corresponding to amyloid deposits; note that the heterogeneous texture of HCM may simulate the sparkled texture of amyloidosis.[33]

d. On ECG, 2 findings are common with the thick amyloid cardiomyopathy, corresponding to replacement of the myocardium by the amyloid material: pseudo-Q waves and low QRS voltage, or at least a QRS voltage that is disproportionate to the thickness of the myocardium. LVH voltage criteria are never seen in the limb leads in amyloidosis.

Hypertensive cardiomyopathy may have the same echocardiographic features and severely restrictive filling as RCM, especially in the elderly or end-stage renal disease. In a patient with a thick myocardium and severely restrictive filling/HF, 3 diagnoses are considered; (i) hypertensive cardiomyopathy: (ii) hypertrophic cardiomyopathy, restrictive phenotype; (iii) infiltrative cardiomyopathy, particularly amyloidosis and Fabry. ECG, echo strain imaging (preserved apex in amyloidosis), and MRI help with the differential diagnosis.

Technetium pyrophosphate cardiac scan (for transthyretin amyloidosis) and monoclonal protein testing are needed in "thick" (≥12 mm), severe HFpEF. Right and left heart catheterization may be performed to confirm the elevation of left-sided pressures, particularly when the predominant picture is right HF, and to differentiate it from constrictive pericarditis.

Causes of RCM:

- Infiltrative disease, most commonly amyloidosis, but also Fabry disease, hemochromatosis, sarcoidosis, and hypereosinophilic syndrome
- Hypertrophic cardiomyopathy, restrictive phenotype (severe diastolic dysfunction regardless of obstruction)
- Scleroderma, lupus, rheumatoid arthritis – Primary idiopathic RCM
- Radiation heart disease, which leads to a combination of RCM, constrictive pericarditis, valvular heart disease (AS/AI, MR, TR), CAD, and pulmonary fibrosis. All these develop 5–30 years after radiation exposure.

D. Constrictive pericarditis

Constrictive pericarditis mimics the presentation of RCM and RV failure.

Tachycardia decompensates any compensated LV failure, particularly HFrEF, by reducing the diastolic time provided for the slow LV filling. On Doppler, a reversed E/A ratio and a slow E flow become a high E/A ratio with a narrow and brief E flow during tachycardia (Figure 4.3). Once LV failure is decompensated, the diastolic filling (E wave) is brief and impeded by the quick rise of LV diastolic pressure. At this point, *mild tachycardia* may be accepted as prolonging diastole does not increase diastolic filling; even if it does, this will not translate into increased stroke volume, as the overloaded LV is on the flat portion of the Starling curve (non-preload dependent). Therefore:

Acutely**, it is rather tachycardia that improves cardiac output and LV filling by providing more cardiac cycles, ***up to a rate of ~110 bpm (beyond which, in HF, energy reserves decline, contractility declines and negates any cardiac output benefit).[34–36]

Chronically, *a controlled heart rate (60–70 bpm) is particularly useful in compensated, sinus-rhythm HFrEF. Contrary to prior teaching, such heart rate reduction has a questionable merit in HFpEF and in AF, where a rate of 75–100 bpm may be preferred. (1) *In a normal LV*, contractility increases with heart rate rise (Bowditch phenomenon); (2) conversely, *in HFrEF*, mechanical and energy reserves are reduced, hence contractility and exercise capacity paradoxically improve with lower peak heart rates (limited Bowditch effect);[34–36] (3) by contrast, *in many HFpEF subsets*, the stiff and small LV cavity has limited capacity to fill at slower heart rates, even in a compensated state, and may fully rely on heart rate to maintain cardiac output. As such, pure heart rate reduction to 60s with ivabradine improved exercise capacity in HFrEF but worsened it in HFpEF, and β-blocker withdrawal improved functional capacity in HFpEF with heart rate <75 bpm.[37–39]

A newly diagnosed tachyarrhythmia at a rate >105–110 bpm, coinciding with a new HF diagnosis, suggests the possibility of tachycardia-mediated cardiomyopathy. This is the case in ~50% of new-onset atrial arrhythmias associated with a new-onset HF and warrants aggressive rate and rhythm control, after treating HF decompensation.[40–42]

III. Right HF

Left HF, whether with reduced or preserved EF, is the most common cause of right HF. Overall, there are 3 mechanisms of RV failure, including isolated RV failure:

a. *Pressure overload:* pulmonary hypertension secondary to left heart disease, lung disease, PE, or pulmonary vascular disease.
b. *Volume overload:* ASD, tricuspid or pulmonic regurgitation. *TR is often functional* and secondary to RV failure but exaggerates its progression through the extra volume load. ***Atrial functional TR*** is a common cause of RV failure in elderly patients with persistent or frequent AF and may be the cause of an otherwise unexplained RV failure.
c. *Intrinsic RV dysfunction:* ARVD or RV infarct (the latter only causes acute, not chronic RV failure). Acute myocarditis, tachycardia-mediated cardiomyopathy, and idiopathic, HIV, or alcoholic cardiomyopathy usually lead to RV and LV involvement, but one may be more predominantly involved than the other.

In an elderly patient with persistent AF and a clinical picture of right heart congestion, always consider **atrial functional TR, a common HFpEF mimicker or overlapping HFpEF finding** in the elderly with AF.

In any HFpEF, besides the "standard" left HFpEF (associated with age, obesity, HTN, AF), think of **4 HFpEF mimickers** and look for their ancillary features, particularly in a **clinical picture of predominant right heart congestion**:

1. *Restrictive cardiomyopathy* from: (i)infiltrative disease, such as amyloidosis (senile wild-type or young-onset genetic), Fabry, or sarcoidosis; (ii) or restrictive HCM (with or without obstruction). RV dilatation frequently coexists at late stages.
2. *Isolated or predominant RV failure*, including RV failure and TR that result from advanced HFpEF and become the dominant picture; and RV failure driven by atrial functional TR. The tricuspid annulus is less fibrous and more compliant than the mitral annulus, hence it readily dilates with RV and RA volume changes.
3. *Constrictive pericarditis*.
4. *High-output HF*.

Tamponade mimics acute right heart failure, while constrictive pericarditis and restrictive cardiomyopathy mimic chronic right heart failure. Restrictive cardiomyopathy is a biventricular failure but frequently presents clinically as a predominant right heart failure.

3. DIAGNOSTIC TESTS

I. Echocardiography

As mentioned under *Definition*, HF is a clinical diagnosis. **Echocardiography is done to corroborate the 3 major categories of HF based on the assessment of EF, valvular function, diastolic dysfunction (low E'), and LA pressure (elevated E/E').**

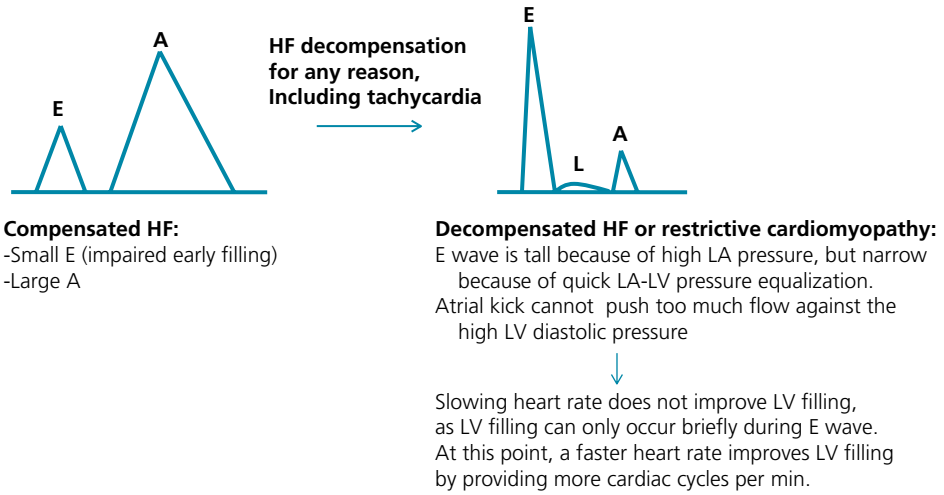

Figure 4.3 Change of LV filling pattern between compensated and decompensated HF. The E and A waves correspond to the transmitral flow in diastole. The L wave is a marker of elevated LA pressure that attempts to push flow throughout diastole.

A normal EF suggests diastolic dysfunction, transient systolic dysfunction (as in ischemia), or dynamic functional MR. One should look for specific signs of diastolic dysfunction such as reduced mitral tissue Doppler E′ (E′ corresponds to myocardial recoil in diastole). A normal E′ is very unusual in diastolic or systolic HF.[23] Patients with diastolic HF usually have signs of elevated LA pressure if they are in active HF (elevated E/E′ ratio > 14), or signs of stage 1, compensated diastolic dysfunction, if they are not in HF (low E′ < 7 cm/s with normal E/E′ ratio) (Figure 4.2).

The septum is thickened in most but not all patients with HFpEF (mean septal thickness 1.18 cm in one study).[23]

Also, almost uniformly, LA is enlarged if the patient is in decompensated HF (whether systolic or diastolic HF). Regardless of decompensation, LA volume and/or diameter is enlarged in 80% of HFpEF.[23]

In the absence of *low E′, high E/E′, or LA enlargement* on echo, reconsider the diagnosis of diastolic HF and consider other causes of dyspnea.[13]

- Echo estimates LA pressure and pulmonary arterial pressure, which, if high, indicate decompensation and some degree of pulmonary congestion. Pulmonary hypertension, per se, may persist after resolution of the pulmonary congestion. In fact, a chronic increase in pulmonary pressure may lead to a reactive pulmonary hypertension that may be slow to resolve after normalization of LA pressure.
- Echo can suggest a cause, such as ischemia in the case of focal wall motion abnormalities (albeit not very specific), or hypertensive or infiltrative cardiomyopathy in the case of a thickened septum, or constrictive pericarditis (septal bounce without LBBB or RV dilatation).

II. BNP

BNP is a peptide synthesized by the myocardium in response to cardiomyocyte stretch. Atrial or ventricular wall stress, especially *LV wall stress* from volume or pressure overload, is the primary driver of BNP secretion, but ischemia and neurohormones may also directly stimulate BNP gene expression. RV and/or atrial stretch may increase BNP to lesser degrees than LV stretch, as RV and the atria have a smaller mass.

ProBNP is the precursor of BNP; it is cleaved into BNP and NT-proBNP. *NT-proBNP value is usually ≈4 × BNP, and more so (>6×) with age >65 or renal failure (Table 4.1)*.

A. BNP >400–500 pg/ml (or NT-proBNP >1200 pg/ml) is highly suggestive of acute left HF in a patient with acute dyspnea. It correlates with increased LVEDP; however, the exact BNP value does not correlate with the exact degree of LVEDP rise. For a given filling pressure, dilated ventricles secrete more peptide because of the greater wall stress/stretch and chamber mass. ***This explains why BNP is higher in LV systolic than in LV diastolic failure***, and how it may be high despite a normal LVEDP. Also, several factors such as age, sex, and renal failure contribute to the absolute BNP levels.

B. BNP <100 pg/ml (or NT-proBNP <300 pg/ml) excludes acute left HF as a cause of acute dyspnea. The patient may, however, have asymptomatic or less acutely symptomatic LV dysfunction (exertional symptoms). In fact, patients with diastolic or even moderate systolic dysfunction who do not exhibit overt HF frequently have BNP values that overlap with normal individuals' BNP. In one study, most patients with asymptomatic LV systolic dysfunction had BNP levels <50 pg/ml.[43] In another study that focused on LV diastolic dysfunction, a significant proportion (~25%) of patients with echocardiographic diastolic dysfunction had BNP <50, but this was uncommon in patients with current clinical HF or severe diastolic abnormalities.[44]

A BNP cutoff of 35 pg/ml (NT-proBNP 125 pg/ml) is a better cutoff to exclude chronic HF as a cause of chronic exertional symptoms *(ESC)*.[8,10]

C. In the acute setting, BNP levels of 100–500 pg/ml are in the intermediate range. Dyspnea may be due to acute left HF but also to acute pulmonary or pulmonary vascular illness (with RA/RV stretch), or sepsis. BNP may also rise because of RV failure, renal failure, or myocardial ischemia.

In the chronic setting, BNP levels of 35–80 pg/ml are in the intermediate range (up to 240 pg/ml if AF).[10] Chronic dyspnea may be due to HF or non-cardiac disease.

D. Evolution and follow-up of BNP levels. In most patients with acute HF, BNP decreases with diuresis and the reduction of LV filling pressure but may not return to normal, as the LV remains dilated even after LVEDP is normalized (BNP may be as high as several hundred pg/ml, but is not usually higher than 1000 pg/ml). This residual BNP correlates with the degree of underlying LV, RV and atrial remodeling.[45,46] Even when euvolemia is achieved and LVEDP normalized, a dilated LV will continue to generate an elevated BNP (called residual, *dry BNP*).

Table 4.1 BNP and NT-proBNP cutoff values in acute and chronic settings.

	BNP	NT-proBNP
Acute HF		
Acute HF rule-in	>400 (higher with AF)	>1200 (higher with AF, older age, and renal failure)
Possible acute HF	100–400	300–1200
Acute HF rule-out	<100 (except obese, <50)	<300
Chronic HF		
Chronic HF rule-in	>80 (>240 if AF)	>300–400 (>660 if AF, >1000 if advanced CKD)
Possible chronic HF	35–80	125–300
Chronic HF rule-out	<35 (<105 if AF)	<125 (<375 if AF)

Also, the reduction in BNP may be delayed because of reduced clearance, especially in renal failure. Thus, daily BNP measurements are not warranted; when clinical euvolemia is established, a *pre-discharge BNP level* may be determined and used in follow-up.[46] A persistently elevated BNP upon discharge is a predictor of HF readmission and has a negative prognostic value. In one analysis, a *30–50% BNP or NT-proBNP reduction during the hospital stay* strongly predicted a reduction in hospitalizations, beyond clinical variables, suggesting that BNP may be used as a target before HF discharge.[47]

BNP levels may be followed in stable outpatients to detect early congestion, but this has pitfalls, because BNP has an intra-individual biological variability of up to 25–50% unrelated to the development of symptoms.[46] Conversely, a rise in BNP of over 25–50% may herald a clinical decompensation and suggests drug titration. Several studies and a meta-analysis have shown the utility of a BNP-guided outpatient drug titration in patients <75 years old with systolic HF (to a target BNP <100– 300 or NT-proBNP <1000 [target used in GUIDE-IT trial]). This strategy reduced HF hospitalizations and improved survival in the meta-analysis (class IIa recommendation).[48,49] In those studies, BNP was checked every 1–3 months. ACE-I, β-blocker, and aldosterone antagonist titration was prioritized over diuretic titration in the absence of clinical congestion. In the GUIDE-IT randomized trial, NT-proBNP-guided HF therapy titration did not improve outcomes, but the caveat is that patients were treated in a tertiary center with frequent and aggressive drug up-titration even in the usual care arm; achievement of NT-proBNP <1000 retained a strong prognostic value.[50] The utility of BNP-guided therapy in older patients and in patients with diastolic dysfunction is unclear; overzealous therapy to reduce BNP in these patients may be associated with more side effects (dizziness, fatigue).

BNP tends to be higher in the elderly, in women, in renal failure, and in cirrhosis. BNP rises within 1 hour of HF, is mostly cleared by tissue peptidase and partially cleared renally. NT-proBNP is much more dependent on renal clearance and more affected by renal dysfunction.

BNP is lower in obese patients because of impaired myocardial BNP synthesis and higher BNP clearance by the adipose tissue, and this reduced BNP is one of the drivers of volume overload in obese HF. BNP declines by ~4% for every 1 kg/m² of BMI above 25.[51] ***Full BNP deficiency, with BNP <50*** despite active HF and abnormal invasive hemodynamics, ***is seen in 5–10% of HF patients, mainly obese patients***.[52] In obese patients, a lower BNP cutoff of 50 ng/ml may be used to diagnose acute HF, but even this cutoff may miss those with full BNP deficiency syndrome.

Also, in comparison with left ventricular HF, HF induced by mitral stenosis or acute mitral regurgitation has a lower BNP (cases where LVEDP is not necessarily increased).

AF, by itself, increases BNP even in the absence of HF, as the atrial tissue releases BNP; BNP may be ~500 even in the absence of HF. Fast AF is more likely to raise BNP, as it further reduces the atrial emptying time (further atrial stretch).[10,53,54]

As a rule of thumb, for the same degree of HF (or lack thereof), BNP value is doubled in patients older than 75 and tripled in AF and advanced CKD;[10] BNP value is halved in obese patients (BMI >35).

In critically ill patients with severe sepsis or shock, BNP levels poorly correlate with left- or right-sided filling pressures; BNP levels higher than 1000 may be found with normal PCWP and rather correlate with renal failure, EF, and LV dilatation (high output) in this setting.[55]

Two conditions may have **normal BNP despite clinical HF, JVD, and edema**: obese HF with full BNP deficiency and constrictive pericarditis.

III. ECG

A completely normal ECG almost excludes the diagnosis of HF, particularly systolic HF and acute HF.[8]

Q waves are *the single most important finding* and point toward ischemic cardiomyopathy. They are seen in ~70% of ischemic cardiomyopathies. Other abnormalities are non-specific but have prognostic values: LVH with strain pattern, ST–T abnormalities, RBBB or LBBB, AF and frequent PVCs (→ treatment target).

Advanced AV block is more characteristic of myocarditis and infiltrative disease than other cardiomyopathies.

The association of a large QRS voltage in the precordial leads with a low QRS voltage in the limb leads suggests dilated LV with low EF.

LBBB with QRS >130 ms suggests LBBB-aggravated cardiomyopathy and has therapeutic implication (→benefit from CRT).

IV. Coronary angiography and other ischemic tests

Coronary angiography is recommended if: (i) progressive exertional angina preceded clinical HF, or (ii) ECG features of old MI or acute or subacute MI are present (Q waves or ischemic dynamic ST abnormality) (class I). Otherwise, coronary angiography is considered for HFrEF without obvious cause that does not improve with medical therapy (no AF, no severe HTN).

Alternatively, **cardiac CTA** may be performed. CTA does not necessarily aim to rule out CAD but rather to evaluate for proximal disease that could cause HF and be a PCI/CABG target. ESC gives it a class IIa in HF with low-to-intermediate CAD probability, i.e., without expectations of heavy calcium, but if properly analyzed with a focus on proximal CAD, it may be considered in higher probability cases. Other non-invasive tests have significant limitations and are discouraged (used in <5% of HFrEF in a Danish registry, class IIb ESC recommendation). ACC guidelines give class IIa for ischemic workup without specifying the modality (coronary angiography vs. noninvasive tests).[8]

In a large Danish registry, only 20% of HF patients underwent ischemic evaluation, mainly coronary angiography, and of those 20%, only 16% – 3% of the total sample – underwent revascularization (the numbers were 27% and ~16% in US Medicare and insurance registry).[56] This is mainly because of the proven limitations of CAD revascularization (REVIVED and STICH trials).[56]

Note that chest pressure is not specific for CAD in patients with decompensated HF, because it frequently reflects the oppressive feeling of HF's dyspnea or the ischemic imbalance of HF; rather, CAD is suggested by *exertional angina preceding* severe HF or by ECG MI features.

The non-invasive tests with significant limitations in EF <40% are:

- *Nuclear rest and stress perfusion* scan, looking for segmental defects suggestive of CAD. However, nuclear defects are common in non-ischemic cardiomyopathy (patchy scar tissue). On the other hand, up to 30% of patients with multivessel CAD have balanced ischemia without any apparent defect.[57,58] Thus, nuclear testing is not sensitive or specific to diagnose CAD as the cause of cardiomyopathy.
- *Stress echocardiography:* a biphasic response (i.e., an initial increase in contractility at low doses of dobutamine followed by a decrease in contractility at higher levels of stress) suggests that LV is viable and able to increase its contraction but gets ischemic with high stress. A uniphasic response with a progressive increase in contractility from lower to higher doses suggests non-ischemic cardiomyopathy, or ischemic cardiomyopathy from a coronary stenosis that has been revascularized, but the myocardium has not recovered yet or full recovery is prevented by a severe subendocardial scar. The absence of any increase in contractility suggests the absence of myocardial reserve: LV dysfunction could be ischemic or non-ischemic and is possibly irreversible (non-viable), but viability and the potential benefit from revascularization should not be ruled out based purely on this finding.

V. Diastolic stress testing

Chronic dyspnea that is associated with a normal systolic function on echo and no clinical signs of HF may be falsely considered a dyspnea of non-cardiac origin. These patients may have normal pulmonary capillary pressure and PA pressure at rest. However, exertion and the increase in venous return into a stiff LV increases their left-sided filling pressures. Thus, ***"diastolic stress testing"*** is valuable in patients with chronic unexplained dyspnea, ***especially if they have borderline BNP or echo findings at rest*** (e.g., low E', large LA, or LVH, but normal E/E' ratio). It consists of reassessing **LA pressure** (E/E' ratio>14) and TR velocity (>3.4 m/s) at peak exercise.[10,12,59] Ideally a semi-supine bicycle test with imaging during exercise, or else a treadmill or upright bicycle with imaging within 2 minutes of peak exercise, is recommended. As an alternative to exercise, passive leg raising may be used (~40% of the eventual PCWP rise already occurs upon passive leg raising).

Some patients with diastolic dysfunction but normal left-sided filling pressure at rest truly have a non-cardiac cause of exertional dyspnea. Diastolic stress testing helps sort out whether dyspnea is due to diastolic dysfunction or a non-cardiac cause.

Diastolic stress testing may also be performed invasively, using a Swan catheter and a supine bicycle.

VI. Endomyocardial biopsy

Endomyocardial biopsy is indicated when severe, progressive myocarditis is suspected, in which case ***fulminant lymphocytic myocarditis*** (reversible) and ***hypersensitivity eosinophilic myocarditis*** (treatable and reversible) need to be distinguished from the downhill progressive ***giant-cell myocarditis***.[60] Fulminant myocarditis often recovers in a few weeks but requires aggressive early support, while giant-cell myocarditis may necessitate cardiac transplantation with immunosuppressive therapy and LV assist device in the interim period. Thus, a biopsy is indicated in the case of unexplained, acute HF (<2 weeks) with shock; or new HF (<3 months) with either failure to adequately respond to 1–2 weeks of usual care, or intractable ventricular arrhythmias or advanced AV block. It is also indicated when drug reaction is suspected but HF is not quickly improving after drug withdrawal (biopsy establishes the diagnosis of eosinophilic myocarditis and allows steroid therapy).

A biopsy may also be performed to diagnose infiltrative disease: (i) if cardiac AL amyloidosis is suspected on serum protein immunofixation but abdominal pad biopsy is inconclusive; (ii) if sarcoidosis is suspected by MRI or chest CT but extracardiac biopsy is not possible.

VII. Cardiac MRI

Normally, gadolinium does not penetrate the myocardial cells and briefly and mildly penetrates the myocardial circulation during first-pass MRI perfusion imaging (myocardial cells are tightly packed with no significant interstitium). Late gadolinium enhancement (LGE) on T1 usually implies necrotic or fibrotic tissue, to which gadolinium has a high affinity. Cardiac MRI has 4 major applications in HF: (i) distinguish ischemic from non-ischemic cardiomyopathy (*subendocardial or transmural LGE* implies ischemic cardiomyopathy, *subepicardial or midwall LGE* in a non-coronary distribution implies non-ischemic cardiomyopathy); (ii) diagnosis of myocarditis in unexplained recent cardiomyopathy or unexplained, large troponin elevation; (iii) diagnosis of infiltrative cardiomyopathy vs. hypertrophic cardiomyopathy in a patient with thick myocardium (*global* subendocardial LGE suggests amyloidosis, patchy midwall LGE suggests HCM, patchy basal inferolateral LGE suggests Fabry or sarcoidosis);[61] (iv) viability assessment in ischemic cardiomyopathy. ESC recommends MRI for (iii) [class I] and for (i) [class IIa].

CHRONIC TREATMENT OF HEART FAILURE

1. TREATMENT OF SYSTOLIC HEART FAILURE

I. Treat the underlying etiology: target BP and AF

HTN should be treated to a goal < 130/80 mmHg. In systolic HF, HTN may get "normalized" or reduced as a result of the low cardiac output; HF drugs are provided regardless of blood pressure, up to SBP of 90–100 mmHg, as long as clinically tolerated.

AF rhythm control is superior to rate control in HF. Rhythm control with **catheter ablation** significantly and dramatically reduced both mortality and HF hospitalizations in systolic HF patients, and dramatically *improved EF by ~10–30%* vs. a medical therapy that consisted mostly of rate control following amiodarone failure (CASTLE AF, CASTLE HTx, and CAMERA-MRI trials).[62,63] *AF ablation may normalize EF in 60% of patients*. The benefit in CASTLE AF occurred despite proper baseline rate control (heart rate 80s) and despite a large LA diameter of 49 ± 6 mm and a 70% proportion of persistent AF (100% in CAMERA-MRI), including 30% long-standing persistent AF (74% in CAMERA-MRI). AF was not eliminated, but it was mostly converted to a paroxysmal AF with low AF burden (AF burden reduced from 51% to 20% in CASTLE trials). **Rhythm control with drugs** likely also reduces cardiovascular mortality compared to rate control in HF (EAST-AFNET trial). The benefit extends to HFpEF based on EAST-AFNET and CABANA trials.[64,65] AF ablation is given class I recommendation in HFrEF and class IIa in HFpEF.

If rhythm control fails, including with AF ablation, AV nodal ablation with CRT pacing may reduce mortality compared to simple rate control in HF with any EF, even if QRS is narrow and a rate of 80s bpm is achieved (APAF-CRT trial).[66] *Rate control seems the least favorable strategy in HF*. If pure rate control is chosen, the target rate is <100 bpm rather than <80 bpm (based on RACE-II substudy, substudies of β-blockers in HF, and Swedish HF registry). Strict rate control improves outcomes in systolic HF with sinus rhythm, but not in systolic HF with AF and not in HFpEF. A higher rate is necessary to compensate for the loss of atrial contribution to stroke volume.

II. Value of revascularization in ischemic cardiomyopathy: STICH trial and REVIVED-BCIS-2 trial

The STICH trial randomized patients with ischemic cardiomyopathy and EF ≤ 35% to revascularization with CABG vs. medical therapy.[67,68] Most of these patients had 3-vessel CAD, often with proximal LAD disease, and a prior history of MI; patients were not excluded based on viability testing. The trial excluded patients with significant (CCS 3 or 4) angina and consisted mainly of patients with LV dysfunction, no or mild angina, and moderate HF (class II–III for the most part). At 5 years, CABG was associated with a trend toward mortality reduction (~8% per year vs. 7% per year, p = 0.12), which became significant at 10 years, and a significant reduction of each of the following endpoints: cardiovascular mortality and hospitalization for HF or cardiovascular causes.

In summary, CABG provided only a late and marginal benefit vs. medical therapy (mortality 59% vs. 66% at 10 years). CABG mortality benefit did not become significant until 5–10 years of follow-up, and the mortality reduction was mild (7% at 10 years, ~10% at both 5 and 10 years in the as-treated analysis and in the higher-risk group). In the medical therapy arm, there was only 11% crossover to CABG in the first year and 20% at 10 years. All this implies that CABG is not urgent in patients with ischemic cardiomyopathy, although it is given a class I recommendation in ESC and ACC CAD revascularization guidelines. On subgroup analyses, the benefit was more pronounced in 3-vessel CAD associated with EF < 27% (~9% mortality reduction at 5 years) and in young patients <55 (~12% at 10 years): those should more readily be offered CABG.[69,70] It is unclear whether the benefit extends to sicker patients with more advanced clinical HF: they have higher surgical risk and may not live long enough to derive the late CABG benefit.

REVIVED-BCIS-2 trial – Aside from the STICH trial, the REVIVED-BCIS-2 trial further questioned the value of revascularization in ischemic cardiomyopathy with severe chronic stable CAD. This trial addressed PCI vs. medical therapy in patients with EF < 35% (median 27%) and stable CAD supplying a large amount of myocardial territory: mainly proximal 2- or 3-vessel CAD (38% 3-vessel CAD) with jeopardy score >50% of the myocardium (mostly >2/3 of the myocardium), and viable myocardium. Even significant left main disease was included (14% of randomized patients). Stenosis cutoff was ≥50% for left main and ≥70% for non-left main arteries. Most patients had no angina (66%) or mild angina (32%), and HF was mostly compensated (NYHA class I–II [77%], III–IV [23%], 33% had HF hospitalization within the prior 2 years). Yet, after a median follow-up of 3.5 years, PCI did not improve any outcome compared to medical therapy (death 32%, MI 10%).[71] Even EF improved similarly with PCI vs. medical therapy (~3%). Of note, patients with recent large acute MI in the last 4 weeks were excluded, as in the STICH trial.

There are **several hypotheses for the failure of PCI in ischemic cardiomyopathy with stable CAD**:

1. PCI is inferior to CABG in patients with severe multivessel disease. Yet even CABG only provided a marginal and late benefit in STICH trial of ischemic cardiomyopathy. Also, medical therapy in STICH trial is inferior to that of REVIVED. Modern medical therapy may prove equipoise not only to PCI, but also to CABG.
2. Revascularization is less beneficial in older patients with LV dysfunction (age in BCIS: 70 ± 9 vs. in STICH: 60 ± 8).
3. An important hypothesis is that ***once advanced myocardial disease occurs, the progression of myocardial disease, clinical HF, and mortality become less dependent on CAD and epicardial coronary mechanics and are rather subject to myocardial mechanics and loading conditions***. In fact, in REVIVED, most of the follow-up events were deaths, likely from pump failure or sudden death, rather than MI (32% and 10%, respectively); a similar phenomenon was seen in STICH. Hence PCI was of no benefit in REVIVED, CABG was of limited benefit in STICH, and statins were of no benefit in the CORONA trial of ischemic cardiomyopathy. Conversely, myocardial pharmacology is of great benefit, far superior to the benefit from CAD revascularization: ***each one of the 4 survival drugs of HFrEF provides faster and more pronounced yearly mortality reduction than CABG did in the STICH trial*** (~2% absolute mortality reduction for each HFrEF drug per year vs. ~1% for CABG). Also, procedures that directly affect myocardial mechanics and loading conditions, such as biventricular pacing, AF ablation in HF with AF, and mitral valve therapy in patients with severe refractory functional MR, appear to reduce mortality in the proper context.
4. Revascularization of stable CAD improves only angina, not hard outcomes, regardless of whether LV function is preserved (COURAGE, ISCHEMIA trials) or severely impaired (REVIVED, and even STICH trial).
5. Some patients with CAD, including multivessel CAD, rather have non-ischemic cardiomyopathy by MRI and the CAD is rather incidental (e.g., HTN-, AF-, or LBBB-induced cardiomyopathy). Revascularization is unlikely to benefit those patients.[72]
6. REVIVED did not provide exact stenosis severity; it is possible that select patients with critical left main or >90% multivessel proximal disease derive a benefit from PCI.

Summary: Indications for revascularization in ischemic LV dysfunction:
Global* revascularization with CABG provides *mild* and *late* benefit in chronic ischemic cardiomyopathy regardless of viability and of eventual EF improvement** (STICH trial), whereas PCI revascularization does not appear beneficial even in patients with viability (REVIVED trial). Viability has limited value and may be used *only occasionally* to guide the specifics of ***regional revascularization, particularly with PCI (e.g., in a patient with CTO of a single vessel, akinesis, Q waves, and questionable angina, viability testing is needed before considering PCI). However, viability is not used to decide for or against the overall multivessel revascularization (viability testing is not recommended in ESC guidelines and is given class IIb in ACC guidelines).

Revascularization of chronic CAD is indicated for lifestyle-limiting ***exertional angina*** in patients with *compensated HF;* beware that in decompensated HF, chest pain may be a manifestation of HF rather than true angina. Aside from angina, revascularization of chronic CAD has limitations; it is *likely best suited for patients with critical left main or proximal multivessel disease >90%, whose CAD is the likely driver of LV dysfunction, particularly in younger patients* (examples: 3-vessel CAD with EF < 27% or age <55–60 years, as suggested by STICH trial analyses).[70,73]

It is unclear whether the limitations of revascularization in REVIVED and STICH apply to ***chronic CAD diagnosed in the setting of acutely decompensated HF, without type 1 MI or large type 2 MI***. STICH and REVIVED did not exclude recent ADHF (they excluded recent shock

<3 days), yet the population was overwhelmingly stable HF with limited proportion of NYHA IV. One may argue that sicker patients with more advanced HF derive amplified benefit from a beneficial therapy, such as ACE-I or β-blockade or AF ablation; yet, they are most harmed from a non-beneficial therapy and have more severe myocardial disease that may be less likely to benefit from revascularization or tolerate its procedural risks. In REVIVED, even patients with the most extensive dysfunctional-yet-viable myocardium did not seem to benefit from PCI.

Acute revascularization remains useful in the setting of ***acute large MI causing acute HF or shock,*** usually marked by extensive ST changes or evolving Q waves (STEMI or large NSTEMI). *This likely extends to large type 2 MI with marked troponin elevation* (e.g., hs-troponin T > 300–400 ng/L), which is difficult to distinguish from NSTEMI. Revascularization is performed within a few days of NSTEMI, after diuresis and HF or shock stabilization, and emergently in STEMI, but not in the case of a STEMI or Q-wave infarct >1–2 days old with a persistently occluded culprit artery responsible for the low EF, as shown in the OAT trial.

III. Limited value of viability testing

In the STICH trial, ~50% of patients underwent viability testing (with echo or SPECT) and were randomized to CABG vs. medical therapy regardless of the result. ***CABG was mildly beneficial regardless of viability and independently of EF improvement, and viability did not provide any discriminatory effect***.[74,75] Viability did predict eventual EF improvement; in fact, EF improved only in patients with viability, but to a similar magnitude with either CABG or medical therapy.[75] Similar findings were seen in the REVIVED-BCIS-2 trial, which only revascularized patients displaying LV viability (defined as ≥4 dysfunctional but viable myocardial segments subtended by diseased coronary arteries): the extent of viability did not predict a benefit of PCI vs. medical therapy, nor did it predict LV recovery or mortality. The extent of non-viable scar was associated with more death and less EF improvement.[76]

In summary, viability testing has not proven a useful guide in the chronic cardiomyopathy setting (STICH, REVIVED trials) or in the recent post-MI setting (OAT trial post hoc analysis). The following pitfalls may explain the limited utility of viability testing:

- Viability tests have positive and negative predictive values of ~65–80%, for both regional and global viability. The assessment of the extent of transmural scarring by MRI is more valid (negative predictive value for LV recovery 90%, positive predictive value 60–80%, depending on the transmural cutoff used, e.g. 50%). Note that, regardless of viability testing, 70% of patients with chronic ischemic LV dysfunction have significant improvement in LV function after revascularization (81% in STICH trial), a number that is not much different from the yield of viability testing.
- The definition is not uniform. In a patient with anteroapical infarction, regional viability addresses the viability of the anteroapical segments to decide whether LAD revascularization is beneficial; conversely, global viability addresses whether there are ≥4 dysfunctional segments that are viable.
- Even without any viability and any contractile and EF improvement, revascularization may improve symptom status, HF, and mortality in the right patient.[77] Revascularization may improve LV remodeling, prevent further deterioration of LV function and further MI, and reduce arrhythmogenesis.

IV. Drugs that affect survival in EF ≤40%

Three compensatory mechanisms occur in HF and are ultimately harmful.

1. LV remodeling is the process of LV dilatation, LV change in geometry, and LV eccentric hypertrophy that attempt to increase the stroke volume of a hypocontractile myocardium. This process may be useful to a certain degree early on. Over time, however, as the LV undergoes progressive remodeling, it becomes less elliptical and more spherical, progressively more dilated, thin, and fibrotic. This leads to increased wall stress (afterload), and chronically increased *preload*, a particularly toxic process causing cardiomyocyte elongation, sarcomere disruption, and apoptosis.[78] All this ultimately decreases the stroke volume.

LV end-systolic volume is the best measurement of LV remodeling. *EF, often considered a contractility index, is affected by preload and afterload and is, in fact, more a remodeling index than a contractility index (Figure 4.4).*

Figure 4.4 Case of chronic HF with LV dilatation and mild increase in PCWP.

Left figure corresponds to LV volume and pressure before diuresis and before drug therapy. After diuresis, RAAS blockade, and β-blockade (*right figure*), LV volume decreases and LV morphology changes from a sphere to an ellipse. Stroke volume increases because of reduced afterload (smaller LV), reduced functional MR, and reduced RV–LV interdependence. Diuresis is beneficial, even though PCWP is only mildly elevated at baseline.

Note that afterload correlates with LV size and is not simply equivalent to aortic pressure (Laplace law):
Afterload = wall stress = LV radius × LV systolic pressure/2× LV thickness

EDV, end-diastolic volume; SV, stroke volume.

2. Increased activity of the sympathetic system increases cardiac contractility but ultimately exhausts the myocardium and its energy reserves, makes it less responsive to catecholamines, and promotes apoptosis.
3. Increased activity of the renin–angiotensin–aldosterone system (RAAS) elicits vasoconstriction and increases blood volume. This aims to maintain the blood pressure and the kidney perfusion, but is deleterious to the LV. In addition, angiotensin II directly acts on harmful myocardial AT1 receptors that promote cellular growth, LV dilatation, and LV fibrosis and increase the release of myocardial norepinephrine.

Six main treatments improve mortality. They reduce LV remodeling, promote reverse remodeling, and, eventually, *increase EF even if myocardial contractility is unchanged* (drugs 2–5 are called **the 4 pillars of HFrEF**):

1. Angiotensin-converting-enzyme inhibitors (ACE-Is) or angiotensin receptor blockers (ARBs). ACE-Is and ARBs improve HF outcomes not only through afterload reduction but also through blocking the harmful RAAS effect on volume status and on the AT1 myocardial receptor. In fact, afterload reduction with amlodipine or with α-blockers does not improve HF outcomes.
2. β-Blockers blunt the high sympathetic tone of HF.
3. Aldosterone antagonists.
4. Neprilysin inhibitor combined with ARB.
5. Sodium-glucose cotransporter-2 (SGLT-2) inhibitors.
6. Hydralazine and nitrate combination. This vasodilator combination reduces mortality and symptoms in black patients and reduces symptoms in white patients.

V. Specifics of drugs that affect survival

ACE-Is/ARBs and β-blockers are indicated in all cases of systolic LV dysfunction with **EF ≤40%,** including asymptomatic patients.

A. ACE-I or ARB*

1. ACE-Is and ARBs increase cardiac output, reduce LV remodeling, and improve EF. They reduce mortality by ~20% and reduce HF hospitalizations by ~30%.[80–83]
2. ARB is an alternative to ACE-I when cough or angioedema occurs with ACE-I. There is a small cross-risk of angioedema with ARB (<5%), and thus extreme caution is advised when substituting ARB for ACE-I in a patient who had angioedema with ACE-I; this is not a contraindication to ARB (CHARM-Alternative). The main ARBs studied in HF are candesartan and valsartan.[79,84–86] When used as an alternative to ACE-I therapy, ARB therapy reduces mortality in systolic HF (CHARM alternative trial and ValHeFT substudy).
3. Cautions and contraindications (ESC):

- *Before initiation of ACE-I, the SBP contraindications are*: symptomatic hypotension <100–110 (dizzy, weak, oliguric) or asymptomatic hypotension <90 mmHg (or <100 mmHg for ARNI). Note that *patients with baseline SBP 90–110 mmHg derive more absolute benefit* from ACE-I/β-blockers vs. those with higher SBP, despite the lower tolerated doses, because their HF is more severe (see Section V.B).
- *After initiation of ACE-I*: Asymptomatic hypotension <90 mmHg is accepted (unlike hypotension <90 mmHg before ACE-I). Even symptomatic hypotension, i.e., dizziness or weakness after ACE-I initiation, does not warrant cessation of ACE-I unless severe and persistent, as symptoms often improve within a few days: keep ACE-I as long as the patient can "*stand, think, and urinate*." Try to reduce nitrates or diuretics, especially in the absence of congestion. Hypotension of *80–90 mmHg* in systolic HF, particularly under ACE-I therapy, may be well tolerated as it helps unload the LV; **BP often rises with time** as ACE-I improves LV function. Compared to higher BP, **hypotension during treatment, whether symptomatic or not, is associated with higher mortality but more dramatic absolute and relative benefit from HF therapies even at lower doses,** such as ACE-I or even more so ARNI, as it reflects sicker HF.[87] These drugs are continued if symptoms are mild or improving with time, or interrupted and restarted at lower dose if symptoms are intolerable. Eventually, they can be continued in >80% of such patients.[85] Even ARNI, which is avoided if baseline SBP <100 mmHg, may be continued if SBP drops to <100 mmHg during treatment without severe symptoms.
- Elevation of creatinine of over 50% within 1–2 weeks of ACE-I/ARB initiation. In advanced HF, the worsening of renal function may be related to the low BP/low kidney perfusion state aggravated by ACE-I initiation, which impairs renal autoregulation (Figure 23.1). Yet, a rise in creatinine of over 25% and/or over 0.3 mg/dl early after initiation of ACE-I, or even over 50%, is not associated with a loss of benefit with continued ACE-I therapy, and renal function largely recovers on follow-up. In fact, in 2 studies, ***patients with early worsening of renal function appeared to derive the largest relative and absolute benefit from continued ACE-I therapy***, partly because renal deterioration is a reflection of severe HF and baseline renal hypoperfusion.[88,89] ***If creatinine rises ≥50% or ≥0.5 mg/dl,*** reduce other BP-lowering drugs, ensure the patient is not using NSAIDs, assess for excessive diuresis and consider reducing the diuretic dose. Along with that, hold the ACE-I for a few days to allow renal recovery then restart half the initial dose. In fact, the prior study suggests that even ACE-I-induced creatinine elevations ≥ 50% do not preclude a large mortality benefit with continued ACE-I.[88] ***Only if creatinine rises ≥ 100%*** or to >3.5 mg/dl, or if GFR drops to <20, ***ACE-I is stopped.***[8]

  ACE-I/ARB is avoided in acute kidney injury, as it may acutely worsen renal perfusion. Short of that, *it may be initiated or up-titrated acutely in decompensated HF*, wherein it improves diuretic response and possibly even renal perfusion.[91,92]

ACE-I/ARB is beneficial in patients with moderate renal deterioration upon initiation. ACE-I/ARB is also beneficial in patients with moderate baseline renal failure, based on the CONSENSUS trial of advanced HF: patients with creatinine 1.4–1.8 mg/dl derived much more mortality benefit than <1.4 mg/dl, despite lower enalapril dose ≥2.5 mg and frequent creatinine rise ≥50%.[90] However, most clinical trials ***excluded patients with baseline GFR <30 ml/min/1.73 m²***, hence ESC guidelines suggest caution in CKD stages 4–5.

*ACE-Is inhibit the conversion of angiotensin I to angiotensin II and increase kinin (and nitric oxide) availability; some angiotensin II is, however, still produced by myocardial chymase. ARBs block the harmful AT1 angiotensin II receptor, without affecting the potentially useful AT2 receptor, but ARBs do not increase the beneficial kinin. Despite this difference, clinical effects of ACE-Is and ARBs are grossly the same, and risks are the same, except for cough and angioedema with ACE-I (related to kinin). In the only large trial comparing them (ELITE II), mortality was similar.[79]

- K >5 mEq/L at baseline or >5.5 mEq/L with therapy. If K rises to 5.5–5.9 upon ACE-I initiation without a severe rise in creatinine, reduce dietary potassium intake and hidden sources (e.g., low salt substitutes, Bactrim), and reduce the dose of the aldosterone antagonist and the ACE-I, then, if needed, add patiromer.

4. Attempt titration every 7–14 days to the optimal dose used in randomized trials, which is approximately one-half of the maximal dose. In comparison with the low dose, the intermediate or high dose further reduces HF hospitalizations by 24% but does not significantly improve mortality (ATLAS trial, where lisinopril 2.5–5 mg was compared with 30–40 mg). Thus, even if a high dose is not reached, it is expected that the low dose will lead to similar benefit on mortality.[93]

Examples of doses:

- Lisinopril (ACE-I): start 5 mg Qday and try to reach 20–40 mg Qday. It is renally eliminated and the effect is doubled in patients with renal failure, wherein the starting dose may be 2.5 mg Qday.
- Enalapril (ACE-I): start 2.5 mg BID and reach 10 mg BID (also renally eliminated).
- Candesartan (ARB): 4 mg Qday; goal, 32 mg Qday (biliary elimination).
- Valsartan (ARB): 40 mg BID; goal, 160 mg BID (biliary elimination).

5. Significant, sometimes drastic, improvement of exercise duration (20–50%) and functional class is seen with ACE-I.[84] Symptomatic improvement may occur within 48 hours of ACE-I initiation but is generally delayed weeks to months. Abrupt withdrawal of ACE-I can lead to clinical deterioration and should be avoided, except in decompensated HF with low output and hypotension, or severe deterioration of renal function (creatinine rise ≥100%).

6. In CHARM-Added trial, the addition of ARB to ACE-I in class II–III HF already receiving a β-blocker reduced HF hospitalizations compared to ACE-I alone, without an effect on total mortality.[85] Yet in patients receiving ACE-I, preference should be given to adding an aldosterone antagonist rather than ARB, and to switching to ARNI, as the latter 2 therapies further reduce mortality. Thus, the ARB/ACE-I combination has no role in HF.

B. β-Blockers

1. β-Blockers used to be contraindicated in HF, and in fact they may worsen HF initially, especially in the first 2–3 weeks after therapy initiation and/or up-titration. This is due to their initial negative inotropic effect. But when used over the long term, β-blockers:

- Improve contractility, EF (by 5–15%), and HF symptoms, and reduce mortality by 35–60% and HF hospitalizations by 40%.[94–96]
- Reverse the deleterious and apoptotic effects of catecholamines on the heart. The reduction in energy demands reduces apoptosis.
- Reverse remodeling and reduce cardiac chamber size by reducing LV wall stress.
- Prevent arrhythmias and sudden death and reduce heart rate, which, by itself, is beneficial in HFrEF

2. The 3 agents that have been shown to improve survival and outcomes in HF are:

a. Long-acting metoprolol (metoprolol succinate): metoprolol is a selective β_1-blocker, but loses selectivity with high doses >100 mg. Long-acting metoprolol has a more sustained effect than metoprolol tartrate; this limits the daily fluctuations of the β-blocker effect and the β-blocker withdrawal effect that occurs between the doses of metoprolol tartrate.

- Dose: Start 12.5 or 25 mg Qday and titrate to 200 mg Qday

b. Carvedilol: carvedilol is a non-selective β_1-blocker, β_2-blocker, and α_1-blocker (vasodilatory effect), with additional antioxidant proper- ties. Despite its α-blocker effect, it is as well tolerated as metoprolol in patients with borderline BP. The non-selective blockade of

adrenergic receptors is advantageous. While metoprolol upregulates β-receptor density toward normal levels, carvedilol maintains a low density of these receptors. Moreover, selective β_1-blockade with metoprolol may enhance the ino- and chronotropic response to β_2-adrenergic stimulation, an untoward effect.[97] Thus, carvedilol is a more potent antiadrenergic agent than metoprolol, as manifested by the more significant reduction of heart rate in the COMET trial and the more marked blunting of heart rate response.[98] With its more comprehensive blockade of all adrenergic receptors, carvedilol improves myocardial function, EF, and cardiac hemodynamics such as stroke volume, PA pressure, and PCWP, more than other β-blockers and reverses remodeling more effectively.[97,98] Because of the α-blocking effect, carvedilol acts as a moderate vasodilator acutely, but with long-term treatment the vasodilator activity is no longer prominent, as tolerance to the α-blocking effect occurs. This transient α-blocker effect is useful, as it allows an early improvement in stroke volume and LV remodeling before the long-term effect of β-blockade kicks in.[99] In the COMET trial, carvedilol reduced mortality vs. metoprolol in HFrEF (caveat: short-acting metoprolol was used).

- Dose: start 3.125 mg BID; titrate to the goal of 25 mg BID if patient's weight <85 kg, 50 mg BID if weight >85 kg.
- A long-acting formulation of carvedilol, Coreg CR, is available. It is given once daily. Coreg CR 10 mg is equivalent to carvedilol 3.125 mg BID. Start Coreg CR 10 mg Qday and titrate up to 80 mg Qday.

c. Bisoprolol, a selective β_1-blocker. Start 1.25 mg Qday; goal, 10 mg Qday.

3. Keys to β-blocker therapy:

a. Start "low and slow." Patients must be euvolemic and stable. During hospitalization for HF, low-dose β-blockade is started before discharge, after the patient has stabilized.

b. Contraindications: overt HF, SBP <90 mmHg or symptomatic hypotension, bradyarrhythmia (bradycardia <55 bpm, any second- or third-degree AV block, PR >0.24 s), bronchospasm.

c. *Double the dose every 2 weeks* and monitor for worsening of dyspnea, edema, weight gain, bradycardia, and hypotension. If the patient is off the β-blocker for over 1 week for any reason, or after an episode of cardiogenic shock, restart at the lowest dose and re-titrate.

d. If *edema* increases or HF develops within a week of titration (worsening dyspnea, weight gain), increase the diuretic dose; if this is not effective, decrease the β-blocker dose and titrate more slowly.

In case of *severe fatigue*, decrease the dose of β-blocker (and sometimes the diuretic) or titrate more slowly. Most often, fatigue resolves spontaneously in a few weeks.

In case of *bradycardia* (symptomatic bradycardia <55 bpm, asymptomatic bradycardia <50 bpm, or AV block), try to decrease the dosage of digoxin and amiodarone first, then, if needed, reduce the β-blocker.

Patients with severe systolic HF can tolerate SBP of 85–90 mmHg, and doses of medications should not be decreased unless the patient is severely dizzy or has signs of low perfusion, in which case the medications should be started at lower doses and titrated slowly, the timing of ACE-I and β-blocker staggered, and the diuretic dose reduced if possible. A spontaneously low SBP (<100 mmHg) is, per se, an adverse prognostic factor; however, it does not limit the benefit and tolerability of β-blockers, ACE-Is/ARBs, or hydralazine–nitrate.[100–102] A substudy of the COPERNICUS trial showed that HF patients with chronic SBP <95 mmHg derived the same relative benefit and *more absolute benefit* from carvedilol compared to patients with higher SBP, despite the lower tolerated carvedilol doses: ***the sickest patients derive the most benefit despite lower doses***. They did not have a significant drop of SBP with carvedilol; in fact, SBP increased over time above baseline, as a result of the increased cardiac output.[102] A similar phenomenon was seen with candesartan in CHARM, valsartan in ValHeft, and hydralazine–nitrate in A-Heft. *In fact, those drugs reduce BP in HTN, but increase BP in patients with severe HF and low BP, after a few days of hazard*.

e. It is not necessary to reach an optimal dose of an ACE-I before starting a β-blocker. In fact, it is preferred to start low doses of both and titrate up in an alternating fashion. The combination of a low β-blocker dose and a low ACE-I dose produces a greater symptomatic improvement and mortality reduction than an increase in the ACE-I dose.

Order of therapy: start low-dose ARB or ACE-I (lisinopril ~5 mg), then start low-dose β-blocker. ***Spironolactone*** *then* ***SGLT2 inhibitor*** *may be sequentially initiated while the patient is still on small doses of ACE-I and β-blocker.* ACE-I/ARB may then be switched to ***ARNI***, followed by up-titration of β-blocker then ARNI, if possible from BP and renal standpoints (see Section G).

f. If the patient has been on a β-blocker for more than a few weeks and is hospitalized with HF decompensation, the β-blocker should not generally be withheld. In low-output HF decompensation with borderline BP, the β-blocker dosage may be reduced. In full-blown shock, or when inotropes are considered, the β-blocker is withheld. Discontinuation of β-blocker therapy is independently associated with increased short- and long-term mortality and should be avoided if possible.[103] If interrupted, β-blocker is restarted at the lowest dose after the patient stabilizes, before hospital discharge, then re-titrated.

g. *How about EF 40–50%?* Major β-blockers trials mainly included patients with EF <35–40%. Yet, 2 small studies that included any EF and a meta-analysis of β-blockers in HF showed that EF 40–50% derives the same mortality benefit as lower EF.[104]

How about AF? Although no specific benefit was seen in AF subgroups on post hoc analyses, major trials included patients with AF at baseline (~15%) and thus, AF patients should receive β-blockers.[105]

Try to reach the high target doses and the high degrees of β-blockade that are proven to be beneficial. In the only trial comparing various doses of β-blockers in HF, carvedilol showed a survival benefit that started at 6.25 mg BID and further increased at a dose of 25 mg BID.[106] Also, LVEF further improved with the high dose. Yet, a bisoprolol trial analysis showed a similarly large relative mortality reduction with low and high doses (low dose used in the sickest patients).[107] A post hoc analysis of a metoprolol XL trial showed that doses of 25–100 mg achieved the same relative and absolute mortality reduction as doses >100 mg. [108]

h. ***Should β-blockers be titrated to achieve a specific target heart rate (HR)?*** The improvement in outcomes with β-blocker therapy is incremental with the following 3 factors, in order of importance: (1) dose achieved; (2) baseline severity of HF; (3) HR achieved and HR reduction.[102,105,109,110] The 3 factors are interactive. The HR achieved with β-blocker therapy depends on the overall HF severity and catecholamine level, rather than just the β-blocker dose. A more severe or decompensated HF is associated with a higher HR yet derives a larger mortality benefit even from a small β-blocker dose. Thus, β-blockers are not necessarily titrated to achieve a specific target HR, although a low HR (~60–70 bpm) is desirable, is associated with a reduced mortality, and implies better HF control through both β-blockade and adjunctive HF therapy. Part of the reason metoprolol XL achieved similar relative benefit vs. placebo at low and high doses is the similar HR achieved with both doses in the trial. ***Either a high β-blocker dose or a low HR (<70 bpm) should at least be achieved***, **and** ***it is crucial to keep pushing the β-blocker dose even if the patient becomes asymptomatic***. Even if HR remains >70 bpm, the mortality is low when a high dose of β-blocker is reached.[109] The relationship between lower heart rate and survival is only true in sinus rhythm, ***not AF***.[105]

While a high HR is essentially secondary to HF, it may also, by itself, perpetuate systolic HF through perpetuating energetic and metabolic inefficiencies. A trial of a pure sinus node blocker (ivabradine) showed that pure HR reduction was associated with reduced HF hospitalizations, confirming a direct role of HR in the pathophysiology of systolic HF.[111]

C. Mineralocorticoid receptor antagonists (spironolactone, eplerenone)

1. The high aldosterone levels seen in HF not only induce renal sodium retention but directly act on the myocardial and arterial aldosterone receptors, leading to myocardial and arterial fibrosis and baroreceptor dysfunction (sympathetic augmentation). In fact, the small doses of aldosterone antagonists studied in HF only have a mild or no diuretic effect (RALES trial).[112] The benefit in HF mainly results from: (i) blockade of myocardial and baroreceptor aldosterone receptors; (ii) increase in potassium (antiarrhythmic effect); (iii) reduction of the tubular resistance to loop diuretics.[113] Aldosterone antagonists *drastically* reduce HF mortality by 30%, HF hospitalization by 30–40%, sudden cardiac death, and improve NYHA functional class (RALES trial).[112,114,115]

Aldosterone acts at the DNA level and induces the genomic synthesis of distal tubular Na channels and basal Na/K pumps that absorb Na and secrete K and H. The aldosterone receptor blockers inhibit this synthesis rather than directly block Na/K pumps, and therefore *have a slow onset of action of 2–3 days and a slow offset (3–4 days), similar to aldosterone and other steroids*.

2. An aldosterone receptor antagonist is indicated in chronic HF with EF ≤35% and NYHA classes III–IV.[112] Aldosterone antagonist therapy has also reduced mortality in class II systolic HF (EF ≤35%) with elevated BNP or recent cardiovascular hospitalization in the last 6 months, and is recommended for these patients (class I recommendation).[114]

It is also indicated after a recent MI (within 30 days) when EF is <40% and any degree of clinical HF or diabetes is present.[115]

3. Contraindications: creatinine >2 mg/dl or GFR < 30 ml/min/1.73 m2; K >5 mEq/L. In the RALES trial, patients with mild renal failure (GFR 30–60 ml/min) had a higher risk of worsening renal function and hyperkalemia with spironolactone in comparison to those with normal renal function, but derived the largest absolute mortality reduction. Thus, patients with mild renal failure are appropriate candidates for this therapy if well monitored.[116] While aldosterone antagonist should not be initiated with GFR <30, it may be continued in patients whose GFR drops to <30 while on treatment. Analysis of the major trials RALES and EMPHASIS suggests that patients whose GFR drops to <30 while on treatment continue to derive a large mortality benefit from aldosterone antagonists, even more dramatically than those whose GFR remains >30, as the former are sicker patients with higher baseline mortality and more need of such therapy.[117]

4. Dosage of spironolactone: 12.5–25.0 mg daily; careful up-titration to 37.5–50.0 mg daily may be tried in patients with refractory HF or persistent hypokalemia. If gynecomastia develops, eplerenone may be used instead of spironolactone. Potassium and creatinine should be checked within 3 days and again at 1 week after therapy initiation, then Q4wk for the next 3 months. Typically, all potassium supplements need to be stopped at the initiation of the aldosterone antagonist; a minority of patients will continue to require a potassium supplement, but this is restarted only after blood testing. In real-world registries, hyperkalemia is common with aldosterone antagonists (up to 20%), therefore justifying careful K monitoring. In fact, these agents should be avoided if K monitoring is not possible (compliance issues), and the patient should be instructed about interruption of therapy should diarrhea or dehydration occur (renal failure). If K rises to 5–5.4 with spironolactone, maintain the same dose; if K rises to 5.5–5.9, hold it for a few days then resume half the dose; if K ≥6, discontinue it.

5. RAAS activation leads to a marked elevation of aldosterone levels in both HF and cirrhosis, exaggerated by the fact that aldosterone catabolism, a hepatic process, is impaired. In cirrhosis, a high dose of spironolactone (100–400 mg), higher than the one studied in HF, has been shown to induce more natriuresis than a loop diuretic. In fact, the avid distal sodium reabsorption induced by hyperaldosteronism makes loop diuretics ineffective in 50% of cirrhotic patients.[118] This high dose has not been largely studied in HF because of the combined therapy with ACE-I, but illustrates the potential value of spironolactone in patients with combined heart and liver failure and the possible role of higher spironolactone doses in patients resistant to loop diuretics.[118] In ATHENA-HF trial, a 4-day course of spironolactone 100 mg in acute HF, on top of furosemide, did not improve urine output, weight loss, and NT-proBNP but was safe (trial limitations: treatment was brief and patients were furosemide-responsive).[119]

6. ***Patiromer*** is a K binder that removes K at the gastrointestinal level, hence lowering K by 0.5–1 mEq/l. It allows the continuation of the same ACE-I and aldosterone antagonist doses when K is 5.5–5.9; and even when K is ≥6, after 1 week of interruption.[120] Yet, DIAMOND trial showed that >80% of patients with prior hyperkalemia tolerate aldosterone antagonist rechallenge even without patiromer; patiromer reduced discontinuation by only 3%.

D. Angiotensin receptor-neprilysin inhibitor ARNI (sacubitril–valsartan combination)

Neprilysin is a peptidase that degrades natriuretic peptides, bradykinin, and adromedullin. Neprilysin inhibition increases the level of these substances via a "double negative" effect, counteracting vasoconstriction, sodium retention, and LV remodeling. In fact, natriuretic peptides reduce maladaptive hypertrophy and fibroblast proliferation in the heart and kidneys. In a trial of patients with HF and EF ≤40%, NYHA II–IV, and BNP >150 or a prior HF hospitalization in the last year, valsartan + neprilysin inhibitor (combined in 1 molecule, not just 1 pill) reduced the 2-year mortality by ~3% in comparison with ACE-I (relative risk reduction 16%).[121] Hospitalization for HF was also reduced by ~3%. Angiotensin-neprilysin inhibitor was associated with more symptomatic hypotension yet less renal dysfunction and hyperkalemia than ACE-I, and slower renal decline over the long term: natriuretic peptides selectively vasodilate the afferent arteriole, thereby increasing renal flow and offsetting the hypotensive effect and the efferent dilatation.[122] This benefit was seen despite a background therapy that included β-blockers and aldosterone antagonists (PARADIGM-HF trial). Most patients had class II symptoms, and the benefit was seen in stable and relatively low-risk patients, which argues that *even early-stage HF patients who are stable on ACE-I are better switched to this therapy*; the indication is more compelling in patients with recent or current HF hospitalization. In-hospital initiation of angiotensin-neprilysin inhibitor dramatically reduces early HF rehospitalizations by 42%, compared to in-hospital ACE-I followed by a later switch to angiotensin-neprilysin inhibitor at 8 weeks (PIONEER-HF trial).[123] Yet, its selective use in advanced class IV HF with a high rate (~80%) of recent HF hospitalizations and with a mean SBP ~110 did not improve outcomes or NT-proBNP vs. ARB, and was plagued by a high rate of hyperkalemia (17%) and intolerance or discontinuation (>30%) mainly related to hypotension (LIFE trial).[124] Also, its initiation in acute MI with low EF ≤40% or congestion was not superior to ACE-I (PARADISE-MI).

In order to prevent angioedema, the recommended washout period between an ACE inhibitor and sacubitril–valsartan is 36 hours. A prior history of angioedema with ACE-I contraindicates the use of sacubitril–valsartan, but a prior history of cough is not a contraindication.

Of note, neprilysin inhibitor is the only HF therapy that increases BNP, a consequence of its direct effect. This affects the diagnostic value of BNP, at least during therapy initiation, but BNP remains useful for monitoring in respect to the new baseline. Conversely, NT-proBNP is not directly affected, as it is not a derivative of BNP, but a byproduct of the same precursor (proBNP).

The same precautions detailed under ACE-I/ARB apply to ARNI, keeping in mind the greater hypotensive effect of ARNI and its poor tolerability in advanced HF. Avoid initiating it if baseline SBP <100 mmHg (PARADIGM-HF), but hypotension <90 *after* initiation, if tolerated, does not diminish the superiority of ARNI. *GFR <30 ml/min/1.73 m²* was excluded from the trials, hence ARNI is contraindicated in case of baseline GFR <30 ml/min/1.73 m^2 per ESC (not ACC). Conversely, ACE-I/ARB can and should be cautiously tried in case of GFR <30 ml/min/1.73 m^2. In patients who are ACE-I/ARB naive, ACE-I/ARB may be initiated then followed by a switch to ARNI, or ARNI may be directly initiated. This de novo ARNI approach is preferred by ACC based on the PIONEER-HF trial, except in advanced HF, borderline BP, or GFR <30 ml/min/1.73 m^2.

Dosage of ARNI – If ACE-I/ARB naive or if on low ACE-I/ARB dose: start 24/26 mg BID, titrate to 49/51 mg BID then 97/103 mg BID. If switching from high ACE-I/ARB dose (>10 mg enalapril): start 49/51 mg BID then up-titrate.

E. Gliflozins = Sodium-glucose cotransporter-2 (SGLT-2) inhibitors (class I recommendation in HFrEF)

SGLT-2 is the main glucose transporter in the proximal renal tubule and is responsible for reabsorption of the filtered glucose in diabetes but also in normal individuals; Na is co-absorbed with glucose. SGLT-2 inhibitors cause glycosuria, and along with it, osmotic diuresis and natriuresis.

Trials of diabetic patients have consistently shown that gliflozins reduce HF hospitalizations (by ~35%) regardless of baseline HF. In a paradigm shift, the DAPA-HF trial specifically randomized HF patients with EF < 40%, with or without (58%) diabetes, with NYHA II–IV, to dapagliflozin (10 mg/day) vs. placebo; a similarly striking reduction of HF hospitalizations was seen in diabetic and non-diabetic patients (~30%), along with symptomatic improvement and significant mortality reduction (17% relative reduction; 1.6% absolute reduction per year), even though patients were already receiving standard diuretic and HF therapies and mostly had NYHA class II.[125] A similar reduction of HF hospitalizations was demonstrated with empagliflozin 10 mg/day in HFrEF with or without diabetes (Emperor-reduced trial).[126] Furosemide dose was unaltered in most patients. This benefit is related to the diuretic effect but also to direct cardiac metabolic effects. The main fuel for the healthy heart consists of free fatty acids, which generate the highest ATP yield; the failing heart, however, switches to glucose, which is less efficient, particularly under anaerobic glycolysis, and begets more HF. SGLT-2 inhibitors increase lipolysis and ketogenesis, forcing the myocardium to use the more ATP-efficient ketones and fatty acids, hence improving myocardial energetics. Also, by eliminating glucose, SGLT-2 inhibitors promote nutrient-depletion signaling, which enhances autophagy, i.e., house cleaning, which eliminates toxic and oxidative products, and promotes myocardial biogenesis and myocardial and renal tubular function.[127] Pump failure but also sudden cardiac death are improved.[128,129] LV size and filling pressure improve, but EF does not consistently improve.[130]

They also have renal benefits: in DAPA-CKD and EMPA-Kidney trials of moderate to severe CKD (GFR ~20–75, mostly with albuminuria), with or without diabetes, SGLT-2 inhibitors led to a dramatic ~40% reduction of major adverse renal outcomes at a median follow-up of 2 years, with a mortality reduction of 30% in DAPA-CKD (major renal outcomes defined as dialysis or >40–50% sustained GFR decline).[131,132] *No cutoff for creatinine rise after therapy initiation dictated SGLT-2i interruption*. An early dip in GFR was seen (average ~10%), followed by a ~50% slower GFR decline over the long term and, more importantly, a reduction of the major renal events. DAPA-CKD patients with an initial GFR decline >10% derived the greatest benefit from SGLT-2i with the slowest GFR decline over the long term. This is likely because the early dip occurs in the most advanced nephropathy. However, no data is available on the safety of acute GFR decline >30%, and this cutoff may warrant therapy interruption.

Diuretic dose is reduced in patients who become weak or dehydrated during therapy, especially if ARNI is added as well. SGLT-2 inhibitors may be used in HF and CKD up to a GFR of 20 ml/min, even 15–20 ml/min based on the EMPA-KIDNEY trial.[133] Because of the small risk of ketosis, SGLT-2 inhibitor should be held for a few days during "sick" days (active infection, GI illness, dehydration, peri-operative state). Genitourinary infections are easily treated and warrant interruption of SGLT-2 inhibitor, but not discontinuation, unless very frequent.

The early initiation of SGLT-2 inhibitor in acute HF during hospitalization (reduced or preserved EF) boosts diuretic response by up to 50% and leads to an early dramatic reduction of death and HF events by 35% at 3 months, and improves quality of life, regardless of EF (EMPULSE trial: death was numerically cut in half).[134] Data from DAPA-HF concur and show that the most dramatic reduction of cardiac events occurs at 4 weeks of therapy (50% relative reduction), particularly in patients with prior hospitalization <12 months.[135]

F. Hydralazine–nitrate combination

In the *V-HeFT-I trial*, the hydralazine–nitrate combination reduced mortality by 34% in comparison to placebo or α-blocker therapy; this was the first trial ever to show a mortality reduction with vasodilator therapy in HF.[136] The mortality reduction was mainly driven by the benefit in black patients. In the *V-HeFT-II trial* of hydralazine–nitrate vs. ACE-I, the hydralazine–nitrate combination reduced mortality as much as ACE-I in black patients, and was superior to enalapril in terms of exercise tolerance and EF improvement.[137–139] The hydralazine–nitrate combination was also beneficial in white patients, in whom it was superior to enalapril in terms of exercise tolerance and EF improvement, although the mortality was lower with enalapril. The reduction in hospitalization with hydralazine–nitrate was similar to enalapril and similar between white and black patients.[139] In the *A-HeFT trial* of class III–IV black patients already receiving ACE-I and β-blocker therapy, the hydralazine–nitrate combination therapy strikingly reduced mortality by an additional 43% and reduced HF hospitalizations by 40%.[140]

Therefore, the combination is indicated as an additional therapy to ACE-I/ARB and β-blocker in black patients with a functional class III–IV despite maximally tolerated HFrEF pillars (class I recommendation). The combination may also be used *instead* of ACE-I or ARB in case of intolerance to ACE-I/ARB, i.e., renal failure occurs with ACE-I/ARB and does not improve by reducing the dose of furosemide, or hyperkalemia occurs with ACE-I/ARB and does not improve with potassium restriction (class IIb recommendation regardless of race).

The benefit is partly related to the afterload and preload reduction. More importantly, nitrates are metabolized into nitric oxide (NO), while hydralazine prevents the oxidation of NO through its antioxidant properties, allowing to maintain the NO effect. ACE-I also prevents NO oxidation and may be beneficial in combination with nitrates. NO promotes endothelial and vascular homeostasis and appropriate myocardial remodeling and contractility, which improves EF by up to 5%. Hydralazine–nitrate combination may also directly reduce pulmonary vascular resistance in patients with left HF-associated pulmonary hypertension. Black patients frequently have a defective genetic variant of NO synthase that may explain the particular benefit; many white patients also have this variant, and thus pharmacogenomics rather than race may guide hydralazine–nitrate therapy in the future.

Dosing: start hydralazine 12.5 mg TID, increase it to 25 mg TID in 2–4 days, then increase by 25 mg/dose Qweek. Target is ~50–75 mg TID (may reduce to BID in renal failure). Start isosorbide dinitrate 20 mg TID and titrate up to 40 mg TID.

BiDil is a pill that combines 37.5 mg of hydralazine and 20 mg of isosorbide dinitrate (ISDN); BiDil may be started at one-half pill TID and titrated up to 2 pills TID. Beware, hydralazine causes a lupus syndrome of rash and arthralgia in 5–10% of patients.

G. Rapid sequential initiation of the 4 pillars of HFrEF therapy (Figure 4.5)

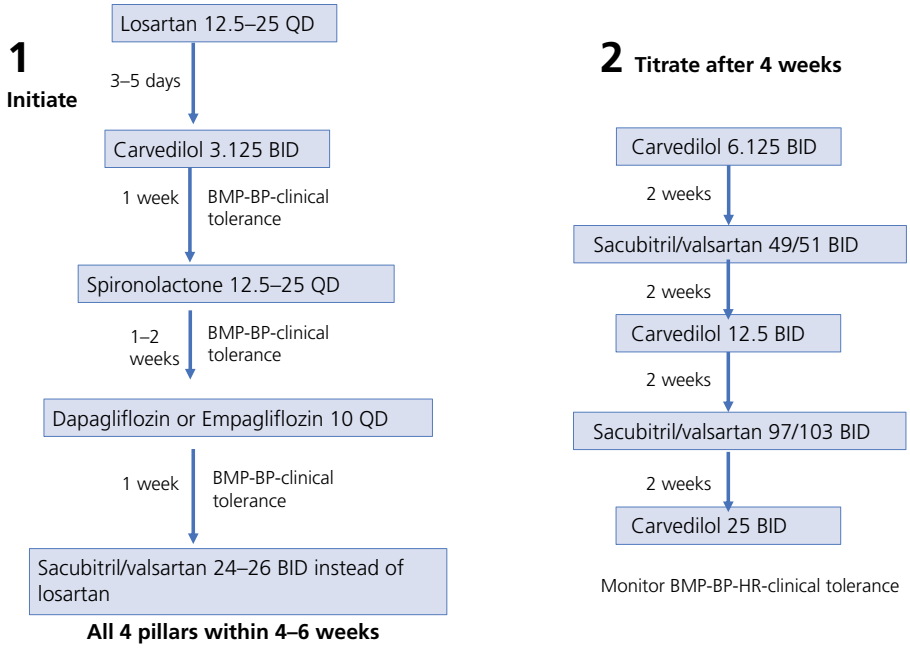

Figure 4.5 Suggested sequential initiation and up-titration of the 4 pillars of HFrEF in the outpatient setting. ARNI may be initiated up front instead of ARB, particularly in congested patients, but not in borderline BP or advanced CKD. Spironolactone and SGLT-2 inhibitor precede carvedilol in congested patients with severe dyspnea. At each level, revert to the preceding step if any of the following occurs: severe dizziness, symptomatic hypotension <90 mmHg, or creatinine rise >50%. All drug doses are in milligrams.

VI. Drugs that improve symptoms and morbidity

A. Diuretics

- *Overview and effect of disease states*. Thiazide diuretics are weak diuretics that block the distal tubule's Na-Cl transporter, which reabsorbs ~3–5% of sodium, and are mainly used in chronic HTN rather than HF. Loop diuretics (furosemide, bumetanide, torsemide) block the ascending loop of Henle (Na-K-2Cl transporter), which reabsorbs ~25% of sodium, and are often the mainstay diuretics in HF. Both loop and thiazide diuretics are secreted by the proximal tubule into the lumen and work from the luminal side of the nephron.

  In HF and renal failure with reduced renal blood flow, less diuretic reaches the kidneys and gets secreted into the lumen, implying the need for *higher doses*. Moreover, the reduced amount of renally filtered sodium reduces the total amount of sodium that can be eliminated with every single diuretic dose.[141]

  All diuretics are highly bound to albumin, which traps them and delivers them to the secretory site of the nephron. In very low albumin states (<2 g/dl), some of the diuretic is lost in the extravascular space, and in nephrotic syndrome, even the diuretic that gets to the nephron's lumen is bound to the urinary albumin, preventing it from acting on the sodium pump.
- *Renal failure and diuretics (especially thiazide)*. In patients with GFR < 30 ml/min, less sodium is filtered overall. Thus, less sodium can be eliminated by any diuretic (especially a thiazide diuretic), particularly because each of the remaining nephrons is already maximizing its sodium elimination. Hence, thiazide diuretics are less effective in patients with advanced renal failure, but, contrary to common belief, remain effective after cumulative dosing or in combination with a loop diuretic that increases the salt delivery to the distal tubule.[99,100] Metolazone, a thiazide-like diuretic that also works on the proximal tubule, maintains its efficacy in advanced renal failure; it also has a prolonged duration of action (~1 week). All thiazide diuretics are renally eliminated and have a long half-life, and thus cumulate in renal failure (not just metolazone), which further potentiates their effect after multiple dosing. Some data suggest that thiazide monotherapy is effective in hypertensive patients with advanced CKD after multiple dosing.[142]
- *Diuretic threshold*. A diuretic dose is only effective if it exceeds the required threshold at the tubular level. This threshold varies between individuals and diseases. Once the threshold is exceeded, there is a point at which maximal natriuresis is achieved, and beyond which no further natriuresis is gained with higher doses.[141]

For a normal subject, the threshold IV dose of furosemide may be 10 mg, while the maximum effective dose is 40 mg. For a patient with HF, where both the diuretic delivery is reduced (reduced renal flow) and nephron responsiveness is reduced, the IV threshold may be 40 mg. In the latter scenario, the administration of 20 mg BID does not achieve any diuresis in comparison to 40 mg Qday. On the other hand, if 40 mg Qday is effective (i.e., urination > 500 ml after the dose) but does not maintain euvolemia, 40 mg BID may be given. Patients with *HF have a reduced maximal response to any single dose*, and therefore, once the threshold is identified, they may be managed by giving this threshold dose (e.g., 40 mg) BID or TID, allowing a sustained diuresis (Figure 4.6). Alternatively, a higher dose (e.g., 80 mg) will maintain furosemide blood level above threshold for longer and will also boost diuresis. With IV furosemide, urine output peaks 30 minutes after dose administration; with oral furosemide, urination starts 1 hour after intake and peaks at ~1.5–2 hours (slower with severe edema).

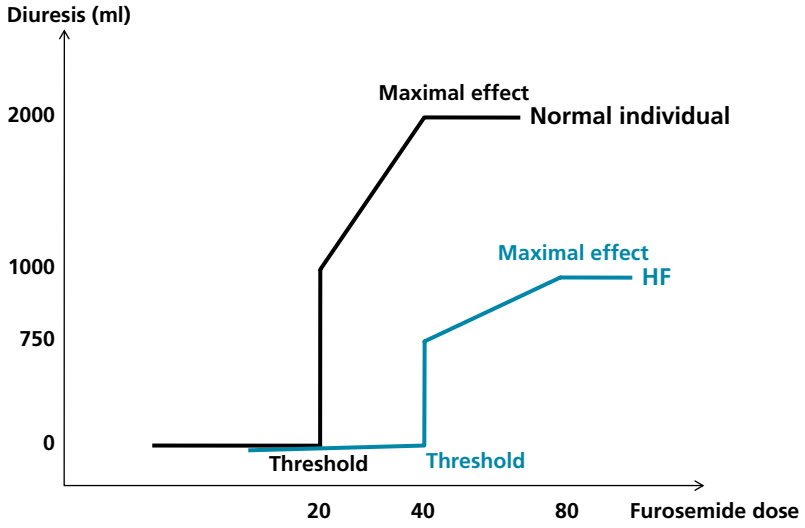

Figure 4.6 Diuretic response in a normal individual and in HF. Note that no diuretic response occurs before achieving the threshold dose. In HF, even more so decompensated HF: (i) the threshold dose is higher, (ii) the diuresis achieved with the threshold dose is lower, and (iii) the maximal effect is lower. This suggests the value of frequent dosing of the threshold dose to increase the overall efficacy. Alternatively, doses larger than the diuretic threshold maintain serum concentrations above the threshold for longer, thereby sustaining diuresis. *Figure inspired by reference 141*.

- *Pharmacokinetics of loop diuretics*.[141] Approximately 50% of oral furosemide is absorbed, with a high intra- and inter-individual variation (10–90%). Thus, in general, the effective oral dose of furosemide is numerically twice the intravenous dose. Bumetanide and torsemide are more consistently and thoroughly absorbed (80–100%). With all these agents, the absorption is slowed by intestinal edema and poor intestinal flow; this flattened absorption curve prevents peaking of the diuretic concentration larger than the diuretic threshold and requires higher doses or an intravenous course of therapy before oral dosing is effective again.

  The duration of action is short (~4–6 hours) and the nephron may avidly retain sodium between doses, which shows the importance of splitting the dose when a high total daily dose is required. Torsemide is twice longer acting (~12 hours) than the other 2 agents, has better oral bioavailability than furosemide, has a hepatic metabolism, and is given once daily. It may be considered in patients with erratic diuretic effect or those with refractory fluid retention; however, the large TRANSFORM-HF trial failed to show any long-term mortality or hospitalization benefit of torsemide vs. furosemide in HF patients discharged after HF decompensation (high-risk patients, ~30% mortality at 2.5 years).[143] While torsemide and bumetanide are metabolized by the liver, furosemide is renally excreted; thus, in renal failure, the elimination of furosemide is delayed, which prolongs its action and narrows its dose equivalence to the other two agents.

  Bumetanide dose equivalent: 1 mg = 40 mg of furosemide (or 20 mg in advanced renal failure); torsemide dose equivalent: 20 mg = 40–80 mg furosemide (40 mg if renal failure).
- Practical use of oral loop diuretics:
  - Use the lowest chronic oral dose to maintain euvolemia: furosemide 20 mg once daily, up to 40–80 mg 2–3 times daily. If the patient has a diuretic response to 40 mg of furosemide and is requiring a total of 80 mg per day, it may be better to give 40 mg BID than 80 mg Qday to provide a more sustained diuretic effect and less metabolic perturbations.
  - The patient needs to take extra dose(s) if weight increases >3 lb in <3 days. He needs to continue taking an extra dose of diuretic daily until the weight returns to baseline. If in 1–2 days, the weight continues to rise, a clinic visit is immediately warranted and metolazone may be added for 1–2 days.
  - Euvolemic outpatients who are minimally symptomatic on a small daily dose of furosemide ≤40 mg may consider furosemide withdrawal (ReBIC trial).[144] On the other hand, patients with severe HF requiring high chronic doses of furosemide (>200 mg/d) may be supplemented with a biweekly or triweekly dose of chlorthalidone or metolazone.
  - Oral potassium (~20–40 mEq per day) may be added, particularly if the patient is not receiving an aldosterone antagonist. K goal is ≥4 mEq/L. *Patients requiring high doses of potassium are often magnesium-deficient and should receive magnesium supplementation*.

In acutely decompensated HF, a rise in BUN and creatinine with diuretic therapy is often related to worsening congestion rather than over-diuresis, as most of these patients remain volume overloaded; diuresis should be maintained or increased until euvolemia is achieved. ***However, in the chronic, stable setting, a rise in BUN and creatinine frequently implies excessive volume contraction***, and a reduction of the diuretic dose is often needed, unless signs of fluid retention are present.[145] Chronic high doses of furosemide (>160 mg/day) may be needed in advanced HF and may even be associated with a mortality reduction on adjusted analysis, as long as BUN is not increased.[145] In fact, one study of stable HF suggests that diuretic therapy favorably affects markers of tubular function.[146]

In the modern era, **2 therapies provide a diuretic effect while reducing mortality and attenuating renal deterioration** and may allow lowering of the loop diuretic dose: angiotensin-neprilysin inhibitor and SGLT-2 inhibitors.

B. Digoxin

Digoxin has the unique property of combining a mildly positive inotropic action with a negative chronotropic action, making it the only positive inotrope that does not increase mortality. Digoxin inhibits the sarcolemmal Na/K-ATPase, which increases intracellular Na and subsequently increases the intracellular Ca through the Ca/Na sarcoplasmic passive exchange, leading to an inotropic effect. Digoxin also increases the vagal tone, which counteracts some of the catecholaminergic hyperactivity in HF, reduces HR, increases HR variability, and achieves some vasodilatation. This ***neurohormonal modulation*** is achieved at low levels of digoxin and actually explains most of the digoxin's benefits in HF and the rate control in AF.[147,148] EF improves with digoxin, including low-dose digoxin (up to 5%).[148]

The inotropic action of digoxin becomes stronger and begins to offset the therapeutic benefits provided by neurohormonal modulation at moderate and high serum digoxin levels, possibly explaining the increased mortality with higher levels.[147] Higher doses may further improve EF and contractility parameters without further symptomatic or rate improvement.[149] In addition, some believe that high digoxin levels have fewer neurohormonal effects than low levels.

Digoxin is considered in HF that is still symptomatic despite all the above medications (class IIb indication). In the DIG trial of patients with HF and sinus rhythm,[150] the addition of digoxin to standard therapy reduced pump failure death but was offset by an increase in arrhythmic death, making it neutral on mortality. Digoxin was overall beneficial and reduced HF hospitalizations by ~30%, particularly in the more severe cases (EF <25%, class III or IV). Women had more hazard with digoxin, probably because of higher serum digoxin levels. In the more modern DIGIT-HF trial of patients with advanced HFrEF, low-dose digitoxin with monitored levels significantly reduced HF hospitalizations (by 1.7% per year) and showed a trend toward mortality reduction (by 1.1% per year), even on top of modern HF therapies.[151] DIGIT-HF enrolled patients with EF <40% and NYHA III–IV (70%), or EF <30% with NYHA II; GFR was 65 ± 23, 27% of patients had AF, and the benefit was seen irrespective of the rhythm. Overall, *these data revive the value of digitalis in patients with advanced HF despite the 4 pillars, or those intolerant to the 4 pillars*.

In a patient with *HF and AF*, digoxin is added as a second-line agent when β-blockers do not achieve appropriate rate control. *Keep in mind that in a landmark meta-analysis of* β*-blocker HF trials,* β*-blockers did not reduce mortality or hospitalizations in HFrEF with A*F, whereas digitoxin proved beneficial in DIGIT-HF.[152]

Once a patient is on digoxin, the withdrawal of digoxin worsens HF and increases HF hospitalizations. Therefore, once digoxin is started, it should not be withdrawn unless toxicity occurs.[153]

Dosing: 0.125 mg daily in most patients. In small patients, women, old patients >70, and patients with renal failure, every-other-day dosing is considered. A dose of 0.25 mg daily may be used in young, large men with normal renal function. Loading doses are not necessary; loading is used for supraventricular arrhythmias rather than HF.

Digoxin level monitoring is encouraged in all patients, once steady state is achieved (~2 weeks after digoxin initiation). This is even more important in cases of renal failure, female sex, drug interactions, or suspicion of toxicity. The goal trough level is ≤0.8 ng/ml (serum level is checked at least 6 hours after the last dose). Trough levels of 0.5–0.8 ng/ml were associated with a lower mortality than placebo in *the DIG trial;* trough levels > 1.1 ng/ml were associated with a higher mortality than placebo.[147] In addition, a dosing study has shown that all of the hemodynamic, EF, and autonomic improvement with digoxin is seen at the lower dose (0.125 mg/day) and lower concentrations, without further improvement at higher doses.[148] *This reflects the importance of neurohormonal modulation over further inotropic activity*.

Signs of toxicity:

- Bradyarrhythmias, tachyarrhythmias (atrial tachycardia with block, non-paroxysmal junctional tachycardia, and VT, including the characteristic bidirectional VT)
- Nausea and vomiting, visual scotomas or halos, neurologic changes

Digoxin toxicity is usually seen with levels >1.5–1.8 ng/ml, but may be seen at lower levels, particularly over the long term or when hypokalemia coexists. Digoxin half-life is ~36 hours, so digoxin effects are expected to last ~4 days after discontinuation. Digoxin Fab antibodies (DigiFab) are indicated for bradyarrhythmias or tachyarrhythmias associated with hemodynamic instability.*

C. Ivabradine

Ivabradine is a pure heart rate reducer (sinus node inhibitor). In the SHIFT trial of patients with class II–IV systolic HF (EF ≤35%), prior HF hospitalization in the last year, and sinus rate ≥70 bpm despite a maximally tolerated β-blocker dose, ivabradine reduced HF hospitalizations and HF death by 26%.[111] However, being a sinus node blocker, it has no role in patients with AF; also, it *increased AF incidence* by >3-fold in a large registry (JACC Adv Dec 2025). After proper β-blocker titration, only 14% of HF patients would qualify for ivabradine, even less so if treated with digoxin.[154] See discussion under Section 1.V.B, last paragraph.

VII. AF ablation and transcatheter mitral edge-to-edge repair (MitraClip) dramatically reduce mortality in HFrEF

See Section I for AF and Chapter 6 for functional MR treatment.

---

* Dose of DigiFab in chronic toxicity: number of vials = digoxin level (ng/mL) × weight (kg)/100 (e.g., a 50 kg patient with a digoxin level of 3 ng/ml would be given 1.5 vials). DigiFab binds to digoxin and then is slowly excreted by the kidneys (half-life 15–20 hours, more prolonged with renal failure). After DigiFab administration, the serum digoxin level remains high or higher for several days and is no longer meaningful. Monitor for hypokalemia with DigiFab treatment.

VIII. Devices

A. ICD

Fifty percent of patients with HF die of VT or VF. The remaining 50% of patients die of end-stage, low-output HF. Late MI contributes up to 28% of both types of mortality in ischemic HF.[155] **Sudden death is less common in absolute value, but more common in relative value, in mild class II HF than severe class IV HF**.

An ICD is indicated as a secondary prevention measure if the patient has a history of sustained VT. It is indicated as a primary prevention measure in ischemic or non-ischemic cardiomyopathy with a low EF (≤35%) that is persistent over time despite optimal medical therapy, a functional class of II or III, and an expected survival of over 1 year. Patients with functional class I qualify for ICD in ischemic cardiomyopathy with EF <30%:[8,156]

- Wait >40 days after an MI.
- Wait >3 months after revascularization for chronic ischemia.
- Wait 3–6 months in non-ischemic cardiomyopathy, to ensure that it is not reversible and that it persists after a few months of medical therapy and BP control. One study suggested further EF improvements between 3, 6, and 12 months in de novo ischemic or non-ischemic cardiomyopathy with EF <35%, especially if medications are titrated to target doses or if AF or uncontrolled HTN was present and got treated. In patients with EF <35% at diagnosis, EF improved to >35% in 46% of them at 3 months and 68% and 77% at 6 and 12 months, respectively. The risk of VT between 3 and 6 months was very low (1.8% in the first 3 months, 0% between 3 and 6 months).[157]

Patients with functional class IV do not have an indication for ICD because of their high mortality. While they have a higher risk of VT/VF than other functional classes, they also have a much higher risk of death from pump failure; ICD simply converts their mode of death from VT to pump failure. If class IV patients are ambulatory and have an indication for BiV pacemaker, the combo BiV/ICD is indicated and improves their mortality as well as their quality of life (COMPANION trial).[158] Similarly to class IV patients, patients with advanced CKD (≥ stage 4 in MADIT 2 trial) or those with many comorbidities (e.g., age >70 with multiple HF hospitalizations) do not clearly benefit from ICD; ICD simply converts their death modality.[159]

B. Biventricular (BiV) pacemaker = cardiac resynchronization therapy (CRT)

Approximately 20–30% of HF patients have QRS >120 ms, mostly LBBB (80%). This leads to dyssynchronous contraction of the LV, which means that different LV segments contract at different times (intraventricular dyssynchrony), and the LV and RV contract at different times (interventricular dyssynchrony), leading to an ineffective ventricular effort and sequential rather than simultaneous mitral leaflets movement (→ MR). A prolonged QRS independently correlates with increased mortality and symptoms. CRT paces LV and RV at approximately the same time and restores the delayed lateral LV contraction.

CRT is indicated in patients with EF ≤35% + QRS ≥150 ms (mainly LBBB morphology or RV-paced rhythm) + functional class II, III, or ambulatory IV despite an adequate medical regimen, whether they are in sinus rhythm or AF. These same patients have an indication for a CRT/ICD combined device. Patients with LBBB but a QRS 130–150 ms, or non-LBBB with a QRS >150 ms, have a class IIa indication for CRT.[8,60]

Thirty percent of patients do not respond to CRT, i.e., do not achieve reverse remodeling on echo, for the following reasons:

- Wide QRS does not always mean dyssynchrony. The wider the QRS (i.e., QRS >150 ms), the more likely a response is seen. Echocardiographic dyssynchrony features help select patients whose QRS is 130–150 ms, according to the CARE HF trial.[160]
- Ischemic cardiomyopathy with large infarcts is poorly responsive to CRT. Irreversible scars respond less well to CRT than non-ischemic cardiomyopathy.
- LV lead placement may not be optimal (apex rather than the basal lateral wall).
- HF with non-specific intraventricular conduction delay >150 ms may be as responsive to CRT as LBBB based on a meta-analysis.[161] However, HF with a pure RBBB is less likely to respond to CRT, especially if the RV is the main side that is dyssynchronous and delayed. RBBB, per se, is associated with at least the same negative prognosis as LBBB but is less responsive to CRT;[161] this partly explains why, *in CRT registries, RBBB is associated with a higher mortality than LBBB*. Patients who, in addition to RBBB, have LV dyssynchrony and slow left bundle conduction may respond to CRT (RBBB would be >150 ms or echocardiographic features of LV dyssynchrony would be present).
- Echocardiographic evaluation of dyssynchrony is likely helpful in selecting patients with QRS 130–150 ms and those with RBBB. Conversely, it is not helpful for QRS <130 ms. Approximately 30% of HF patients with QRS <130 ms have dyssynchrony on echo; however, CRT is not beneficial in these patients.[162]

CRT improves survival (CARE-HF and RAFT trials), symptoms, and EF. It decreases LV systolic size (= reverse remodeling) and reduces functional MR (the two leaflets bulge up at the same time when all segments contract simultaneously).[160,163] CRT improves diastolic function as it reduces systolic time, thus increasing the diastolic filling time. It leads to immediate improvement of symptoms, then reverse remodeling within months.

While the major trials validated CRT for patients in sinus rhythm, data show that AF patients with EF ≤35% and wide QRS benefit from CRT pacing to the same extent as patients in sinus rhythm. However, patients with AF need to have aggressive rate control to guarantee continuous CRT pacing instead of spontaneous QRS conduction (this includes, in most patients, AV nodal ablation followed by CRT).[164] Even AF with narrow QRS benefits from AV nodal ablation + CRT if AF fails ablation, as pure rate control is the least effective strategy in AF with any HF (APAF-CRT trial).

Approximately 5–10% of patients with HF and low EF (≤35%) develop bradyarrhythmias that mandate PM placement for rhythm rather than heart failure purposes. If frequent ventricular pacing is required (>20% pacing per ESC and HRS), the implantation of a BiV PM rather than a RV PM is the best option for EF ≤35%, and even for EF 36–50% (per BLOCK-HF trial and ACC/ESC guidelines): this is given a class IIa recommendation regardless of the functional class.[60,164–166] Left bundle branch area pacing is an alternative, particularly for EF 36–50%. This also applies to AF that requires AV nodal ablation.

Both ICD and BiV devices improve survival.

Major CRT studies included only a few patients with class IV (~15%). Yet the benefit appears striking in those patients.[158] While it is generally not recommended to implant CRT in advanced, inotrope-dependent class IV patients, some data indicate that the latter patients with wide QRS >150 ms derive a dramatic benefit from CRT: the survival is dramatically improved at 1 year, and 93% of patients are weaned off from inotropes.[167]

IX. Other therapeutic measures

A. Sodium restriction <2–2.5 g/day. More stringent restriction to <1.5 g/day was not beneficial in the Sodium HF trial.[168] Fluid restriction to 1.5–2 liters/day is considered in advanced HF, decompensated HF, or hyponatremia.[60]

B. Exercise training in stable HF. Exercise training improves vascular function, muscular O_2 extraction, and symptoms.

C. Omega-3 fatty acids. Omega-3 fatty acids, at a dose of 1 g/day, have been shown to slightly reduce mortality in class II–IV HF with any EF, in the GISSI-HF trial (9% relative risk reduction, class IIa recommendation).[169] Depending on the brand, 1 gram of fish oil contains 350–850 mg of omega-3 acids; the goal is 850 mg of omega-3 acids daily (ESC).

D. Anticoagulation is indicated for patients with AF, LV thrombus, or a history of stroke or transient ischemic attack in the context of severe LV dysfunction. Aspirin is indicated for ischemic cardiomyopathy. Aspirin's benefit is uncertain in HF patients without CAD, and being a NSAID, it may counteract some of the benefit of ACE-Is. In an analysis of WATCH trial, aspirin was associated with increased HF hospitalization.

Two trials have addressed the use of aspirin vs. warfarin in patients with severe ischemic or non-ischemic LV dysfunction and sinus rhythm (EF <35%) (WATCH and WARCEF trials).[170,171] In both trials, the yearly risk of ischemic stroke on aspirin therapy was low (~1.3%), and while it was significantly reduced in half with warfarin, intracranial and major hemorrhage increased. As a result, the overall risk of death/MI/stroke was not different between groups. This lack of benefit of warfarin is mainly due to the low stroke risk of stable HF patients who are in sinus rhythm.

E. Avoidance of NSAIDs, non-dihydropyridines (negative inotropic effect), glitazones, and anti-TNF-α drugs.

F. Dihydropyridines are not indicated for HF per se, but are not contraindicated either, with the exception of nifedipine, which has a mild negative inotropic effect. They have been shown to be safe in HF with EF <30% (amlodipine [PRAISE trials], felodipine) and may be used in combination with ACE-I/β-blocker for HTN or angina control, if needed.[172,173]

G. 25% of HF patients have obstructive sleep apnea (OSA). The rostral displacement of peripheral edema to the pharyngeal structures during sleep precipitates OSA. Also, central sleep apnea attenuates the pharyngeal tone and triggers an obstructive form of apnea, i.e., mixed apnea. Treatment with CPAP and nocturnal oxygen improved LVEF in multiple small studies (by 8% in one study). It also improved LV diastolic function, RV function, and functional capacity.[174] However, there is no evidence of benefit on clinical HF outcomes.

Up to 35–50% of HF patients, especially patients with more advanced HF, have central sleep apnea (Cheyne–Stokes). It is treated with nocturnal O_2, which leads to symptomatic improvement. *Non-invasive ventilation is not beneficial* in central sleep apnea (CANPAP trial, CPAP) and may rather increase mortality (SERVE-HF trial).[175,176]

H. Iron therapy. Iron deficiency is highly prevalent in HF, affecting ~40% of patients, including ~30% of patients without anemia. Iron deficiency impairs myocardial and musculoskeletal metabolism, even in the absence of anemia. In HF, higher cutoffs of ferritin are used to define iron deficiency, as some iron is misused and blocked in the reticuloendothelial system (ferritin <100, or 100–300 with iron saturation <20%). In several HFrEF trials trials, intravenous iron therapy improved walking distance and NYHA class and reduced HF hospitalizations (IRONMAN trial in outpatients, AFFIRM-AHF in hospitalized patients); hence its **ESC class IIa indication** in HF with EF <50%.[177] IV iron is administered at 2 time points: initial 1000 mg followed by 500–1000 mg 6 weeks later. Conversely, erythropoietin therapy did not provide any benefit.[178]

I. Vericiguat is a soluble guanylate cyclase stimulator, which enhances cGMP in the vasculature (vasodilatation), but also in the heart (cardiac remodeling). It has shown a mild reduction of HF hospitalizations and mortality in patients who were mostly already receiving the 4 pillars, with limited hypotensive effect (class IIb ACC).[179]

Obstructive sleep apnea not only worsens right HF but also left HF. The deep negative intrathoracic pressure increases the LV transmural pressure (= LV pressure minus surrounding pressure), and thus increases the LV wall tension (= afterload), an opposite effect to positive-pressure mechanical ventilation. Venous return is also increased, which distends the RV and creates RV–LV ventricular interdependence, further reducing LV flow. In addition, the episodes of hypoxia lead to sympathetic activation and systemic and pulmonary vasoconstriction, and thus both left and right HF and ischemia.[180] ***While a normal individual may recover from these effects quickly upon apnea termination, recovery is delayed in patients with underlying HF***. LV filling pressure, LV diastolic function, but also LVEF and myocardial ischemia are affected by sleep apnea.

X. Prognosis

The average yearly mortality of patients with class II or III HF is ~6–10%. Half of deaths are sudden deaths (~3% per year with contemporary medical therapy), the other half are pump failure deaths. MI contributes up to 28% of each death modality in ischemic HF.[155] Sudden death is less common in absolute value, but more common in relative value, in class II HF than class IV HF. Several factors negatively affect prognosis in HF patients:[181,182]

- Severely decreased EF (<30%).
- Refractory functional class III.B or IV: 1-year mortality 30–50%.
- Hospitalization for decompensated HF is associated with a high mortality, especially in the first few months after hospitalization (4- to 10-fold higher mortality). The risk progressively decreases throughout the ensuing 12 months but does not reach the level of risk of the patient without HF hospitalization. The risk further increases with the number of HF hospitalizations in the last year (up to 10-fold).[183]
- Low-output profile, i.e., renal failure, poor response to diuretics, hypotension, resting tachycardia, cachexia, hyponatremia < 133 mmol/l, anemia of HF with Hb <12 g/dl.
- Borderline BP < 100 mmHg with inability to tolerate ACE-I and/or β-blocker therapy, or a need to discontinue them in hypotensive, low-output states with frequent episodes of renal deterioration.[100–102]
- Low peak oxygen consumption on exercise testing (<14 ml/min/kg).
- Mortality of ischemic HF is approximately 1.5–2 times that of non-ischemic HF.[14,16]
- Right ventricular failure in addition to left ventricular failure.
- Enlarged LV size/volume is a powerful negative prognostic indicator and a reflection of negative LV remodeling and HF decompensation. Current therapies (ACE-I, β-blockers, spironolactone, BiV pacing) decrease LV size and remodeling.
- Severe functional MR and AF.
- Baseline renal failure (including cardiorenal syndrome) and renal failure upon hospital discharge (see *Acute heart failure*).

2. TREATMENT OF HFpEF

HFpEF is epidemiologically characterized by an older age, less underlying CAD, and more HTN, AF, and female sex than systolic HF. While two epidemiologic studies have suggested that the long-term mortality of HFpEF approximates that of systolic HF,[184,185] a meta-analysis has shown that the yearly mortality of HFpEF is lower than the mortality of systolic HF (~30% lower), particularly cardiovascular mortality.[27] Overall, however, the mortality in HFpEF is high, and this is partly explained by the old age and the non-cardiac comorbidities of HFpEF, which lead to a relatively high non-cardiac mortality. Furthermore, in contrast to systolic HF, no specific therapy improves survival in HFpEF.

In fact, in HFpEF, the mode of death is cardiovascular in 60% of patients.[186] Only 15% of deaths are due to HF, while 27% are sudden deaths and 5% are MI deaths. This contrasts with systolic HF, where cardiac death (sudden or HF) accounts for 85% of the deaths. Patients with HFpEF may develop ischemia secondary to increased LVEDP, LVH, and demand/supply mismatch, as well as underlying CAD, which explains arrhythmia and sudden death. Sudden death may also be related to the scattered increase in collagen and myocardial fibrosis seen with HFpEF. Thus, patients with HFpEF have an increased risk of sudden death, albeit less than patients with systolic HF (the more prevalent CAD, myocardial distension, and scarring contribute to the higher rate of arrhythmias in systolic HF).[123] Currently, there is no indication for ICD therapy in HFpEF per se.

Both types of HF are associated with the same yearly risk of rehospitalization for HF.[186]

Unlike systolic HF, no drug has been shown to improve survival in HFpEF per se, and thus no drug is specifically indicated to improve survival in HFpEF. Outcomes are mainly improved with aggressive treatment of the underlying disease (HTN, obesity, AF). HF hospitalizations and symptoms are significantly reduced with the following 2 classes of drugs, which, nonetheless, have no effect on mortality: (1) **SGLT-2 inhibitors** (class I ESC), and (2) **aldosterone receptor antagonist** (finerenone, spironolactone).

1. SGLT-2 inhibitors – SGLT-2 inhibitors unequivocally reduced HF hospitalizations and quickly improved quality of life in 2 randomized trials of HF with preserved or mildly reduced EF. In the EMPEROR-Preserved trial, empagliflozin reduced HF hospitalizations from 6% to 4.3% per year, i.e., ~30% reduction.[187] In the DELIVER trial, dapagliflozin reduced HF hospitalizations from 6.5% to 5% per year (HF hospitalizations were already significantly reduced by day 15). SGLT-2 inhibitors were beneficial irrespective of age, AF, BNP levels, and BMI, and in the DELIVER trial, irrespective of EF, even EF > 60%.[188] They reduce resting and, even more so, exertional PCWP. Of note, all modern HFpEF trials mandate the presence of elevated BNP *and* structural echo abnormalities to confirm the diagnosis of HFpEF (e.g., LVH, LA enlargement, or high E/E').

2. Aldosterone (or **mineralocorticoid**) **receptor antagonist.** Specifically, a nonsteroidal very selective aldosterone antagonist, Finerenone, reduced the relative risk of HF events by 18% in HF with preserved or mildly reduced EF in the FINEARTS-HF trial (CV death or any worsening HF event: 14.9% vs. 17.7% per year).[189]

In the TOPCAT trial of HF with preserved or mildly reduced EF, spironolactone was associated with a 26% reduction of cardiovascular mortality (from ~5% to 3.5% per year) and a 20% reduction of hospitalization for HF (from 10% to 8% per year) in patients recruited from American countries, but not in the overall trial.[190] Benefit is expected to be higher in sicker patients, as long as objective evidence of HF is present (high BNP) (ACC guidelines class IIb).

A. Treatment of HTN to <130/80 (ACC and ESC HTN guidelines)[191]

Afterload reduction has lusitropic effects and improves the LV pressure–volume relationship.[192–194] In addition, vasodilator therapy with ACE-I or CCB improves arterial compliance, the impairment of which being a cornerstone of HFpEF and exertional HTN.[195]

Afterload reduction also improves *stroke volume*. However, excessive afterload reduction may not be as well tolerated in diastolic HF as in systolic HF. ***Vasodilators are less likely to increase stroke volume and more likely to reduce BP in patients with diastolic HF than systolic HF, and thus vasodilators may not be tolerated in diastolic HF with normal or low-normal BP.***[196] Explanation: systolic HF is more afterload sensitive than diastolic HF, so afterload reduction improves stroke volume in systolic HF more than diastolic HF, particularly when BP is not severely elevated (Figure 5.4). A borderline BP (e.g., SBP 110 mmHg) is less tolerated in diastolic HF than systolic HF. In a large registry analysis of elderly HFpEF (mean age 79), SBP <130 mmHg was associated with increased mortality and HF readmission.[197]

B. Decongestion with diuretics, not nitrates

Patients with decompensated HFpEF and peripheral edema usually tolerate high doses of diuretics. However, in light of the steep pressure–volume relationship, a high PCWP may be seen despite a normal LV volume, i.e., an LV volume that is necessary to maintain cardiac output. This is the preload dependency of severe diastolic failure (see Figure 5.5). Therefore, diuretics are more likely to reduce cardiac output in these patients than in systolic HF. Hence, chronically, a smaller diuretic dose is usually advised, unless florid RV dilatation or peripheral edema coexists.

Long-acting nitrate has decongestive effects, Yet, in the NEAT-HFpEF trial, nitrate did not improve exercise capacity and rather worsened activity level in stable patients with HFpEF, most of whom had normal NT-proBNP.[9]

HFpEF requires afterload reduction to improve relaxation and cardiac output, and preload reduction to reduce congestion, but the therapeutic window is narrower than in systolic HF.

C. Rhythm control of tachyarrhythmias, especially in the chronic setting

AF rhythm control is superior to rate control in HFpEF based on EAST-AFNET4 and CABANA trial analyses, provided that long-term maintenance of sinus rhythm can be expected. In the EAST-AFNET4 trial, patients with HF, mainly consisting of HFpEF and HFmEF, derived double the yearly benefit from early rhythm control, including twice the cardiovascular mortality reduction (vs. non-HF patients); treatment mainly consisted of flecainide (~40%) – which appeared safe in HFpEF and HFmEF – dronedarone, or amiodarone. In CABANA, AF ablation reduced mortality in HF patients (most of whom had HFpEF). AF ablation is given ACC class IIa recommendation in HFpEF.

D. Revascularization of CAD that is extensive enough to contribute to HF

In the small HFpEF subgroup of the ISCHEMIA trial, revascularization was associated with a reduction of the combined endpoint MI-CV death, but not overall death.[198] Yet, the value of revascularization in any HF remains questionable, as discussed in Section 1.II.

E. Avoid heart rate reduction: β-Blockers, non-DHP calcium channel blockers, ivabradine

Acute use – As explained in Figure 4.3, slowing the heart rate does not improve diastolic filling in decompensated HF, where the diastolic filling is brief and limited and cannot be improved by prolonging diastole. Therefore, acute heart rate of up to 110–120 bpm is accepted. Unlike acute systolic HF, β-blockers and non-DHP can be used when a fast tachyarrhythmia (>110–120 bpm) dictates acute rate control.

Even chronically, it is unlikely that prolonging diastole translates into any symptomatic relief in HFpEF. To the contrary, heart rate slowing likely *worsens symptoms in the subset of patients with chronotropic incompetence (~50% of HFpEF)*, or *patients with a small and stiff cavity and limited preload reserve, whose cardiac output totally depends on heart rate*. In fact, according to 2 trials, *pure heart rate slowing with ivabradine was harmful in HFpEF*; it worsened exercise capacity in one, and worsened E velocity and LA size in the second.[40,41] Also, most data suggest that β-blockers do not improve outcomes in HFpEF and may actually worsen HF hospitalizations.[199–201] One trial suggests that β-blocker *withdrawal* improves functional capacity, quality of life, and diastolic E/E' in HFpEF with resting heart rate <75 bpm and chronotropic incompetence (PRESERVE-HR trial).[202] ***Chronic heart rate reduction is more valuable in HFrEF than HFpEF***.

In HFpEF patients who already have a pacemaker, 2 trials suggest that higher baseline atrial pacing rate (~75–80 vs. 60 bpm) improves quality of life and BNP, and reduces AF (myPACE trial).[203,204] However, implanting a pacemaker in those with a baseline pulse ~75–80 bpm to raise the chronotropic response is not beneficial (RAPID HF trial).[205]

F. ACE-I, ARB, or sacubitril-valsartan

Beyond their use for HTN and beyond having the greatest LVH reverting effect, the role of ACE-I or ARB in HFpEF is questionable. Candesartan marginally reduced HF hospitalizations in the CHARM-Preserved trial (by an absolute value of only 2% at 3 years);[206] other trials, like I-PRESERVE and PARAGON-HF, failed to show a benefit from ARB or sacubitril-valsartan on death or even HF hospitalizations.[26,207] In all 3 trials, HTN was well controlled at baseline with SBP of ~130–135 mmHg.

In addition, while early worsening of renal function after ACE-I/ARB initiation does not affect the long-term benefit from this therapy in systolic HF, early worsening of renal function after ACE-I/ARB initiation is associated with worsening of cardiovascular outcomes and mortality in HFpEF (worsening renal function defined as a creatinine rise ≥0.3 mg/dl, or GFR decline ≥20%).[208]

G. Obesity treatment – GLP-1 agonists

In obese HFpEF with BMI > 30, GLP-1 agonists tirzepatide and semaglutide improve quality of life and reduce HF events and hospitalizations, without mortality reduction, owing to ~14% weight loss in the treated patients (SUMMIT trial: HF events reduced from 8.2% per year to 4.5% per year).[209]

H. Consider device therapies

- MitraClip for atrial functional MR (class IIb), and tricuspid clip for atrial or ventricular functional TR refractory to aggressive diuresis.
- CardioMEMS PA sensor implantation to reduce hospitalizations in patients with HF hospitalization in the last year and NYHA III (class IIb).

Note: Nitric oxide-cGMP pathway: Sildenafil is not indicated in HFpEF

The NO-cGMP pathway is a major contributor to ventricular relaxation and flexibility, besides arterial flexibility. Sildenafil boosts the cGMP pathway, yet 2 trials of sildenafil in HFpEF, including HFpEF with pulmonary hypertension (postcapillary +/– mild precapillary component), have not shown any benefit of sildenafil on exercise capacity, peak VO_2, and hemodynamics, even in patients with elevated PA pressure and impaired RV/PA coupling.[210,211] Of note, *boosting this NO-cGMP pathway may be beneficial in HFrEF*: vericiguat, a guanylate cyclase stimulator, reduced HF rehospitalizations in Victoria study; sildenafil reduced HFrEF symptoms in 1 trial, but not in SilHF trial.[212,213]

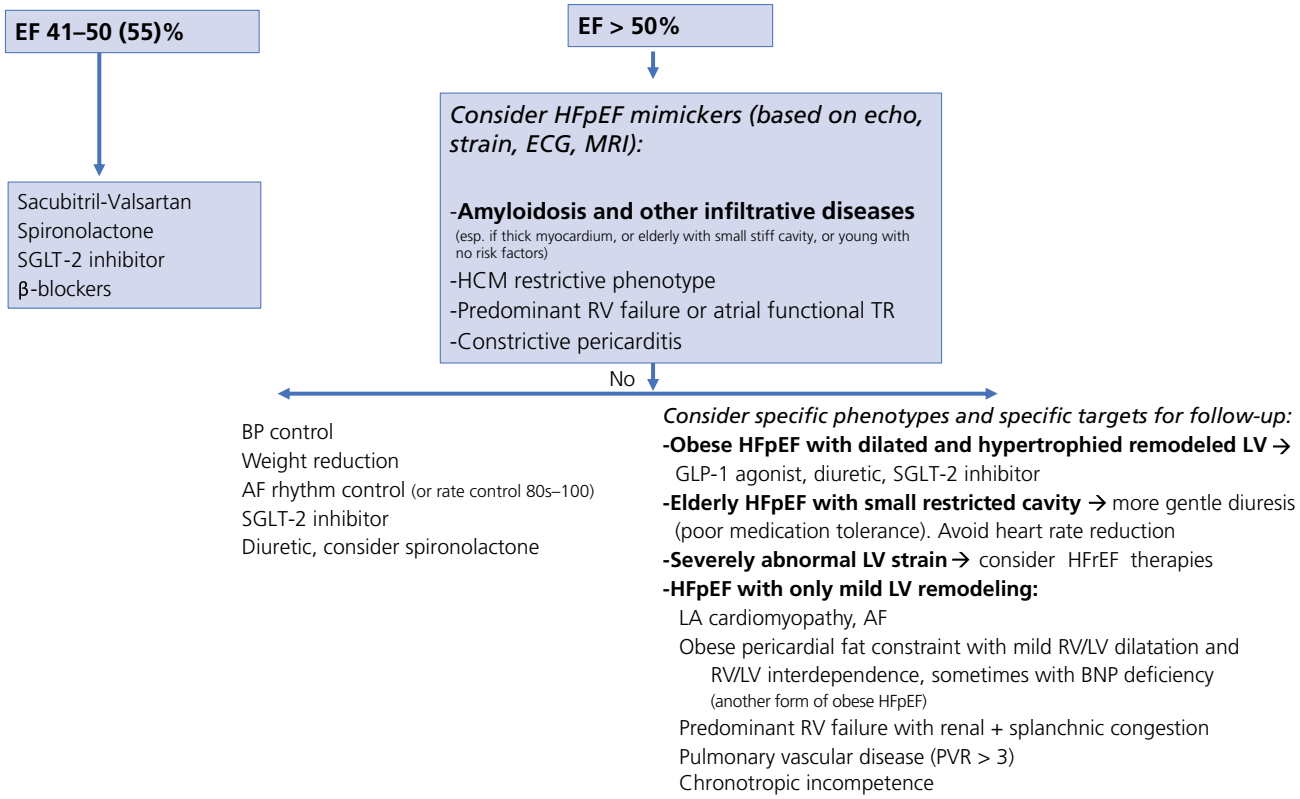

Figure 4.7 Treatment of HFmEF and HFpEF.

3. TREATMENT OF HFmEF

HFmEF and HFpEF used to be lumped together from a treatment standpoint. However, post hoc analyses of HFpEF trials showed that patients with EF of 41–50% (up to 57%) benefit from the cornerstone HFrEF therapies, although the benefit is less marked than in HFrEF and mainly consists of a reduction of HF hospitalization rather than mortality:[214–217] ARB (CHARM-preserved), spironolactone (TOPCAT), sacubitril-valsartan (PARAGON-HF), β-blockers (meta-analysis), and SGLT-2 inhibitors (EMPEROR-preserved) (ESC class I for SGLT-2 inhibitors, ACC-ESC class IIb for the rest). PARAGON-HF suggests that the benefit extends to an EF of 57%. Hence the EF cutoff for HFmEF may be extended to ~55%, and possibly 60% in women because women have smaller LV cavity and therefore higher baseline EF. The idea is that HF with any decline of systolic function, regardless of exact EF cutoffs, and possibly fine-tuned with other LV assessment modalities (e.g., strain), may benefit from neurohormonal therapies (Figure 4.7).

ACUTE HEART FAILURE

Overall, ~50–60% of patients who present with acute HF have systolic HF; the rest have HFpEF. Acute HF (AHF) presentation encompasses 3 syndromes:[218–221]

1. ***Acute decompensation of a chronic previously diagnosed HF.*** This is the most common form of acute HF presentation (~70%). It is sometimes called ADHF (acute decompensated HF),[8] but is better called ADCHF (C for chronic/previously diagnosed), as some sources, such as ACC, equate ADHF with the wider AHF umbrella.
2. ***Newly diagnosed HF (or new-onset HF or de novo HF)*** constitutes approximately a third of acute HF presentations. (i) *Most of the cases are first presentation of a chronic, progressive undiagnosed HF*. (ii) A subset is *acute quickly developing HF* and is characterized by a non-dilated or less dilated LV (MI, severe myocarditis, hypertensive crisis with acute diastolic HF, acute valvular regurgitation). Regardless, patients with de novo HFrEF tend to be younger than the decompensated known HFrEF. They have better decongestive response and better outcomes at 1 and 6 months—except for cardiogenic shock—reflecting an earlier stage of HFrEF.
3. A small proportion of acute HF presentations (~5%) are secondary to a chronic severe systolic HF with a relentless and progressive deterioration of a low-output state.

While volume overload is evident clinically in most patients (*clinical congestion or volume overload*), up to 35% of patients, particularly those with abrupt onset of symptoms, have only a mild degree of volume overload yet a severe rise in LV filling pressure (*hemodynamic congestion, fluid redistribution, or acute pulmonary edema* per ESC).[6,8,220,221] Although symptoms may be rapid, *hemodynamic congestion* does not necessarily imply a new cardiac process and emanates at least as commonly from *chronic HF* (ADCHF) as de novo HF. It is characterized by arterial dysfunction with abrupt afterload spikes. Alternatively, it is driven by venous constriction with mobilization of the venous reservoir (where 70% of blood volume resides), particularly the splanchnic venous reservoir, into the heart and the arterial circulation,

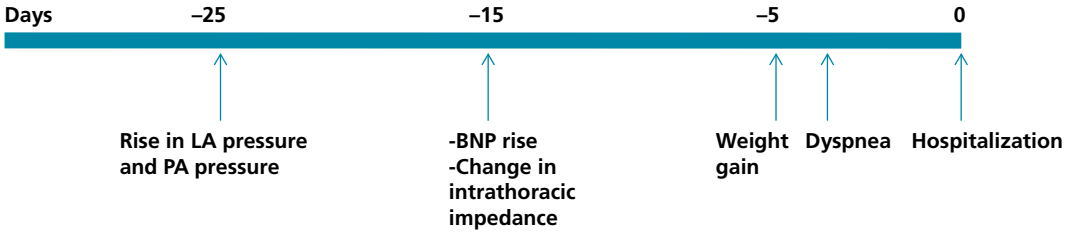

Figure 4.8 Hemodynamic decompensation starts several weeks before clinical decompensation, even when the presentation seems abrupt and the weight gain is only mild, and even in HFpEF. This may be driven by arterial or venous constriction from neurohormonal activation. Modified from Zile et al. (2008).[222]

causing LVEDP rise and pulmonary congestion.[6,220,221] As such, HF decompensates quicker with any small rise of circulatory volume, compared to patients with more accommodating venous and arterial systems. This explains why, even in hemodynamic congestion, the rise in LV filling pressure precedes the clinical presentation by several days or weeks and, in contrast to the abruptness of symptoms and the limited weight gain, the hemodynamic change is generally progressive over weeks (Figure 4.8).[222]

I. Triggers of acute decompensation, their diagnosis and treatment

A. Non-compliance with medical therapy, salt and fluid restriction, or NSAID use

B. Acute HTN. The abnormal vascular compliance leads to marked blood pressure lability with relatively minor changes in the intravascular volume; this causes a precipitous increase in afterload and decompensates LV failure. 50% of ADHF patients have HTN on presentation; 70% of patients have HTN at baseline.[218–221,223]

Note, however, that acute HTN may at least partly be the result of the acute pulmonary edema and the accompanying sympathetic surge. This explains the precipitous blood pressure fall commonly seen with initiation of diuresis. Besides which, the impaired vascular compliance leads not only to a sudden blood pressure rise with a slight volume change but also to a sudden blood pressure fall.

While vasodilatation increases stroke volume of the failing heart, excessive vasodilatation, seen sometimes in patients who get intubated and sedated, may not be matched by enough rise in cardiac output, as the cardiac reserve is limited, which leads to precipitous hypotension. Thus, the aggressive initiation of vasodilators or multiple antihypertensive drugs on admission should be avoided until diuresis has been started.

C. Acute ischemia. ACS is responsible for up to 14% of acute HF presentations, especially de novo HF. CAD without ACS is documented in another ~30% of patients with acute HF.[220,221] Diffuse ischemia may lead to acute diastolic dysfunction, systolic dysfunction, or ischemic MR.

Note that with acute HF, the LV end-diastolic pressure increases, leading to microcirculatory coronary compression and reduction of the gradient between the aortic pressure and LVEDP, i.e., the pressure gradient that drives coronary microcirculatory flow. This explains the common mild troponin increase in ADHF, unrelated to any thrombotic coronary event. In 6% of ADHF, troponin rises to striking levels >1 ng/ml, regardless of the presence of coronary disease.[224] Troponin is a marker of increased mortality in acute HF independent of coronary disease.

In decompensated HF, dyspnea is frequently described as chest tightness; thus, **acutely, chest tightness does not equate with angina and is not a specific marker of CAD.**

MI is considered the cause of acute HF (type 1 MI) rather than the result of it in the setting of extensive dynamic ST abnormalities, evolving Q waves, or marked troponin I rise >1000 ng/L. In this case, antiplatelet and anticoagulant therapies are initiated with a plan for an invasive strategy within a few days, preferably after diuresis and hemodynamic stabilization. Revascularization is emergent in cases of STEMI or this triple combination: *unstable HF* (cardiogenic shock or intubated massive pulmonary edema) associated with *profound* and *persistent* ST depression.

Outside of acute MI, what is the value of detection and treatment of chronic CAD in HF, specifically AHF? What is the value of coronary angiography? Even outside MI, coronary angiography may be performed as part of acute or severe HF workup after appropriate diuresis, unless previously done or another cause is obvious, such as AF or severe HTN. However, PCI was not beneficial in ischemic cardiomyopathy with extensive ***chronic CAD*** (REVIVED BCIS-2 trial), and CABG provided only a late and marginal benefit (STICH trial). This calls into question the value of aggressive CAD diagnosis and therapy in HF. Revascularization likely remains useful for this chronic CAD in case of critical left main disease or proximal multivessel CAD >90%.

D. Arrhythmias, such as AF with a rapid ventricular rate. Approximately 30–40% of patients with ADHF have AF.[145,225] AF may be a cause or a consequence of ADHF, and either way perpetuates ADHF.

A rate of 100–110 bpm is appropriate in decompensated HF and allows an increase in cardiac output and left atrial emptying (Figure 4.3). **AF rate >110–120 bpm is, however, counterproductive** and reduces the contractility of the energy-depleted myocardium (particularly HFrEF, which loses the Bowditch effect);[226,227] it needs to be slowed, with an **acute goal of <110 bpm (ESC). A rate >120–130 bpm with severe hemodynamic compromise** (shock, severe pulmonary edema) often needs acute cardioversion to improve LV energetics and contractility. Cardioversion improves CO, not so much by restoring the atrial kick – which is marginal acutely – but by improving LV contractility at lower

heart rates and by regularizing the rhythm, which by itself can raise CO by up to 18%.[228] Compared to DC cardioversion, amiodarone may be a more realistic and successful option for cardioversion acutely, and is, anyway, the main option for rate control acutely (+digoxin) (Chapter 10, Section VIII).

Besides rate control, perform ***elective, pre-discharge rhythm control*** and DC cardioversion for persistent AF that is believed to be a major contributor to the HF exacerbation, even if the rate is appropriate. At the compensated stage, DCCV is more likely to succeed, and the atrial kick is substantial: ***reinstitution of atrial systole and rate regularity improve HF outcomes and increase EF by >10% compared to rate control, according to AF ablation trials.***[229,230] Also, a new HF coinciding with a newly diagnosed atrial tachyarrhythmia is a tachycardia- or AF-mediated cardiomyopathy ~50% of the time, further justifying elective rhythm control.[231]

A patient with decompensated HF typically has an elevated rate (80–110 bpm). *AV block or sinus bradycardia,* even at a rate of 50–60 bpm, is inappropriate and signifies that the bradyarrhythmia is a factor underlying HF decompensation.

E. Any systemic infection; anemia. Normally, in infectious states and chronic anemia, as in exercise, both preload and inotropism increase, allowing cardiac output to increase and match the high metabolic demands. In systolic or diastolic dysfunction, 3 untoward effects occur: (i) LV is unable to accommodate the increased preload, which raises filling pressures; (ii) stroke volume cannot increase enough to match the dilated circulation, which reduces tissue perfusion; (iii) the supervening tachycardia may decompensate HF.

F. Acute valvular insufficiency, including dynamic functional MR. Eventual MitraClip should be considered for severe functional MR that persists despite diuresis and HF therapy.

G. Acute fulminant myocarditis. Consider endomyocardial biopsy for a new, rapidly deteriorating HF with shock or VT or conduction abnormalities yet no CAD.

H. Notes

On admission, 30–64% of acute HF patients have moderate or severe renal failure. This is, most often, a result of HF and is not usually related to over-diuresis. Renal failure worsens the volume overload and leads to further neurohormonal activation, increasing the susceptibility to dietary indiscretions and ultimately worsening HF, which leads to a vicious circle of mutual HF-renal damage.

PE may exacerbate RV failure. It does not usually lead to pulmonary edema.

Hyponatremia usually signifies advanced low-output HF with high vasopressin and hemodilution from hypervolemia. *Outpatient hypernatremia signals dehydration* and is very unusual in acute HF.

40–50% of acute heart failure episodes have no known precipitant.[232]

II. Profiles of acute HF: congestion without low cardiac output, congestion with low cardiac output

A. Always assess for:

1. Congestion, also known as "wet" picture[233]

- Orthopnea (90% sensitive), bendopnea, peripheral edema, crackles (uncommon), pleural effusions, ascites
- Elevated JVP, S_3, loud P_2 that is heard at the lower left sternum or apex
- Also, the lack of a 30% decrease in systolic and pulse pressures during the strain phase of Valsalva maneuver is a highly sensitive and specific (~90%) sign of volume overload*[233–235]

2. Peripheral perfusion. Low-output signs are referred to as "cold" signs and portend a worse prognosis, with a *mortality that is twice as high as "warm" HF*.[233] Cold signs are:

- Borderline or low SBP (<90–110 mmHg), narrow pulse pressure (pulse pressure < 25% SBP, reflecting a reduced stroke volume), or pulsus alternans. *A narrow pulse pressure is the most sensitive and specific finding in low stroke volume* (less sensitive in the elderly whose stiff arteries widen the pulse pressure, even with a low stroke volume).
- Sinus tachycardia.
- Cool extremities. Cool forearms and legs are more specific for low cardiac output than cool hands and feet.
- Severe fatigue, drowsiness (patient falls asleep during interview), Cheyne–Stokes respiration.
- Severe worsening of renal failure or oliguria with poor response to IV diuretics.
- Hyponatremia.

B. Then classify the acute HF into the following hemodynamic profiles:

1. Wet and warm: pulmonary/peripheral edema without signs of low cardiac output. This is the most common AHF profile (~2/3 of the cases).

2. Wet and cold: pulmonary/peripheral edema with signs of low cardiac output (~30% of the cases). Shock, the extreme form of "cold" HF, is present in only 3–4% of acute HF.[8,218–221] **Shock** is defined as cold HF with *elevated lactic acid and often with low SBP <90*, but SBP may be borderline (90–110 mmHg, normotensive shock).

3. Dry and cold: low output is present without edema. This may be due to hypovolemia, or a euvolemic low-output severe HF (~5% of acute HF), in which case it portends the worst AHF prognosis.

Note: While cardiogenic shock is classically described in patients with acute large MI, it is also seen in patients with chronic severe cardiomyopathy and decompensating factors (acute infection, arrhythmia, excessive vasodilators or sedation, cases where the limited cardiac output reserve cannot match the dilated circulation). In addition, volume overload by itself reduces myocardial perfusion and cardiac output and may initiate a vicious circle of progressive HF deterioration and shock.

* This is done using continuous non-invasive pressure monitoring and a 10–15 s strain; alternatively, using a BP cuff inflated at systolic pressure or slightly above it, Korotkoff sounds remain heard throughout the strain phase of Valsalva and do not overshoot after the release.

III. Treatment of acute HF: diuretics, cardiorenal syndrome, aggressive decongestion, ultrafiltration

A. Diuretics

Loop diuretics are the mainstay of acute HF therapy. Furosemide dosing:

- The starting intravenous bolus dose is typically 40–80 mg and must be numerically equal or superior to the chronic, oral unit dose. A 40 mg intravenous dose of furosemide is approximately equivalent to 80 mg of oral furosemide, but if a patient chronically receives 80 mg doses of oral furosemide, the intravenous unit dose should be at least 80 mg (80–160 mg).
- Intravenous 20 mg is rarely effective (may be effective in patients with mild HF who are not receiving chronic furosemide therapy). Doses larger than 80 mg may be needed in renal failure or diuretic resistance (up to 200 mg single dose).
- Acutely, intestinal edema and low intestinal perfusion may prevent any response to oral loop diuretics. Their absorption is slowed, and even if they are eventually absorbed, the absorption curve is flat, and the concentration does not peak beyond the natriuretic threshold at any time. Moreover, the natriuretic threshold is higher in AHF.

IV furosemide provides immediate relief via venodilatation. This is followed by a diuretic effect that starts at 5 minutes, peaks at 30 minutes, and lasts ~4–6 hours. When the patient is euvolemic, IV furosemide is switched to a lower, maintenance dose of oral furosemide.

Two diuretic targets need to be achieved in decompensated HF: **(i) proper response to a single bolus dose** of IV loop diuretic (>500 ml of urine in 1–2 hours, or >750 ml at 6 hours, or urinary Na >50–70 mEq/L at 1–2 hours); **(ii) proper 24-hour urine output of 4–5 liters usually**. The lack of response to dose "X" in ~1–2 hours means that "X" is below a patient-specific threshold dose. Twice the dose "X" should be administered in 1–2 hours. In HF without renal failure, the furosemide IV threshold is usually 40–80 mg; in renal failure, higher single doses may be needed (up to 200 mg IV dose given over 30 minutes).[141,236] After a dose is determined to be effective, the frequency of administration is tailored to achieve the 24-hour goal (e.g., 4 liters of urine output). Doses over 120 mg are ototoxic and are best administered slowly, over 30 minutes, to reduce this risk.

Administer multiple daily doses of furosemide in acute HF, such as Q6–12 h. Once a diuretic threshold is defined, providing a higher single dose will only moderately increase immediate diuresis, as a ceiling is quickly reached in HF (Figure 4.6). Yet, this will likely have an additional diuretic effect per 24 hours, as it will maintain serum diuretic concentrations above the threshold for longer. Alternatively, frequent administration of the threshold dose prevents rebound sodium reabsorption that occurs during the diuretic-free intervals. Thus, both higher frequency and higher dosing improve the 24 hour response, once a threshold is defined. Furosemide may also be administered as IV drip when more than 250 mg of IV furosemide is required per day (drip of 10–40 mg of furosemide per hour). *A drip may only be started after an effective bolus dose initiates a diuretic response*, and each time the drip is up-titrated, the bolus dose is typically administered again.

In a patient receiving chronic loop diuretic therapy, the bolus dose of IV diuretic should be numerically equal or superior to the single oral dose, and *the total daily IV dose should be numerically ~2.5 times the total daily oral dose, as in the DOSE-AHF trial (~5 times in terms of dose equivalence)*. Those are starting doses and need to be adjusted to the 2 diuretic targets. This regimen proved beneficial in 2 trials.[237,238] For a patient chronically using 60 mg of oral furosemide Q12h, an appropriate initial regimen in AHF may be 120 mg IV Q12h, or 100 mg IV Q8h. ***This dose is tailored according to: (i) the response to the first dose, and (ii) the 24-hour diuresis goal (3.5–5 liters of urine)***.

If there is* no response *to the maximal single dose of furosemide (<500 ml in 2 hours), 2 diagnoses should be considered: (1) very low renal flow resulting from an inappropriate cardiac output at the renal level or inappropriate BP (e.g., 90–100 mmHg); (2) acute, intrinsic kidney injury unresponsive to the diuretic (e.g., acute tubular necrosis). Inotropic therapy is administered and often initiates diuresis in the case of low renal flow (1). Otherwise, acute tubular necrosis is suspected and hemodialysis may be required depending on the speed of renal recovery.

If there is a* moderate response *to the maximal single dose of furosemide (e.g., 500 ml of urine output over several hours after a 160–200 mg dose), *with suboptimal 24-hour response*, the diagnosis is distal tubular reabsorption of sodium and water, beyond the Henle loop; a thiazide diuretic, ADH antagonist, acetazolamide, or SGLT-2 inhibitor may be added to boost the overall, 24-hour urine output (sequential nephron blockade).[236,239–241]

Examples of thiazide diuretics include oral metolazone 2.5–20 mg Qday, oral hydrochlorothiazide 25–50 mg Qday, or IV chlorothiazide 500–1000 mg Qday. Tolvaptan is an ADH-receptor antagonist that allows distal tubular water aquaresis (15–30 mg daily). Thiazide diuretics and tolvaptan attenuate the distal tubular escape from the loop diuretic effect; thus, *they increase the total diuresis but do not initiate diuresis in unresponsive patients*. Note that metolazone is a thiazide-like drug that works on both the proximal and distal tubules and remains effective in advanced renal failure. Other thiazide diuretics also remain effective in advanced renal failure, particularly when combined with loop diuretics. Thiazides are long acting and do not need to be administered 1 hour before the loop diuretic.[239] High-dose spironolactone may also be used,[8,236] but it has a slow onset of action (2–3 days) and did not acutely increase diuresis in ATHENA-HF.[119]

In the ADVOR trial, acetazolamide (500 mg IV daily) boosted furosemide response and improved decongestion and daily urinary volume (+0.25 L/day), even when universally applied to furosemide-responsive patients (median creatinine 1.5 mg/dl).[242] Response was further amplified among patients with baseline GFR ≤ 40 or higher baseline HCO3 levels ≥27 mEq/L.[243] Yet, acetazolamide did not improve clinical outcomes and was associated with more hypotension and in-hospital renal deterioration.

Goal of diuresis:

2–3 liters of net negative fluid balance per day, which corresponds to 3.5–5 liters of urine/day.[236–238] The same goal applies for congested, acute right heart failure.[244] The goal is lower when both of the following conditions are met: no significant peripheral edema *and* no LV or RV dilatation (steep pressure–volume relationship).*

Adverse metabolic effects and potential solutions:

- *Hypokalemia*, *hypomagnesemia, hypocalcemia*.
- *Hyponatremia*. The urine induced by loop diuretics is half-tonic, like 0.45% half-saline, and thus can cause *hyper*natremia in patients with no water intake. However, *hypo*natremia is much more common and results from ADH and neurohormonal activation, especially since angiotensin II is a potent thirst inducer. Thiazides work on the distal tubule, which is the nephron diluting segment, and create a more concentrated urine. Thus, the *loop diuretic-thiazide combination* creates a "saltier" urine than loop diuretic and is associated with more marked hyponatremia and hypokalemia.[240,241]

  Potential solution: If severe <125, vasopressin (ADH) V_2-antagonist may be used to create aquaresis (e.g., oral tolvapatan 15 mg, 1 or 2 doses).
- *Contraction metabolic alkalosis* signals chloride depletion and the need to slow the diuresis or replete the potassium deficit. Diuresis needs to be continued in patients with persistent volume overload, possibly at a slower rate with aggressive potassium replacement.

