- IVC plethora or poor inspiratory collapse implies high RA pressure and probable RV volume overload. Note, however, that IVC dilates with positive-pressure ventilation. Thus, for patients who are mechanically ventilated, IVC dilatation and IVC respiratory variations correlate poorly with RA pressure, yet a small IVC < 1.2 cm at end-expiration still correlates with low RA pressure; even slight IVC collapsibility (>15%) correlates with volume responsiveness.
- Cardiac output can be estimated from the LVOT pulsed-wave Doppler. Aortic or LVOT flow variation > 15% with respiration (mechanical ventilation) or with passive leg raising predicts volume responsiveness.

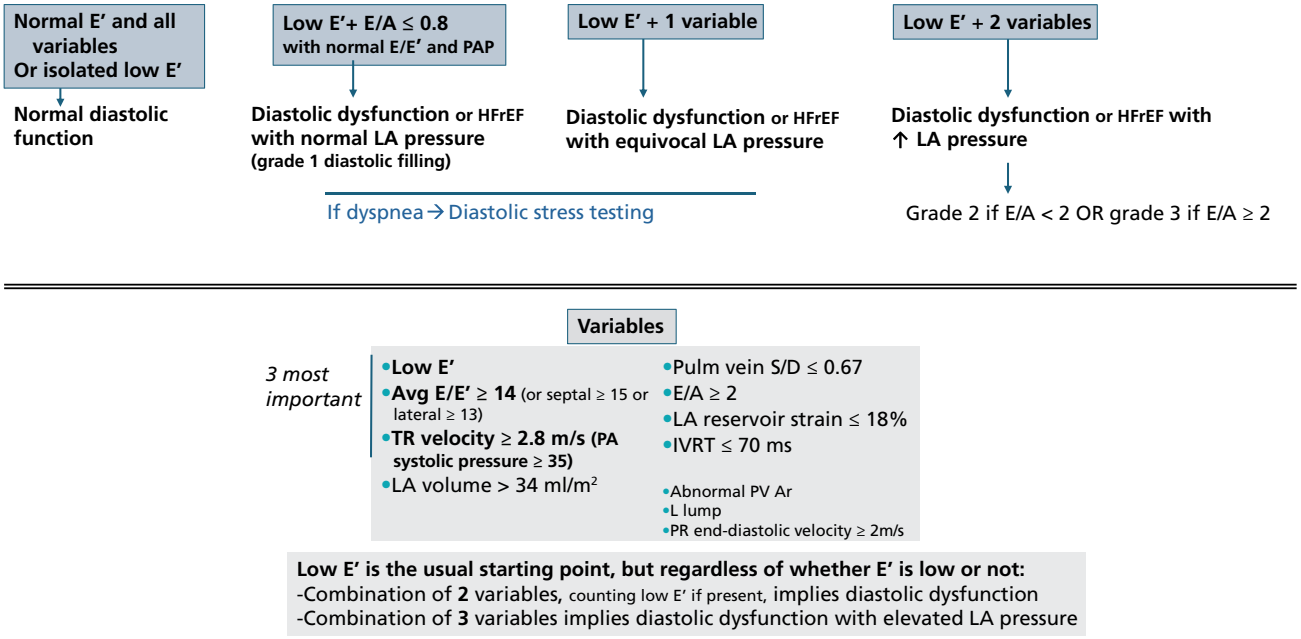

Figure 33.47 Diagnosis of diastolic dysfunction and assessment of LA pressure.
Notes:

- Low E′ is defined as septal <6 or lateral <7 or average <6.5 cm/s. For patients 40–65 years old, the cutoffs are <6, <8, and <7 cm/s, respectively. For patients <40 years old, the cutoffs are <7, <10, and <9 cm/s, respectively.
- *HFrEF inherently has diastolic dysfunction*. The goal in HFrEF is not to diagnose or report diastolic dysfunction, but to assess LA pressure.
- **Diastolic stress testing consists of measuring E/E′ and TR velocity during *exercise testing or 1 min passive leg raising* to establish diastolic HF in dyspneic patients with grade 1 diastolic dysfunction or with equivocal diastolic function**. Up to 50% of HFpEFs have exertional dyspnea with normal LA pressure at rest, but usually with some features of diastolic dysfunction, typically low E′. In normal individuals, E increases with exercise (higher venous return), but myocardial recoil and compliance increase as well (E′), so E/E′ remains unchanged. In diastolic dysfunction, E′ minimally increases or not at all, whereas E rises excessively. Exertional E/E′ ≥15 (septal) or ≥14 (average) or TR velocity >3.2 m/s establishes diastolic HF. A higher TR velocity cutoff of 3.2 m/s is used during exercise, as PA pressure may normally rise to 50–55 mmHg with exercise (flow mediated). Semi-supine cycling is typically used, with imaging at peak stress, but treadmill testing may be used with imaging at 1–2 minutes of recovery, at a heart rate of ~100 bpm. In fact, even if peak imaging is possible, mitral E and E′ velocities are assessed once E and A are no longer fused. When elevated, filling pressures remain so for a few minutes in recovery.

This figure is compliant with 2025 ASE guidelines.

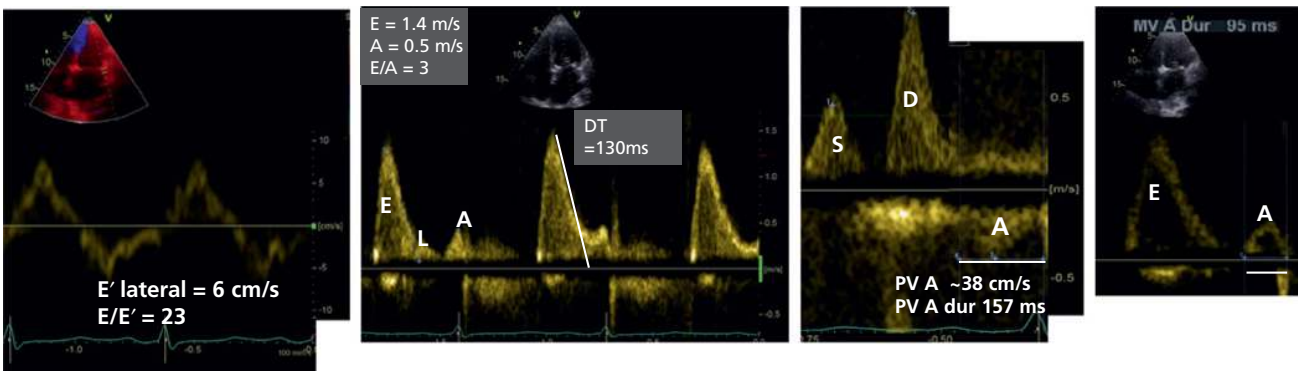

Figure 33.48 Severe grade 3 diastolic dysfunction with: (i) low lateral E′ 6 cm/s and very low A′, barely visible; (ii) high E/E′ of 23; (iii) high E/A >2; (iv) short E deceleration time <160 ms; (v) L lump between E and A; (vi) pulmonary vein S depression with S/D ratio of ~0.5 (<0.67); (vii) pronounced pulmonary vein (PV) A reversal indicating high LVEDP, with PV A velocity >35 cm/s and (PV A duration-mitral A duration) >30 ms (62 ms).

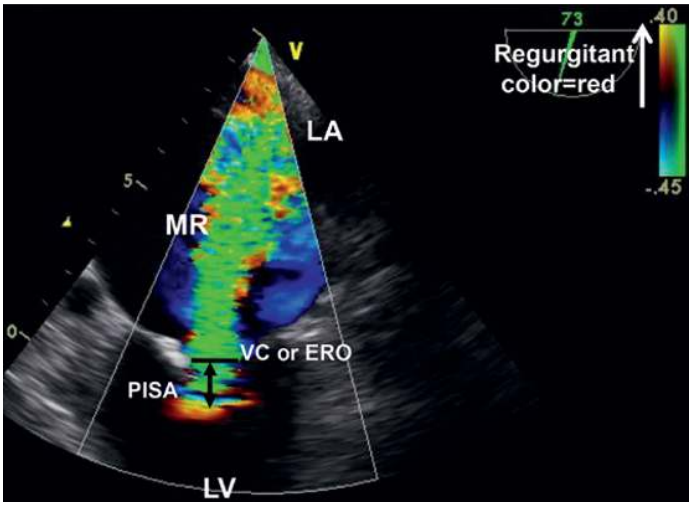
VIII. Additional echocardiographic hemodynamics

Doppler hemodynamics mostly rely on the Bernoulli equation:

$$\text{Peak instantaneous pressure gradient} = 4\left(\text{peak velocity}^2{}_{\text{across the orifice}} - \text{peak velocity}^2{}_{\text{proximal to this orifice}}\right)$$

The velocity proximal to the obstruction being usually ~1 m/s, the square of this velocity is negligible in patients with a high velocity across the obstruction. High-flow states with diffusely elevated velocity proximal to the obstruction (e.g., throughout a hyperdynamic LV-LVOT) are an exception. Outside this exception, the simplified Bernoulli equation is applied:

$$\text{Peak instantaneous pressure gradient} = 4\,\text{peak velocity}^2{}_{\text{across the obstruction}}$$



MR flow at the LA side = MR flow coming from the LV
ERO x Peak MR velocity on CW Doppler = PISA area x aliasing velocity of the red color
= 2π (PISA radius)^2 x aliasing velocity

→ERO = 2π (PISA radius)^2 x aliasing velocity/ peak MR velocity
~ (PISA radius)^2 /2 if aliasing 40 cm/s

Regurgitant volume = ERO x MR VTI
Regurgitant fraction = Regurgitant volume/ total forward mitral flow
= Regurgitant volume/ forward stroke volume at the mitral annulus (diastole)

Figure 33.49 Aliasing velocity of the regurgitant color, which is red in this case and equal to 40 cm/s, is used for PISA calculation. It is the one that should be set at 40 cm/s for the simplified equation. The PISA calculation may also be performed for AI: the peak velocity of the AI spectral envelope is used to calculate ERO, and the VTI of the AI envelope is used to calculate the regurgitant volume. ERO, effective regurgitant orifice area; VC, vena contracta.

A. Proximal isovelocity surface area (PISA) of MR (Figure 33.49)

As blood flows back from the LV to the LA, it accelerates and converges into multiple sequential hemispheres before reaching the narrow neck of the mitral orifice. This is the convergence flow seen on the LV side, and it is equal to the regurgitant flow seen in the LA. The closer this flow is to the mitral orifice, the higher its velocity, at one point equaling then superseding the aliasing velocity. All points across one hemispheric line have the same velocity.

If the line where aliasing occurs is chosen, the velocity of this line would be equal to the Nyquist limit. The inner boundary of the flow convergence is the vena contracta, and the outer boundary is the aliasing color. Because PISA is a hemisphere rather than a 2D circle, its surface area equals $2\pi r^2$ rather than πr^2, and its velocity is equal to the aliasing limit. The aliasing velocity of the regurgitant color (usually blue on TTE, red on TEE) is the one used for calculation.

The effective regurgitant orifice area (ERO), which corresponds to the narrow regurgitant orifice (or vena contracta), is then calculated using the continuity equation. An ERO ≥ 0.4 cm^2 indicates severe MR. In order to accurately visualize a rounded PISA and measure its radius, the Nyquist limit should be reduced to 40 cm/s; moreover, at this Nyquist limit, the simplified ERO equation applies (ERO ~ PISA radius^2/2).

The PISA principle may also be used to calculate the aortic ERO in AI in an apical view, but it is more technically challenging to delineate the hemisphere of PISA AI than MR; ERO ≥ 0.3 cm^2 indicates severe AI and this usually corresponds to PISA radius ~0.7 cm. PISA may also be used to calculate MVA in MS.

Peak CW velocity of MR is used to calculate ERO by the PISA method. Subsequently, VTI velocity of the same CW MR waveform is used to calculate the regurgitant volume (Figure 33.49). For AI, peak early AI velocity is used to calculate ERO, then VTI velocity of the same CW AI waveform is used to calculate the regurgitant volume.

In case of multiple MR jets, one study validated the use of both radii for calculating PISA area: PISA area = $2\pi R1^2 + 2\pi R2^2$ (Papolla C, et al. J Am Soc Echocardiogr 2020; 33: 838). This is followed by ERO calculation, and equates to calculating then adding the EROs of both jets, using the same peak MR velocity.

B. Other modality of regurgitant volume calculation

As an alternative to PISA, the regurgitant volume of MR or AI may be calculated using the continuity equation at the level of the LVOT and the mitral valve (**volumetric method**):

Stroke volume at the LVOT = LVOT VTI × 0.785 × LVOT diameter^2

Stroke volume at the mitral annulus = transmitral VTI × 0.785 × annular diameter^2

Transmitral VTI is obtained by tracing the diastolic PW annular inflow, E–A, in an apical view. The cursor is placed at the level of the annulus, more proximal than the standard MV inflow at the leaflets' tips; mitral annular diameter is also measured in diastole, in an apical view.

The difference between these 2 stroke volumes is the regurgitant volume of MR or AI. LVOT stroke volume is the larger stroke volume in AI, while mitral stroke volume is the larger stroke volume in MR. **In both MR and AI, a regurgitant volume ≥60 ml/beat**

or a regurgitant fraction ≥50% indicates severe regurgitation. This calculation has pitfalls, particularly the measurement of the mitral annular diameter. LVOT and the mitral annulus are assumed to be circular, while they are in fact elliptical. Moreover, it cannot be used in patients with combined MR and AI, as the flow at neither the LVOT nor the mitral annulus represents the net forward flow. Flow at the RVOT represents the net input and output flow of the left heart regardless of left-sided regurgitations, and can be used to calculate both MR volume (mitral annular volume-RVOT volume) and AI volume (LVOT volume-RVOT volume). Also, MS or severe MAC increases mitral annular velocity in the convergence zone and falsely increases the mitral annular flow. With the volumetric method, **ERO may be backcalculated** after obtaining the regurgitant volume: ERO = Regurgitant volume/regurgitation VTI.

The same regurgitant volume and fraction define severe MR and severe AI, yet a smaller ERO defines severe AI (0.3 cm^2) vs. MR (0.4 cm^2). This is because diastole is longer than systole, hence AI flow is more prolonged and results in a similar regurgitant volume for a smaller ERO than MR (regurgitant volume = ERO × regurgitant VTI, the latter being affected by flow duration). Conversely, for TR, an ERO of 0.4 cm^2 corresponds to a smaller regurgitant volume (45 ml), as the regurgitant VTI is smaller on the right (lower RV-to-RA pressure gradient).

C. Pitfalls in MS assessment, pitfalls in mitral valve area calculation using pressure half-time, and various methods of mitral valve area calculation (Figures 33.50, 33.51)

Since it is easy to align the Doppler beam with the mitral inflow on the apical views, the echocardiographic determination of transmitral gradient is usually highly accurate.

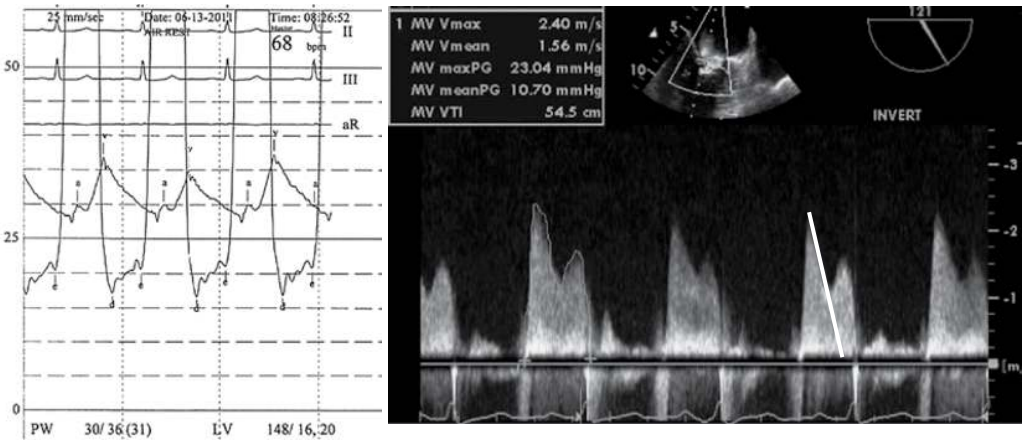


Figure 33.50 Simultaneous LV pressure and PCWP recording is shown on the left, with a mean transmitral pressure gradient of 10 mmHg. The transmitral Doppler flow velocity is shown on the right. The peak velocity is >2 m/s, which suggests MS (may also signify MR or severely restricted LV filling with hypervolemia). The mean pressure gradient obtained by tracing the Doppler envelope is ~11 mmHg at a rate of 70 bpm, suggesting severe MS.

The valve area calculation using the pressure half-time method, i.e., the steepness of deceleration of E velocity (*white line*), yields a valve area of 2.6 cm^2. In fact, E velocity falls steeply with a pressure half-time of 80 ms. However, the valve area is calculated invasively at 1.3 cm^2. This discrepancy is expected in light of the patient's severe systemic hypertension (180/100 mmHg) and increased LVEDP. When LV compliance is impaired, LV diastolic pressure increases steeply and therefore, for the same orifice area, LA–LV diastolic pressure gradient decrements faster. This leads to a faster pressure half-time for the same orifice area and creates the false impression of a larger orifice area. The pressure half-time method of orifice area calculation is inaccurate in cases of impaired LV compliance and high LVEDP. However, *even in this case, there is no LA-LV diastasis and E-wave decay never touches the baseline before A onset, which implies severe MS regardless of MVA calculation (when heart rate < 80 bpm)*. A similar limitation of the pressure half-time is seen when MS is associated with AI.

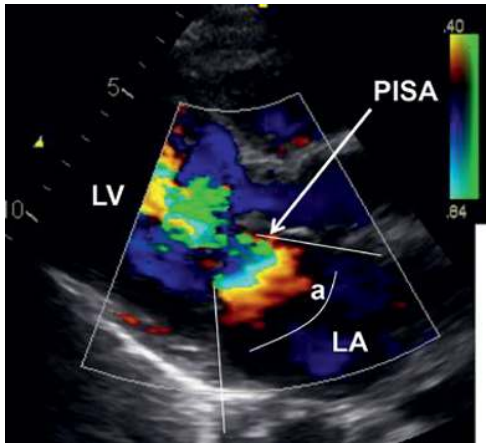

Figure 33.51 PISA of MS on a long-axis view. PISA of MS consists of flow acceleration on the LA side of the mitral valve (≠ PISA of MR, which is on the LV side). On the LA side, the mitral leaflets form an acute angle (≠ obtuse angle on the LV side for MR); thus, PISA of MS is not usually a hemisphere but a cone with an angle (*a*) that corresponds to the angle formed by the mitral leaflets, and angle adjustment is applied during PISA calculation:

MVA × peak diastolic velocity across the mitral valve = 2 π (PISA radius)^2 × red aliasing velocity × **a/180°**

On continuous-wave Doppler, the downslope of the mitral inflow E wave can be used to estimate the mitral valve area. A *slow decay* corresponds to severe MS, wherein the LA pressure remains higher than LV pressure throughout diastole (no diastasis). The time it takes the pressure gradient to decrease in half, i.e., the time it takes the peak velocity to decrease by 29%, is the pressure half-time (PHT): PHT = 0.29 × deceleration time (Figure 33.36). Mitral valve area (MVA) is equal to 220/PHT. However, for the same valve area, LA and LV pressures more readily approximate in the case of poor LV compliance or severe AI that briskly increases LV diastolic pressure, which makes the decay look steeper and leads to overestimation of the mitral valve area (i.e., less severe). *This is more commonly the case in elderly or severely hypertensive patients with MS.* However, even in those cases, *there is no LA-LV diastasis, i.e., E wave decay never touches the baseline before A wave, which implies severe MS regardless of MVA calculation (when heart rate < 80 bpm).* The reverse may happen in the first ~3 days after mitral valvuloplasty, wherein the impaired LA compliance maintains a high LA pressure, which prolongs PHT, even though MVA has improved; yet, E wave achieves diastasis, which serves as a hint to MS amelioration.

In the case of MS associated with concomitant MR or high-output state, the early LA–LV gradient is increased, creating a steep early E flow decay; however, because of MS, the slope of the E flow decay in mid/late diastole is slow. MVA calculation by the pressure half-time method remains accurate using this later slope. In atrial fibrillation, the pressure gradient varies between beats but the shape and the slope of the mitral Doppler envelope remain unchanged, and thus MVA calculation remains accurate.

There are three other modalities for the calculation of MVA:

a. *Continuity equation.* The stroke volume across the LVOT is: (LVOT area × LVOT VTI). The stroke volume across the mitral valve is: (MVA × MV VTI). Therefore:

$$\text{MVA} = \left(0.785 \times \text{LVOT diameter}^2 \times \text{LVOT VTI}\right) / \text{MV VTI}$$

This equation cannot be used in cases of: (i) concomitant MR, where the flow across the LVOT is lower than the flow across the mitral valve, or (ii) AI, where the flow across the LVOT is higher than the flow across the mitral valve.

b. *PISA of the mitral valve.* As opposed to PISA of MR, which is seen on the LV side, a hemisphere of flow acceleration is seen on the LA side in MS. An adjusted PISA equation may be used (Figure 33.51).

c. *Planimetry.* Planimetry consists of tracing the restrictive orifice on the mitral valve short-axis view ("fish mouth"). However, the image should be frozen at the actual leaflet tips, not more proximally where the valvular area would be overestimated. On the other hand, calcium or a high gain may blur the orifice boundaries and underestimate the valvular area. Nevertheless, *planimetry— particularly by 3D TTE— is considered* ***the superior method of MVA calculation by echo***, as it does not require complex calculations and is independent of chamber compliance.

The estimation of the valvular area using 1 of the 4 methods (mitral inflow pressure half-time, continuity equation, PISA method, and planimetry) may be subject to measurement errors. While echo measures the gradient very accurately, a high gradient does not necessarily imply severe MS; mild MS with MVA > 1.5 cm^2 may have a severe gradient in the presence of tachycardia or high-output state. Invasive hemodynamics may be valuable for the assessment of MS whenever there is discrepancy between echocardiographic MVA and transmitral gradient; and whenever it is not clear whether the patient's symptoms or pulmonary hypertension are purely secondary to MS, or rather secondary to mild MS + high-output state, MS + LV diastolic dysfunction, or intrinsic pulmonary arterial hypertension. *A hybrid method may be used for MVA: measure CO invasively and measure transmitral gradient simultaneously by echo*. Then apply Hakki equation: MVA = CO/√gradient. The LA and LV pressure behavior and diastasis cannot be directly assessed by this method, but may be indirectly gauged by the E slope on echo. **In summary**, a practical definition of severe MS may consist of the following—esp. (iii): *(i) mean gradient >10–15 mmHg at a heart rate <75–80 bpm; or* ***(ii) slow E-wave*** *decay and PHT, regardless of rate; or* ***(iii) E wave that never returns to baseline at a rate <75–80 bpm*** *(lack of diastasis)*.

D. Pitfalls in PHT use for AI assessment (Figure 33.52)

A compensated or mildly decompensated chronic AI is characterized by a gradual LV diastolic pressure slope and an increase in LVEDP that remains much lower than the aortic pressure, e.g., LVEDP of 20 mmHg with a diastolic aortic pressure of 70 mmHg. On Doppler, this corresponds to a gradual drop of the regurgitant flow velocity with a PHT that is > 250 ms, even if AI is severe (but remains <400 ms). Acute AI or decompensated chronic AI with LV failure is characterized by a steeply rising LV diastolic pressure and equilibration of LVEDP and aortic end-diastolic pressure. On Doppler, this corresponds to a steep drop of regurgitant flow velocity with a short pressure half-time < 250 ms. Thus, a reduced PHT not only correlates with the severity of AI but with its acuity and the LV state (compensated vs. decompensated). Occasionally, AI with severe underlying LV dysfunction may have PHT < 250 ms even if AI is only moderate.

E. Correlation between hepatic venous Doppler and RA pressure. Correlation between pulmonary venous Doppler and LA pressure (Figure 33.53)

F. Systolic PA pressure

$$\text{In the absence of pulmonic stenosis: Systolic PA pressure} = 4\ \text{TR}_{\text{velocity}}{}^2 + \text{RA pressure.}$$

G. Diastolic PA pressure

Measure the end-diastolic velocity of the pulmonary regurgitant flow. The end-diastolic gradient between PA and RV is 4 × (end-diastolic velocity of PR)^2. Thus:

$$\text{Diastolic PA pressure} = 4 \times \left(\text{end-diastolic velocity of PR}\right)^2 + \text{RV end-diastolic pressure}$$

RV end-diastolic pressure being equal to RA pressure:

$$\text{Diastolic PA pressure} = 4 \times \left(\text{end-diastolic velocity of PR}\right)^2 + \text{RA pressure}$$

PR velocity being a small number, smaller than TR velocity, the calculation of PA diastolic pressure is more subject to error than the calculation of PA systolic pressure. A 0.3 m/s error is relatively larger than 0.3 m/s error on TR velocity.

H. Other modality of PA pressure assessment

Assess *RV ejection* across the pulmonic valve using PW on the short-axis view. A **notched peak ("W shape") signals mid-systolic closure of the pulmonic valve** as RV succumbs against a high pressure (94% of pulmonary arterial hypertension have the W sign). This W sign may also be seen with M mode across the pulmonic valve. Also, quick peaking of this RVOT velocity in <90 ms (=acceleration time) indicates PH. In fact, mean PA pressure may be estimated as = 80 – (0.5 × acceleration time).

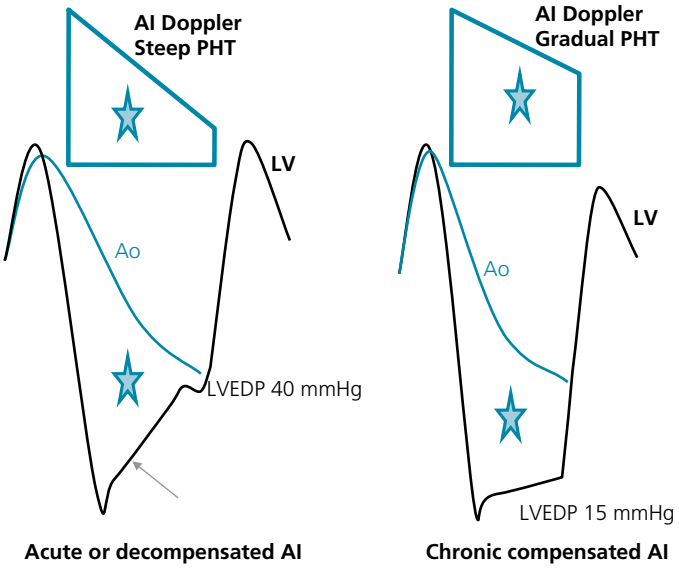

Figure 33.52 LV–aortic pressure tracings in acute AI and chronic AI. In acute AI, the steep diastolic approximation of LV and aortic pressures (triangle, *star*) translates into a similarly steep AI Doppler. PHT: pressure half-time.

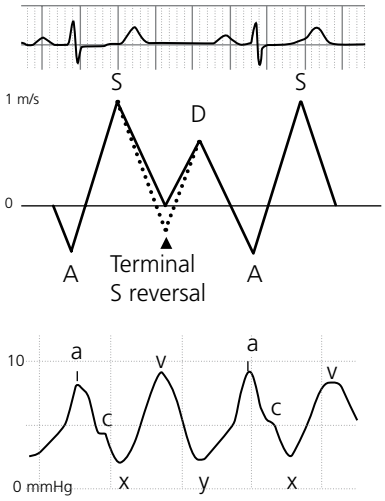

Figure 33.53 Correlations between A, X, V, and Y waves on the LA pressure tracing and S, D, and A flow velocities on the pulmonary venous Doppler. S flow corresponds to the X descent, D flow corresponds to the Y descent, and the A wave corresponds to A-flow reversal (S=X, D=Y). S and D flows are antegrade, while A flow is retrograde. The S wave may be notched and divided into S_1 and S_2 as a result of the C wave. Normally, D (Y) is slightly larger than S (X) in young individuals < 40 years old, who have a brisk diastolic LV "sucking"(Y), and less prominent rise of LA pressure during atrial kick (lower A wave and post-A descent X). S is larger than D in individuals older than 40, more so with further aging (as A and post-A descent become more prominent). Disease states:

- In the case of *LV failure* with elevated atrial pressure, the V wave is large, the Y descent is deep, and the X descent is usually blunted because it is carried up by the large V wave. The blunted X descent leads to ***S-flow blunting*** with terminal S reversal, and the deep Y descent leads to a large D flow.
- Retrograde A wave is pronounced and prolonged and X (S) is large, >D, in *compensated* diastolic dysfunction, wherein LA and LV pressures are high during the A kick (LVEDP ↑), but normal throughout the remainder of diastole. S goes from blunted in decompensated LV failure to extra-large in compensated LV dysfunction.
- S flow is blunted or fully reversed in the case of MR.
- *Tamponade,* on the other hand, is characterized by a ***blunted Y descent/D flow*** because of impeded diastolic filling.
  Similar correlations apply to RA pressure and IVC/hepatic venous Doppler flow.

I. Calculation of LVEDP from AI Doppler flow

The end-diastolic AI velocity corresponds to the gradient between the diastolic aortic pressure and the LVEDP. Using the non-invasive blood pressure:

$$\text{LVEDP} = \text{diastolic BP} - 4 \times (\text{end-diastolic AI velocity})^2$$

J. Calculation of LA pressure from MR Doppler flow in patients with any degree of MR

The peak MR velocity corresponds to the gradient between LV systolic pressure and LA pressure. LV systolic pressure being equal to the aortic systolic pressure in the absence of AS (~ non-invasive systolic BP), LA pressure is equal to:

$$\text{Systolic BP} - 4 \times (\text{MR velocity})^2$$

K. Calculation of the peak LV systolic pressure in patients with AS

The peak-to-peak gradient in AS corresponds to ~70% of the peak instantaneous gradient. Therefore:

$$(\text{systolic LV pressure} - \text{systolic BP}) = 0.7 \times \left(4 \times \text{peak velocity}^2\right)$$

If the systolic BP is 140 mmHg, and the peak velocity is 5 m/s, the systolic LV pressure is:

$$0.7 \times \left(4 \times 5^2\right) + 140 = 210\,\text{mmHg}$$

L. Calculation of Qp/Qs ratio in the case of a shunt

Normally, the pulmonary flow (Qp) is equal to the systemic flow (Qs). In left-to-right shunt, Qp is larger than Qs, while in isolated right-to-left shunt Qs is larger than Qp. Qp/Qs is the pulmonary-to-systemic flow ratio. Qp/Qs is equal to:

$$(\text{VTI} \times \text{diameter at the RVOT}) / (\text{VTI} \times \text{diameter at the LVOT})$$

PW Doppler is used. RVOT measurements are done on the aortic short-axis view, tilted to the RVOT. The reverse ratio is used for Qp/Qs calculation in PDA. In PDA, the flow across the RVOT is proximal to the shunt and corresponds to Qs, whereas the flow across the LVOT corresponds to Qp.

IX. Prosthetic valves

A. Differentiate a biprosthetic valve from a mechanical valve (see Figures 33.54–33.56)

A bioprosthetic valve is characterized by an echodense sewing ring and *3 large struts/vertical columns* in the center of the valvular orifice. The prosthetic leaflets are attached to those struts. Two leaflets may be seen in a single view. The sewing ring and the struts are usually mounted over a metallic frame (stented bioprosthesis). Occasionally, an aortic prosthesis may be stentless.

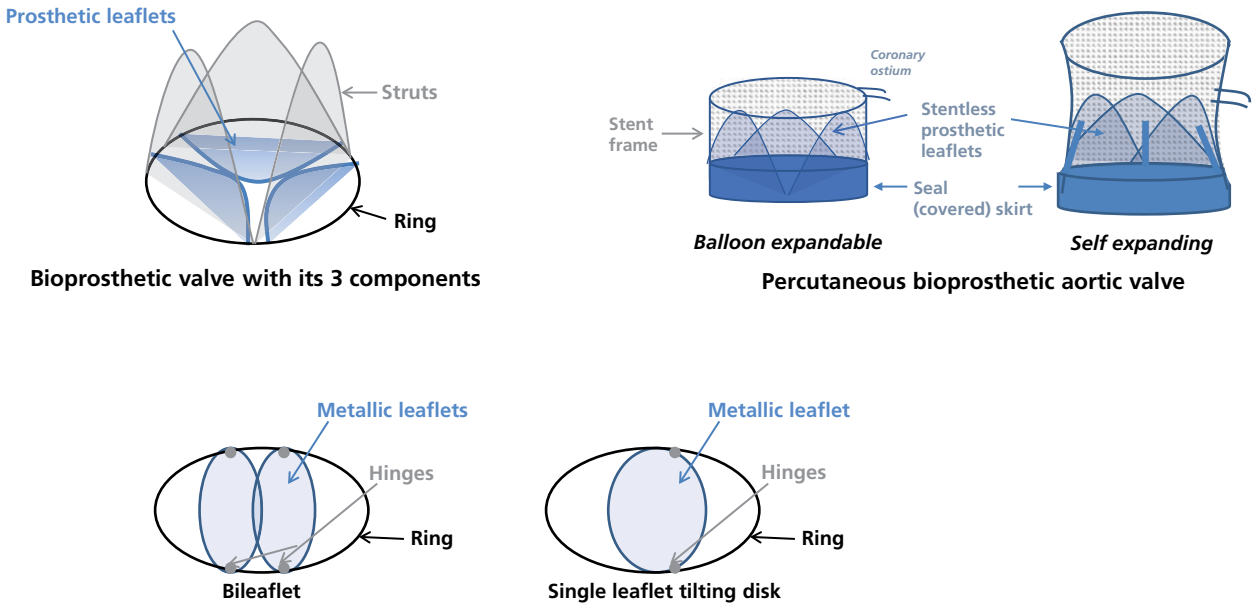

Figure 33.54 Types of prosthetic valves. Surgical bioprostheses typically have a metallic stent frame that extends from the sewing ring to each strut. They have 3 struts and 3 leaflets even in the mitral position. Percutaneous bioprostheses have no struts bulging inside the valve, hence the lower profile. A bileaflet metallic valve has 2 hinges and 3 orifices – 1 smaller central and 2 lateral. *The rings of prosthetic valves are* ***circular and flat***, unlike the complex 3D native valve annuli *and mitral annuloplasty rings*.

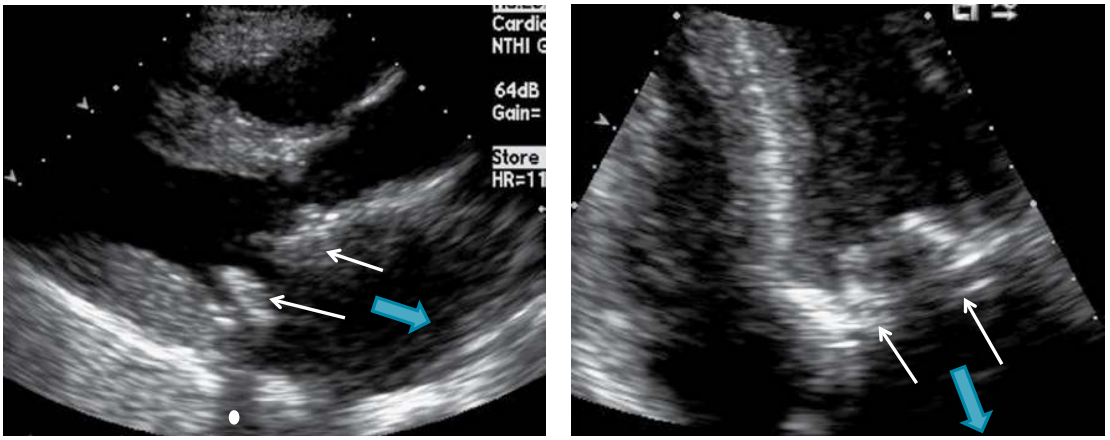

Figure 33.55 Bioprosthetic porcine valve as evidenced by the large struts/vertical columns in the center of the mitral orifice on the long-axis view and 4-chamber view (2 of the 3 struts are seen, *arrows*). The ring and the struts are hyperechogenic because of the metallic stent frame.

It may be difficult to see prosthetic valves because of the sewing ring at the annulus. This may shadow the valvular structure and the Doppler flow. Here, black shadowing is seen posteriorly, behind the struts (*dot*). Also, there is shadowing/reverberations from the leaflets themselves in the case of a mechanical valve or a heavily calcified bioprosthetic valve, which limits visualization.

However, it is often ***possible to assess aortic prosthesis regurgitation by TTE Doppler***. This is done on parasternal long-axis and apical views, because the ventricular side is not intercepted by the valve. It is ***hard to assess mitral prosthesis regurgitation by TTE Doppler*** because the regurgitant flow and the LA are both shadowed behind the mitral valve (*thick arrow*). However, there would still be a large PISA on the ventricular side, and the increased forward E velocity can still be assessed. TEE is most helpful for mitral prosthesis assessment, because TEE looks directly at the LA.

It is possible to assess aortic or mitral prosthesis stenosis by analyzing forward flow velocities.

(a) **(b)**

Figure 33.56 **(a)** Metallic mitral prosthesis. As in bioprostheses, a hyperechogenic metallic ring is seen (*arrows*). In metallic prostheses, thin reverberating leaflets are moving within the ring (*arrowhead*), while in bioprostheses, thick struts/columns are seen within the ring.

(b) Aortic mechanical prosthesis, with 2 metallic points (hinges) in the middle of the aortic orifice (*arrows).* This is a St. Jude bileaflet valve. Evaluation of AI with color Doppler is possible, as the flow will be directed toward the LV (*arrowhead*) and not shadowed by the valve or its ring.

A mechanical valve has an echodense ring but *does not have struts*. It has 1 or 2 metallic hinges that are seen as points or lines in the center of the orifice when the valve opens. The leaflets shadow and reverberate around those hinges during motion. There are 2 hinges in a St. Jude metallic valve, and 1 hinge in a single-leaflet tilting disk. In addition, with mechanical valves, prosthetic valve clicks are seen on spectral Doppler (dark narrow band on spectral display); these are not seen with normally functioning bioprostheses.

A mitral valve annuloplasty ring is seen as a dense echogenic annulus. A partial posterior ring often mimics posterior mitral annular calcifications, while a full ring may mimic the ring of a bioprosthetic valve (on the parasternal long-axis view, an echodense dot is seen both posteriorly and anteriorly at the annular level).

Prosthetic leaflets are difficult to see because of the sewing ring at the level of the annulus. This may shadow the valvular structure and the Doppler flow. Also, there is shadowing and/or reverberation from the valve itself in case of a mechanical valve or a heavily calcified bioprosthetic valve, which limits visualization. Shadowing means that metal or calcium creates a black shadow that hides all structures behind it, including the Doppler flow. Reverberation means that the ultrasound signal "ping-pongs" back and forth between metallic or calcified structures, such as between different sides of a prosthesis or ring or calcified valve, creating multiple duplicates of these structures.

B. Prosthetic valve gradients

Inherently, prosthetic valves are mildly obstructive. In fact, a peak velocity of up to 3 m/s and a mean gradient of up to 20 mmHg are normally seen across the aortic valve; a velocity of 3–4 m/s or a mean gradient of 20–35 mmHg may also be seen across a normally functioning aortic prosthesis but requires further evaluation. A peak velocity of up to 1.9 m/s and a mean gradient of up to 6 mmHg may be seen across the mitral prosthesis. Several mechanisms explain these Doppler gradients across structurally normal valves (Table 33.4). Higher

Table 33.4 Besides the occluder profile, 4 causes of pressure gradient across a prosthetic valve.

1. **Pressure recovery, particularly across a bileaflet valve**
   The smaller central orifice in bileaflet valves may give rise to a high-velocity jet. This corresponds to a localized pressure drop that is largely recovered once the central flow reunites with flow from the 2 lateral orifices. Doppler recording often includes this high-velocity jet, which leads to overestimation of the gradient and thus, underestimation of EOA
2. **Patient/prosthesis mismatch**
   Prosthetic EOA is too small in relation to the patient's body size, resulting in abnormally high postoperative gradients (EOA ≤ 0.85 cm^2/m^2 of BSA for aortic prosthesis, ≤1.2 cm^2/m^2 for mitral prosthesis). Prosthesis may function adequately at rest but is unable to accommodate the hemodynamics of exercise
   Mostly occurs with mitral prosthesis ≤ 27 mm in size or aortic prosthesis ≤ 21 mm
3. **High-flow state or severe regurgitation across the valve increases velocity and gradients**
   a. In this case, the use of the simplified Bernoulli equation ($P = 4\ V_A^{\ 2}$) further overestimates gradient. Use the true Bernoulli equation ($P = 4\ [V_{prosthesis}^{\ 2} - V_{LVOT}^{\ 2}]$), acceleration time, or dimensionless index (LVOT VTI/aortic VTI) for assessment of aortic stenosis. For mitral prosthesis, use PHT (<130 ms suggests high-flow state or MR rather than MS)
   b. Dynamic LVOT obstruction following aortic valve replacement: ~10% of AS patients have asymmetric septal hypertrophy (>1.5:1). Upon relief of the aortic obstruction, the afterload reduction unmasks dynamic subaortic obstruction, and SAM may be seen
4. **Prosthetic obstruction** (thrombus, pannus, degenerated bioprosthesis)

Because of the occluder profile, most prostheses have EOA of 1.5–3 cm^2 with mild gradient.
EOA, effective orifice area; VTI, velocity–time integral.

velocities/gradients may be related to structural disease (thrombus, pannus, degenerated bioprosthesis); on the other hand, high gradients may not be manifest in patients with prosthetic dysfunction and low cardiac output state, hence the importance of using other features to diagnose valvular dysfunction (Tables 33.5, 33.6; Figures 33.57, 33.58; see also Question 25 in Chapter 6). The analysis of leaflet motion and structure on TEE allows the differentiation between a dysfunctional prosthesis that requires operative correction and a structurally normal prosthesis. For instance, a high transprosthetic gradient with a normal leaflet motion corresponds to a normally functioning valve with a high velocity. Also, cinefluoroscopy is a very helpful adjunctive technique that allows analysis of the mechanical prosthesis leaflet excursion (to assess stenosis) and the prosthesis seating (to assess dehiscence and regurgitation). Gated cine-CT is helpful as well.

Table 33.5 Echocardiographic differentiation between a physiologically high gradient and an intrinsic aortic prosthesis obstruction.

	Normal	**Stenosis**
Peak velocity	<3 m/s	>4 m/s
TEE and cinefluoroscopy	Normal leaflet excursion and structure	Abnormal
Dimensionless index[a]	>0.30	<0.25
Contour of transaortic Doppler	Triangular, early peaking	Rounded, symmetrical
Acceleration time (AT)[b]	<100 ms	>100 ms
Effective orifice area (EOA)[c]	>1.2 cm^2	<0.8 cm^2

[a]Dimensionless index = LVOT VTI/aortic VTI.
[b]AT (acceleration time in milliseconds) is measured as the duration from the onset of aortic ejection to the maximal jet velocity.
[c]EOA is calculated using the continuity equation.

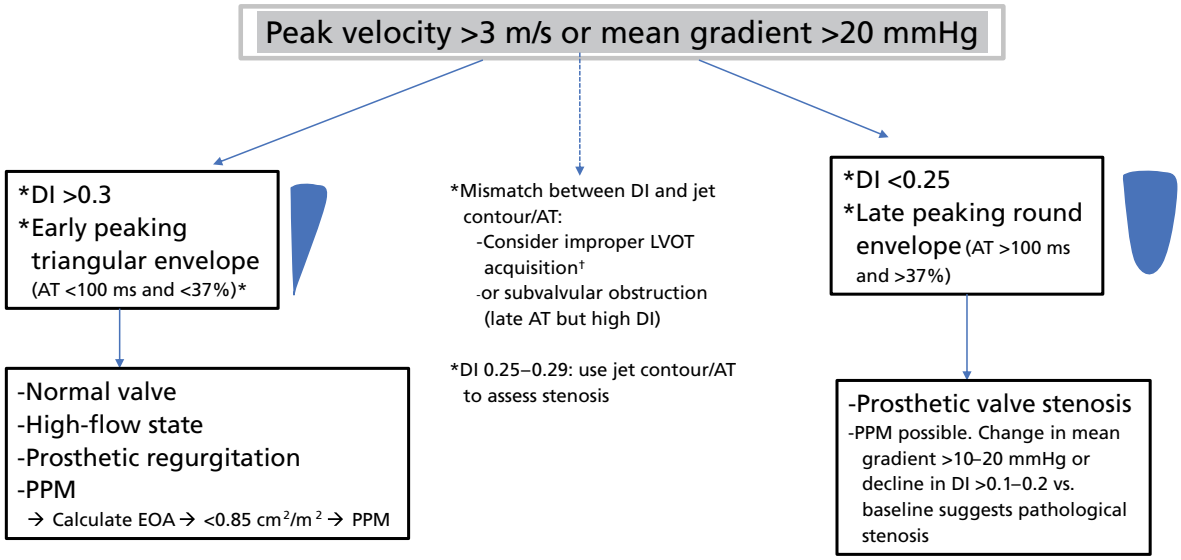

Figure 33.57 Approach to elevated prosthetic aortic gradient. *AT <100 ms or <37% of the whole ejection time is short AT. †LVOT cursor too close or too far from the valve. DI, dimensionless index.