  Potential solution: Acetazolamide inhibits the proximal tubule's carbonic anhydrase. Thus, it eliminates $HCO3^-$ and Na and counteracts metabolic alkalosis; it may be added to loop diuretics when significant metabolic alkalosis develops.

Worsening of renal function occurs in ~30% of patients hospitalized with AHF (worsening = ↑ creatinine by ≥0.3 mg/dl or ≥1.5× or ↓GFR ≥30%).[237,245] If the patient is still clinically or radiographically congested, continue diuresis even if creatinine rises. In this case, the rise in creatinine is due to the persistent or worsening venous congestion (cardiorenal syndrome) rather than "overdiuresis." In fact, in most patients, "underdiuresis" and rising filling pressures coincide with worsening of renal function.[245–248]

B. Acute cardiorenal syndrome

Acute cardiorenal syndrome (type 1) refers to worsening renal function with persistent and progressive volume overload in a patient with acute HF.[238] This syndrome reduces diuretic response. While it may be related to a low-output cold HF, the ESCAPE trial suggests a poor correlation between cardiac index and baseline or worsening renal function.[246] In fact, ***cardiac output may be normal at the central level but the local renal flow is reduced***. Cardiorenal syndrome is most often related to the following mechanisms, in order of importance:

- ***Volume overload itself***, which increases the ***renal venous afterload*** and consequently impedes the forward renal flow.[245–249] In fact, renal flow is driven by the gradient between mean arterial pressure and renal venous pressure. This gradient should be high enough to overcome the renal arteriolar resistance. According to several analyses, the admission and post-therapy RA pressure is the most important factor driving renal deterioration in acute HF.[246,247,250]
- ***Low systemic arterial pressure and its reduction with therapy***. Multiple analyses showed that renal deterioration in AHF strongly correlates with mean and systolic BP reduction during therapy (e.g., >15% reduction, or >10–15 mmHg reduction from a baseline SBP of ~115 mmHg).[251–253] Again, renal blood flow = ΔP/R; ΔP is the difference between renal arterial pressure and venous (RA) pressure. The kidney "sees" this local ΔP more than the systemic cardiac output. Normally, R (resistance) autoregulates to maintain renal filtration when ΔP drops, via afferent arteriolar dilatation and efferent constriction, but in HF and CKD, it is already maximally autoregulated. Further autoregulation and afferent dilatation are impaired, and in fact the afferent artery may paradoxically constrict with the extreme angiotensin and sympathetic activation, making the kidneys more susceptible to ΔP (Figure 4.9).
- Reduced cardiac output at the central level (low-output cold HF).
- Slow plasma refill. Diuresis initially removes fluid from the intravascular compartment; the latter is then briskly refilled from the overhydrated interstitium, thanks to ↓intravascular hydrostatic pressure and ↑intravascular oncotic pressure. The plasma refill time is the time required for the extracellular edema to refill the intravascular volume that is being diuresed. If diuresis matches the plasma refill rate, the intravascular volume does not decline despite marked reduction of interstitial volume.[254] Conversely, a patient with 20 liters of volume overload may not tolerate a negative balance of 5 L/d or 2 L in 2 hrs, which creates transient effective hypovolemia and reduces GFR, even if central cardiac output is eventually preserved.[255]
- Increased intra-abdominal pressure, secondary to ascites and visceral edema, leads to an abdominal compartment syndrome with increased renal venous pressure and reduced renal perfusion, regardless of the central venous pressure.[249]

Moreover, baseline CKD is one of the strongest risk factors, as it reflects reduced renal autoregulation reserve and an inability to withstand hemodynamic stress. This overall pathophysiology explains why many cases of cardiorenal syndrome (up to 50%) occur in patients

* The daily diuresis goal is also reduced when congestion is largely limited to ascites. The volume clearance across the peritoneal membrane cannot exceed 500 ml/day; in patients with predominant ascites, a diuresis of 2 liters per day comes at the expense of the intravascular volume.

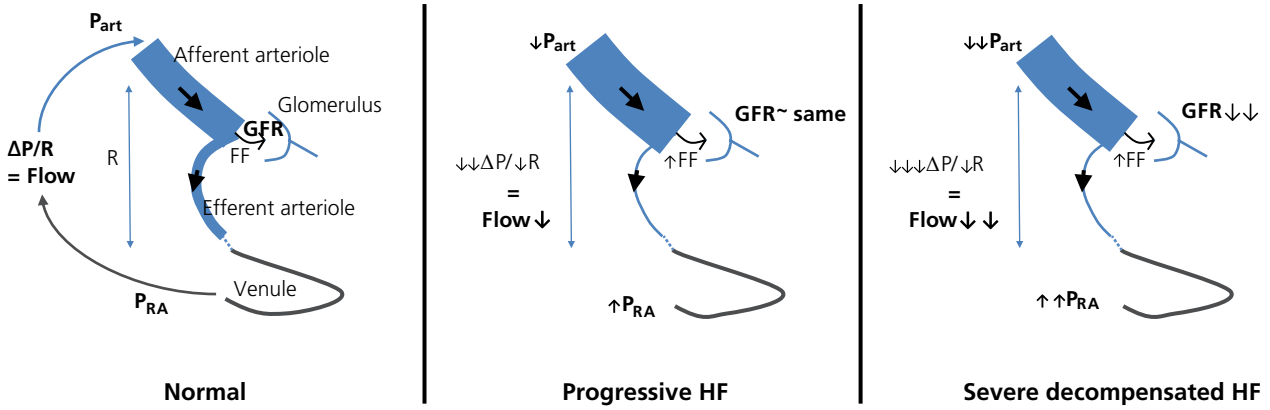

Figure 4.9 Effect of HF on renal blood flow and GFR. Renal blood flow is affected by **ΔP** (arterial pressure-venous pressure) and arteriolar resistance **R**. **GFR** is affected by renal blood flow but also by how much of this renal flow is filtered (filtration fraction [**FF**], normally ~20%). In the case of hypertension, ΔP↑, but renal flow remains unchanged, as arteriolar resistance (mainly pre-glomerular) increases.

In hypotension or in HF with reduced local renal flow, ΔP↓, but autoregulation and low tubuloglomerular feedback (low distal Na) cause afferent vasodilatation, hence reducing R and somewhat maintaining renal flow, the so-called autoregulation. In severe HF, this afferent dilatation starts to get exhausted, particularly with rising levels of vasoconstrictors, including angiotensin II. R cannot further ↓, renal flow declines, yet GFR has a second line of protection when afferent vasodilatation is exhausted: efferent vasoconstriction, which allows more filtration (e.g, >50%), maintaining GFR even when renal flow is reduced several folds.

In very severe HF, ΔP continues to decline and R is less dilated. Even the increased FF cannot maintain GFR: GFR becomes fully dependent on ΔP. Reducing RA pressure and increasing arterial pressure would have a direct, nearly linear effect on GFR at this point; also, re-dilating the afferent artery improves GFR.

with EF > 40%. This syndrome may potentially worsen with diuresis, but more often improves with diuresis. In fact, although ~30% of acute HF patients have worsening of renal function during therapy,[246] slightly over 50% of patients have an improvement in renal function with adequate diuresis, even more so when creatinine is assessed at 30–60 days after hospitalization.[237,238] This is related to:

- Reduction of renal venous pressure and renal venodilatation with loop diuretics and vasodilators (↓ renal "afterload")
- Reduction of intra-abdominal pressure
- Reduction of right and left ventricular volumes, and, as a result, improvement of cardiac output (Table 4.2).

Thus, congestion is at the center of acute HF syndromes. Aggressive decongestion greatly improves renal and myocardial flow and ventricular loading conditions. This allows renal function to improve enough to sustain diuresis with lower diuretic doses. This also allows the patient to tolerate lower systemic pressure without compromise of myocardial or renal perfusion.

While cardiorenal syndrome is the most common form of progressive renal dysfunction encountered in acute HF, *intrinsic acute renal failure may occur as well*, and should be considered in patients who are oliguric and diuretic resistant. Acute tubular necrosis may occur as a result of the sustained ischemic injury and may persist for 7–10 days, requiring hemodialysis in the interim. On the other hand, post-renal obstruction, glomerulonephritis, or NSAID or acute interstitial nephritis may be present and make renal failure the cause rather than the result of acute HF. Urinalysis and urinary microscopic exam are thus warranted, seeking parenchymal disease.

Notes:

- Renal failure is more common in combined RV-LV failure than in isolated LV failure.[250] In fact, RV failure causes: (a) RA pressure rise, (b) further reduction of LV output from the septal push toward the LV and the pericardial constraint, (c) further reduction of LV contractility as the septum shifts to the right in systole. Aggressive diuresis attenuates all 3 effects.
- ***The combination of 2 particular factors predicts a poor renal tolerance of acute diuresis:*** (i) no or minimal peripheral edema, and (ii) non-dilated LV and RV with steep pressure–volume relationship (e.g., de novo acute HF, RCM). The preload volume is not dramatically increased, but the preload pressure (LVEDP) is. Mild and careful diuresis is the best option (e.g., negative fluid balance 1–1.5 L/day).
- Other types of cardiorenal syndrome:[256] (i) type 2 or chronic cardiorenal syndrome: renal dysfunction results from chronic HF and has similar mechanisms to type 1 syndrome, except that these mechanisms are more persistent; (ii) type 3 or acute renocardiac syndrome: acute

Table 4.2 Reduction of ventricular volume improves cardiac output through 4 mechanisms.

1. Reduction of ventricular wall tension, which is afterload (↓ afterload → ↑ cardiac output)
2. Reduction of functional MR and TR
3. Reduction of RV–LV interdependence
4. Reduction of LVEDP and RVEDP, which improves myocardial perfusion

kidney injury leads to HF decompensation; (iii) type 4 or chronic renocardiac syndrome; (iv) type 5: systemic illnesses, such as diabetes, HTN, or vasculitis cause combined cardiac and renal dysfunction.

C. Importance of aggressive decongestion, even in the face of a rising creatinine

One analysis has shown that aggressive decongestion with hemoconcentration (rise in hematocrit and albumin) is associated with a profound 70% reduction in mortality at 6 months, despite a strong association with creatinine rise.[257] In fact, in this and other analyses, the incomplete relief of congestion during acute heart failure, rather than the worsening of creatinine levels, strongly contributed to HF progression and worsening survival.[243,257,258] Therefore, the increase in creatinine does not portend a negative prognosis *if* decongestion is achieved.[245,258] Besides, the rise in creatinine does not necessarily imply a worsening of renal function; it may simply reflect hemoconcentration, a desired effect. In fact, one study has shown that the worsening of creatinine with aggressive diuresis is not associated with increased markers of renal tubular injury.[259]

Other data corroborate that baseline renal function has a prognostic value, but not the in-hospital worsening of renal function.[246,252] In addition, in the DOSE trial, a high dose of diuretic was associated with more worsening of renal function at 72 hours but better clinical outcomes. The creatinine level eventually trended down at 60 days in patients receiving the high diuretic dose, while it progressively trended up and surpassed the high-dose group at 60 days in patients who did not achieve appropriate decongestion. Although creatinine may fluctuate initially, it generally becomes lower than baseline at 30–60 days in patients appropriately decongested.[237]

How about a rising BUN? Contrary to a common misconception, a rising BUN and a BUN/creatinine ratio ≥20 in *acute HF* is often associated with more severe signs of congestion (rather than hypovolemia), a higher BNP, and a lower SBP, yet a higher likelihood of renal recovery.[260] Those patients tend to be sicker and have higher long-term mortality and recurrent renal dysfunction. Only a BUN that starts to rise *after several liters of diuresis and full clinical decongestion (no edema, normal JVP)* may imply hypovolemia.

D. Continuous loop diuretic drip vs. intermittent boluses – Limited role of ultrafiltration

The bolus diuretic dose induces pulse diuresis (e.g., 1 liter in 1 hour) that may be faster than the plasma refill rate, potentially leading to a transient effective hypovolemia with subsequent RAAS and sympathetic activation and avid post-diuretic sodium reabsorption. This is how, in theory, diuretics may increase mortality, but, as shown below, this did not prove to be true.

The use of a continuous infusion of furosemide, rather than bolus doses, may allow a steady-state fluid removal at the plasma refill rate. Yet, in the DOSE trial, a continuous diuretic infusion was associated with similar renal and clinical outcomes as bolus administration. Conversely, the use of a high diuretic dose, as opposed to a low dose, achieved more net fluid loss and weight loss, superior decongestion, more dyspnea reduction, and a trend toward lower hospitalizations despite a transient worsening of renal function.[237] The lack of benefit of a continuous infusion was further confirmed in the DOPA-ROP trial, where a continuous infusion was potentially harmful with more worsening of renal function.[261]

Continuous ultrafiltration constitutes a non-pharmacological modality of fluid removal. One device, Aquadex, is simpler than renal replacement devices and uses a smaller central or peripheral venous catheter with a lower venous flow (10–40 ml/min) and a small blood volume outside the body (40 ml) that is more tolerated hemodynamically. It removes fluid at a rate of 100–250 ml/h (≤6 L/day). In theory, the intravascular volume remains unchanged as fluid shifts from the extravascular space to the intravascular space at the plasma refill rate, with potentially less harmful neurohormonal activation and with removal of isotonic rather than half-tonic fluid. Yet, in the CARRESS-HF trial of patients with acute HF and cardiorenal syndrome, ultrafiltration at a rate of 200 ml/h was not more effective than high-dose diuretics in achieving decongestion or clinical improvement, and led to significantly more creatinine rise that persisted at 60 days.[238] Ultrafiltration probably failed because of catheter-related complications and a frequent need to interrupt therapy (e.g., catheter clotting). It is also possible that diuretics have protective renal effects through blocking the ATP pump at the loop of Henle and reducing medullary O_2 consumption.[146] Also, loop diuretics block the tubuloglomerular feedback, wherein tubular Na at the distal Henle loop causes afferent constriction; hence, they cause afferent arteriolar dilatation.

Those 2 trials illustrate that the principal goal of acute HF therapy is aggressive decongestion, achieved through a high-volume diuresis and a high diuretic dose if needed (urine output 3.5–5 liters/day), even in the face of an increase in creatinine. Only patients with fluid redistribution without significant peripheral edema and with a non-dilated LV and RV may not tolerate this high-volume diuresis.

E. Role of enhanced decongestive therapy with a second agent in diuretic-responsive patients – Focus on early SGLT-2 inhibitor use

In diuretic-responsive patients, the enhancement of diuretic response with acetazolamide or thiazide improves congestion but causes more renal deterioration, hypotension, and hypokalemia without improving long-term risk of death and HF readmissions, and thus cannot be routinely recommended outside diuretic resistance (ADVOR and CLOROTIC trials).[262] On the other hand, the *acute use of SGLT-2 inhibitors in the first 24 hours of HF hospitalization (DICTATE-AHF, EMPAG-HF), or beyond 24 hours (EMPULSE)* boosts clinical decongestion, urination, and weight loss for the same dose of furosemide by up to 50% without increasing the risk of renal, BP, or potassium deterioration. Critically, this occurs while also improving HF readmission and death at 30–90 days across all EF levels (EMPULSE, SOLOIST, and DICTATE-AHF trials).[262–266] Even in diuretic-resistant patients, SGLT-2 inhibitor was nearly as effective as metolazone in achieving decongestion, with less hypotension and hypokalemia in the DAPA-RESIST trial.[267] Crucially, these trials only excluded patients with GFR <20–30, not specifically those with acute creatinine rise. DAPA-resist and EMPULSE even included a GFR as low as 20; despite this, creatinine rose less with SGLT-2 inhibitor than with metolazone or placebo. Yet, caution is warranted if creatinine has already ↑ >50% prior to initiation.

F. Diuretic resistance

Even in normal individuals, the kidneys must "brake" some of the diuretics' effect to allow their safe use: if blocking the loop of Henle results in excretion of 25% of the filtered sodium and water (180 L/day), 45 liters of urine would be generated daily! Some braking is necessary, but when excessive, this braking mechanism is called diuretic resistance, and is defined as reduced diuresis and natriuresis despite intermediate or high loop diuretic doses, precluding the resolution of congestion. This is more specifically defined as: (i) limited response to

a single dose (<500 ml at 2 hours or <100–150 ml/hr at 6 hours), (ii) net negative fluid balance < 2 liters/day despite a daily dose of intravenous furosemide >160–240 mg, or (iii) post-diuretic urinary sodium concentration that is less than the expected "0.45% half-saline" (<50–70 mEq/L on a spot urine sample 1–2 hours post-dose).[236] It is seen in up to 25% of AHF cases. Several mechanisms are implicated:

- Reduced renal flow, partly related to a high renal venous afterload and a renal compartment syndrome (high outflow pressure), and partly related to a low local cardiac output and a low systemic pressure (low inflow pressure).
- Intrinsic renal failure.
- Activation of the renin–angiotensin–aldosterone system.
- Hyperfunction of the Henle loop with repeated loop diuretic administration after a first dose.
- Post-diuretic rebound effect, i.e., avid tubular reabsorption of sodium between doses, by the upregulated loop and distal transporters.
- ***Hyperfunction and hypertrophy of the distal tubules after repeated loop diuretic administration (most important mechanism*** → thiazide and tolvaptan benefit); + hyperaldosteronism exaggerating the distal sodium retention (spironolactone benefit).
- Hypochloremic metabolic alkalosis: chloride avidity impairs the tubular ability to eliminate Na.

The last 4 tubular mechanisms are called "braking phenomenon." As mentioned earlier, this is treated by increasing loop diuretic dose and frequency of administration, and by combining it with a thiazide diuretic or tolvaptan (3T trial) or acetazolamide (ADVOR trial) or SGLT-2 inhibitor (DAPA-resist and DICTATE-AHF).[236,240,241]

Patients who do not achieve any diuresis with a high diuretic dose generally have a very low renal flow; inotropic therapy is considered for these patients. If no response is achieved with inotropic therapy, acute tubular necrosis is suspected, and hemodialysis may be required.

After 24–48 hours of inotrope-supported diuresis, diuretic responsiveness is often maintained even after weaning inotropes, as cardiac output improves with the reduction of afterload, RV–LV interdependence, and functional MR, while renal perfusion improves with the reduction of renal venous afterload.

In unresponsive HF with severe intrinsic renal failure (GFR <30 ml/min), full hemodialysis rather than ultrafiltration may be needed: in a small case series of such patients, Aquadex was safe but hemodialysis was still required in half of the patients and mortality was high.[268]

IV. Treatment of acute HF: vasodilators

Vasodilators decrease afterload and improve cardiac output; they also have a venodilatory effect that reduces preload, relieves pulmonary edema, and reduces renal afterload. However, since even *transient hypotension* impairs renal function and outcomes, ***vasodilators are avoided if SBP <110 mmHg*** **(ESC)**.[269,270] *Vasodilators are only started after ensuring that SBP is stable at ≥110 mmHg, rather than maintained by the high catecholamine state of HF* (in which case BP may precipitously drop with the relief of dyspnea). When properly used, a ***low and slow vasodilator dose*** increases cardiac output, thereby counteracting any direct hypotensive effect. Vasodilators are considered in "warm-wet" HF, particularly the fluid redistribution type (in which HTN and vascular dysfunction are primary targets).[8,270–272] However, the modern GALACTIC trial failed to show any benefit of acute vasodilator therapy in AHF (hence the low ESC recommendation, class IIb).[273]

Caution: Patients with ***diastolic HF*** are more vasodilator-sensitive than those with systolic HF, and may have a precipitous BP drop with vasodilators, even if they are hypertensive on presentation. Patients with ***low-output, cold HF*** have a limited cardiac output reserve that may prevent them from filling a dilated circulation: BP and tissue perfusion may precipitously drop with vasodilators. ESC and ACC recommend against vasodilators in case of SBP <110 or hypoperfusion.[8] ***In general, initiate diuresis and ensure BP is stable before initiating vasodilator therapy, low and slow***.

A. Intravenous nitroglycerin (NTG). Nitroglycerin is a venodilator that acts as a mixed venous and arterial vasodilator at medium doses, particularly in the context of severely increased systemic vascular resistance or high-dose diuresis (diuretics may activate RAAS and lead to vasoconstriction). Nitrate tolerance develops after several hours of therapy and appears to be improved by the combination with hydralazine or ACE-I. Start with 10 mcg/min, then titrate by 10–20 mcg/min every 5 minutes, up to 200 mcg/min, as long as SBP ≥110 mmHg.

B. Intravenous nitroprusside. Nitroprusside has arterial, venous, and pulmonary vasodilatory properties. Classically, an arterial line is needed to monitor BP during nitroprusside therapy, but this is not always necessary. One study suggested improved outcomes with the acute use of a low-dose nitroprusside infusion in high-risk, cold HF.[271]

C. Initiate ACE-I/ARB in HFrEF when BP is stable, as early as 12–24 hours. The hydralazine-nitrate combination may be initiated in black patients. See Section VI.

V. Treatment of acute HF: IV inotropic agents

IV inotropic agents may worsen survival over the long term even when used temporarily; therefore, they should be avoided if possible.[273] In the OPTIME-HF trial, the short-term use of milrinone increased in-hospital death and the 60-day risk of death or rehospitalization in ischemic HF, and increased arrhythmias in all HF.[274–276] Exogenous cardiac stimulation, at a time when the myocardium is significantly energy-depleted, may result in further ischemic and apoptotic damage and lead to the poor outcomes associated with these agents, despite immediate short-term hemodynamic improvement. Note that OPTIME-HF did not include cases where inotropic therapy was considered essential. ***An inotrope, typically at a low dose, is still indicated temporarily in: (i) wet and cold HF*** **with** ***SBP < 90 mmHg*****, or** ***(ii) wet and cold HF not responding to diuretics*** (SBP usually borderline <110 mmHg or frankly low); (iii) wet and cold HF with elevated lactate (= cardiogenic shock). SBP may not be frankly low in cardiogenic shock, the so-called normotensive shock, in which case the initiation of inotropes may await a few hours until the assessment of initial diuretic response.[8] If the latter conditions persist despite low-dose inotropic support, a **percutaneous ventricular assist device, such as IABP or Impella, may be considered** (as a bridge to improvement or to surgical VAD) (see Chapter 22). **Inotropes and support devices are typically considered in severe HFrEF. Inotropes have no value for the LV in HFpEF,** but may still be valuable when HFpEF is associated with severe and predominant RV failure/dilatation.

A. Dobutamine (β1- and β2-agonist) and milrinone (phosphodiesterase-3 inhibitor) have inotropic and vasodilatory effects
Milrinone is a phosphodiesterase-5 inhibitor that increases intracellular cAMP along the β-receptor pathway. It has more marked vasodilatory and hypotensive effects and a more prolonged effect than dobutamine, with a 2.5-hour half-life, more so in renal failure. Milrinone should be avoided if SBP <80 mmHg, and the dose should be reduced by 50% in renal failure. Also, the bolus dose of milrinone is particularly hypotensive and is better avoided. Start a small drip of milrinone (0.2 mcg/kg/min) and titrate it very slowly every few hours, allowing the increase in cardiac output to catch the vasodilatory effect, therefore preventing hypotension. Milrinone has significant pulmonary vasodilatory potential and may be the preferred inotrope in patients with pulmonary hypertension.

Dobutamine has a marked β_1-agonist effect, and a less marked β_2- and α_1-agonist effect. The β_2- and α_1-receptors have counter effects on the vasculature (vasodilatation and vasoconstriction, respectively), which explains that the vasodilatory and hypotensive effects of dobutamine are usually minimal, and in fact BP often improves with the increase in cardiac output. Only in critical patients with severe vasoconstriction and occupancy of all α-receptors, dobutamine may have an unopposed β_2 and vasodilatory effect. A low dose of dobutamine (2–5 mcg/kg/min) usually provides the desired effect. Higher doses (up to 10 mcg/kg/min) may be required in patients previously receiving β-blockers.

The most common arrhythmia with milrinone is AF (up to 25%), while the most common arrhythmia with dobutamine is sinus tachycardia. Asymptomatic PVCs and NSVT are common with both, more so dobutamine, but VT is rare. CAPITAL trial compared milrinone with dobutamine in cardiogenic shock. There was no difference in mortality, hospital course, renal outcomes, or arrhythmias between the 2 drugs.[277]

Note that chronic β-blocker therapy with carvedilol and, to a lesser extent, metoprolol, may lessen the hemodynamic effects of dobutamine, mandating higher doses.[278,279] On the other hand, chronic β-blocker therapy seems to enhance the effects of milrinone. Milrinone increases cAMP downstream of the β-receptor pathway, uninhibited by blockade of the β-receptor.

B. Norepinephrine and dopamine have inotropic and vasoconstrictive effects. These agents are used in severe hypotension (SBP < 70–80 mmHg). For a similar increase in cardiac output, dopamine produces greater elevation in heart rate and more arrhythmias than dobutamine and norepinephrine. The so-called low renal dose of dopamine (2–3 mcg/kg/min) has no role in acute HF management: it does not improve diuretic response, decongestion, or renal function based on ROSE and DOPA-ROP trials.[280]

C. Levosimendan (in Europe) is a calcium sensitizer, i.e., it enhances the sensitivity of myofilaments to calcium without increasing intracellular calcium concentration. It also exerts direct peripheral vasodilator effects by blocking ATP-dependent K channels in vascular smooth muscles. **It is the only inotrope that does not increase oxygen consumption or ischemia and has data suggestive of mortality reduction** (vs. dobutamine and placebo).[281–283] It is not affected by β-blockade. Yet, it increases AF (>dobutamine) and VT,[284] has a long half-life (70 hours), and like milrinone, is associated with a significant hypotension risk, and thus the bolus and high-infusion rates are avoided, especially when SBP is <90 mmHg.[8]

Inotropes can often be weaned off within a few days (or 1 day in the case of levosimendan, considering its long half-life). Inotropes initiate diuresis and reduce ventricular volumes, and thus improve ventricular afterload, functional MR/TR, and myocardial perfusion in a sustained fashion. This allows the patient to tolerate inotrope discontinuation and tolerate lower systemic pressures without compromise of myocardial perfusion. Also, renal function improves enough to allow the sustainment of diuresis. In patients with less severe HF, aggressive diuresis achieves a sustained hemodynamic benefit comparable to that achieved after inotropic therapy (Figure 4.10).

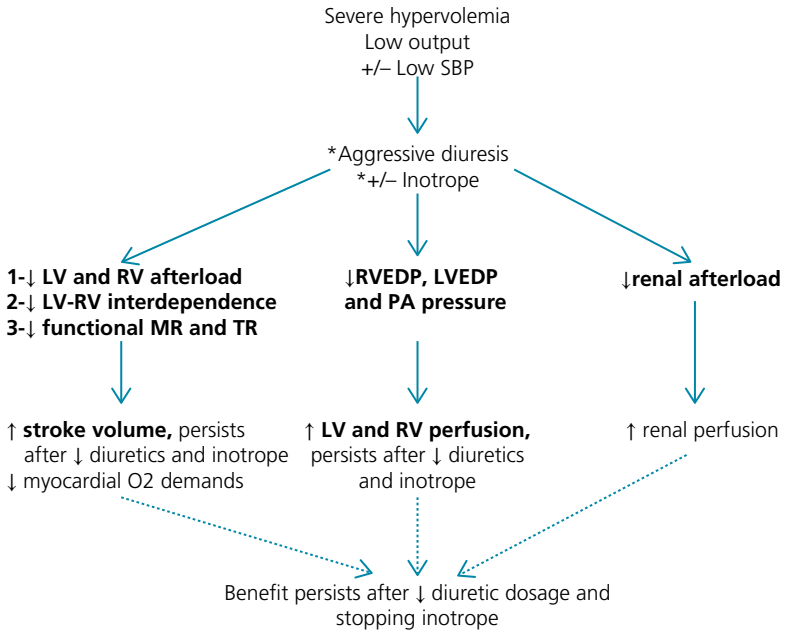

Figure 4.10 Mechanisms through which diuresis and inotropes initiate a benefit that is sustained over time and that allows inotrope discontinuation. LV perfusion is mainly diastolic and depends on the gradient between aortic DBP and LVEDP. RV perfusion is diastolic and systolic and depends on the gradient between aortic DBP and RVEDP, as well as the gradient between aortic SBP and RV systolic pressure. A reduction in LVEDP improves LV perfusion, while a reduction in RVEDP and RV systolic pressure, i.e., PA pressure, improves RV perfusion. ***SBP of 80–90 mmHg is poorly tolerated in congestive states at both the cardiac level (LV-RV perfusion) and the periphery, but is often tolerated once congestion is relieved*** (same BP, different implication).

VI. In-hospital and pre-discharge use of ACE-I/ARB, angiotensin-neprilysin inhibition, β-blockers, mineralocorticoid antagonist, and SGLT-2 inhibitors (the first 3 for low EF, the last 2 for any EF) **(Figure 4.11)**

Prior therapy with ACE-I and β-blockers should be continued in most acute HF cases, except: (i) severe renal deterioration with creatinine rise ≥100%, and possibly 50–100% (discontinuation of ACE-I), or (ii) *low-output HF with borderline or low BP and consideration of inotropes (discontinuation of both)*.

- A patient who is receiving chronic ACE-I/ARB should continue to receive it even if there is some worsening of renal function during the hospital stay (creatinine ↑ <50–100%). Holding ACE-I/ARB with the aim of improving kidney function actually impairs outcomes and worsens diuretic response.[236]
- If the patient was not on an ACE-I/ARB chronically, ACE-I/ARB may be started early, after waiting 12–24 hours to ensure hemodynamic stability. Acute ACE-I/ARB *increases diuresis*, as it curbs angiotensin II's effect on tubular reabsorption, and does not alter renal function, as long as SBP does not dramatically decline.[91,92] In fact, excessive angiotensin II worsens renal perfusion via excessive afferent renal vasoconstriction, overwhelming the efferent vasoconstrictive benefit; ACE-I/ARB may counterintuitively *improve renal perfusion*.[91,92,285]
- Better yet, in-hospital initiation of angiotensin-neprilysin inhibitor is superior to discharging the patient on an ACE-I with a delayed switch 8 weeks later.[123]
- In the case of AKI, or cold HF with low BP, ACE-Is and β-blockers should be initiated or reinitiated ≥24 hours before discharge, after amelioration of the cold state and azotemia. The pre-discharge initiation of β-blockers reduces the 60-day mortality by 59%.[103]
- If the patient has required inotropic support, β-blocker may be initiated ≥1 day after inotropic discontinuation, followed by one or more additional days of monitoring. The same monitoring applies when ACE-I is initiated in a patient recovering from azotemia.
- Initiate SGLT-2 inhibitor during hospitalization, in patients with stable SBP and diuretic response. An early enhancement of decongestion and diuretic response is seen, and a dramatic early benefit (death, rehospitalization) is expected within 30–90 days, regardless of EF (EMPULSE, SOLOIST-WHF, EMPAG HF, DICTATE HF trials: their meta-analysis shows ~20% mortality reduction with early SGLT-2i).
- Consider the following sequence of initiation, starting at day 1: SGLT-2 inhibitor → ARB → spironolactone → β-blocker → switch to ARNI. Keep in mind that ACE-I/ARB and SGLT-2 inhibitors may be carefully used in advanced CKD (GFR up to 20 for both). The STRONG HF trial showed that rapid initiation of the HF pillars before discharge and up-titration to optimal doses within 2 weeks dramatically reduces HF readmission by one-third at 3 months and improves symptoms.[286]

VII. Treatment of acute HF: O_2, non-invasive ventilatory support (CPAP, BiPAP), intubation

CPAP or BiPAP may be acutely used in severe respiratory distress as a bridge until pulmonary edema is relieved with diuretics. CPAP or BiPAP should only be tried in a patient with appropriate level of wakefulness who is not severely hypoxic or acidotic (pH > 7.2), and not hypotensive, and should be quickly removed within <30 minutes if it proves ineffective. Its prolonged ineffective use may paradoxically increase and prolong respiratory work, gastric distension and aspiration, and delay a salutary intubation. Intubation is required in patients with severe respiratory distress if CPAP/BiPAP and furosemide have not been effective quickly.

Intubation with positive-pressure ventilation reduces both LV preload and afterload, creating optimal LV loading conditions and an immediate reduction of pulmonary edema. Intracavitary LV pressure is not the only pressure affecting afterload; a positive pressure surrounding the myocardium negates some of the intracavitary pressure and reduces the tension against the inner myocardial wall. In fact, afterload correlates with the transmural pressure (LV pressure minus pericardial pressure) and is reduced with positive-pressure ventilation. Conversely, extubation may be poorly tolerated in HF patients or patients with critical CAD, as it drastically increases both preload and afterload.

Contrary to the LV effect, positive pressure ventilation directly increases RV afterload (PA pressure) and may worsen cardiac output in predominant RV failure. This may be counterbalanced by the relief of hypoxia, which reduces PVR, and by ↓ RV size and transmural pressure.

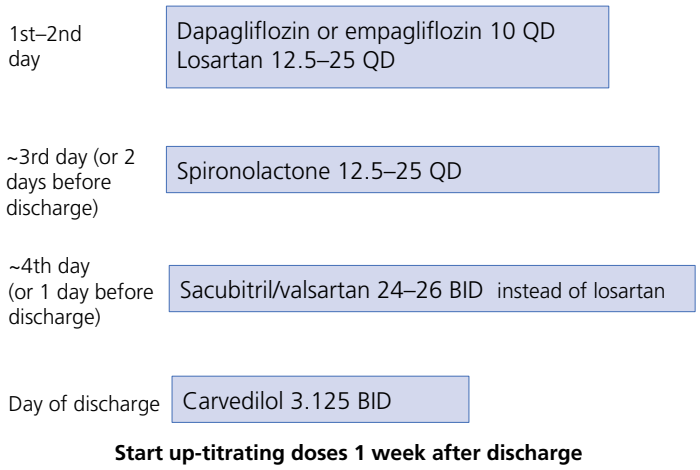

Figure 4.11 Suggested sequential initiation and up-titration of the 4 pillars of HFrEF in patients hospitalized with severely decompensated HFrEF. The idea is to *sequentially initiate all of them before discharge*, **once a proper response to IV diuresis is initiated (e.g., net fluid balance 3 L/day)** and BP and creatinine are relatively stable. Early SGLT-2 inhibitor, within 24 hours or beyond, boosts the diuretic response by up to 50%. Also, early ACE-I likely boosts diuresis. Monitor BP, creatinine, and potassium daily, and revert to the preceding step if symptomatic hypotension occurs or creatinine rises >50%. All drug doses are in milligrams.

Table 4.3 Acute HF therapy according to volume status and peripheral perfusion status.

	Overload/congestive signs	
Perfusion signs	***Wet***	***Dry***
Warm	Diuresis +/– vasodilators	Not HF
Cold	Diuresis +/– low-dose vasodilators If no response to diuretics or if SBP < 90 mmHg or lactate > 2: inotropes	Could be hypovolemia → hold diuretics and give volume gradually (oral rather than IV replacement) Consider the possibility of overdosage with medical therapy (especially if hypotension)[a] Consider inotropes if still hypoperfused

[a] Swan–Ganz catheter may be of use to guide therapy in this patient group.

VIII. Summary: keys to the treatment of acute HF (Table 4.3)

The clinical assessment of "wet" and "cold" signs is usually enough to guide initial therapy. The routine use of a Swan–Ganz catheter (PA catheter) in acute HF does not improve outcomes (ESCAPE trial).[287] It is used selectively to monitor RA pressure, pulmonary capillary wedge pressure, and cardiac output, and to guide escalation of therapy +/– support devices in the following cases:

- The volume status is unclear with deteriorating BP or respiratory status and poor response to diuretics.
- Severe shock (requiring moderate or high doses of vasopressors-inotropes) or suspicion of mixed shock (cardiogenic and septic). Though a third of patients in the negative ESCAPE trial required inotropes, ESCAPE was not a trial of cardiogenic shock (mean SBP 106 mmHg), and did not exclude the role of PA catheter in cardiogenic shock or in patients requiring a support device (IABP or Impella).

IX. Discharge

The patient needs to achieve near optimal volume before discharge*: **normal JVP, no bendopnea, no "orthoedema" (no orthopnea, no edema)***.[288] **NT-proBNP or BNP should have declined >30%**.[47,289] Assess for dyspnea during a 1-minute flat position, and while bending down for 15 seconds. The patient should be able to ambulate without dizziness and with minimal dyspnea. Transition from intravenous to oral diuretic needs to be completed and stable for a few hours before discharge. Oral diuretic dose should maintain a slightly negative input/output balance. If the patient was receiving 80 mg of IV furosemide Q12h, he is placed on a maintenance dose of 40 mg of oral furosemide, twice a day (i.e., a total oral furosemide dose that is numerically 0.5–0.75 the intravenous dose used, taking into account how well decongested the patient is). This oral dose is far lower than the intravenous dose in terms of dose equivalence (~4 times lower), but is usually effective enough at the compensated stage in a patient who is almost euvolemic with improved renal perfusion. *This IV-to-oral conversion is the reverse of the oral-to-IV conversion performed on admission*. Appropriate diuresis should be ensured within a few hours of the oral dose. **Early clinical and creatinine/K/BNP checkup should be performed within a week of discharge, and the oral dose of furosemide up- or down-titrated during this visit, along with up-titration of the 4 HFrEF pillars.**

The in-hospital mortality of acutely decompensated heart failure, whether systolic or diastolic, is ~4%. There are 4 major prognostic risk factors (ADHERE database):[236,290] ↑ BUN or creatinine on admission, SBP <115 mmHg, "cold" low-output HF, positive troponin (especially >1 ng/ml, regardless of the presence of ischemia). Mortality can go up to 10–20% with one or more of these factors and down to 2% with no factors. After discharge, 6-month mortality and HF rehospitalization rates are ~15% and ~30%, respectively, notably higher than post-MI rates.[237,265,266,286,291,292] These numbers are reduced by up to one-third with early initiation and titration of the HF pillars.[265,286]

X. Inability of severe HF to tolerate vasodilatation or hemodialysis

In patients with severely *limited cardiac output reserve*, vasodilatation may not be matched by enough rise in cardiac output to fill the dilated circulation, which leads to precipitous hypotension. This is similar to critical AS.

While decongestion improves cardiac output, quick fluid removal during dialysis (2–3 liters in 3 hours) exceeds plasma refill time and creates transient reduction of intravascular volume. In patients with preserved cardiac function, the LV increases its contractility, stroke volume, and EF to fill the empty circulation. This cannot happen in patients with *limited cardiac output reserve*, especially those whose BP is borderline low and are receiving vasodilators. BP will precipitously drop during dialysis. Norepinephrine may be used to constrict the empty circulation and maintain BP during dialysis; in hypotension, norepinephrine does not increase afterload untowardly, as it only raises the SBP to 90–100 mmHg.

XI. Outpatient monitoring of HF and prevention of hospitalization

Fluid accumulation in the lungs generally occurs over time, typically 1–3 weeks, and is generally believed to precede episodes of overt decompensation in most patients, even those with abrupt presentations (Figure 4.8).[293] Daily monitoring of body weight is the easiest method of monitoring fluid status, with a gain of over 2–3 lb in 1 day or 5 lb in <1 week indicating the need for extra doses of diuretics. However, weight gain is not sensitive enough to detect HF deterioration, and the weight increase is smaller than considered clinically relevant in >50% of patients (~2 lb).[294,295] Fluid redistribution with only mild fluid retention might explain this diagnostic gap.[6] Afterload increase, ischemia, AF, and infection may all cause a *rapid deterioration that may not be heralded by weight gain*. As importantly, fluid weight gain may be masked by reduced food intake and body wasting that accompanies decompensated HF. In fact, in one study using a PA sensor, changes in the continuously monitored PA diastolic pressure reliably predicted HF hospitalization, while weight minimally changed

throughout the decompensation.[222] PA diastolic pressure started to rise ~20 days prior to HF hospitalization, even earlier in systolic HF. Thus, in stable HF outpatients, several monitoring methods have been developed to prevent HF hospitalization:

- BNP monitoring Q1–3 months, particularly in patients <75 years of age with systolic HF.[48,49]
- Impedance cardiography. The chest bioimpedance or resistance correlates with intrathoracic fluid volume and is measured non-invasively using external electrodes (the higher the fluid volume, the lower the chest resistance).[296] Bioimpedance may also be monitored more accurately with implantable devices (ICD, CRT) that perform a daily measurement of electrical impedance between the device box and the right-ventricular electrode (OptiVol feature). This information may be transmitted daily and wirelessly to a bedside communicator that transmits it to a service center. OptiVol produces an audible alert once the impedance is lower than a certain cutoff. Bioimpedance change has ~70–80% sensitivity and positive predictive value for HF decompensation and warrants at least a clinic visit and a probable up-titration of diuretics, vasodilators, and HTN therapy.[293,297] It correlates with PCWP changes and fluid loss in patients hospitalized with HF.[293] Home monitoring of ICD and CRT devices improves clinical outcomes in HF, through impedance monitoring but also through the early detection of atrial and ventricular arrhythmias (IN-TIME trial).[298]
- A wearable home vest can detect daily change in lung volume content using built-in electromagnetic emissions (Remote Dielectric Sensing).[299]
- Invasively implanted hemodynamic monitors, such as CardioMEMS, which is a small, invasively implanted PA sensor that wirelessly transmits PA pressure. In patients with class III HF and prior HF hospitalization in the last year, CardioMEMS-guided therapy reduced the risk of recurrent HF hospitalizations, whether EF was reduced or preserved (CHAMPION trial, ACC class IIb).[300] The PA pressure is recorded by the patient every morning and the numbers are telemonitored by the physician at least once weekly. Decongestive therapy is titrated to achieve a normal PA pressure. An upward trend over several days is more alarming than daily fluctuations.

Appendix 1. Management of isolated or predominant RV failure

A. Causes of right HF (see Table 4.4)[301,302]

Causes of RV failure have been discussed under *Causes of heart failure* (Section 2.III) and are organized in 3 categories: **(i) pressure overload, (ii) volume overload, and (iii) intrinsic RV disease**.

Acute RV failure is caused by RV infarct, acute PE, or a decompensation of any of the chronic causes by acute pulmonary hypertension or volume overload-mediated RV dilation, which begets a vicious cycle of more dilation.

B. RV morphological features; echocardiographic and hemodynamic features of RV dysfunction

As opposed to the LV, which has an elliptical shape, the RV has the shape of a pyramid connected to an infundibular tube. Unlike the LVOT, which is a fibrous mitroaortic continuity, the RVOT (infundibulum) is fully muscular and is separated from the tricuspid valve beneath it by a supraventricular crest, which continues into the moderator band at the septum (septomarignal trabeculation). While the RV diameter is smaller than the LV diameter on the apical 4-chamber view*, the 3-dimensional RV volume is actually larger than the LV volume, which implies that normally the RV EF is lower than LV EF*, with 45% as the lower limit of normal (EF = stroke volume/ventricular diastolic volume; for the same stroke volume, the ventricular volume is larger on the right). In pathological states, the dilated RV assumes a spherical shape.

Histologically, the LV has 3 layers of muscular fibers: outer oblique, mid-wall circumferential, and inner longitudinal fibers. Each layer is responsible for a specific motion: torsion, radial, and longitudinal motions, respectively. Conversely, the thinner RV does not have the outmost oblique layer and rather has 2 layers: outer circumferential (25% of RV thickness) and inner longitudinal (75% of RV thickness).

On echo, the diagnosis of subtle RV dilatation is difficult because of the complex RV geometry. RV that is larger than LV on the 4- chamber view, or RV that is spherical rather than crescentic on the long-axis view, suggests RV dilatation but is not specific. RV septal motion should be analyzed for: (i) RV volume overload (RV expands and pushes the septum toward the LV in diastole, then paradoxically sucks it toward the RV in systole), and (ii) RV pressure overload (septum pushed toward the LV in systole with a flat D-shaped morphology) (Figure 4.12).

Two echo indices are valuable for the assessment of RV systolic function: (i) *TAPSE* (tricuspid annular plane systolic excursion, normal >16 mm), which is the systolic excursion of the lateral tricuspid annulus toward the apex, measured on M-mode; (ii) *tissue Doppler of the lateral tricuspid annulus* (called S′, normal > 10 cm/s). *TAPSE/PASP* measures the ability of RV contractility to adapt to rising afterload (=RV-PA coupling): a ratio <0.31-0.35 indicates RV dysfunction. RV volume and EF are better assessed by MRI or first-pass nuclear scan.

Invasive hemodynamic features of severe RV failure:

-Elevated RA pressure >15 mmHg or RA pressure/PCWP ratio >0.63–1

-PA pulsatility index = PA pulse pressure/RA pressure. This index combines forward failure (PA pulse) and backward failure (RA pressure). A value <2 in a patient with HF predicts poor outcomes, including after LVAD; a value <1 is severely reduced.

-RV stroke work index = (mean PA pressure-RA) × stroke volume index <0.25 mmHg.L/m^2

-↓RV end-systolic elastance (RV systolic pressure/RV end-systolic volume) and RV-PA coupling (see Figure 5.7)

Unexplained RV dilatation or unexplained pulmonary hypertension often warrants TEE and a bubble study seeking an *overlooked ASD* (e.g., sinus venosus ASD).

Table 4.4 Diagnosis of the underlying mechanism of RV failure and tricuspid regurgitation: measurement of PA systolic pressure and PVR (pressure overload vs. volume overload vs. intrinsic RV disease).

PA pressure > 50 mmHg, *or* PVR ↑

Pulmonary hypertension, possibly from left HF. PA pressure may be normal if cardiac output is poor (severe RV failure), but PVR unveils the diagnosis of pulmonary hypertension

PA pressure normal or <50 mmHg, and PVR normal

Isolated right HF from *volume overload* (ASD, TR, including atrial functional TR), or *intrinsic RV disease* (cardiomyopathy, RV MI). A mild pulmonary hypertension with normal PVR is rather a result than a cause of RV failure (ventricular interdependence→mild LA pressure rise→passive PA pressure rise)

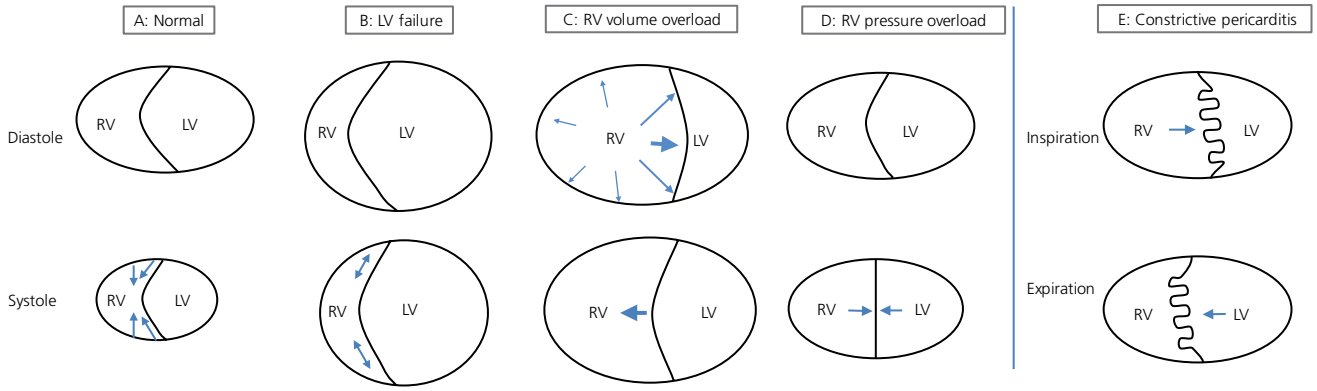

Figure 4.12 Septal motion and LV-RV interdependence in various disease states. **(A)** Normally, the septum "shrinks" down both the LV and RV (*arrows*), contributing to the stroke volume of both. **(B)** In LV failure, the limited septal contraction limits the RV ejection as much as the LV ejection (*double arrows*). **(C)** In RV volume overload, RV is severely dilated, and pushes the septum toward the LV in diastole, then paradoxically sucks it toward the RV in systole (as RV systolic pressure<LV); as such, the septum does not contribute to the LV ejection anymore, and actually "sucks" away some of the LV stroke volume but improves RV output. **(D)** In RV pressure overload, the septal position is ~normal in diastole, but gets excessively pushed toward the LV in systole by the high RV pressure (straight, D-shaped septum); of note, RV is frequently dilated in pressure overload states, in which case the septum behaves, mostly, as in RV volume overload, yet may remain partially pushed toward the LV (D-shaped) in systole. **(E)** In constrictive pericarditis, the abnormal septal motion is not dictated by systole vs. diastole and is rather dictated by inspiration vs expiration. RV pushes the LV in inspiration and is pushed by the LV in expiration. A second septal abnormality is septal bounce, which is a constant "jitter" of the septum in diastole (nearly a "zigzag" septum on M mode).

C. Pathophysiology, ventricular interdependence

1. *Afterload sensitivity*. The thin RV poorly tolerates an increase in PA pressure and quickly fails and distends. *As opposed to the normal LV, the RV is very sensitive to acute afterload changes and quickly fails in acute pressure overload* (such as pulmonary embolism).[303,304] This is because the RV wall is thinner than the LV wall, afterload inversely correlating with myocardial thickness (Laplace law: wall stress or afterload = pressure × radius/[2 × wall thickness]). Chronic pulmonary hypertension stimulates thickening of the RV wall, which helps reduce wall tension; this is not seen in the acute setting, where RV is intolerant to any rise in afterload.

RV is also intolerant to dilatation, as it increases RV wall stress as well, per Laplace law. As the RV severely fails and dilates, *progressive RV dilatation leads to progressively more wall stress on the thin walls, which leads to further RV dilatation and TR (vicious circle of RV dilatation and TR). At this point, TR and PR are very poorly tolerated and aggravate RV dilatation*. The pericardium is helpful in those cases as it tries to contain the RV; pericardiotomy/cardiac surgery may lead to massive RV dilatation.

2. *Ventricular interdependence*. LV failure leads to RV failure through pulmonary hypertension and through the loss of septal contribution to RV function. In fact, the septum and the RV free wall contribute almost equally to the RV function, and 20–40% of RV systolic pressure and output result from LV contraction.[303] On the other hand, RV failure, particularly when acute, may lead to LV failure. RV dilatation causes pericardial stretching and functional pericardial constriction, which forces the RV to eventually compress the LV in diastole. These changes decrease LV distensibility and preload while simultaneously raising LVEDP, hence causing a steep LV pressure-volume relationship. Also, LV contractility is reduced by the paradoxical septal motion to the right in systole (loss of septal contribution), which conversely improves RV output, RV EF, and PA flow: *paradoxical septal motion is a "double-edged sword."* In fact, ***the interdependent effect on the LV reduces cardiac output more than the loss of RV contraction***.[244]

3. *Secondary right-to-left shunt*. The high RA pressure may induce a large right-to-left shunting in patients with PFO. That is how severe RV failure may lead to refractory hypoxemia.

4. In patients with severe pulmonary hypertension, the PA pressure may decline into the mild/moderate range as RV failure develops. In those patients, a high systolic PA pressure predicts recovery of RV function with therapy and better outcomes than patients with lower systolic PA pressure. How well RV function matches the PA afterload is expressed as ***RV-PA coupling*** and is assessed on echo by: RV TAPSE/systolic PA (normally >0.31 mm/mmHg) (see Figure 5.7).[304,305]

The Fontan procedure illustrates the concept that, in patients with normal PA pressure, the RV may not be a necessary structure for many years and blood can flow passively from the RA to the PA. Therefore, RV failure is only detrimental if PA pressure is elevated, TR is present (further reducing the forward cardiac output), or severe RV dilatation compresses the LV. The septum maintains its stability and function as long as the RV is not dilated. *In a way, it is better not to have an RV (Fontan) than to have an enlarged, dysfunctional RV*.

As opposed to the adult RV, the thick congenital RV tolerates pressure overload and does not fail (e.g., pulmonic stenosis, Eisenmenger syndrome).

D. Treatment of acute RV failure (isolated or predominant RV failure)

- *Respiratory failure with hypoxemia* should be aggressively treated, with mechanical ventilation if needed.
- *Preload management:* diuresis is very beneficial to reduce RV dilatation and afterload, improve functional TR (secondary to RV dilatation), and reduce ventricular interdependence, all of which improve cardiac output. As such, aggressive diuresis (2–3 liters negative balance/day) is pursued in acute on chronic cases, while gentler diuresis (0.5–1 L/day) may be pursued in chronic cases.[244,306]

  In acute RV failure secondary to RV MI or PE, two concepts may allow *small* volume loading: (i) a non-dilated RV increases its stroke volume with increasing preload, before reaching the point of ventricular interdependence; (ii) a high CVP, up to 10–14 mmHg, does not imply a high preload in acute, de novo, RV failure.[307] The RV pressure-volume relationship is shifted leftward, meaning that the CVP rises even if RV volume is normal. Thus, if *RV is not dilated and if CVP <10–14 mmHg*, administer a 250–500 ml saline load at a time.[244] If there is no hemodynamic response (i.e., increased BP and urine output), if the RV is dilated, or if CVP >14 mmHg, volume loading should be avoided, as it may lead to further RV dilatation, failure, and hemodynamic compromise. At this point, consider inotropes and consider afterload reduction with inhaled nitric oxide. Note that digoxin may also be useful in RV failure.[308]
- *Maintenance of an appropriate systemic systolic blood pressure (SBP) and resistance (SVR)*

As opposed to the failing LV, the failing RV is less tolerant of a low SBP. In LV failure, a low SBP reduces afterload of the exquisitely sensitive LV and may significantly increase cardiac output. The RV, on the other hand, is not favored by a low SBP from an afterload standpoint and, in fact, the RV depends on an adequate SBP for its coronary perfusion. While the LV coronary flow is mostly diastolic, the RV coronary flow is at least 50% systolic, and depends on the gradient between SBP and systolic RV pressure. If the SBP is low in a patient with a high PA pressure, the gradient between SBP and systolic RV pressure is drastically reduced, which reduces RV coronary flow leading to RV ischemia and failure. The ratio of SBP/systolic PA pressure, or SVR/PVR, is an important ratio in RV failure.[309]

Thus, norepinephrine, which increases RV contractility and increases SVR, is often the preferred inotrope in RV failure; it does not have a significant effect on PVR at low/medium doses (<0.5 mcg/kg/min), and thus favorably affects the SVR/PVR ratio.[308]

Systemic vasodilators are poorly tolerated in RV failure because of the reduction of SVR but also because the underfilled LV cannot increase its output to match the vasodilated circulation. Low-dose dobutamine (<10 mcg/kg/min) and milrinone increase RV contractility and reduce PVR; however, they are also systemic vasodilators and thus must be used in conjunction with vasopressors, such as norepinephrine or vasopressin.

- *Afterload reduction (PVR):* Treatment of hypoxemia is key. Moreover, inhaled NO, inhaled milrinone, or inhaled epoprostenol effectively reduces PVR and RV distension. Inhaled vasodilators dilate the pulmonary vessels in ventilated areas and preferentially redistribute blood flow to these areas (reduce shunt effect). Hence, NO improves oxygenation in ARDS, with little effect on systemic SVR.[310]
- *Maintain sinus rhythm and AV synchrony:* AF or AV dissociation may have more profound hemodynamic effects in RV failure than LV failure. In RV failure, the LV is small and underfilled, which makes it highly dependent on the left atrial kick. Also, RA contraction directly raises RV pressure and, thus, flow into the PA; in fact, **acute RV failure is characterized by a very large RA and RV A wave, pushing blood into the PA**. Consider prompt DC cardioversion in AF associated with acute RV shock, even if the rate is reasonably controlled.[306] Also, AV synchronous pacing should be performed in RV shock associated with AV block (temporary atrial and ventricular leads are placed through 2 separate venous accesses).

  As in decompensated LV failure, an increase in heart rate (80–110 bpm) is often necessary to allow RV filling and emptying through providing more cardiac cycles.
- *Effect of mechanical ventilation:* Mechanical ventilation reduces hypoxemia, and thus indirectly improves PVR and RV output. However, positive-pressure ventilation directly increases RV afterload (PA pressure) *unlike its effect on the LV* (directly reduces LV afterload). A strategy of low tidal volume with limited plateau pressure should be implemented.
- *Right-to-left shunting through a PFO* serves to unload the RV, reduce RA pressure, and increase the LV filling and cardiac output. Thus, although this shunt induces hypoxemia (arterial O_2 saturation 80–85%), some degree of shunting improves the cardiac output, the overall oxygen delivery, and the patient's symptoms and functional status, and should not be closed. In fact, patients with Eisenmenger syndrome (with inherent R–L shunt) and patients with idiopathic pulmonary hypertension who have a PFO live longer than patients with pulmonary hypertension and no shunt.[311,312] That is why balloon atrial septostomy has been beneficial in cases of refractory right HF.[313] Only excessive shunting, as in patients with very high RA pressure >20 mmHg and very poor RV function, may drastically reduce pulmonary blood flow and induce profound hypoxemia (overall untoward effect).
- IABP and mechanical circulatory support for refractory RV shock (right-sided Impella RP, Protek Duo Tandem heart, VA-ECMO): See Chapter 2, Section 2.I, and Chapter 22.

QUESTIONS AND ANSWERS

Question 1. A 62-year-old man with a history of HTN, moderate COPD, CKD, and obesity (BMI 37 kg/m^2) presents with dyspnea on exertion. Exam does not reveal significant volume overload. Echo shows normal EF, moderate LVH, and LA enlargement. Grade 1 diastolic dysfunction is present with normal LA pressure and PA pressure (E′ is reduced but E/E′ ratio is < 8). What is the next step in assessing his dyspnea?

A. BNP
B. Echo measurement of E/E′ ratio and PA pressure with leg raising or exercise
C. Right and left heart catheterization with measurement of PCWP and LVEDP at rest and with leg raising, exercise or adenosine testing
D. Any of the above
E. None of the above. Dyspnea is due to obesity and COPD

Question 2. A 62-year-old man with a history of HTN, moderate COPD, CKD, and obesity (BMI 37 kg/m^2) presents with dyspnea on exertion. Exam does not reveal significant volume overload. Echo shows normal LVEF and moderate LVH. LA size is normal. Diastolic function appears normal (normal E') with normal LA pressure and PA pressure. What is the next step in assessing his dyspnea?
A. BNP
B. Echo measurement of E/E' ratio and PA pressure with leg raising or exercise
C. Right and left heart catheterization with measurement of PCWP and LVEDP at rest and with leg raising, exercise or adenosine testing
D. Any of the above
E. None of the above. Dyspnea is due to obesity and COPD

Question 3. A 64-year-old man presents with progressive dyspnea on exertion. He has a history of HTN, CKD, and moderate COPD. Cardiac exam reveals a persistently split, loud S_2, heard at the upper but also lower left sternal border; and an early systolic murmur most prominent at the left lower sternal border. He has a left parasternal lift. The left apical impulse is discrete. JVP is elevated at 15 cmH_2O, with prominent V waves and Kussmaul's sign. The abdominal exam reveals mild hepatomegaly with a pulsatile liver. Mild peripheral edema is present. Chest X-ray shows enlarged RA and PA, with small pleural effusions but no parenchymal findings. BNP is 400 pg/ml. What is the most likely cause of the patient's presentation?
A. RV failure secondary to primary TR
B. RV failure secondary to pulmonary arterial hypertension
C. RV failure secondary to a shunt
D. Restrictive cardiomyopathy
E. Intrinsic RV dysfunction
F. Constrictive pericarditis
G. B, C, or D
H. B or C
I. All of A through F

Question 4. In the patient of Question 3, echo shows enlarged RA and RV with plethoric IVC. PA pressure is 70 mmHg. The LA is enlarged and LV is small and hyperdynamic. No shunt is seen. A chest CT does not show any pulmonary embolus. What is the next step?
A. TEE looking for a left-to-right shunt
B. Pulmonary function testing
C. Sleep study
D. Right and left heart catheterization

Question 5. A 60-year-old man presents with a clinical picture of severe RV failure and anasarca. BP is 85/60, heart rate is 105 bpm, and he has cool extremities with oliguria. On echo, RV is severely dilated, while LV is small with normal EF. Right and left heart catheterization reveals a severely elevated RA pressure ~25 mmHg with a large V wave, and elevated PCWP and LVEDP ~25 mmHg. PA pressure is 75/28 mmHg. Cardiac index is 1.7 L/min/m^2. During simultaneous RV–LV pressure recording: (i) in diastole, RV and LV end-diastolic pressures are equalized, with LV pressure exceeding RV pressure at times; (ii) diastolic dip-plateau pattern of LV-RV; (iii) in systole, RV and LV peaks are concordant. What is the diagnosis?
A. Restrictive cardiomyopathy with a stiff, failing LV, secondary pulmonary hypertension, and secondary RV failure
B. Constrictive pericarditis
C. Isolated RV failure secondary to pulmonary arterial hypertension. LVEDP is elevated from RV compression

Question 6. How is the patient in Question 5 acutely treated?
A. Diuretic therapy
B. Diuretic and vasodilator therapy
C. Diuretic therapy and inotropic therapy with dobutamine
D. Diuretic therapy and inotropic therapy with norepinephrine
E. Diuretic therapy, inotropic therapy, and pulmonary vasodilators
F. Pericardiectomy

Question 7. A 56-year-old patient presents with a new diagnosis of HF and LVEF of 20%. His symptoms improve with diuresis and initiation of medical therapy. He has no significant CAD on coronary angiography. What is the likelihood of significant improvement or full recovery of his LVEF in the next 6 months, under proper medical therapy?

Question 8. A 60-year-old with a history of non-ischemic cardiomyopathy (LVEF 25%) presents with ADHF (progressive dyspnea and edema over the last week). He chronically takes furosemide 40 mg BID, carvedilol 6.25 mg BID, and lisinopril. BP is 145/85 mmHg, JVP is 13 cmH_2O. ECG shows AF, rate 125 bpm (newly diagnosed AF). What is the next step?
A. Furosemide 80 mg IV Q8h, digoxin load, and same dose of carvedilol
B. Furosemide 80 mg IV Q8h, digoxin load, and increase carvedilol to 12.5 mg BID
C. Furosemide 80 mg IV Q8h and acute DC cardioversion of AF
D. Furosemide 40 mg IV Q12h and acute DC cardioversion of AF
E. Furosemide 80 mg IV Q12h, digoxin load, and nitroglycerin IV

Question 9. A 60-year-old with a history of non-ischemic cardiomyopathy (LVEF 25%) presents with ADHF (progressive dyspnea and edema over the last week). He chronically takes furosemide 40 mg BID, carvedilol 6.25 mg BID, and lisinopril. BP is 145/85 mmHg, JVP is 13 cmH_2O. ECG shows sinus bradycardia 55 bpm. What is the next step?
A. Furosemide 80 mg IV Q8h, continue same dose of carvedilol
B. Furosemide 80 mg IV Q8h, reduce carvedilol
C. Furosemide 40 mg IV Q12h, reduce carvedilol

Question 10. A 60-year-old with a history of non-ischemic cardiomyopathy (LVEF 25%) presents with ADHF (progressive dyspnea and edema over the last week). He chronically takes furosemide 40 mg BID, carvedilol 6.25 mg BID, and lisinopril 10 mg daily. BP is 98/70 mmHg, heart rate is 85 bpm, JVP is 15 cmH_2O. Creatinine is 2.4 mg/dl (baseline 1.4 mg/dl), and he is drowsy and weak with cool extremities. What is the initial treatment?
A. Furosemide IV and inotropic therapy. Discontinue carvedilol and lisinopril
B. Furosemide IV. Discontinue lisinopril and reduce the dose of carvedilol. Inotropes are initiated in case of poor response to furosemide

Question 11. A 60-year-old with a history of non-ischemic cardiomyopathy (LVEF 25%) presents with ADHF (progressive dyspnea and edema over the last week). He is initiated on a proper dose of diuretic and achieves a proper response (3 liters of urine output). Next day, he is still congested clinically with JVP 12 cmH_2O, but his creatinine rises from 1.5 mg/dl to 1.9 mg/dl. BP is 110/70 mmHg.
A. Hold the diuretic therapy
B. Continue the same diuretic dose
C. Add inotropic therapy

Question 12. A 60-year-old man with ischemic cardiomyopathy and LVEF 20% is started on furosemide 40 mg BID, lisinopril 5 mg, and carvedilol 3.125 mg BID. A week later, he complains of dizziness and fatigue. His JVP is normal with no peripheral edema. His BP is 120/75 mmHg, with significant orthostatic drop. His creatinine rises from a baseline of 1.3 mg/dl to 1.7 mg/dl, BUN rises from 24 mg/dl to 50 mg/dl, and K rises to 5.5 mEq/l. What is the next step?
A. Discontinue lisinopril
B. Reduce the dose of furosemide to 40 mg Qday
C. Reduce furosemide and discontinue lisinopril
D. Hold furosemide then resume it at a lower dose, hold lisinopril for 4 days, then start lisinopril 5 mg Qday

Question 13. A 60-year-old man with ischemic cardiomyopathy and LVEF 20% is started on furosemide 40 mg BID, lisinopril 5 mg, and carvedilol 3.125 mg BID. A week later, he complains of mild exertional dyspnea but no dizziness. JVP is normal with no peripheral edema. BP is 120/75 mmHg, without orthostatic drop. His creatinine rises from a baseline of 1.3 mg/dl to 1.7 mg/dl, BUN rises from 24 mg/dl to 32 mg/dl. What is the next step?
A. Discontinue lisinopril
B. Reduce the dose of furosemide to 40 mg Qday
C. Reduce furosemide and discontinue lisinopril
D. Reduce furosemide, hold lisinopril for 4 days, then start lisinopril 2.5 mg Qday
E. Continue the same regimen

Question 14. A 60-year-old man with ischemic cardiomyopathy and LVEF 20% is started on furosemide 40 mg BID, lisinopril 5 mg, and carvedilol 3.125 mg BID. A week later, he complains of dizziness and fatigue. His JVP is still mildly increased (~8–9 cm), with 1+ peripheral edema. His BP is 105/75 mmHg with a significant orthostatic drop, and heart rate is 60 bpm. His creatinine rises from a baseline of 1.3 mg/dl to 1.7 mg/dl, BUN rises from 24 mg/dl to 32 mg/dl. What is the next step?
A. Discontinue lisinopril
B. Reduce the dose of furosemide to 40 mg Qday
C. Reduce furosemide and discontinue carvedilol and lisinopril
D. Reduce furosemide, hold lisinopril for 4 days, then start lisinopril 2.5 mg Qday
E. Continue furosemide, reduce lisinopril to 2.5 mg, and hold carvedilol

Question 15. A 69-year-old man with no known cardiac history presents with decompensated HF. ECG shows LVH and ST depression. Echo shows anteroapical dyskinesis with LVEF 25%. The myocardial thickness of the anterior wall is 7 mm. Coronary angiography shows a totally occluded LAD with grade 3 collateral flow and severe RCA disease. Exercise stress testing is performed and shows a large, mainly fixed anteroapical defect with 55% uptake, and mild, reversible inferior defect. The patient walked 3 minutes and experienced chest tightness early on. Besides proper medical therapy, what is the best revascularization option?
A. Revascularization does not improve outcomes at this point
B. Revascularize with CABG without further testing
C. Perform viability testing. Perform CABG only if the anterior wall is viable

Question 16. A 69-year-old man with no known cardiac history presents with decompensated HF. He does not have exertional chest pain. ECG shows anterior Q waves. Echo shows anteroapical dyskinesis with EF of 25%. The myocardial thickness of the anterior wall is 7 mm. Coronary angiography shows a totally occluded LAD with grade 3 collateral flow and severe RCA disease. Stress testing is performed and shows a large, mainly fixed anteroapical defect, and inferior reversible defect. The patient only walked 3 minutes and experienced severe dyspnea and dizziness. Besides proper medical therapy, what is the best revascularization option?
A. Revascularization does not improve outcomes at this point
B. Revascularize with CABG without further testing
C. Perform viability testing with MRI. Perform CABG if the anterior wall is viable
D. Perform viability testing with MRI. Perform CABG if four segments of the anterior or apical wall are deemed viable

Question 17. A 37-year-old man presents with severe chest pain and diffuse ST elevation. A rub is heard on exam. Troponin peaks at 20 ng/ml. Echo shows global hypokinesis with inferior akinesis (EF 25%) and no pericardial effusion. A coronary angiography is performed and shows normal coronary arteries. He develops acute pulmonary edema and severe hypoxia requiring mechanical ventilation. He does not improve with diuresis and develops a shock requiring 2 vasopressors. What is the next step?
A. IABP, endomyocardial biopsy
B. LVAD and cardiac transplant listing

C. ECMO and cardiac transplant listing
D. IABP and immunosuppressive drugs

Question 18. A 64-year-old hypertensive man with CKD presents with severe dyspnea and lower extremity edema. On exam, BP is 85/72 mmHg, JVP is >15 cmH_2O, ascites is present. S_2 is loud and persistently split, with S_3 gallop. ECG shows low QRS voltage in the limb leads and no features of LVH; septal Q waves are present. His echo shows severe LV thickening (septum = 18 mm) with small cavity and normal EF, dilated RV, and biatrial enlargement. What workup and treatment should be performed?
A. This is most likely an advanced stage of hypertensive cardiomyopathy. Diurese. Once stable, initiate carvedilol
B. Endomyocardial biopsy, diuretic therapy
C. Serum and urine immunofixation and myocardial scintigraphy with bone radiotracers. Avoid digoxin, ACE-I, and β-blocker in this condition
D. Serum and urine protein immunofixation and myocardial scintigraphy with bone radiotracers. Avoid digoxin; ACE-I and β-blocker may be used in this condition

Question 19. A 50-year-old Mexican man presents with dyspnea on exertion and orthopnea. On exam, he has elevated JVP with a deep Y descent, hepatomegaly, ascites, and peripheral edema. Lungs are clear. Echo shows normal LVEF and LV size, and a dilated IVC. Which of the following initial tests is *not* appropriate?
A. Fat pad biopsy
B. Right and left heart catheterization
C. Chest CT
D. Tuberculin skin testing
E. Coronary angiography
F. Iron studies

Question 20. A 54-year-old man with a history of non-ischemic cardiomyopathy (EF 15% for 5 years) had 2 admissions for ADHF in the last 4 months. He presents with severe dyspnea and fatigue on exertion. On exam, he is cachectic (BMI 20) and lethargic, with BP 90/70 and pulse 100 bpm. JVP is 8–9 cmH_2O. Extremities are cool without peripheral edema. He has MR murmur. Korotkoff sounds are heard throughout the strain phase of Valsalva. Creatinine is 1.7 mg/dl. What is the next step?
A. Discontinue carvedilol and lisinopril
B. Administer intravenous furosemide
C. Right heart catheterization

Question 21. The patient in Question 20 undergoes right heart catheterization, which shows RA pressure of 8 mmHg, PCWP of 18 mmHg, PA pressure of 38/20 mmHg, and cardiac index of 1.7 $L/min/m^2$. What is the next step?
A. Inotropic therapy and referral for LVAD and transplant
B. Hold β-blocker and diuretic therapy and encourage fluid intake
C. Add intravenous vasodilator then increase lisinopril dose to increase cardiac output

Question 22. The patient improves with inotropic therapy but deteriorates 2 weeks later. SBP is 75–80 mmHg. His cardiac index worsens (1.6 $L/min/m^2$) and his PCWP rises to 30 mmHg despite inotropic therapy. LVAD is placed. What is the likelihood of RV failure after LVAD placement (high or low), and what are the predictive variables?

Question 23. A 28-year-old man presents with chest pain, palpitations lasting 10 seconds, and mildly elevated troponin I (0.09 ng/ml). No HF is present on exam. ECG shows deep, biphasic anterior T waves. Coronary angiography shows normal coronary arteries. Echo shows normal LVEF and no pericardial effusion. CRP is normal but mild leucocytosis is present. What is the diagnosis, and how should it be confirmed?
A. MI resulting from a plaque rupture that has healed. Perform IVUS
B. Coronary vasospasm. Perform intracoronary acetylcholine testing
C. Mild acute myocarditis. Perform cardiac MRI

Question 24. Three weeks later, the patient of Question 23 presents with prolonged palpitations and dyspnea. ECG shows VT, which is successfully cardioverted. His ECG then shows intermittent Mobitz 2 AV block. EF has deteriorated to 25% (global hypokinesis) and the ventricular walls are unusually thickened. BP is 90/70 mmHg after cardioversion. Beside placing a transvenous pacemaker and initiating amiodarone, what is the most important next step?
A. Cardiac MRI
B. Endomyocardial biopsy
C. EP study and consideration for ICD

Question 25. A 38-year-old man presents with HF. He has a history of HTN and end-stage renal disease requiring dialysis for 2 years. HTN has always been well controlled. Echo shows severe biventricular hypertrophy, biatrial enlargement, restrictive LV filling, and a small pericardial effusion. ECG shows normal voltage in the limb leads, prominent voltage in the precordial leads, and short PR with delta wave. What is the diagnosis?
A. Hypertensive cardiomyopathy
B. Hypertrophic cardiomyopathy
C. Genetic amyloidosis (transthyretin gene deficiency)
D. Fabry disease
E. B, C, or D
F. Any of the above

Question 26. Had the patient in Question 25 not had renal failure, what would the most likely diagnosis be?
A. Hypertensive cardiomyopathy
B. Hypertrophic cardiomyopathy
C. Genetic amyloidosis (transthyretin gene mutation)
D. Fabry disease
E. B, C, or D
F. Any of the above

Question 27. A 41-year-old woman from Guatemala presents with dyspnea, orthopnea, and severe peripheral edema and ascites. She has a history of tuberculosis and a prior history of heavy menometrorrhagia. She had coronary angiography showing normal coronary arteries 3 years ago. On exam, BP is 110/50, pulse is 100 bpm, JVP is 15 cmH_2O, RV lift is present, S_2 is loud, and 3/6 murmur is heard at the left lower sternal border. Echo shows LVEF of ~45% with mild LV dilatation, marked RV dilatation, severe TR, and systolic PA pressure of 70 mmHg. On catheterization, RA and PCWP are severely elevated and equal (~20 mmHg with V wave of ~30 mmHg), and cardiac index is 4 L/min/m^2. BNP is 650 pg/ml. What is the most likely diagnosis?
A. Constrictive pericarditis (tuberculosis)
B. Restrictive cardiomyopathy
C. Pulmonary arterial hypertension with secondary RV failure and secondary TR
D. RV failure from intrinsic dysfunction, primary TR, or shunt
E. High-output HF

Question 28. A 50-year-old man presents with syncope followed by severe lightheadedness. He is found to have a monomorphic VT. After successful DC cardioversion, echo shows LVEF of ~35% with inferior wall akinesis. Coronary angiography shows normal coronary arteries. The patient continues to experience breakthroughs of VT despite amiodarone therapy. What is the diagnosis and the next step?
A. Ischemic scar related to prior cocaine use or vasospasm. Perform cardiac MRI
B. Sarcoidosis. Perform endomyocardial biopsy, cardiac MRI, or chest CT
C. Severe myocarditis, including giant-cell myocarditis. Perform endomyocardial biopsy or cardiac MRI
D. ARVD. Perform MRI
E. B or C
F. B, C, or D

Question 29. A 70-year-old woman with chronic systolic HF of ischemic origin presents with progressive dyspnea and edema. She receives chronic therapy with lisinopril, carvedilol, furosemide, and digoxin. Intravenous diuresis is initiated. Dyspnea improves, but the patient starts to experience fatigue, nausea, and anorexia on day 2. She notes a yellow vision once. On exam, BP is 120/75, pulse is 65 bpm, edema has resolved, and JVP is normal. Her creatinine has risen from 1.1 to 1.3 mg/dl and BUN has risen to 25 mg/dl. What is the next step?
A. Hold the diuretic
B. Reduce the dose of carvedilol
C. Discontinue digoxin
D. Administer a small saline bolus

Question 30. A 58-year-old man with ischemic cardiomyopathy, EF 20% and multiple hospitalizations with low-output HF is placed on chronic inotropic therapy. ACE-I and β-blockers are discontinued because of hypotension. On right heart catheterization, PCWP is 12 mmHg, and RA pressure is 16 mmHg, cardiac index is 2 L/min/m^2 at rest (on inotrope therapy). He has LBBB with QRS of 155 ms. What is the best device therapy?
A. LVAD
B. LVAD + RVAD
C. CRT

Question 31. A 65-year-old man presents with progressive dyspnea and fatigue. He has a history of well-controlled HTN. ECG shows sinus rhythm with complete LBBB, and echo shows LVEF of 35–40% with global hypokinesis, and severe pulmonary hypertension. Right heart catheterization confirmed severe pulmonary hypertension (PA pressure 75/35 mmHg) that is precapillary/arterial in nature (PCWP = 12 mmHg). Coronary arteries are normal. MRI shows delayed enhancement of the basal and inferolateral walls with inferior LV aneurysm. What is the most likely diagnosis?
A. Cardiac amyloidosis
B. Cardiac sarcoidosis. ICD is indicated
C. Cardiac sarcoidosis. ICD is not indicated
D. Idiopathic pulmonary arterial hypertension
E. Cardiac sarcoidosis. Endomyocardial biopsy is indicated

Question 32. A 62-year-old woman with no prior medical problem presents with chest pain and dizziness after an argument with a co-worker. She is hypotensive (80/55) and tachycardic (110 bpm). She has a loud mid-systolic murmur at the right upper sternal border. ECG shows 1 mm ST elevation in the anterior leads with T inversion. On catheterization, her coronary arteries are normal. Yet on the left ventriculography, she has anterior akinesis with EF of 30%, moderate MR, and a 45 mmHg pressure gradient between the LV and aorta. What is the next step?
A. This is likely a self-aborted STEMI. Place IABP temporarily for support
B. Place IABP and administer inotropic therapy
C. Check echo for AS and consider AVR ± MVR
D. Avoid IABP and administer α-agonist therapy

Question 33. A 33-year-old woman without prior medical history presents with fever and shock requiring norepinephrine. Bedside echo shows small ventricular chambers with severely reduced left and right ventricular function (LVEF ~20%). The patient remains hypotensive despite norepinephrine and dobutamine. A right heart catheterization shows severely elevated RA and LA pressures (20 mmHg and 30 mmHg, respectively), with a cardiac index of 1.8 L/min/m^2 despite inotropes. Coronary angiography is normal. What is the diagnosis and next diagnostic step?

Question 34. What is the next therapeutic step for the patient of Question 33?
A. Impella
B. LVAD
C. Extracorporeal biventricular VAD (CentriMag)
D. Venoarterial ECMO
E. C or D

Question 35. A 70-year-old man was recently admitted and treated for HFpEF. His creatinine is 1 mg/dl. His HTN is well controlled now, but he still has dyspnea NYHA III. His medications are furosemide 40 mg once daily, lisinopril, and metoprolol. On exam, he has no edema and JVP is normal. Which of the following is appropriate?
A. Add spironolactone to reduce HF hospitalization
B. Implant a CardioMEMS (PA monitor device). If PA pressure is elevated, increase the dose of diuretic or add a nitrate
C. Increase the diuretic dose
D. A and B

Question 36. A 62-year-old man with a history of HTN (on lisinopril and thiazide) presents with progressive dyspnea and peripheral edema. He is hypoxemic, with BP of 190/110 and a heart rate of 105 (sinus). Troponin is 0.15 ng/ml (2nd set 0.18 ng/ml), creatinine is 1.6 mg/dl, BNP is 1000 pg/ml. ECG shows LVH with lateral ST depression. Echo shows normal EF. Which of the following is *incorrect*?
A. Diurese then perform coronary angiography
B. This is acutely decompensated, hypertensive HFpEF. Diurese and administer intravenous NTG for persistent HTN, and institute oral anti-hypertensives in the first 24 hours
C. The troponin rise is not of coronary etiology
D. Obtain pre-discharge BNP and ensure it drops >30–50% before discharge
E. After discharge, patient should have follow-up with BNP reassessment. Consider CardioMEMS if class III symptoms persist

Question 37. A 69-year-old hypertensive, obese woman presents with dyspnea on exertion. BP is 150/90 mmHg and pulse is 100 bpm. Echo shows normal EF and grade 1 diastolic dysfunction. Right heart catheterization shows a normal mean PCWP at rest, but severe rise of PCWP and PA pressure with supine cycling. Cardiac output rose, but not enough, and stroke volume index did not significantly rise with exercise. She became hypoxemic with exercise. All of the following can improve her dyspnea, *except* which one?
A. The 2 most important interventions are weight loss and HTN control, both of which have lusitropic effects
B. Heart rate reduction with β-blocker therapy improves filling and stroke volume
C. O_2 therapy with exercise
D. Small dose of furosemide
E. Spironolactone

Question 38. Compared to HF in men, HF in women is associated with (may choose multiple answers):
A. Higher mortality in all subsets
B. Higher mortality in systolic HF only
C. Lower mortality overall, partly because of a higher prevalence of HFpEF
D. Lower mortality even in HFrEF, except in the ischemic subset (similar mortality)
E. More mortality benefit from CRT than in men
F. Less mortality benefit from ICD than in men

Question 39. A 68-year-old man, obese (BMI 38) and hypertensive, presents with severe dyspnea on exertion. BP 132/84, pulse 65, no edema, JVP normal. On echo, EF is normal, LA is mildly enlarged, E/E′ = 11, PA systolic pressure = 60 mmHg. What is the next step?
A. Add furosemide
B. Add SGLT-2 inhibitor
C. Right heart catheterization at rest and with exercise
D. NT-pro-BNP

Question 40. A 76-year-old man has a history of HFpEF and recurrent AF. He presents with severe dyspnea. SBP 110s–120s, and he is in sinus rhythm rate 90 bpm. He has no crackles on exam, and no peripheral edema. Creatinine 1.8 mg/dl on admission. With IV Lasix 80 mg Q8 hours, urine output is 1 L/day and creatinine is rising to 2.5 mg/dl. Lactic acid is 1.9 mg/dl. JVP 20 cm. What is the next step?
A. Initiate dobutamine
B. Stop furosemide and gently hydrate
C. Up-titrate furosemide to 200 mg IV Q6 hours, in combination with thiazide
D. Right heart catheterization to assess PCWP, CO, and RA pressure

Answer 1. D. The differential diagnosis of dyspnea includes diastolic HF or a combination of COPD, obesity, and deconditioning. LVH, LA enlargement, and the mild diastolic dysfunction suggest the possibility of diastolic HF. To establish the diagnosis of diastolic HF, beyond just diastolic dysfunction, one must prove high left-sided filling pressures at rest (≥3 out of the 4 echo diastolic markers), or if normal at

rest, high left-sided filling pressures at stress, whether by echo or catheterization. The mere presence of 1 or 2 diastolic markers does not prove diastolic HF. Stress may be performed using exercise testing or passive leg raising. Adenosine infusion is another option in the cath lab (increases LV preload). BNP measurement is an alternative testing. An elevated BNP >100 pg/ml, along with borderline echo abnormalities (LVH, LA enlargement, grade 1 diastolic dysfunction), is diagnostic of diastolic HF in the chronic setting (ESC). A BNP that ranges between 35 and 100 pg/ml is in the gray zone for chronic diastolic HF; BNP <35 may be used to exclude chronic diastolic HF (ESC).

Answer 2. D. The combination of normal LA size and normal diastolic function, especially normal E′, makes diastolic HF unlikely, but with high H2FPEF score, diastolic HF is still possible. This patient's H2FPEF score is 3, which is in the moderate range (see Figure 4.2). Obesity, HTN, and LVH imply that diastolic HF is a possible cause of the patient's dyspnea. Measure BNP and assess stress hemodynamics.

Answer 3. G. The loud S_2 implies pulmonary hypertension, while the persistent S_2 split in inspiration and expiration implies RV failure or RBBB (delayed closure of the pulmonic valve). The left parasternal lift implies RV enlargement. The large JVP V waves, and particularly the pulsatile liver, imply severe TR. Kussmaul's sign, wherein JVP further increases with inspiration, may be seen in constrictive pericarditis, or, commonly, severe RV failure. Causes A through F are all causes of RV failure. In this patient, RV failure is associated with pulmonary arterial or venous hypertension, and thus it is not intrinsic RV dysfunction or primary TR. Constrictive pericarditis is a mimic of RV failure, but severe pulmonary hypertension and large V waves make it unlikely. Also, the elevated BNP makes constrictive pericarditis unlikely. While the patient does not have clinical or X-ray signs of left HF, an overlooked left HFpEF is a common cause of RV failure, particularly at his age and with his history of HTN and CKD (lung findings are frequently absent in chronic left HF).

Answer 4. D. Frequently, HFpEF is characterized by a small and stiff LV, which, despite being hyperdynamic, has a limited filling reserve and thus limited stroke volume reserve. In fact, a small LV does not contradict the diagnosis of HFpEF. Cardiac catheterization will be done to:

1. measure PCWP and LVEDP, seeking a diagnosis of left HF—if left HF is absent, the diagnosis of pulmonary arterial hypertension is made;
2. perform oximetry run to diagnose left-to-right shunt.

In the absence of left HF, TEE is reasonable to further investigate a left–right shunt. This patient was eventually diagnosed with a sinus venosus ASD, missed by TTE. Oximetry run confirmed a shunt and TEE made the diagnosis. ASD and anomalous pulmonary venous return are forms of left-to-right shunt that may manifest late in life, as LA pressure rises and leads to more shunting. This patient's LA enlargement is not caused by the ASD shunt, but it is relevant in ASD as it causes an amplification of the shunt.

Answer 5. A. This is restrictive cardiomyopathy with severely elevated right- and left-sided pressures. RV is dilated and RV failure is more prominent clinically and echocardiographically than LV failure, as is common in restrictive cardiomyopathy, but the LV is failing as well (LVEDP ≥ RVEDP).

Answer 6. D. The patient has a picture of hypotension (SBP < 90) and low-output state; he is not likely to respond to standalone diuretic therapy. BP <100–110 mmHg is a contraindication to acute vasodilator therapy in decompensated HF. While inotropic therapy will not help the LV, which is small with limited diastolic filling rather than limited contractile reserve, it will help the severely dysfunctional RV. More importantly, in a patient whose systolic PA pressure matches the systemic pressure, the RV is not perfused (50% of RV perfusion occurs in systole and depends on the gradient between SBP and RV systolic pressure, which is only 10 mmHg in this case). Thus, inotropic therapy, besides improving RV contractility, must raise systemic pressure to improve RV perfusion, hence the preferred therapy is norepinephrine. Once inotropic therapy is started, the patient will respond to diuretic therapy. Diuresis will further improve ventricular perfusion by reducing RVEDP and LVEDP, and improve cardiac output by reducing RV–LV interdependence and functional TR.

Answer 7. 70–75%.

Answer 8. A. The new AF is likely the decompensating factor for HF. However, once HF is decompensated, the atrial kick (if restored) would not contribute much to the ventricular filling (see Figure 4.2, and *Acute heart failure and acutely decompensated heart failure*, Section III). In addition, some degree of tachycardia may be compensatory in ADHF, up to 110–120 bpm. The best strategy is to treat HF with diuretic therapy, which will indirectly slow AF, and initiate digoxin therapy. In the acute setting, the goal heart rate is < 110 bpm; if needed, amiodarone may be added temporarily, the first day, for rate control. Eventually, 1 or 2 days later, once HF has improved, β-blocker therapy may be initiated or up-titrated to achieve a better rate. A few days later, AF may be cardioverted after TEE rules out LA appendage clot. The total 24-hour dose of intravenous furosemide used in ADHF is ~2.5 times the chronic oral daily dose. The dose is adjusted according to the diuresis goal (negative balance of 2–3 liters/day). IV nitroglycerin may be administered; however, BP may precipitously fall with diuretic therapy after relieving the distress of pulmonary edema. Nitroglycerin is better reserved for a patient who remains hypertensive after the initial diuretic administration.

Answer 9. B. A patient with ADHF is expected to have a compensatory increase in heart rate. A heart rate <55–60 bpm during decompensation is inappropriate and implies a loss of chronotropic reserve. This may be a factor contributing to the HF decompensation. While carvedilol is generally continued in ADHF, it may be reduced in this case of inappropriate bradycardia.

Answer 10. B. The patient has ADHF, wet and cold category, with narrow pulse pressure and acute kidney dysfunction. His SBP is >90 mmHg, and thus inotropic therapy does not absolutely need to be initiated on admission. Yet, considering the poor cardiac output, the patient may not respond to diuretic therapy, in which case inotropic therapy is initiated. Lisinopril needs to be discontinued because of the acute severe azotemia. Carvedilol needs to be reduced because of the severity of ADHF (low-output state with borderline BP). If an inotrope needs to be started, carvedilol is fully interrupted.

Answer 11. B. The patient is still congested, and thus the rise in creatinine is due to the congestion itself rather than diuresis (acute cardiorenal syndrome). With further diuresis, creatinine level improves in most congested patients. In fact, creatinine level correlates with RA pressure and renal venous afterload more than cardiac output.

Answer 12. D. Note that, as compared to Question 11, this patient is a stable outpatient with no volume overload on exam. The rise in BUN and creatinine likely represents hypovolemia from furosemide. This is evidenced by the dizziness, orthostatic hypotension, and the more striking rise of BUN than creatinine in the absence of congestion. The renal injury is aggravated by the initiation of ACE-I. The diuretic may be held for 2 days then resumed at a lower dose. While unlikely to be a culprit for this creatinine rise, lisinopril is still held for a few days to allow renal recovery.

Answer 13. E. Note that, as compared to Question 12, the patient is not dizzy and does not appear hypovolemic. Moreover, the rise in creatinine is within the acceptable range (<0.5 mg/dl, < 50%). Such a rise in creatinine may be related to the low output/low BP/low kidney perfusion state aggravated by ACE-I initiation. This early rise in creatinine after ACE-I initiation is not associated with a loss of benefit from continued ACE-I therapy, and renal function largely recovers on follow-up. The patient is not hypovolemic, so furosemide does not have to be reduced; in some instances, one may choose to reduce the furosemide dose, in a long-term fashion or for 1 or 2 days to allow better tolerance of ACE-I initiation.

Answer 14. E. The rise in creatinine is not due to hypovolemia, nor a direct effect of lisinopril. It is due to a symptomatic hypotension that was triggered by the combination of all the drugs. Orthostatic hypotension, in this case, is due to the interruption of the autonomic baroreceptor reflex by carvedilol and ACE-I, atop of the limited cardiac output reserve, rather than hypovolemia. Since the patient still shows signs of hypervolemia, furosemide should be continued. Since creatinine rose <50%, lisinopril does not need to be discontinued. Mild dizziness and hypotension will likely resolve spontaneously with continued therapy, but it is wise to hold carvedilol and re-initiate it 1–2 weeks later. The timing of drug intake should be staggered.

Answer 15. B. Without a history of a recent large MI, the anterior wall is likely hibernating rather than infarcted and revascularization is likely helpful. Stress testing is not needed and does not predict the benefit from CABG, as per STICH trial, but assesses for the following when it is done: (i) large reversible defects imply extensive ischemia and a definite benefit from revascularization; (ii) also, a moderate fixed defect (>50% nuclear uptake), particularly with no Q waves, or exertional ST changes or chest pain often implies hibernation and ischemia rather than infarction. Thus, CABG is indicated in this patient.

Answer 16. B. Based on STICH trial and PARR-2 trial, viability testing does not predict post-CABG outcomes. Q waves do not exclude the potential benefit from CABG and were not an exclusion criterion from the latter trials. If viability testing is done, global viability is sought when deciding about CABG. Global viability implies that 4 of the dysfunctional segments, in this case anterior segments, are viable (4 segments correspond to ~25% of the whole LV).

Answer 17. A. The patient has acute myocarditis with manifestations of pericarditis (rub, pain, ST elevation) and severe HF/cardiogenic shock. This myocarditis is very severe. It may be reversible (fulminant myocarditis) or irreversible (giant-cell myocarditis). It may also be a hypersensitivity eosinophilic myocarditis. IABP needs to be immediately placed for support, and endomyocardial biopsy needs to be done. This patient will need LVAD or ECMO support as a bridge to recovery (fulminant myocarditis) or bridge to transplant (giant-cell myocarditis). The choice of LVAD vs. ECMO is based on the degree of RV failure (if severe → ECMO). Percutaneous LVAD may be used (Impella). Immunosuppressive drugs may be used if the biopsy reveals giant-cell myocarditis; steroids may be used for eosinophilic myocarditis.

Answer 18. C. The clinical picture suggests severe left and right HF. Echo suggests a restrictive process, which may result from hypertensive disease, HCM, or infiltrative disease. Hypertensive cardiomyopathy is unlikely, as the ECG shows a disproportionately low QRS voltage and pseudo-Q waves. The latter suggest that myocardial thickening results from infiltration rather than hypertrophy. Amyloid cardiomyopathy is suspected (TTR amyloidosis → cardiac scintigraphy with Technetium pyrophosphate; AL amyloidosis → protein immunofixation studies seeking monoclonal peak). The pressure–volume relationship is very steep, and thus LA pressure may be elevated despite a normal or even reduced LV volume. Diuresis may further reduce stroke volume and must be gentle. The very limited stroke volume reserve in advanced HF, particularly amyloidosis, may lead to profound hypotension with vasodilator therapy, as stroke volume cannot rise to match the dilated circulation. Also, this limited stroke volume makes cardiac output dependent on heart rate and explains the intolerance to β-blockers.

Answer 19. E. The exam is consistent with RV failure. This may be due to isolated RV failure (from pulmonary arterial hypertension or shunt), restrictive cardiomyopathy, or constrictive pericarditis. Heart catheterization is useful for the diagnosis of all the prior diagnoses. Fat pad biopsy (amyloidosis) and iron studies (hemochromatosis) are useful for the diagnosis of restrictive cardiomyopathy. Chest CT and tuberculin testing are useful for the diagnosis of constrictive pericarditis and pulmonary disease. Coronary angiography is not useful as CAD does not explain severe restrictive cardiomyopathy.

Answer 20. C. The patient has a cold picture without clear congestion on exam (possibly dry and cold). Cardiac output is significantly reduced, as evidenced by the narrow pulse pressure, tachycardia, lethargy/fatigue, cachexia, and rise in creatinine. Right heart catheterization helps confirm the low cardiac output and define his filling pressures (→ need to hold the diuretic if filling pressures are low vs. need for inotropes).

Answer 21. A. The patient's right filling pressure is normal while the left is mildly elevated. His symptoms are due to the reduced cardiac output. In fact, besides the low cardiac output at rest, the cardiac output reserve is severely impaired with inability to augment cardiac output with exertion. Cardiopulmonary stress testing can confirm this inability to increase cardiac output and O_2 consumption, which would remain <14 ml/kg/min at anaerobic threshold. At this stage, since inotropic therapy is considered, carvedilol may be withheld. The issue is cardiac function rather than hypovolemia, hence holding the diuretic or administering fluid will not help. The lack of BP decline with Valsalva implies that the LV is at the flat portion of the Starling curve and is not fluid responsive. Vasodilators are unlikely to be tolerated in patients with such limited cardiac output reserve. Vasodilatation without any capacity to raise cardiac output leads to severe hypotension.

Answer 22. RV failure is a common complication after LVAD placement and is predicted by the baseline RV function. In this case, RA pressure is <0.63 × PCWP, and RV stroke work index, a measure of the overall RV performance, is >300 (stroke work index = stroke volume index × [mean PA – RA pressure] = 306). Thus, RV failure is not likely.

Answer 23. C. The patient has acute myocarditis presenting as a chest pain syndrome (pericarditis syndrome). It is mild as EF is normal and no HF is present. A and B may explain the patient's presentation but are less likely in light of the normal coronary arteries. The ECG of myocarditis may show diffuse pericarditis findings but may also show focal findings and a pseudoinfarction pattern as in this case (Q waves and focal ST elevations may be seen).

Answer 24. B. The severe, rapidly progressive myocarditis with VT and AV block in a young patient is concerning for giant-cell myocarditis. The differential diagnosis also includes cardiac sarcoidosis, necrotizing eosinophilic myocarditis, and fulminant non-giant-cell myocarditis, which are more likely to recover after supportive therapy. The thick walls are consistent with the edema of hyperacute myocarditis. He has a class I indication for endomyocardial biopsy (sensitivity of 85% for giant-cell myocarditis). If giant-cell myocarditis is confirmed, a downhill course is expected, and thus immunosuppressive therapy is initiated and VAD and cardiac transplantation are considered. If lymphocytic myocarditis is found (clinically fulminant form), improvement is expected but the patient may require aggressive hemodynamic support.

Answer 25. D.

Answer 26. E. Ventricular hypertrophy at a young age, without severe HTN, should suggest hypertrophic or infiltrative cardiomyopathy, rather than hypertensive cardiomyopathy, especially when hypertrophy is biventricular. The accessory pathway is further suggestive of a primary cardiomyopathy. The ECG is consistent with hypertrophic cardiomyopathy or Fabry (high voltage) rather than amyloidosis. Renal failure may be seen in systemic amyloidosis and in Fabry disease, but not in genetic amyloidosis.

Answer 27. E. The patient has congestive signs of right HF, which may be seen with any of the cases A through E. However, the wide pulse pressure is only characteristic of a high-output HF. Catheterization shows biventricular failure with equalization of RA and PCWP. This may be seen with constrictive pericarditis or restrictive cardiomyopathy; however, both conditions are characterized by a low cardiac output and a non-dilated LV. Also, constrictive pericarditis is unlikely in the presence of large V waves, severe pulmonary hypertension, and elevated BNP. In this patient with biventricular failure, cardiac index >3.5 L/min/m^2 is diagnostic of high-output HF, which may be due to chronic severe anemia. TSH and thiamine need to be checked, and fistulas should be sought by physical exam, especially at the site of the prior femoral access.

Answer 28. E. The patient has a non-ischemic cardiomyopathy that is prone to frequent recurrences of VT. This is most suggestive of one of the following 4 entities: hyperacute myocarditis, sarcoidosis, ARVD, or Chagas disease. ARVD is unlikely in the absence of RV involvement. Segmental wall motion abnormalities may be seen with any non-ischemic cardiomyopathy, especially sarcoidosis, myocarditis, or Chagas disease.

Answer 29. C. The patient's fatigue and creatinine rise may be related to excessive diuresis. However, it is more likely that, with diuresis and the rise in creatinine, less digoxin is excreted and the patient is experiencing digoxin toxicity (nausea, visual halos). This should always be considered in a patient receiving chronic digoxin therapy who is admitted with an acute condition. Older women with a small body mass are particularly susceptible to the rise in digoxin level. In fact, digoxin level should have been checked before symptoms of toxicity developed. If digoxin level is >1.1 ng/ml, 1 or 2 doses are held and a lower maintenance dose is initiated.

Answer 30. B. CRT is beneficial in patients with class IV symptoms who are still ambulatory. CRT is not indicated in inotrope-dependent patients, although some data indicate that the latter patients with QRS>150 ms derive a dramatic benefit from CRT.[167] RA pressure is higher than PCWP, implying severe RV failure. This is a contraindication to isolated LVAD therapy, as RV failure worsens following LVAD placement.

Answer 31. B. LBBB may be seen with any cardiomyopathy. However, the basal delayed enhancement is highly suggestive of cardiac sarcoidosis. In context, the pulmonary arterial hypertension also supports the diagnosis of sarcoidosis. Endomyocardial biopsy is poorly sensitive for sarcoidosis (~25%), as the septal involvement is basal. The most common cause of death is arrhythmia, and ICD is indicated whenever late gadolinium enhancement is present, even if EF >35%. Chest CT is indicated to look for noncardiac involvement.

Answer 32. D. The patient has takotsubo cardiomyopathy, with ECG changes mimicking STEMI and a clinical presentation mimicking ACS and cardiogenic shock. The hypercontractile LV base leads to LVOT obstruction and a sucking effect on the anterior mitral leaflet, hence the MR. The murmur and pressure gradient are due to dynamic LVOT obstruction, not AS (the lack of aortic valve calcium and the shape of the LV-aortic tracings help make that distinction). Inotropic therapy and afterload reduction (e.g., IABP) will worsen LVOT obstruction, hypotension, and MR. If needed, α-agonist may be used until the patient stabilizes. These patients typically stabilize quickly.

Answer 33. The patient likely has severe, progressive myocarditis: either lymphocytic fulminant myocarditis (will eventually reverse) or giant-cell myocarditis (will keep progressing). An endomyocardial biopsy is indicated.

Answer 34. E. The patient is in refractory cardiogenic shock with biventricular failure. Temporary devices are preferred to implantable devices, as the condition may be reversible (bridge to recovery or bridge to decision). Biventricular support is preferred to LV Impella. ECMO may be used for a few days, while CentriMag may be used for weeks. CentriMag requires surgical placement of the cannulae in the cardiac chambers.

Answer 35. D. The TOPCAT trial strongly suggests that spironolactone reduces HF hospitalization in HFpEF. In a patient who appears euvolemic clinically, increasing the diuretic dose should be guided by objective measurement of PA pressure or left-sided filling pressure, or BNP, rather than just symptoms.

Answer 36. A. The patient has acutely decompensated, hypertensive HFpEF. The troponin rises to a mild degree (<0.5–1 ng/ml) without a typical rise-and-fall pattern (<20–50%) and without other features supportive of NSTEMI. The ST depression is consistent with LVH strain pattern. Ischemia is secondary to HF and HTN, rather than the cause of HF. Coronary angiography is not absolutely indicated.

Answer 37. B. The LV cavity is small and stiff and is unable to dilate and accept the increased venous return (limited preload reserve). It is unable to use the Frank–Starling mechanism, wherein a higher preload raises stroke volume. It does not accept preload, which backs up in the pulmonary circulation. Hence, LV is unlikely to increase its preload with β-blocker therapy, and cardiac output may worsen, as it is totally dependent on heart rate rather than stroke volume. Diuretic therapy would prevent some of the exertional rise in filling pressures and improve dyspnea but may reduce stroke volume and cause dizziness; it is tried carefully. Spironolactone has the additional benefit of improving LV diastolic function (AldoHF). Exertional hypoxemia may be partly related to HF but is mostly related to a lack of appropriate rise of ventilation during exercise (obesity).

Answer 38. C, D, E, and F. HF has a lower mortality in women than men, partly because HF is less often systolic in women. Yet even systolic HF has a better prognosis in women, as it is more often non-ischemic; ischemic systolic HF has similar mortality in men and women.[314] Women derive more mortality benefit from CRT than men, partly because of the higher prevalence of LBBB and non-ischemic cardiomyopathy in women.[315]

Answer 39. C. The patient has a high H2FPEF score (5), and thus he likely has HFpEF. Had PA pressure not been severely elevated (e.g., 35–50 mmHg), the likely diagnosis would be HFpEF and furosemide and/or SGLT-2 inhibitor may be started empirically. However, because PH is in the moderate to severe range, right heart catheterization is needed to distinguish pre-capillary PH from a likely post-capillary PH or combined PH with elevated PCWP. IF PCWP is normal at rest, as suggested by E/E′, exercise PCWP is required in this patient with many HFpEF risk factors to rule out a post-capillary component.

Answer 40. C. This patient has advanced-stage HFpEF with severe RV failure as complication of prolonged undertreated HFpEF and pulmonary hypertension. RV failure may also be aggravated by a component of functional TR, whether ventricular-functional TR from RV failure itself (which begets a vicious circle of more RV failure), or atrial functional TR from AF. Crackles are insensitive and non-specific for assessment of left HF. Peripheral edema is specific for HF in the right setting, but insensitive, as >3–4 liters of volume overload is required to see it, and some patients have a propensity for ascites more than lower extremity edema.

Patients with RV-LV failure have a higher risk of acute renal failure than isolated LV failure. This is due to: (1) elevated RA pressure directly impacts renal afterload and perfusion, and is the biggest predictor of cardiorenal syndrome; (2) LV compression with dramatic reduction of LV filling and LV transmural pressure despite a severe rise in LVEDP. Some worry that diuresis may further reduce preload of the underfilled LV, but diuresis is actually very helpful to counteract (1) and (2), and improve LV filling and LV output. Even LV contractility is improved, as paradoxical septal motion is reduced and the septum contributes to LV output, instead of shifting paradoxically toward the RV in systole. Moreover, RV output is improved by reducing RV preload and shifting it away from the descending limb of Starling curve (Figure 5.3). Thus, diuresis is justified by this isolated finding of elevated JVP, and it is best to confirm the elevated JVP via ultrasound. Right heart catheterization will not alter management at this stage; the addition of inotropes is dictated by the lack of response to diuretic up-titration, or by worsening SBP (<90 mmHg) along with poor diuretic response.

Questions and answers 204

1. SPECIFIC CARDIOMYOPATHIES

I. Arrhythmia-induced cardiomyopathy

The 3 forms of arrhythmia-induced cardiomyopathy (A, B, C) are reversible within 2–12 weeks of arrhythmia control and are not usually associated with significant LV scar. The arrhythmia may be the sole cause of the cardiomyopathy or, in a patient with underlying cardiomyopathy, it aggravates it and further reduces EF.

A. Tachycardia-induced cardiomyopathy

Biventricular dilatation then failure may develop with any uncontrolled tachyarrhythmia that persists for over 2 weeks (range: 3 days to 6 months). This ventricular failure results from cytosolic calcium overload but also depletion of energy stores; in a way, it is a form of

ischemic hibernation. Both LV and RV dilate with mild thinning and no hypertrophy. While faster rates increase the risk and speed of its occurrence, this cardiomyopathy may be observed with chronic rates of only 105–110 bpm, rates that are usually well tolerated chronically and do not come to medical attention until the patient develops HF. It is seen with uncontrolled AF, atrial flutter, atrial tachycardia, or the slow and incessant form of AVRT (PJRT).[1] *Interestingly, the tachyarrhythmia may not be persistent; tachycardia that occurs over 10–15% of the day may cause a cardiomyopathy*.[2]

A newly diagnosed tachyarrhythmia at a rate >105–110 bpm, coinciding with HF exacerbation, suggests the possibility of tachycardia-mediated cardiomyopathy.[3,4] This is the case in 50% of new–onset AFs or atrial arrhythmias coinciding with a new HF presentation.[2,4,5] *Also, the persistence of the fast heart rate after diuresis and HF improvement suggests this diagnosis*.

After HF is treated (diuresis) and compensated, the tachyarrhythmia is targeted with a *heart rate goal <100 bpm* (as good as a goal <80 bpm based on RACE-II HF substudy, substudies of β-blockers in HF, and Swedish HF registry).[6] In addition, rhythm control is attempted (e.g., ablation for atrial flutter and atrial tachycardia, DC cardioversion and ablation or antiarrhythmics for AF). This cardiomyopathy usually reverses several weeks after rhythm control, typically between 2–12 weeks (initial improvement of LV contractility, followed by LV size reduction).[1,4] Rate control only achieves marginal improvement. Residual ultrastructural abnormalities persist, explaining a *fast recurrence of LV dysfunction with recurrence of the arrhythmia*.

B. PVC-induced cardiomyopathy

Frequent PVCs, with a *burden of >10%* of the patient's total rhythm on a Holter monitor, may lead to LV dilatation followed by reduced EF. ***About 7–30% of patients with a PVC burden >10% develop cardiomyopathy***, particularly when the PVC burden is >24%.[3,7] In a canine model, half the canines with an induced PVC burden of 33% developed cardiomyopathy. This cardiomyopathy generally develops slowly, over months or years, and resolves 2–12 weeks after ablation.

PVC-induced cardiomyopathy is partly explained by calcium mishandling. Normally, calcium is pumped into the cytosol in systole, triggering actin-myosin cross-bridging; it is then actively pumped out in diastole. When 2 close systolic cycles occur, as is the case with PVC, calcium is not pumped out effectively and cytosolic calcium overload occurs. Post-PVC contraction initially increases, but calcium channels are eventually downregulated leading to an eventual reduction in contraction; also, the pause initiates a harmful catecholamine activation. However, calcium and catecholamine overload cannot be the sole mechanism, as ***frequent PACs with similar heart rate irregularity do not induce cardiomyopathy***.[3,8,9] In fact, the degree of LV dyssynchrony induced by the PVC is a major predictor of LV dysfunction, explaining why PVCs with QRS>150 ms (or PVCs originating from the epicardium) more readily induce cardiomyopathy, mimicking RV pacing.[3,9] Variable coupling intervals create more irregularity and more risk of cardiomyopathy. Also, AV dyssynchrony in PVC, i.e., atrial contraction against a closed valve, further reduces cardiac output and EF and causes a cannon A wave; this is more prevalent with shorter coupling intervals of <450 ms.[10] Pulse deficit during the PVC (inability to generate stroke volume) and marked post-PVC potentiation also predict PVC-induced cardiomyopathy, as they indicate a reduction of LV output and, consequently, backup of volume in the LV: this is more marked with short coupling intervals.[11]

Conversely, *the more extreme irregularity of AF may induce cardiomyopathy solely through a more sustained calcium mishandling*. Also, the sustained tachycardia of tachycardia-induced cardiomyopathy results in a more pronounced calcium overload than PVC-cardiomyopathy.[12]

Of note, fibrosis and apoptosis do not usually occur with PVC-cardiomyopathy, and only functional and electrical remodeling occurs;[3,7] mild fibrosis may be seen with tachycardia-induced cardiomyopathy (ischemic process) and more questionably, AF-induced cardiomyopathy.

In patients with cardiomyopathy and frequent PVCs >10%, PVCs are the cause of the cardiomyopathy or an aggravating factor in ~85% of the cases. Lack of scar on MRI, younger age and lack of CAD/comorbidities, monomorphic PVC pattern (rather than multifocal), and global hypokinesis favor the role of PVCs. Post-PVC potentiation, with increased SBP and pulse pressure by 10 mmHg after a PVC, strongly predicted LV recovery with ablation in one study.[10]

Holter monitoring, preferably for 6 days, is performed to quantify PVC burden. Before the development of cardiomyopathy, frequent symptomatic PVCs may be treated with β-blockers or verapamil, keeping in mind a limited efficacy of 10–24%; alternatively, class Ic drugs (flecainide) are highly effective (>70–90%).[3] Spontaneous reduction of PVC burden may also occur (12% in one study, CHF-STAT, but up to 44% in another at ~15 months).[13,14]

Once cardiomyopathy develops, the options are limited to ablation vs. amiodarone or flecainide therapy, all of which are highly effective in suppressing PVCs (70–80% efficacy, defined as reducing the burden >80%).[3,13] While classically contraindicated in LV dysfunction because of the CAST trial, flecainide has been shown to be safe and highly effective in non-ischemic cardiomyopathy with high PVC burden, with or without ICD, and may be considered (>90% efficacy in reducing PVC burden) (class IIa ESC).[15,16] Also, *bilateral cardiac sympathetic denervation* has been highly successful in patients with refractory PVCs and non-ischemic cardiomyopathy who have failed catheter ablation.[17]

Asymptomatic frequent PVCs with normal LV do not have any indication for therapy. Since cardiomyopathy is reversible, aggressive preventive therapy is not warranted.[3] A watch-and-wait approach is adopted, with LV monitoring every 6–12 months.

C. AF-induced cardiomyopathy (see Chapter 10, Section VIII, and Chapter 6)

AF may induce a low EF through a fast ventricular rate, i.e., a form of tachycardia-induced cardiomyopathy. However, even when rate controlled, AF, per se, may induce LV systolic dysfunction. This is partly related to: (a) loss of atrial contribution to LV preload and stroke volume; (b) pronounced irregularity that blunts stroke volume on short R-R intervals: for the same heart rate, an irregular rhythm generates lower cardiac output and creates significantly more calcium mishandling and overload than a regular rhythm.[3,12] ***In fact, in patients with rate-controlled AF and HF, AF ablation improves EF by 10–18% and normalizes EF in 58% of patients*** (e.g., CAMERA-MRI trial).[18] Patients with AF, no LV scar on MRI, and a persistently low EF despite rate control are suspicious for AF-induced or aggravated cardiomyopathy.

In addition, AF may cause severe functional MR or TR, the so-called atrial functional MR or TR, driven by progressive atrial dilatation. Atrial MR and TR develop at the rates of ~2.5% and 1.3% per year, respectively, and improve with AF rhythm control.

D. LBBB-induced cardiomyopathy

Patients with isolated LBBB and no associated myocardial or coronary disease may develop a dilated cardiomyopathy secondary to LV dyssynchrony. This likely occurs in a minority of patients with LBBB (<5–10% in 1 study vs. 17–30% in less selective registries), over years to decades (mean 4.5–11.6 years),[19–21] particularly when LBBB is very wide ≥150 ms. This is supported by several data:

- Long-term follow-up of middle-age patients with isolated LBBB shows a 2-to-3-fold higher risk of HF (Swedish and Framingham data).[22,23]
- About 20–25% of patients with low EF and LBBB are super-responders to CRT, i.e., EF normalizes with CRT, suggesting that dyssynchrony is the primary cause of the cardiomyopathy. This is more likely the case in women with non-ischemic cardiomyopathy and LBBB ≥150 ms.[19,24]
- In a retrospective analysis of cardiomyopathy with LBBB, standard HF therapy did not improve EF.[24]

E. RV pacing–induced cardiomyopathy

Similarly to LBBB, RV pacing induces inter- and intraventricular dyssynchrony, which may worsen LVEF and increase LV volume. Even in patients with normal EF, RV pacing is associated with an ~7% reduction in EF vs. CRT; ~9% of patients with normal EF have EF reduction to <45% within 1 year of RV pacing.[25] Other data suggest that the incidence of RV pacing–induced cardiomyopathy is 12–20% after 1–5 years.[26,27] This applies to patients who are frequently RV paced, i.e., >20–40% of the time. Therefore, RV pacing induces deleterious mechanical dyssynchrony even in patients with normal EF. This effect is only expected to be more prominent in patients with reduced EF.

CRT prevents this deleterious negative remodeling and is associated with better symptom and HF control in patients with normal or low EF, as has been shown in patients with permanent AF requiring AV junctional ablation.[28,29] Another randomized study (BLOCK HF) addressed patients with EF ≤ 50% and HF functional class I–III requiring ventricular pacing for AV block and showed that CRT reduces HF hospitalization and LV remodeling in comparison with RV pacing.[30] Alternatively, pacing at the His level or the left bundle branch area, rather than the RV apex, allows a physiological, simultaneous activation of both ventricles without dyssynchrony and may be considered instead of CRT.[31–33]

Therefore, CRT or conduction system pacing is recommended in patients with EF ≤ 50% requiring ventricular pacing >20% of the time for AV block, regardless of the functional class (class IIa recommendation); this also applies to AF patients requiring AV nodal ablation and patients who already have RV pacemaker and suffer EF decline to ≤50% (HRS), especially ≤35% (BUDAPEST-CRT trial).[34,35] *CRT upgrade in patients who already have a pacemaker is more risky than de novo CRT implantation in pacing-naive patients, which may justify a lower EF cutoff ≤35% for CRT upgrade*: in BUDAPEST-CRT, CRT upgrade reduced death and HF by >60%.

The application of BiV pacing to patients with normal EF requiring ventricular pacing is premature, but those patients require echo follow-up to check for any ventricular deterioration and may be considered up front for His or left bundle branch area pacing (HRS class IIb).

II. Viral myocarditis

There are several forms of viral myocarditis:

- ***Subclinical myocarditis*** signifies asymptomatic myocarditis (no HF). It is usually self-limited, but a minority of patients develop chronic HF and are diagnosed years later with idiopathic dilated cardiomyopathy.
- ***Clinical myocarditis*** implies myocarditis that manifests clinically with HF or with signs of pericarditis. It can take several forms:

a. ***Myopericarditis*** presents clinically as pericarditis with normal LV but with ↑ troponin – ***Mild acute myocarditis*** presents with LVEF of 40–50% and sometimes mild HF, along with acute pericarditis signs. It usually recovers, in >90% of the patients, within weeks or months.[36]
b. ***Severe acute myocarditis*** is a myocarditis that manifests as HF or significant LV dysfunction. It reverses in ~35%, significantly improves in ~40%, and progresses to a more severe HF in ~25% of patients.[37] The overall 5-year mortality of patients with persistent HF is similar to idiopathic DCM (~50%).[38]
c. ***Very severe acute myocarditis (fulminant)*** manifests as severe HF of recent onset (typically 2 weeks) with cardiogenic shock or ventricular arrhythmias, usually with a *normal-size LV* that has not had time to dilate and with *severe thickening of the ventricular walls from edema*, sometimes leading to low QRS voltage. There are two forms of very severe myocarditis: (i) ***fulminant lymphocytic myocarditis***, in which the patient is unstable acutely but often fully recovers if appropriately supported with vasopressors or ventricular assist devices, as the process mainly consists of myocardial depression by cytokines rather than necrosis (the long-term prognosis was excellent in old registries, with >90% survival at 10 years, but not as good in a contemporary registry, 80% at 60 days);[39–41] (ii) ***giant-cell myocarditis***, in which autoimmune myocardial destruction occurs and the illness continues its aggressive downhill course and intractable ventricular arrhythmias occur; multinucleated giant cells are seen (of histiocytic origin). These very severe forms are seen in young patients with aggressive immune systems.

Myocarditis is associated with 2 types of clinical manifestations:

- *New LV dysfunction/HF*, which may evolve through 3 stages: (i) progressive LV dysfunction, (ii) HF of progressive severity, (iii) shock or malignant arrhythmias (AV block or sustained VT).
- *A syndrome mimicking MI* may be seen with any acute or hyperacute myocarditis, along with pericarditic chest pain and ECG changes, increased CRP, and an inflammatory pericardial effusion. ***ECG changes may be diffuse, similar to acute pericarditis, or more localized, mimicking STEMI, particularly inferolaterally (local myocarditis with "pseudoinfarction" pattern)***. Coronary angiography frequently needs to be performed to rule out CAD in these patients with ST elevation and troponin rise.

In a patient presenting with acute HF and no CAD, a large troponin rise, higher than seen with HF, is a hint to myocarditis. LV dysfunction is often global but may be segmental.

In young patients with AV block or VT, consider: sarcoidosis, ARVD, myocarditis (such as giant cell or eosinophilic myocarditis), lamin A/C mutation, and Chagas disease. They have a predilection for arrhythmia even before overt myocardial disease.

Diagnosis and treatment

A definitive diagnosis of myocarditis is made by endomyocardial biopsy: lymphocyte-rich inflammatory infiltrate *and* myocyte necrosis or degeneration (Dallas criteria); or positive viral genome on molecular analysis. Because of patchy myocardial involvement, the biopsy only has a 35–50% sensitivity. The yield is higher (85%) in giant-cell myocarditis, where the myocardium is more diffusely involved and multinucleate giant cells are seen. *Biopsy is only indicated in cases of very severe myocarditis with shock or VT*, in which case ***fulminant lymphocytic myocarditis*** (reversible) and ***eosinophilic myocarditis*** (treatable and reversible) need to be distinguished from the downhill progressive ***giant-cell myocarditis***. In the latter, 2 to 3 of the following are generally administered: prednisone, mycophenolate, azathioprine, cyclosporine, muromonab. LVAD and transplant are considered for unresponsive patients. Immunosuppressive therapy has significantly improved the prognosis of giant cell myocarditis, with transplant-free survival rates of 69% at 1 year and 58% at 5 years.[42,43]

Regarding *lymphocytic myocarditis*, steroids+/– azathioprine are considered, but only *for severe clinical HF* or *refractory LV dysfunction*: 3 old randomized trials failed to show any benefit from steroids in acute myocarditis,[44] but 2 trials showed that prednisone (initial 1 mg/kg/day) combined with azathioprine dramatically improves EF and symptoms in select patients with biopsy-proven acute lymphocytic myocarditis, negative viral PCR (i.e., immune myocarditis with no active viral infection), and persistently reduced EF at >6 months (EF improved from 26% to 46% with immunotherapy).[44–46]

In patients acutely presenting with chest pain, troponin rise, and ST abnormality (diffuse or focal), a presumptive diagnosis of perimyocarditis is made after coronary angiography rules out CAD, in the absence of a takotsubo pattern of LV dysfunction.

MRI has emerged as a useful modality for the diagnosis of myocarditis and is particularly useful in *new severe unexplained HF* or in cases mimicking *acute MI* (Lake Louise criteria):[47] (i) increased T2 signal indicates edema (acute inflammation), (ii) late gadolinium enhancement (LGE) on T1 indicates cellular necrosis and/or scarring; (iii) increased T1 signal on T1 map before gadolinium injection indicates increased extracellular volume, in this case from *hyperemia and capillary leak*; further increased T1 signal on early gadolinium enhancement also indicates high extracellular volume and allows calculation of extracellular volume ratio (high >35%). (i) + (ii) or (iii) is diagnostic of myocarditis. These findings ***tend to predominate in the inferior and lateral walls in >50%***.[48] Acute MI has similar findings, but unlike acute MI, the abnormalities of myocarditis are ***patchy within a particular myocardial segment***, and ***the pattern is different (subepicardial or mid-wall in myocarditis vs. subendocardial or transmural in MI)***. The subendocardium is usually spared in myocarditis, and transmural enhancement is rare.[47]

III. Acute eosinophilic myocarditis

Acute eosinophilic myocarditis may be due to drug hypersensitivity, Churg and Strauss vasculitis, hypereosinophilic syndrome (the latter 2 also cause chronic eosinophilic myocarditis, i.e., Loeffler syndrome), or may be idiopathic.

It is frequently accompanied by eosinophilia (75%), which sometimes is transient and not seen on admission but later. Fever, rash or constitutional symptoms may also be present.[49] Even without eosinophilia, a patient with drug reaction (e.g., penicillins, sulfa) and newly reduced EF or troponin elevation should be suspected of eosinophilic myocarditis. The eosinophils attack and damage the endomyocardium, resulting in acute LV and/or RV thrombi (15–30%). This myocarditis may be severe but transient and reversible if the drug is withdrawn and corticosteroids are used. Unlike other forms of myocarditis, this form responds well to high-dose corticosteroids.[44,49] Endomyocardial biopsy, which is indicated in severe progressive cases of uncertain cardiomyopathy, shows eosinophilic infiltration.

IV. HIV cardiomyopathy

HIV cardiomyopathy is often related to a direct myocardial HIV infection, but is sometimes related to an autoimmune process triggered by HIV, coinfections (e.g., cytomegalovirus, Toxoplasma, Epstein–Barr virus), or selenium deficiency. It should be distinguished from a reversible, acute illness cardiomyopathy sometimes seen in hospitalized HIV patients. HIV cardiomyopathy is typically seen in patients with CD4 counts <400 and develops in ~8% of these patients over a 5-year follow-up;[50] it may present as acute myocarditis. Dilated cardiomyopathy is associated with a high mortality risk of >50% at 2 years that is partly related to the advanced HIV disease.[51,52] Patients with a progressive course should undergo an endomyocardial biopsy to rule out and treat opportunistic coinfections. The effect of highly active antiretroviral therapy on stabilizing HIV cardiomyopathy is unclear. Diastolic dysfunction is common in HIV and may not affect the long-term prognosis in the absence of a reduced EF.[52]

V. Chagas disease

Chagas disease occurs in endemic Latin American countries. It is due to a parasite (trypanosome) that is transmitted through the bite of a bug. Acute infection is mild; it rarely leads to a picture of acute myocarditis with HF that is usually reversible. Years later, ~30% develop chronic Chagas disease, which is characterized by a progressive biventricular failure and, frequently, a characteristic large apical aneurysm. Thromboembolic complications, conduction blocks, and arrhythmias are common. Chagas disease, whether acute or chronic, is due to a combination of active and persistent myocardial infestation and a damaging immune response.[53] The diagnosis is confirmed by serology. Besides HF therapy, benznidazole (antiparasitic agent) is useful in acute disease and may be useful in slowing the progression of early chronic disease, before severe HF develops. Yet, in In one large randomized trial of chronic Chagas cardiomyopathy that is not advanced clinically (EF mostly normal, no advanced HF), benznidazole failed to reduce cardiovascular events, despite the early cardiomyopathy stage and despite significant reduction of parasite detection on blood samples.[54]

VI. Sarcoidosis

Sarcoid cardiomyopathy is characterized by myocardial sarcoid infiltration, with granulomas and edema early on and fibrosis later on. The LV wall may be thickened by granulomas, which leads to LV diastolic dysfunction; or thinned by fibrosis with localized aneurysms, which leads to LV systolic dysfunction.

Sarcoidosis typically involves the basal septum and the lateral LV, leading to localized akinesis or dyskinesis of these segments.[55,56] This basal septal involvement leads to *infra-His ≥2nd-degree AV block, RBBB, or LBBB*, as well as pseudo-Q waves. VT, frequent PVCs, and atrial arrhythmias are also common. Echo is not very sensitive for detecting the early small granulomas and localized dysfunction, and arrhythmias or conduction blocks may be the earliest manifestation. The RV base may be directly involved; pre-capillary pulmonary hypertension may also occur and lead to secondary RV failure.

Approximately 20–30% of patients with sarcoidosis have myocardial involvement, but only 5% have clinical myocardial involvement. Even in patients with no known extracardiac manifestations, pulmonary/mediastinal involvement is highly prevalent and seen in 80–90% of patients with cardiac sarcoidosis. Yet, ~5–20% of cardiac sarcoidosis is limited to the heart, i.e., isolated cardiac sarcoidosis. Sudden death from ventricular tachyarrhythmias or conduction blocks is the most common cause of death in cardiac sarcoidosis, accounting for 30–65% of deaths.[55] Progressive cardiomyopathy is the second most common cause of death.

Diagnosis: Cardiac sarcoidosis is considered in 2 settings:

i. Patients with established extracardiac sarcoidosis, even if asymptomatic from a cardiac standpoint:

Any patient with extracardiac sarcoidosis should be screened for cardiac involvement with clinical history, ECG (RBBB, LBBB, ≥2nd-degree AV block, frequent PVCs, VT, SVT), echo, and Holter. **Any significant abnormality on the latter tests dictates cardiac MRI**, which, if abnormal, strongly suggests the diagnosis of cardiac sarcoidosis; if normal, it implies a low probability of cardiac sarcoidosis. Cardiac MRI assesses for scar tissue, which correlates with sudden death (→ need for ICD), and may capture the earlier stage of inflammation and edema.[57–59] The location of late gadolinium enhancement is characteristic of sarcoidosis: basal septum and basal inferolateral wall (patchy, subepicardial or midwall involvement, rarely transmural). *Fluorodeoxyglucose PET* assesses for active myocardial inflammation, which may improve with steroid therapy (cases when AV block, VT, and LV dysfunction may improve with steroid therapy). MRI and PET may be used as complementary tests, each addressing one stage of cardiac sarcoidosis.[56]

ii. Patients with no known extracardiac sarcoidosis but with suggestive cardiac findings:

- Young patient <60 with VT, conduction block, cardiomyopathy with RBBB or LBBB
- Non-ischemic cardiomyopathy with thick walls, segmental dysfunction, or pseudo-Q waves

The diagnosis is suggested by non-cardiac sarcoid involvement (CT chest, eye exam) and MRI finding of either edema or late gadolinium enhancement at the basal septal and inferolateral walls. A histological diagnosis is generally required per HRS, and often may be achieved via mediastinal or pulmonary biopsy. In isolated cardiac sarcoidosis, cardiac biopsy is required per HRS, but is not mandatory per ESC 2024 and the Japanese Society if ECG and MRI findings are typical, and no alternative diagnosis exists. RV endomyocardial biopsy has a low sensitivity (~25%) as the septal infiltration is patchy. Septal biopsy guided by EP electroanatomic mapping, targeting the low voltage areas, increases the biopsy yield.

Treatment: At an early stage, granulomas, MRI defects, and myocardial contractility improve with steroid therapy; however, AV block and the risk of VT do not reliably improve with steroids.[55,56] The prognosis of sarcoid cardiomyopathy is similar to idiopathic DCM, and much better than other infiltrative cardiomyopathies (e.g., amyloid).[51]

Patients with high-degree AV block have a high risk of VT on follow-up (up to 50% at 2–3 years), justifying ICD therapy early on. ICD is also justified for these indicators of sudden death risk: unexplained syncope, low RVEF, LVEF < 35%, or LVEF > 35% with late gadolinium enhancement on MRI (especially of the RV, or ≥22% of the LV), or with inducible VT on EP study (ACC and ESC guidelines).[59] NSVT and bundle branch blocks, per se, do not warrant ICD but may justify further risk stratification with EP study and/or MRI and require careful follow-up (HRS 2014).[56]

VII. LV non-compaction, preferably called: Excessive LV trabeculation

Embryologically, the normal myocardium has subendocardial and subepicardial layers that are initially loose then become packed and thin, i.e., compacted. In LV non-compaction or "spongy myocardium," the subepicardium becomes compacted but the subendocardial meshwork remains loose, leading to prominent trabeculations and deep recesses, particularly in the mid-LV and apex. Doppler flow is seen through the recesses and thus helps define the excessively trabeculated morphology. LV non-compaction has been defined as an end-systolic ratio of the loose inner myocardium to the compacted outer myocardium ≥ 2, with an impaired or normal LVEF (Jenni criteria). By MRI, a ratio of >2.3 in end-diastole is used, and specificity is improved when >20% of the LV mass is trabeculated. Occasionally, LV non-compaction may be mistaken for LV thrombus, but echo contrast allows the differentiation. Early reports suggested that non-compaction is frequently associated with severe LV dysfunction and high incidence of arrhythmia and thromboembolic complications.[60] In fact, the deep sluggish recesses may favor thrombus formation. Later reports suggested that non-compaction, per se, may not carry any additional diagnostic or prognostic value beyond that provided by EF and HF status.[61]

Viral and hypertensive cardiomyopathies may lead to prominent trabeculations, that, at times, may fulfill the definition of LV non-compaction (false-positive diagnosis).[62] In the latter cases, the prominent trabeculations are acquired rather than congenital. In fact, in one analysis, ~25% of patients with systolic HF fulfilled the diagnostic criteria of LV non-compaction,[63] including many patients with underlying CAD (CAD was present in 29% of HF with LV non-compaction).[64] Hypertrabeculation may also be seen in HCM. In addition, up to 8% of normal individuals, particularly black individuals, have prominent trabeculations that fulfill the diagnosis of LV non-compaction.[63] One analysis has shown that 8% of healthy women develop a non-compaction morphology during pregnancy, which reverses in the few months postpartum without any untoward clinical events or EF deterioration.[65] Also, 8% of athletes have a

non-compaction morphology. A proportion of patients with chronic renal disease or chronic anemia, such as thalassemia or sickle cell disease, develop non-compaction morphology as a result of elevated preload. ***Thus, LV non-compaction is a non-specific phenotype, sometimes transient, induced by physiological adaptation or by volume overload***.[66] In a subgroup of patients, particularly those with LV dysfunction or family history of sudden death or cardiomyopathy, or unexplained syncope or repetitive NSVT, LV noncompaction may be a genetic cardiomyopathy: 9–32% of patients with LV noncompaction test positive on a general cardiomyopathy gene panel, particularly if they have LV dysfunction, with no one gene specific for noncompaction.[67,68]

The prognosis depends on the underlying LVEF and HF functional status, and the impact of the non-compaction morphology, per se, is unclear. Patients with normal EF at baseline have an excellent prognosis, with no increased risk of death or HF and no deterioration of LV function at 9.5 years.[61,64,69]

VIII. Takotsubo and other stress-related cardiomyopathies

A. Takotsubo cardiomyopathy (TC, also called "stress-induced cardiomyopathy" or "apical ballooning syndrome")

This is a transient form of cardiomyopathy that occurs after a major stress and typically leads to dyskinesis and "ballooning" of the ventricular apex. Massive catecholamine surge leads to contraction band necrosis, which is actually a form of stunning rather than necrosis, similar to what is seen with cocaine overdose. Multivessel spasm and microvascular spasm have been incriminated as well; in fact, acetylcholine-induced vasospasm is common in TC. Atypical variants of TC have been described, such as the mid-ventricular ballooning and the basal ballooning (inverted TC).

TC typically involves post-menopausal women (~95% of cases), and only 2% of affected patients are <50 years of age. TC uncommonly presents as HF and more typically mimics ACS, particularly STEMI, and presents with chest pain, anterior ST elevation with deep anterior T-wave inversion, and elevated troponin. *ST elevation is seen in > 60%* of the cases and involves the *anterior and lateral leads*, with occasional inferior extension but rare reciprocal ST depression (<10%); isolated inferior ST elevation is not seen. ST elevation evolves into deep anterior T-wave inversion and prolonged QT within 24–48 hours; patients frequently present at the stage of T-wave inversion without residual ST elevation, *T-wave inversion being the most universal finding*. Transient anterior/lateral Q waves are seen in 30% of the cases. On echo and left ventriculography, the apex is akinetic/dyskinetic while the base is hypercontractile, and the overall EF is ~30% (20–40%). RV is commonly involved (~1/3 of cases). Up to 17% of TCs are mid-cavitary rather than apical and 2% are basal.[70,71]

The ECG and echo findings characterize anterior MI as much as TC, and coronary angiography should be performed in all these cases to rule out LAD disease. In TC, no significant CAD is found. Troponin increases to mild degrees (up to 5 ng/ml), much less than in anterior STEMI. As opposed to STEMI and myocarditis, MRI does not show any LGE (while helpful, MRI is not a necessary diagnostic tool).

All cases of TC are reversible within 2 months (half of them resolve within a week). *In fact, the diagnosis can only be made in retrospect, once recovery of LV function is confirmed*. A risk of recurrence of 11% has been described over a 4-year follow-up.[72]

TC has a good prognosis, with ~1% in-hospital mortality. Complications similar to STEMI complications may be seen acutely but are less common than in STEMI: HF (17%), shock (4%), VT/VF (1–6%), LV thrombus (2.5%) with a stroke risk of ~1%, usually within 48 hours.

HF and cardiogenic shock may result from the poor LV function but also from the basal hypercontractility that leads to LVOT obstruction, the latter being seen in ~15% of TCs. These two forms of HF or shock need to be differentiated by echo and are treated differently. In LVOT obstruction, inotropes are avoided; β-blockers are used if HF is present (carefully), while α-agonists are used if shock is present. Functional MR is seen in ~20% of TCs, and results from either LV dilatation or LVOT obstruction/SAM.

There are 3 types of triggers for TC (each accounting for a third of cases), and the prognosis varies according to the trigger:[73] (1) emotional stress → benign short- and long-term prognosis (1% acute mortality); (2) physical stress (acute medical or neurological illness, procedures, physical exertion) → much higher short-term (~7–10% vs. 1%) and long-term mortality, mainly related to the underlying illness and comorbidities; (3) no clear trigger → intermediate prognosis (2% short-term mortality).

B. Other stress-related transient cardiomyopathies

- *Neurogenic stress cardiomyopathy* is seen in up to 20–30% of patients with subarachnoid hemorrhage, and less often in ischemic stroke. As opposed to TC, it usually involves the basal and mid-ventricular segments and spares the apex (inverted TC pattern).
- *Septic or acute medical illness cardiomyopathy:* ~50% of septic patients develop a septic cardiomyopathy. It results from the myocardial depressant effect of cytokines (TNF-α) and is usually characterized by diffuse global hypokinesis rather than a TC pattern. A subgroup of patients develops a typical TC pattern, depending on the relative effect of catecholamine surge vs. cytokines. The RV is involved as well. Septic cardiomyopathy always normalizes within 7–10 days.

IX. Infiltrative restrictive cardiomyopathy: Amyloidosis

Amyloidosis is the aggregation of misfolded proteins, called amyloids. There are three forms of cardiac amyloidosis:

1. Amyloid light-chain (AL) amyloidosis results from myocardial light chain deposition and may be primary or secondary to multiple myeloma. It is seen at an age over 40–50 and is associated with amyloid renal failure and nephrotic syndrome, macroglossia, jaw claudication, and bruising around the eyes.

2. Mutant transthyretin amyloidosis results from the amyloid deposition of transthyretin fragments (autosomal dominant). It leads to cardiomyopathy and peripheral or autonomic neuropathy (no renal involvement). Nearly 3.4% of African Americans carry a specific transthyretin mutation, which is autosomal dominant but has a low penetrance (~10–20%), and late expression (mean age 69), mimicking senile transthyretin amyloidosis.

3. Wild-type (senile) transthyretin amyloidosis occurs most commonly in elderly men (median age 75) but may be seen in women (5–50% of cases are women). It may lead to neuropathy as well, in ~10% of the cases, albeit less commonly and less severely than genetic amyloidosis. *It is* ***the most common form of cardiac amyloidosis***. Approximately 1% of individuals older than 75 years without clinical HF have subclinical cardiac TTR amyloid deposits.[74,75] This is much more ***prevalent in HFpEF (~10–15%)***.

Transthyretin (TTR) is a tetramer, which means it is made up of 4 copies of the same protein. As long as the 4 copies remain linked, no pathology occurs. Should the tetramer break apart, the resulting monomers misfold and aggregate in the heart and peripheral nerves causing amyloid fibrils. Both mutant and senile transthyretin amyloidosis result from this same process of transthyretin dissociation; mutation (in the former) or aging (in the latter) results in an unstable transthyretin that is more likely to break, particularly in areas of high shear stress, like the heart. *Both are more slowly progressive than AL amyloidosis (survival after HF onset: 5 years vs. 15 months); patients with TTR amyloidosis typically have more pronounced abnormalities of wall thickness and hemodynamics than AL amyloidosis, yet look better clinically*. AL amyloidosis is clinically more severe despite more subtle echocardiographic findings.[76,77]

Carpal tunnel syndrome, typically bilateral, is prevalent in all types of amyloidosis and may precede clinical presentation by several years. *Spinal stenosis* may be seen in senile amyloidosis from spinal ligament infiltration.

About **13% of elderly HFpEF and ~15% of elderly low-output AS have TTR amyloidosis**.[76–80] **Clinical hints to amyloidosis:**

- Low to normal BP in a previously hypertensive patient, intolerance to ACE-I/beta-blockers, and requirement for discontinuation of antihypertensives
- HFpEF with chronic, marked elevation of BNP or persistent troponin elevation
- HFpEF with marked RV failure
- Carpal tunnel syndrome or spinal stenosis or biceps tendon rupture; autonomic neuropathy (orthostatic hypotension or GI) or peripheral neuropathy
- QRS voltage disproportionate to the thick LV
- Apical sparing on strain echo ("red" apex, "cherry sundae")

A. ECG and echo features

Amyloidosis leads to severe myocardial thickening (mean septal thickness 15 mm in AL amyloidosis, 18 mm in TTR amyloidosis), mimicking hypertrophic cardiomyopathy. The thickening may occasionally (20–25%) be asymmetric and lead to LVOT obstruction. *Think of amyloidosis whenever hypertrophic cardiomyopathy (HCM) or hypertensive cardiomyopathy is considered and before finalizing the diagnosis, whether in the young (mutant TTR amyloidosis) or the elderly (wild-type TTR or AL amyloidosis)*. Hints to amyloidosis are initially derived from the ECG. Amyloidosis' ECG classically shows: (1) low-voltage QRS and (2) pseudo-Q waves. A truly low voltage is insensitive and is only seen in 30% (transthyretin) to 50% (AL) of the cases. However, the near universal finding is that the *QRS voltage is not high and is disproportionately low relatively to the LV thickness*. Pseudo-Q waves are seen in 60–70% of TTR amyloidosis cases.

Additional hints are derived from the echo, specifically the 2D speckle strain echo: the longitudinal strain may be abnormal at the base but normal "red" at the apex (=apical sparing, apical/base ratio >2, or better >2.9 per ESC). This suggests amyloidosis but has a limited sensitivity (<70%) and specificity (<65%) based on most recent data, even at a higher ratio >2–3, as it may be seen in other cardiomyopathies (e.g., HTN, HCM).[81] More importantly, amyloidosis frequently involves the myocardium diffusely and causes more severe impairment of the global longitudinal strain (GLS) than HCM or HTN (e.g., 10 vs. 17), with a highly distinctive EF/GLS ratio >4.1.[82] Also, severely reduced E', A', S' (all <5 cm/s), valvular thickening, RV thickening, and especially interatrial thickening are characteristic of amyloidosis. AS may be combined with senile amyloidosis: the shear stress of AS increases TTR deposition, causing ~10% of elderly AS to be associated with TTR amyloidosis.

B. Diagnosis

After being suspected by ECG and echo features, the diagnosis of amyloidosis is established via ordering **2 tests** (Figure 5.1):[76,77,80,83,84]

i. For the diagnosis of TTR-amyloidosis (genetic or senile): ***Myocardial nuclear scan using bone scintigraphy tracers (e.g., technetium pyrophosphate or Tc-HDP)***, which are taken up by the cardiac amyloid tissue. A cardiac uptake that equals or exceeds rib uptake is highly sensitive (>99%) and specific (86%) for transthyretin amyloidosis (occasionally positive with AL amyloidosis, ~30%).

ii. For the diagnosis of AL-amyloidosis: ***Serum and urine immunofixation electrophoresis*** (more sensitive than simple electrophoresis) looking for a monoclonal M peak and ***serum free light chain*** (sFLC) assay (the latter measures the levels of free light chains kappa and lambda and reports the kappa/lambda ratio, which could be abnormally high or low in AL amyloidosis). The combination has a 99% sensitivity for the diagnosis of AL amyloidosis.

Additional supportive tests may be performed:

- ***Cardiac MRI***, showing ***global subendocardial LGE*** and/or marked extracellular volume expansion is 90% sensitive and specific for any cardiac amyloidosis. The atrial thickening manifests as atrial LGE.
- ***Genetic testing*** may be performed once myocardial scan confirms TTR amyloidosis, to distinguish mutant TTR from wild-type TTR amyloidosis. Even the elderly TTR amyloidosis may be gene-positive in 5–10% of cases.

ESC suggests performing (i) and (ii) simultaneously, while ACC recommends sequential testing: monoclonal proteins first (ii), then scintigraphy if the result is negative.[83,84]

Incidentally, 2–8% of elderly patients have monoclonal gammopathy of undetermined significance and may have a monoclonal peak unrelated to the cardiomyopathy.[76,77] **Biopsy is needed when monoclonal protein testing is abnormal, even when scintigraphy is positive, to establish amyloidosis and distinguish AL vs. TTR:**

- ***Periumbilical fat pad biopsy*** (sensitivity 60–80% in AL amyloidosis and mutant TTR amyloidosis, but only 14% in senile TTR amyloidosis).

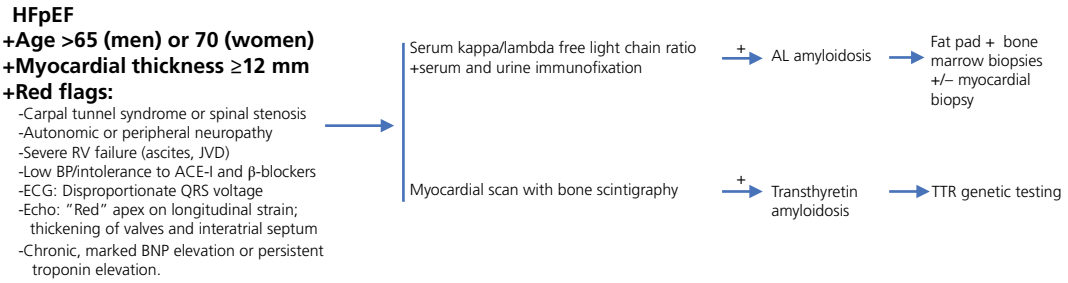

Figure 5.1 Diagnosis of amyloid cardiomyopathy. If both tests are positive, the diagnosis is generally AL amyloidosis, but may be TTR amyloidosis with incidental monoclonal gammopathy: biopsies are needed to establish a diagnosis. Kappa/lambda ratio is normally 0.26–1.65, but is higher in severe CKD: 0.54–3.3.

- ***Bone marrow biopsy***, looking for amyloid deposits (AL or TTR) and for plasma cells (>10% plasma cells in multiple myeloma and sometimes in primary AL amyloidosis). The sensitivity of finding bone marrow amyloid deposits in AL amyloidosis is 69%.[77]
- ***Endomyocardial biopsy if the above 2 biopsies do not show amyloid deposits*** (~100% sensitivity for the diagnosis of cardiac amyloidosis). The tissue sample should be subjected to protein analysis to confirm the subtype of amyloid (light chain vs. transthyretin).

Where does cardiac MRI fit in those algorithms? Only ESC provides an explicit role for cardiac MRI in the following cases:

- In patients with *monoclonal protein and negative scintigraphy and surrogate site biopsy*, cardiac MRI may be performed before proceeding with endomyocardial biopsy; a negative MRI makes cardiac amyloidosis unlikely, possibly allowing the avoidance of tissue biopsy.
- *Scintigraphy result is borderline* (e.g., some cardiac uptake of bone tracers, but less than the ribs).
- *Both scintigraphy and monoclonal protein are negative, but the clinical suspicion remains high.*

C. Treatment

LV cavity is small and stiff and is unable to expand and accept the increased venous return (limited preload reserve). Hence PCWP is severely elevated despite a normal or reduced preload, which hampers the use of significant doses of diuretics; high diuretic doses remain necessary in patients with severe right heart congestion. Digoxin should be avoided as it has a high affinity for the amyloid material and thus a high toxicity even at therapeutic doses. The severely limited stroke volume reserve may lead to profound hypotension with vasodilator therapy, such as ACE-I, as stroke volume cannot rise to match the dilated circulation. Also, this limited stroke volume makes cardiac output dependent on heart rate and explains the intolerance to β-blockers. Autonomic dysfunction further compounds hypotension. AF is highly prevalent in senile amyloidosis and is challenging to rate control: first, a higher heart rate should be respected in restrictive cardiomyopathy, as cardiac output depends on it; and second, amyloid patients very poorly tolerate CCB and β-blockers. Amiodarone may be the only option, even for rate control.

Transthyretin amyloidosis, whether senile or mutant, has a better prognosis than AL amyloidosis and is responsive to 2 major drug classes: **(i) TTR stabilizers and (ii) TTR production inhibitors**. (i) Oral Tafamidis binds to transthyretin and prevents its dissociation into monomers and has shown a large reduction of all-cause mortality (29% vs. 42% at 2.5 years, ATTR-ACT trial, mutant or wild-type TTR amyloidosis, NYHA 1–3).[77] Acoramidis is another oral TTR stabilizer, more efficient than tafamidis with >90% TTR stabilization. It improved combined clinical events in the ATTRIbute CM trial of mutant or wild-type TTR amyloidosis (NYHA 1–3, NT-BNP < 8,500).[85]

(ii) Vutrisiran is an mRNA interference molecule that reduces TTR hepatic production by 80%. It is administered subcutaneously every 12 weeks. In the Helios B trial, it reduced mortality, hospitalizations, and symptoms in mutant and wild-type early cardiac TTR amyloidosis, even in patients already taking tafamidis (NYHA 1–3, NT-BNP < 3,000; mortality 18% vs. 26% at 3.5 years).[86] Patisiran also inhibits TTR production and is approved for hereditary TTR neuropathy; it has improved quality of life in TTR cardiomyopathy, but not mortality (APOLLO B trial).

SGLT-2 inhibitors may be used in amyloidosis, and a large registry suggests they may be beneficial.[87]

Regarding amyloidosis concomitant to severe AS: one prospective study tested all AS patients undergoing TAVR (mean age 83.4) with scintigraphy and found ~10% prevalence of amyloidosis (vs. <1% in an unselected population aged over 80). TAVR dramatically improved their outcomes, with a similar 2-year survival to TAVR performed for lone AS, despite a limited use of tafamidis.[79] TAVR reduces LV shear stress and may slow the amyloid process.

AL amyloidosis is treated with chemotherapy, immunotherapy, and bone marrow transplant. When cardiac involvement is advanced with severe, refractory HF, the prognosis is guarded, and the patient is unlikely to tolerate high-dose chemotherapy.

Myocardial thickness, strain, diastolic parameters, and BNP do not usually improve with tafamidis,[78,85,88] but they are stabilized and cardiac disease progression is attenuated.

X. Other infiltrative restrictive cardiomyopathies

A. Sarcoidosis

See Section 1.VI.

B. Hemochromatosis

Hemochromatosis is an autosomal recessive disorder characterized by multi-organ iron deposition leading to infiltrative cardiomyopathy, diabetes, skin tanning, and cirrhosis. Ferritin and iron saturation are elevated.

C. Fabry disease: genetic metabolic storage disorder

Fabry disease, an X-linked deficiency of α-galactosidase, leads to deposition of glycosphingolipids in the myocardium (LV ± RV thickening) and the kidneys (proteinuria, advanced renal failure), and sometimes the skin (purple rash in a bathing suit distribution) and the nervous system. It manifests in men but also heterozygous women. Accessory pathways are common. ***As opposed to the low QRS voltage of amyloidosis, high voltage (LVH) is seen in Fabry***. The severe manifestations are usually seen in the third or fourth decade of life, but sometimes later, especially in women. The diagnosis may be established by a tissue biopsy, genetic testing, but also by checking galactosidase activity on peripheral leukocytes. The disease is treatable with α-galactosidase infusions.

In a patient with ventricular thickening and restrictive filling, 4 diagnoses are possible: hypertrophic, hypertensive, amyloid, and Fabry cardiomyopathy. MRI late gadolinium enhancement (LGE) helps in the differential diagnosis and reveals *global subendocardial LGE in amyloidosis* versus *patchy sand-like mid-wall LGE in HCM, particularly at the septum, and basal-inferolateral mid-wall LGE in Fabry disease*. Also, echo longitudinal strain helps, and shows a pattern of "red apex" in amyloidosis with EF/GLS >4.1. While concomitant renal failure frequently suggests hypertensive disease, Fabry or amyloidosis should be considered in the right setting.

In a *young* patient with biventricular thickening and restrictive filling, consider the possibility of genetic TTR amyloidosis, Fabry disease, or hypertrophic cardiomyopathy with restrictive phenotype.

D. Loeffler endocarditis is secondary to ***chronic*** severe systemic eosinophilia: Churg-Strauss disease, primary (neoplastic) hypereosinophilic syndrome, or systemic parasitic infection. It leads to severe eosinophilic *endocardial* infiltration with secondary restrictive cardiomyopathy, MR/TR, and cavitary thrombus formation. It is treated with steroids in case of Churg-Strauss, antiparasitic agents in case of systemic parasitic infection, and chemotherapy in case of primary hypereosinophilia.

An overlapping disorder, *endomyocardial fibrosis*, is a form of Loeffler endocarditis that progresses to extensive endocardial fibrosis. It is seen in tropical Africa, tropical America, and the Middle East.

E. Autoimmune rheumatic diseases: Scleroderma, lupus, rheumatoid arthritis, mixed connective tissue disease, polymyositis/dermatomyositis, vasculitis. Those disorders may lead to: (i) myocardial inflammation then fibrosis with a variety of patterns on MRI: epicardial, subendocardial, transmural or diffuse; (ii) microvascular disease with abnormal vasoreactivity, or CAD; and (iii) even valvular disease (valvular disease only with lupus and scleroderma).

The three cardiomyopathies with the worst prognosis are: HIV cardiomyopathy, infiltrative cardiomyopathy from amyloidosis or hemochromatosis, and doxorubicin cardiomyopathy. The survival is <50% at 2 years.[51]

2. ADVANCED HEART FAILURE: HEART TRANSPLANT AND VENTRICULAR ASSIST DEVICES (VADs)

I. Stages of HF

- Stage A: Patients at risk for HF, but without structural heart disease or HF (e.g., HTN, CAD without MI, diabetes)
- Stage B: Structural heart disease but no HF (e.g., previous MI, LVH, reduced EF, or severe valvular disease)
- Stage C: Structural heart disease with prior or current HF functional class II, III, or IV (unlike stage D, it is not refractory to medical therapy)
- Stage D: HF functional class IV or advanced class III *refractory to medical therapy*, recurrently hospitalized

Stage D- Neurohormonal therapies (ACE-Is, β-blockers, spironolactone) should be sequentially tried at very low doses in stage D patients if SBP is ≥85 mmHg and in the absence of severe signs of hypoperfusion. Medical therapy is, however, poorly tolerated at this stage (hypotension and worsening of renal failure occur with ACE-Is; hypotension and worsening of HF occur with β-blockers).

In addition, stage D patients may not be able to be weaned off inotropic therapy because of severe low output and low organ perfusion, and these patients may require chronic outpatient inotropic support. IABP, including ***long-term ambulatory IABP*** *support for weeks via axillary access,* or Impella 5.5 via axillary access, may be used while awaiting LVAD or transplant. IABP is superior to inotropes in raising SvO2 and cardiac power output.[89]

II. Cardiac transplantation

A. Indications

The 5-year survival after cardiac transplantation is ~70–75%. Transplant is indicated in HF patients whose 2-year survival is <50% (ACC and transplant society):[90,91]

- Patients dependent on IABP or percutaneous ventricular assist device (highest priority for transplantation); and patients dependent on inotropes. Patients with a properly functional LVAD have a lower priority for transplantation.

- Patients with class III or IV HF that is refractory to medical therapy (stage D), with *peak O_2 consumption ≤14 ml/kg/min on a maximal cardiopulmonary stress testing* where anaerobic threshold is achieved (it is quickly achieved in severe HF, e.g., 1 minute), and with objective evidence of impaired hemodynamics on right heart catheterization (high filling pressures, reduced CO). These patients have typically had multiple HF hospitalizations in the last year. LVEF is usually <30% but not necessarily (e.g., restrictive cardiomyopathy). A 12 ml/kg/min cutoff is used in patients receiving β-blockers.*
- Young patients (<50) with peak O_2 consumption ≤50% of the predicted value have a relative indication for transplant. The muscles of a young patient, particularly a former athlete, have a large capacity to extract O_2 even with poor O_2 delivery, which allows the patient to maintain borderline O_2 consumption even at an advanced HF stage. As such, a higher value may qualify him for transplant.

B. Contraindications

- **Severe precapillary pulmonary hypertension with PVR >3 Wood units**, which is associated with a high risk of postoperative RV failure. Patients with any PVR elevation should undergo a vasodilator challenge (e.g., nitroprusside) to assess PVR reduction. If PVR does not decrease acutely, short-term (24–48 hours) therapy with inotropes, diuretics, and vasodilators (milrinone, nitroprusside), +/– IABP may be performed with continuous hemodynamic monitoring. If PVR can be reduced to <3 Wood units, the patient becomes a transplant candidate with perioperative vasoactive therapy.[90] In those with refractory pulmonary hypertension, the complete LV unloading with LVAD is often effective in reversing pulmonary hypertension 3–6 months later and bridging the patient to transplant.[91]
- Uncontrolled diabetes, irreversible renal dysfunction (GFR <40), cirrhosis, or treated cancer in the last 5 years.
- Active tobacco usage in the last 6 months, current or ± recent (2 years) alcohol or drug use.
- Obesity (BMI >30) is a strong relative contraindication, as it is associated with twice the 5-year mortality and a higher risk of rejection and allograft vasculopathy.
- Age >70 is a relative contraindication.

C. Notes

ABO compatibility is important but not Rh compatibility (Rh is not expressed on myocardial cells). Testing for preformed HLA-reactive antibodies, or panel reactive antibodies, is performed in the recipient, and is repeated after blood transfusions, as those can trigger HLA antibodies (anti-leukocytes).

A hyperacute rejection occurs within minutes to hours and results from ABO incompatibility or anti-HLA antibodies, and is usually fatal unless treated urgently with retransplantation or mechanical support. Acute cellular rejection is T-cell mediated and is the most common type of rejection, the one for which immune therapies are used. It is most common in the first 3 months, but late rejections can occur. It is caught early on surveillance biopsies.

D. Immune therapies

Immune therapies consist of a calcineurin inhibitor (cyclosporine, tacrolimus) and an antimetabolite (azathioprine, mycophenolate), an inhibitor of cell proliferation. Steroids are used early on but are tapered and sometimes discontinued later on. Sirolimus is frequently used instead of a calcineurin inhibitor. Sirolimus has the advantages of less allograft vasculopathy and less renal failure than calcineurin inhibitors, but a higher risk of discontinuation because of poor tolerance (oral ulcers, diarrhea, peripheral edema) and potentially more cellular rejection. Sirolimus needs to be stopped 1 week before and 4–6 weeks after elective surgery and replaced by calcineurin inhibitors to allow wound healing.

Statin therapy started early after transplantation reduces mortality, rejection, and cardiac allograft vasculopathy.[92]

E. Complications

1. Acute rejection occurs most frequently in the first few months after transplant but may occur later. It is the leading cause of death in the first month after transplant. Surveillance biopsies are performed weekly early on, then monthly up until 6 months, then every 3–6 months. A blood test, dd-cfDNA (donor derived cell-free DNA) is highly sensitive for rejection and may obviate the need for biopsy if negative; but its positive predictive value is low.

A clinical acute rejection is an emergency. It should be suspected in any transplant patient presenting with acute HF, especially if fever is present. When suspected clinically, it should be treated emergently with IV steroids, even before a biopsy is performed.

2. RV failure is the second leading cause of death in the first month, particularly in patients with irreversible pulmonary hypertension.

3. Nosocomial infections occur in the first 30 days and are followed by opportunistic infections, such as pneumocystis, cytomegalovirus, toxoplasmosis, especially in the first 6 months. The latter are prevented by trimethoprim/sulfamethoxazole and antiviral prophylaxis.

4. Malignancy, especially skin cancers and lymphomas.

5. Renal dysfunction, mainly from calcineurin inhibitors.

6. Cardiac allograft vasculopathy: this is a diffuse and progressive coronary arteriopathy characterized by excessive proliferation of the intimal layer. The mechanism is both immune and non-immune (metabolic syndrome, hyperlipidemia, older age, prolonged ischemic time), and it is the ***leading cause of death beyond the first year of cardiac transplantation***, with an estimated incidence of 8% in the first year, 30% within 5 years, and 50% within 10 years. Since it is a progressive process, the definitive treatment is eventually retransplantation, which is required when the diffuse disease becomes severely obstructive. Being diffuse, the disease is missed or underestimated by coronary angiography and is better assessed by IVUS. Preliminary therapy consists of PCI for focal stenoses, statin, switching to sirolimus, and aggressive therapy of the metabolic syndrome. Many centers recommend yearly coronary angiography with IVUS as a screening modality for this vasculopathy, although it does not change immediate management. IVUS is more sensitive than angiography for detection of this diffuse process, which is characterized by diffuse intimal thickening >0.5 mm over >180-degree arc.[93] Also, IVUS can assess the true severity of coronary obstruction.

---

*1 metabolic equivalent (MET) corresponds to 3.5 ml/kg/min. Inability to reach peak O2 consumption of 14 ml/kg/min implies an inability to perform 4 METs from a cardiorespiratory standpoint, rather than from joint or pain limitation, as evidenced by the fact that the patient reaches the anaerobic threshold. Obese patients more readily have an abnormal result if peak O2 consumption is divided by their true body weight; since fat is not as metabolically active as other organs, ideal body weight is used in obesity.

III. Left ventricular assist devices (LVADs)

LVADs may be used as a ***bridge to transplant***. They help stabilize patients hemodynamically so they can tolerate medical therapy (ACE-Is, β-blockers, spironolactone). They improve organ perfusion and kidney function, PA pressure and survival rate, and make patients better candidates for transplant. LVADs may also be used as a ***destination therapy*** in patients ineligible for heart transplant, or a ***bridge to a possible myocardial recovery*** (e.g., reperfused MI with cardiogenic shock, severe myocarditis, post-cardiac surgery shock, severe but possibly reversible non-ischemic cardiomyopathy). The destiny of the LVAD is sometimes only elucidated with time. Many patients with non-ischemic cardiomyopathy improve significantly with the combination of LVAD and medical therapy, their ventricles recover, and LVAD may be explanted after 1–2 years (~15–20%).[94]

In the REMATCH trial of refractory class IV HF, HeartMate LVAD drastically improved survival at 1 and 2 years in patients with any advanced cardiomyopathy who were not transplant candidates (survival at 1 year was 52% with LVAD vs. 25% without LVAD).[95]

A. Types of ventricular assist devices

LVAD supports the LV and consists of a pump, an inflow cannula inserted in the LV apex and an outflow cannula inserted in the ascending aorta. Those 3 components are intracorporeal, with the pump in the preperitoneal or pericardial space; in older devices, the pump was extracorporeal. The pump is connected to an external controller and an external battery through a transcutaneous driveline, a potential source of infection.

A right ventricular assist device (RVAD) supports the RV, the inflow cannula being inserted in the RA or RV and the outflow cannula in the PA. BiVAD consists of LVAD and RVAD. RVAD is not as effective in supporting the right circulation as LVAD is for the left circulation. This is because the reduced vascular resistance on the right side can induce excessive pump flow into the pulmonary circulation, with a resultant pulmonary congestion and flow-induced severe pulmonary hypertension. Pump speed must be adjusted to a lower speed, and RVAD only used temporarily. Also, the requirement for additional surgeries for implantation and explantation increases the bleeding and infectious risk.

There are several LVAD pump designs:

1. The first-generation devices, such as HeartMate, had a pulsatile pump with 2 valves. Despite improving mortality, the HeartMate device had a high malfunction rate of 35% at 2 years in the REMATCH trial, which translated into a drop of 2-year survival to 24% (albeit much better than no device).

2. Continuous-flow axial pump, such as HeartMate II: since no reservoir is needed, these devices are much smaller and require less energy, with less risk of malfunction. In the HeartMate II trial, the HeartMate II device was associated with a substantially lower rate of reoperation to repair or replace the pump at 2 years (10% vs. 36%), and less infection and bleeding (less surgical dissection), which translated into a better 2-year survival in comparison with HeartMate (58% vs. 24%).[96]

3. Continuous-flow centrifugal pump (such as HeartMate 3 and HeartWare). The rotor is magnetically levitated with no mechanical bearings, allowing a smaller size with fully intrathoracic positioning; one trial suggested less pump thrombosis and need for reoperation with HeartMate 3 vs. HeartMate 2, along with superior 5-year survival (58% vs 44%) (Momentum 3 trial).

All VADs are PRELOAD DEPENDENT and AFTERLOAD SENSITIVE. The flow generated by the continuous-flow devices depends on the pump's "*delta pressure*," which is the uphill outflow pressure (aorta) minus the inflow pressure.[58] The lower this delta pressure, the higher the flow. A higher outflow pressure translates into a lower pump flow, hence the importance of keeping a low afterload (mean BP <90 mmHg) and a high preload.

Depending on the remaining intrinsic cardiac output, some pulsatility is seen with non-pulsatile devices. The residual LV contraction generates an inflow pressure that is higher in systole than diastole, and thus flow through the pump is higher in systole than diastole. Hypotensive patients with severely reduced LV systolic pressure and increased LVEDP have the lowest pulsatility. Overall, the extra flow provided by the pump is highest in patients with the worst intrinsic function, where aortic pressure is reduced and inflow is high in diastole. A centrifugal pump is more sensitive to delta pressure changes and may shut off its flow if delta pressure is high.[97]

B. Indications for LVAD and other considerations

The hemodynamic indications for LVAD are similar to those for transplant:

- Refractory NYHA class IIIB or IV, including patients with frequent readmissions for HF despite appropriate medical therapy, or low-output patients who cannot tolerate β-blocker/ACE-I therapy
- *and* EF ≤25%
- *and* Peak O_2 consumption ≤14 ml/kg/min, or inotrope dependence for over 2 weeks, or IABP dependence for over a week (HeartMate II trial criteria).[96,98]

The most definitive indication for LVAD is inotrope dependence. It is unclear whether the risk of LVAD therapy (stroke, bleeding, sepsis, AI) is warranted in patients who are not inotrope-dependent, but may be so in severe functional limitation (ROADMAP study).[99]

Patients may be treated with IABP for weeks while awaiting LVAD placement. Transaxillary IABP permits ambulation.[89]

Age and obesity are not significant contraindications to LVAD.

Fixed pulmonary hypertension, a contraindication to cardiac transplantation, is not a contraindication for LVAD, which frequently allows the reversal of pulmonary hypertension. On the other hand, it is important to address **baseline RV failure** prior to LVAD implantation. In fact, in patients with RV dysfunction, *a high PA pressure may be more favorable for LVAD implantation than a normal PA pressure, as a high PA pressure predicts better RV function*. RV failure is a major complication that occurs in up to 20% of patients post-LVAD and is predicted by the presence of elevated RA pressure (RA pressure >20 mmHg or RA pressure >0.63 × PCWP), reduced RV stroke work index, PA pulsatility index <1.85,* or preoperative signs of RV dysfunction on echocardiography. LV unloading by LVAD is beneficial for the RV, and the RV eventually improves in most of these patients. Early on, however, total LV unloading can shift the septum to the left and further exaggerate RV

*RV stroke work index = stroke volume × (mean PA pressure – RA pressure)/BSA. Must normally be >300 mmHg.ml/m^2. PA pulsatility index = PA pulse pressure/RA pressure.

dilatation and reduce the septal contractile contribution to RV systolic function. Also, the surging LV output increases the preload of the RV and overwhelms it. RV failure is treated conservatively with inotropes and pulmonary vasodilators but may require RVAD if refractory.[98]

Patients with severe AI need to have AVR concomitant to LVAD placement, to avoid a closed loop circulation between the LV and the aorta. Bioprosthetic rather than mechanical AVR is used to reduce the risk of thrombosis of this unloaded valve; if the patient has a prior mechanical AVR, it may need to be replaced with a bioprosthetic AVR.

C. Some technical aspects

The following LVAD parameters are displayed:

1. ***Pump speed***, in rpm, is ***the only adjustable*** LVAD variable.
2. *Power* is the energy generated by the LVAD. Power correlates with pump speed and pump flow (it takes more work to move more blood), and inversely correlates with the resistance that opposes the LVAD flow (delta pressure).
3. *Pulsatility index (range 1–10)* corresponds to how much cardiac output is generated by the native LV. The lower the pulse index, the higher the amount of support provided by the pump, reflecting severe LV dysfunction, although a low preload or a high LVAD speed is also a possibility. It is calculated as the difference between the maximal flows (systole) and minimal flows (diastole) averaged over 10–15 seconds and divided by the average flow (then multiplied by 10). Normally, it is between 3 and 7.
4. *Flow* correlates with pump speed and inversely correlates with delta pressure (like power). It is not directly measured, but rather *calculated* based on pump power and speed, and blood viscosity (hemoglobin). This measured flow is the pump flow and *does not account for the intrinsic LV flow* into the aorta. The total CO measured by Swan is the sum of the pump flow and the intrinsic LV flow and is higher than the measured pump flow, especially in patients with more intrinsic LV function and higher pulse index.

Power and pulse index are measured by the LVAD; flow is not directly measured but calculated.

Causes of increased power – For the same speed, an increase in power may correspond to an ***increase in flow*** (*high flow alarm*). This may result from high metabolic demands or vasodilatation, in which case the pulse index is also high as the intrinsic LV flow also increases; or AI; or may simply be an excessive pump flow with a resultant HTN. The latter case dictates a reduction of the pump speed.

+An increase in power may also indicate *rotor pump thrombosis*; the flow estimate is paradoxically and falsely increased (the true cardiac output obtained by Swan is low). It takes more energy to move the thrombosed blades, hence the higher power. Pump thrombosis is associated with hemolysis; LDH is a sensitive marker for early detection of even subclinical thrombosis.

Causes of reduced power – Reduced power correlates with ***reduced flow*** and indicates low preload or high afterload (*low flow alarm*). For example, it may indicate an empty LV with a suckdown of the LV walls. It may also indicate RV failure, tamponade, inflow or outflow cannula obstruction (kink or thrombosis), or HTN (mean BP should be kept <90 mmHg).

Since pulsatility is significantly attenuated with continuous-flow devices, the pulse is often not palpable and blood pressure measurement may be difficult non-invasively. An arterial Doppler is used during non-invasive BP measurement; the continuous noise heard during BP cuff deflation corresponds to mean BP. The mean BP goal is 65–90 mmHg.

HTN dramatically increases stroke risk in LVAD patients. It may be due to high pump flow, or more often, to vasoconstriction that actually impedes pump flow. The latter case requires antihypertensives.

In a patient with VAD, ***hypotension*** may be:

- VAD-related: RV failure; VAD pump failure or thrombosis; inflow or outflow obstruction; LV suction or excessive pump speed
- Not VAD-related: sepsis, tamponade, hemorrhage

LV suction onto the inflow cannula, per se, is secondary to *low preload* (hypovolemia or RV failure) or to high pump speed. It is treated with fluid administration and slowing the pump speed. On echo, the septum should be kept in the middle; a septum that is excessively pulled toward the LV mandates a reduction of the LVAD speed. At the polar opposite of LV suction, a dilated LV may imply LVAD pump thrombosis or low speed.

Ramp test consists of progressively incrementing LVAD pump speed in patients with suboptimal LV unloading or suboptimal PCWP, while assessing: (i) *by echo*, LV size (reduce it without bowing the septum to the left), RV size (avoid dilating it), MR (reduce it), and aortic valve (allow intermittent opening); (ii) *+/– by RHC*, PCWP and RA pressure; and (iii) *LVAD parameters*.

Obstructed LVAD flow or pump is suspected when PCWP fails to drop and measured CO fails to rise at higher LVAD speed and LVAD-calculated flows.

CO measured by Swan may be higher than pump flow because of the intrinsic LV contribution to CO. However, *when CO is lower than pump flow*, significant AI is suggested, vs. pump thrombosis, vs. LVAD flow calculation error.

In patients with biventricular VADs, the flow values displayed may differ between the RVAD and LVAD. While the net CO is the same on the right and left (in the absence of shunt), the difference in pump flows is related to the difference in intrinsic ventricular contributions to CO (+/– AI if present).

Echo of the inflow or outflow conduits: TTE standard views may adequately visualize the *inflow* cannula and its velocity (abnormal if >1.5 m/s), but it may be difficult to align the ultrasonic beam with the axis of the blood flow, and metallic artifacts may appear on 2D and on Doppler assessments. The mid and distal *outflow* conduit and its anastomosis into the ascending aorta may be imaged by TTE using atypical, high parasternal views: obstruction is suggested by peak velocity >2 m/s and low flow is suggested by a low VTI. The more proximal outflow graft may not be well visualized. TEE and 3D CT are better modalities to assess inflow and outflow grafts.

D. Complications

1. Device failure:
   - Continuous-flow axial pumps: the failure of axial pumps can be catastrophic, as these pumps lack valves, which creates the equivalent of severe AI.
   - Pulsatile pumps: failure of the pump is less catastrophic than with an axial pump, as the valves protect from severe regurgitation of flow. However, failure of one of the valves can create the equivalent of severe AI.

2. Sensitivity to low preload: axial pumps generate such a negative pressure that there is a risk of collapse of the ventricle leading to flow cessation, thrombus formation, hemolysis, and VF. This issue is further compounded by the fact that the flow of axial pumps does not cease with a low inflow pressure and keeps sucking. Conversely, centrifugal pumps stop pumping when the inflow pressure is very low and the inflow–outflow uphill gradient is high (better response to physiology).
3. RV failure (~20% early after LVAD placement, ~10% late). It is acutely treated with inotropes and inhaled pulmonary vasodilators (NO), then RVAD if it is refractory.
4. Infections (~20% at 2 years).
5. Thromboembolic complications: except for the first HeartMate, LVAD implants require warfarin therapy. HeartMate II requires INR of 2–3.[57] In the HeartMate II post-approval study, ~12% of patients had a stroke at 2 years.
6. Hemorrhagic complications (54% at 2 years), including a high risk of postoperative bleeding because of liver congestion, poor nutrition, and warfarin therapy. Also, the continuous flow may lead to arteriovenous malformations and may degrade von Willebrand factor, resulting in GI bleed in 1/3 of patients. If bleeding persists, urgent cardiac transplantation may be needed to allow withdrawal of LVAD and anticoagulation.
7. AI: as blood flows through the LVAD, it bypasses the aortic valve and causes it to remain closed and eventually fuse. Aortic valve fusion leads to AI, a serious complication that may develop in up to 30% of LVAD patients at 3 years and requires AVR. Adjusting LVAD speed to have intermittent aortic valve opening reduces this risk.
8. Hemolysis with continuous pumps, more so in case of pump thrombosis.
9. Arrhythmias such as VF. When stable LVAD patients develop VF, they feel tired but they do not develop circulatory arrest. The LV becomes fully dependent on the pump. The RV arrests but in stable patients with low PA pressure, blood flows passively through the arrested RV, similarly to a Fontan circulation. This does not apply to the early postoperative period, where the RV function is critical in surpassing the left septal pull and the high PA pressure.

3. PATHOPHYSIOLOGY OF HEART FAILURE AND HEMODYNAMIC ASPECTS

I. LV diastolic pressure in normal conditions and in HF (whether systolic or diastolic)

Normally, LV diastolic pressure slightly increases throughout diastole and has an initial dip in early diastole that "sucks" blood from the LA, particularly in young patients with a highly compliant LV ("suckers"). LV end-diastolic pressure (LVEDP) is the LV pressure that immediately follows the A wave; in normal individuals, this pressure approximates LV diastolic pressure before the A wave.

An elevated LVEDP (>16 mmHg) usually signifies LV dysfunction and is the most used surrogate of LV dysfunction (systolic or diastolic dysfunction). In fact, ***an elevated LVEDP with normal EF and normal LV volume equates with LV diastolic dysfunction and is a prerequisite for defining diastolic heart failure***. In patients with clinically compensated LV systolic or diastolic dysfunction, LV pressure only increases significantly at the end of diastole, particularly after atrial contraction. This leads to an elevated LVEDP and an increased LV "A" wave despite a normal or mildly elevated pre-A LV diastolic pressure and mean LV diastolic pressure (Figure 5.2). Indeed, a compliant LA will accommodate the volume load during systole and early diastole, keeping its pressure normal or minimally elevated until late diastole. Thus, mean LA pressure is normal and is discrepant with the elevated end-diastolic LV and LA pressure. Such findings correlate with S_4 on physical exam and transmitral E/A reversal on echocardiography. The patient is not in pulmonary edema at rest but may increase LA pressure with any stress.

In decompensated or acute LV failure (systolic or diastolic failure), the early diastolic LV compliance is overwhelmed, leading to increased LV pressure throughout diastole. LA compliance is also overwhelmed, which increases LA pressure and allows it to "push" flow into the LV. A high early diastolic LA–LV gradient corresponds to a large E wave and a high E/A ratio on echocardiography. The large early filling leads to S_3 on physical exam, which is heard at the end of the LV diastolic dip, when the LV is stretched to its limit. Thus, isolated S_4 represents elevated LVEDP but normal pre-A LV diastolic pressure, while S_3 represents volume overload of the LV and LA and a "push" from LA to LV in early diastole.[100]

> Patients with compensated LV systolic or diastolic dysfunction have normal LA pressure/PCWP at rest but are prone to raising LA pressure and E/A ratio during exercise or tachycardia, *and* are less capable of increasing stroke volume, which explains exertional dyspnea and fatigue in these patients despite the normal resting LA pressure.

II. Definition of afterload

Ventricular afterload corresponds to the tension the myocardium is pumping against during systole, called *ventricular wall tension or stress*. **Afterload is not simply the aortic pressure.** Afterload depends on the intracavitary systolic pressure but also the intracavitary size, i.e., the intracavitary stretch (the more the myocardium is stretched, the higher the tension against the myocardial wall). At a given pressure, afterload or wall stress increases as the ventricle further dilates. Moreover, the intracavitary pressure is not the only pressure affecting afterload; a positive pressure surrounding the myocardium negates some of the intracavitary pressure and reduces the tension against the inner myocardial wall. Therefore, the transmural pressure, which equals the intraventricular pressure minus the pericardial pressure, is the afterload pressure.

Afterload also depends on the ventricular wall thickness. The thicker the wall, the less tension is experienced by each sarcomere unit. This explains why the RV, being thinner than the LV, is more afterload-dependent than the normal LV.

In summary, the afterload is defined as ventricular wall stress and, according to Laplace's law, is equal to:

$$(\text{systolic LV radius} \times \text{systolic LV transmural pressure}) / 2 \times \text{myocardial thickness}$$

Beside reducing preload, diuresis reduces afterload by reducing systolic LV radius. Positive-pressure ventilation reduces afterload by reducing LV transmural pressure (pericardial pressure being positive in positive-pressure ventilation).

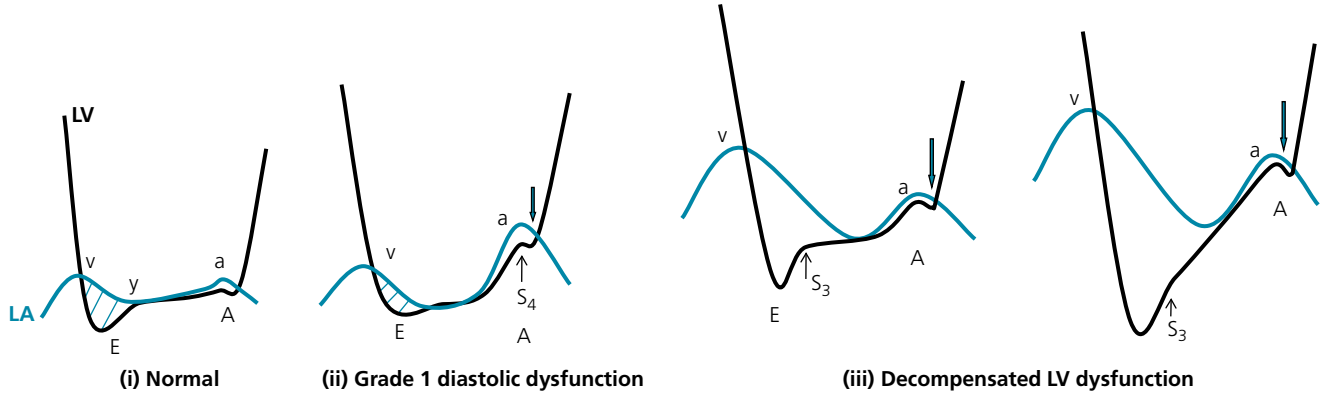

Figure 5.2 Simultaneous LA and LV pressure recordings in diastole.

i. Normal. Assess:

1. *LV relaxation pattern,* as manifested by the sharpness of LV descent. The relaxation descent of the LV is evaluated by the variable *tau*, which corresponds to the full duration of relaxation. On tissue Doppler, LV relaxation is best characterized by the annular velocity E′ (E′= myocardial recoil or relaxation).

2. *LV stiffness and compliance*, as manifested by the slope of LV diastolic pressure (the sharper it is, the less compliant the LV is), and by the post-A LV pressure or LVEDP.

3. *Early diastolic gradient between LA and LV*. This early gradient is determined by LV relaxation (sucking effect of the black curve) and by LA pressure (pushing effect of the blue curve), and corresponds to E wave on Doppler.

ii. Diastolic dysfunction is characterized by 2 features: poor LV relaxation and reduced LV compliance. *Poor LV relaxation* explains the absence of the LV dip in early diastole. This leads to poor early diastolic LV filling. *Reduced LV compliance* explains the elevated LVEDP: when the volume that has cumulated in the LA in early diastole suddenly rushes into the LV during A wave, LV pressure strikingly increases leading to elevated LVEDP (*arrow*). Note that LV diastolic pressure and LA pressure are normal outside A wave, particularly when LA is compliant enough to prevent an increase in LA pressure outside A wave. E/A is reversed and E′ is reduced.

iii. In decompensated LV diastolic or systolic dysfunction, LA pressure is high with an early LA–LV diastolic gradient (= LA pressure is a "pusher" in early diastole). The LV relaxation slope is slow, hence the diminished early LV diastolic dip. LV is also poorly compliant, more so than in compensated dysfunction, and this manifests as a sharp increase in LV pressure after the dip, which quickly attenuates the LA–LV pressure gradient and LV filling. E is high but narrow because the flow is very brief, which explains the short E deceleration time. Despite the increase in LV pressure during A wave, there is no significant flow during A wave (small A with E/A >1.5–2). **Since E = LA pressure × LV relaxation; and E′ = LV relaxation → E/E′ = LA pressure.**

III. Cardiac output, relation to preload and afterload

The cardiac output depends on:

- *Inotropism*. Inotropism is the pure intrinsic contractile function at a given length of the sarcomere, independent of loading conditions. Preload and afterload change contractility, but not inotropism.
- *Chronotropism*. An acutely decompensated heart is unable to increase stroke volume with longer filling times; thus, *tachycardia increases the cardiac output and should be respected in decompensated states*. It also increases intrinsic contractility, up to a certain point (Bowditch effect).
- *Preload*. Preload is the LV stretch in end-diastole (= LV end-diastolic volume). Increasing preload increases stroke volume up to a certain point, after which the stroke volume may decrease. In fact, a higher preload leads to LV dilatation, which increases systolic afterload and worsens myocardial O2 demands and functional MR, ultimately decreasing cardiac output (Frank–Starling curve, Figure 5.3).
- *Afterload*.

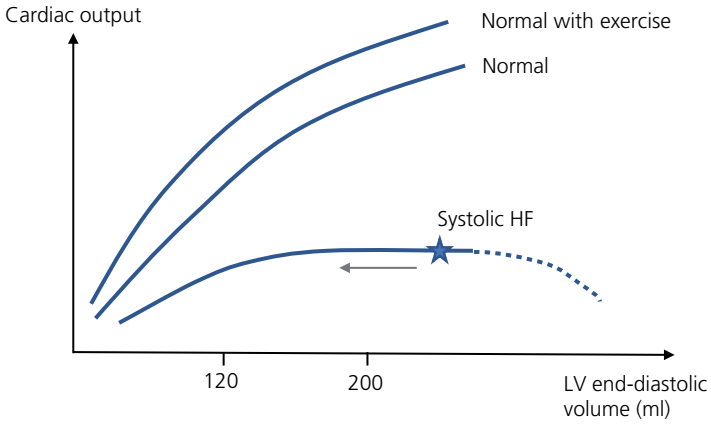

Figure 5.3 Cardiac output–preload relationship (Frank–Starling curve = length-tension relationship). Note that preload is end-diastolic volume, not end-diastolic pressure. Patients with decompensated systolic HF are on the flat or even descending portion of the Frank–Starling curve (*star*); they are not preload dependent, hence diuresis does not reduce their cardiac output and typically raises it (*arrow*).

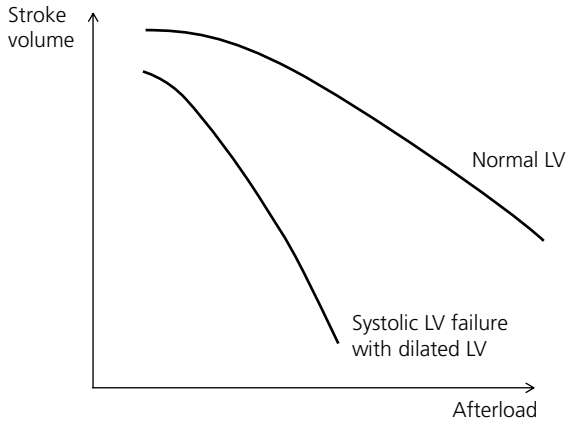

Figure 5.4 Force (afterload)–velocity relationship. The failing LV is exquisitely sensitive to changes in afterload. In systolic LV failure, note how the stroke volume varies sharply with afterload variation (much more than a normal LV). **The normal RV is also exquisitely sensitive to afterload changes, like the failing LV**.

The failing LV is much more ***afterload sensitive*** than a normal heart (Figure 5.4).[101,102] Small increases in afterload can produce large drops in stroke volume. It is also deeply harmed by increases in preload beyond a certain point, making it ***very preload sensitive rather than preload dependent*** (flat and descending portions of the Starling curve; Figure 5.3). As such, the failing LV is both preload and afterload sensitive. Even a normal LV is sensitive to volume overload/high preload (e.g., LV poorly tolerates chronic MR).

In HF, a decrease in preload is usually well tolerated and improves pulmonary edema without affecting the cardiac output, explaining that diuresis is well tolerated (flat cardiac output–preload curve).[103] The only exceptions are severe diastolic HF and new-onset acute systolic HF (e.g., massive MI), conditions in which LV end-diastolic volume is not increased, yet pulmonary edema develops at a normal preload because of a very poor ventricular compliance and a steep pressure–volume ventricular relationship. These patients are less tolerant of a decrease in their "normal" LV volume and should be carefully diuresed.

IV. LV pressure–volume relationship in systolic vs. diastolic failure: therapeutic implications

- *Systolic LV failure* is characterized by impaired LV contractility; as a result of the low volume ejected, the LV progressively dilates, which initially serves to maintain the stroke volume on the Frank–Starling curve, but eventually becomes harmful as LV dilatation increases afterload, MR, and myocardial O2 demands.
- *Diastolic LV failure* is characterized by two features: slow LV relaxation, which is an active ATP-dependent process (tau index) (Figure 5.2 [ii]), *and* steep LV pressure–volume relationship in diastole (compliance, beta index) (Figure 5.2 [ii–iii]; Figure 5.5). LV is not dilated. In fact, a normal-size LV with elevated LVEDP indirectly suggests a steep pressure–volume relationship.

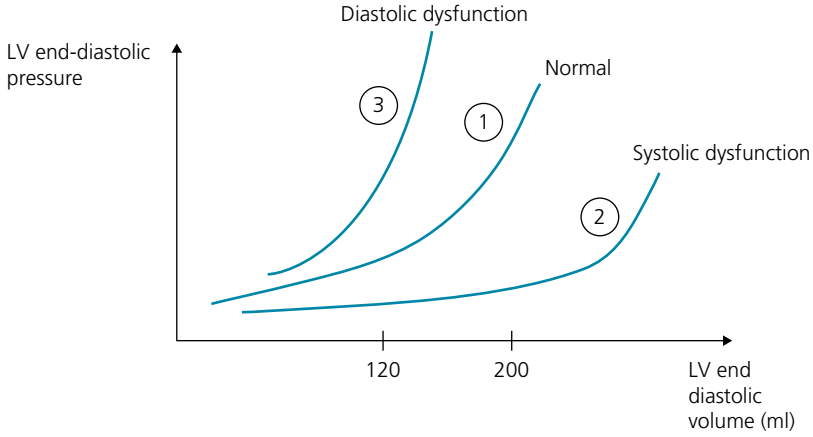

Figure 5.5 Compliance curve, i.e., pressure–volume relationship in diastole.

LV is compliant in severe systolic dysfunction and is poorly compliant in severe diastolic dysfunction. In decompensated systolic dysfunction, however, the LV volume is high enough to be at the steep, non-compliant portion of the curve. In severe diastolic dysfunction, a normal 100–120 ml end-diastolic volume, which is necessary to maintain cardiac output on the Frank–Starling curve, leads to a high LV end-diastolic pressure and pulmonary edema. That is why such patients are less likely to tolerate diuresis; they are preload-dependent, unlike systolic HF which is compromised by high preload (Starling curve). An improvement in the relaxation pattern will move curve 3 to 1 and is called the *lusitropic effect*; *afterload reduction has a lusitropic effect*.

All patients with decompensated systolic LV failure are at a point on the pressure–volume curve where LV is stiff and thus have "diastolic failure" as well. In addition, all patients with systolic dysfunction, compensated or not, have impaired relaxation that is characteristic of diastolic dysfunction. Thus, *systolic LV failure also has characteristics of diastolic failure, and every systolic heart failure is actually a combined systolic and diastolic heart failure*. Yet, less volume is necessary to overwhelm the LV compliance in diastolic dysfunction than in chronic systolic dysfunction, which is characterized by an LV that remains compliant up to a large volume load (Figure 5.5). Some patients with systolic failure only have a mild increase in LV volume yet a marked increase in LV diastolic pressure; this represents a form of systolic failure wherein the diastolic function is more impaired than usual and the LV pressure rises more steeply than usual, a form of predominant diastolic failure (e.g., HFmEF with EF 40–50%).

The goals of diuresis and preload and afterload therapy are to normalize PCWP and RA pressure. Even if severe, reactive pulmonary hypertension usually reverses with reduction of PCWP but may lag several weeks behind PCWP normalization. ***In the failing dilated LV, cardiac output is not reduced with preload reduction, because the cardiac output–LV volume curve is at a flat portion (Figure 5.3).***[100–105] While a degree of LV dilatation is necessary to maintain stroke volume, too much of it becomes counterproductive. ***In fact, PCWP of 15–18 mmHg corresponds to an unnecessary increase in LV end-diastolic volume (preload) and may be safely reduced to 12 mmHg in chronic systolic LV failure, including acutely decompensated chronic systolic failure*** (Figure 5.6). ***Diuresis improves stroke volume as a result of the following:***[100,105] (1) diuresis reduces LV volume, which, besides defining preload, is a major determinant of LV wall stress, i.e., LV afterload; (2) by reducing LV volume, diuresis reduces the severity of functional MR and, consequently, improves forward cardiac output; (3) in RV failure, diuresis reduces RV volume and thus reduces the compression of the LV by the RV and reduces TR; (4) preload being one determinant of myocardial O2 demands, reducing preload attenuates myocardial ischemia. Therefore, patients with *decompensated systolic LV failure* should be treated with afterload and preload reduction and should tolerate PCWP <15 mmHg and a drastic reduction of their LV volume. Stroke volume is highest at a low PCWP. This may not apply to patients with poor LV compliance, such as patients with severe diastolic LV failure or new-onset acute LV failure. In fact, patients with *severe restrictive cardiomyopathy* may require high PCWP to keep an adequate end-diastolic volume and cardiac output. **Slower diuresis is warranted when *both of these conditions* are met: (i) no florid peripheral edema *and* (ii) no LV or RV dilatation** (steep pressure–volume relationship). Even with small and stiff LV/RV, extreme intra- and extravascular volumes allow diuresis to be well tolerated. Volume is removed from the vascular space, which then equilibrates with the extravascular space at the capillary refill rate, while LV/RV volumes remain steady.

Case of concomitant RV-LV failure –The LV P-V relationship is further complicated in patients with severe RV failure. In severe RV failure with RV/LV interdependence, the pericardial pressure rises. While LVEDP may be 30 mmHg, the transmural LVEDP may be only 5 mmHg. Pericardial pressure best correlates with RA pressure, so if RA pressure is 25 mmHg, the LV transmural pressure in diastole is only 30 minus 25. The LV may be underfilled despite pulmonary edema, and even LV systolic failure behaves like LV diastolic dysfunction with stiff P-V relationship in Figure 5.6. Diuresis is still useful in this case, to reduce RA pressure and RV size and hence increase LV transmural pressure and filling. It also improves LV contractility via better septal contribution to the LV output.

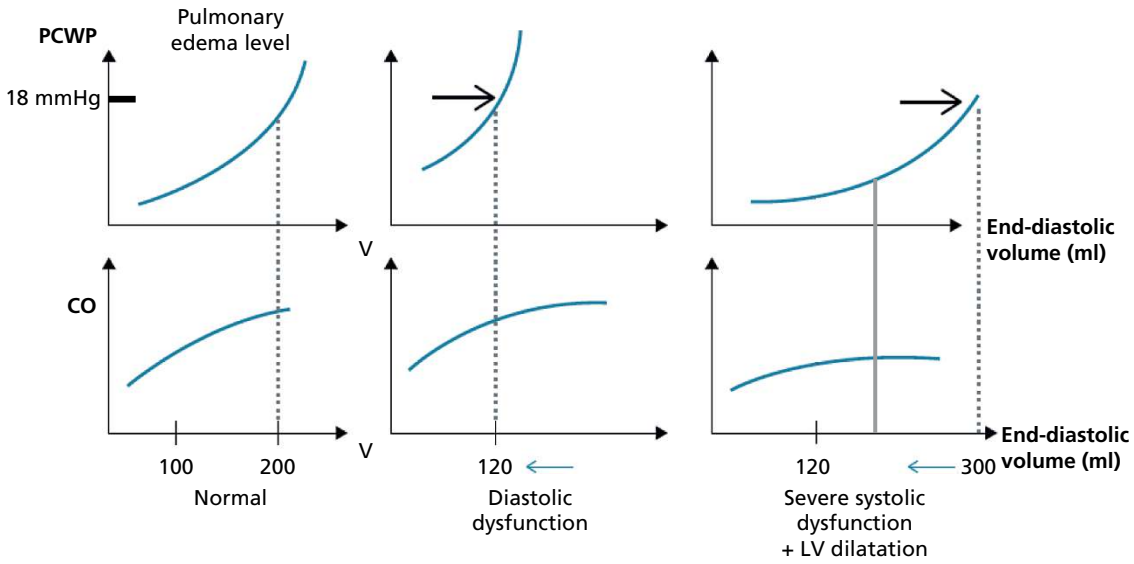

Figure 5.6 Important HF figure, showing a diastolic superimposition of the Frank–Starling curve (= cardiac output–end-diastolic volume curve) (*lower curve*) and the pressure–volume curve (*upper curve*) in three situations.

In severe diastolic dysfunction, the LV volume is normal, yet the steep pressure–volume curve causes an elevated PCWP at a normal preload. Diuresis to a volume of 100–120 ml corresponds to a PCWP of 15–18 mmHg, which may need to be accepted.

In chronic systolic dysfunction, the LV volume is excessively increased even at a PCWP of only 18 mmHg. PCWP of 10–12 mmHg usually corresponds to the LV volume that provides maximal cardiac output: this optimal LV volume is only slightly enlarged, rather than severely so (*gray line*). The pressure–volume curve is initially flat, i.e., LV is compliant despite increased volume, then becomes stiff at high volumes only. When the patient is in decompensated heart failure, whether from systolic or diastolic failure, the LV is at a steep and poorly compliant point of the pressure–volume curve (*black arrows*).

Modified from Gorlin R. Primary Cardiol 1980; 6: 84.

V. Optimal heart rate in HF

Patients with compensated diastolic or systolic LV failure and reversed E/A decompensate with tachycardia or AF or any volume load (Chapter 4, Figure 4.3). Once the patient is in decompensated failure (high E/A ratio), diastolic filling occurs only briefly in early diastole during the LA-to-LV "push" (E wave), with minimal filling in mid- and late-diastole. Except in cases of tachycardia >110 bpm, slowing the heart rate to prolong diastole or reestablishing atrial contraction does not help at this point, since LV fills minimally outside early diastole, and even if it does, it is on the flat portion of Frank–Starling curve (stroke volume does not rise with preload). In fact, **tachycardia of up to 110 bpm may be *acutely* helpful as it provides peak contractility**, and increases cardiac output and LA emptying by increasing the number of emptying cycles per minute; tachycardia >110 bpm becomes counterproductive in HF. Once systolic HF is compensated and E/A reduced, ***chronically* reducing heart rate to <70 bpm improves metabolic efficiency and LA emptying. Note that this tight chronic heart rate control benefits systolic HF, but not HFpEF or AF, not even systolic HF with AF, in which case a heart rate of 75–100 bpm is acceptable and even preferred** (outside angina).[6] As such, ivabradine improved exercise time and symptoms in systolic HF, not HFpEF.

Limitation of heart rate >110 bpm in systolic HF – In healthy subjects, an increase in heart rate causes an increase in contractility, the so-called Bowditch phenomenon. In systolic HF, an increase in heart rate at rest or exertion is only beneficial up to a certain point, which is lower than in healthy subjects; **the lower mechanical and energy reserves prevent the increase in contractility seen at higher rates in healthy subjects.** There is a heart rate beyond which effective calcium handling and cardiac contractility decline, and exercise capacity and peak VO_2 decline, whether the rhythm is sinus or AF; **the peak effective heart rate is lower in systolic HF than in healthy subjects (103 ± 22** vs. 126 ± 15 bpm; age 70s), which may explain their somewhat adaptive chronotropic incompetence.[106–109]

Value of higher baseline and exertional heart rate in HFpEF – In HFpEF, the stiff and small LV cavity has limited capacity to raise its filling at slower heart rates, even in a compensated state, and may fully rely on heart rate to maintain cardiac output. While a heart rate >120 bpm may impair lusitropy,[110] moderately high **heart rates up to 120 bpm** enhance myocardial contractility and *accelerate relaxation kinetics, particularly as the LV operates at a smaller volume and a more compliant portion of the P-V relationship* (Figure 5.5).[111] A moderately elevated rate may also reduce LV wall thickness over the long term and thus increase LV volume, the preload-dependent stroke volume, and LV distensibility. Hence, in a study of patients who already have pacemakers in place, faster backup pacing in HFpEF (~75 bpm vs. 60 bpm, atrial +/– His pacing) resulted in better quality of life, lower BNP, and higher activity levels.[111] In the HFpEF ivabradine trials, untreated patients (heart rate mid-70s) had better exercise capacity, chronotropic response (129 bpm), and peak VO_2 than the treated patients (resting heart rate ~60, peak 107 bpm).[112] In another trial, β-blocker withdrawal improved exercise capacity, peak heart rate (127 bpm), peak VO_2, quality of life, and diastolic E/E' in HFpEF with resting heart rate <75 bpm and chronotropic incompetence.[113]

Summary of the target resting and peak heart rate in different conditions:

1. HFrEF, chronically at rest in sinus rhythm: <70
   HFrEF, decompensated or during exercise: up to 100–110s
2. HFpEF, chronically at rest: 75–100
   HFpEF, decompensated: likely 100–120
   HFpEF, mild/moderate exercise: likely 110–120s
3. AF chronically at rest: 75–100 (even if HFrEF)
   AF with decompensated HF: 100–110s
   AF with decompensated HF: convert it to sinus rhythm pre-discharge → this improves CO: (i) long-term (atrial kick); and (ii) even acutely, not so much by restoring the atrial kick, which is marginal acutely, but via making the heart rate regular and via improving LV energetics (HFrEF) and lusitropy (HFpEF), which are impaired by AF rate >120 bpm.
   Yet, immediate cardioversion is only warranted in case of *shock +AF rate* >120-130 bpm (in HF), or shock + *AF rate* >150 (in the absence of HF).

VI. Mechanisms of exercise intolerance in HF

Normally, during exercise as during infectious states, LV end-diastolic volume increases (preload), end-systolic volume decreases (contractility), which allows stroke volume to increase and match the high metabolic demands. LVEDP decreases but may slightly increase (≤2 mmHg) in elderly patients since the myocardial contractility fails to increase as much as in young individuals. In systolic dysfunction with poor inotropic reserve, or in diastolic dysfunction, 2 untoward effects occur:

i. LV is unable to accommodate the increased preload, leading to an increase in filling pressures and a lack of appropriate increase in stroke volume.

ii. ***Cardiac output may be normal at rest during a hemodynamic study but the cardiac output reserve is poor.*** Patients with HF and reduced or even preserved EF are characterized by a blunting of the increase in stroke volume index compared to normal or hypertensive controls who do not have HF, which partly explains the early fatigue and exercise limitation of patients with HF.[114–116]

In a patient with HF and preserved EF, the LV cannot significantly increase its filling and its end-diastolic volume during exercise despite the increased venous return (small and stiff LV cavity with no preload reserve, inability to use the Frank–Starling mechanism).[114] This lack of preload reserve prevents the rise in stroke volume and induces a backup increase in LA pressure. Moreover, these patients have impaired capacity to increase LV contractility during exercise, despite a preserved baseline EF.[115] They also manifest a blunted exercise-induced vasodilatation; this elevated afterload during exercise further reduces stroke volume and subsequently increases PCWP during exercise.[114,115]

VII. Pressure–volume (PV) loops

The PV loop expands on the pressure–volume relationship shown in Figure 5.5 to incorporate the systolic behavior. The PV loop is bounded inferiorly by the end-diastolic pressure–volume relationship, which is dictated by *chamber stiffness* and diastolic function; it is bounded on top by the end-systolic pressure–volume relationship (ESPVR) or elastance, which is dictated by *myocardial contractility* (Figure 5.7). *Stroke volume* corresponds to the width of the PV loop. The total PV area corresponds to the *stroke* work (stroke volume × [mean arterial pressure - LV diastolic pressure]) and closely correlates with the myocardial oxygen uptake, as well as the overall pumping function of the ventricle.

VIII. Additional features of HF with preserved EF

HFpEF, often called diastolic HF, is differentiated from systolic HF by a normal EF, a non-dilated or only mildly dilated LV during decompensation (LV end-diastolic volume <75 ml/m^2 or <90 ml/m^2, respectively), and a steep pressure–volume relationship. However, HFpEF is not simply diastolic HF; besides diastolic dysfunction, additional mechanisms are seen in a substantial proportion of patients:

a. Increased arterial stiffness and impaired capacity to vasodilate during exercise, with increased afterload and exaggerated hypertension during exercise.[114,115]

b. Mild impairment of LV contractility is common in HFpEF. In particular, the capacity to increase contractility and EF with exercise is significantly impaired.[117] EF, which equals stroke volume/end-diastolic volume, is determined not only by contractility but also by loading conditions. For the same contractility, a reduction in preload reduces the EF denominator and thus increases EF; a reduction in afterload increases stroke volume and thus increases EF. Thus, a normal EF may be seen in a patient with impaired contractility but a small LV with low afterload. **EF is more a marker of remodeling than intrinsic contractility**; as such, impaired systolic function is better diagnosed by: (i) reduced LV strain on echo, which is highly prevalent in HFpEF (~50% in TOPCAT trial, even more so in amyloidosis); (ii) impaired capacity to reduce end-systolic volume with exercise; (iii) **end-systolic elastance Ees,** which is the true measure of contractility and is independent of loading conditions = end-systolic pressure (SBP)/end-systolic volume (Figure 5.7).

c. As opposed to the dilated LV of systolic HF, the LV of HFpEF is often small, particularly in the elderly non-obese patients.[118–120] The small LV size implies severe LV diastolic dysfunction with inability of the LV to distend and provide stroke volume; in fact, as compared to matched controls or hypertensive patients, HFpEF patients have a smaller LV diastolic volume,[118] and an impaired capacity to increase LV volume and stroke volume during exercise (limited preload reserve = limited Frank–Starling mechanism).[115,119] This makes them fully reliant on heart rate to increase their cardiac output.

β-Blockers may be harmful in patients with small LV, i.e., patients whose preload reserve and stroke volume are limited and who depend on heart rate to increase their cardiac output.

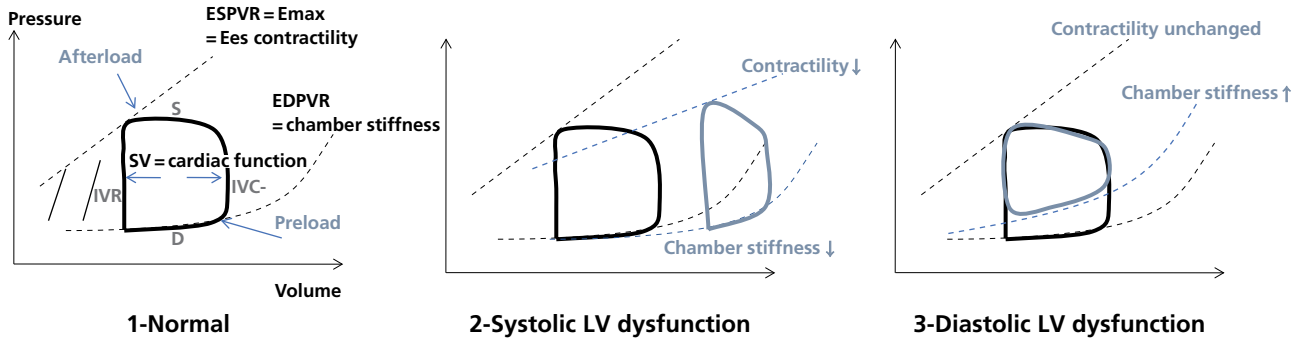

Figure 5.7 Pressure-volume loops

1. Normal individuals, with pressure–volume relationship during diastole (D), systole (S), isovolumic contraction (IVC-), and isovolumic relaxation (IVR). Four parameters determine the pressure–volume loop: (1) chamber stiffness line; (2) intrinsic contractility line, or end-systolic ESPVR line, or Ees line; (3) preload, which is the end- diastolic volume, a point on the chamber stiffness line; (4) afterload, which is the end-systolic volume and pressure. Stroke volume corresponds to the width of the loop, while stroke work (SW) corresponds to the area of the loop.

   For the same preload, a stiffer chamber will have a higher pressure in diastole. For the same intrinsic contractility, afterload reduction moves the curve down along ESPVR, which increases stroke volume. *Ejection fraction (= stroke volume/end-diastolic volume) is affected not only by intrinsic contractility but by preload and afterload.* ***The Ees slope is the true measure of intrinsic contractility, regardless of loading conditions, and equals: end-systolic pressure (SBP)/end-systolic volume.*** Arterial *afterload* may be assessed as *arterial elastance* Ea, and approximates SBP/stroke volume. *Ventriculo-arterial coupling* is measured as Ea/Ees ≈ end-systolic volume/SV (normally 0.6-1, corresponds to EF ~50-65%). VA uncoupling occurs when Ea>>Ees.
2. Systolic LV dysfunction: the contractility line (end-systolic line) is tilted down and afterload is increased. The chamber stiffness improves, yet the preload is severely increased, hence the end-diastolic volume is on the steep portion of the chamber stiffness line. The loop is narrow (low stroke volume), with *contractility/afterload mismatch. The ESPVR line being down, changes in afterload more strikingly affect stroke volume than in a normal heart*.
3. Diastolic LV dysfunction: the chamber stiffness line is up. As opposed to systolic dysfunction, a decrease in afterload results in less increase in stroke volume and more decrease in systolic pressure.

EDPVR, end-diastolic pressure–volume relationship; ESPVR, end-systolic pressure–volume relationship; Ees, end-systolic elastance; SV, stroke volume.

d. While the LV is often small or normal in size, in a subgroup of patients with HFpEF, LV is mildly dilated and *hypervolemia* is the mechanism of HF. This is characteristic of the **obese HFpEF, which overlaps with high-output HF.** [120] As may be seen on the pressure–volume relationship in Figures 5.5 and 5.6, even patients with normal LV function can have an increase in LVEDP and PCWP when the LV volume is excessive, e.g., over 250 ml, as in advanced kidney disease and high-output states.

e. Tachycardia, whether induced by pacing or exercise, is associated with a more potent contractility and relaxation in normal individuals (Bowditch effect), but further impairment of relaxation in diastolic HF when heart rate > 120 pm.[110,121,122] ***Yet blunting of the heart rate and β-blockade may be harmful, as some patients cannot increase their ventricular filling with a longer diastole and rely on their heart rate to maintain cardiac output.*** Also, *50% of HFpEF patients actually have chronotropic incompetence that may be a major contributor to their exercise intolerance*.[115,123,124] This is likely secondary to *autonomic dysfunction*, which is common in any HF, a result of reduced β-receptor sensitivity and impaired vagal tone. Vagal tone controls heart rate variability; a steady vagal tone that does not diminish with exercise attenuates heart rate response, and its lack of augmentation in recovery attenuates heart rate recovery, with an overall limited rate variability.[123] All this may be aggravated by β-blockade, hence β-blocker withdrawal improved functional capacity, exertional heart rate, and diastolic E/E' in a study of HFpEF with resting heart rate <75 bpm and chronotropic incompetence.[113]

f. Pulmonary hypertension disproportionate to the rise of PCWP. One study documented a high prevalence of pulmonary hypertension in patients with HFpEF; 83% of patients in this study had pulmonary hypertension, the median PA systolic pressure being 48 mmHg.[125] Interestingly, PA pressure was out of proportion to what would be expected from the rise in PCWP. Thus, besides the postcapillary pulmonary hypertension, a precapillary pulmonary arterial hypertension frequently coexists or develops during the course of HFpEF and may be an independent contributor to the symptomatology of HFpEF.

g. Atrial cardiomyopathy with stiff LA. LA is poorly compliant and poorly contractile and is further compounded by AF.

h. *Vasodilators are more likely to reduce systolic BP and less likely to improve stroke volume in patients with diastolic HF than systolic HF, and thus they may not be tolerated in diastolic HF with normal or low-normal BP*.[126] The latter is the result of 3 mechanisms:
(i) Vasodilators are also venodilators that reduce preload; diastolic HF is more preload-dependent than systolic HF, and thus the stroke volume is less likely to increase with vasodilators in diastolic vs. systolic HF. (ii) Afterload reduction results in less stroke volume increase and more BP drop in diastolic HF than systolic HF (Figure 5.4). However, this equation also depends on how elevated the baseline afterload is. Patients with severe hypertension benefit from vasodilators regardless of the type of HF. (iii) In addition to ventricular stiffening, diastolic HF is characterized by arterial stiffening, making BP more sensitive to small changes in vascular resistance. A small increase in vascular resistance is harmful as a result of the striking increase in BP, but excessive reduction may not be tolerated either. Patients without HTN and with severe restrictive cardiomyopathy, such as amyloidosis, very poorly tolerate vasodilators and consequently develop severe hypotension.

IX. High-output HF

High-output HF is characterized by elevated left ± right filling pressures, yet a cardiac index that is at the upper limit of normal or elevated (≥4 L/min/m^2 or cardiac output ≥ 8 L/min), and a wide rather than a narrow pulse pressure. **The top 3 causes of high-output HF are: (1) morbid obesity, (2) severe anemia, and (3) lung disease.** Other causes include cirrhosis, large AV fistula (including dialysis fistula, Paget bone disease), hyperthyroidism, thiamine deficiency (beriberi, especially in an alcoholic), or volume overload in a patient with advanced kidney disease.[127] In lung disease and anemia, cardiac output rises to improve O2 delivery and compensate for the low arterial oxygenation or low hemoglobin; hypercapnia causes vasodilation and further raises cardiac output. In obesity, cardiac output rises to meet the demands of a larger body and a dilated adipose microcirculation.

The high output is typically related to significant systemic vasodilatation or AV fistula. The worst outcomes are seen in patients with the lowest systemic vascular resistance. High-output HF has 2 pathophysiological characteristics:

1. The systemic vasodilatation or the fistula requires a high cardiac output to maintain the systemic pressure, which eventually leads to renal salt retention and a ***high venous return/preload***. *As a result of this severely increased preload, the left- and right-sided filling pressures increase*. Even if LV compliance is normal, the LV diastolic pressure increases when LV diastolic volume exceeds 250–300 ml (Figures 5.5 and 5.6). In many cases, these patients also have a degree of ventricular dysfunction that further makes them sensitive to the rising preload.
2. While increased in absolute value, the cardiac output may not be high enough to fill the vasodilated circulation, meaning it is a relatively low cardiac output with limited exertional cardiac output reserve. This is similar to the exertional response of any HF: ***cardiac output increases in absolute value (e.g., 2× the baseline), but is below the required increase (4–5 times the baseline), with inability to accommodate the high venous return***.

LV is usually dilated or at the upper limit of normal. LVEF is often normal or high, higher than normal control subjects (hyperdynamic).[127] EF may deteriorate over time as a result of the chronically increased preload, as the LV poorly tolerates volume overload conditions, similarly to the pathophysiology of chronic MR, but the EF decline is not usually severe. Diuretics, particularly spironolactone and possibly SGLT2 inhibitors, are the mainstay treatment.[128] Vasodilators such as CCBs aggravate the problem and are best avoided; ACE-I, if needed, may not be as harmful as it blocks the angiotensin-aldosterone axis at the center of salt retention.

X. Peripheral interplay of venous volume, arterial volume, interstitial volume, and lymphatic drainage in HF

About one-fourth of the extracellular volume is intravascular, while the rest is extravascular (interstitial). The fluid shift from the intravascular capillaries to the interstitium is dictated by the hydrostatic and oncotic pressure in each department (Starling law). The pressures in the arterial and venous capillaries are averaged to calculate mean functional capillary pressure for the entire length of the capillary;

normally, there is a slight net pressure toward the interstitium, causing a filtration from the arterial capillary higher than the absorption from the venous capillary, i.e., a net filtration. The lymphs drain this net filtration. The net filtration is much higher when venous pressure is elevated.

The concept of "interstitial expansion and edema with intravascular volume depletion" is often untrue. An overhydrated interstitium quickly refills a depleted plasma volume, as the low intravascular hydrostatic pressure and high intravascular oncotic pressure create a pressure gradient toward the plasma. Therefore, edematous patients usually have excess intravascular volume.

Thus, except for cases of local venous obstruction causing local edema, peripheral edema signals expansion of both extravascular and intravascular volumes. Yet, the degree of edema does not linearly correlate with the rise of total body volume and is affected by the venous capacitance. Approximately 70% of blood volume resides in the venous reservoir; therefore, changes in venous tone affect venous return, edema, and the rise of ventricular filling pressures and arterial volume.[129]

While cardiac hemodynamics and the increase in cardiac filling pressures are at the center of HF, the peripheral circulation plays a critical role in attenuating or exaggerating HF effects.

Role of the venous capacitance – Decompensation of chronic HF typically involves an increase in circulatory volume (arterial and venous) with increased intravascular pressure and a spillover in the interstitial space (***systemic congestion, volume overload phenotype***). However, a subset of decompensated HF patients may not have a severely increased total body fluid volume, but rather venous constriction with mobilization of the venous reservoir, particularly the splanchnic venous reservoir, into the heart and the arterial circulation causing congestion, especially at the pulmonary level as LVEDP rises. This is the ***hemodynamic congestion***, ***pulmonary congestion***, or ***fluid redistribution*** phenotype of HF (interstitial and circulatory volume only mildly increased). These patients develop HF more abruptly with any small rise of circulatory volume, compared to patients with a more accommodating venous system who develop gradual HF with more severe hypervolemia and systemic congestion.[129–131]

In contrast, some patients may have increased LVEDP, RA pressure, and total body volume, but the venous reservoir dilates and accommodates the excess volume, preventing a severe increase of cardiac and arterial volume and intravascular pressure. Eventually, at some point, the high venous volume will exceed the venous compliance and cause a rise in venous pressure and venous return to the heart and the arterial circulation, as well as systemic edema.

Role of arterial dysfunction – Besides venous hemodynamics, arterial dysfunction may explain abrupt decompensation of chronic HF. Arterial noncompliance may cause acute BP and afterload rise with any mild increase in arterial tone or volume; the failing heart being very sensitive to afterload, this triggers a quick rise in LVEDP and pulmonary congestion even without severe hypervolemia. This is another form of *pulmonary congestion* or ***fluid redistribution*** phenotype of HF.

Of note, *neurohormonal activation* is at the center of venous constriction, arterial dysfunction, and total fluid volume increase.

Registry data suggest that systemic congestion/volume overload is more common than pure hemodynamic pulmonary congestion (70% vs. 30%), but the *2 pathophysiologies very frequently coexist*.[132] Hemodynamic congestion is relatively more common with de novo HF (30–40% of de novo HF vs. ~30% of decompensated chronic HF).

Role of the lymphatic drainage – Starling forces control initial fluid shifts between the plasma and interstitium, but lymphatic vessels play a key role in draining any net fluid shift in the interstitial space and reducing congestion, particularly in chronic HF. A markedly increased lymphatic function (up to 30-fold flow, via dilatation and lymphangiogenesis) initially drains the interstitial fluid and prevents fluid accumulation in chronic HF.[133] Eventually, when lymph flow reaches a plateau, transudation from the capillaries into the interstitium causes fluid to build up in the interstitial space.

Case of hyperacute de novo HF (acute large MI, myocarditis) – In hyperacute de novo HF, LV and LA are less compliant than chronic HF, so LVEDP and LA pressure rise with much less LV and LA dilatation and less volume overload. Also, the venous capacitance (of the systemic and pulmonary veins) and the lymphatic vessels have not adapted to the excessive fluid shift, hence severe pulmonary congestion occurs with milder rise of LA pressure and milder volume overload than chronic cases.

In summary, HF develops abruptly in 3 cases, with a predominant phenotype of *fluid redistribution* rather than *fluid overload*:
- -Hyperacute de novo HF
- -Venous constriction with mobilization of the venous reservoir
- -Arterial noncompliance and vasoconstriction

The last 2 cases are partially driven by neurohormonal activation and may cause abrupt acute presentation of a chronic HF.

XI. "Hypervolemia and edema with intravascular volume depletion" is often an incorrect concept

The concept of "hypervolemia and edema with intravascular volume depletion" is often untrue. An overhydrated interstitium quickly refills a depleted plasma volume, as the low intravascular hydrostatic pressure and high intravascular oncotic pressure create a pressure gradient toward the plasma. Therefore, edematous patients usually have an excess of intravascular volume. Occasional exceptions are seen, such as at the onset of septic or hemorrhagic shock in a patient who previously had peripheral edema.

Even patients with marked hypoalbuminemia and nephrotic syndrome do not develop edema if their extracellular volume is normal, because albumin level drops in the interstitium as well as the blood, thanks to the protective effects of interstitial protein washdown (by fluid shift) and washout (by lymphatic system). Only expansion of the extracellular volume causes edema, such as "overfilling" and primary salt retention by the nephrotic kidneys.[134,135] Once edema happens, it characteristically is more pronounced than in normal albumin states,

and excess volume is more predominant in the interstitium than the blood. This is because, in profound hypoalbuminemia <2 g/dl, interstitial protein concentration drops to zero during edema, in such a way that any further decline of intravascular oncotic pressure is not accompanied by parallel decline of extravascular oncotic pressure, hence interstitial edema predominates. Thus, what differentiates nephrotic patients is that when the extracellular volume expands, the excess fluid predominates in the interstitial space, vs. both the intravascular and interstitial spaces in pure HF. These patients require diuresis, but the key is to be slower, as the intravascular fluid is less increased than in normal albumin states. Diuresis allows extravascular to intravascular fluid shifts once the intravascular hydrostatic pressure declines and its oncotic pressure rises.[134]

Of note, the scenario of "edema with non-increased intra-arterial volume" may be seen in patients with local venous disease, such as superficial or deep lower extremity venous insufficiency. When the venous valves are incompetent, the venous blood cumulates and eventually causes a rise in venous pressure. This reduces the arteriovenous pressure gradient across the peripheral circulation and raises the mean capillary pressure causing edema. The venous blood is not reaching the heart and the arterial circulation and does not "communicate" with the remainder of the body; hence the intra-arterial volume is not increased despite edema, and cardiac preload may drop with diuretic therapy.

QUESTIONS AND ANSWERS

Question 1. A 67-year-old man with TTR amyloidosis presents with weakness and dizziness. He is found to have AF, rate 140 bpm, with SBP 105 mmHg. Which one of the following agents should be used?
A. Digoxin
B. Metoprolol
C. Amiodarone
D. Diltiazem

Question 2. A 55-year-old-man undergoes ECG recording before hernia surgery. He is found to have 3 unifocal PVCs on this recording, having LBBB morphology with vertical axis (RVOT origin). Holter demonstrates 22% PVC burden. All of the following increase the risk of PVC-induced cardiomyopathy, except:
A. PVC QRS duration
B. PVC burden
C. Interpolated PVC
D. RVOT origin
E. Male sex
F. Asymptomatic status
G. Experiencing the PVCs for a long duration (years)

Question 3. The echo of the patient from Question 2 shows dilated LV with EF 30%. He has no CAD on coronary angiography. What is the best next step?
A. Watchful waiting as long as he remains asymptomatic
B. Beta-blocker therapy
C. PVC ablation
D. Amiodarone
E. ICD placement

Question 4. A 52-year-old asymptomatic woman has an irregular pulse on exam. ECG shows frequent unifocal PVCs and is otherwise normal. Echo is normal. Holter demonstrates a PVC burden of 22%. What is the next step?
A. Beta-blockade
B. Flecainide
C. Catheter ablation
D. Repeat echo and Holter in 6–12 months
E. A or B

Question 5. If in Question 4, the same patient had symptoms (palpitations) with normal echo, what would the next step be (same A through E options)?

Question 6. A 75-year-old woman with a history of stable ischemic cardiomyopathy, EF 35% for several years, presents with increasing palpitations and dyspnea. ECG and Holter show frequent PVCs of at least 3 different morphologies, with a PVC burden of 20%. Echo shows a decline of EF to 20%. Nuclear SPECT shows fixed old defects, with no new ischemia. She has CKD. What is the best management?
A. Increase the dosage of her beta-blocker
B. Catheter ablation of PVCs
C. Amiodarone
D. Flecainide
E. Sotalol
F. Dofetilide

Question 7. A 55-year-old woman with dilated cardiomyopathy and LVAD HeartMate II implantation 3 years previously presents with weakness and dyspnea. On exam, her arterial pressure measured 65 mmHg by Doppler. She has severely elevated JVP, 3+ edema, and ascites. LVAD interrogation shows reduced pump flow, stable power, and reduced pulsatility. LDH is mildly increased. What is the diagnosis?
A. Pump thrombosis
B. RV failure
C. Inappropriately low LVAD speed
D. Inappropriately high LVAD speed

Question 8. A patient with LVAD presents with fatigue, a Doppler arterial pressure of 60 mmHg, and a picture of severe RV failure, confirmed by echo and cath. The septum is bowing to the left on echo. What is the next management step?
A. Intravenous diuresis
B. Placement of RVAD
C. Intravenous diuresis and reduce LVAD pump speed from 2600 rpm to 2550 rpm
D. Intravenous diuresis and increase LVAD pump speed from 2600 to 2650

Question 9. In HFrEF, what heart rate leads to the highest LV contractility and likely the highest cardiac output?
A. 220 minus age
B. 100–110 bpm
C. 60–80 bpm
D. It depends on: compensated vs. decompensated HF, sinus rhythm vs. AF

Question 10. An 80-year-old man has a history of ischemic cardiomyopathy and CABG, with an EF of 25% at baseline. Over the last few months, he has deteriorated clinically, with multiple HF admissions, and with a drop in BP necessitating interruption of ACE-I and carvedilol; in fact, he is requiring midodrine for severe hypotensive episodes. Echo shows EF of 35% with inferoapical akinesis. He has LVH with septal thickness of 16 mm. ECG shows AF and non-specific conduction delay with a QRS of 140 ms. What is the next step?
A. CRT
B. Serum and urine immunofixation and serum light chain ratio
C. Myocardial technetium pyrophosphate scan
D. Cardiac MRI
E. Coronary angiography

Question 11. An 80-year-old man with severe HF, CKD, and suspected cardiac amyloidosis has a monoclonal protein band on serum electrophoresis. Immunofixation shows IgG lambda monoclonal peak. Serum light chains kappa and lambda are both elevated with a normal ratio. What is the next step?
A. Bone marrow biopsy
B. Endomyocardial biopsy
C. Technetium pyrophosphate scan
D. Cardiac MRI
E. A or B
F. A or B or C

Question 12. A 70-year-old black man has severe heart failure and a wall thickness of 16 mm. Technetium pyrophosphate SPECT shows grade 3 myocardial uptake. The kappa free light chain was severely elevated with a kappa/lambda ratio of 16 (normal, 0.25–1.65). Bone marrow biopsy shows 12% kappa plasma cell clone with no amyloid deposits. What is the next step?
A. Initiate tafamidis
B. Perform endomyocardial biopsy
C. Initiate plasma cell-directed chemotherapy
D. Perform genetic TTR testing

Question 13. A 72-year-old man has severe HFrEF with dilated LV, EF 25%, and wall thickness of 12 mm. Technetium pyrophosphate scan (planar imaging) shows grade 2 cardiac uptake. The serum light chain kappa/lambda is normal and no monoclonal gammopathy is noted on serum and urine immunofixation. What is the next step?
A. Perform technetium pyrophosphate myocardial SPECT
B. Start tafamidis
C. Perform TTR genetic testing

Question 14. A 47-year-old man with no known medical history collapses while driving and has a car accident. He is found to be in complete AV block with ventricular escape rhythm of 30 bpm. No concordant ST elevation is noted. He is resuscitated and temporary pacemaker is urgently placed. Echo shows severe global LV dysfunction that persists after several days of pacing. What is the most likely diagnosis?
A. Myocardial infarction
B. Lamin A/C genetic mutation
C. ARVD
D. Sarcoidosis
E. AV block secondary to chest contusion

Question 15. A patient with LVAD has a mean BP of 100 mmHg. LVAD pump flow is 4 L/min and power is slightly reduced, with a low pulsatility index. Which of the following is true (multiple possible answers)?
A. The goal mean BP in LVAD is 60–80 mmHg
B. HTN is caused by high pump speed and flow. Reduce pump speed
C. HTN is reducing pump flow and pulsatility index
D. HTN is caused by vasoconstriction and arterial noncompliance. Initiate antihypertensives

Question 16. A patient with LVAD has a pulsatility index of 5. Which of the following is true?
A. Pulsatility index is unaffected by the pump speed
B. He has some intrinsic LV function, making him less reliant on LVAD
C. He has very limited native heart function, making him more reliant on LVAD

Question 17. A 58-year-old man receives LVAD. One year later, he develops dyspnea, along with progressive tachycardia and a rising pulse pressure. LVAD interrogation shows a progressively rising power and flow over the last 5 days. What is the diagnosis?
A. LV suction
B. Bleeding
C. Pump thrombosis
D. Outflow cannula thrombosis
E. HTN

Question 18. A 65-year-old man is undergoing LVAD placement for advanced left HF. He also has severe functional MR, severe AS, and iatrogenic ASD from a prior VT ablation. Which of the following lesions is most consequential after LVAD placement?
A. Aortic stenosis
B. Mitral regurgitation
C. ASD

Answer 1. C. Amyloid patients very poorly tolerate CCB and β-blockers. Amiodarone may be the only option, even for rate control. Besides, a higher heart rate (up to 110–120 bpm) should be respected in restrictive cardiomyopathy with very limited stroke volume reserve, as cardiac output depends on it.

Answer 2. D. Epicardial origin and QRS duration increase the likelihood of cardiomyopathy, not RVOT vs. LV.

Answer 3. C. Beta-blockade should be given, but significantly reduces PVC burden in only 10–24% of patients. PVC ablation is first-line treatment of PVC-indiced cardiomyopathy (class I ESC); alternatively, felcainide or amiodarone may be considered if ablation fails or is not desired (Class IIa).

Answer 4. D. There is no indication for treating frequent PVCs in asymptomatic patients with normal LV.

Answer 5. E.

Answer 6. C. Her baseline cardiomyopathy appears to have deteriorated because of frequent PVCs, and thus, PVC therapy is indicated. Catheter ablation is not the best option when multiple PVC morphologies are present. Flecainide is contraindicated in CAD. Sotalol and dofetilide have limited safety and efficacy data in patients with PVCs and cardiomyopathy, and the efficacy is reportedly modest; also, they should be used carefully in CKD.

Answer 7. B. Exam suggests RV failure. RV failure is seen in 20–40% of LVAD patients and may occur early or late. It is due to leftward septal pull by the LVAD, and the increased cardiac output and venous return, both of which dilate the RV. RV "sees" higher venous return after LVAD placement and must match that by increasing its stroke volume, otherwise it dilates and fails.

LVAD pump thrombosis manifests as increased rather than reduced power, along with increased LDH >2× upper limit (from hemolysis).

Answer 8. C. Management of RV failure post LVAD focuses on diuresis, LVAD pump speed reduction to avoid septal shift and reduce venous return, which eventually maximizes flow, and treatment of exacerbating factors such as atrial arrhythmia and loss of AV synchrony.

Answer 9. B. As per 2 Bowditch revisited trials, the heart rate that leads to peak contractility and peak VO_2 and exercise time is 103+/– 22 in stable HFrEF patients (mean age 72) vs. 126 +/– 15 in matched, healthy elderly subjects. Programming their pacemaker's rate response to such a peak heart rate continued to improve exercise parameters at 6-month follow-up. This peak rate was not affected by AF vs. sinus rhythm (a third of patients had AF). The blunting of Bowditch phenomenon is related to metabolic exhaustion in HFrEF and thus, peak effective heart rate is unlikely to be higher at the decompensated stage. In fact, this peak effective heart rate is mainly useful for decompensated states and exertion; the heart rate goal *at rest* is <70 bpm for chronic *compensated, sinus-rhythm* HFrEF. Note that HFpEF and AF do not benefit from this tight resting heart rate goal.

Answer 10. B. Although the patient has ischemic cardiomyopathy, the recent unexplained deterioration, the pronounced hypotension, and the LV thickening on echo should suggest amyloidosis. Echocardiographic "LVH" in an elderly HF patient should not be simply attributed to HTN, and amyloid deposition should be considered when red flags are present. The first 2 diagnostic steps are technetium pyrophosphate scan and AL monoclonal protein testing. In fact, it is best to start with monoclonal protein testing, as 22% of AL amyloidosis cases have a positive technetium pyrophosphate scan. Serum and protein electrophoresis, compared to immunofixation electrophoresis, are not sensitive enough and may miss a small amount of monoclonal protein.

Answer 11. A The abnormal monoclonal testing is worrisome for AL amyloidosis, with or without multiple myeloma. The monoclonal immunoglobulin peak may also be related to monoclonal gammopathy of unknown significance, which is common at this age (up to 12%); as such, the patient may have TTR amyloidosis or no amyloidosis at all. Technetium pyrophosphate is less helpful once monoclonal testing is abnormal, and tissue biopsy is required. A bone marrow biopsy looks for plasma cell dyscrasia, i.e., plasma cells >10% of bone marrow cellularity (vs. <10% in monoclonal gammopathy of unknown significance); and for amyloid deposits by Congo red stain. Amyloid deposits are not always seen in the bone marrow in amyloidosis; if no amyloid deposit is found in the bone marrow, endomyocardial biopsy is done. The amyloid deposit is subtyped into AL vs. TTR using mass spectroscopy. *Note:* CKD raises free light chains, particularly kappa, but in a polyclonal fashion. This may explain elevation of both kappa and lambda with a normal ratio or a slightly elevated kappa/lambda ratio.

Answer 12. B. In a patient with monoclonal gammopathy, the diagnosis of AL amyloidosis must be sought by bone marrow or fat pad biopsies, and if negative, by endomyocardial biopsy. The latter is not required when other biopsies are positive for amyloidosis, but is required when those biopsies are negative to diagnose or exclude AL amyloidosis. In this patient, endomyocardial biopsy showed TTR amyloid deposits, and genetic testing showed genetic TTR mutation. Yet, genetic testing should not precede endomyocardial biopsy in this case.

Answer 13. A. Single-plane chest scintigraphy looks at the cardiac silhouette in one view (like CXR) and cannot delineate whether the technetium is cumulating in the myocardium itself or the LV cavity, as part of blood pooling in low-output states. Conversely, multi-plane myocardial SPECT imaging delineates the uptake to the myocardium vs. blood pool. Technetium pyrophosphate myocardial SPECT, rather than planar imaging, is recommended in suspected amyloidosis. In addition, the clinical probability of amyloidosis is low in this patient, and scintigraphy was not indicated altogether.

Answer 14. B. AV block may result from cardiac contusion, but in the setting of AV block and car accident, AV block is far more likely to be the cause than the consequence of the accident. MI is not likely, as MI that causes AV block is a STEMI with definite ST elevation on ECG. Causes B through D are all possible, but the combination of AV block and cardiomyopathy at a young age is mostly suggestive of lamin A/C cardiomyopathy. In one study, one-third of patients with AV block and new LV dysfunction had lamin A/C mutation (Arbustini E, et al. J Am Coll Cardiol. 2002 Mar 20;39(6):981–90). Moreover, lamin A/C mutation may lead to AV block or VT (sudden death) before any overt myocardial disease. It is autosomal dominant with high penetrance; in one study, over 50% of the proband's family members who carry the gene develop a cardiac manifestation (AV block or LV dysfunction).

Answer 15. C and D. Mean BP goal is 65–90 mmHg in LVAD patients. HTN may be caused by high pump speed and flow (high readings on flow and power). Conversely, it may rather be a primary process that causes reduced pump flow and power, as in this case.

Answer 16. B. Pulse index is normally 3–7. Higher values indicate more reliance on native heart function, and the converse is true with lower values.

Answer 17. C. Hypovolemia or bleeding reduces pump flow and power. The same process is seen with LV suction event; pulse index may also decline as the intrinsic LV flow declines as well. Outflow cannula obstruction increases delta pressure and reduces flow and power. A similar process is seen with HTN, plus a low pulse index. Only pump thrombosis is associated with increased power, along with a falsely increased flow calculation (the true cardiac output obtained by Swan is lower). It takes more energy to move the thrombosed blades, hence the higher power. Pulsatility increases as flow is more reliant on native heart function.

Answer 18. C. LVAD unloads the LV and reduces functional MR, which thus does not need to be corrected during LVAD implantation. The LVAD inflow is in the LV, while its outflow is in the aorta; LVAD bypasses AS. AI, on the other hand, causes flow recirculation and needs to be corrected with a bioprosthetic valve during LVAD implantation. In a patient with small ASD or PFO, which is otherwise innocuous, LVAD reduces LA pressure and creates a sucking effect from the RA, leading to a significant right-to-left shunting and postoperative hypoxemia; any intracardiac shunt needs to be corrected at the time of LVAD surgery.

107. Gierula J, Paton WF, Lowry JE, et al. Rate-response programming tailored to the force frequency relationship improves exercise tolerance in chronic heart failure. J Am Coll Cardiol HF 2018;6:105–113 (Bowditch Revisited trial). *Patients with LVEF <50% (32+/–11), age 72, and pacemaker were paced at various rates, and contractility assessed at various rates (contractility assessed by the ratio SBP/LVESVI, which is Ees LV elastance). The heart rate with peak contractility was 103+/–22 in HF vs. 126+/– 15 in matched age control patients with normal EF and no HF. Also, peak contractility was lower in HF, and the slope of contractility rise with heart rate was slower in HF. This may not correspond to the rate providing peak stroke volume during exercise, as the latter is also affected by the venous return of exercise. Yet, importantly, patients of this trial underwent exercise testing: programming the rate response to a lower peak (as calculated in the prior phase), rather than a high peak of ~140 led to 50 s more exercise time and higher pVO2. 28% of patients had AF, and this did not seem to affect the heart rate of peak contractility*.

108. Gierula J, Lowry JE, Paton MF, et al. Personalized rate-response programming improves exercise tolerance after 6 months in people with cardiac implantable electronic devices and heart failure: A Phase II study. Circulation 2020;141(21):1693–1703. *This study again confirms the blunted Bowditch phenomenon in HFrEF; it took patients with HFrEF who have a CRT (mostly) or ICD, age 74; their pacemakers were randomized to a rate-response peak heart rate that corresponds to the peak contractility (105+/–18), vs. standard, higher peak heart rate. The lower heart rate was associated with superior exercise time (75 sec) at 6 months, and no EF deterioration (vs. EF decline with standard settings). AF was present in 36% of patients*.

Questions and answers 264

1. MITRAL REGURGITATION

I. Mechanisms of mitral regurgitation

The mitral valve anatomy is shown in Figure 6.1. Normally, each papillary muscle provides chordae to both leaflets. The free edges of the leaflets coapt over a length of several millimeters, at a depth of 3–7 mm from the mitral annular plane.

Mitral valve competence depends on: (a) appropriate ventricular contractility that pushes the papillary muscles, chordae, and valvular leaflets up (mitral closing force); (b) appropriate chordal length and tension that restrain the leaflets from prolapsing in the LA; (c) slim leaflet tissue that allows a tight seal in systole (as opposed to a bumpy, redundant tissue).[1]

There are 4 major mechanisms of mitral regurgitation (Carpentier's classification) (Figure 6.2):[2]

Type I: MR occurs despite normal leaflet motion and leaflet tip position. Type I MR may occur with leaflet tear(s) secondary to endocarditis or blunt trauma.

Type II: *Prolapse* of 1 or both leaflets, i.e., the billowing body of the leaflet is >2 mm above the annular plane (the free edge of the leaflet is at the annular plane or above it). If, in addition to the prolapse of the leaflet body, the free edge is overriding the other leaflet and turned toward the LA rather than the LV, the leaflet is called a *flail leaflet*; this is usually secondary to chordal rupture and a piece of chordae is usually seen flopping in the LA. Type II MR may also result from papillary muscle rupture (MI).

Type IIIa: The leaflets and chordae are thickened, retracted, and shortened, with chordal fusion (rheumatic or rheumatic-like process). The mitral motion is restricted in both systole and diastole, potentially leading to both MS and MR.

Type IIIb: Functional MR. A localized, inferior ventricular dysfunction pulls the posterior papillary muscle and chordae posterolaterally, predominantly restricting the motion of the posterior leaflet (leaflet tethering). In severe global LV dysfunction, the ventricular geometry changes from an ellipse to a sphere, which pulls both leaflets posterolaterally and apically, restricting their closure. Three additional mechanisms contribute to MR: (a) annular dilatation, which reduces leaflet coaptation; (b) reduced LV systolic pressure, which reduces the mitral valve closing force and sometimes leads to MR even when tethering is mild; (c) papillary muscle dyssynchrony in some patients with LBBB or RV pacing: one ventricular wall contracts while the other is relaxed; therefore, one leaflet is pushed up while the other is still down, which creates a gap between the 2 leaflets.

II. Specifics of various causes of mitral regurgitation

A. Acute MR

Causes of acute MR:

a. Mitral valve endocarditis: the vegetations may interfere with proper leaflet coaptation or may destroy and perforate the leaflet(s) or chorda(e)
b. Papillary muscle rupture occurring in the context of an acute MI
c. Chordae tendinae rupture. Causes: idiopathic, mitral valve prolapse, endocarditis, trauma
d. Acute functional MR secondary to an acute ventricular process (MI, myocarditis), even without papillary muscle rupture

In acute MR, *EF increases* to allow an increase in total stroke volume, the forward stroke volume remaining, however, low. The patient is in shock with pulmonary edema, LA pressure is severely increased, yet the intrinsic LV function is normal, and the LV diastolic pressure may be normal.

Blunt chest trauma during the isovolumic contraction may lead to acute MR (rupture of the papillary muscles, chordae, or leaflets).

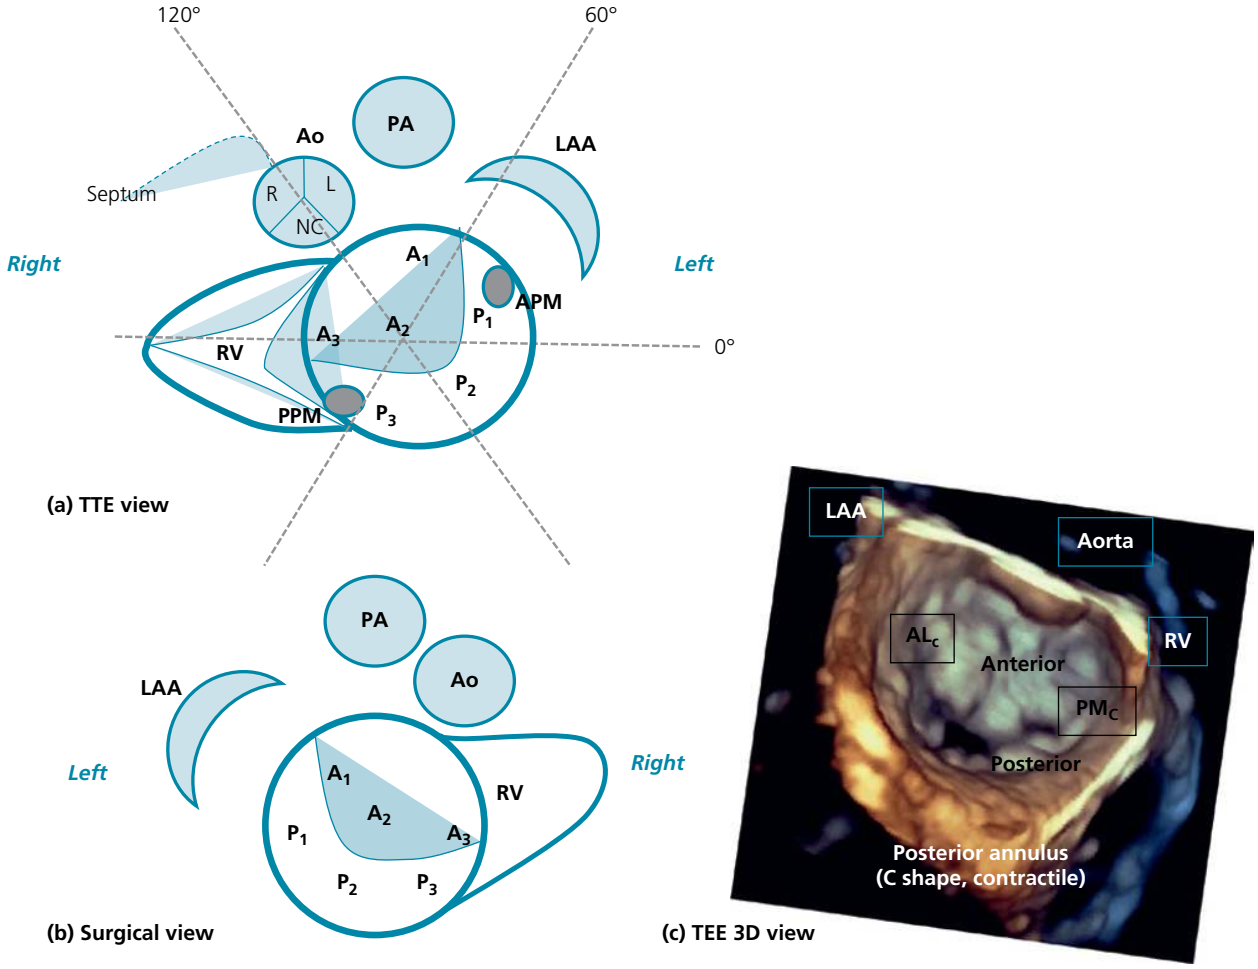

Figure 6.1 **(a)** Cross-sectional view of the mitral valve on transthoracic echocardiography, showing the relationship of the cusps with the papillary muscles, aortic valve, and left atrial appendage (LAA). Also, illustration of how various TEE rotations cut the mitral valve. A_1–A_3 are various anterior leaflet cusps, and P_1–P_3 are various posterior leaflet cusps (A_3 and P_3 are the ones attached to the septum). Note that the anterolateral and posteromedial papillary muscles (APM and PPM) are located between the 2 leaflets rather than underneath the corresponding leaflet (they are underneath the commissures). As such, *each papillary muscle provides chordae to both leaflets*. Note the continuity of the mitral and aortic valves: the mitral annulus surrounding the anterior leaflet and connecting the anterior leaflet with the aortic valve is fibrous and relatively straight, and forms the *mitroaortic curtain* (the 2 edges of the mitroaortic curtain are the 2 fibrous trigones). The posterior mitral annulus has a C shape, is muscular, and constitutes 2/3 of the annular circumference.

(b) Illustration of how the mitral valve looks surgically when approached from inside the LA through the anterior heart/RA. A_3 and P_3 are on the right (flipped view in comparison with TTE).

(c) 3D TEE view of the mitral valve (en face view). This view is similar to the surgical view. For orientation, identify the anterior leaflet (leaflet with the convex border) and the posterior annulus. The posterior annulus has a C shape, is muscular and contractile. It contracts in systole and contributes to the mitral valve competence. There are 2 commissures: anterolateral (AL_c), next to the LAA, and posteromedial (PM_c).

Note: When approached from a side, both the mitral and tricuspid annuli are *saddle-shaped*, not flat.

B. Degenerative mitral valve disease or mitral valve prolapse (MVP)

MVP (Figure 6.3) is defined as:

- **i.** One or two cusps prolapse >2 mm into the LA above the annulus level, i.e., above the leaflets' insertion site, in the long-axis view
- **ii.** Thick cusps ≥ 2 mm (myxomatous, redundant valve)
- **iii.** Cusp/chordae elongation

There are 2 forms of MVP:[1,3] (1) mitral fibroelastic deficiency, wherein the prolapsed leaflet(s) are thin (i + iii); (2) Barlow's disease or classic MVP, wherein the prolapsed leaflets and chordae are thick (i + ii + iii). Fibroelastic deficiency is a local disease that usually affects a single cusp, with the remaining cusps being normal and non-prolapsed. These patients typically do not have a long history of murmur, and MR may appear and progress rapidly (months), with a frequent chordal rupture. Conversely, Barlow's disease is a chronic process (years) associated with a long history of click or murmur and with thickening of the whole valve. Fibroelastic deficiency is most common in older patients (>50 years old), while Barlow's disease is most common in patients <50 years of age, often women, may be associated with connective tissue disorders (e.g., Marfan), and may have a familial predisposition.

Fibroelastic deficiency is the most common cause of severe intrinsic MR requiring surgery.

A prolapse seen in the apical 4-chamber view is less specific and should not be used to define MVP.

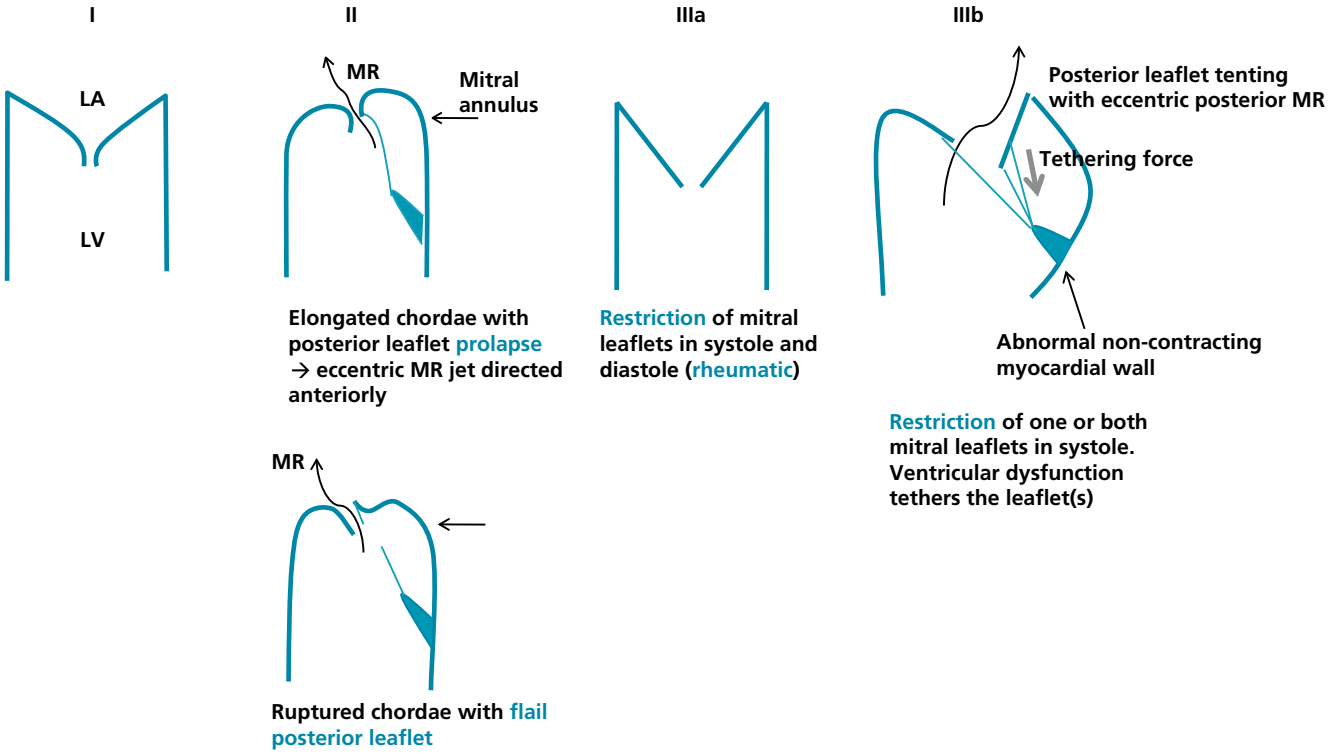

Figure 6.2 Carpentier's classification of the mechanisms of mitral regurgitation.

Type I: Normal mitral leaflet motion with the coaptation point being 3–7 mm below the mitral annular plane (saddle-shaped mitral valve). Normally, the leaflets coapt over a minimum length of 4–5 mm, more so at A2-P2 level. Type I MR may occur with a leaflet tear secondary to endocarditis or blunt trauma.

Type II: Prolapse of one or both leaflets. The billowing body of the prolapsed leaflet is over 2 mm above the annular plane. The free edge may be above the annular plane, less markedly than the leaflet body. When the free edge is significantly prolapsed and looking into the LA rather than the LV, the leaflet is called a *flail leaflet*. ASE states: "A flail leaflet occurs when the leaflet edge, not just the leaflet body, is located in the LA with free motion."

Type IIIa: Rheumatic or rheumatic-like process. The leaflets and chordae are thickened, retracted, and shortened, with chordal fusion. The mitral motion is restricted in systole and diastole, potentially leading to both MS and MR.

Type IIIb: Ventricular dysfunction pulls the posterior papillary muscle and chordae posterolaterally, restricting the motion of one or both leaflets, predominantly the posterior leaflet.

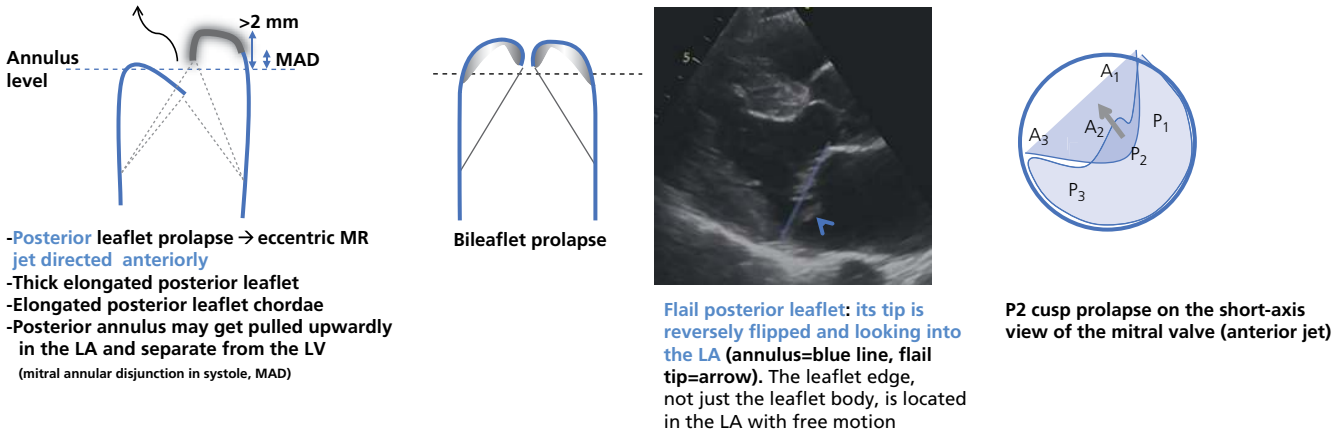

Figure 6.3 Mitral valve prolapse. The long-axis view defines prolapse, while the short-axis view defines which cups are involved (particularly when color Doppler is added).

In early MVP, the LV may be small, and further reduction in cavity size "squeezes" the mitral leaflets up in the LA, aggravating prolapse. This explains why in early MVP, MR predominates in late systole, when LV is smaller, and is worsened by lower preload and afterload. Once MR becomes severe, however, it is usually holosystolic and less affected by LV cavity size, as LV is no longer small; in fact, higher afterload further worsens MR.

Notes on MVP (degenerative MV disease)

- MVP is usually benign and occurs in 1–2% of the population with a familial trend. Female-to-male ratio = 2:1.
- MVP most commonly involves the posterior leaflet, especially the posterior cusp P_2. While two-thirds of MVPs are posterior MVPs, the anterior leaflet (often A_2) or both leaflets are involved in one-third of the cases. When confined to a single cusp, the prolapsed or the flail leaflet may be missed by TTE: TTE shows MR, often very eccentric, hugging the LA wall and underestimated in some views, without obvious structural abnormality. The jet is directed opposite to the prolapsed leaflet.
- MVP may be associated with tricuspid prolapse (in ~40%) and aortic valve prolapse (in ~10%).
- 15% of MVP cases are severe, meaning that they progress to severe MR at a mean follow-up duration of 15 years.
- Risk factors for severe MVP:
  - Man > 50 years old. MVP in an elderly patient is generally more serious than MVP in a young woman
  - Very thick valve (≥5 mm)
  - Significant MR at baseline with MR murmur
- Classic MVP, even without significant MR, significantly pulls and stretches the papillary muscle and may eventually engender a local injury and scar. This may cause frequent PVCs and rarely, VT and sudden death.
- MVP, regardless of its severity, can be associated with autonomic dysfunction (e.g., orthostatic intolerance) and atypical complaints (chest pain, fatigue, palpitations).

C. Ventricular functional MR, ischemic and non-ischemic (Figures 6.4 and 6.5)

Ischemic MR is not a valvular problem; it is a problem of segmental ventricular distortion and, to a lesser extent, increased ventricular sphericity. ***A posterior change in LV geometry tethers the posterior papillary muscle posterolaterally; consequently, both leaflets are tethered, predominantly the posterior leaflet****, as it is orthogonal to the posterior tethering force*. In fact, *local geometric remodeling that specifically tethers the posterior papillary muscle* is a more important determinant of ischemic MR than global LV remodeling, global LV sphericity, LV dilatation, or EF.[3] Severe MR may be seen with a relatively preserved EF: the majority of patients with ischemic MR secondary to inferior MI have a normal or a mildly reduced EF and a normal LV volume. Studies have shown a higher incidence and greater severity of ischemic MR in patients with inferior as opposed to anterior MI, despite a lower EF and more LV dilatation in anterior MI.[4] This is related to the greater local geometric remodeling seen with inferior MI causing greater posterior papillary muscle displacement. For a given LV volume, local posterior LV remodeling is the determinant of MR severity.[5]

Overall, ~80% of cases of ischemic MR are associated with inferior or inferolateral MI (RCA or LCx), while 20% are associated with anterior MI (LAD),[4,5] although some series found that anterior MI is responsible for ~50% of ischemic MR.[6–8] In 2 studies of ischemic MR, approximately half the patients had inferior MI, half had anterior MI, and a quarter had infarcts in both territories, with a mean EF of 35–40%.[6,8]

Anterior ventricular dysfunction, which exerts longitudinal tension on the anterior papillary muscle and the leaflets, does not lead to enough ***oblique tethering*** to provoke MR. Tethering relates to posterior and apical rather than anterior shift of the papillary muscles, directing papillary muscle tension away from the axial direction that closes the leaflets.[4,9,10] This explains why anterior MI cannot provoke ischemic MR unless global remodeling and posterolateral and apical tethering, usually of both papillary muscles, occurs.[7] Ischemic MR that occurs with anterior MI is, thus, associated with a much lower EF, a larger LV volume, and a larger and more symmetric annular dilatation.[7] Global remodeling may apically tether both leaflets equally (symmetric tethering with central jet); it may also tether the posterior leaflet more prominently, leading to a posterior jet (asymmetric tethering).[10]

An eccentric, anteriorly directed jet cannot be seen with ischemic MR.

Note that annular dilatation, by itself, is not the primary driver of functional MR. The ratio of leaflet area to annular surface area being normally >2:1, very severe annular dilatation would be required to cause inadequate mitral coaptation. Annular dilatation is, however, a contributing factor in ischemic MR and is the main driver of atrial functional MR. In addition, the annulus normally has a contractile function in systole, the loss of which reduces the coaptation of the tented leaflet and contributes to MR.

Contrary to an old belief, ischemic MR is not related to ischemic papillary muscle dysfunction. In fact, papillary muscle ischemia, per se, does not usually produce MR; it is the underlying wall dilatation that produces MR.

In summary: With either inferior or anterior MI, local posterior remodeling or global remodeling with posterior involvement is necessary to produce ischemic MR. The posterior remodeling tethers the posterior papillary muscle, which tethers both leaflets, predominantly the posterior leaflet, and leads to a posteriorly directed MR. Apical tethering of both papillary muscles and leaflets may also occur, especially with a globally remodeled anterior MI.

Functional MR may be secondary to ischemic or non-ischemic global LV dysfunction, with an MR jet that is central or posteriorly directed. Approximately 20% of patients with severe systolic HF have severe MR.

In the setting of acute inferior MI, acute ischemic MR related to leaflet restriction should be distinguished from papillary muscle rupture (the leaflet is restricted in the former vs. prolapsed in the latter). Any process leading to acute ventricular dysfunction may be associated with acute leaflet tethering and acute functional MR. Examples include acute ischemia or infarction, but also takotsubo cardiomyopathy, myocarditis, and postpartum cardiomyopathy.

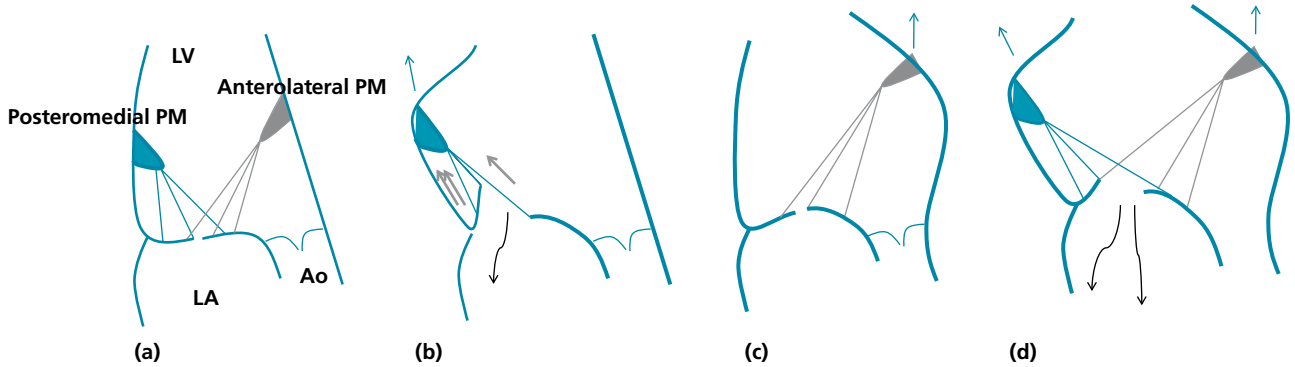

Figure 6.4 Illustration of ischemic MR on longitudinal views. (a) Normal valvular anatomy. Both papillary muscles (PM) provide chordae to both mitral leaflets. **(b)** Inferior akinesis with posterolateral displacement of the posterior papillary muscle. This leads to major restriction of the posterior leaflet and minor restriction of the anterior leaflet. The tethering force being more orthogonal to the posterior leaflet, the latter is more restricted than the anterior leaflet. In fact, the anterior leaflet overrides the posterior leaflet. **(c)** Anterior akinesis, by itself, does not lead to major restriction of any leaflet as it pulls the leaflets axially rather than sideways. **(d)** Anterior MI with global LV remodeling and global LV dilatation pulls both the anterior and posterior papillary muscles apically and posterolaterally. The more the LV is dilated and spherical, the more laterally the leaflets are pulled, the more severe the MR. Both leaflets are tethered, and the jet may be central or predominantly posterior (if the posterior leaflet is more tethered than the anterior leaflet). Note that ischemic MR cannot be anteriorly directed: it is either central or posterior.

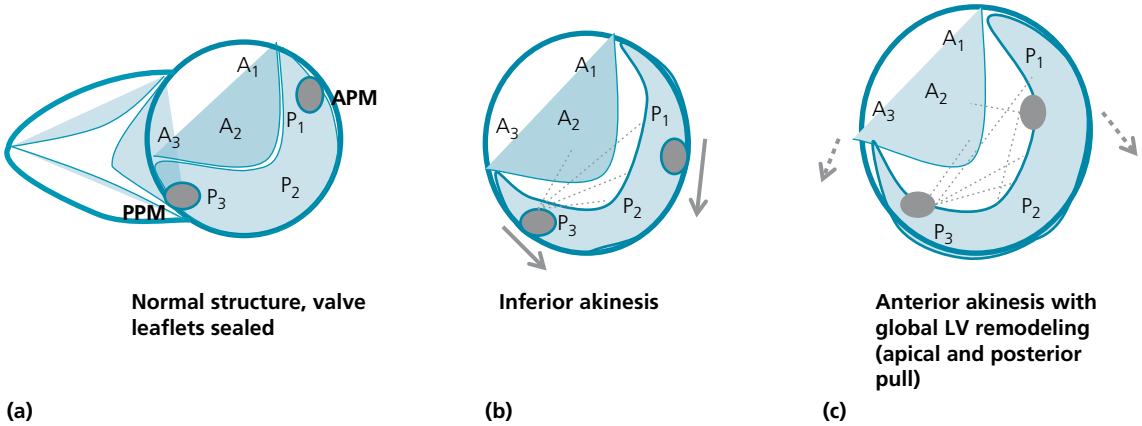

Figure 6.5 (a) Horizontal cut across the mitral valve. Normal structure of the valve and papillary muscles (anterior, APM; and posterior, PPM). *Both papillary muscles provide chordae to both leaflets*: more specifically, APM provides chordae to the adjacent lateral A_1+P_1, PPM provides chordae to the medial A_3+P_3, while A_2 and P_2 receive chordae from both papillary muscles. **(b)** Inferior and inferolateral akinesis with posterior displacement of the posterior papillary muscle. As a result, the posterior leaflet is getting tethered with a posteriorly directed MR. The anterior leaflet is less affected. **(c)** Anterior akinesis with global spherical remodeling of the LV and posterolateral displacement of both papillary muscles. In addition, the apical remodeling leads to apical tethering of both papillary muscles. As a result, the posterior and anterior leaflets are getting tethered with a jet that is central (symmetric tethering of both leaflets) or posterior (predominant tethering of the posterior leaflet). Thus, posterior leaflet tethering may occur with anterior MI.

Functional MR is dynamic

Ischemic MR (or any functional MR) may vary with dynamic changes in LV volume and geometry. Symptomatic patients with an ischemic mild or moderate MR at rest may have *dynamic MR* that worsens with exercise, i.e., with increased venous return and LV volume.[6,8] The increase in venous return increases LV dimension, leaflet tethering, and annular dilatation, which worsens functional MR. The concept of dynamic MR is an important concept, as it may explain exertional or nocturnal symptoms and pulmonary edema in patients with mild ischemic MR at rest. In this case, MR, LA pressure, and PA pressure increase during exercise or during sleep with the increase in venous return. *In fact, as opposed to patients with mild ischemic MR and no pulmonary edema, patients with mild or moderate ischemic MR who present with pulmonary edema usually have dynamic MR that worsens with exercise or at night*; this apparently "mild" MR is actually a major contributor to their pulmonary edema. This is proven by stress echocardiography, wherein MR severity and PA pressure worsen without any ECG or echocardiographic signs of ischemia (effective regurgitant orifice area increases by ≥13 mm^2).[8]

On the other hand, the minority of patients with inferior MI who have a significant improvement in global myocardial contractility and LV systolic volume with exercise may have a reduction in the severity of resting leaflet tethering and MR.[8]

However, before presuming that dynamic MR is due to a combination of baseline tethering and added loading, always rule out another cause of dynamic MR: off-and-on ischemia. In the latter case, the wall motion abnormality and tethering that drive MR are fleeting rather than persistent, and revascularization will reverse MR. Stress echo will show a dynamic wall motion abnormality coinciding with the dynamic MR.

Ischemic MR is typically characterized by *chronic, unchanging LV dysfunction/infarction* with MR that varies according to the loading conditions. Conversely, another form of ischemic MR is induced by *off-and-on ischemia* and is characterized by off-and-on LV wall motion abnormality without infarction.

Dynamic MR may explain the puzzle of patients who only have an old inferior infarct with an overall preserved EF, no residual ischemia, and mild MR at rest, yet present with pulmonary edema or significant dyspnea on exertion.[6] Functional MR may be suggested by simple physical exam maneuvers: **elicit the MR murmur with leg raising or after a fast walk in the clinic.** ***Exertional echo assessment of MR is invaluable in moderate functional MR, including atrial functional MR, associated with refractory exertional dyspnea.***

Avoid assessing ischemic MR intraoperatively. The unloading conditions of anesthesia convert a dynamic, severe ischemic MR into mild MR.

D. Atrial functional MR

Functional MR results not only from LV dilatation but also LA dilatation, even if LV systolic function and size are preserved. This is seen with ***HFpEF*** and/or ***long-standing persistent AF*** and is called ***atrial functional MR***. Significant functional MR (moderate or severe) is seen in 6–7% of patients with isolated AF and up to 18% of patients with decompensated HFpEF, more so in restrictive cardiomyopathies. This MR dramatically improves with AF rhythm control (in >75% of patients).[11–13] One study showed that moderate or severe atrial functional MR develops at a rate of 2.6% per year in patients with AF, mainly persistent/permanent AF, and more so in older women (>65) or patients with concomitant severe diastolic dysfunction and more severe LA dilatation.[14] Importantly, atrial functional MR frequently regresses, especially with AF rhythm control, diuresis, and shrinkage of LA volume and pressure; regression is more frequent in younger men. Overall, regression of atrial MR is more frequent than its progression.

Unlike ventricular functional MR, atrial functional MR is primarily driven by severe annular dilatation and requires severe LA dilatation, more than seen with ventricular MR. Annular dilatation flattens the mitral leaflets and pulls their coaptation zone up. Thus, unlike ventricular MR, atrial MR is centrally directed rather than eccentric (Figure 6.6). However, since the annulus mainly expands posteriorly and upwardly, the posterior leaflet may remain anchored and tethered down by the chordae, causing an eccentric posterior MR jet ("hamstringing" of the posterior leaflet in 20–30% of the cases).[15]

Also, severe HTN aggravates functional MR. HTN makes it harder for the LV to pump forward, which creates the backward leak. This functional MR component quickly improves with HTN control.

HTN worsens *functional MR,* while reduction in preload and afterload improves functional MR. Changes in loading conditions (HTN, exercise) do not affect the severity of an *organic MR,* yet they do affect the regurgitant volume, the LA pressure, and the degree of pulmonary edema.

E. Rheumatic fever

Rheumatic fever leads to scarring and retraction of the leaflets and the subvalvular apparatus, restricting mitral valve closure (→ MR) and opening (→ MS). A predominant or isolated MR may be seen with rheumatic heart disease.

F. Other causes of MR

- Healed, old endocarditis with progressive scarring and retraction of the mitral leaflet(s) may lead to late MR.
- Systolic anterior motion of the anterior leaflet and chordae in HOCM.
- Severe posterior mitral annular calcifications (MAC). MAC may immobilize the basal portion of both mitral leaflets, preventing their normal excursion in diastole (→ MS) and in systole (→ MR). Also, the mitral annulus loses its expansile function (→ MS) and contractile function (→ MR).

Causes of transient severe MR

1. Dynamic MR that results from *acute, transient* LV dysfunction (e.g., off-and-on ischemia).
2. Dynamic MR that results from *chronic, persistent* LV dysfunction, or severe LA dilatation. This MR worsens with an increase in loading conditions (exercise, prolonged supine position, HTN). The acute increase in preload and/or afterload worsens a mild functional MR.

Important situation: severe MR with severe LV dysfunction

MR could be the cause of LV dysfunction (primary MR) or, much more commonly, the result of it (functional or ischemic MR). These 2 conditions are treated differently: intrinsic MR requires valvular repair, whereas functional MR primarily requires treatment of the underlying LV dysfunction.

Severe organic MR leads to symptoms very long before severe LV dysfunction. *Thus,* ***when severe LV dysfunction is associated with severe MR, LV dysfunction is generally the primary issue and MR is usually functional, unless there is a long history of severe MR***. The definite diagnosis relies on assessment of the mitral valve structure. If the valve leaflets are thick and prolapsed, MR is organic. Conversely, if the leaflets are not significantly deformed (except for mild age- or injury-related thickening), but exhibit restricted motion, MR is functional. TEE often helps in that regard, as it provides better leaflet visualization.