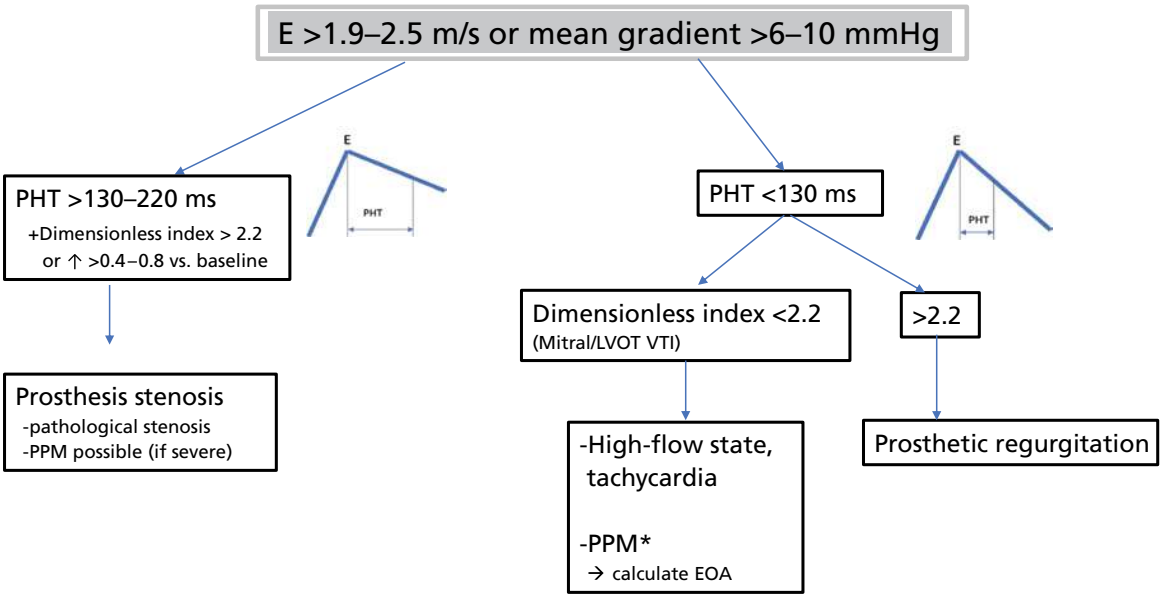

Figure 33.58 Approach to elevated prosthetic mitral gradient. *PPM is often not severe, hence PHT is often <130 ms (it may be prolonged in severe PPM).

C. Prosthetic and periprosthetic valvular regurgitation

Prosthetic valves normally have mild closure backflow, which manifests as a small central jet with a tilting disk valve and 2 small crisscross jets with a bileaflet valve. Also, paravalvular leaks are frequently seen, especially early postoperatively (5–20%), and these are usually mild and hemodynamically insignificant. Several echocardiographic and fluoroscopic features suggest significant regurgitation. More specifically, dehiscence or rocking movement suggests paravalvular regurgitation, while immobile "stuck" strut(s) suggests valvular regurgitation. On echo-Doppler, the following features, some of which are indirect features, suggest significant regurgitation:

a. Worsening of LA or LV size or function, or worsening of PA pressure and RV function
b. Paraprosthetic regurgitation involving *>30% of the sewing ring* circumference. This is assessed on the short-axis view of the aortic and mitral valves. 10–30%= moderate
c. Aortic diastolic flow reversal in the case of aortic prosthesis
d. A very large jet diameter (vena contracta). This is typically visible in transprosthetic regurgitation rather than the paraprosthetic one, especially in the aortic position (long- and short-axis).
e. Large PISA (on the apical view for the mitral valve, long-axis view for the aortic valve, i.e., views where PISA is not hidden by shadowing)
f. Green color suggesting turbulent flow
g. Intensity and shape of the CW Doppler envelope (dense regurgitant envelope in AI or MR; steep deceleration in AI with a steep PHT)
h. In the case of mitral prosthesis, high E velocity with high dimensionless index may suggest severe regurgitation or severe stenosis. If PHT is also low, <130 ms, regurgitation is the likely cause of the high velocity

X. Brief note on Doppler physics and echo artifacts

A. Doppler physics

The Doppler probe emits echoes at a certain frequency and captures the frequency of the reflected pulses; the change in frequency is called Doppler shift. This shift allows the calculation of the flow velocity (the flow is what modifies the emitted frequency). In PW Doppler, reflected echoes are detected from only one particular site, called the sample volume. The transducer "gate" opens for a specific period of time that corresponds to the depth of the sample volume. The transducer emits pulses and captures reflected pulses intermittently, at a specific rate called pulse repetition frequency (PRF) or sampling rate, which corresponds to the depth of the volume interrogated.

The PW must sample each reflected pulse at least twice during each cycle to appropriately measure the reflected frequency (and thus the velocity) (Figure 33.59). If the reflected frequency is more than half the sampling rate, this frequency cannot be accurately measured. The maximum frequency that can be accurately measured is half the PRF and is called the Nyquist limit (the Nyquist limit frequency has a corresponding Nyquist velocity limit). Thus, if blood flow is faster than the Nyquist velocity, its velocity cannot be appropriately sampled and measured. Deeper structures necessitate longer travel time and, thus, a lower sampling rate or Nyquist limit. As compared with superficial structures, it is harder to detect higher velocities of deeper structures, particularly if a high-frequency transducer (TEE) is used.

To measure higher velocities, increase the Nyquist limit and shift the baseline in one direction, so that velocities up to 2× Nyquist limit can be detected.

Color Doppler is a collection of PW Dopplers, as it captures multiple sample volumes along the sector interrogated, and displays a color for each sample volume. The size of the color corresponds to the size of the flow but also to its velocity in relation to the Nyquist limit; that is how the same MR volume may look more or less severe depending on the setting, flow velocity, and eccentricity. Changing the Nyquist limit or the color gain changes the perceived size of the flow.

CW Doppler continuously sends out and receives ultrasound waves, and thus does not have a Nyquist limit.

The transducer emits waves of a certain frequency (both for ultrasound and for Doppler imaging) and captures the reflected frequency of blood (Doppler) but also cardiac structures (ultrasound). A high frequency provides better axial and lateral resolution; however, the high-frequency waves get more attenuated and have reduced penetration. Therefore, TEE and vascular ultrasound transducers are high-frequency transducers (~7.5 MHz) as the imaged structures are superficial. A TTE transducer has a low frequency (~2.5–3.5 MHz). Deeper structures necessitate longer travel time and, thus, longer pulse wave duration and lower pulse frequency; the velocities of deeper structures are better resolved with a lower-frequency transducer.

B. Artifacts

While being aligned with the flow allows better assessment of velocities, being orthogonal to a structure allows a better 2D definition of this structure, a better definition of its dimension (e.g., LVOT diameter is better measured in the long-axis than the apical view), and a better assessment of myocardial thickening. It also allows a better measurement of Doppler jet diameter (e.g., vena contracta of MR or AI is best measured in the parasternal long-axis view). This is due to the fact that axial resolution is superior to lateral resolution. *Moreover, lateral resolution worsens with depth, as it depends on the beam width at each level.* In fact, at a deep level, signals are reflected and backscattered from the entire slice thickness. This is called ***beam width artifact*** and may affect both echo and Doppler signals (Figures 33.60, 33.61). In addition, at a certain depth, strong reflectors adjacent to the image plane may appear in the image plane; this is called ***side lobe artifact***. A calcified aortic valve may create the impression of calcium in the LA on the apical view; the posterior mitral annular calcium may create a band artifact in the LA.

Range ambiguity artifact. For both echo imaging and color Doppler, the ultrasound probe samples signals from a certain depth at a determined time interval. A structure B that is at twice the depth of structure A will reach the transducer at the next sampling time for A, which results in this deep structure appearing close to the superficial structure A. This is called *range ambiguity artifact* and is seen with deep imaging.

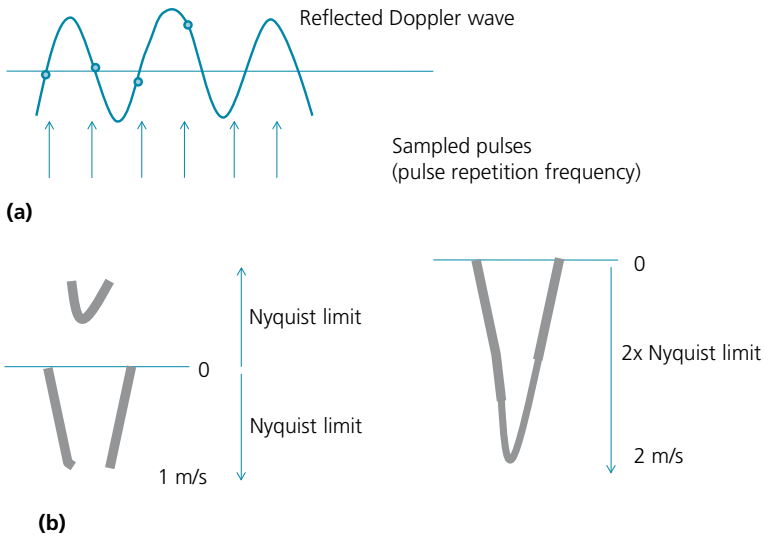

Figure 33.59 **(a)** Frequency of the reflected wave. On pulsed-wave Doppler, there must be two sampled pulses for every reflected wave, allowing adequate tracing of the waves (*dots*) and measurement of the frequency. One pulse per cycle does not allow appropriate delineation of the waves. **(b)** If the PW velocity exceeds the Nyquist limit (leading to aliasing), shift the baseline into one direction; this allows sampling of velocities of up to 2× Nyquist limit. The thickness of the envelope corresponds to the range of frequencies across the sample volume. Slow flow leads to a large range of velocities across the sample volume and a thick envelope (spectral broadening).

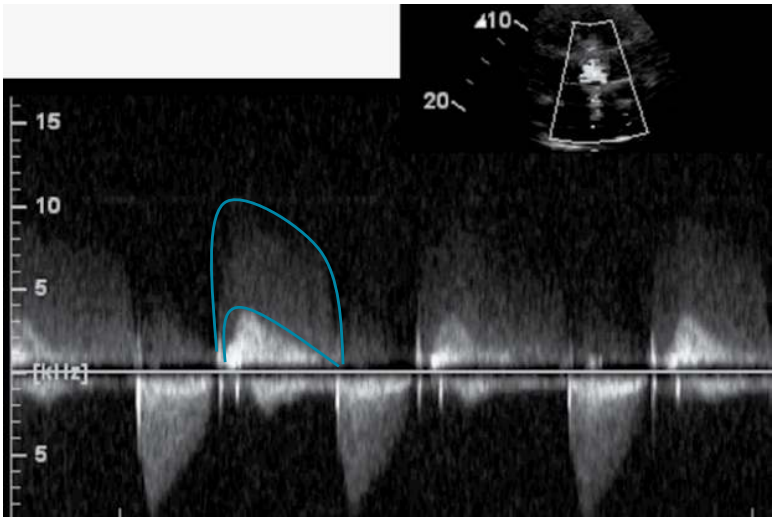

Figure 33.60 In this interrogation of the aortic valve in the apical 5-chamber view, 2 envelopes are seen in diastole (above the baseline): AI and another, more dense envelope that corresponds to the LV inflow (E wave). Despite being in another plane, LV inflow is superimposed on the AI flow as a result of the *beam width artifact.* Similarly, **MR flow may be superimposed on AS flow, leading to overestimation of AS severity.**

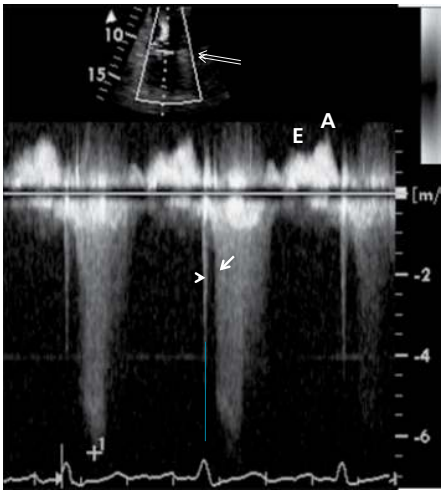

Figure 33.61 The Doppler cursor is placed across the mitral valve (*double arrow*). In diastole, E and A velocities are captured. In systole, the flow below the baseline suggests MR. However, no MR is seen on color Doppler. Also, this flow (*arrow*) does not start at the peak of R wave, nor immediately after A wave, which suggests an aortic or LVOT flow rather than a mitral flow. In fact, a narrow line corresponding to a trivial MR is seen at the peak of R wave (*arrowhead*). This flow occurs later than MR and represents the dagger shape of LVOT obstruction. It is captured on the mitral interrogation because of beam width artifact.

While reflection creates an image, refraction may create a ***double image or mirror image artifact***. This may be seen on echo but also on Doppler (e.g., mirror image of MR velocity seen on the other side of the baseline; mirror image of the pulmonary artery reflects in the ascending aorta on TEE, mimicking dissection flap). This may be attenuated by reducing the gain.

Reverberation and shadowing artifacts may also be seen, and these have been discussed in Section IX, *Prosthetic valves*. One form of reverberation artifact is the rib projection on the echo image, creating, for example, the impression of a "grainy" apical thrombus on the apical views. This grainy structure, however, does not follow the heart motion.

2. TRANSESOPHAGEAL ECHOCARDIOGRAPHY (TEE) VIEWS

The TEE probe and transducer can be manipulated in several planes (Figure 33.62):

- Up and down motion of the whole probe.
- Rotation from an axial horizontal plane (0°) to a vertical plane (90°).
- Clockwise or counterclockwise turn of the whole probe. Clockwise turn moves the tip toward the right-sided structures.
- Anteflexion moves the tip superiorly, while retroflexion moves the tip inferiorly. A result similar to anteflexion may be achieved by pulling the probe up.
- 2D X-plane (biplane) imaging allows simultaneous visualization of an orthogonal 90° image without rotating the probe (e.g., 30° and 120°).

Instead of analyzing multiple structures in one view, focus on a single structure at a time and track it through multiple TEE views.

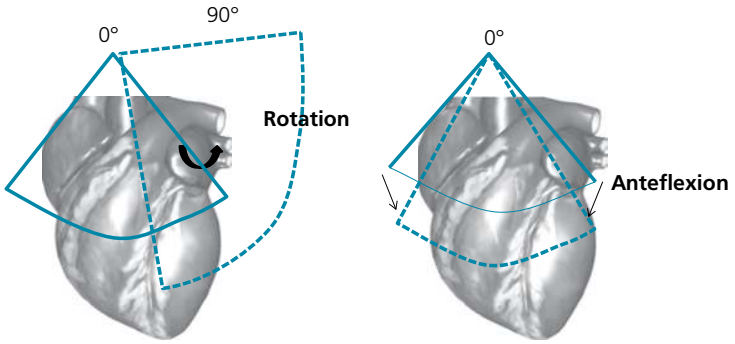

Figure 33.62 Illustration of angle rotation and anteflexion on TEE.

A. First step: mitral valve and left-sided chambers (see Figures 33.63–33.70)

Start with the following transesophageal views, focusing on the mitral valve and the left-sided chambers: *four-chamber view* at 0° rotation, *2-chamber view* at 60–90° rotation, and *long-axis view* at 90–120° rotation. On each view, record the image without color for structural assessment, then use color for mitral assessment. The mitral valve cusps are identified on these views.

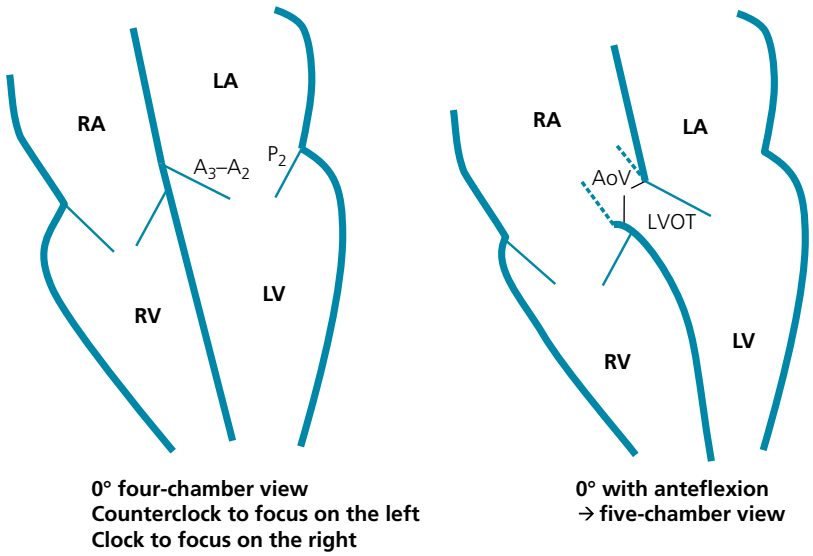

Figure 33.63 TEE: **0° 4- and 5-chamber views**.

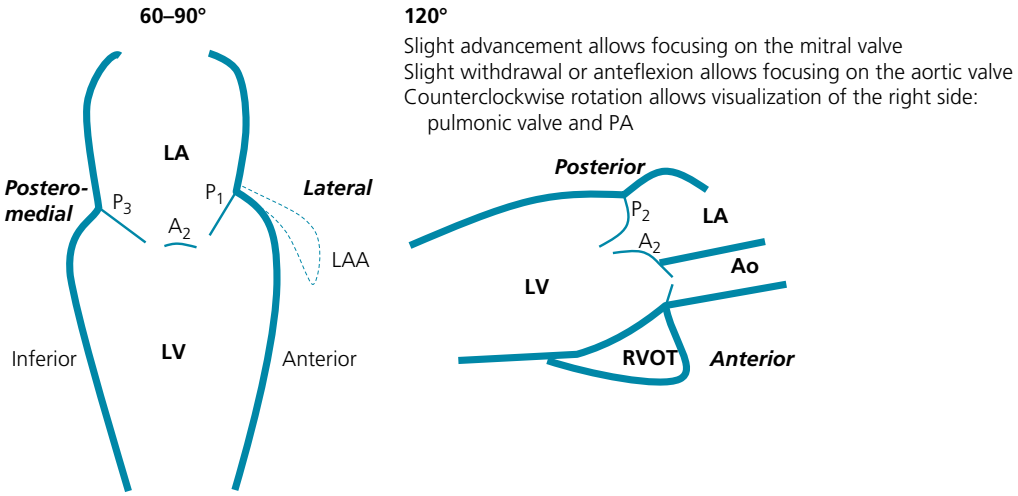

Figure 33.64 TEE **2-chamber and long-axis views.** To understand the orientation, look at Figure 33.65. *The 2-chamber view* looks at the intercommissural mitral plane (from the posteromedial commissure to the lateral commissure), the LAA being at the lateral side. The *3-chamber view* looks at the anterior–posterior mitral plane, at the center of the mitral valve (A_2–P_2). The posterior aspect is closest to the esophageal probe and is seen on top, while the anterior structures, aorta and RV, are away from the probe. Both these views are critical during percutaneous positioning of a MitraClip.

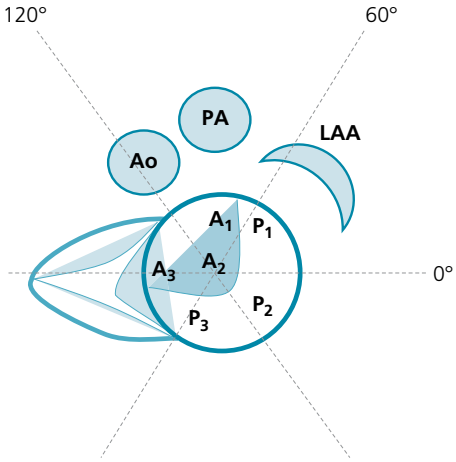

Figure 33.65 Illustration of a cross-sectional view of the mitral plane, showing the relationship of the cusps with the septum, aorta, and LAA. Also, **illustration of how various TEE rotations cut the mitral valve**. Those cuts approximate TTE cuts (0° correlates with the apical four-chamber view, 60° correlates with the apical 2-chamber view, and 120° correlates with the long-axis view). ***A_1 and P_1 are lateral, close to LAA.***

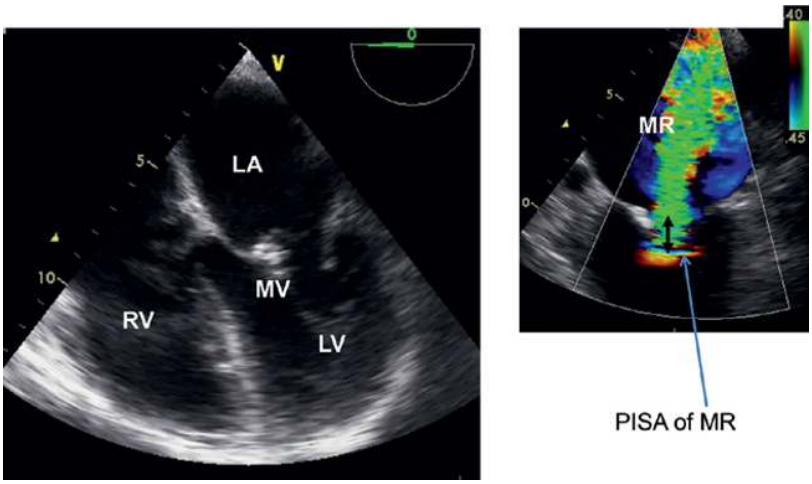

Figure 33.66 TEE **4-chamber 0° view**. Note the calcification of the mitral valve. This is a rheumatic valve with leaflet restriction not just in diastole but also in systole, the latter explaining the severe MR on Doppler. PISA of MR represents flow acceleration as the regurgitant flow comes from the LV toward the LA. PISA of MR is seen on the LV side. The *double arrow* indicates the PISA radius.

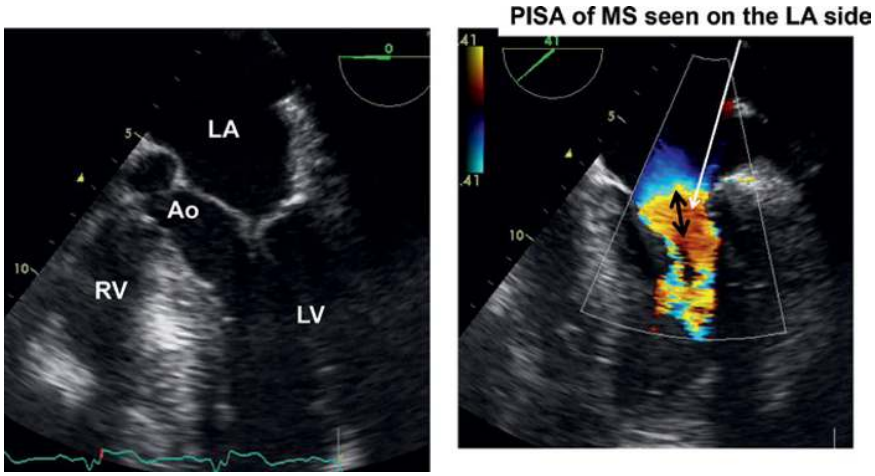

Figure 33.67 TEE **5-chamber view**. Another case of restricted leaflets from a rheumatic process. In this case, no significant MR is seen on Doppler, but significant MS is present, secondary to leaflet restriction in diastole. A large PISA of MS is seen on the LA side (*double arrow*).

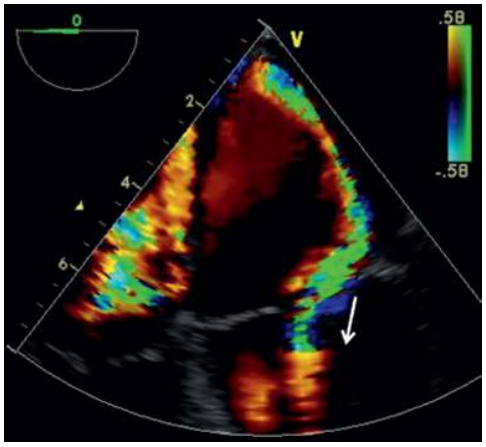

Figure 33.68 Severe eccentric MR is seen on the TEE 4-chamber view, "hugging" the LA wall (Coanda effect). The posterior leaflet is tethered (direction of the *arrow*) in a patient with prior inferior infarct, resulting in a posteriorly directed jet.

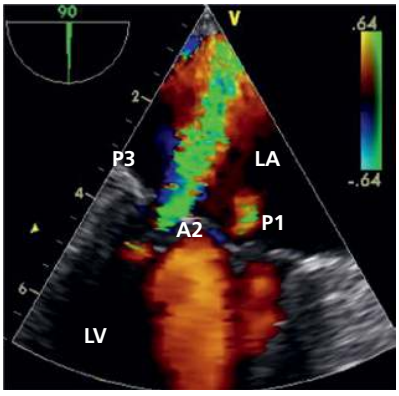

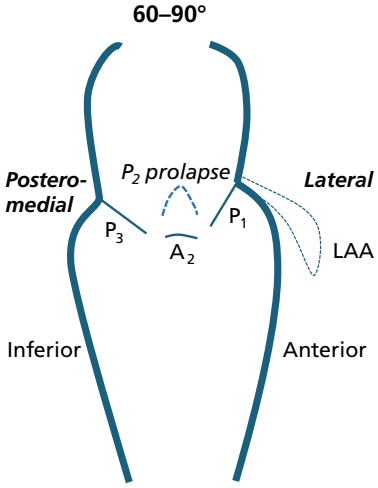

Figure 33.69 MR is seen on the 90° 2-chamber view. Note that, in this view, the mitral orifice is cut at 2 different locations, creating 2 jets. One anterior cusp is hanging between 2 posterior cusps. P2 is not normally seen in this view, but **if a shadow is seen flopping behind A2** (*right image*), **in the same plane as A2, this would be a prolapsed P2**. Thus, this view is particularly effective for diagnosing **all posterior cusps prolapses**.

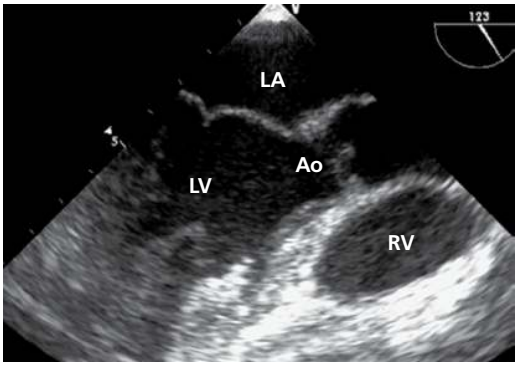

Figure 33.70 TEE **long-axis (120°) view**.

B. Second step: aortic valve evaluation (see Figure 33.71)

Go to 0° again, anteflex or pull the probe until the aortic valve is opened (*5-chamber view*). Then rotate to 30–50° while anteflexed or pulled, which allows the acquisition of the *short-axis view of the aortic valve*. Then further rotate to 120°, obtaining a *long-axis view with a focus on the aortic valve.* This is similar to the long-axis view obtained under the "First step," except that the focus is on the aortic valve. In fact, from the 120° long-axis view focused on the mitral valve, the aortic valve may be targeted by slight withdrawal or anteflexion of the probe.

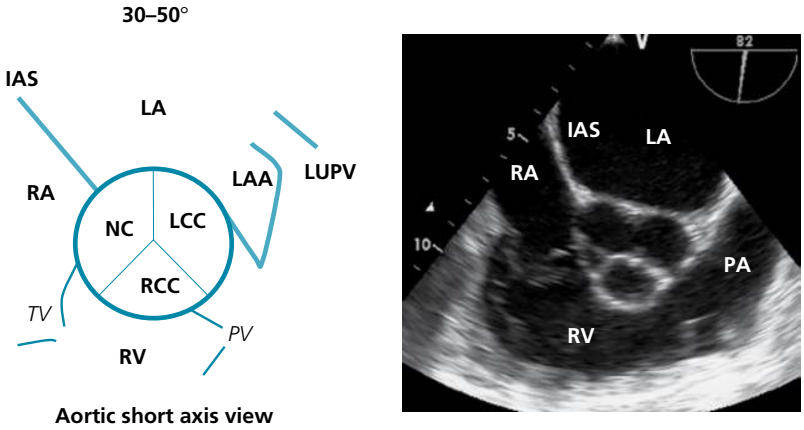

Figure 33.71 Aortic valve short-axis view. Anteflexion is necessary to see the aortic valve (at the level of the high LA). More anteflexion or slight probe withdrawal allows visualization of LAA, which is higher than the aortic valve. Note that the non-coronary cusp is the cusp in line with the interatrial septum.

Clockwise rotation from this view allows a focus on the right side and excellent visualization of the tricuspid and pulmonic valves. IAS, interatrial septum; LUPV, left upper pulmonary vein; LCC, left coronary cosp; NC, noncoronary cusp; PV, pulmonic valve; RCC, right coronary cusp; TV, tricuspid valve.

C. Third step: left atrial appendage (Figure 33.72)

The left atrial appendage (LAA) is best seen through a modification of the short-axis aortic view obtained under the "Second step." The LAA is slightly higher than the aortic valve, which is higher than the 4-chamber view. To see the LAA, further anteflex or pull up from the aortic short-axis view. After the LAA is visualized and centered, it is inspected at multiple rotation angles (30°–90°). The LAA is a pencil-like structure, bordered laterally by a ridge sometimes called the "coumadin ridge"; the latter separates the LAA from the left upper pulmonary vein.

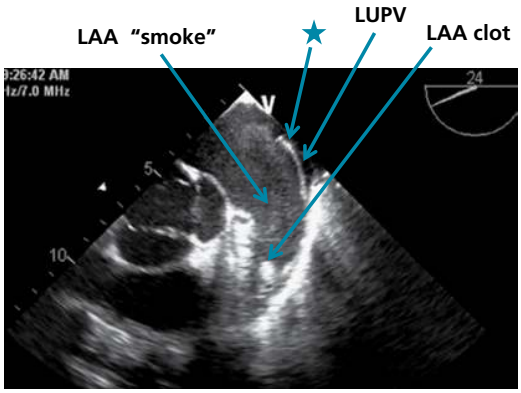

Figure 33.72 Anteflexion from the level of the short-axis view leads to the **LAA view**. A thrombus is seen at the tip of the LAA, along with spontaneous echo contrast ("smoke") in the LAA and LA. The structure identified by the *star* is the "coumadin ridge," a normal band separating the LAA from the left upper pulmonary vein (LUPV). Counterclockwise torque of the probe allows better visualization of the LUPV.

D. Fourth step: right-sided structures (see Figures 33.73, 33.74)

On any of the prior views (especially 4-chamber, long-axis, and aortic short-axis views), a *clockwise torque* of the probe moves the ultrasound tip toward the right chambers and allows evaluation of the RA, RV, tricuspid and pulmonic valves.

E. Fifth step: interatrial septum (see Figures 33.75–33.78)

The 3 best views to visualize the interatrial septum (IAS) are:

- 0° 4-chamber view with a clockwise torque to the right (mitral and posterior IAS rims)
- 30–50° aortic view with a clockwise torque to the right (aortic and posterior IAS rims)
- Bicaval 90° view: from the 0° view or the aortic view torqued towards the right-sided structures, a 90° rotation allows visualization of the SVC and IVC (bicaval view) (SVC and IVC rims). The interatrial septum and the fossa ovalis, i.e., the overlap of the septum primum and secundum, are well seen. The septum primum is membranous and thin, whereas the septum secundum is muscular. In a PFO, the septum primum and secundum are not coapted and a tunnel is visualized in between. In ASD, the issue is not a lack of coaptation; rather, a defect is present in the IAS between the septum primum and septum secundum, usually >8 mm. An ostium primum ASD is characterized by an absent mitral rim, while a sinus venosus ASD is characterized by an absent SVC rim.

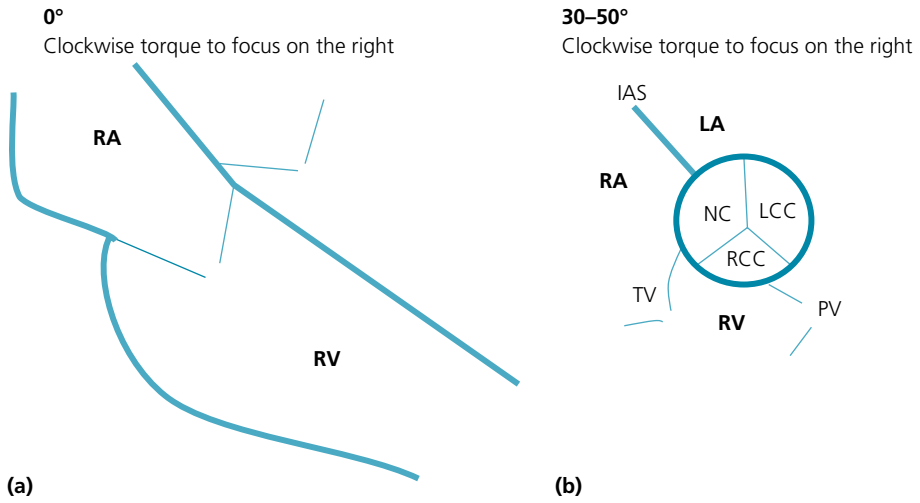

Figure 33.73 **(a)** Clockwise torque from the 0° 4-chamber view allows a **focus on the right-sided structures**. The crista terminalis ridge may be seen by an anteflexion/retroflexion sweep of the RA.

(b) Clockwise rotation from the aortic short-axis view allows a focus on the right side and excellent visualization of RV inflow and tricuspid valve. The interatrial septum is also well visualized. The pulmonic valve may be visualized in the same plane or may require counterclockwise rotation.

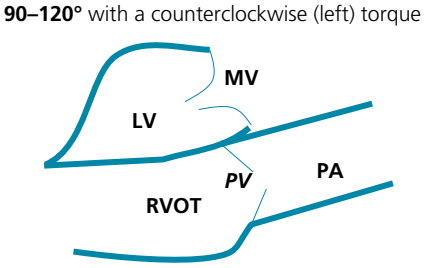

Figure 33.74 From a 90–120° LV/aortic view, torquing the TEE probe to the left, using a counterclockwise maneuver, usually allows visualization of the RVOT, pulmonic valve, and PA (whereas a torque to the right using a clockwise maneuver allows visualization of the RA/RV). *The RVOT, pulmonic valve, and PA are the only "right-sided" structures that may require counterclockwise rotation.* Actually, PA and RVOT are to the left of the aorta.

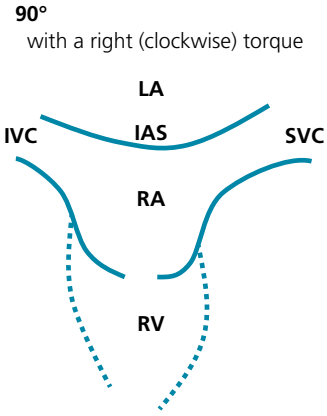

Figure 33.75 **Interatrial septum (IAS) bicaval view** ("Mickey Mouse" view). Try to slightly torque the probe to see the thinnest portion of the IAS, i.e., the membranous septum primum, which meets and overlaps with the septum secundum to form the fossa ovalis.

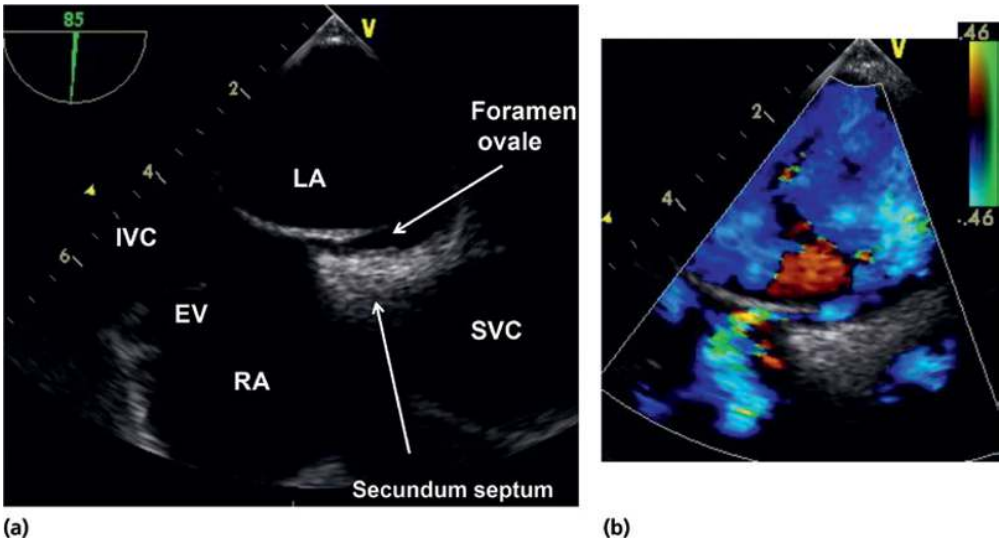

Figure 33.76 **(a)** Bicaval view opening the thin part of the interatrial septum and the fossa ovalis, and showing the 2 flaps of a patent foramen ovale. The thick, muscular flap is the septum secundum, while the thin, membranous flap is the septum primum. **(b)** Flow is seen across the foramen ovale. EV, Eustachian valve.

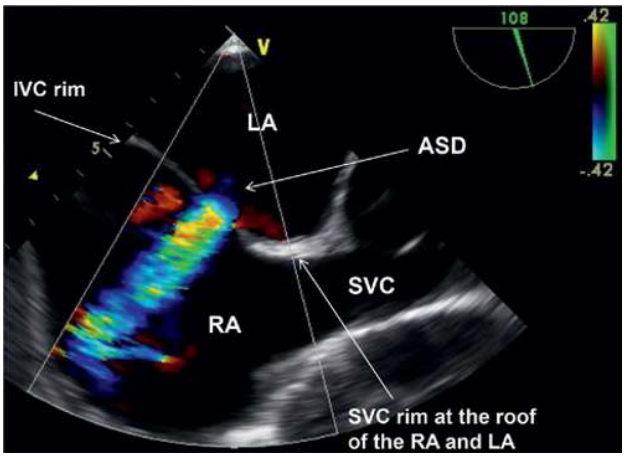

Figure 33.77 Bicaval view showing an ostium secundum ASD. ASD is a defect; in contrast, PFO is a tunnel resulting from malapposition of the primum and secundum septa, without any defect (Figure 33.76).

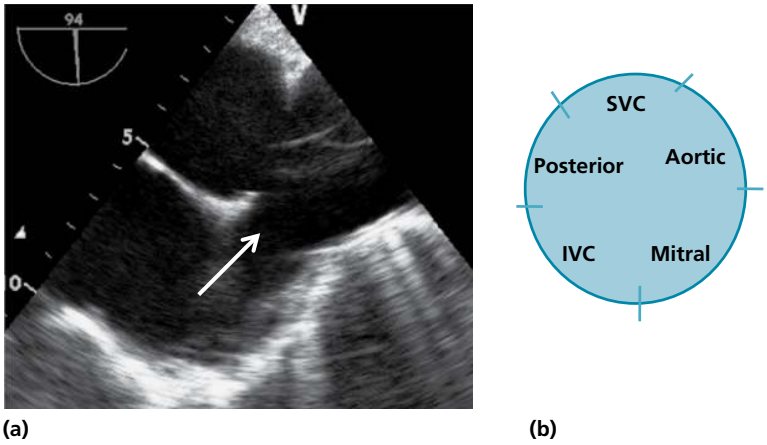

Figure 33.78 **(a)** Bicaval view showing sinus venous ASD (*arrow*). Note the lack of any SVC rim. **(b)** Interatrial septum viewed from the side. Various rims are identified. The SVC and IVC rims are seen on the bicaval view, the aortic and posterior rims are seen on the aortic short-axis view, while the mitral rim is seen on the 4-chamber view.

F. Sixth step: structures at the base of the heart (see Figures 33.79, 33.80)

Go back to the aortic short-axis view or the 4-chamber view, then pull the probe up at a 0° angle. From right to left, the following structures are visualized:

Right upper pulmonary vein, SVC, aorta, PA, LAA, left upper pulmonary vein (pulmonary veins are at the extreme, aorta is more rightward than PA).

Anteflexion from this level allows the visualization of the main PA bifurcating into the right and left PA.

The left upper pulmonary vein is visualized through a left torque. The left lower pulmonary vein is visualized by advancing the transducer slightly or reducing the anteflexion. The right upper pulmonary vein (RUPV) may be visualized by clockwise torque of the probe to the right. If this is unsuccessful, 2 other maneuvers allow visualization of the RUPV:

- From the 5-chamber view, the probe is turned to the right. The RUPV is seen next to the SVC.
- From the bicaval view (~90° view), the probe is rotated 20° or slightly turned to the right. The RUPV will appear next to the SVC.

The RUPV is the most important vein to assess, as it is involved in 90% of anomalous pulmonary venous return (an anomalous RUPV drains into the RA or SVC, while an anomalous left pulmonary vein drains into the innominate vein).

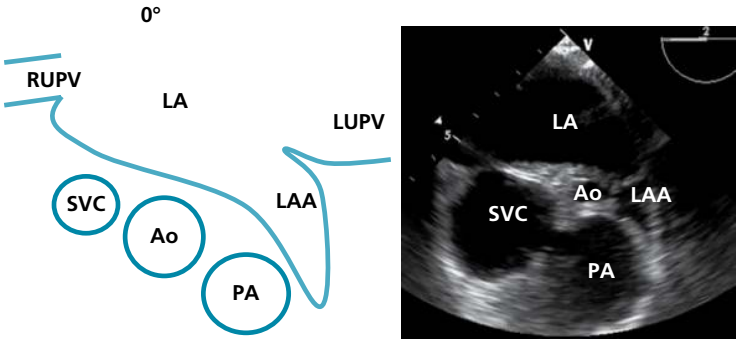

Figure 33.79 0° view at a high level, allowing visualization of structures at the base of the heart. This view shows the left upper pulmonary vein (LUPV), but may not show the right upper pulmonary vein (RUPV) well. In order to properly visualize the RUPV:

- From the 5-chamber view, the probe is turned to the right. The RUPV is seen next to the SVC.
- From the bicaval view (~90° view), the probe is rotated 20° or slightly turned to the right; the RUPV will appear next to the SVC.

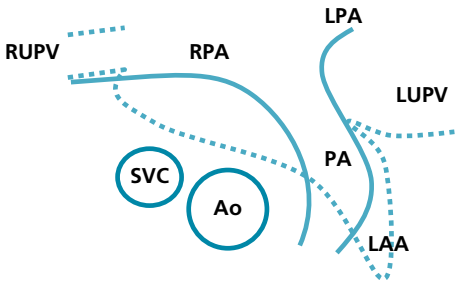

Figure 33.80 Anteflexion from Figure 33.79 shows an even higher level. The PA is seen bifurcating into left PA (LPA) and right PA (RPA).

G. Seventh step: transgastric views (see Figures 33.81–33.84)

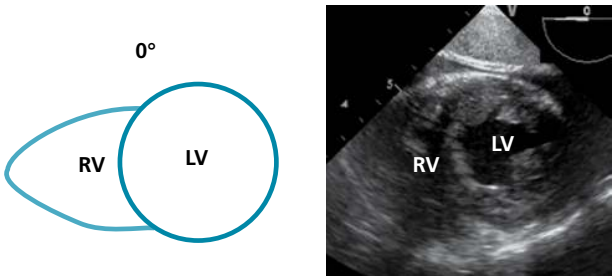

Figure 33.81 Short-axis 0° transgastric view, showing both the LV and RV.

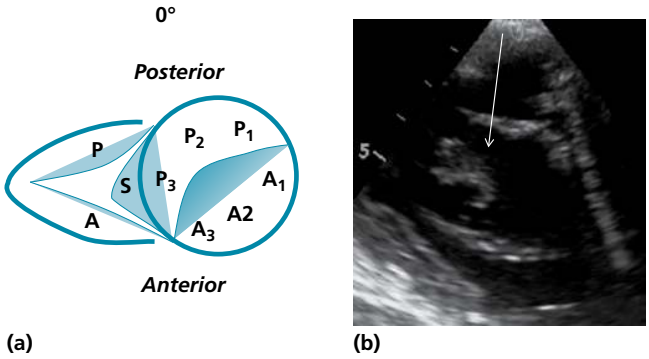

Figure 33.82 **(a)** Short-axis 0° transgastric view with more anteflexion than in Figure 33.81, allowing a focus on the mitral and tricuspid valves. The **ventricles/valves are seen in reverse compared with TTE, with the posterior leaflets appearing on top**. **(b)** Short-axis transgastric view, focusing on the tricuspid valve (*arrow*).

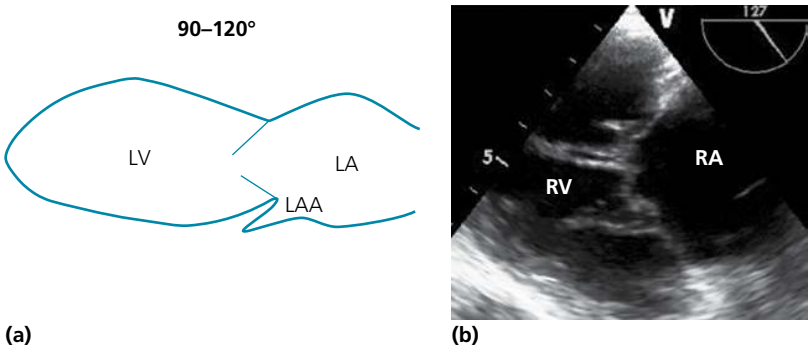

Figure 33.83 **(a)** Transgastric 2-chamber view showing the LA–LV (90°). **(b)** Clockwise rotation from the LA–LV allows visualization of the RA–RV (right-sided 2-chamber view).

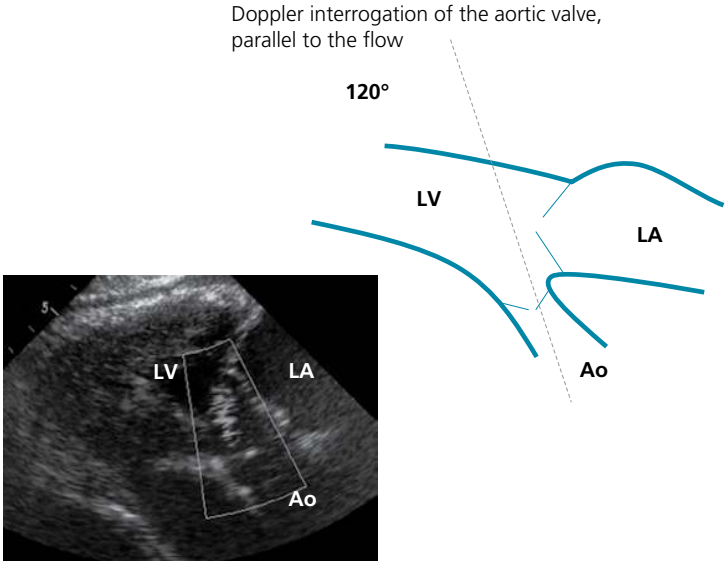

Figure 33.84 Transgastric long-axis view (120°) (deeper gastric level than Figure 33.83). This is one of the two TEE views that allow measurement of the AS gradient.

These views are mainly useful to:

- Assess LV function and RV function, as the transesophageal views foreshorten the LV and RV, particularly the apex.
- Assess the transaortic valve gradient.
- Further evaluate the mitral and tricuspid valves.

From the 0° transesophageal view, advance the probe into the stomach then perform anteflexion to look toward the heart. This allows the acquisition of the RV/LV cross-sectional (short-axis) view. More anteflexion or slight withdrawal allows visualization of the mitral and tricuspid valves. Then, rotate the probe to 90° to acquire a 2-chamber view of the left side. Clockwise rotation at 0° and 90° allows a focus on the right side.

Further advance the probe and rotate to 120°. This allows evaluation of the aortic valve and is a good TEE view for transaortic velocity measurement (the aorta is in a straight line with the Doppler signal). To best assess AS, further advance the probe at 0° and anteflex it, allowing it to nearly touch the apex and create a 5-chamber view. However, both these views are challenging to obtain because of gastric air, poor tissue contact, and gag reflex. *TTE is thus superior for capturing aortic valve velocity*.

H. Eighth step: aorta

(a) Ascending aorta

The ascending aorta is assessed through the transesophageal long-axis view (120°). From this view, the probe is progressively pulled up above the aortic valve, allowing visualization of the whole ascending aorta in a longitudinal plane. Also, a progressive pull from the aortic short-axis view (30°) allows visualization of the ascending aorta in an axial plane.

(b) Descending aorta

At a low transesophageal or transgastric level (0° rotation), the probe handle is flipped 180°, i.e., flipped on itself, until the circular descending aorta is seen. The descending aorta is then sequentially imaged on progressive pullback, until the longitudinal aortic arch is seen.

I. Advantages and indications of TEE

- TEE is mostly useful for: (a) determining the severity of MR, especially in acute cases or eccentric jets, and the mechanism of MR (determine if the leaflets/cusps are thickened, prolapsed or flail); (b) diagnosing mitral or aortic vegetations and the abscess complications of endocarditis; and (c) assessing mitral prostheses and, less so, aortic prostheses.
- *TEE is complementary to TTE in native aortic valve disease, in MS, and in the assessment of tricuspid endocarditis.* For example, in *MS*, TTE is superior to TEE in defining the severity of subvalvular thickening, as the TEE best "sees" the LA rather than the LV side of the mitral valve. For *AI severity assessment*, TTE is as good as TEE; TEE is superior for defining the aortic valve structure (e.g., bicuspid, endocarditis). For *AS gradient calculation*, TTE is superior to TEE; in fact, obtaining AS gradient by TEE requires adequate transgastric views, which cannot be obtained in all patients. For *tricuspid endocarditis*, TTE and TEE may have similar diagnostic yield; however, TEE is superior in case of pacemaker leads or indwelling catheter.
- When endocarditis is suspected, perform a TTE first (TTE has a sensitivity of 60%). If TTE is negative and the clinical suspicion is not low, perform TEE.
- TEE is used to diagnose left atrial appendage thrombus before AF cardioversion.
- TEE may be performed in *very select* stroke cases: (i) young patient with ESUS, PFO, and no major stroke risk factors; (ii) vascular patient with suspected aortic arch atheroma and thrombi (CTA is an alternative); +/- (iii) no documented AF but high probability of intermittent AF and LAA thrombosis (many AF risk factors or severe LA enlargement); (iv) possible vegetation. For PFO assessment, inject agitated saline intravenously and look for right-to-left shunting during the release phase of Valsalva, within 3–5 cardiac cycles of RA filling. If air bubbles are seen in the left chambers later than 5 cardiac cycles after reaching the RA, the shunt is at the pulmonary rather than the cardiac level.
- TEE is excellent for the diagnosis of aortic dissection type A or B.
- TEE may also be useful if the TTE windows are poor.

J. What is spontaneous echo contrast (SEC)?

Also called "smoke," it is seen on TEE in the left atrial appendage ± left atrium, and consists of increased blood echogenicity from red blood cell aggregation (not platelet aggregation). It is due to blood stasis and occurs under low-flow states, mainly AF. It is not a clot and is independent of the coagulation and platelet cascades, but is a strong predictor of thrombus formation and future thromboembolic events (risk of embolic events, 12% per year). SEC, per se, is not suppressed by antiplatelet or anticoagulant therapy. SEC may also occur in the absence of AF, in cases of cardiomyopathies with low flow and severely enlarged and dysfunctional LA.

Should "smoke" preclude DC cardioversion of AF? Not per se, but it should raise the suspicion of an associated thrombus. Heavy smoke and/or a severely depressed left atrial appendage emptying velocity (<25 cm/s [normal, >40 cm/s]) may preclude DCCV if a clot cannot be definitely ruled out by TEE (i.e., look more carefully for clots in the presence of heavy smoke).

K. Three-dimensional TEE of the mitral valve (see Figure 33.85). See also Appendix, Section XI, Questions 3-5

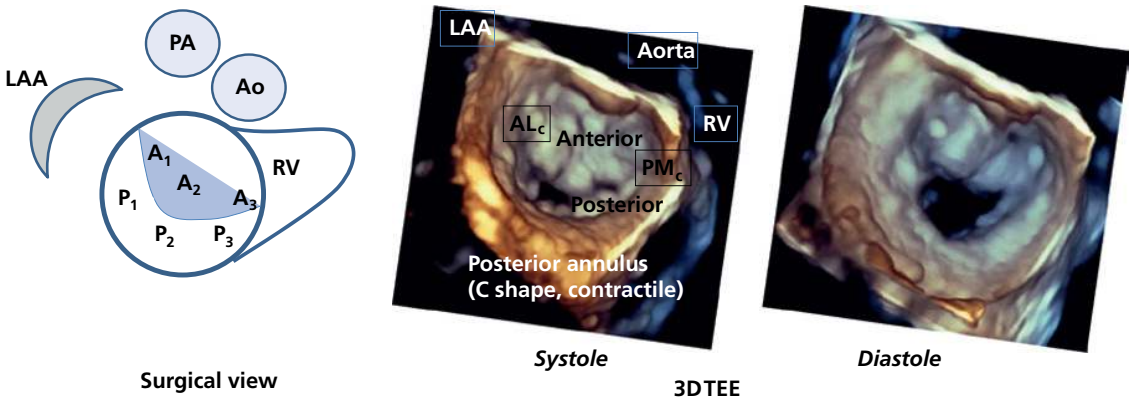

Figure 33.85 Three-dimensional TEE view of the mitral valve (en-face view). This view mimics the surgical view of the mitral valve, as the valve is inspected through the LA (left/right flip of Figure 33.65). For orientation, identify the anterior leaflet (leaflet with the convex border), the anterior annulus (flat), and the posterior annulus (C-shaped). The posterior annulus has a C shape and is muscular and contractile. It contracts in systole and contributes to mitral valve competence, which explains how the annulus is narrower in systole than in diastole. There are 2 commissures: posteromedial (PM_c) and anterolateral (AL_c). Aorta is anterior, LAA is anterolateral. Note the gap between A_2 and P_2 in systole, the source of MR.

Appendix 1. Note on LV mechanics and myocardial tissue strain

LV has 3 layers of myocardial fibers that generate 3 types of myocardial contractility (Figure 33.86):

- Outer subepicardial layer of oblique fibers: create torsion or twist of the LV, *with counterclockwise rotation at the apex and clockwise rotation at the base*.
- Mid-wall layer of circumferential fibers: generate circumferential LV shortening (circular "narrowing").
- Inner subendocardial layer of oblique fibers: mainly generate LV longitudinal shortening.

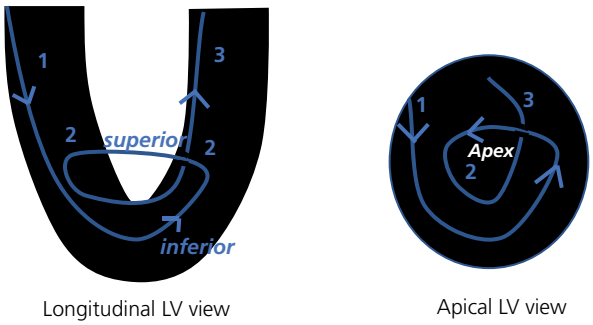

Figure 33.86. Three layers of LV myocardial fibers: (1) outer oblique fibers (→ LV twist, counterclockwise at apex, clockwise at base), (2) midwall circumferential fibers (→ circular "squeezing"), (3) inner oblique fibers (→ longitudinal shortening). All 3 layers are connected, they originate at the outer base, loop around the apex, and then return to the inner base forming a helical structure. The septum shows less torsion than the anterior and lateral walls. RV, on the other hand, has 2 layers: outer circumferential and inner longitudinal layers (25% and 75% of RV thickness, respectively).

All those fibers are interconnected, and all 3 types of contractility contribute to the stroke volume. Twisting is a major contributor to stroke volume, and the apex is the "engine" of this twist, which explains the dramatic consequence of apical dysfunction (Apex=CounterClockwise, mnemonic "ACC").

The 3 types of myocardial motion may be objectively assessed using myocardial tissue speckle tracking (a form of 2D echo, not Doppler). This allows measurement of myocardial deformation or strain, which is the % change in distance between 2 points = (distance between 2 points $_{\text{in systole}}$ – distance $_{\text{in diastole}}$)/distance $_{\text{in diastole}}$ (Figure 33.40). *Strain can be measured longitudinally* (a byproduct of the inner layer), *circumferentially* (a byproduct of the middle layer), *and radially* (a byproduct of the thickening of all 3 layers). The *LV twist* angle may also be assessed. The myocardium shortens *longitudinally*, leading to shortening of the distance between 2 points, hence negative longitudinal

strain values: the normal longitudinal strain is ≤–12% regionally and ≤–16% globally (e.g., –20%) in the apical views. The myocardium thickens *radially*, leading to elongation of the distance between 2 points, hence positive radial strain values: the normal radial strain is 35–50% in the short-axis view. The myocardium shortens *circumferentially*, leading to negative circumferential strain on the short-axis view. Current softwares of echo speckle tracking more reliably address longitudinal strain than radial or circumferential strain. *LV twist* may be assessed by speckle tracking in the short-axis view (in degrees, ~+10–15°)

Strain assessment by tissue tracking is much less angle dependent than strain assessment by Doppler. Unlike EF, strain is less dependent on loading conditions and is a better evaluator of contractility; it detects subtle myocardial abnormalities that are missed by "eyeball" segmental analysis (e.g., small or medium-size area of ischemia or scar).

Segmental patterns of dysfunction (e.g., ischemic, amyloid) may be assessed via segmental strain color map (the normal, negative values are coded in red, "*red is good, blue is bad*"). Strain may be assessed globally by averaging segmental strain findings; a commonly used parameter is *global longitudinal strain* (GLS), which is normally ≤–16%. GLS is frequently reduced in cardiomyopathies even when EF is normal, such as in hypertensive heart disease, LVH, and *the majority of HFpEF cases*, attesting to the fact that contractility is frequently impaired in HFpEF. In addition, GLS is valuable in LV assessment before chemotherapy and detection of subclinical myocardial dysfunction during chemotherapy (a decline of GLS of >15% is significant).

MRI also assesses the 3 myocardial motions and is the best modality addressing LV twisting.

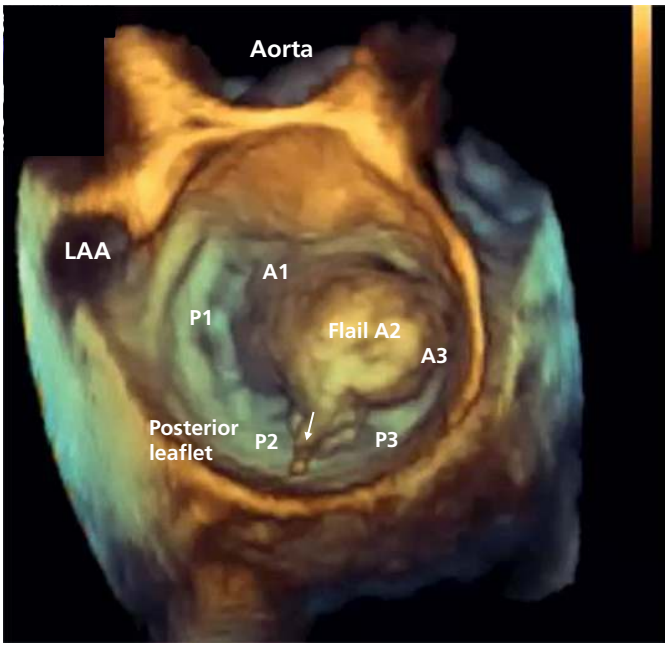

Figure 33.87 Standard en face view of the mitral valve through the LA (surgeon's view). This is a "3D zoom" image. Aorta is at 12 o'clock, LAA is at 9–12 o'clock. The image may be flipped to look at the mitral valve from below, through the LV, which flips the LAA toward the right side. However, by convention, the aortic valve should always be displayed at 12 o'clock. Note the standard distribution of A1–A3 and P1–P3 (A1 and P1 next to LAA). The anterior cusp A2 is thick myxomatous and not only prolapsed but flail with torn chordae looking into the LA (*arrow*).

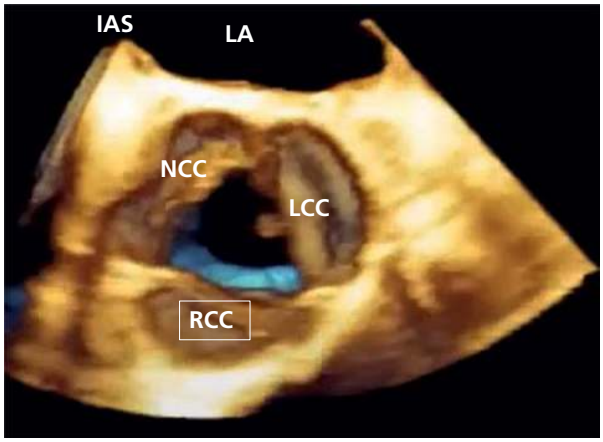

Figure 33.88 Standard aortic valve 3D zoom view. The aortic valve is viewed from above, through the aorta. The image may be flipped to look from below, through the LV, which moves the interatrial septum (IAS) to the right side of the image. But RCC is always displayed at 6 o'clock.

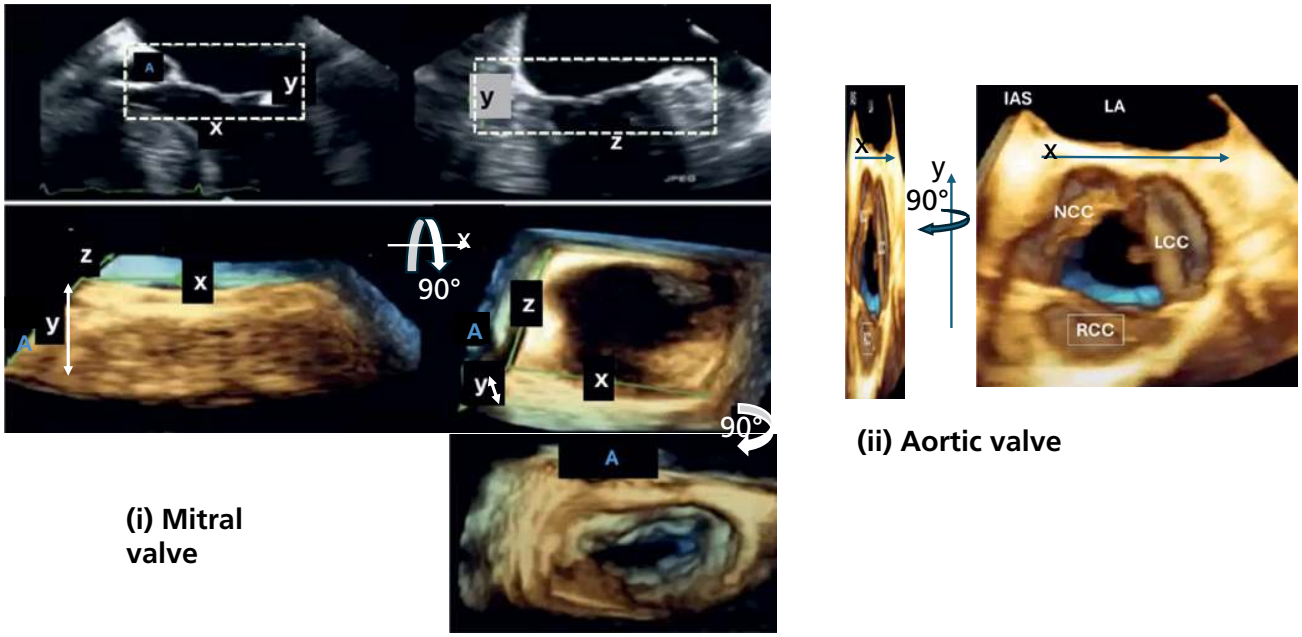

Figure 33.89 **(i)** How to acquire 3D zoom imaging of the mitral valve?

1. Start with optimized biplane imaging of the mitral valve at any angle (e.g., 0° and 90°).
2. Then center the structure of interest, i.e., mitral valve, inside an acquisition box on A plane (x-axis [horizontal] and y-axis [thickness]), which will translate into another image, a depth image in the orthogonal B plane (z-axis [depth] and y-axis).
3. Then press the "3D zoom" button, which will generate a 3D slice of the mitral valve. A, aortic valve.
4. Tilt the 3D image down 90° around the *x*-axis, to obtain an en face view of the mitral valve. This is done by pressing the "3D rotate button" and using the trackball to rotate the image.
5. Press the "Rotate Z" button and rotate 90° clockwise to position the aortic valve anteriorly at 12 o'clock. (4) and (5) are done on a frozen image (the image is grabbed and rotated around, a form of post-processing).

(ii) For 3D zoom image of the aortic valve, obtain biplane images of the aortic valve, at the aortic short-axis and long-axis levels (~30° and 120° angles). Then center the acquisition box on the aortic valve and generate a 3D zoom image of the aortic valve. The en face view of the aortic valve is on the y plane. Rotate the image 90° around the y-axis to generate en face view of the aortic valve.

Note: Depending on the interventional procedure, 3D zoom slices may also be obtained for the LAA and for the interatrial septum, after acquiring biplane images focused on those structures.

Appendix 2. Three-dimensional echocardiography basic tips and images

Three-dimensional imaging is mainly done with TEE but may be done with TTE. With TTE, 3D is mainly useful for assessing LV or RV volume, mass, and function.

For 3D imaging, we start with acquiring a specific 2D echo view. The key to a good 3D image is good 2D image acquisition. Poor 2D windows translate into poor 3D images. Optimize the image gain: too little gain causes dropouts that may mimic aortic or mitral valve perforation, while too much gain causes noise or "snow" over the image. Color Doppler is therefore necessary to confirm a true valvular perforation.

A 3D image may be acquired *live* by pressing the *"live 3D"* button (thin pyramidal slices) or the *"3D zoom"* button (zoomed truncated sectors, useful in valvular assessment). 3D images may also be acquired via "*3D full image display*": full *thickness wide* sector is obtained and then post-processed using the "cropping" function (large dataset image, not live imaging). In all 3D imaging, temporal resolution is lower than in 2D imaging. However, it may be improved with multibeat acquisition (gated, as usually, to the ECG), and by narrowing the sector, as with 2D imaging. Spatial resolution is also lower in 3D echo and further deteriorates with deep respiratory swings or irregular rhythm, particularly if a wide thick sector is imaged (stitch artifacts). Figures 33.87 and 33.88 show landmark 3D zoom images of the mitral and aortic valves. Figure 33.89 demonstrates how to acquire 3D zoom images of the mitral and aortic valves.

I. Indications for stress testing

Stress testing is indicated for diagnostic and, more importantly, prognostic evaluation of CAD. Its sensitivity is reduced in single-vessel CAD and in non-LAD disease.

A. Stable chest pain presentation

1. Stress testing is useful for:

- The diagnostic and the prognostic assessment of patients with *intermediate or high CAD probability*

2. Stable angina is defined by 3 features: (1) chest pain, (2) occurs with exertion, and (3) resolves with rest or with NTG, within 30 seconds to 5 minutes.

3. The presence of all 3 features implies that angina is typical. The combination of angina features, age, sex, and risk factors establishes the probability of CAD (ESC prediction model, Chapter 3, Figure 3.1). **Chest pain must be exertional to have an intermediate pre-test probability of CAD and to warrant coronary testing**. Even typical exertional chest pain is not highly predictive of CAD (only 10–50% CAD probability, depending on age, sex, and risk factors). Also, dyspnea is a poor angina equivalent and has at best a 10–25% predictive value for CAD.[1–3]

4. According to Bayes' theorem, stress testing is particularly useful in patients with an *intermediate pre-test probability* of CAD, in whom the stress test result significantly increases or reduces the probability of CAD.

Besides its diagnostic value, stress testing has a prognostic value and helps determine if the patient may benefit from revascularization. Extensive ischemia may warrant coronary angiography and revascularization, particularly if associated with refractory severe angina, whereas medical therapy is the appropriate first-line option for a low- or intermediate-risk stress test.

If the *pre-test probability of CAD is low* (<15%), stress testing is not warranted. Even if the stress test is positive, the probability of CAD will only increase from <15% up to 20% according to the Bayes theorem, which means that the stress test is likely falsely positive.

> Stress testing of patients with low pre-test probability of CAD is the most common cause of a false-positive stress test. In fact, pre-test probability is the most important determinant of the validity of stress test results.

B. Acute chest pain presentation, with non-ischemic ECG and negative troponin 3 hours after symptom onset, and with no typical exertional angina at low levels of exertion.

C. Recent STEMI (>24 hours) that was not urgently reperfused with PCI, whether thrombolysis was acutely administered or not
In the absence of angina recurrence (which definitely warrants a coronary angiogram), either late coronary angiography or stress testing may be performed. Submaximal stress testing may be performed at 3–5 days (before discharge) to see if there is any residual ischemia within or around the infarcted territory, whether reperfused or not, or in other areas.

D. Known CAD of borderline significance on the coronary angiogram (45–70% stenosis)
In this case, stress imaging may be performed *after* coronary angiography to determine if the stenosis is hemodynamically significant and if chest pain can be attributed to it. A significant stenosis leads to ischemia in the correspondent territory on the echo or nuclear images. Alternatively, fractional flow reserve (FFR) may be performed during coronary angiography to determine whether the stenosis is significant.

II. Contraindications to all stress testing modalities

- Recent STEMI ≤ 2 days
- NSTEMI (perform coronary angiogram)
- Active HF
- Severe symptomatic AS
- Arrhythmias: uncontrolled AF, uncontrolled VT, second-degree Mobitz II or third-degree AV block
- HTN >180/110 mm Hg

Additional contraindication for adenosine nuclear testing: history of severe asthma or current, decompensated COPD.

Risk of death from stress testing is <1/10,000. Morbidity (MI, arrhythmias) is 5/10,000. The risk is greater when the test is performed in the early post-MI setting.

Stress testing may be indicated after STEMI but is less justifed after NSTEMI, even a stabilized NSTEMI. In NSTEMI, the myocardial injury is small and most of the myocardium is ischemic rather than necrotic; revascularization is needed to prevent MI recurrence or progression to a large MI. Conversely, in non-reperfused STEMI, the territory may be fully infarcted already, and one has to prove ischemia by stress testing or angina recurrence before proceeding with revascularization. Yet, stress testing may be justified after type 2 MI or gray zone hs-troponin elevation.

Carefully assess for AS and HOCM on physical exam, and perform an echo before stress testing if a suspicious murmur is heard.

The contraindications to treadmill testing and the risks apply to pharmacological stress testing as well.

III. Stress testing modalities

Three stress testing modalities are available:

1. ***Treadmill stress ECG***
2. ***Treadmill stress imaging*** (echo, nuclear). Echo assesses ischemia (exercise-induced hypokinesis), while ***nuclear imaging assesses the difference in coronary flow reserve*** between the area subtended by a stenosis and the areas subtended by non-obstructed coronary arteries.
3. ***Pharmacological stress imaging*** (echo, nuclear, MRI). Dobutamine, often with atropine, is used for stress echocardiography; adenosine is used to assess the difference in coronary flow reserve with nuclear imaging. Dobutamine may be used for nuclear imaging, but is less sensitive than adenosine in nuclear imaging. The cardiac workload is less with dobutamine than with exercise, and thus dobutamine echocardiography is also less sensitive than maximal exercise echocardiography or exercise nuclear imaging.

Since exercise achieves the highest cardiac workload and provides prognostic information independent of imaging (exercise time, symptoms, ECG response, BP response, and heart rate response), exercise stress testing is preferred to pharmacological testing. The selection of a stress test modality depends on 3 factors (Figure 34.1): (i) the patient's ability to walk; (ii) the presence of baseline ECG abnormalities that preclude ischemic assessment on stress ECG, mainly LBBB or resting ST-segment depression >1 mm; (iii) compelling indication for treadmill stress imaging (for its higher sensitivity and specificity), such as high pre-test probability of CAD or prior revascularization.

In patients with LBBB or ventricular paced rhythm, adenosine nuclear stress testing is classically the best testing modality, even if the patient is able to exercise. In LBBB, the septum contracts earlier with earlier interruption of diastolic blood flow than the remaining LV segments; thus, a septal perfusion defect is expected. The perfusion defect and the abnormal septal motion worsen with stress, particularly exercise or dobutamine. However, exercise or dobutamine stress echo may be done and interpreted cautiously and correlates with angiographic findings; analyzing anterior and apical thickening rather than septal excursion improves the specificity.[4] In nuclear imaging, focus on anterior/apical defects rather than the septal defect.

The Bruce treadmill protocol is the exercise protocol most commonly used. It consists of 3-minute stages, with an increase of speed and inclination at each stage (Table 34.1).

IV. Diagnostic yields and pitfalls of stress ECG and stress imaging

A. Diagnostic yield of exercise stress ECG
For the exercise stress ECG or imaging to be valid, the patient should:

1. Reach target HR, which is 85% of the maximal HR (=85% of [220 – age])
   or, more clinically relevant,
   Achieve a good workload ≥6–7 METs, which means finish 5 minutes of the Bruce protocol.

2. Or attain high-risk criteria before this goal.

Adequate workload is more important than heart rate for ischemia detection and is far more prognostically reassuring in negative tests (as suggested by DTS score, section C). *Target HR is mainly sought in those who do not achieve proper workload:* one study suggested that a negative stress ECG at a submaximal heart rate was still predictive of low CV risk if ≥7 METs were achieved.[6] At lower workloads, the test is less sensitive, but remains valuable for determining whether angina develops at the patient's peak activity, even if limited, given that revascularization primarily improves exertional angina. Note that, more than with exercise ECG, exercise imaging maintains adequate sensitivity even if heart rate or workload targets are only partially achieved.

Achieving the appropriate heart rate is more important with dobutamine stress echocardiography than exercise stress echocardiography, as dobutamine induces less cardiac workload and thus less ischemia than exercise.

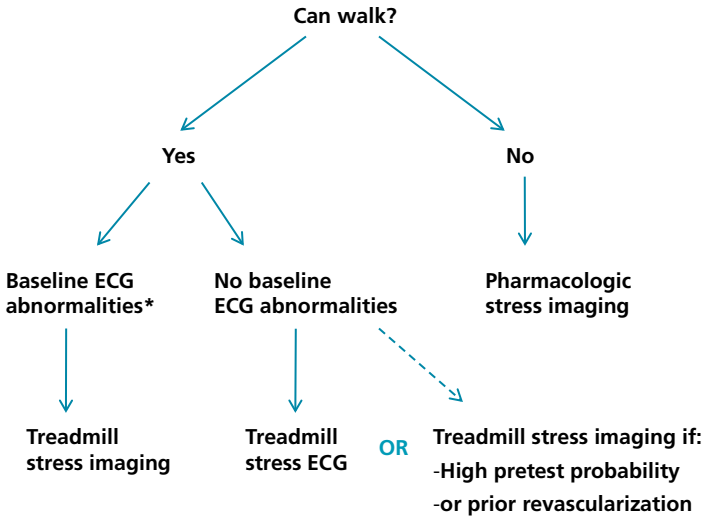

Figure 34.1 Stress testing modality.

****Baseline ECG abnormalities precluding stress ECG interpretation:***

- LBBB, paced rhythm, or non-specific intraventricular conduction delay ≥120 ms
- Any ST depression ≥1 mm
- LVH or digoxin therapy with any ST depression, even if <1 mm
- Pre-excitation (WPW)

These conditions will routinely have worsening of the ST depression during stress and during tachycardia, regardless of ischemia (false-positive result).

Other ECG abnormalities and clinical situations:

- Resting ST depression <1 mm ↓ specificity of stress ECG but does not preclude interpretation.
- LVH without any resting ST depression: stress ECG remains reasonably specific for ischemia.
- RBBB may inherently cause ST depression in leads V_1–V_3: hence this is not considered an abnormal response. The more important leads V_4–V_6 are not generally affected. Stress ECG sensitivity may be reduced, but it remains a valuable test.[5]
- AF: patients may become quickly tachycardic or may not increase their heart rate enough if they are on rate-controlling medications. Exercise testing, is, however, appropriate and assesses the adequacy of rate control.
- History of PCI or CABG: stress imaging is preferred to stress ECG. Stress ECG is less sensitive in this context and cannot localize ischemia. Stress ECG is poorly sensitive for the diagnosis of single-vessel restenosis.

Table 34.1 Standard Bruce treadmill protocol.

Stage	Inclination (°)	Speed (mph)	MET
1	10	1.7	5
2	12	2.5	7
3	14	3.4	10
4	16	4.2	13
5	18	5	16

In patients who are not able to cope with the workload of a standard Bruce protocol (e.g., elderly, weak), a **modified Bruce protocol** may be performed. Stages 1, 2, and 3 of the modified Bruce protocol consist of an inclination of 0°, 5°, and 10°, respectively, for a speed of 1.7 mph. Thus, stage 3 of the modified Bruce protocol is equivalent to stage 1 of the Bruce protocol. The energy expenditure achieved with the modified Bruce protocol is much lower than the energy expenditure of the standard Bruce protocol. A modified Bruce protocol is also called "submaximal stress testing."

The metabolic equivalent (MET) corresponds to the energy expenditure for an activity level. The reference, 1 MET, is the resting metabolic rate obtained during quiet sitting and corresponds to the consumption of 3.5 ml/kg/min of O_2. METs and O_2 consumption increase with the peak exercise achieved.

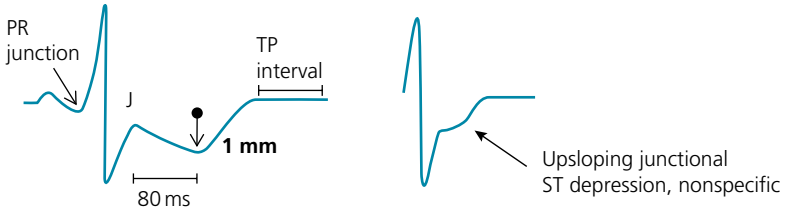

Figure 34.2 During sinus tachycardia, atrial repolarization becomes accentuated and extends over the ST segment, leading to PR depression + junctional ST depression. Referencing the ST segment to the PR junction accounts for the effect of atrial repolarization.

B. Positive stress ECG

A positive stress ECG is defined as descendant (downsloping) or horizontal ST depression ≥1 mm measured at 60–80 ms past the J point, during exercise or within 3 minutes of recovery in at least one lead. While ST displacement should generally be measured relative to the TP segment, PQ or PR junction is chosen as the isoelectric point during exercise (Figure 34.2). If baseline ST depression is present, the exertional worsening of ST depression, rather than the absolute ST depression during exercise, is used to assess ischemia. If baseline ST elevation is present, exertional ST depression is measured in absolute values.

The lateral precordial leads (especially $\mathbf{V_5}$) are the most specific and most sensitive for exercise-induced ischemia. Isolated inferior changes are less specific and are often a false-positive result.

ST depression occurring during exercise usually persists ≥3 minutes into recovery.[7] If it does not, the ST depression is considered less specific; in particular, quick recovery of ST depression in <1 minute was predictive of a low risk of cardiac events and CAD, as low as a negative ECG result.[6]

About 10% of patients develop the diagnostic ST depression only during recovery, most typically and most specifically *during the first 3 minutes of recovery*,[7] often preceded by equivocal or upsloping ST depression at peak exercise. *This recovery-only ST depression is as predictive of CAD and coronary events as ST depression that starts at peak exercise*.[8]

Slow upsloping ST depression (≥1.5–2 mm at 80 ms) that does not become horizontal or downsloping in recovery is non-specific; its diagnostic yield differs between studies, yet it has a *value in patients with a high pre-test likelihood of CAD* or chest pain elicited by exercise testing. In the landmark DTS study, only horizontal or downsloping ST depression was used in DTS calculation.

In summary, ***ST depression is more definitely ischemic when it is horizontal or downsloping in lead V_5 and seen at 1–3 minutes of recovery***. **ECG at 1–3 minutes of recovery** is the most sensitive and specific for ischemia, as true exertional ST depression persists at 1–3 minutes recovery. Furthermore, a non-specific exertional upsloping ST depression must worsen and become horizontal/downsloping at 1–3 minutes recovery to be specific for ischemia.

Notes

- ST depression does not localize ischemia and often occurs in V_5 regardless of whether ischemia is anterior or inferior.
- T-wave inversion is not specific. Normalization of an inverted T wave during exertion may be a true normalization of a non-specific T abnormality or an ischemic pseudo-normalization (less frequent).
- The mere upright position may induce new ST depression in some patients. This is not indicative of ischemia and may cause false positive ST depression with exercise.
- ST elevation in areas without prior Q waves indicates a local transmural myocardial ischemia, implying either a very tight stenosis or exercise-induced spasm (high-risk finding). ST elevation localizes ischemia.

  ST elevation in areas with baseline Q waves does not mean active ischemia, but indicates greater dysfunction of the infarcted myocardium (possible dyskinesis) and a worse prognosis.
- The occurrence of LBBB or RBBB does not necessarily mean ischemia; it is frequently rate-related and not specific for ischemia. Stress testing may be interrupted if one cannot be sure the wide complex rhythm is sinus (vs. VT).
- Normally, during exercise, the QRS axis becomes more vertical as the heart empties. The paradoxical occurrence of left axis or LAFB is very specific for ischemia. Also, the occurrence of a full right axis (LPFB) implies ischemia.
- Even without ST changes, distressing chest pain that starts during testing and resolves with rest or within 5 minutes of NTG is concerning and may dictate coronary angiography, particularly if occurring early (stage 2 or less) or associated with distress or diaphoresis (=typical, low-level exertional angina). In fact, even with a normal ST response, a typical angina is almost as predictive of coronary events and CAD as an abnormal ST response, especially in men (CAD prevalence ~30s%).[6] At least 10–20% of CAD patients have chest pain during stress testing without ST changes.[6]

C. High-risk positive stress ECG (see Table 34.2)

In general, 40% of Duke Treadmill Score (DTS) results fall in the low-risk category (no further testing is needed), 10% fall in the high-risk category (indication for a coronary angiogram), and 50% fall in the intermediate-risk category, where stress imaging or CTA may need to be performed to further delineate the risk.[12]

DTS score is not well validated in elderly patients and in patients with a history of coronary revascularization. DTS has a strong independent prognostic value that is additional to that provided by coronary anatomy, EF, and history of CAD/MI. The original analysis that validated DTS included patients with MI (~30% of patients had prior MI) but excluded patients with prior revascularization; most patients were <65 years of age. An analysis from the GISSI trial also validated DTS in post-MI patients.

Table 34.2 High-risk stress ECG and Duke Treadmill Score (DTS).

1. Early ST depression or severe angina at stages 1 or 2 (at <5 METs)
2. ST depression ≥2 mm, especially if >5 leads
3. ST elevation in leads without prior Q waves (→ signifies transmural ischemia, very high risk)
4. Sustained reduction of SBP >10 mmHg in comparison with the baseline, inability to increase SBP beyond the baseline with progressive exercise
5. Arrhythmias:
   - Sustained VT
   - Non-sustained VT or complex PVCs (couplets, triplets, polymorphic, or >10/min) associated with other ischemic signs[a]
6. Heart rate:
   - A decrease in HR of <12 bpm in the first minute of recovery is a strong predictor of cardiovascular mortality (implies lack of vagal reactivation soon after exercise)
   - Inability to achieve 85% of maximal heart rate (chronotropic incompetence) not only reduces stress test sensitivity but also implies an increased mortality (because of autonomic dysfunction *and* an association with twice the risk of CAD and perfusion defects).[9] A similar prognostic value is found for a low chronotropic reserve index: (peak HR – resting HR)/([220 – age] – resting HR) (low if <0.8, or <0.62 if on β-blockers)

Duke Treadmill Score[b]
= Exercise time on Bruce protocol – 5 × (the most severe ST depression) – 4 × (angina score)

- Score ≥+5: Low cardiovascular risk (<1% mortality and cardiac events per year)
- Score +4 to –10: Intermediate cardiovascular risk (1–3% mortality, 1–5% cardiac events per year)
- Score ≤–11: High cardiovascular risk (>3% mortality, >5% cardiac events per year)

[a] Complex exercise-induced PVCs (frequent >10/min or multiform or ≥2 PVCs in a row) are common in asymptomatic subjects and are not independently associated with increased mortality,[10] with the possible exception of complex PVCs occuring at mild submaximal exertion.[11] Even exertional NSVT does not independently predict mortality in subjects with no heart disease.

Conversely, post-exertional frequent or complex PVCs may be seen with or without heart disease and independently associate with mortality, regardless of the presence or absence of heart disease, CAD, ST deviation, or symptoms.[10,11] This is because they imply a lack of vagal reactivation soon after exercise. Complex exertional or recovery PVCs are more prevalent with age, HTN, and diabetes (up to 5%).

Monomorphic VT may be a form of idiopathic benign VT initiated by exercise (e.g., RVOT VT), or ARVD, or may in fact be SVT with rate-related bundle branch block.

[b] Exercise time is the time spent on a standard rather than modified Bruce protocol; 9 minutes on a modified Bruce protocol does not give a score of 9, but is equivalent to 3–4 minutes on a standard Bruce protocol. Angina score is 0 if no angina, 1 if non-exercise-limiting angina, 2 if exercise-limiting angina.

Note: blood pressure response during exercise

Normally, SBP increases with exercise (high stroke volume) while DBP remains unchanged or decreases (vasodilatation). SBP may decrease during progressive exercise after an initial peaking from the catecholaminergic surge, but it does not decrease below baseline.

Exertional hypotension may be due to:

- Extensive ischemia.
- Cardiomyopathy: the lack of contractile reserve in systolic HF, or the lack of filling reserve in diastolic HF, prevents the increase in stroke volume. If cardiac output cannot increase and fill the dilated systemic space induced by exercise, BP decreases (BP = [CO × SVR]: if SVR ↓ but CO cannot ↑, BP ↓).
- AS or HOCM: LVOT obstruction prevents the exertional increase in stroke volume.
- Hypovolemia or antihypertensive drugs.

On the other hand, ***post-exertional hypotension*** is usually benign and is related to the sudden reduction of venous return and cardiac output while the systemic space is still dilated; also, the empty, hypercontractile ventricle may trigger a vasovagal response. Post-exertional hypotension may also be seen with severe AS or HOCM upon sudden cessation of activity (i.e., sudden decrease in venous return, AS and HOCM being very sensitive to preload reduction).

In hypovolemic patients, dobutamine may induce hypotension as it reduces diastolic time and preload; this paradoxically reduces stroke volume in patients who are preload dependent, on the upslope of the Starling curve. Besides, dobutamine may trigger LVOT obstruction within the small LV. Conversely, exercise increases venous return and preload and does not cause hypotension, except in cardiomyopathies or extensive CAD.

An increase in SBP to >214 mmHg, or an increase in DBP, may imply abnormal systemic vasoreactivity and a risk of future HTN.

D. Limitations of DTS and exercise stress ECG: value of stress imaging

Exercise stress ECG has a low sensitivity for CAD detection, especially in patients with single-vessel non-LAD disease. While it is more sensitive in patients with more extensive CAD, a significant proportion of these patients is still missed. In the Duke stress testing database of *symptomatic* patients, *most of whom had definite or possible angina* (2 or 3 angina features), a low-risk DTS was still associated with a ~10% risk of left main and/or 3-vessel CAD, and a ~10% risk of 2-vessel or proximal LAD disease.[12] Thus, ***a high-risk subgroup is concealed within the symptomatic low DTS group and is often picked up by nuclear imaging.***[13–15] Also, ~12% and 55% of patients with 3-vessel CAD had a low and intermediate DTS score, respectively. However, a very low-risk DTS with over 10 METs of exercise capacity (~8 minutes of Bruce protocol) and no ST depression has been associated with an extremely low prevalence of moderate or severe ischemia on nuclear imaging (<2%).[16]

Thus, while DTS has a good prognostic value, a low-risk DTS does not exclude CAD and, *depending on the pre-test clinical probability and risk,* may conceal some high-risk subgroups. Those high-risk subgroups are often picked up by stress imaging. This explains why stress imaging may be the preferred testing modality in patients with exertional chest pain and high pre-test probability (to avoid missing CAD, especially high-risk CAD).[14] ***In patients with intermediate pre-test probability, stress ECG is an appropriate and preferred test and has a high negative predictive value (ACC).***[14] ***Also, a very low-risk DTS of >+8, as opposed to a low-risk DTS of 5–8, is associated with a very low prevalence of moderate or severe ischemia, obviating the need for stress imaging.***[16]

Table 34.3 Sensitivity and specificity of various stress tests.

Test	Sensitivity	Specificity
Stress ECG	65%	70% (lower in women)
Stress echo	75–80% (lower with dobutamine)	85%
Stress nuclear	80–85%	70% (lower in women)

For all these tests, the sensitivity is higher in left main or 3-vessel CAD. Also, the prognostic value is superior to the diagnostic value.

Importantly, the high-risk DTS had a definitive diagnostic value, with a 99% risk of significant CAD (slightly less in women), and a 75% risk of left main or 3-vessel CAD.[12]

In addition to sensitivity, stress ECG has specificity limitations, particularly in women. In *symptomatic* patients, ST depression has a good positive predictive value of ~75% in men, but only ~50% in women.[17] In fact, exertional ST depression is common in women in general, including *asymptomatic* women. In asymptomatic women, ST depression is encountered on ~5% of stress tests and does not, per se, affect long-term prognosis, even when the ST is depressed >2 mm.[18–20] This is particularly related to the lower pre-test probability, but also the higher prevalence of microvascular dysfunction in women, and a digoxin-like effect of estrogen on the ECG. Yet, the lack of ST depression retains a good rule-out value in women, similar to men (~75–80%); the presence of **ST depression retains a prognostic and diagnostic value in *symptomatic women with typical exertional chest pain and an intermediate to high pre-test probability*** (those are the only cases where stress test should be done anyway). Also, DTS and exercise parameters maintain a prognostic value in women similar to that in men.