Hint for acute presentations: in acute primary MR, LV is hypercontractile, i.e., EF is increased rather than decreased. *Acute HF with low EF and severe MR usually implies functional rather than primary MR.*

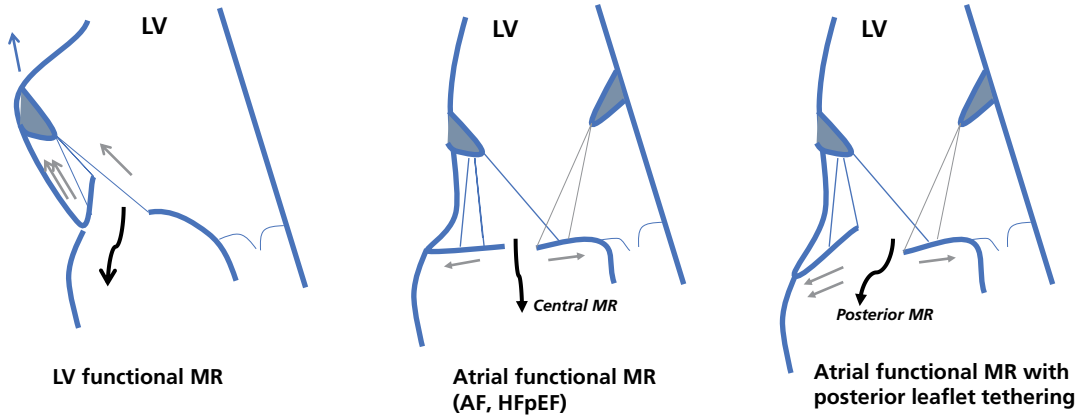

Figure 6.6 Atrial functional MR vs. LV functional MR. In atrial functional MR, the LA and the mitral annulus are more dramatically dilated and leaflet tethering plays a lesser role. Leaflets typically adapt and lengthen to compensate for annular dilatation; insufficient leaflet lengthening contributes to MR. Impaired mitral annular contraction plays a role as well (especially if MAC is present). In a smaller subgroup of atrial functional MR, the chordae cannot cope with the upward and posterior annular expansion; they hence tether the posteriorly pulled posterior leaflet, resulting in eccentric MR.

In both A-MR and V-functional MR, the mitral annulus is dilated, more definitely so in the former: AP mitral annulus diameter >35 mm on the long-axis view, *or* ratio of mitral annulus diameter/anterior leaflet diastolic length > 1.3 (esp. A-MR). *Unlike V-MR, in A-MR*: (i) leaflet coaptation is flat at the annular level (or <8 mm deep, vs >8 mm in V-MR), (ii) LA is more severely ↑ while LV is not ↑, hence LA systolic volume/LV diastolic volume ratio >0.56.[11]

III. Assessment of MR severity

A. TTE (see Chapter 33: Figures 33.24–33.27, Section VIII, and Table 33.1)

Beside *LA enlargement, which is a necessary finding in chronic severe MR*, the following are severe MR criteria:

a. Regurgitant color jet fills >40% of the area of the LA, at a proper color gain and a Nyquist limit of 50–60 cm/s. Eccentric MR is underestimated by the jet area.
b. High early mitral inflow velocity (E wave >1.2 m/s) is highly sensitive.
c. Large PISA, which is the regurgitant jet hemisphere on the side of the ventricle (≥0.9 cm at 40 cm/s Nyquist limit); and large effective regurgitant orifice (ERO) area ≥40 mm^2. Note that *30 mm^2 better defines severe ischemic MR*, especially in patients with low stroke volume in whom a smaller regurgitant volume (<60 ml) is impactful and translates into a large regurgitant fraction of 50%;[6,8] also, PISA being frequently squashed (flat) rather than round, the short PISA distance underestimates the full PISA area (as the calculation assumes it is round).
d. A flail leaflet is highly specific for severe MR, regardless of color jet findings (*only feature that does not rely on Doppler*).
e. Pulmonary vein systolic flow reversal is mainly seen in decompensated or acute MR and corresponds to the large V wave.

Eccentric MR may be underestimated by TTE. Echo color correlates with velocity more than volume: eccentric MR hits the LA wall and its velocity and color may abate quickly. Similarly, *acute MR* may be underestimated. The increased LA pressure reduces the LV–LA pressure gradient and the MR velocity, which may reduce the color signal and turbulence; also, acute MR may be eccentric. Thus, if a patient has pulmonary edema with a questionable MR severity and a normal or hyperdynamic LV, think of severe MR and perform TEE or left ventriculography.

B. TEE or cardiac MRI for indeterminate MR

TEE is performed if the severity or the cause of MR is unclear by TTE. It is also valuable in planning mitral surgery: assess which cusp(s) is involved and whether repair is feasible. MRI is another excellent modality for assessing valvular pathology and quantifying regurgitant volume.

C. Left ventriculography

Left ventriculography is indicated if the echo data are inconclusive or when there is discrepancy between the echo data and the clinical findings. When properly done, ventriculography is highly accurate in MR grading, as it semi-quantitatively addresses the regurgitant volume rather than velocity. Color doppler frequently underestimates the severity of eccentric MR, as color correlates with velocity more than volume: MR volume may be high, yet color velocity abuts the LA wall eccentrically and quickly abates.

In severe MR, LA entirely fills with contrast, as intensely as LV (=3+ MR). It is very severe (4+) if LA fills approximately as densely as the LV on the first beat and ends up with greater density than the LV (LA > LV).

D. Right heart catheterization

Right heart catheterization may be performed as an adjunct to left ventriculography when the severity of MR is unclear. The finding of an ample V wave that exceeds 45 mmHg or is twice the mean PCWP suggests severe MR. However, the V wave may not be that ample in severe but compensated MR (Figure 6.7). On the other hand, ample V wave more commonly reflects decompensated HF than MR.

In addition, the invasive measurement of PA pressure and PCWP *at rest and with stress* is valuable in addressing the surgical indication when MR is severe but symptoms are mild and non-specific. An elevated PCWP implies that MR is likely functionally limiting, even if the patient denies any symptom.

E. Stress testing and BNP

Besides an elevated PCWP and PA pressure, a stress test showing a limited exercise tolerance (*class IIa*), or an elevated BNP, or an abnormal LV echo longitudinal strain, may indicate surgery in patients who deny symptoms.

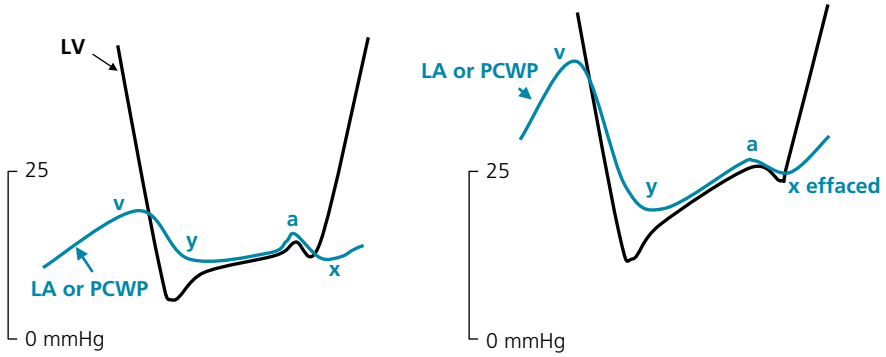

Figure 6.7 Difference in V wave and LV diastolic pressure between (1) chronic compensated MR and (2) acute or decompensated MR. In decompensated MR, V wave gets larger, Y descent gets deeper, while X descent gets shallower. LA pressure may switch from (1) to (2) with simple maneuvers: handgrip (↑ afterload), small volume loading, exercise. LA pressure may switch from (2) to (1) with sedation, acute hypertension control, or nitroprusside infusion (↓ preload and afterload). Reproduced with permission from Hanna EB. Mitral regurgitation. In: Hanna EB, Glancy DL. Practical Cardiovascular Hemodynamics. New York, NY: Demos Medical, 2012, p. 112.

IV. Natural history and pathophysiology of organic MR

Even among asymptomatic patients with normal LV function, severe MR leads to symptoms or LV dysfunction in 100% of patients at ~5 years. Asymptomatic severe MR is associated with the following yearly risks: 0.8% sudden death, 5–6% overall death (double that of the general population or those with milder MR), 10% combined cardiac death, HF, or AF, and ~20% death or requirement for valvular surgery (fast progression).[16]

Once symptomatic, the mean survival of severe MR is ~3 years without surgical correction.

In chronic MR, the LV pumps a double stroke volume in 2 directions, including an "easy" low-pressure LA. This explains how EF is increased if LV is normal and is helped early on by the low afterload. LV diastolic size increases to allow an increase in total stroke volume and the maintenance of a forward stroke volume, whereas LV end-systolic size decreases (EF ↑↑).

Eventually, the chronically high preload reduces intrinsic LV function. This is due to: (i) ***LV more poorly tolerates chronically high preload than high afterload:*** cardiomyocyte thickening does not occur in high preload conditions, and instead, maladaptive progressive cardiomyocyte elongation occurs, which results in sarcomere disorganization and disruption and cell death.[17] The lack of concentric hypertrophy causes the LV mass-to-volume ratio to be <1, thus the LV muscle works harder and fails earlier than pressure overload states. (ii) High preload raises O_2 demands. (iii) Limitation of Frank–Starling relationship (stroke volume stops rising beyond a certain preload → EF declines → more LV dilatation). (iv) Afterload eventually rises, as the LV systolic size expands and raises the radius component of afterload (= systolic wall stress = pressure × radius/2 × thickness).

Once LV intrinsic contractility starts to fail, EF decreases toward the normal range and LV end-systolic size starts to increase. *An EF of 50–60% is already abnormal and indicates an intrinsic myocardial dysfunction that may not be fully reversed with surgery and may indeed worsen postoperatively*. LV afterload is reduced early on but increases with time as LV systolic size increases.

V. Treatment of organic (primary) MR

A. Surgical indications in primary MR

The patient must have severe MR *and* one of the following findings:[18,19]

a. Symptoms (functional limitation class II–IV) (*class I indication*).
b. EF ≤60% or LV end-systolic diameter (LVESD) ≥40 mm or ≥20 mm/m^2 (*class I indication*).
c. Asymptomatic patient with normal EF but any of the following 3: moderate pulmonary hypertension (systolic PA pressure >50 mmHg at rest) or new-onset AF or severe LA dilatation >55 mm or 60 ml/m^2 (*ESC class IIa indication, and class I when all 3 are present, if surgical risk is low and if high likelihood of durable repair*). Pulmonary hypertension implies a risk of HF and symptomatic progression in paucisymptomatic patients; even lesser degrees of pulmonary hypertension are associated with impairment of long- term survival.[20] As compared to sinus rhythm, AF is associated with excess mortality under watchful management.[21] Also, as opposed to patients with AF >3 months, patients with AF <3 months have a very low recurrence of AF on long-term follow-up after mitral repair, as early LA remodeling is reversed.[22]
d. When EF is <30%, MR is usually secondary to LV dysfunction rather than primary. If primary, mitral surgery remains reasonable, especially if MV repair is likely, or MV replacement with chordal preservation is feasible.
e. Severe primary MR (*class I*) undergoing cardiac surgery for another indication. In a patient undergoing AVR, AVR + mitral repair is preferred to double valve replacement (lower operative risk).
f. *MV repair is reasonable in asymptomatic severe MR with EF >60%, normal LV size, and normal PA pressure, as long as the likelihood of successful repair is >95% and the operative mortality <1% (class IIa, mainly for posterior leaflet prolapse)*. In fact, there is a significant risk of events associated with severe MR during the watchful waiting period, with a doubling of cardiac mortality and quadrupling of cardiac events compared with the general population: ~6% vs. 3% mortality per year, the excess mortality surpassing the operative mortality of mitral repair in low-risk patients.[16,23–27] Furthermore, when surgery is performed in symptomatic patients or those with early LV dysfunction, LV dysfunction frequently persists postoperatively or deteriorates.

Excess mortality persists after surgery in patients operated with EF ≤60% (especially <50%) or severe symptoms III/IV, whereas life expectancy is restored to normal in patients operated with no or minimal symptoms and EF >60%.[28,29] Notably, the 5-year mortality of patients who undergo surgery with EF of 50–60% is almost double the mortality of those with EF >60%, with double the risk of long-term HF and EF deterioration.[28] This 5-year mortality risk is tripled for EF <50% (>10% per year). Data suggest an improvement in long-term survival and risk of HF with early intervention (vs. watchful waiting), as long as mitral repair is performed.[25,27] Early surgery prevents the risk of adverse LV remodeling that occurs in the waiting period or postoperatively. A BNP ≥105 pg/ml is also predictive of increased long-term mortality under conservative management.[30]

g. Along the same lines as (f), MV surgery (repair or replacement) is reasonable in asymptomatic patients with EF >60% and LVESD <40 mm who, nonetheless, have a progressive increase in LV size or reduction of EF within this normal range on 3 serial echos (class IIb). In fact, one study suggested that LV dysfunction of MR is irreversible once EF <64% or LVESD ≥37 mm.[31]

LV function may deteriorate after mitral surgery:

i. This is partly related to damaging the subvalvular annular–chordal–papillary muscle continuity during mitral valve replacement, which leads to a change in the LV geometry and the effectiveness of LV contraction. In fact, the LV changes from elliptical to spherical, which strongly limits longitudinal motion.

ii. LV deterioration is also related to the fact that, in MR, *mild EF reduction is a sign of an already advanced LV contractile dysfunction* that is unveiled by closing the low resistance leak (raising afterload).

iii. Closing the low-resistance leak may increase afterload in the immediate postoperative period. This *"afterload mismatch"* contributes to early EF deterioration. Yet, afterload mismatch does not worsen long-term EF compared to non-operated patients, as reducing MR reduces LV volume and protects long-term EF. Also, even if EF and total stroke volume decline, the forward stroke volume improves as the regurgitant loss of volume is eliminated.

On average, *afterload remains unchanged* postoperatively as the reduction in LV diastolic size and SVR offsets the propensity of LV systolic size and pressure to rise, the latter 2 remaining unchanged as a result.[32,33] On average, even in patients with baseline LV dysfunction, EF does not change or only slightly declines postoperatively.[32,33] However, up to 25% of patients develop acute postoperative rise in afterload and major EF decline (absolute EF drop >10% in primary MR, >5–7% in secondary MR).[34–36] This is more common in patients with the most dilated and dysfunctional LV at baseline. Depending on the study, EF recovers to baseline in ~1/3 to >1/2 of patients within weeks to months of follow-up. Recovery is less likely in primary MR, where EF decline may reflect irreversible LV dysfunction caused by MR, than in secondary MR, where LV dysfunction may stem from a more reversible etiology that is aggravated by the extra load of MR.[34–37]

Mitral valve repair or chordal preservation during mitral replacement lessens LV deterioration (Figure 6.8). Chordal preservation consists of fixing the chordae and attached mitral leaflet pieces to the annulus before implanting the new valve; this way, the chordae suspend the LV to the annulus and prevent sagging and ballooning of the LV.

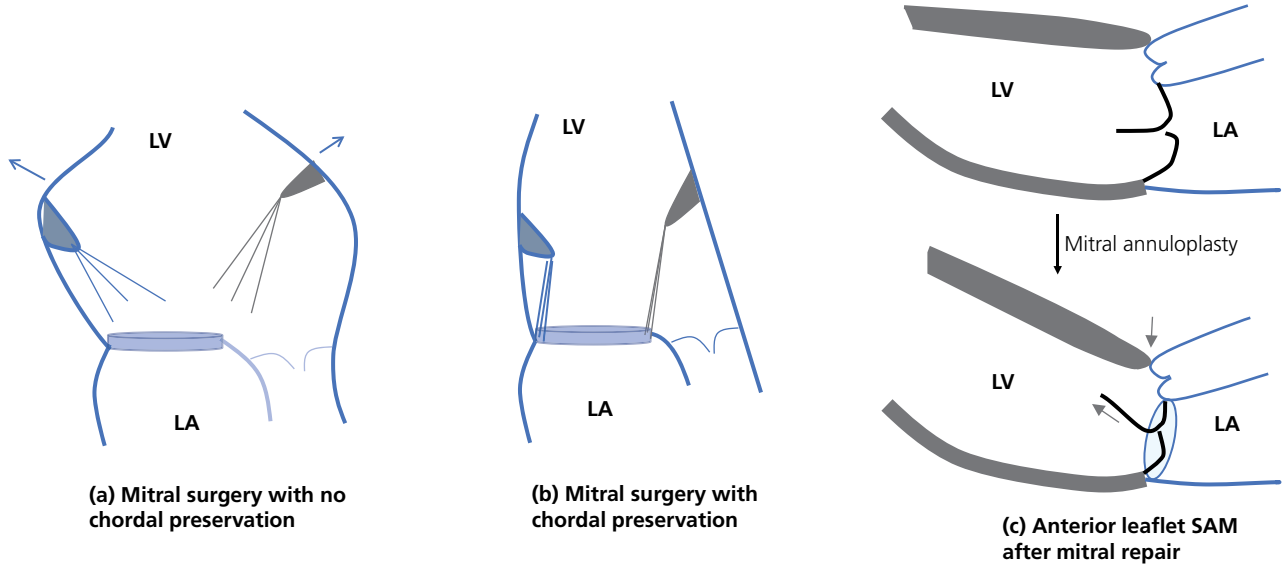

Figure 6.8 Unlike **(a)**, the chordae are tied to the mitral annulus before implanting the new valve in **(b)**, preserving LV geometry and preventing LV ballooning. In **(c)**, after MVP repair, the elongated anterior leaflet is squeezed down (*arrow*) by the narrow ring, and the mtiroaortic angle becomes more acute (*vertical arrow*), which causes SAM and LVOT obstruction.

B. MV repair is preferred to MV replacement in isolated posterior leaflet prolapse limited to less than half of the posterior leaflet (class I), where MV replacement is now contraindicated unless repair has been attempted (*class III*). It is also indicated with anterior or bileaflet prolapse, when durable repair seems probable (*class I*).

a. MV repair preserves the subvalvular apparatus and the LV geometry. Even if MV replacement is performed, the MV apparatus should be preserved and fixed to the annulus rather than resected to preserve the ventricular geometry.

b. MV repair protects from the LV deterioration that commonly occurs after MV replacement, especially with EF ≤60%, but even with EF >60%. MV repair is associated with over 50% improved long-term survival, whether performed for posterior or anterior MVP (vs. MV replacement). In addition, the postoperative mortality after MV repair may be very low (<1%) and approximates half the mortality of MV replacement when expeditiously done (meta-analysis that included Mayo Clinic data).[38]

c. MV repair does not necessitate chronic anticoagulation therapy.

d. *Reoperation rate is ~5–10% at 10 years with posterior MVP, and 20–30% with anterior or bileaflet MVP*. Reoperation is performed for progressive, recurrent MR, often (70%) related to initial technical failure.

e. MV repair of a posterior prolapse typically involves resection of the redundant cusp and placement of an annuloplasty ring. Conversely, anterior prolapse consists of a larger area of cusp prolapse that is more difficult to correct. As opposed to resection of the abnormal cusp, repair of an anterior prolapse consists of chordal transfer: a normal segment of the posterior leaflet is identified, cut and attached with its chordae to the unsupported, prolapsed portion of the anterior leaflet (the cut posterior leaflet is then repaired in a sliding fashion). Chordal transfer may also be performed from the belly of the anterior leaflet to its edge; chordal replacement with PTFE chords may also be performed. An annuloplasty ring is placed at the end. Anterior leaflet repair is improved with these techniques, but there is a higher need for reoperation at 10 years (30% vs. 10% for posterior leaflet).

MV repair may, therefore, be more technically challenging than MV replacement and, in case of failure, requires longer pump time, which may not be tolerated in the sickest patients.

f. ***Immediately postoperatively, ~10% of patients undergoing MV repair for MVP develop significant SAM of the anterior leaflet*** with LVOT obstruction and significant MR. This MR may be misdiagnosed as failed repair. SAM is secondary to the anterior leaflet being "squeezed" down into the LV by the narrow annuloplasty ring and therefore touching the septum, particularly if the LV cavity is small and the anterior leaflet is long and redundant. Moreover, the increase in steepness of the mitroaortic angle moves the leaflet coaptation line anteriorly toward the LVOT (Figure 6.8). SAM immediately improves with fluid administration and cessation of inotropic drugs.

C. Medical therapy

Medical therapy does not have a role in primary severe MR, except for the use of ACE-Is or CCBs for an associated hypertension. Vasodilators may reduce regurgitant volume but do not diminish clinical deterioration or LV remodeling, and may aggravate MVP by reducing afterload and LV cavity size.

VI. Treatment of secondary MR (ischemic and non-ischemic functional MR)

While ischemic MR is initiated by ventricular disease, the ventricular function is frequently normal or mildly/moderately reduced. Therefore, ischemic MR frequently becomes the primary driver of functional limitation, pulmonary edema, and progressive LV remodeling, which begets worsening of MR.[6,8] Treating MR may stop this deleterious process. Three questions need to be addressed before deciding to surgically target functional MR.

A. What is the primary driver of HF (MR vs. underlying LV failure)?

MV repair is not likely to help patients with underlying severe LV enlargement (LV end-diastolic diameter >65 mm) or extensive scarring and non-viability, in which case LV is the primary driver of symptoms and events. LV is irreversibly remodeled and will continue to dilate even after mitral correction. This is called ***proportionate functional MR***, i.e., MR severity is simply tracking LV dilatation, not driving it. This MR relies primarily on HF medical therapy. In fact, ***40–60% of ischemic or functional MRs improve within 1–3 months of HF medical therapy*** **(and CRT if LBBB).**[39] CRT improves MR in >60% of patients with severe functional MR, but may also worsen MR in ~10% of patients.[40,41] This is related to the degree of reverse remodeling (reduction of LV volume) achieved with CRT. An immediate improvement results from coordinated papillary muscle contraction and increased LV pressure, followed by further improvement over the ensuing 3 months.

B. Will revascularization alone reverse MR?

Moderate MR frequently improves with CABG revascularization alone, but this is less often the case with severe MR, as LV remodeling and dilatation may not improve enough even when some myocardial contractility recovers. In two registries of severe MR, ~50% of patients improved their MR with CABG and <10% became mild MR or no MR.[42,43] Conversely, up to 70% of patients with moderate MR show an improvement with CABG alone, per the CTSN trial, mainly when inferoposterior dysfunction is reversible. The evidence is less compelling for PCI.

Standalone revascularization is expected to improve dynamic MR that is associated with *off-and-on* dysfunction of a myocardial segment (e.g., ACS) without chronic infarction. This must be distinguished from dynamic MR that results from fluctuations of loading conditions on top of a *fixed, chronic* myocardial dysfunction. The latter MR, when severe, does not consistently improve with revascularization.

Off/on inferior akinesis with off/on MR → revascularize without MV repair
Steady inferior akinesis with off/on or steady severe MR → revascularize with MV repair

C. Can MR therapy reverse the underlying HF?

Treatment options for functional MR – (a) Transcutaneous MitraClip consists of a clip that approximates the edges of both mitral valve leaflets. This creates a double mitral orifice (edge-to-edge repair) and stabilizes the anteroposterior annular dilatation. It is delivered percutaneously through a trans-septal puncture. One or sometimes 2 clips (~40%) may be needed. (b) *Surgical mitral valve replacement or annuloplasty repair,* which consists of suturing a downsized ring to the endocardial surface of the mitral annulus to reduce the annular size.

Thus, ***rather than addressing the underlying LV dysfunction and tethering, both MitraClip and mitral surgery attempt to compensate by addressing the other end of the mitral apparatus***. Yet, data support the use of those therapies when MR is the driver of HF, i.e., MR is *disproportionate* to the severity of LV dilatation and persists despite optimal HF medical therapy and CRT.[44,45]

COAPT trial of MitraClip in functional MR – In the COAPT trial, patients with severe functional MR (ERO mostly >30 mm^2, ischemic 60%) who had failed several months of maximal medical therapy +/– CRT derived a dramatic benefit from MitraClip (~40% reduction in mortality, 29% vs. 46% at 2 years, and ~50% reduction of HF hospitalizations, ~36% vs. 68% per year). The key in COAPT was to select patients truly refractory to maximal medical therapy whose LV is not severely dilated. In those patients, severe MR is a key driver of further LV deterioration and dilatation, which is stopped by the MitraClip (***disproportionate MR***). LV stopped dilating or slightly declined in size in the MitraClip group vs. further dilated in the control group. At baseline, mean EF was 31% (20–50%), LVESD was mostly <6 cm, LVEDD was <7 cm, LV end-diastolic volume <200–250 ml, ERO was 40 ± 15 mm^2, and PA systolic pressure was ≤70 mmHg.[46] Thus, **MR was the biggest driver of HF, more so than LV dilatation: this is called disproportionate functional MR = greater MR severity with less severe LV dilatation** *–ERO >30 mm² while LVEDV <200 ml – the key being a regurgitant fraction >50%*. In contrast, the less selective MITRA-FR trial, which recruited patients with less severe functional MR, more dilated LV, and less aggressive medical therapy failed to show a benefit from MitraClip.[47]

Two more recent trials support the use of MitraClip in functional MR:[48] (1) RESHAPE-HF2 trial randomized functional MR that is less severe than COAPT (mean ERO 0.23 cm^2 [0.2–0.3], ischemic 65%) to MitraClip vs. medical therapy, and showed again a dramatic reduction in HF hospitalizations (27% vs. 47% per year) and a trend toward mortality reduction (22% vs. 29% at 2 years, less dramatic than COAPT as HF and MR less severe). (2) MATTERHORN trial randomized functional MR that is less severe than COAPT (ERO 0.23 mm^2) and with no CABG indication to MitraClip vs. mitral surgery (72% repair). MitraClip reduced death/HF as effectively as surgery but was safer with much less perioperative events such as bleeding, AF (9% vs. 33%), and stroke (0% vs. 4.4%); the efficacy of MitraClip was similar for atrial functional MR vs. ventricular functional MR. This trial took a lower-risk population, with 1-year mortality of 8–10% and HF hospitalizations of 3% (MitraClip) to 6.9% (surgery). All the trials had a high proportion of patients with prior HF hospitalizations in the last year (60s%).

Surgical correction of functional MR – In a case series of patients with severe ischemic MR and mean EF ~30%, CABG + downsized complete annuloplasty showed a sustained improvement in MR, functional status, and reverse remodeling.[49] This benefit mainly applied to patients with LVEDD <65 mm,wherein reverse remodeling occurred, and 5-year survival was high (80%); patients with more enlarged LV were at an irreversible stage of remodeling and had a low 5-year survival rate despite annuloplasty (49%). Further support was provided by a STICH trial subanalysis of patients with severe MR, which suggested improved survival with CABG + mitral repair vs. CABG only.[49] The benefit in moderate ischemic MR is less clear, with one trial showing a lack of benefit and an early hazard of adding annuloplasty to CABG, particularly that MR improved in 70% of patients undergoing stand-alone CABG (CTSN trial).[50] The perioperative mortality of CABG + mitral annuloplasty is 3% (RIME) to 8%.[49,51]

In a CTSN trial of patients with severe ischemic MR and moderate EF reduction (40% ± 10%) who for the most part were undergoing CABG (~75%), *mitral valve replacement with chordal preservation proved equivalent to annuloplasty repair in terms of survival and reverse remodeling*. However, replacement provided a more durable MR correction and less HF and repeat hospitalizations at 2 years.[52] In fact, moderate or severe MR recurred at 2 years in ~60% of the mitral repair patients (severe MR in 14%). Thus, ***when treated surgically, ischemic MR benefits at least as much from MV replacement as from MV repair, unlike MVP.*** This is because: (i) annuloplasty repair is not sustained in the dysfunctional LV as LV remodeling progresses, and it is possible that restrictive annuloplasty augments posterior leaflet tethering by pushing its insertion forward; (ii) even moderate residual or recurrent MR is poorly tolerated by the dysfunctional LV; (iii) evolution of valve replacement with chordal sparing may account for the improved MV replacement outcomes. When annuloplasty is done, the best results are obtained with a rigid or semirigid full-circumference ring rather than a posterior band, sized according to the anterior leaflet circumference and downsized two sizes (24–28 mm).

All of the above surgical data address adjunctive mitral surgery in patients who, for the most part, are undergoing CABG, and mainly show a benefit in patients without a severely enlarged LV, where MR is the driver of HF. HF and LV remodeling improve, with a less clear survival benefit. Mitral surgery has a questionable value in functional MR with no CABG indication but may be considered as in the MATTERHORN trial. The latter patients are better served by MitraClip.

D. Guidelines for the management of ischemic or non-ischemic functional MR

Patients undergoing CABG or AVR – Guidelines recommend adjunctive mitral surgery in patients undergoing CABG or AVR who have functional severe MR (*class IIa, replacement or repair*). In patients with moderate ischemic MR, a low-dose dobutamine test assessing wall motion and MR response may help select those who are most likely to benefit.

Patients with no CABG indication – Patients with severe functional MR who do not have an indication for CABG should receive HF therapy, aggressive hypertension control, and CRT (if indicated) as first-line therapy. ***The severity of MR improves with diuresis and the 4 HF pillars in 40–60% of patients, more so if CRT is used for LBBB.***[53] HF pillars are rapidly uptitrated (<6 weeks), with expected MR improvement in 1–3 months. Percutaneous repair with MitraClip may be performed if severe MR (ERO >30 mm²) and symptoms persist despite medical therapy and CRT, and ***LV is not severely dilated*** (regardless of whether EF is more or less than 30%) (*class IIa* in ACC, class I in ESC guidelines).[18] In those cases, MR is the biggest driver of HF, more so than LV dilatation, and is called ***disproportionate functional MR***.[54] Conversely, MR correction is less compelling in patients with severe LV dilatation (LV end-diastolic volume >200–250 ml or 96 ml/m^2, LVESD >6 cm or LVEDD >7 cm), as MR may not be the driver of symptoms or the negative remodeling process: progressive LV dilatation and deterioration may continue despite mitral surgery *(proportionate functional MR)*.[45]

MitraClip is favored over MV surgery in isolated functional MR (surgery is given *class IIb*, with a preference for MV replacement).

For atrial functional MR (normal EF) that persists despite AF and HFpEF therapy, MitraClip or MV surgery may be considered (*class IIb*).

Unlike the ERO cutoff of 40 mm² used to define severe primary MR, a cutoff of 30 mm² better defines severe secondary MR. This is because secondary MR is a dynamic MR, and therefore a resting ERO of 30 mm^2 generally corresponds to a much larger exertional

ERO and hemodynamic impact. Also, a smaller regurgitant volume is more impactful in patients with low EF and low stroke volume (compared to those with high stroke volume). In fact, in patients with low EF 30% and LV that is not severely dilated (e.g., 200 ml EDV, yielding a total stroke volume of 60 ml), a regurgitant fraction of 50% corresponds to a regurgitant volume of ~30 ml and ERO of ~30 mm^2. Larger LV volume necessitates larger ERO and regurgitant volume to reach a regurgitant fraction of 50%: this is the concept of disproportionate MR. The larger the LV, especially with a less impaired EF, the higher the ERO required for MR to be considered out of proportion.[44,45] The 30-mm^2 cutoff has been prognostically validated in registries and in the COAPT trial, which mainly recruited ERO >30 mm^2, and is suggested by ESC guidelines.[6,8,46,54] Yet, ACC guidelines recommend using 40 mm^2 as a more specific cutoff for surgical decisions, with this being used in CTSN trials.[50,52]

VII. Treatment of acute severe MR related to acute MI

In case of papillary muscle rupture, perform emergent valvular surgery + CABG. Place IABP preoperatively and consider IV vasodilators (nitroprusside) if blood pressure allows, as in all cases of acute severe MR. MV replacement is often performed, as it is difficult to sew necrotic and friable papillary/LV tissue, but repair may be performed in select subacute cases.

In acute severe MR secondary to acute mitral leaflet tethering, treat the patient medically with vasodilators and place IABP for temporary support. It is expected that leaflet tethering will improve once the function of the reperfused territory improves. Surgery should be considered as a second-line therapy for those patients who do not improve with medical therapy.

VIII. Percutaneous mitral valve repair technical ideas (transcatheter edge-to-edge repair)

The MitraClip consists of a clip that approximates the edges of both mitral valve leaflets. This creates a double mitral orifice (edge-to-edge repair) and stabilizes the anteroposterior annular dilatation. Besides its great value in functional MR, it may be used in primary MR that is considered high surgical risk. The EVEREST II trial randomized patients with both organic (73%) and functional (mostly ischemic) (27%) severe MR to MitraClip vs. mitral surgery, mostly mitral repair.[55] At 1 year, a substantial proportion of MitraClip patients had residual moderate (27%) or severe (~20%) MR, and 22% had to undergo mitral valve surgery at 1 year. However, 3 subgroups of patients seemed to achieve equivalent benefit and equivalent freedom from death and mitral reoperation with MitraClip: functional MR, patients >70 years old, and patients with EF <60%. *Thus*, ***MitraClip is best suited for functional MR or high-surgical-risk cases (ACC class IIa).***[18,56–58]

Anatomically, based on EVEREST criteria, when MitraClip is used for functional MR, the coaptation depth must be <11 mm below the annulus, the leaflets must coapt over ≥2 mm adjacent to the MR jet, and the posterior leaflet length must be >7 mm. When used for degenerative MR, the following are exclusion criteria: severe flail (gap between leaflets ≥10 mm in height or ≥15 mm in width), bileaflet flail, or severe bileaflet prolapse. MVA must be >4 mm^2 without any degree of MS and without heavy MAC involving the leaflets. Those are ideal cutoffs, but COAPT and later trials did not mandate those criteria, and data suggest the feasibility of MitraClip even with less favorable anatomy, particularly in functional MR.[59] Regarding *transcutaneous MV replacement*, see Question 43.

2. MITRAL STENOSIS

I. Etiology and natural history

- Mitral stenosis (MS) is usually secondary to ***rheumatic fever*** and occurs several decades after the initial infection, as the injured valve gets progressively traumatized by the turbulent blood flow. Rheumatic MS is more common in women (2:1), and occurs at a young age in third-world countries (20s–30s) vs. a later age in developed countries (role of recurrent infections?).
- The fibrotic process initially involves the mitral commissures and the leaflet edges, and manifests as commissural fusion. The process then progressively involves the whole valve and subvalvular apparatus with progressive calcifications. The leaflets and subvalvular apparatus (chordae) are thickened, fused, and progressively calcified.
- The subvalvular apparatus shortens and pulls on the leaflets, potentially creating rheumatic MR beside MS.
- Symptoms progress more slowly than with other valvular disorders (it takes 5–10 years to progress from early functional class II to functional class III–IV). Asymptomatic or minimally symptomatic patients with moderate/severe MS often remain so for many years.
- Without surgical or percutaneous therapy for class II or III symptoms, the survival is ~50% at 10 years, which is low yet better than other valvular disorders left untreated. However, class IV patients have a mean survival of <1 year without invasive therapy.[60,61]
- Other causes of MS:
  - ***Mitral annular calcification*** **(MAC) or** ***senile MS*** – MAC is related to: (i) aging, (ii) atherosclerotic processes (e.g., smoking and diabetes), and (iii) hemodynamic stress on the mitral valve, as caused by severe HTN or even chronic MVP. It is very common in renal disease, and initially develops at the posterior annulus without causing any inflow obstruction. MAC can progress from the posterior annulus and involve the bases of the posterior leaflet, then the anterior leaflet; the valvular edges and commissures remain freely mobile (Figure 6.9).[62,63] *This is opposite to rheumatic MS, which starts at the valvular edges and commissures*. **Severe MAC rarely leads to MS but may lead to MR (sometimes severe),** as MAC impairs annular contraction and the overall leaflet mobility and coaptation, particularly posterior leaflet, and is often associated with LA dilatation from AF and diastolic HF, and thus a concomitant atrial functional MR. Severe MAC may extend into the adjacent myocardium and papillary muscles, the conduction system, and rarely, the anterior annulus (mitroaortic fibrosa). Since it does not consist of commissural fusion, valvuloplasty is not an effective therapy. Also, annular calcium precludes placement of an adequately sized prosthesis, unless calcium is debrided (which risks rupturing the AV junction). Since MAC mainly narrows the leaflets base rather than the tips, it rarely impedes mitral flow (Figure 6.10). **Beware that a mitral gradient in patients with severe MAC does not necessarily mean MS**.[63] Patients with severe MAC often have diastolic HF and pronounced E wave that creates the false illusion of a gradient; unlike true MS, the E wave has a sharp downslope and on catheterization, the Y descent is steep (see II.B).
  - *Rheumatic-like inflammatory process* – rheumatoid arthritis, lupus, carcinoid syndrome.
  - *Congenital MS* usually consists of a single papillary muscle to which all chordae converge (parachute mitral valve). This chordal convergence restricts valvular opening. It usually presents early in life.

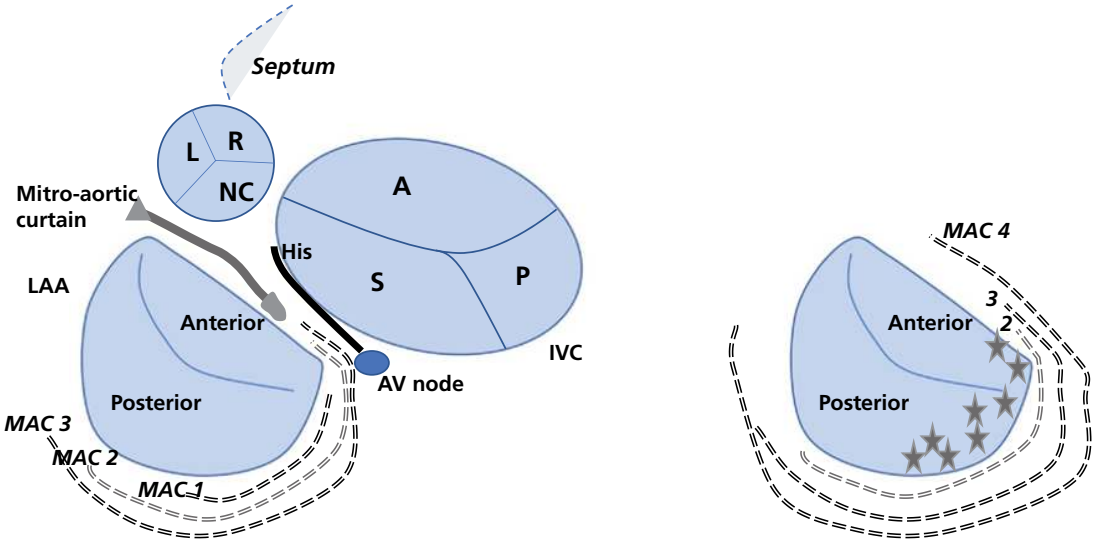

Figure 6.9 MAC anatomy and progression. MAC mainly involves the posterior annulus, as it is more difficult to calcify the fibrous anterior annulus (mitroaortic curtain). Note that the posterior annulus partially surrounds the anterior leaflet, beside the posterior one. Hence posterior MAC progressively surrounds then invades the bases of both the posterior and anterior leaflets (progression from MAC 1 to MAC 2, 3, and 4). It progressively extends into the leaflets themselves (MAC 2 and beyond, *right image*), the conduction system (AV block), then the myocardium, and rarely, into the anterior annulus. The latter is mainly involved in *radiation heart disease*.

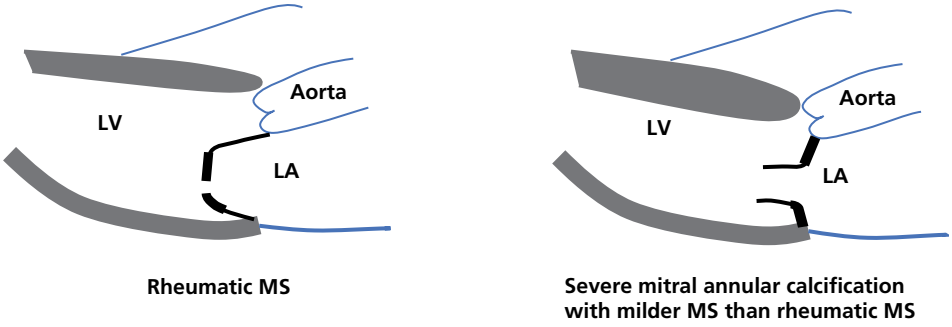

Figure 6.10 Difference between rheumatic MS and MAC MS. In rheumatic MS, the leaflets tips are affected and tied together, leading to a funnel-shaped stenosis. In MAC, the obstruction is outward, at the leaflet base, with relatively unrestricted leaflet tip motion and minimal valvular impedance. Beware that patients with MAC and LV failure have large E wave on echo and are often overcalled as MS.

II. Diagnosis (Table 6.1)

A. Echocardiographic features (see also Chapter 33)

a. Early on, the commissures are fused and the free edges are immobilized, while the body of the anterior leaflet is free-moving. This gives the anterior mitral leaflet a hockeystick shape. The posterior leaflet appears stiff, immobile (Figure 6.11).

b. On the mitral valve M-mode, the E–F slope is flattened because there is no diastasis in mid-diastole (Figure 6.11). The posterior leaflet is pulled toward the anterior leaflet because of the commissural fusion.

c. The valve and subvalvular apparatus are thick ± calcified. The chordal thickening is particularly well visualized on the apical views.

d. Commissural fusion ± commissural calcium are seen on the mitral short-axis view and lead to a "fish mouth" shape of the mitral orifice.

Table 6.1 Severity of MS.

	Mitral valve area	Mean mitral gradient at a normal heart rate (60–80 bpm)
Moderate MS (formerly mild MS)	>1.5 cm^2	<5–10 mmHg
Severe MS	1–1.5 cm^2	≥10 mmHg
Very severe MS	≤1 cm^2	>10–15 mmHg

The mitral valve area (4–6 cm^2) is normally larger than the aortic valve area (3–4 cm^2). As a result, severe AS is classified as valvular area ≤1 cm^2, while severe MS is classified as valvular area ≤1.5 cm^2. Percutaneous or surgical intervention is indicated in severe MS with symptoms or pulmonary hypertension (systolic PA pressure >50 mmHg at rest or >60 mmHg with exercise). Stress gradient may be obtained with *passive leg raising* or exercise and is significant if >15 mmHg.

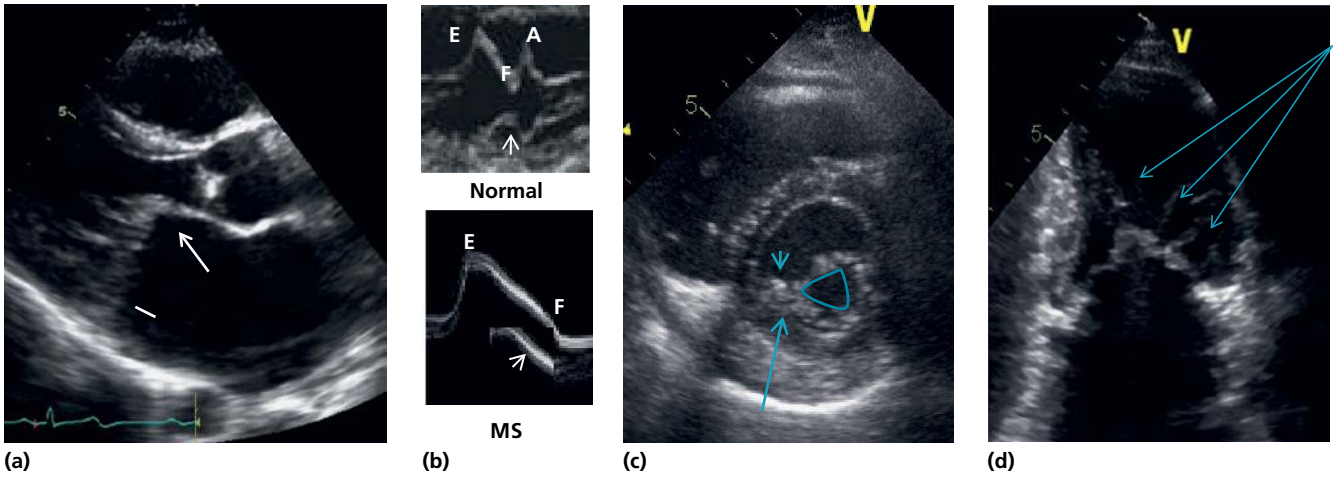

Figure 6.11 **(a)** Long-axis view in diastole. See the hockeystick shape of the anterior leaflet (*arrow*), the tip of which looks attached to the stiff posterior leaflet (*line*), with no diastolic opening. In fact, **both leaflets are tied together by the commissural fusion. (b)** M-mode across the mitral valve. The E–F slope is flattened and the posterior leaflet is dragged toward the anterior leaflet (*arrowhead*). **(c)** Commissural fusion on the mitral short-axis view (*arrow*). Commissural calcium is seen (*arrowhead*). Rather than oval, the mitral opening has a "fish mouth" shape. **(d)** Apical 4-chamber view shows severe chordal thickening extending to the papillary muscles (*arrows*). The mitral leaflets are thickened, and the thickening and immobility extend beyond the edges into the body of the leaflets. The Wilkins score is 10 (leaflet thickness = 2, calcium = 2, leaflet mobility = 2, chordal thickening = 4).

e. On mitral Doppler, *E wave is high and its downslope is slow*, as E flow is limited by the mitral valve (unlike the E wave of HF or MR, which is high but its downslope is sharp).

f. Since it is easy to align the Doppler beam with the mitral inflow on the apical views, the echocardiographic determination of the trans-mitral gradient is highly accurate. However, the estimation of the mitral valve area (MVA) using 1 of the 4 echo methods (mitral inflow pressure half-time, continuity equation, PISA method, and planimetry) may be subject to measurement errors, and thus MVA is better assessed with invasive hemodynamics, if needed.

MVA is a better determinant of MS severity than the mitral gradient. In fact, transmitral pressure gradient being proportional to the square of the transmitral flow, tachycardia or a high-output state (e.g., anemia, heavy vasodilator use, sepsis) may convert an *anatomically mild MS into a hemodynamically severe MS with a severely increased transmitral gradient. Hence, in any echo or invasive study of MS, it is always important to report the heart rate*. Heart rate reduction and diuresis are appropriate first-line therapies in an anatomically mild MS, which underlines the importance of invasive assessment of cardiac output and MVA in selective cases. Overall, invasive hemodynamics are valuable for the assessment of MS whenever there is discrepancy between echocardiographic MVA and a large transmitral gradient; and whenever it is not clear whether the patient's symptoms or pulmonary hypertension are purely secondary to MS, or rather secondary to mild MS + LV diastolic dysfunction (especially in the MAC subset), mild MS + high-output state and tachycardia, or intrinsic pulmonary arterial hypertension. ***The invasive calculation of MVA and cardiac output is invaluable in these cases, and is often performed in patients whose echocardiographic MVA is in the mild or moderate range***.

Another scenario: a patient with severe diastolic dysfunction and mild/moderate MS (MVA >1.5 cm^2) may have severe LVEDP elevation with a PCWP that is only slightly larger than LVEDP, implying a more dominant role of LV dysfunction in the patient's symptomatology. Stress testing may be performed: a disproportionate rise of PCWP and transmitral gradient (>15 mmHg) in comparison to LVEDP implies significant MS.

Valve area vs. gradient for defining stenosis severity: differences between AS and MS – In AS, a high mean gradient ≥40 mmHg is highly specific and diagnostic of AS, regardless of AVA calculation. Conversely, in MS, an elevated gradient is not specific enough for defining severe MS, for 2 reasons:

1. The 10 mmHg cutoff chosen in MS barely translates into MVA <1.5 cm^2 under normal flow conditions: MVA ~ CO/$\sqrt{\text{mean gradient}}$ → for a CO of 5+ L/min and MVA of 1.5 cm^2 → mean gradient ~11+ mmHg by Hakki's equation.
2. MS gradient is more labile with heart rate fluctuations than AS gradient: tachycardia reduces diastolic time while increasing systolic time; hence diastolic flow per second across the mitral valve (CO/diastolic time) increases, whereas systolic flow per second (CO/systolic time) is much less affected (both CO and systolic time increase in tachycardia).

Thus, **valve area is more important than gradient in defining the severity of MS,** as even mild MS may yield a gradient >10 mmHg in tachycardia or high-output states. On the flip side, *gradient is more accurately measured by echo than valve area, and consequently, a practical definition of severe MS may consist of the following combination:* **(i)** ***mean gradient >10–15 mmHg at a heart rate <75–80 bpm;*** **(ii)** ***slow E-wave decay that never returns to baseline with a solid E-A envelope throughout diastole, at a rate <75–80 bpm,*** reflecting absent LA-LV pressure diastasis (Figure 6.12). By contrast, **in AS, both valve area and gradient are important, with gradient being more specific.**

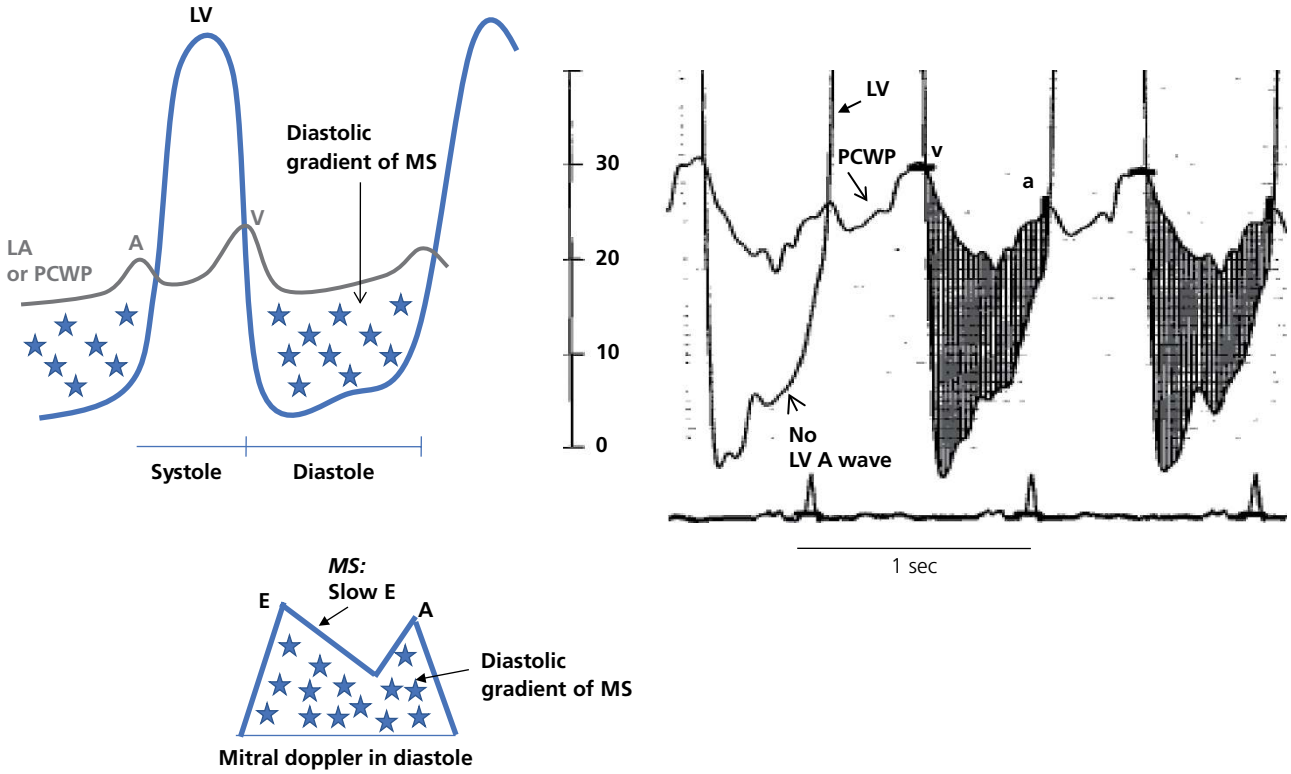

Figure 6.12 Two examples of mitral stenosis with a diastolic pressure gradient between PCWP and LV at a heart rate of 60 bpm (*dark filled areas)*. Due to phase delay, the tracing of PCWP has been shifted to the left so that the *peak of the V wave almost intersects the LV downslope*. There is no LA–LV diastasis, i.e., LA pressure remains higher than LV pressure throughout diastole, signifying severe MS. *LA A wave is pronounced but LV A wave is reduced because of ventricular underfilling*. **The lack of diastasis translates into a slow E downslope on echo, which does not return to the baseline. In fact, the *starred* Doppler E-A envelope** (*bottom image*) **corresponds almost exactly to the *starred* invasive LA-LV area** (*top image*). With more severe MS, the LA pressure tracing is higher and the intersection between V wave and LV occurs earlier; *this translates into an opening mitral snap that is closer to* S_2.

B. Catheterization

If invasive assessment of MS is needed, simultaneous LA–LV pressures should be obtained, and, ideally, LA pressure should be directly measured through a trans-septal puncture. PCWP is sometimes used as a surrogate of LA pressure, and PCWP–LV simultaneous recordings are used to assess MS (Figure 6.12). Three pitfalls attend the use of PCWP and lead to overestimation of the transmitral gradient:

- PCWP tracing is delayed by 50–150 ms in comparison to LA pressure tracing.
- PCWP is more damped than LA pressure with less deep and steep Y descent.
- The obtained PCWP may not be a true PCWP and may rather be a damped PA pressure or a hybrid PA–PCWP. True PCWP has well-defined A and V waves with: (1) unlike systolic PA pressure, the V wave of PCWP peaks after the T wave and intersects the LV descent; (2) the segment between peaks is horizontal or upsloping with A wave in PCWP vs. downsloping in damped PA pressure; (3) V wave is narrow-peaked with slow upslope and sharp downslope, opposite to PA.

To correct for the phase delay, one may shift the PCWP leftward until the peak of the V wave is bisected by the LV downstroke. ***Two situations particularly exaggerate the PCWP pitfalls, mandating a trans-septal LA pressure measurement:***[64]

- Large V wave, where the "spread-out," damped V downslope creates a false gradient (Figures 6.13 and 6.14).
- Pulmonary hypertension. Pulmonary hypertension makes it difficult to wedge the PA and obtain a true PCWP. Even when PCWP is obtained, it is usually a damped, flat tracing that falsely suggests a high PCWP–LV gradient (Figure 6.14).

Typically in severe MS, LV and LA pressures do not equalize at the end of diastole (diastasis is not reached), even when the heart rate is controlled at 60–75 bpm. In fact, the lack of diastasis at a heart rate <75 bpm or a pause of 1 second implies severe MS. Also, a large LA A wave with a discrepantly absent LV A wave suggests MS (LV underfilling).

When MVA is in the severe range but the heart rate is slow (≤60 bpm) and the cardiac output is low, diastasis may be reached at the end of diastole and the gradient may decline to 5–10 mmHg.

Conversely, tachycardia (or heart rate >80 bpm) may convert a mild MS gradient into a severe MS gradient with no diastasis. The gradient of MS increases during tachycardia (short diastole) and decreases during long R–R cycles.

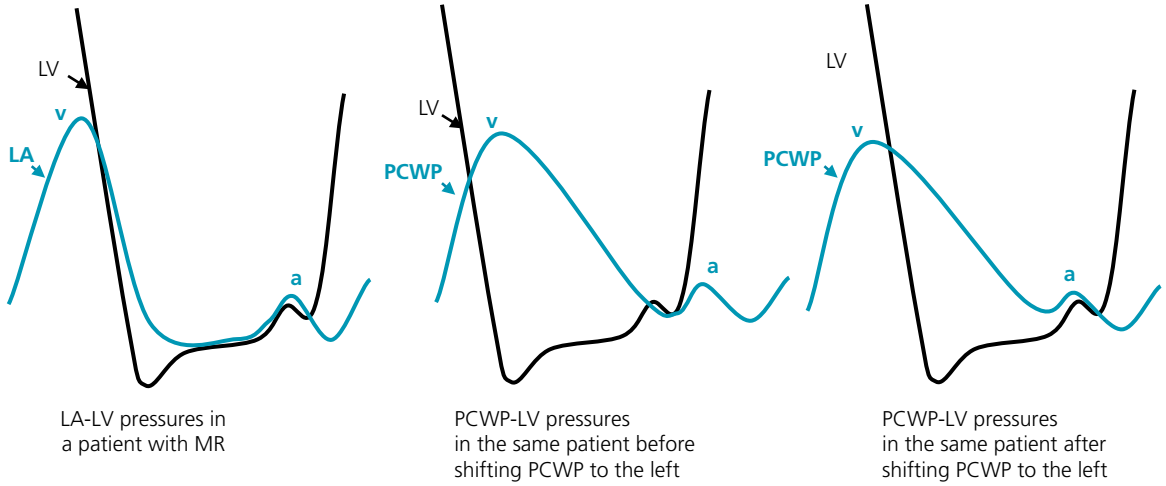

Figure 6.13 False impression of MS resulting from the use of PCWP as a surrogate for LA pressure in a patient with large V wave (severe MR, severe MAC). When LA–LV pressures are simultaneously recorded, an early diastolic gradient is seen between LA and LV and is quickly followed by diastasis. However, when PCWP–LV pressure recording is performed, the damped and prolonged Y descent creates the impression of a large pressure gradient and a lack of diastasis, even when PCWP is appropriately shifted to the left, thus creating the impression of MS. Even in true MS, PCWP overestimates the transmitral gradient if V wave is large/MR is present.

Note that LV A wave is still present and prominent, arguing against severe MS.

Reproduced with permission from Hanna EB. Mitral stenosis. In: Hanna EB, Glancy DL. Practical Cardiovascular Hemodynamics. New York, NY: Demos Medical, 2012, p. 101.

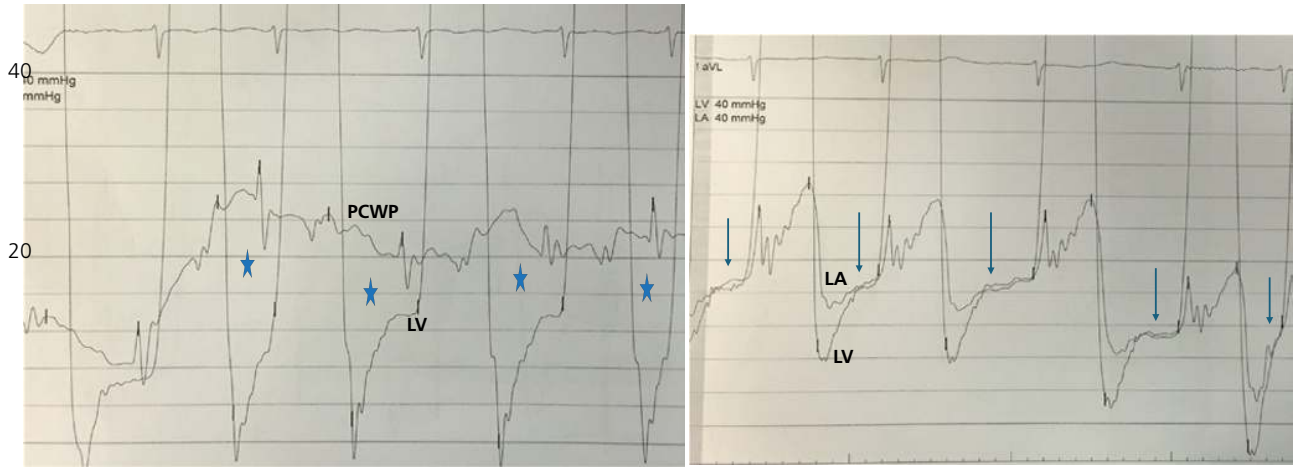

Figure 6.14 (***Left***) Simultaneous LV-PCWP recording of a 70-year-old man with AF and recurrent HF hospitalizations. Multiple echocardiograms are read as significant MS with heavy MAC and subvalvular calcium. PCWP is very damped and creates the illusion of a PCWP-LV gradient (*stars*).
(***Right***) Trans-septal LA–LV recording shows full diastasis in early diastole, i.e., full equalization of LA and LV in early diastole (*arrows*), ruling out significant MS. The patient rather has MAC and restrictive cardiomyopathy with elevated LA pressure and LVEDP. The high E wave was misread as MS on echo.

Note that patients with elevated LA pressure and ample V wave, such as patients with severe mitral regurgitation or HF, have an early diastolic pressure gradient between LA and LV, but in contrast to severe MS, LA and LV pressures equalize at mid-diastole (diastasis) and there is no LA–LV end-diastolic gradient.

While true MS may occur with MAC, MAC "MS" is often a misnomer, and the hemodynamics of MAC predominantly correspond to diastolic HF (+/– mild MS), more than true MS (Figures 6.14 and 6.15).[63] A mean gradient >10 mmHg is still prognostically relevant, although less predictive of a benefit from MV replacement than rheumatic MS, as LA and LV are also severely impaired.[65]

Because echo is highly accurate for assessing MS gradient but less so for MVA, a *hybrid method may be used for MVA: measure CO invasively and measure transmitral gradient simultaneously by echo*. Then apply Hakki's equation: MVA = CO/√gradient. The LA and LV pressure behavior and diastasis cannot be directly assessed by this method, but may be indirectly gauged by the E slope on echo: a slow E downslope that does not return to the baseline, with a solid E-A envelope throughout diastole, correlates with the lack of LA–LV diastasis (see the E slope in Figures 6.12 and 6.15). Trans-septal LA recording remains the gold standard in equivocal cases.

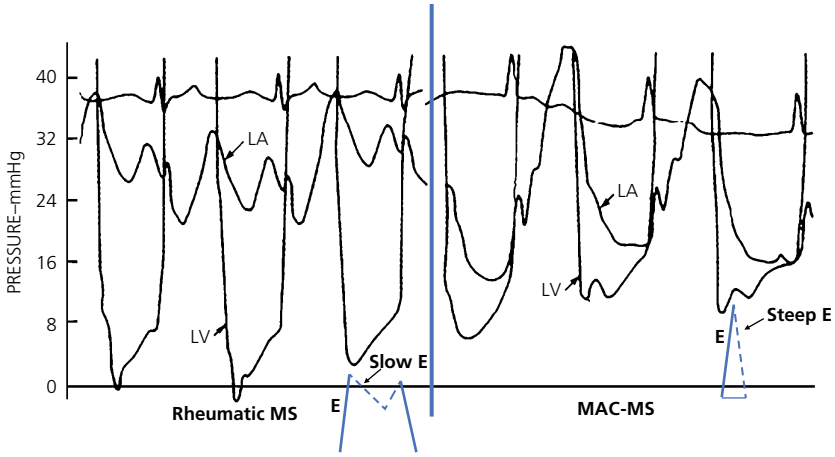

Figure 6.15 Illustration of the difference between rheumatic MS and MAC-MS. In **MAC-MS**, LV and LA per se are "sick," with a large V wave, reflective of poor LA compliance; and a high LVEDP, reflective of poor LV compliance. Also, there is AF in this case. LA pressure is high in both cases, but in MAC-MS, it is much more due to LV and LA disease than to valvular obstruction. As such, note the brisk LA y descent and the rapid equalization of LV and LA pressures on a longer RR interval, demonstrating the low valvular impedance in MAC MS. This corresponds to a steep E descent on mitral Doppler: E is high but narrow; do not confuse high E velocity with a high transmitral gradient. Had PCWP been used here, the false impression of significant MS would have been exaggerated, as in Figure 6.14. By contrast, note in **rheumatic MS** the slow LA y-descent and the lack of LA-LV diastasis even in end-diastole, translating into a slow E descent on Doppler.

C. Echocardiographic Wilkins score

The Wilkins score is an assessment of the severity of the valvular and subvalvular distortion and a rough estimate of suitability for percutaneous mitral valvuloplasty. It consists of the following 4 elements, each one being graded from 1 to 4:[66]

i. valve thickness (only tips are thick vs. the whole valve is thickened)
ii. valve mobility (only leaflet tips are immobile vs. tips and body vs. tips, body, and base are immobile)
iii. valve calcification (spots of calcium vs. the whole leaflet is calcified)
iv. chordal thickening and calcification (thickening only underneath the leaflets vs. thickening extends toward the papillary muscles).

A score ≤8 makes the valve appropriate for commissurotomy. An additional feature that determines suitability for commissurotomy is the presence of calcium at the commissures (Figure 6.11c). Commissural fusion is present in MS, but commissural calcium is only seen at a later stage and precludes successful commissurotomy, even if the Wilkins score is low. In general, Wilkins score is higher in patients older than 60–70 years of age.

D. TEE

In general, TEE does not offer additional information regarding the severity and morphology of MS (Wilkins score). The apical TTE views "look" directly into the subvalvular apparatus and allow estimation of the subvalvular thickening better than TEE, which "looks" at the mitral valve through the enlarged LA.

However, TEE is indicated prior to percutaneous valvotomy, in order to assess: (i) severity of MR, and (ii) presence of left atrial appendage thrombus.

E. Stress testing and other maneuvers for MS

Resting transmitral gradient may not reflect the true severity of MS. As expressed in Gorlin's equation, for the same mitral valve area, the transmitral gradient is directly proportional to the square of the per-second flow across the valve (MVA ≈ transmitral flow/√transmitral gradient). Thus, if the per-second diastolic flow doubles because the cardiac output increases and/or the diastolic filling time decreases (tachycardia), the pressure gradient across the valve quadruples.[66–69]

Stress testing is useful in symptomatic patients with *mild/moderate MS*, *after ruling out tachycardia or high-output state as an aggravating factor*, and helps sort out whether their symptoms are due to MS or LV failure. In MS, PCWP and transmitral gradient increase with exercise while LV diastolic pressure remains unchanged; in LV failure, both PCWP and LV diastolic pressure increase with exercise while the gradient remains unchanged. MS is clinically significant and would likely benefit from an intervention if the mean transmitral gradient increases to >15 mmHg; or if systolic PA pressure or PCWP increases to >60 mmHg or >25 mmHg, respectively, without a significant increase in LVEDP.

A second condition where stress testing is helpful is asymptomatic severe MS. An exertional increase of systolic PA pressure to >60 mmHg signifies that the patient is likely limited functionally and will likely benefit from an intervention to avoid the consequences of prolonged pulmonary hypertension.

Note that, similarly to exercise, the heavy use of vasodilators increases cardiac output and the mitral gradient. Also, passive leg raising increases venous return and the mitral gradient. In fact, *passive leg raising is routinely performed during echo assessment of MS*. Dobutamine may also be used.

III. Treatment

A. Medical therapy

- Diuretics and β-blockers often produce substantial symptomatic improvement. β-Blockers increase diastolic time, allowing more time for the slow LA emptying. A heart rate of 60 bpm should be targeted. Medical therapy is not usually indicated as a standalone therapy, as

even patients with class II symptoms have impaired long-term outcomes without mechanical relief of MS. Standalone medical therapy may, however, be used in select patients with class II symptoms:
  - Patients with class II symptoms who do not have appropriate morphological features for percutaneous mitral balloon valvotomy (PMBV). Class II symptoms are not severe enough to warrant surgery.
  - Patients who improve after PMBV but have residual symptoms.
  - Patients with mild/moderate MS that is symptomatic because of hemodynamic disturbances (tachycardia, high cardiac output).
  - Sedentary, elderly patients with mild symptoms on exertion.[70] This includes MAC MS.
- Treatment of AF: β-blockers and/or digoxin are used for rate control. Rhythm control may be attempted for a new AF, but repeated DC cardioversions should be avoided in light of the associated stroke risk and the fact that, over time, rhythm control is difficult to achieve in MS. The yearly risk of stroke with the AF–MS combination is 10–15%, implying a critical role of warfarin therapy.

Note the effect of β-blockers on the transmitral gradient (Figure 6.16). The reduction of PCWP and transmitral gradient with a longer diastole makes acute β-blocker therapy important in decompensated MS with pulmonary edema. ***A similar benefit of acute β-blockade is seen when pulmonary edema is related to HOCM. No other case of decompensated left heart failure, whether systolic or diastolic, is acutely served by β-blockers***.

B. Indications for percutaneous or surgical therapy

A mechanical intervention is indicated for select patients with ***severe*** (≤1.5 cm^2) ***or very severe MS*** (≤1 cm^2):[18,19]

- Symptoms class II–IV for PMBV or III–IV for MV *surgery* (*class I indication*).
- Asymptomatic patient with moderate pulmonary hypertension qualifies for PMBV (systolic PA pressure >50 mmHg at rest, >60 mmHg with exertion) (*class IIa*). Pulmonary hypertension more readily indicates mechanical correction in MS than MR, as pulmonary hypertension of MS more quickly progresses to precapillary pulmonary hypertension and RV failure.
- Asymptomatic patient with plans for pregnancy or major high-risk surgery qualifies for PMBV (*ESC class IIa*).
- Asymptomatic patient with AF. PMBV may be performed, but the strength of this recommendation is weak (*IIb*), as PMBV has not been universally successful in preventing or reverting rheumatic AF (≠ MV repair for MR).[70]

Also, as explained above, symptomatic patients with moderate MS (MVA 1.5–2 cm^2) and moderate gradient at rest need to be assessed with stress testing. A severe increase in transmitral gradient (>15 mmHg) without a significant change in LVEDP implies that MS is hemodynamically significant and may benefit from PMBV (*class IIb*). ***On the other hand, patients with moderate anatomic MS who have a severe gradient at rest need to be invasively assessed and treated for associated hemodynamic disturbances:*** tachycardia, high-output state (e.g., anemia, vasodilator therapy). In the absence of those hemodynamic disturbances, moderate MS may be the cause of the severe gradient and the pulmonary hypertension and may warrant PMBV (also, a valve area of 1.6 cm^2 may imply severe MS when indexed for body size).

For patients who are not PMBV candidates, mitral valve replacement is not usually considered unless symptoms are class III/IV, i.e., more severe than required for PMBV, as valve replacement has a higher operative mortality than PMBV. Patients with class II symptoms and a valve morphology that is not favorable for PMBV generally undergo medical therapy with 6-month follow-ups rather than surgery. Yet, those patients with severe pulmonary hypertension are likely more symptomatic than they claim and qualify for valve replacement (*class IIa in older guidelines*).

On the other hand, patients with class III/IV symptoms and a valve morphology that is not optimal for PMBV who are at a high surgical risk may still undergo PMBV (*class IIb*).

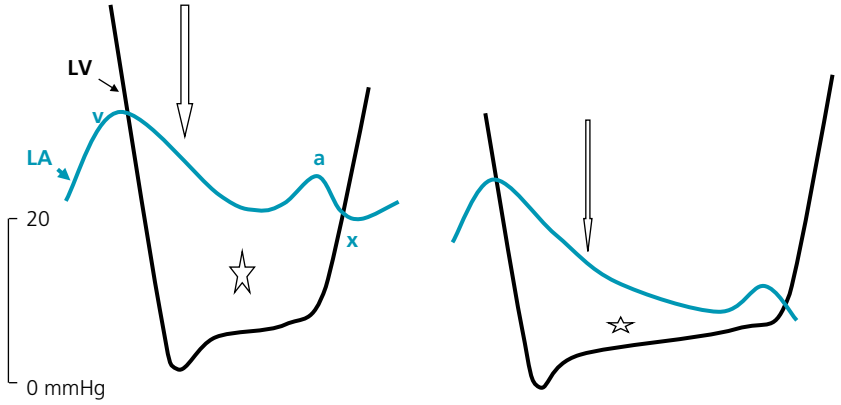

Figure 6.16 β-Blockers slow the heart rate and allow more LA emptying, which ultimately reduces LA pressure, V and A waves. The slope of the LA descent is unchanged (*arrows*); however, a longer diastole allows a longer duration of emptying and approximation of LA and LV pressures. Diastasis may be achieved if MS is not very severe. The height of LA pressure ↓ after several long R–R cycles as LA volume ↓. Reproduced with permission from Hanna EB. Mitral stenosis. In: Hanna EB, Glancy DL. Practical Cardiovascular Hemodynamics. New York, NY: Demos Medical, 2012, p. 107.

C. Percutaneous commissurotomy (or percutaneous mitral balloon valvotomy [PMBV])

When feasible, PMBV is the therapy of choice for MS.

1. Mortality = 1–2%, stroke ~1%
2. Risk of severe MR ~2–5% (moderate MR ~15%)
3. A successful PMBV is defined as a post-PMBV valvular area ≥ 1.5 cm^2 with ≤ moderate (2+) MR[71]
4. PMBV should be considered if:
   - **i.** Wilkins score ≤ 8 with no commissural calcium. The extent of calcifications and the subvalvular involvement are the 2 most important features of Wilkins score.
   - **ii.** No MR, or mild MR.
   - **iii.** No thrombus in the left atrium or left atrial appendage (ruled out by TEE). If thrombus is present, give 1–3 months of anticoagulation then reassess and attempt PMBV if the thrombus resolves. Surgical commissurotomy is an alternative.

Valvotomy works by splitting the fused commissures. Unlike AS, early MS mainly consists of a ***commissural fusion that is not calcified***. Tearing this fusion opens the mitral orifice, and thus balloon valvotomy is effective in treating early MS. Once the fibrosis and the immobility extend to the body of the leaflets or the subvalvular apparatus, or once calcium develops, valvotomy becomes less effective and risks tearing the stiff unyielding valve or the subvalvular apparatus in the process of dilating the orifice. Also, the balloon may get stuck in the thick subvalvular apparatus and tear it upon inflation. This is how Wilkins score and commissural calcium predict outcomes with PMBV.

In its original description, a Wilkins score ≥ 12 particularly predicted poor results with PMBV, while over a third of patients with an intermediate Wilkins score of 9–11 had a good result with PMBV. In one large analysis, ***~80% of patients with Wilkins score ≤8 and 56% of those with Wilkins scores 9–11 achieved a successful result with PMBV*** (>1.5 cm^2), and even patients with Wilkins score ≥ 12 improved MVA, although a full success was uncommon (30%).[71] In an analysis of elderly patients >70 years of age, MVA and symptoms improved with PMBV in most patients, even those with Wilkins score >8; *half of patients with Wilkins score >8 had improvement of MVA from 0.8 to >1.2 cm^2*, with functional class improvement.[72] Also, while moderate 2+ MR predicts a 4× higher failure rate, it does not prohibit PMBV.[66,71] In the original Wilkins paper, no patient with moderate MR developed severe MR after PMBV.[66] In a large PMBV series, ~6.5% of patients had moderate baseline MR.[71] Balance Wilkins score with the degree of MR (Wilkins score of 10 without any MR may be as amenable to PMBV as Wilkins score of 8 with mild-to-moderate MR).

Thus, while a surgical approach is advisable in high scores, PMBV may still be beneficial in intermediate (9–11) or even high scores, or patients with 2+ moderate MR when the surgical risk is high.[71–73] Hence, ACC guidelines consider PMBV a reasonable therapy for patients with class III/IV symptoms and a valve morphology that is not favorable for PMBV if the surgical risk is high (*class IIb indication*).

After a successful PMBV, ~25% of patients require MV replacement within 5 years, whether for restenosis (10–25%), progression of a suboptimal result, or progression of MR; this risk is higher in patients with an unfavorable early result or a high Wilkins score (up to 50%).[71,74] Wilkins score is associated not only with short-term but also with long-term failure.[74,75] Redo PMBV may be performed with a high success rate (~75%) if favorable echocardiographic features are still present.[74]

Besides a young age <60–70 years, 2 clinical findings imply that the valve is pliable and is likely to respond to PMBV: loud S_1 *and* the presence of an opening snap.

D. Surgical mitral commissurotomy

1. Perioperative mortality = 1–2%
2. Indications: pliable mitral leaflets with no severe subvalvular involvement, but with a left atrial appendage thrombus that precludes percutaneous therapy, CAD that necessitates CABG, or unavailability of percutaneous therapy. In general, for the same patient, surgical commissurotomy has the same success rate as PMBV.

E. Mitral valve replacement; MAC-MS; AF procedures

MV replacement is necessary in the case of extensive mitral valve calcification, high Wilkins score, or combined MS and MR. The operative mortality is ~4–6%, which increases to ~12% if significant pulmonary hypertension has developed. Since MV replacement has a higher risk than PMBV, patients who do not qualify for PMBV qualify for MV replacement later in the course of the disease, i.e., for more severe symptoms (III–IV).

MS from severe MAC is often functionally mild and managed medically. Moreover, MVR is flawed, as outward MAC restricts prosthesis sizing just as it restricts the native valve.

In a patient with persistent or paroxysmal AF, biatrial ablation lines that include the pulmonary veins, the venae cavae, and the valvular annuli (maze procedure) may be performed during *any cardiac surgery* and are associated with a high success in maintaining sinus rhythm (up to 80%), even in patients with left atrial enlargement (*class I in mitral surgery, class IIa in other cardiac surgeries*).[76] When radiofrequency is used instead of cutting and sewing, maze procedure may not significantly add to the complexity and risk of a mitral valve procedure as the LA is already open.[18] A less invasive uniatrial or isolated pulmonary vein ablation (mini-maze) may be performed, with similar efficacy in one trial.[77] Excision of the LA appendage further reduces stroke risk on top of chronic anticoagulation (LAAOS III trial).

Patients with severe MS and chronically elevated PCWP >25 mmHg may develop reactive changes in the pulmonary arteriolar bed, severe increases in the pulmonary vascular resistance (PVR), as high as 25 Wood units, and very severe pulmonary arterial hypertension disproportionate to the PCWP. This may be associated with severe RV failure. Even at this stage, however, patients usually respond to correction of MS; the elimination of the passive postcapillary component of pulmonary hypertension

results in an immediate drop in PA pressure, followed by a slow and gradual decline in the reactive and hypertrophic component.[78–80] In fact, PA pressure and PVR decline toward normal over the course of several weeks to months. Therefore, invasive treatment is still warranted at the stage of severe pulmonary hypertension. In the majority of patients, an almost complete normalization of pulmonary hypertension is expected. Pulmonary vasodilators (endothelin antagonist, intravenous prostacyclin) may be temporarily used in the early postoperative period.

3. AORTIC INSUFFICIENCY

I. Etiology

A. Acute AI

a. *Endocarditis:* the vegetation may perforate the leaflet(s) or prevent valvular coaptation.

b. *Aortic dissection* leads to AI through 3 potential mechanisms: (i) dilatation of the sinotubular junction; (ii) dissection extends into the leaflet attachment at the sinotubular junction, resulting in leaflet prolapse and eccentric AI; (iii) dissection flap prolapses through the aortic orifice and prevents leaflet coaptation. AI may also be pre-existent, secondary to a bicuspid aortic valve.

c. *Closed chest trauma* may lacerate the aortic leaflet or its sinotubular insertion, causing it to prolapse. Being anterior, the aortic valve is the valve most commonly involved in chest trauma.

B. Chronic AI

a. *Dilatation of the ascending aorta with secondary AI:* this is the most common cause of severe AI. Dilatation of the ascending aorta may lead to dilatation of the junction between the tubular aorta and the sinuses of Valsalva, called the *sinotubular junction*, precluding the coaptation of the aortic leaflets (Figure 6.17). Aortic dilatation is a primary process that can cause AI or coexist with bicuspid aortic valve disease. While potentially causing AI, aortic dilatation may reciprocally be induced or worsened by the high stroke volume of AI; it is also worsened by the high post-stenotic jet of AS (post-stenotic dilatation).

Causes of ascending aortic disorders:

- **i.** Degenerative aortic dilatation, related to age and HTN, is the most common cause of ascending aortic dilatation.
- **ii.** Cystic medial necrosis, which occurs in younger patients: (1) Marfan or Marfan fruste, (2) bicuspid aortic valve, (3) spondyloarthropathies.

b. *Aortic valve disorders*

- **i.** Bicuspid aortic valve is the most common valvular cause of severe AI. AI results from prolapse of a leaflet or incomplete closure of a thickened redundant valve.
- **ii.** Old, healed endocarditis. Subacute endocarditis may only be associated with mild or moderate AI early on, but progressive valvular deformity results from the healing process and leads to progressive AI (progressive widening of a perforation or progressive retraction and malcoaptation of the scarred leaflet(s)).
- **iii.** Idiopathic valvular degeneration with increased and disorganized collagen and elastic fibers. Anatomically, a mild degree of thickening/retraction, redundancy, or myxomatous degeneration is seen. This was the most common cause of isolated AI in one study.[81]

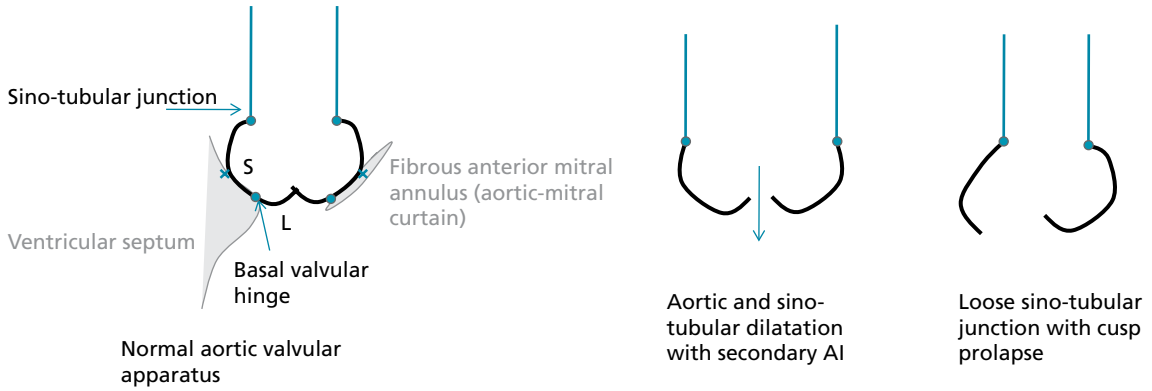

Figure 6.17 Aortic leaflets and their relation to the ascending aorta. A normal valve apparatus consists of aortic tissue that extends from the *sinotubular junction* and forms local aortic dilatations called *aortic root or sinuses of Valsalva (S)* that attach to the LV septum and mitral annulus. The *aortic annulus* is a ring formed by connecting the basal valvular hinges, i.e., the bottom of the cusps' insertion on the septum and the mitral annulus: it is a virtual annulus, as there is no anatomical ring, and it corresponds to the upper LVOT. This is the ring measured during TAVR procedures: avoid measurement at the upper portion of the valvular–ventricular junction (X) and at the lower LVOT, which is often smaller and more elliptical. The aortic *leaflets* (L) are the semi-lunar *cusps* that extend from the hinges.

The sinuses of Valsalva are an extension of the aortic wall tissue and are supported or "suspended" by the sinotubular junction, a ridge rich in elastic tissue. When this junction is disrupted by aortic dissection, cusp prolapse ensues. The coronary arteries originate from the upper portion of the sinuses of Valsalva.

Two-thirds of the circumference of the aortic valve is connected to the muscular ventricular septum anteriorly, while the posterior one-third is in fibrous continuity with the anterior mitral leaflet (mitro-aortic fibrosa, close to the non-coronary posterior cusp) (see Figures 6.1 and 6.9). At one point posteriorly, the aortic valve is in continuity with the membranous ventricular septum. Note that the same mitro-aortic fibrosa, which constitutes 1/3 of the aortic ring, also constitutes 1/3 of the mitral annulus and <1/3 of the tricuspid annulus (Figure 6.9).

iv. Rheumatic fever with fibrosis and retraction of the leaflets. Fibrosis and fusion of the commissures also leads to AS. The aortic valve is immobile and does not open or close (combined AS/AI).
v. Prolapse of an aortic valve leaflet in the context of bicuspid aortic valve, endocarditis, trauma, or myxomatous degeneration.
vi. Degeneration of a bioprosthesis.

II. Pathophysiology and hemodynamics (Figure 6.18)

A. Acute AI

In acute AI, LV is non-compliant and LV volume is normal. Thus, the regurgitant volume leads to a severe increase in LVEDP and **the aortic and LV diastolic pressures come close together** (Figure 6.13). LV diastolic pressure exceeds LA pressure in mid- or late-diastole (Figure 6.13), leading to a reverse LV–LA gradient and forcing the mitral valve to close prematurely (functional MS), a finding typical of decompensated AI.[82,83] Since LV is not dilated, the stroke volume is reduced in acute AI. Therefore, in addition to the low DBP, SBP is usually low (e.g., BP 90/40 mmHg). **As opposed to chronic AI, pulse pressure is only mildly widened, but this already suggests acute AI in a patient with acute heart failure**, wherein the arterial pulse pressure is typically narrow. Tachycardia is an important compensatory response in acute AI as it increases the cardiac output and reduces the regurgitant time, and thus should be respected.

B. Chronic compensated AI

In chronic compensated AI, LV volume increases, the total stroke volume increases, leading to a high pulse pressure (e.g., 160/60 mmHg), and the forward stroke volume is maintained. The LV is large and compliant in a way that it accommodates the regurgitant volume without an increase in LVEDP. The aortic and LV pressures do not approximate at the end of diastole; on Doppler, this corresponds to a gradual rather than steep drop of the regurgitant flow velocity with a pressure half-time that is >250 ms, even if AI is severe. While a wide pulse pressure (>½ SBP or >60–80 mmHg) is a very sensitive finding in chronic severe AI, it is not a specific finding and may be seen in a poorly compliant aorta and in high-output states with low afterload (patent ductus arteriosus, hyperthyroidism, anemia, fever, and arteriovenous fistula).

The peripheral femoral pressure may get *excessively amplified* and exceed the central systolic pressure by >50 mmHg. This is an exaggeration of a normal effect and is due to the large initial stroke volume percussing the less compliant, muscular peripheral arteries. This large percussion is followed by aftershock waves that get reflected in the periphery and cause a second systolic pressure peak (pulsus bisferiens).

C. Chronic decompensated AI

In chronic decompensated AI, LV function starts to decline, and EF decreases such that the forward stroke volume declines and the LV volume further increases. LV compliance starts deteriorating and LVEDP rises, only with exercise initially. Similarly to acute AI, LV and aortic pressures approximate in end-diastole.[82,83] On Doppler, this corresponds to a steep drop of regurgitant flow velocity throughout diastole with a short pressure half-time <250 ms. Total stroke volume remains elevated, and thus the pulse pressure remains elevated. At an advanced stage, when EF is severely reduced, total stroke volume and pulse pressure may decline.

As opposed to other valvular disorders, chronic AI is well tolerated during exercise. In fact, tachycardia reduces diastole and the time available for regurgitation, and the vasodilatation associated with exercise reduces the regurgitant volume, which allows an increase in cardiac output during exercise. That is why severe AI, as opposed to MR, is well tolerated for years before symptoms develop. In addition, in AI, unlike in MR, LV dysfunction is slower, milder, and more related to high afterload than intrinsic dysfunction. Symptoms develop very gradually and the patient adapts to them over the years, sometimes not realizing the change in functional status.

Note that both preload and afterload are increased in severe AI. Afterload = wall stress = LV systolic pressure × radius/(2 × LV thickness). **Thus, afterload is proportional to both LV systolic pressure and LV radius and dramatically rises with LV dilatation, often matching the increased afterload observed in AS,** though the mechanism differs.[84,85] LV hypertrophy allows the LV to adapt to this load increase up to a certain point, beyond which the LV succumbs to afterload. The initial decline in EF is the result of a progressive increase in LV size and afterload rather than an intrinsic LV contractile dysfunction (**afterload mismatch**). ***This process is fully reversible with AVR and is different from the early EF decline in MR, which already implies a significant contractile dysfunction that may be irreversible, LV afterload being reduced with MR early on.*** With time, however, even in AI, intrinsic dysfunction progressively becomes a major contributor to the decline in EF and may not be fully reversed with surgery, particularly when EF is <25% or the decline has persisted over 18 months preoperatively.

Compared to MR, why is LV dysfunction milder in AI, and why does it occur later?
Despite the severe rise in both preload and afterload (vs. mainly preload in MR), LV dysfunction in AI is not only more reversible than MR, it occurs later and more slowly. This is because in AI, LV hypertrophy is more pronounced and attenuates the systolic and diastolic wall stress of LV dilatation (both eccentric and concentric LV hypertrophy occur, with a mass-to-LV volume ratio of ~1, as in normal individuals).[17,86] Conversely, in MR and pure volume overload, **mass-to-volume ratio is <1; thus, the LV muscle works harder and fails earlier**, and becomes more spherical than elliptical (myocardial elongation rather than thickening, adverse geometry). Animal data suggest that the lack of hypertrophy that develops in MR compared with AS causes the existent muscle to bear a greater workload, particularly when the LV starts to succumb, which may, in turn, be responsible for the more progressive contractile abnormalities and fibrosis on MRI.

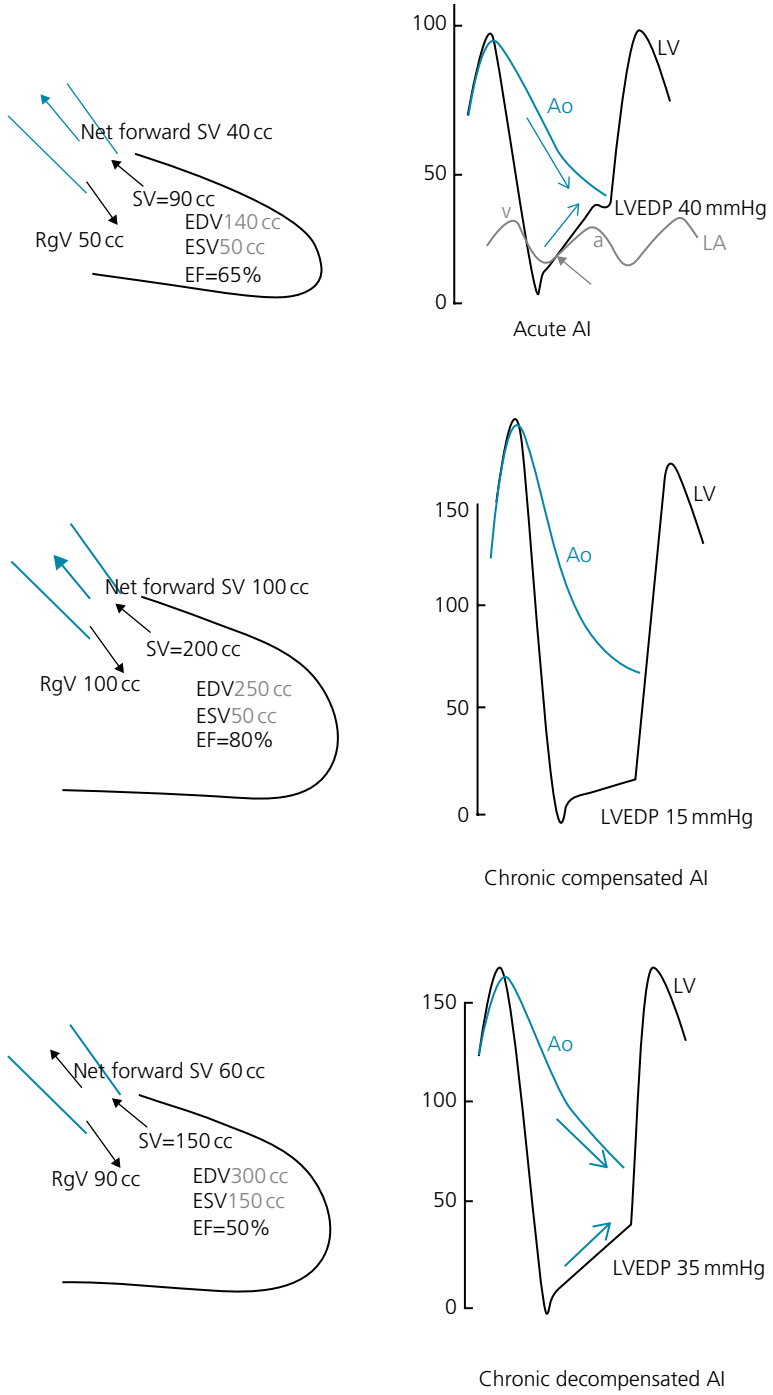

Figure 6.18 **1.** In acute AI, LV volume is normal and the regurgitant volume leads to a severe increase in LVEDP. The LV and aortic pressures approximate in end-diastole forming a **diastolic triangle** *(blue arrows)* (Δ<30 mmHg or <25% of SBP). LV diastolic pressure exceeds LA pressure in mid or late diastole (*gray arrow*): this causes functional MS in early diastole, followed by early closure of the mitral valve and diastolic MR.

2. In chronic AI, LV volume increases and the total stroke volume increases, thus leading to a high pulse pressure, and the forward stroke volume is maintained. The LV is large and compliant in a way that it accommodates the regurgitant volume without an increase in LVEDP.

3. In chronic decompensated AI, the LV function starts to be impaired, EF is reduced in a way that the forward stroke volume is reduced, and the LV volume increases, leading to increased LVEDP. Total stroke volume remains elevated, and thus, the pulse pressure remains elevated. LV and aortic diastolic pressures converge; the trapezoid they form corresponds to the Doppler AI envelope (steep PHT).

Note the attenuation or loss of the dicrotic notch, especially in acute AI. In chronic AI, the aorta may improve its compliance, causing the dicrotic notch to re-emerge. EDV, end-diastolic volume; EF, ejection fraction; ESV, end-systolic volume; RgV, regurgitant volume; SV, stroke volume.

LV thickness, the denominator of systolic and diastolic wall stress, poorly adapts to volume overload compared to pressure overload. **As such, LV function more poorly adapts to high volume overload (high preload) than to pressure overload. Consequently, its adaptation is poorest in MR** (pure volume overload), **intermediate in AI** (combined pressure and volume overload), **and best in AS** (pure pressure overload). Hence (i) **LV function declines earlier in MR, later in AI, and latest in AS,** and (ii) when dysfunction occurs, it more readily reflects **intrinsic MYOCARDIAL disease in MR vs. AFTERLOAD mismatch in AI and especially AS**. ***This explains why the surgical EF cutoffs are 60%, 55%, and 50%, respectively***.

In the volume overload of MR, the limited hypertrophy leads to a disadvantageous LV geometry in which the diastolic but also the systolic wall stress paradoxically increase despite the unloading of the left ventricle by the regurgitant pathway; in MR with LV dysfunction, wall stress is increased (LV is not truly unloaded).[33,86]

III. Diagnosis

A. TTE. See Chapter 33, Figures 30–33 and 52.

TTE is useful to diagnose the severity and etiology of AI. The following features suggest severe AI:

- The narrowest AI neck, measured *at the aortic valve* level and called vena contracta, is >6 mm (long-axis view). The width of the regurgitant jet *just below the vena contracta*, at the LVOT, is >60% of the LVOT diameter (long-axis view), or >60% of the LVOT area (short-axis view), at a Nyquist limit of 50–60 cm/s. Eccentric jets may be underestimated as the color jet abuts the mitral valve or the septum and shrinks in color speed.
- Holodiastolic flow reversal in the descending aorta (most important feature).
- On the spectral Doppler, pressure half-time of the regurgitant flow is <250 ms; this correlates with AI acuity and the status of the LV, and corresponds to how steeply LV and aortic pressures converge in Figure 6.18. Pressure half-time may be 250–400 ms if AI is severe but chronic and compensated. Conversely, pressure half-time may be <250 ms in patients with moderate AI but underlying severe LV dysfunction (from CAD or HTN).
- Quantitatively, guidelines consider AI severe if regurgitant fraction ≥50% or regurgitant volume ≥60 ml, like MR. Those are often calculated with the volumetric method (Chapter 33, VIII.B). However, MRI data suggest that surgical indications (LV remodeling and/or symptoms) frequently occur at the lower cutoffs of 35% and 38 ml, respectively.[87]
- Also, in chronic severe AI, LV is generally dilated. Yet the diagnosis should not rely on pronounced LV dilatation; symptoms frequently develop in patients with only *mildly increased LV dimensions (LVESDi ≥ 20 mm/m^2), or even a normal LVESDi in absolute value* that is high relative to the patient's baseline.[88]

B. TEE and cardiac MRI

TEE is not significantly superior to TTE for the assessment of the severity of AI. TEE is superior for the anatomical assessment of the aortic valve and aortic annulus (bicuspid morphology, endocarditis), and for the assessment of the ascending aorta.

Cardiac MRI is the best non-invasive modality for assessing AI, via quantifying antegrade and retrograde aortic volumes, or the difference between LV and RV stroke volumes. It is valuable when AI severity is unclear by echo. It is also valuable for assessing MR.

C. Invasive assessment (aortic root angiography and hemodynamic measurements)

As in other valvular disorders, invasive assessment of AI is indicated when echo is inconclusive regarding the severity of AI or when there is discrepancy between clinical findings and echo results.

On aortic root angiography, severe AI is characterized by LV filling that is as dense (3+) or denser (4+) than aortic filling. Hemodynamically, severe AI is characterized by four features (Figures 6.18 and 37.18): (1) wide aortic pulse pressure, particularly seen in chronic AI; (2) loss of the aortic dicrotic notch, particularly seen in acute AI; (3) LV end-diastolic pressure approximates aortic pressure; (4) LV end-diastolic pressure exceeds mean PCWP and even end-diastolic PCWP (the last 2 findings are seen in acute or decompensated AI).

IV. Natural history and symptoms

Asymptomatic severe AI with normal LV function has a slow progression: <0.2% sudden cardiac death per year, 4.5% progression to symptoms and/or LV dysfunction per year.[18] Class II dyspnea develops slowly and insidiously and may be overlooked. Patients with LVESD >50 mm or LVEDD >70 mm have the highest risk of progression to symptoms and/or LV dysfunction (10–20% per year).

Conversely, symptomatic AI or AI with LV dysfunction has a mean survival rate of ~3 years without surgical intervention: yearly mortality 5–10% if NYHA class II dyspnea, >10% if angina, >20% if class III–IV HF, wherein the mean survival is 1.5 years.[89]

AI symptoms appear late in the disease process, usually after LV has enlarged, but may appear earlier in patients with a stiff LV that cannot dilate much. Fortunately, **LV better adapts to AI than to the pure volume overload of MR, thanks to the protective hypertrophy. LV enlargement and dysfunction do not necessarily indicate intrinsic damage and are partly due to afterload mismatch.** Class II *dyspnea* appears earlier than *angina* and *severe HF*. Subendocardial coronary flow being driven by the perfusion pressure gradient between aortic diastolic pressure and LVEDP, angina is often functional and related to the severe drop in aortic diastolic pressure and the increase in LVEDP. Moreover, O_2 demands of the large LV are severely increased. Angina may be nocturnal rather than exertional, aggravated by bradycardia, wherein the aortic diastolic pressure decreases to very low levels. Diastolic reversal of coronary flow may be seen in severe cases. *Palpitations* may appear early on and are related to the ejection of a large LV volume, especially after a PVC; they are not, per se, an indication for surgical correction.

V. Treatment

A. Medical therapy

Aortic valve surgery is the only effective therapy for severe AI that requires treatment. Vasodilators (ACE-I, CCBs) are useful for systolic HTN. Systolic HTN is inherent to severe AI and may prove difficult to control, particularly that reducing SBP may come at the price of a harmful

drop of DBP and myocardial ischemia: β-blockers decrease DBP, while ACE-I, by reducing AI volume, may not adversely reduce DBP. Vasodilators may also be used in patients who are not undergoing surgery because of high risk. By prolonging diastole, β-blockers may aggravate symptoms and DBP and are best avoided, except in arrhythmias. They may be used post-AVR, along with ACE-I, for EF <55%.

In severe asymptomatic AI with mildly dilated LV and no indication for surgery, vasodilators may slow LV dilatation; however, a randomized trial has disproved this theory, and thus vasodilators are not routinely recommended in severe asymptomatic AI.[90] Mild exercise is allowed in asymptomatic severe AI. Athletic activity may be allowed in some cases, after performing stress testing for safety purposes; the long-term effect of exercise on severe AI is, however, unknown.

B. Indications for surgery

Aortic valve surgery is indicated for severe AI with any of the following:[18,19]

- Symptoms (NYHA functional class ≥ II)
- EF ≤55% (as compared to EF ≤60% for MR)
- LVESD >50 mm (as compared to ≥40 mm for MR) or >25 mm/m^2 of BSA
- Asymptomatic severe AI while undergoing CABG or other cardiac/aortic surgery. AVR is also reasonable for moderate AI while undergoing cardiac/aortic surgery (*class IIa indication*)
- LVEDD correlates with AI volume overload but less strongly with LV systolic function (unlike LVESD). Surgery is considered for LVEDD >65 mm, particularly when LV dilatation is rapidly progressive and the surgical risk is low (*class IIb*). Surgery is also considered for EF of 55–60% when there is evidence of progressive EF decline (*class IIb*)

In modern registries, *symptoms (particularly class II) occur earlier and more frequently than pronounced LV enlargement*; ~85% of symptomatic, operated patients had LVESD and LVEDD below surgical cut-points. This is particularly true in older patients with stiff LV that does not dilate and accommodate the AI volume overload, thus raising LVEDP early on.[88] The less LV can dilate, the earlier symptoms develop. Furthermore, modern data suggest that indexed LVESD >20–22 mm/m^2, rather than 25 mm/m^2, is a strong predictor of AI mortality and surgical benefit and may be a better cut-point for surgical referral (ESC class IIb).[88] At the very least, asymptomatic patients with less severely enlarged LV (LVESD 40–50 mm or LVEDD 55–65 mm) should be re-evaluated by echo in 3 months then every 6–12 months if the LV dimensions are stable. If unstable, surgical correction should be considered.

AI is tolerated for a long period of time before symptoms develop. Even when symptoms develop, they are insidious in a way that the patient may not realize his functional limitation. *Before considering AI asymptomatic, exercise testing is often warranted*.

Patients with advanced symptoms or LV dysfunction: As opposed to MR, LV function does not usually deteriorate postoperatively and is likely to improve even with markedly reduced EF.[91] Early on in AI, the reduced EF is secondary to the high afterload rather than intrinsic dysfunction (afterload mismatch). AVR reduces regurgitant flow, which reduces LV wall stress/afterload and allows an improvement of EF, the earliest sign being a reduction of LV size. However, long-term postoperative survival is significantly reduced, ~ in half, in patients with NYHA class III–IV symptoms or EF < 50% preoperatively, especially if LV dysfunction has been prolonged >18 months, severe (EF < 25%), or not recovering early postoperatively (long-term mortality 5–10% per year).[89,92,93] Patients with EF < 25% may have irreversible myocardial damage and persistent LV dysfunction postoperatively, yet most of these patients have a meaningful postoperative recovery, particularly if LV dysfunction is recent and if HF significantly improves with preoperative diuretics and vasodilators.[18,91] *No EF cutoff is prohibitive of AVR*. Postoperatively, the earliest sign of LV improvement is a decrease in LV diastolic size, which should occur within 2 weeks of surgery. In fact, 80% of LVEDD decline occurs within 2 weeks, and correlates with the eventual improvement of EF that ensues within 6–12 months.[18] A lack of early reduction of LV size implies intrinsic LV dysfunction.

C. AI and ascending aortic dilatation

Ascending aortic replacement is indicated for: (i) ascending aortic dilatation, ≥5.5 cm in most patients, including bicuspid valve patients, or ≥5 cm in patients with Marfan syndrome or bicuspid valve with family history of aortic dissection; or (ii) ascending aortic dilatation ≥0.5 cm/year. The same 5.5 cm cutoff is used for aortic dilatation at the level of the sinuses of Valsalva *or* beyond the sinotubular junction. When dilatation extends to the sinuses, the ascending aorta is replaced with an aortic graft that is sutured to the aortic ring, and the valve is spared if no AI (valve-sparing aortic root replacement: reimplantation technique [David's surgery], or remodeling technique [Yacoub]); the coronaries are reimplanted, sometimes with an interposition graft (Figure 20.9).[94–96]

Patients with *combined severe ascending aortic disease and moderate or severe AI* may undergo a composite graft replacement of both the aortic root and the aortic valve (Bentall procedure, or Cabrol procedure if an interposition graft is used for coronary reimplantation). The composite graft typically has a mechanical valve, but biological composite grafts are available. The *valve may be spared and reimplanted* rather than replaced if the cusp's tissue quality is good and the valve is not calcified or severely deformed, this being associated with an acceptable long-term result and a 5–15% risk of reoperation for AI at 10 years.[94–96] Even a bicuspid valve may be repaired if non-calcified and regurgitant rather than stenotic, sometimes along with resuspension of a prolapsed cusp (*class IIb*).

Regarding patients with *moderate ascending aortic dilatation along with severe AI or AS*: besides aortic valve replacement, replace the ascending aorta when it is ≥4.5 cm rather than 5.5 cm (*class IIa*). If unoperated, ~60% of patients with a bicuspid valve and an aorta of 4.5–4.9 cm go on to develop significant aortic events requiring aortic surgery over the next 15 years, mainly progressive aortic dilatation;[96] thus, in this range, concomitant aortic surgery is particularly applied to young patients and those at a low operative risk.

D. Aortic valve repair

Aortic valve reimplantation, a form of aortic valve repair, may be performed in patients with severe or moderate AI whose primary disorder is aortic root disease and whose cusp tissue quality is good even if the valve is bicuspid (ACC class IIb-ESC class I in a young patient with good valve tissue quality, regardless of AI severity). Resuspension of a prolapsed cusp may additionally be performed.

While aortic valve replacement remains the standard surgery for AI due to aortic valve disease without severe aortic dilatation, aortic valve repair may be performed for a minority of cases, such as prolapse of an elongated, non-calcified leaflet (cusp resuspension with resection or plication of the edge) or leaflet perforation from healed endocarditis (patch repair). The prolapsed valve is commonly bicuspid, wherein the conjoint cusp elongates and prolapses; this cusp is re-suspended and the raphe of the conjoint cusp resected. Since annular dilatation is common in these patients, subcommissural annuloplasty is often performed.

4. AORTIC STENOSIS

I. Etiology

A. Age-related calcific degeneration

This is the most common cause of AS. It is related to endothelial valvular injury from atherosclerotic risk factors and hemodynamic stress, like MAC. Calcifications develop throughout the valve leaflets *rather than specifically over the commissures*. Non-stenotic aortic valve sclerosis (thickening) precedes AS, is present in ~20% of patients older than 65 years, is associated with an increased risk of cardiovascular death and CAD, and progresses to some degree of AS in ~10% of patients at 5 years.

B. Bicuspid aortic valve

a. Bicuspid aortic valve is the most common congenital heart disease (~1.3% of the population). It is present in >50% of patients with aortic coarctation and ~10% of women with Turner syndrome. It has a familial trend (10% bicuspid valve prevalence and 30% aortic dilatation in first-degree relatives) and is more prevalent in men (3:1).[97] Screening of the patient's children is appropriate.

b. Two of the 3 cusps are fused, most commonly the right and left cusps (80%), followed by the right and non-coronary cusps (20%). A residual raphe is often seen at the fusion site (Figure 6.19). A pliable bicuspid valve does not usually impede aortic flow, per se. However, the presence of 2 rather than 3 leaflets leads to a smaller surface in contact with the high-pressure stroke volume and marked leaflet bending, making the bicuspid valve more susceptible to shear stress. Progressive stress leads to calcific degeneration and AS later in life. The more asymmetrical the cusps are, the higher the stress is, and the faster AS develops.

c. Yet bicuspid valves may be stenotic at birth, in childhood, or in early adulthood, before calcium develops, when a significant degree of commissural fusion is present or when the valve is, in fact, unicuspid. This early AS may be treated with valvuloplasty.

d. Later on, in early adult life *between the ages of 20 and 50 years, 20% of bicuspid valves develop AI*.[98] The remaining patients develop progressive aortic calcification and stenosis over time, as the bicuspid valve is more prone to mechanical and shear stress than a tricuspid valve. Severe AS usually appears in patients >40 years old, and 75% of bicuspid patients eventually develop severe AS over their lifetime.[98,99] Bicuspid aortic valve is the most common cause of AS in patients <70 years old (~two-thirds of AS), more so if <60 years old. In patients older than 70 years, bicuspid AS is the cause of 40% of severe AS.[98]

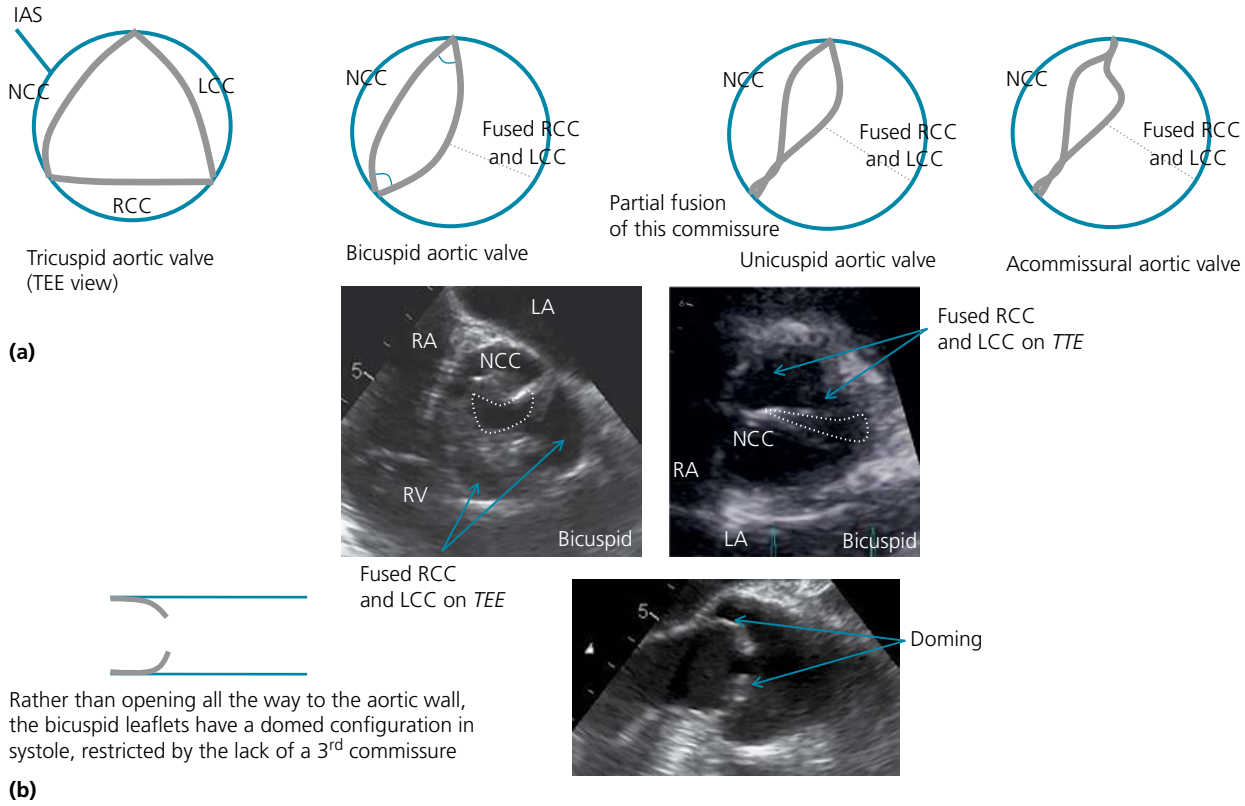

Figure 6.19 **(a)** Difference in aortic orifice shape between the tricuspid and bicuspid aortic valves (short-axis view). Bicuspid valves are in fact "bicommissural" valves, while unicuspid valves are "unicommissural" or "acommissural" valves. The commissures of a bicuspid valve (*arc*) may be partially fused, leading to AS at an early age; otherwise, AS develops later in life. Note that aortic opening/closure becomes eccentric in bicuspid valves; this is seen on M-mode analysis of the aortic valve. On echo, instead of analyzing how many cusps are seen when the valve is closed, it is best to analyze how the aortic valve opens: an elliptical rather than a triangular opening is a hint to a bicuspid valve. RCC and LCC are often fused, NCC being the cusp looking toward the IAS. **(b)** Doming of the bicuspid aortic valve on a long-axis view.

IAS, interatrial septum; LCC, left coronary cusp; NCC, non-coronary cusp; RCC, right coronary cusp.

e. While AS is the most common result of a bicuspid valve, severe AI or the combination of AI/AS is also possible. AI, which often develops at a younger age than AS, may be related to a dilated aortic root, but also to: prolapse of the asymmetrically large cusp (can't support the extra weight of blood in diastole), myxoid thickening with malcoaptation, retraction of a fibrotic/calcified leaflet, or endocarditis.
f. Patients with a bicuspid aortic valve have a high risk of *ascending aortic dilatation or dissection*. Aortic dilatation >3.7 cm occurs in 50–60% of patients with bicuspid aortic valve by the age of 30, and occurs as frequently in young patients with a normally functioning aortic valve as in patients with aortic stenosis, regurgitation, or AVR.[100] This aortopathy is mainly secondary to cystic medial necrosis and is partly exaggerated by AS's post-stenotic high velocity or AI's volume and pressure load. Unlike the ascending aortic dilatation that is seen with age and HTN, this aortopathy frequently involves the aortic sinuses beside the tubular aorta; yet tubular aorta remains more involved 64% of the time. Patients with bicuspid valve should undergo, at least once, a screening with CT to assess the whole aorta. If dilatation is found to predominantly involve the sinuses, sinotubular junction, or early tubular aorta, TTE is usually appropriate for surveillance. A surveillance echo is recommended every year in patients with aortic size >4 cm at the sinuses or higher, and every 2 years in bicuspid patients with aortic size <4 cm. The lifetime risk of aortic dissection in bicuspid patients is ~3–6%, vs. 40% in Marfan patients. Dissection is often preceded by aortic dilatation, sometimes mild,[100] and in general, ~60% of all dissections occur at a diameter <5.5 cm.

C. Rheumatic fever (rare): in this case, AS almost always occurs with rheumatic involvement of the mitral valve and is often associated with severe AI.

II. Echo and catheterization diagnosis, pitfalls, and hemodynamics

The diagnosis of severe AS is often made by TTE (Table 6.2). An invasive hemodynamic study is only indicated when the physical exam suggests severe AS (absent A_2, pulsus parvus and tardus), yet the echocardiogram suggests a milder degree of AS or vice versa; or when the echocardiography data are inconclusive (for example, the valve area is ≤1 cm² but the gradient is low).

A. Echo and Doppler features of severe AS

Aortic valve peak velocity, which translates into transaortic peak pressure gradient (4 × velocity²), is the most important diagnostic feature of severe AS. However, Doppler may underestimate the pressure gradient if the cursor is not perfectly aligned with the transaortic flow. Therefore, the aortic velocity must be assessed in multiple views: the apical 5- and 3-chamber views, but also the suprasternal view and a special right parasternal view, wherein the transducer is aligned with the ascending aorta to the right of the sternum (a special pencil probe, Pedof, allows easier right parasternal access between the ribs and has a high signal-to-noise ratio). If only apical windows are used, the gradient is underestimated in 20% of cases.

Note that the transaortic gradient is difficult to assess by TEE because only one view is aligned with the aortic flow, the transgastric 5-chamber view, a view that is not always obtainable, hence the limited value of TEE in AS.

Aortic valve area (AVA) is calculated using the continuity equation and is subject to the additional pitfalls of measuring the LVOT diameter and velocity: AVA = LVOT area × (LVOT velocity/aortic valve velocity) [*note:* peak velocities or better, VTI velocities may be used in this equation]. ***Echocardiographic AVA measurement is even less accurate and reproducible than the transaortic gradient***. LVOT is elliptical, and its anteroposterior diameter (long-axis view) is smaller than the septal-lateral diameter (Figure 6.20). Thus, the assumption of a circular LVOT underestimates the LVOT area and subsequently the AVA (by approximately 0.2 cm² on average).[101–103] LVOT area may be measured by planimetry using CT, 3D TEE or 3D TTE (if good transthoracic echogenicity), then AVA calculated via continuity Doppler equation. This is the hybrid method of AVA calculation, which has one caveat: surgical AVA cutoff of 1 cm² is not well validated with the hybrid method, and some studies suggest a better prognostic value of 1.2 cm² with this method.[104]

Doppler gradients rarely overestimate the severity of AS. ***A high velocity ≥4 m/s is diagnostic of severe AS in a patient with a calcified, poorly mobile valve,*** regardless of AVA calculation. Doppler may, however, underestimate AS.

Note that, according to Hakki's equation for invasive AVA calculation (AVA = CO/√mean gradient), ***a patient with a normal cardiac output of 5.5 L/min and an AVA of 1 cm² will have a mean gradient of 30 mmHg.*** Therefore, a mean gradient of 30 mmHg may very well be consistent with severe AS in patients with normal output (resting conditions): this is the so-called ***misalignment of AVA-gradient cutoffs in the definition of severe AS.*** This is particularly true in patients with a small body habitus, who have a relatively lower cardiac output. This gradient would strikingly increase with a slight increase in cardiac output, as the gradient is proportional to the square of the cardiac output. On Doppler, a gradient ≥ 40 mmHg is used as a more specific cutoff for defining severe AS, keeping in mind that a gradient of 30–40 mmHg may be consistent with a normal-flow severe AS, and a gradient of 15–30 mmHg may be consistent with a low-flow severe AS. Underestimation of gradient by Doppler is an additional possibility, and invasive confirmation of a small AVA is often needed in the latter 2 cases.

Table 6.2 Classification of AS severity.

	Mean transaortic gradient	Peak aortic velocity	Aortic valve area
Mild AS	<20 mmHg	2–2.9 m/s	>1.5 cm²
Moderate AS	20–40 mmHg	3–3.9 m/s	1–1.5 cm²
Severe AS	≥40 mmHg	≥4 m/s	≤1 cm² or indexed area ≤ 0.6 cm²/m² (more specific if ≤0.8 cm²)
	60 mmHg for very severe	5 m/s for very severe	

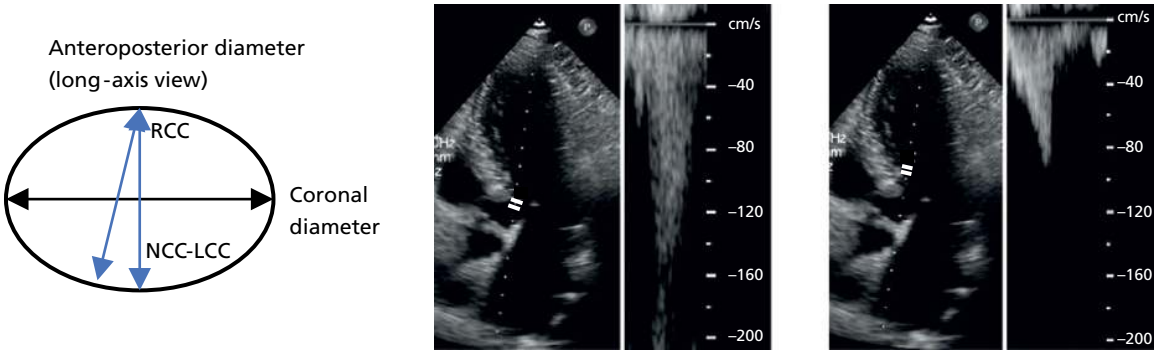

Figure 6.20 *Left image:* Axial cut of the LVOT, which is elliptical rather than circular. The anteroposterior diameter measured on long-axis is smaller than the coronal diameter; it may be further truncated by an oblique cut. LVOT is best measured at the annulus, i.e., at the leaflets' insertion site, not below it: this is where it is usually largest and less elliptical. There is a standard formula for predicted LVOT diameter: LVOT= (5.7 × BSA) +12.1. This may, however, overestimate LVOT in obese patients.

Middle image: The LVOT pulse-wave velocity is sampled too close to the aortic valve, capturing the flow acceleration just upstream of the aortic valve, which is actually part of the AS obstruction. The high LVOT velocity (1.6 m/s) leads to erroneous measurement of a high dimensionless index and AVA. This is particularly the case in this patient with septal bulge, further extending the LVOT acceleration.

Right image: LVOT velocity should be captured farther away from the aortic valve and the septal bulge, before the flow acceleration (0.9 m/s).

AVA of 0.8 cm², rather than 1 cm², typically corresponds to a mean gradient of 40 mmHg *and is a more specific cutoff for defining severe AS, particularly on echo, which frequently underestimates AVA (by an average of 0.2 cm²).*[102,103] AVA ≤1.0 cm² is a sensitive criterion for severe AS, while mean gradient ≥40 mm Hg is a specific criterion. ***AVA of 0.8–1 cm² with a discordant gradient <40 mmHg is truly severe AS ~50% of the time, in which case it would, indeed, benefit from valve surgery***; the remaining cases mostly represent AVA miscalculation (Section IV).[102–110] AVA-gradient discordance is seen in a third of AS cases with AVA ≤1 cm².

Other features suggestive of severe AS:

a. While aortic valve velocity ↑ (obstruction), LVOT velocity ↓ (reduced stroke volume). Typically, in severe AS:
- Peak LVOT velocity is <1 m/s.
- LVOT velocity/aortic valve velocity is ≤0.25. This is called the dimensionless index (DI) or Doppler velocity index (DVI) and is in fact a component of AVA calculation (AVA = LVOT area × DI). Either peak velocity or VTI may be used. **DI ≤0.25 implies AVA ≤25% of LVOT and ≤25% of normal**. As opposed to AVA calculation, the dimensionless index is not subject to the bias of LVOT diameter measurement.

Pitfalls – LVOT velocity may be higher than 1 m/s when severe AS is associated with moderate AI or high-output states (anemia, fever), but DI remains ≤0.25. Yet, both LVOT velocity and DI may be falsely elevated if the pulsed cursor is placed too close to the aortic valve, in the aliasing zone (Figure 6.20). Also, up to 10% of patients with severe AS develop significant, sometimes severe, septal hypertrophy with septal bulge and LVOT flow acceleration. The LVOT velocity and DI may be increased, leading to the false calculation of a large AVA, but this LVOT acceleration is actually part of the AS remodeling and not a dominant LVOT obstruction, unless LVOT velocity is higher than the aortic valve velocity; this high LVOT velocity should not be used in AVA calculation. Rather, LVOT velocity should be captured farther away from the aortic valve and the septal bulge, before the flow acceleration (see Chapter 7, Appendix 1).

In low-gradient AVA ≤1 cm² – If AS is truly severe, the low gradient is related to low or low-normal flow, hence LVOT velocity should be <1 m/s with a low DI. While a low DI does not prove severe AS (may be pseudo-severe AS), a **high DI often rules out severe AS in patients with low gradient and AVA ≤1 cm²** and indicates LVOT measurement error.

b. *M-mode of the aortic valve shows flattening of the aortic box*. The aortic valve does not clearly open in the parasternal views.

However, a bicuspid aortic valve may appear to open moderately well on a long-axis view despite being severely stenotic. Since it only opens eccentrically between the non-coronary cusp and the fused cusp, the bicuspid valve is 3-dimensionally more stenotic than it may appear on the long-axis view, which captures the largest opening. This is similar to assessing eccentric coronary artery stenosis on angiography: the stenosis may appear mild in one view but severe in another.

c. *Small AVA by planimetry. Planimetry of the aortic valve area is performed on CT or TEE short-axis view, especially if the edges are well defined on TEE*. The cut may be slightly above or below the true valvular orifice, which overestimates AVA.

d. *A bicuspid valve is characterized by eccentric closure on M-mode and, when not severely stenotic, systolic doming on the long-axis view*.

e. The lack of LV hypertrophy is unusual but does not exclude AS. In fact, ~10% of AS patients do not develop concentric hypertrophy, and 4% do not even develop concentric remodeling, i.e., an increase in LV thickness, especially patients with small body habitus.[111] Those patients may have a higher mortality risk after AVR.

B. The three types of transaortic pressure gradients

The peak instantaneous gradient obtained by echocardiography is different from the peak-to-peak gradient obtained by catheterization and from the mean gradient (Figure 6.21). *The mean and peak-to-peak gradients have almost equivalent values*. The value of the mean gradient is ~65% that of the peak instantaneous gradient.

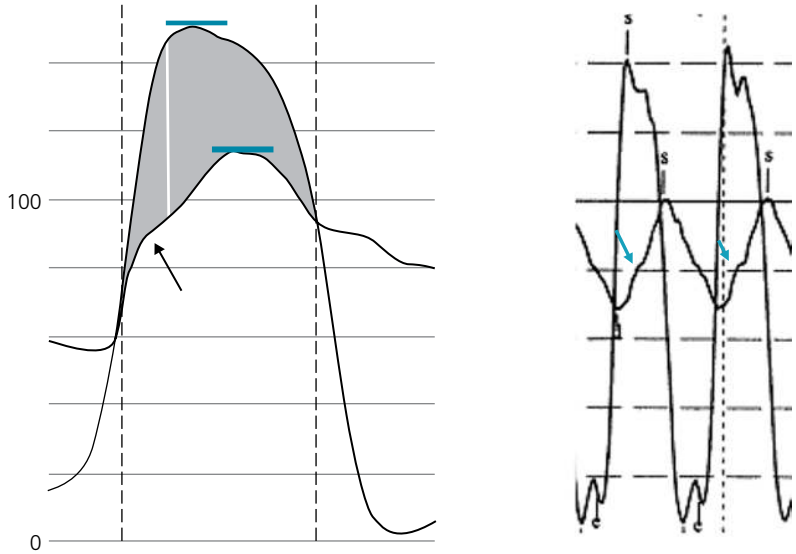

Figure 6.21 Peak-to-peak gradient is the difference between the 2 peaks (*horizontal bars*). **Peak instantaneous gradient** is the largest difference between the 2 curves (*white vertical line*). **Mean gradient** is the integration of all gradients (*gray area*). LV pressure peaks early and the aortic pressure peaks late, which is the opposite of what is found in HOCM.

Note the anacrotic notch beyond which the aortic upstroke is slowed (*arrows*). The aortic upstroke starts normally as the valve opens normally in the first 0.8 cm^2; then the valve abruptly stops opening, which sharply impedes the flow and creates this bend called anacrotic notch. The aortic pressure has a *slow upstroke after the anacrotic notch and peaks late (pulsus tardus)*. Also, the pulse pressure is reduced because of reduced stroke volume (*pulsus parvus*). In elderly patients with reduced arterial compliance, the pulse pressure may be preserved and sharp without anacrotic notch. The mean gradient usually approximates the peak-to-peak gradient and is about 65% the peak instantaneous gradient.

The peak-to-peak gradient is frequently slightly smaller than the mean gradient in mild/moderate AS with steep aortic upstroke. It is slightly larger than the mean gradient in severe AS with damped aortic upstroke.

Note that, in AS, **the aortic pressure upstroke is less steep than the LV pressure upstroke**; if the LV and aortic upstrokes are superimposed, suspect HOCM obstruction or error in zeroing creating a false gradient (e.g., the LV and aortic transducers were zeroed at two different levels). Reproduced with permission from Hanna EB. Aortic stenosis. In: Hanna EB, Glancy DL. Practical Cardiovascular Hemodynamics. New York, NY: Demos Medical, 2012, p. 79.

C. Effects of tachycardia and AF

Tachycardia is associated with an increase in inotropism up to a certain rate (Bowditch phenomenon), which may raise the transaortic flow and hence the gradient. However, there are 3 pitfalls: (i) the rise in flow also depends on whether the preload and stroke volume can be maintained despite the shorter diastole. They are more likely maintained during the sinus tachycardia of exercise vs. the inappropriate tachycardia of pacing or arrhythmia. (ii) Bowditch is limited in LV dysfunction, beyond 110–120 bpm. (iii) CO is particularly limited in AF.

AF, even if rate controlled, is a low-flow state that reduces AS gradient. Irregularity, by itself, reduces CO: stroke volume is particularly reduced with R-R interval <500 ms. The highest, long R-R gradient best correlates with severity and should be used to evaluate AS, instead of averaging down gradients. For AVA calculation, use LVOT VTI and aortic valve VTI obtained after similar R–R cycle lengths (preferably the highest).

III. Low-gradient AS with aortic valve area (AVA) ≤1 cm^2 and low EF <50%

In the case of a moderate-range mean gradient (30–40 mmHg) and AVA ≤1 cm^2, the patient likely has a truly severe AS. In the case of a mean gradient <30 mmHg, AVA ≤1 cm^2, and EF <50% (especially <40%), the patient may have: (1) a truly severe AS with a low gradient resulting from the low cardiac output, or (2) a pseudo-severe AS with a valve that is mildly or moderately stenotic, the excursion of which is further limited by the reduced cardiac output, leading to underestimation of the true AVA. Gorlin's equation shows that the transvalvular pressure gradient directly correlates with the square of the cardiac output (AVA ~ CO/√mean gradient); thus, a patient with AVA of 1 cm^2 and a cardiac output of 3.5 L/min will have a mean gradient of only 15 mmHg. On the other hand, a patient with a cardiac output of 3.5 L/min and a gradient of 15 mmHg may not have severe AS even if Gorlin's equation yields AVA ≤1 cm^2, as the valve opening is flow dependent. A dobutamine study is indicated to increase the cardiac output and assess AS, and may be performed during *an echo or an invasive study*. Dobutamine is started as an infusion of 5 mcg/kg/min. The increase in cardiac output, AVA, and gradient are assessed then dobutamine up-titrated every 5–8 minutes if the diagnostic features are not met, the maximum dose being 20 mcg/kg/min. There are 3 possible responses:[112,113]

1. Stroke volume increases by ≥20%, mean gradient increases to ≥40 mmHg (or by >10 mmHg), or velocity increases to ≥4 m/s, AVA remains unchanged or increases but remains ≤1 cm^2 (or <1.2 cm^2 in one study):[112] truly severe AS with good contractile reserve. The reduced EF and output are due to afterload mismatch rather than intrinsic contractile abnormality and will reverse with surgery.

LVOT and aortic valve velocities similarly ↑ → Ratio (DI) remains unchanged or ↓.

2. Stroke volume increases by ≥20%, gradient remains <40 mmHg, and AVA increases to >1 cm^2: pseudo-severe AS.

LVOT velocity ↑ more than aortic valve velocity → DI ↑.

3. Stroke volume does not significantly increase (<20%), gradient and AVA do not significantly change: poor contractile or flow reserve. This may represent an advanced stage of AS with poor LV systolic function, or a combination of AS and cardiomyopathy.

The last subgroup has the worst prognosis but may still benefit from AVR, and more so TAVR.[114,115] However, before considering that the patient has a poor and irreversible contractile reserve, make sure he is not hypovolemic. Hypovolemia, which is suggested by low cardiac filling pressures, may explain the lack of increase in cardiac output and may be solved by a small volume load. Also, make sure the patient does not have a severely increased afterload from hypertension and high SVR. In this case, a careful nitroprusside infusion with titration may allow an increase in cardiac output, prove a good flow reserve, and allow evaluation of the severity of AS. Nitroprusside may precipitously drop the systemic pressure in patients with truly severe AS who cannot increase their cardiac output to match the dilated circulation, and should be used with great caution. CT calcium scoring of the aortic valve may also be used to suggest AS severity.

IV. Low-gradient AS with aortic valve area (AVA) ≤1 cm² but normal EF: paradoxical low-flow/low-gradient severe AS *and* normal-flow/low-gradient severe AS

In normal EF, a low gradient <40 mmHg with AVA ≤1 cm^2 may reflect any of the following 3 diagnoses:

i. Echo mismeasurements: AS is not severe ~50% of the time (AVA is undercalculated).
ii. Low-flow, low-gradient truly severe AS: the low gradient is explained by a low flow despite a normal EF.
iii. Normal-flow, low-gradient truly severe AS: the low gradient is explained by the misalignment of AVA and gradient cut-points in the guidelines under normal flow conditions (e.g., AVA of 1 cm^2 may normally correspond to a gradient of 30 mmHg).

A normal EF does not signify a normal cardiac output. Thus, even if EF is normal, patients with severe AS may have a reduced cardiac output that leads to a reduced gradient <40 mmHg. This situation is seen in 10–20% of severe AS cases, particularly in elderly and female patients, and **low flow** usually reflects:

1. Associated mitral valve disease that reduces flow across the aortic valve; or severe preload reduction (hypovolemia)
2. Most importantly, this situation is commonly seen in severe systemic hypertension. Hypertensive patients may have severe AS with a paradoxically low flow and low gradient for the following reasons:[116–121]
   i. The global LV afterload is the sum of AS and HTN (this is called double load or valvuloarterial impedance). HTN increases total afterload, which reduces stroke volume and cardiac output even if EF is normal. Consequently, the transvalvular gradient but also the systemic pressure are reduced and "pseudo-normalization" of HTN may be seen in up to 30% of cases of high double load. Thus, both HTN and AS appear less severe in patients with high total afterload and low stroke volume. Calculate the stroke volume, using LVOT velocity and diameter, and the valvuloarterial impedance, which is equal to (systolic blood pressure + mean gradient)/stroke volume index. A low stroke volume <35 ml/m^2 and an elevated valvuloarterial impedance (>3.5–4.5 mmHg/ml/m^2) suggest an increased total afterload and masked AS and HTN.
   ii. Patients with HTN may have significant concentric left ventricular hypertrophy with reduced LV cavity size, limited diastolic filling, and thus reduced stroke volume even if EF is normal. In a small restricted LV, both SV and LVEDV are low; EF, which is SV/LVEDV, is normal.
3. AF, even if rate controlled, is inherently a low-output state that reduces AS gradient. To compensate for AF's low-flow state, take the highest gradient, usually after a short-long sequence, instead of averaging gradients from multiple beats.[122]
4. Severe bradycardia. The true flow across the valve is not stroke volume, but stroke volume/ejection duration or CO/systolic time (numerator of Gorlin's equation). In bradycardia, stroke volume may increase, but the duration of ejection may increase to an even larger degree and CO declines. Consequently, the true valvular flow frequently decreases (→gradient decreases). Also, stroke volume may not rise much because: LV stiffness limits further filling, and LV contractility declines at lower rates (Bowditch effect). In fact, it has been suggested that a low flow rate across the valve (<250 ml/sec) better defines a low-flow state than stroke volume index.
5. Transthyretin cardiac amyloidosis may explain the low gradient in 15% of elderly low-gradient AS cases.