Exercise stress imaging has a stronger *diagnostic and prognostic value* than stress ECG. It has a higher sensitivity than stress ECG, and similar specificity (stress nuclear) or higher specificity (stress echo) (Table 34.3). It picks up the false-negative stress ECG and the significant CAD in ~20% of patients with low-risk DTS;[12–15] also, in intermediate-risk DTS, it better delineates the patient's risk as low or high.[13] On the other hand, in patients with abnormal ECG response, a normal stress imaging usually overrules the result of the stress ECG.[13] Even in patients with a markedly positive exercise ECG (≥2 mm ST depression), a normal stress echo or nuclear scan usually implies a low risk.[21–23] The following exceptions apply:

- A high-risk DTS is usually high risk, regardless of imaging results.[12]
- An abnormal ST-segment or chest pain response with a normal stress imaging is usually a low-risk stress test. However, *if the patient's pre-test probability of CAD is high*, the abnormal ECG or chest pain response may dictate coronary angiography even if imaging is normal. Nuclear stress testing may miss multivessel disease because of balanced ischemia; exercise stress echo may miss an ischemic response if echocardiographic windows are suboptimal; and dobutamine stress echo has reduced sensitivity because of its inherently lower workload. In patients with *high clinical probability of CAD*, the ECG, chest pain, BP, and exercise parameters may pick up those imaging pitfalls. The assessment of both ECG and imaging responses improves the sensitivity of the study in a patient with a high pre-test probability. When both ECG and imaging are abnormal, the specificity is boosted.

In sum, a normal stress imaging or a low-risk stress ECG is associated with <1% risk of cardiac events per year for the next 2 years ("warranty period" of 2 years).[12,13,24] Within this low-risk population, a high-risk subgroup exists and is captured using the pre-test clinical probability of CAD and a combination of ECG, imaging, and exercise parameters. *For all these tests, the sensitivity is higher in left main or 3-vessel CAD. Also, the prognostic value is superior to the diagnostic value*.

E. Stress echocardiography

Normally, the myocardial segments become hypercontractile with stress, meaning the myocardial *thickening* and *excursion* increase with stress. An ischemic response is characterized not only by a lack of hyperkinesis, but by a paradoxical worsening of contraction in comparison to baseline: a normal myocardial segment at rest becomes hypokinetic or akinetic with stress, a hypokinetic segment becomes akinetic or dyskinetic. The change from akinesis to dyskinesis is the only deterioration that does not, by itself, imply ischemia. Also, isolated hypokinesis of the inferobasal or inferoseptal segments is frequently seen in normal individuals and is not diagnostic of ischemia.

Exercise-induced contractile dysfunction resolves ~4–25 minutes after resolution of ischemia (later in more severe ischemia). Thus, imaging in recovery does not usually miss ischemia, even if heart rate has significantly declined.

Two other responses are taken into account but are less specific for ischemia (their value depends on the pre-test probability of CAD):

i. Lack of hypercontractile response. This may be related to ischemia, but is often related to inappropriate workload, severe HTN, underlying cardiomyopathy, imaging in early recovery after heart rate has declined, prior β-blocker therapy, or older age.
ii. Tardokinesis of a myocardial segment, meaning delayed contraction of a segment.

The following cases scenarios complicate ischemic assessment with stress echo:

i. Baseline hypokinesis: ischemia may manifest as worsening of hypokinesis or extension of hypokinesis to adjacent segments. However, this adjacent hypokinesis may be missed if the adjacent segments are tethered by the normal myocardium, or it may be overcalled if the adjacent segments are tethered by the dysfunctional myocardium. Nuclear testing is preferred in patients with baseline wall motion abnormality because of its higher sensitivity.
ii. LBBB or abnormal postoperative septal motion: the assessment of myocardial thickening, rather than excursion, of the anterior wall and apex rather than the septum provides appropriate diagnostic yield.[4,25]

F. Nuclear myocardial perfusion imaging (MPI), using single photon emission computed tomography (SPECT)

While having an excellent prognostic value, superior to stress ECG and overruling abnormal stress ECG results, SPECT MPI is flawed by a small but significant risk of missing multivessel disease. **The brightness of the nuclear uptake is not an absolute radioactive count, it is comparative to the pixel with the highest radioactive count:** resting segments are compared to other resting segments, while stress segments are compared to other stress segments. This means that in **diffuse balanced ischemia**, in which all the myocardium is equally ischemic (severe triple-vessel CAD), nuclear counts are equally low, which makes all pixels appear bright and the images appear normal. Since one area is usually more ischemic than the others, **the more common caveat is that only one area looks ischemic, while the others look normal despite being ischemic.** Thus, nuclear testing may miss assessing the true extent of ischemia in multivessel disease. A patient with severe LAD stenosis, but more severe RCA stenosis, may appear to have only an inferior defect, because the anterior wall is less ischemic and may thus look bright.

In one study, despite angiographically severe 3-vessel CAD, SPECT MPI showed no defect in 18% of patients and a single-vessel disease pattern in 36% of patients.[26] A nuclear substudy of the FAME trial found that in patients with angiographic multivessel disease, ~50% of vessels with FFR <0.80 were not identified on nuclear imaging, and 34% of patients with ischemia by FFR had a negative nuclear scan.[27] Thus, in multivessel disease, the lack of defect in one territory on nuclear imaging does not imply the lack of ischemia in that territory, and a completely normal scan is not uncommon. A high pre-test probability of CAD, chest pain during exercise testing, abnormal ECG or BP response, transient ischemic dilatation (TID), and EF on gated SPECT allow the diagnosis.

TID is the ratio of LV volume at stress compared to rest, the LV volume used being time-averaged from both systole and diastole using the non-gated perfusion images (ECG-gated LV volumes may be used with more weight provided for the systolic volume than the diastolic volume).[28,29] A post-exertional TID (ratio >1.2) proved highly specific (95%) for severe and extensive CAD, with a higher sensitivity than perfusion imaging in extensive CAD (71% vs. 33%).[28]

While a falsely negative stress ECG is "bailed out" by stress imaging, a falsely normal nuclear scan may be bailed out by TID or by the stress ECG portion. Those situations are suspected in patients with a high pre-test probability of disease.

Nuclear imaging also has specificity issues. Soft tissue attenuation may create the impression of fixed or sometimes partially reversible defects, i.e., defects that are present at rest and worsen with stress. Classically, an inferior artifact related to diaphragmatic attenuation is seen in men, while an anterior defect related to breast attenuation is the dominant artifact in women. As the soft tissue moves between rest and stress, the attenuation artifact may vary between rest and stress and mimic a reversible defect. Alternatively, true ischemia in a territory that has an attenuation artifact may be difficult to diagnose (the change in defect severity between stress and rest may be missed).

A fixed defect may signify any of the following:

i. Attenuation artifact. The attenuation artifact is associated with normal wall motion on gated SPECT imaging *and* is usually mild (>50–60% nuclear uptake) *and* with no Q waves.
ii. Myocardial scar.
iii. Hibernating myocardium.

Both scar and hibernation are associated with abnormal wall motion on SPECT imaging. The defect is usually mild/moderate in hibernation, vs. severe in scar (<50% nuclear uptake in scar). Thus, a fixed defect with a wall motion abnormality is not necessarily a scar and may represent a hibernating, ischemic myocardium, especially if there are no Q waves, if the defect is not severe, or if the patient has angina. In one study, 75% of fixed defects without Q waves reversed with revascularization.[30] A coronary angiogram is therefore indicated when a large, fixed defect is associated with angina. Most of those fixed defects normalize after revascularization.[30] In the COURAGE trial, rest defects improved by 50% with PCI and medical therapy, again implying hibernation.[31]

In general, however, when it is not associated with severe symptoms or reduced EF, a fixed defect, even if real (e.g., patients with prior MI), does not imply an increased cardiac risk in comparison to a normal scan, as the fixed defect is mostly a small scar with appropriate LV compensation.[32,33]

In comparison with stress echo, nuclear imaging has the advantage of a higher sensitivity, particularly in: (i) single-vessel disease; (ii) patients with underlying myocardial wall motion abnormalities; (iii) poor echo windows. Stress echo has the advantage of a higher specificity, especially in women prone to breast attenuation artifact on nuclear imaging and ST depression on stress ECG.

Note: value of the ECG during pharmacological stress testing

ST changes that occur with dobutamine should be taken into account and may imply ischemia; however, the sensitivity and specificity are less than those of the imaging part of the test. ST depression with adenosine is uncommon, because adenosine does not usually induce ischemia; however, when ST depression occurs (in ~1–2% of tests), it implies severe CAD with vasodilator-induced steal from the diseased coronary artery. Thus, ST depression induced by adenosine is insensitive but is very specific for CAD (even more so than ST depression induced by exercise) and has a strong prognostic implication.

G. Use of antianginal agents before stress testing

These agents prolong the time to onset of ST depression, increase the exercise tolerance, and may normalize the ECG or the images. Also, β-blockers prevent the heart rate from achieving the target. Thus, if possible, the last dose of β-blocker and other antianginal agents is held before stress testing.

On the other hand, stress testing may be performed under maximal medical and β-blocker therapy to assess the effectiveness of medical therapy and the prognosis under medical therapy. In fact, when treatment fails to reduce the ischemic myocardium by >5% (absolute value), or when residual defects involve >10% of the myocardium, the coronary event risk is high (COURAGE nuclear substudy).[31]

In general, in patients without a history of CAD who are referred for diagnostic evaluation of a possible angina, the last dose of antianginal drug(s) is withheld before the test to increase its *diagnostic yield*. In patients with known CAD who are referred for a change in symptoms, stress testing may be performed on the current antianginal therapy to assess for residual ischemia despite medical therapy, and thus the *residual prognosis*.

A summary of high-risk stress test features and risk stratification is provided in Table 34.4. Indications to stop a stress test are provided in Table 34.5. General factors that affect the sensitivity and specificity of stress testing are provided in Table 34.6.

Table 34.4 Risk stratification with stress testing.

High risk: cardiac mortality >3%/year, cardiac events >5%/year
- DTS ≤ −11
- Reversible large and/or severe perfusion defect (summed difference score ≥+8, corresponding to ischemia involving >10% of the myocardium)[a]
- Fixed large or severe perfusion defect with LV dilatation/low EF (ischemia may not be present, but mortality is high from prior MI/low EF)
- Stress-induced drop in EF ≥10% or TID
- On stress echo: ischemia of ≥3 segments (out of 17), or >1 coronary distribution, especially if it occurs at a low rate <120 bpm or a low dose of dobutamine (≤10 mcg/kg/min)

Intermediate risk: cardiac mortality 1–3%/year, cardiac events 1–5%/year
- DTS −10 to +4
- Summed difference score 4–8

Low-risk: cardiac mortality and cardiac events <1%/year (~0.5% with stress imaging). Warranty period ~2 years
- DTS ≥+5 (≥ +8 is very low risk)
- No perfusion defect or small perfusion defect with a summed difference score <4

[a]On nuclear imaging, the myocardium is divided into 20 segments. Each segment is given a score of 0 (no defect) to +4 (very severe defect, <25% nuclear uptake), at rest and at stress. The summed rest and stress scores are obtained by adding the scores of all segments with defects. The difference between the stress and rest scores is the summed difference score, which quantifies the extent of ischemia; a score ≥+8 is severe. Since the maximum summed score is 80 rather than 100, the summed score is multiplied by 1.25 to obtain the percent of myocardium at risk.

Table 34.5 Indications to stop the stress test.

1. Achievement of high-risk criteria (severe ST ↓ ≥3 mm, ST ↑, sustained VT, ↓ SBP >10 mmHg below baseline)
2. Occurrence of some arrhythmias that do not necessarily make the test positive for ischemia but mandate interruption of the test (relative indication): ventricular triplet or NSVT, SVT or AF with a fast rate, high-degree AV block
3. Severe chest pain or chest pain accompanied by high-risk criteria
4. HTN (>250/120 mm Hg)
5. Severe dyspnea/cyanosis/ataxia

In the absence of the preceding, do not simply stop the stress test if the target heart rate is achieved; the patient needs to achieve a good workload

Table 34.6 Factors that reduce the sensitivity and specificity of any stress testing modality.

Reduced specificity
- *Low pre-test probability (<10–20%): this is, by far, the most common cause of a false-positive stress test*
- Abnormal baseline ECG, LVH
- Severe acute or chronic HTN can lead to ischemic signs on ECG/imaging even without CAD
- Any cardiomyopathy
- Anemia, hypokalemia (diuretic therapy → check K before testing), mitral valve prolapse
- AF or SVT that develop during stress may cause non-ischemic ST ↓ and EF ↓. The EF reduction results from decreased preload, and the loss of Bowditch effect at a certain rate
- Female sex (partly because of the lower pre-test probability in women, and because women more commonly have microvascular spasm)

Reduced sensitivity
- Poor workload
- Single-vessel, low-risk CAD
- Use of antianginal agents

V. Mechanisms of various stress modalities

Exercise or dobutamine effect on ECG and echo

Exercise and dobutamine elicit ischemia by increasing myocardial demands, which translates into ST depression on ECG and hypokinesis on echo. Dobutamine increases inotropism and chronotropism, but reduces LV diastolic volume (preload); conversely, exercise increases preload, and thus, the cardiac workload is higher with exercise than with dobutamine. Hence dobutamine is less sensitive than a maximal exercise echocardiogram.

Exercise or dobutamine effect on nuclear imaging

The increased myocardial demand elicits coronary microvascular dilatation, which increases the coronary flow by 4–5 times in normal coronary arteries. A flow-limiting coronary stenosis limits the increase in coronary flow; therefore, on nuclear perfusion imaging, areas with significant stenosis light up much less with stress than stenotic areas.

While ECG and echo detect ischemia, nuclear imaging detects the disparities in coronary flow induced by exercise or dobutamine.

Adenosine effect on nuclear and MRI perfusion imaging

Adenosine often assesses CAD without eliciting ischemia. Adenosine vasodilates the coronary microvasculature and, similarly to exercise, increases coronary flow differentially between areas subtended by a stenosis and those that are not; areas with significant stenosis light up much less with adenosine than normal areas. *The same differential flow effect is detected by MRI perfusion imaging*. Since this occurs without an increase in O_2 demands, the difference in coronary flow reserve is detected on nuclear or MRI flow imaging even without inducing ischemia, wall motion abnormality, or ECG changes (the patient being at rest, a lack of increase of coronary flow in the stenotic artery does not translate into ischemia). This is also why adenosine echo is not a sensitive test for CAD. Adenosine may, however, induce ischemia and ECG changes via ***coronary steal*** in critical multivessel CAD. Let's take the example of an occluded RCA receiving collaterals from a diseased LAD: adenosine dilates the LAD microcirculation, but LAD flow cannot increase enough to match this dilated circulation because of the LAD stenosis, hence LAD pressure declines, i.e., the perfusion pressure of the RCA collaterals declines.

Adenosine increases coronary flow at least as much as exercise, and thus adenosine nuclear imaging is at least as sensitive as exercise nuclear imaging and more sensitive than dobutamine imaging. The prognostic value of exercise nuclear imaging is, however, superior to adenosine nuclear imaging, as exercise parameters are strong prognostic markers.

Regadenoson (Lexiscan) is more selective for adenosine α_{2a} receptor and has fewer side effects than adenosine, including less risk of bronchospasm. It is administered as a bolus, and has a 2–3-minute half-life.

Depending on its severity, ischemia induces the following sequence:

Impaired perfusion (seen on nuclear stress testing) → abnormal diastolic function → abnormal systolic function (seen on stress echo) → abnormal ECG (seen on stress ECG) → angina

This explains the difference in sensitivity between various tests. The abnormal contractility seen on echo develops ~20 seconds after ischemia, and resolves ~4–25 minutes after resolution of ischemia (the more severe the ischemia and extent of CAD, the longer the abnormal motion persists).[34] This explains why echocardiographic imaging after peak exercise does not usually miss wall motion abnormalities, even if heart rate has significantly declined (particularly in the case of severe ischemia).

VI. Nuclear stress imaging (see Figures 34.3–34.5)

Nuclear stress testing is usually performed using ***SPECT imaging*** *and SPECT tracers*, but may be performed with positron emission tomography (*PET) imaging and PET tracers*, such as rubidium and nitrogen. ***PET has a higher resolution than SPECT (less artifacts) and while the obtained images are relative perfusion images (like SPECT), PET can provide an absolute quantification of myocardial flow***. Absolute flow measurement by PET, and the calculation of stress/rest flow ratio, may circumvent the limitations of SPECT in 2 situations: (i) balanced ischemia, (ii) impaired flow with no CAD, the so-called microvascular dysfunction. Nuclear imaging has resting and stress parts. Nuclear agent injections at rest and stress can be done the same day.

A. SPECT

Two nuclear isotopes may be used for SPECT: technetium and thallium. The ***technetium*** carrier (e.g., sestamibi, Myoview) is taken up by the mitochondria of myocardial cells and does not redistribute out of the cells; technetium rather decays inside those cells, within 24 hours. A higher-dose injection during the second part of the study (i.e., stress) is therefore necessary to identify stress defects if the rest study was performed the same day.

- For 1-day technetium studies: first injected dose = 10 mCi; second injected dose, ~2 hours later = 30 mCi. A "rest–stress" or "stress–rest" sequence may be performed, but *rest–stress is preferred as it provides a true rest study* and prevents the contamination of rest images with the previously taken stress images, increasing the ability to detect reversibility. In the stress–rest sequence, a stress-induced defect may partially persist onto the rest images and look partially fixed.
- A dual-isotope technique may be used: thallium at rest, then technetium at stress 4 hours later.
- For 2-day technetium studies: inject 30 mCi each time. Two-day studies are indicated for obese patients, as thallium or a 10 mCi dose of technetium may not allow good image acquisition.

Thallium is extracted by the myocardial cells, similarly to potassium, and quickly starts to redistribute out of the cells 10–15 minutes later. It has a long physical half-life (73 hours) but a short stay in the myocardium. Thallium uptake is reduced in ischemia but its redistribution becomes slower, in such a way that 3–4 hours later the nuclear concentration should be equal in ischemic and non-ischemic territories; in stress-induced ischemia, images taken 4 hours post-stress will show redistribution and reversibility of a defect that was present at stress.

A defect that is present during stress only is a reversible, ischemic defect. An infarcted, non-viable myocardium, and sometimes a hibernating or stunned myocardium, have a low nuclear uptake at stress and rest (fixed defect). A severely reduced nuclear uptake at rest, i.e., <50% uptake in comparison to a reference region, is more likely a non-viable infarction than hibernation.

Technetium has a shorter half-life than thallium, and thus higher doses than thallium can be used with a lower overall radiation exposure. In addition, the photon energy of technetium is higher (140 keV vs. 80 keV). For these reasons, *technetium provides better-quality images with fewer artifacts, even more so in obese patients*.

Also, ***nuclear SPECT gated to the ECG*** may be used to compare myocardial counts in systole and diastole (myocardial brightening in systole corresponds to myocardial thickening), and to define endocardial excursion between systole and diastole. This allows EF calculation and

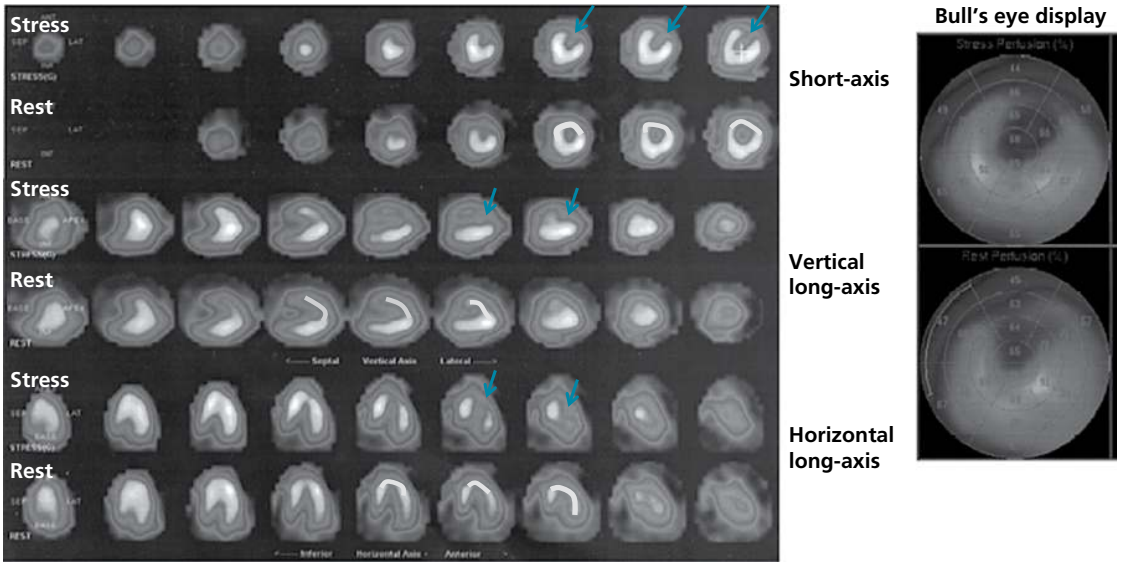

Figure 34.3 Nuclear images are displayed in 3 views:
- *Short-axis cuts* going from the apex to the base
- *Vertical long-axis cuts* (VLA cuts): similar to the echocardiographic apical 2-chamber cuts, these cuts show the anterior and inferior walls, going septal to lateral.
- *Horizontal long-axis cuts* (HLA cuts): similar to the apical 4-chamber cuts, these cuts show the septal and lateral LV walls, going anterior to inferior.

The upper images of each series are the stress images, the lower images are the rest images. A defect of the anterior wall (*arrows*) is visible on the short-axis, HLA, and VLA views, extending from the base of the anterior wall to the apex. This defect is largely reversible and suggests anterior ischemia. A "bull's-eye" map displays the myocardium in a 2-dimensional plot, the center being the apex, the contour being the base.

Beware of attenuation artifacts: diaphragmatic attenuation of the inferior wall leading to a false, fixed inferior defect, breast attenuation of the anterior wall leading to a fixed anterior defect, and artifacts related to extracardiac tracer activity (bowel or liver uptake will look bright and will attenuate the counts of the inferior wall at stress and/or at rest). A true fixed defect should lead to regional wall motion abnormalities (infarct or hibernation). If gated SPECT does not show any wall motion abnormality, the defect is likely an attenuation artifact. Conversely, a defect that is severe (<50% nuclear uptake) is usually a true defect. Occasionally, breast attenuation may be associated with an anterior defect that is partially reversible, as the breast moves between rest and stress imaging, therefore reducing the specificity of any anterior defect in women.

Note that **the color intensity and brightness are comparative to the pixel with the highest radioactive count** (rest pixels are compared to each other; stress pixels are compared to each other, not to the rest pixels). It is not an absolute radioactive count. This means that in **diffuse balanced ischemia**, in which all the myocardium is equally ischemic, the images may look normal, as nuclear counts are equally low and all pixels appear bright. Since one area is usually more ischemic than the others, **the more common caveat is that only one area looks ischemic, while the others look normal despite being ischemic.** Thus, nuclear testing may underestimate the true extent of ischemia in multivessel disease. A patient with severe LAD stenosis, but more severe RCA stenosis or inferior scar, may only have inferior defect, because the anterior wall has better nuclear uptake and thus may look bright. Looking at some extra high-risk features can compensate for this: LV dilatation on the perfusion stress images (called *transient ischemic dilatation* [TID]), which is a sign of diffuse ischemia with stress. TID index >1.15 (115%) with exercise or >1.35 with adenosine is significant. TID is not always seen even with severe ischemia, as the images are taken 15–30 minutes post-stress, giving time for the myocardium to recover its function. Another sign of severity is *lung nuclear uptake*, seen when imaging is performed 10–15 minutes post-stress, mainly with thallium; lung uptake is a sign of increased pulmonary capillary pressure with exercise, related to severe ischemia with exercise or to LV dysfunction. While the RV may be normally visualized by increasing the gain, *transient RV visualization* on stress images without gain change is a sign of severe ischemia.

is usually done on the post-stress images, usually with technetium studies (because technetium provides higher nuclear counts); it may be done at rest as well, for comparison of rest and stress EF and LV systolic volumes. A striking difference between echocardiographic EF (at rest) and nuclear EF (post-stress) may be due to ischemia but also to gating errors, such as gating the cardiac cycle from R to T rather than from R to R, or a flat QRS that prevents appropriate R-to-R gating. Also, poor gating may occur when the R-to-R cycle is strikingly variable, as in AF. Note that ***TID*** is not usually measured on those same LV EF images; TID compares the rest vs. stress cavity size on the perfusion images.

With technetium SPECT, the radiotracer is first administered at rest, and rest images are taken 60 minutes later. Then, 2 hours after this first dose, the patient undergoes either exercise or adenosine infusion, and a second, larger dose of the radiotracer is administered at peak stress. Imaging is then conducted 15–30 min after exercise or 60 min after adenosine. This waiting time allows clearance of the liver/GI uptake, this uptake being lower during exercise (less GI diversion of the cardiac output). The perfusion images are reflective of the nuclear uptake at the time of injection, not at the restful time of imaging, as the nuclear agents do not redistribute during this short period of time. However, the myocardial contractility and excursion are reflective of the myocardial function at the time of imaging. EF obtained is a post-stress EF and may miss exercise-induced myocardial dysfunction, unless ischemia is severe and stunning persists >15 min post-exercise. With thallium, since it redistributes quickly, images are taken 10–15 minutes after exercise, then 4 hours later to assess the redistribution.

If the patient is unable to walk, stress testing may be performed with adenosine or dobutamine. Adenosine (or regadenoson) testing increases coronary flow at least as much as exercise, and thus adenosine testing is at least as sensitive as treadmill nuclear imaging, and is more sensitive than dobutamine nuclear imaging. The latter should only be performed if asthma precludes adenosine use. A negative adenosine stress test result, however, has a shorter warranty period over the long term than a treadmill stress test, because exercise time, per se, has a prognostic value. Adenosine is a short-acting vasodilator administered as a 4- to 6-minute infusion (half-life 30 seconds). The

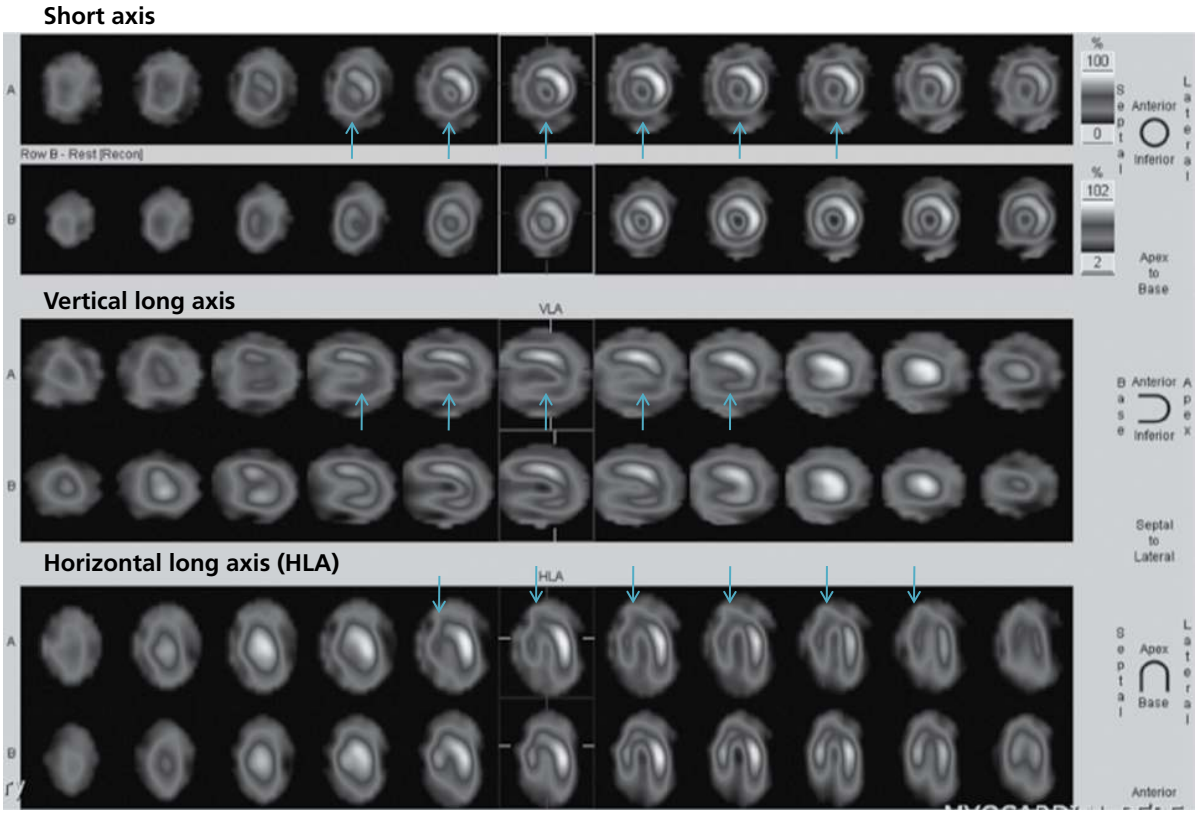

Figure 34.4 A severe defect (*arrows*) is noted in the inferior and septal walls at stress. This defect reverses to a large extent on the rest images. The ischemia is severe, as the defect is severe and extends into more than one coronary distribution. In fact, over 10% of the myocardium is ischemic (taking into account the extent but also the severity of the nuclear defect). No TID is noted. Severe RCA stenosis is suspected.

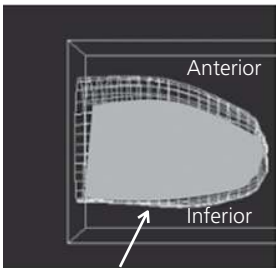

Figure 34.5 Gated SPECT myocardial excursion of the previous case (Figure 34.4). LV end-systolic volume is shown in gray, while LV end-diastolic volume is marked by the "fishnet." Note that the excursion of the inferior and apical wall is diminished (hypokinesis, *arrow*). The calculated EF is 50%.

nuclear agent is injected at 2–3 minutes of infusion. Adenosine vasodilates the microcirculation and increases coronary flow 4–5 times but cannot increase coronary flow past significant stenoses >50–70%; therefore, areas without significant stenosis will light up much more with adenosine than stenotic areas. This difference in vasoreactivity is detected even without inducing ischemia or ECG changes, as myocardial workload is not markedly increased. Caffeine is a competitive antagonist of adenosine at the receptor level and should not be used for 24 hours prior to the test. In case of bronchospasm occurring with adenosine, administer IV aminophylline.

Perform low-level treadmill exercise along with vasodilator stress testing; this reduces the common side effects of adenosine (flushing, non-specific chest pain or dyspnea, nausea) and reduces the splanchnic/GI nuclear uptake, eventually lessening artifacts and improving image quality. Also, drinking cold water before imaging may accelerate elimination of the tracer from the GI tract. When a significant GI artifact is present, stress images may be repeated a little later, providing more time for tracer clearance.

Review of the raw, moving cine images allows a better appreciation of whether a defect is an attenuation artifact or a true defect. The dark breast contour is identified over the heart, and photopenia expected behind this contour; the breast position may vary between the rest and stress studies, creating a falsely reversible defect, and this is identified on the raw cine images.[35] A defect in the anteroapical wall outside the breast contour is a true defect. A superiorly placed diaphragm may lead to inferior attenuation artifact (the superior diaphragm is identified as a linear density on the lateral heart view). GI uptake close to a defect is suspicious for GI uptake artifact. Excessive cardiac motion with its inherent artifacts may also be appreciated.

B. PET

PET perfusion imaging, using ^{82}Rubidium or ^{13}N provides clearer images vs. SPECT because of the higher energy of the photons emitted (511 kev), yet lower radiation exposure because of their very short half-life (75 seconds for ^{82}Rb, 10 minutes For ^{13}N). PET is more sensitive and specific than SPECT, particularly in obese patients or patients with baseline artifacts. *Most patients with equivocal SPECT have a conclusive PET study*. Moreover, PET machines have CT imaging integrated, allowing CT correction of soft tissue artifacts and further risk stratification by calcium scoring. Con: because of Rb's very short half-life, imaging is performed almost simultaneously to the injection, making imaging after exercise challenging, and favoring vasodilator stress.

Myocardial blood flow may also be calculated using dynamic PET imaging, which starts 10 seconds before radiotracer injection and tracks the speed of change of nuclear activity at the myocardial level over minutes (like thermodilution technique). This is done at rest and during vasodilator stress, allowing the calculation of a flow ratio for each coronary territory: it helps diagnose ischemia (ratio <1.6–2), whether local or diffuse, and, in the absence of CAD, microvascular dysfunction.

PET perfusion imaging may be combined with **metabolic imaging** (radiolabeled glucose). The normal myocardium mainly uses fatty acids for ATP generation rather than glucose (aerobic oxidation), particularly in the fasting state; in the fed state, high insulin levels increase myocardial glucose utilization. However, the ischemic myocardium shifts to glucose regardless of feeding state (anaerobic glycolysis). This leads to cardiac accumulation of non-metabolized fatty acids, further damaging the myocardium. Thus, low perfusion with high glucose activity, the so-called perfusion-metabolism mismatch, indicates ischemia, and is enhanced by loading with oral glucose and insulin. By contrast, normal perfusion with high glucose uptake in a fasting state may indicate inflammation, as seen in sarcoidosis.

VII. Coronary CT angiography and coronary calcium scoring

A. Role and indications of coronary CT angiography (see Figures 34.6–34.9)

Traditionally, CTA has somewhat had the same indications as stress testing and has been an alternative to stress testing in intermediate-probability stable chest pain and negative-troponin acute presentation.[36] It has also been useful for an equivocal stress test result.

Modern data have expanded the application of coronary CTA over stress testing:

- *In intermediate CAD probability*, the SCOT-Heart trial showed that routine CTA on top of functional testing reduces the 5-year MI risk in patients with chest pain, typical or atypical, compared to functional testing alone.[37]
- *In high CAD probability or high-risk stress test*, CTA is an alternative to coronary angiography when angina is not severe. CTA is done to rule out left main disease and confirm CAD. A conservative strategy may then be chosen as a safe alternative to revascularization in stable, non-left main CAD (ISCHEMIA trial).[38] Indirectly, ISCHEMIA trial suggests that CTA is the preferred testing modality when the clinical probability of CAD is high.

The ideal candidate must have a very regular, normal ***sinus rhythm that can be slowed to <65 bpm***, must not have frequent PVCs/PACs or AF, and must not be obese. CTA cannot adequately assess stented coronary segments <3 mm and ***heavily calcified coronary arteries***. In patients with bypass grafts, CTA can assess the bypass graft bodies, but not the anastomoses with the native arteries or the native arteries distal to the anastomoses.

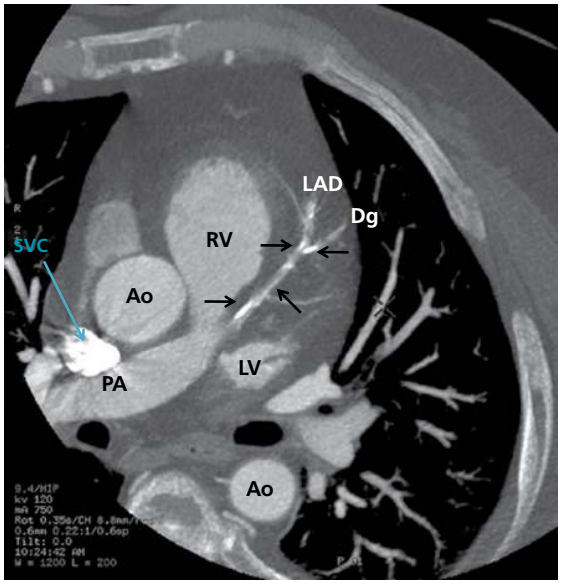

Figure 34.6 This is an axial CT view. The right ventricle is the most anterior structure, the left ventricle is posterior. The main pulmonary artery (PA) and its distal branches are visible. The ascending and descending aorta (Ao) as well as the SVC are seen. The LAD is the artery that runs between the right and left ventricles, over the septum. Left circumflex would run in the left AV groove, between the LA and LV (not seen in this image). RCA would run in the right AV groove, between RA and RV. LAD has some brightness (calcium) proximally and distally (*right-facing horizontal arrows*) and in one of its branches as well (second diagonal [Dg], *left-facing horizontal arrow*). These are calcified stenoses that seem eccentric, and, when assessed in multiple views, are ~50% stenotic.

The LAD also has a soft, non-calcified stenosis in the mid segment (*oblique arrow*) between the 2 calcified stenoses. This stenosis looks dark, darker than contrast (soft, non-calcified stenosis). It is a severe 80% mid-LAD soft stenosis. This soft stenosis is responsible for this patient's ACS.

Always assess lesions in 2 views (or more if appropriate): axial, oblique, curved, sagittal, or coronal.

Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

A normal CTA has a very high negative predictive value (90%) for significant stenosis over 70%. However, the positive predictive value is more limited (70–80%), especially in the presence of heavy calcifications, such as a calcium score >400.[39] CTA does not provide any information on the functional ischemic effect of a lesion; however, a computer modeling of fluid dynamics allows generation of a virtual FFR value based on the morphology and the length of the lesion by CT (CT-FFR) (calcium remains a limitation).

The large PROMISE trial randomized symptomatic outpatients with intermediate pre-test clinical probability of CAD to coronary CTA versus stress testing (mostly stress imaging). An abnormal result was slightly more frequent in the CTA group (~12% vs. 8%), with relatively more true-positive findings (~75% vs. 50%).[40] *However, both strategies were associated with a low and similar rate of cardiac events at 2 years, which attests to the validity of both strategies*. In the SCOT-heart trial, CTA was superior to stress testing alone.[37] **While both stress testing and coronary CT have ~similar diagnostic value in assessing the cause of chest pain, coronary CTA, and even coronary calcium score, likely have superior prognostic value as they quantify the patient's plaque burden, a major predictor of MI beyond the degree of coronary stenosis**.

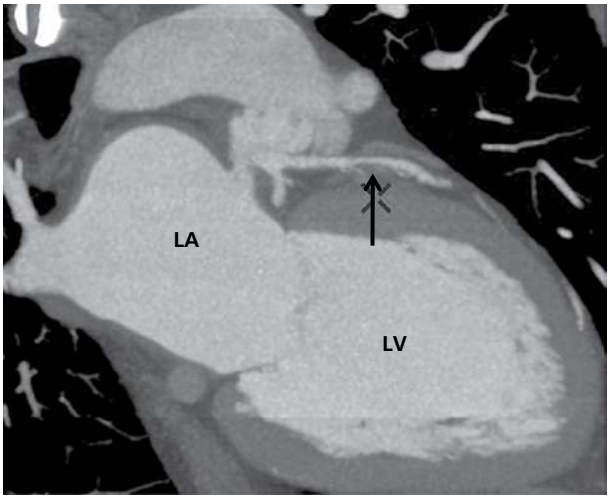

Figure 34.7 This is an oblique view of the proximal LAD (a vertical cut through the LAD plane). A soft stenosis is visible in the mid-LAD and is rated at 50% (compare the lumen proximal to the stenosis with the lumen at the level of the stenosis, *arrow*). LA and LV are also visible. Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

Figure 34.8 This is a curved view of the RCA. The curved view is a processed view in which the coronary artery of interest is straightened and shown in one plane. This is also called multiplanar reformation (MPR). There is a proximal plaque that has calcium and a soft component as well (mixed plaque) (*top arrow*). Further down in the mid-vessel, a cutoff is seen, beyond which the opacification is severely decreased (*bottom arrow*). There must be a severe stenosis or an occlusion at this level. Coronary angiography confirmed the presence of mid-RCA occlusion. Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

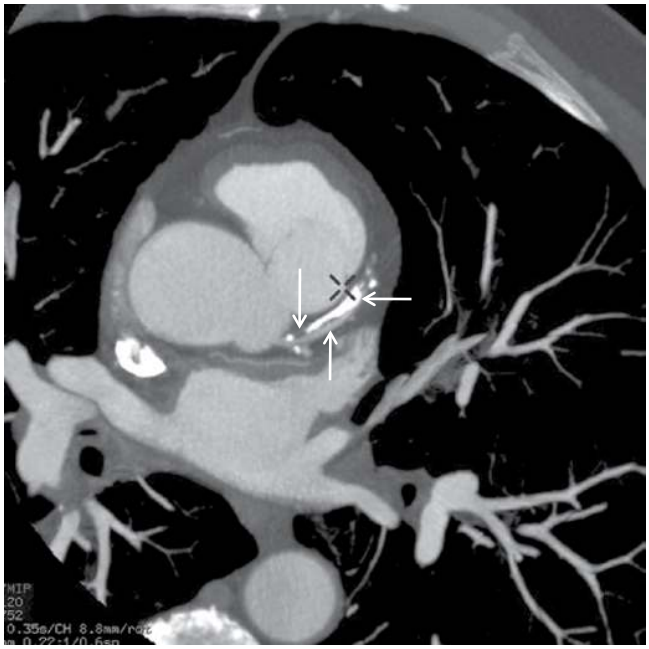

Figure 34.9 This is an axial CT view. The LAD has a soft plaque proximally (short stenosis ~50%, *down arrow*). It is followed by eccentric calcification that seems to obstruct less than 50% of the lumen (*up arrow*). Further down, this calcification seems to hide the whole vessel (*horizontal arrow*). It may simply be a rim of concentric calcium, mildly stenotic, that prevents the reader from seeing and assessing the underlying lumen, but it may also be a severe calcified stenosis. When the calcium is concentric and hides the lumen in multiple views, the significance of the underlying stenosis cannot be evaluated. ***Severe calcifications are the most important limitation to coronary CTA and significantly reduce the specificity of the test.*** Reproduced with permission from Hanna EB, Quintal R, Jain N. Cardiology: Handbook for Clinicians. Arlington, VA: Scrub Hill Press, 2009.

Cardiac CTA may be used to assess LV function in patients with technically limited echo. CTA is very valuable for the assessment of congenital coronary anomalies.

B. FFR estimation by CTA

FFR-CT uses computational fluid dynamics to estimate FFR; the software incorporates lesion severity, morphology, angulation, length, and the myocardial volume supplied to estimate FFR. It has a high correlation with invasive FFR. FFR is measured 2 cm past the lesion, and in case of serial disease or diffuse disease with heavy plaque burden, FFR may be measured distally along with virtual FFR-CT pullback to assess each stenosis. Virtual post-PCI FFR may also be done to estimate how much FFR could improve with stenting one lesion. As such, FFR-CT allows CTA to not only provide anatomical assessment but also detailed functional assessment of a stenosis, with an even better spatial resolution than stress imaging. However, FFR-CT depends on good CT image acquisition and is limited by heavy calcifications, motion, and misregistration.

C. CT guidance of PCI

CTA may be used to guide PCI. Some of the information may even be obtained from a non-cardiac dedicated chest CT. CT provides 4 key components for PCI guidance (Figure 34.10):

a. *MIP (maximum intensity projection)* of the whole coronary anatomy
b. *Axial image across the aortic sinuses and coronary ostia*
c. *MPR (multiplanar reformation)* of each coronary artery
d. *Short-axis cross sections* at the stenosis and around it

(a) and (b) guide catheter selection, working views, and the general wiring and support strategies, whereas (c) and (d) guide the exact lesion treatment strategies. In addition, FFR-CT may be performed, including FFR-CT pull-back and virtual post-PCI FFR (how much a certain stent length will improve FFR).

D. Brief CTA technique

CT imaging is prone to artifacts, mostly related to the temporal resolution, the heart being a moving organ. With 64-slice CT imaging (0.6 mm thickness per slice), multiple gantry rotations are required to cover the cardiac length (~4 cm per rotation); 256-slice CT can cover the whole heart in one rotation and one cardiac cycle.

Also, during each rotation, the same cardiac structure moves within the cardiac cycle. A 64-slice CT performs a 180° rotation in ~160 ms only; in patients with slow heart rate (cardiac cycle >1 second), this corresponds to a small window of the cardiac cycle, during which the motion is limited. A dual-source CT scans an area with only 90° of rotation, thus requiring ~80 ms only. This improves the temporal resolution.

With retrospective gating, each slice is acquired multiple times at multiple phases of the cardiac cycle. Multiple gantry rotations (180 ms) and multiple acquisitions are performed over each slice, using the spiral CT technique. The table moves slowly, allowing images of

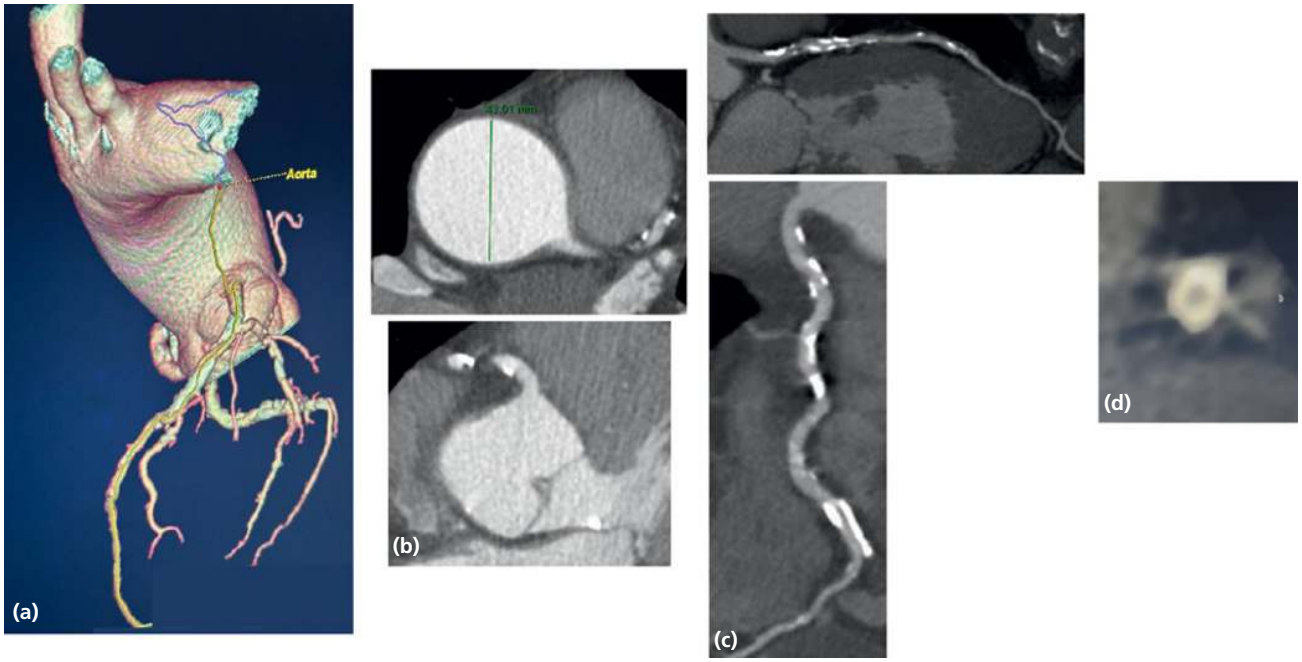

Figure 34.10 CT provides 4 key components for PCI guidance:

(a) MIP (maximum intensity projection): provides a 3D reconstruction of the whole coronary anatomy not focused on lesions. MIP shows the coronary course, tortuosity, and the best angles for lesion visualization.

(b) Axial image across the sinuses and coronary ostia allows the selection of the proper guiding catheter and EBU size. Normal RCA is at 11 o'clock and LCA at 4 o'clock. Aortic diameter of 4–4.5 cm at the sinuses of Valsalva suggests the need for EBU 4 guiding catheter (EBU size ≤0.5 cm of the aortic root diameter).

(c) MPR (multiplanar reformation): MPR straightens the whole vessel of interest and displays it in one cut (one plane), in an elongated or curved fashion, as opposed to axial or coronal cuts that show one segment on each cut. Multiple MPR planes of the vessel are used to assess stenoses. MPR evaluates ***lesion length, severity, and calcium distribution***, as well as stent length.

(d) Short-axis cross sections at the stenosis and around it: allow the assessment of **calcium across the lesion** (what is the arc of calcium? calcium thickness? calcified nodule?), plaque burden, and the proximal and distal reference lumen diameters.

the same area to overlap. The fact that each area is imaged at multiple points of the cardiac cycle allows a retrospective search for the cardiac phase during which the images have less artifacts. This reconstruction is called *multiphasic retrospective gating*.

Sequential prospective gating images each slice at one cardiac phase only and is more sensitive to rate irregularities between the different gantry rotations. This may be less of a problem with 256-slice CT covering the whole heart in one rotation and one cycle.

E. CTA Artifacts

- Irregular heart rate may cause misalignment of adjacent slices, because adjacent slices are at different phases of the cardiac cycle for the same R–R phase (e.g., 70% of R–R corresponds to a different cardiac phase during a different cardiac cycle). This is called *step artifact*. Fast heart rate may also cause it by increasing the number of cardiac cycles acquired during the ~10 seconds of imaging, and by increasing the relative importance of slight timing variations. Respiratory motions may also cause these malalignments.
- Motion artifacts related to cardiac, coronary, or respiratory motion may occur during each cardiac cycle, leading to streaks and blurring artifacts. These artifacts are less likely to occur in the relatively quiet mid- to end-diastolic phase (~60–80% of R–R interval), and at the end-systolic phase when the coronaries are relatively stationary (~30% of R–R interval). These artifacts are increased in case of fast rate (less stationary time). Motion and step artifacts may be less pronounced at one R–R phase, hence the need to analyze the coronaries at multiple phases and the value of multiphasic reconstruction in this context.
- Increased image noise (grainy appearance) in obese patients. This may be improved by increasing the tube voltage.
- Partial volume effect or *blooming artifact* is the artifact caused by an adjacent structure that has a high/bright CT attenuation (PM lead, coronary calcification, stent). A high CT number will be assigned to the whole pixel, which will thus appear bright. The edges of the calcification "spill over," making the calcium appear thicker and more obstructive, and causing overestimation of coronary stenosis.
- Poor timing of contrast injection leading to inappropriate aortic and coronary filling (the left side appears less dense than the right side of the heart).

VIII. Role of CT imaging for coronary calcium scoring

CT can assess the total coronary calcium burden and the calcium burden of each coronary artery. Coronary calcium is quantified using the Agatston score. Coronary calcium correlates strongly and closely with the extent of atherosclerotic plaque burden. Coronary calcium score also strongly correlates with the long-term occurrence of coronary events. Coronary calcium is the tip of the atherosclerotic iceberg, ~20% of the total plaque burden is calcified, while ~80% of plaques are lipid-rich or fibrotic. Thus, plaque burden goes up dramatically with higher calcium scores. Atheroma may be seen on the CTA of ~13% of patients with calcium score of 0, more so if LDL is >190 mg/dl, but the overall

atheroma burden is low and the risk of cardiac events is low, even if obstructive disease is present or even if LDL is >190 mg/dl (0.7% per year).[41] On a lesion level, dense coronary calcium is less vulnerable to plaque rupture than lipid-rich plaque or lower-density spotty calcium (<90° arc +<3 mm length); however, this does not make it less dangerous: in fact, on a patient level, dense calcium is associated with heavier total plaque burden, including lipid plaques and dangerous calcified nodules prone to plaque rupture, and more risk of coronary events.[42] According to the calcium score, the coronary events at 5 years are: score 0 <1%; score 1–100 = 3–4%; score 101–400 (moderate risk) = 6.5%; score >400 (high risk) = 11%.[43]

Outside of NSTEMI, a score of 0 makes the risk of coronary events very low, <0.5% per year, and the presence of significant CAD very unlikely, <5% (very high negative predictive value). On the other hand, **a high calcium score only has a moderate correlation with the presence and severity of angiographic stenosis.** On CTA analysis, <1% of asymptomatic patients with calcium score of 0 had obstructive coronary stenosis, vs. 7% for a score of 11–100, 24% for a score of 100–400, and 45% for a score >400.[44] Obstructive CAD is more prevalent in symptomatic patients with higher pre-test likelihood, where up to 3% of young patients and 6% of older patients with calcium score of 0 have obstructive CAD (of 1 vessel only), and 40% and 70% of those with calcium scores >400 and >1,000 have obstructive CAD, respectively.[45–47] ~14% of patients with obstructive CAD have calcium score of 0, relatively more so women and patients <40–50 years old (>20% calcium score 0), as early atherosclerotic lesions are more often noncalcified.[47] *However, even if obstructive CAD is present, a calcium score of 0 still predicts a low death/MI event rate of ~0.7% per year*.[45,47] Conversely, even without obstructive CAD, a calcium score >400 is as predictive of future MI as a prior coronary event (>3% per year) and may qualify for secondary prevention measures.[45,48] **Importantly, coronary calcium score is a measure of plaque burden, which is at least as big a driver of MI as the extent of obstructive CAD, as suggested by a CTA analysis.[45]**

Calcium scoring is also useful in patients with acute chest pain presentations and negative troponin, where a calcium score of 0 rules out CAD in >99% of patients.[49] In acute presentations with elevated hs-troponin + type 1 MI picture, calcium score is not useful and at least 15% of those with a calcium score of 0 may have obstructive CAD (up to 20% of all patients with significant CAD have a calcium score of 0).[49]

Currently, CT calcium imaging is mainly indicated in *asymptomatic* patients at an intermediate risk of cardiovascular events (5–20% per 10 years) in whom statin therapy is uncertain. Statin is indicated if calcium score is ≥100 or ≥75th percentile for age; it is considered for calcium score of 1–99 (ACC lipid guidelines). Calcium score continues to be useful even at an older age, up to 70–75: in the MESA registry, where the mean age was 62 ± 10, 50% of asymptomatic patients had calcium score of 0.[43] In young patients <40, early plaques may not be calcified yet; while a score of 0 retains a strong prognostic value over the next 5 years, any calcium (even score of 1) indicates an elevated risk at this age and is relatively uncommon (prevalence of ~10%).[47] Also, even zero calcium is less reassuring in the young, where the 5-year warranty is less relevant, and where long-term prognosis is paramount and is better gauged by plaque burden on CTA.

Even a gross assessment of calcium on a nondedicated chest CT (e.g., CT for cancer screening or PE rule out) is useful in risk stratification: in the absence of visible calcium, the coronary risk is low (1.2% at 6 years), vs. 4-fold higher risk with moderate or severe calcium.[50]

Calcium scoring has also proven useful in *stable symptomatic patients*. According to a large Danish registry, calcium scoring dramatically improves the prediction of obstructive CAD and prognosis, beyond the Diamond-Forrester approach, and classifies as low probability most patients with calcium score <100.[51]

A high calcium score in an asymptomatic patient does not dictate coronary angiography or CTA/stress testing, as: (i) calcium score strongly predicts coronary events but is less strongly predictive of obstructive CAD; (ii) obstructive CAD is better predicted by the combination of exertional chest pain with high calcium score; (iii) a high calcium score is a powerful predictor of events regardless of the presence of obstructive CAD (3–5% per year); seeking and treating obstructive CAD does not clearly alter the prognosis, which is driven by plaque burden, and a lack of obstructive CAD is not reassuring (high event rate regardless); (iv) seeking and revascularizing obstructive CAD in asymptomatic patients has not proven beneficial (except for left main disease): it is rather risk factor control and statin that improve outcomes.

Coronary calcifications tend to progress over time, and the speed of progression may have a prognostic value. In a study of patients with a calcium score of 0 and mean age of 58, the conversion to a positive calcium score occurred, on average, at 3–7 years of follow-up.[52] Calcium scoring may be repeated in 3–5 years in patients with a baseline calcium score of 0. Outside that, there are no data supporting repeat calcium scoring. Although it is thought that statins may increase calcium score, they actually reduce calcium score progression compared to matched untreated patients with similar baseline calcium scores, and even compared to matched patients with naturally low LDL that matches levels achieved with statin.[53] Statins may increase calcium density of the severely calcified plaques, but attenuate overall plaque progression and the appearance of new calcium.[54]

IX. Cardiac MRI: summary of applications and findings

Normally, *the myocardial cells do not uptake gadolinium*. The interstitium uptakes gadolinium, but normally, the myocardial cells are tightly apposed with no significant interstitium, which prevents any gadolinium uptake by the myocardium. As such, gadolinium only briefly and mildly penetrates the *myocardial circulation* during first-pass MRI perfusion imaging. Conversely, both fibrotic tissue and necrotic tissue (ruptured cellular membranes) uptake gadolinium, slowly, and thus, late gadolinium enhancement (LGE) on delayed imaging is an indicator of scar, or acute necrosis in acute MI, i.e., irreversible injury. LGE imaging is performed 10 minutes after gadolinium administration, using T1 sequence. LGE is white, while the normal myocardium is black on T1.

The following are the most important cardiac applications of MRI:

1. **Myocardial viability:** In ischemic cardiomyopathy, a myocardial segment is non-viable when LGE is present and involves >50% of the transmural thickness (Figure 34.11).
2. **Prognostic value in cardiomyopathies:** In both ischemic and non-ischemic cardiomyopathies, the presence and extent of LGE is a prognostic marker; the more extensive LGE, the lower the likelihood of myocardial recovery and the higher the propensity for VT.
3. **Diagnostic value in cardiomyopathies:** The pattern of LGE helps determine the etiology of a cardiomyopathy. An ischemic scar is subendocardial or transmural and cannot be isolated to the midwall or the subepicardium (Figure 34.12).[55]
4. **Excellent assessment of RV and LV volumes and EFs. Also, mitral and aortic regurgitation and regurgitant volumes may be assessed**. This is done with ***no gadolinium***, using bright blood-black myocardium cine images. MRI allows the estimation of blood velocity across each pixel and the drawing of a flow curve across the aortic root and the PA in systole (forward flow) and diastole (backward flow);

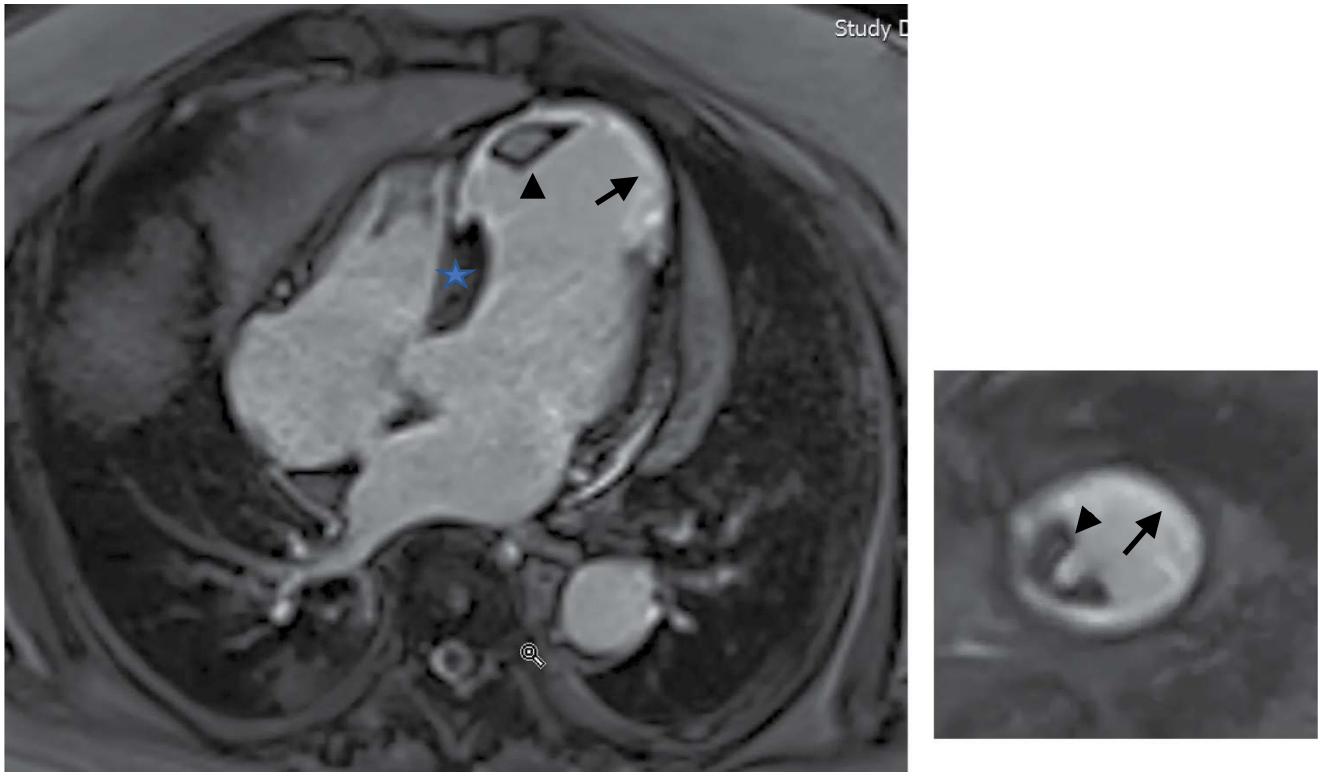

Figure 34.11 The basal septum is normal, that is, *black* and does not enhance with gadolinium (*star*). The LV apex is scarred, thin with full-thickness late gadolinium enhancement (white, *arrow*). An apical thrombus (black, *arrowhead on the left image*) is noted.

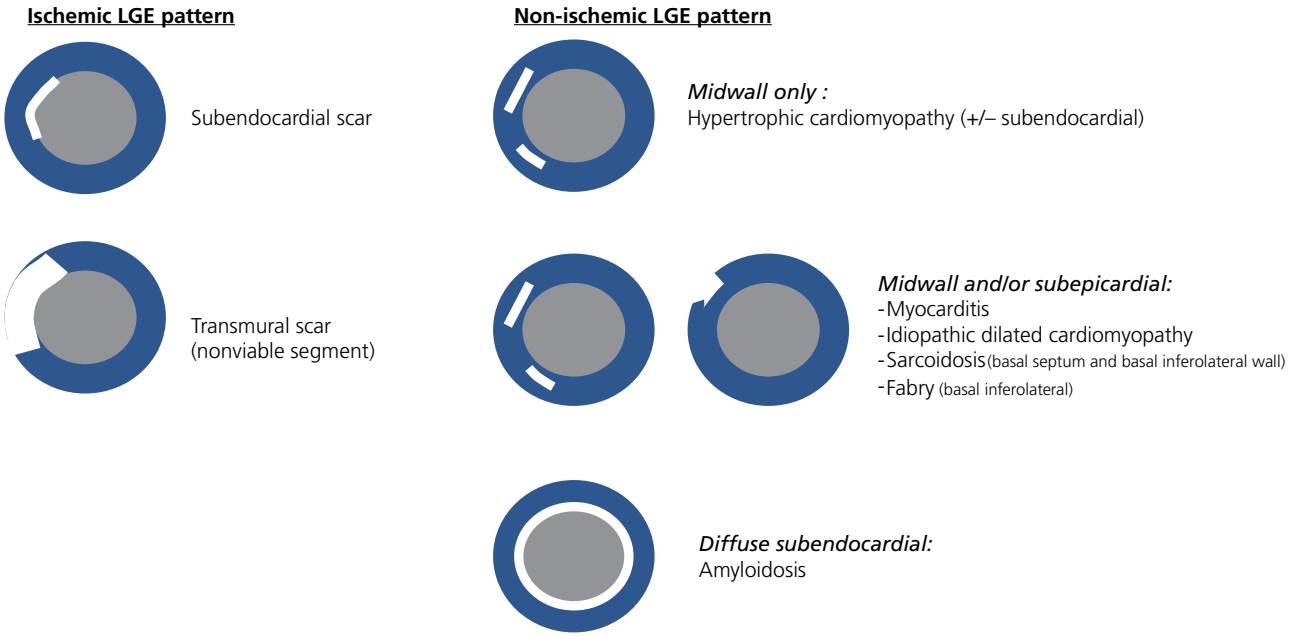

Figure 34.12 Patterns of LGE in ischemic and various non-ischemic cardiomyopathies.

total forward volume and backward volume is then measured across the aortic root and the PA (more difficult across the mobile mitral and tricuspid annuli). In addition, LV and RV stroke volumes are measured by planimetry. As such, *MR volume* is best assessed as the difference between LV stroke volume and aortic total forward stroke volume, and *AI regurgitant volume* is directly measured as the reverse diastolic volume just above the aortic valve. The regurgitant volumes of MR and AI may also be estimated as the **difference between LV and RV stroke volumes,** but unlike the first method, this is inaccurate in mixed valvular disease.

The 3 LV motions (radial, longitudinal, and twisting) are well assessed by MRI.

5. Acute MI: In acute MI, there is within the ischemic territory: (a) necrosis (LGE), (b) edema that accompanies necrosis but also ischemia. Edema may uptake gadolinium, and thus, not all acute LGE (within 48–72 hours of MI) is irreversible injury. The whole *myocardium at risk is identified as edema* on T2-weighed edema imaging and encompasses (a) and (b).[56]

When MRI is repeated 1 week to 2 months later, LGE area typically shrinks 30–40%.[56,57] This is because the LGE was partly taken up by edematous, but not necessarily necrotic tissue; moreover, even necrotic tissue, which was inflated by edema, constricts as it forms a scar (healthy scar remodeling after reperfusion).

6. Differentiation of acute MI from other acute myocardial processes in a patient with elevated troponin, and diagnosis of myocarditis: There are 3 major differential diagnoses in a patient with chest symptoms, elevated troponin, yet unobstructed coronary arteries: MI, myocarditis, takotsubo cardiomyopathy. LGE on T1 and edema on T2 may be seen in both myocarditis and infarction. Only edema may be seen in takotsubo, not LGE. The distribution of the anomaly distinguishes myocarditis from an ischemic pattern (Figures 34.13, 34.14):

- MI: Distribution consistent with an arterial territory + subendocardial or transmural predominance
- Myocarditis Lake Louise criteria: (i) increased T2 signal, which indicates edema (acute inflammation); (ii) LGE on T1; (iii) increased T1 signal on T1 map before gadolinium injection, which indicates increased extracellular volume, in this case from *hyperemia and capillary leak*. A further rise in T1 signal intensity on early gadolinium enhancement also indicates high extracellular volume and allows calculation of extracellular volume ratio (high if >35%). (i) + (ii) or (iii) is diagnostic of myocarditis. The findings may be segmental, most commonly inferolaterally, but unlike acute MI, the findings are patchy within a myocardial segment and involve the subepicardium or mid-wall.

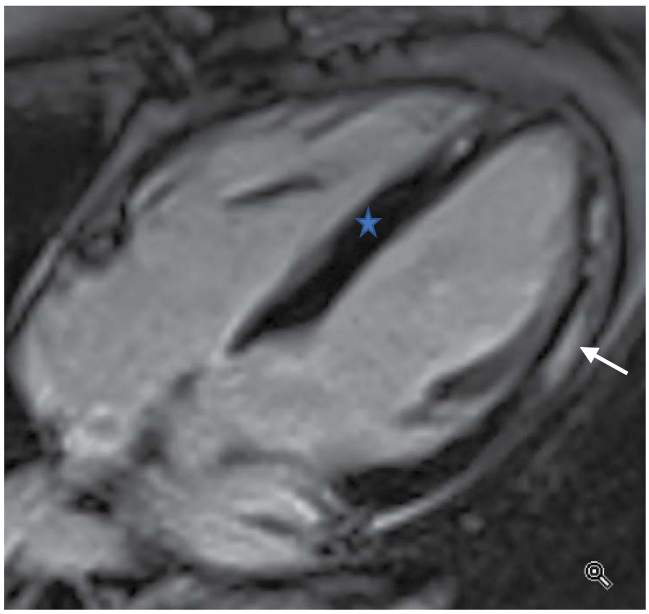

Figure 34.13 Myocarditis in a 26-year-old man. Note the subepicardial white streaks of LGE (*arrow*). Compare that to the normal black myocardium (*star*).

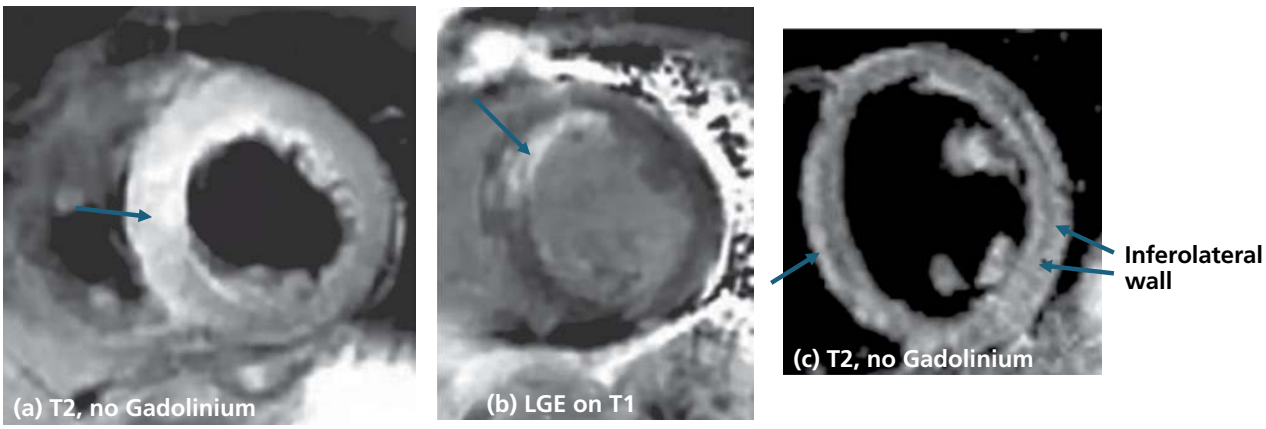

Figure 34.14 **(a)** Anterior MI with transmural anteroseptal edema on T2 (white, *arrow*). **(b)** Anterior MI with LGE (*arrow*). **(c)** Myocarditis with diffuse edema on T2 (white, *arrows*), patchy, subepicardial at the septum, thicker in the inferolateral wall, where myocarditis tends to predominate.

7. MRI perfusion imaging using gadolinium: Cardiac MRI can assess myocardial perfusion by measuring the myocardial signal intensity of gadolinium upon first-pass imaging; this is different from late gadolinium imaging. Myocardial perfusion reserve is reflected by the change of this signal intensity with adenosine. Impaired perfusion reserve implies coronary stenosis, or, in patients with no CAD, microvascular disease.

X. Cardiopulmonary exercise testing (CPET)

CPET is the analysis of gas exchange during exercise. It may be performed in a patient with dyspnea or functional limitation and helps diagnose HFpEF as well as pulmonary dysfunction. It is an alternative to echo diastolic stress testing and invasive stress hemodynamics (Chapter 4, Figures 4.1, 4.2). The CPET system measures during exercise, breath-by-breath, through a nonrebreathing mask, the volume of oxygen taken up (V_{O2}), and the volumes of carbon dioxide expired (V_{CO2}) and air expired (V_E). V_{CO2} and V_{O2} slopes are drawn. Anaerobic threshold (AT) is defined as the point of V_{O2} when the respiratory exchange ratio (V_{CO2}/V_{O2}) rises >1 consistently (intersection point of V_{CO2} and V_{O2} = anaerobic threshold). Testing can be done using treadmill or stationary bicycle, with a gradual workload increase. Analysis of findings:[58,59]

- **Peak O2 consumption (V_{O2}) <14 ml/kg/min despite reaching the anaerobic threshold (V_{CO2}/V_{O2} >1.05): HFpEF is highly likely. Peak V_{O2} >20 ml/kg/min: HFpEF is unlikely.** Predicted peak V_{O2} is normally ~25–30 ml/kg/min (~40 in young individuals).
- **Low O2 saturation** suggests a respiratory illness. HF causes exertional hypoxemia only when florid decompensation is present on exam CXR.
- **Low respiratory exchange ratio (V_{CO2}/V_{O2}<1), i.e., not reaching the anaerobic threshold**, implies orthopedic limitation, pain, or poor effort.
- **High ventilation for any CO2 production (V_E/V_{CO2} slope) ≥34 suggests V/Q mismatch and thus cardiac or pulmonary limitation**. In context, it supports HF diagnosis and prognosis *even if the anaerobic threshold is not reached*.
- **In deconditioned patients with normal cardiopulmonary function**, the muscles cannot *extract* O2 well and cannot use it efficiently even if the heart and lungs *deliver* proper O2 amounts. **Peak V_{O2} is low-normal or mildly reduced in deconditioned patients because of this reduced O2 extraction, but also because of a deconditioned cardiopulmonary O2 delivery. Thus, peak V_{O2} may be slightly reduced, but not <14 ml/kg/min, and V_E/V_{CO2} is normal**. The low O2 extraction also explains that deconditioned patients reach AT quickly and spend relatively longer time under anaerobic conditions; AT is attained early relatively to their peak V_{O2} (V_{O2} at AT is <60% of their peak V_{O2}, the normal being >60–70%); AT is also attained early relatively to the predicted peak V_{O2} (V_{O2} at AT is <40% of the peak predicted V_{O2}).
- AT is often reported as the V_{O2} at which AT is attained, whether an absolute V_{O2} value in ml/kg/min, or a % of the *predicted* maximal V_{O2} (> or <40%). AT is abnormal with deconditioning, cardiopulmonary disease, or anemia.
- Less often, end-tidal CO2 (in mmHg) is analyzed: a low value <35–40 mmHg indicates circulatory or ventilatory inefficiency.

XI. Viability testing and limitations

In the STICH trial, ~50% of patients underwent viability testing (with echo or SPECT) and were randomized to CABG vs. medical therapy regardless of the result. ***CABG was mildly beneficial regardless of viability and independently of EF improvement, and viability did not provide any discriminatory effect***.[60,61] Viability did predict eventual EF improvement; in fact, EF improved only in patients with viability, but to a similar magnitude with either CABG or medical therapy.[61] Similar findings were seen in REVIVED-BCIS-2 trial, which only revascularized patients displaying LV viability (defined as ≥4 dysfunctional but viable myocardial segments subtended by diseased coronary arteries): the extent of viability did not predict a benefit of PCI vs. medical therapy. The extent of non-viable scar was associated with more death and less EF improvement, but the extent of dysfunctional-yet-viable myocardium did not predict LV recovery.[62]

In summary, viability testing has not proven a useful revascularization guide in the chronic cardiomyopathy setting (STICH, REVIVED trials) or in the recent post-MI setting (OAT trial post hoc analysis). This suggests that ***global* revascularization with CABG provides *mild* and *late* benefit in chronic ischemic cardiomyopathy regardless of viability and of eventual EF improvement** (STICH trial), while PCI revascularization does not appear to be beneficial even in patients with viability (REVIVED trial). Viability is not used to decide for or against the overall multivessel revascularization (viability testing is not recommended in ESC guidelines and is given class IIb in ACC guidelines).[63,64]

A. Definition of global and regional viability; viability tests

Viability implies that a dysfunctional myocardium is still metabolically active but is hibernating from persistent severe ischemia; or stunned after a transient episode of severe ischemia, even if perfusion is re-established. Those processes are called *hibernation* and *stunning*, respectively. A dysfunctional myocardial area is considered viable if:[65–69]

- The regional dysfunction significantly improves after revascularization by at least one point (from akinesis to hypokinesis, or from hypokinesis to normal). This is called ***regional viability***.
  or
- The overall EF significantly improves (>5%). This is called ***global viability***.

Thus, *viability can only be confirmed in retrospect, after revascularization is performed*. In general, 70% of patients with chronic ischemic LV dysfunction have significant improvement in LV function after revascularization (81% in STICH trial). Four imaging modalities have been used to assess viability:

- *Thallium myocardial uptake* at rest and at 4 and 24 hours post-rest injection (rest-redistribution imaging). An uptake ≥50% at rest or after thallium redistribution implies that the regional myocardium is viable.[70] Also, an absolute change of 12% during redistribution implies regional viability even if the uptake remains < 50%.[60,71] In addition to Thallium, *technetium uptake* at rest (or after nitrates administration) may be used to assess viability.
- *Low-dose dobutamine echocardiography* evaluates for an improvement of myocardial contraction in response to low doses of dobutamine (<10 mcg/kg/min): from dyskinesis or akinesis to hypokinesis, or hypokinesis to normal contraction (a change from dyskinesis to akinesis is not considered improvement). This is called *myocardial contractile reserve*. A decline in myocardial contraction at subsequent higher doses reflects ischemia; this biphasic response is highly predictive of myocardial recovery and viability. Conversely, a uniphasic

response (progressive increment of contractility at higher doses of dobutamine) suggests that the coronary flow is not compromised and, thus, revascularization cannot provide any benefit; myocardial dysfunction is non-ischemic, or ischemic with subendocardial scarring that persisted after blood flow was re-established. The absence of any response may imply non-viability; yet, 25–30% of viable segments do not augment with dobutamine. Nuclear studies are more sensitive for viability, albeit less specific.

- *PET scan* assesses metabolic uptake of a glucose analog tracer (metabolic viability). It can also assess perfusion with N^{13} or Rb^{82} tracer. A mismatch between a low perfusion and a high metabolic uptake implies viability. A reduction in both perfusion and metabolic uptake implies irreversible injury. PET has the highest sensitivity (~90%) but the lowest specificity (~58%) for viability assessment.
- *Cardiac MRI:* late myocardial hyperenhancement 10 minutes after gadolinium injection is a sign of scarring and highly predicts non-viability when it involves >50% of the transmural myocardial thickness. Transmural involvement <25% highly predicts viability, whereas 25–50% involvement is less specific but usually viable.

Also, several ECG, echocardiographic, and angiographic features are helpful, to a limited extent, in assessing viability:

i. *The lack of Q waves* implies less scar and necrosis, and strongly predicts recovery (prevalence of viability >90% per PET).[72,73] However, although the presence of Q waves predicts more extensive scarring and less ischemic or viable myocardium, it does not rule out viability, as Q waves may be seen with a hibernating myocardium.[72]

ii. *As compared to akinesis, hypokinesis does not* necessarily imply a higher likelihood of recovery with revascularization. After revascularization, akinesis and dyskinesis frequently improve, whereas occasionally hypokinesis does not improve. The hypokinetic wall may be tethered by adjacent akinetic walls or extensive subendocardial necrosis and scarring.[74] Yet, hypokinesis implies the presence of viable tissue, and thus revascularization of a hypokinetic wall may prevent further deterioration of LV function and is more readily performed.

iii. *A thin and bright myocardium ≤5.5 mm* on echo may imply a scarred, non-viable myocardium. Yet, if it is not extensive, it does not preclude a revascularization benefit to the surrounding walls. Also, one study showed that 18% of thin myocardial regions have a limited scar burden by MRI and recover myocardial thickness and contractility with revascularization, with Q-wave regression; thus, a thin myocardium does not preclude revascularization.[75]

iv. Severe LV dilatation (end-diastolic volume ≥ twice normal, which often corresponds to a *diastolic diameter ≥70 mm*) usually implies extensive scarring and negative remodeling that would not be reversed with revascularization and predicts a poor prognosis after revascularization.[76]

v. When a dysfunctional segment is supplied by an occluded artery, *good collateral flow* predicts myocardial recovery.[77] In one study, the presence of grade 2 or 3 collaterals on coronary angiography, i.e., good collaterals that reconstitute partially or fully the epicardial vessel, predicted regional and global myocardial recovery in 81% of the cases.[78]

B. Variations in the definition of global viability

In the STICH trial, global LV viability has been defined as viability of ≥65% of all myocardial segments (11 of 17 segments), counting both dysfunctional segments and segments with normal contractility.[60,79,80] Conversely, most studies, including REVIVED-BCIS-2, have defined global viability with a focus on the dysfunctional segments. When the viable dysfunctional segments constitute ≥25% of the LV, global viability is considered present and a global improvement of EF is expected (e.g., ***≥4 dysfunctional myocardial segments are viable***).[65–69,71,81]

C. Limitations of viability testing

Viability testing has the following limitations:

- Viability tests have positive and negative predictive values of ~75–80%, for both regional and global viability. This is particularly the case with thallium or technetium nuclear viability testing (sensitivity ~80%, specificity ~60%) and dobutamine echocardiography (sensitivity 65%, specificity 85%), which were used in the STICH trial.[65,82] The assessment of the extent of transmural scarring by MRI is more valid (sensitivity and negative predictive value 90%, positive predictive value 60–80%, depending on the transmural cutoff used, e.g. 50%).
- The definition is not uniform. In a patient with anteroapical infarction, *regional viability* addresses the viability of the anteroapical segments to decide whether LAD revascularization is beneficial; conversely, *global viability* addresses whether there are ≥4 dysfunctional segments that are viable.
- Even without any viability and any contractile and EF improvement, revascularization improves symptom status and may improve HF and mortality.[83] Revascularization may improve LV remodeling, prevent further deterioration of LV function and further MI, preserve infarct border zone integrity, and reduce arrhythmogenesis.
- The benefit from CABG may be higher in the sickest patients, such as those with limited viability.[60,84] In fact, a STICH analysis has shown that patients with the most severe ischemic cardiomyopathy derive the most benefit from CABG (~9% mortality reduction at 5 years); this was defined as a combination of 2 of the following 3 factors: 3-vessel CAD, EF <27%, dilated LV with end-systolic volume index >79 ml/m^2.[84]

D. Role of ischemic testing; difference between ischemia and viability

The concepts of ischemia and viability are different, and ischemia is a stronger marker of prognosis and functional myocardial recovery than the mere presence of viability.[85–88] On nuclear imaging, *viability* implies that at rest, the dysfunctional territory uptakes significant nuclear agent. *Ischemia* implies that at stress, the nuclear defect of the dysfunctional territory is significantly more intense or more extensive than at rest, or significant ST-segment deviations occur. *An ischemic territory is viable; conversely, a viable territory may not be ischemic*. The lack of ischemia means that the myocardial territory is already receiving enough blood supply and should be able to recover its function without revascularization if truly viable, which questions the value of revascularization (Figure 34.15).[89]

Nonetheless, the assessment of ischemia in LV dysfunction with significant baseline defects is cumbersome, as fixed wall motion abnormality on echo or **fixed defects on nuclear imaging may very well represent severe ischemia with hibernation, particularly if the nuclear uptake is ≥50%, or no Q wave is present, or the patient has angina or ST deviation**; up to 75% of these defects reverse with revascularization.[90,91] This lessens the predictive value of ischemic testing in LV dysfunction; *in the STICH stress substudy, ischemia did not predict prognosis or response to CABG*.[92]

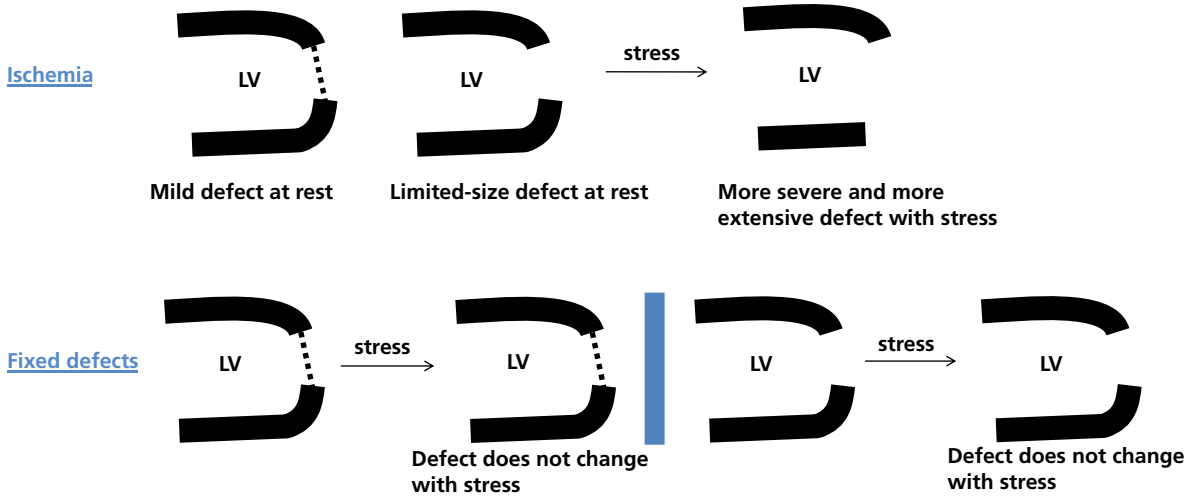

Figure 34.15 (*Top*) The worsening of a resting defect is indicative of ischemia. (*Bottom*) A fixed defect suggests the lack of ischemia. Yet, if the patient has angina and no Q waves, or if the nuclear uptake is ≥50%, this fixed defect may indicate hibernation and ischemia.

XII. Lung ultrasound and lung CT scan in heart failure

A. Lung ultrasound (Figures 34.16–34.18)

The lung is scanned with a probe held vertically, across 2 ribs. A peripheral, curvilinear transducer probe or an echocardiogram probe may be used, with a low frequency to assess significant depth (e.g., ~10 cm). In a supine patient, each side of the chest is divided in 4 zones (2 anterior, 2 lateral). Comet-shaped white B lines of ≥2–3 per intercostal space indicate interlobular septal thickening, from fluid (pulmonary edema, pneumonia) or fibrosis. In the right context, when present in at least 2 lung zones, they indicate cardiogenic pulmonary edema.

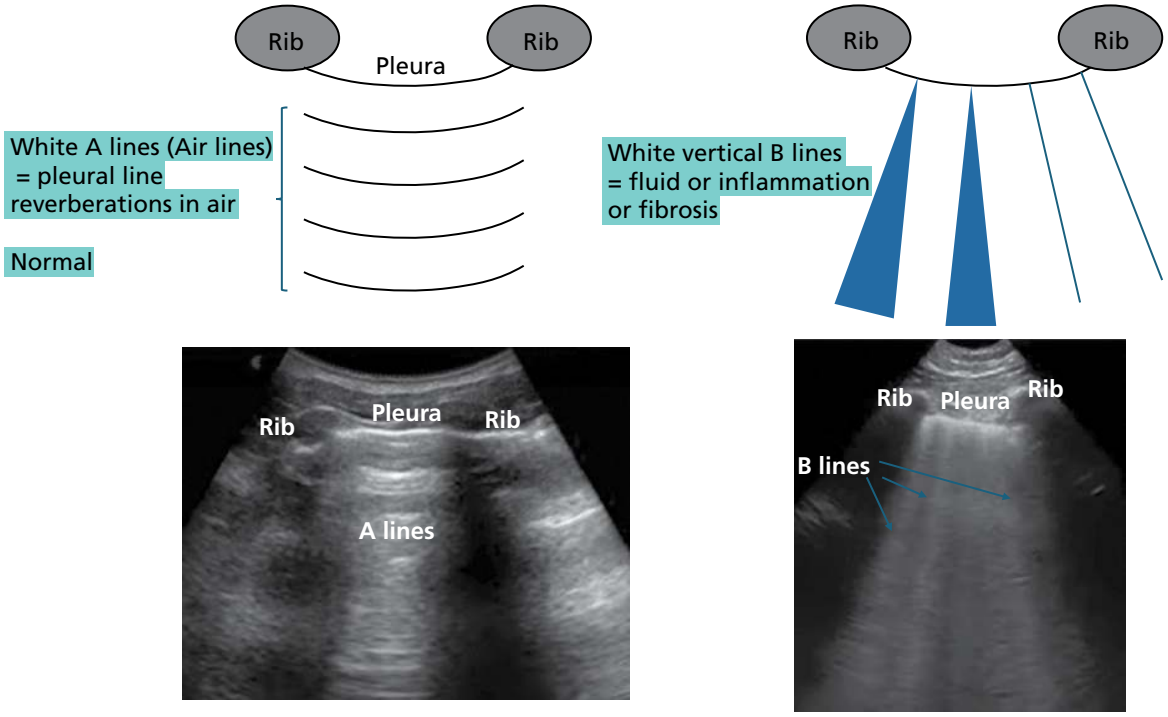

Figure 34.16 The lung is scanned with a probe held vertically, across 2 ribs. A deep field of view is often used (e.g., ~10 cm). Normally, a white hyperechoic pleural line is seen between 2 ribs, along with curved white **A lines** reverberations of the pleura that attenuate with depth. The pleura has a *horizontal shimmering motion* called ***lung sliding***, which corresponds to the sliding and rubbing of the visceral and parietal pleurae during respiration. On a shallower depth analysis, including in M mode, this lung sliding creates reverberation A lines beneath the pleura that are interrupted, dynamic ("seashores"), rather than straight lines. Lung sliding is lost in pneumothorax, with a lung point that separates the non-sliding vs. the sliding areas. This lung point is highly specific for pneumothorax, but the loss of lung sliding by itself is not. Lung sliding is lost in pleural effusion, but also pneumonia when both pleural layers are adherent, and sometimes in atelectasis and COPD.

B lines are reverberations from thickened interlobular septa (most commonly fluid, but may also be fibrosis). True B lines have a comet shape, arise from the pleural line, are *mobile* and move along with lung sliding (better appreciated on dynamic images), *reach all the way to the far field*, and do not attenuate with depth. B lines, when present, erase the A lines. To be pathological, 2–3 B lines in same intercostal space are seen. To indicate pulmonary edema, they must be seen in at least 2 lung zones.

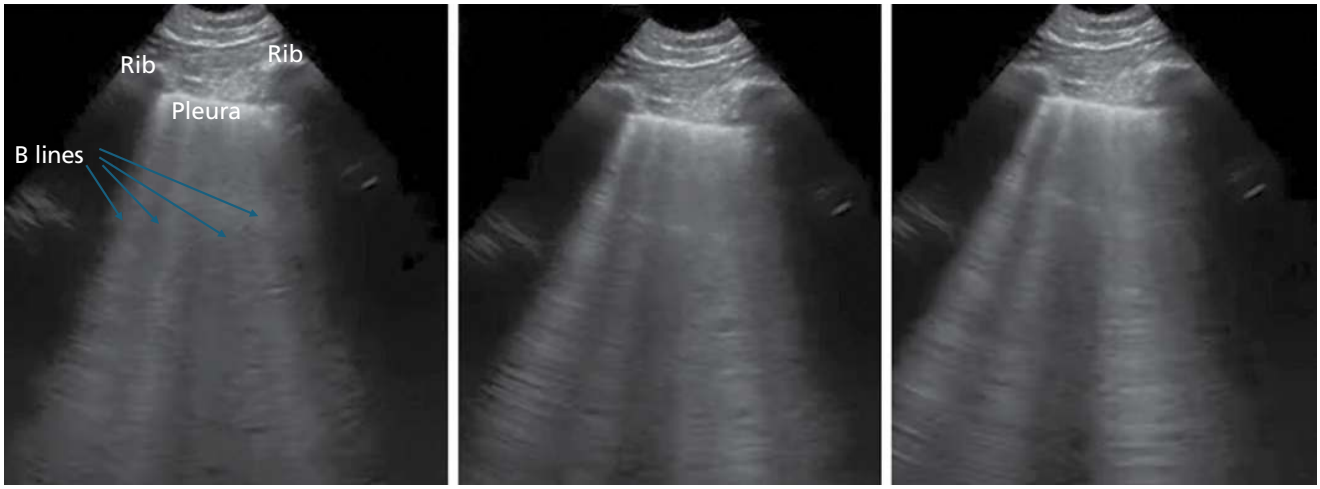

Figure 34.17 Illustration of extensive ultrasonographic B lines in a patient with pulmonary edema.