Dobutamine testing is unlikely to be useful in these patients: flow is reduced because of low preload (impaired diastolic filling) and high afterload, not impaired contractility. In fact, dobutamine may further compromise LV filling by reducing LV cavity size and preload. An increase in mean gradient to >40 mmHg with dobutamine still suggests severe AS, but gradient decline or lack of change is not diagnostic. Conversely, ***nitroprusside and exercise testing improve these loading conditions*** and may be used to re-calculate AVA and gradient in low-gradient AS; an improvement in flow may increase the gradient or may, conversely, change a pseudostenotic, compliant aortic valve to >1 cm^2.[123,124] ***PVC is helpful as well. Post-PVC*** gradient >40 mmHg nearly establishes the diagnosis of severe AS; a post-PVC rise in gradient >33% strongly suggests severe AS.[125]

On a similar note, it is useful to reassess gradients after normalization of systemic pressure, which improves flow. This may be done acutely in the cath lab by the cautious administration of intravenous nitroprusside.

While it may seem that a gradient of <30 mmHg is not high enough to benefit from valvular surgery, and that HTN is the largest component of the afterload, valve replacement is actually an important aspect of therapy. Valve replacement reduces the severe gradient that is seen after HTN is controlled and after cardiac output rises. Also, valve replacement improves cardiac output reserve, allowing cardiac output to increase under exertional conditions (as opposed to the static, limited cardiac output in severe AS). In fact, a low-gradient truly severe AS is associated with a worse prognosis than a high-gradient AS, and a low survival with medical therapy; survival is markedly improved with AVR. [101–110,116–118,126–128]

Note that **normal-flow, low-gradient AVA≤1 cm^2 is also common (stroke volume ≥35 ml/m^2), in fact more common than low-flow, low-gradient AVA≤1 cm^2**. It may be truly severe AS (~50% of the time) with discordance of AVA-gradient related to the misalignment of AVA and gradient cut-points in the guidelines under normal flow conditions.[105,107] It may also be due to an actual low cardiac output despite a normal stroke volume (bradycardia) (phenomenon 4 above). Stroke volume, which equals (LVOT area × LVOT VTI), is the numerator of the AVA equation: AVA = (LVOT area × LVOT VTI)/aortic valve VTI. A *low stroke volume* does not necessarily imply low flow

because it may reflect the *same undercalculation of LVOT area as a low AVA*. However, compared to a normal stroke volume, a low one is more frequently associated with low LVOT VTI, low DI, and truly severe AS. It may be better to just assess DI. While ESC guidelines suggest that normal-flow, low-gradient AS frequently reflects moderate AS, several studies show that normal-flow, low-gradient AS with a true valve area ≤1 cm² and DI ≤0.25, or high aortic valve calcium score, is truly severe AS and benefits from AVR, similarly to low-flow, low-gradient AS.[104–110]

In up to 50% of the cases, low-gradient AVA ≤1 cm² is not truly severe AS and rather corresponds to AVA miscalculation by echo. Stroke volume may be calculated (low: <35 ml/m²) but has the above pitfalls. Low-gradient AVA ≤1 cm² with normal EF is managed as follows:

1st step – AVA ≤0.8 cm² with a gradient that is not too low (30–40 mmHg) and DI ≤0.25 is likely truly severe AS.

2nd step=Echo review – *Avoid underestimation of AS gradient:* ensure acquisition of the highest aortic valve velocity, aligned with the flow. *In AF,* take the highest gradient instead of averaging gradients. *Avoid undercalculation of AVA:* ensure proper LVOT measurement (generally ≥2.1 cm), + consider the possibility of pressure recovery if aorta is small (<3 cm). High DI >0.25 makes low-gradient severe AS unlikely.

3rd step – Repeat AVA and gradient measurements after HTN control.

4th step – Aortic valve calcium score ≥2000 Agatston units in men, ≥1200 in women supports the diagnosis of truly severe AS.[101,105,106] This is measured on a non-contrast cardiac CT and has been validated in patients with preserved EF, whether they have low or normal flow, and has also been recommended in low-EF, low-gradient AS (ESC and ACC).[19] However, data in patients with low EF suggest significant overlap in values between moderate and severe AS, with these values providing only 50% sensitivity and specificity for distinguishing severe from moderate AS.[129]

Alternative 4th step – Invasive measurements to confirm gradient and valve area calculation, especially after HTN control. Consider: (i) nitroprusside challenge, or, less favorably, dobutamine; (ii) post-PVC gradient. AVA by cath is more specific than AVA by echo, but is still marred by variability in CO measurements and technical pitfalls in gradient recording.

V. Pressure recovery phenomenon

In patients with AS, pressure (potential energy) is generated by the LV. A significant portion of this energy is lost across the narrow aortic valve orifice and becomes kinetic energy. Downstream from the valve, the flow becomes laminar again and there may be a reincrease in pressure and in potential energy, particularly in female patients with a narrow aorta (diameter at the sinotubular junction <2.6–3 cm) (Figure 6.22). This reincrease in pressure a few centimeters downstream of the valve, at the sinotubular level, is called pressure recovery. The true gradient is the gradient between LV pressure and pressure downstream of the valve.[126–129] This gradient, obtained by catherization, represents the true loss of energy the ventricle is subject to. In this case, the transaortic gradient obtained by echo is the pressure gradient between the LV and the vena contracta and overestimates the physiologic AS; in addition, AVA calculated by the echocardiographic continuity equation is smaller than the true AVA.[130–133] One study has shown that 45% of patients with moderate transaortic pressure gradient and severe AS per echocardiographic AVA, who do not have HTN or high valvuloarterial impedance, have, in fact, significant pressure recovery with milder degrees of AS.[130] The pressure recovery is less prominent at high gradients. This explains why catheter-derived AVA tends to be higher and gradient tends to be lower than Doppler-derived measurements in individuals with valve areas of 1–1.5 cm². When echocardiography suggests severe AS but significant pressure recovery is suspected in a patient with small tubular aorta <3 cm, recalculate AVA using an energy loss index (ELI) correction that accounts for the aortic diameter, or, better, perform cardiac catheterization.

To better understand pressure recovery, imagine a coronary stenosis: a 1-mm residual lumen in a 3-mm vessel is less flow obstructive than a 1-mm residual lumen in a 5-mm vessel. Pressure recovery occurs in the former case. *A small aorta downstream from the valve (pressure recovery) or a small LVOT upstream of the valve (AVA/LVOT area >25%, i.e., DI >0.25) may explain how AVA of 1 cm² may not be severely obstructive in some patients.*

Ensure that this combination of moderate gradient with AVA in the severe range is not related to severe HTN. In HTN, pressure downstream of the valve increases because of impaired vascular compliance, rather than pressure recovery. Unlike pressure recovery, HTN is harmful and increases the overall afterload; thus, the true effort the LV generates in this case is the LV–vena contracta gradient. Unlike

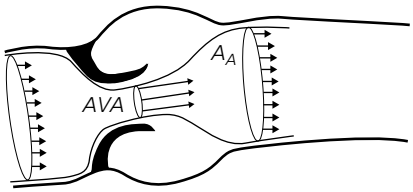

Figure 6.22 Pressure recovery phenomenon. Pressure (potential or static energy) is generated by the LV (*left-sided arrows*). This pressure/energy is partially converted into kinetic energy across the narrow aortic valve area (AVA) (*middle arrows*). Downstream from the valve, the kinetic energy may be fully lost if the aorta is large and the flow swirls around; however, if the aorta is small, the kinetic waves will abut the aortic wall and partially recover into pressure energy, so that the overall energy loss and the overall pressure drop are less severe. *While the true anatomic AVA may correlate better with the maximal pressure drop at the aortic orifice, the physiologic AVA better correlates with the net pressure drop after pressure recovery*. Pressure recovery is particularly seen when the aortic area (A_A) is small. Reproduced with permission of Elsevier from Briand et al. (2005).[121]

pressure recovery, AVA is truly small and the echo gradient between the LV and the aortic valve orifice is the true gradient. To use the coronary analogy, a 1-mm residual lumen in a 5-mm vessel may seem less obstructive (higher FFR) in case of downstream microvascular dysfunction, which diminishes the overall flow and the trans-stenotic pressure gradient. The obstruction is severe but masked, unlike the 1-mm lumen in a 3-mm vessel, which is not severely obstructive.

Table 6.3 provides an overview of the causes of low-gradient AS. Table 6.4 lists the causes of a high gradient with an AVA that is, nonetheless, calculated >1 cm^2. **In practice, echocardiography much more often underestimates than overestimates AS gradient, and thus, *gradient >40 mmHg is usually severe AS even if AVA is calculated as >1 cm^2*.**[134]

VI. Symptoms

The following symptoms may be seen in AS:

1. Dyspnea and reduced functional capacity: related to the elevated LVEDP and the inability to raise cardiac output with exercise.
2. Syncope: related to the fixed cardiac output that cannot increase with exertion or to the occurrence of arrhythmias. Vasodilatation occurs during exertion, but cardiac output cannot increase because of the fixed, severe outflow obstruction. Thus, the systemic pressure drops (pressure = CO × SVR).
3. Angina occurs in two-thirds of the patients and is associated with CAD in 50% of these patients. In the other 50%, it results solely from increased O_2 demands (LVH) and reduced myocardial perfusion (↑ LVEDP compresses the subendocardial microcirculation).
4. Bleeding tendency is seen, especially GI bleed from AV malformations. It is due to the disruption of von Willebrand molecules as they cross the stenotic valve. This improves with AVR.

VII. Natural history

Severe asymptomatic AS almost always becomes symptomatic within 5 years (fast progression, similar to MR); ~50% of patients become symptomatic within 2 years, more so if the transaortic velocity is ≥5 m/s or increases >0.3 m/s/yr.[135,136] Sudden cardiac death rate is low, <1% per year in truly asymptomatic AS.[135] While it used to be thought that overall death was low in severe asymptomatic AS, contemporary data suggest a more aggressive course, particularly in elderly sedentary patients, whose initial presentation is frequently severe, abrupt HF, and who fare poorly with any intercurrent illness.[136,137]

Severe symptomatic AS is associated with a survival of 2–3 years only without surgical correction. Classically, the survival is ~3 years in patients with syncope, angina, or early dyspnea, and 1–2 years in patients with HF. *Sudden death is a frequent cause of death* in symptomatic patients, thus justifying prompt surgery.

Table 6.3 Causes of low-gradient AS (AVA ≤ 1 cm^2 with a mean gradient < 40 mmHg) (~20–30% of AS with AVA ≤ 1 cm^2).

In patients with low EF (particularly <40%)
- Low EF with truly severe AS. Low gradient is explained by a low cardiac output
- Low EF with mild/moderate AS. Low cardiac output causes poor valve excursion and a small calculated AVA (pseudo-severe AS)

In patients with normal EF
- Truly severe AS with false measurement of the aortic gradient: if Doppler beam is not parallel to LV–aortic flow, the gradient is underestimated
- Truly severe AS with **hypertension** at the time of the study, particularly if concentric LV hypertrophy is present. In this case, the low gradient is due to a low output despite a normal LVEF
- Truly severe AS with AF
- Truly severe AS with severe mitral regurgitation or stenosis (i.e., low forward cardiac output)
- A gradient of 30–40 mmHg is consistent with normal-flow severe AS (cardiac output of 5.5 L/min with AVA of 1 cm^2 translates into a mean gradient of 30–40 mmHg)
- **Moderate AS with false AVA measurement, moderate AS with indexed AVA >0.6 cm^2/m^2, or moderate AS with pressure recovery:**
  - Erroneous measurement of LVOT diameter or LVOT velocity (leading to a falsely small AVA and small stroke volume)[a]
  - In small patients, LVOT is truly small and even an AVA that is truly <1 cm^2 may not be severe, as it may be >25% of LVOT area. This is moderate AS, marked by DI > 0.25 and AVA > 0.6 cm^2/m^2.
  - Pressure recovery phenomenon in patients with a small aorta: true gradient is smaller and true AVA is larger than obtained by echocardiography

[a] AVA = LVOT area × LVOT velocity/aortic valve velocity. LVOT diameter should be measured at the aortic annulus, i.e., at the insertion of the aortic valve leaflets, in early systole (largest diameter). LVOT is often oval and is frequently underestimated on the echo long-axis view; LVOT area is more accurately assessed by CT.

Table 6.4 Causes of AVA >1 cm^2 with a mean gradient >40 mmHg (~10% of severe AS).

- Severe AS in a patient with a large body size: AVA >1 cm^2 but indexed AVA <0.6 cm^2/m^2. LVOT is large, so AVA may be >1 cm^2 even with a truly severe AS. This is marked by AVA <25% of LVOT (DI <0.25). A larger LVOT is more common in men and bicuspid valves
- Severe AS with overestimation of AVA when secondary septal hypertrophy is present with high LVOT velocity, or when LVOT velocity is overestimated (misplacement of the LVOT cursor)
- Moderate AS with a high gradient secondary to high-output states (anemia, sepsis, associated AI). In associated AI, the high gradient describes the combined effect of AS/AI and still indicates surgery
- Less likely: moderate AS with pressure recovery (less common at high gradients)

In moderate or severe AS, AVA ↓ by ~0.12 cm^2, aortic velocity ↑ by 0.3 m/s, and aortic mean gradient ↑ by 7 mmHg per year. AS progresses faster in patients with heavy calcifications or advanced renal failure. Some of the latter patients may progress from mild/moderate AS to severe AS within 3–4 years.

VIII. AS should be differentiated from subvalvular and supravalvular AS in children or young adults

While most congenital aortic obstructions are due to bicuspid AS, 14% are due to fixed subvalvular AS, and a minority are due to supravalvular AS. The latter 2 conditions mainly present in children or young adults.

A. Subvalvular AS

Fixed subvalvular aortic stenosis is present at birth and is most often caused by a discrete fibrous membrane that encircles the outflow tract beneath the aortic valve. The subvalvular stenosis creates a turbulent blood flow jet that hits the aortic valve, causing thickening of the aortic leaflets and aortic regurgitation. It is also commonly associated with VSD. Less commonly, subvalvular AS consists of a thick fibromuscular ridge or a prolonged segment of LVOT thickening (tunnel obstruction). Surgical therapy is indicated in severe fixed subvalvular stenosis to prevent the progressive AI that is seen in >80% of untreated patients, regardless of symptoms (as long as mean gradient ≥40 mmHg). In asymptomatic patients, surgery is readily recommended in cases of LVH, low surgical risk, or any AI that is progressive or more than mild (ESC). There is a long-term risk of restenosis after surgical correction, ~10% at 5 years. Restenosis is faster and more likely in those operated at a young age <18 (~20s%).[138]

B. Supravalvular AS

Supravalvular stenosis results from aortic narrowing at the superior margin of the aortic sinuses. Stenosis may be a focal hourglass type of narrowing (most common form), a discrete supravalvular membrane, or diffuse hypoplasia of the ascending aorta (the least common form). It results from medial thickening that may also be seen in the thoracic and abdominal branches of the aorta and may cause focal luminal narrowing in these arteries (e.g., subclavian, carotid artery). Like the aortic sinuses, the coronary arteries are subject to large systolic and pulse pressures, as the stroke volume overfills the small aortic chamber prior to the obstruction. Frequently, the coronary arteries are diffusely dilated and develop ostial stenoses. Aortic valve thickening and regurgitation may develop. Surgical therapy is indicated in supravalvular AS with mean gradient ≥40 mmHg that is symptomatic, or asymptomatic with LVH, or asymptomatic with EF <50%. Supravalvular AS is often non-syndromic but may be associated with Williams syndrome (hypercalcemia, elfin facies, mild mental retardation) and may be genetically transmitted. This condition is frequently associated with peripheral pulmonary artery stenosis.

In both those conditions, Doppler shows high velocity across the transaortic plane with a structurally normal aortic valve. The actual site of narrowing/membrane may be seen. On color Doppler, the turbulence is seen below or above the aortic valve. TEE may be required in young patients with aortic obstruction to further define this anatomy. Invasively, pressure pullback with an end-hole catheter confirms the site of obstruction; in contrast to HOCM, the gradient is not dynamic and does not have a dagger shape. *On exam,* A_2 is loud rather than attenuated (≠ AS) and a systolic click is not heard (≠ bicuspid AS). In subvalvular AS, the murmur does not consistently radiate to the carotids. In supravalvular AS, the narrow jet goes preferentially toward the right side of the aorta as it abuts the aortic wall, and thus the pulses are stronger in the right vs. left arm, and the murmur only radiates to the right carotid with suprasternal thrill.

IX. Treatment

A. Antihypertensives

Antihypertensives should be carefully used if HTN coexists. Normally, when vasodilators are administered, the systemic pressure is maintained thanks to an increase in cardiac output (pressure = cardiac output × resistance). Severe AS may limit the increase in cardiac output, and thus severe hypotension may ensue. Conversely, HTN is common in AS (>50% of patients), worsens LV afterload, and leads to double loading of the LV with a low-flow/low-gradient state. Thus, careful antihypertensive therapy is beneficial as it reduces the total afterload and increases cardiac output.

B. Indications for aortic valve replacement (AVR) (the first 4 are class I indications)

a. *Severe, symptomatic AS* (syncope/pre-syncope, dyspnea, or angina). GI bleed, per se, is not an indication for AVR.

b. *Severe asymptomatic AS with reduced LV function (EF <50%).* ESC suggests AVR when low EF is "without other cause". However, AVR is justified even if low EF results from other causes, as AS/high afterload will have a greater impact on a dysfunctional LV, inclined to further dilatation and eccentric remodeling rather than concentric hypertrophy.[139]

c. *Low-gradient severe AS with a low EF*, after dobutamine confirmation of truly severe AS. EF reduction is mostly due to *afterload mismatch* and improves or normalizes in most of these patients after AVR.

d. *Symptomatic, low-gradient severe AS with normal EF* (ensure no echo measurement error, and repeat echo after HTN control). It is best to prove that AS is truly severe by catheterization or by CT grading of the aortic valve calcification (aortic valve calcium score ≥1200 in women, ≥2000 in men).[105,106]

e. *Low-gradient severe AS with low EF and no flow reserve:* AVR has a high operative mortality (~32%), but superior long-term survival and EF and symptomatic improvement vs. no AVR.[114] TAVR is the better option here and is considered once *CT calcium scoring corroborates that AS is severe*. In one registry, TAVR was associated with a relatively low postoperative mortality (3.8%) in patients with low-EF, low-gradient, severe AS, regardless of contractile reserve and dobutamine testing result. EF significantly improved in most patients, quickly, regardless of contractile reserve (EF improvement of 8.5% within few days).[115]

f. *Severe AS that is initially considered asymptomatic, but an abnormal response is seen during exercise testing*: low functional capacity for age and sex or drop in SBP below baseline (class IIa).

g. Symptoms associated with a combination of moderate AS (AVA 1.0–1.5 cm^2) and moderate AI (class I).[140] This combination usually results in aortic mean gradient >40 mmHg (high valve flow).
h. Severe (*class I*) or moderate (*class IIb*) asymptomatic AS undergoing other cardiac surgery. In moderate AS, AVR is performed to prevent the need for redo cardiac surgery in ~5 years (long-term benefit).

The mortality risk of AVR is ~3%, and may be as low as 1–2% in low-risk young patients and as high as 10% in patients with low EF, especially low EF with low-gradient AS.[114] AVR may be performed safely in octogenarians, albeit at a higher perioperative mortality risk (~6%). Concomitant CAD, particularly multivessel CAD requiring CABG, increases the perioperative mortality, especially in octogenarians. Rather than CABG, it is the underlying CAD and comorbidities of those patients that explain the increased surgical risk. In fact, leaving *proximal CAD* untreated increases the perioperative risk of ischemia and MI, and thus, CABG is rather salutary for these patients.

LV systolic dysfunction is seen in many symptomatic, high-risk AS cases (e.g., 23% in PARTNER 1 trial). AS, per se, rarely leads to LV dysfunction before symptoms, yet AS readily and quickly aggravates any pre-existing mild or subclinical LV dysfunction due to other causes (such as CAD, HTN, AF, LBBB), even if baseline EF is 50–60% and even at a valve area cutoff of 1.2 cm^2.[139] Fortunately, LV dysfunction readily improves in patients with AS, more than in those with AI or MR, as it is usually due to *afterload mismatch* rather than contractile/fibrotic dysfunction. LV mass decreases over the course of one to several years postoperatively.

The TAVR-UNLOAD trial studied patients with symptomatic HF-EF < 50% and *moderate AS* (defined as AVA 1–1.5 cm^2, mean 1.2 cm^2; mean gradient was 19 ± 6). Immediate TAVR did not improve clinical outcomes or EF compared to optimized HF therapy coupled with deferral of TAVR until AS was deemed severe.[141] Yet, 43% of patients in the surveillance group underwent TAVR within 1 year, which attests to either the rapid progression of AS in these patients or the difficulty in distinguishing moderate from severe AS in low EF.

C. Ross procedure

The Ross procedure consists of pulmonary artery + pulmonic valve autograft placement in the aortic position, while a homograft valve is placed in the pulmonary position. This procedure is mainly used in young patients. It has the advantage of not requiring anticoagulation. Moreover, the autograft grows when used in children.

However, this procedure should be avoided in cases of AI with dilated ascending aorta, as the dilated aorta will put tension on the grafted pulmonary artery, with a risk of neoaortic root dilatation and late AI.

There is a long-term risk of severe AI of the neoaorta of ~5% at 10 years and ~13% at 20 years, particularly in the case of baseline AI where the pulmonary autograft tends to dilate and fail over time.[142] The biggest long-term hazard is degeneration of the pulmonary homograft with pulmonic stenosis and/or regurgitation (in ~20% at 20 years), which may be treated with transcatheter pulmonary valve implantation.

D. Surgery for severe asymptomatic AS with normal EF

As long as they remain asymptomatic, patients with AS and normal EF have a low yearly risk of sudden cardiac death, and thus watchful waiting is reasonable. *Once symptoms develop, even for a few months, the prognosis becomes guarded with a significant risk of sudden death and death from severe heart failure* (>20% per year).[135,143] Thus, patient education and echo and clinical follow-up (every 6 months) are recommended.

Moreover, it is reasonable to verify that these patients are truly asymptomatic by performing stress testing. Since exercise limitation may be related to reduced fitness or orthopedic factors, stress testing is mainly useful in physically active young patients (<70 years old) and is considered abnormal if symptoms develop, particularly at <7 METs, if SBP drops ≥10 mmHg below baseline, or if functional capacity is below the standard for age and sex.[144] During testing, truly severe dyspnea should be distinguished from mild transient breathlessness. Dizziness is the most specific symptom and the one most likely to predict symptomatic progression over the next year.[144]

Two registries have suggested that severe HF is frequently the first presentation during watchful waiting (up to 43%), and there is a significant risk of death (9%) from: rapid HF, sudden death (1.5% per year), and poor tolerance of intercurrent illnesses (e.g., pneumonia).[136,137] This is particularly true if aortic velocity is ≥5 m/s, and in the elderly patient with impaired mobility (>70 years old), whose activity is too limited to manifest exertional dyspnea. Also, long-term post-operative mortality ~doubles if surgery awaits the onset of HF or severe symptoms III–IV, as seen in the registries and in EARLY-TAVR trial.[136]

The Korean RECOVERY trial randomized patients with very severe AS (defined as AVA ≤0.75 cm^2 with mean gradient ≥50 mmHg or peak velocity ≥4.5 m/s) to early AVR vs. later AVR that awaits class I indications. Early AVR dramatically reduced cardiovascular mortality at 6 years of follow-up (1% vs. 15%).[145] The EARLY TAVR trial randomized severe asymptomatic AS with AVA ≤1.0 cm^2 and mean gradient ≥40 mmHg or peak velocity ≥4 m/s to early TAVR vs. later TAVR that awaits symptoms. Early TAVR reduced unplanned CV hospitalizations, including for HF, most notably within the first 2 years, with no effect on mortality.[146] ***Thus, early surgery or TAVR seems reasonable in asymptomatic, very severe AS with a low operative risk.*** ACC and ESC guidelines suggest any of the following as an indication for early intervention, *if procedural risk is low*: ≥5 m/s velocity or mean gradient ≥ 60 mmHg, peak velocity progression ≥0.3 m/s/year, or elevated BNP (>300 pg/ml or 3× upper limit for age-sex) (class IIa), or EF of 50–60% with evidence of progressive decline (class IIb).[144] Of note, data suggest that even a lower BNP (>1–2× normal, >130 pg/ml) is associated with increased AS-related events.[144]

E. MR associated with severe AS

MR frequently coexists with severe AS and is often functional, secondary to LV and LA remodeling and the increased LV systolic pressure (>15% of AS patients have moderate or severe MR). MR often improves by ≥1 grade in 50–90% of patients after AVR, especially if functional and not severe. MR improves in 2 waves (immediate and late).[147]

Mitral annuloplasty repair is generally performed concomitantly to AVR if MR is severe, or if MR is moderate with low surgical mortality and with pulmonary hypertension, LA enlargement/AF, or intrinsic mitral valve disease.[147] Alternatively, in TAVR candidates who are at high or even low surgical risk, TAVR may be done first, and followed by MitraClip at a later time if severe MR persists ≥3 months (ACC guidelines).

F. Percutaneous aortic valvuloplasty

Valvuloplasty, which consists of inflating a balloon across the aortic valve, is only a palliative therapy and is only effective over the intermediate term. Valvuloplasty may be performed as a bridge to eventual AVR in patients with severe AS who are hemodynamically unstable with multiple organ failure. Once the patient is stabilized, surgical or transcutaneous AVR may be performed at a lower risk.

In early rheumatic MS, valvuloplasty is effective as it opens the *fused* but *non-calcified* commissures. In calcific AS, the whole valve is calcified and the process is not limited to the commissures. Aortic valvuloplasty temporarily fractures the calcified framework of the valve, making it more flexible/pliable; also, it mildly tears the valve and opens the commissures. It is usually moderately effective and converts critical AS into severe AS (with a roughly 1.5% risk of AI and 2% risk of stroke in a modern registry). Calcium quickly regrows and leads to recurrence of AS within 6–12 months.

Valvuloplasty may be used as a long-term therapy in children or young adults with *non-calcified bicuspid AS* wherein commissural fusion is the cause of stenosis, and where valvuloplasty produces small commissural tears. The results usually last 10–20 years, and most patients eventually require AVR later in adulthood. Moreover, there is an early and late risk of AI (~15% at 3–4 years). Valvuloplasty is indicated in children or young adults with symptomatic severe AS, asymptomatic severe AS with peak velocity ≥5 m/s, or asymptomatic and planning pregnancy or athletic activity.

G. Transcutaneous aortic valve replacement (TAVR) vs. surgical AVR. *For anatomy tips, see Figures 6.9, 6.17 and Section 5-Figure 6.24*

TAVR is performed through a femoral approach (~16 Fr sheath). In patients with small or severely diseased iliofemoral arteries/aorta, balloon lithotripsy may augment arterial size. Alternative accesses may be considered in ~5%, such as transaxillary, transcarotid (via a surgical carotid cutdown), or transcaval, or rarely, thoracic surgery with transapical or ascending aortic access. The valve is balloon expandable (Sapien valve) or self-expanding (Corevalve Evolut), and is deployed across the aortic orifice pushing aside the native valve leaflets (Figure 6.23). It consists of a thin stent frame that contains 3 bioprosthetic leaflets with no metallic struts. Without the bulk of the sewing ring and the stented struts, the transcutaneous valve has a larger orifice area and less gradient than a surgical bioprosthesis (~0.4 cm^2 larger), with less patient/prosthesis mismatch.

In high-surgical-risk patients (STS score ≥ 8%), TAVR was associated with a lower postoperative mortality than surgical AVR (3.4% vs. 6.5%) but similar 1-year mortality. In inoperable, high-risk patients, TAVR drastically reduced 1-year mortality in comparison with conservative management (30% vs. 50% 1-year mortality) (PARTNER 1 trial).[148] The mean age in the PARTNER 1 trial was 84 years (84 ± 7), functional class was mainly III–IV, and prior CABG, stroke, or advanced COPD was common; ~20% of patients had associated moderate or severe MR.

Figure 6.23 TAVR valves and relation to the coronary ostia. TAVR valves consist of a thin stent frame that contains 3 metal-free bioprosthetic leaflets. Both types of TAVR valves have a short, fabric-covered skirt at the base (~10 mm in Sapien valve; 13 mm in Corevalve), which sits at the aortic annulus and partly extends in the LV (≥4 mm with Corevalve, 20% of the whole stent frame in Sapien valve). With Corevalve, the fabric extends even higher in a narrow fashion at the level of the 3 prosthetic commissures. The skirt very rarely covers and occludes the coronary ostia, unless they are low, <10 mm from the aortic annulus.

While the covered skirt is short, *the Corevalve stent frame is long (45 mm) and covers the coronary ostia; yet, the stent being mostly an open mesh, it does not occlude the coronary ostia*. The Sapien stent frame is short, ~18–20 mm, and frequently (~70% of the time) does not cover the coronary ostia. The stent frame is deployed inside the native aortic leaflets and pushes them out. The stent may "squeeze" the native leaflets up, onto the coronary ostia, and cause coronary occlusion, especially in those with narrow aortic sinuses that cannot assimilate the bulk of the native leaflets, or those with low coronary origins (<12 mm from the aortic annulus). The *coronary occlusion does not usually result from the stent frame itself*.

Corevalve makes future coronary PCI difficult, more than Sapien valve: (1) the long Corevalve frame covers the coronary ostia and makes guiding catheter engagement difficult, particularly at the level of the commissures, where the covering fabric extends even higher; (2) the prosthetic leaflets are not inserted at the stent base (annulus) but above it, at the top of the covered skirt, very close to the coronary arteries, making catheter engagement difficult from below the coronary arteries or even from their side (tight space); they have to be engaged from above using a short catheter, like JL 3. Conversely, Corevalve has this advantage: the annulus being the narrowest point in the native valve complex, the supra-annular leaflet position allows superior leaflet expansion and a larger effective orifice area than Sapien valve.

Approximately 9% of patients had radiation heart disease and ~20% had extensively calcified aorta. The mean transaortic gradient was 43 ± 15 mmHg; in fact, PARTNER 1 trial included a significant proportion of patients with low-flow/low-gradient AS (with low EF [15%] or normal EF/paradoxical low gradient [14%]). Those demonstrated the highest mortality and the most drastic survival improvement with TAVR in comparison with medical management, whether EF was reduced or not.[149] In the Corevalve high-risk trial, TAVR with Corevalve was associated with a *lower 1-year mortality than surgical AVR (similar at 3 years)*.[150] As such, TAVR is given an ACC class I recommendation in high-surgical-risk patients.

TAVR in low-risk patients: The PARTNER 2A trial of intermediate-surgical-risk patients with STS score 4–8% suggested a better 1-year survival with transfemoral TAVR vs. surgical AVR, but similar 5-year survival.[151] PARTNER 3 and Evolut low-risk trials studied low-risk patients, whose mean age was 73, and showed a similar mortality, but less stroke, AF, and rehospitalization, better quality of life, and lower valvular gradient with TAVR vs. surgical AVR at 2 years.[152] However, in PARTNER 3, TAVR mortality rose faster after 1 yr and exceeded SAVR at 7 yrs—significantly so on the 1–7 yr landmark analysis—with significant ↑ in valve thrombosis; in Evolut, the reintervention rate, primarily for central AI, was higher with TAVR at 7 years. As such, **both TAVR and surgical AVR are given *ACC class I* indication in low- or intermediate-surgical risk patients who are 65–80 years old. TAVR is favored in low-risk patients who, nonetheless, are >80 years old or have <10 years life expectancy** (*class I TAVR, class IIa for surgical AVR*)**, while surgical AVR is favored in low-risk patients <65 years old** (or <70 years old per ESC).[18]

***Cases where TAVR is still not favored*:** (a) low- or intermediate-risk patients <65 years old, who rather benefit from a surgical mechanical prosthesis or a surgical bioprosthesis with more robust long-term data than TAVR; (b) bicuspid aortic valve; (c) severe AI.

TAVR is not typically used in patients with a *clearly bicuspid* valve, where the aortic opening *and* annulus are more elliptical than in tricuspid valves, which prevents symmetrical apposition of the cylindrical prosthesis and allows paravalvular leaks. Also, bicuspid valves exhibit heavier and more asymmetric calcification, notably of the *fused raphe*, which particularly hinders valve expansion. TAVR may be done in select cases with less adverse calcium (class IIb), though with a higher risk of stroke and paravalvular AI than tricuspid TAVR.

The use of TAVR in severe AI is limited by: (1) coexistent aortic root disease and large annular size, which increases the risk of dehiscence and persistent AI; (2) frequent lack of significant valvular calcifications, which serve as a fluoroscopic landmark for valve positioning and as an anchor at the lower part of the stent frame; (3) difficulty in positioning in a patient with regurgitant jet. One valve specifically designed for AI, Trilogy, has anchors to attach to the 3 leaflets of the aortic valve and proved safe in high-surgical risk AI patients.[153] ESC gives it a class IIb indication for AI at high surgical risk.

Special complications:

a. While first-generation TAVR valves were associated with increased stroke risk, later-generation TAVR valves actually have a lower stroke risk than surgery (<2% in PARTNER 3 and Evolut low risk).

b. *Moderate or severe paravalvular regurgitation* used to be common but is now reduced to ~3.5% with the newest generations of both Sapien and Corevalve (mild: circumferential extent <10%; moderate: 10–29%; severe: >30%). Even when it occurs, it spontaneously improves at 1 year in >70% of patients, as the stent continues to expand over time (particularly Corevalve).[150] Moderate regurgitation is associated with a 2.5-fold increase in long-term mortality. Mild regurgitation yielded increased mortality in PARTNER 1, but not 2 and 3.

c. The ventricular portion of the TAVR stent may impinge on the ***His and left bundle areas***, which sit over the membranous septum: PPM is required after ~20% of Corevalve, vs. ~7% of Sapien and ~5% of surgical AVR. Post-TAVR high-grade AV block usually occurs early (<24h) but may develop at 2–7 days in <3% of cases, or rarely, weeks later. AV block resolves within 24 hours half the time, but is unlikely to resolve if it persists longer, justifying PPM implantation. Baseline *RBBB is the biggest predictor of AV block, followed by new, persistent post-TAVR LBBB and PR* ↑. Post-TAVR LBBB occurs in ~25% of the cases: when associated with new PR↑ or QRS >150 ms, it justifies 5 days of hospital monitoring or an EP study, with PPM implantation for HV >70 ms (15% may evolve into late AV block) (ESC). This strategy also applies to any worsening of pre-existing conduction disease, such as RBBB with further QRS or PR widening.

d. Rare coronary obstruction (<0.5%).

e. Subclinical leaflet thrombosis, discussed under *Prosthetic valves*, Section 8.V.B.c.

TAVR in patients with CAD: timing of PCI: (1) In a patient with proximal CAD who is stable from the AS standpoint, PCI is generally performed before TAVR, thereby averting the difficult post-TAVR coronary cannulation through the TAVR stent cells (ACC class IIa). (2) The performance of PCI in a patient with severe untreated AS is generally safe and is only associated with increased mortality and complications if AS is unstable, i.e., associated with HF, EF <30%, or high STS risk score >10%.[154] In those cases, Sapien TAVR may be performed first and followed by PCI at a later setting. (3) If proximal CAD is complex and requires a complicated PCI (e.g., left main rotablation), or if both proximal CAD and AS are unstable, aortic balloon valvuloplasty and/or Impella or ECMO may be done to facilitate PCI, followed by TAVR in the same setting or later on. Routine PCI for stable CAD peri-TAVR is controversial. Pro-TAVI trial showed that selective PCI after TAVR (for persistent symptoms only) was non-inferior to systematic pre-TAVR PCI and reduced bleeding; most stenoses were proximal or ≥90% obstructive (60%). Notably, only 11% in the deferred arm eventually required PCI. Conversely, NOTION-3 found that PCI of stenoses ≥90% (mostly pre-TAVR) reduced long-term MI—a strategy suggested by ESC (class IIa).[155]

5. TRICUSPID REGURGITATION AND STENOSIS

I. Etiology of tricuspid regurgitation (TR)

A. TR is often secondary to RV pressure or volume overload (ventricular functional TR, 65% of all significant TRs) (Figures 6.24 and 6.25)

i. PA pressure >50 mmHg *or* PVR >3 Wood units often indicates that TR is secondary to RV failure from pulmonary hypertension:[156,157]

- LV dysfunction or left valvular disorders with pulmonary hypertension
- Pulmonary arterial hypertension from pulmonary vascular disease or lung disease

The high RV systolic pressure as well as the RV dilatation, annular dilatation, and leaflet tethering lead to TR. Unlike functional MR, where leaflet tethering predominates, both annular dilatation and leaflet tethering are important factors in functional TR (the right papillary muscles are highly placed and less severely tether and constrain the tricuspid leaflets compared to the mitral system). The tricuspid

annulus has less fibrous component than the mitral annulus and is over 2/3 muscular, even more so than the mitral annulus, and is less constrained by the papillary muscles. Thus, it dilates more easily than the mitral annulus and less readily reverses with diuresis. The oval, saddle-shape annulus becomes circular and planar (flat) when it dilates (Figure 6.25).

ii. PA pressure <40–50 mmHg with normal PVR favors either primary TR, atrial functional TR, or TR secondary to a pure RV volume overload (ASD, ARVD).[157]

In severe ventricular functional TR, RA pressure is always elevated with a large V wave and a dilated IVC, as, by definition, decompensated RV failure is present. *RA pressure may normalize with diuresis, but only if the failing RV substantially improves and, consequent to this,* RV-driven *TR regresses*. Conversely, in severe primary TR or atrial functional TR, the RA may be highly compliant and RA pressure may be normal.

In *torrential TR,* RV and RA become a common chamber and thus, TR velocity is low and cannot be used to calculate PA pressure. Simplified Bernoulli equation (pressure = 4× velocity^2) assumes an increase in velocity at the level of an orifice and cannot be applied in the absence of tricuspid flow acceleration. Right heart catheterization is needed to define PA pressure. RA pressure is ventricularized; in systole, RV, RA and PA pressures are near equal. JVP mimics the carotid pulse on exam.

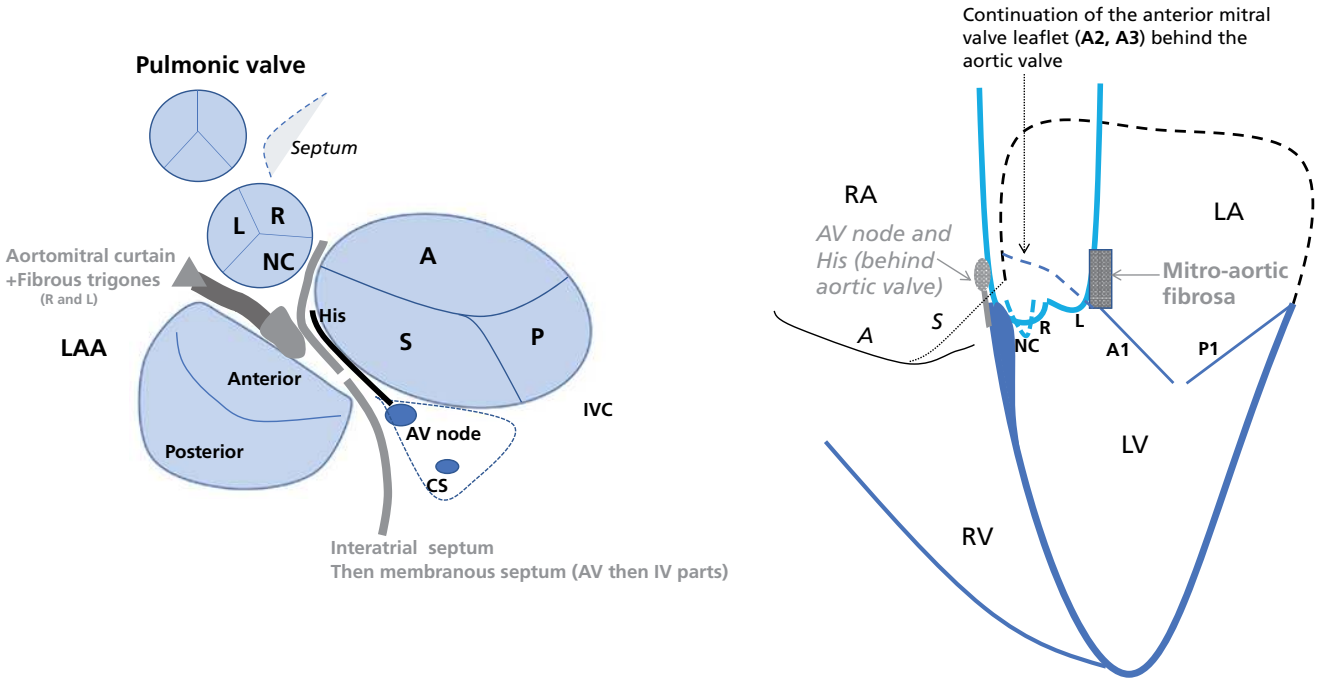

Figure 6.24 (***Left***) **Normal tricuspid anatomy as viewed from the RA (surgeon's view)**, similar to Figure 6.1b. Note the relationship with the mitral valve, aortic valve, and interatrial septum. AV node is at the level of the interatrial septum. His bundle emanates from the AV node and spreads into the membranous interventricular septum, just behind the noncoronary cusp of the aortic valve. The dashed triangle is the triangle of Koch. The tricuspid valve is the largest cardiac valve, and its leaflets are thinner than the mitral leaflets. Regarding the tricuspid annulus, only its septal portion adjacent to the mitral trigone and the membranous septum is fibrous, whereas the rest (>2/3) is muscular. Comparatively, the mitral annulus has thicker fibrous tissue; it is fibrous anteriorly around the anterior leaflet and forms the aortomitral curtain with 2 fibrous trigones at its edges (marked in *gray*); it is muscular and D-shaped in the posterior 2/3. **Note how the fibrous cytoskeleton (gray) connects the aortic, mitral, and tricuspid valves, and constitutes ~1/3 of the circumference of each of the 3 annuli.**

AV, atrioventricular; IV, interventricular; aortomitral curtain = mitroaortic fibrosa.

(***Right***) Aortic, mitral, and tricuspid valves relationships in a frontal view. Posterior structures are indicated by *interrupted lines*. Note, on both images, how the aortic valve is in fibrous continuity with the mitral and tricuspid annuli and the membranous septum posteriorly, while it abuts the muscular septum anteriorly.

B. Primary TR (5–10% of all TRs)

- Endocarditis
- Tricuspid valve prolapse, which is seen in more than 25% of patients with severe MVP causing severe MR. In this setting, 23% of tricuspid prolapses are associated with moderate-severe TR.[158]
- Rheumatic fever (beside secondary TR, one-third of rheumatic MS cases have intrinsic tricuspid involvement)
- Flail leaflet from blunt thoracic or abdominal trauma (abdominal trauma briskly increases IVC pressure, which may rupture the tricuspid valve), carcinoid syndrome, Ebstein anomaly

C. Atrial functional TR (15% of significant TRs)

In atrial functional TR, the valvular leaflets are grossly normal, and typically, the RV size and function are normal or only mildly impaired (unlike ventricular functional TR).

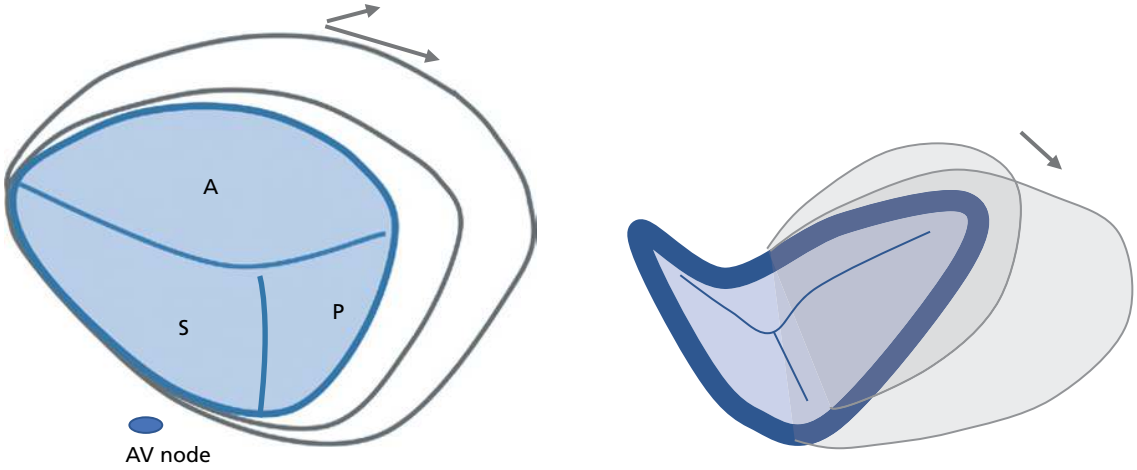

Figure 6.25 The tricuspid valve is normally oval-shaped in a horizontal plane, and saddle-shaped in a 3-dimensional plane. The anterior leaflet is largest. The posterior (P) and septal (S) leaflets are smaller, the septal leaflet being often the smallest. The septal leaflet (S) is also the least mobile, as it attaches to the fibrous septal annulus. AV node is behind the septal leaflet, at the top of the Koch triangle. In functional TR, the tricuspid annulus dilates outward and becomes more circular and planar/flat (*arrows*). It dilates along its anterior and posterior muscular segments, away from the rigid fibrous septal portion. The outward expansion explains why tricuspid clips are mostly placed between the septal leaflet on the one hand, and the anterior and/or posterior leaflet on the other hand. Besides annular dilatation and flattening, the leaflets are tethered downward in ventricular functional TR, vs. no or minimal tethering in atrial functional TR.

There is usually one dominant and large anterior papillary muscle, which gives chordae to the anterior and posterior leaflets. The septal leaflet frequently gets its chordae directly from the septum without a papillary muscle. Additional small papillary muscles may be present (one posterior and one or multiple septal muscles). The anterior leaflet (A) is the one seen on most echo views. The posterior leaflet being small, it is often only seen on one echo view, the aortic short-axis.

This TR is most commonly related to **AF in an elderly patient. AF dilates the atria, cancels presystolic annular contraction, and initiates tricuspid annular dilatation, which begets more TR and progressively more annular dilatation, particularly in the elderly population (>70).**[159,160] One long-term follow-up study showed that moderate or severe isolated TR develops at a rate of ~1.3% per year in patients with AF, mainly persistent/permanent AF and more so in older women (>65).[161] Also, age-related annular degeneration, annular dilatation, and impaired tricuspid annular contraction/mechanics may be responsible for this phenomenon in elderly patients without AF: up to 38% of patients with atrial functional TR do not report a history of AF.[162] Atrial functional TR is generally ***more prevalent and severe than atrial functional MR***, as less annular dilatation is required to create atrial TR than atrial MR (40% vs. 75% annular dilatation).[162] This is because the papillary muscles are smaller and more widely separated, exerting less constraint on the leaflets' coaptation; leaflets are pulled up and their coaptation pulled apart with less annular dilatation: it is easier to get a coaptation gap with tricuspid than with mitral dilatation. Also, the tricuspid annulus has a thinner fibrous component than the mitral annulus with only one fibrous trigone, and >2/3 of its circumference is muscular (vs. 2/3 muscular for mitral). Hence, it is more distensible and dilates more readily than the mitral annulus; it is more prone to irreversible elastic deformation and less likely to regress.

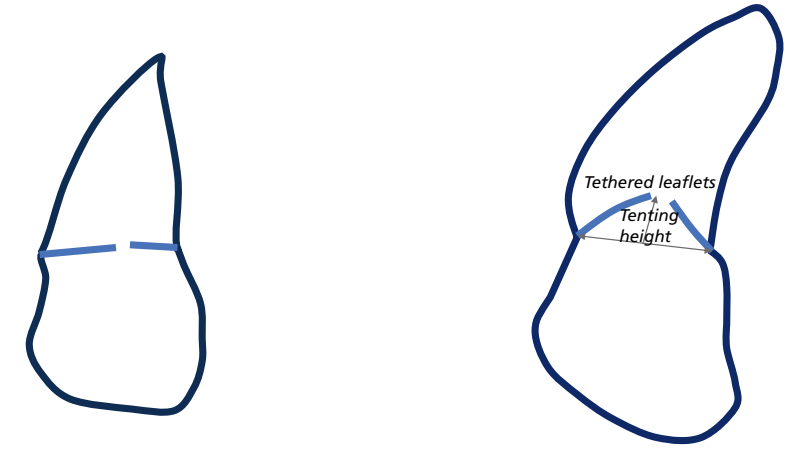
In atrial functional TR (with or without AF), leaflet tethering is much less pronounced than in ventricular functional TR, where the RV dilates longitudinally. The annulus is not necessarily more dilated than in ventricular functional TR,[163] as by definition, in all functional TRs, the tricuspid annulus dilates with a diameter >40 mm (22 mm/m²) for men and >35 mm (21 mm/m²) for women on echo 4-chamber view.[162] However, the RV is normal in size (≤38 mm mid-RV diameter) and is conical (vs. longitudinally elongated and elliptical in ventricular functional TR). The tricuspid annulus/mid-RV diameter ratio is higher in atrial vs. ventricular TR (Figure 6.26).[157,162] Some patients may have both atrial and ventricular functional TR mechanisms and overlapping features, as in the following cases: (i) late-stage atrial TR causing RV dilatation, or (ii) combined left heart disease + PH + AF with atrial TR. Besides annular dilatation and leaflet tethering, the severity of TR depends on the degree of compensatory leaflet growth.

D. Pacemaker or ICD lead-induced TR (10–15% of TRs)

After pacemaker or ICD placement, new severe TR is seen in 4% of patients at 1 month and 8% at 4 years (large Cleveland Clinic registry), and moderate TR in up to 38% of patients.[164,165] ***But blame the lead last: if other obvious cause of functional TR is present (e.g., left HF), the lead is unlikely to be the primary driver of TR***.

In a Mayo clinic registry, pacemaker or ICD-related TR was the cause of severe TR in 26% of patients with pacemaker/ICD requiring tricuspid surgery,[166] sometimes years after device implantation. Importantly, TTE and TEE diagnosed pacemaker-related injury as the cause of TR in only ~20% and 45% of the cases, respectively. 3D echocardiography improves the spatial resolution and is the diagnostic modality of choice, but the diagnosis is frequently a diagnosis of exclusion. TR may result from valve perforation but more commonly results from lead impingement on the leaflets or chordae (41%), or lead adherence to the valve (37%).[167] The septal and posterior leaflets are most commonly involved, esp. in their central portion; a lead in a commissure is less likely to interfere and be the cause of TR. When treatment is required for symptomatic RV failure, surgery is the main option (tricuspid repair or replacement). Standalone lead extraction may improve TR in ~1/3 of the cases, mainly when the lead impinges on a leaflet or loops and entangles the chordae without adherence or damage. However, it frequently worsens TR, especially with old leads >7 years (11% risk of TR worsening), and should not be performed without a back-up surgical strategy.[157,168]

TR, whether due to the lead or not, may be treated with a tricuspid clip when the lead is lying in a commissure rather than centrally; the lead can often be kept in place. ~20% of patients in clip studies had a PPM. If the lead is extracted, it is replaced with an epicardial lead, a CS lead, or a leadless PPM.



Atrial functional TR	Ventricular functional TR
Tenting height ≤ 9 mm	>9 mm
RV mid-ventricular diameter ≤ 38 mm but may↑	>38 mm
RA volume/RV volume in end systole ≥1.5	<1.5
Tricuspid annulus/mid-RV diameter ↑ >1.1–1.2	
RV function and size ~ normal in early stages, TAPSE > 17 mm, S' ≥ 9, FAC ≥ 35%	RV dilated and impaired
RV conical (sphericity index <55)*	RV elliptical (sphericity index >55)
PA systolic pressure <50 mmHg and PVR <3	Often >50 mmHg

In both: -Tricuspid annular dilatation + impaired contraction
-RA dilatation
-Insufficient leaflet growth/remodeling

Figure 6.26 Morphological differences between atrial functional TR and ventricular functional TR. Numbers inspired from Muraru et al.,[162] Schlotter et al.,[163] and Welle et al.[157] *Sphericity index: RV mid-diameter × RV length/RV basal diameter. RV length is >83 mm in V-TR. FAC, fractional area shortening.

II. Natural history of TR

A primary or isolated severe TR may be well tolerated for months or years before it leads to RV failure, as long as the RV is not significantly dilated and the pulmonary arterial pressure is normal (e.g., the case of valvectomy performed for tricuspid endocarditis). ***However, once RV dilatation occurs, a vicious circle of progressive RV dilatation, annular dilatation, and TR rapidly ensues.*** The thin RV is very sensitive to afterload (wall stress); it cannot withstand the high afterload of RV dilatation and progressively succumbs to it.

Unlike the mitral annulus, the "flimsier" and less fibrous tricuspid annulus may lose its elastic recoil after being excessively stretched, leading to irreversible annular distortion. This is particularly consequential as a mere 40% increase in annular area can precipitate severe functional TR. Consequently, ***severe functional TR is less likely to undergo meaningful regression than functional MR***. In the conservative arm of the Tri.Fr trial, ~45% of severe TRs improved by ~1 grade within 1 year, but typically only from "massive" to "severe," with <10% reaching moderate TR. Similarly, Kucuk et al. (Mayo Clin Proc. 2025;100: 440) found that *43% of severe functional TRs improved with diuresis and left HF therapies*, but the improvement was limited and recurrence was common (50%).

In TR secondary to left valvular disease, percutaneous or surgical correction of the left valvular problem reduces PA pressure and may eventually reduce TR. However, *TR often does not improve*, and rather leads to more annular dilatation, TR and RV dilatation, particularly in patients with dilated tricuspid annulus >35–40 mm on TTE (or >21 mm/m^2). ***Tricuspid annular dilatation is an ongoing progressive process that results in more annular dilatation***, such that an initially mild TR may progress over time and become the primary driver of RV failure. Mild TR with annular dilatation or moderate TR, if not corrected at the time of left valve surgery, will progress in ~25% of patients over several years.[169] Therefore, adjunctive tricuspid annuloplasty is reasonable in severe TR, moderate TR, or mild TR with severe annular dilatation, and is associated with improved functional capacity and reduced long-term risk of TR and HF (yet questionable survival benefit).[169] In general, tricuspid annuloplasty concomitant to mitral surgery does not significantly increase the surgical risk, whereas reoperation for severe progressive TR after mitral surgery is associated with a high mortality of 10–25%, further justifying early, concomitant surgery.[18] One randomized trial confirmed that in patients undergoing mitral surgery for degenerative MR who also have moderate TR, or milder TR with annular dilatation, concomitant tricuspid annuloplasty reduced the 2-year progression to severe TR (6% vs. <1%) without raising operative mortality (~1%), although it increased pump time by ~33 minutes and the need for permanent pacemaker to 14%.[170] The benefit may accentuate on longer follow-up as untreated TR may further progress. The benefit was rather confined to moderate TR, not milder TR with annular dilatation.

III. Treatment of TR

A. Medical therapy of RV pressure or volume overload

Medical therapy consists of diuretics and treatment of LV failure, lung disease, or pulmonary arterial hypertension. AF rhythm control should be considered if viable (e.g., AF <1 year, no massive RA/LA dilatation). Medical therapy may shrink the RV and tricuspid annulus and improve TR in ~45% of patients, but this improvement is often limited and non-durable. Per ESC: "medical therapy has very limited effect on the evolution of TR severity ...and should not delay evaluation of an intervention".

B. Indications for surgical repair/replacement or transcutaneous repair/replacement

a. Severe, symptomatic TR (fatigue, dyspnea, right HF) (ESC *class I*). This applies to: (i) primary TR, but also to (ii) *atrial functional TR* refractory to AF therapy and diuresis, and (iii) *ventricular functional TR* refractory to diuresis and to treatment of PH or left heart disease (including functional TR in patients with previous left valve surgery).

b. Severe TR with progressive RV dilatation or dysfunction, even if asymptomatic (ESC *class IIa*). At this stage, progressive RV dilatation drives more annular dilatation and more TR. It is best to intervene before severe RV dysfunction or severe clinical HF, such as ascites, occurs (at which time mortality is high and right HF may be irreversible). Similarly to (a), this applies to primary TR, and to refractory atrial functional TR and ventricular functional TR.

For both (a) and (b), surgical correction may be performed: tricuspid repair (preferably) with an annuloplasty ring or tricuspid valve replacement with a bioprosthetic valve. *Percutaneous* tricuspid clip (TEER) has also proven safe in TRILUMINATE and Tri.Fr trials, which primarily enrolled functional TR with a coaptation defect <1–2 cm (>90% functional, >90% AF, ~15% PPM): low procedural mortality (<1%), dramatic improvement of quality of life, and 30–40% reduction of 2-year HF hospitalizations. Yet, 1- and 2-year mortality remained unchanged. Also, *percutaneous tricuspid valve replacement* reduced symptoms and HF hospitalizations in the as-treated 2-year analysis, though with a high need for new PPM (17%, TRISCEND II trial).[171–173]

Tricuspid repair or replacement is avoided if PA pressure is >70 mmHg,[171,172] as TR is not the primary driver of HF, and the RV may succumb to the high afterload after correcting TR.

c. In a patient undergoing left-sided valve surgery, tricuspid valve surgery should be performed if secondary *severe TR* is present (*class I*). Tricuspid annuloplasty is preferred to replacement. Tricuspid annuloplasty may also be performed for *moderate TR* (class IIa), or *mild TR* associated with annular dilatation >40 mm or prior right HF (ESC class IIb).[18] Annular dilatation and TR continue to progress after mitral surgery even if pulmonary pressure is eventually reduced (*class IIa*); this is particularly true if baseline PA pressure is not severely elevated and does not appear to be the driver of TR. When measured intraoperatively on an arrested heart, annular dilatation >70 mm, rather than 40 mm, indicates repair.

d. In MS, if the mitral valve is amenable to PMBV, PMBV may be performed and TR reassessed. If the mitral valve is treated surgically, TR is concomitantly repaired to avoid the risk of progressive TR and a second surgery.[18]

There are 2 types of surgical tricuspid annuloplasty (Figure 6.27): (1) ring annuloplasty; (2) suture annuloplasty, which consists of a single suture tied circumferentially around the posterior and anterior aspects of the annulus (de Vega). A ring has more sustained long-term efficacy than a suture, lasting >5 years, but requires more surgical time (~30 minutes). De Vega annuloplasty usually requires <5 minutes and does not significantly add to the operative ischemic time. If valve replacement is chosen, a bioprosthesis is preferred to a mechanical prosthesis because of the high thrombotic risk on the right side, where the closing pressure is low. Also, a bioprosthetic valve lasts longer in a low-pressure system (i.e., tricuspid, or, even better, pulmonic position, compared to mitral or aortic position).

Regarding tricuspid clip in the major studies, ~85% of patients required 2 or 3 clips, mostly anteroseptally and posteroseptally.

C. Timing of tricuspid valve intervention

Severe TR that persists despite diuresis, whether functional or primary, needs to be treated procedurally ***early on***, before progressive RV dilatation or progressive right HF occurs.[174] Severe TR with clinical signs of right HF leads to the following 3 consequences: (1) progressive RV dilatation; (2) liver failure and cirrhosis, even in a matter of months; (3) renal failure, more than seen with isolated left HF, as high RA pressure directly reduces renal flow. Any of these complications dramatically increases mortality and may preclude surgery. In fact, tricuspid surgery has one of the highest single-valve surgical mortalities (may exceed 10%).[174] Even a clip is of limited utility at this advanced stage. ***A high Tri-SCORE, which reflects these 3 consequences, identifies a disease stage where any intervention, including clip, may become futile and no longer confers a survival advantage*** (ESC, TRIGISTRY). *Note:* While a severely dysfunctional RV may acutely fail following TR correction due to loss of a "pop-off" leak, this is rare. It ultimately depends on how high PA pressure and PVR are compared to RA pressure, into which the RV is leaking. RA pressure is very high, and as such, TR is not a "low-pressure" leak. In fact, RV afterload usually improves with TR correction via the reduction of RV volume.

IV. Tricuspid stenosis

Causes: rheumatic (in which case it is always associated with left valvular disease), carcinoid syndrome, and cardiac tumors obstructing the tricuspid orifice. Carcinoid heart disease is related to the secretion of serotonin by a neuroendocrine tumor (usually a gastro-intestinal tumor). This leads to thickening of the right-sided valves, particularly the tricuspid valve. Since serotonin is degraded by the lungs, the left

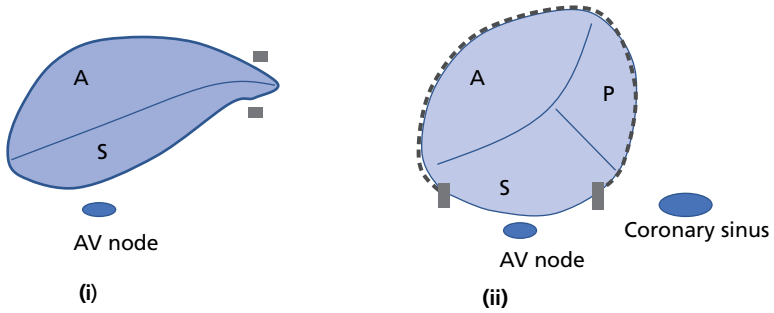


Figure 6.27 Repair of functional TR:

(i) Kay bicuspidization: plication of the posterior leaflet and suturing of the annulus at the free wall. The problem is that the posterior leaflet is normally hypofunctional and the annulus tends to continue expanding anteriorly.

(ii) Annuloplasty: a quick suture annuloplasty (DeVega) may be done around the anterior and posterior leaflet, while avoiding the septal aspect and the AV node (the septal aspect dilates the least anyway). A ring annuloplasty may also be done but is more time-consuming. A rigid, saddle-shaped ring is used and is typically incomplete, covering the anterior and posterior annulus, which is most prone to dilatation, while sparing the AV node area (26–28 mm ring, as this is the normal annular size).

valves are not involved unless right-to-left shunt or pulmonary metastasis is present. The tricuspid leaflets become thickened and completely immobile along their entire length, with lack of opening or closure, which explains the combined stenosis and regurgitation.

6. PULMONIC STENOSIS AND REGURGITATION

I. Pulmonic stenosis (PS)

PS is usually congenital. While the normal pulmonic valve is tricuspid, the stenotic pulmonic valve is often a domed valve with extensive commissural fusions, leading to an acommissural morphology with a small central orifice (no commissure, or 1 or 2 commissures). The domed appearance is recognized on angiography.[175] Rarely, the valve is tricuspid with diffuse myxomatous thickening and little or no commissurall fusion (dysplastic valve, e.g., Noonan's syndrome). Other causes of PS: rheumatic, carcinoid (always in conjunction with other valvular diseases).

Pulmonic stenosis leads to RV hypertrophy but not RV dilatation and failure. In fact, RA pressure is characterized by a large A wave but a normal V wave. The congenital RV maintains its function for years even when the RV pressure is in the systemic range; thus, in RV failure, one should look for an associated "volume" lesion such as ASD, TR, or PR. Usually in PS, RV does not fail until later in life (fifth decade) or unless atrial arrhythmias develop. On chest X-ray, PS is characterized by a dilated main and left pulmonary arteries (post-stenotic dilatation). As opposed to Eisenmenger syndrome, the lung perfusion is normal (no oligemia).

PS is considered severe when the *peak velocity is >4 m/s or mean gradient is >35 mmHg; PS is moderate when the peak velocity is >3 m/s, which corresponds to a catheter peak-to-peak gradient of 30–40 mmHg* (ACC congenital disease guidelines 2025).[176] The gradient in PS, particularly mild or moderate PS, usually remains stable over the long-term follow-up, but most moderate PS patients eventually develop symptoms during a 25-year follow-up and require valvotomy.[177] Severe PS is usually symptomatic and is treated with percutaneous balloon valvotomy with excellent long-term result (no recurrence over >20 years follow-up). In the ACC guidelines, percutaneous valvotomy is indicated for symptomatic, moderate or severe PS; or asymptomatic, severe PS. Moderate-to-severe pulmonary regurgitation may subsequently be seen in up to 20% of patients, but is not usually clinically significant; <10% eventually require surgery for PR, years later. Dysplastic PS does not respond to valvuloplasty, as the primary process is not commissural fusion.

Athletes with severe asymptomatic PS can participate in low-intensity competitive sports or can be referred for intervention. Two to four weeks after valvuloplasty, asymptomatic athletes with no more than mild residual PS and normal ventricular function can participate in all competitive sports.[178]

Patients with PS have a hypertrophied RVOT. Following percutaneous valvuloplasty, the reduction in RV afterload reduces RV volume and may cause a dynamic obstruction across the hypertrophied RVOT and a residual gradient that is actually an intraventricular gradient. This gradient should not be confused with a persistent transpulmonic gradient, and the diagnosis is confirmed on a slow PA-to-RV pressure pullback. The RVOT obstruction may be severe ("suicide RV") and is initially treated with fluids, β-blockers, and calcium channel blockers. This gradient resolves gradually.

II. Pulmonic regurgitation (PR)

The most common cause of PR is pulmonary hypertension, which leads to a *secondary form of PR*. This is classically seen with MS. *Primary PR* may be seen decades after surgical therapy of tetralogy of Fallot, valvotomy for PS, or after Ross procedure. It may also be seen with endocarditis and carcinoid syndrome.

When associated with pulmonary hypertension, PR leads to Graham Steell's PR murmur, which is a diastolic murmur similar to AI, except that it is only heard at the left second intercostal space and increases with inspiration.

PR secondary to pulmonary hypertension is seldom severe enough to require any specific therapy. Valve replacement may be required for severe primary PR (e.g., after surgical correction of tetralogy of Fallot) in the following cases: *symptomatic RV failure (class I); asymptomatic, progressive RV dilatation or mild/moderate RV dysfunction (class IIa, congenital guidelines)*.[176] Note that the RV usually tolerates severe PR for years, sometimes decades, as long as it is not significantly dilated. RV size tends to normalize, and functional status improves when pulmonic valve replacement is performed for PR late after tetralogy of Fallot repair. However, RV function may not fully recover once marked enlargement and systolic dysfunction are evident.[179] Transcatheter pulmonary valve implantation has emerged as a safe and efficient alternative to surgical valve replacement (Melody or Sapien valve).

7. MIXED VALVULAR DISEASE; RADIATION HEART DISEASE

I. Mixed single-valve disease

In mixed moderate or severe stenosis *and* moderate or severe regurgitation of the same valve, i.e., MS + MR or AS + AI, one lesion usually predominates over the other (stenosis or regurgitation) and the pathophysiology resembles the dominant lesion. However, the non-dominant lesion worsens the effect and the symptomatology of the dominant lesion, and these patients are more prone to elevate PCWP and develop pulmonary edema than patients with isolated stenosis or regurgitation. Since the flow across the valve is increased, the transvalvular gradient is increased in comparison to valvular stenosis without regurgitation. This leads to overestimation of the anatomic severity of the stenosis when assessed by gradient. ***The elevated gradient, however, correlates with the physiologic consequences of the mixed stenosis–regurgitation and properly correlates with the overall disease severity***.[140] The valvular area is unchanged when calculated by Doppler echocardiography (continuity equation for AS or MS, or pressure half-time for MS). The valvular area may be underestimated, i.e., the stenosis may appear more severe, if Gorlin's equation is used with the net forward cardiac output (e.g., thermodilution) rather than the total output across the valve.

In moderate mixed disease in a symptomatic patient, a hemodynamic study is useful in addressing the selective impact of valvular vs. myocardial disease. If mixed mitral disease is the cause of the patient's symptoms, PCWP and PA pressure will rise with exercise disproportionately to LVEDP. If mixed aortic valve disease is the cause of the patient's symptoms, the LV–aortic gradient is in the severe range even if the valve area is not (aortic valve velocity ≥4 m/s and mean gradient ≥40 mmHg), LV and aortic end-diastolic pressures are approximated, the dicrotic notch is attenuated, and an anacrotic notch is seen.

II. Multiple valvular involvement (combined stenosis or regurgitation of two different valves)

Multiple valvular involvement may be caused by: rheumatic disease (MS with AI or AS, MR with AI), radiation, endocarditis, severe AS or AI with functional MR, myxomatous degeneration of both the aortic and mitral valves, or AI due to aortic dilatation and MR due to MVP in patients with connective tissue disorders. Functional TR may occur secondarily to severe mitral disease.

Moderate or severe multiple valvular disease is poorly tolerated. One valvular lesion may mask the hemodynamic manifestation of the other. *The proximal lesion tends to mask the severity of the more distal lesion by reducing the flow across the distal lesion, whereas the distal lesion tends to exacerbate the hemodynamic effect of the proximal lesion because of increased backward volume and/or pressure*. In general, the clinical effect of the proximal lesion is more prominent than that of the distal lesion.

In ***severe MR or MS associated with AS***, AS worsens the hemodynamic effects of MS or MR and may worsen the severity of MR (from moderate to severe). In combined MR and AS, the LV is exposed to both pressure and volume overload. In combined MS and AS, AS may lead to underestimation of MS severity: mitral gradient may fall with reduced CO and MVA may be falsely increased by the echocardiographic pressure half-time method. On the other hand, the severity of AS may be underestimated by gradient assessment as a result of the low cardiac output but may be overestimated by AVA assessment (low-flow/low-gradient pseudo-severe AS). If surgery is indicated for the mitral valve, consider anatomic assessment of the severity of AS during surgery (palpation of the aortic valve) to decide about concomitant aortic valve replacement. When MS is associated with mild AS and mitral balloon valvuloplasty is planned, reassess the aortic valve after treatment of MS.

In ***severe MS with AI***, the hemodynamic effect of MS is exacerbated. In order to allow transmitral flow, LA pressure must increase in parallel to the rising LV diastolic pressure. On the other hand, the hemodynamic effect of AI is reduced. Overall, the patient has a higher LA pressure than a patient with isolated MS, but less LV dilatation and less elevated LVEDP than a patient with isolated AI. The severity assessment of MS or AI by catheterization and of AI by echo Doppler are not affected; MVA calculated by Doppler pressure half-time is falsely increased.

Combined *MR–AI* is the most poorly tolerated combination. The LV gets a *double volume load in diastole* and is more severely enlarged than with either lesion alone. MR is aggravated, and the regurgitant MR volume is more severe than with isolated MR, as LV volume is larger and LV afterload is higher. LV and LA filling pressures and volumes are more severely increased than with each lesion alone. The combination does not affect the echocardiographic or invasive assessment of either lesion. MR may be functional, secondary to LV dilatation; AVR alone often improves functional MR, but MV annuloplasty is usually warranted.

In combined ***severe AS–moderate-to-severe MR***, MR is often functional, related to the LV pressure overload, and often improves after aortic valve intervention. MR is worsened by AS, and AS severity may be underestimated by gradient assessment because of the low flow secondary to MR. If MR is severe, these patients often undergo mitral valve repair along with aortic valve replacement; if MR is moderate, mitral repair may be warranted when MR is organic rather than functional or when the surgical risk is low.

III. Radiation heart disease

Mediastinal radiation causes calcification of the cardiac valves and fibrous skeleton, with cardiac abnormalities becoming evident over 5–10 years, sometimes decades, after radiation. This seems related to a phenotypic shift of the interstitial cells toward osteoblastic activity. The pericardium is the cardiac structure that is most sensitive to radiation and is the most common site of clinical involvement (early acute pericarditis +/– effusion, then late constrictive pericarditis +/– effusion). The *aortic valve* (anterior) is the valve most commonly affected, AI or the combination of AS and AI being the most common radiation-induced valvular disease. MR is also common (second in frequency), followed by TR. The following valves are encountered from anterior-most to posterior-most (Figures 6.1 and 6.24): pulmonic, aortic, tricuspid, and mitral; yet the *left-sided valves* are more affected, likely because the higher left-sided pressure makes them more prone to injury. The early process consists of fibrosis of the aortic and mitral leaflets with subsequent valvular retraction and regurgitation. This is followed by progressive thickening and calcification of the valves but also the cardiac skeleton, valvular annuli, and mitroaortic curtain.[180–182] As opposed to rheumatic disease, the mitral leaflets' base is involved, but the mitral leaflets' tips and commissures are spared. Sometimes, the heavy calcium of the mitroaortic curtain protrudes into the LVOT and causes subvalvular AS, rather than true AS. In addition, radiation leads to: **(1)** ostial or diffuse CAD, mainly involving the left main, ostial RCA, or mid-LAD (anterior); **(2)** myocardial fibrosis with restrictive cardiomyopathy and sometimes mild LV systolic dysfunction; **(3)** conduction abnormalities in up to 75% of patients, especially RBBB (anterior structure), infranodal blocks, and sick sinus syndrome; and **(4)** heavily calcified porcelain aorta. All this complicates valvular surgery and limits its efficacy. The severe calcifications limit the size of the aortic prosthesis that can be implanted. In addition, interstitial lung disease, recurrent pleural effusions, and impaired skin and sternal healing complicate the operation.[18]

Senile mitral annular calcifications are usually posterior; hence, anterior mitral annular calcifications on the long-axis view suggest radiation heart disease. This corresponds to *calcification of the mitroaortic intervalvular fibrosa,* a hallmark of radiation heart disease.

8. PROSTHETIC VALVES

I. Bioprosthesis versus mechanical prosthesis

A surgical bioprosthesis is a trileaflet valve, made of porcine leaflets or bovine pericardial tissue, with 3 components: ring, struts bulging inside the valve, and leaflets arising from the struts. The ring and the struts are mounted over a metallic stent frame. The leaflets, per se, do not contain any metal. Less commonly, stentless porcine or homograft valves are used: they have a thin ring and thin struts and are only available for the aortic position. The modern stentless bioprostheses (e.g., Freestyle) have excellent mid-term but unclear long-term durability (Figures 6.28 and 6.29).

The percutaneous aortic prosthesis consists of leaflets mounted inside a thin stent frame without the bulky struts.

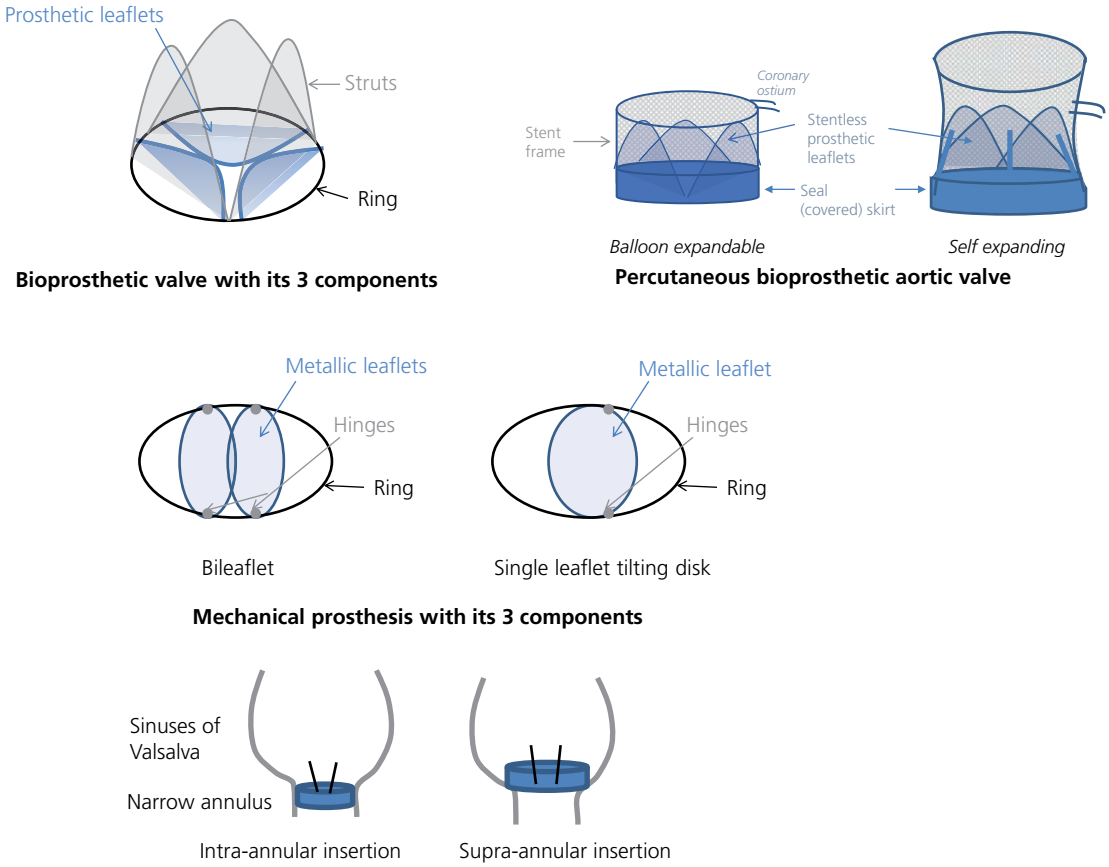

Figure 6.28 Prosthetic valves. Surgical bioprostheses typically contain metal in the ring and struts and are hence called stented bioprostheses. Stentless bioprostheses have very thin rings and struts without any metal. Percutaneous bioprostheses have no struts bulging inside the valve, hence the lower profile. In patients with a small aortic annulus, a prosthesis with a supra-annular design may be used and allows the insertion of a larger ring and a larger effective orifice area (the ring is sutured on top of the annulus rather than inside it); this design is available for bioprostheses and for bileaflet mechanical valves.
Note: the rings of prosthetic valves are ***circular and flat***, unlike the complex 3D native valve annuli (e.g., mitral and tricuspid annuli are saddle-shaped and elliptical). They appear oval here as they are viewed from the side.

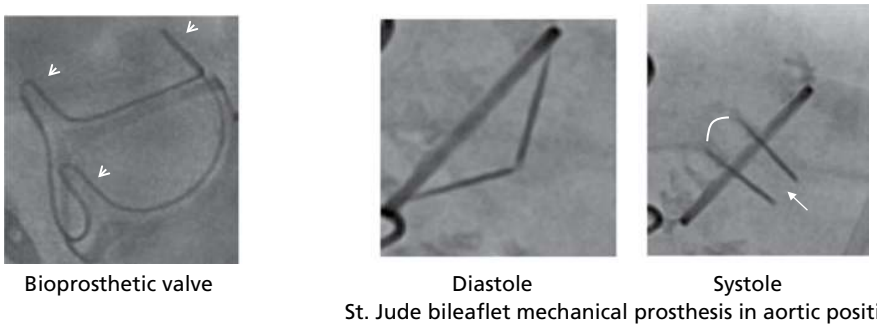

Figure 6.29 (Left image) Bioprosthetic valve as seen on fluoroscopy. The ring and the three struts (*arrowheads*) are mounted over a metallic stent frame, which explains their visualization on fluoroscopy. The leaflets, per se, do not contain any metal and are not visualized.
(Right images) St. Jude bileaflet valve with closed and open leaflets. Note the narrow angle between leaflets in systole (<15°, *arc*). The arrow indicates the direction of blood flow. A wider angle suggests leaflet obstruction.

A mechanical valve may be bileaflet (e.g., St. Jude, Carbomedics) or single-leaflet tilting disk (Medtronic-Hall). Only bileaflet valves are currently manufactured. Both mechanical and tissue prostheses may be attached to an aortic graft conduit for concomitant ascending aortic replacement (Bentall surgery).

The average longevity of a bioprosthetic valve is ~15 years, and 1/3 of bioprostheses degenerate in 10–15 years. Scarring/calcification and tears/perforations occur over time. Leaflet fibrosis and calcification may lead to stenosis but also regurgitation from leaflet retraction. Cuspal tears and perforations lead to regurgitation.

A bioprosthesis degenerates more quickly in younger patients (<65 years, high cardiac output) and in the mitral position (high valvular closing pressure). In patients older than 65 years, a bioprosthetic AVR has a risk of degeneration of only 10% over 15 years.[183] Atherosclerotic risk factors accelerate degeneration, while statin therapy may slow it (conflicting retrospective data).

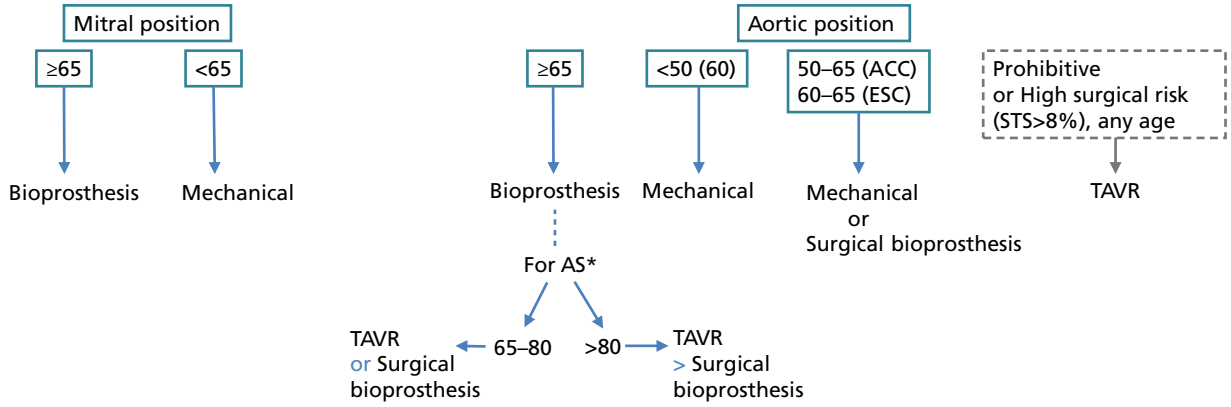

Figure 6.30 Choice of a mechanical prosthesis vs. bioprosthesis vs. TAVR, according to age. *ESC uses age cutoff ≥70 years and favorable coronary height, tricuspid morphology, and annulus features for endorsing TAVR over surgical bioprosthesis.

In aortic valve endocarditis, a cadaveric homograft is preferred as it allows antibiotic penetration. In case of a small scarred annulus, the lowest profile valves are the best option: TAVR or stentless bioprosthesis (e.g., Freestyle).

The one advantage of a bioprosthesis over a mechanical prosthesis is the lack of anticoagulation requirement. Thus, it is preferred in patients *of any age* with bleeding diathesis, compliance concerns, a desire to avoid anticoagulation, or a job with impact injuries (class I), and in women contemplating pregnancy (class IIa).

Regarding age (Figure 6.30):[18,19,184,185]

- **For mitral valve:** ***Age ≥65 years*** → bioprosthesis. ***Age < 65 years*** → mechanical prosthesis (class IIa)
- **For aortic valve:** ***Age ≥65 years*** → either TAVR or surgical bioprosthesis (**>80:** TAVR preferred)
  Age <50 years →mechanical prosthesis (class IIa)
  Age 50–65 years (per ACC) or 60–65 years (per ESC) → either mechanical prosthesis or surgical bioprosthesis (class IIa).

In the last age range, should bioprosthetic degeneration occur, valve-in-valve TAVR would be considered. A mechanical prosthesis may be favored in this last age range when anticoagulation is already used for other conditions, such as AF, but this has a weak recommendation (ESC class IIb), as interruption of anticoagulation is far less risky in AF compared to mechanical prosthesis, and NOAC is an option in AF patients receiving a bioprosthesis (vs. warfarin in mechanical prosthesis).

The stentless bioprosthesis, the TAVR bioprosthesis, and the bileaflet mechanical valve have the lowest profile (i.e., the largest orifice area and lowest gradient for the same ring size).

II. Determinants of valve degeneration and valve thrombosis; anticoagulation guidelines

A. Bioprosthetic valve degeneration depends on:

- *Cardiac output:* the higher stroke volume of the young active patient is associated with faster degeneration; also, the higher heart rate of the physically active patient means more frequent opening and closing of the valve, and thus more injury.[186]
- *Valvular closing pressure*, which is the difference between LV systolic pressure (e.g., 130 mmHg) and LA pressure (e.g., 10) for the mitral valve, or the difference between aortic diastolic pressure (e.g., 80) and LV diastolic pressure (e.g., 10) for the aortic valve. Thus, *the closing pressure is highest for the mitral valve, which degenerates the fastest, followed by the aortic valve, then the right-sided valves* (tricuspid then pulmonic valve). A bioprosthesis is often long-lasting in the right-sided position.
- *Atherosclerotic* risk factors and *immunological* response. The latter is more marked in young patients.

B. Prosthetic valve thrombosis depends on:

Valvular closing pressure. The low closing pressure on the right side explains the high thrombotic risk of prosthetic valves in this position, *another reason why bioprosthesis may be favored*. Despite a higher closing pressure, the mitral valve has a higher thrombotic risk than the aortic valve, because of its proximity to the diseased, sluggish LA, prone to microthrombus formation.

Anticoagulation goals[18,19]

- Aortic mechanical prosthesis that is bileaflet or current-generation single-leaflet tilting disk (e.g., Medtronic-Hall), without thromboembolic high-risk factors: warfarin with an INR goal of 2–3. Thromboembolic risk is high with any of the following four factors: history of embolic events, AF, LV dysfunction, thrombophilia. ESC recommends starting warfarin +/– heparin bridging within 24 hours of surgery (yet heparin is commonly delayed 2–3 days).
- Mitral mechanical prosthesis or aortic mechanical prosthesis outside the exception noted above: warfarin with an INR goal of 2.5–3.5. The addition of aspirin reduced stroke and mortality in old studies using old prostheses. Aspirin is not routinely recommended by ESC nor ACC (class II in case of associated atherosclerotic disease and low bleeding risk).
- Bioprosthesis without thromboembolic high-risk factors: consider aspirin 81 mg indefinitely (class IIa ACC, class IIb ESC). Give warfarin for 3–6 months postoperatively, until the sewing cuff endothelializes, in low-bleeding-risk patients (*class IIa* recommendation). Anticoagulation for the first 3–6 months was associated with a mortality reduction in a large registry.[187]
- Bioprosthesis with AF: NOAC is preferred over warfarin beyond 3 months by ESC (class IIa) and may even be considered sooner (per ESC and RIVER trial).[188]

- Stroke despite appropriate anticoagulation, mechanical valve: increase the level of anticoagulation, i.e., increase the INR goal from 2–3 to 2.5–3.5, or from 2.5–3.5 to 3.5–4.5. Also, add aspirin if not used previously.
- Stroke in a patient with bioprosthesis: assess for subtle leaflet thrombosis by TEE or CT, then consider warfarin or NOAC.
- Mitral valve repair: aspirin lifelong, warfarin for 3 months postoperatively.
- TAVR: lifelong aspirin only. The addition of clopidogrel is not beneficial (Popular TAVI trial) and ESC recommends against it (class III). *If TAVR patient has AF*: warfarin or NOAC, without any antiplatelet.[189]

Correction of excessive anticoagulation

- In case of a high INR (4.5–10) without bleeding, hold warfarin. If INR > 10, give oral vitamin K 1–2.5 mg.
- In case of bleeding or emergent surgery, give prothrombin complex concentrate or less favorably, fresh frozen plasma (ACC).
- Prothrombin complex is short acting (12–24 hours), and fresh frozen plasma is even shorter acting (~8 hours). To sustain INR reversal in life-threatening bleeds, a high dose of vitamin K may be used even with a mechanical prosthesis (10 mg oral or IV, ACC and ESC). In controlled bleeds, this high dose is often avoided because it may overcorrect to a hypercoagulable state. A 1.0–2.5 mg oral or IV dose of vitamin K is safe.

Bridging for a planned procedure

- Hold warfarin 4–5 days before the procedure; start subcutaneous LMWH or IV unfractionated heparin when INR falls below 2 (typically 2 days after warfarin discontinuation, after omitting 2 doses of warfarin), and give the last LMWH dose 24 hours before the procedure. Restart LMWH as soon as possible afterward (typically 24–48 hours), and restart warfarin on the day of the procedure. LMWH is also an acceptable alternative to UFH in pregnancy (*class I*). For patients with bileaflet mechanical AVR without high-risk factors, bridging is not necessary per ACC; warfarin is stopped 2–4 days before and resumed 24 hours after the procedure. However, ESC is less in favor (IIb) of the latter no-bridging strategy.
- For minor procedures (dental extractions, cataract, skin procedures), warfarin is not interrupted (or partial 2-day interruption as suggested by ACCP guidelines).

III. Particular cases: women who wish to become pregnant and dialysis patients

During pregnancy, the hypercoagulable state increases the risk of mechanical valve thromboembolic complications even with appropriate anticoagulation. The maternal mortality is 1–4% in patients with mechanical valves.[18,19] Moreover, warfarin has fetal risks between 6 and 12 weeks and has to be replaced with UFH or LMWH during this period. LMWH and UFH are not as effective as warfarin in pregnancy; most valvular thromboembolic events in pregnancy occur while the mother is receiving heparin. Yet even with warfarin anticoagulation throughout pregnancy, the risk of valve thrombosis is 4% (vs. 9% if heparin is used between 6 and 12 weeks).[190] Therefore, knowing that the risk associated with valvular reoperation is low and only slightly higher than that of the first operation, bioprosthesis may be the best option in women who wish to become pregnant, despite the rapid bioprosthetic degeneration at this age (possibly accelerated by the high cardiac output of pregnancy) (ESC and ACC, class IIa).[19] Pre-pregnancy percutaneous valvuloplasty may be the best option for patients with non-calcified, severe AS, whether symptomatic or not. For MR, mitral valve repair is performed if possible. Pregnancy before valvular surgery is an option in patients with severe asymptomatic AI or MR and normal EF/ LV dimensions, after confirming the asymptomatic status and the normal PA pressure by exercise testing. Symptomatic patients (class I), or asymptomatic patients with severe AS or MS (class IIa), require an intervention before pregnancy.

Dialysis patients have a high mortality following valve replacement, whether with mechanical or biological prostheses. Although bioprosthesis degenerates faster in this population, it seems a reasonable choice given the high bleeding risk and the limited survival, except in the very young (<35 years).

IV. Echocardiographic follow-up of prosthetic valves

Postoperative echo should be performed 6 weeks postoperatively to obtain baseline function and gradient across the prosthesis. This baseline gradient provides a reference in case of any future deterioration. Follow-up echo is indicated at 6–12 months in patients with severe LV dysfunction to assess for improvement in LV size and function. Otherwise, echo is only indicated if there is a change in symptoms.

Routine echo is not indicated for a mechanical prosthesis, not even years after valve replacement. Conversely, yearly echo surveillance of bioprostheses is reasonable after 10 years, or 5 years in young patients, to detect severe deterioration early on before LV dysfunction or HF occurs (*class IIa*). After TAVR, more stringent echo surveillance is recommended: before discharge, at 30 days, then yearly.

After mitral valve repair, echo is recommended at 1 year then every 2–3 years.

V. Complications

(rate, ~2–3% per year)

A. Degeneration

Degeneration occurs with bioprosthetic valves and leads to valvular stenosis or regurgitation. Reoperation is necessary once symptoms develop (*class I*), or even in asymptomatic patients with severe regurgitant dysfunction (*class IIa*, ESC and ACC guidelines), or severe stenotic dysfunction (*class IIa*, ESC). Since dysfunction is progressive, sometimes suddenly so with further leaflet tearing, early reoperation at a stable stage reduces the risk of this second operation and thus may be justified. In fact, the risk associated with reoperation in a stable patient is only slightly higher than the risk of the first operation (ESC).[19] Treating bioprosthetic aortic or mitral valve failure by transcatheter valve-in-valve implantation is feasible and is an alternative in high-risk patients.

B. Prosthetic valve thromboembolism and thrombosis

a. ***Thromboembolic events:*** without anticoagulation, the risk of thromboembolic events with a mechanical prosthesis is 8% per year, but up to 20% in the highest-risk patient, e.g., MVR with AF or history of embolic events. Anticoagulation reduces the risk to 1–2% per year. Many thromboembolic events result from an intermittently subtherapeutic INR, but some of them occur despite a therapeutic INR.

b. ***Major mechanical valve thrombosis:*** 0.2–0.5% per year. It leads to a stenotic murmur and a muffled closing click on exam, and is diagnosed by analyzing leaflet motion on TEE, gated CT, or fluoroscopy. Urgent initial treatment with *either thrombolysis or surgery is recommended (class I)*. Surgery, which consists of thrombus removal or prosthesis replacement, is somewhat favored in patients with a large thrombosis (> 0.8 cm^2 or 10 mm) or functional class IV; thrombolysis is favored when functional class is I–III and thrombus is <0.8 cm^2, or when surgical risk is high, e.g., when the patient has shock requiring multiple vasopressors. Historically, thrombolysis was associated with a high thrombo-embolization rate (13%) and bleeding risk (6% major bleeding, 3% intracranial hemorrhage) when administered in high dose and quickly (100 mg of r-tPA over 2 hours).[191] However, a TEE-guided *slow infusion of r-tPA* is associated with a higher success rate (>90%) and a lower risk of embolization (<2%) and major bleeding (<2%) (r-tPA administered as 25 mg over 6 or 25 hours; may be repeated daily, up to 6 times, in case of residual thrombus size >25% or residual obstruction on TEE).[192,193]

Alternatively, in a minimally symptomatic patient with a small clot and recent inadequate anticoagulation, intravenous heparin infusion may be tried for a few days before proceeding with thrombolysis.

Thrombolysis is first-line therapy for right-sided thrombosis, even if it is large or symptoms are advanced, as the success rate is high and systemic embolization is unusual.

c. Subclinical bioprosthetic leaflet thrombosis (SLT): SLT is seen with 4% of surgical bioprostheses and 13–30% of TAVR valves on CT scans performed a few months to a year postoperatively.[194–197] Subclinical thrombosis is characterized on CT by hypoattenuated leaflet thickening (HALT) +/– reduced leaflet motion (RLM) of variable degree. Most subclinical thromboses are asymptomatic incidental findings without significant rise in aortic gradient, and depending on the degree of RLM and aortic gradient rise, they may not influence mortality.[194,195] Spontaneous resolution within 3–12 months occurs in 35–54% of patients without any anticoagulation.[194] Subclinical thrombosis may have 3 consequences: (1) early valve dysfunction defined as a rise of aortic pressure gradient by ≥10 mmHg or to ≥20 mmHg (~20% of SLTs); (2) clinical valve thrombosis with thromboembolic events in up to 8% of SLTs; (3) clinical valve thrombosis with progressive HF in up to 8% of SLTs.[195–197] Also, *long-term valve durability* may be affected (faster degeneration).[198] In practice, SLT is often diagnosed after echo shows increased gradient or cusp thickening or immobility, at which time CT or 3D TEE is done to confirm HALT and RLM; hence SLTs encountered in practice are higher-risk SLTs.

Leaflet thrombosis is far less common with anticoagulant therapy than aspirin or DAPT; it resolves within ~3 months in nearly all patients who switch to anticoagulant therapy (warfarin and NOAC are likely similarly effective).[194,196,197] However, the systematic use of anticoagulation after TAVR is not recommended: GALILEO and ATLANTIS trials showed that in patients with a mean age of 80, routine anticoagulation (rivaroxaban or apixaban vs. antiplatelets) increased mortality and major cardiovascular events despite reducing leaflet thrombosis.[199] Even the combination of aspirin and clopidogrel did not reduce thrombotic events compared to aspirin alone.[189]

d. ***Treatment of SLT:***[194,200] (i) Anticoagulation is suggested if bleeding risk is low (ACC and ESC class IIa), using either NOAC or warfarin (ESC). (ii) Alternatively, anticoagulation is deferred in favor of clinical and echo/gradient surveillance every 3–6 months, +/– CT is repeated at 3–6 months to check for possible SLT resolution. (iii) Anticoagulation (warfarin or NOAC) is more readily considered for severe RLM on CT, incremental transprosthetic gradients, or the presence of vague equivocal symptoms of dyspnea or fatigue. Anticoagulation, if chosen, is given at least until CT shows resolution of HALT, with consideration of repeat CT 3–6 months later, as ~20+% may have recurrence. (iv) Anticoagulation with *warfarin* (not NOAC) is absolutely indicated for clinical thrombosis and considered indefinitely (ESC), with consideration of thrombolysis if thrombus persists on CT.

C. Paraprosthetic leak

With surgical valves, paraprosthetic leaks may be due to loose sutures or heavy annular calcium that prevents complete prosthetic apposition and suturing, potentially leading to late suture dehiscence.[201] They are observed with both mechanical and bioprosthetic valves. Paravalvular leaks are rarely severe and symptomatic (~1.5%); they may appear early postoperatively (loose suture) or months or years later if a suture suddenly dehisces from a calcified annulus, if early paravalvular channels enlarge and mature with the continuous flow, or if endocarditis develops (~50% of late leaks in some series).[201,202] Moderate/severe paravalvular leaks are more common after TAVR (~2–3%).

Valvular dehiscence is an extreme form of paravalvular leak that involves >30–40% of the sewing ring circumference. It manifests as a "rocking" movement of the prosthesis on echo and fluoroscopy.

Small, asymptomatic leaks, i.e., involving <10% of the sewing ring, are occasionally seen after surgical valve replacement on postoperative TEE (<10%) but are more common after TAVR (~25%). Those decrease or resolve in the ensuing days or months with the healing process.

Severe hemolysis may be seen with large paravalvular leaks but also with central leaks of degenerated bioprostheses or, rarely, with small, high-jet leaks even if the regurgitation is not severe.[203] Iron replacement may be an effective therapy.

Repair is indicated for a severe paraprosthetic leak associated with HF or severe hemolysis requiring repeated transfusion (fortunately, the leak and the chronic hemolysis are often mild). The leak is repaired *percutaneously*, via plug insertion, or *surgically*, via additional sutures or valvular re-replacement. A severe paravalvular leak without clear HF or symptoms does not, per se, have a clear indication for repair;[19] *yet, even moderate leaks are associated with a late increase in mortality and progressive HF, particularly if the underlying LV is abnormal, which may justify early repair before HF occurs; this is true for TAVR and surgical valves*.

D. Endocarditis

(~0.5% per year, the frequency being highest in the first 6–12 months)

a. Early endocarditis (<60 days to 1 year postoperatively, usually a complication of valve surgery): *Staphylococcus coagulase*–negative and –positive. Second in frequency are enterococcal and gram-negative infections. With TAVR, *Enterococcus* (from the moist femoral area) and *Staphylococcus aureus* are the most common organisms.

b. Late endocarditis (>1 year postoperatively): the microbiology resembles that of native valve endocarditis. *Streptococcus* species (*viridians*, *bovis*) are the most common, followed by staphylococci and enteroccoci. Coagulase-negative staphylococcus may still be seen, especially after central line placement.

E. Patient/prosthesis mismatch (PPM)

In this case, the prosthesis is small and obstructive. This occurs more commonly in patients with a small scarred mitral or aortic annulus, forcing the surgeon to place a small prosthesis. PPM is defined as an indexed prosthetic effective orifice area (EOA) ≤ 0.85 cm^2/m^2 in the aortic position and ≤ 1.2 cm^2/m^2 in the mitral position. While classically described with aortic prostheses, it is actually seen with up to ~30–50% of both mitral and aortic prostheses, albeit less severe in the mitral position.[183,204–206] This is more likely to occur with valvular replacement performed for aortic or mitral stenosis rather than regurgitation, as the annulus is usually scarred in these cases.

These patients have a relatively stenotic prosthesis with a pressure gradient across the prosthesis at rest and much more so with exercise. They often do well in the intermediate term but have a reduced functional capacity and an impaired long-term survival and prognosis, with frequent persistence of LV dysfunction, hypertrophy, or pulmonary hypertension. PPM has a particular impact on young active patients or patients with pre-existing LV dysfunction, especially when in the severe range (aortic EOA <0.65 cm^2/m^2, mitral EOA <0.9 cm^2/m^2); the effect of moderate PPM is significant but much less striking.[204,205]

PPM may be prevented by avoiding valves ≤21 mm in the aortic position, and ≤27 mm in the mitral position, if possible, and accounting for the patient's body size. Charts correlating the in vitro prosthetic diameter of each brand with the effective orifice area are available. For example, a 23 mm bioprosthesis in the aortic position has an EOA of 1.4 ± 0.3 cm^2; for a patient with a BSA of 2 m^2, the indexed EOA is 0.7 cm^2/m^2, consistent with PPM. A 25 mm bioprosthesis (EOA 1.7 cm^2), or a different prosthesis, such as a TAVR prosthesis or a mechanical prosthesis (0.4 cm^2 larger EOA), should be selected for this patient.[183] *Supra-annular implantation is another alternative*. TAVR valves only have a thin stent frame without sewing ring and without stented struts, and thus have larger orifice areas and less PPM than surgical bioprostheses.

F. Mechanical valve obstruction

Mechanical valve obstruction occurs at a frequency of 0.5% per year. It leads to the loss of the prosthetic click on exam, and to HF and hemodynamic compromise clinically. Causes (all these processes may also be seen with a bioprosthetic valve, at a lower frequency):

a. Pannus formation = fibrosis that grows from the endocardium surrounding the sewing ring and extends onto the prosthesis. Compared to a thrombus, a pannus is smaller and sometimes missed by TEE (mean size 1 cm), symptoms develop more progressively (over a month or more), and anticoagulation is usually adequate.
b. Thrombosis (more common than pannus formation).
c. Early postoperative prosthetic obstruction may be due to severe annular calcification that impinges on leaflet motion.

G. Differential diagnosis of a high transvalvular prosthetic gradient (see also Chapter 33, Section IX)

A high gradient, up to a certain degree, may be seen with a normally functioning prosthetic valve or may be due to 4 states:

a. prosthetic obstruction (thrombus, pannus, degenerative bioprosthesis)
b. patient/prothesis mismatch
c. pressure recovery in the case of a bileaflet valve
d. high flow state, subvalvular obstruction, or significant regurgitation across the valve

On the other hand, a falsely low gradient, within the normal range for a prosthesis, may be seen in patients with prosthetic obstruction but low-flow state. The following ideas help establish the diagnosis:[19,183,207]

1. A velocity of up to 3 m/s across the aortic prosthesis (mean gradient up to 20 mmHg) and 1.9 m/s across the mitral prosthesis (gradient up to 6 mmHg) is within the normal range unless the cardiac output is low. For the aortic valve, an early peaking, triangular rather than round aortic Doppler with a time-to-peak <100 ms (acceleration time) also suggests no obstruction. For the mitral valve, a fast E decay with a low PHT <130 ms suggests no obstruction.
2. A high transaortic velocity with a high LVOT velocity and a normal dimensionless index (LVOT VTI/aortic valve VTI), >0.30, usually implies a high-flow state, an associated subvalvular obstruction, or prosthetic aortic regurgitation. High mitral velocity with a normal DI (mitral VTI/LVOT VTI) <2.2 implies a high-flow state. The calculated EOA would be within normal range.*
3. A valve with a small manufacturer-reference EOA that results in a low indexed EOA for the patient's size is diagnostic **of *PPM, which is by far the most common cause of a high transprosthetic gradient.*** Dimensionless index and Doppler envelopes are often normal in PPM, unless PPM is very severe. In PPM, *the small calculated EOA matches the manufacturer's EOA*.
4. Outside the above conditions, the patient may have a true obstruction or, in the case of a bileaflet valve, pressure recovery phenomenon. The smaller central orifice of the bileaflet valve gives rise to a high-velocity jet; this corresponds to a localized pressure drop that is largely recovered once the central flow joins flow originating from the 2 lateral orifices.

The analysis of leaflet motion and structure on *TEE* allows differentiation between a structurally normal prosthesis and a true obstruction that requires operative correction. TEE often demonstrates abnormal leaflet motion and may show a large thrombus. Conversely, a high trans-prosthetic gradient with a normal leaflet motion corresponds to a normally functioning valve with a high velocity (PPM, pressure recovery, high-flow state). Also, *cinefluoroscopy* is a very helpful adjunctive technique that allows analysis of the mechanical prosthesis leaflet's excursion (to assess stenosis) and the prosthesis seating (to assess dehiscence and regurgitation). *Cardiac CT* (gated cine-CT) is an additional diagnostic modality.

---

*A decline in aortic DI ≥0.2 or an increase in mitral DI ≥0.8 compared to baseline echo suggests severe valvular dysfunction (0.1 and 0.4 correspond to moderate dysfunction). Mean gradient ≥30 mmHg for the aortic valve (or a rise of ≥20 mmHg) and mean gradient ≥10 mmHg for the mitral valve suggest severe dysfunction.

9. AUSCULTATION AND SUMMARY IDEAS

I. Auscultation and other physical findings (see Table 6.5)

A. MR murmur

- Blowing, high-pitched holosystolic murmur at the apex. S_3 indicates severe MR.
- In posterior mitral leaflet prolapse, the regurgitant jet is directed anteriorly and radiates to the aorta. In anterior leaflet prolapse or posterior leaflet tethering (ischemic MR), the jet is directed posteriorly and radiates to the axilla, back, and sometimes skull. MR murmur does not radiate to the neck.
- The murmur could be end-systolic in mitral valve prolapse when MR is not severe yet. It becomes holosystolic with worsening of MR severity or chordal rupture. In fact, a ***murmur that is only end-systolic argues against severe MR***.
- A mid-systolic click is heard after S_1 in mitral valve prolapse, sometimes simulating gallop or S_1 splitting.
- May become musical ("seagull cry" murmur) in case of a ruptured chorda that gets "shaken" by the regurgitant flow like a guitar chord.
- In acute MR or MR with severe LV dysfunction, the murmur may be soft or absent because of diminished LV–LA pressure gradient and flow. It also tends to be early-systolic only: left atrial pressure being so high, LV–LA pressure gradient diminishes quickly (large V wave).

B. MS murmur

- Low-pitched, diastolic rumble heard at the apex. It is best heard in mid-diastole. When it extends to late diastole, it suggests the persistence of gradient in late diastole and, thus, severe MS. It is best heard in a left lateral decubitus position that puts the apex against the chest wall, and *unveiled by exercise or leg raising*.
- While the diastolic rumble may be difficult to hear, a *loud S_1* is the most characteristic finding in some patients (see explanation under paragraph L). S_1 is loud when the leaflets are pliable, and becomes muffled later on, as the leaflets fully immobilize. A mitral valve opening snap is also heard with pliable leaflets.
- Severe MS is characterized by: (i) short interval between S_2 and the opening snap; (ii) long MS murmur. The higher the LA pressure, the earlier the mitral valve opens during LV relaxation, which leads to a short S_2–opening snap interval (<70–100 ms).
- A diastolic mitral rumble may also result from the functional mitral obstruction caused by the regurgitant flow of AI (Austin–Flint murmur), or from the high flow recrossing the mitral valve in severe MR.

C. AS murmur

- Harsh, crescendo–decrescendo mid-systolic murmur best heard at the aortic site, which is at the right upper sternal border (RUSB), as the aorta is on the right, while the PA is on the left.
- Radiates to the carotids; and may radiate to the apex and be loudest at the apex. High-frequency vibrations may get transmitted through the LV cavity and lead to a predominant apical, "musical" murmur. Aortic ejection click may be heard with bicuspid valve in early systole.
- ***Signs of severe AS:***
  - Reduced, paradoxically split, or absent aortic component of S_2, i.e., reduced S_2 at the RUSB and apex **(S_2<<S_1)**. S_2 (P_2) continues to be heard at the LUSB, and may even ↑ in decompensated AS with PH. ***A normal aortic component of S_2 reliably excludes severe AS***.
  - Carotid upstroke characterized by pulsus parvus (weak) and tardus (slow and delayed). The carotid upstroke may, however, remain brisk in elderly patients with stiff arteries.
  - Murmur peaks late in systole and is prolonged.

D. AI murmur

- Blowing diastolic murmur best heard in a sitting/leaning-forward position that puts the aorta against the chest wall, *particularly at end-expiration*. Since the retrograde aortic flow goes to the left, the murmur is best heard at the left upper sternal border (LUSB) in intrinsic valve disease. As opposed to AI, the turbulent flow of AS is directed toward the aorta (right), hence the AS murmur is best heard at the RUSB. Only when AI is secondary to aortic root disease, which is on the right side of the chest, is the AI murmur best heard at the RUSB.
- ↓ S_1 with LV enlargement, ↓ S_2 (A_2).

Table 6.5 Auscultation features.

	Systolic							Diastolic[a]		Continuous
	MR	**TR**	**AS**	**HOCM**	**VSD**	**PS**	**CoA**	**AI**	**MS**	**PDA**
Duration	Holo (may be early in ischemic MR, late in MVP)	Holo	Mid	Mid	Holo	Mid	Mid	Holo, or early	Mid, may extend to late	Continuous, peak at S_2
Location	Apex	LLSB	RUSB	LLSB	LLSB	LUSB	LUSB	LUSB	Apex	Left infraclavicular
Quality	Blowing	Blowing	Harsh	Harsh	Harsh	Harsh	Harsh	Blowing	Low pitch	Machinery
Radiation	Axilla + back vs. base	–	Carotids, ± apex	–	–	–	Back	–	–	–

[a] PR also leads to a diastolic murmur that is mainly heard if pulmonary hypertension is present.
LLSB, left lower sternal border; LUSB, left upper sternal border; RUSB, right upper sternal border.

- **Duration of the murmur correlates with the severity of AI. Pandiastolic murmur = severe AI:** this is very specific, but in acute AI or in the case of a severely decompensated LV, the murmur may be soft and short as aortic and LV pressures ~equalize in end-diastole.
- Pulse abnormalities in *chronic severe AI*:
  - A wide pulse pressure is seen with chronic severe AI, reflecting the large increase in stroke volume (e.g., 170/70). In acute AI, while the diastolic pressure is low, the LV is small and the stroke volume is low, which prevents the pulse pressure from being particularly wide (e.g., 90/40). *A wide pulse pressure is very sensitive for the diagnosis of chronic severe AI. In fact, a normal pulse pressure almost excludes chronic severe AI*. However, a wide pulse pressure is not a specific finding and may be seen in patients with stiff non-compliant arteries, wherein the systolic pressure quickly rises and falls, and in disease states with diastolic runoff (PDA, AV fistula). Rarely, the pulse pressure may not be wide in chronic severe AI with severely low EF, an advanced stage where the total stroke volume is reduced.
  - The pulse may be double-peaked (bisferiens) as the large stroke volume causes a large percussion wave followed by aftershock waves that get reflected through the peripheral arteries. This bisferiens pulse may also be seen in any high-output state and in HOCM.

E. TR murmur

- Holosystolic murmur heard at the left lower sternal border (fourth intercostal space). The murmur may extend and become prominent at the apex if the RV is severely enlarged, or may extend below the xiphoid in patients with COPD pushing the heart down.
- Loudness is related to the degree of pulmonary hypertension (murmur is mild and short in primary TR).
- The murmur increases in intensity with inspiration (Carvallo's sign).
- Associated with pulsatile hepatomegaly and large and prolonged V waves on JVP. These V waves mimic the carotid pulsations. ***In fact, a JVP that mimics a carotid pulse is a ventricularized JVP, pathognomonic of TR.***

F. HOCM murmur

- Harsh, mid-systolic, crescendo–decrescendo murmur, which may simulate AS but predominates at the left sternal border (as opposed to *AS:* RUSB; *MR:* apex).
- May radiate to the base but, in contrast to AS, ***does not radiate to the carotids***.
- Carotid pulse is brisk (in contrast with severe AS, which weakens the carotid upstroke) and double-peaked (spike and dome).
- Usually associated with another type of murmur at the apex, a mid-to-late systolic MR murmur related to SAM of the mitral valve.
- Varies with maneuvers (paragraph J).

G. Patent ductus arteriosus

- Continuous, crescendo–decrescendo murmur that peaks around S_2 and is loudest at the left infraclavicular region. The murmur becomes softer when severe pulmonary hypertension develops.
- ***A continuous murmur is different from a systolo-diastolic murmur***. In the latter, two peaks, one systolic and one diastolic, are heard. A systolo-diastolic murmur may be heard with combined AS/AI.
- A continuous murmur that peaks anywhere outside the LUSB suggests another fistula: coronary fistula to the RA/RV/PA, ruptured sinus of Valsalva aneurysm that communicates with the RA or RV.

H. Other pathological murmurs

- *VSD*: harsh holosystolic murmur at the left lower sternal border (in contrast to AS: harsh mid-systolic murmur).
- *ASD:* no murmur is heard across the low-pressure ASD shunt, but the increased right-sided flow translates into an outflow tract murmur that may mimic PS.
- *Pulmonic stenosis:* mid-systolic murmur at the LUSB with early systolic click. *In inspiration, the murmur increases while the click diminishes*. In inspiration, the RV diastolic pressure increases and equalizes with the PA diastolic pressure, leading to premature soft opening of the pulmonic valve in diastole, which reduces the opening click. P_2 decreases in severe PS (like A_2 in severe AS).
- *Coarctation of the aorta:* mid-systolic murmur at the LUSB (≠ AS), radiates to the back through the intercostal collateral flow.
- *Pulmonary regurgitation:* holodiastolic murmur is heard at the LUSB *mainly when pulmonary hypertension is present*, i.e., when there is a high gradient between PA and RV (Graham Steell). This diastolic murmur increases with inspiration.
- *Peripheral pulmonary artery stenosis* (e.g., associated with supravalvular AS): murmur is heard at the back.

I. Benign murmurs

- Benign murmurs are mid-systolic.
- In children or young adults, they are due to vibrations across the flexible pulmonic valve leaflets or the pulmonary trunk and are best heard at the LUSB. They may also be due to vibrations across the aortic leaflets and are heard at the mid-left precordium (Still's murmur). Those vibratory murmurs are musical and sound like a "guitar string."
- In older patients, a benign murmur is due to aortic valve sclerosis. Even if the leaflets open fully, fibrocalcific deposits create turbulence leading to a murmur. This murmur does not radiate to the carotids.
- A murmur is considered benign at any age, especially young age, when it is mid-systolic (not early systolic or holosystolic), grade 1 or 2/6 in loudness, without any associated clinical findings, without radiation to the carotids, and without worsening during Valsalva. Being a flow murmur, it may improve with the reduction of ventricular filling upon sitting, standing, or Valsalva. Echo is not needed in these cases. Conversely, a diastolic murmur is not benign and always requires echo assessment.

J. Effects of different maneuvers on murmurs

1. All right-sided murmurs increase with inspiration, except the systolic ejection click of pulmonic stenosis, which becomes softer with inspiration.

2. A reduction in LV volume further narrows the LVOT in HOCM, and further "squeezes up" the prolapsed mitral leaflet(s) in MVP. LV volume is reduced with a reduction in preload or afterload.

Thus, the straining phase of Valsalva's maneuver, standing, or NTG:
- ↓venous return and ↓ LV volume.
- ↑ HOCM murmur, ↑ MVP murmur (+ the MVP click moves closer to S_1) and ↓ all other valvular murmurs (AS, severe MR).

3. Handgrip, squatting:
   - ↑ afterload.
   - ↓ HOCM murmur, ↓ MVP murmur (+ the MVP click moves further away from S_1), and ↑ regurgitant and VSD murmurs. *If MVP has progressed to severe MR, the murmur would increase with handgrip*.
4. ***A* murmur that increases after a pause** (as in the first beat after a PVC) **is typical of HOCM and AS.** *The pulse decreases after a pause in HOCM (Brockenbrough sign), whereas it increases after a pause in AS*. **MR murmur does not intensify after a pause (like VSD),** as DBP ↓ and forward LV flow into the aorta relatively increases.
5. ***Dynamic MR murmur increases with leg raising and mild exercise***. Same applies to ***MS murmur***.

K. Second heart sound (S_2) abnormalities and splits

- The aortic valve normally closes before the pulmonic valve: the low pulmonary resistance allows blood to continue flowing forward even after RV contraction stops, longer than what the high systemic resistance allows. Thus, the aortic component A_2 (RUSB) usually occurs before the pulmonic component P_2 (LUSB) (***A_2 then P_2***). A_2 is normally the loudest and is the second heart sound heard across all the precordium. P_2 is mainly heard at the LUSB. Inspiration further increases RV volume and RV ejection time and delays P_2. Thus, a *split S_2 can be normally heard during inspiration, especially in young patients*, and is best heard at the LUSB. S_2 is not usually split in older patients, as the delayed LV relaxation delays valve closure, i.e., A_2. Split abnormalities are generally best heard at the LUSB.
- A *persistently* split S_2 that is worse with inspiration suggests right-sided pathologies and is heard at the LUSB: RV failure, including pulmonary HTN associated with RV failure, PE, RBBB.
- A loud P_2 (on the left sternal border) suggests pulmonary hypertension and translates into a loud P_2 that extends throughout the precordium. Practically, in a patient with HF, a loud S_2 reflects a loud P_2 and implies ***decompensated HF,*** particularly when ***S_2 is louder than S_1 at the LLSB + apex (PA >50 mmHg)***. *S_2 is normally louder than S_1 at the upper sternal area, not the apex*.
- A *paradoxically* split S_2, i.e., a split S_2 that is worse with expiration, suggests a pulmonic valve closure before the aortic valve closure: LBBB, RV pacemaker, advanced AS, or advanced HOCM.
- A fixed-split S_2 suggests ASD. Inspiration increases right-sided flow, which leads to a proportionate reduction in the left-to-right shunt and an unchanged overall right-sided flow. The right and left ventricular outputs remain unchanged with inspiration.
- A loud A_2 (on the right sternal border) suggests systemic hypertension.
- ***A* diffusely faint S_2 *with* $S_2 < S_1$ *at the RUSB suggests AS.***

L. S_1, S_3, S_4

- S_1 may be soft in case of a depressed LV function or ***loud in case of a short PR interval, MS, or tachycardia***:
  - When PR is short, ventricular contraction may occur before the end of atrial contraction, at a time when the mitral leaflets are wide open and would close more vigorously. In MS, the persistent LA–LV pressure gradient in late diastole keeps the mitral leaflets open until the ventricle contracts, which shuts them vigorously.
  - S_1 is variable in intensity in AF and in AV dissociation. If S_1 is variable in intensity and the patient has a regular tachycardia, the diagnosis is VT; if the patient is bradycardic, the diagnosis is AV block.
- S_3 occurs during the rapid diastolic filling phase and implies that LA pressure is elevated and forcefully fills the LV ("pusher" effect). This corresponds to a decompensated LV systolic or diastolic failure. S_3 may, however, be heard in severe MR without ↑ LA pressure, as a result of ↑ flow. It may also be normally heard in patients <40 years old and during pregnancy, wherein the flow is high and LV is "super-compliant" and forcefully "sucks" blood from a normal-pressure LA.
- S_4 corresponds to an elevated LV end-diastolic pressure (LVEDP), i.e., elevated LV pressure after A wave. LV compliance is overwhelmed, which leads to a striking rise of LV pressure after atrial contraction. S_4 is heard in any systolic or diastolic LV dysfunction (e.g., LVH with abnormal relaxation, active ischemia, dilated cardiomyopathy). LVEDP generally approximates mean LA pressure, yet in compensated LV dysfunction, LVEDP may be elevated (= S_4) with a normal mean LA pressure. Thus, S_4 predicts an increase in LA pressure, but less reliably than S_3, and the increase in LA pressure with isolated S_4 is less than that seen with S_3. Approximately 35% of patients with S_4 have normal LA pressure and compensated HF.
- ***S_4 cannot be present in AF. S_3 and S_4 cannot be present in severe MS, as MS restricts diastolic LV filling.***
- ***Both S_3 and S_4 are dull, muffled, low-pitch sounds heard at the apex in left decubitus*** (unlike the crisp sounds of split S_2, MVP click, and bicuspid AoV click).

M. Precordial palpation of the apical impulse in the left lateral decubitus position: point of maximal impulse (PMI)

The PMI is normally located at or medial to the mid-clavicular line in the sub-mammary space. PMI is normally smaller than the size of a quarter. The PMI is *enlarged and displaced laterally* and downward in LV dilatation (systolic HF, AI). A *double bulge* (early then late systolic bulge), or sometimes triple bulge, implies HOCM. A *forceful PMI* that is sustained throughout systole implies LV hypertrophy; the apex is not necessarily displaced laterally or enlarged. A *hyperkinetic PMI* implies a large stroke volume and is seen in severe AI and MR. In severe MR, a sucking thrill may be felt after the initial systolic PMI bulge.

Acute AI/MR, all severe valvular disorders, and low cardiac output states may be associated with a paradoxical reduction of murmur intensity.

In any valvular disease, some common associated signs indicate complicated, severe disease: loud P_2 (= pulmonary hypertension), RV heave, LV enlargement (PMI is displaced laterally and is enlarged, i.e., larger than a coin), and S_3. S_3, however, is usually found with any severe MR and is not necessarily a sign of decompensated MR.

II. General ideas and workup

A. There is no role for medical therapy in symptomatic, severe primary valvular disorders or in valvular disorders associated with secondary LV dysfunction

The only effective therapy at this point is surgery, the exceptions being severe functional MR or TR (ventricular or atrial functional), and MS with very mild symptoms in a debilitated patient.

B. Transesophageal echocardiography (TEE)

- TEE is indicated in severe MR. It establishes the severity of MR, the anatomic cause of MR, the feasibility of mitral repair (cusps involved), and guides mitral repair.
- TEE is not superior to TTE in assessing the severity of AS or AI. In fact, it is difficult to get the aortic valve gradient by TEE. TEE is superior to TTE for the anatomic assessment of the aortic valve and for the diagnosis of endocarditis.
- TEE can identify a left atrial appendage thrombus in patients with MS or AF, the presence of which dictates the deferral of percutaneous valvuloplasty.

Intraoperative TEE is indicated in all cases of valvular surgery, particularly mitral valve repair. It immediately detects a suboptimal result or postoperative technical problems, especially in the case of mitral repair or valvular endocarditis with abscess. In the immediate preoperative setting, it should not be relied upon for the assessment of valvular disease severity, particularly functional MR, as general anesthesia decreases the cardiac loading conditions and may make functional MR appear less severe. A mild ischemic MR on preoperative TEE may actually be moderate or severe, especially during exertion.

C. Exercise testing

Patients with severe valvular disease and equivocal symptoms should undergo exercise testing to assess for dyspnea and functional capacity impairment. A functional capacity 1–2 METs below average is concerning for symptomatic valvular disease.

Predicted METs for men: 18 – (0.15 × age); women: 14.7 – (0.13 × age).[208,209]

Exercise testing is also used to assess the exertional PA pressure in mitral valve disorders and the dynamic worsening of ischemic MR. It is valuable for the assessment of blood pressure response to exercise in asymptomatic, severe AS. Stress testing may be risky in severe AS and needs to be carefully monitored by a cardiologist.

D. Preoperative coronary angiography, CTA, and preoperative angiographic and hemodynamic assessment of valvular disease

- Coronary angiography is used to identify CAD in cases of angina, man >40 years old or postmenopausal woman, or patients with >1 CAD risk factor. The presence of ***proximal CAD*** dictates a combined CABG + valvular surgery. Besides being an appropriate therapy for CAD, CABG reduces the risk of postoperative infarction and LV failure. Coronary angiography may be forgone in emergent valvular surgery (acute regurgitation, endocarditis, aortic dissection).
- CTA is an alternative to coronary angiography before any valvular surgery in case of CAD probability <50% (class I ESC, based on a meta-analysis of CTA vs. coronary angiography, age 65 ± 6).[210]
- ESC valve guidelines allow the omission of coronary angiography in *TAVI* candidates *when CTA excludes relevant proximal CAD* (class IIa). This is based on a large Cleveland registry analysis showing a great correlation between pre-TAVR CTA and invasive angiography in *proximal* stenoses >70%, even in elderly patients with calcified disease, with a positive predictive value (PPV) of 83%.[211] A meta-analysis showed that the PPV of pre-TAVR CTA is ~65% for stenoses >50%.[212]
- A hemodynamic study of AS or MS and a hemodynamic and angiographic study of MR or AI can help define the severity of the valvular disorder. This invasive valvular assessment is indicated if the echo data are inconclusive *or* if there is discrepancy between the echo and the clinical findings.

E. Endocarditis prophylaxis

- Not routinely indicated for native valvular disease of any severity.
- Only indicated in patients with high-risk cardiac conditions who are undergoing an invasive gingival, dental, or respiratory procedure (not gastrointestinal or genitourinary, per ACC) (one dose of oral amoxicillin or IV ampicillin/cefazolin/ceftriaxone 30–60 minutes before the procedure, or azithromycin in case of allergy):
  - Prosthetic valve or history of valvular repair using a prosthetic material.
  - History of infective endocarditis.
  - Unrepaired cyanotic congenital heart disease, any partially repaired congenital heart disease with persistent defects adjacent to a prosthetic material, or in the first 6 months after full repair of any congenital heart disease.
  - Transplant valvulopathy.

F. Follow-up echo

- Q6 months, or Q3–6 months if LV is starting to dilate, for severe valvular disease without symptoms and without surgical indication (more spaced for MS: Q1 year for very severe MS, Q1–2 years for severe MS)

- Q1–2 years for moderate valvular disease without symptoms and without surgical indication (more spaced for MS: Q3–5 years for moderate MS)
- Q3–5 years for mild valvular disease

G. Surgical mortality
- CABG: ~1–5%
- Redo CABG: ~10%
- AVR: ~3–4%; 1–2% in low-risk patients, up to 8% in patients with low EF. TAVR mortality is lower in high-risk patients.
- AVR + CABG: 6%
- AVR in octogenarians: ~4–6% (6.4% in PARTNER trial), increases to >10% if AVR + multivessel CABG
- MVR: ~5%; MV repair: ~1–3% (half the mortality of MVR)
- MVR + CABG: 11%. This is mainly due to the higher baseline comorbidity of these patients; the risk is related to CAD rather than CABG itself and is potentially higher if CAD is left untreated.
- AVR + aortic aneurysm repair: 9%
- Multiple valve replacement: 9%
- Redo valve replacement: 5–15% (depending on age and comorbidities; if operated early on before symptoms reoccur, mortality is low)

H. Volume and pressure overload with valvular disease
- MR leads to an increase in LV preload. LV afterload is initially reduced because of the low-pressure leak. However, at an advanced stage, LV afterload (= wall stress) increases because of LV dilatation and lack of concentric hypertrophy.
- AS leads to an increase in LV pressure afterload.
- AI leads to an increase in preload but also a severe increase in afterload from the LV dilatation and the increased pulse pressure. This increase in preload, volume afterload, and pressure afterload explains the massive LV dilatation and the ensuing progressive rise in LV afterload. LV has eccentric and concentric hypertrophy. In comparison with AS, AI is associated with similarly high afterload, albeit a different mechanism, and the highest LV mass.
- In MS, HF results from mitral obstruction without any LV abnormality, unless intrinsic LV disease coexists.

AI and AS cause symptoms then ↓ EF often before intrinsic LV dysfunction occurs, whereas in MR, intrinsic LV dysfunction is already present by the time of ↓ EF or severe symptoms.

QUESTIONS AND ANSWERS

Question 1. A 69-year-old woman presents with acute HF and severe HTN (SBP 180 mmHg). Echocardiography shows normal LVEF, AS with a mean gradient of 27 mmHg and AVA of 0.9 cm^2, and moderate MR. If this is severe AS, what can explain the paradoxically low gradient?
A. Hypertension at the time of the study, particularly if concentric LV hypertrophy is present. In this case, the stroke volume is reduced because of the double afterload (HTN and AS) and the small LV cavity
B. MR, which reduces forward cardiac output
C. Truly severe AS with false measurement of aortic gradient (Doppler beam not parallel to aortic flow)
D. All of the above

Question 2. If the patient in Question 1 actually has moderate AS, what could explain the low AVA calculation?
A. Echocardiographic error in measurement (underestimation of LVOT diameter leads to a falsely low AVA)
B. Pressure recovery phenomenon in a patient with a small tubular aorta (true gradient is smaller and true AVA is larger)
C. The AVA is truly <1 cm^2 but the patient has a small body size and the indexed AVA is >0.6 cm^2/m^2, implying a truly moderate AS
D. All of the above

Question 3. In the above patient, how can one make a diagnosis of severe AS vs. moderate AS?
A. Try to obtain aortic gradient in multiple views and try to be coaxial to the aortic flow. Ensure proper echo measurement of LVOT at the aortic annulus in early systole
B. Measure aortic gradient after control of HTN
C. A high LVOT velocity >1 m/s suggests that the stroke volume is preserved, reducing the likelihood of low-gradient severe AS.
D. Invasive measurements may be required to measure cardiac output, true gradient and AVA, especially after control of HTN
E. Dobutamine testing
F. A through C
G. A through D
H. All of the above

Question 4. A patient has dyspnea on exertion and a mid-systolic murmur with absent A_2. Echo shows AS with calcified aortic valve, a mean gradient of 48 mmHg and AVA 1.1 cm^2. No AI is present. Is AS severe?
A. AS is severe. When the gradient is >40 mmHg on echo, AS is severe even if AVA >1 cm^2
B. AS is possibly severe. AVA may be over-calculated in a patient with a septal hypertrophy and a high LVOT velocity
C. This is an equivocal result. Cardiac catheterization is necessary to assess AS severity
D. This is an equivocal result. Perform CT scoring of the aortic valve

Question 5. A 76-year-old man with a prior history of CABG and low LVEF is admitted with severe HF. His echo shows severe LV dysfunction with EF ~25%, a severely calcified aortic valve with a mean gradient of 22 mmHg and AVA 0.8 cm^2. A dobutamine infusion is performed

(started at 5 mcg/kg/min and raised to 20 mcg/kg/min). His stroke volume increases from 50 ml to 65 ml, gradient increases to 35 mmHg, and AVA increases to 1 cm^2. Does he have severe AS?
A. AS is severe
B. AS is pseudo-severe (poor valve excursion related to the poor flow rather than severe AS)
C. Poor contractile reserve
D. Perform cardiac catheterization to establish the diagnosis

Question 6. In the patient of Question 5, what happens to the dimensionless index (DI) during dobutamine testing?
A. Remains the same or declines
B. Increases

Question 7. What is the best treatment of the patient in Question 5?
A. Surgical AVR
B. TAVR is an option in low-gradient AS
C. Conservative management

Question 8. A 62-year-old man is admitted with acute HF. He is found to have severe LV dysfunction with global hypokinesis, inferior akinesis, and overall EF 25%. He has a posteriorly directed mitral regurgitation with a calculated effective regurgitant orifice (ERO) of 0.30 cm^2. His coronary angiogram shows severe 3-vessel CAD with a subtotally occluded RCA. CAD appears amenable to PCI. Besides medical therapy, what is the best treatment option?
A. Medical therapy only
B. Repeat echo after diuresis. If MR improves, revascularize with PCI
C. CABG
D. CABG + MV repair using annuloplasty ring
E. CABG + MV repair or replacement

Question 9. A patient with a history of anterior MI presents with HF. He is found to have severe MR. Can a patient with anterior MI and no inferior MI have severe ischemic MR? If so, would it be anteriorly directed?
A. Yes, a centrally directed MR
B. Yes, an anteriorly directed MR
C. Yes, a posteriorly or centrally directed MR
D. No

Question 10. A patient presents with severe chest pain and dynamic, diffuse ST segment depression. BP is 170/93 mmHg. A holosystolic MR murmur is heard. Bedside echo shows inferior akinesis with severe MR. Troponin rises to 1.2 ng/ml. After aspirin, heparin, and nitrate therapy, chest pain resolves. The murmur is not heard anymore, and a bedside echo performed a few hours later shows an improvement of the inferior akinesis. Coronary angiography is performed and shows a 90% thrombotic RCA stenosis and a 75% mid-LAD stenosis. Both lesions are amenable to PCI. What is the next step?
A. PCI of RCA and LAD
B. CABG with mitral repair or replacement

Question 11. A 64-year-old asymptomatic woman is found to have an apical murmur radiating to the base. An echo shows posterior leaflet prolapse with severe, eccentric MR. The LV size is normal (LV end-systolic diameter is 37 mm) and LVEF is 65%. The LA is enlarged, with an anteroposterior diameter of 4.8 cm. Her PA pressure is 40 mmHg at rest. The patient is in sinus rhythm. She can perform her daily chores without limitation. What parameters help determine if MV surgery is appropriate now, as opposed to surveillance?
A. Exercise testing with determination of functional capacity (worrisome if <6 METs)
B. In the echo lab, measure PA pressure after isometric exercise or leg raising
C. TEE to assess the extent of posterior leaflet abnormality
D. Right heart catheterization, with measurement of PA pressure and PCWP at rest and with leg raising and exercise
E. BNP >100 pg/ml
F. All of the above

Question 12. A 44-year-old woman presents with dyspnea on exertion. Echo shows a restricted posterior leaflet with a hockeystick anterior leaflet and immobile leaflet tips. The transmitral gradient is 10 mmHg at rest, 15 mmHg with leg raising, and the MVA is 1.6 cm^2 by echo, at a heart rate of 100 bpm. The valve is pliable and the subvalvular apparatus is not heavily calcified (Wilkins score of 8). The patient has been having heavy menstruations and hemoglobin is 7.5 g/dl. What is the next step?
A. Transfusion and PMBV
B. Transfusion and right and left heart catheterization
C. TEE

Question 13. Heart catheterization is performed in the patient in Question 12. A good PCWP waveform is obtained. There is a lack of dia- stasis between PCWP and LV at end-diastole, the mean transmitral gradient is 12 mmHg at a heart rate of 100 bpm, cardiac output is 7.5 L/ min, and the mitral valve area is 2 cm^2 by Gorlin's equation. PCWP is 24 mmHg and systolic PA pressure is 50 mmHg. What is the next step?
A. Transfusion, metoprolol, and diuresis
B. Transfusion, metoprolol, diuresis and PMBV

Question 14. A patient has severe valvular disease and LVEF of 40%. He undergoes valvular replacement. In which valvular disease does EF more readily improve after surgical correction?
A. AS > AI > MR
B. AI > AS > MR
C. AS > MR > AI

Question 15. A 55-year-old man presents with HF. He has a history of mechanical bileaflet AVR performed 5 years previously. An echo is performed and shows a transaortic gradient of 30 mmHg and a peak velocity of 3.5 m/s, without a significant AI. Hemoglobin is 13 g/dl. What is the most likely cause of the gradient across the valve?
A. Normal gradient across a normally functioning valve
B. Patient/prosthesis mismatch
C. High-flow state
D. Pressure recovery
E. Valvular obstruction, further suggested if metallic S_2 is muffled

Question 16. If the patient in Question 15 is presenting with atypical chest pain or a non-cardiac complaint rather than HF, what would the diagnosis be?
A. Normal gradient across a normally functioning valve
B. Patient/prosthesis mismatch
C. High-flow state
D. Pressure recovery
E. Valvular obstruction, further suggested if metallic S_2 is muffled

Question 17. If the patient in Question 15 is presenting with HF, but a review of a postoperative echo shows a similarly increased velocity and gradient across the prosthetic valve, what would the diagnosis be?
A. Normal gradient across a normally functioning valve
B. Patient/prosthesis mismatch
C. High-flow state
D. Pressure recovery
E. Valvular obstruction, further suggested if metallic S_2 is muffled

Question 18. What is the next step for the patient in Question 15?
A. TEE
B. Cinefluoroscopy
C. A and B
D. No further workup, as the cause is benign

Question 19. A 60-year-old patient presents with shock and pulmonary edema. He is intubated and requires vasopressor support. He has a history of mechanical MVR 5 years previously. An echo shows a large gradient across the prosthetic valve (35 mmHg). On fluoroscopy, one mechanical leaflet is totally immobile, while the other one has restricted motion. INR is 1. What is the next step in management?
A. Thrombolytic therapy
B. Valvular surgery
C. Anticoagulation with heparin

Question 20. Which of the following patients with severe MR does not have an indication for mitral valve surgery?
A. LV end-systolic diameter 40 mm
B. LVEF 60%
C. Recently diagnosed HF with LVEF 20% and severe MR
D. LVEF 45%

Question 21. Answer each option as true or false:
A. S_3 and S_4 are present in MS
B. Persistently split S_2 suggests RV failure
C. Loud S_2 split suggests pulmonary hypertension
D. Absent A_2 with midsystolic murmur suggests severe AS
E. A loud S_1 characterizes MS or a short PR interval
F. A short S_2-opening snap interval implies severe MS
G. A wide pulse pressure with a diastolic murmur implies severe AI
H. A high JVP that peaks simultaneously with the pulse suggests TR
I. HOCM murmur changes in an opposite direction to preload and afterload

Question 22. A 55-year-old man with a history of radiation for lymphoma 20 years ago presents with hypoxia and peripheral edema. On exam, he has lung crackles, an elevated JVP with a high V wave peaking along with the pulse, and a pulsatile liver. He has a holosystolic murmur at the LLSB that increases with inspiration. A holosystolic murmur is also heard at the apex and radiates to the axilla. At the RUSB and LUSB, a mid-systolic murmur is heard. An early, decrescendo diastolic murmur is heard at the LUSB. S_2 is normal. Carotid upstroke is weak. RV heave is present. PMI is not enlarged. BP is 105/75 mmHg. What abnormalities does this patient have? (multiple choices)
A. Severe TR, severe MR, severe AS
B. Severe TR, moderate MR, severe AS

C. Severe TR, severe MR, moderate AS and moderate AI
D. On echo, AS gradient will seem less severe because of MR and TR. Conversely, the MR volume and hemodynamics are exaggerated by AS and AI. AI does not affect the severity assessment of MR
E. Restrictive cardiomyopathy is likely present

Question 23. Once symptoms arise in severe AS, AI, or MR, what is the mean survival without surgical correction?
A. 1 year
B. 2–3 years
C. 5 years

Question 24. A 44-year-old obese, hypertensive woman presents with dyspnea on exertion. On exam, she has a diastolic rumble and a loud S_1. Echo shows LA dilatation with typical MS. The mean gradient at rest is 6 mmHg (heart rate 85 bpm) and the MVA is calculated as 1.7 cm^2 by PHT method. Systolic PA pressure is ~35 mmHg at rest. The valve is pliable, not heavily calcified, with a Wilkins score of 7. With exercise testing, the gradient increases to 12 mmHg and systolic PA pressure increases to 45–50 mmHg. What is the next step?
A. MV replacement
B. Percutaneous mitral balloon valvuloplasty
C. Diuretic therapy
D. β-Blocker therapy and clinical follow-up in 6–12 months

Question 25. A patient with a mechanical aortic prosthesis presents with hypotension. Echo is performed and shows increased velocity across the aortic valve (Figure 6.31). Is it prosthetic obstruction with cardiogenic shock?