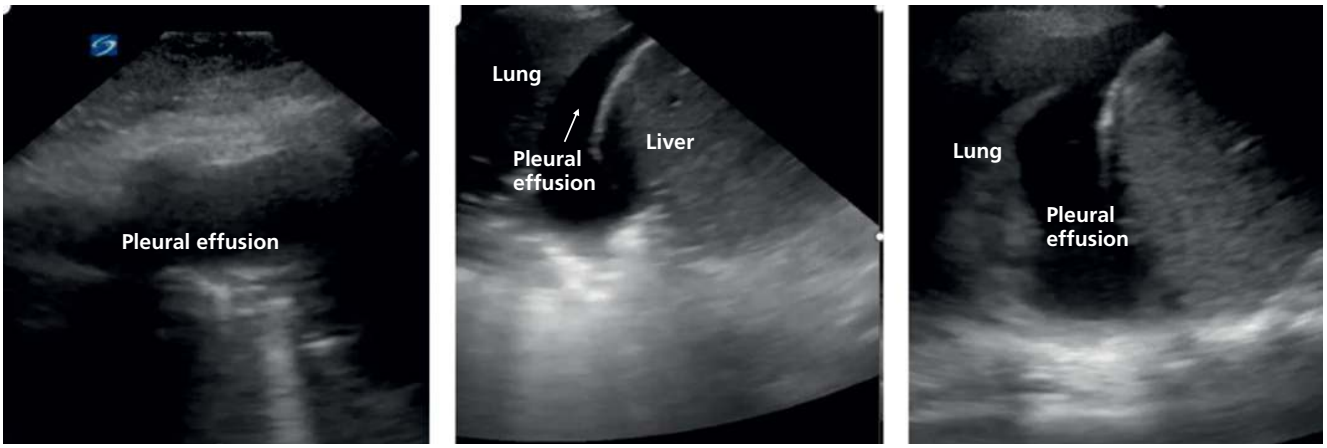

Figure 34.18 Pleural effusion is anechoic or hypoechoic, between the chest wall and the visceral pleura/lung line. It is best seen in the dependent posterolateral lung areas, especially above the diaphragm/liver. On the *right image*, the lung is nearly as echogenic as the liver, which indicates lung consolidation, sometimes with dark dots of air bronchogram. When the pleural effusion is larger than the visualized lung, the diagnosis is possibly pleural effusion with secondary lung shrinking (atelectasis); when the solid lung is larger than the effusion, the diagnosis is lung disease with secondary pleural effusion.

Other pathological findings:

- Dark anechoic space at the surface = pleural effusion
- When the lung is seen as a mass similar to the liver (white, echogenic), this indicates lung consolidation, sometimes with dark dots of air bronchogram

Cardiogenic pulmonary edema progression: (1) 2–3 B lines in 2 lung areas and small anechoic pleural effusion → (2) More extensive B lines in 4 or more lung areas, with larger effusion → (3) Extensive B lines, pleural effusion, and lung consolidation (hepatization) with air bronchogram. Same progression may be seen in pneumonia with ARDS (except for less extensive pleural effusions).

B. Lung CT (Figures 34.19–34.21)

XIII. Jugular venous pressure by physical exam and by ultrasound

The jugular vein acts as a manometer for the RA pressure. JVP (jugular venous pressure) is assessed by analyzing the height of the jugular venous pulsations in relation to the sternal angle of Lewis, which is 5 cm above the RA. The right or left side may be analyzed. The analysis starts at an ~45° patient position, then the position is adjusted according to the visualization of the pulsations. The ***internal jugular*** pulsations are sought and are seen as A and V vibrations or "flickers" over the neck; the internal jugular vein itself is not visible. Thus, most often, you look for pulsations on a non-visible vein. The jugular vein pulsations may also be analyzed over the *external jugular vein* in case it is distended (jugular venous distension [JVD]). The highest point of pulsations is the JVP point: JVP is the vertical distance between the venous pulsations and the angle of Lewis plus 5 cm; it is abnormal when ≥9 cm (Figures 34.22, 34.23). The analysis starts at an ~45° patient position: in patients with JVP of 5 cm or less, the JVP pulsations would be at the same level as the RA, so they would not be visible on the neck in a semi-upright position, and the patient needs to be laid farther down. In patients with severe JVP elevation, the pulsations may be at the level of the earlobes, so the patient needs to be further elevated to see the upper JVP extent.

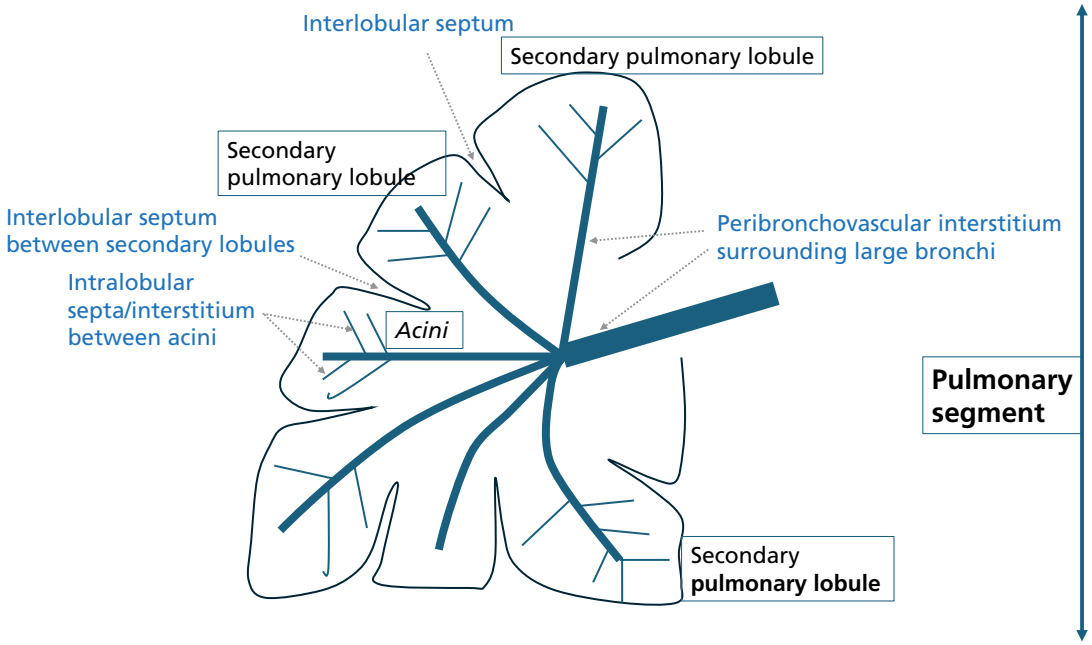

Figure 34.19 Components of a pulmonary segment. The lung is split into lobes, and lobes are split into segments (on the right: 3 in the upper lobe, 2 in the middle lobe, and 5 in the lower lobe; on the left: 5 in the upper lobe, 5 in the lower lobe). Segments are split into secondary pulmonary lobules, then acini or primary pulmonary lobules via septa. Normally, **the pulmonary lobules are not well demarcated on CT** (their outlines are not well visualized). **They become well demarcated in the presence of interlobular septal thickening:** smooth interlobular septal thickening is overwhelmingly indicative of cardiogenic pulmonary edema (hydrostatic edema) and is mostly visible at the periphery of the lung, in axial and coronal views. It manifests as **small well-delineated polygons at the periphery of the lungs,** laterally or medially, top or bottom; they may seem more central on axial cuts. These are the Kerley B lines seen on CXR. In cardiogenic pulmonary edema, they are typically associated with: pleural effusions and ground- glass opacities (mild white veil over some parenchymal areas, typically in a mosaic pattern, indicative of mild interstitial or parenchymal thickening).

Bronchovascular interstitial thickening may also be seen and is identified by thick central dots or bullets.

Occasionally, smooth interlobular septal thickening may be caused by lymphatic obstruction from lymphangitic carcinomatosis, in which case the thickening may be smooth but is more commonly nodular and asymmetric (vs. symmetric in cardiogenic edema).

Interlobular septal thickening is not usually seen with the inflammatory edema of ARDS, because in ARDS, protein and fluid leak into the alveoli, creating peripheral consolidations that obscure the septal lines. Conversely, the **edema of HF is a hydrostatic interstitial process that only becomes alveolar once the septa can no longer hold the fluid**; that is why it starts in the interstitium and septa, including perihilar and peribronchovascular septa. Additionally, pleural effusions are common in HF, but not in ARDS.

Irregular septal thickening may be seen in interstitial lung disease and fibrosis, sometimes with dense "crazy paving" pattern and, in extreme cases, honeycomb pattern. The septal thickening is not smooth, it is rather "wrinkled" and unevenly thick.

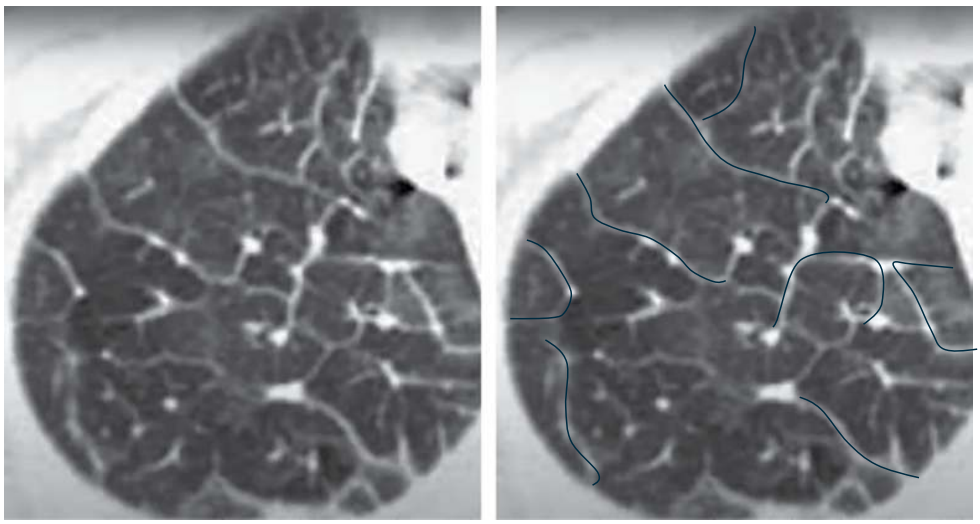

Figure 34.20 Illustration of interlobular septal thickening (highlighted on the right by the *blue line*): **small well-delineated polygons at the periphery of the lungs**, laterally or centrally/medially. There is also ground- glass lung density in some areas (the "whiter" lung areas). This is suggestive of cardiogenic pulmonary edema.

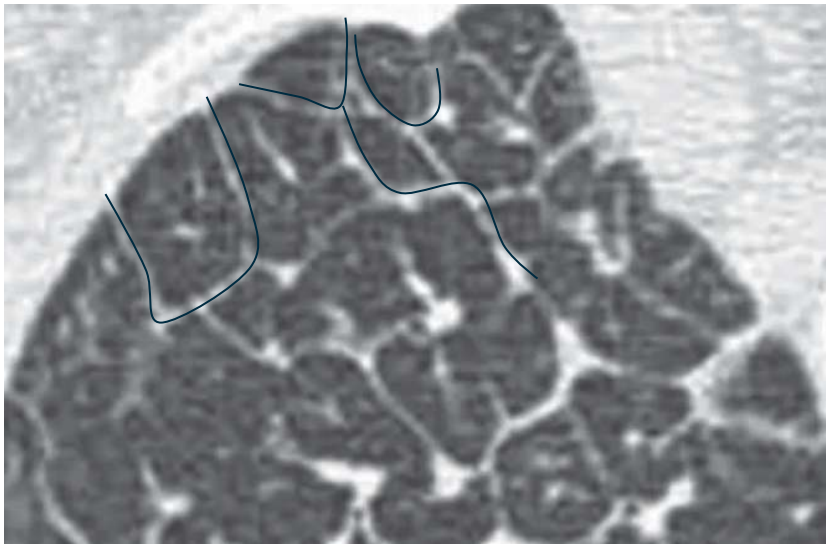

Figure 34.21 Another illustration of smooth interlobular septal thickening from pulmonary edema.

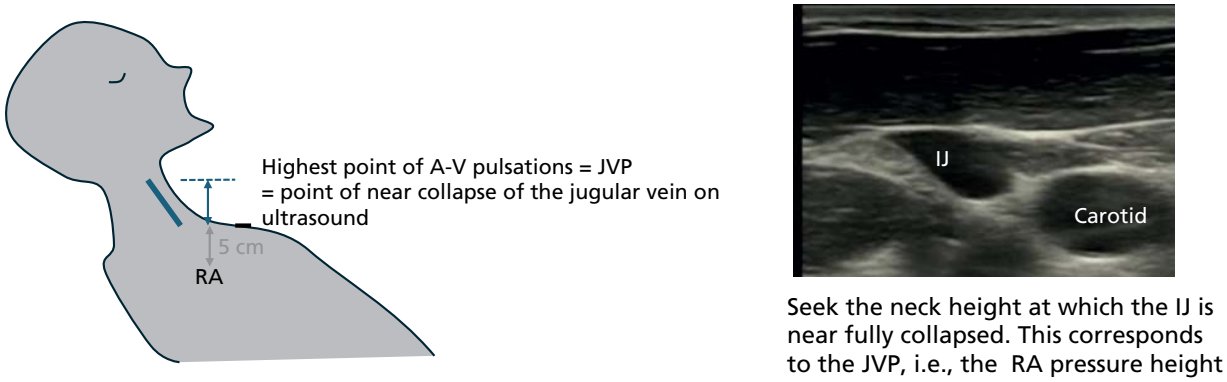

Figure 34.22 How to measure JVP clinically and by ultrasound.

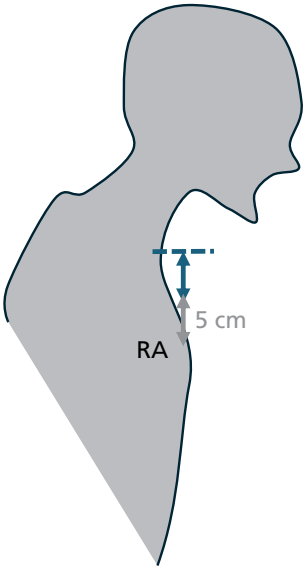

Figure 34.23 At 90°, a JVP that is visualized close to the bottom of the neck is already high JVP, because it is already >3–4 cm above the angle of Lewis. Along those lines, if the internal jugular vein is larger than the carotid at the bottom of the neck in an upright 90° position, JVP is high.

JVD is different from JVP and signifies external jugular distension; when seen in an upright position, JVD signifies elevated JVP. However, JVD is insensitive in HF: **most patients with elevated JVP, well seen on the internal jugular vein, do not have JVD.**

The distinction between JVP pulsations and carotid pulse may be difficult:

1. Morphology: JVP is undulant with 2 upward flickers (A-V) and 2 downward flickers (X-Y) per cardiac cycle, while the carotid pulse has a single, more prominent pulsation in each cardiac cycle. The exceptions are severe TR, severe right HF, and +/– AF, where a dominant V wave mimics the pulse (ventricularized JVP in TR, also called CV wave). In AF, 2 flickers may still be seen: C and V waves.
2. Deep inspiration makes X and Y more pronounced.
3. JVP level on the skin varies with patient position: it goes up as the patient is placed down, maintaining the same height vs. the RA.
4. Hepatic pressure for ~10–20 seconds may enhance the JVP over the carotid pulse, as it makes the JVP pulsations more visible and more pronounced in most patients, even in those with normal JVP. In addition, in patients with a high JVP, the hepatojugular pressure will raise the JVP height by >3 cm.

It is easiest to use jugular vein ultrasound**: the point of spontaneous near-collapse of the internal jugular vein corresponds to the height of RA pressure, i.e., the JVP point**. So, in a semi-upright position, scan the internal jugular vein in a transverse view from the bottom of the neck upward, and localize the height at which it collapses; a longitudinal view may also show the point of transition from open vein to near-collapse ("wine bottle" morphology). The Annals paper used this criterion to define the JVP point: "point at which the internal jugular vein is smaller than the adjacent carotid artery throughout the entire respiratory cycle."[93] The patient's position may need to be adjusted: if, at 45°, the jugular vein is already fully collapsed at the bottom of the neck or not well seen, lay the patient farther down; it is likely that the RA pressure is low. If the jugular vein does not spontaneously collapse at any neck height, the JVP is high, and the patient may be positioned further upright to find a higher point of jugular collapse.

Notes:

- Distinguish, on ultrasound, the carotid artery from the jugular vein: (i) the vein is collapsible with probe pressure (except rarely in severe HF, where it would be much larger than the artery even in upright position); (ii) the vein varies greatly in size with respiration (except in severe right HF), (iii) with position, (iv) with Valsalva, (v) with hepatojugular maneuver, and (vi) throughout the neck height. Conversely, the artery does not collapse with probe pressure and has prominent pulsations. Also, the jugular vein is more lateral than the carotid artery in >95%.
- For JVP measurement, **seek *spontaneous* jugular venous collapse, not collapse with *probe pressure***; the vein is collapsible with probe pressure, and this is how it is initially distinguished from the carotid artery, but the JVP point is the point of spontaneous jugular vein collapse, while holding very light probe pressure.
- Episodic robust, pounding neck pulsations may constitute large cannon A waves and are seen in AV dissociation, such as during PVCs and in complete AV blocks.

Questions and answers 875

I. Right coronary artery

A. Course

The right coronary artery (RCA) courses over the right AV groove, turns around and continues over the posterior AV groove, then reaches the intersection of the AV groove and the posterior interventricular groove (designated the crux), where it gives the PDA and PLB branches.

B. Branches (proximally to distally) (Figure 35.1)

1. *Conus branch* (CB) is the first RCA branch. It supplies the RVOT and has a separate ostium in 1/3 of individuals.
2. *Sinus node or sinoatrial branch* (SN) originates from the proximal RCA in 60% of individuals and from the proximal LCx in 40%.This sinoatrial branch is the second RCA branch.
3. *Acute marginal branches* (AM) supply the RV (1–3 branches).
4. *Posterior descending artery* (PDA) runs on the posterior interventricular groove and supplies inferior septal branches to the inferior 25–30% of the septum (known as "inferior wall"). PDA runs parallel to the LAD, which supplies the anterior 70–75% of the septum.
5. *Posterolateral branches* (PLBs) originate from the posterior AV groove past the crux and supply the posterior wall. The AV nodal branch arises from the posterior AV groove portion of the RCA, before the PDA or, most commonly, after it, around the PLB branches.

C. Segments of the RCA

- Proximal RCA: RCA before the AM branches.
- Mid-RCA: RCA around the AM branches.
- Distal RCA: RCA past the AM branches, including distal RCA at the level of the crux, PDA, and PLBs.

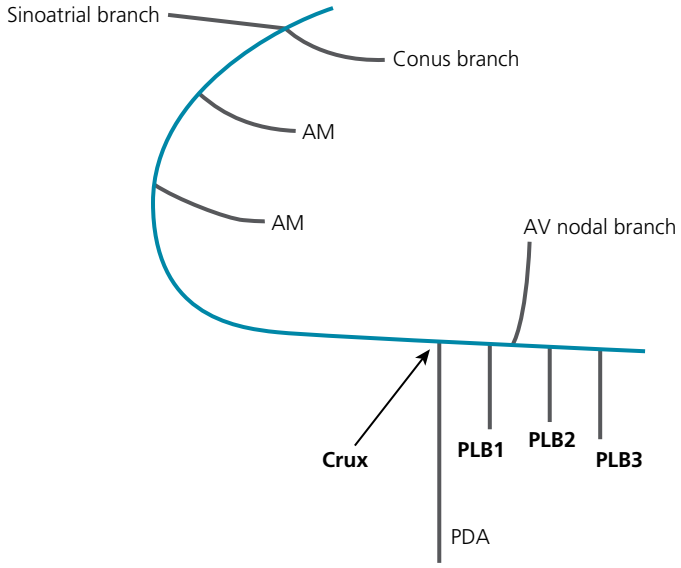

Figure 35.1 RCA course and branches. The intersection of the AV groove and the inferior septum is the crux.

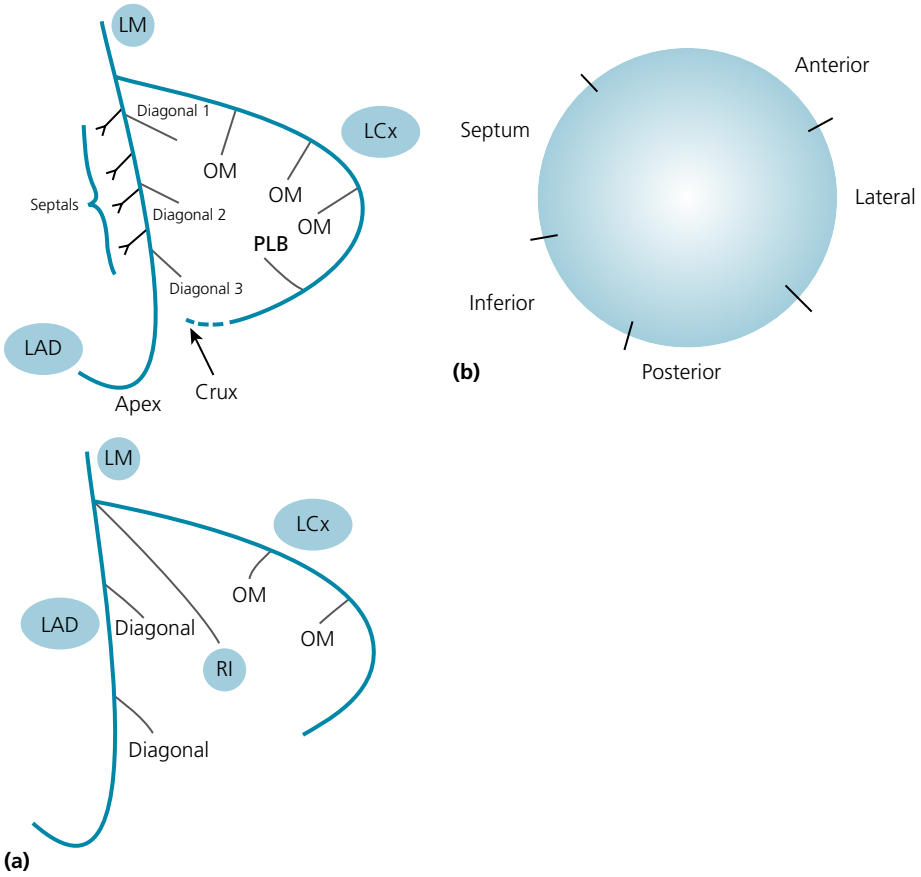

Figure 35.2 **(a)** Left coronary system on LAO cranial view. **(b)** LV walls on cross-sectional view of the LV.

II. Left coronary artery

A. Left main (LM) branches into the left anterior descending and left circumflex arteries

B. Left anterior descending artery (LAD) (see Figure 35.2)

1. LAD courses over the anterior interventricular groove, then reaches and frequently (80%) wraps around the apex distally. LAD gives: (i) *diagonal* (Dg) branches, usually 1–3 large diagonal branches that supply the anterior and high lateral walls; and (ii) *septal* branches that supply the anterior septum, i.e., ~70–75% of the thickness of the septum. The inferior septum is supplied by the PDA, which runs parallel

to the LAD. Some patients have a dual LAD system, in which one trunk (frequently intramyocardial) gives all the septal branches and another trunk gives all the diagonal branches.

2. Segments
- Proximal LAD = LAD proximal to the first septal branch (which is often, but not always, proximal to the first diagonal branch)
- Mid LAD = LAD around all the major diagonal branches
- Distal LAD = LAD distal to the major diagonal branches

C. Left circumflex coronary artery (LCx) (see Figure 35.2)

1. LCx courses over the left AV groove (like the RCA on the opposite side). It does not usually reach the crux, unless the left system is dominant.

2. Branches
- **a.** One to several obtuse marginal (OM) branches supply the LV free lateral wall.
- **b.** One or more left PLBs arise from the left AV groove before the crux. These left PLBs are adjacent to the right PLBs.
- **c.** PDA branch may arise from the distal LCx at the crux level in a dominant or co-dominant left system.

D. Ramus intermedius (RI) branch

Sometimes, the left main (LM) trifurcates into LAD, RI, and LCx (instead of bifurcating into LAD and LCx). RI is, in a way, a very proximal diagonal or a very proximal OM, and supplies the anterolateral wall.

Dominance refers to which artery, RCA or LCx, gives the PDA (inferior wall) and the PLB branches (posterior wall).

- RCA dominance (85% of the population): RCA gives both the PDA and the PLBs. LCx gives only the OM branches and may give some, but not all, PLBs. LCx does not reach the crux.
- Left dominance (8% of the population): LCx gives both the PDA and the PLBs. In this case, RCA is small and does not reach the crux.
- Co-dominance (7% of the population): RCA gives the PDA while LCx gives all of the PLBs and sometimes a second, parallel PDA.

At or near the crux, the dominant artery gives rise to the AV nodal branch.

In ~25% of patients with RCA dominance, there are significant anatomic variations in the origin of the PDA: double PDA, early origin of the PDA proximal to the crux, or partial supply of the PDA territory by a low AM branch that wraps around the inferior RV wall and reaches the inferior septum (*low-lying AM branch*) (Section VII.F). Also, the inferior wall may be partially supplied by a long wraparound LAD or by OM branches that wrap around the posterior wall.

In ACS, the unstable ruptured lesion is identified as:

1. Eccentric stenosis with irregular, overhanging borders
2. Contrast staining at the lesion site after it clears from the rest of the vessel
3. Round filling defect inside the lumen, with swirling around it

The latter 2 features signify ***thrombus*** (Figure 35.3). Unlike angioscopy or OCT, coronary angiography allows thrombus visualization in only 50% of the cases.

Lesion haziness may signify (Figure 35.3):

1. Ulcerated plaque, with contrast faintly seeping inside the ruptured intima
2. Eccentric stenosis unseen on the current view (in this case, an orthogonal view may show severe stenosis)
3. Heavy calcification

III. Coronary angiography views. Recognize the angle of a view: LAO vs. RAO, cranial vs. caudal

A. Differentiate left anterior oblique (LAO) from right anterior oblique (RAO) views

Look at the spine or the central catheter in the descending aorta (if femoral access), then see whether the tip of the catheter is at your left-hand side (LAO) or your right-hand side (RAO). For example, *in the LAO view, one "grabs" the* ***catheter tip*** with the ***left hand*** *while "grabbing" the spine with the right hand* (Figure 35.4). If the catheter tip overlaps with the spine, it is an anteroposterior (AP) view or a shallow-angled view. Other technique: **look at the ribs, and see if they are going down toward your left hand (LAO)** or right hand (RAO).

B. Differentiate cranial from caudal views

In cranial views, the dome of the diaphragm is seen over the heart shadow (Figure 35.5).

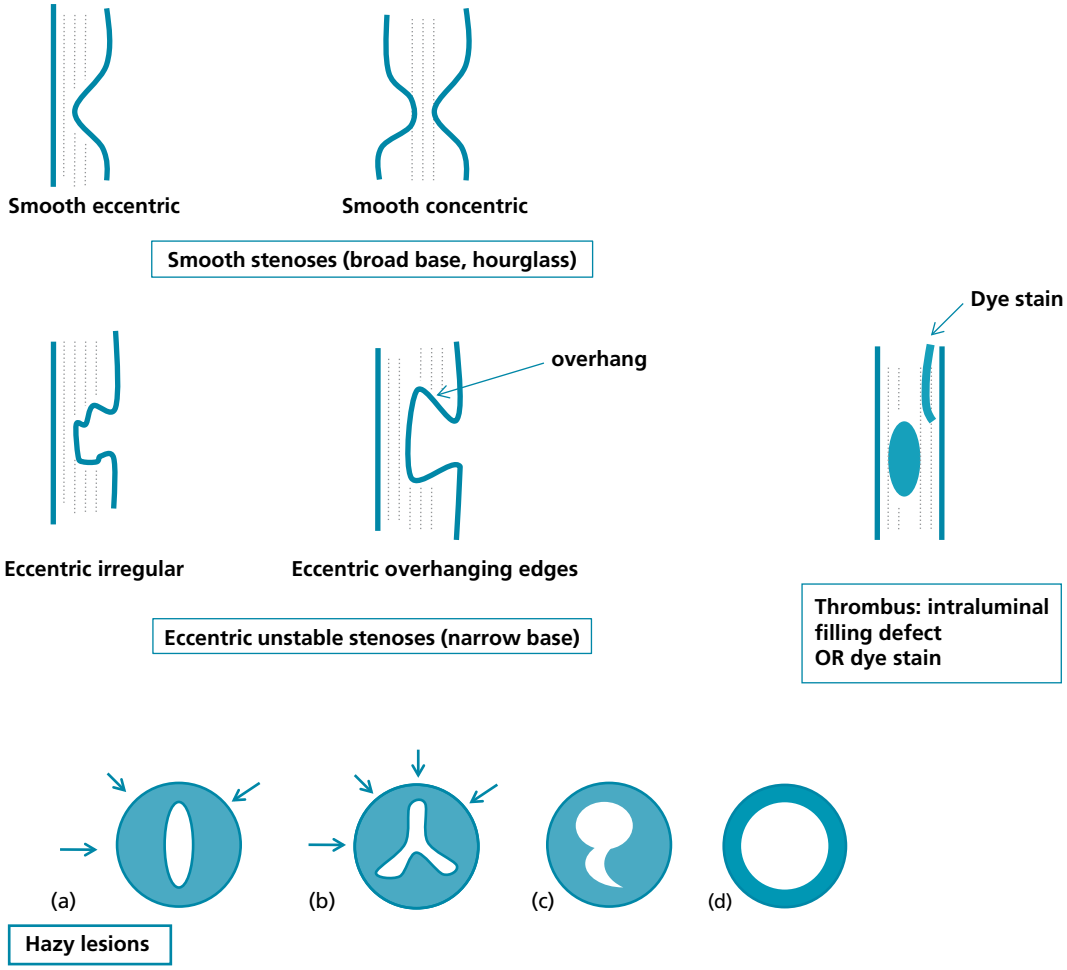

Figure 35.3 The top 2 rows show the difference in morphology between stable stenoses (usually smooth), unstable stenoses, and thrombus.

The bottom row shows hazy lesions. A hazy lesion could be an eccentric stenosis with no angiographic view orthogonal to the narrow lumen (**a and b**, *arrows* are angiographic angles). The narrow lumen is *white* and falsely projects as a large lumen at all angles. A hazy lesion could also be **(c)** a ruptured plaque, or **(d)** a lesion surrounded by a concentric shell of calcium. It often implies severe or unstable stenosis.

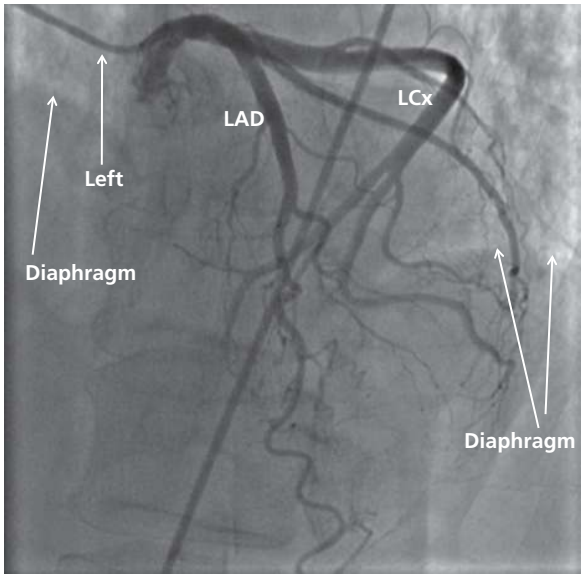

Figure 35.4 LAO view, cranial. Note the diaphragm overlapping with the heart shadow, and note the catheter tip at the left of the central aortic catheter/spine.

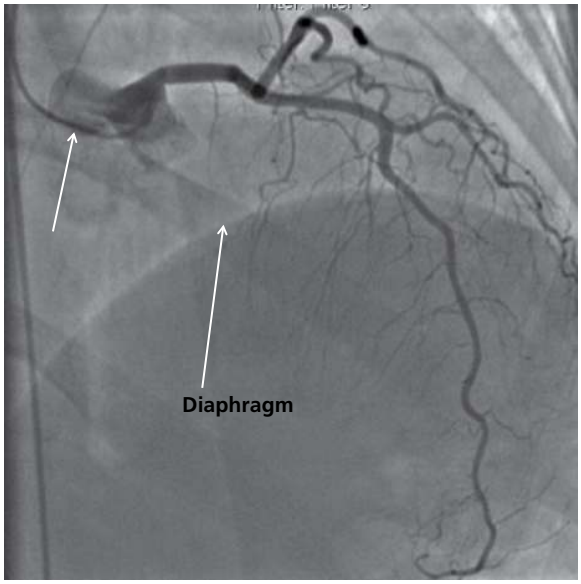

Figure 35.5 Shallow RAO view, cranial. Note the diaphragm overlapping with the heart shadow and the catheter tip slightly to the right of the central catheter in the descending aorta (the catheter tip is grabbed with the right hand, while the central catheter is grabbed with the left hand). **Also, if the ribs are looking down toward the right-hand side of the operator, the view is RAO**.

IV. Coronary angiography views. General ideas: cranial vs. caudal views

- **Caudal views** properly assess the distal LM bifurcation, proximal LAD, and the whole LCx. The mid and distal LAD segments are usually foreshortened and overlapped with the Dg branches.
- **Cranial views** properly assess the mid and distal LAD, diagonal branches, and septal branches. Cranial views are usually good views for the ostial LM, but are often inadequate for the LM bifurcation area (distal LM and proximal LAD and LCx) (Figure 35.6).
- In fact, LCx moves in the same direction as the image intensifier, whereas LAD moves in an opposite direction. Hence, on the ***caudal views, LCx is down***, LAD is up; LAD and LCx are well separated, and their bifurcation off the LM is well visualized. On the ***cranial views, LCx moves up***, along with the cranial angulation, and overlaps with the proximal LAD ± first diagonals; in addition to the overlap, the distal LM bifurcation and the proximal LAD are foreshortened. Yet, in patients with a vertical heart or a long LM, the caudal views may not open up the LM bifurcation properly; the cranial views may prove better for this purpose, particularly upon deep inspiration, which makes the heart even more vertical.

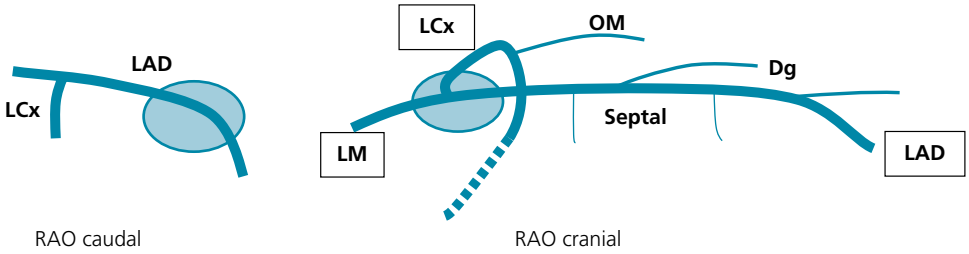

Figure 35.6 Illustration of the difference between caudal and cranial views. *Caudal* views show well the LM bifurcation into the LAD and LCx, as well as the LCx. *Cranial* views pull the LCx up and do not properly show the LM bifurcation and the proximal LAD–LCx area, but show the areas outside it (mid and distal LAD and ostial LM). The *circles* indicate the areas that are not well seen in each view.

V. Coronary angiography views. General ideas: foreshortening and identifying branches

A. Foreshortening

A coronary segment is best assessed by a view orthogonal to it, i.e., a view that lays it out and fully expands it. Foreshortening implies looking at a coronary segment in line with its path, which, in 2-dimensional imaging, condenses this segment and hides a stenosis by the contrast filling proximal and distal to it (Figure 35.7).

B. Arteries running on the border of the heart shadow

On any standard view, arteries that run on the border of the heart shadow, or are directed toward that border or touch it are usually diagonal or OM branches (depending on the view), **not LAD.**

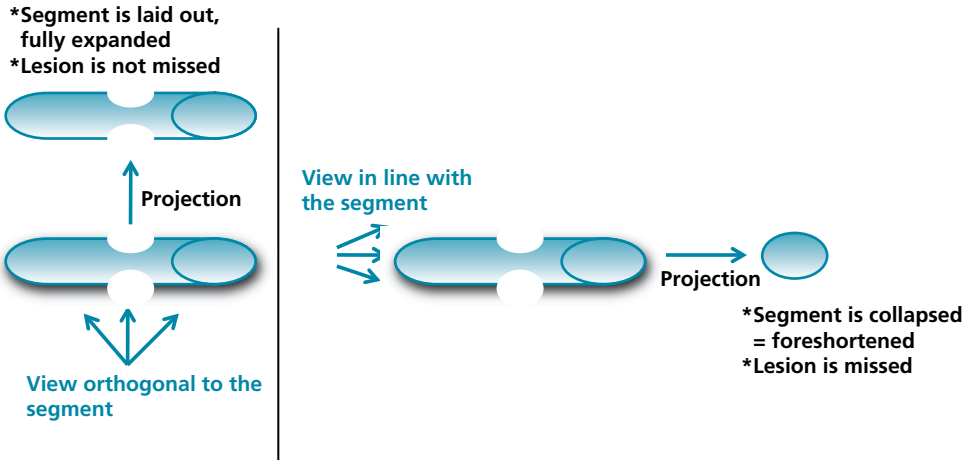

Figure 35.7 View orthogonal to a segment vs. view foreshortening a segment.

VI. Left coronary views (see Figure 35.8)

A. RAO caudal (15° RAO, 25° caudal)

This is the best overall view and the **best LCx view** (Figures 35.9–35.12). In addition, it allows good assessment of the **distal LM and the proximal LAD**. The mid LAD is not well seen on this view as it is often foreshortened and overlapped with Dg branches that run above it and underneath it. The very distal apical LAD is usually well seen. If the ostial LCx overlaps with the distal LM, going more caudal will better separate the ostial LCx and the distal LM.

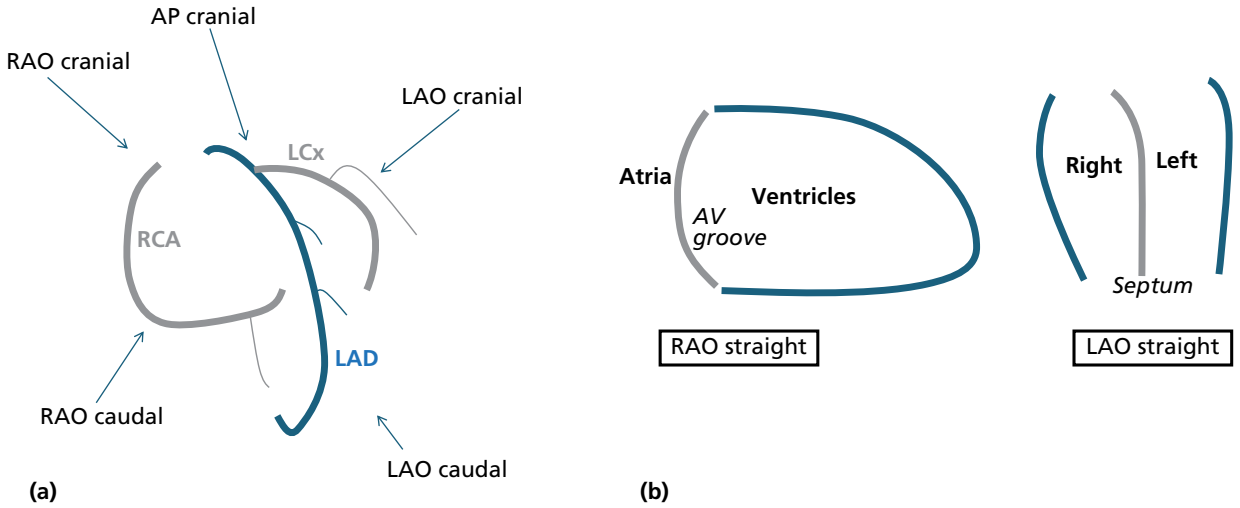

Figure 35.8 **(a)** Heart in an anteroposterior view. Imagine how you look at the coronary arteries from various angles.
(b) RAO straight view looks directly toward the AV groove and separates the ventricles on one side, and the atria on the other. LAO straight view looks toward the septum and separates left structures (LA + LV) from right structures (RA + RV).

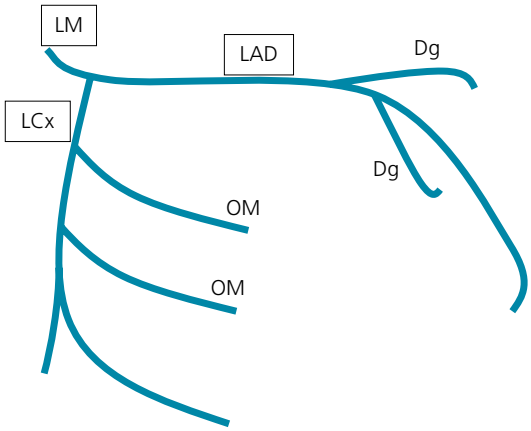

Figure 35.9 **RAO caudal view** (25°, 25°).

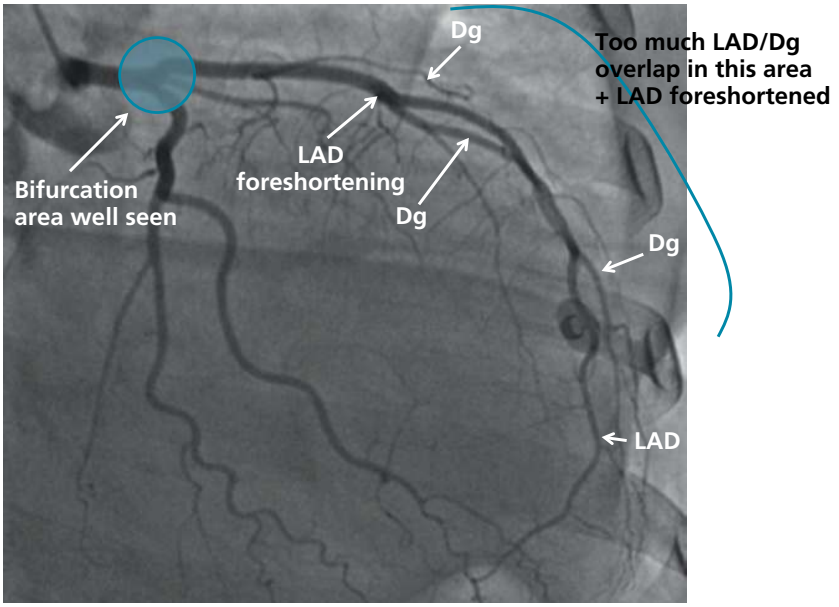

Figure 35.10 RAO caudal view. Distal LM bifurcation area is well seen; if not, the view may be angled more caudally to pull the LCx down. The mid-LAD is foreshortened and overlapped with diagonal branches. The foreshortened area looks more dense, as it is "squashed." The proximal LCx has a foreshortened area: this may be improved by imaging in deep inspiration, which straightens tortuosities.

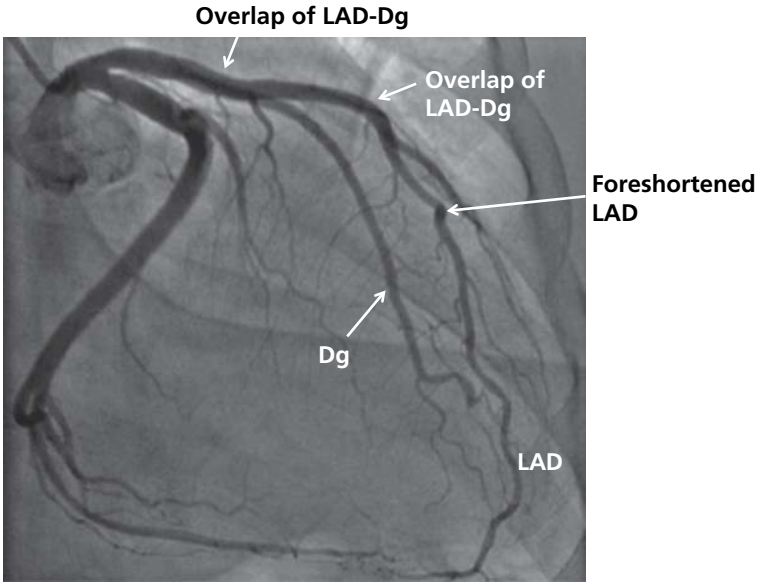

Figure 35.11 RAO caudal view. The ribs are looking down toward the right-hand side of the operator (RAO view) and the diaphragm is not seen (caudal view). Note how this view is good for the distal LM bifurcation, and how the mid-LAD overlaps with the diagonals and has some bends looking toward the X-ray detector (foreshortening). The distal LAD is well seen.

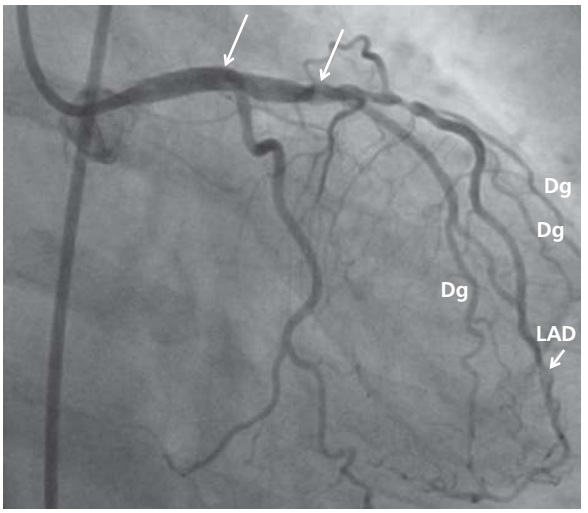

Figure 35.12 RAO caudal view in a patient with a vertical heart. Note that, in this particular case, even the LM bifurcation is not well opened. The distal LM, ostial LCx, and ostial LAD are overlapped (*left arrow*). This bifurcation may be opened by going more caudal; since the LCx follows the image intensifier, going more caudal pulls the LCx down and the LAD up, which opens up the bifurcation. In addition, the first diagonal is overlapped with the proximal/mid LAD (*right arrow*), which is expected in RAO caudal view.

The RAO caudal view may be confusing when the LAD is totally occluded, in which case a large diagonal may simulate the LAD; a diagonal aims toward the heart border, whereas the LAD remains within the center of the heart shadow (Figure 35.13). In this instance, the cranial views further define whether the artery in question is LAD or Dg.

In patients with a tortuous or sharply angulated LCx, this view may foreshorten the proximal LCx, the proximal tortuosity, and even a proximal stenosis. This is reduced by deep inspiration (elongates the LCx). Also, AP caudal or LAO caudal complements this limitation of RAO caudal by showing the ostial/proximal angulation and tortuosity.

The **AP caudal view** often gives similar information to the RAO caudal view (Figure 35.14).

LCx moves in the same direction as the image intensifier, while LAD and anterior structures (e.g., sternal wires) move in an opposite direction. When LM and proximal LCx are overlapped on RAO caudal view, going more caudal pulls LCx farther down and LAD up, opening up the LM bifurcation.

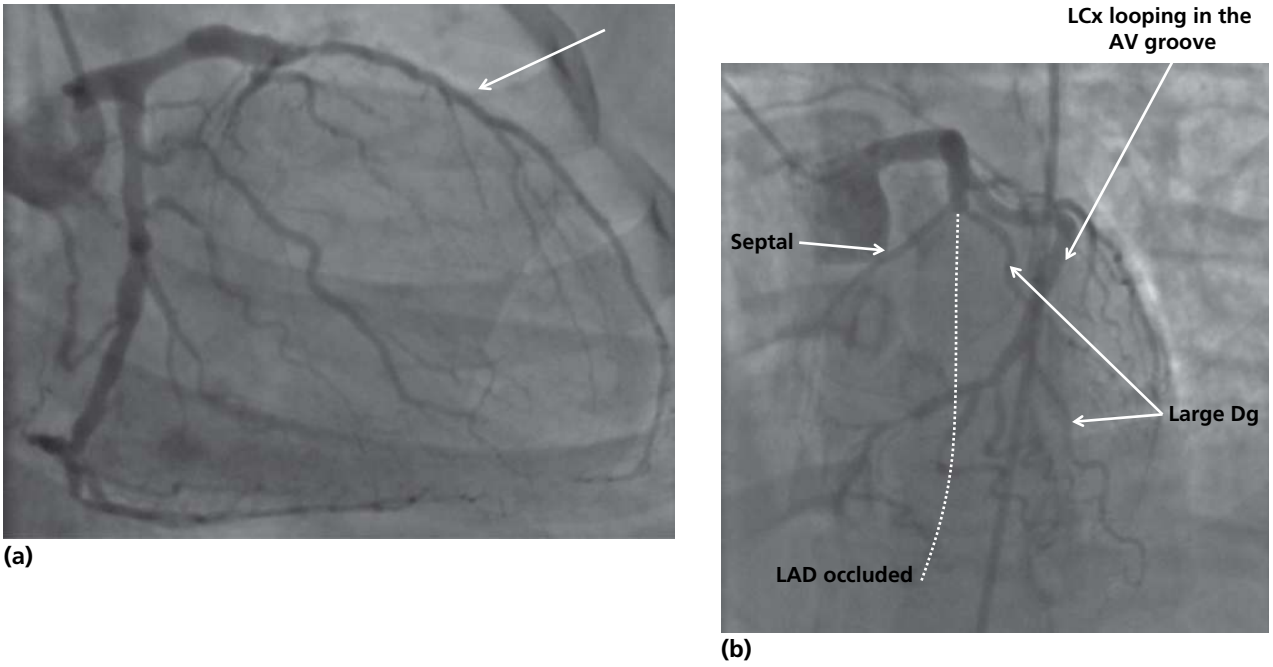

Figure 35.13 **(a)** RAO caudal with a large diagonal and a totally occluded LAD. The arrow points to a diagonal branch that simulates the LAD. The fact that it goes *out toward the heart border* implies that it is a diagonal branch rather than LAD, the LAD being totally occluded.

(b) LAO cranial of the same patient. LAO cranial shows the Dg going to the side, toward the heart border. No LAD is seen in the center of the heart shadow; the LAD is occluded past the diagonal and septal branches. Of note, the LAD usually runs parallel to the spine on this view (*dashed line*). This view confirms that the LAD is occluded when the RAO caudal view is suspicious.

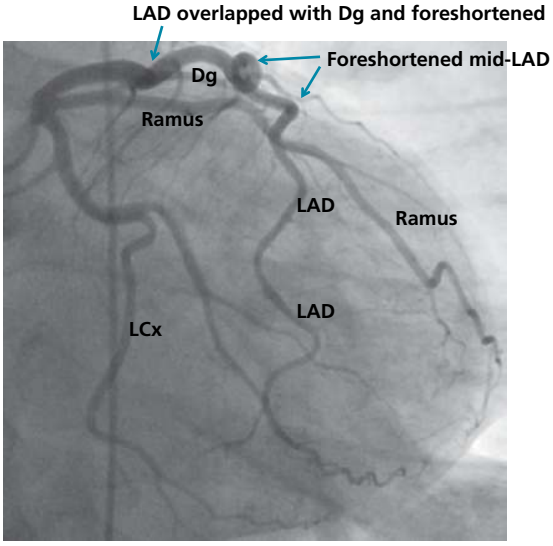

Figure 35.14 **AP caudal view.** Similarly to RAO caudal view, the AP caudal view shows the distal LM and the proximal LAD and LCx. The LM trifurcation is well visualized here. Note the foreshortening of the mid-LAD, wherein a large mid-LAD loop is looking toward the detector. The ramus reaches out toward the heart border, while the LAD remains centered inside the heart shadow.

B. LAO caudal (40° LAO, 30° caudal)

This view allows a good assessment of the **LM, proximal LAD, proximal LCx**, and proximal branches (Figure 35.15).

To obtain a good LAO caudal view, angle the image intensifier so that the tip of the catheter is positioned in the center of the cardiac silhouette. If it is not in the center of the cardiac silhouette, move the image intensifier more caudal or less LAO to obtain a good LAO caudal view, or instruct the patient to hold his breath in end-expiration, which makes the heart more horizontal.

This view looks at the heart from below and is best in patients with a horizontal heart, where the image intensifier can be almost perpendicular to the heart. This view may not properly open the LM bifurcation in patients with a vertical heart, and may be suboptimal in obese patients with a lot of soft tissue attenuation (may skip this view in those cases and rather obtain an AP caudal view). On the other hand, *in patients with a vertical heart or a long LM, cranial views may allow better delineation of the distal LM and proximal and early mid-LAD than caudal views* (Figures 35.16–35.18).

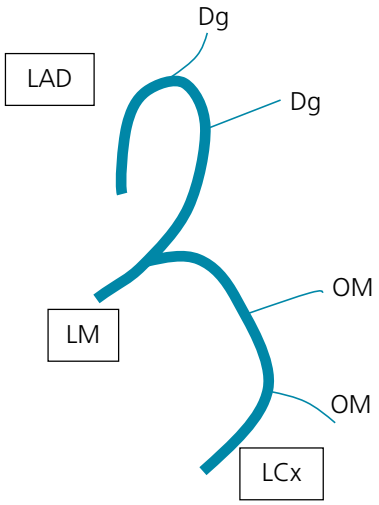

Figure 35.15 LAO caudal view (40°, 30°). Catheter tip is at the center of heart shadow. LM is at the center, LAD is up, and LCx is down. OM and Dg are in the sector between LAD and LCx.

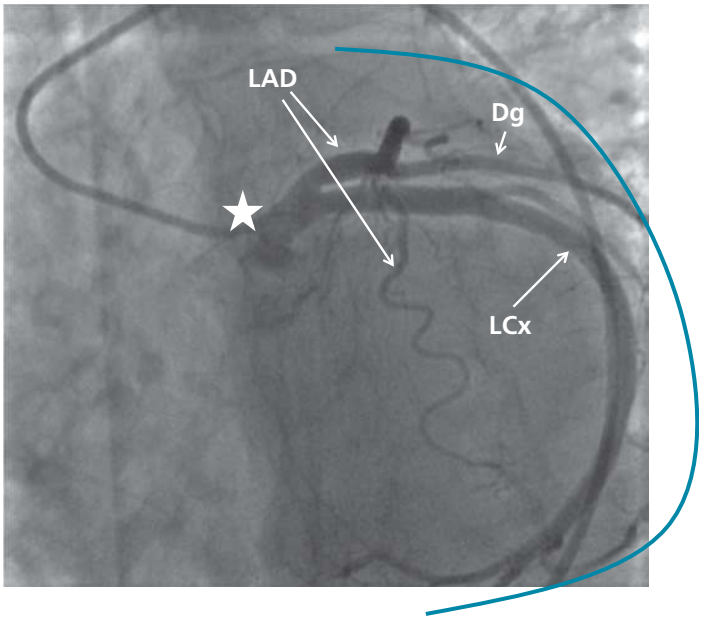

Figure 35.16 LAO caudal view of a vertical heart. The catheter tip (*star*) is not in the center of the heart shadow (delineated by the *blue line*); hence the distal LM bifurcation is not properly opened. The view needs to be angled more caudally or less LAO to center the catheter tip, or the view needs to be taken in deep expiration to make the heart horizontal. LAO caudal is difficult to optimize in patients with a vertical heart.

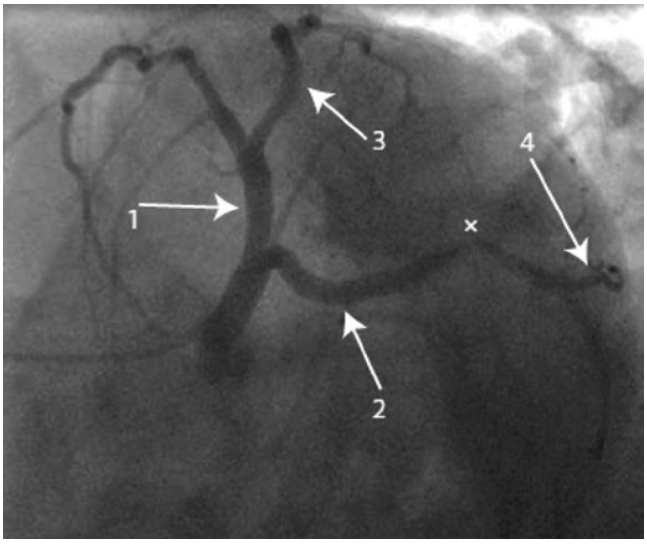

Figure 35.17 LAO caudal view of a horizontal heart. Note that the catheter tip is at the center of the cardiac silhouette, and the delineation of the LM bifurcation is excellent. 1, LAD; 2, LCx; 3, diagonal; 4, OM; x, LCx stenosis.

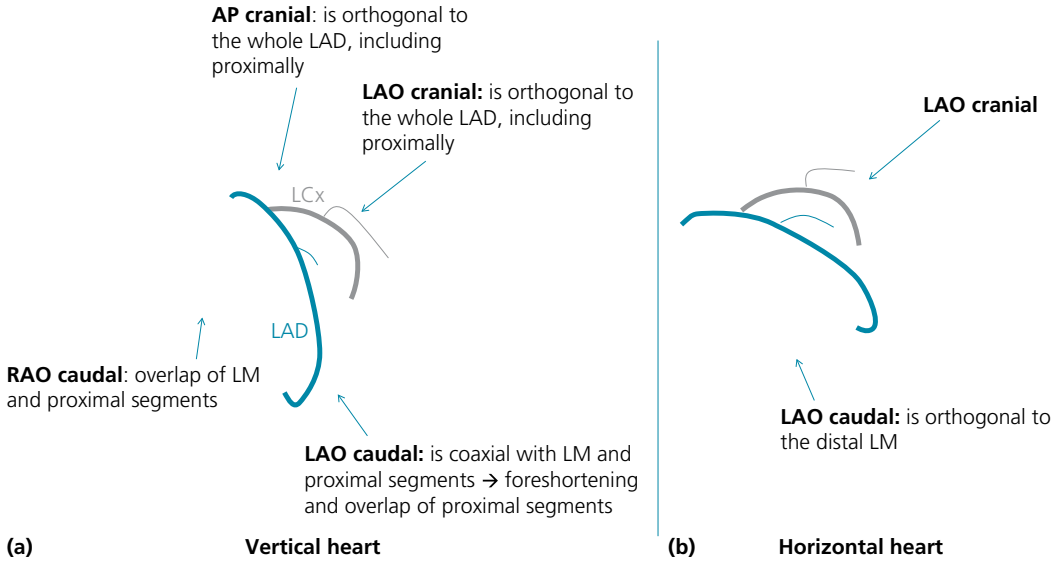

Figure 35.18 (a) Vertical heart. LAO caudal is not orthogonal to the LM bifurcation and does not "see" it well. Cranial views, on the other hand, are orthogonal to the LM bifurcation and may allow good visualization of the distal LM/proximal LAD.

(b) Horizontal heart. LAO cranial view is suboptimal with overlap and foreshortening of the proximal and mid LAD/LCx/Dg. LAO caudal view, on the other hand, is optimal and opens the bifurcation well. Deep inspiration makes the heart more vertical and may optimize the LAO cranial view, particularly the LM bifurcation, while imaging at end-expiration provides a better LAO caudal view.

C. AP cranial or shallow RAO cranial (5° RAO, 35° cranial) (shallow RAO moves the left main away from the spine)

This view allows good assessment of the ***mid and distal LAD***, as well as the diagonal and septal branches that originate from the mid and distal LAD and their points of bifurcation from the LAD. The distal LM, proximal LAD, proximal LCx, and the proximal branches are overlapped together and not well delineated (Figures 35.19, 35.20). Disease in the proximal portion of the LAD, LCx, ramus, or Dg may look like distal LM disease. Away from the LM bifurcation, the ostial LM is often well seen, as in most cranial views.

Sometimes, however, in patients with a vertical heart or a long LM, the distal LM bifurcation is well seen, especially with deep inspiration.

D. LAO cranial (40° LAO, 30° cranial)

This view allows a good assessment of the **mid and distal LAD**, as well as the diagonal and septal branches that originate from the mid and distal LAD. The distal LM, proximal LAD, and proximal LCx are overlapped and foreshortened. The LCx is not well seen because of its overlap with the OM branches, but the mid/distal segments of the OM branches may be well seen as they run over the heart border (Figures 35.21–35.24). *Similarly to the AP cranial view, the distal LM bifurcation may be well seen without foreshortening in patients with a vertical heart or long LM, particularly with deep inspiration*.

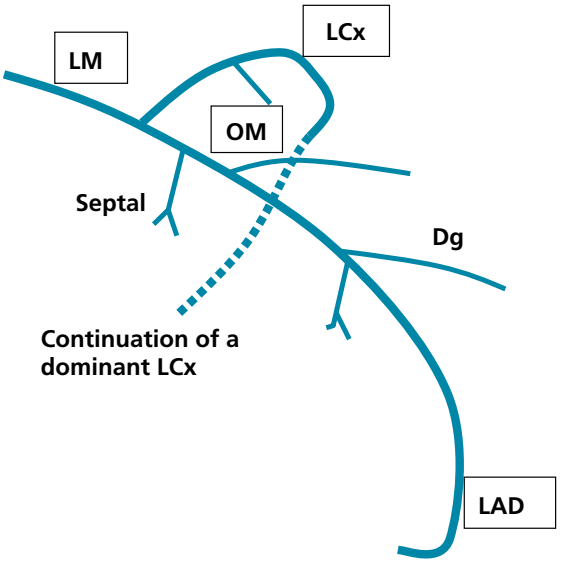

Figure 35.19 Shallow RAO cranial view (5°, 35°).

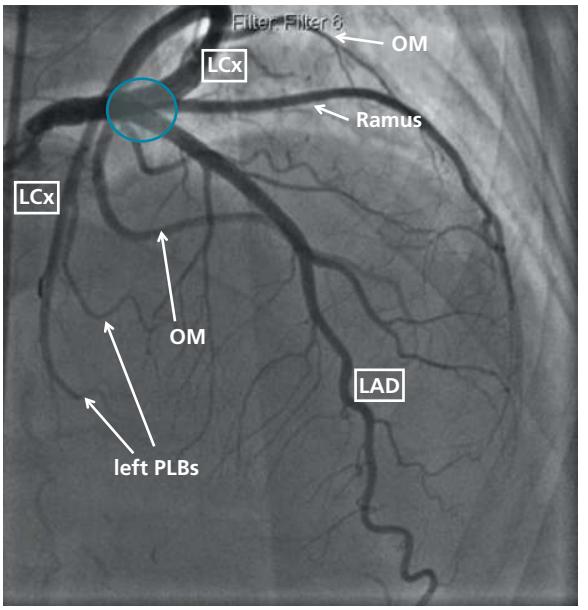

Figure 35.20 Shallow RAO cranial view. Note the overlap of the distal LM, proximal LAD, proximal LCx, and proximal ramus (*circled area*). When LCx is dominant, the distal LCx and distal OMs (left PLB branches) may be well seen on cranial views, including this view, but more so on the LAO cranial view.

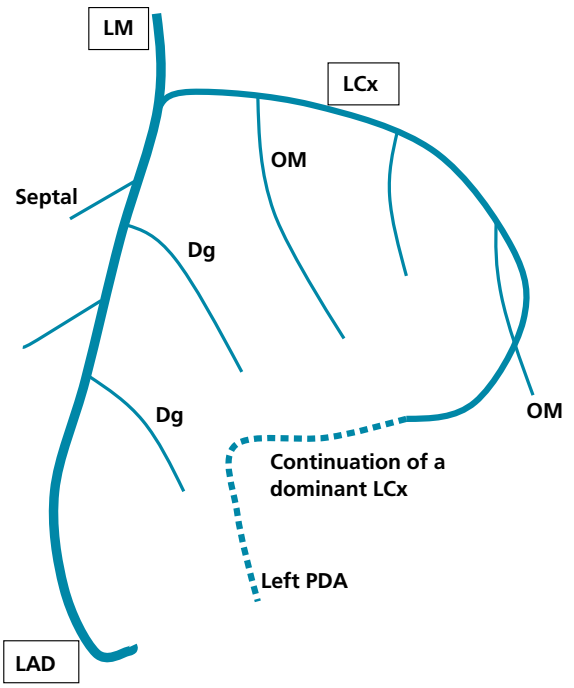

Figure 35.21 LAO cranial view (40°, 30°). The LCx and OMs run on the border of the heart shadow in this view, whereas the LAD runs over the center of the heart shadow, parallel to the spine. Steeper LAO is required to move the LAD away from the spine. The diagonal and OM branches are in the sector between the LAD and LCx.

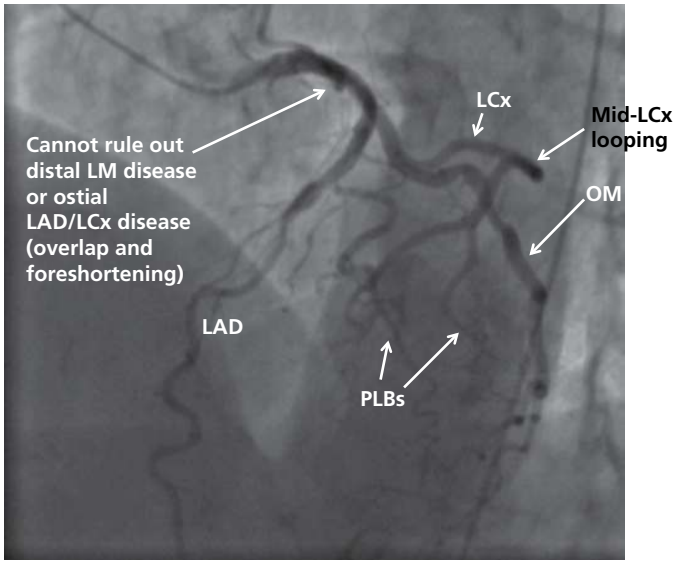

Figure 35.22 LAO cranial view. Note the overlap at the level of the distal LM.

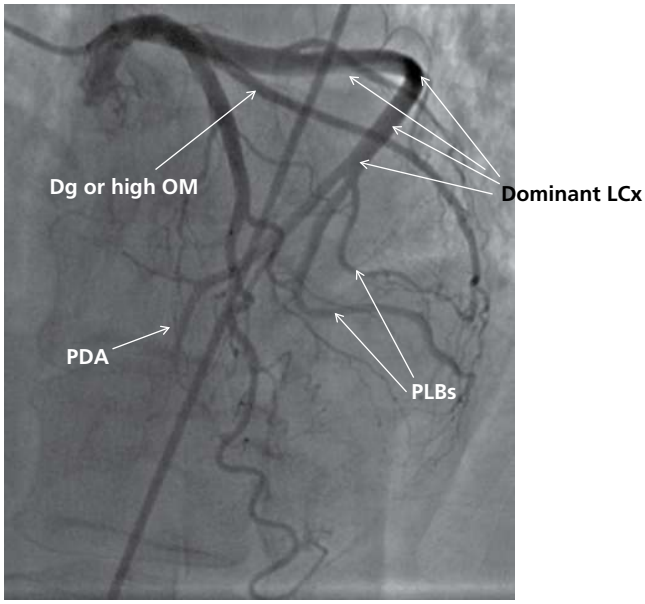

Figure 35.23 LAO cranial view showing a dominant LCx. The distal PLBs and PDA are well seen on this view. This view is the best view for the distal, dominant LCx.

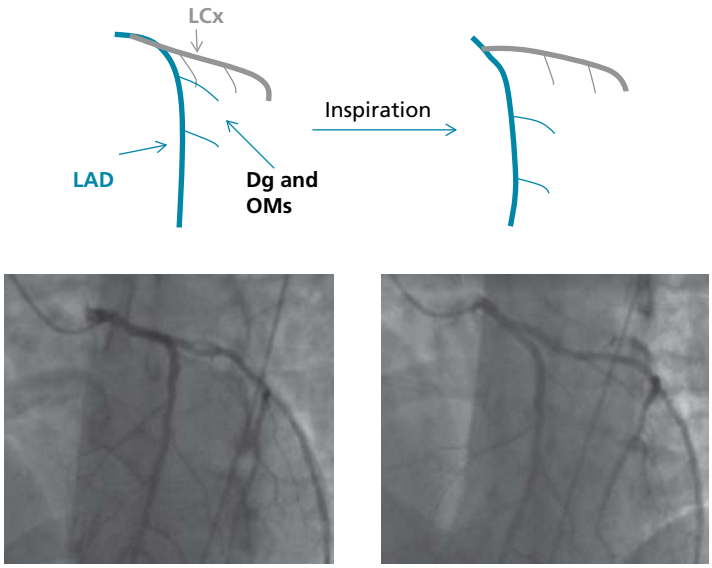

Figure 35.24 LAO cranial view. If there is too much overlap in the proximal area (*left-sided images*), move the view more cranially, as this will bring the LCx up and the LAD down. Alternatively, one may image in end-inspiration (*right-sided images*), which makes the heart more vertical and relieves the proximal overlap. **Cranial views are usually best in patients with a vertical heart.**

This is also the best view to determine whether the LCx is a dominant LCx (Figure 35.23). In such a case, the LCx is seen looping all the way down the AV groove until the crux and giving a left PDA that runs parallel to the LAD. Thus, the LAO cranial view allows a good assessment of the distal, dominant LCx as well as the left PDA, the same way it allows a good assessment of the distal RCA and right PDA.

This view is also the view that best differentiates a large Dg branch from the LAD in the case of a totally occluded LAD. Two features distinguish the LAD from an enlarged diagonal:

1. The diagonal loops to the left and reaches toward the border of the heart shadow, whereas the LAD runs parallel to the spine and loops at the apex (Figures 35.25, 35.26). Occasionally, in an enlarged LV, the apex is moved to the left and thus the LAD course may simulate a diagonal course.
2. The LAD always gives septal branches, straight parallel branches that buckle or torque very little in systole. In contrast, the diagonal and its branches buckle and curl in systole (as the apex and LV free wall torque in systole).

Shallow RAO cranial may also help define a dominant LCx, and may help in the LAD/diagonal differentiation when the LAD is totally occluded.

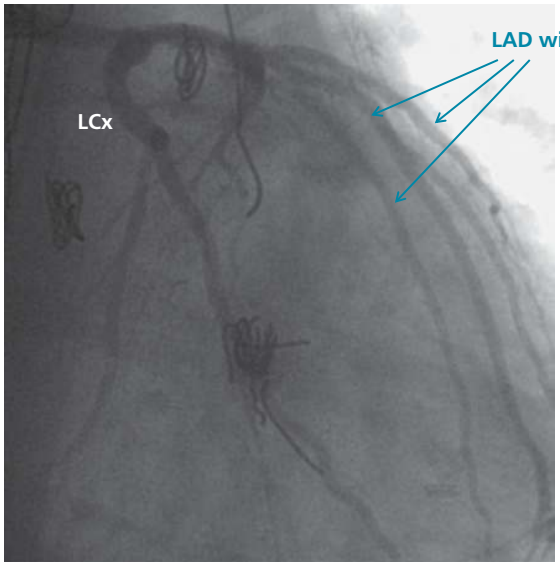

Figure 35.25 RAO caudal view. One gets the impression that the LAD is patent and is seen along with large diagonal branches. See Figure 35.26.

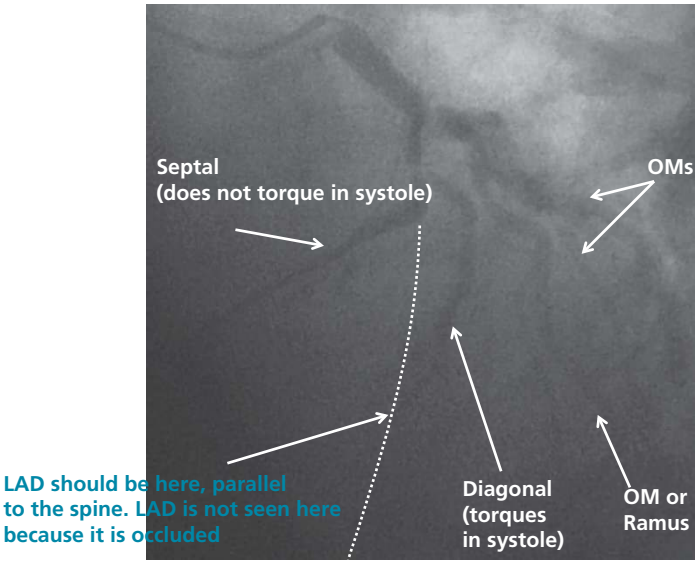

Figure 35.26 LAO cranial view of the patient from Figure 35.25. What seems like LAD on the RAO caudal view is actually a ramus or a high OM. On Figure 35.25, the outmost branch indicated by the arrow is a diagonal branch (which runs on the heart border of an RAO caudal view), while the other 2 branches, including the large branch that mimics LAD, are OM branches.

E. RAO cranial (30° RAO, 30° cranial)

Similarly to other cranial views, this view allows good assessment of the mid and distal LAD and the diagonal branches originating from the mid and distal LAD (Figure 35.27). Compared to AP cranial, there is greater superimposition of diagonal branches and wider diaphragm excursion over the coronary arteries, making this view suboptimal. AP cranial is also superior in quality to LAO cranial, which overlaps considerably with the moving diaphragm and the spine. AP cranial is often the best LAD PCI view.

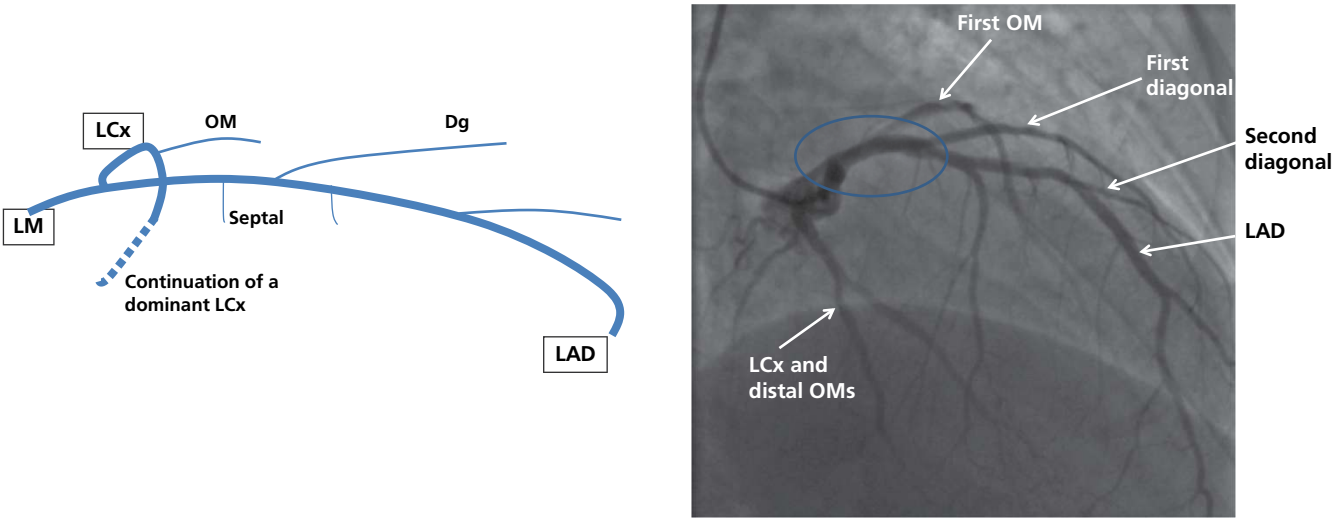

Figure 35.27 RAO cranial view (30°, 30°). The circled area is the area where the distal LM, proximal LAD, first diagonal, and first OM overlap.

F. Other views: 90° left lateral, LAO straight, RAO straight

The 90° left lateral view is appropriate for the assessment of the very proximal and the distal LAD. It is usually inadequate for the assessment of the mid-LAD, because of LAD–diagonal overlap at the mid-LAD level. It is particularly useful **when other views do not adequately display the ostial/proximal LAD** and may be the only view that shows the ostial LAD.

RAO straight resembles RAO caudal, and LAO straight resembles LAO cranial, with more overlap. Straight views are particularly useful during interventions in obese patients. They reduce the blurriness induced by soft tissue (caudal views) or the diaphragm (cranial views).

G. Views useful for left main assessment (Figure 35.28)

For **ostial LM: LAO and AP views, straight or cranial**. Specifically, the shallow LAO straight view (10–15°) may be the best view for ostial LM and moves it away from the spine. AP and LAO are orthogonal to the left main ostium, allowing it to be well splayed. RAO views, conversely, are aligned with the left main ostium and foreshorten it. Caudal views may superimpose the aortic cusp, filled with contrast, over the ostium and obscure it. Collimation with magnification over the LM is also helpful.

For **distal LM: all caudal views**, as well as shallow RAO straight (15°), which sees the LM as it courses anteriorly beyond its origin.

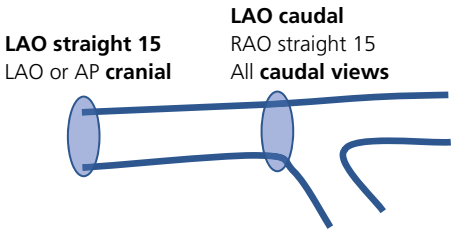

Figure 35.28 Best views for ostial left main, and best views for distal left main.

H. A minimum of 2 views is required for left coronary assessment

The **RAO caudal view** and **one cranial view** may be performed. The former allows the assessment of LM, LCx, and proximal and apical LAD; the latter allows the assessment of the mid and distal LAD and diagonal branches.

VII. Right coronary views

A. LAO straight

This is an **en face view of the AV groove**. It allows good assessment of the proximal and mid RCA. The distal RCA, PDA, and PLBs are all overlapped (Figures 35.29, 35.30).

B. LAO cranial (30° LAO, 15° cranial)

This is the best RCA view. It shows the proximal and mid RCA, but also opens up the distal RCA bifurcation (Figures 35.29, 35.30).

Cranial views are important for the assessment of the distal RCA bifurcation, and one should obtain at least an LAO cranial or AP cranial view.

C. AP cranial (30° cranial)

This view allows the **best assessment of the distal RCA bifurcation** and serves as an adjunctive view when LAO cranial does not open up the bifurcation well. This view foreshortens the mid-RCA, and thus is not appropriate for mid-RCA assessment (Figure 35.31).

On the LAO straight, LAO cranial, and AP cranial views, the true RCA course has 2 bends (Figure 35.32). The lack of those bends signifies that the artery seen is actually a large AM branch rather than the main RCA continuing into the PDA. In this case, the main RCA is either non-dominant or occluded and does not provide a PDA. Moreover, in some anatomical variants, one large AM branch loops down to the inferior septum and provides a distal PDA. *This AM branch is called low-lying AM or streaker branch; it has no bend, and should not be confused with the true RCA* (Figures 35.33, 35.34).

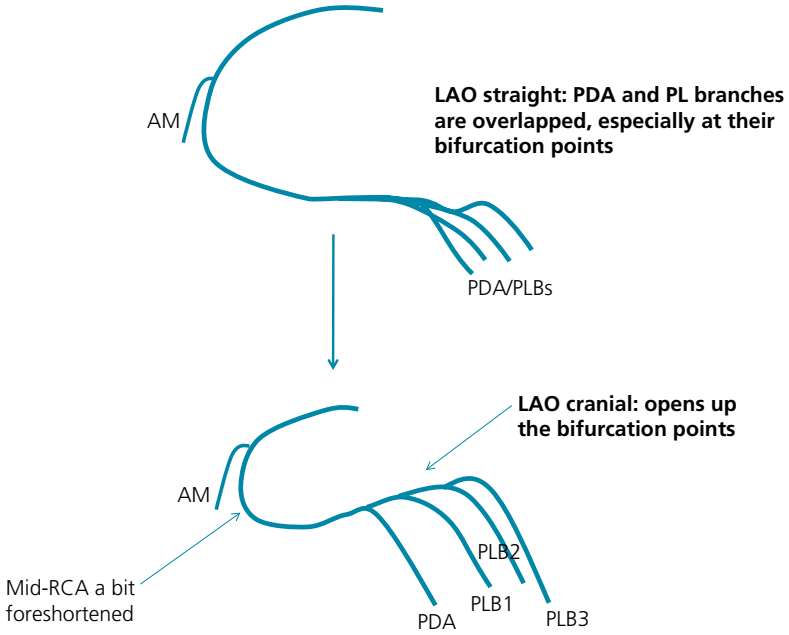

Figure 35.29 RCA views: **LAO straight vs. LAO cranial**. LAO cranial opens the distal RCA bifurcation.

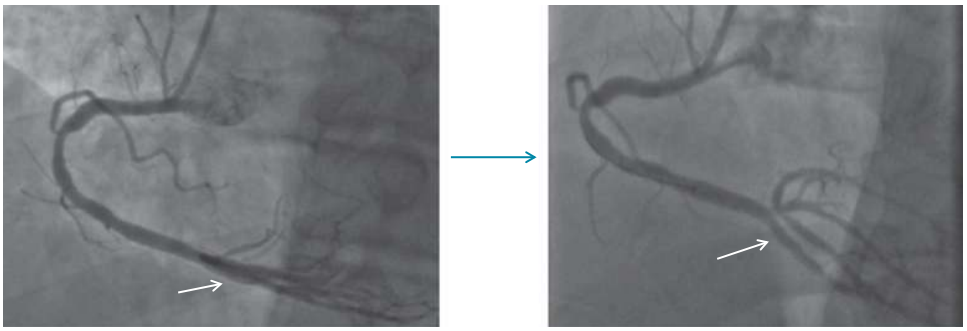

LAO straight **LAO cranial**

Figure 35.30 Note how the LAO cranial opens the distal RCA branches (*arrows*).

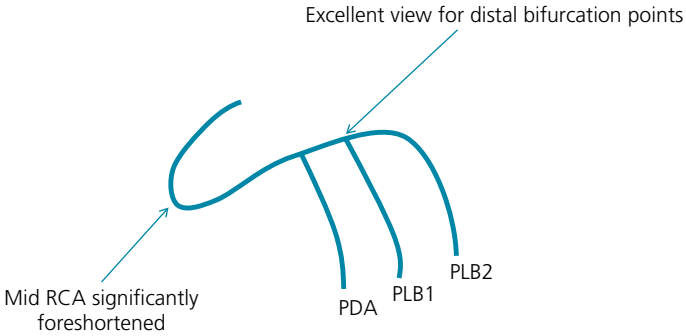

Figure 35.31 AP cranial view. Note how the distal RCA is well laid out.

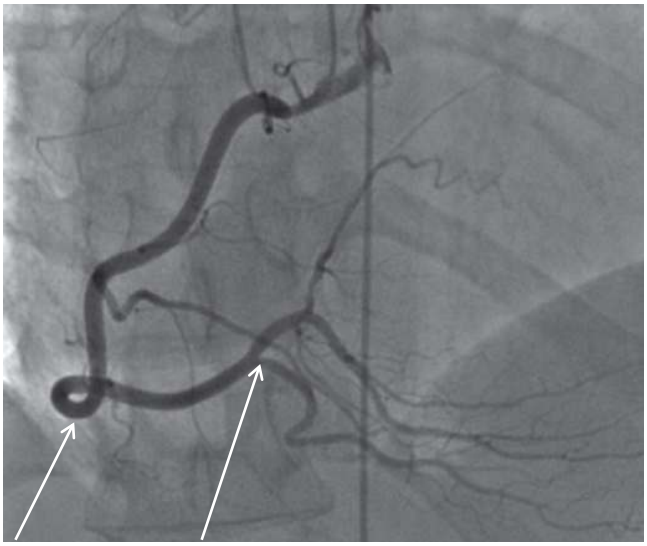

Figure 35.32 The true RCA has 2 distal bends on the LAO and AP cranial views (*arrows*). This is an AP cranial view.

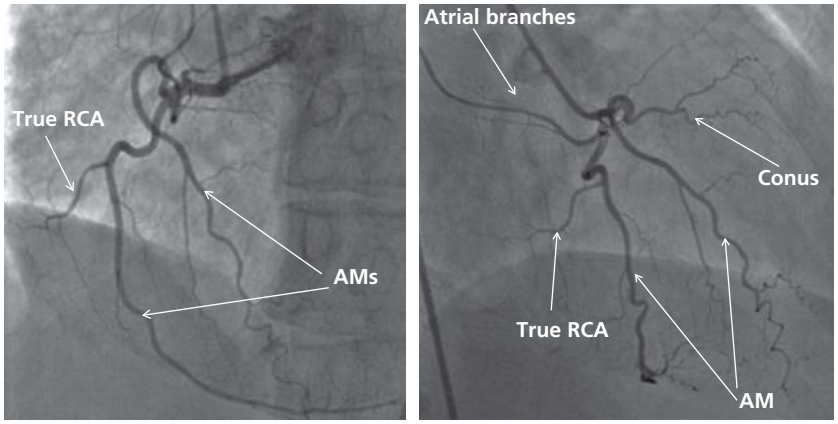

(a) **(b)**

Figure 35.33 (a) LAO cranial view. It may seem that the RCA continues down and gives the PDA. In reality, the RCA finishes early in the AV groove (true RCA being the posterior-most straight branch). The branch continuing down is actually an AM branch. The lack of any bend is the clue to this interpretation. The patient either has a non-dominant RCA or an occluded mid-RCA. RAO view would confirm this interpretation. In this case, the RCA is non-dominant.

(b) RAO straight view from the same patient. The main RCA is posterior, in the AV groove. This view separates the AM branches, which go to the right of the image, from the atrial branches, which go to the left of the image.

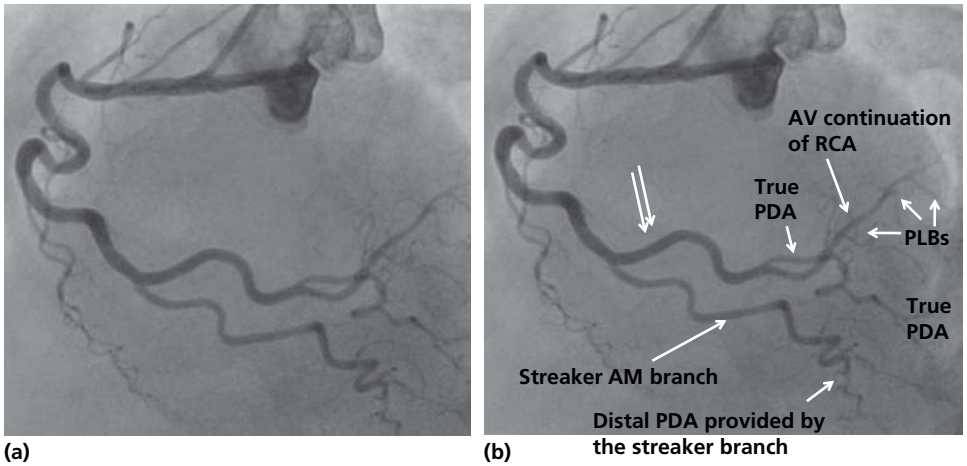

Figure 35.34 **(a)** LAO cranial view of the RCA. Try to identify the true RCA, PDA, and PL branches. **(b)** Same LAO cranial view with annotations. The true RCA makes a bend (*double arrow*). The branch that does not make a bend is actually a distal AM branch that loops down to the inferior septum and provides a distal PDA; this AM branch is called the streaker branch.

D. RAO straight (30° RAO)

This view looks at the AV groove from the side, and thus directly looks at the mid-RCA running in the AV groove, allowing excellent assessment of the mid-RCA. The proximal RCA is foreshortened ("looking toward us"), the distal RCA is foreshortened, and the distal RCA branches (PDA, PL) are overlapped as they run toward the apex (Figure 35.35).

This view has 2 additional uses: (1) if, on the LAO view, there is a question whether the artery seen is the true RCA ending into a PDA vs. a large AM branch in a patient with occluded or non-dominant RCA, the RAO view will delineate the true RCA in the AV groove. The true RCA will keep looping down toward the crux, as opposed to an AM branch, which will run to the right (Figure 35.33); (2) during coronary interventions, this view indicates whether the guide is coaxial with the ostium ("looking toward us") and facilitates wiring of the true RCA instead of AM branches.