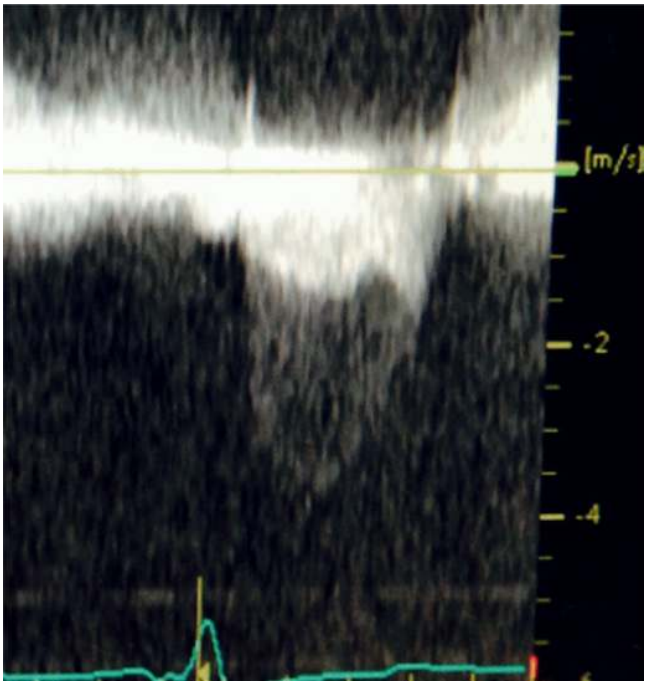

Figure 6.31

Question 26. A 47-year-old man has a history of bicuspid aortic valve with AI. He is active and asymptomatic with excellent functional capacity. A surveillance echo shows severe AI, LVEF 58%, LVESD 52 mm, and LVEDD 68 mm. Note that LV dimensions have increased by ~4 mm over the last 6 months. The aortic root size is 46 mm. What is the next step?
A. AVR + ascending aortic replacement
B. AVR
C. Continue surveillance
D. Exercise testing

Question 27. A 70-year-old woman presents with severe dyspnea. She is found to have AF at a rate of 110 bpm, BP 110/70, and pulmonary edema. Echo shows normal LV systolic function, mitral thickening, biatrial enlargement, and mild RV dilatation. After rate control, diuresis, and cardioversion, a hemodynamic study is performed (Figure 6.32). What is the diagnosis?
A. Severe MR
B. Severe MS
C. LV diastolic dysfunction and restrictive cardiomyopathy

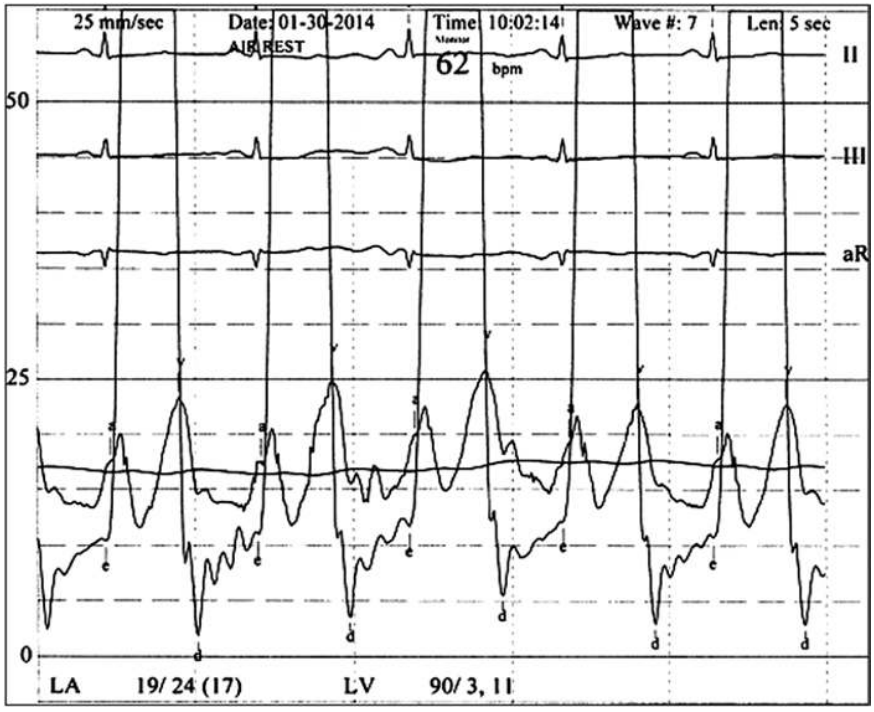

Figure 6.32

Question 28. A 70-year-old woman presents with progressive dyspnea. She is severely hypertensive (BP 180/95 mmHg). Echo shows normal LVEF, biatrial enlargement, and mild MR. A hemodynamic study is performed (Figure 6.33). What is the diagnosis, and what is the next step?

A. Severe MR (underestimated by echo)
B. Severe MS
C. Severe LV diastolic dysfunction and restrictive process from severe HTN

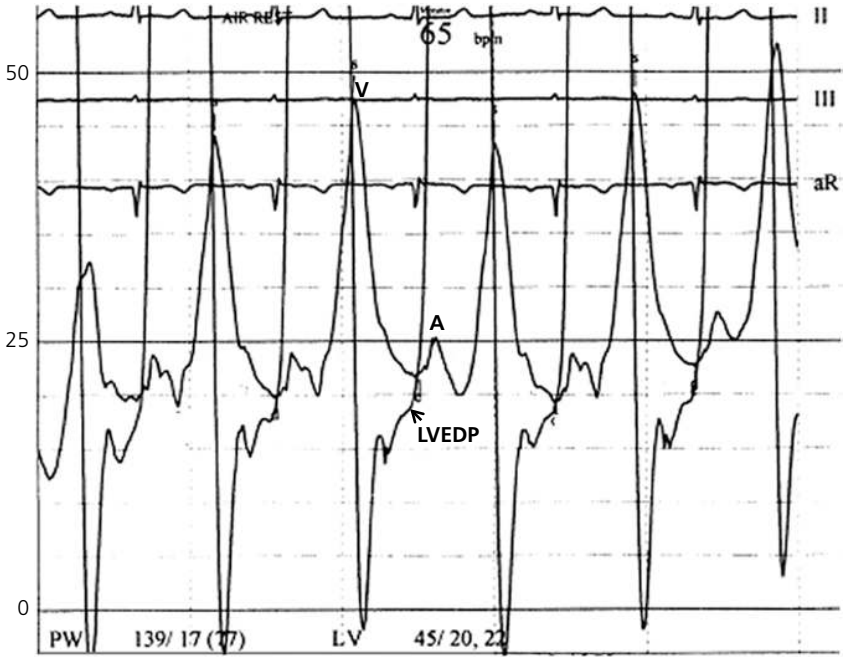

Figure 6.33

Question 29. A 67-year-old man has end-stage renal disease. He presents with pulmonary edema, SBP 85 mmHg, and 2 episodes of syncope over the last 3 weeks. On exam, 3/6 midsystolic murmur is heard throughout the precordial area, with absent A_2, and delayed and narrow carotid pulse. ECG shows anterolateral Q waves. Echo performed 2.5 years previously showed mild AS with AVA >2 cm^2. What is the diagnosis?
A. Ischemic HF. AS is unlikely, as AVA declines by 0.12 cm^2/year and it takes >5 years to progress from mild AS to severe AS
B. Combination of ischemic HF and severe AS. AS may progress faster in end-stage renal disease

Question 30. A 65-year-old end-stage renal disease patient presents with pulmonary edema. Echo shows severe AS with an EF of 25%, and coronary angiography shows a totally occluded LAD without significant anterior wall viability on thallium testing. Attempts to perform hemodialysis and ultrafiltration are impeded by the occurrence of severe hypotension during hemodialysis. His surgical STS score for AVR is 14%. What is the best management option?
A. Perform hemodialysis supported by dopamine, then PCI of LAD supported by Impella, then TAVR
B. Perform hemodialysis with the support of norepinephrine. Perform CABG + AVR once pulmonary edema has resolved
C. Perform hemodialysis with the support of norepinephrine. Perform TAVR once pulmonary edema has resolved

Question 31. Which of the following statements is *incorrect*?
A. MR is associated with reduced afterload early on, then LV dilatation and increased afterload later on
B. AI is associated with a rise in preload and afterload
C. AI is associated with a similar rise in afterload as AS
D. In MR, the earliest EF reduction reflects intrinsic LV dysfunction and may be irreversible
E. In AI and AS, the earliest EF reduction reflects afterload mismatch rather than intrinsic LV dysfunction and is reversible with AVR
F. In acute AI, pulse pressure is severely widened and peripheral systolic pressure is much higher than central aortic pressure

Question 32. The valve shown in Figure 6.34 is seen on fluoroscopy. What type of valve is it?
A. Surgical bioprosthesis
B. Transcutaneous bioprosthesis
C. Mechanical prosthesis (St. Jude)
D. Mechanical prosthesis (single-leaflet tilting disk)

Figure 6.34

Question 33. A 67-year-old man has dyspnea on exertion. On exam, a mid-systolic murmur is heard, A_2 is absent, and pulsus parvus and tardus is present. His echo shows a mean aortic gradient of <40 mmHg and an aortic valve area of >1 cm^2. What is the diagnosis and what is the next step?
A. AS is moderate. No need for further workup
B. AS is probably severe. Cardiac catheterization and invasive AVA calculation are indicated

Question 34. A 67-year-old man has dyspnea on exertion. He has a loud holosystolic apical murmur with S_3. Echo shows a small eccentric MR jet. What is the diagnosis, and what is the next step?
A. MR is mild or moderate. No further workup is needed
B. MR is likely severe. Perform TEE

Question 35. A 60-year-old man is asymptomatic. He has a mild end-systolic murmur at the apex without S_3. Echo is performed and shows mitral valve prolapse with severe MR by jet area and ERO. LA size is normal. What is the diagnosis?
A. Severe MR from mitral valve prolapse
B. Mild-to-moderate MR from mitral valve prolapse

Question 36. A 60-year-old man has dyspnea on exertion, with holodiastolic murmur at the base, enlarged PMI, and wide pulse pressure. Echo shows a bicuspid aortic valve with mild-to-moderate AI jet. AI pressure half-time is 320 ms. LV is enlarged. What is the diagnosis?
A. Severe AI. Further testing is needed (TEE, invasive aortogram)
B. Mild-to-moderate AI

Question 37. A 68-year-old hypertensive woman has dyspnea on exertion and a long diastolic murmur at the apex extending into end-diastole. Echo shows a rheumatic mitral valve with transmitral pressure gradient of 12 mmHg at rest and systolic PA pressure of 55 mmHg (heart rate of 70 bpm). The mitral valve area is calculated at 1.7 cm^2.
A. MS is severe
B. MS is mild/moderate anatomically, and the gradient is exaggerated because of a high cardiac output

Question 38. A 72-year-old man with a bioprosthetic mitral valve is presenting with dyspnea on exertion and a holosystolic apical murmur. Echo shows thickened prosthetic leaflets, mild mitral regurgitation, and a peak E velocity of 2.4 m/s. What is the diagnosis?
A. Prosthetic valve obstruction
B. Prosthetic valve regurgitation
C. Normally functioning mitral prosthesis

Question 39. A 67-year-old woman has mild dyspnea on exertion. On exam, he has a mid-systolic murmur with a well-heard A_2 and a preserved carotid upstroke. His echo shows a mean aortic gradient of 38 mmHg and an aortic valve area of 0.9 cm^2. What is the diagnosis, and what is the next step?
A. AS is severe. No need for further workup
B. AS is likely moderate. Cardiac catheterization is indicated

Question 40. In a patient with normal EF, echocardiography shows AVA of 0.85 cm^2, peak aortic velocity of 3.5 m/s, mean gradient of 28 mmHg, stroke volume index of 38 ml/m^2, and a hybrid AVA (LVOT area measurement by CT) of 1.1 cm^2. What is the diagnosis?
A. Normal-flow, low-gradient AS, unclear if moderate or severe
B. Paradoxical low-flow, low-gradient AS, unclear if moderate or severe
C. Severe AS
D. Moderate AS

Question 41. In a patient with EF of 25%, echo shows AVA of 0.8 cm^2, peak velocity of 3.2 m/s, mean gradient of 25 mmHg, stroke volume index of 27 ml/m^2, and a dimensionless index of 0.21 (stroke volume 54 ml, systolic duration 0.35 second). Dobutamine echocardiography is done: stroke volume index increases to 34 ml/m^2 (stroke volume 68 ml, systolic duration 0.28 second), AVA increases to 0.88 cm^2, and mean gradient increases to 34 mmHg. What is the diagnosis?
A. Classical low-flow, low-gradient truly severe AS
B. Classical low-flow, low-gradient pseudo-severe AS
C. Indeterminate AS severity. Recommend calcium CT scoring of the aortic valve
D. Indeterminate AS severity. Recommend dobutamine study during catheterization

Question 42. In a patient with normal EF, echo shows: AVA 0.8 cm^2, peak velocity 3.5 m/s, mean gradient 30 mmHg, stroke volume index of 33 ml/m^2, and a dimensionless index of 0.36. What is the diagnosis?
A. Normal-flow, low-gradient AS, unclear if moderate or severe
B. Paradoxical low-flow, low-gradient AS, unclear if moderate or severe
C. Measurement error

Question 43. A 73-year-old man has a history of mitral valve repair with annuloplasty ring 10 years prior. He is presenting with symptomatic, severe recurrent MR. He has a high surgical risk and transcutaneous mitral valve replacement (TMVR) is considered. Which of the following is true?
A. TMVR is not an option if a ring is in place
B. The stent tube of TMVR may narrow the LVOT and cause hemodynamic collapse
C. LVOT narrowing post-TMVR is highest if the LVOT is orthogonal to the mitral valve (angle <115 degrees) or the anterior leaflet is short
D. Paravalvular leak post-TMVR is as common with TMVR-in-MAC and TMVR-in-mitral prosthesis

Question 44. An 85-year-old woman with permanent, rate-controlled AF presents with severe dyspnea and a picture of right heart congestion. Echo shows normal LV EF, severe TR, and PA systolic pressure of ~40–45 mmHg. The RV is not grossly dilated and TAPSE is 17 mm. Which of the following is true or expected?
A. PCWP >20 mmHg
B. She has HFpEF with secondary RV failure and TR
C. AF is the primary driver of TR
D. RV is elliptical and globally dilated
E. TR severity and JVP do not improve with diuretic therapy

Question 45 An 83-year-old woman has severe AS and severe MAC with mild mitral gradient. She undergoes TAVR, then develops complete AV block and becomes V dependent on V pacing. The mitral valve is reassessed afterward: mean gradient 8.5 mmHg at a heart rate of 80 bpm (Figure 6.35), and MS PISA is seen on the LA side (*arrow*). Why did the mitral valve gradient increase? How to improve her mitral stenosis?

A. Transcatheter mitral valve replacement
B. Add bisoprolol
C. Add bisoprolol and reduce the paced PR interval
D. Add bisoprolol and increase the paced PR interval
E. Bisoprolol cannot affect the rate (pacemaker dependency). Reduce the baseline pacing rate from 80 to 60 bpm

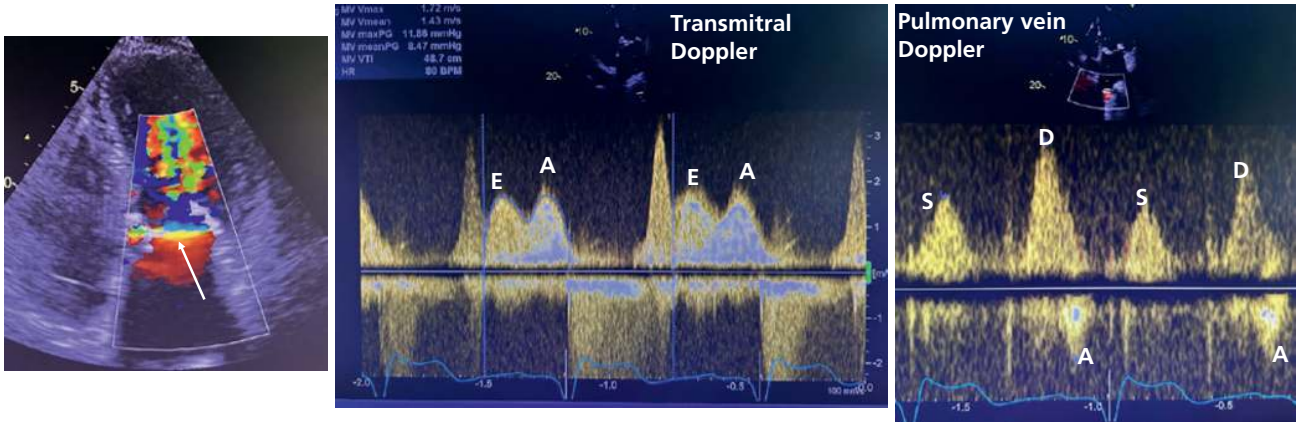

Figure 6.35

Question 46 A 50-year-old obese man presents with abrupt dyspnea that started after lifting a heavy weight, with near syncope and without chest pain. Exam findings: BP 100/70, heart rate 110 bpm, O2 saturation 86% on ambient air; bibasilar crackles, faint S3, and mild early systolic murmur. ECG shows sinus tachycardia. Bedside echo is technically difficult and shows a hyperdynamic LV with mild MR, and B lines on lung scan. Hs-troponin T is 30. What is the next step?

A. Coronary angiography
B. TEE
C. Chest CTA PE protocol
D. Chest CTA aortic protocol

Answer 1. D.

Answer 2. D.

Answer 3. G. The indexed AVA in this patient is calculated at 0.45 cm^2/m^2. The stroke volume index is calculated at 25 ml/m^2, suggestive of low flow. After control of HTN, the flow increased and the aortic gradient increased to 39 mmHg, confirming the effect of low flow on her gradient. Thus, she has a paradoxical low-flow, low-gradient severe AS related to severe HTN. In patients with normal EF and paradoxical low-gradient AS, the reduction in flow is secondary to the high afterload and the small underfilled ventricular cavity rather than impaired contractility. In this setting, dobutamine testing is not a suitable way of increasing cardiac output.

Answer 4. A. Echo rarely overestimates aortic valve gradient. It rather frequently underestimates the gradient. If the aortic valve is calcified and poorly mobile on echo imaging, a high gradient implies severe AS, even if AVA is calculated as >1 cm^2. An exaggeration of LVOT velocity or diameter may exaggerate the calculated AVA: AVA = LVOT area × LVOT velocity/aortic valve velocity. CT scoring of the aortic valve is useful in low-gradient AS, not when a high gradient is present.

Answer 5. A. The patient has low-gradient AS related to poor EF. The low gradient here is likely related to poor flow rather than errors in echo measurements. Dobutamine testing is appropriate. The stroke volume rose >20%, implying proper contractile (or flow) reserve. The gradient rose >10 mmHg to >30 mmHg, and the AVA remained ≤1 cm^2, implying a truly severe AS. ACC guidelines recommend a 40 mmHg cutoff, but 30 mmHg is reasonable when AVA is consistent with severe AS, as per reference 112. In a pseudo-severe AS, the increase in flow leads to more valvular opening: gradient does not significantly increase, while the valve area dramatically increases, usually to >1.2 cm^2.

Answer 6. A. In truly severe AS, LVOT velocity increases with dobutamine, but aortic velocity increases similarly or further. DI, which is LVOT velocity/aortic velocity, remains unchanged or declines. In pseudo-severe AS, the aortic velocity increases less than LVOT (→ DI increases).

Answer 7. B. In light of the low-gradient/low-EF AS and the prior cardiac surgery, the surgical mortality is elevated, at least 8%. Formal STS score calculation should be performed and the patient referred for TAVR. In the PARTNER 1B trial, patients with a low-gradient AS derived

the largest mortality benefit from TAVR, as compared to conservative management. In operable patients (PARTNER 1A), TAVR and surgical AVR had similar mortality.

Answer 8. E. The patient has ischemic MR due to an akinetic inferior wall. The presentation is HF, rather than acute ischemia; the inferior wall akinesis is a steady, persistent abnormality rather than an off/on ischemia and does not have a high likelihood of fully reversing with revascularization. MR only has a 50% chance of improving with CABG revascularization. CABG along with mitral surgery is indicated in a patient with multivessel CAD and severe MR. Ischemic MR is dynamic and may improve with diuresis and improvement of preload and afterload. However, inferior wall akinesis is steady and MR easily reverses back to severe with a reversal of loading conditions, such as exercise or supine position (night), further attesting to the need for mitral surgery.

Answer 9. C. Anterior wall akinesis, per se, does not produce enough oblique leaflet tethering and MR. Anterior MI may, however, lead to global remodeling with posterolateral and apical tethering of the papillary muscles and leaflets. This leads to ischemic MR, which may be centrally or posteriorly directed.

Answer 10. A. As opposed to Question 8, where the patient had a chronic persistent dysfunction of the inferior wall with HF presentation, this patient is having acute, fleeting ischemic dysfunction of the inferior wall with MR. The dynamic MR is dictated by ischemia, not just loading conditions. It is expected that this MR will reverse with revascularization of the acute RCA lesion. MV surgery is not immediately required here.

Answer 11. F. All these tests are reasonable in the asymptomatic patient with severe MR. On stress testing, if the patient develops severe dyspnea that persists into late recovery, or if functional capacity in METs is below expected (14.7 – [0.13 × age]), she is unlikely to be NYHA class I and MV surgery is reasonable. If the prolapse is limited to P_2 cusp, MV repair is likely to be successful and durable, and is reasonable even in an asymptomatic patient (class IIa). Elevated BNP, pulmonary hypertension, or elevated PCWP suggests that MR is starting to have hemodynamic repercussions and implies a high risk of HF and symptomatic deterioration, as well as an impairment of long-term outcomes; MV surgery is reasonable.

Answer 12. B. MVA is a better determinant of MS severity than the mitral gradient. In fact, transmitral pressure gradient being proportional to the square of the diastolic mitral flow, tachycardia or a high-output state may convert an *anatomically mild MS into a hemodynamically severe MS with a severely increased transmitral gradient*. Invasive hemodynamics are valuable for the assessment of MS whenever there is discrepancy between the echocardiographic MVA and transmitral gradient; and whenever it is not clear whether the patient's symptoms or pulmonary hypertension are purely secondary to MS, or rather secondary to mild MS + high-output state and tachycardia.

Answer 13. A. The cardiac output is markedly increased because of anemia and the heart rate is increased, both of which converted an *anatomically mild MS* (valve area 2 cm^2) into a *hemodynamically severe MS*, with a high gradient and lack of diastasis. Anemia should be corrected, the heart rate should be reduced to 55–60 bpm with β-blockade, and a small dose of diuretic may be administered. PA pressure and transmitral gradient should be assessed afterward. Once exacerbating factors are treated, valvuloplasty is considered for mild MS (MVA >1.5 cm^2) only if the patient remains symptomatic with exertional increase in PA pressure and transmitral gradient (>15 mmHg) (class IIb).

Answer 14. A. In AS and AI, the low EF is usually related to the high afterload rather than an intrinsic LV dysfunction (afterload mismatch). Thus, valvular surgery improves afterload and EF. This is not the case in MR: (1) afterload is usually reduced in MR, and thus the low EF is due to intrinsic myocardial dysfunction; (2) MV surgery may disrupt the subvalvular apparatus and LV geometry, further reducing EF.

Answer 15. E. The five listed causes are the main causes of a high gradient across a prosthetic valve. The severity (>3 m/s) makes normal gradient less likely (not option A). The fact that he is presenting with HF implies a need to rule out valvular obstruction.

Answer 16. B or D. C is unlikely in the absence of anemia or sepsis.

Answer 17. B or D.

Answer 18. C. The next step consists of assessing the leaflet structure and excursion. This is done by using both TEE and fluoroscopy. If the structure and excursion are normal, patient-prosthesis mismatch or pressure recovery is the cause of the valvular gradient.

Answer 19. A. The mitral obstruction is the cause of shock in this patient. The differential diagnosis includes thrombus or pannus formation. The acuity of onset and the normal INR are suggestive of thrombus. TEE may be performed to show the large thrombus but is not mandatory at this point. Patients with large prosthetic thrombosis or functional class IV should undergo surgical replacement or, if surgery is deemed high risk, thrombolytic therapy through a slow infusion. Surgery is high-risk in a patient with shock requiring multiple vasopressors. Serial echocardiograms need to be performed to document a reduction of gradient. Fluoroscopy may document improvement of disk mobility.

Answer 20. C. MR that occurs with a very low EF is likely a functional MR (unless a longstanding history of severe symptomatic MR precedes HF and low EF). Surgery is not first-line therapy for functional MR, particularly functional MR with no CABG planned or from a nonischemic cardiomyopathy. Surgery is indicated in patients with MR and secondary LV dysfunction, manifested as EF ≤ 60%.

Answer 21. A is false (S_3 and S_4 cannot be present in MS). All the remaining statements are true.

Answer 22. C, D, and E. The patient has clinical signs of severe TR (ventricularized JVP, pulsatile liver). He has MR that is likely severe, as he has pulmonary edema. AS is not severe by the fact that S_2 is not attenuated. The weak carotid pulse is due to the low-output state from the combined valvular disease rather than severe AS. AI is unlikely to be severe as the pulse pressure is narrow; however, a concomitant MR, TR, and cardiomyopathy may attenuate the total stroke volume and the pulse pressure of severe AI. PMI is not enlarged, strongly arguing against severe AI, especially AI combined with MR, where LV would be severely dilated. In combined mitral and aortic valvular disease, the

aortic disease exaggerates the severity of the mitral disease and the rise in LA pressure. Conversely, the mitral disease reduces AS gradient and leads to underestimation of true AS severity. Despite MR and moderate AS/AI, LV is not enlarged by PMI. This suggests a concomitant restrictive cardiomyopathy from radiation.

Answer 23. B.

Answer 24. D. This patient has mild MS by MVA (>1.5 cm^2). A gradient of 5–10 mmHg with a pulse >80 bpm may be consistent with an anatomically mild/moderate MS that is rendered more severe hemodynamically by the heart rate. For this MVA, intervention is only considered if the mean gradient increases to >15 mmHg with stress or PA pressure increases to >60 mmHg with stress, after ruling out tachycardia or a high-output state as a cause of the high gradient. In this patient, obesity or diastolic LV dysfunction may be the cause of dyspnea. It is reasonable to perform heart catheterization and verify that MVA is truly in the mild/moderate range and that a high CO (from obesity) is likely aggravating the gradient. Heart catheterization will also allow a diagnosis of LV diastolic dysfunction (LVEDP rises with stress more than the transmitral gradient does).

Answer 25. First, ensure the tracing obtained is truly an aortic tracing rather than MR. It is a true aortic tracing by the fact that is starts after the peak of the electrocardiographic R wave (this is opposite to MR, which starts exactly at the peak of R, i.e., at the isovolumic contraction). Second, address why the velocity is increased. The contour of the transaortic envelope is round and symmetrical, consistent with AS. However, within this envelope, there is another envelope that is late-peaking and consistent with an increased LVOT velocity ("whiter" envelope). Thus, the aortic velocity is ~4 m/s, but the LVOT velocity is ~2 m/s, implying a dimensionless index of ~0.5 (>0.3), which is not consistent with severe valvular or prosthetic obstruction. In addition, by using the true Bernoulli equation, the peak gradient across the prosthesis is not in the severe range: gradient = $4 \times (V_{aortic\ valve}^2 - V_{LVOT}^2)$ rather than $4 \times V_{aortic\ valve}^2$. The velocity across the prosthesis is likely mildly increased at baseline (e.g., some degree of patient/prosthesis mismatch), and is now worsened by the increased LV velocity (hypercontractile state from sepsis, hypovolemia, or fever). Also, a fast time-to-peak <100 ms or <37%, as in this case, suggests normal prosthetic function.

Answer 26. A. EF is still above the surgical cutoff (EF <55% being an indication for AVR). However, LVESD >50 mm and LVEDD >65 mm are class II indications for surgery. This is even more worrisome when progressive LV dilatation is noted.

Answer 27. B. This tracing represents simultaneous PCWP–LV pressure recording. Despite a rate of 60–75 bpm (in this case, 62 bpm), there is a lack of PCWP and LV diastasis at end-diastole, which suggests severe MS. Also, PCWP A wave is prominent while LV A wave is attenuated, which further suggests MS. V wave is prominent; this does not necessarily imply MR and is common in MS.

Answer 28. A. This tracing represents simultaneous PCWP–LV pressure recording. Note the very large V wave (~47 mmHg), which mainly suggests severe MR, but may also be seen with severe LV failure, such as restrictive cardiomyopathy. One may get the false impression of a gradient between PCWP and LV in diastole. Yet note that, when using PCWP as a surrogate of LA pressure, a large V wave exaggerates the transmitral gradient and may falsely suggest MS. In fact, the large V wave of PCWP has a slower downslope than the V wave of LA pressure, which exaggerates the space between PCWP and LV. Severe MR may have been missed on TTE for various reasons: (1) dynamic functional MR from hypertensive cardiomyopathy and severe LA enlargement (MR may have been milder at the time of the echo and was worsened by HTN); (2) extremely eccentric MR, such as MR related to MVP, underestimated on many TTE views. The next step is to reassess MR on echo using dynamic maneuvers, such as exercise or leg raising.

Answer 29. B. The exam suggests severe AS, and ECG suggests anterior infarct. It is true that AVA only declines by 0.12 cm^2/year and mean gradient only increases by 7 mmHg per year, but those are average numbers. Progression is faster in renal patients and in those with heavy valvular calcifications.

Answer 30. C. While decongestion improves cardiac output, quick fluid removal during dialysis (2–3 liters in 3 hours) exceeds plasma refill time and creates transient reduction of intravascular volume. In patients with *limited cardiac output reserve*, the LV cannot increase its stroke volume and EF to fill the empty circulation. BP will precipitously drop during dialysis. Norepinephrine may be used to constrict the empty circulation and maintain BP during dialysis; in hypotensive patients, norepinephrine does not increase afterload untowardly as it only raises the SBP to 90–100 mmHg. In order to reduce perioperative complications, it is important to properly decongest the patient before a cardiac intervention. Considering his STS surgical risk score of ≥8%, TAVR is preferred to surgical AVR. While non-viability does not preclude a benefit from CABG revascularization (STICH trial), non-viability with Q waves reduces the likelihood that LV function will improve with CTO PCI[213]; furthermore, CTO PCI has not improved EF or death/MI in any randomized trial, and its use for HF and EF improvement is questionable.[214,215] Had PCI been deemed appropriate, Impella could have been considered to support complex PCI in unstable AS, as long as AVA >0.6 cm^2.

Answer 31. F. Pulse pressure is severely widened when the total stroke volume is markedly increased, as in chronic AI, where the LV is dilated, not acute AI. In AI, the early EF reduction reflects a reduction of stroke volume from the high afterload (stroke volume is the EF numerator).

Answer 32. A. The leaflets are not visualized (bioprosthetic leaflets). The classic stented bioprosthesis has metallic ring and struts, as seen on this image.

Answer 33. B. The echo findings should always be analyzed in the context of the physical exam. Since the exam suggests severe AS, echo may have underestimated the gradient because of poor alignment of the Doppler beam with the transaortic flow.

Answer 34. B. The exam, particularly S_3, suggests severe MR. On color Doppler, an eccentric MR (mitral valve prolapse) jet occupies a smaller area of the LA than a central jet of similar severity; MR may be underestimated. E velocity remains elevated at >1.2 m/s even when severe MR is eccentric, and is a hint to severe MR.

Answer 35. B. The color assessment of MR, whether by color jet area or color PISA calculation, assumes that MR occurs throughout systole. Inherently, an end-systolic MR that looks severe by color and PISA may only be mild or moderate when one accounts for the fact that it only

occurs at the end of systole. The auscultation (end-systolic rather than holosystolic murmur, no S_3), and the normal LA size suggest that MR is overestimated by color. Also, color M-mode across the mitral valve shows that MR is limited to a portion of systole. LA size cannot be normal in chronic severe MR.

Answer 36. A. In a patient with a bicuspid aortic valve, AI may be eccentric and may appear mild by color Doppler, as the color abuts the septum or the mitral valve and its speed attenuates. Pressure half-time is typically <250 ms in severe AI, but may be >250 ms in chronic compensated AI. The holodiastolic murmur is specific for severe AI and the enlarged LV suggests severe AI. Holodiastolic flow reversal of the descending aorta on the suprasternal view would confirm severe AI.

Answer 37. A. MS is severe, as suggested by physical exam and by the high transmitral gradient and PA pressure despite a heart rate of <80 bpm. The holodiastolic murmur suggests the persistence of gradient in end-diastole with no diastasis, and thus, severe MS. MVA measurement by echo is less reliable than transmitral gradient. The high MVA is likely a miscalculation by the pressure half-time method; for the same MVA, impaired LV compliance leads to quicker rise of LV pressure and a quicker approximation of LA and LV pressures, and thus a shorter pressure half-time (MVA is calculated as 220/pressure half-time).

Answer 38. B. The high velocity across the mitral prosthesis (>1.9 m/s, especially if >2.2 m/s) is abnormal and suggests prosthetic obstruction or alternatively, as implied by exam, regurgitation across the prosthesis. Regurgitation is underestimated because prosthetic struts lead to acoustic shadowing into the LA.

Answer 39 B. While echo suggests severe AS, the auscultation suggests mild-to-moderate AS. In light of the physical exam, this is likely moderate AS with pressure recovery exaggerating the gradient and falsely reducing the calculated AVA.

Answer 40. A. The hybrid AVA of 1.1 cm^2 may suggest moderate AS if 1 cm^2 is used as a severity cutoff, but a prognostic study has suggested a higher cutoff of 1.2 cm^2 for severe AS with this method. The severity of AS remains uncertain, and calcium scoring of the aortic valve, using a non-contrast CT, is recommended.

Answer 41. A. The patient has stroke volume reserve, as his stroke volume increased >20%. Yet, the study did not provide a definitive answer regarding AS severity, as mean gradient and AVA remained discordant (gradient <40 mmHg). This is because the stroke volume did not increase enough; it did not normalize. It is likely true severe AS; one equation estimates the AVA at a normalized flow rate of 250 ml/s and may confirm true severe AS. Flow rate is stroke volume/ejection duration (one systole), which is different from cardiac output: stroke volume/duration of a whole cardiac cycle (systole and diastole). The projected AVA estimates what AVA would be if the flow is hypothetically increased to normal:[216]

$$AVAprojected = AVArest + [(AVApeak - AVArest)/(Qpeak - Qrest)] \times (250 - Qrest)$$

AVAprojected <1 cm^2 implies severe AS. In this patient, Q rest = 54 ml/0.35 = 154 ml/s. Q peak = 68 ml/0.28 = 243 ml/s, which is close to 250 ml/s, and implies that AVA peak is ~AVA projected. Thus, AS is severe. Alternatively, calcium scoring may be used; in fact, the above study validated the AVAprojected equation using CT calcium scoring.

Answer 42. C. The initial numbers suggest low-flow (low stroke volume), low-gradient AS. However, DI is not severely reduced, and suggests that the LVOT velocity is ~1.3 m/s (3.5 × 0.36); in severe AS, particularly low-gradient AS, LVOT velocity is reduced. In fact, a high DI in low-gradient AS often rules out severe AS and suggests a measurement error: LVOT diameter is underestimated→falsely small AVA and stroke volume. Hence, AS is moderate. LVOT velocity may be overestimated by placing the LVOT cursor too close to the AS jet, but this typically causes a falsely high AVA, not a low AVA.

Answer 43. B. Transcutaneous mitral valve replacement (TMVR) through a RA-LA trans-septal puncture is an option in 3 subsets of mitral patients, who have a radio-opaque solid mitral anchor that can hold the stent valve in place: (1) prior mitral bioprosthesis (converts the mitral annulus from saddle-shaped ovale, to uniplanar and circular, providing the most predictable insertion site for the circular TMVR stent); (2) prior mitral ring (particularly complete semi-rigid ring, which is ovale but conforms to the circular TMVR shape, unlike a rigid ring); (3) heavy MAC. Paravalvular leak post-TMVR is highest in patients with TMVR-in-MAC and TMVR-in-ring. The most dreaded complication after TMVR is LVOT narrowing by the mitral stent valve, which is more likely if the aorta is near-orthogonal to the LV axis on the long-axis view (aortomitral angle <115 degrees, similar to Figure 6.8.c), or the anterior leaflet or prosthetic leaflet is long.

Answer 44. C. The most likely cause of severe TR and right HF picture in an elderly patient with permanent AF is atrial functional TR. A, B, and D could be present as well but are unlikely to be the primary driver of her clinical picture. The non-dilated RV, normal TAPSE, and PA pressure <50 mmHg make ventricular functional TR secondary to left HFpEF unlikely. RV is smaller and conical, rather than elliptical. The tricuspid annulus is >2/3 muscular and very dynamic; it readily dilates but also shrinks in response to diuretic therapy, even more than the mitral annulus, and thus TR severity may improve with diuretic therapy.

Answer 45. C. This patient had combined AS and MS. AS worsens the hemodynamic consequences of MS: to allow transmitral flow, LA pressure must increase in parallel to the rising LV diastolic pressure. However, AS reduces MS gradient and may mask the severity of MS, as CO is further reduced with combined AS–MS. Also, MS reduces AS gradient and may mask the severity of AS. After TAVR, CO increases and transmitral gradient rises with the rise in flow, as per Gorlin's equation.

MS from severe MAC is often functionally mild and managed medically. Moreover, MVR is flawed, as outward MAC restricts prosthesis sizing just as it restricts the native valve. The rhythm is P-sensed, V-paced; the rate is dictated by the sinus node, not the pacemaker that simply tracks the sinus P. Hence bisoprolol is useful to reduce the heart rate and gradient. The pulmonic vein flow shows near superimposition of D and A, hence a PR interval that is too long. Shortening the PR interval will increase E and A transmitral separation and lengthen E slope, allowing more LA emptying.

Answer 46. B. The abrupt onset of dyspnea with Valsalva strain could be consistent with: (i) acute PE (abrupt migration of a DVT during deep inspiration that follows Valsalva); (ii) acute coronary plaque rupture/MI/SCAD; (iii) severe MR in a patient with baseline MVP who

develops acute chordal rupture during abrupt afterload rise; (iv) aortic dissection. Severe acute MR is commonly underestimated on exam and TTE echo Doppler, especially because the ensuant giant V wave attenuates LV–LA gradient in late systole and color Doppler severity. MR jet and murmur predominate in early systole. PE is unlikely as there are left HF signs on exam and lung scan.

J Am Coll Cardiol 2017;70:1339–1348. *This study analyzed low-gradient AS measured invasively (mean gradient 24 ± 6, AVA 0.8 ± 0.1). ~40% of patients had normal flow, and most were hypertensive (but not necessarily). Nitroprusside was administered as 0.5 mcg/kg/min and titrated up. ~25% of patients with paradoxical low gradient (whether low flow or normal flow) had an increase of AVA to >1 cm² with nitroprusside, leading to a reclassification into moderate AS. The increase in stroke volume with nitroprusside may unveil a compliant aortic valve (pseudo-severe AS)*.

139. Ito S, Miranda WR, Nkomo VT, et al. Reduced left ventricular ejection fraction in patients with aortic stenosis. J Am Coll Cardiol 2018;71: 1313–1321. *This Mayo registry has shown that 21% of patients with severe AS have EF <50% (mainly if coexisting conditions, CAD/CABG/MI/PCI, LBBB, AF). Prior echos of those patients were assessed: EF starts to sharply deteriorate when AVA becomes 1.2 cm² in patients with baseline EF <60%, but not >60%, implying that EF <60% is particularly unable to accommodate the stress of AS, even moderate AS. Maybe EF 60% should be cutoff for AVR in AS, not 50%.*

Questions and answers 299

I. Definition and features of HCM

A. Definition

Hypertrophic cardiomyopathy (HCM) is defined as LV hypertrophy ≥15 mm, or ≥13 mm with a family history of HCM, without an identifiable cause (no valvular disease, no hypertension, or the degree of hypertrophy is disproportionate to the severity of hypertension). The prevalence in the general population is 1 in 500. HCM is genetic. It is familial, autosomal dominant in 50% of the cases, with high penetrance; the remaining 50% are due to new mutations, or, in older adults, a sporadic polygenic susceptibility to the effects of HTN, obesity, and aging.

B. Asymmetry

The septal thickness is usually greater than 15 mm (13–14 mm is diagnostic if family history of HCM or positive genetic test). The hypertrophy is usually asymmetric and involves the septum and the anterolateral wall with a septal-to-posterior wall thickness ratio of >1.3:1, and more specifically >1.5:1, but it may be symmetric and diffuse, involving the posterior wall in 10–20% of the cases (= concentric hypertrophy).[1–3] One report suggests that the posterior wall is involved in cases of diffuse hypertrophy,[3] while another report suggests that posterobasal wall involvement is very unusual even when hypertrophy is diffuse.[4] Either way, the posterior wall is the site *least* frequently thickened in HCM. Hypertrophy most often involves 2 or more myocardial segments in an asymmetric and sometimes "bumpy" fashion, but may involve only 1 segment.

Severe LVOT obstruction leads to severe afterload elevation that may result in a global LV hypertrophy with time; hence, septal reduction not only reduces septal thickness but also the LV thickness at distant segments.

C. LVOT obstruction

When obstructive, HCM is called *hypertrophic obstructive cardiomyopathy* (HOCM) and is usually characterized by septal hypertrophy that narrows the left ventricular outflow tract (LVOT). The increased velocity across the LVOT exerts drag on the anterior mitral leaflet and its chordae during systole, which further narrows the LVOT and creates LVOT obstruction. This process is called systolic anterior motion (SAM) of the anterior leaflet (both the leaflet edge and chordae); *it is required for generating the LVOT obstruction*. A significant obstruction is characterized by a resting gradient >30 mmHg or a gradient >50 mmHg with provocative maneuvers (peak instantaneous gradient).[1,2] Only 30% of patients with hypertrophic cardiomyopathy have a resting gradient, while 45% have a gradient with provocative maneuvers; the remaining patients have non-obstructive hypertrophic cardiomyopathy.

The gradient is within the LV, i.e., pressure is elevated throughout the LV body and a portion of the LVOT then drops at one point in the LVOT rather than across the aortic valve. On echo-Doppler, the velocity is increased across the point of LVOT obstruction and is decreased proximal to this point (LV inflow and mid-LV cavity) and distal to this point (aortic valve) (Figure 7.1). Mild or moderate MR is usually seen and is associated with SAM of the mitral valve. In up to 10% of HOCM cases, the hypertrophy and the obstruction may be mid-ventricular, as is the case with mid-ventricular HOCM, apical HOCM, or HOCM with anterolateral papillary muscle inserting directly onto the mitral leaflet. The marked septal hypertrophy may also contribute to RV outflow tract obstruction, particularly in children with HOCM.

LVOT obstruction is associated with more symptoms and a higher HF-related mortality, but only a weak correlation with sudden death.

D. Causes of MR in HOCM; mitral valve abnormalities in HOCM

MR is mainly related to SAM; it is ***directed posteriorly*** and peaks in mid and late systole (Figures 7.1–7.3).[5–7] The severity of MR correlates with the severity of the LVOT gradient.[5] MR may be severe (in ~10%) if the posterior leaflet is not elongated enough to meet with the "sucked" anterior leaflet. Severe MR with a relatively short posterior leaflet is expected to improve after myectomy, while severe MR despite an elongated posterior leaflet, or central or anteriorly directed MR, is concerning for a structural mitral abnormality.[8]

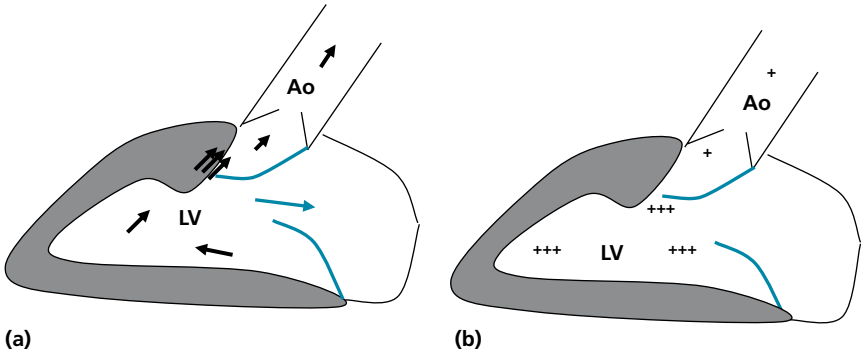

Figure 7.1 **(a)** Asymmetric septal hypertrophy with increased velocity across the LVOT (*3 arrows*). This increased systolic velocity drags the anterior mitral leaflet (SAM) and creates LVOT obstruction as well as a posteriorly directed MR (*blue arrow*). Note the anatomic contiguity of the mitral and aortic valves. Pulsed-wave Doppler should be used to sequentially interrogate the LV from apex up to the LVOT in order to confirm the anatomical level of obstruction. Note the normal velocity across the LV body, LVOT proximal to the obstruction and distal to it, and aorta (*single arrows*). **(b)** Display of pressure throughout the LV in HOCM. Pressure is increased throughout LV inflow, LV body, LVOT (+++), and drops beyond the LVOT obstruction (+). Even pressure at the mitral valve level (inflow tract pressure) is elevated.

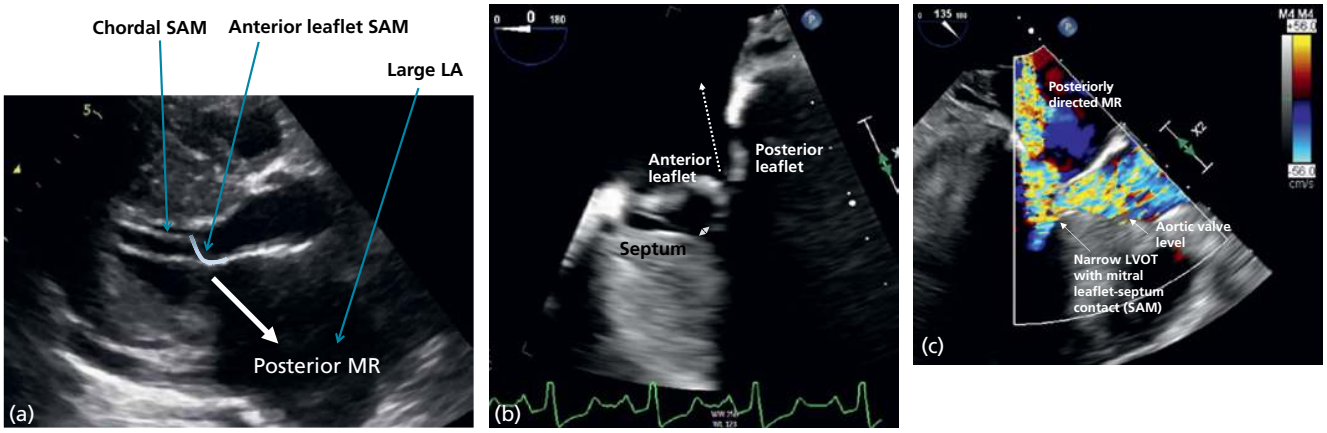

Figure 7.2 **(a)** Parasternal long-axis view of a patient with HOCM, showing SAM of the anterior leaflet tip. Not just the leaflet gets drawn to the septum, but also the chordae (chordal SAM). **(b)** 0° four-chamber TEE view showing SAM of the anterior leaflet. The double arrow shows SAM, i.e., dragging of the anterior leaflet toward the thick septum. The arrow indicates the posterior MR direction. **(c)** 135° long-axis TEE view showing the aliasing of posteriorly directed MR and the aliasing across the narrow LVOT.

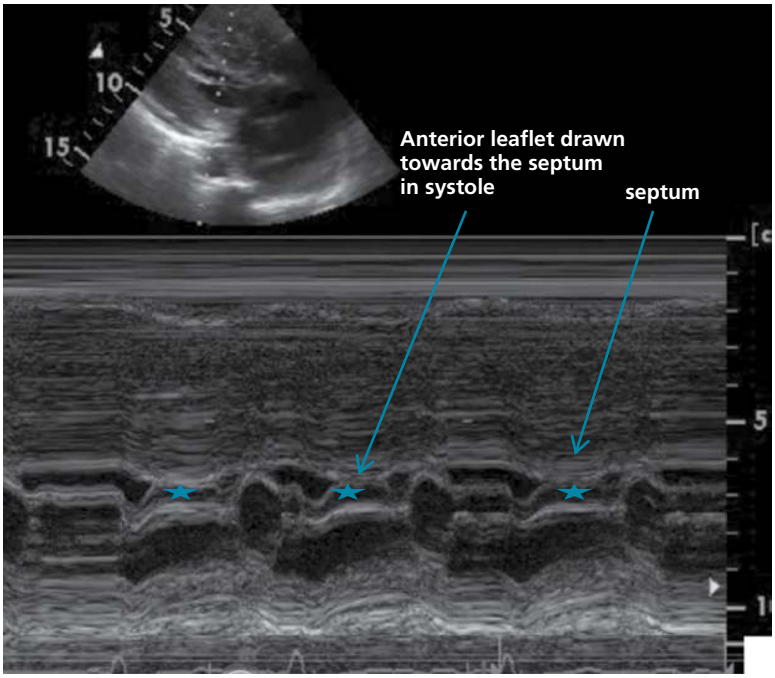

Figure 7.3 M-mode of SAM. The *star* corresponds to the gap between the anterior and posterior leaflets in systole, leading to severe MR in this patient.

- ***Mitral valve abnormalities that aggravate SAM and LVOT obstruction***. Structural valvular abnormalities are common (~20%) and may consist of:
  i. *Anterior leaflet elongation >30 mm*, which provides extra slack and facilitates SAM and LVOT obstruction
  ii. *Central/anterior papillary muscle malposition* (as opposed to anterolateral position)
  iii. *Chordal insertion at the base rather than the tip of the anterior leaflet*
  All these abnormalities facilitate SAM and LVOT obstruction, even in patients with milder degrees of septal hypertrophy ≤ 18 mm. Specifically, (ii) and (iii) lead to tenting of the anterior leaflet anteriorly, into the LVOT stream. Papillary muscle insertion directly on the anterior leaflet, without chordae, may cause LVOT obstruction (as it directly abuts the septum with each beat) and anterior tethering/MR.
- ***Mitral valve abnormalities that can cause a primary form of MR***. Some primary valvular abnormalities can cause MR independent of SAM, and these are seen in 10–20% of HOCM:[5] (i) extreme elongation and prolapse of the posterior mitral leaflet (~9% of operated HOCM);[8] (ii) chordal rupture; (iii) papillary muscle insertion directly onto the anterior leaflet. This primary MR is characterized by a *central or anteriorly directed jet that is usually holosystolic* and is not expected to resolve with septal reduction.[5,6]

E. Apical mid-cavitary HCM. See Section XIII.

II. Natural history and mortality

The HCM phenotype usually develops at the end of the second decade, and screening in adolescence may therefore miss it. The local hypertrophy does not usually worsen in the adult. However, progressive global LV hypertrophy may develop as a result of the LVOT obstruction and increased LV workload, which leads to a vicious circle of more LVOT obstruction and LV hypertrophy. Approximately 5% of patients eventually succumb to this chronically elevated afterload and develop a late phase of LV cavity dilatation with reduced systolic function (*burned-out phase* of HCM).

HCM onset may occur late, in the elderly. Moreover, it is not uncommon for an early HCM to present and be diagnosed late. In fact, in alcohol ablation studies, the median age was 64. In a cohort study, ~25% of HCM patients were elderly (≥75 years old).[9] Elderly presentations are usually associated with milder LVH yet more obstruction.

A population study has shown that the mortality of unselected HCM patients is ~1% per year, which is not different from the mortality of the general population.[9] On the other hand, the annual mortality is 3–6% in high-risk patients with multiple predictors of sudden death or in patients with severe LVOT obstruction, which is predictive of HF-related death.[10]

The gradient is strongly associated with symptom progression, progressive HF, and cardiac death secondary to HF and stroke (AF).[11–13] In fact, in observational studies, patients with obstructive HCM had a higher mortality than patients with non-obstructive HCM or operated obstructive HCM.[11,12] *This is particularly true for patients with severe resting gradient (>100 mmHg, even if asymptomatic), symptoms* (NYHA II or III–IV)*, or functional limitation.*[13,14] A gradient <100 mmHg without symptoms and with a normal functional capacity (>85% of predicted METs) does not impair long-term survival.[13,14] While LVOT obstruction is associated with HF-related death, the specific relation of obstruction to sudden cardiac death (SCD) is significant but weak. The positive predictive value for sudden death is low.

A large cohort analysis has shown that there are 3 modes of death in HCM: SCD (~50%, age 45 ± 20), progressive HF (~36%, age 56 ± 19), and AF-related stroke. SCD, while a relatively more common cause of death in young patients <50 years old, actually has a similar yearly incidence in the older population; neither sudden nor heart-failure-related death showed a statistically significant, disproportionate age distribution.[15]

III. Symptoms and ECG

Most patients with HCM or HOCM are asymptomatic. *Dyspnea* and HF may result from LVOT obstruction and/or the small LV cavity with severely reduced diastolic filling (*restrictive HCM, with or without obstruction*). *Angina* may result from increased demands and from the elevated LVEDP, which impairs coronary microcirculatory flow; myocardial bridging is also common and may contribute to ischemia. Severe functional limitation (class III or IV) is uncommon but may eventually develop in up to 45% of patients with LVOT obstruction, over the course of 10-year follow-up.[11] Conversely, up to 23% of patients may have a paradoxical reduction of gradient with exercise, which partly explains how some patients are asymptomatic.[16]

Two types of *syncope* must be distinguished: (i) exertional and (ii) post-exertional. Exertional syncope is more ominous and is secondary to arrhythmia (e.g., VT or AF) or dynamic LVOT obstruction that worsens with exertion. Conversely, in the post-exertional phase, the reduced peripheral venous pumping reduces venous return to the hypercontractile LV. This increases LVOT obstruction and may lead to syncope, but may also activate the myocardial C receptors of the small hypercontractile cavity, leading to a vasovagal syncope. *HOCM is sensitive to the post-exertional preload reduction and is prone to vasovagal syncope in light of the small, hypercontractile LV cavity*.

Unfortunately, ~70% of patients who die suddenly have no or only mild symptoms prior to SCD, and thus SCD is often the first manifestation in patients who die suddenly. SCD often occurs at rest or with mild activities, but 15% of SCDs occur during moderate or heavy activity (relatively more so in athletes).[15]

ECG shows LVH voltage with a strain pattern, and/or deep T-wave inversion in leads V_2–V_6 even without LVH voltage. Prominent septal depolarization may lead to large Q waves in the lateral and inferior leads (pseudoinfarct pattern). Approximately 10% of HCM patients have a normal ECG, which is a limitation of pre-athletic ECG screening.

IV. Exam (see Table 7.1)

Table 7.1 Exam findings in HOCM vs. AS.

	HOCM[a]	**AS**
Quality	Harsh, crescendo–decrescendo mid-systolic murmur	Harsh, crescendo-decrescendo mid-systolic murmur
Location	LLSB	RUSB
Radiation	Apex/axilla, not carotids	Carotids
Carotid pulse	Brisk, double-peaked (bisferiens)	Slow, small amplitude
Dynamic with maneuvers (Valsalva, handgrip, standing)	++++	+ (changes are not usually audible)
Apical impulse	**Enlarged, triple ripple** (systolic ejection, systolic obstruction, and S_4)	Enlarged, single impulse

[a] MR murmur (SAM) may also be heard with HOCM: blowing, mid-to-late systolic murmur at the apex (while HOCM murmur is best heard at the LLSB). This MR murmur is also worse with Valsalva. The 2 murmurs are heard at 2 different locations and are both dynamic.

V. Invasive hemodynamic findings

In the presence of a gradient between the LV and aorta and if HOCM is suspected, use an end-hole catheter, rather than a multihole catheter, and slowly pull back across the LVOT to localize the site of pressure drop. In addition to the subaortic pressure gradient, the aortic and LV pressure tracings are characterized by the following (Figure 7.4):

1. Systolic aortic pressure has an early "spike" and a late "dome" ("spike and dome" appearance). In fact, LVOT obstruction is dynamic and is less severe in early systole when LV volume is largest, allowing a "peak" in aortic pressure. Obstruction is worst in mid- and late systole when LV volume is reduced, explaining the late "dome."

2. Since LV obstruction is worst in late systole, LV pressure proximal to the obstruction peaks late and has a *late-peaking* "dagger" shape (similar to the spectral Doppler "dagger" shape velocity across the LV).

3. After a premature beat, LV volume increases, but LV contractility increases even more and overwhelms the benefit derived from LV volume, producing an increase in LVOT obstruction. LV pressure increases but the stroke volume decreases, and thus the aortic pulse pressure decreases (*Brockenbrough phenomenon*); the aortic systolic pressure decreases as well. This contrasts with AS, wherein the fixed obstruction does not prevent the increase in stroke volume and aortic pulse pressure after a premature beat; the gradient increases with the increase in flow, as per Gorlin's equation, but the aortic pressure increases as well (Figure 7.5). In both HOCM and AS, the gradient and the murmur increase after a premature beat, but more so in HOCM, and the pulse only decreases in HOCM.

4. Pressure gradient is dynamic with provocative maneuvers. Being dynamic, the gradient may be labile and varies with changes of loading conditions. In fact, the gradient may vary spontaneously at rest if recordings are obtained over 1 to several minutes, without clear provocation. This may be related to gradient variations with respiration or with the patient's wakefulness.

Mid-apical HCM may have true intra-LV focal obstruction with gradient, mainly in the case of apical aneurysm. But beware of the *false gradient* that may occur with any HCM, particularly diffuse HCM: the catheter may get entrapped and compressed intramurally with each LV contraction, creating a systolic spike across the LV tracing simulating an LV–aortic pressure gradient (but not dynamic and no Brockenbrough effect).

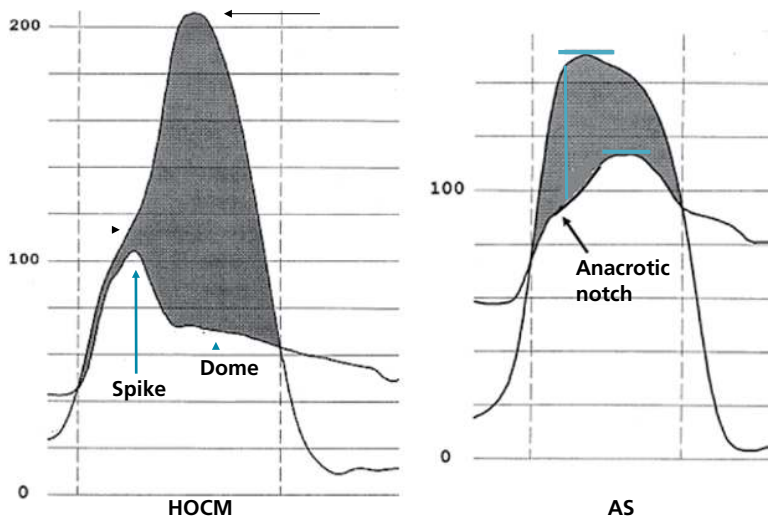

Figure 7.4 HOCM hemodynamics.

Note the early aortic pressure peaking (*blue vertical arrow*), the late LV pressure peaking (*horizontal arrow*), and the late gradient (*gray area*). The aortic pressure peaks in the first 80 ms of systole; then, LVOT obstruction worsens, the LV pressure tracing "bends" then peaks in mid- to late systole while the aortic systolic pressure adopts a "dome" appearance (LV pressure bend, *black arrowhead*). This contrasts with AS, where the aortic pressure bends and peaks late while the LV pressure peaks early.

As opposed to AS, the mean gradient in HOCM does not characterize the obstruction well, as it integrates the unobstructed early part of systole and under-represents the LVOT obstruction. As opposed to AS, **the peak-to-peak gradient approximates the peak instantaneous gradient in HOCM, and both those gradients are used to classify the severity of HOCM (≠ AS, where mean gradient is used).**

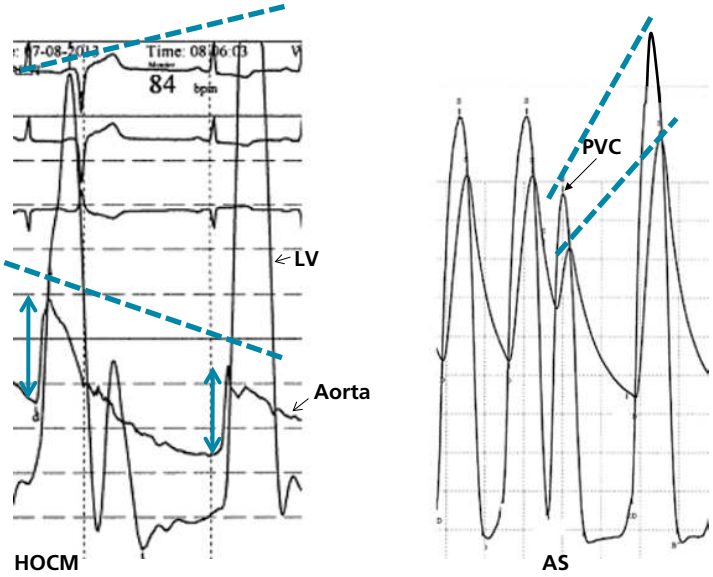

Figure 7.5 Brockenbrough phenomenon after a premature beat in HOCM. Note the increase in pressure gradient (*interrupted lines*) but the reduction in aortic pulse pressure (*double arrows*) after a pause in HOCM, vs. the increase in pressure gradient with an increase in aortic pulse pressure in AS. Note the "spike and dome" appearance of the aortic pressure in HOCM, which becomes more pronounced with worsening obstruction (after the pause).

VI. Echocardiographic findings

Besides the often asymmetric LV hypertrophy, the obstructive form of HCM is characterized by SAM. SAM is seen on the parasternal long-axis view and on the M-mode of the mitral valve (Figures 7.2 and 7.3). The greater the degree and duration of mitral–septal contact (e.g., >30% of systole), the more severe the obstruction. In addition, M-mode of the aortic valve shows mid-systolic closure due to the mid-systolic obstruction. LA enlargement is universal in HCM (*a normal LA size makes HCM unlikely*).

Pulsed-wave Doppler interrogation reveals that the velocity is increased across one point in the LVOT, but is normal (~1 m/s) or low in the LV body and distally across the aortic valve. However, the velocity may also increase in the LV body when hypertrophy is generalized with cavity obliteration, even if the obstruction is mainly at the LVOT level. The LVOT gradient is late peaking, with a "dagger" shape on spectral Doppler. It is dynamic and may be unveiled or worsened by Valsalva maneuver, which should be performed in all cases of

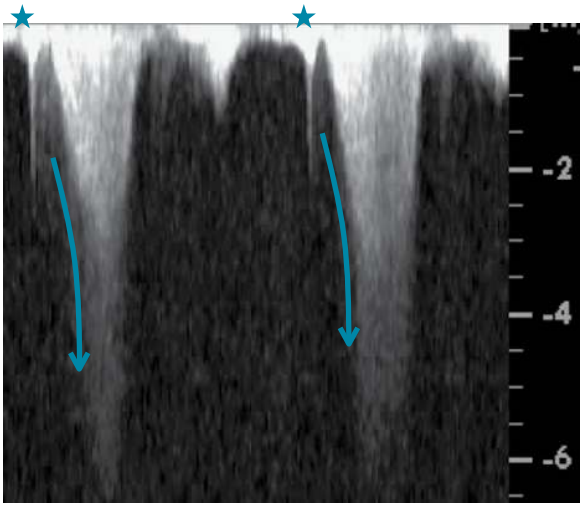

Figure 7.6 LVOT velocity in HOCM: late-peaking dagger-shape LVOT velocity (*arrows*). This is opposed to the parabolic, symmetrical AS Doppler. Occasionally, an older patient may have both AS and HOCM. The continuous-wave Doppler will show two superimposed but distinct ejection envelopes (e.g., AS envelope within the HOCM envelope).

Note the notch in early systole, before the LVOT envelope (*stars*). This notch corresponds to MR and is characteristic of LVOT interrogation in HOCM. In fact, in HOCM, MR is frequently captured on LVOT interrogation, as the mitral flow is in close proximity to the LVOT. Also, LVOT may be captured on MR interrogation.

HCM (Figure 7.6). Aliasing typically occurs across the point of LVOT obstruction rather than the aortic valve. After localizing the site of obstruction with pulsed-wave Doppler, continuous-wave Doppler is required to capture the peak velocity (without the aliasing of PW).

In obstructive mid-HCM with apical aneurysm, mid-LV velocity may be normal because of complete cessation of flow through the obstruction, besides the lower flow generated by the aneurysm. Catheterization, on the other hand, continues to show significant gradient.[17]

Cardiac MRI may be used to further delineate the LV geometry and thickness and mitral geometry when echo is inconclusive (class I recommendation).

VII. Provocative maneuvers

Patients without any gradient at rest may develop a significant gradient with maneuvers. The gradient increases with decreased preload (Valsalva maneuver, hypovolemia, nitroglycerin), decreased afterload (vasodilators), or increased inotropism (exercise, inotropic drugs such as dobutamine). Each of these changes results in closer approximation of the ventricular septum and anterior mitral leaflet during systole. For instance, a reduction in preload or afterload reduces LV volume and the high LV end-systolic pressure that holds the LVOT walls apart. Accordingly, the following circumstances affect the gradient: (i) gradient may rise with faster heart rates if contractility increases; (ii) gradient rises when atrial systole is lost, as in AF, as a result of reduced diastolic filling (preload); (iii) gradient may vary with respiration, particularly deep breathing: inspiration increases LV afterload and reduces the gradient, causing aortic pressure to rise (="reverse pulse paradoxus").

While dobutamine increases the intraventricular gradient in patients with HOCM, dobutamine also induces a significant gradient in up to 20% of patients undergoing dobutamine echocardiography without suspected HOCM or even without LV hypertrophy.[18,19] *Dobutamine-induced gradient does not necessarily imply exertional gradient and should not be used to diagnose HOCM*. In fact, exercise increases myocardial contractility but also preload, which reduces cavity obliteration and the potential for intracavitary obstruction; dobutamine increases myocardial contractility but does not increase preload, and thus more readily creates intracavitary obstruction even in the absence of HOCM. Physiological maneuvers rather than pharmacological interventions should be used to assess provocable gradient (exercise, Valsalva). Valsalva elicits gradients in only 50% of patients with exertional gradients. Thus, in a patient with exertional symptoms, exercise echo is warranted for gradient provocation if Valsalva is negative. As shown in a modern trial, *the highest gradient tends to be in the post-exertional phase, when contractility is still increased but preload drops*: during treadmill stress test, echo measurement of this post-exertional gradient is not only technically easier than measuring the exertional gradient but also more sensitive for gradient detection.[20]

VIII. Genetic testing for diagnosis; screening of first-degree relatives

Genetic testing identifies definite single-gene pathogenic mutations in only 40–60% of HCM cases. While the genes affected in HCM are known, the specific nucleotide variants vary widely; some sequences represent definite pathogenic mutations of the gene, while others may represent predisposing variants that may develop into HCM with environmental factors (HTN) or multi-gene involvement. Therefore, a positive test definitely establishes the HCM genotype, but a negative test is unhelpful.

Genetic testing of an index patient is indicated for family screening purposes. If the patient tests positive for a definite pathogenic mutation, first-degree family members should be screened for that same mutation. The absence of this mutation excludes the risk of HCM occurrence in these relatives and obviates the need for ongoing clinical surveillance. A positive genotype with a negative phenotype in a family member indicates a considerable risk of developing HCM; routine ECG and echo follow-up is performed throughout life. The risk of SCD is low, and these individuals may participate in intense athletic activities with proper surveillance (ACC class IIa).

Short of genetic testing, first-degree relatives of HCM patients should undergo yearly ECG and echocardiograms starting in early adolescence and until the age of 21.[21] Approximately 25% of those patients will develop HCM. Afterward, they need to be screened every 5 years for the late development of HCM (more frequent interval in case of athletic activity [e.g., 1 year] or family history of SCD).

IX. Differential diagnosis of LVOT obstruction

The differential diagnosis of dynamic LVOT obstruction includes the following:

1. Patients with hypertension and generalized *or* asymmetric LV hypertrophy may develop intracavitary LV obstruction, particularly in case of hypovolemia. LVOT obstruction and a true LVOT gradient may be seen, but the gradient is mild (rarely exceeds 100 mmHg). This is called **"hypertensive hypertrophic cardiomyopathy" or "hypertensive obstructive cardiomyopathy,"** and unlike HOCM, is not associated with myofibrillar disarray.[22,23]

- *Similarities with HOCM*. While hypertensive obstructive cardiomyopathy is typically symmetric,[23] ~5% of all hypertensive patients have asymmetric septal hypertrophy and up to 34% of cases of severe hypertensive LV hypertrophy are asymmetric and predominantly septal (septal-to-posterior wall thickness >1.5), particularly in elderly patients with sigmoid septum, which further mimics HCM.[24–26]
- *Differences from HOCM*. As opposed to HCM, the septal thickness in hypertensive cardiomyopathy does not usually exceed 20 mm,[23] the hypertrophy does not have a bumpy heterogeneous morphology, SAM is less common,[23] and there is usually a diffuse increase in velocity throughout the LV, including the mid-cavity, directing the attention toward globally abnormal ejection hemodynamics. Ancillary signs of severe HTN are typically present and help distinguish this entity from HOCM (aortic sclerosis, aortic dilatation, nephropathy). Severe MAC, on the other hand, may be seen with either HOCM or severe HTN, and is induced by the stress of high LV systolic pressure. This obstructive cardiomyopathy is more prevalent in the elderly female, particularly black female, in whom the LV cavity is small.[22,23]

In a patient with systemic HTN, a diagnostic dilemma frequently arises in determining whether the markedly increased LV wall thickness is solely a reflection of HTN or, alternatively, whether it is a manifestation of a coexistent, genetically determined HCM.[24] In addition, it is possible that some of these patients have a genetic HCM substrate that evolves into a HCM phenotype when exposed to longstanding HTN.[23] Genetic testing, if positive, or a family history of HCM helps point toward genetic HCM. On the other hand, ancillary manifestations of HTN, such as aortic dilatation or nephropathy, support the diagnosis of chronic severe HTN. One study, however, has shown that severe hypertrophy with LVOT gradient in severely hypertensive patients is indistinguishable from hypertrophic cardiomyopathy in normotensive patients, with similar SAM rates, pressure gradient (frequently exceeding 100 mmHg), and septal thickness, implying that "hypertensive obstructive cardiomyopathy" may, in fact, be a genetic HOCM with coexistent HTN rather than a hypertensive cardiomyopathy.[27]

For practical purposes, LVH >15–20 mm with significant SAM and LVOT obstruction, in the absence of severe hypovolemia or sepsis, is pathophysiologically a HOCM, even in a hypertensive patient and even if hypertrophy is symmetric, and is managed as HOCM.[27] In fact, a firm diagnosis of genetically determined HOCM is not always present in patients treated for the disease, even in HOCM studies and even when invasive therapies are used. This is related to the phenotypical overlap of HOCM and severe hypertensive cardiomyopathy and the limitations of genetic testing. Over 50% of patients in HOCM studies are hypertensive.

2. Severe asymmetric septal hypertrophy with subaortic obstruction is also seen in ~10% of patients with severe AS and is unmasked after aortic valve replacement (septal thickness up to 22 mm).[28] Doppler flow acceleration develops postoperatively and is attributed to LVOT obstruction and SAM in some series, while other series attribute it to the hyperdynamic small LV cavity that totally obliterates in systole. This obstruction is associated with postoperative hypotension, increased morbidity and mortality, and long-term persistence of a gradient in some patients. It is mainly treated medically (β-blockers, avoidance of inotropes, fluid resuscitation); a limited pre-emptive myectomy has been selectively used in patients with severe septal bulge, with good results (see Appendix 1).[29]

3. LVOT obstruction is frequently seen in patients receiving dobutamine regardless of the presence of LV hypertrophy and does not signify HOCM per se, as the obstruction may not be reproduced during exercise in most of these patients. It may also be seen in hospitalized patients with severe hypovolemia or sepsis and an empty, hypercontractile LV cavity, even if LVH is mild.

4. A pattern of LVOT obstruction and mitral SAM may also be seen in patients with apical dyskinesis and hypercontractile LV base, as in large anteroapical infarction or takotsubo cardiomyopathy.

Another form of subvalvular obstruction is subvalvular aortic stenosis that results from a discrete fibrous membrane or fibromuscular thickening within the outflow tract, just below the aortic valve (see Chapter 6). It leads to a fixed obstruction, the characteristics of dynamic LVOT obstruction being absent: no dagger-shaped LV pressure, no spike-and-dome aortic pressure, and no Brockenbrough phenomenon. *As opposed to HOCM, the gradient does not worsen with maneuvers such as Valsalva*.

X. Differential diagnosis of severe LV hypertrophy

Severe LV hypertrophy (septal thickness >15 mm, sometimes >20 mm) may be seen in ***hypertension or AS*** and may be asymmetric and/or obstructive.

In older patients, elongation of the aorta changes the angle of the aortic–septal junction and leads to a ***sigmoid septum***. A sigmoid septum exaggerates the degree of asymmetric septal hypertrophy and may lead to LVOT obstruction (Figure 7.7).

A severe increase in septal thickness may also be seen with infiltrative disorders such as ***amyloidosis***; in this case, thickening of the valve leaflets and the interatrial septum is often seen, along with a pericardial effusion. The increase in LV thickness is related to infiltration rather than true hypertrophy and is usually diffuse but may be asymmetric and obstructive. The familial form of TTR amyloidosis may be seen at a young age and is, therefore, more likely to simulate HCM. An ECG showing a disproportionately low voltage differentiates amyloidosis from HCM but is insensitive. Technetium pyrophosphate scan *and* serum and urinary protein immunofixation allow the diagnosis or exclusion of amyloidosis.

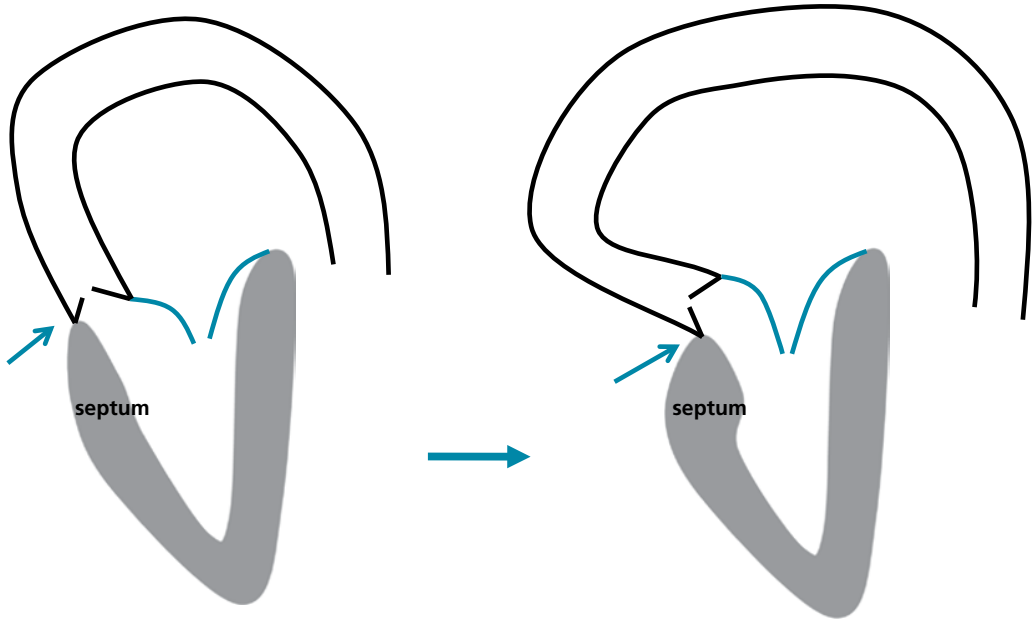

Figure 7.7 In the elderly, elongation of the aorta sharpens the angle between the aorta and the septum (*arrow*) and leads to a sigmoid "stocky" septum. A mild septal hypertrophy is transformed into a more severe, discrete septal thickening (DUST: discrete upper septal thickening).

Table 7.2 Athlete's heart vs. HOCM.

	Athlete's heart	**HOCM**
Septum thickness	≤13 mm, gray zone: 13–15 mm	≥15 mm, but can be less (gray zone)
LV diastolic diameter	Normal (>45 mm)	<45 mm (small cavity)
LA enlargement	Mild or none	≥ mild
LV filling (diastology)	Normal	Abnormal diastology
Family history	None	(+) for HCM, SCD
LVH response to deconditioning (weeks)	↓ LVH	No ↓ LVH
SAM	No SAM	(+) SAM

Fabry disease (X-linked, α-galactosidase deficiency) causes sphingolipid myocardial deposition and biventricular thickening; unlike amyloidosis, QRS voltage is increased. **In a young patient with severe ventricular thickening, consider HCM, TTR amyloidosis, and Fabry disease. Besides specific amyloidosis and Fabry tests, LGE pattern on MRI helps differentiate between the 3** (see Chapter 5, Section 1. X).

While the septal thickness is usually ≥15 mm in HCM, it can be 13–15 mm in up to 15% of the patients, overlapping with the degree of wall thickening commonly found in hypertensive cardiomyopathy and occasionally found in normal athletes (Table 7.2). Hypertrophy can also be concentric in 10–20% of patients. *In these cases, a mild hypertrophy that is otherwise unexplained in a young patient suggests HCM*.

XI. Treatment of symptoms

A. Chronic traditional medical therapy of HOCM

Medical therapy consists of agents that reduce inotropism and chronotropism: ***β-blockers*** or ***non-DHP CCBs***. By reducing inotropism and the LV ejection speed, they reduce the mitral valve drag. By reducing the heart rate, they increase preload and diastolic filling time, and reduce functional ischemia. A third agent, ***disopyramide***, may be used (class Ia antiarrhythmic drug with potent negative inotropic effect and mild vasoconstrictive effect).[7] These drugs do not affect SCD.

β-Blocker therapy titrated to a heart rate of 60 bpm is the first-line therapy. It mainly blunts the provocable gradient and is mostly effective in patients who have a provocable gradient with no or mild gradient at rest,[30,31] or patients with baseline tachycardia. Yet, a modern randomized trial showed ~70% reduction of resting, exertional, and post-exertional gradients with ß-blocker therapy, along with MR reduction and symptomatic and troponin T improvement. However, no effect was seen on peak VO_2, peak workload, peak PCWP, BNP, or diastolic parameters (likely because of its negative lusitropic effect).[32,33] In addition, despite increasing stroke volume at rest and with exercise, ß-blocker therapy slightly reduced exertional CO by blunting heart rate. The symptomatic relief was likely solely due to reducing the myocardial ischemia elicited by high LV pressure.

Overall, β-blocker therapy is associated with a 50–60% initial success. This success is higher in patients whose main gradient is a provocable gradient, and is lower in patients with severe resting gradient or class III–IV symptoms at baseline.[30,31] In non-responders who have a mild resting gradient, a switch to verapamil may control symptoms. In non-responders who have a high resting gradient, β-blockade may be combined with disopyramide. The combination of a β-blocker and a CCB is best avoided, except, if needed, for AF rate control.

Verapamil has more vasodilating and hypotensive effects than β-blockers and may paradoxically worsen the gradient through a reduction of afterload (rare). In fact, verapamil is associated with an early mortality risk when used in patients with severe dyspnea (at rest) or severe LVOT gradient >100 mmHg and should be reserved for patients with mild gradients.

Disopyramide has a minimal bradycardic effect and , unlike β-blockers and CCBs, is highly effective in reducing the resting gradient. In one study, the addition of disopyramide reduced the resting gradient by ~50% and controlled symptoms in two-thirds of patients, without any proarrhythmia or safety concern.[34]

Hypovolemia should be avoided in these patients at all times. ***Diuretics and vasodilators worsen LVOT obstruction by reducing preload and afterload, respectively, and thus should be avoided.*** In fact, a symptomatic patient who is receiving a diuretic and/or a vasodilator experiences a significant symptomatic improvement upon cessation of these agents.

Yet, a small diuretic dose may be carefully used in HOCM patients with persistent congestive symptoms or HTN (class IIb).

B. HTN concomitant to HOCM

Patients with HOCM and severe HTN that is not controlled with a ß-blocker or a non-DHP may undergo a nitroprusside challenge in the cath lab to see whether vasodilators can lower BP without worsening LVOT obstruction. Alternatively, consider outpatient trial of a vasodilator or diuretic. If LVOT obstruction worsens, eradicate the gradient with mavacamten or septal reduction before aggressive HTN therapy.[35]

C. Myosin inhibitors, e.g., mavacamten

Mavacamten is a myosin inhibitor that acts as a negative inotrope. It may be added to β-blocker or CCB, with a dramatic improvement of symptoms and LVOT gradient: >60% reduction of resting and post-exertional gradient (EXPLORER-HCM trial), and 81% complete SAM resolution.[36] Also, NT-proBNP, LV mass, E', and LA volume significantly improve with mavacamten, unlike in the beta-blocker trial.[37] It is so efficacious that it frequently obviates the need for septal reduction therapy in symptomatic patients who previously required it. In the VALOR-HCM trial of severely symptomatic patients eligible for septal reduction, 82% no longer required the procedure 4 months after mavacamten treatment.[38] It is given a class I ACC recommendation for HOCM patients with persistent symptoms despite first-line treatment with ß-blockade.

Mavacamten has no reported pro-arrhythmic side effects. It inherently reduces EF by ~4%, and the only hazard is excessive EF reduction to <50%, which occurs in ~5–10% of patients and reverses with temporary 2- to 4-week mavacamten interruption. The starting dose is 5 mg/day; echo is performed every 4 weeks and is used to titrate drug dosage based on LV EF and LVOT gradient (titrate to 10 mg then 15 mg if high gradient persists, or interrupt for 4 weeks then use a lower dose if EF declines to <50%).

A newer cardiac myosin inhibitor, aficamten, has a shorter half-life than mavacamten (3 vs. 8 days), and thus reaches steady-state faster (in 2 vs. 6 weeks) and allows quicker up-titration and quicker washout, with fewer CYP450 interactions and less EF reduction. It also dramatically reduces LVOT gradient by >60% while improving diastolic parameters (MAPLE-HCM trial).

D. AF

Paroxysmal or persistent AF eventually develops in 20% of patients with HCM. In an old registry, AF was associated with a striking increase in long-term mortality (>3×), owing to increased HF-related death and stroke (>2%/year) and functional impairment. This risk was particularly high with early AF onset (≤50 years) or LVOT obstruction.[39,40] Persistent AF was associated with a particularly adverse prognosis and ~3-fold more adverse outcomes than paroxysmal AF.[39,40] However, in a modern registry where patients were mostly rhythm controlled, AF was no longer associated with increased mortality or HF or symptomatic progression.[39,40] Overall, this suggests the importance of rhythm control as the preferred first-line strategy (ACC HCM guidelines). Amiodarone is the most effective antiarrhythmic drug, but sotalol or disopyramide may also be used,[1,39,40] and catheter ablation is appropriate for drug failure. Surgical Maze is most effective (75% freedom from AF at 1 year) and should be considered in HOCM with AF undergoing surgical myectomy.[39,40] Digoxin is preferably avoided in light of its positive inotropic effect.

HCM-related AF is associated with a high risk of thromboembolic events regardless of CHADS2 score, and thus warrants chronic anticoagulation.

E. Acute therapy of acute HF or shock

Patients with HOCM or hypertensive obstructive cardiomyopathy who develop pulmonary edema are acutely treated with *β-blockers*. Diuretics may worsen LVOT obstruction and thus, paradoxically, worsen pulmonary edema.

Mitral stenosis and HOCM are the only 2 conditions wherein acute pulmonary edema is treated with β-blockers.

Patients with HOCM who develop hypotension are treated with *intravenous hydration*. If pulmonary edema is also present, *α-agonists* may be used, as they increase afterload and thus reduce LVOT obstruction. Positive inotropes should be avoided.

F. AV sequential ventricular pacing

Ventricular apical pacing leads to a delayed and less effective contraction of the basal septum, which reduces the LVOT narrowing. AV delay must be programmed short enough to ensure ventricular pacing without A truncation (~100 ms). Studies have shown a moderate efficacy of DDD pacing on the reduction of gradient (40–50% gradient reduction, with substantial variability). However, despite a real reduction of gradient in most patients, the effect of pacing on symptoms is more controversial: 40–60% of patients show symptomatic improvement with DDD pacing, yet the same number of patients show symptomatic improvement with atrial pacing (placebo), and the objective functional capacity only shows limited improvement.[7,41] This implies that most of the symptomatic benefit from pacing is a placebo effect. Pacing appears more efficacious in patients over 65 years of age, where objective functional improvement is seen. DDD pacing with

ventricular capture is recommended in patients who otherwise have an indication for pacing or symptomatic patients older than 65 undergoing ICD placement anyway for sudden death prevention (consider dual-chamber ICD instead of single-chamber ICD, class IIa).

G. Invasive septal reduction

Septal reduction is indicated in patients with class III/IV dyspnea or angina refractory to ≥1 drug at optimal dose, septal thickness ≥ 16 mm, and a peak instantaneous gradient of >50 mmHg at rest or with physiological maneuvers (not dobutamine). Also, recurrent syncope or near-syncope, whether exertional or post-exertional in nature but not clearly vasovagal, is an indication for septal reduction.

Septal reduction strikingly improves symptoms and the long-term risk of HF-related death. Myectomy may also reduce the risk of SCD.

There are 2 modalities of septal reduction:

1. **Surgical myectomy.** Myectomy consists of resecting the septal bulge through the aortic valve and has a low operative mortality (<1%). It achieves total abolition of the gradient and symptom resolution in >90% of patients, with normalization of long-term survival.[12] In addition, it appears to be associated with a reduction of the risk of ventricular arrhythmia (reduction of yearly ICD discharges). MR, even when severe, totally resolves with septal ablation. Yet, the minority of patients with severe independent MR (e.g., MR related to posterior leaflet prolapse) require mitral repair. Also, LVOT obstruction related to mitral abnormalities may require concomitant anterior mitral plication or papillary muscle/chordal reorientation.[6,42] The latter is particularly suggested when LVOT obstruction is associated with a relatively thin septum ≤ 18 mm.[42]

   Cutting the left septum is associated with a high risk of LBBB (~40%) and a low risk of complete AV block (~2%).

2. **Alcohol septal ablation.** Alcohol septal ablation is a percutaneous coronary procedure that consists of wiring the first or large septal branch that supplies the basal septum and injecting it with alcohol through a balloon catheter. This leads to infarction of the basal septum. The operative mortality is ~1%, and the symptomatic improvement is similar to that of myectomy. A retrospective analysis has shown that alcohol ablation is associated with a 4-year survival free of severe symptoms similar to myectomy (~80%) but may be less effective on symptoms and survival in patients <65 years of age.[43,44] An acute response with a striking gradient reduction—due to a mixture of septal necrosis and stunning—is followed by a gradient rise to about 50% of the pre-procedural level the next day(s) because of edema-induced septal thickening and recovery of stunning. This is succeeded by progressive septal thinning and scarring, with a great reduction of the gradient over 3 months. MR also improves with septal ablation.[44]

   Limitations – Alcohol ablation abolishes the gradient (83%) less commonly than myectomy and is associated with an early risk of VT/VF (as with any MI). Its value is more limited in patients with 1, and particularly 2, of the following: severe septal hypertrophy (>25 mm), resting LVOT gradient >100 mmHg, age <65 years.[43,45] It is also limited in patients with mitral valve abnormalities that are contributing to LVOT obstruction, *hence the* ***importance of careful preoperative assessment of anterior leaflet length, papillary malposition, and chordal insertion, using TEE and MRI if needed.*** The success is dependent on identifying a major septal branch supplying the focal hypertrophy, as proven by contrast echocardiography (echocardiographic contrast injected in the septal artery while echo is performed). Since it induces a myocardial scar, there is a concern about a long-term arrhythmogenic potential, not seen with myectomy.[46] This was shown in one analysis of alcohol septal ablation that used high doses of alcohol, but not in others.[43,46]

   Conduction abnormalities – Since the first septal branch supplies the right bundle, alcohol ablation is associated with a high risk of RBBB (~50% RBBB vs. LBBB with myectomy). It is also associated with a risk of high-grade AV block requiring permanent pacing (~12%, higher than the risk of AV block with myectomy).

   Both septal reduction strategies are favored by ACC guidelines.[1] Take into account structural mitral abnormalities, severity of gradient and septal thickness, and baseline LBBB (the latter 3 favor surgical myectomy), as well as coronary septal anatomy, surgical risk, and local expertise.

Note that, following septal reduction, there is a reduction of LV thickness in remote (non-ablated) areas and a decrease in the overall LV mass. In fact, severe LVOT obstruction, whether due to symmetric or asymmetric LV hypertrophy, increases LV workload and thus potentiates a vicious circle of progressive LV hypertrophy. Therefore, in HOCM, a component of LVH is secondary to the LVOT obstruction itself. Thus:[47–49]

1. Septal reduction therapies are likely useful in patients with symmetric global hypertrophy who exhibit LVOT obstruction.[47]
2. While septal reduction studies have only aimed to treat genetically determined HOCM, it is likely that many patients with hypertensive obstructive cardiomyopathy were inadvertently included in these studies, particularly given that distinguishing these 2 disease entities is not always possible. In fact, in a large registry that proved the efficacy of alcohol septal ablation, the mean age was 64 (mostly women), 54% of patients had hypertension, and 37% of patients had concentric hypertrophy (mean LV thickness 20 mm), implying that some of these patients who were labeled HOCM and who benefited from septal ablation may in fact have had hypertensive obstructive cardiomyopathy.[43] *Thus, in the right patient with severe hypertrophy and LVOT obstruction, septal ablation may be considered for a HOCM pathophysiology even if the diagnosis of genetic HOCM is uncertain*. Two small studies have shown positive results of alcohol septal ablation in the treatment of obstructive hypertensive hypertrophy that is concentric and severe and in the treatment of obstructive hypertrophy with sigmoid septum, which is not usually a genetic form of HOCM.[47,48]

H. Activity restriction

Traditionally, it has been thought that exercise increases LV obstruction and LV ischemia, exposing the athlete to an immediate risk of arrhythmia and a long-term risk of progressive fibrosis, hence the restriction of physical activity to low-intensity sports. Yet, data suggest that moderate or even high-intensity sports are safe and associated with favorable LV remodeling (improved LV compliance → increased LV

diastolic volume, reduced overall LV thickness, increased VO_2).[50] Also, higher conditioning improves vagal tone and potentially arrhythmias (including VT). Thus, vigorous sports are given class IIa by ACC guidelines. Even competitive athletic activity may be considered (class IIb), after comprehensive risk evaluation and ICD placement if independently indicated. In fact, multiple prospective studies showed that HCM patients engaging in competitive athletics did not experience a higher arrhythmic risk than patients exercising less or not at all, or patients who withdrew from athletics.[51–53]

Data from the ICD sports registry suggests that it is relatively safe for HCM patients with ICD to engage in athletic activity (class IIb).[54] Most shocks occurred outside training or competition with no shock-related injuries.[54]

I. Nonobstructive HCM

Nonobstructive HCM may cause a restrictive phenotype with severe symptoms related to diastolic impairment. General HFpEF therapies apply, such as diuretics and AF, HTN, and obesity control. HFpEF data suggest against heart rate reduction and β-blockade, a finding replicated in a crossover trial of bisoprolol vs. verapamil vs placebo in nonobstructive HCM. Bisoprolol worsened exertional VO_2, symptoms, NT-proBNP, and diastolic indices (LA volume, E, and TR velocity) vs. placebo. Verapamil was neutral on peak VO_2, symptoms, and diastolic indices, but improved E′ and NT-proBNP (some lusitropic effect).[55] Notably, peak heart rate was 157 ± 19 bpm with placebo and got blunted by bisoprolol > verapamil (120 vs 141 bpm). Thus, β-blockade is harmful in nonobstructive HCM, whereas verapamil remains a viable option, especially for angina or palpitations.

In the ODYSSEY-HCM trial that specifically studied non-obstructive HCM, mavacamten did not improve symptoms or peak VO_2, although it dramatically reduced NT-proBNP by ~60% and troponin by 51%, and improved diastolic echo parameters.[55] EF declined to <50% in ~20% of patients, which could explain the lack of improvement of the primary endpoint.

XII. Treatment: sudden cardiac death risk assessment and ICD therapy

In a retrospective analysis of a large cohort of patients with HCM who received an ICD, ICD therapy for VT/VF occurred at a rate of ~11% per year in patients with a prior SCD, and ~3.5% per year in patients with any one of the following: HCM-related death in first-degree relative(s) younger than 50 years, prior unexplained syncope (inconsistent with vasovagal syncope), massive LVH ≥ 30 mm, or 1 or more runs of NSVT on Holter.[56] A study of unselected HCM patients suggests that the combination of 2 or more risk factors, including an abnormal BP response to exercise, more specifically predicts an increase in SCD.[56]

The ACC guidelines recommend ICD placement in HCM patients who have any one of the following:[1]

1. Prior history of SCD or sustained VT (class I)
2. Family history of SCD in one or more first-degree relatives (IIa)
3. LV wall thickness ≥ 30 mm (IIa)
4. Unexplained, recent syncope (IIa). Being preload-dependent, HCM patients are prone to neurally mediated syncope and LVOT-obstruction syncope, such as syncope occurring after a rapid change in posture, emotion, micturition, prolonged standing, or *after* exertion. Syncope occurring in these contexts is not associated with an increased risk of SCD.[57] Unexplained syncope is syncope not due to LVOT obstruction or vagal mechanism, and may occur at rest, during sitting, lying, light activity, or during peak exercise. Unexplained syncope that is recent (<6 months) is associated with a 5-fold increase in SCD; unexplained, remote syncope may also be associated with some increase in SCD (unless remote >5 years, or remote >6 months in a patient >40 years old).[57]
5. Reduced LVEF < 50%, or apical aneurysm (class IIa)
6. In the absence of the above, perform Holter monitoring seeking NSVT, then cardiac MRI. ICD is considered for NSVT, mainly fast runs that last ≥ 10 beats and occur ≥3 times within 48 hours, or for late gadolinium enhancement on MRI involving ≥15% of the LV mass (class IIb).

When indicated, a subcutaneous ICD or a single-lead, single-coil RV ICD is preferred, to reduce the long-term risk of lead failure (except when pacing is also contemplated to reduce LVOT obstruction in a patient >65 years).

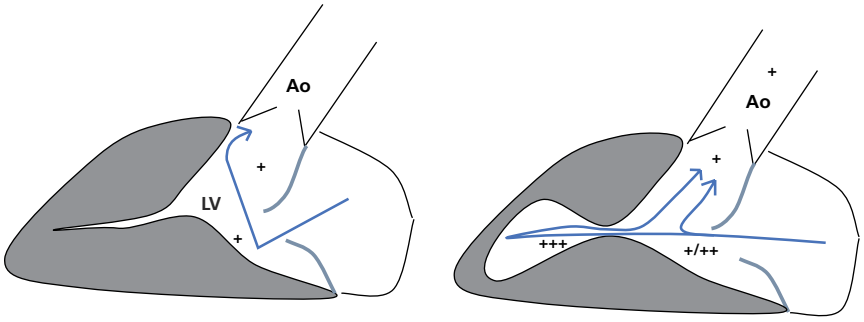
XIII. Apical HCM, mid-cavitary HCM, and mid-cavitary HCM with apical aneurysm

Apical and mid-cavitary HCMs are a continuum. This form of HCM starts as diffuse mid-cavitary and apical thickening, *with or without mid-LV obstruction* (Figure 7.8):

- Diffuse apical HCM does not cause apical obstruction per se, as the whole apex obliterates, pushing blood away rather than holding it in a pouch. Patients may be severely symptomatic from the severely restricted LV cavity size and diastolic filling.
- Mid-cavitary obstruction may occur because of thickened papillary muscles or more predominant mid-cavitary thickening.
- Mid-cavitary obstruction particularly occurs and becomes pronounced when apical HCM evolves into apical aneurysm, at which time a pouch is created with a point of obstruction between the apex and the LVOT. ~95% of patients with apical aneurysm have mid-LV obstruction.[17]

About 10–20% of patients with mid-cavitary and apical HCM may eventually infarct the apex over the course of 7–10 years and develop LV apical aneurysm.[17] This is the result of: (i) coronary flow steal away from the apex by the more proximal mid-cavitary hypertrophy; (ii) mid-cavitary obstruction, when present, causes the apex to generate high systolic pressures, making it subject to much more ischemia than the rest of the LV. This, coupled with its severe apical hypertrophy (high O_2 demands) and more intense micro-coronary compression, creates severe apical ischemia. The higher the papillary muscles insert at the base of the LV, the higher the mid-LV obstruction and the larger the apical aneurysm. When apical aneurysm forms, mid-LV obstruction is seen in 95% of the patients with a clear obstruction point between the apical pouch and LVOT → this worsens the pressure inside the aneurysm, causing further ischemia and dilatation of the aneurysm over time.[17]

As compared to apical-mid-cavitary HCM without obstruction, apical-mid-cavitary HCM with mid-LV obstruction coincides with apical aneurysm in the vast majority of the cases, whether because apical aneurysm is more likely to result from mid-LV obstruction or because apical aneurysm creates a point of mid-LV obstruction. Mid-LV obstruction is relevant prognostically; practically, however, *assessing whether there is mid-LV obstruction in a symptomatic patient is a moot point, as symptoms in apical HCM are mostly driven by*



(A) Apical-mid HCM with no obstruction

(B) Apical-mid HCM with apical aneurysm and obstruction

Figure 7.8 (A) To have LV obstruction, there must be a discrete narrowing between 2 LV zones. In diffuse apical HCM, there may not be any obstruction as blood swirls from the LV inflow to the outflow and bypasses the obliterated apex (*blue arrow*). LV velocities may be diffusely increased, but there is no pressure gradient. Those patients may be symptomatic from the severe reduction of LV cavity size and diastolic filling (restrictive process), but not from LV obstruction. Plus sign (+) indicates the local pressures. **(B)** In mid-cavitary HCM with apical aneurysm, there is a discrete intra-LV occlusion as blood flows between the apical pouch and the LVOT (*blue arrow*). Thus, a pressure gradient is present between the apex on the one hand (high pressure +++) and the LVOT on the other hand (lower pressure +). The inflow may or may not build a pressure gradient: this depends on how much inflow blood bypasses the apex and ejects directly in the LVOT. On Doppler, there may be a point of high velocity at the mid-cavitary obstruction, but not always, as there may be complete flow cessation at the occlusion point.

the small cavity restriction and qualify for apical myectomy even without LV obstruction.[58] Mid-cavitary HCM with apical aneurysm has a particularly unfavorable prognosis with a high risk of sudden death, LV obstruction, and LV thrombus formation, mainly when the aneurysm is larger than 2 cm^2.[59] Although apical HCM was originally considered benign, recent data suggest an annual mortality of 0.5–4%, approaching that of classic HCM, and much more so when apical aneurysm forms.[59]

Treatment of apical HCM

Regardless of the presence of intra-LV obstruction, patients with apical HCM are symptomatic from the diffuse apical hypertrophy causing a very small cavity size and restricted diastolic filling. Severely symptomatic patients with LVEDV < 50 ml/m^2 may benefit from apical myectomy, wherein the thick myocardium is shaved to augment the LV cavity and filling (class IIb).[58] The shaving extends from the apex all the way up to the midventricular level and to any potential mid-LV obstruction. Patients with apical aneurysm (~20% of apical HCM) may still undergo this procedure, with total resection of the aneurysm and shaving of the remaining, non-aneurysmal mid to apical LV. Practically, *assessing for mid-LV obstruction is a moot point, as most symptoms in apical HCM are driven by LV cavity restriction regardless of obstruction*: in the Mayo study, only 23% of patients benefiting from apical myectomy had mid-LV obstruction.[58] A concomitant LVOT obstruction (20%) is more relevant for surgical planning as it dictates additional myocardial excision. Also, apical aneurysm is highly relevant prognostically and surgically.

Septal ablation is inherently not an option, as the hypertrophy is more diffuse than in LVOT obstruction, the LV obstruction is not particularly relevant, and the dreaded hazard of this entity is LV aneurysm, which is only aggravated by septal ablation-induced infarction.

XIV. Athlete's heart

Endurance-exercise athletes (dynamic exercise) tend to develop *LV dilatation with eccentric hypertrophy* as a result of a sustained increase in workload. Resistance-exercise athletes (static/isometric) may rather exhibit *concentric hypertrophy* driven by bursts of high pressure (e.g., weightlifting, boxing). This also depends on sex and race. For instance, black athletes tend to have a concentric, non-dilated pattern of hypertrophy. Yet, generally, most athletes (~70%) have normal LV geometry, with ~20% of endurance athletes of either sex having eccentric hypertrophy, and ~15% of male endurance athletes having concentric geometry (remodeling or, less often, hypertrophy); the latter is less common in women, ~5%.[60,61] Upon detraining, LV thickness normalizes but LV size does not normalize in ~20% of patients (unclear significance). Even when LVH is present, all patients have normal indices of diastolic function.[60,61]

Athlete's LV and study of NBA basketball players – In one study of NBA players, LVH, defined as LV mass >115 g/m^2, was common (**27.4%**, with 7% moderate or severe). LV thickness was 13 mm in 12%, and 14–15 mm in only 2.5%. No player had LV thickness >15 mm, despite height and athleticism. LVEDD was dilated ≥59 mm in **36%** of athletes (even ≥65 mm in 4%) but was not dilated when adjusted for height.[61] Unlike HCM, LVEDD was >45 mm in nearly all patients. LVEDD is determined by both athletic activity and height, and absolute LVEDD is probably a better determinant of remodeling than the height-adjusted one.

LV hypertrophy was eccentric and dilated in most white athletes (~50%), but concentric and mostly non-dilated in ~70% of black athletes. EF was almost always >50% (except in 1%, wherein it still augmented normally with exercise).

LA was frequently dilated by LA volume index (16%), mostly mild dilatation (4% moderate, 1% severe). LA diameter was 25–49 mm (mean 38 mm).

LV diastolic function was normal in all patients, regardless of LVH.

The maximum aortic root diameter was 4.2 cm, and only 4.6% of athletes had an aortic root ≥ 4 cm, despite extreme height.

In a study of female NBA athletes, a similar proportion had LV dilatation. LVH was less common (16%, mainly eccentric), and LV thickness ≥13 mm was exceedingly rare. In female athletes, a cutoff of 13 mm is concerning for HCM. Concentric hypertrophy was uncommon in both white and black female athletes (5%), but concentric remodeling (19%) was more common than in endurance female athletes.[61]

Athlete's RV – RV and RA enlarge in athletes, more so endurance athletes. RVOT enlargement compatible with ARVD is seen in the short-axis or long-axis views of 32% of athletes, even when indexed to BSA; RVOT enlargement compatible with major criteria for ARVD is seen in 4%.[62] Furthermore, other features of ARVD are common in athletes: prominent trabeculations (37%), rounded apex (81%). However, RV systolic function is normal in all (TAPSE and RV S'), and RV/LV ratio remains <0.9 in all. In fact, RV dilatation is part of a harmonious 4-chamber dilatation.

Athlete's LA – LA dilates in athletes by ~4 mm, more so in endurance-trained athletes. Using LA volume index or LA diameter, ~20% of athletes have mild LA enlargement (40–45 mm), 3% have moderate LA enlargement (45–49 mm), and none has severe LA enlargement.[63,64] Some data suggest that athletes with large LA ≥4.1 cm have a slightly higher risk of AF vs. athletes with no LA enlargement, particularly as they get older ("athlete's AF").[65] AF remains extremely uncommon in young athletes <30 years old, even with large LA (0.3%), and is not more prevalent than in the general population.[63,64] LA dilatation is likely just a physiologic remodeling without immediate adverse/AF consequences, but with increased AF risk decades later in some athletes.[61,63,64]

XV. Athlete's heart: Is athletic activity associated with increased cardiac risk or sudden death in young and middle-aged individuals?

As shown by the Copenhagen city heart study (mean age 40s), there is a U-shape relationship between the frequency and intensity of exercise and mortality.[66,67] Light and moderate joggers (defined by pace, frequency, and duration) have lower mortality than sedentary individuals. Conversely, whereas strenuous joggers have a mortality rate not statistically different from that of the sedentary group. The lowest risk was in 2.5–4 hours of weekly exercise, slow or moderate pace.

Effect of athletic activity on coronary atherosclerosis in middle-aged athletes – The Master@Heart study (men, median age 55 years) has shown that lifelong athletic activity not only increases calcified coronary plaques and coronary artery calcium score, but also non-calcified plaques, mixed plaques, and proximal plaques (all by about 2-fold), compared to healthy and fit individuals with similarly low cardiovascular profile.[68] This was also demonstrated in a study of British male athletes >40 years old (mean age 54 ± 8 years): 11% of them had calcium score >300 (vs. 0% in low-risk controls), and 14% of them had LGE on MRI (vs. 0% in controls), half of which was consistent with MI pattern.[69] In another study of marathon runners >50 years of age, coronary artery calcium (CAC) was not only higher in athletes than a similar-risk matched population (median CAC: 36 vs. 12, p = 0.02), it was also predictive of coronary events, particularly when >100 (CAC >100 seen in 36% in that study); hence an elevated coronary calcium score is not benign in athletes.[70] Calcium score percentile values and number of marathons also independently predicted the presence of LGE on MRI (prevalence = 12%).[70] Of note, CAC score was not increased in female athletes in the British study.[69]

Effect of athletic activity on myocardial fibrosis – Athletic activity is associated with increased risk of myocardial fibrosis and late gadolinium enhancement (prevalence of up to 15%, particularly in older athletes aged 30s–50s years, vs. <5% in non-athletes).[71] This high prevalence is seen even after excluding LGE of the watershed area in the inferior basal septum, the so-called RV hinge point, which is also more prevalent in athletes but is unlikely to have a prognostic effect.[69–71] LGE may have an ischemic or non-ischemic pattern with arrhythmogenic potential.[71]

Athletic activity and sudden death in young athletes – Athletic activity in young individuals is associated with a 2.5-fold increased risk of sudden death compared to matched healthy non-athletes, as shown in the Veneto study.[72] This was also demonstrated in a US high school study (3.65-fold increase in sudden death among athletes) and in a French analysis (sudden death during sport activity was 4.5 times higher in competitive young athletes than in recreational sports participants of the same age [10–35 years]).[73,74] It is likely that the increase in sudden death is not directly due to sport, but to the increased risk of manifesting sudden death from genetic channelopathies and cardiomyopathies during sport. More than 80% of athletes and non-athletes who die suddenly are men.

Athletic activity and the risk of AF and arrhythmia in middle age – Although moderate exercise is associated with a lower risk of AF, athletic activity is associated with higher AF risk, *particularly over the long term, at middle age (40s–60s)*. This may be related to a degree of atrial fibrosis, but also to an increase in vagally triggered AF. *The increased risk of AF is not seen in young athletes <30*. A long-term follow-up of Swedish skiers showed ~25% higher risk of AF in the most accomplished athletes—those with the most and fastest races—compared to other athletes, mainly when they reach the age of 50s–60s.[75,76] The AF risk was several-fold higher in 2 separate studies of former Swiss cyclists and middle-aged Finnish athletes compared to non-athletes.[77] This applies to former athletes who reach middle age (Swedish and Swiss registries) and to current middle-aged athletes with a long history of athleticism (Finnish registry).

A long-term follow-up of Swedish skiers showed a higher yearly incidence of bradycardia and pacemaker requirement in male skiers compared to male non-skiers, mainly at the age of 60s, the mechanism being primarily sick sinus syndrome as opposed to AV block in non-skiers.[78] This was highest in the most accomplished skiers. As such, long-term effects of exercise-induced bradycardia may not always be reversible. However, the mortality of skiers with or without pacemakers was much lower than non-skiers.

Appendix 1. Cases of mixed septal bulge and calcific aortic stenosis = mixed LVOT obstruction and aortic stenosis. How to figure out the main level of obstruction?

1. ***Important concept:*** Some patients have calcific aortic stenosis along with septal hypertrophy or septal bulge and a high pressure gradient across the whole LVOT-aortic valve zone. The differential diagnosis is:

- Severe AS with secondary septal hypertrophy and LVOT acceleration. Even in AS, and as part of AS physiology, there may be a mild gradient across the LVOT, more so if septal bulge is present.[79] In fact, on echo, aliasing starts upstream of the valve, with a continuum of flow acceleration and pressure gradient that peaks at the aortic valve (PISA of AS; Figure 7.9). This continuum is particularly seen and lengthy in patients with septal bulge. This is part of the AS physiology; this is often not LVOT obstruction and is often not mixed AS/HOCM,[79] unless the velocity at the LVOT is severe or higher than the aortic valve velocity, whether at rest or with dynamic maneuvers.
- Mixed HOCM and AS of varying severities.

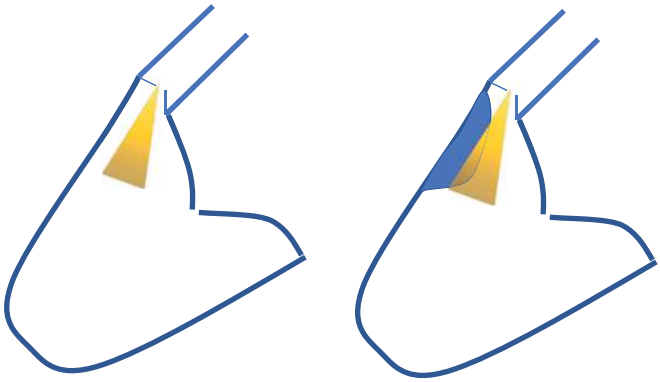


Figure 7.9 Even in AS, and as part of AS physiology, there may be a milder gradient across the LVOT, even more so if septal bulge is present. On Doppler, aliasing starts upstream of the valve with a continuum of flow acceleration and pressure gradient that peaks at the aortic valve (PISA of AS). This needs to be distinguished from true LVOT obstruction. For AVA calculation, LVOT velocity is generally captured lower, before the flow acceleration.

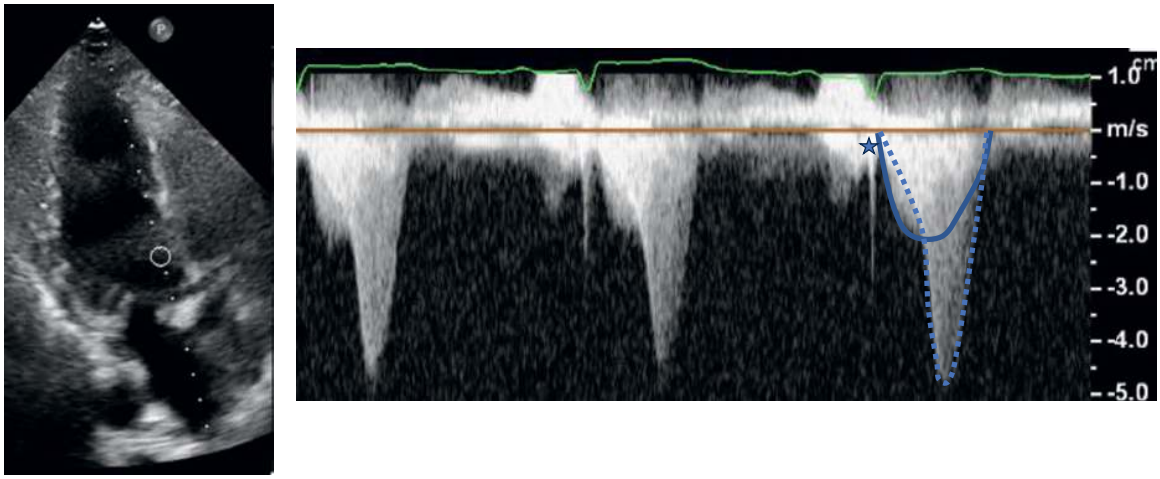

Figure 7.10 Superimposition of 2 distinct waveforms: (i) an early, rounded one (AS, *solid line*), and (ii) a late-peaking dagger-shaped one (dynamic LVOT obstruction, *interrupted line*). Also, note the MR signal (*star*).

2. *In mixed HOCM-AS, determine by continuous wave Doppler: (i) the presence of both processes; (ii) which process is dominant* (Figure 7.10): in mixed AS-LVOT obstruction, CW Doppler waveform shows the superimposition of 2 distinct waveforms:

i. an early, rounded one (AS; Figure 7.10, *solid line*)
ii. a late-peaking dagger-shaped one (dynamic LVOT obstruction; Figure 7.10, *interrupted line*)

Each velocity indicates the severity of each pathology. If LVOT is most severe, the dagger-shaped envelope will be largest and will be dynamic with maneuvers. If AS is the primary process, the rounded envelope will be largest, and if truly severe, its peak velocity will be >4 m/s and the envelope's mean gradient would be >40 mmHg (the dagger-shaped envelope would be buried inside it). In Figure 7.10, LVOT velocity is highest (5 m/s) and is this patient's primary, predominant pathology; he has severe LVOT obstruction and concomitant mild AS (peak velocity 2 m/s). Conversely, in Figure 7.11, the aortic valve velocity (rounded waveform) is highest and higher than 4 m/s, indicating predominant AS with elevated LVOT velocity from septal bulge. This LVOT velocity should not be used in AVA or DI calculation, as it reflects an obstruction rather than a diffusely elevated LV velocity from a high flow state (unlike Question 25 of Chapter 6).

Septal bulge may occasionally need to be treated even in patients with predominant AS envelope, particularly when septal thickening is severe with a LVOT envelope velocity >3–4 m/s, or a LVOT envelope that is mild or unnoticed at baseline but becomes prominent >3–4 m/s after Valsalva or post-PVC with a late-dagger morphology (Figures 7.11 and 7.12).

3. *Differentiate by left heart catheterization:*

- Pressure measurement during pullback of an end-hole catheter across the LVOT helps sort out how much of the RESTING gradient is LVOT vs. aortic valve.
- Morphology of the LV and aortic simultaneous recording: late-peaking LV dagger with aortic spike and dome implies predominant LVOT obstruction rather than AS. Late-peaking aortic pressure with anacrotic notch implies a predominant fixed obstruction, usually AS (occasionally subaortic fixed AS).
- Perform dynamic maneuvers. The following dynamic changes point toward LVOT as the predominant obstruction:
  i. classic change in morphology post-PVC (Brockenbrough + spike and dome aortic pressure post-PVC)
  ii. worsening of the obstruction with Valsalva

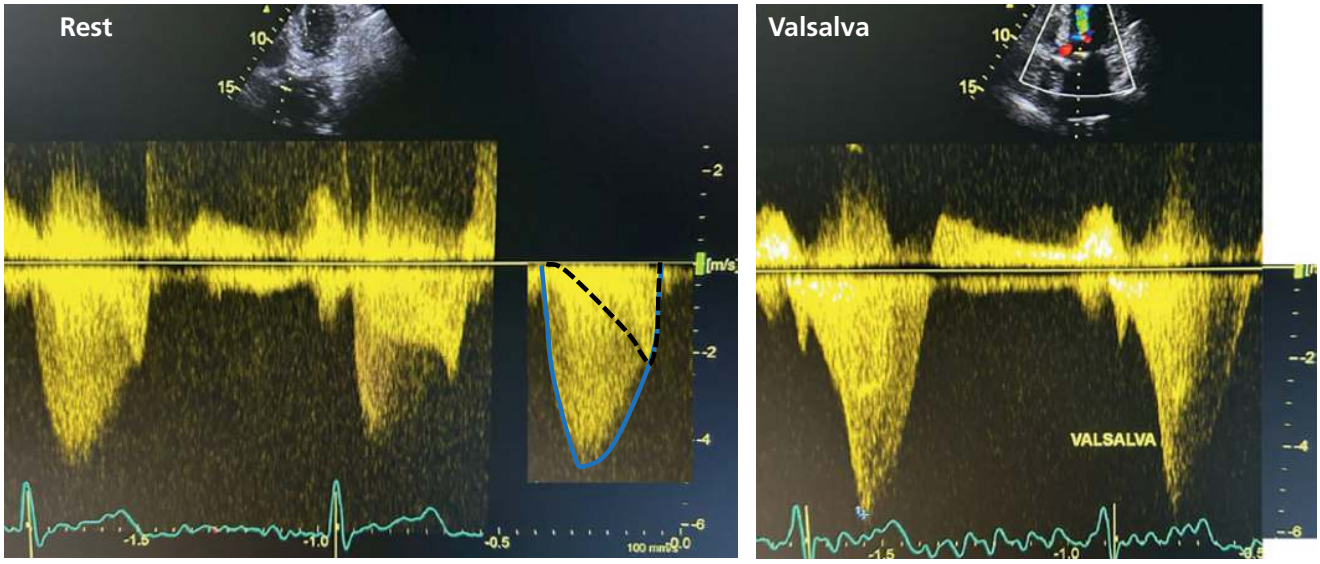

Figure 7.11 Doppler across the aortic valve shows a round envelope with a velocity >4 m/s, suggestive of severe AS (*blue line*). Within this envelope, there is another, late-peaking velocity suggestive of LVOT flow acceleration (*interrupted line*). LVOT velocity is only mildly elevated and not suggestive of significant LVOT obstruction at rest. With Valsalva, the velocity severely rises with a classic late-peaking dagger shape, implying severe dynamic LVOT obstruction → this patient has severe AS but also severe dynamic HOCM and needs treatment of both entities.

The case would be more difficult if severe resting LVOT obstruction is associated with AS velocity in the moderate range. HOCM reduces flow across the aortic valve and may cause AS gradient underestimation, and conversely, AS may cause underestimation of LVOT velocity. If AS velocity is 3–4 m/s along with significant LVOT velocity, it is possible that AS is severe, but AVA cannot be calculated as there is no zone of laminar flow in the LVOT to measure focal LVOT velocity and diameter and apply the continuity equation. IV β-blockade or leg raising may be performed to reduce LVOT obstruction and potentially elicit a higher AS gradient, besides allowing AVA measurement (as LVOT flow becomes more laminar). Alternatively, the patient may undergo surgical or procedural correction of both AS and HOCM, or HOCM may be treated with mavacamten then AS reassessed and treated if needed.

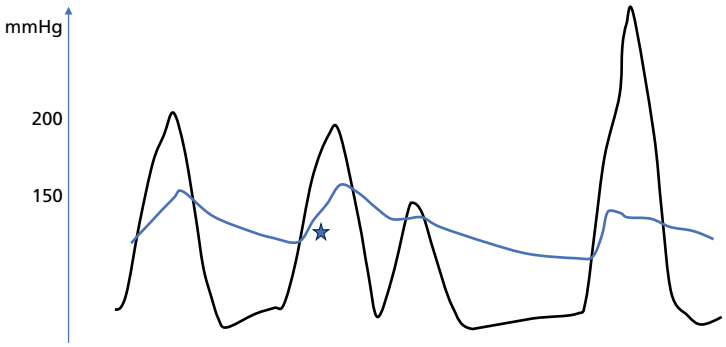

Figure 7.12 LV-aortic recording. The first 2 beats show an aortic morphology consistent with severe fixed obstruction, typically AS (or occasionally fixed subaortic AS): slow, late-peaking aortic upslope, not parallel to the LV upslope, with an anacrotic bend (*star*). The peak-to-peak gradient is ~50 mmHg, consistent with severe AS. *After PVC*, the aortic and LV morphologies change: the aortic upslope is now sharp and parallel to the LV, with a spike-and-dome morphology, while the LV has a late-dagger shape. Also, a classic Brockenbrough phenomenon is seen: the aortic pulse pressure drops while the gradient dramatically rises. Thus, this patient has *2 processes: (i) severe AS with severe AS gradient, and (ii) associated severe dynamic LVOT obstruction* (possibly from a severe septal bulge induced by AS). Both processes need to be treated during surgery.

4. *Occasionally, combined severe AS and severe LVOT obstruction may be seen.* In those cases, the baseline LV-aortic pressure recording may show late-peaking aortic pressure, i.e., AS, yet a Brockenbrough phenomenon is seen post-PVC or gradient severely worsens with Valsalva (Figures 7.11 and 7.12).

5. Regarding the more difficult situation of SEVERE RESTING LVOT velocity (>3 m/s or >30 mmHg LVOT gradient invasively) and moderate, NON-SEVERE AORTIC velocity (~3 m/s), the AS may be severe, but its gradient is attenuated by the LVOT obstruction. In this case: (i) aortic valve calcium score is valuable; (ii) maneuvers may be performed to attenuate LVOT obstruction and help enhance AS gradient (acute IV β-blocker or leg raising); (iii) alternatively, both processes are treated surgically; (iv) for the percutaneous option, one may treat LVOT obstruction with mavacamten or alcohol ablation, then reassess AS and treat it with TAVR if needed.

Appendix 2. Common error: LVOT flow may be confused as MR on echo spectral Doppler (and vice versa) (Figures 7.13 and 7.14)

LVOT waveform may be seen even when the CW Doppler cursor is placed across the mitral valve, because of the proximity of LVOT and mitral flow (beam width effect). A late-peaking morphology suggests LVOT velocity rather than MR, but SAM-induced MR may also be late peaking as it increases in late systole with further LVOT narrowing. The onset of the waveform may distinguish MR from LVOT and aortic valve flow (MR starts at the peak of R, whereas the latter 2 are more delayed), but this is not always clear. In Figure 7.13, both the MR envelope and the later-peaking LVOT envelope are captured by the mitral Doppler. In Figure 7.14, one late-peaking envelope is captured by the mitral Doppler: this may be LVOT velocity or a mixture of LVOT velocity and MR. Three ideas are helpful:

- Sweeping the cursor slightly around the area may help capture 2 distinct velocities, as in Figure 7.14.
- A severely elevated velocity (e.g., 7 m/s) is unlikely to be LVOT velocity, as it would imply an LVOT gradient of 4 × velocity^2, i.e., 196 mmHg, and therefore a LV systolic pressure of 300 mmHg or more (LV systolic pressure = LVOT gradient + SBP)

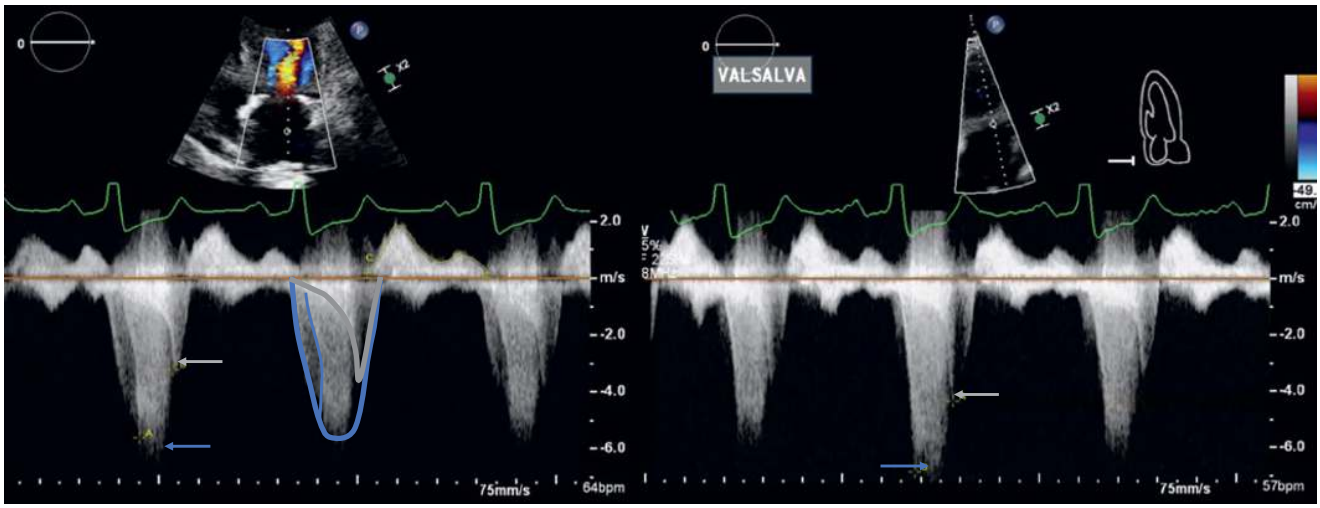

Figure 7.13 ***(Left)*** Doppler cursor is placed across the mitral valve. The image is capturing 2 envelopes. (i) The parabolic, higher-velocity envelope is MR (*blue envelope, blue arrow*), which has 2 components, an early mild component and a denser late component related to SAM. The latter worsens in late systole like LVOT obstruction. (ii) The second, late-peaking dagger-shaped envelope (*gray envelope, gray arrow*), corresponds to the LVOT velocity. ***(Right)*** With Valsalva, both LVOT obstruction/velocity and SAM-induced MR worsen (*gray and blue arrows*, respectively).

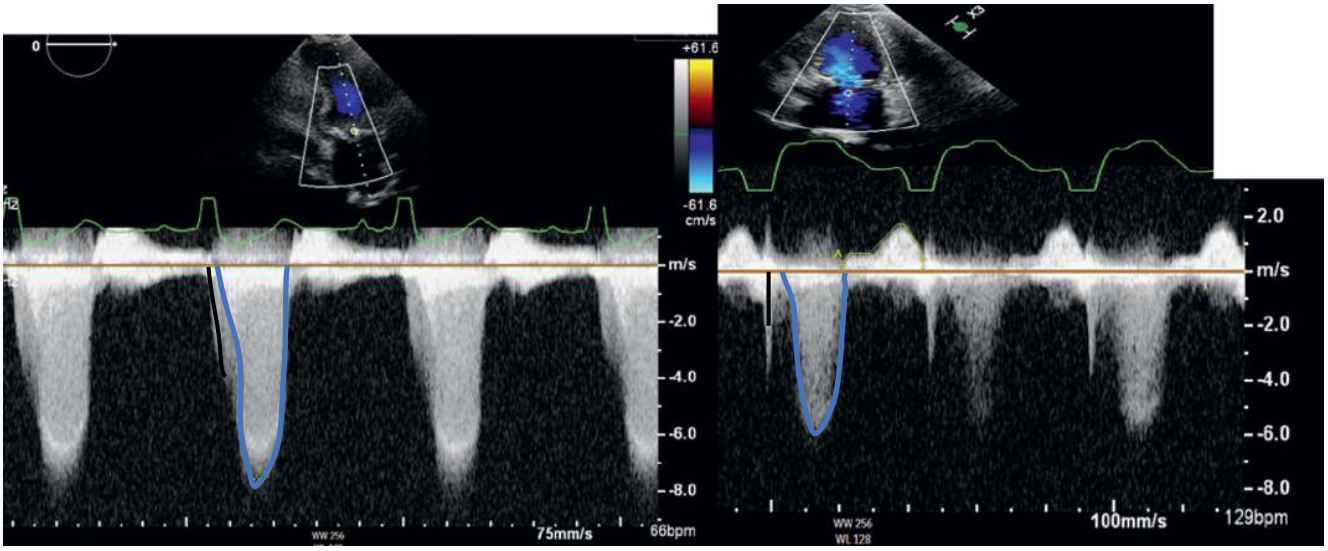

Figure 7.14 ***(Left)*** Doppler cursor is placed across the mitral valve. The late-peaking *blue envelope* suggests that we may be capturing the LVOT velocity, but SAM-induced MR may also be late peaking as it increases in late systole. The *black line* corresponds to MR onset (at the peak of R), but the *blue envelope* could be either MR or LVOT velocity. ***(Right image)*** Sweeping the cursor slightly around the area helped capture a lower velocity that is also late-peaking: the higher-velocity envelope over 7 m/s on the left image is more physiologically consistent with MR, while the lower velocity on the right image may be LVOT (6 m/s), particularly that its onset is further delayed in reference to the black line. A severely elevated velocity (e.g., 7 m/s) is unlikely to be LVOT velocity, as it implies LVOT gradient of 4 × velocity^2, i.e., 196 mmHg, and therefore an LV systolic pressure of 300 mmHg or more.

- One may assume the high velocity is MR and back-calculate LVOT gradient using cuff SBP. Depending on SBP, a lesser but still significant LVOT gradient may be proven. For example, in Figure 7.14, SBP is only 100 mmHg and peak velocity, assumed to be MR, is 7.7 m/s:
  - LV systolic pressure–LA = 4 × MR velocity^2 → LV systolic pressure = 237 + LA → LV systolic pressure ~252 mmHg, assuming LA pressure of ~15 mmHg
  - LVOT gradient = LV systolic pressure – SBP = 152 mmHg (which approximates the 6 m/s velocity on the right image of Figure 7.14)
  - Thus, even if the very high velocity is assumed to be MR, LVOT gradient is still significant and LVOT obstruction is proven. This gradient is also more physiologically plausible than a 7.7 m/s LVOT velocity, which translates into an LVOT gradient of 237 mmHg and LV pressure of 337 mmHg.

QUESTIONS AND ANSWERS

Question 1. A 68-year-old man with a history of severe HTN and CKD presents with progressive dyspnea on exertion (class III). He takes metoprolol, HCTZ, and lisinopril. On exam, BP is 110/65 mmHg, heart rate is 70 bpm, and a mid-sytolic murmur is heard at the LLSB. The murmur increases with Valsalva and improves with handgrip. Echo shows asymmetric septal hypertrophy with septal thickness of 19 mm, posterior wall thickness of 13 mm, and SAM of the mitral valve with LVOT gradient of 75 mmHg at rest and 120 mmHg with Valsalva. ECG shows LBBB. What is the appropriate next step?
A. Myectomy
B. Alcohol septal ablation
C. The patient has hypertensive cardiomyopathy. Discontinue HCTZ and lisinopril, titrate metoprolol, then add mavacamtem
D. The patient has genetic hypertrophic cardiomyopathy. Discontinue HCTZ and lisinopril, titrate metoprolol, then add mavacamtem
E. Add disopyramide

Question 2. Drug changes were performed in the patient of Question 1. Two months later, his symptoms have improved but he still gets dyspneic on activities of daily living. On Doppler, LVOT gradient is 40 mmHg at rest and increases to 75 mmHg with Valsalva. What is the next step?
A. Titrate mavacamtem
B. Myectomy
C. Alcohol septal ablation
D. AV sequential pacing with short AV delay

Question 3. A 75-year-old man who has a history of severe HTN presents with exertional dyspnea (class III) and chest pain. He receives chronic metoprolol. On exam, he has two murmurs: (1) a holosystolic murmur heard at the LLSB, apex, axilla, worse with Valsalva, (2) a mid-systolic murmur heard at the base with radiation to the carotids. S_2 is normal and carotid upstrokes are normal. Echo shows asymmetric septal hypertrophy, with a septal thickness of 17 mm and a posterior thickness of 11 mm. SAM is present with a posteriorly directed, severe MR. A high LVOT gradient is present: 100 mmHg at rest and 160 mmHg with Valsalva. The aortic valve is calcified. The color Doppler shows aliasing at both the LVOT level and the aortic valve level. The continuous-wave (CW) spectral envelope shows 2 superimposed but distinct envelopes: one is dagger-shaped with a peak velocity of 5 m/s, and the other is parabolic with a peak velocity of 2.5 m/s. What is the patient's diagnosis?
A. Severe AS
B. Severe AS and HOCM
C. HOCM with mild–moderate AS
D. Hypertensive cardiomyopathy with mild–moderate AS

Question 4. What is the next step for the patient of Question 3?
A. TEE
B. Right and left heart catheterization with maneuvers + coronary angiography
C. Myectomy

Question 5. What is the best treatment for the patient of Question 3?
A. Myectomy
B. Myectomy + MVR
C. Myectomy + AVR
D. Alcohol septal ablation
E. C or D

Question 6. Patient X has a mid-systolic murmur that drastically increases after a pause (on the beat that follows a pause). His radial pulse, however, decreases after this pause. Patient Y has a mid-systolic murmur that increases after a pause (less than patient X); his radial pulse also increases in intensity after the pause.
A. Patient X has HOCM, patient Y has AS
B. Patient X has AS, patient Y has HOCM

Question 7. A 72-year-old man presents with dyspnea, NYHA class III. He has asymmetric septal hypertrophy (~19 mm) with SAM of the anterior leaflet. The LVOT gradient is 25 mmHg at rest and rises to 130 mmHg with Valsalva. He has severe MR at rest, directed anteriorly. Besides the anterior leaflet elongation, the posterior leaflet is excessively elongated and overrides the anterior leaflet. He does not have CAD. What is the best strategy?
A. Alcohol septal ablation
B. Septal myectomy
C. Septal myectomy + MV repair
D. No septal ablation as the gradient at rest is <50 mmHg

Question 8. Which statement concerning myectomy vs. alcohol septal ablation is *incorrect*?

A. The reduction of gradient after alcohol septal ablation is less immediate than after myectomy. Some of the gradient declines immediately, but the gradient reduction may take 12 months to catch with myectomy.
B. RBBB is common after alcohol septal ablation (60%). Thus, alcohol ablation is not favored in patients with underlying LBBB
C. LBBB is common after myectomy (~40%)
D. Transient complete AV block is common after alcohol ablation (up to 50%), and typically develops within 72 hours. This justifies placing a temporary pacing wire before alcohol ablation in all patients, and leaving it for 72 hours
E. The risk of lethal ventricular arrhythmias is consistently similar with alcohol septal ablation vs. myectomy

Question 9. A 25-year-old healthy asymptomatic man has a murmur and an abnormal ECG. Echo shows a thick septum of 24 mm, with LVOT gradient of 60 mmHg after Valsalva. He has no family history of sudden death. Holter shows PVCs, and exercise testing reveals no BP drop but a reduced functional capacity. What is the next step?

A. ICD
B. Metoprolol
C. Cardiac MRI
D. Alcohol septal ablation

Answer 1. D. The differential diagnosis includes genetic HOCM (elderly presentation), hypertensive cardiomyopathy, or discrete upper septal thickening in the hypertensive elderly. An ancillary sign of HTN is present (CKD), yet this does not rule out HOCM. HOCM is the likely diagnosis in light of SAM and the severe gradient >100 mmHg. HOCM may be difficult to distinguish from hypertensive obstructive cardiomyopathy; in fact, in a genetic HOCM patient, the phenotype of HOCM is more readily expressed if severe HTN is present. For practical purposes, severe LVH with LVOT obstruction and SAM is pathophysiologically considered HOCM and treated as such. Before considering ablative therapies, the medical regimen needs to be optimized. HCTZ (preload reduction) and lisinopril (afterload reduction) aggravate the gradient and symptoms in HOCM. The discontinuation of those drugs may drastically improve symptoms.

Answer 2. B. The patient has refractory symptoms and a gradient >50 mmHg despite proper medical therapy. Myectomy is the first-line ablative therapy, unless the surgical risk is high. Moreover, in a patient with LBBB, alcohol septal ablation will lead to RBBB in 50–60% of the cases and thus complete AV block.

Answer 3. C. The exam suggests HOCM and AS. The holosystolic dynamic murmur at the LLSB and apex is the combination of HOCM and its MR murmur. The murmur that radiates to the carotids is not characteristic of HOCM, and rather implies AS. The normal S_2 and the normal carotid upstroke imply that AS is not severe. The echo confirms this diagnosis. The two envelopes within the LVOT CW Doppler correspond to the LVOT envelope (dagger-shaped) and AS envelope (parabolic). The LVOT velocity is very high, while the aortic valve velocity is mild, implying severe HOCM obstruction rather than AS obstruction. The severity of the SAM and the gradient suggests HOCM rather than hypertensive cardiomyopathy.

Answer 4. B. An end-hole catheter is positioned in the LV and pulled back slowly across the LVOT and aortic valve, allowing the measurement of the LVOT gradient (between LV and LVOT) and the AS gradient (between LVOT and aorta). This study is performed and confirms the severity of the LVOT gradient (peak-to-peak 100 mmHg), and the rather mild AS gradient (peak-to-peak 18 mmHg, AVA 1.5 cm^2 using Gorlin's equation). Since most of the gradient is determined to be across the LVOT, simultaneous LV–aortic recording is subsequently performed using a double-lumen pigtail catheter, and maneuvers are performed. Coronary angiography is necessary to see if a large proximal septal branch is available for alcohol septal ablation. Conversely, extensive CAD would favor CABG + myectomy. TEE may be performed to calculate the AVA by planimetry and determine the severity of AS, but has a lower yield than catheterization.

Answer 5. E. The MR is severe but posteriorly directed, suggesting it is purely related to SAM. Unless posterior leaflet prolapse is present (anterior or central jet), MR usually resolves with septal ablation. The patient has moderate AS by catheterization, and thus, *if* he is undergoing cardiac surgery, AVR would be reasonable (class IIa). Note that the AS gradient will increase once the LVOT obstruction is relieved (aortic flow will increase → gradient increases). Yet this non-severe AS should not necessarily drive the choice between myectomy or alcohol septal ablation. Alcohol septal ablation is an acceptable option, especially in a patient >65 years old with a septal thickness <30 mm and no LBBB.

Answer 6. A. This case illustrates how the Brockenbrough phenomenon may be assessed by physical exam.

Answer 7. C. The patient has LVOT gradient >50 mmHg (rest or stress) and septal thickness >15 mm; thus, he qualifies for septal ablation. As opposed to the patient in Question 3, this patient has abnormalities of the posterior mitral leaflet and an anteriorly directed MR, implying a form of primary MR (this MR is not simply secondary to SAM). Septal reduction, per se, will not abolish MR.

Answer 8. E. The risk of VT may be higher after alcohol septal ablation, although this is not substantiated by recent series.

Answer 9. C. This patient does not have the major predictors of sudden death. He has reduced functional capacity, which predicts symptom progression and HF-related mortality, but not clearly sudden death. MRI is useful to further stratify his risk of sudden death, as echo may underestimate LV thickness in a subset of patients, particularly when hypertrophy is confined to the anterolateral wall or apex. As such, this patient's LV thickness may be 30 mm. Moreover, extensive LGE (≥15% of LV) or apical aneurysm would dictate ICD.

Part 5 ARRHYTHMIAS AND ELECTROPHYSIOLOGY

8 Approach to Narrow and Wide QRS Complex Tachyarrhythmias

I. The unstable patient (shock, acute pulmonary edema) 305
II. Initial approach to any tachycardia 305
III. Approach to narrow QRS complex tachycardias 306
IV. Approach to wide QRS complex tachycardias 307
V. Features characteristic of VT, as opposed to SVT with aberrancy 308
VI. Features characteristic of SVT with pre-excitation 312
VII. Role of adenosine in establishing a diagnosis 313
VIII. Differential diagnosis of a wide complex tachycardia on a 1-lead telemetry or Holter monitor strip 314
IX. Various notes 314
X. General management of SVT 314
XI. Non-tachycardic wide complex rhythms 315
XII. Practice ECGs of wide complex tachycardias 315

I. The unstable patient (shock, acute pulmonary edema)

In a hemodynamically unstable patient with supraventricular tachyarrhythmia (shock or severe HF), **always ask yourself: did the tachyarrhythmia cause the shock or did the shock cause an increase in heart rate with a secondary SVT or AF**? Typically, **to attribute a shock to SVT or AF, the heart rate must be >150 bpm, or >130 bpm in systolic HF.** In addition, clinical features suggestive of another primary process should be sought (sepsis, acute bleed/severe anemia, tamponade, massive PE); in these cases, tachycardia is not the isolated cause of the instability, it is rather the consequence.

For example, in a patient with BP 75/50 mmHg and AF rate of 125 bpm, AF is likely secondary to the shock rather the cause of the shock.

If a tachyarrhythmia faster than 130–150 bpm is assumed to be the cause of instability, emergent DC cardioversion should be performed.

II. Initial approach to any tachycardia

When analyzing a tachycardia, start by looking at 3 features:

1. Narrow QRS vs. wide QRS (≥120 ms) (choose the lead where QRS is widest)
2. Regular vs. irregular ventricular rate
3. Look for P waves and their relationship with QRS complexes. P waves are usually seen as notches or deflections that fall over the ST–T segments and have a *consistent morphology* and *timing*, i.e., those deflections are regularly placed and can be marched out. Try to confirm that these deflections are P waves, rather than artifacts or parts of T wave, by analyzing multiple leads. Once P waves are found, their relationship with QRS complexes is analyzed.

P waves are often best seen in lead II, which is generally parallel to the spread of atrial depolarization; and in the lead where T and QRS are smallest (opening up room to see the scattered P waves).

In wide QRS tachycardia, analyze: (i) AV dissociation, and (ii) the number of P waves compared to the number of QRS complexes. In narrow QRS tachycardia, assess the length of the RP interval.

III. Approach to narrow QRS complex tachycardias (see Figures 8.1, 8.2)

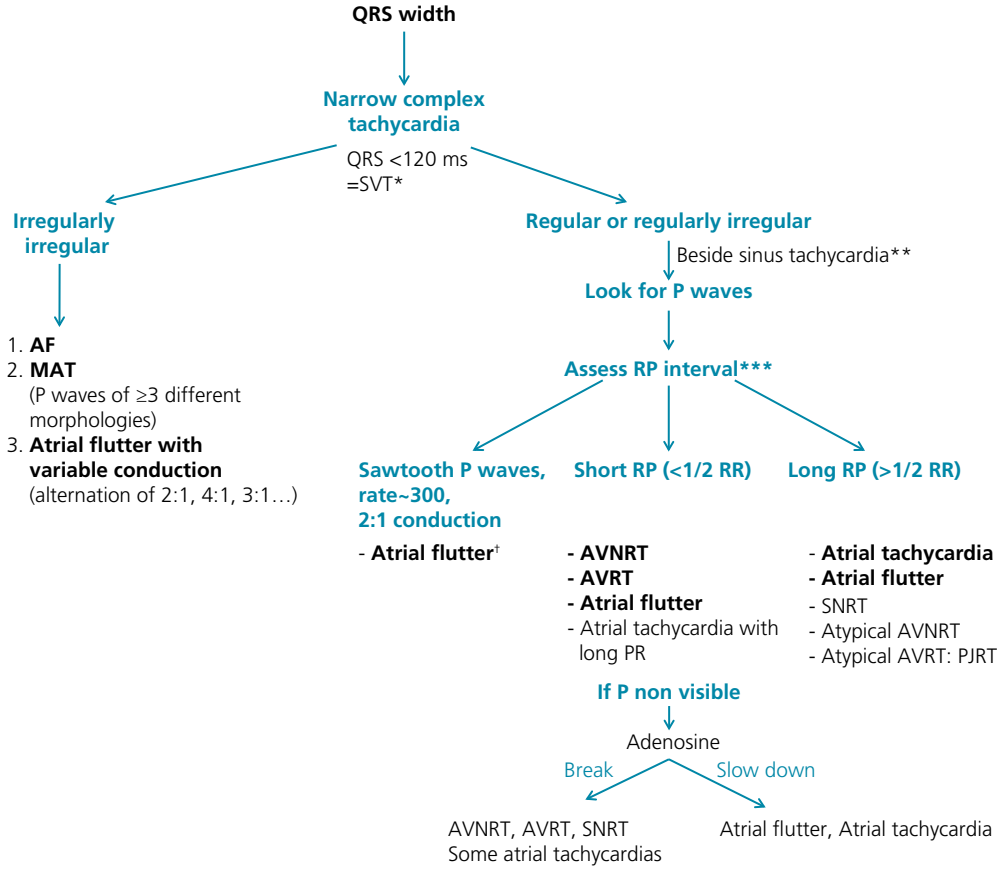

Figure 8.1 Approach to narrow QRS complex tachycardias.
*A narrow QRS tachycardia may occasionally be VT. If QRS is relatively narrow (~110–120 ms) but different in morphology from the baseline QRS, consider it VT or SVT with aberrancy.
As opposed to other tachycardias, sinus tachycardia has a gradual onset and termination and does not have a fixed rate. ***Tachyarrhythmias typically have a sudden onset and offset and a very fixed rate, although they may have a quick warm-up at the beginning*. For example, a tachycardia with a fixed rate of 122 bpm on a telemetry monitor suggests arrhythmia. The P wave of atrial tachycardia or SNRT may have a sinus P-wave morphology; the abrupt onset and the steady rate help differentiate these arrhythmias from sinus tachycardia.
***RP interval points to the interval between onset of QRS and onset of the following P wave. The P wave may be a retrograde P wave in AVNRT or AVRT. If this interval is <1/2 of the R–R interval, the tachycardia is a short RP tachycardia. A very short RP interval, i.e., <90 ms, is diagnostic of AVNRT.
†**Atrial flutter** may mimic short RP tachycardia if only the flutter wave following the QRS is seen, or may mimic long RP tachycardia/atrial tachycardia if only the flutter wave preceding the QRS is seen. ***Atrial tachycardia with negative P waves preceding the QRS complexes in the inferior leads may, in fact, be atrial flutter.*** Look carefully for flutter waves to make the diagnosis.

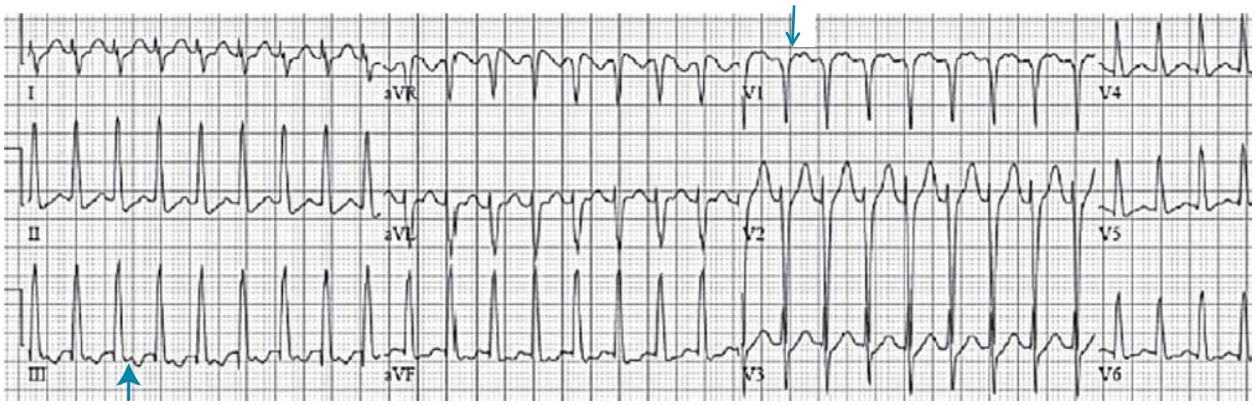

Figure 8.2 Narrow complex tachycardia, regular, rate ~200 bpm. Differential diagnosis: AVNRT, AVRT, atrial tachycardia with 1:1 conduction, or atrial flutter with 2:1 conduction.
1. Look for P waves: Ps are seen in leads III, aVF, and V_1 (*arrows*).
2. The RP interval is <1/2 R-R interval, so it is a short RP tachycardia. It is, thus, either AVNRT or AVRT. If RP interval is very short (<90 ms), and if P falls within or immediately past the QRS, looking like pseudo-S in the inferior leads or pseudo-r' in V_1, the tachycardia is AVNRT rather than AVRT. On this ECG, RP is >90 ms, and therefore either AVNRT or AVRT is possible.

IV. Approach to wide QRS complex tachycardias

The differential diagnosis of a wide QRS complex tachycardia includes:

1. VT.
2. SVT (including AF) with aberrancy. Aberrancy signifies the occurrence of a functional RBBB, LBBB, or RBBB + LAFB during a supraventricular tachycardia, leading to a wide complex morphology simulating VT. Aberrancy occurs when the refractory period of one of the bundles or fascicles is surpassed during the tachycardia (Figure 8.3). In addition, SVT with bundle branch block can be due to a pre-existing bundle branch block, in which case the QRS morphology during the tachycardia is similar to the QRS morphology during the sinus rhythm, sometimes slightly wider.
3. SVT (especially AF) with pre-excitation (Figure 8.4). This means that the SVT is conducted antegradely over an accessory pathway that connects 1 atrium to 1 ventricle, short-circuiting the AV node.
4. Other diagnoses: hyperkalemia; drug toxicity (class I antiarrhythmic agents, tricyclics); ventricular pacemaker tracking an atrial arrhythmia (lack of mode switch), or pacemaker-mediated tachycardia.

A wide complex tachycardia that is very grossly irregular is AF: AF with aberrancy, AF with pre-excitation, or AF with class I antiarrhythmic drug therapy. Polymorphic VT is a distant second possibility. On the other hand, a slightly irregular rhythm, with only slight variations of the R–R interval, may be seen with VT or any SVT at its onset (the first 20 beats).
A wide complex tachycardia is not necessarily "wide" (≥120 ms), as VT or aberrancy originating high in the septum near the His bundle or the bundle branches may be 110–120 ms wide, even narrower than a wide baseline QRS. The QRS morphology during tachycardia is, however, different from the baseline QRS morphology. *In particular, in patients with a wide baseline QRS, a tachycardia with a narrower QRS is VT*.

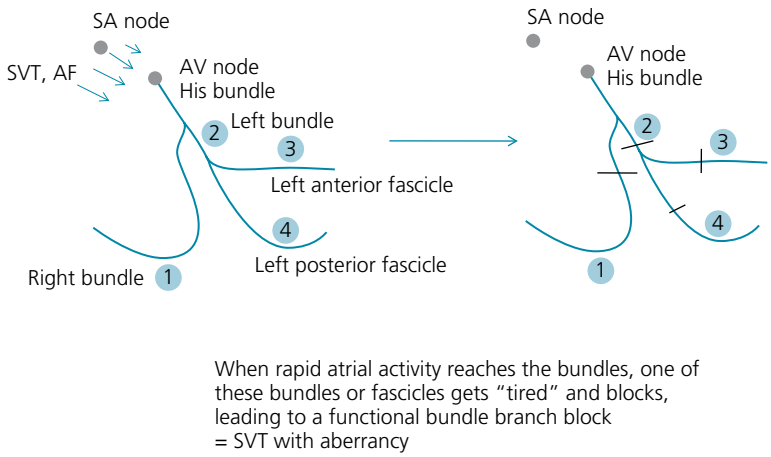

Figure 8.3 Explanation of how a wide QRS complex (aberrancy) may occur with SVT. RBBB, LBBB, or RBBB + LAFB may be seen. RBBB + LPFB is rare.

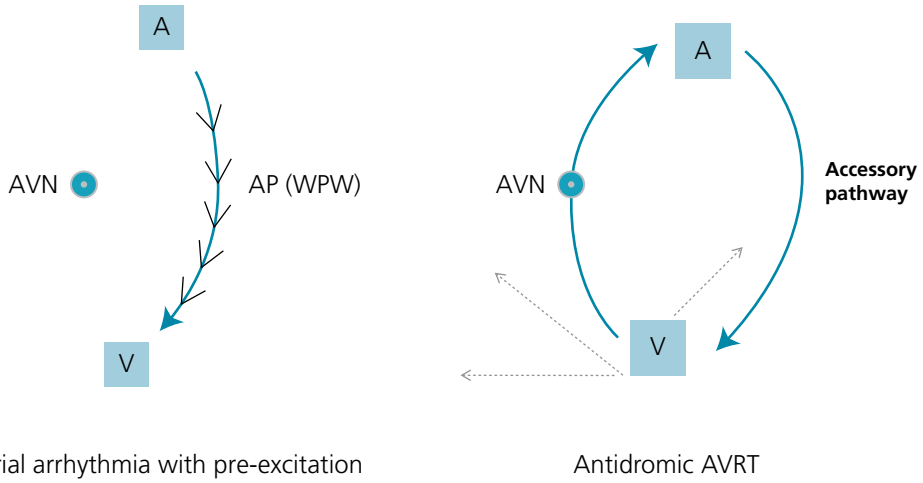

Figure 8.4 There are 2 types of SVT with pre-excitation, i.e., SVT with antegrade conduction over an accessory pathway (WPW syndrome):
- AF or any atrial arrhythmia with pre-excitation. The atrial waves are preferentially conducted through the fast accessory pathway, leading to a very fast ventricular rate.
- Antidromic AVRT. The electrical stimulus spreads down through the accessory pathway then up through the AV node. The ventricles get depolarized through the pre-excited ventricle (*dashed arrows*), not through the His bundle, and thus have a wide QRS morphology.

Approximately 80% of wide complex tachycardias are VTs (95% in case of CAD or HF). Thus, if one is unsure of the diagnosis, it is safer to consider the arrhythmia VT than SVT and treat it as such. However, it is best to look for features characteristic of VT and establish a definitive diagnosis.

V. Features characteristic of VT, as opposed to SVT with aberrancy

A. Four features are most helpful in differentiating VT from SVT. The presence of any one VT feature is immediately diagnostic of VT

a. ***The presence of AV dissociation***. AV dissociation is characterized by P waves that do not have any consistent relationship with the QRS complexes. In tachycardia, AV dissociation is ~100% specific for VT. AV association, on the other hand, does not necessarily imply SVT and may be seen with VT. In fact, retrograde ventriculoatrial (VA) conduction is seen in ~25% of VTs, especially VTs slower than 170 bpm, leading to retrograde P waves that are regularly associated with the QRS complexes. This manifests as 1:1 AV association (1:1 retrograde conduction) that is indistinguishable from SVT. At times, other ratios of VA conduction may be seen (e.g., 2 QRS complexes with 1 P wave, 3 QRS complexes with 2 P waves), in which the number of QRS complexes is greater than the number of P waves, implying VT.

Thus, VT is diagnosed if either: (i) AV dissociation is present, or (ii) QRS complexes outnumber P waves (with AV association or AV dissociation). *P waves are often best seen in lead II, which is generally parallel to the spread of atrial depolarization, or leads with the smallest QRS and T wave*.

b. ***QRS morphology***. A QRS morphology that is not consistent with a typical RBBB, LBBB, or RBBB + LAFB is characteristic of VT. In particular, a *QS or Qr pattern in V_4–V_6, i.e., deep Q wave in V_4–V_6, is particularly suggestive of VT*. In addition, in bundle branch blocks, the initial portion of the QRS complex corresponds to the quick localized depolarization at or near the septum and thus is narrow (LBBB → rS in V_1 with a narrow r; RBBB → rSR′ in V_1 with a narrow r). On the other hand, in VT, the electrical activity often starts away from the septum, and thus the initial QRS deflection is not narrow (Figures 8.5–8.7).

Rare caveats: VT that starts in the septum has a narrower QRS than free wall VT and may simulate RBBB morphology (e.g., idiopathic left fascicular VT). Also, bundle branch reentrant VT (macroreentry down the right bundle and up the left bundle), rarely seen in dilated non-ischemic cardiomyopathy, may have a typical LBBB morphology.

c. ***The onset of the tachycardia on ECG or telemetry monitor***. A tachycardia that starts with a PVC and has a morphology similar to this PVC is VT. A tachycardia that starts with a wide aberrant PAC and has a morphology similar to this aberrant PAC is SVT. Also, a tachycardia that is similar in morphology to a previous PVC is VT. A tachycardia that starts with a PVC but does not have the morphology of that PVC is likely VT, but may be SVT initiated by the PVC.

How to distinguish a PVC from an aberrant PAC? A wide QRS complex that coincidentally falls on the top of a regularly occurring sinus P wave is a PVC (the regularly occurring sinus P wave shows up as a "blip" within the PVC). PVC may also fall after the regular sinus P wave

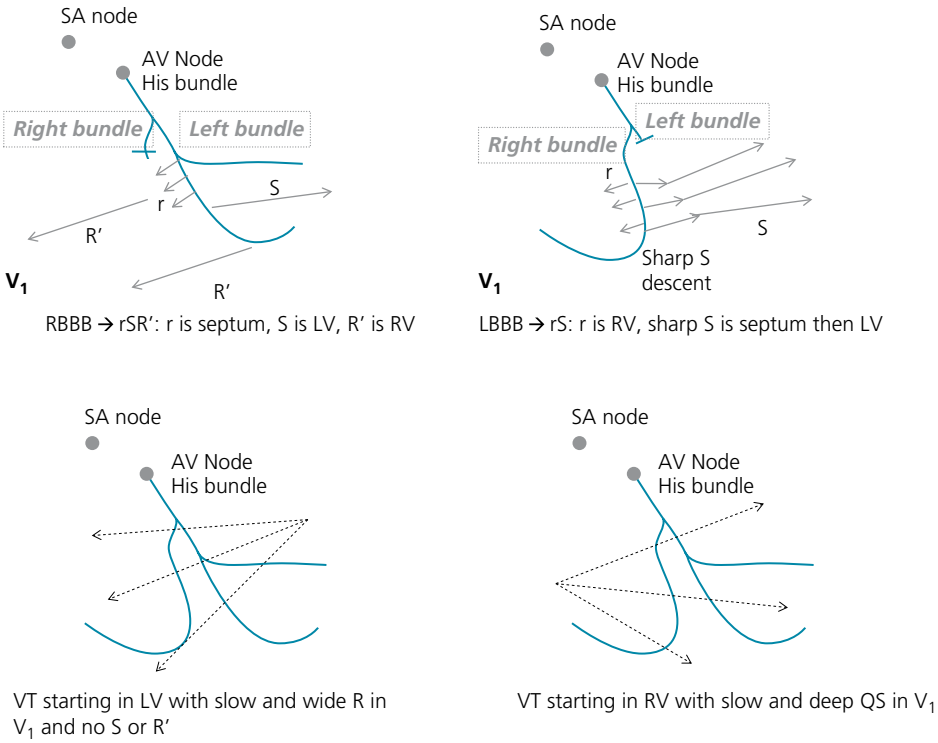

Figure 8.5 Difference in QRS morphology between bundle branch block and VT. The QRS description is in reference to lead V_1.

at a shorter PR distance. A PVC does not disrupt the underlying sinus/atrial rhythm, and P waves keep occurring regularly through it. On the other hand, an aberrantly conducted PAC starts after a premature and different-looking P wave that may fall within the preceding T wave and deform it. A deformation of the T wave preceding the premature complex suggests PAC.

d. *If the patient has a pre-existing RBBB or LBBB, or any intraventricular conduction delay, and the tachycardia has the* ***exact morphology of the baseline QRS****, the tachycardia is SVT.*

Figures 8.5 to 8.12 illustrate these concepts.

B. Other features (again, the presence of any one feature is suggestive of VT)

a. ***Brugada criteria***. The Brugada criteria include 4 features, 2 of which have already been discussed: (1) AV dissociation, (2) QRS morphology inconsistent with a typical RBBB or LBBB, (3) onset of R-to-nadir of S >100 ms in any precordial lead, (4) monophasic QRS concordance in all precordial leads. The presence of *any 1 of these* is diagnostic of VT with a high sensitivity and specificity (~98%). The *lack of all 4* is diagnostic of SVT with a high sensitivity and specificity (~98%).

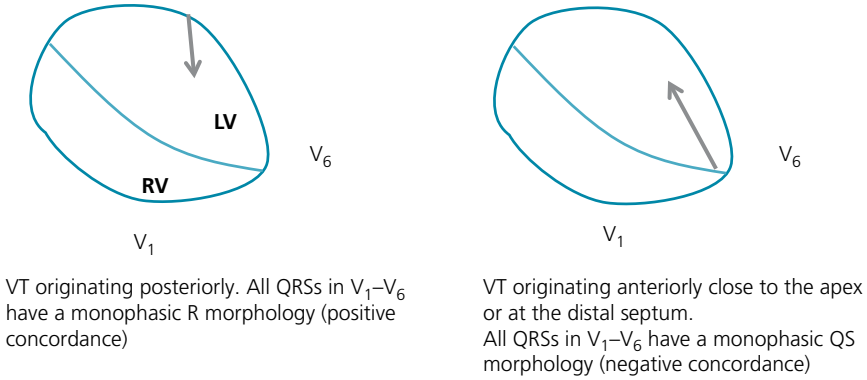

Figure 8.6 QRS morphology when VT originates in the posterior wall or the apical wall.

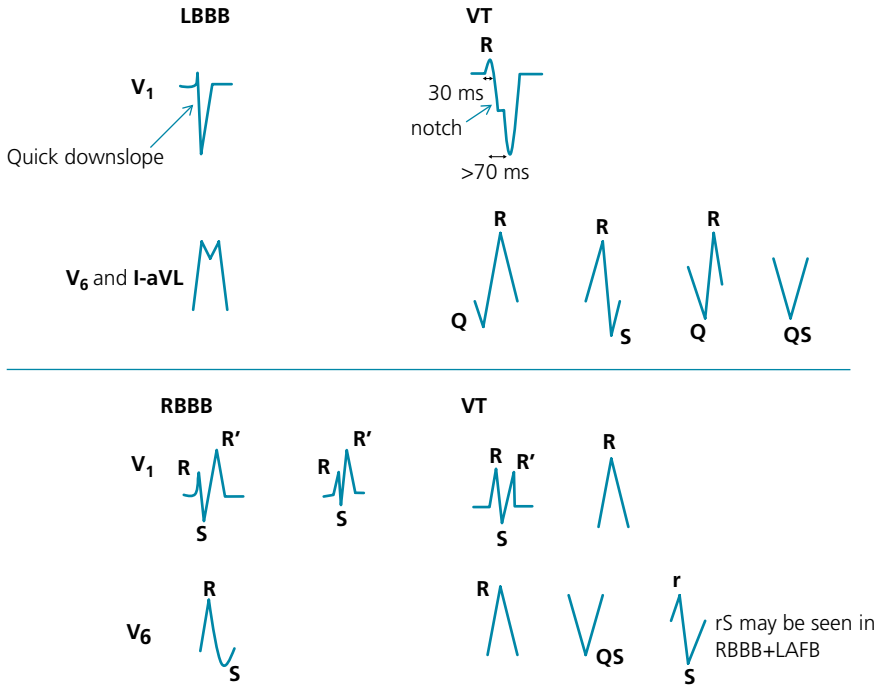

Figure 8.7 Differences in morphology between SVT with aberrancy and VT. SVT with aberrancy has a typical LBBB or RBBB morphology. Conversely, VT is suggested by:

- LBBB with a wide initial R wave >30 ms, R-to-nadir of S >70 ms, or notched S descent in V_1; or Q wave in V_6.
- RBBB with a wide R pattern in V_1 instead of RSR′, R > R′ in V_1, or monophasic R or QS in V_6. RBBB with a left axis or with a rS pattern in V_6 does not necessarily imply VT (could be RBBB + LAFB).

While rS pattern in V_6 is not typical of LBBB or RBBB, it may be seen with atypical LBBB (enlarged LV) or RBBB + LAFB. **Deep Q in V_6 (QS or Qr) implies VT.** Left QRS axis may be seen with LBBB or RBBB + LAFB. Right QRS axis, on the other hand, is not typically seen with either LBBB or RBBB and usually implies VT.

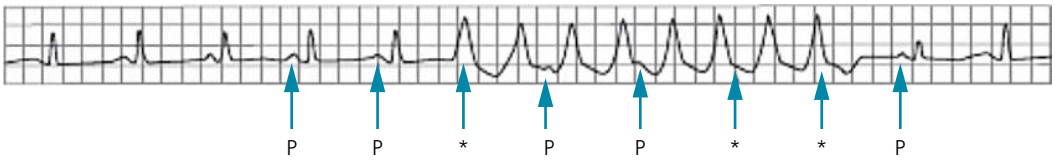

Figure 8.8 Run of wide complex tachycardia on a telemetry strip: is it VT or SVT?
1. See how it starts: the first wide complex is not preceded by any premature P wave and there is no deformation of the preceding T wave. This initial complex is a PVC, and the tachycardia has a morphology similar to this initial complex: this suggests that the tachycardia is VT.
2. Look for P waves. Some notches are visible inside the wide complex run. Try to march them out with the preceding and following sinus P waves → they do march out at the same rate as the sinus P rate, independently of the wide complex rhythm and scattered inside it. Some P waves are hidden within QRSs and cannot be seen (marked with an *asterisk* [*]). The 2 visible P waves that are dissociated from the QRS complexes imply AV dissociation, characteristic of VT.
3. The initial upslope of the wide QRS complex is slower and less steep than the upslope of the baseline QRS. This is suggestive of VT.

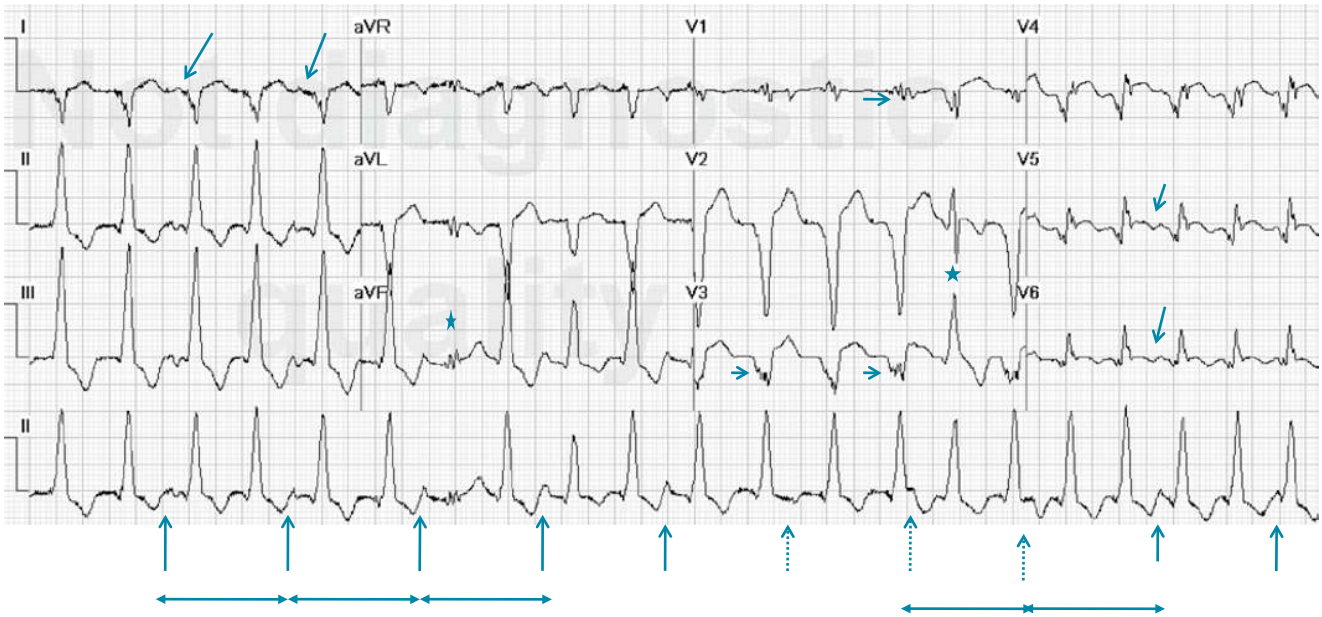

Figure 8.9 Wide complex tachycardia: VT or SVT?
1. Look for P waves, i.e., look for scattered "blips" that: (a) have a consistent morphology and timing, and (b) can be marched out. Blips are seen in lead II (*vertical arrows*). These blips can be marched out (*calipers*) and have a consistent morphology; they are not part of the T wave, as they do not consistently fall on every T wave. They are also seen in other leads (I, V_5, V_6, *arrows*), further adding to the evidence that these are P waves, not artifacts or parts of T wave. They do not have a consistent relationship with the QRS complexes, and some of them fall inside the QRS complexes and are not seen (*dashed arrows*). Thus, P waves are dissociated from QRS complexes and are less numerous than QRS complexes. This is diagnostic of VT. **The variable T-wave morphology is usually a hint to the presence of P waves that are dissociated from QRS/T and falling variably over some T waves.**
2. Analyze QRS morphology. QRS has a LBBB-like morphology in lead V_2. However, there is a QR pattern in V_5–V_6, QS pattern in lead I, and right-axis deviation (QRS negative in lead I), not consistent with LBBB. Besides, QRS has excessive notching, best seen in leads V_1 and V_3 (*horizontal arrows*). Thus, this is VT.
3. Additional findings:
- Wide QRS complexes of different morphology are scattered within the tachycardia (*stars*). Those may represent fusion complexes or PVCs. Being wide, they have no diagnostic value.
- ST-segment elevation, concordant with QRS, is seen in the anterolateral leads. This is concerning for STEMI.

Figure 8.10 Two short tachycardia runs. The tachycardia starts after a regularly occurring sinus P wave (*bar*) at a shorter PR interval (the *bar* marches out with the *arrows*). This is typical of a PVC, which occurs without disrupting the timing of the underlying sinus P waves. PAC would have started with a premature P wave. Thus, the tachycardia starts with a PVC and has the same morphology as the PVC. This is VT.

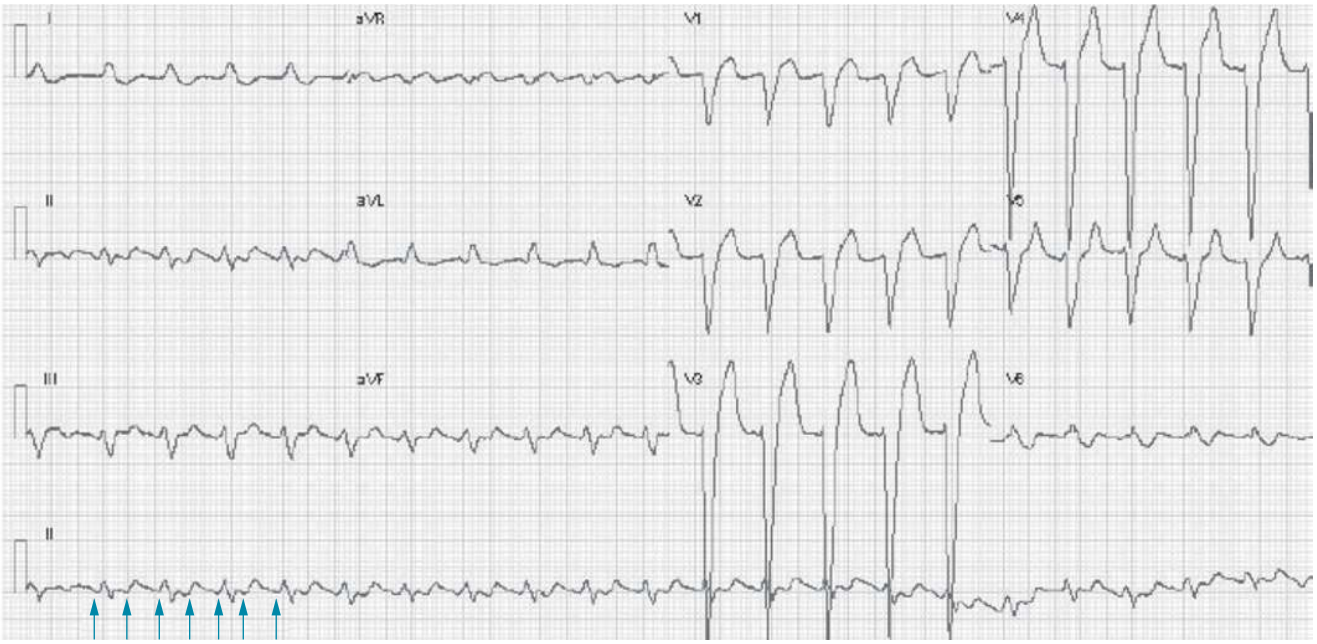

Figure 8.11 Wide complex, regular tachycardia, at a rate of ~135 bpm. QRS looks narrow in some leads; this is due to the fact that part of the QRS is isoelectric in those leads. That is why QRS should be measured in the lead where it is widest. QRS is wide (~140 ms) in lead V_3 in particular.

1. QRS looks like a typical LBBB in leads I, aVL, and V_1. This suggests SVT with LBBB aberrancy.

2. P waves are seen. A negative P wave is overlying the ST–T segment and another P wave is just preceding QRS (*arrows*); these deflections are recognized as P waves, as opposed to being fragments of T wave, by the fact that they have a *consistent morphology* and can be *marched out*. Thus, this tachycardia is an atrial tachyarrhythmia with 2:1 AV conduction, the atrial rate being 270. The atrial rate (>240) as well as the sawtooth shape seen in leads II and aVR and the lack of isoelectric baseline make the diagnosis atrial flutter.

Final diagnosis: Atrial flutter with 2:1 AV conduction and wide QRS due to LBBB aberrancy.

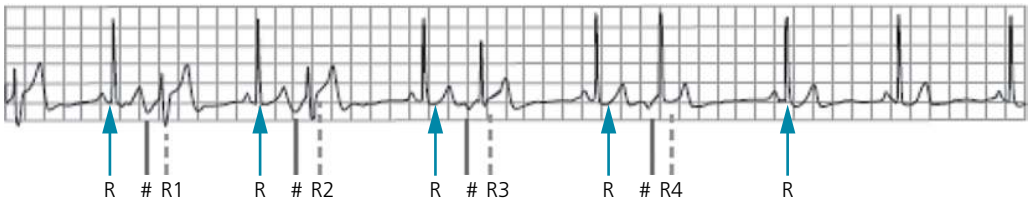

Figure 8.12 The baseline rhythm is sinus, consisting of QRS complexes (R) preceded by sinus P waves. Outside these complexes, there are premature complexes occurring in a bigeminal pattern (R1, R2, R3, R4). These could be PVCs or PACs with aberrancy. Look for P waves preceding these complexes: there is a P wave before each complex, marked #. It is an inverted, non-sinus P wave and occurs prematurely. This means that R1–R4 are PACs with aberrancy rather than PVCs. These PACs have aberrant conduction because they occur very prematurely, while the right bundle is still in its refractory period, which leads to RBBB morphology. Note that the aberrancy (QRS widening) is less pronounced when PAC is less premature. This is a form of ***Ashman's phenomenon***. R–R1 interval <R–R3 interval <R–R4 interval; hence, R4 is not aberrant.

Monophasic QRS concordance in the precordial leads signifies that all QRS complexes in V_1 through V_6 are monophasic and pointing in the same direction, either upward or downward. In other words, these QRS complexes are either monophasic R or monophasic QS complexes. Concordance is not present if any of the 6 leads has a biphasic QRS (e.g., qR or RS complex).

b. ***Northwest axis or right axis.*** The typical forms of aberrancy, LBBB, RBBB, or RBBB + LAFB, are not associated with a right axis (RBBB may be associated with a right axis when RVH coexists, as seen on the baseline ECG). On the other hand, VT most frequently originates from the ventricle with the largest mass, i.e., LV, and therefore frequently has a right axis.

c. *In patients with a wide baseline QRS (LBBB or RBBB or non-specific intraventricular conduction delay),* ***a tachycardia that is wide but narrower than the baseline QRS is VT.*** Aberrancy can only widen QRS, not narrow it, whereas VT may paradoxically be narrower than the baseline rhythm. Also, a tachycardia with a bundle branch block morphology contralateral to a baseline bundle branch block is usually VT (e.g., in a patient with RBBB at baseline, a tachycardia with LBBB morphology is VT).

d. ***QRS >160 ms suggests VT if the baseline QRS is narrow*** *and in the absence of class I antiarrhythmic drug therapy*.

e. ***Presence of capture or fusion complexes.*** When an impulse originating from the sinus node conducts down the AV node and captures the ventricles, instead of allowing the VT focus to capture the ventricles, the result is a *capture complex squeezed within the VT*. If this impulse partially captures the ventricles, while the VT focus partially captures the rest of the ventricles, the resulting complex is a *fusion*

complex. A capture complex has the same morphology as the baseline sinus beat, while a fusion complex has a morphology intermediate between the sinus beat and VT. A fusion complex may start like the sinus-originating beat and terminate like the VT beat, or vice versa. *Only when the beat squeezed in the tachycardia is narrow can one be certain that it is a capture or a fusion complex, confirming VT*. A QRS complex that is wide but of different morphology than the tachycardia (narrower or not) may be a fusion complex, or it may be a PVC in a patient with SVT or VT.

f. ***In VT, the QRS complex is wide in its initial portion and has a slow initial upslope or downslope.*** Conversely, in SVT with aberration, QRS has a narrow initial deflection that corresponds to the septal depolarization, followed by widening of the terminal QRS portion. In addition, in VT, the impulse frequently spreads over a diseased, fibrotic myocardium and meets "bumps" on the road, creating *atypical notching of the QRS complex* (notching of S descent or R wave, different from bundle branch block).

g. *In aVR, VT is suggested by: (i) large or wide initial R wave, or (ii) QR pattern with a slowly downsloping Q wave >40 ms*. Normally, aVR consists of a sharp and deep negative deflection, sometimes preceded or followed by a small r wave (QS, rS, or Qr pattern).

VI. Features characteristic of SVT with pre-excitation

Once a diagnosis of VT is made using the above criteria of VT vs. aberrant SVT, step back and consider the diagnosis of pre-excited SVT before closing. Since the ventricular stimulation does not spread down from the His bundle, the QRS morphology of a pre-excited SVT resembles the QRS morphology of VT, i.e., not a typical LBBB or RBBB morphology. The initial portion of QRS is slurred, but this is seen with VT as well (slow upslope) and does not help differentiate VT from pre-excited SVT. *Seeing the slurred delta wave on the baseline ECG is diagnostic of pre-excitation; seeing it during tachycardia is not diagnostic and is consistent with VT as much as pre-excited SVT*.

The most typical pre-excited arrhythmia is AF with pre-excitation. In this case, the wide tachycardia is irregular, implying AF rather than VT. AF with pre-excitation is diagnosed when AF has VT morphological features; or when AF is wide and polymorphic (QRS varies in height and width), bizarre looking, or very fast (>200 bpm) (Figure 8.13).

- When AF has the morphological features of VT or is too fast (>200 bpm), consider pre-excited AF (WPW syndrome).
- Also, as opposed to AF with aberrancy, where the QRS becomes more aberrant and wider after a shorter R–R interval (Ashman's phenomenon), pre-excitation may become more evident and the QRS may become wider after a longer R–R interval that allows recovery of the accessory pathway's refractory period.

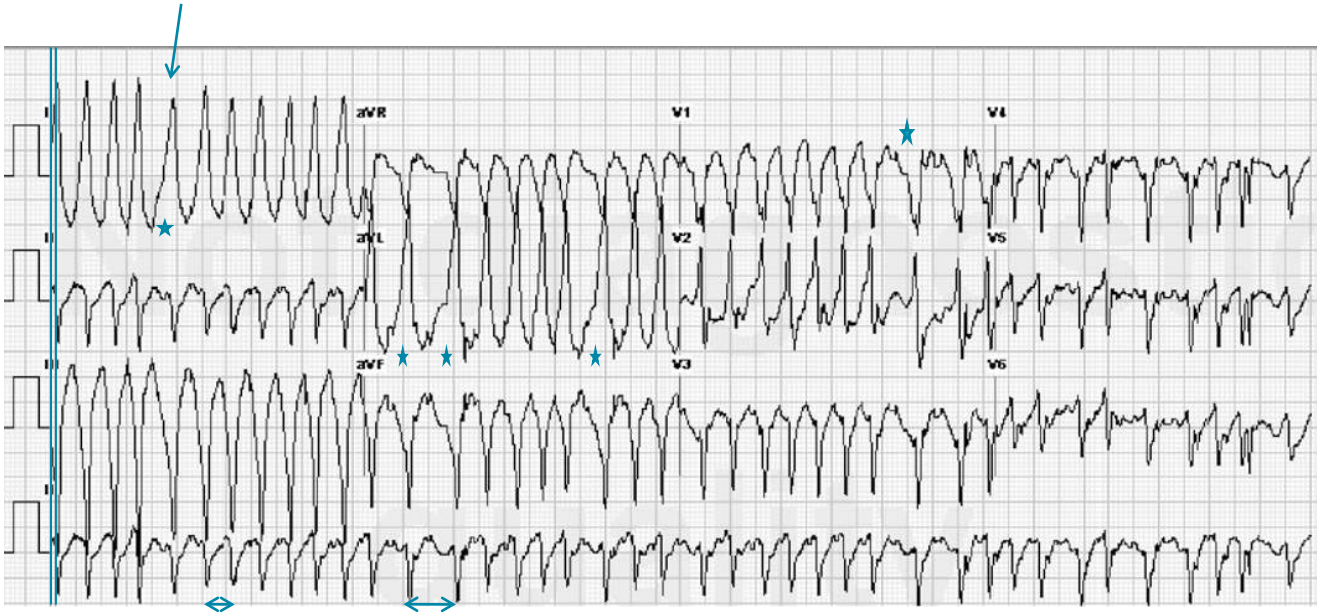

Figure 8.13 Very wide QRS complex tachycardia (particularly wide in lead I, ~200 ms), very fast (rate ~240 bpm), and grossly irregular. Because it is so fast, it may initially seem regular; but on careful assessment one sees that R–R intervals are grossly irregular, with some R–R intervals being half the size of other R–R intervals, without any particular pattern (irregularly irregular) (*double arrows*).

Differential diagnosis:

1. VT: VT is usually regular or slightly irregular, not grossly irregular. However, it may be grossly irregular in case of **polymorphic VT**, which is a very fast VT that quickly degenerates into VF. This could be the case here.

2. Being irregular, this tachycardia is likely **AF with wide QRS** complexes. AF is wide in the case of **(a) aberrancy**, or **(b) accessory pathway (WPW)**. Aberrancy is unlikely because QRS morphology does not fit with a typical RBBB or LBBB. In fact, QRSs are too wide and polymorphic, with some complexes being ~200 ms wide (*arrow*). Thus, this is AF with VT features, implying AF with conduction over an accessory pathway. Note that QRS gets wider when the R–R interval increases (*stars*), which is consistent with pre-excitation rather than aberrancy.

A regular SVT with pre-excitation is less common than AF with pre-excitation (e.g., antidromic AVRT, atrial tachycardia with pre-excitation). Since the QRS morphology simulates VT, other features help differentiate VT from SVT with pre-excitation:

- AV dissociation *or* QRS complexes outnumbering P waves (→ VT).
- A predominantly negative QRS complex in leads V_4–V_6 implies ventricular activity originating close to the apex, and thus VT rather than pre-excitation, as the accessory pathway cannot be apical. For the same reason, negative monophasic concordance in all precordial leads can only be VT, not pre-excitation. Positive monophasic concordance may be seen in pre-excitation from a left posterior or lateral accessory pathway.

Acutely, AF or any other SVT with pre-excitation is treated as VT. The administration of AV nodal blocking agents that are typically used for AF, particularly calcium channel blockers or digoxin, may shorten the accessory pathway's refractory period and allow more atrial activity to conduct over the accessory pathway, thus leading to a faster rate. Give procainamide if the patient is stable, then perform DC cardioversion if the arrhythmia does not respond or if the patient is unstable.

Table 8.1 summarizes the approach to wide QRS complex tachycardias.

VII. Role of adenosine in establishing a diagnosis

Adenosine may help differentiate various types of SVT. AVNRT, AVRT, SNRT, and a subgroup of atrial tachycardias often totally break with adenosine, but they may remain unchanged or may slightly and transiently slow down if the slow pathway (AVNRT) or the AV node (AVRT) is slowed rather than blocked. Atrial flutter and most subgroups of atrial tachycardia usually do not break but develop AV block with adenosine, which slows the QRS rate and allows one to see and assess the hidden P waves and make the diagnosis (Figure 8.14). AV block during tachycardia (e.g., 2:1 conduction) excludes AVRT and makes AVNRT less likely. The AVRT loop is dependent on both the atrial and ventricular myocardium; thus, a drop of atrial or ventricular activity leads to cessation of the arrhythmia.

VT is not affected by adenosine (except idiopathic VT). While potentially helpful in distinguishing SVT from VT, adenosine IV or verapamil or diltiazem IV should be avoided in wide complex tachycardias of uncertain diagnosis, because these should be presumed VT and treated as such. Diltiazem, verapamil, or adenosine are vasodilators that can lead to hemodynamic collapse in case of VT, in which the patient's systemic pressure is merely maintained by vasoconstriction. They can also lead to rate acceleration and VF in case of WPW (i.e.,

Table 8.1 Summary of the approach to wide QRS complex tachycardia.

(1) VT vs. **(2)** SVT (including AF) with aberrancy vs. **(3)** SVT (especially AF) with pre-excitation

1. VT is the most likely diagnosis (>80%), especially if history of heart disease. **Features that further support VT**:
- P waves are seen scattered within QRS complexes or ST–T segments and are unrelated to QRS complexes (**AV dissociation**); and/or number of P waves <number of QRS complexes
- Morphology of QRS is not consistent with a typical LBBB or a typical RBBB
- Tachycardia onset with a PVC rather than a PAC (no premature P wave)
- Exam: variable pulse despite a regular rhythm, off-and-on cannon A waves on JVP exam

2. SVT with aberrancy: this diagnosis is most confidently made if a baseline bundle branch block is present and the tachycardia has the same morphology as this baseline block. Otherwise, the lack of any VT feature supports the diagnosis of SVT

Also, if the wide complex tachycardia is very grossly irregular, AF with aberrancy or pre-excitation is the likely diagnosis, rather than VT (VT may be slightly irregular, but not grossly irregular).

3. AF with pre-excitation: tachycardia is irregular, polymorphic, bizarre looking. The QRS morphology is wide but not consistent with aberrancy (not a typical RBBB or LBBB)

A wide complex tachycardia that is very grossly irregular is AF: AF with aberrancy or AF with pre-excitation. Polymorphic VT is a less likely possibility

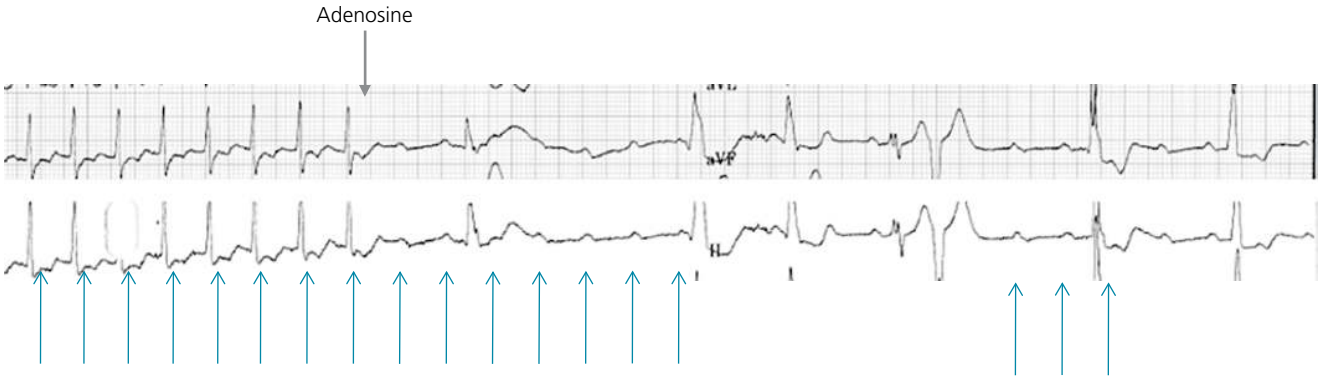

Figure 8.14 Short RP narrow complex tachycardia, initially suggestive of AVNRT or AVRT (*arrows* indicate P waves). After adenosine, the P waves keep marching out at the same rate unaffected by adenosine, while AV conduction is blocked and ventricular escape beats are seen. Thus, this is atrial tachycardia. Adenosine was helpful in establishing the diagnosis. Soon afterward, the 1:1 AV conduction will resume.

SVT with pre-excitation). Adenosine can trigger AF in 12% of the treated patients, which destabilizes those with antegrade accessory pathway conduction.

VIII. Differential diagnosis of a wide complex tachycardia on a 1-lead telemetry or Holter monitor strip

These features, selected from the preceding sections, suggest VT:

- AV dissociation.
- QRS >160 ms if the baseline QRS is narrow.
- Tachycardia similar in morphology to a prior PVC.
- Tachycardia starts with a PVC rather than a premature P wave and has the same morphology as the PVC.
- The initial portion of the wide QRS is wide, slurred or slow, sometimes with a notched descent. Conversely, the presence of a narrow initial deflection q or r (qR or rS, with narrow q or r <1 mm), or a fast downstroke of a QS pattern or a fast upstroke of an R pattern makes SVT more likely. In case of SVT with aberration, the QRS starts normal, then becomes slow, wide, and aberrant in its terminal portion.

IX. Various notes

A. Retrograde P wave

AVNRT and orthodromic AVRT have retrograde P waves, that is, negative P waves in the inferior leads II, III, and aVF. P waves may fall within the QRS or just after the QRS; P waves may not be visible if they fall within the QRS, as is common with AVNRT. VT may also lead to retrograde P waves; in fact, VA conduction, often 1:1 conduction, occurs in 25% of VTs.

P waves of atrial tachycardia may look retrograde in the case of a low atrial focus; otherwise, they are antegrade, upright in leads II, III, and aVF.

B. Ashman's phenomenon

Aberrancy of one or multiple consecutive beats can occur after a long–short QRS sequence in AF, or after a very premature PAC (Figure 8.12).

The QRS occurring at a short R–R interval may be wide and typically has an RBBB morphology, or RBBB + LAFB morphology. This is related to the fact that one of the bundles, often the right bundle, is still in a refractory period when the supraventricular stimulus comes early. The right bundle normally has a longer refractory period than the left bundle. A long R–R interval further prolongs the bundles' refractory period and makes a QRS that falls shortly after it aberrant (*long–short sequence*). The aberrancy may have an LBBB morphology, especially if the left bundle has underlying disease (such as incomplete LBBB). The aberrancy may be perpetuated for multiple beats, even if the R–R interval lengthens over the subsequent beats, as a result of the delayed trans-septal activation of the blocked bundle (see Chapter 13, Figure 13.27).

C. How the tachycardia starts

Looking at how the tachycardia starts helps distinguish VT from SVT in wide complex tachycardia, as discussed previously. A tachycardia that starts with a PVC and has the same QRS morphology as the PVC is VT; a tachycardia that starts with a PAC is usually SVT.

Once a diagnosis of SVT is made, whether narrow or wide SVT, focus on the P wave that initiates the tachycardia. If the premature P wave that starts the tachycardia has an identical morphology to the subsequent P waves of the tachycardia, and/or marches out with those subsequent P waves, the tachycardia is an atrial tachycardia (mainly the automatic form). However, if the P wave does not resemble subsequent P waves and does not march out with them, the tachycardia could be any SVT, including AVNRT, AVRT, or reentrant atrial tachycardia.

D. How the tachycardia ends, particularly the P-wave pattern at the end

Examining how the tachycardia ends is helpful, although less so than examining how it starts:

- If it ends with a QRS complex – the tachycardia can be VT or any SVT.
- If it ends with a P wave – the tachycardia can be VT (with retrograde VA conduction), or any SVT except atrial tachycardia. Atrial tachycardia ends when the abnormal P wave vanishes rather than gets blocked at the AV node, as the AV node is not part of the reentrant circuit. AVNRT ends when the slow pathway intrinsically slows down (vagal tone) or a PAC enters the reentry loop and blocks it.
- If it ends with a premature P wave, i.e., a P wave that does not march out with the P waves of the tachycardia and has a different morphology – the tachycardia is not VT. It can be any SVT except automatic atrial tachycardia.
- A tachycardia with 1:1 AV association that ends with a regularly occurring QRS, rather than P, is unlikely to be VT with 1:1 VA conduction.

E. Role of physical exam in the differential diagnosis of wide complex tachycardia

Two exam features are characteristic of AV dissociation and imply VT:

1. Cannon A waves on JVP exam. Forceful A waves are sometimes felt by the patient ("neck pounding") and imply that the atria and ventricles contract simultaneously. Regular, every-beat cannon A waves imply AVNRT, whereas ***irregular cannon A waves imply AV dissociation (in this case, VT)***.

2. ***Variable pulse and variable first heart sound despite a regular rhythm implies AV dissociation***. The variable pulse and variable first heart sound make VT mimic AF on exam; however, the monitored rhythm shows a regular rhythm, and this "irregular-sounding regular rhythm" is actually VT.

X. General management of SVT

A. Management of AF or atrial flutter (Table 8.2)

Table 8.2 Management of an acutely presenting, hemodynamically stable AF or atrial flutter.

1. Rate control	
• If no acute systolic HF	β-blocker (metoprolol 5 mg IV × 3 Q10min, then oral metoprolol) Diltiazem (0.25–0.35 mg/kg IV, then drip 5–15 mg/h, then oral diltiazem)
• If acute systolic HF	Diuresis, digoxin and amiodarone

2. Start **acute anticoagulation** (UFH, LMWH)
3. 60% of acute AF cases spontaneously convert at 24 hours
If AF persists at 24 hours, consider **TEE + DC cardioversion** (rhythm control for symptomatic AF)
+ Warfarin or non-vitamin K oral anticoagulant for 1 month after DC cardioversion, then decide about longer-term anticoagulation based on CHA_2DS_2–VAS score
+ Typical atrial flutter may be ablated with >90% cure rate, obviating the need for long-term anticoagulation

B. AVNRT, AVRT

Convert with: vagal maneuvers, adenosine 6–12 mg IV (first-line therapy if no asthma), metoprolol 5 mg IV, diltiazem 20 mg IV.

C. Focal atrial tachycardia (Table 8.3)

Table 8.3 Management of focal atrial tachycardia.

1. Rate control (same protocol as AF and atrial flutter)
2. Rhythm control
- **a.** Adenosine, β-blockers, diltiazem: all may slow down atrial tachycardia or convert it to sinus rhythm. Antiarrhythmic drugs are used as second-line agents
- **b.** Digoxin is not usually used, because it can cause atrial tachycardia
- **c.** DC cardioversion may not be successful, as many atrial tachycardias are caused by enhanced automaticity rather than reentry. DC cardioversion is only attempted if the patient is unstable

3. Anticoagulation is not usually necessary for atrial tachycardia per se, but may be necessary in an older patient whose atrial tachycardia frequently coexists with AF

Figure 8.15 Two types of QRS complexes are seen: (1) narrow complexes preceded by sinus P waves; (2) wide complexes that seem, at times, to be preceded by sinus P waves (*arrows*) but are, in reality, coming too close to the P waves and dissociated from them, with a variable PR interval (ventricular complexes).
The wide complex rate is close to the sinus rate, which makes those wide complexes fall around the sinus P waves. Whenever the sinus rate accelerates, P waves get conducted; when the sinus rate slows down, the wide rhythm expresses itself. The wide complex rhythm is an *accelerated idioventricular rhythm*, an automatic ventricular rhythm that competes with the sinus rhythm (rate ~65 bpm). The dissociation between P and QRS during those beats is *isorhythmic AV dissociation*.

Always remember to seek an underlying cause of the tachycardia and treat it. This alone may control the rate ± the rhythm:
- HF decompensation, hypovolemia, acute bleed, sepsis, PE, hypoxia, hyperthyroidism

XI. Non-tachycardic wide complex rhythms (see Figures 8.15–8.17)

XII. Practice ECGs of wide complex tachycardias

Review every ECG and attempt to make a diagnosis of SVT vs. VT (Figures 8.18–8.25).

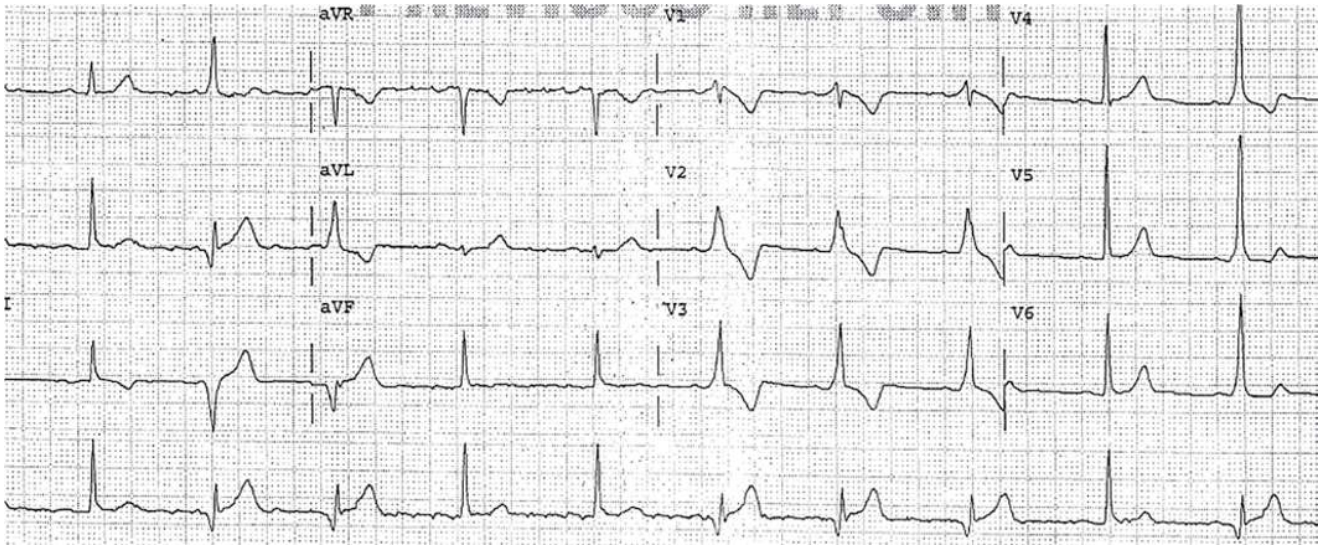

Figure 8.16 Again, 2 types of QRS complexes are seen: (1) narrow complexes preceded by a sinus P wave; (2) wide complexes preceded by the same sinus P wave (best seen in V_2–V_6). These wide complexes are not premature, hence they are not PVCs.

They may represent an idioventricular rhythm similar to Figure 8.15; however, the P and QRS relationship remains constant throughout those beats. *This intermittent widening of the QRS may represent intermittent bundle branch block or intermittent pre-excitation*. The morphology of the wide QRS favors pre-excitation. A positive delta wave with a short PR interval is seen on the wide complexes in leads V_5–V_6 and I, while a negative delta wave (pseudo-Q wave) is seen in the inferior leads. This intermittent conduction across the accessory pathway implies a long refractory period and an inability to consistently conduct even at a normal rate (good prognosis).

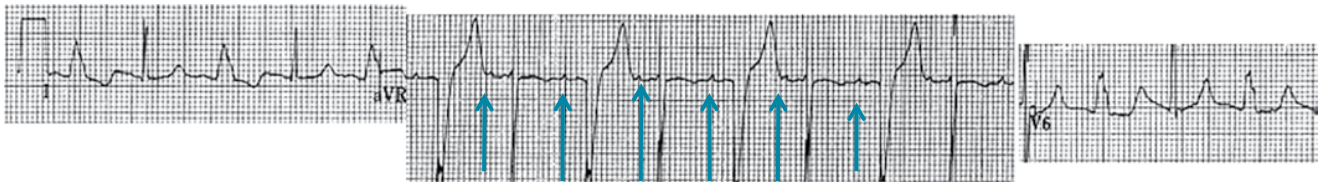

Figure 8.17 Alternation between wide and narrow QRS complexes. Both QRS complexes are occurring regularly after the regular sinus P waves (*arrows*), with a constant P–QRS relationship. The P–P interval and PR intervals are constant. The morphology suggests intermittent LBBB. Diagnosis: sinus rhythm with alternating LBBB.

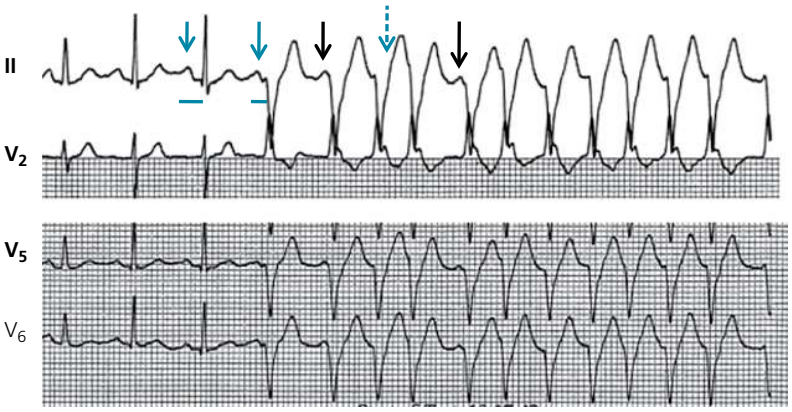

Figure 8.18 A run of wide complex tachycardia. It is irregular, but this does not necessarily imply AF. In a short run of VT or at the onset of VT, VT may be irregular.

1. See how it starts: tachycardia starts after a regularly occurring sinus P wave (*blue arrows*), at a shorter PR interval (*bars*). This implies that it starts with a PVC, a beat that does not interrupt the regularly occurring sinus P wave. The tachycardia has the same morphology as this PVC; thus, the tachycardia is VT.

2. Look for P waves: two P waves are seen within the tachycardia, in leads II, V_5, V_6 (*black arrows*). The first P wave has a similar morphology to the sinus P wave and comes at an interval that is equal to the sinus P–P interval. The second P wave falls at twice the sinus P–P interval. Another sinus P wave is expected to fall in between and is hidden in the QRS complex (*dashed arrow*). Those P waves fall around the QRS and ST–T segments at their own rate and are dissociated from QRS, implying VT.

3. Look at the QRS morphology. The QRS has a ***QS morphology in V_5–V_6***, which is not seen with LBBB or RBBB, and is ***pathognomonic of VT***.

Final diagnosis: VT.

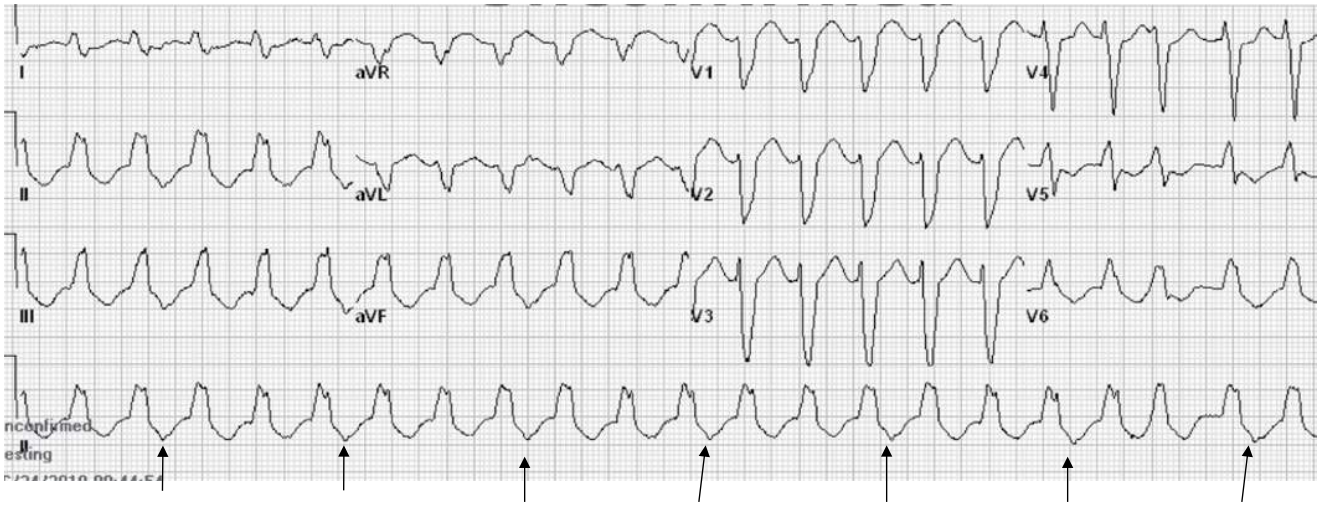

Figure 8.19 Regular wide complex tachycardia, QRS width ~180 ms (lead II).
1. QRS morphology suggests LBBB in leads V_1–V_6. However, LBBB is not typical: QRS is negative in aVL and has RS morphology in I rather than a slurred R morphology. Also, on closer look at V1, R wave is wide ~1 box.
2. Look for P waves in all leads. One can identify inverted blips that have a consistent *morphology* and *timing* and that can be marched out in lead II (*arrows*), and in leads III and aVF. They occur after every third QRS and have a consistent relationship with QRS. Thus, there is AV association, with 3 QRS complexes for every P wave. Since the number of QRS complexes > number of P waves, this is VT. The P waves are retrograde P waves, secondary to a 3:1 ventriculoatrial conduction.

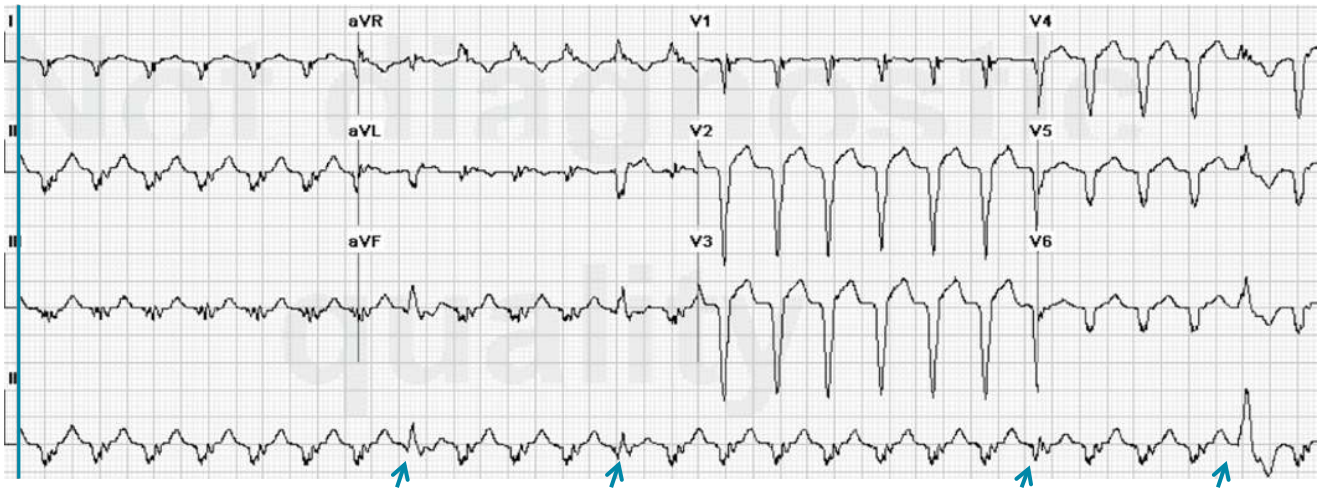

Figure 8.20 Wide complex tachycardia, regular, at a rate of ~155 bpm. The QRS is widest in lead aVF (~140 ms).
1. P waves are not seen. One cannot comment on AV dissociation.
2. QRS morphology. There is monophasic negative QRS concordance in V_1–V_6, with a QS pattern, pathognomonic for a VT that originates apically (likely from an apical MI scar). The axis is northwest (QRS negative in leads I and aVF), which is also suggestive of VT. QRS has a lot of notching, particularly seen in the inferior leads and in lead V_1, also characteristic of VT. A large dominant R wave is seen in lead aVR, also characteristic of VT.

Wide complexes of a different morphology are scattered in the tachycardia (*arrows*). The first three are possibly fusion complexes, whereas the fourth is very wide and is likely a PVC from another focus.

Figure 8.21 This is the baseline ECG of the patient in Figure 8.20. It shows an anterior MI pattern; however, the QS pattern does not extend all the way to V_6 and the axis is normal. Note the morphology of QRS in leads II, aVL and aVF; the 3 different-looking complexes in Figure 8.20 are unlikely to be fusion between this native QRS and the VT's QRS: neither the beginning nor the end of those 3 complexes reflects the native QRS.

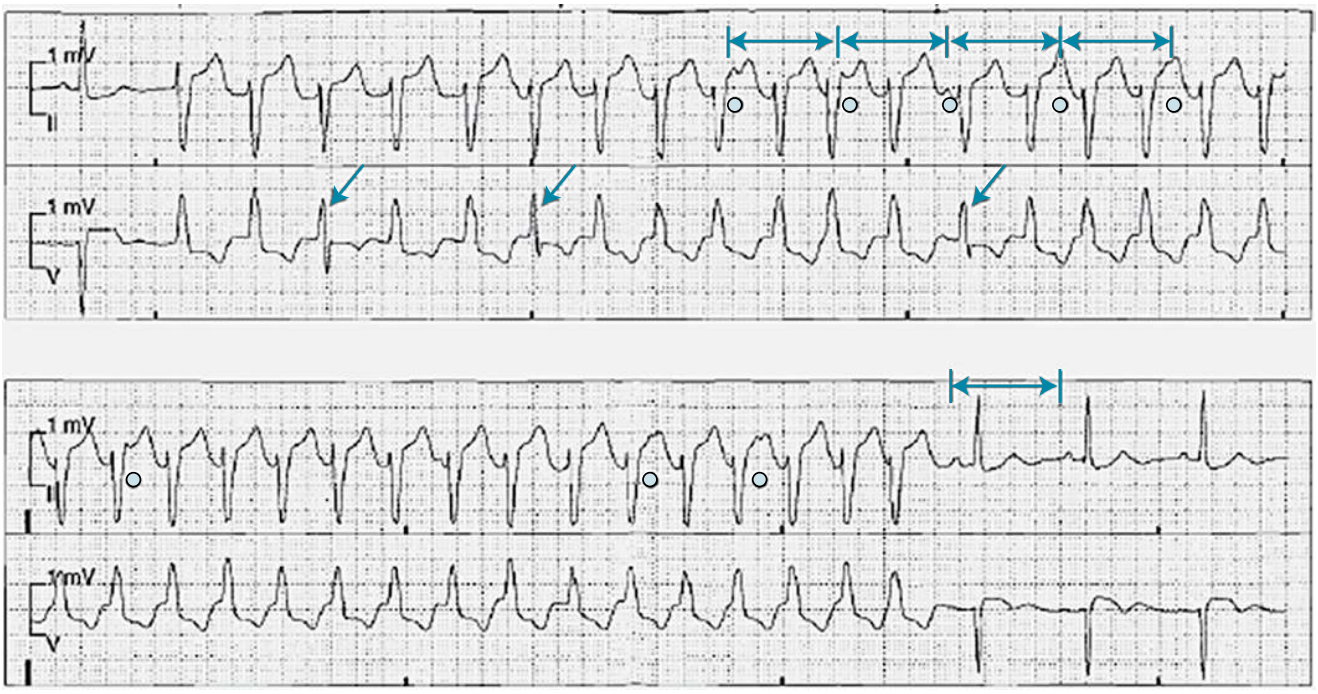

Figure 8.22 Wide complex tachycardia on telemetry or Holter monitoring. Is it SVT or VT?

1. See how it starts. The first complex is not preceded by a P wave or a deformation of the T wave, and thus is a PVC. The tachycardia starts with a PVC and has a morphology similar to the PVC → VT.

2. Look for AV dissociation: scattered notches are visible on the T waves (*blue dots*), and can be marched out (*blue calipers*). They are at equal distance from each other, and this distance is the same as the distance between 2 sinus P waves (marked by the last caliper). They are dissociated from QRS complexes. These are sinus P waves that keep marching through the tachycardia without any relation to it → VT. ***Deformation of a T wave is usually a hint to a hidden P wave***.

3. There are 3 narrower complexes scattered within the tachycardia (*arrows*). They start similarly to the tachycardia's QRS and end similarly to the sinus beat's QRS, suggesting fusion complexes in a patient with VT.

4. The tachycardia is irregular. This does not necessarily imply AF, as any SVT or VT may be irregular at its onset (the first 20 beats).

Conclusion: VT.

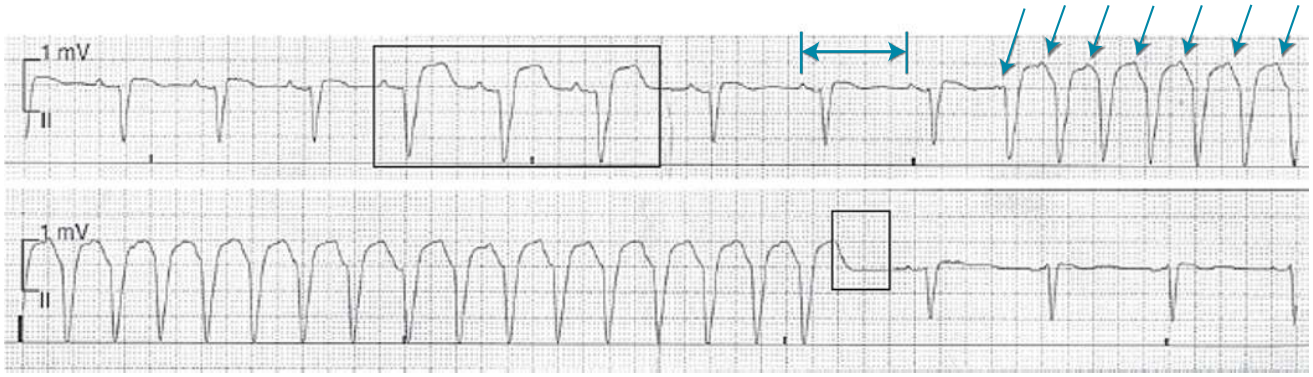

Figure 8.23 Run of wide complex tachycardia. Is it VT or SVT?

1. Look at how it starts. The first QRS of the tachycardia is preceded by a P wave (*first arrow*) that is premature in comparison to the sinus P waves (*caliper*); thus the first QRS is a PAC with aberrancy. A tachycardia that starts with a PAC and has a morphology identical to the PAC is SVT.

2. Throughout the tachycardia, one sees P waves (*arrows*) having a consistent 1:1 association with QRS. AV association does not prove the tachycardia is SVT, as it may also occur in up to 25% of VT.

3. What are the complexes in the area marked by the rectangle? Three wide complexes are preceded by sinus P waves with the same PR interval as the sinus rhythm. These are sinus beats conducted with aberrancy (LBBB aberrancy, QRS being negative in II). The patient probably has intermittent, rate-related LBBB. In fact, the sinus rhythm is a bit faster at the time of these 3 complexes. This proves that the left bundle is prone to rate-related block. The wide complex tachycardia is SVT having the same LBBB aberrancy.

4. Look at how the tachycardia ends (*box*). There is no P wave at the end; the tachycardia ends with a QRS complex. A presumed VT with 1:1 VA conduction usually ends with the retrograde P wave; thus, in this case, the lack of P wave at the end argues against VT.

So this is SVT. The next question is: what type of SVT? Is it AVNRT, AVRT, or atrial tachycardia?

1. Look at the RP interval. RP interval being over half the RR interval, this is a long RP tachycardia. The diagnosis includes atrial tachycardia vs. atypical AVNRT vs. SNRT.

2. The fact that the first P wave (PAC) marches out with the subsequent P waves means that each one of these P waves originates, like the PAC, from the same atrial focus and conducts antegradely. This favors automatic atrial tachycardia.

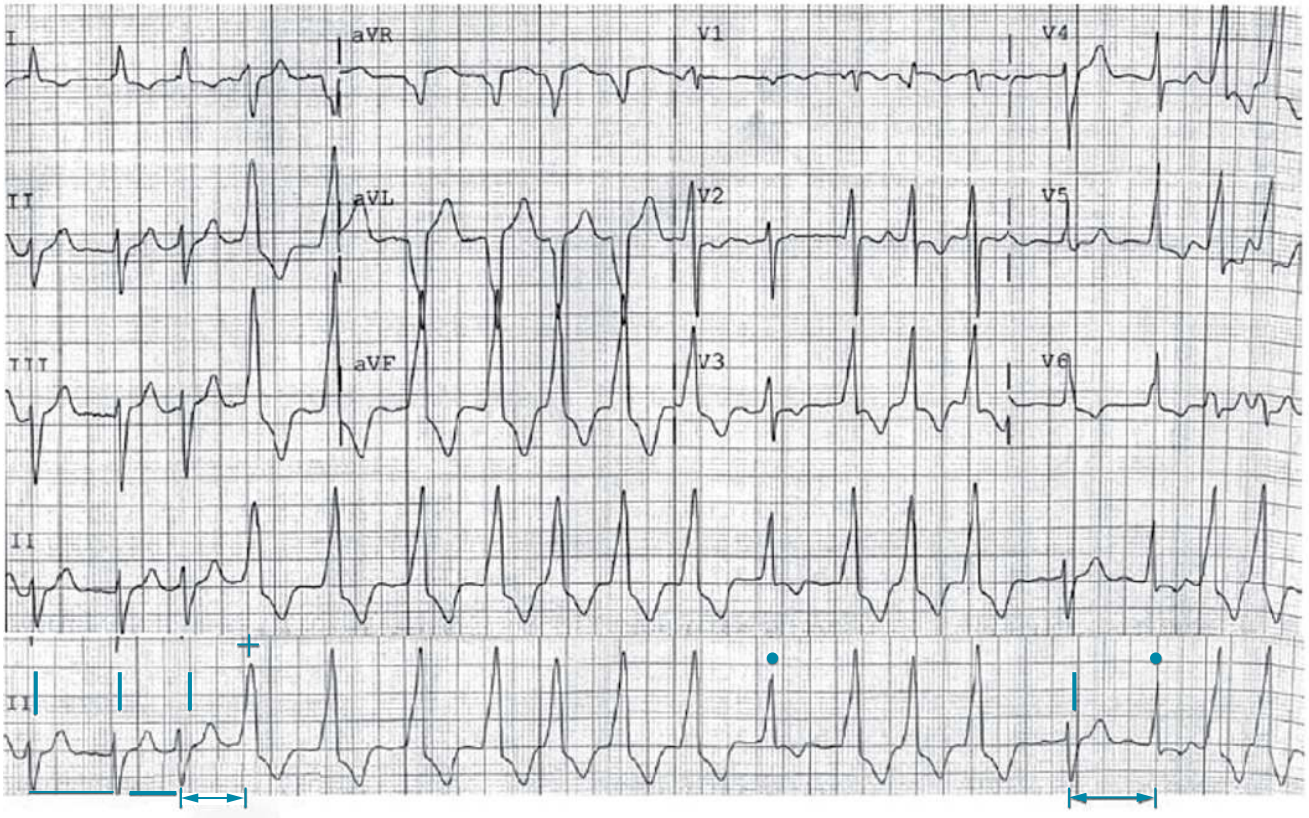

Figure 8.24 The baseline rhythm is AF and the baseline QRS is marked by *lines*. Runs of wide complexes are seen. **In a patient with baseline AF, are the wide complex runs VT or aberrant runs of AF?**

1. Use the rhythm strip with a different set of criteria, focused on Ashman's phenomenon:

a. Does the wide run follow the Ashman rule, meaning it occurs after a long–short sequence? The first run (*cross*) starts after an interval that is not too short (*first caliper*), as there is, on the same ECG, a "longer–shorter" sequence without aberrancy (the sequence of the first 2 complexes, *underlined*). This argues against aberrancy. The second run (*second caliper*) starts after a long R–R interval. This again argues against aberrancy.

b. Two complexes of intermediate morphology are seen (*dots*). These complexes are fusion complexes, further supporting VT (the complex starts similarly to the ventricular complex, and ends as a summation between the ventricular complex and the baseline QRS).

c. If the coupling interval of the wide complexes was constant (timing of onset in relation to the normally conducted complex, *calipers*), it would have further supported VT (this is not the case here).

2. Use the 12-lead ECG to analyze the morphology of the wide complexes (i.e., the complexes that are not marked by a *line* or a *dot* on the rhythm strip) (e.g., Brugada criteria):

- The wide QRS complex morphology does not fit with a typical LBBB or RBBB; it is close to LBBB in V_4–V_5, but the R wave of the RS complex in lead V_2 is wide (>30 ms), and QRS is negative in leads I and aVL, arguing against LBBB; the right-axis deviation of the wide complexes also argues against typical LBBB. This is VT.
- The onset/initial part of QRS is more slurred than its later part (leads II, aVF, and V_3–V_5), which implies VT.
- The notch on the descending limb of QS in leads aVR and aVL is consistent with VT.

Final diagnosis: AF with 2 runs of VT.

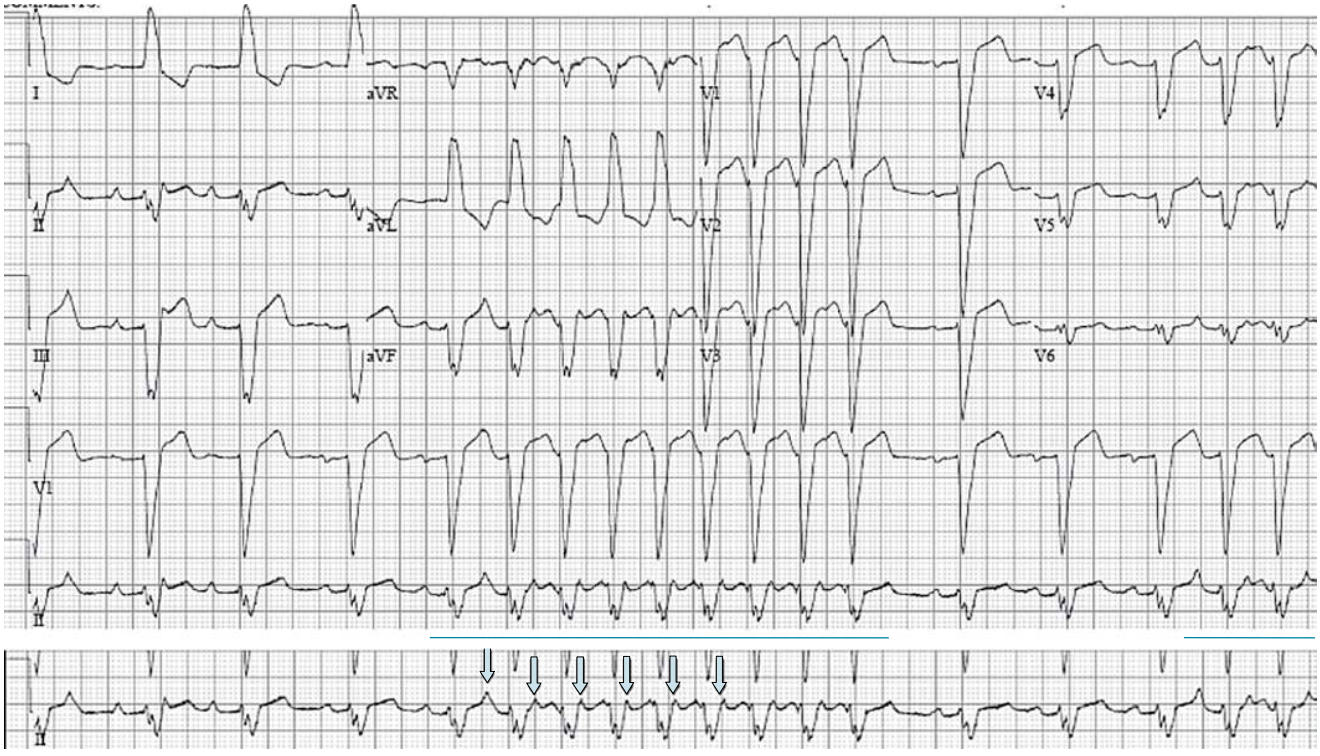

Figure 8.25 Baseline sinus rhythm with LBBB morphology. Two runs of wide complex tachycardia are seen (*horizontal lines*). Are these runs VT or SVT with aberrancy?

- Look at how the run starts. It starts with a P wave that occurs prematurely and deforms the preceding T wave, giving it a peaked appearance (*first arrow*), thus a PAC. The QRS of the tachycardia has the same morphology as this aberrant PAC. Thus, this is SVT.
- The morphology is similar to the baseline QRS morphology. A tachycardia that keeps the same bundle branch block morphology as the baseline is SVT.
- Look for P waves and for AV dissociation: there are notches after each QRS, likely P waves, associated with QRS in a 1:1 fashion (*arrows*). These notches deform the T wave in multiple leads (II, III, aVL, aVR, V_5–V_6). This 1:1 AV association implies SVT or VT with retrograde VA conduction (not here). The fact that the tachycardia ends with a QRS and no P wave argues against VT with 1:1 VA conduction.

This is SVT. What type of SVT is it? It is a short RP tachycardia, which could fit with AVNRT, AVRT, or atrial tachycardia with long PR interval. The P wave of the initial complex (PAC, *first arrow*) keeps marching out with the subsequent P waves, arguing that each one of these P waves is, like the first P wave, coming from the same atrial focus and conducting antegradely to the ventricles. Thus, the tachycardia is likely an automatic atrial tachycardia. Also, the upright P morphology in lead II indicates that the P wave is not a retrograde P wave, and thus the tachycardia is unlikely to be AVNRT or AVRT, which favors atrial tachycardia. The tachycardia ends with a QRS, as no P notch is seen at the last QRS complex. It is consistent with automatic atrial tachycardia, wherein the P vanishes as the automatic focus becomes quiescent.

Final diagnosis: sinus rhythm with LBBB, runs of a wide complex atrial tachycardia.

Questions and answers 339

I. Premature ventricular complexes

In the absence of heart disease, premature ventricular complexes (PVCs) are generally benign and do not clearly portend an increased risk of sudden or cardiac death, regardless of their frequency (>1 per minute) or pattern (e.g., couplets). Frequent PVCs are relatively common in an apparently healthy population (prevalence 1–4% at a mean age of ~50).[1–3] Benign PVCs generally occur at rest and improve with exercise; yet some idiopathic PVCs are triggered by exercise. Very frequent PVCs (>5–10% burden) are overwhelmingly benign and idiopathic. but warrant echo to exclude structural heart disease; occasionally, stress test +/– MRI may be performed, particularly for exercise- or recovery-induced PVCs. Even in the absence of underlying heart disease, very frequent PVCs may lead to a reversible PVC-mediated cardiomyopathy: in fact, among patients referred for PVC ablation, ~10–30% of those with PVC burden >10% have reduced EF; EF typically normalizes with PVC ablation.[4–8]

In patients with prior MI, frequent or complex PVCs or non-sustained VT portend an increased mortality independently of other baseline variables, according to most post-MI studies.[8] However, targeted therapy of PVCs or non-sustained VT is not indicated. In fact, the use of class I antiarrhythmic drugs to suppress PVCs worsens outcomes (as a result of the proarrhythmic side effects of these drugs) and should be avoided in patients with prior MI. In the landmark CAST trial of patients with a history of MI and EF <55% (mean 36% ± 10%), PVC suppression with class I antiarrhythmics tripled cardiac death at 10 months (sudden death and acute MI death).[9]

For patients without obvious heart disease on ECG or echo, monomorphic PVCs are usually benign idiopathic. β-Blockers and verapamil are the safest treatment for such PVCs when symptomatic, but they have reduced efficacy (10–24%) in high PVC burden.[8] Conversely, flecainide and catheter ablation are highly effective (~80%) for these PVCs. Catheter ablation or flecainide is indicated for frequent PVCs (>10% burden) with either: (i) symptoms (palpitations, fatigue) or (ii) EF decline <50%.

In the particular case of frequent PVCs (>10% burden on 24-hour Holter) with LV systolic dysfunction, there are 2 possible diagnoses: (1) LV dysfunction causing PVCs, in which case extensive Q waves or MRI LV scars are seen, and PVCs may arise from a single focus or multiple foci (multifocal PVCs with distinct morphologies); (2) frequent PVCs, usually unifocal, leading to a PVC-mediated or PVC-aggravated cardiomyopathy. It is reasonable to suppress PVCs with amiodarone, flecainide (if no MI), or catheter ablation and see if EF improves. In fact, EF substantially improves in over 80% of these patients.[4–8]

Asymptomatic patients with frequent PVCs (>10% burden) but normal LV dimensions and EF do not have any indication for therapy; rather, a watch-and-wait approach is adopted, with LV assessment every 6–12 months (risk of cardiomyopathy up to 10–30%, reversible).[8] Notably, spontaneous PVC resolution may occur in up to 44% of normal-EF cases at 3–60 months.[5]

How to differentiate PVC from PAC with aberrancy

PVC is a wide premature complex with ST–T changes opposite in direction to QRS. A PVC does not affect the sinus P waves, which keep marching through the PVC at their regular rate. Therefore, a sinus P wave falls within the PVC and distorts it, or precedes the PVC at a PR interval shorter than baseline; *a wide premature complex preceded by a sinus P wave at a shorter PR interval is a PVC* (*Figure 9.1*). This also means that the PVC does not reset the sinus node. Hence the R–R interval between the complex before and the one after the PVC is equal to twice the regular R–R interval, and it looks like there is a pause after the PVC. PVC may, however, be *interpolated* between 2 normally conducted P-QRS complexes, with no pause (Figure 9.2).

PAC with aberrancy (functional bundle branch block) mimics a PVC.* PAC, however, starts with a premature P wave of a different shape than the sinus P wave (may fall in the T wave and manifest as a change in the preceding T-wave morphology: deformity, peaking). PAC often conducts retrogradely to the sinus node and resets it, making it fire after the PAC at a rate close to baseline. Thus, the interval after a PAC is not a fully compensatory pause and is only slightly longer than the baseline R–R interval. The R–R interval between the complex before and the one after the PAC is less than twice the normal R–R interval. PAC with aberrancy is often of RBBB morphology. Interpolated PACs are possible but unusual, and only occur when the sinus node is not reset by the PAC.

While frequent PVCs are benign in patients with no identifiable heart disease, frequent PACs are associated with a 3-fold risk of AF and stroke in patients 55–75 years of age (prolonged rhythm monitoring may be warranted to detect periods of AF).[10]

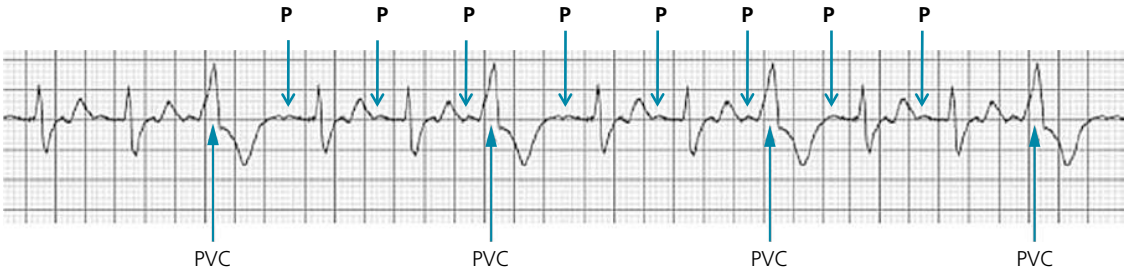

Figure 9.1 Wide premature complexes occurring in a trigeminal pattern. These are typically PVCs but must be distinguished from PACs with bundle branch block (aberrancy). They fall after normally occurring, non-premature P waves with a ***shorter PR interval than the sinus beats, which is typical of PVCs***. Sinus P waves keep marching out through the PVCs.

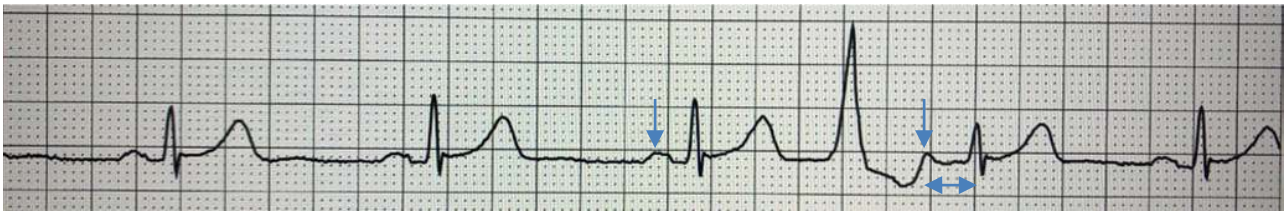

Figure 9.2 Interpolated PVC. Unlike the common PVC, an interpolated PVC does not prevent the conduction of the preceding or following sinus P wave (*arrows*) and there is no pause after the PVC. It is mainly seen when the sinus rate is slow. Instead of being blocked, the P wave that follows the PVC is conducted with a longer PR interval (*double arrows*).

- Frequent PVCs = PVCs >30 per hour or >1 per minute.
- Very frequent PVCs with a risk of tachycardia-mediated cardiomyopathy: total PVC burden >5–10% of the total QRS complexes, or >20,000 PVCs per day.
- Complex PVCs = polymorphic PVCs, or couplets or triplets of PVCs.
- *Unifocal or monomorphic PVCs* have a single morphology. *Multifocal PVCs* are PVCs arising from different foci, typically scars, with distinct morphologies (e.g., 2–3 different morphologies from 2–3 foci). This is different from the completely erratic morphology of *polymorphic PVCs* suggestive of ongoing ischemia or channelopathy.
- Bigeminy means the alternation of 1 sinus beat with 1 PVC; trigeminy means the occurrence of 1 PVC after every 2 sinus beats (Figure 9.1). This is different from couplet (2 PVCs in a row), or triplet (3 PVCs in a row).
- Ventricular parasystole corresponds to an automatic ventricular focus that fires at a regular rate (~30–60 per minute), independently of the basic sinus or supraventricular rhythm and uninhibited by this rhythm (the parasystolic focus is protected by an entrance block). This focus impulse propagates to the ventricles whenever they are not in their refractory period. Parasystole manifests as PVCs that have *no fixed relationship* with the baseline QRS (non-fixed coupling), with inter-PVC intervals that are a multiple of the shortest inter-PVC

*PVC and PAC with aberrancy are wide but may be narrow if the PVC or the aberrancy originates high in the septum close to the His bundle. They will, however, look different than the baseline QRS. In case of a wide baseline QRS, a PAC with aberrancy is wider than the baseline; a QRS narrower than the baseline is diagnostic of PVC.

interval. Fusion complexes are particularly common. Parasystole may be seen in the presence or absence of heart disease and does not affect prognosis. Even frequent parasystolic PVCs are benign, per se.

In contrast to ventricular parasystole, typical PVCs are due to a reentrant circuit that is initiated by the supraventricular rhythm, and thus show *fixed-interval coupling*.

- **Site of origin of the PVC (PVC looks away, i.e., looks negative, from where it originates):**

i) right vs. left:	right ventricular origin → LBBB morphology left ventricular origin → RBBB morphology
ii) anterior vs. inferior:	anterior origin → QRS (+) in the inferior leads (vertical axis) inferior origin → QRS (–) in the inferior leads (left axis)
iii) basal vs. apical:	basal origin → QRS complex is upright in all precordial leads, and (–) in I-aVL if lateral origin apical origin → QRS complex is negative in all precordial leads, as it looks away from them, particularly V_3–V_6

II. Ventricular tachycardia (VT)

A. Types (Figure 9.3)

- Sustained VT = VT lasting >30 seconds or VT associated with hemodynamic compromise (such as syncope/presyncope)
- Non-sustained VT: at least 3 consecutive ventricular beats, with a total VT duration <30 seconds and no hemodynamic compromise

Also, by definition, the ventricular rate must be >100 bpm. A ventricular rhythm slower than 100 bpm is accelerated idioventricular rhythm (AIVR); a ventricular rhythm slower than 40 bpm is a ventricular escape rhythm.

B. Causes of sustained VT

Sustained VT is typically secondary to an underlying heart disease:

- Acute or chronic ischemia. **Acute ischemia typically leads to polymorphic VT, whereas a prior ischemic scar/old infarct leads to monomorphic VT**, or sometimes direct VF, or occasionally, polymorphic VT. **Monomorphic VT typically results from a scar and is not due to acute ischemia** (ACC guidelines).[11] It may rarely be seen in acute MI, but even in this case, it is likely a marker of a permanent substrate from a prior scar; ischemia may facilitate the induction of monomorphic VT, but is rarely the underlying cause of it.
- Any cardiomyopathy, especially with EF <35%. More specifically, the following ***5 cardiomyopathies are particularly prone to VT:*** fulminant myocarditis, sarcoidosis, ARVD, Chagas disease, and dilated cardiomyopathy due to LMNA gene mutation.
- Some forms of "benign" monomorphic VTs occur without heart disease in young patients with normal hearts (i.e., idiopathic left ventricular VT, right ventricular outflow tract VT). These VTs are benign as they do not lead to sudden death. They account for ~10% of all VT referral cases.
- Some forms of "malignant" VT/VF occur without obvious heart disease: Brugada syndrome, ARVD, idiopathic polymorphic VT (see Sections VI–VIII, *Specific VTs*).
- Antiarrhythmic drugs and electrolyte abnormalities can trigger polymorphic VT. They can also trigger monomorphic VT but are not usually the sole cause of monomorphic VT (there is usually some underlying cardiac structural or electrical disease).[11]

C. Causes and prognosis of non-sustained VT

Non-sustained VT typically occurs in patients with underlying heart disease; however, it occurs occasionally in healthy individuals, more so than sustained VT (prevalence of NSVT in the healthy population, ~1%).[1] Approximately 1% of asymptomatic individuals without apparent heart disease develop NSVT during exercise testing; in the absence of ST changes on the sinus beats, NSVT does not affect long-term prognosis and is typically a form of monomorphic idiopathic VT.[1,12]

NSVT is likely an independent predictor of mortality in patients with cardiomyopathy. In the SCD-HeFT trial of ischemic and non-ischemic cardiomyopathies with EF <35%, and in the MERLIN-TIMI trial of ACS with predominantly preserved EF, NSVT was independently associated with increased mortality.[13,14]

D. Acute management of sustained VT

- Acute DC cardioversion (DC cardioversion is a shock synchronized to R wave).

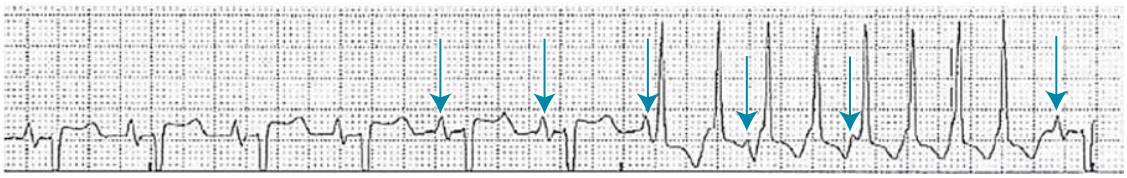

Figure 9.3 Tachycardia that seems narrow but has a different morphology than the native QRS and is associated with secondary ST/T abnormalities → VT or SVT with aberrancy. To differentiate, see how the tachycardia starts. It does not start after a premature P wave, but rather starts after a regularly occurring sinus P wave (*third arrow*) with a shorter PR interval: this means it starts with a PVC, and it has the same morphology as this PVC → the tachycardia is VT. Also, one can regularly march out sinus P waves scattered within the tachycardia and dissociated from the QRS complexes, which is diagnostic of VT. These P waves are marked by *arrows*. One P wave falls within a QRS (marked by an *interrupted line*).

- Prior to DC cardioversion, if the patient is hemodynamically stable, one may attempt IV **procainamide** (10-17 mg/kg over 20–30 min i.e., ~500–1000 mg), IV **amiodarone** (150 mg over 10 minutes), or IV **lidocaine** (1 mg/kg). One drug is attempted one time only if the patient is stable. If the drug fails, DC cardioversion is performed.

  The PROCAMIO study randomized patients with ongoing stable VT to acute procainamide vs. acute amiodarone. VT terminated within 40 minutes in 67% of procainamide vs. 38% of amiodarone patients. Most patients had structural heart disease (CAD ~50%), and mean EF was 40% ± 13%; despite that, procainamide was associated with less hypotension and pulmonary edema than amiodarone.[15] As a result, procainamide is preferred over amiodarone for acute stable VT in ACC guidelines 2017 (class IIa for procainamide, IIb for amiodarone).[11] It may even be used in electrical storm or unstable VT (JACC 2023;81: 2189)

  Regarding lidocaine, a modern trial (ROC ALPS) compared amiodarone, lidocaine, and placebo in out-of-hospital VT/VF arrest. Both lidocaine and amiodarone were equally effective and superior to placebo for survival to hospital admission in all patients, and for survival to hospital discharge among patients with witnessed cardiac arrest.[16]
- Then, after VT cardioversion (whether with DC cardioversion or drugs), and after a loading dose of one of these drugs, an IV drip of the drug is typically administered for 24 hours. Also, a β-blocker is started if BP can tolerate and in the absence of HF (e.g., metoprolol 5 mg IV followed by oral metoprolol; or landiolol for unstable BP). Maintain K at 4.5–5 mEq/L.
- Always look for an underlying heart disease. Coronary angiography and urgent coronary revascularization are performed if ACS is suspected, particularly in polymorphic VT or VF. Also look for electrolyte abnormalities.
- In VF or pulseless VT, perform defibrillation. As opposed to DC cardioversion, defibrillation is a shock that is not synchronized to R wave.

Electrical storm is defined as ≥3 episodes of sustained VT within 24 hours. The management includes treating potential causes (including urgent coronary angiogram ± PCI), *amiodarone or procainamide*, and β-blockers—especially *Landiolol* in borderline hemodynamics. If ineffective, lidocaine may be added to amiodarone. *Quinidine* is considered for very short-coupled polymorphic VT occurring a few days post-MI. *General anesthesia with propofol* is the ultimate means of controlling the electrical storm. *Acute sympathetic denervation* may be done via thoracic epidural anesthesia or cervical ganglion block. *Mechanical circulatory support* may also be needed to stabilize the patient hemodynamically but also to control VT, as VT's hypotension creates myocardial ischemia that self-perpetuates VT.

When VT/VF recurs despite antiarrhythmic drugs and sedation and the resting sinus rate is relatively slow, consider that *VT/VF is actually triggered or accentuated by the low catecholaminergic tone* (e.g., Brugada syndrome, early repolarization VF, pause-induced VT or torsades, short QT syndrome, congenital LQT3). *In those cases, isoproterenol is the solution* (+ quinidine for Brugada and early repolarization VF), not β-blockers or sedation.[17,18]

E. Chronic management of sustained VT

- Place an ICD after any sustained VT, *except* in the following 3 cases:
  - Polymorphic VT/VF occurring within the first 48 hours of a STEMI.
  - Polymorphic VT occurring during acute ischemia, typically with marked ST changes and troponin rise, which eventually gets treated with revascularization. In that respect, monomorphic VT should not be considered as solely due to transient ischemic episodes, and revascularization of a lesion producing ischemia is not enough to prevent VT/VF. Rather than a purely reversible ischemia, an underlying irreversible scar is probably present. Also note that VT, by itself, often leads to low-level troponin elevation. As stated in the ACC guidelines, "*Sustained monomorphic VT with prior MI is unlikely to be affected by revascularization*."[19]
  - Idiopathic monomorphic VT: No underlying heart disease and no ECG suspicion of malignant electrical disorders.
- Revascularization for ongoing or recurrent ischemia contributing to polymorphic VT or exercise-induced VT.
- Chronic β-blocker therapy.
- After VT, and beside ICD placement, antiarrhythmic drugs are used to prevent VT and future shocks (mainly amiodarone or sotalol); they do not clearly reduce mortality. In the older primary VT prevention GESICA trial, amiodarone reduced mortality in patients with ischemic or non-ischemic HF;[20] however, this was not shown in the more modern SCD-HeFT trial.[21] As opposed to class I agents, amiodarone is at least proven to be safe in the HF population.
- In a patient with prior MI who develops a first VT event, either VT catheter ablation or chronic amiodarone is adopted as the first-line strategy, besides ICD if not already in place. The VANISH-2 trial shows that first-line VT ablation reduces VT events (mainly ICD shocks) compared to sotalol, not amiodarone, without an effect on mortality.[22,23] VT ablation is more important in patients with scar VT who continue to have recurrent ICD shocks despite amiodarone therapy: in this cohort, VT ablation reduces recurrent events by ~45% compared to antiarrhythmic escalation (increasing amiodarone to 300 mg/day and adding mexiletine) (VANISH-1 trial).[22,23] Thus, in patients with ICD shocks, either VT ablation or amiodarone is an effective first-line therapy; if amiodarone fails, VT ablation should be considered; less effectively, mexiletine or ranolazine may be added to amiodarone.
- Target K level of 4.5–5 mEq/L. In POTCAST trial, ICD patients with a baseline K of 4 ± 0.2 mEq/L were randomized to a K level of 4.5–5 via K supplementation or MRA therapy. This strategy achieved a reduction of VT and ICD therapies of 1.6% per year, with trends to lower death and HF hospitalizations.[24]

Note that a *monomorphic* VT occurring in the context of electrolyte abnormalities or antiarrhythmic drugs or CAD is still typically managed with an ICD. In general, monomorphic VT is not due solely to these factors or to ischemia, but rather to a pre-existing arrhythmogenic scar. These factors, per se, can cause polymorphic rather than monomorphic VT. Keep a low threshold for placing an ICD for monomorphic VT, even in the context of seemingly reversible causes.[11,19]

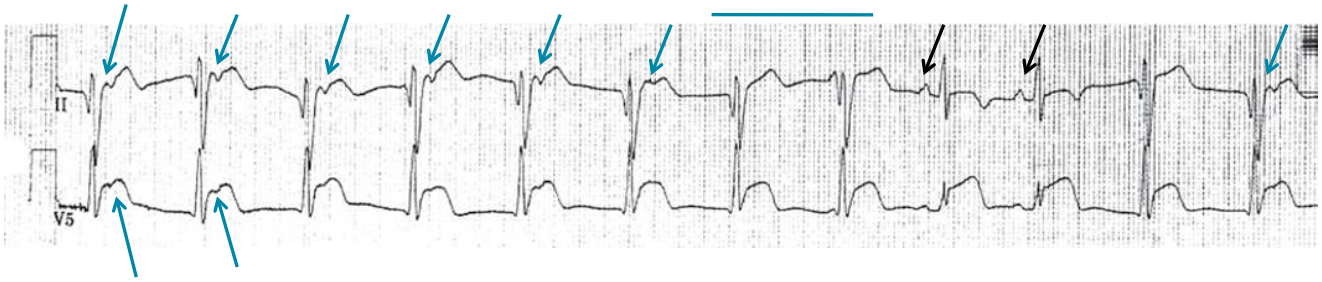

Figure 9.4 Wide complex rhythm at a rate of 70 bpm. P waves are initially seen after every QRS (*blue arrows*). This could be consistent with a ventricular rhythm with 1:1 VA conduction. However, further down the strip, those P waves start coming sooner and fall onto the QRS complexes (*two complexes under the bar*), then appear before the QRS complexes and get conducted (*black arrows*). Thus, these P waves are actually sinus P waves dissociated from the ventricular rhythm. This dissociation is an isorhythmic AV dissociation, wherein the ventricular and sinus rhythms have close rates: when the sinus rhythm speeds up, it takes over and P waves get conducted. When it slightly slows down, the ventricular rhythm takes over. This is AIVR in a patient with anterolateral STEMI. While classically seen after reperfusion, it may very well be seen in non-reperfused infarcts such as this one. ST elevation is seen on both the ventricular and sinus-originating complexes. ST elevation that is concordant to QRS is indicative of STEMI, even in ventricular complexes.

F. NSVT management

No acute therapy is indicated. Underlying heart disease is sought (echo, stress testing).

Long-term treatment: NSVT does not dictate ICD by itself. ICD is dictated by the underlying cardiomyopathy (EF ≤35%).

G. Accelerated idioventricular rhythm (AIVR)

AIVR is defined as a slow VT that has a rate of 60–120 bpm. It usually competes with the underlying sinus rhythm with alternation of ventricular and sinus-originated complexes (Figure 9.4). AIVR may be seen in: (1) acute ischemia (including STEMI, whether reperfused or not), (2) up to 8% of HF cases and cardiomyopathies (including hypertensive or valvular cardiomyopathy), (3) digoxin or antiarrhythmic drug toxicity, and (4) electrolyte abnormalities (hyperkalemia). It may also be seen in patients with sinus node disease, where AIVR is *a form of accelerated ventricular escape*.

Treatment: there is no convincing evidence linking AIVR to VT/VF, and thus no specific treatment for AIVR is necessary. AIVR suppression is not indicated, particularly when AIVR is thought to be an escape rhythm. Only in symptomatic patients with sinus node disease and coexisting pauses or chronotropic incompetence is pacemaker therapy indicated.

H. Workup of VT occurring without obvious heart disease on echo and coronary angiography (see Sections VI–VIII)

Rule out the following diseases by ECG, exercise ECG, family history, and cardiac MRI:

- Brugada syndrome (diagnosed by ECG; dictates ICD placement).
- Long QT syndrome.
- ARVD: ARVD is characterized by RV fatty infiltration and is diagnosed by ECG, echo, and cardiac MRI.
- Sarcoidosis: bundle branch blocks, AV blocks and ventricular arrhythmias are common in cardiac sarcoidosis. Sarcoidosis is diagnosed by extracardiac involvement + cardiac MRI. ICD is indicated for secondary prevention, or primary prevention in patients with extensive late gadolinium enhancement on MRI.
- WPW: leads to a pre-excited SVT that mimics VT. WPW is treated with ablation.
- Catecholaminergic polymorphic VT: characterized by polymorphic or bidirectional VT occurring during exercise testing. It dictates ICD.

If none of the above diagnoses is evident, and if VT is monomorphic, the patient is diagnosed with idiopathic VT and is treated with β-blockers or CCBs (idiopathic VT is the only VT in which CCBs are effective). Alternatively, the ventricular focus may be ablated.

III. Polymorphic ventricular tachycardia

A. Morphology and types

Polymorphic VT is a VT with a continuously changing and erratic QRS morphology (~ no 2 QRS complexes are alike). This is different from having *multifocal VTs* (= multiple monomorphic VTs, each with a distinct but repetitive morphology).

1. The most common polymorphic VT is a **polymorphic VT without baseline QT prolongation.** In other words, the sinus rhythm's QTc interval is normal or only mildly prolonged. It is related to:

- Acute ongoing ischemia, from an acute coronary event or from severe shock of any origin
- Decompensated HF, with secondary ischemia and cellular stretch
- Channelopathies, metabolic abnormalities or drug toxicity (class I agents, tricyclics)
- *Polymorphic VT with short coupling interval in patients with CAD* but no ongoing ischemia, typically a few days after a large MI or CABG. This VT is triggered by very short-coupled PVCs (<400 ms) atop a normal or mildly prolonged QTc (<500 ms, the so-called *pseudo-TdP*).[25,26] It is distinguished from the polymorphic VT occurring during ongoing STEMI by its timing and by the non-ischemic ECG. The short-coupled PVCs are somewhat narrow and originate from ischemia-resistant Purkinje fibers that survived in an area of infarction: this VT is also called "angry Purkinje syndrome." In true TdP, which may occasionally occur after MI, the coupling interval is much longer, usually >500 ms, and QTc is much longer (>550–600 ms).

Acutely, polymorphic VT is treated similarly to any sustained VT. The underlying metabolic abnormalities are treated, and urgent ischemic evaluation and revascularization are performed. As opposed to TdP, amiodarone may be used.

Short-coupled polymorphic VT (pseudo-TdP) after recent MI causes arrhythmic storms that are refractory to ß-blockers, lidocaine, and amiodarone, but highly responsive to oral quinidine therapy (hence this VT is also called "quinidine-responsive polymorphic VT").[25,26]

2. Torsades de pointes is a polymorphic VT with changing QRS polarity occurring in the context of a prolonged baseline QTc interval (often > 500 ms) or abnormal U wave. **VT with twisting QRS polarity similar to Figure 9.5, but normal baseline QTc interval, is a non-TdP polymorphic VT and is usually an ischemic or post-ischemic rhythm.** TdP typically occurs in short runs < 20 seconds interceded with baseline rhythm but may become persistent or degenerate into VF (Figures 9.5–9.8).

There are 2 types of TdP:

- *TdP secondary to congenital QT prolongation*, where TdP is often dependent on increased catecholaminergic tone. The long QT is secondary to a genetic channelopathy affecting potassium channels (LQT1 and 2), or, less often, sodium channels (LQT3), and leading to prolongation of repolarization with early afterdepolarizations. It is often inherited in an autosomal dominant fashion.
- *TdP secondary to acquired QT prolongation*, where TdP is related to a combination of:
  - Bradycardia, which further prolongs and disperses repolarization (pause-dependent TdP).
  - Long–short R–R sequences: a pause is followed by an early PVC that falls in the ventricular repolarization period and triggers TdP.
  - One of 4 factors prolonging QT:
    - **i.** Electrolyte disorders (↓ K, ↓ Ca, ↓ Mg)
    - **ii.** Drugs (AAD class I and III, neuroleptics, macrolides, cocaine)
    - **iii.** Ischemia
    - **iv.** Other: any cardiomyopathy, hypothyroidism, diabetic autonomic neuropathy, or cerebrovascular event (with tall or inverted T waves). Acquired TdP is three times more common in women than men.

3. Even without QT prolongation, bradycardia and long pauses may lead to early afterdepolarizations and spontaneous action potentials that initiate reentry in a patient with underlying myocardial disease (acute ischemia, myocardial scar). Bradycardia not only prolongs but disperses repolarization across the myocardium, allowing the sustainment of reentry. Thus, bradycardia may trigger polymorphic VT or monomorphic VT even without QTc prolongation. In fact, in a patient with acute MI, frank bradycardia < 50 bpm can trigger VT/VF.[27]

As opposed to a steady-state bradycardia, acute bradycardia that occurs after a period of tachycardia is associated with a more striking prolongation of repolarization that facilitates the induction of polymorphic VT.[28] For instance, this is seen when AV nodal ablation is performed in patients with AF. As a result, the latter patients are paced at a rate of 80–90 bpm for ~1 week to prevent VT.

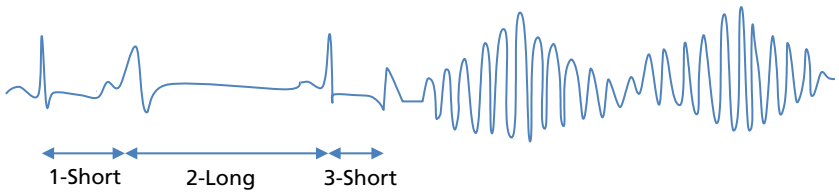

Figure 9.5 Torsades de pointes initiation, via short-long-short sequence: (1) PVC; (2) long post-PVC pause, which creates a long and dispersed refractory period; (3) another PVC hits this dispersed refractory period, leading to TdP. The PVCs, per se, arise from early afterdepolarizations.

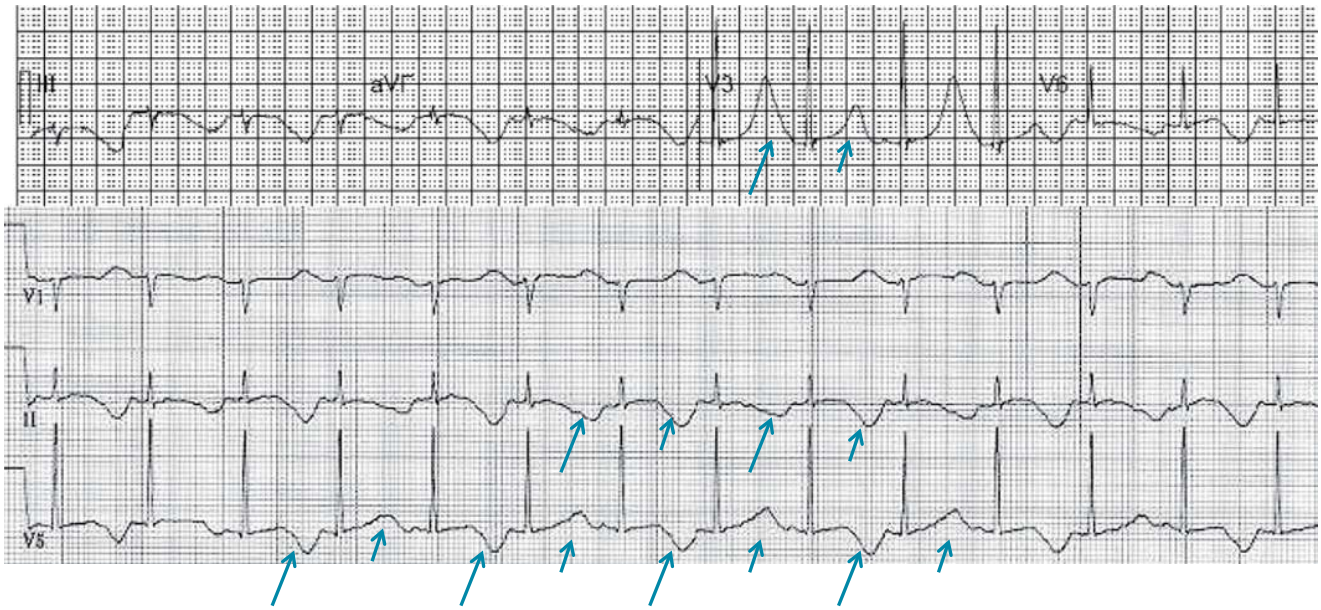

Figure 9.6 QT interval is markedly prolonged (QTc = 730 ms). T wave is wide and ample in lead V_3, is deeply inverted in the inferior leads, and demonstrates beat-to-beat alternation in morphology and amplitude, the so-called macroscopic T-wave alternans. In addition, alternation in T-wave polarity is seen in lead V_5. T-wave alternans may be seen with any cause of prolonged QT and implies severe heterogeneity of ventricular repolarization and an *imminent risk of TdP*; it is more characteristically seen in congenital long QT syndromes. While this patient has hypokalemia, the wide and ample T-wave morphology without ST depression is not consistent with hypokalemia. The shape is consistent with long QT syndrome or ischemia. *Arrows* of 2 different lengths point to the 2 different T-wave morphologies.

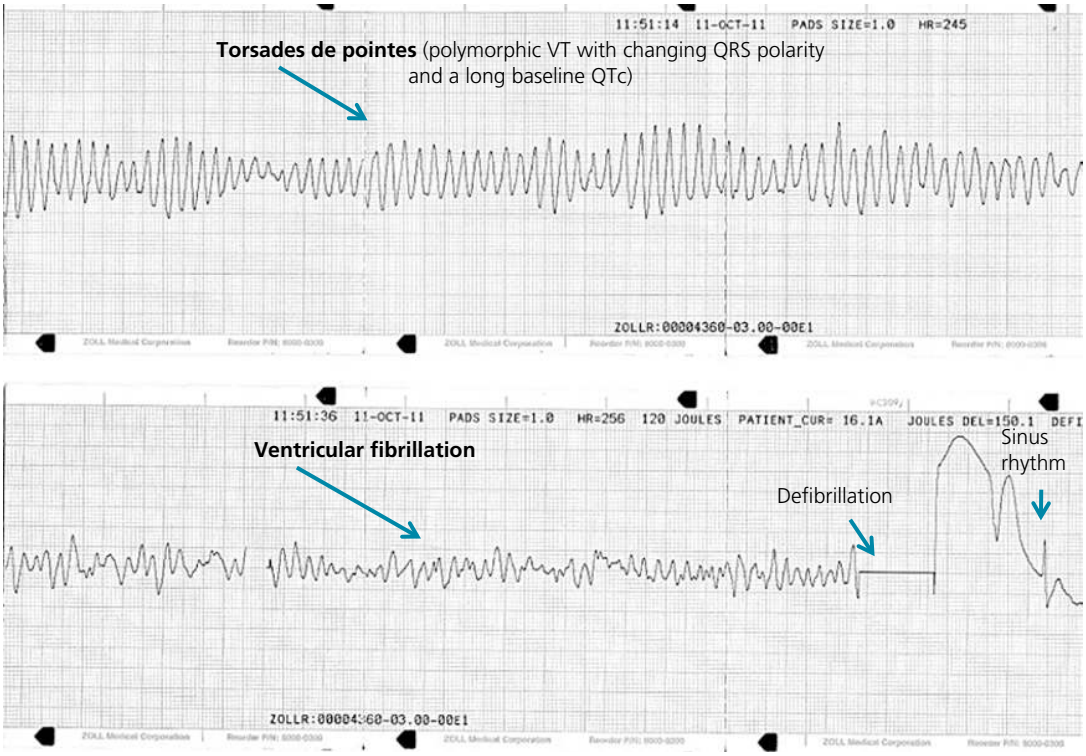

Figure 9.7 Torsades de pointes that degenerates into VF (same patient as Figure 9.6).

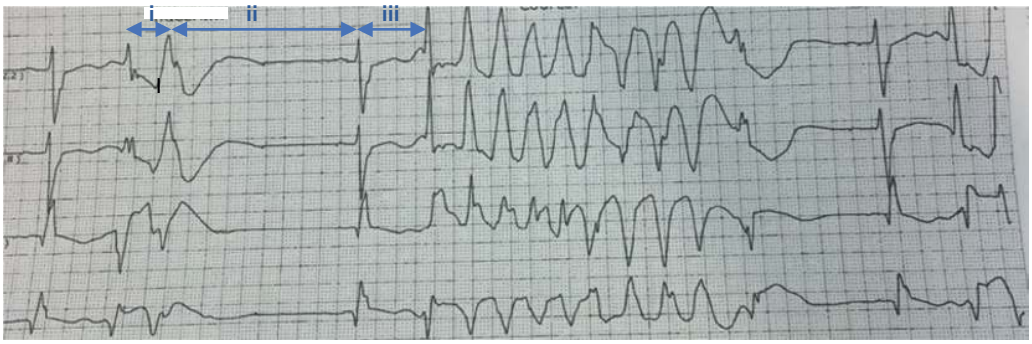

Figure 9.8 Example of TdP in a patient whose baseline QTc is 530 ms. Note the twisting QRS polarity. TdP is initiated by a short-long-short sequence (*double arrows*) and is recurrent but not sustained yet.

B. Treatment of TdP

Acutely, 3 lines of therapies are applied:

- Defibrillation if TdP is sustained.
- IV magnesium 2 g bolus (effective in >75% of patients, regardless of Mg levels).
- **(a) TdP from acquired long QT** is treated with ***acute pacing (between the episodes of TdP, rather than during TdP)***. *IV isoproterenol* (= β_1-agonist) may alternatively be used if pacing is not immediately available. ***Increasing the heart rate prevents the recurrence of pause-dependent TdP. β-Blockade is avoided in acquired long QT and pause-dependent TdP (unlike congenital long QT).*** Bradycardia further prolongs QT and further disperses repolarization delays across the myocardium. Bradycardia is a major trigger of TdP, particularly in patients with acquired long QT. Pacing to a rate of 80–100 bpm prevents TdP recurrence. Note that this is different from "overdrive pacing," wherein an *ongoing* monomorphic tachyarrhythmia is paced at a rate faster than its rate with the hope of breaking into its reentry cycle (e.g., monomorphic VT, atrial flutter).

  (b) TdP from congenital long QT: ***Congenital long QT's torsades, as opposed to acquired long QT, are often triggered by a catecholamine surge*** and may be associated with sinus tachycardia, in which case pacing may not be effective (Figure 9.6). In fact, for TdP secondary to congenital LQT1 or 2, *acute β-blockade* is used rather than β-stimulation.[11,29] *Pacing* is still considered in congenital LQT's TdP, as in acquired long QT, in case of pauses or bradycardia.[11,29]

  In addition, offending agents are withheld and K is corrected to 4.5–5.0 mEq/L.

Long-term treatment:

- Congenital long QT with a history of TdP: ICD + β-blockers.
- Asymptomatic congenital long QT: β-blockers. In case of borderline QT prolongation but suspicious history, a stress test may be performed. Further prolongation of QT with exercise or T-wave alternans (beat-to-beat alternation of T-wave morphology) establishes the diagnosis.
- Acquired bradycardia (pause)-dependent TdP or bradycardia-dependent polymorphic VT, persistent after potassium correction and after discontinuation of the offending drugs: permanent PM placement.

IV. Congenital long QT syndrome (LQT)

A. Types

The most common LQT syndromes are LQT1 (~35%), LQT2 (25%), and LQT3 (~5–10%). LQT1 and 2 are related to loss of function of K channels (I_{Ks} and I_{Kr}, respectively), leading to prolongation of repolarization with a broad and ample T wave in LQT1, and a long and notched T wave in LQT2 (Figure 9.9).[30] LQT3 is related to a gain of function of Na channels, leading to increased depolarization and thus prolongation of the plateau phase of repolarization, i.e., prolongation of the ST segment with a normal-width T wave. The prolongation of repolarization (QT) elicits 2 untoward processes: (i) afterdepolarizations, and (ii) increased transmural dispersion of repolarization, which allows afterdepolarizations to propagate and sustain reentry and arrhythmias.

In LQT1 and 2, TdP is triggered by catecholaminergic activity, which increases the amplitude of early afterdepolarizations. In particular, swimming or physical or emotional stress may trigger TdP in LQT1. Sudden noise or emotion as well as postpartum may trigger TdP in LQT2 (not exercise), whereas sleep may trigger TdP in LQT3.

LQT is mainly autosomal dominant with variable penetrance (Romano–Ward syndrome).

B. Problems with the definition of long QT and with the diagnosis

A prolonged QT is defined as a QTc >460 ms in women and >450 ms in men. In the absence of reversible metabolic, drug, or ischemic causes, LQT syndrome is suspected, particularly if QTc >480 ms. Up to 10% of normal individuals have QTc that is mildly prolonged (up to 480 ms), and 10–15% of patients with long QT syndrome have normal baseline QTc (mainly 400–460 ms).[31] Furthermore, 24-hour ambulatory monitoring of QTc has shown that the QTc of healthy individuals varies throughout the day by an average of 76 ms and may reach 480–490 ms at night or in the early morning: this is partly related to a direct QTc prolonging effect of vagal tone (even at a constant heart rate), and also to inaccuracies in QTc equations.[32]

In patients with QTc prolongation, rule out the transient causes (e.g., drugs) and perform an echo to rule out underlying cardiomyopathy (any cardiomyopathy may prolong QT). **If QTc > 480–500 ms without any reversible cause, the diagnosis of LQT is virtually established. In patients with borderline QTc prolongation of 450–480 ms, further testing may need to be performed**, particularly in case of syncope or family history of sudden death: further prolongation of QTc with exercise testing (measurement performed a few minutes into recovery, as the heart rate slows down), epinephrine infusion, Valsalva, immediate standing, or post-PVC implies LQT1.

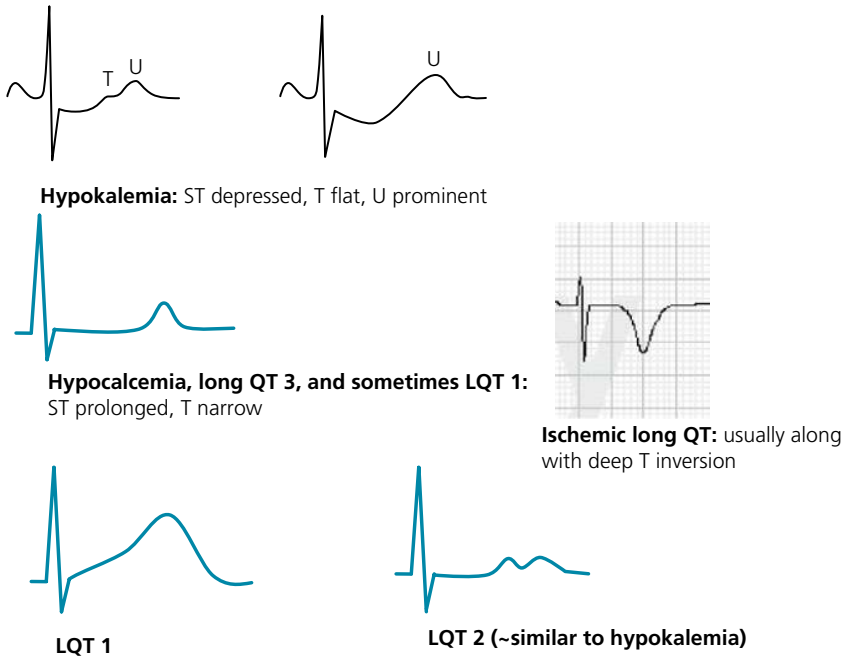

Figure 9.9 Typical ST–T morphologies in hypokalemia, hypocalcemia, and congenital long QT syndromes (LQT). In hypokalemia, ST segment is depressed and U wave is large while T wave is flattened. In hypocalcemia and LQT3, QT interval is prolonged as a result of ST-segment prolongation and, as opposed to other congenital LQT or QT prolongation secondary to drugs, there is no significant widening of the T wave. In LQT1, T wave is wide and ample without ST-segment depression, similar to Figure 9.5. In LQT2, T wave is wide and notched (double hump). LQT1 may have a morphology similar to LQT3 (~15%) and is actually the most common LQT with this morphology. ***In all long QT cases, particularly congenital LQT, the T wave may become notched after a pause, the notch representing the early afterdepolarization (EAD) wave that triggers TdP.***

QTc >445–470 ms at 2–4 minutes of recovery is predictive of long QT syndrome.[11] In normal individuals, QTc is reduced with exercise or epinephrine infusion.[33] In addition, the presence of macroscopic T-wave alternans supports the diagnosis of LQT. Other supportive features in case of borderline QTc prolongation: syncope, family history of LQT or sudden death, familial screening with ECG (marked prolongation of QTc in a family member may confirm the diagnosis in the index patient).

QT interval is best measured in the lead that shows a distinct T-wave termination with the best separation of T and U waves.[34] The QT interval may be artificially shortened in some leads, because an isoelectric segment may be recorded at the beginning of the QRS complex or at the end of the T wave in those leads. On the other hand, QT is often longest in leads V_2–V_3, but those leads show the least separation between the T wave and the normal U wave and may therefore overestimate the length of the QT interval. Leads I, aVR, and aVL do not have the normal diastolic U wave but do not always show a distinct T wave. Thus, QT interval is often best measured in leads II and V_5 or V_6.

A normal U wave (<25% of T wave) or an abnormal U wave that is not merging with the T wave should not be used in QT calculation. **In practice, a wave that exceeds 25% of the T wave *and* that merges with the T wave giving a "bifid" T-wave appearance should be taken into account; this is a part of the T wave (TU wave) rather than a true diastolic U wave.**

QT interval shortens with increasing heart rate (17.5 ms for every 10 beats). ***The corrected QT corresponds to the patient's predicted QT interval had the heart rate been 60 bpm***; it is often calculated using the Hodges formula: QTc = QT + 1.75 × (rate – 60). The purpose of QTc is to provide a constant QT value regardless of rate variations in a given state. However, uncorrected QT remains relevant, particularly in acute situations, as it reflects the effects of both QTc and bradycardia, which together can facilitate TdP.

C. Epidemiology and risk of sudden death

The long QT syndrome phenotype is more common in women than men (~1.5:1).

Sudden death and syncope mainly occur in childhood or early adulthood before the age of 40 (Table 9.1). QTc >500 ms, female sex with LQT2, or male sex with LQT3 confer the highest lifetime risk.[35] Female sex confers a higher risk of sudden death in adulthood, including LQT1, whereas male sex is a risk factor for sudden death in childhood.[36] Overall, ~50% of LQT syndrome patients experience TdP with syncope or sudden death during their lifetime.

Patients with long QT syndrome genotype but normal phenotype (normal QTc) have a real risk of sudden death, albeit smaller than patients with prolonged QTc, and should be treated with β-blockers.

While the risk of sudden death attributed to long QT syndrome is highest in the first 40 years of life, this syndrome remains associated with a 2.65-fold increased risk of sudden death in patients 41–60 years of age, particularly with LQT2 or 3, according to an LQT registry. The risk beyond the age of 60 is attenuated, partly because the risk of death from other illnesses increases at this stage.[37]

D. Genetic testing

Genetic testing is negative in 20–25% of patients with LQT1–3, mostly due to uncharacterized mutations of identified genes.[38] Thus, testing is not useful to rule out the diagnosis, but may rule it in when positive in a patient with borderline clinical criteria. Testing is useful for 2 more reasons: (i) identify the type of LQT, which has prognostic implications; (ii) once a mutation is identified in a proband, family members are checked for that same mutation with a very high rule-out yield.

E. Therapy

The mainstay of therapy of congenital LQT1 is β-blockade. β-Blockers should be prescribed to all patients, including silent carriers. The most effective β-blockers are the non-selective nadolol and propranolol. They should be up-titrated to target doses (nadolol ~1 mg/kg/day, once daily, or propranolol ~3 mg/kg/day). Blunting of the exertional heart rate and QTc reduction (by ~20 ms or to <500 ms) have also been used as targets.[38,39] Up-titration is done slowly over 2–6 months in asymptomatic patients. *Metoprolol is much less effective*, and the switch from nadolol to metoprolol has been associated with tragic recurrences.[40,41] β-Blockade reduces the risk of cardiac events by ~70% in LQT1 and LQT2.[38–41] β-Blockade is less effective in LQT3 but remains moderately effective, depending on the genetic mutation.[11,40,41] In patients with prior syncope, β-blockers reduce the 5-year risk of recurrent syncope to 30%, and the 5-year risk of sudden death from long QTc to 3%.[38–41] In addition to β-blockade, long-term therapy of symptomatic or asymptomatic congenital LQT includes the maintenance of a normal electrolyte balance and avoidance of drugs that prolong the QT interval. Athletic participation is often allowed after optimization of QTc, symptoms, and drug dosage, and consideration of ICD based on individual risk.

LQT type is identified by genetic testing or by the effect of exercise or epinephrine on the QTc (in LQT1, QTc prolongs with exercise or epinephrine, while in LQT2 or 3, QTc shortens). *Mexiletine*, a class Ib antiarrhythmic, shortens QT and may be considered in all types of LQT when β-blocker is ineffective, particularly in LQT3 where it blocks the defective Na current: it is considered effective when it shortens QTc by ≥40 ms. Left cardiac sympathetic denervation, consisting of removing the left paravertebral stellate ganglion, is highly effective in preventing cardiac events in all types of congenital LQT and may be used for: recurrent cardiac events despite β-blockade, QTc >500 ms despite

Table 9.1 Risk of sudden death and cardiac events in patients with long QT syndrome before the age of 40.

	LQT1	LQT2 or LQT3
Risk of sudden death before the age of 40	10% Same risk in men and women[a]	20% Highest risk if woman LQT2 or man LQT3 (~25%)
Risk of sudden death or syncope before the age of 40 Highest risk when QTc >500 ms, regardless of LQT type (70% risk)	30%	~50%

Data from Priori et al. (2003).[35]

[a]Same risk in men and women in reference 35, higher risk in women in reference 36, where only adult patients were considered. QTc shortens with adult age in men (testosterone effect), and adult men are thus at lower risk of sudden death than women. Overall, the yearly risk of sudden death averages <0.5–1% per year.

β-blockade, or β-blockade intolerance (including asymptomatic patients). It is also indicated in patients with ICD who experience recurrent shocks.[11]

ICD is indicated in patients with LQT syndrome and prior cardiac arrest (class I indication). In patients with syncope, β-blockade therapy may be enough for LQT1 or 2, particularly if QTc declines to <500 ms.[42] Left sympathetic denervation and/or ICD is the second-line therapy if syncope recurs.[42] Note that TdP is self-terminating, so ICD may not be very helpful in patients with syncope; in fact, the ICD shock triggers anxiety and further catecholamine surge, which may provoke more TdP and VF. Hence ACC and ESC give a class I ICD recommendation for syncope only in case of recurrence despite β-blockade or intolerance to β-blockade.[11] ICD implantation is rarely considered (class IIb) in asymptomatic patients at high risk of sudden death, such as those with QTc >500 ms despite β-blockade in combination with LQT2 (women) or LQT3, the latter 2 being less responsive to β-blockade and having a higher residual risk of cardiac events despite β-blockade. Women with LQT2 have a particularly high risk of sudden death in the 9 months postpartum, 7 times higher than their pre-pregnancy and pregnancy risks, and may receive LifeVest during that period, if not ICD.[11,43]

V. Indications for ICD implantation

A. Secondary prevention

ICD is indicated for any sustained VT, regardless of EF (AVID, CIDS trials),[44,45] *except*:

- Polymorphic VT or VF occurring the first 48 hours after a large MI or STEMI.
- Idiopathic monomorphic VT, with no structural heart disease, and no specific channelopathy/electrical disease.

VT occurring in a patient with CAD but without acute MI or with only low-level troponin elevation qualifies for ICD regardless of EF and of the potential for complete revascularization.[46] VT that is monomorphic, or even polymorphic with no acute MI, usually signals an underlying scar and its inducibility is unaffected by revascularization.[47] According to the ACC guidelines: "In patients with ischemic heart disease and sustained monomorphic VT, coronary revascularization alone is an ineffective therapy to prevent recurrent VT."[11]

B. Primary prevention means ICD implantation in a patient without a history of sustained VT or sudden death

It is indicated in ischemic or non-ischemic cardiomyopathy if EF is ≤35% and the patient is symptomatic, NYHA functional class II or III, despite optimal medical therapy (ACC class I recommendation). The following waiting periods are required before implanting the ICD:

- >40 days after acute MI.
- >3 months after revascularization for chronic ischemia.
- >3 months of guideline-directed medical therapy for non-ischemic cardiomyopathy. This ensures the cardiomyopathy is not reversible before proceeding with ICD implantation.[46]

Note that, in ischemic cardiomyopathy with EF ≤ 30%, ICD is indicated even if the functional class is I, i.e., if the patient is asymptomatic (class I recommendation). Also, in ischemic cardiomyopathy, ICD is indicated if EF is 36–40%, NSVT is present, and VT is inducible on EP study (class I recommendation).

Those recommendations are based on the MADIT II and SCD-HeFT trials.*[21,48] The absolute yearly reduction in mortality was 3.5% in MADIT II and 2% in SCD-HeFT. In these 2 trials, the survival curves of ICD therapy and placebo progressively diverged with time; however, in both trials, the curves did not begin to diverge until 12 months, indicating that ***the benefit from ICD in primary prevention is a long-term benefit that is seen in patients healthy enough to survive several years.*** The yearly number needed to treat (NNT) to prevent 1 death is 25 in the MADIT II trial. The benefit is less marked in non-ischemic cardiomyopathy, particularly the one that qualifies for CRT and hence may reverse with CRT: the DANISH ICD trial of non-ischemic HF patients, most of whom had wide QRS and concomitant CRT implantation (~60%), did not show a mortality reduction with ICD in the overall population, but mortality was reduced in patients ≤70 years old.[49]

While the risk of sudden death is highest in the first 40 days after MI, ICD implantation is not beneficial during this time frame. One hypothesis is that, during this early period, patients at highest risk of VT/VF are patients with large infarctions and severe heart failure who may eventually succumb to pump failure even if resuscitated from VF (DINAMIT, IRIS trials).[50,51] While early ICD implantation reduces sudden death by ~50s%, it simply converts arrhythmic death into pump failure death or pulseless electrical activity (PEA) in many of those patients and does not prevent the eventual mortality. Also, the untoward effects of the periprocedural stress of ICD implantation may hinder the benefit. Building on this data, an analysis of the MADIT II trial suggests that the benefit of ICD is mainly seen in patients whose MI is older than 1.5 years; while sudden death is highest in the early MI period, pump failure death, HF events, and recurrent acute coronary events are also highest during this period, reducing the effect of ICD on the overall mortality.[52] ICD is mainly effective in patients who have been stable for a prolonged duration after their MI, wherein the risk of isolated arrhythmic death from the arrhythmogenic scar becomes a relatively bigger concern. Even then, the benefit from an ICD does not emerge until after 1 year of follow-up.[52]

The sickest patients with the highest risk of sudden death (e.g., class IV HF, recent MI, recurrent HF hospitalizations) also have a high risk of death related to pump failure and comorbidities. Preventing sudden death may not prevent the ultimate death, but rather converts it from sudden death to pump failure death or death related to comorbidities (e.g., MI, stroke, CKD). In fact, data suggest that old patients (>65 years old) with ≥3 HF hospitalizations have a high mortality despite ICD placement, showing once more that ICD is mostly useful in stable patients, even though stable patients have a lower absolute sudden death risk.[53] The highest-risk patients in the MADIT II trial, such as those with advanced renal failure, did not benefit from ICD.**[54]

*MADIT II: ischemic cardiomyopathy >40 days post-MI, LVEF ≤ 30%, NYHA class I–III, 75% of patients had their MI >1.5 years prior to randomization (median of ~5 years). SCD-HeFT trial: ischemic or non-ischemic cardiomyopathy, LVEF ≤ 35%, NYHA class II or III, placebo vs. amiodarone vs. ICD.

**MADIT II identified high-risk criteria that, combined with reduced EF, increase the likelihood of benefit from an ICD in primary prevention: AF, QRS > 120 ms, functional class II–III, mild renal failure, age >70 years old. On the other hand, very high-risk patients with ≥3 high-risk features, advanced renal failure, or functional class IV seem less likely to benefit (U curve); ICD reduces their sudden death but does not reduce their ultimate death (pump failure, comorbidities).[54]

The 3-month wait time after revascularization is derived from MADIT II, which excluded patients who received revascularization in the prior 3 months. The CABG-PATCH trial further supports this concept: patients with EF < 35% who received an epicardial ICD at the time of CABG surgery did not derive any mortality benefit, as revascularization by itself improved LV function and the risk of sudden death.[55] Hence, in stable CAD, the need for ICD should be reassessed several months after revascularization. Yet, similarly to the first 40 days after MI, the first 3 months after revascularization carry the highest risk of sudden death. Beyond 3 months, the risk of sudden death declines in revascularized patients.

One study suggested further EF improvements between 3, 6, and 12 months in de novo ischemic or non-ischemic cardiomyopathy with EF <35%, especially if medications are up-titrated or if AF or uncontrolled HTN was present and treated. Hence a longer wait time may be selectively accepted. In patients with EF < 35% at diagnosis, EF improved to >35% in 46% of them at 3 months and 68% and 77% at 6 and 12 months, respectively, with a very low VT risk between 3 and 6 months.[56]

ICD is not indicated for patients with a functional class of IV unless they also qualify for BiV pacemaker or unless they are transplant or LVAD candidates. The COMPANION trial has shown that BiV–ICD, in comparison to BiV only or no device therapy, reduces mortality in HF patients with functional class III or ambulatory class IV.[57]

C. Syncope of undetermined origin with inducible sustained VT or VF on EP study (performed as part of syncope evaluation) (class I recommendation in ACC VT guidelines).

This includes unexplained syncope with any of the following features justifying EP study: EF 36–49%, CAD, AF, or severe LV hypertrophy with normal EF.

D. Hypertrophic cardiomyopathy

ICD is indicated if risk factors for sudden death are present (unexplained syncope, family history of sudden death, septum >30 mm).

Note: Wearable, external cardioverter defibrillator (LifeVest)

A LifeVest may be temporarily used in patients who are at high risk of sudden death yet do not have an ICD indication. This includes patients with a newly diagnosed non-ischemic cardiomyopathy, in whom EF frequently improves, and patients in the first 40 days after MI. In the WEAR-IT registry, these groups received a LifeVest for up to 3 months; 1.1% of the patients, mainly ischemic cardiomyopathy patients, had a sustained VT/VF that was prolonged, unstable, and treated by LifeVest. All those VT/VF patients eventually survived to the end of follow-up (they did not die of PEA or pump failure).[58] Eventually, beyond the first 3 months, the risk of sudden death declines and EF improves to >35% in over 40% of patients. ICD implantation is required in 40% of patients at the end of 3 months.[58] Only one randomized trial, VEST, addressed LifeVest and specifically selected patients with recent MI <7 days and EF <35%. Similarly to registries, 3 months of LifeVest reduced arrhythmic death by 0.8%, but the p value was 0.18; most LifeVest patients who died were not wearing the device at the time of death, and a marginally significant benefit was seen in patients consistently wearing it.[59] As such, LifeVest is not indicated on a large scale, but may be used very selectively in some high-risk, motivated post-MI patients (class IIb). Of note, early post-MI amiodarone has reduced arrhythmic death by a similar relative extent in the old EMIAT and CAMIAT trials vs. placebo (~35%), hence it may be an alternative option in high-risk patients.

Note: Subcutaneous ICD. Unlike transvenous ICD, a subcutaneous ICD is placed in the midaxillary line with a subcutaneous lead extending to the sternum (no venous lead). It is considered in young patients as they have a high long-term cumulative risk of lead issues, patients without a good venous access, or patients at a high risk of infection. It does not have a pacing capability.

EF is an imperfect predictor of sudden cardiac death (SCD) risk. While EF < 35% is associated with substantially increased SCD risk and a benefit from ICD, most patients with SCD (~75%) have EF > 35% or normal EF. *EF < 35% is only the tip of the pyramid of SCD (Figure 9.10)*.[60,61] In the context of EF >35%, SCD is related to: (i) acute MI in a patient with no cardiac history (most common SCD), or in a patient with known CAD but normal or mildly reduced EF; (ii) cardiomyopathies with EF > 35%, such as prior MI with EF >35%, or dilated cardiomyopathy with extensive fibrosis or high-risk gene, or sarcoidosis or ARVD; (iii) primary electrical disorders.

MRI, genetic tools, and artificial intelligence processing of subtle ECG, echo, and echo strain features (after machine deep learning) may help identify patients under (ii) who would benefit from ICD. This may also better select which patients with EF <35% benefit from ICD. For (i), prevention of SCD relies on CAD/MI prevention. **The risk of SCD in individuals with no cardiac disease is lowest, yet in absolute numbers, most SCDs occur in this population as it is, by far, the largest.**

VI. VT with no obvious heart disease: VT related to subtle, overlooked cardiomyopathy

A. Arrhythmogenic right ventricular dysplasia or cardiomyopathy (ARVD/ARVC)

ARVD is a genetic cardiomyopathy characterized by progressive replacement of the RV by fibro-fatty tissue, leading to RV dilatation, localized RV aneurysms, then LV involvement. RV apex, RVOT, and inferior RV inflow are most commonly involved. The disease often starts at the subepicardial myocardium and progresses toward the endocardium.

ARVD presents between 10 and 50 years of age, more commonly in men, and is familial in 30–50% of the cases (usually autosomal dominant with 30% penetrance). The remaining patients have de novo mutations or express a mutation that was silent in family members. ~30–50% of patients have well-identified mutations of desmosomal genes, while the remainder may have abnormal genes not yet identified.[62]

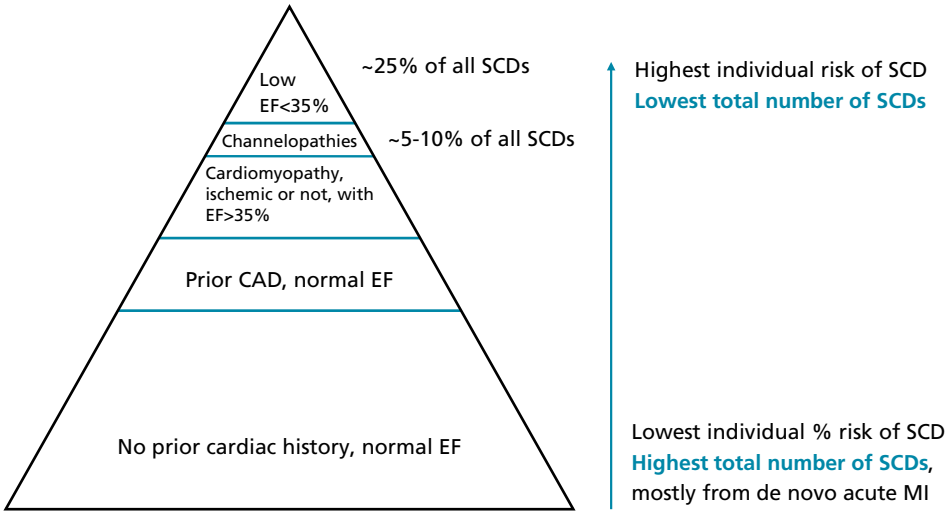

Figure 9.10 SCD in different population subsets. The individual risk of SCD is contrasted with its total toll in the general population.

Plakophilin-2 (PKP-2) mutation is the most common and is the one associated with the highest risk of sudden death and HF. ARVD manifests as ventricular arrhythmias early on, then progressive right and left HF.

ECG features of the localized RV delay[63]

- T-wave inversion is frequently seen (85%) in leads V_1 through V_3. In the absence of complete RBBB, this T inversion is highly suggestive of ARVD in both adult men and women. Normal women may have T-wave inversion in V_1 and V_2 that only rarely (4%) extends to V_3.
- ECG typically shows a prolongation of QRS ≥110 ms that is localized to leads V_1 through V_3, and more importantly, a delayed S upstroke (nadir of S to end of S ≥55 ms in 95% of patients). QRS is normal in lead V_6.
- A small positive deflection, called an *epsilon wave*, may be seen immediately after QRS in V_1–V_3 in ~30% of patients (Figure 9.11).
- RBBB, whether complete or incomplete, is uncommon but may be seen in advanced stages.

ECG abnormalities become more prevalent with time. Late potentials on signal-averaged ECG are also sensitive for ARVD diagnosis. VT that is due to ARVD originates from the RV and thus has an LBBB morphology.

Echo features of ARVD[64]

- RVOT enlargement on the long- or short-axis views (≥29 mm or 32 mm, respectively; ≥32 or 36 mm, respectively, are major criteria)
- Hyperreflective moderator band
- Hypertrabeculated RV
- Regional RV akinesis or aneurysms. MRI criteria: RVEDV ≥100–110 ml/m² or RV EF<40–45%

Diagnosis of ARVD[64]

The diagnosis of ARVD requires ≥2 of the following:

a. Echo or MRI structural features
b. ECG features (epsilon, T inversion, or prolonged QRS with slow S upslope)
c. VT (sustained or non-sustained) of LBBB morphology or frequent PVCs (>500/24 hours)
d. Family history of ARVD or sudden death

Treatment of ARVD

Sudden death is common in ARVD; in fact, 25% of patients die suddenly, most commonly during exercise or stressful situations. ICD is indicated in patients with sustained VT, or one or more risk factors for sudden death: severe RV or LV dysfunction (EF ≤35%), syncope with arrhythmic features, or milder RV or LV dysfunction with NSVT or inducible VT on EP study.[11] β-Blockers are used for primary prevention of VT in case of frequent PVCs or NSVT (ACC class I), and possibly in all ARVD patients (class IIa).[11] Amiodarone, sotalol, or flecainide may be

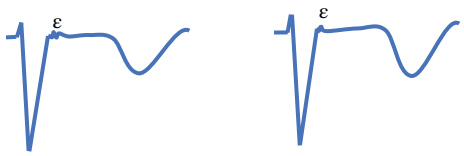

Figure 9.11 Epsilon wave in ARVD. Epsilon wave is a small wiggle wave or a small spike at the beginning of the ST segment, which corresponds to delayed depolarization of the diseased epicardial RV. Note the inverted T wave and the slow S upslope (≥55 ms), which are more common features of ARVD.

added for recurrent VT. Since the ARVD process starts at the epicardial level, VT ablation is only effective if ablation is performed at both the endocardial and epicardial levels. When arrhythmic death is prevented, patients live long enough to develop severe right then left heart failure.

B. Cardiac sarcoidosis

Cardiac sarcoidosis affects the electrical system early on and leads to tachy- or bradyarrhythmias, as well as bundle branch blocks. Inferobasal scarring is common but may be overlooked on echo. The diagnosis is made by MRI. ICD is indicated for secondary prevention, or primary prevention in patients with extensive late gadolinium enhancement on MRI (see Chapter 5).

C. Mitral valve prolapse

Classic, thick mitral valve prolapse, even without severe MR, exerts chronic traction on the papillary muscle and creates local electrical irritation then, occasionally, scarring of the papillary muscle and the adjacent inferobasal LV. This may cause unifocal PVCs arising from the papillary muscle, or more complex PVCs, or rarely, VT and sudden death. QT prolongation and T inversion on the baseline ECG correlate with increased arrhythmic risk. Ablation may be performed for unifocal PVCs but does not clearly reduce sudden death. Patients with MVP and frequent complex PVCs may be considered for cardiac MRI (management is not standardized).[11]

D. Lamin A/C and other high-risk genetic cardiomyopathies

Lamin A/C cardiomyopathy is associated with a high risk of sudden death, up to 5–10% per year (ESC).[11] Examples of other high-risk genetic mutations are PLNC, FLN, and TMEM43. ICD is indicated whenever lamin A/C mutation is identified in a patient with manifest phenotype, even if EF is >35% (EF <50%, significant LGE on MRI, NSVT, any AV block) (ESC cardiomyopathy guidelines, 2023).

ARVD, sarcoidosis, Chagas disease, familial cardiomyopathy with lamin A/C mutation and giant-cell myocarditis are 5 cardiomyopathies with predilection for *both VT and conduction blocks,* even before overt myocardial disease.

VII. VT with no obvious heart disease: VT related to electrical disorders and channelopathies

Except for WPW syndrome, the following syndromes are related to **genetic ion channelopathy and called sudden arrhythmic death syndrome (SADS)**.

A. Brugada syndrome

A *Brugada pattern* is defined by 2 ECG characteristics:

- ST elevation in V_1–V_3, typically coved and gradually descending into a negative T wave (Figure 9.12).
- Pseudo-RBBB, or occasionally, true RBBB. In pseudo-RBBB, rSR′ is seen in V_1–V_3 but the QRS is normal in the lateral leads. PR interval is frequently prolonged.

There are classically 3 types of Brugada patterns, but only type 1 is prognostically relevant:

- Type 1: coved ST elevation ≥2 mm at the J point in ≥2 of the leads V_1–V_3, with T-wave inversion
- Type 2: saddleback ST elevation ≥1 mm with upright or biphasic T wave
- Type 3: coved ST <2 mm or saddleback ST <1 mm

Type 1 Brugada pattern can be transient. Being due to a loss of function of Na channels, it can be unveiled by Na channel blockers, such as flecainide or procainamide (class I AAD), cocaine, fever, excessive alcohol, anesthesia (propofol, lidocaine), or tricyclic drugs, or RV ischemia/PE. Moving V_1–V_2 up to the second intercostal space may improve the detection of these abnormalities as the electrical substrate of Brugada syndrome is at the level of the RVOT (high in the chest).

The spontaneous type 1 Brugada pattern is the only one specifically associated with sudden death and most specifically called *Brugada syndrome*. *The other two patterns are seen in healthy individuals and do not portend an adverse prognosis*. Provocation of type 1 pattern suggests the diagnosis in patients with suspicious syncope or family history; however, the prognosis of provoked type 1 Brugada is much better than the spontaneous type 1 Brugada, hence the importance of syncope or family history to diagnose Brugada syndrome in provoked cases. In fact, provocation with drug or fever is quite common and not specific, when asymptomatic, with 2–4% prevalence in healthy subjects (ESC). Conversely, the prevalence of spontaneous type 1 Brugada pattern on the ECG of asymptomatic individuals is 0.01–0.1%, the higher prevalence being described in Thailand and Japan.[65] The syncope/sudden death

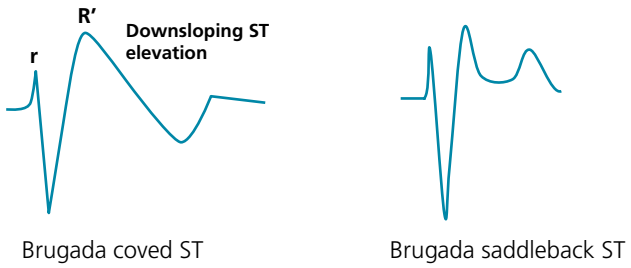

Figure 9.12 Brugada patterns.

rate for the spontaneous type 1 pattern is ~0.4% per year.[66,67] Sudden death is higher in patients with inducible VT on EP study (0.7% per year vs. 0.2% if not inducible, based on Italian registry).[68] The risk is very low in asymptomatic fever- or drug-provoked type 1 pattern (0.03% per year), unless it becomes spontaneous on ECG follow-ups, hence the importance of ECG follow-ups in this group (several per year).[68] Types 2 and 3 are not associated with an increased event rate.

Brugada syndrome is due to a sodium channel mutation with loss of function, predominantly at the level of the *epicardial RVOT*, creating the ECG abnormalities in V_1–V_3.* It is autosomal dominant but mainly expressed in men; 90% of affected patients are men. A family history of sudden death at an age <45 is often present.

Brugada syndrome leads to polymorphic VT or VF, not monomorphic VT. The arrhythmia often occurs during sleep, or after triggers, such as fever or anesthesia. In fact, fever is a major trigger of sudden death in these patients, as fever further inactivates the Na channels. In one report, 51% of patients with a Brugada-type pattern on ECG during an acute event, especially fever or anesthesia, developed cardiac arrest or syncope.[69] Brugada syndrome frequently manifests as sudden death. VF may self-terminate and cause syncope rather than sudden death ~30% of the time.[70] Yet, this self-termination is less common than in LQT's TdP. ICD is indicated if there is a history of sudden death, or a history of unexplained syncope along with a spontaneous or inducible type 1 pattern. *Quinidine* is highly effective in reducing VT, as it blocks the hyperactive I_{Kto} channel, and may be used in symptomatic patients who decline ICD and in VT storm. β-Blockers are avoided, and it is rather β-stimulation with isoproterenol that terminates a Brugada VT storm.

In asymptomatic type 1 pattern, an EP study may be performed; an inducible VF implies a higher risk of sudden death and weakly supports ICD placement (class IIb). A family history of sudden death supports the diagnosis but is not predictive of sudden death and does not dictate ICD. The main treatment of asymptomatic Brugada consists of avoiding fever and drug triggers. Asymptomatic type 2 or 3 patterns do not require any specific workup and are normal variants rather than specific predictors of life-threatening ventricular arrhythmias.[71]

B. Idiopathic catecholaminergic polymorphic VT

This is a form of polymorphic VT that occurs in the absence of ischemia, acute metabolic insults, or long QT. VT and sudden death occur during exercise or acute emotion, and most often manifest before the age of 20 and almost always before the age of 40. It is genetic and usually familial, related to excessive calcium release from the sarcoplasmic reticulum with subsequent delayed afterdepolarization (RyR gene). ***VT may look bidirectional*** as in digoxin toxicity (QRS alternation between left and right axis). It is treated with β-blockers and ICD. Flecainide and left cardiac sympathetic denervation are also very effective therapies, and flecainide is suggested as first-line treatment in conjunction with β-blockers and ICD in patients with prior VT.

C. WPW

AF or atrial flutter that is conducted antegradely over an accessory pathway leads to a pre-excited, fast atrial arrhythmia that mimics polymorphic VT and may lead to sudden death.

D. Congenital long QT syndrome (see Section IV)

E. Congenital short QT syndrome

This is a rare, highly lethal genetic channelopathy. The diagnosis is established if the QT interval is markedly abbreviated (≤320 ms, or 320–360 ms with suspicious syncope or family history). Characteristically, the ST segment is nearly absent with peaked and symmetrical T waves. ICD is used in patients with sudden death or suspicious syncope.

F. Malignant early repolarization and idiopathic VF

Early repolarization is defined as ≥1 mm (0.1 mV) elevation of the J point (QRS-ST junction) in 2 or more contiguous leads (anterior, inferior, or lateral leads). While it is traditionally considered a benign finding, studies have shown that early repolarization in leads other than V_1 through V_3 is associated with an increased risk of sudden cardiac death. In fact, early repolarization is identified in 30–60% of patients with idiopathic VF.[72–74]

J point may be slurred or notched. A notched J point forms a positive deflection ("hump") at the end of the QRS complex, also called J wave, and is more predictive of sudden death than a slurred J point.[73,75]

More specifically, the combination of several of the following 4 features has been associated with an up to 3-fold increased risk of sudden cardiac death, henceforth leading to the nomenclature of "malignant early repolarization" (Figure 9.13):[73–77]

1. horizontal/descending ST segment: J point is elevated, but the ST segment that follows it descends rather than rapidly ascends. The ST segment, per se, may be depressed in those cases
2. inferior lead involvement
3. J-point elevation ≥ 2 mm
4. notched rather than slurred J point

Note, however, that while malignant forms of early repolarization are associated with a relative increase in the risk of sudden death, the absolute increase in risk remains small (0.07% per year).[78] Therefore, early repolarization remains an innocuous finding in the overwhelming majority of asymptomatic subjects.

Special subgroup: A subgroup of idiopathic VF is triggered by very short coupled PVCs (<400 ms) arising from the Purkinje system, and called "*short-coupled pseudo TdP/VF.*"[79] It has ECG features similar to the polymorphic VT occurring a few days after MI and is responsive to quinidine and isoproterenol.

*This mutation reduces the sodium inflow current in phase 0 of the action potential, thereby reducing the action potential duration, which is opposite to LQT3 (SCN5A gene, Na ion channel). This effect is heterogeneous across the cardiac layers, which leads to dispersion of repolarization between the subepicardium and the myocardial M cells and subsequent reentrant circuits → VT–VF.

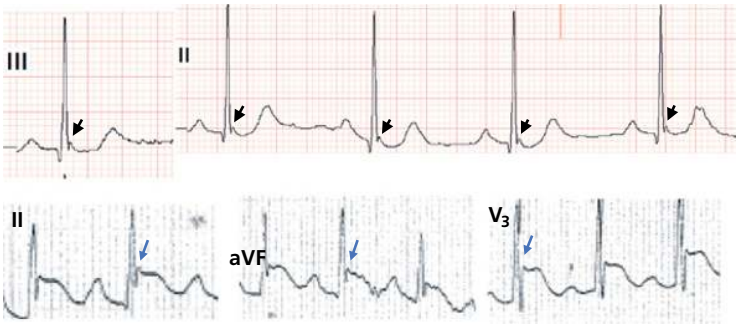

Figure 9.13 ***(Top)*** Early repolarization J wave followed by a downsloping ST segment. J wave is notched (*arrows*). This pattern has been associated with an increased risk of sudden death, particularly in the inferior leads, although the absolute risk remains very low (<0.1% per year).
(Bottom) The same patient developed VF. The ECG recorded immediately after VF shows accentuation of the height and width of the J wave ("fatty" waves), and elevation of ST segment, with a coved downsloping shape.

VIII. VT with no obvious heart disease: idiopathic outflow tract PVC or VT and idiopathic left fascicular PVC or VT

These VTs occur without any underlying heart disease and are **benign**. RVOT VT arises from the RVOT, LVOT VT arises from the LVOT or its myocardial extension to the right or left aortic cusp. LV fascicular VT arises from the left posterior fascicle (posterior septum, near the apex), or rarely the left anterior fascicle. The mechanism, ECG, and therapy of LVOT VT are closely related to RVOT VT. More rarely, idiopathic VT/PVC arises from the right or left papillary muscles or the free walls.

Idiopathic PVCs and VTs frequently present as palpitations and dizziness, usually in young patients (<50 years old); syncope is rare and sudden death is very rare. RVOT VT and LVOT VT most commonly (60–90%) manifest as repetitive, non-sustained salvos of VT that may occur with exertion or stress, but also at rest. LV fascicular VT typically occurs at rest but may be triggered with stress and is more frequently sustained, occasionally leading to a tachycardia-mediated cardiomyopathy.

These VTs have specific ECG features (during VT, not during sinus rhythm):

- **RVOT VT**: LBBB with vertical, almost right axis, looking toward the inferior leads. QRS is small and nearly equiphasic in lead I. ARVD-associated VT may mimic RVOT VT.
- **LVOT VT**: RBBB with vertical axis; or LBBB with vertical axis (particularly right cusp VT), but R transition in V_2, earlier than RVOT VT.
- **Fascicular VT (Belhassen):** RBBB with LAFB. Since it originates near the normal conduction system, QRS is relatively narrow (~140 ms). Therefore, this VT is *difficult to differentiate from SVT*.

The ECG is typically normal between the VT episodes (≠ ARVD).

Underlying heart disease must be ruled out. MRI may be needed in RVOT VT to exclude ARVD. Therapy includes *verapamil* (effective in all idiopathic VTs) or *β-blockers* (only in outflow tract VT). Verapamil and β-blockers have a limited efficacy of 25–50% in idiopathic VT, even less so in frequent PVCs (10–24%);[8] *flecainide, amiodarone, and catheter ablation of the PVC focus* are highly effective for VT and frequent PVCs.[8,80] ICD is not indicated, as these VTs do not lead to sudden death. RVOT VT and LVOT VT represent cAMP-mediated triggered activity, and therefore may acutely resolve with adenosine. ARVD does not respond to adenosine, and thus the response to adenosine helps differentiate RVOT VT from ARVD. LV fascicular VT represents reentry across abnormally oriented posterior fascicular Purkinje fibers and only rarely responds to adenosine or β-blockers, but responds very well to *IV verapamil acutely*, as described by Belhassen, more than chronic verapamil. *IV verapamil is highly effective for fascicular VT storm*.

PVC catheter ablation is recommended in patients with: (i) sustained VT, or (ii) PVC burden >10% and severe symptoms of palpitations or fatigue, or (iii) PVC burden >10% and EF decline <50%. Alternatively, amiodarone or flecainide may be used (efficacy ~70–80%). Verapamil or β-blockers may be attempted, but they are less efficacious. Flecainide was traditionally contraindicated in low EF, but data suggest its safety in PVC-induced cardiomyopathy with no CAD (class IIa ESC guidelines).

Do not confuse idiopathic VTs with bundle branch reentrant tachycardia; the latter is a very malignant and fast VT occurring in patients with cardiomyopathy and scar tissue across the Purkinje system (bundle branches). It may also be seen after valvular surgery damaging the Purkinje system, or TAVR. Unlike idiopathic VT, baseline QRS conduction delay is present. The circuit is a macro-reentry with down conduction across the right bundle, and up conduction across the left bundle, leading to a *typical LBBB morphology*.

IX. Sudden cardiac death and athlete's ECG screening

A. The mechanism of sudden cardiac death (SCD) is usually VT/VF

Causes of SCD in patients older than 35 years

- Ischemic heart disease (most common cause of SCD at this age)
- Dilated and hypertrophic cardiomyopathies
- Severe valvular heart disease
- Electrical causes listed under *Patients younger than 35 years*

Causes of SCD in patients younger than 35 years[81–84]

1. Structural cardiac disease

- Hypertrophic cardiomyopathy is the most common structural cause (10–30% of SCD at this age)

- ARVD: SCD mostly occurs during exertion
- Coronary artery anomalies (~5% of SCDs at this age)
- Coronary vasospasm; CAD
- Cardiac sarcoidosis
- Myocarditis
- Lamin A/C or other dilated cardiomyopathy; LV noncompaction; toxin-related cardiomyopathy (cocaine)
- Aortic stenosis secondary to a bicuspid aortic valve

2. Electrical diseases explain up to 40% of SCDs at this age (also called sudden arrhythmic death syndrome or SADS). See Sections IV, VI, VII

- Long QT syndrome: SCD mostly occurs with exertion (especially swimming), emotion, or noise stimulation
- Brugada syndrome: SCD commonly occurs at rest, or during sleep, fever, anesthesia, or drug use
- Idiopathic catecholaminergic polymorphic VT: SCD occurs during exertion
- Idiopathic VF, including malignant early repolarization
- Short QT syndrome
- WPW
- Cocaine use
- Commotio cordis in athletes (blunt trauma to the chest during myocardial repolarization/T wave may lead to VF)

B. Athlete pre-participation ECG analysis

Pre-participation cardiac screening of athletes is a matter of controversy. The implementation of a systematic ECG screening strategy has led to a striking 90% reduction of SCD in Italy.[85] A screening ECG is fairly sensitive and specific for the detection of underlying cardiac disease. Normal ECG patterns seen in the athlete's heart need to be distinguished from pathological patterns:[86–88]

- *Normal athlete's heart patterns:* LVH or RVH by voltage criteria only, early repolarization pattern accentuated by a high vagal tone, incomplete RBBB, high vagal tone effects: first-degree AV block, Mobitz I AV block, atrial or junctional escape rhythm.
- *Abnormal patterns:*
  - LVH with secondary ST–T abnormalities or LA enlargement rather than just LVH voltage criteria
  - ST-segment depression
  - ≥1 mm T inversion extending beyond V_2 in white athletes (up to V_2 can be normal), beyond V_3 in young athletes<16, and beyond V_4 in black athletes (→ ARVD, HCM, Brugada, dilated cardiomyopathy)
  - ≥1 mm inferior or lateral T inversion in ≥ 2 adjacent leads (lateral=I+aVL+either V_5 or V_6)
  - Pathological Q waves (→ cardiomyopathy or WPW, wherein Q represents a negative delta wave)
  - LBBB (which may suggest cardiomyopathy or progressive, premature conduction disorder)
  - Profound nonspecific intraventricular conduction delay with QRS ≥140 ms
  - Frequent PVCs (≥2 per 10-second tracing)
  - Brugada pattern; long QTc (especially ≥470 ms in men, 480 ms in women)
- *Borderline patterns* (they do not warrant further workup if isolated): complete RBBB; right- or left-axis deviation; right or left atrial enlargement. Right-axis deviation in a young athlete is defined as axis > +120° rather than +90°.

The abnormal patterns are seen in 7–10% of athletes, more so black athletes, and warrant echo +/– MRI to rule out HCM, ARVD, sarcoidosis or other cardiomyopathies. The majority of patients with abnormal patterns are not found to have any structural abnormality on echo but deserve close follow-up. Only 1–2% get disqualified from sport after echo assessment. MRI may be indicated in select cases to fully eliminate cardiomyopathy (e.g., deep T inversion, high PVC burden).

QRS widening – Complete LBBB is very rare in young adults (<0.1%) and usually represents myocardial disease (HCM, ARVD, sarcoidosis, dilated cardiomyopathy); it warrants aggressive workup with echo and MRI if echo is unrevealing.[86] LBBB may also reflect premature, inherited, progressive AV conduction disease in which AV block can develop with exertion (stress testing). Conversely, ***complete RBBB*** is found in ~2.5% of young athletes and is generally a benign reflection of the adaptive RV dilatation, which may reverse with detraining; investigation is only needed if QRS is ≥140 ms or additional anomalies are present (axis, T inversion). ***Nonspecific intraventricular conduction delay*** <140 ms may be seen in athletes, and likely reflects conduction slowing from increased myocardial mass or neurally mediated effects. More severe delays, ≥140 ms, suggest cardiomyopathy.[86]

T inversion – A proportion of white athletes with deeply inverted T waves (≥2 mm) in the anterolateral precordial leads are at risk of having or developing cardiomyopathies or electrical disease, and thus are at risk of SCD. These T inversions are seen in ~3% of white athletes, of whom 6–25% end up having structural heart disease, sometimes not apparent on the initial echo.[89] In white athletes, these T inversions are not always reflective of the "benign athlete's heart," and thus further workup (echo, MRI) and close follow-up is necessary (e.g., ARVD, Brugada, HCM). T inversions are, however, commonly seen in leads V_1–V_4 in black athletes (~25%) and are benign, not warranting further investigation; T inversion is usually preceded by ST elevation, a form of early repolarization with T inversion. The lack of preceding ST elevation may reflect cardiomyopathy.[86–88] *T inversion in the inferior or lateral leads* (≥2 mm) is highly predictive of cardiomyopathy in any race.[86]

Frequent PVCs and NSVT may be recorded in athletes without any heart disease and are frequently a benign reflection of the "athlete's heart syndrome" when suppressed by exercise.[90] NSVT is as common in athletes as in the normal population (~2%) and is often benign, but deserves a special attention in the athlete. High PVC burden is more concerning: cardiomyopathies may be present in 30% of athletes with high PVC burden >2000/day. Echo, exercise testing, and Holter (to evaluate PVC burden) are performed in athletes with frequent PVCs or NSVT; MRI is then done if PVC burden >2000/day or if PVCs worsen with exercise or in recovery.[86]

Q waves – Physiological LVH may cause deep lateral or inferior Q waves, a result of the thick septal depolarization: this mimics pathological Q waves and is suggested by a normal echo. Pathological LVH, prior myocarditis, or WPW may also cause Q waves.

An early repolarization pattern is very common in athletes; however, a downsloping ST-segment or a J point that is notched and wide (≥1 mm) or elevated ≥2 mm in the inferior leads identifies individuals at increased risk of sudden death; the absolute risk remains very low and this pattern does not prohibit athletic activity.[75–77]

ECG is highly sensitive and is reasonably reliable to exclude lethal cardiac disorders in young athletes. However, ~10% of HCMs have a totally normal ECG, and thus may be missed by ECG screening. The family history and symptoms help fill this 10% gap. The routine large-scale use of echocardiographic screening is not justified.

On echocardiography, some features differentiate "athlete's heart" hypertrophy from hypertrophic cardiomyopathy **(see Chapter 7, Sections XIII–XIV)**.

C. Workup of SCD survivors

In survivors of SCD, perform coronary angiography and echo to look for structural disease, and *analyze ECG for electrical causes*. In those without obvious structural disease or with only transient LV dysfunction, perform the following tests:[79]

- ECG exercise testing, in an effort to unveil long QT syndrome 1 or catecholaminergic polymorphic VT.
- Intravenous procainamide testing, in an effort to unveil Brugada pattern.
- Advanced imaging (cardiac MRI, chest CT) looking for ARVD, sarcoidosis, and myocarditis.
- Consider coronary angiogram with provocative testing for vasospasm, especially in patients who show dynamic ST changes on telemetry monitoring or those with evidence of infarction (by MRI or by marked troponin elevation).
- If all the above is negative, consider targeted genetic testing for SADS channelopathies (including for concealed, negative-phenotype Brugada and long QT syndrome), keeping in mind that the yield is low, ~10%.[91]

X. Competitive high-intensity sports for athletes with various cardiovascular abnormalities

Abnormal ECG, syncope, exertional angina, family history of SCD, and murmur on exam are red flags that warrant the performance of an echocardiography.

A. Valvular heart disease[92]

Severe symptomatic valvular disease requires correction before athletic activity. Even if asymptomatic, ***severe AS, severe PS, or severe MS*** needs correction with a valvular procedure or surgery before competitive athletic activity. For example, if a teen or a young adult is found to have severe AS from a non-calcified bicuspid valve, or significant PS, valvuloplasty would be indicated even if the patient is asymptomatic. ***Severe asymptomatic MR and AI*** with normal LV function and dimensions (accounting for athlete's remodeling) are not contraindications to athletic activity. Also, ***moderate AS, moderate PS, and moderate MR and AI*** are not usually contraindications to high-intensity sports in asymptomatic patients with normal LV and RV.[92] **Exercise testing to competitive intensity** is recommended in presumed asymptomatic valvular disease to confirm the absence of symptoms.

B. HCM and ARVD

Asymptomatic HCM, whether at low or high risk of SCD, is not a contraindication to competitive sports (ACC class IIb), after shared decision-making and consideration of ICD in high-risk cases.[92–96] Also, it is possible to consider athletic activity in *asymptomatic phenotype positive ARVD with negative PKP-2 gene*, after consideration of ICD in high-risk cases. Only ARVD with positive PKP-2 gene mutation is clearly advised against competitive sports, because of the high risk of SCD and progression of myocardial disease with exercise.[92,97] Genotype+/phenotype– patients with HCM or ARVD, even PKP-2+, may pursue competitive sports (close imaging follow-up is warranted to detect phenotypic conversion, especially for PKP-2+, with echo (+/– MRI), stress test, and Holter every 6–12 months).

Regarding DCM, it is reasonable for genotype+/phenotype– patients to participate in competitive sports, although this is less certain for lamin A/C mutation. It may be reasonable for DCM with mild phenotypic conversion and EF >40% to participate in competitive sports, this being again less certain for lamin A/C mutation and other high-risk genes for SCD.[92,98]

C. Myocarditis

Athletes with myocarditis may resume competition after at least 4–6 weeks (in case of mild myocarditis with normal LV function) or 3 months (in case of severe myocarditis with initially impaired LV function). Competition may only be resumed if: (i) no cardiopulmonary symptoms; (ii) echo, MRI inflammation (T2), troponin, and CRP have fully recovered; (iii) no evidence of frequent PVCs or repetitive NSVT on Holter and stress testing. *Persistent LGE on MRI, in isolation, is of unclear significance and does not preclude competition* (ACC, ESC).[92,99]

D. Aortopathy

Patients with *aortopathy* and aortic dilatation ≥45 mm are advised against competitive sports. Aortopathy with lesser aortic dilatation is not a contraindication to athletic activity, with close patient monitoring.[92] Patients with heritable thoracic disease, such as Marfan, should likely avoid competitive sports even with milder aortic dilatation.

E. Anomalous coronary arteries

Patients with *anomalous left coronary artery arising from the right cusp* with interarterial course are advised against athletics and should consider surgical correction. Athletics may be resumed after surgical correction, in the absence of ischemia on stress testing. Patients with anomalous LCA with other courses (posterior, anterior, septal) may undergo athletics in the absence of symptoms and ischemia on exercise stress testing. Similarly, *anomalous RCA from the left cusp with interarterial course* may undergo athletics in the absence of symptoms and ischemia on exercise stress testing.[92]

F. ECG abnormalities

Patients with *significant ECG abnormalities* but with no symptoms and with negative clinical and imaging evaluation may pursue competitive sports but with longitudinal imaging surveillance.[92]

G. Channelopathies

Patients with *LQT syndrome* may pursue competitive sports, even phenotype-positive LQT with QTc ≥480 ms, and even if previously symptomatic, as long as they are receiving β-blockers and other appropriate therapies.[92] A large cohort of LQT athletes showed no mortality and low yearly event rate (1.6% per year).[93,100] Stability must be ensured for at least 3 months after an arrhythmia. Patients with *Brugada syndrome* have no athletic restriction, as long as they avoid VF triggers such as heat exhaustion and dehydration.

H. Athletic activity in patients with ICD

The ICD Sports Registry recruited patients with any electrical or myocardial disease that mandated ICD, who continued to pursue athletic activity; ~ half of patients had a history of preimplantation VT/VF. Vigorous, high-intensity, competitive sports were safe in these ICD patients (soccer, running, basketball, skiing, cycling, tennis, etc. …). By 4 years, 10% of subjects had received appropriate shocks during competition or practice, at a rate of 3 per 100 person-years, and the frequency of shock during competition was similar to the frequency of shock during other, routine physical activities or rest. This was the case in HCM and most other illnesses, except ARVD (higher likelihood of shock during sport). No patient had sudden death or required external defibrillation.[101] Thus, sports participation is reasonable in patients with primary or secondary prevention ICD. Sports with impact or collision present a particular risk of ICD system damage and dysfunction, but even those sports may be permitted after discussion of the risks and benefits.[92]

QUESTIONS AND ANSWERS

Question 1. A 41-year-old with a history of hypertension presents with palpitations. His palpitations are sustained for 1 to several minutes and associated with near-syncope. During one of those episodes, the pulse checked by his wife was 150 bpm. ECG performed in the office shows sinus rhythm, borderline QRS width (~100 ms) with incomplete RBBB pattern, and biphasic T wave (mild terminal T inversion) in leads V_1–V_3. Echo shows a normal LV and borderline RV size, with no segmental akinesis. What is the next step?

A. Reassurance
B. 2-week event monitor
C. Cardiac MRI

Question 2. A 50-year old man presents with palpitations and near-syncope. ECG shows sinus rhythm with incomplete RBBB pattern and biphasic T waves in leads V_1–V_3. Event monitor reveals multiple runs of NSVT (3–12 beats, polymorphic) during the first 2 days of monitoring. What is the next step?

A. Admit the patient and perform coronary angiography
B. Cardiac MRI
C. Signal-averaged ECG

Question 3. For the patient in Question 2, coronary angiography shows normal coronary arteries. Cardiac MRI shows apical akinesis of the RV with late gadolinium enhancement of this portion of the RV. The RV is mildly enlarged by volume assessment, with RVEF 40–45% (mildly reduced, normal RVEF being >45%). What is the diagnosis?

A. ARVD
B. Brugada syndrome
C. Idiopathic RVOT VT
D. Myocarditis

Question 4. For the patient in Questions 2 and 3, what is the next step?

A. High dose of metoprolol, or sotalol. If this fails, switch to amiodarone and consider VT ablation
B. ICD
C. Genetic testing for the purpose of diagnosing the disease in his children
D. All of the above

Question 5. A 55-year-old woman presents with syncope. She had diarrhea for a week and her potassium is 3 mEq/L and calcium and magnesium are low. She has the ECG shown in Figure 9.6. What is the most likely underlying diagnosis?

A. Electrolyte abnormalities
B. Acute ischemia
C. Drug effect
D. Congenital long QT syndrome 1
E. Congenital long QT syndrome 2

Question 6. Which statement is *incorrect*?

A. VT with twisting QRS polarity is called TdP even if baseline QTc is normal
B. Bradycardia may elicit polymorphic VT even in the absence of a prolonged QTc (bradycardia-induced VT)
C. LQT1 and 2 are due to a loss of function (of K channel), while LQT3 is due to a gain of function (of Na channel)
D. Brugada syndrome is due to a loss of function of Na channel, while LQT3 is due to a gain of function of this same channel
E. If QTc >480–500 ms without any reversible cause, the diagnosis of long QT syndrome is likely
F. In patients with borderline QTc 450–480 ms, further testing may need to be performed (e.g., effect of exercise or epinephrine on QTc)
G. In patients with QTc 430–450 ms who have syncope or a family history of sudden death, further testing may need to be performed

Question 7. A 30-year-old man who grew up in Mexico presents with syncope during basketball exercise. ECG and echo are normal. Stress testing reveals a monomorphic VT with a QRS upright in V_1, negative in the inferior leads and lateral leads I-aVL. Coronary arteries are normal on angiography. What is true?
A. Idiopathic VT originating from the left posterior fascicle
B. Idiopathic VT arising from the RVOT
C. Myocardial VT arising from the inferolateral LV wall
D. Myocardial VT arising from the LVOT

Question 8. A 26-year-old Mexican immigrant has exertional syncope. Monomorphic VT occurs on stress testing. Cardiac MRI shows a large inferolateral scar. In addition, the patient develops a complete RBBB on his ECG a few months later. What is the diagnosis (multiple possible answers)?
A. Sarcoidosis
B. Chagas disease
C. ARVD
D. Giant-cell myocarditis
E. Some genetic cardiomyopathies (mutation of desmosomal genes)

Question 9. A patient experiences anterior MI and undergoes LAD PCI. His post-MI LVEF is 25%. Which of the following is true?
A. His highest risk of sudden death is in the first 40 days after MI. ICD is indicated in the first 40 days
B. His highest risk of sudden death is in the first 40 days after MI. But ICD implantation is not beneficial in the first 40 days. LifeVest may be used in the first 40 days
C. His highest risk of sudden death is in the first year (risk equally spread throughout the year). ICD is indicated at ≥40 days

Question 10. A patient has LVEF 30% and is found to have severe LAD and RCA disease for which he undergoes PCI. Is the following statement true or false? The first 3 months after PCI constitute the highest-risk period of sudden death, yet ICD is only indicated beyond those 3 months if EF remains ≤35%.

Question 11. A 40-year-old man has had daily palpitations described as "skipped beats" for 4 months, mostly at rest but also during emotional stress. He never had sustained palpitations or syncope. He is active and cycles 30 minutes every day without cardiac symptoms. ECGs capture frequent ectopic beats, of the same morphology (Figure 9.14). His baseline sinus rate is ~65 bpm. Echo is normal. What is the first-line therapy?
A. Metoprolol
B. Flecainide
C. Verapamil
D. Catheter ablation

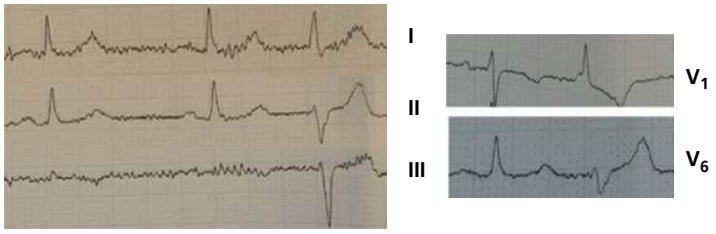

Figure 9.14

Question 12. A 25-year-old woman with no prior health issues had 2 episodes of syncope in the last month; they both occurred during exertion. ECG shows a sinus rate of 70 bpm with prolonged QTc of 520 ms and a markedly prolonged T wave. Basic lab tests are normal. She is considering pregnancy. What is the next step?
A. Propranolol 40 mg BID
B. ICD placement
C. Genetic testing

Question 13. You are assessing a 30-year-old man whose father had cardiac arrest and was diagnosed with Brugada syndrome and a positive SCN5A gene mutation. His ECG is normal and he is asymptomatic. What is the next step?
A. Propranolol
B. Genetic testing
C. ICD
D. No further workup. Regular surveillance

Answer 1. B. In patients with unsuspected cardiac disease, palpitations frequently correspond to non-arrhythmic awareness of one's heart beat (anxiety, stress) or to benign premature complexes. However, this patient has 2 worrisome elements in his history: (i) palpitations are sustained and associated with true near-syncope (in the absence of a myriad of functional complaints), and (ii) a fast pulse is documented. The ECG has borderline findings that, in an asymptomatic patient, may be considered normal (QRS being <110 ms). However, in a patient

with palpitations, the borderline RBBB pattern and the mild T inversion are suggestive of underlying structural heart disease (e.g., any cardiomyopathy), early ARVD, or even a hidden Brugada pattern. ST elevation must be present to make a Brugada diagnosis and may be unveiled with provocative testing or with moving the V_1–V_2 electrodes one interspace higher. One should attempt to document the cardiac rhythm during the index palpitations.

Answer 2. A. Based on the history of more sustained palpitations, the patient likely had, at times, more sustained episodes of VT. This warrants hospitalization. Polymorphic VT, even if non-sustained, is suspicious for myocardial ischemia.

Answer 3. A. The patient fulfills many criteria of ARVD, although none of them is a major criterion: (i) RV akinesis and scar on MRI; (ii) borderline but suggestive ECG; (iii) NSVT. RV involvement on MRI or echo would be a major criterion for ARVD if the RV were more than mildly dilated or EF were more severely reduced (<40%). Genetic testing and signal-averaged ECG, looking for late fragmented QRS potentials (microscopic epsilon waves), may further support the diagnosis. Myocarditis is possible but is a less likely diagnosis considering the constellation of findings.

Answer 4. D.

Answer 5. D. Electrolyte disturbances, acute ischemia, drug side effect and congenital long QT syndrome are the four major causes of a prolonged QT interval. While the electrolyte abnormalities accentuate the QT prolongation, the patient has another underlying cause of prolonged QT that explains the broad T-wave morphology, such as congenital long QT syndrome or acute ischemia. In long QT syndrome 1, T wave is wide and ample without ST-segment depression, similar to our patient. T-wave alternans is most characteristic of congenital long QT syndrome.

Answer 6. A. VT with twisting QRS polarity, but normal baseline QTc, is a non-TdP polymorphic VT.

Answer 7. C. The normal ECG and echo suggest that VT may be idiopathic, but the occurrence of syncope and the inferolateral origin make idiopathic VT less likely. VT with upright QRS in V1 suggests LV origin; negative QRS in the inferior leads and lateral leads suggests an origin from those very same areas (inferolateral). A left posterior fascicular origin would lead to RBBB+LAFB morphology, and as such, QRS would be upright in leads I and aVL.

Answer 8. A, B, and E. All 5 listed answers are specific causes of cardiomyopathy with focal scarring and a predilection for arrhythmia and conduction abnormality. In this case, ARVD is unlikely (no RV issue on imaging). The lack of HF and the slow course do not suggest giant-cell myocarditis. Sarcoidosis, Chagas, or lamin A/C cardiomyopathy is the most likely disease. Next, serologic testing for Chagas disease and a search for non-cardiac sarcoid involvement should be carried out.

Answer 9. B.

Answer 10. True.

Answer 11. C. This is a relatively narrow PVC (~140 ms) with a morphology of RBBB + LAFB. It may get confused with an aberrant PAC. This PVC morphology and width is characteristic of idiopathic LV fascicular PVC originating from the left posterior fascicle. It is characteristically responsive to verapamil, but this is particularly true for the *IV form of verapamil in fascicular VT*. Catheter ablation or flecainide is a second-line therapy (high success rate). As opposed to idiopathic RVOT PVC, this PVC is not usually responsive to metoprolol. The normal echo and the lack of other cardiac symptoms are necessary for the diagnosis of idiopathic fascicular PVC/VT; the same morphology may be seen with a scar PVC originating from an inferoseptal scar. Of note, depending on symptom severity, clinical surveillance with no drug therapy is an option. Holter is necessary to quantify the PVC burden and the risk of PVC-induced cardiomyopathy, which may dictate echo surveillance.

Answer 12. A. Her ECG is suggestive of LQT syndrome, likely type 1 (broad T in type 1 LQT, double humped T in LQT2). The first-line therapy for syncope is β-blockade, not ICD. ICD is reserved for sudden death or for syncope that recurs despite β-blockade or with intolerance to β-blockade. LQT2 has a high sudden death risk in the 12 postpartum months, at which time LifeVest may be considered.

Answer 13. B. Genetic testing has a relatively low yield for the diagnosis of Brugada syndrome and most genetic cardiomyopathies (only 30–40%). However, once a positive gene is identified in a proband, it is highly valuable to test first-degree relatives, as a negative gene fully excludes the disease and obviates the need for future surveillance. A positive Brugada gene does not dictate any therapy in this patient and does not change immediate management, but is still valuable as it dictates avoidance of triggers (e.g., fever, alcohol, many drugs) and routine clinical and ECG surveillance. Propranolol may be used in gene+/phenotype– LQT syndrome; β-blockers are avoided and are potentially harmful in Brugada syndrome where VF occurs at low catecholamine tone (as per www.BrugadaDrugs.org). Rather, sympathomimetics are helpful in Brugada syndrome with VF storm. Of note, had no definite mutation been identified in the father, routine clinical and ECG surveillance of his son and first-degree relatives would be recommended.

Questions and answers 365

Atrial fibrillation (AF) is the most common sustained arrhythmia that requires treatment.[1] ~3–4% of patients aged 65–75 years have clinical AF, and 10% of patients aged 80 years or older have clinical AF; 4% of patients with heart failure (HF) functional class I and 50% of patients with functional class IV have AF.[2] On the other hand, HF is present in 34% of AF patients.[3] *Subclinical brief AF* is even more common and may be detected in *30s% of patients older than 65–70 years* with cardiovascular risk subjected to continuous ECG monitoring for >1 year (ASSERT II and LOOP studies). AF is typically initiated by one or more premature atrial complexes, often originating around the pulmonary veins, or by atrial tachycardia or atrial flutter.

I. Predisposing factors (see Table 10.1)

Age >65, obesity, and hypertension are the 3 most common factors associated with AF on a population basis; coronary artery disease (CAD) and HF are the most common associated features in hospital series.[4] Between 30% and 45% of paroxysmal AF cases, and 20–25% of persistent AF cases occur in patients without obvious heart or lung disease and without hypertension (formerly called "lone AF").[5] Even in the case of lone AF, there are structural atrial abnormalities and some degree of atrial dilatation and dysfunction, as well as an increased

Table 10.1 Factors predisposing to atrial fibrillation.

- Age >65
- Obesity[a]
- Hypertension
- Coronary artery disease
- Heart failure
- Any acute or chronic structural heart disease
- Atrial inflammation: pericarditis, myocarditis
- Metabolic disorders: alcohol, hyperthyroidism, hypokalemia
- Pulmonary diseases: COPD, pulmonary embolism
- Postoperative state (cardiac, pulmonary, or esophageal surgeries)

[a]Sleep apnea is seen in >40% of patients with AF. Yet, CPAP did not reduce AF burden in the A3 randomized trial.

prevalence of high-normal blood pressure (i.e., systolic pressure 130–140 mmHg), that are contributive to AF.[6,7] As they age, these patients may develop hypertension or heart disease that contributes to the progression of AF.

The most frequent histopathological feature of AF is atrial fibrosis, which may precede the onset of AF. Atrial dilatation is present in over 50% of patients with AF, with a mean left atrial diameter of ~40 ± 8 mm in the Canadian Registry of non-valvular AF; atrial dilatation is less prevalent in patients with non-recurrent AF and lone AF.[7] Atrial dilatation may be not only a cause but also a consequence of AF, as evidenced by the fact that the left atrial size further increases with time, over months to years, in patients with persistent AF.[8,9] On the other hand, left atrial size decreases after AF cardioversion.[10,11] Atrial electrical remodeling, i.e., *progressive shortening of the effective refractory period*, further explains how prolonged AF makes restoring and maintaining sinus rhythm less likely ("AF begets AF").[2]

AF requires a trigger that initiates the arrhythmia *and* a substrate that sustains it. The most common triggers are premature atrial beats originating from the pulmonary veins. Atrial stretch and atrial fibrosis shorten the atrial effective refractory period and disrupt the electrical interconnections between the muscle bundles, causing local conduction heterogeneity. This allows ectopic activity originating from the pulmonary veins or elsewhere to get conducted and initiate multiple microreentry cycles (atrial wavelets). Those microreentrant cycles collide like "tornadoes" and generate new tornadoes that propagate throughout the atria.

The autonomic system may contribute to the initiation of AF, i.e., an increase in the sympathetic or parasympathetic drive may trigger ectopy in the pulmonary veins and AF. Conversely, low-level vagal stimulation, below the bradycardia threshold, may reduce AF burden.

II. Types of AF

There are 3 types of AF: paroxysmal, persistent, and permanent:[2,12]

- ***Paroxysmal AF*** is defined as AF that terminates spontaneously in less than 7 days (often 24–48 hours). AF that is terminated with cardioversion at ≤7 days of onset is also considered paroxysmal AF in the most recent classification.
- ***Persistent AF*** is AF that persists over 7 days or requires cardioversion at >7 days (or unknown duration). *Long-standing persistent AF* is continuous AF that persists greater than 12 months, yet the adoption of a rhythm-control strategy is still planned.
- ***AF is considered permanent*** in cases of failure of cardioversion attempts, early recurrences after cardioversion, or decision not to cardiovert. A decision may be made not to cardiovert a patient who is asymptomatic after rate control and has a high likelihood of recurrence (e.g., longstanding AF of over a year or severe left atrial enlargement >5 cm).

Paroxysmal and persistent AF may be recurrent. Over time, patients may alternate between paroxysmal and persistent AF. For example, in a particular patient, most of the AF episodes may be self-terminating, while some of them may require cardioversion. While a paroxysmal AF may recur as paroxysmal AF for years, AF is generally progressive over time, with a rate of progression to persistent or permanent AF of ~15% within the first year.

The term ***"acute AF"*** or ***"recent-onset symptomatic AF"*** is applied for acutely symptomatic, new AF or recurrent AF. It is a form of paroxysmal or early persistent AF. This is different from the term ***"newly diagnosed AF"*** *(or first-detected AF)*, which is often acute and symptomatic but not necessarily; 21% of patients in whom AF is newly diagnosed are asymptomatic, and AF is diagnosed by routine pulse exam during an office visit.[13] In the latter patients, AF is likely several weeks, months, or years old, and may be long-term persistent or permanent.

"*Subclinical AF*" refers to asymptomatic AF detected only on implanted devices or wearable monitors: it is subdivided into AF <24 hrs (true subclinical AF) and AF >24 hrs (conveying definite stroke risk and managed ~similarly to clinical AF). "*Clinical AF*" refers to AF documented on a standard ECG tracing in a clinical setting or identified by clear symptoms (ACC).

III. General therapy of AF

There are 4 main consequences of AF: (i) thrombus formation in the left atrial appendage (LAA) followed by thrombus embolization; (ii) fast heart rate that leads to compromised ventricular filling; (iii) loss of the atrial kick that contributes to up to 40% of the cardiac output in stable HF patients; (iv) rhythm irregularity, per se, reduces cardiac output compared to a similar rate that is regular. Also, a rapid ventricular response of ≥110 beats per minute that persists for over 2 weeks can cause tachycardia-mediated cardiomyopathy and HF.

A. Anticoagulation

Administer an anticoagulant regardless of whether ***AF is paroxysmal or permanent. AF often recurs, and asymptomatic recurrences are 12 times more common than symptomatic recurrences***.[14] In the AFFIRM study, the risk of ischemic stroke was strongly related to absent or suboptimal anticoagulation even in the rhythm-control strategy.[15] Rhythm control makes AF recurrences shorter and slower, hence less symptomatic; the stroke risk diminishes if AF burden is dramatically reduced, as in successful AF ablation, but it persists.

B. Rate control

Three classes of drugs may be used: β-blockers, non-dihydropyridine calcium channel blockers (CCBs) (diltiazem or verapamil), and digoxin.

β-Blockers are effective as monotherapy in up to 70% of patients with AF,[16] and are first-line therapy in compensated systolic HF. They also have an antiarrhythmic effect and may convert adrenergically mediated AF into sinus rhythm.

Digoxin is less effective for rate control during exertion. Digoxin is only used as monotherapy in decompensated systolic HF, when the acute initiation of β-blockers is not possible. Digoxin is effective in combination therapy: the combinations digoxin–β-blocker and digoxin–CCB are at least as effective and safe as the combination β-blocker–CCB.[16]

Two modern trials compared rate-controlling drugs:[17] (i) RATAF compared monotherapy with CCBs vs. β-blockers; CCBs improved exercise capacity, symptoms, peak VO2, and NT-pro-BNP levels vs. β-blockers, despite a similar rate reduction; (ii) RATE-AF compared monotherapy with digoxin vs. bisoprolol (age ~75, half of patients had HF, 20% had HFrEF); digoxin improved functional class and NT-proBNP vs. bisoprolol, with a similar rate reduction and dramatically less adverse events and hospitalizations.

First-line treatment: CCB or β-blocker. *Second-line:* add digoxin or combine β-blocker + CCB. CCB is not an appropriate option in EF <50%, but diltiazem may be cautiously considered in EF 40–50% (ESC and ACC, based on DiDi trial). The combination of β-blocker and verapamil has a strong negative inotropic effect and should be avoided in all patients. Triple combination is required in ~15–20% of patients but increases the risk of excessive pauses. Pharmacological therapy can achieve rate control in >80% of patients.[16] The remaining patients cannot be rate-controlled with drugs and require rhythm control, provided that long-term success can be expected, or failing that, atrioventricular nodal ablation with ventricular pacing. ***Patients with AF, including fast AF, may alternate with AF pauses, sinus pauses (immediately after AF converts to sinus rhythm), or sinus bradycardia; this limits the use of rate-controlling agents and requires tight rhythm control or pacemaker placement***.

In symptomatic patients, the goal of therapy was to reduce heart rate to <80 bpm at rest, <110 bpm with moderate activity, and <100 bpm (average) on 24-hour Holter monitoring. This goal was adopted in the AFFIRM and RACE trials, which established the efficacy of a rate-control strategy. However, in the RACE II trial, this strict rate control did not offer any benefit over a more lenient control (a resting heart rate <110 bpm at rest) in patients with permanent AF and mild or no AF-related symptoms.[18] There was no significant difference in hard outcomes (death, hospitalization for HF, stroke) or in symptom control at 3-year follow-up. Note, however, that most patients in the lenient group had a heart rate ***<100 bpm*** (85 ± 14 bpm), which implies that 100 bpm may be a better lenient goal than 110 bpm.

Rate control in HF- A wealth of data indicate that strict rate control improves outcomes in systolic HF with sinus rhythm, but not in systolic HF with AF and not in HFpEF. A higher rate is necessary to compensate for the loss of atrial contribution to stoke volume; also, nocturnal pauses that accompany tight rate control may be particularly harmful in HF (induce VT, low flow). ***For AF associated with HF, the target rate control remains <100 bpm*** rather than <80 bpm (based on RACE-II substudy, substudies of β-blockers in HF, and Swedish HF registry).[19] To improve HF outcomes, consider AF ablation rather than strict rate control. In fact, even *β-blockers did not reduce mortality in HFrEF with AF* in a landmark analysis.[20]

AF rate tends to gradually slow down over time, as more fibrosis extends from the atria into the AV nodal area, and rate-controlling drugs may need to be gradually reduced. **When AF becomes slow and regular, complete AV block with a junctional escape rhythm is diagnosed**. Also, AF pauses >3–5 seconds during wakefulness imply high-grade AV block. This may be related to excessive dosing of the rate-controlling drugs or, more often, to AV conduction disease. If this AV block persists after drug discontinuation, a permanent pacemaker is indicated.

An on/off rhythm that alternates between *fast paroxysmal AF and sinus bradycardia or post-conversion pauses* is the most difficult to rate control, more difficult than persistent or permanent AF, and requires tight rhythm control or pacemaker placement.

C. Rhythm control

Rhythm control with antiarrhythmic drugs, as compared with rate control, did not reduce mortality, stroke rate, or HF hospitalizations in old landmark trials of patients at high risk of stroke or AF recurrences (AFFIRM and RACE trials),[21,22] and of patients with stable HF and EF <35% (AF-CHF trial).[23] In fact, rhythm control was associated with a higher rate of hospitalization for recurrent AF and drug-related brady- and tachy-arrhythmias. In addition, in the AFFIRM trial, rhythm control was associated with increased non-cardiac mortality, particularly when amiodarone was used (pulmonary and cancer mortality).[24,25] Amiodarone was the most commonly used drug in the AFFIRM trial, while sotalol was the most commonly used drug in the RACE trial. These studies enrolled persistent AF (RACE), and paroxysmal or persistent AF (AFFIRM and AF CHF), and AF duration was mostly <1 year.

This failure of rhythm control was partly related to the withdrawal of anticoagulation, the marginal efficacy of antiarrhythmic drugs, and their toxicity: only 62% of patients in the rhythm-control arm of AFFIRM and 39% of the rhythm-control arm of RACE were in sinus rhythm on follow-up.[22] Secondary analyses of these trials showed that the presence of sinus rhythm on follow-up was associated with improved quality of life (RACE)[26] and survival (AFFIRM),[24] regardless of the treatment strategy or the use of antiarrhythmic drugs. Antiarrhythmic drugs, per se, were associated with reduced survival.[24]

Conversely, modern trials have shown that a rhythm-control strategy is superior in 2 settings: *HF* or, less dramatically, *early AF* (≤1 year, symptomatic or not, paroxysmal or persistent); as long as a safer and more effective rhythm-control regimen is used, focused on AF ablation, over a background of anticoagulation and comprehensive risk factor management:

- Compared to rate control or rhythm control with drugs, rhythm control with catheter ablation significantly and dramatically reduced both mortality and HF hospitalizations in systolic HF patients (CASTLE AF).[27]

- Compared to mostly rhythm control with drugs, catheter ablation also showed a trend toward improvement in cardiovascular outcomes in all comers with AF, albeit modest (CABANA trial).[28] The benefit was more dramatic in HF, which mainly consisted of HFpEF in this trial.[29]
- In new AF ≤ 1 year, a stepwise rhythm-control strategy focused on class Ic drugs (44%), dronedarone, AF ablation (20%), and less so, amiodarone (11–20%) slightly but significantly improved cardiovascular mortality by 0.3% per year, the overall cardiovascular outcomes by 1.1% per year, and stroke, compared to rate control. Sinus rhythm was maintained at 2 years in 82% of patients. This early AF control attenuates or reverses atrial cardiomyopathy.[30] (EAST AFNET4 trial: mean age 70, median BMI 28, median AF duration 36 days, LA diameter 4.4 +/– 0.8 cm, asymptomatic AF in 30% of patients, first AF episode in 38%, paroxysmal AF in 36%, HF in 28%).
- In ATHENA trial, dronedarone significantly reduced cardiovascular mortality (0.7%/yr), hospitalizations, and stroke compared to rate control.
- In HF, the rhythm-control benefit extends to HFpEF and to rhythm control with drugs based on CABANA and EAST-AFNET4 trial analyses.[31–33] Furthermore, it is beneficial in patients with functional TR or MR, which may be a form of atrial functional TR or MR driven by AF and atrial enlargement.

In patients with BMI >27 kg/m^2, ***weight loss >10%, by itself, dramatically reduces the recurrence of AF***. Weight loss, by itself, is almost as effective as antiarrhythmic drugs in preventing AF recurrence, and it allows interruption of antiarrhythmic drugs in many patients (~50% freedom from AF and antiarrhythmic drugs over several years of follow-up, vs. <20% if no weight loss). Also, weight loss is synergistic with AF ablation and antiarrhythmic therapy (87% freedom from AF over several years of follow-up after ablation, vs. <40% if no weight loss). This is enhanced by aggressive control of HTN, diabetes, lipids, sleep apnea, and smoking (LEGACY, ARREST AF, and RACE-3 studies).[34,35]

Rhythm control is a valid strategy in: (i) HF; (ii) **early AF (≤1 year)**, even if symptoms are controlled; and (iii) patients who are **symptomatic despite rate control *and* who have a good likelihood of maintaining sinus rhythm** (Table 10.2 without Table 10.3 criteria). Rate-control drugs should be continued during a rhythm-control strategy to ensure adequate rate control during AF recurrences, and **the focus should be on risk factor management**, especially weight and hypertension.

AV nodal ablation with ventricular pacing is the ultimate and definitive therapy for AF that cannot be rate- or rhythm-controlled.

Table 10.2 Six cases in which a rhythm-control strategy should be considered.

- Intolerable symptoms despite rate control (palpitations or functional limitation that associates with AF), or vague uncertain symptoms that may associate with AF
- Difficulty in achieving rate control; or alternation of fast AF with sinus bradycardia, precluding the optimal use of rate-controlling drugs
- Any HF, whether HFpEF, HFrEF, or RV failure, particularly if AF ablation can be done.[27] This is even more important in decompensated HF (after stabilization and diuresis), or advanced, class III–IV HF (not well represented in the AF-CHF trial)
- Newly diagnosed AF (≤1 year), even if symptoms get controlled with rate reduction (EAST-AFNET4 trial)[a]
  EAST-AFNET4 recruited patients >65, but this is likely even more important in a young patient <65[b] [2]
- Functional MR or TR, which may be induced by AF ("atrial functional MR or TR")
- AF secondary to a treated precipitant (ischemia, sepsis, surgery, hyperthyroidism)[2]

[a]21% of patients in whom AF is newly diagnosed are asymptomatic and their diagnosis is incidental (AF likely several weeks or months old); these patients are unlikely to benefit from a rhythm-control strategy.[13]
[b]Most patients in the AFFIRM and RACE trials were older than 65. A meta-analysis suggests that rhythm control may improve mortality in patients younger than 65.[36]

Table 10.3 Risk factors associated with failure of direct-current cardioversion, recurrence of AF after cardioversion, or progression of paroxysmal AF to persistent AF (first five are most important). **The best candidate for rhythm control is the patient having Table 10.2 criteria with none of Table 10.3 main 5 criteria**.

- Severe left atrial enlargement, i.e., anteroposterior diameter >4.5–5 cm
- AF duration of more than 1 year
- Decompensated medical condition that has not been treated, including decompensated HF or hyperthyroidism
- Previous recurrences of AF, especially ≥2 recurrences requiring cardioversion
- Morbid obesity

- Underlying structural heart disease (the more severe, the less likely rhythm control is to succeed). This, however, is an incentive for AF rhythm control, particularly with ablation (as in the HF trials), the aim being to reduce AF burden while accepting a *frequent requirement* for repeat ablations
- COPD
- Age >75 years

The Euro Heart Survey developed a risk score, somewhat similar to $CHADS_2$ score, that predicts the progression from paroxysmal to persistent or permanent AF: HAT_2CH_2 (**H**ypertension, **A**ge >75, **T**IA or stroke 2 points, **C**OPD, **H**F 2 points). HATCH score of 0 or 1 → <10% risk of progression; 2–5 → 25–30% risk of progression; 6 or 7 → 50% risk of progression at 1 year.[37] **Potentially harmful drugs and interventions, including cardioversion, may be avoided in a high HAT_2CH_2 score.**

IV. Management of a patient who presents with acute, symptomatic AF

1. Direct-current cardioversion (DCCV) is indicated emergently in cases of severe shock, acute HF with massive pulmonary edema, or myocardial ischemia attributed to AF. Typically, **to attribute severe hemodynamic compromise to AF and to justify urgent cardioversion, heart rate must be >150 bpm, or >120–130 bpm in systolic HF, or >130 bpm in HFpEF**. Look for potential causes of shock that might have triggered both hypotension and AF. See the limitations of acute DCCV under Section IX.B.

2. Acute rate control is achieved with β-blockers or CCBs (= first-line agents) in the absence of hypotension or decompensated HF. These agents are given intravenously if AF is severely symptomatic, with an initial target <110 bpm (Table 10.4).

- ***In the case of decompensated HFrEF or borderline BP, there are 3 options: IV digoxin or IV amiodarone or IV landiolol, with adjunctive magnesium*** *(ESC and ACC). Amiodarone has the theoretical risk of acutely cardioverting AF in a patient who may have an atrial appendage thrombus, but the short-term (<24 hours) likelihood of cardioversion is only slightly higher and faster than spontaneous cardioversion: ≈20–25% higher (70s% vs. 50s% at 24 hours).[38,39] This may be a hazard one has to accept, similarly to cardioversion of unstable AF. Neither ACC nor ESC guidelines insist on this risk*.
- *β-Blockers may be used acutely in low EF without clinical HF. β-Blockers and diltiazem may be cautiously used in HFpEF and even HFmEF with EF 41–50% per ACC/ESC*.
- ***IV magnesium*** *boosts rate control and is recommended as an adjunct in all settings (class IIa ACC guidelines).*[40]

The onset of action of IV drugs is fast (a few minutes), except for digoxin (1–5 hours).

3. Acute AF often spontaneously resolves by 24 hours, in ~60% of the cases (70% at 48 hours), even more so in the absence of heart disease. Thus, a 24-hour wait-and-see strategy is reasonable, with potential discharge after rate control and NOAC initiation, followed by reassessment the next day, as in RACE 7 trial (ESC class IIa).[41] If AF persists beyond 24 hours:

i. Perform **acute cardioversion at 24 hours** (DCCV or pharmacological cardioversion), after TEE or CTA rules out left atrial appendage thrombus. The patient needs to receive acute anticoagulation with heparin, enoxaparin, or NOAC. Another option is to provide oral anticoagulation for 3 weeks then perform DCCV without TEE.

ii. Alternatively, for acute AF with symptoms <24 hours, or if the patient is already on chronic anticoagulation, immediate pharmacological cardioversion—or, failing that, DCCV—may be attempted with any of the following 4: (i) intravenous procainamide (30-minute infusion, ~60% success rate at 1 hour, rare hypotensive effect) (RAFF2 trial); (ii) oral flecainide load (200–300 mg, ~70% efficacy at 3–6 hours);[41,42] (iii) IV ibutilide (up to 50% success at 30 minutes); or (iv) less favorably, IV amiodarone, which is slower (~12 hours) and less effective for acute cardioversion (~50% at 12 hours, ~70% at 24 hours).[2,38,39] IV vernakalant may be used outside the US (60% success at 30 min). Moreover, IV infusion of K and Mg may double the cardioversion rate in case K is <4 mEq/L.[40]

iii. *May allow the progression to a rate-controlled permanent AF*. This depends on the severity of AF-related symptoms, their persistence despite rate control, the age of the patient (young → cardiovert), and the likelihood of AF recurrence.

4. Hospitalize the patient with severe symptoms or HF.

5. Perform an echocardiogram and look clinically for underlying cardiac or systemic diseases: acute HF, MI, PE, bleeding, thyrotoxicosis. Correcting these factors (e.g., diuresis and vasodilators for HF) may control the rate and eventually convert AF to sinus rhythm. In fact, DCCV is often ineffective in the presence of uncontrolled triggers or uncontrolled HF, as AF quickly recurs after cardioversion.

Table 10.4 Dosage of the drugs used for acute rate control.

1. Metoprolol 5 mg IV, to be repeated Q5 min up to 15 mg total. Then start oral metoprolol 25–50 mg Q6h if the IV doses prove effective and tolerated. The IV metoprolol effect lasts 5–8 hours. Alternatively, esmolol IV drip may be given (short-acting; effect lasts 10–20 min after the drip is off). *Landiolol* IV drip, an ultra-short acting β1-blocker with limited negative inotropic and hypotensive effects, may be used in hemodynamic instability or decompensated HFrEF (ESC) (half-life 4 min).

2. Diltiazem IV 0.25 mg/kg (~20 mg) bolus. May re-bolus with 0.35 mg/kg (~25 mg) in 15 min if no response to 20 mg, then start 5–15 mg/h IV drip in responders. The IV diltiazem effect lasts a few hours.[a] In comparison with β-blockers, diltiazem has:

- more hypotensive effects in general (vasodilatation)
- similar hypotensive effects in pre-shock, wherein BP depends on both the adrenergic and vascular tone
- less negative inotropic effect (than verapamil as well), but still not advised in systolic HF

3. Digoxin needs to be given as a load (0.5 mg, then 0.25 mg Q6–8 h × 1 or 2 = 0.75–1 mg load, oral or IV). The load is followed by 0.125–0.25 mg Qday

4. Magnesium: total IV dose ~5 g (e.g., 2 g over 15 minutes, followed by 3 g over 3 hours). It boosts the achievement of a rate <100 bpm by >50% via blocking the inward calcium channels in the AV node, hence prolonging AV nodal conduction.[40] It is recommended as an adjunct in all settings (class IIa ACC guidelines).

Acute monotherapy with β-blockers or CCBs is effective in most cases, the target ventricular rate in the acute setting being usually 80–110 bpm (ESC). In case of total non-response to one agent, switch to another; in case of partial response to one, combine two agents, then try to wean off the first one. β-Blockers are more effective in hyperadrenergic states (e.g., postoperatively). Avoid digoxin as a sole agent to control the heart rate, except with decompensated heart failure or low blood pressure.

[a]IV diltiazem may be used for a few hours, then oral diltiazem started 3 hours after discontinuation of the IV drip, with a daily oral dose equal to (mg/day): IV drip rate in mg/hr × 30 + 30. Short-acting diltiazem may initially be used Q6h.

V. Peri-cardioversion anticoagulation management

The risk of stroke in the peri-cardioversion period is ~8%, reduced to <0.5% with appropriate anticoagulation. For an AF episode that has lasted ***≥24 hours***:

1. Left atrial appendage imaging (TEE or CTA) or 3 weeks of anticoagulation is required before DCCV.
2. Anticoagulation is required for at least 4 weeks *after spontaneous or active cardioversion*, regardless of whether the patient's risk factors dictate long-term anticoagulant therapy.[2] AF conversion to sinus rhythm is followed by a few weeks of atrial hypocontractility, during which a thrombus may form then embolize once the atria fully recover their contractility. If the patient does not have an indication for chronic anticoagulant therapy, administer an oral anticoagulant for 4 weeks only. If warfarin is initiated, bridging with LMWH is necessary during the critical first few days after cardioversion.

For acute AF < 24 hours – Cardioversion of AF that has lasted <24 hours does not mandate TEE or oral anticoagulation before DCCV; heparin or one dose of LMWH is provided peri-cardioversion.[2,43] The issue is, however, that AF may have been asymptomatic for some time before symptoms developed; symptoms may correspond to acceleration of AF rather than its onset. In addition, one study has found that as many as 4% of patients with AF <48 hours have LAA thrombus, particularly if underlying heart disease is present.[44] A registry analysis found a stroke rate of ~1.1% after cardioversion of AF < 48 hours, exclusively in patients with CHA_2DS_2-VA ≥2.[45] A Finnish study found a similar risk of 1.1% in patients with AF duration of 12–48 hours (cardioversion much safer at <12 hours).[46] Thus a safe approach may be to perform TEE even if the presumed AF duration is <24 hours, except in patients with AF <12 hours *or* <24 hours with CHA_2DS_2-VA of 0 or 1, as per ESC, ACC, and Canadian guidelines, and to mandate 4 weeks of anticoagulation after DCCV even if AF <24 hours.[2,47,48] ACC and ESC accept forgoing the 4 weeks of anticoagulation when AF <24 hours with CHA_2DS_2-VA of 0 (class IIb).[43]

If the initial TEE shows LAA thrombus, anticoagulation should be given for at least 3–6 weeks, followed by a repeat TEE to document thrombus resolution before cardioversion. If thrombus persists, accept a rate-control strategy.[2]

For patients with LAA occlusive device who are not on anticoagulation, peri-cardioversion TEE or CT may be considered (class IIb) to rule out device thrombosis or peri-device leak, especially >5 mm, in which case acute and chronic anticoagulation would be recommended. In the absence of a large leak, peri-cardioversion anticoagulation does not seem necessary based on one registry.[49]

VI. Antiarrhythmic management after the acute presentation

In 10–20% of patients, DCCV fails or AF recurs after a few seconds or minutes of sinus rhythm, more so in the case of an active trigger, such as acute HF.[50] In up to 50% of patients, AF recurs within 2 weeks, which is the highest risk period.[50] ***Distinguish DCCV failure* from *immediate recurrence: in failure, no sinus conversion occurs at any time, not even for a beat,* whereas *in immediate recurrence, one or few sinus beats are seen before recurrence of AF. Failure*** is treated with a higher DCCV energy, a change in pad position/defibrillation vector, IV ibutilide pretreatment, or by pushing down the pads over an obese chest to improve the energy penetration. ***Immediate or early recurrence*** may benefit from a second attempt at DCCV after preparation with an antiarrhythmic drug for 3–4 days. Antiarrhythmic drugs reduce immediate recurrence but do not necessarily help with DCCV failure, as most of them actually increase the atrial defibrillation threshold (except ibutilide, sotalol, and dronedarone).

The AF recurrence rate is 70–80% at 1 year after cardioversion. Even when antiarrhythmic agents are used, the recurrence rate is ~35–60% at 1 year (~half),[50] this rate being higher in patients with multiple risk factors (Table 10.3).[37,51] This high failure rate underlines why a **rate-control strategy is the most realistic strategy in patients with many risk factors for recurrence or progression,** even more so if DCCV fails or if AF recurs within 2 weeks despite antiarrhythmic therapy. **The alternative would be AF ablation with acceptance of the potential need for multiple future ablations**, which is particularly compelling in HF.

Conversely, in *lower-risk* patients, antiarrhythmic therapy may be *considered after a recurrence rather than the first episode*, *and a shorter antiarrhythmic duration is desirable, as most recurrences occur early on (e.g., 1 month of flecainide);*[2] this may be followed by an as-needed, pill-in-the-pocket cardioversion of recurrences with flecainide. In fact, 55% of lower risk patients with low AF burden may experience a decline in AF burden over time (LOOP substudy).

The goal of a rhythm-control strategy is symptom control and quality of life improvement; thus, short and infrequent recurrences or mildly symptomatic recurrences of paroxysmal AF are not considered treatment failures in a patient who previously had severely symptomatic paroxysmal or persistent AF. Rate-slowing drugs should be continued throughout the rhythm-control approach to ensure adequate rate control during AF recurrences, unless the baseline sinus rate is slow.

Off-and-on, fast AF is typically more difficult to rate-control than permanent AF, as slowing AF spells leads to excessive slowing of the baseline sinus rate; this AF frequently requires tight rhythm control, including catheter ablation, or pacemaker placement.

An alternative to antiarrhythmic therapy is catheter isolation of the pulmonary veins, which successfully prevents AF in 70% of the treated cases over 1 year of follow-up.[2,12,52] It is indicated for the prevention of recurrent symptomatic paroxysmal or persistent AF, as second-line or even first-line therapy (Appendix 3).[2,12] If it fails, thoracoscopic surgical ablation is a next option. As a last resort, AV nodal ablation with ventricular pacing may be required.

VII. Decisions about long-term anticoagulation, including after bleeding events

A. Long-term anticoagulation

The annual risk of stroke in patients with AF not receiving any antithrombotic therapy ranges from 1% to 18%, and averages ~5% per year.[53] The risk is increased in both paroxysmal and permanent AF, although *less so in paroxysmal AF if AF burden is low or if AF is brief and infrequent* (Section X). Two validated clinical schemes, $CHADS_2$ and CHA_2DS_2-VA scores, help predict this risk (Table 10.5).[53] CHA_2DS_2-VA improves the predictive value of $CHADS_2$ and is particularly useful for further classifying a $CHADS_2$ score of 0 or 1.[2,54,55] For any level of $CHADS_2$ score, warfarin reduces the stroke risk by 75% and increases major bleeding ~2.5-fold.[56] ***The absolute stroke reduction with warfarin only overcomes the bleeding risk when the stroke risk is ≥1.7% per year; the equipoise point is 0.9% with the non-vitamin K oral anticoagulants (NOACs)***.[57] Aspirin has no effect on AF-induced stroke, and only reduces vascular-induced stroke by 21% while increasing major bleeding by 60%.[2,56]

Table 10.5 Stroke risk in patients with non-valvular atrial fibrillation not treated with anticoagulation.

$CHADS_2$ score		CHA_2DS_2-VA score[a]		Yearly stroke risk according to $CHADS_2$ score[b]	Yearly stroke risk according to CHA_2DS_2-VA score[b]
C: Congestive heart failure[c]	1	C: Congestive heart failure	1	0: 1.9%	0: <1%
H: Hypertension	1	H: Hypertension	1	1: 2.8%	1: 1.5–2%
A: Age ≥75	1	A: Age ≥75	2	2: 4.0%	2: 2.5–3%
D: Diabetes	1	D: Diabetes	1	3: 5.9%	3: 3.2%
S: prior stroke or TIA	2	S: prior Stroke or TIA	2	4: 8.5%	4: 4%
		V: Vascular disease (CAD, PAD, aortic plaque)	1	5: 12.5%	5: ~7%
		A: Age 65–74	1	6: 18.2%	6–9: 10–15%
			1		

[a]Female sex used to be included in this score, which used to be called CHA_2DS_2-VAS score. However, female sex conveys increased risk only in patients who already have a high stroke risk and with ≥2 non–sex-related risk factors, not in lower-risk patients with a non–sex-related score of 0 or 1. Hence ESC guidelines recommend eliminating sex from the score and just using the CHA_2DS_2-VA score.
[b]Numbers obtained from references 2 and 53.
[c]"C" mandates either one of the following (ESC): (i) reduced EF, or (ii) documented HF decompensation, whether EF is reduced or normal (i.e., diastolic HF included).

In the ESC and ACC guidelines, no antithrombotic therapy (not even aspirin) is recommended for patients with a CHA_2DS_2-VA score of 0, where the absolute stroke reduction with anticoagulation is marginal (≤0.5%), not justifying the bleeding risk. Anticoagulation is recommended for a score ≥2, and NOACs are recommended over warfarin. For a CHA_2DS_2-VA score of 1, ACC and ESC guidelines suggest oral anticoagulation after assessment of bleeding risk (class IIa).[2,43] In fact, for a score of 1, the benefit of anticoagulation is marginal, as the absolute stroke risk is 1.5–2% per year; the stroke reduction only slightly outweighs the bleeding risk. Anticoagulation is likely beneficial if the risk factor is age 65–74 (stroke risk ~3% per year), if the risk factor is severe (uncontrolled diabetes, severe HF), or if a NOAC is used.[58] Aspirin is not indicated for AF purpose in any subgroup (ESC class III).

$CHADS_2$ score does not apply to patients with *mechanical prosthetic valves* or *rheumatic MS*, who have a high stroke risk and require anticoagulation with warfarin regardless of the score. Warfarin is used in these patients, rather than NOACs. Also, regardless of $CHADS_2$ score, patients with hypertrophic cardiomyopathy and AF have a high stroke risk that warrants anticoagulation.

B. Bleeding risk

Before starting anticoagulation or aspirin, the patient's bleeding risk should be assessed. The HAS-BLED bleeding risk score may be used:[59]

> H, hypertension; A, abnormal liver/kidneys; S, stroke; B, bleeding history; L, labile INR; E, elderly >65; D, drugs (antiplatelet drugs or NSAID) or alcohol

A score ≥3 implies a high bleeding risk and requires frequent evaluations of anticoagulation therapy (Table 10.6). ***A high HAS-BLED score warrants the correction of bleeding risk factors rather than the exclusion of anticoagulation*** (ESC guidelines). Five of the seven HAS-BLED risk factors are modifiable: control hypertension, address prior gastrointestinal bleed, switch to NOAC if labile INR, avoid alcohol and NSAIDs, correct acute renal dysfunction.[2,60] ***Patients with a high HAS-BLED score usually have a high CHA_2DS_2-VA score and a high stroke risk, the absolute stroke risk increasing more sharply than the bleeding risk. Thus, these patients derive an even greater net clinical benefit from anticoagulation than patients with a low HAS-BLED score and should generally receive anticoagulation.***[60,61] The bleeding risk is not only high with anticoagulation but may be as high with aspirin in those patients.[62]

Along the same lines, a patient receiving anticoagulation who develops gastrointestinal bleed must receive optimization of his bleeding risk (PPI, endoscopies, interruption of aspirin and other insults).[63,64] Data suggest that anticoagulation may be safely resumed beyond the first 7 days of the bleed, with a dramatic reduction of thromboembolic risk and a similar bleeding safety compared to anticoagulation re-initiation later than 30–90 days.

C. Anticoagulation in acute TIA or stroke, and after intracranial bleed

Patients with AF who develop TIA should be started on effective anticoagulation as soon as possible. Conversely, anticoagulation is started 2–4 days after minor or moderate stroke, and 7–14 days after major stroke, given the risk of hemorrhagic transformation. The ELAN trial [65]

Table 10.6 Major bleeding risk associated with HAS-BLED risk score in patients receiving warfarin.

HAS-BLED score	Major bleeding per year
0	1%
1	1%
2	1.9%
3	3.75%
4	8.7%
5	12.5%

Data from Euro Heart Survey.

compared early initiation of DOAC (within 2 days for minor or moderate stroke, and days 6–7 for major stroke) vs. later initiation (days 3–4 for minor stroke, days 12–14 for major stroke): early initiation was safe and associated with a strong trend toward reduction of recurrent stroke at 30 days. It is reasonable to rule out hemorrhagic transformation by head CT before starting anticoagulation.

After an intracranial bleed, anticoagulation may be reconsidered at 4–12 weeks in patients with very high thromboembolic risk, especially mechanical valve or prior ischemic stroke, whose bleeding risk factor has been treated (e.g., HTN that is now controlled, berry aneurysm that is coiled or clipped, subdural hematoma that is either small or large but evacuated).[2] Anticoagulation is generally avoided after lobar/cortical bleed (amyloid angiopathy), but may be considered after limited deep cerebral bleeds. Meta-analyses of retrospective data showed a benefit of resuming anticoagulation after ICH.[2] In an analysis of ICH survivors with AF, a composite net benefit balancing ischemic stroke and ICH occurred when anticoagulation was resumed at 7–8 weeks after ICH.[66] However, 2 small randomized trials initiated NOAC at a median of 6–15 weeks after intracranial bleed (>3 weeks): recurrent intracranial bleed was numerically 2–4× higher with NOAC, and the 2-year mortality and ischemic stroke were similarly high with and without NOAC (APACHE-AF and SOS-start trials).[67] Thus, treatment is individualized, and anticoagulation is mainly considered in patients at highest embolic risk (e.g., mechanical valves, very high CHA_2DS_2-VA). LAA closure may also be done, as it only mandates a short anti-thrombotic course.

D. Therapy in patients with AF and CAD: Question of triple combination of aspirin, clopidogrel and oral anticoagulation

The major bleeding risk is ~1–2% per year with aspirin, and ~3% per year with warfarin. The addition of aspirin to warfarin increases the yearly bleeding risk to ~4% per year.[68,69] On the other hand, the triple combination of aspirin, clopidogrel, and an anticoagulant has a 4× higher major bleeding risk than aspirin + anticoagulant (12% vs. 3–4% yearly bleeding risk).[69] In patients with AF or LV thrombus who undergo stent placement, the question is whether the risk of this triple combination is warranted. According to WOEST (using warfarin), PIONEER-AF (rivaroxaban), RE-DUAL PCI (dabigatran), and AUGUSTUS (apixaban) trials, patients with AF undergoing PCI with DES may be treated with the **dual combination of clopidogrel and one anticoagulant**, with no aspirin therapy beyond the first 3–7 days after PCI (ACS in 50–61% of patients).[70–74] In fact, the dual combination clopidogrel-anticoagulant was much safer than the triple combination aspirin-clopidogrel-anticoagulant, used for 1–6 months, with similar protection from MI and stent thrombosis, significant bleeding reduction, and mortality reduction in one of the trials (WOEST). The combined inhibition of the thrombin pathway with anticoagulation and the ADP pathway with clopidogrel may lessen the importance of cyclooxygenase inhibition with aspirin. As a result, initial double therapy is currently recommended and preferred over initial triple therapy in all patients (clopidogrel + warfarin or preferably NOAC: apixaban 5 mg BID, rivaroxaban 15 mg QD, or dabigatran 150 mg BID).[2,75] Triple therapy, for 1 month only, may be considered in patients who have a combined high ischemic risk/low bleeding risk, as suggested by AUGUSTUS substudy.[76]

Beyond 1 year of PCI or MI, single therapy with an anticoagulant is recommended over combination therapy with clopidogrel or aspirin. This approach reduces mortality and bleeding without increasing ischemic events compared to anticoagulant + single antiplatelet (AQUATIC trial with any anticoagulant, mostly apixaban, AFIRE trial with rivaroxaban, and EPIC-CAD with edoxaban).[77–79] In the AQUATIC trial, patients who underwent stenting >6 months previously and who had a high residual ischemic risk derived dramatic mortality reduction with single anticoagulant vs. anticoagulant + aspirin (8.4% vs. 13.4% at 1.7 years) and a dramatic, >3-fold reduction of major bleeding. PCI was done for MI (72%) or was a complex or multivessel PCI; despite this high-ischemic risk, MI was not reduced by the addition of aspirin. *In fact, anticoagulation, per se, reduces not only embolic events but coronary events as well*; this was also well shown in old warfarin trials.[80–82]

E. Role of clopidogrel

The ACTIVE W study has shown that in patients with AF and moderate to high thromboembolic risk ($CHADS_2$ score 2 ± 1), warfarin monotherapy is clearly superior to the combination of aspirin and clopidogrel for the reduction of cardiovascular events (yearly rate 3.9% vs. 5.6%, $p < 0.001$), stroke (1.4% vs. 2.4%, $p < 0.001$), and even MI (trend), with a similar major bleeding risk (~2% per year).[83]

The ACTIVE A study has shown that the combination of aspirin and clopidogrel is superior to aspirin monotherapy for stroke prevention in AF (yearly rate 2.4% vs. 3.3%, $p < 0.001$), at the cost of more major bleeding (2% per year vs. 1.3% per year, $p < 0.001$).[84] Thus, the combination of aspirin and clopidogrel appears to be an option superior to aspirin but inferior to warfarin. Since this combination has the same bleeding risk as warfarin, it has no definite role in AF therapy, particularly with the availability of NOACs that facilitate chronic therapy.

VIII. Special situation: atrial fibrillation and heart failure. Optimal heart rate in heart failure

A. AF with acute HF

In a patient presenting with decompensated HF, AF may be:

a. secondary to HF
b. the cause of the cardiomyopathy and HF (AF-mediated cardiomyopathy)
c. the major trigger of HF decompensation in a patient with a previously stable cardiomyopathy

It should be assumed that either (b) or (c) is the case, but at the stage of decompensated HF, immediate DCCV may not be helpful.

In compensated HF, AF contributes to ~30–40% of cardiac output. Those patients have a large A wave with E/A reversal on echo, confirming the crucial role of atrial contraction. In fast AF, the loss of atrial systole and the reduction of diastolic filling time reduce cardiac output, which increases LA pressure and decompensates HF. However, once HF is decompensated, even if the patient converts back to sinus rhythm, the contribution of atrial systole to cardiac output will be marginal. In fact, decompensated patients have a very small A wave on echo, as the high LV diastolic pressure does not allow much filling during atrial contraction (Figure 10.1). At this point:

- ***Tachycardia of 100–110 bpm*** may be helpful, as it increases cardiac output and LV emptying by increasing the number of cardiac cycles per minute. Cardiac contractility also increases up to a heart rate of 100–110s in HFrEF, but declines beyond that (Bowditch revisited trials). Cardiac output and likely contractility and lusitropy improve up to a rate of 110s–120s in the stiff LV of HFpEF (based on pacing trials and β-blocker withdrawal trial; see Chapter 5, Section 3.V).

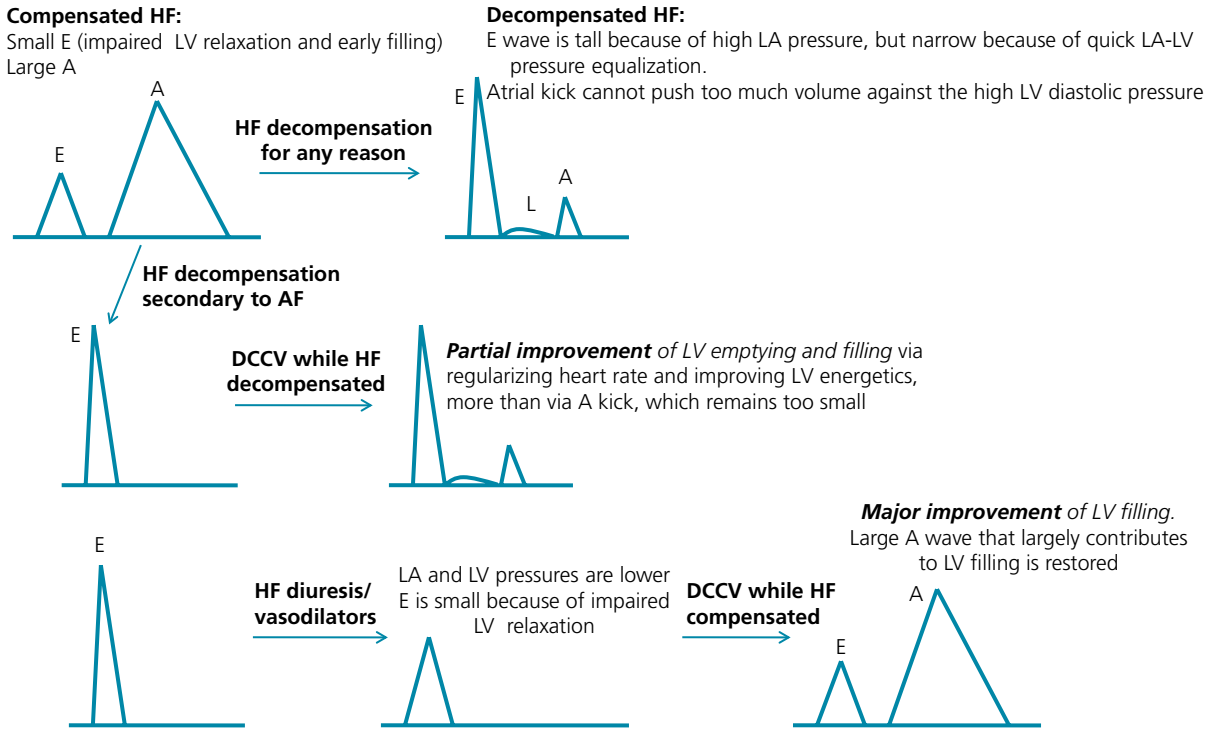

Figure 10.1 LV diastolic filling pattern in compensated HF, decompensated HF, decompensated HF secondary to AF, and effects of DCCV.

- ***Tachycardia >120 bpm*** is however counterproductive and reduces the contractility of the energy-depleted myocardium, cardiac output and VO_2 (particularly HFrEF).[85,86] AF needs to be acutely rate controlled to <110 bpm (ESC).
- ***Tachycardia >120–130 bpm*** (HFrEF) ***or >130 bpm*** (HFpEF) **with *severe hemodynamic compromise*** (shock, severe pulmonary edema) often needs acute cardioversion to improve LV energetics and contractility, unless AF is known to be permanent. Cardioversion improves CO, less so by restoring the marginal atrial kick, and more so by improving LV contractility and lusitropy at lower heart rates and by restoring a regular ventricular rhythm. However, DC cardioversion is plagued by the hazard of sedative drugs and a high risk of immediate AF recurrence in acute HF. Hence, pharmacological cardioversion with (i) IV amiodarone, and rate control with (ii) IV landiolol, (iii) IV digoxin, and (iv) IV magnesium may be the more realistic options. Amiodarone is, regardless, a top option for rate control acutely.

In addition, treatment of HF with diuresis and vasodilators slows down AF and possibly converts it (situation (a) above). ***Once HF is stabilized and diuresed,*** the target AF rate becomes ***<100 bpm***. Better yet, cardiovert AF; at the compensated stage, DC cardioversion is more likely to succeed, and the restored atrial kick is substantial. Also, sinus rhythm reverses AF-mediated cardiomyopathy.

In a patient presenting with new HF and a newly diagnosed AF, AF-mediated cardiomyopathy is the diagnosis in 50–60% of the cases (situation (b) above).[87–89] In any case, elective DCCV should be strongly considered after acute HF therapy (rhythm-control strategy). ***Awaiting HF stabilization increases the success and sustainability of cardioversion***.

B. Rate control in HF (Table 10.7)

C. Effect of AF on EF and value of AF ablation in HF

AF, by itself, even when rate controlled, reduces stroke volume and EF (=AF-induced cardiomyopathy). That is why trials of AF ablation in HFrEF have consistently shown an ***EF rise of 10–30% after ablation and EF normalization in 50–60% of patients***, mainly in persistent AF, even when AF rate is controlled (e.g., CAMERA-MRI trial and Hsu trial, where patients with controlled ventricular rate had EF improvement of 18 +/–13% after ablation).[88–90] Even in the PABA-CHF trial that compared AF ablation to AV nodal ablation with biventricular pacing, EF was 8% higher in sinus rhythm than in AF.[91]

This is partly explained by the *Frank–Starling relationship*. Less ventricular filling (preload) per cycle results in less contractility (preload-related contractility), lower stroke volume and therefore, lower EF. Patients must be at a compensated stage, preload dependent, able to increase their filling with atrial systole to benefit from the Frank–Starling relationship.

As importantly, ***irregularity of ventricular rhythm, by itself, reduces cardiac output*** (CO).[92,93] As such, one study of AF patients undergoing AV nodal ablation showed that irregular V pacing mimicking AF is associated with a 16% lower CO and a higher PCWP than regular V pacing at the same rate.[92] The very short RR interval reduces stroke volume more than the long RR interval makes up for it.[92,94] Rate irregularity creates harmful calcium mishandling and overload in the myocardium, as well as catecholamine activation (during pauses).

Table 10.7 Rate control of AF with or without HF.

No HF	β-Blocker or CCB or combination
Decompensated HF with low EF	No β-blocker and no CCB Diuresis/HF therapy IV digoxin or amiodarone or Landiolol IV magnesium (synergistic) Once compensated, start β-blocker then uptitrate it
Decompensated HFpEF +/– HFmEF	May use β-blocker or CCB
Compensated HF with low EF	β-Blocker (may be up-titrated faster than usually done in HF), digoxin

AF ablation in HFrEF – AATAC trial showed a mortality reduction with AF ablation vs. amiodarone in HFrEF (8% vs. 18% at 2 years).[95] CASTLE-AF trial randomized patient with systolic HF and symptomatic AF (paroxysmal or persistent [70%, long-standing persistent 30%]), who are relatively young (median age 65) and not morbidly obese (median BMI 29), to AF ablation vs. medical therapy (rhythm control in 30%, and rate control in the remainder as they previously failed amiodarone).[90] In comparison to medical therapy, AF ablation dramatically reduced mortality by 45% (13% vs. 25% at 3 years) and HF hospitalizations, despite the moderate-to-severe LA enlargement (median LA diameter 4.9 cm). Moreover, it improved EF by 7.3% in paroxysmal AF and 10% in persistent AF (vs. 0.2% in medical therapy). While AF recurrence rate was 50% in the ablation arm, AF burden was dramatically reduced by ablation, and, in fact, ***it was not necessary to eliminate AF but to reduce its burden***; AF burden best correlated with outcomes (AF burden was reduced from a mean of 51% at baseline to ~25% with AF ablation; AF burden <6% was associated with 3.3 times less death and HF hospitalizations). Repeat AF ablation was required in 24% of patients at a mean of ~1 year, and that was also common in AATC and CAMERA-MRI trials (33%). ***Persistence of some AF burden AND a frequent need for repeat ablations within one to several years seems the norm, but an effective one nonetheless.*** Even more dramatically, in the CASTLE-HTx trial of advanced HFrEF getting considered for LVAD or transplant, AF ablation showed a dramatic mortality reduction compared to medical therapy – amiodarone or rate control after amiodarone failure (6% vs. 20% at 1.5 years). AF ablation was beneficial despite proper baseline rate control (heart rate 80s), LA diameter of 49 ± 6 mm, 70% persistent AF at baseline, and a residual 20% AF burden. AF ablation is given a class I recommendation in HFrEF in both ACC and ESC guidelines, particularly when favorable features are present: AF believed to be the cause of HF, early HF stage, no severe atrial myopathy, paroxysmal or early persistent AF, no extensive LV scarring, and younger age.

Value of rhythm control with drugs and value of AV nodal ablation + CRT in all HF – Although AF ablation is preferred in HF patients with AF, rhythm control with drugs is likely also beneficial, based on EAST AFNET4 analysis of the HF subgroup. When rhythm control cannot be achieved, the APAF-CRT trial showed that ***AV nodal ablation with CRT pacing is still superior to medical therapy for permanent AF, even if QRS is <110 ms and the rate is controlled <100 bpm (mean 82 bpm)***. This strategy resulted in much less mortality (11% vs. 29% at ~2.5 years), HF hospitalizations, and physical limitation/dyspnea (HF with prior hospitalization and with any EF, EF < 50% in 70% of patients).[96,97] Hence ESC gives AV nodal ablation + CRT a class IIa recommendation in permanent AF with prior HF hospitalization and persistent symptoms (any EF, especially if age >70). In the HF setting, pharmacological rate control for symptomatic AF is least effective on HF outcomes and functional limitation (harmful irregularity +/– inadequate rate control).

HFpEF – Rhythm control, particularly via AF ablation, is highly beneficial in HFrEF, as in the earlier studies. But the **benefit likely extends to HFpEF and, to a lesser degree, to rhythm control with drugs**. In fact, in the *EAST-AFNET trial*, the subgroup of patients with HF (mostly consisting of HFpEF and HFmEF) derived twice the yearly benefit from rhythm control than non-HF patients (2.2% reduction in yearly CV events and 1.2% reduction in CV mortality).[31] Treatment mainly consisted of flecainide or propafenone (~40%), amiodarone, and dronedarone. Note that flecainide and dronedarone were avoided only in HFrEF, not HFpEF or HFmEF. In the *CABANA trial*, AF ablation significantly reduced mortality in HF patients (most of whom had HFpEF, 6.1% vs. 9.3% mortality at 4 years) and reduced CV hospitalizations in all patients with a high H2FPEF score.[32,33] As such, AF ablation is given a class IIa for HFpEF in the ACC AF guidelines.

IX. Special situation: atrial fibrillation with hemodynamic compromise: special rate-control and rhythm-control considerations

A. AF with borderline BP or with non–AF-related shock

In critical illness, a fast rate of up to 120 bpm may be appropriate and tolerated. In patients with borderline BP (90–100 mmHg), or full-blown shock not caused by AF (e.g., septic shock with AF at 120–150 bpm), 4 agents may be used for acute rate control <120 bpm. (i) IV amiodarone is usually the top agent. Amiodarone may precipitate hypotension but only during fast boluses (<30 minutes). Amiodarone has limited rhythm controlling effect in the first 12 hours. (ii) Digoxin IV may also be used but its vagal effect is ineffective in high catecholamine states. (iii) Landiolol and (iv) adjunctive magnesium are other options.

β-Blockers are not only avoided in shock but in pre-shock state, wherein the patient is dependent on the adrenergic tone and wherein β-blockers drop BP precipitously (e.g., severe hypovolemia, sepsis, bleeding). The exception is Landiolol IV drip, an ultra-short-acting and ultra-selective β1-blocker with limited negative inotropic and hypotensive effects, which may be used in cases of instability or decompensated HFrEF (ESC). In studies of ICU patients—including acute HF, cardiogenic or septic shock—even those requiring β-agonists, landiolol ↑ CO without ↓ BP; it selectively targets chronotropism without hampering the inotropic and vasoconstrictive effects of the β-agonists.[40]

B. AF with hemodynamic compromise attributed to AF (shock or massive pulmonary edema)

AF with clear-cut shock *and* a rate >150 bpm (or >120–130 bpm in HFrEF or >130 bpm in HFpEF) is often contributive to the shock and cardioverted emergently, except if AF is known to be permanent or a clear cause of hypotension is identified, such as massive

gastrointestinal bleed. Acute electrical cardioversion is, however, problematic as it requires sedation, unless the patient is in extremis: sedation, by itself, aggravates hypotension. Also, there is a high risk of immediate or quick AF recurrence after DCCV. As such, any of the following 2 antiarrhythmic options (plus 2 rate-controlling options) may be considered: (i) IV procainamide, cautiously, to be avoided in acute HFrEF as it has a negative inotropic effect (~60% cardioversion at 30–60 minutes); or (ii) IV amiodarone (fast rate control but slow cardioversion, ~50% at ~8–12 hours, 70–75% at 24 hours). (iii) IV magnesium is considered in all cases. (iv) IV Landiolol is considered for rate control of unstable patients that prove difficult to cardiovert. Regarding the concerns of using procainamide, it actually proved safer than amiodarone in stable VT in the PROCAMIO trial, with less hypotensive effect (patients with baseline EF 40% ± 13%).

DCCV has 2 drawbacks in unstable patients: (i) When there is an active trigger of AF (e.g., sepsis, HF), DCCV is unlikely to be successful and AF will likely recur soon after DCCV; (ii) it requires sedation, which exacerbates hypotension. As such, in the unstable patient, amiodarone or procainamide may be the only successful treatment acutely. Amiodarone is anyway the main option for acute rate control in unstable patients, besides Landiolol.

X. AF burden as a correlate and a driver of HF progression

As highlighted by CASTLE-AF, **AF burden** is a key concept in patients with off-and-on AF. AF burden is the percentage of time the rhythm is AF. Not all paroxysmal AFs are alike: a higher AF burden is strongly associated with a several-fold increase in the risk of HF and stroke. Along those same lines, progression from subclinical brief AF <24 hours to clinical AF or to AF episodes >24 hours is associated with a 4-time higher risk of HF hospitalization.[98] Also, the progression from paroxysmal to persistent AF is associated with more HF, stroke, and death.[99,100] Those concepts emphasize the importance of preventing AF burden progression through weight loss and BP reduction.

Appendix 1. Optimal heart rate and AF rate for optimal cardiac output

Atrial systole contributes to ~20–40% of LV filling (more so in stable HF, less so in decompensated HF). With loss of atrial systole, stroke volume declines and cardiac output risks declining by up to 40% at a similar heart rate.[101] In order to maintain cardiac output (CO), heart rate must rise; therefore, for the same patient under the same conditions, when going from sinus rhythm to AF, the heart rate rises. *AF rate has to be higher than sinus rate*, which explains why aggressive rate control in AF (rate <80 bpm, as in sinus rhythm) has not been more beneficial than lenient rate control. This may also explain that in HFrEF, lower heart rates <80 bpm have been associated with better outcomes only in sinus rhythm, not in AF.[102] One study has shown that AF only mildly affects exercise performance (duration), thanks to this heart rate increase.[103]

What heart rate achieves the maximal cardiac output in general? CO being equal to heart rate (HR) × stroke volume, 3 factors affect CO change with HR: changes in HR per se, contractility, and preload (the latter 2 determine stroke volume). Hence resting state must be distinguished from exertional states. ***At rest***, an increase in heart rate increases CO and increases myocardial contractility (Bowditch phenomenon) up to a certain point. However, there are pitfalls: (i) Beyond a certain point, an increase in heart rate at rest is accompanied by a reduction in diastolic time and LV preload, which may lead to a reduction of LV stroke volume (*particularly in preload-sensitive patients, on the upslope of Starling curve*). (ii) Bowditch effect is limited in HFrEF and lusitropy is limited in HFpEF (inotropism and lusitropy may not ↑ beyond 110 and 120 bpm, respectively). Eventually, the reduction in stroke volume (e.g., by half) overwhelms the increase in HR, and CO starts declining; an extreme of that would be a tachycardia >200 bpm, leading to hemodynamic collapse. Another example would be hypotension occurring during dobutamine stress testing: increasing HR to 130 may cut stroke volume by >50% in hypovolemic patients with low preload.

Conversely, ***during exercise***, venous return increases (→ ventricular preload increases), and therefore, not only HR increases but also stroke volume. Therefore, CO continues to rise with rates up to the maximal HR (220 – age), except potentially in the Bowditch-limited HFrEF (Bowditch revisited trials).

What heart rate achieves the maximal cardiac output in AF? In AF, the effect of HR is further compounded by its irregularity; in fact, LV filling and stroke volume sharply and exponentially decrease with a short RR cycle length <500 ms (>120 bpm), while they more gradually increase with lengthening of the RR cycle length, up to 700 ms only (85 bpm). The very short RR interval reduces stroke volume more than the long RR interval makes up for it.[92,94] In addition, the pre-preceding RR interval affects stroke volume in a manner opposite to the preceding RR interval: a long-short RR sequence may lead to a pulse deficit (the long R-R interval empties the ventricles and is followed by a short R-R interval on an empty underfilled ventricle).

In a resting state, in AF, one study using echocardiography VTI monitoring at various RR intervals has shown that CO continues to rise until HR of 90–140 bpm (depending on the preload), then it starts declining.[104] ***The mean heart rate at which cardiac output was maximal was 122 bpm, which is somewhat consistent with Gosselink et al (85–120 bpm)***.[94]

How about systolic HF? In HF, the maximal CO seems to be achieved with a HR ~***100–110 bpm*** at rest and with exertion, in sinus rhythm or AF, not because of reduced diastolic filling beyond this rate, but because of a paradoxical reduction in contractility (Bowditch revisited trial).[86]

How about HFpEF? A moderately high **heart rate up to 120 bpm** enhances myocardial contractility and *accelerates relaxation kinetic*, but a heart rate >130 bpm impairs lusitropy.[105,106]

Appendix 2. Antiarrhythmic drug therapy

Antiarrhythmic drugs (AADs) have 3 main uses. *First*, they are used to prevent AF recurrences if a rhythm-control strategy is selected (most important use of AADs) (Figure 10.2). *Second*, AADs are used as an adjunctive therapy that increases the effectiveness of DCCV by reducing immediate recurrence of AF. For this purpose, these drugs are mainly given when AF has been persistent for >3 months, or there has been an early recurrence after DCCV. *Third*, AADs may be used to acutely cardiovert AF (this is their least effective use).

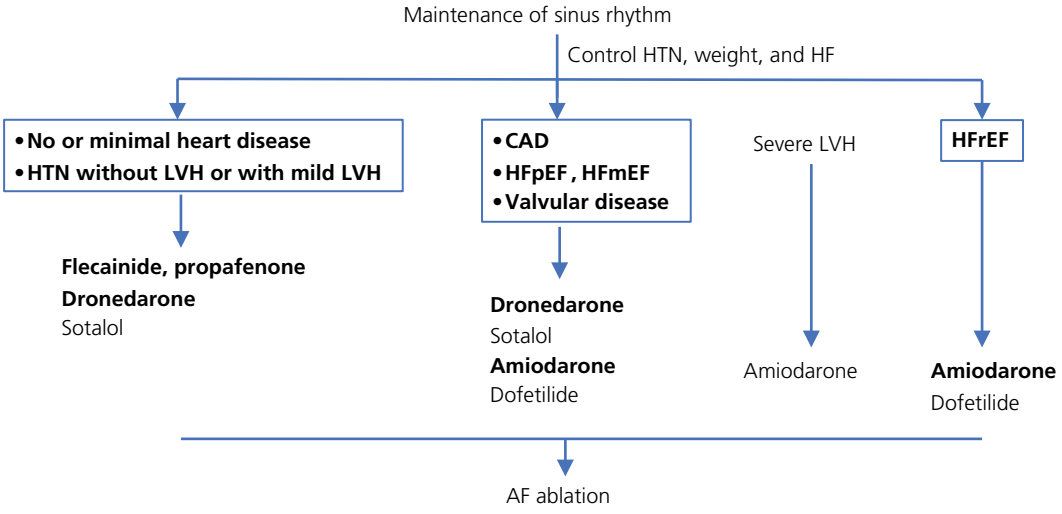

Figure 10.2 Chronic antiarrhythmic drug therapy for the prevention of recurrent paroxysmal or persistent atrial fibrillation. Inspired by the ESC and ACC guidelines.[2]

β-Blockers have shown a moderate efficacy in reducing AF recurrence, comparable to sotalol in 2 studies,[107,108] which makes them an appropriate first-line therapy in many instances. However, these agents may potentially aggravate vagally mediated AF.

A. Class III agents

- ***Amiodarone*** is a class III AAD that can ***be used in any cardiac condition, including HF or any cardiomyopathy, without an increase in cardiac mortality***. It is the only drug that can be used with substantial LVH. It is also the most effective drug for long-term prevention of AF. In addition, it possesses a class I Na blocking effect and a sympatholytic effect that allows rate control.

  It has a fast-onset AF rate-controlling effect and VT/VF antiarrhythmic effect (minutes in case of IV administration, 1 to several hours in case of oral administration), but a slow-onset atrial antiarrhythmic effect (~12 hours with IV administration). Most of the early amiodarone effect is a β-blocker effect rather than a class III effect, which explains that, at 24 hours, amiodarone is only slightly superior to placebo in cardioverting AF.[108]

  The amiodarone sympatholytic effect is a downstream effect on the β-adrenergic pathway, not a direct β-blocker effect. Despite its sympatholytic effects, amiodarone has little to no negative inotropic effect, and by itself, it causes mild vasodilatation yet no significant hypotension; therefore, it is well tolerated in HF. The issue is with the IV formulation of amiodarone, which is mixed with solvents having pronounced vasodilatory effects and some negative inotropic effects, causing hypotension in ~15% of patients. This is aggravated by a quick administration of the IV bolus and much reduced by a slow administration (e.g., 30–60 minutes). Hypotension is neither seen with oral amiodarone (mild vasodilatory effect) nor with an aqueous IV formulation free of solvent.

  Being fat-soluble, amiodarone has a large volume of distribution and a very long half-life (60–120 days).
  - Amiodarone IV dose: 150 mg IV over 10 minutes followed by 1 mg/min infusion for 6 hours, then 0.5 mg/min. When used for VT/VF, amiodarone may be reloaded with 150 mg IV for breakthrough VT/VF, up to 2.2 g/day. Switch to oral amiodarone the next day or a few days later.
  - Amiodarone oral dose: start with an oral load of 600–800 mg/day for 10 days for a total of ~10 g, then 100–200 mg/day.

Note also that amiodarone may raise the levels of digoxin and warfarin (the "A–D" and "A–W" interaction). These drugs should routinely be reduced by one-half and levels followed closely when amiodarone is started. Amiodarone also increases the levels of the NOACs, particularly rivaroxaban.

- ***Sotalol*** is an oral class III AAD with a non-selective β-blocker effect. The β-blocker effect starts at low doses and is already half-maximal at 80 mg/day, while the class III effect starts at doses of 160 mg/day. Sotalol is inferior to amiodarone but is particularly effective for chronic AF prevention in patients with CAD, where it may be as effective as amiodarone.[109] It is not typically used for acute AF cardioversion as it has limited acute efficacy (up to 30%). IV sotalol may be used, but no modern trial addressed it (in one study from 1998, it was inferior to IV flecainide). Sotalol is associated with a 1.5–2% risk of TdP that is dose-dependent. Use sotalol cautiously in HF and renal failure (↓ dosage to once daily if GFR <60, and avoid if GFR <40). In HF, sotalol may be used slowly but is better avoided, because, in HF, the β-blockers that have demonstrated a positive effect on mortality are preferred.
- ***Dronedarone*** is a drug similar to amiodarone without the iodine moiety. It lacks the pulmonary and thyroid toxicity of amiodarone, affects QTc less than amiodarone, and has a shorter half-life (1–2 days compared to 2 months). It is less effective than amiodarone in the prevention of AF recurrence, but ***it is the only AAD that has shown a reduction in cardiovascular hospitalizations, cardiovascular mortality, and stroke in patients without HFrEF*** (ATHENA trial); however, it increases mortality in class III or IV HFrEF and in persistent AF, and should not be used in persistent AF without a planned DC cardioversion.[110–112] It ***may be used in CAD*** (unlike class Ic)***, stable HFpEF, and HFmEF***

(ESC and ACC HFpEF pathway). It was commonly used in HFpEF and HFmEF in the EAST-AFNET4 trial.[31] The ATHENA substudy suggests that dronedarone improves cardiovascular outcomes in HFpEF and HFmEF.[113]

Dronedarone has numerous drug interactions. It interacts with digoxin, diltiazem, and the NOACs, but not with warfarin.

- ***Oral dofetilide*** may be used for chronic rhythm control and is relatively safe in HF and CAD (DIAMOND trials). It is associated with a 2–3% risk of TdP. Use it cautiously in renal failure and avoid it with GFR <20. It has a slow and limited efficacy for AF cardioversion (up to 30–40% at 2 days, SAFIRE-D trial).
- ***Intravenous ibutilide*** may be used for acute rhythm control (1 mg infused over 10 minutes). Ibutilide is the drug with the fastest acute cardioversion effect (10–30 minutes) and is effective in 30–50% of patients. A second dose can be given 10 minutes later. Ibutilide also increases the efficacy of DC cardioversion in those who fail the first attempt.[114] It increases QTc by ~60 ms. The risk of TdP is ~3–4%, and this is increased if EF <30% (5–10%). Magnesium infusion (2 g) immediately before ibutilide may mitigate this risk. *It is contraindicated in decompensated HF or EF <30–35%*.