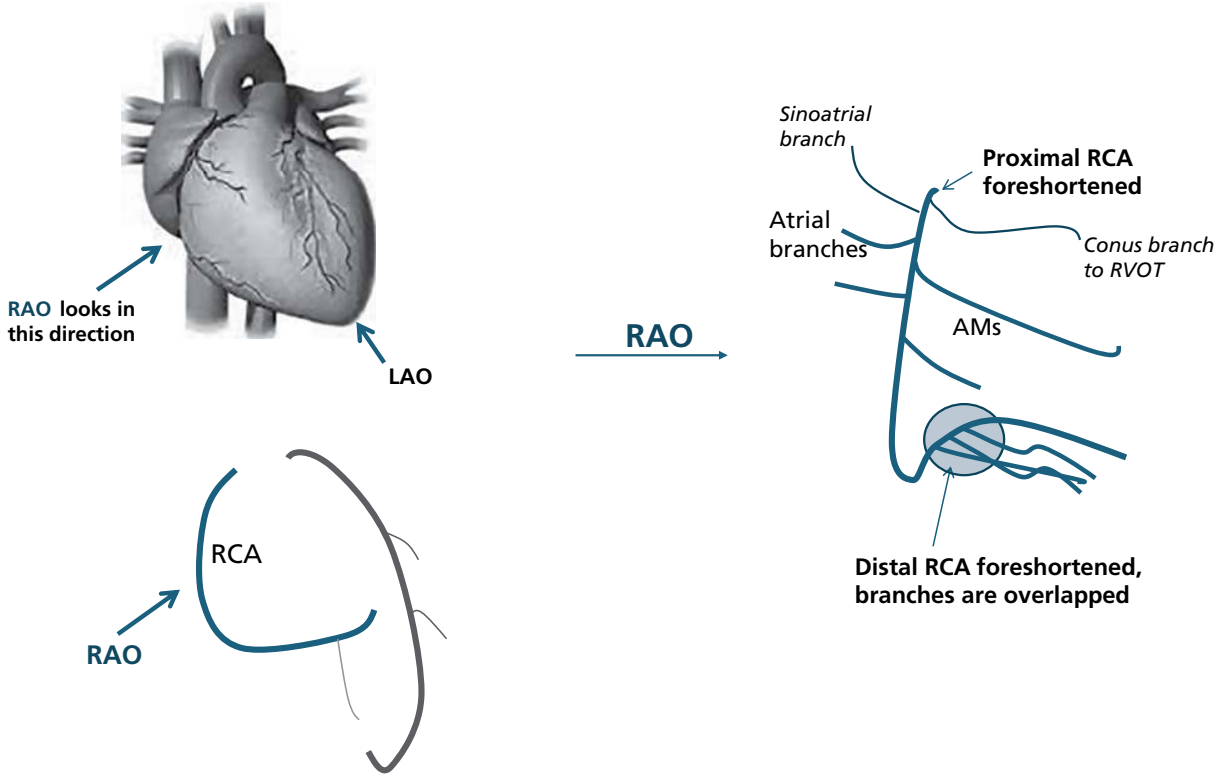

Figure 35.35 ***RAO straight*** (30°) looks at the AV groove from the side rather than en face, and shows the mid-RCA. It separates the ventricle from the atrium. AM branches go toward the ventricular side, while atrial branches go toward the atrial side. Note the first 2 RCA branches: (1) conus branch, then (2) sinoatrial branch.

E. Routine RCA views

In routine cases, image the RCA in 2 views: LAO cranial and RAO straight. Alternatively, one may obtain LAO straight and AP cranial views. Take at least 1 cranial view, sometimes 2, to define distal bifurcation disease.

If the ostial RCA needs to be further assessed, 2 views are particularly useful: steep LAO view (50–60°) and LAO caudal view (or LAO cranial view based on a CTA study). These views are also useful during stent positioning in the ostial RCA.

F. Interaction between RCA and LCx in the AV groove and summary of RCA branches (Figure 35.36)

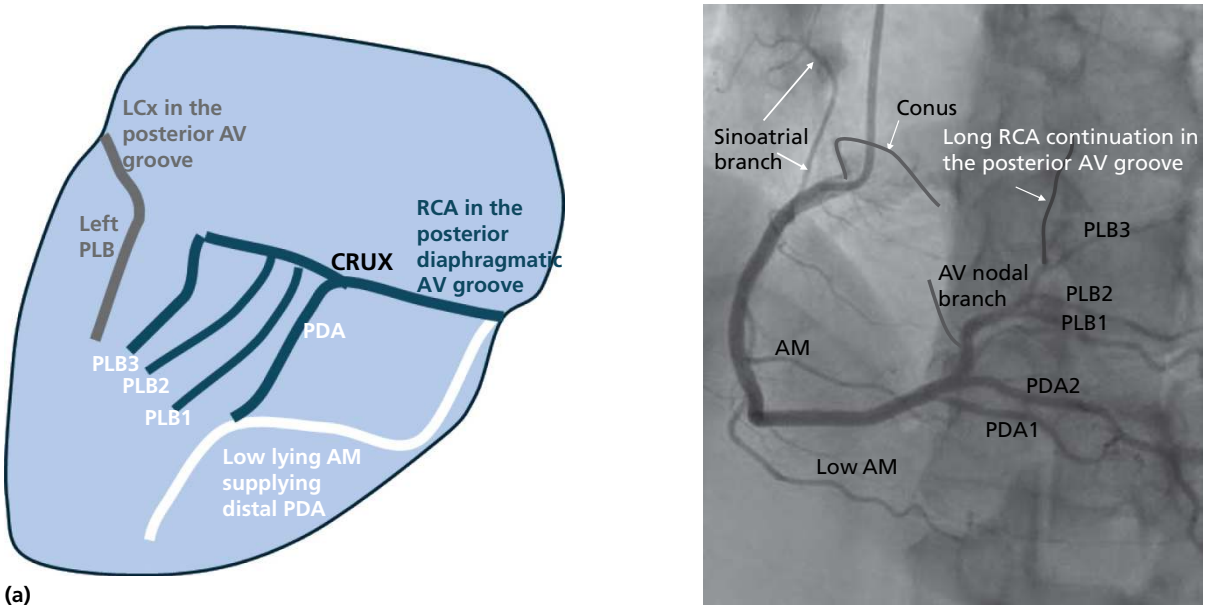

Figure 35.36 **(a)** View of the posterior diaphragmatic surface of the heart and the AV groove. The distal RCA and distal LCx nearly meet in the posterior AV groove. The longer the RCA is in that AV groove, the shorter the LCx. For example, if a superdominant RCA reaches high up the left AV groove and gives many PLBs, the LCx will be short and will terminate early in the left AV groove. Conversely, when a dominant LCx reaches all the way down to the crux, the RCA terminates early in the right AV groove.

Note how a low-lying AM arises from the margin of the heart, then travels under the inferior RV and may reach the distal inferior septum, supplying distal PDA territory.

(b) Illustration of RCA branches and of a long distal RCA climbing up in the left AV groove. Two PDA branches are present under the inferior septum, followed by many PLBs. Note the *sinoatrial branch* (second RCA branch after the conus). Conversely, the *AV nodal branch* is a distal branch that often arises from the posterior AV groove distal or proximal to the PDA, and sometimes arises from the PDA itself. SA nodal branch arises from the proximal RCA (60%) or proximal LCx (40%), regardless of dominance, and may arise from both in ~20% (dual supply). AV nodal branch arises from a dominant RCA (90%) or dominant LCx (10%).

VIII. Improve the angiographic view in case of vessel overlap or foreshortening: effects of changing the angulation, effects of respiration, and vertical vs. horizontal heart

A. LCx moves with the image intensifier

In case of overlap of branches that need to be set apart, remember that ***the LCx and posterior structures (e.g., spine) move in the same direction as the image intensifier, whereas the LAD, Dg, catheter tip, and sternal wires (anterior structures) move in the opposite direction***. For example, if the image intensifier moves to a steeper LAO angle, LCx will move to the left of the patient and the catheter tip will move to the right.

Examples:

- *On LAO cranial view*:
  - Steeper LAO allows more LAD–LCx separation.
  - Steeper cranial allows more LAD–LCx and diagonal–LCx separation (similar to deep inspiration, Figure 35.24).
- *On RAO cranial view*:
  - If the LCx overlaps with the LAD and is a bit above the LAD, move the image intensifier more cranial or take the picture during deep inspiration to lift the LCx further above the LAD; or move leftward to AP cranial view to move the LCx a bit more leftward.
  - If the LCx (or OM) overlaps with the LAD and is a bit below the LAD, go less cranial.
  - If the first diagonals overlap with the LAD and are a bit above the LAD, go more cranial. Moving to AP cranial also helps.

B. Effects of respiration

Expiration makes the heart horizontal, thus improving the vessel separation on the LAO caudal view but worsening the vessel overlap on the LAO cranial and RAO cranial views, i.e., the overlap of LAD, Dg, and proximal LCx/proximal OMs.

Deep inspiration makes the heart more vertical. On a cranial view, if the LCx is overlapped with the LAD or is slightly above it, deep inspiration will push the LCx further up and the diaphragm down, allowing better exposure of the LAD (Figure 35.24). The effect is similar to going more cranial. On a caudal view, if the LCx is overlapped with the LAD, deep inspiration will worsen the proximal LAD/LCx overlap.

Deep inspiration also moves the diaphragm out of the field of view. It elongates the heart and thus straightens tortuosities, allowing better visualization of tortuous segments.

C. Vertical vs. horizontal heart

In the case of a vertical heart, LAO caudal is not orthogonal to the LM bifurcation and does not "see" it well. Cranial views, on the other hand, are orthogonal to the LAD and LCx planes and may allow good visualization of the distal LM and proximal LAD (Figure 35.18).

IX. Saphenous venous graft views

For the angiographic assessment of SVGs, obtain at least 2 views:

1. One straight oblique view, typically the view used to engage the graft (RAO for a left graft and LAO for a right graft). This view is useful to assess the ostium and body of the graft.
2. One angled view for the assessment of the graft anastomosis and the native vessel. For example (Figures 35.37–35.40):
   a. RAO caudal or AP caudal view for an OM graft
   b. RAO cranial, AP cranial, or LAO cranial view for a Dg or LAD graft
   c. LAO cranial ± AP cranial for an RCA graft (Figure 35.37).

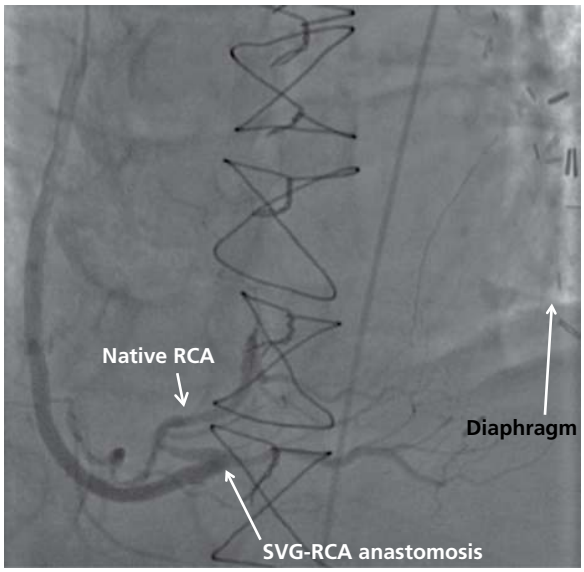

Figure 35.37 AP cranial view properly showing the SVG-to-RCA anastomosis and the native RCA.

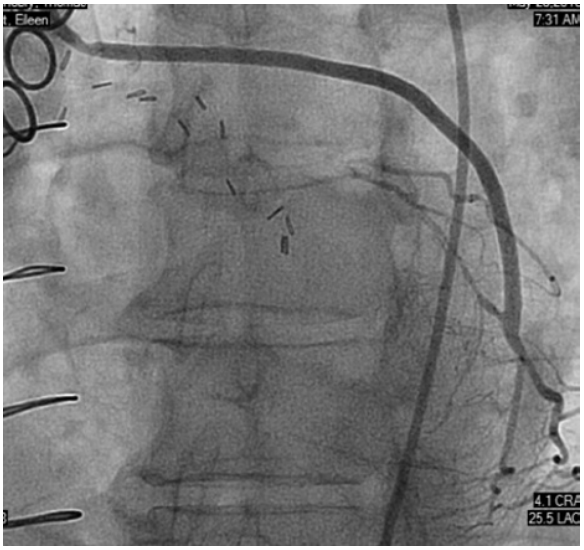

Figure 35.38 On this LAO cranial view, the grafted artery is at the left rather than right heart shadow → left coronary branch. It is running at the border of the heart, which, on LAO cranial view, implies OM branch rather than Dg.

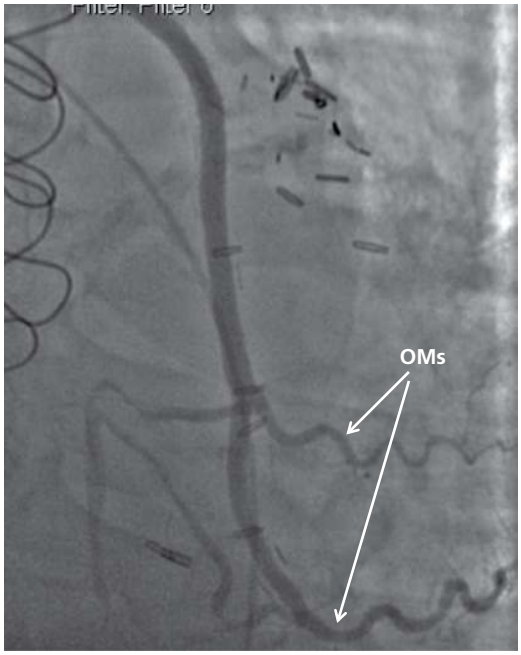

Figure 35.39 AP caudal view showing sequential SVG to OM2 and OM3. In this view, diagonal branches would be on top, running on the border of the heart shadow.

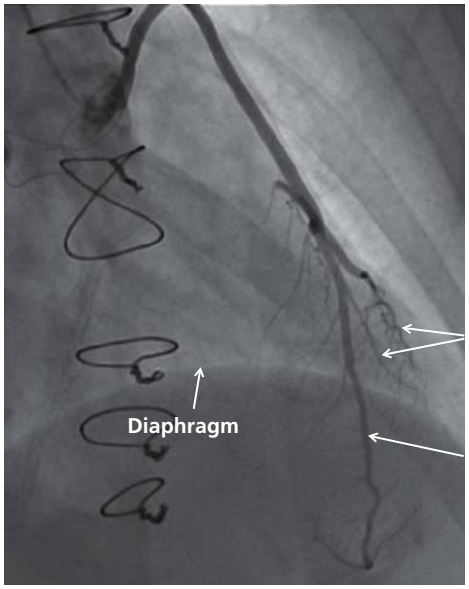

Figure 35.40 RAO cranial view (diaphragm is seen over the heart shadow, ribs are looking down toward the right). Is this SVG connected to a Dg, LAD, or OM? The anastomosed artery is not running at the border of the cardiac silhouette and is going to the apex. Thus, SVG is connected to the LAD and retrogradely fills a diagonal.

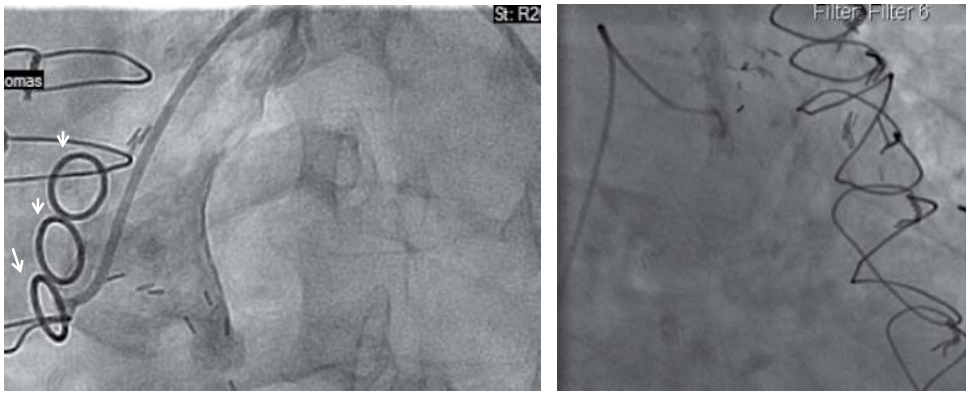
If one view does not allow proper assessment of the anastomosis, obtain the second listed view. In addition, similarly to the LIMA-to-LAD, a left lateral view may be used to assess the anastomosis of the SVG-to-LAD graft.

In many cases, it is difficult to define whether the native branch is an OM or a Dg branch, especially when the native branch is a proximal OM or Dg. The LAO cranial (or straight) often proves helpful: in this view, OM branches run on the border of the cardiac silhouette, whereas Dg branches run over the heart shadow (Figure 35.38). RAO caudal and LAO caudal may prove useful as well (Figure 35.39). ***The comparison of the graft angiogram and the native vessel angiogram obtained in the same view*** also allows the identification of the grafted branch. In addition, there are cases where one needs to identify which OM is grafted or if the grafted OM is the same OM visualized on the native angiogram (as opposed to an OM that is totally occluded and not visualized on the native angiogram). Again, comparing the graft angiogram and native vessel angiogram obtained in the same view and referencing vessels to the sternal wires will prove useful.

At the end, provide your assessment in terms of flow to the 3 myocardial territories (LAD, LCx, RCA). Example of a report: (1) LIMA fills the distal LAD, with no retrograde flow into Dg1; the diseased native LM+LAD supply Dg1, before the LAD occlusion point. (2) LCx system has a patent OM1; OM2 is occluded and its SVG is occluded; (3) RCA graft is occluded, but the native artery is stented and patent.

In order to identify the original target of a totally occluded SVG, see which view is orthogonal to the ostium/stump. *If the **LAO** view is orthogonal to the ostium, it is a **right**-sided graft; if the **RAO** view is orthogonal to it, it is a **left**-sided graft* (Figure 35.41). If multiple SVGs are occluded, confirm that you are engaging different ones by referencing to the sternal wires in a straight view (RAO or LAO).

Some grafts connect to 2 or more distal targets (Figure 35.42). A *sequential graft* (or jump graft) connects to one branch, e.g., OM1, in a side-to-side anastomosis, then continues and connects to another branch, e.g., OM2, in an end-to-side anastomosis. A *split graft*



(a) (b)

Figure 35.41 **(a)** Occluded SVG to ***RCA*** on ***LAO*** view (catheter at the left of the spine). In this case, the surgeon had placed rings around the venous grafts' origins to allow identification during angiography: the bottom ring is SVG to RCA, followed up by SVG to diagonal, then SVG to OM (highest). **(b)** SVG to a ***left*** coronary branch on ***RAO*** view (catheter tip at the *right* of the spine, ribs are looking down toward the *right*).

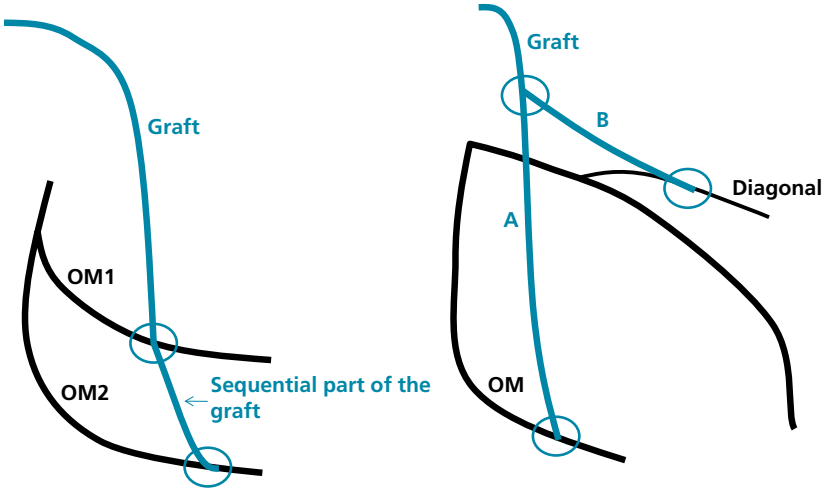


Figure 35.42 Sequential and split grafts (RAO caudal view). Graft anastomoses are circled.

(or Y graft) consists of 2 grafts, A and B, with a common stem: graft A connects to one branch, e.g., OM1, and graft B comes off graft A and separately connects to another branch, e.g., diagonal. Sequential and jump grafts reduce the number of aortic anastomoses and may, in selective cases, have a lower likelihood of failure as a result of the higher flow across the graft.

X. LIMA-to-LAD or LIMA-to-diagonal views

Three views should be obtained in case of LIMA graft:

- The LIMA ostium and body are assessed in a straight view, typically the view used to engage the LIMA (e.g., RAO straight or AP view).
- The native LAD is assessed in a view that is good for the LAD, such as AP cranial or LAO cranial view.
- The LIMA-to-LAD anastomosis is best assessed on a 90° lateral view, a view that is routinely obtained in LIMA cases (Figure 35.43). It requires that the arms be raised up away from the chest. Alternatively, in transradial cases, RAO straight or LAO caudal view may prove helpful.

Furthermore, when redo CABG or heart surgery is contemplated in a patient with a previously placed LIMA graft, the left lateral view is very important in planning surgery as it shows how close the LIMA is to the sternum. In addition, a straight AP view will be useful to assess how far the LIMA is from the midline.

XI. Left ventriculography

A. RAO, LAO, and LAO cranial views

The RAO view allows the assessment of the anterior, apical, and inferior walls, whereas the LAO view allows the visualization of the septal, posterolateral, and apical walls (Figure 35.44). The LAO cranial view is preferred to the straight LAO view; in fact, the straight LAO view foreshortens the lateral wall and septal wall and overlaps the septal wall with the anterior wall, whereas the LAO cranial, by being orthogonal rather than aligned with the heart, opens up the septal and lateral walls, as well as the base (LVOT) and the LA (Figures 35.45–35.47).

The standard views are RAO (30°), LAO (40–60°), and LAO cranial (40–60° LAO, 20–25° cranial). The standard injection is 7–8 ml/s for a total of 20–24 ml (an enlarged LV may require a larger volume). ***The pigtail catheter should be positioned in the mid-cavity, midway between the base and the apex, and should be free-moving.*** A position too close to the apex induces ventricular ectopy,

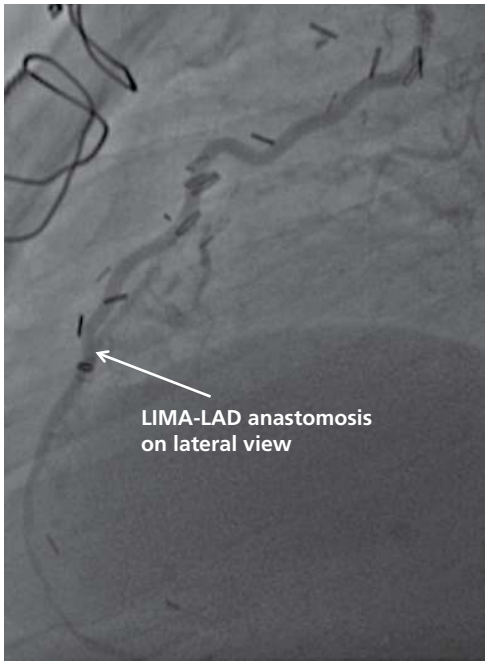

Figure 35.43 Left lateral view showing the LIMA-to-LAD anastomosis.

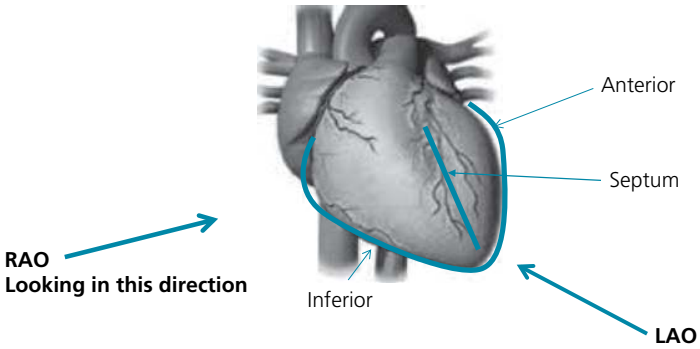

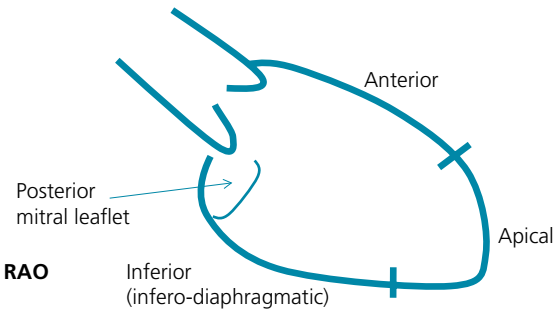

Figure 35.44 Top figure: Illustration of how the RAO and LAO views "look" at the heart. **Lower figure:** RAO view. The left ventriculogram being a 2-dimensional luminogram, the anterior wall and the apex are seen, but the septum and the posterolateral wall are not seen.

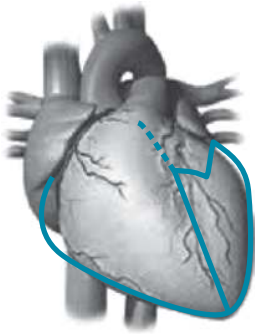

LAO cranial view looks in this direction. LV walls are well displayed with septal (rather than anterior), apical, and lateral walls, in addition to the LVOT and LA posteriorly. **Without the cranial angulation, the walls are foreshortened and overlapped, and the LA is hidden behind the LV.**

LAO straight view (foreshortens LV walls)

Figure 35.45 LAO straight vs. LAO cranial view. LAO cranial better opens the LV walls without foreshortening.

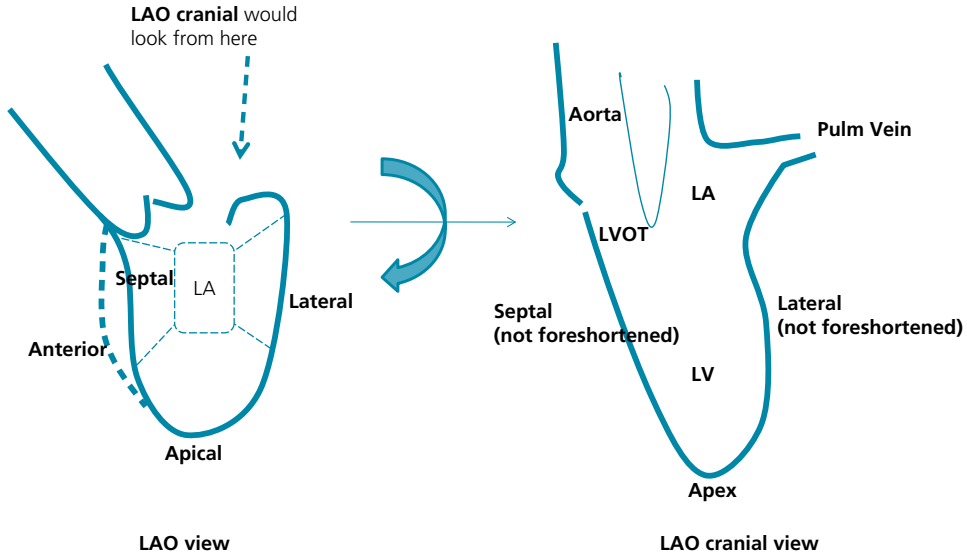

Figure 35.46 Left ventriculogram on **LAO straight view vs. LAO cranial view**.

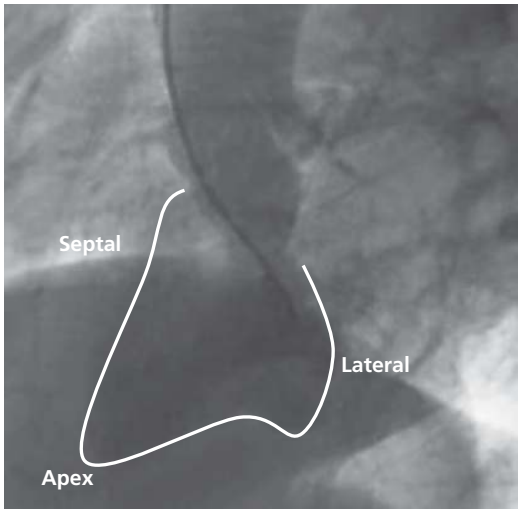

Figure 35.47 Left ventriculogram performed in LAO straight view.

while a position too close to the LVOT/aorta does not fill the LV appropriately. A position too close to the base/mitral valve, particularly when the catheter feels "stuck" and not freely moving, often implies catheter impingement somewhere in the mitral apparatus (e.g., chordae). This may induce and overestimate mitral regurgitation; it may also lead to myocardial stain wherein the whole volume is injected over the impinged area, with a risk of LV perforation. In the latter situation, the catheter should be pulled out and repositioned before injection. *A pigtail multihole catheter is used rather than an end-hole catheter*, to avoid the risk of myocardial stain.

If LVEDP or PCWP >25 mmHg, ventriculography is avoided or only performed after giving nitroglycerin, using a small contrast volume.

Typically, one RAO view is performed. An LAO cranial view is additionally or alternatively performed when either of the following is suspected: (1) posterolateral MI; (2) VSD; (3) MR; (4) LVOT obstruction (e.g., HOCM, goose-neck deformity of the LVOT in primum ASD).

B. Mitral valve

The 2 leaflets of the mitral valve are shown in Figure 35.48. While one may get the impression of 2 leaflets on the RAO view, this often shows only the posterior leaflet, which engulfs the anterior leaflet by virtue of its crescentic shape.

C. Assessment of mitral regurgitation

When the severity of a regurgitation on echo-Doppler is unclear or not consistent with the clinical presentation, invasive assessment is justified. Left ventriculography and aortography are the most accurate invasive methods of mitral and aortic regurgitation assessment, respectively. In order to appropriately assess mitral regurgitation:

1. Use a 6 Fr pigtail catheter (rather than 4 Fr)
2. Inject a large bolus of contrast per second and sustain it for 4 seconds, to allow a steady-state contrast opacification of the LV and LA (e.g., 12 ml/s for a total of 48 ml). In severe MR, the large LA requires a large amount of contrast to be adequately filled and outlined
3. Ectopy should be avoided or minimized

4. The catheter should be in the mid-cavity (LVOT placement reduces LV and LA filling)
5. Use a view that allows full visualization of the LA. In the standard 30° RAO, the LA overlaps with the descending aorta behind it, which blurs how strongly and fully the LA is opacified (Figure 35.49). Hence it is important to go steeper on the RAO angulation (45–60° RAO) to provide a clear area between the mitral valve and the aorta (Figure 35.50). Alternatively, the LAO cranial view may be used.

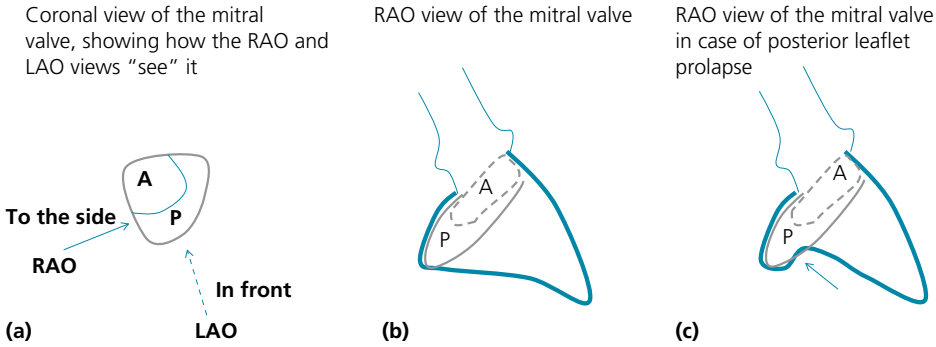

Figure 35.48 **(a)** Illustration of how the RAO and LAO views look at the mitral valve. RAO looks at the mitral valve from the side (right heart side), while LAO looks from in front. **(b)** Illustration of how the mitral valve is seen on the RAO view (in gray). The anterior leaflet is not often seen on the RAO view, as it is engulfed within the crescent-shaped posterior leaflet. **(c)** In posterior prolapse, the mitral valve bulges at the base of the LV (*arrow*).

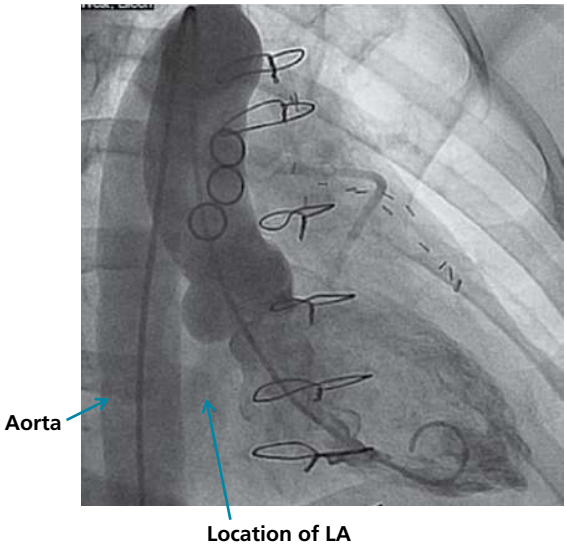

Figure 35.49 RAO view of the LV. Look how the aorta overlaps with the LA. Go steeper RAO to separate the aorta from the LA.

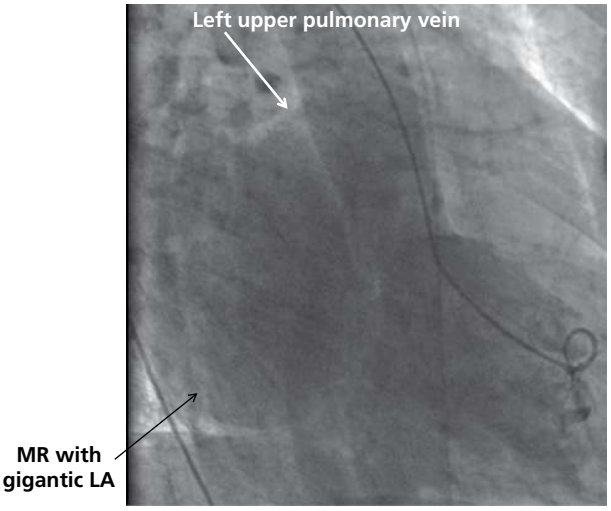

Figure 35.50 Steep RAO view shows severe MR with full delineation of the LA, which opacifies at least as much as the LV. Contrast spills back into the pulmonary vein. Thus, MR is graded 4+. LA is aneurysmal and approximates LV size.

To grade mitral regurgitation, the extent of LA opacification is compared to the LV opacification during the period of maximal LV filling:

1+ (mild MR): a small puff of regurgitant contrast is seen in the LA but does not fully opacify the LA.
2+ (moderate MR): LA is fully opacified, but faintly (LA < LV).
3+ (severe MR): LA is fully opacified and is as well opacified as the LV (LA = LV).
4+ (very severe MR): LA fills ~ as densely as the LV on the first beat and ends up with greater density than the LV (LA > LV), and/or contrast is seen refluxing in the pulmonary veins. In grades 3+ and 4+, LA is enlarged.

When LA is so large, larger than the LV, it is difficult to opacify the LA as much as the LV even when 50% of the flow is regurgitant; thus, 3+ severe MR may appear 2+.

Mitral regurgitation may also be graded using the *angiographic regurgitant fraction*. After calibration of fluoroscopic dimensions using the diameter of the pigtail loop, the LV end-diastolic and end-systolic volumes are derived from measurement of the end-diastolic and end-systolic areas. The difference between the 2 is the *total stroke volume*. Only part of this volume, the *forward stroke volume*, eventually reaches the systemic circulation and is measured using thermodilution cardiac output. The regurgitant fraction is equal to: *(total stroke volume – forward stroke volume)/total stroke volume* (>50% is severe).

XII. Aortography for assessment of aortic insufficiency

Aortography is best performed in the LAO view. This view is orthogonal to the aortic arch and opens the aortic arch without foreshortening and without overlap of the ascending and descending aorta. This allows assessment of the aorta along with AI, aortic dilatation being one of the most common causes or accompaniments of AI. It is an excellent modality of AI assessment in questionable cases. Echo frequently underestimates the severity of eccentric AI, wherein the color abuts the mitral valve or the septum and quickly abates. Color Doppler correlates with velocity as much as volume, whereas aortography demonstrates AI volume.

Aortography is performed using a 6 Fr pigtail catheter, with a large injection of 20 ml/s for 50–60 ml. The large per-second volume of 20 ml is necessary to fill the large aorta.

AI is graded similarly to MR:

1+ Small puff of regurgitant contrast is seen in the LV but does not fully opacify it.
2+ LV fills fully but is less opacified than the aorta.
3+ LV fills fully and is as opacified as the aorta.
4+ LV fills ~ as densely as the aorta on the first beat and ends up with greater density than the aorta. LV is enlarged in grades 3+ and 4+.

XIII. Coronary anomalies

Coronary artery anomalies occur in 0.3–0.9% of individuals without structural heart defects, and in 3–36% of those with structural heart defects. Among all patients undergoing coronary angiography, the most common coronary anomalies are the following:

1. Separate ostia of the LAD and LCx (0.41%).
2. Origin of the LCx from the RCA or the right sinus of Valsalva (LM only gives LAD and looks unusually long in this case) (0.37%).
3. Anterior and unusually high origin of the RCA (higher than the sinus of Valsalva) (0.18%).
4. RCA originating from the left sinus of Valsalva (0.13%).
5. Left main originating from the right sinus of Valsalva (from the RCA or from a separate ostium) (0.02%).
6. Less common anomalies: coronary artery fistula (to RV, RA, or PA usually) (0.1–0.2%); anomalous coronary artery originating from the PA.

The 3 most common anomalies are benign and are not, per se, associated with any hemodynamic effect. In the case of anomalous LCx origin, the LCx always courses posterior to the aorta, hence the benign nature of this anomaly.

An anomalous LCx origin is suspected when the first left angiographic view shows an unusually long LM, this long LM being in fact the LAD, as the LCx is missing.

A. Anomalous LM or RCA origin and course

To understand the anomalous course, note that the PA is normally anterior, leftward, and superior to the aortic origin. In the case of anomalous LM or RCA originating from the opposite sinus, the anomalous artery may follow one of the following 4 courses (Figure 35.51): (1) anterior to the PA; (2) posterior to the aorta; (3) subpulmonic, also called septal (the anomalous coronary artery dives in the septum beneath the RVOT then re-emerges more distally); (4) interarterial. The interarterial course is the one most associated with myocardial ischemia during exercise, with a subsequent risk of VT/VF and sudden cardiac death during exercise. "Squeezing" of the coronary artery between the aorta and PA is often offered as a simplistic, yet inaccurate, explanation. When the course is interarterial, the anomalous coronary artery has a sharply angled, oblique origin, sharper than seen in the other anomalies. This sharp origin creates a slit-like ostium (fish mouth) that gets stretched when the aorta distends during exercise, and thus it further narrows and leads to exertional ischemia. In addition, this anomalous origin is prone to torsion, or kinking, or a long intramural course through the aortic wall. The interarterial course is the most common course of anomalous LM and even more so anomalous RCA (>75%). The other 3 anomalous courses have been associated with sudden death less frequently, mainly in the presence of a slit-like orifice, intramural course, or acute angle.

In order to define the anomalous course, **left ventriculography or aortography should be performed in an *RAO view***, and **the anomalous coronary is spotted as a "dot" or an "eye" around the aorta** (the eye is a loop anterior to the aorta) (Figures 35.52, 35.53). It is most important to remember that an ***anterior dot implies interarterial course***, whereas a posterior dot (retroaortic course) or an eye/loop (subpulmonic or anterior course) are benign. These rules also apply to the anomalous RCA originating from the left sinus and to the anomalous LAD originating from the right sinus. CT or MRI is used to confirm those findings (class I).

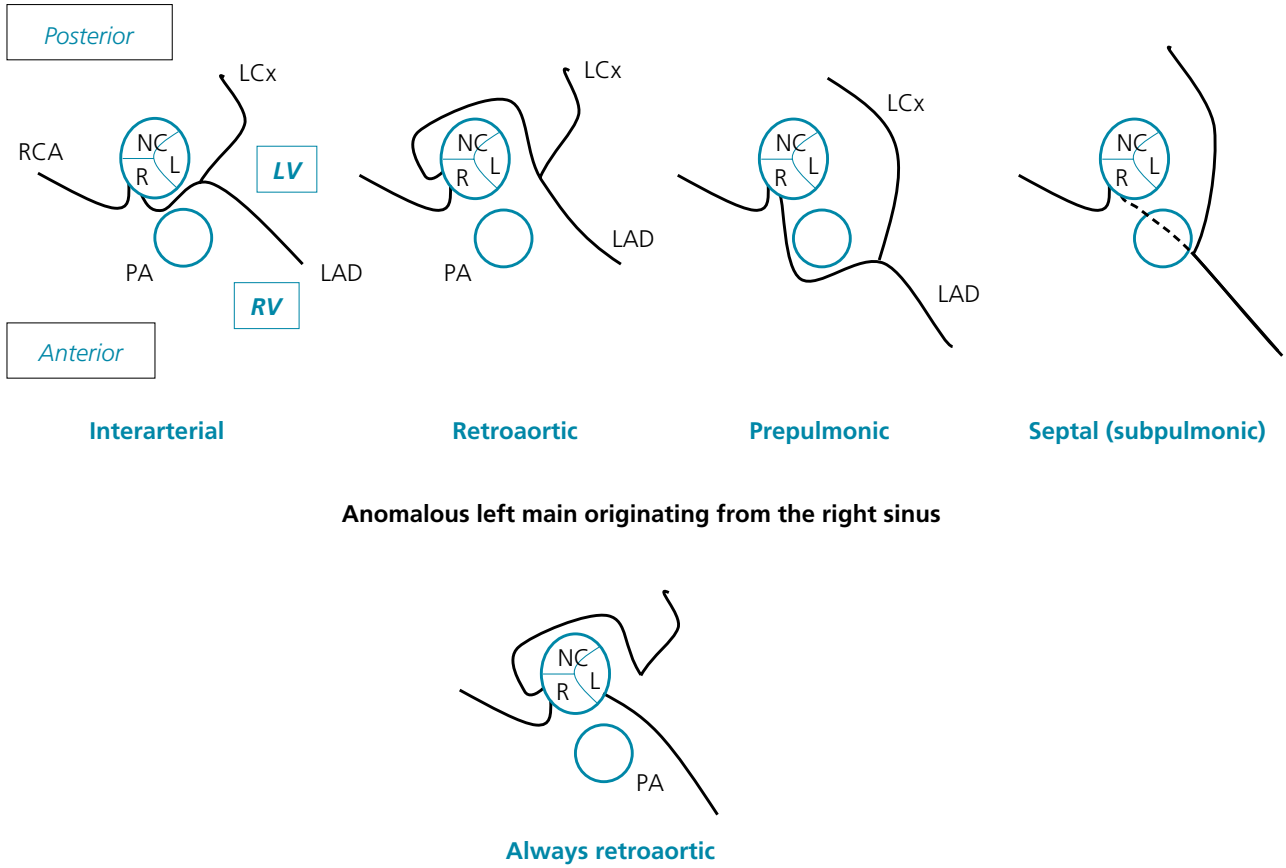

Figure 35.51 Axial cuts across the aortic cusps and the PA, showing the course of anomalous left main artery and anomalous left circumflex artery originating from the right sinus.

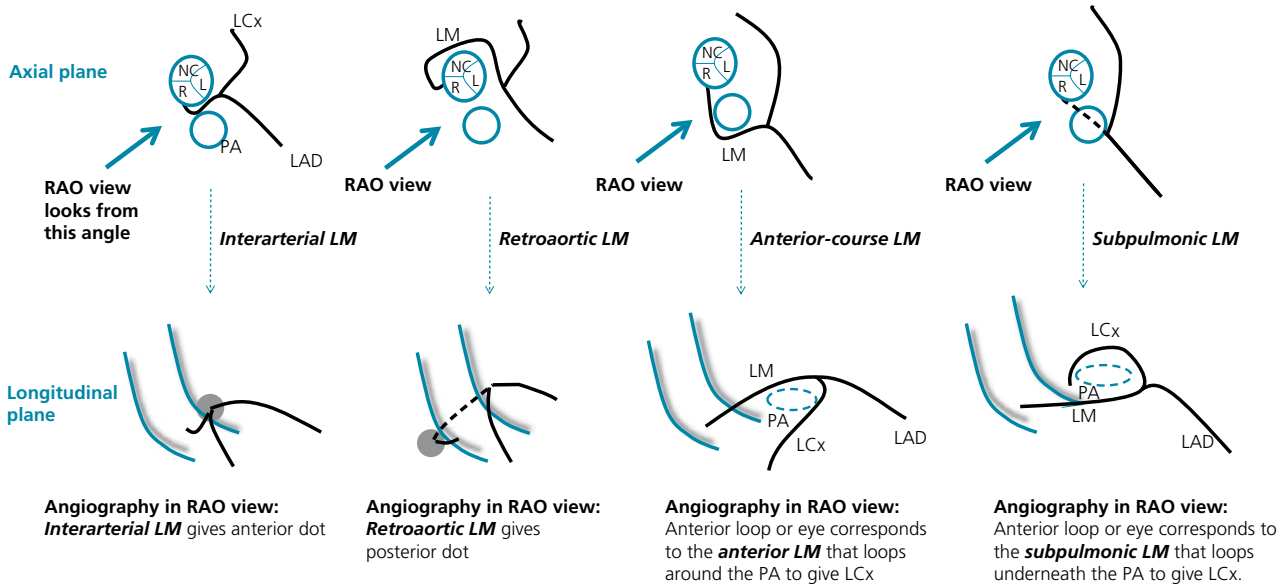

Figure 35.52 Anomalous origin of LM as visualized on RAO aortography. Always think of the coronary anatomy in the axial plane and imagine how the anomalous coronary artery projects on the RAO angle (dot vs. loop/eye). The eye of an anterior-course LM is formed by the upward loop of the LM and the downward loop of the LCx. The eye of a subpulmonic LM is formed by the downward loop of the LM and the upward loop of the LCx.

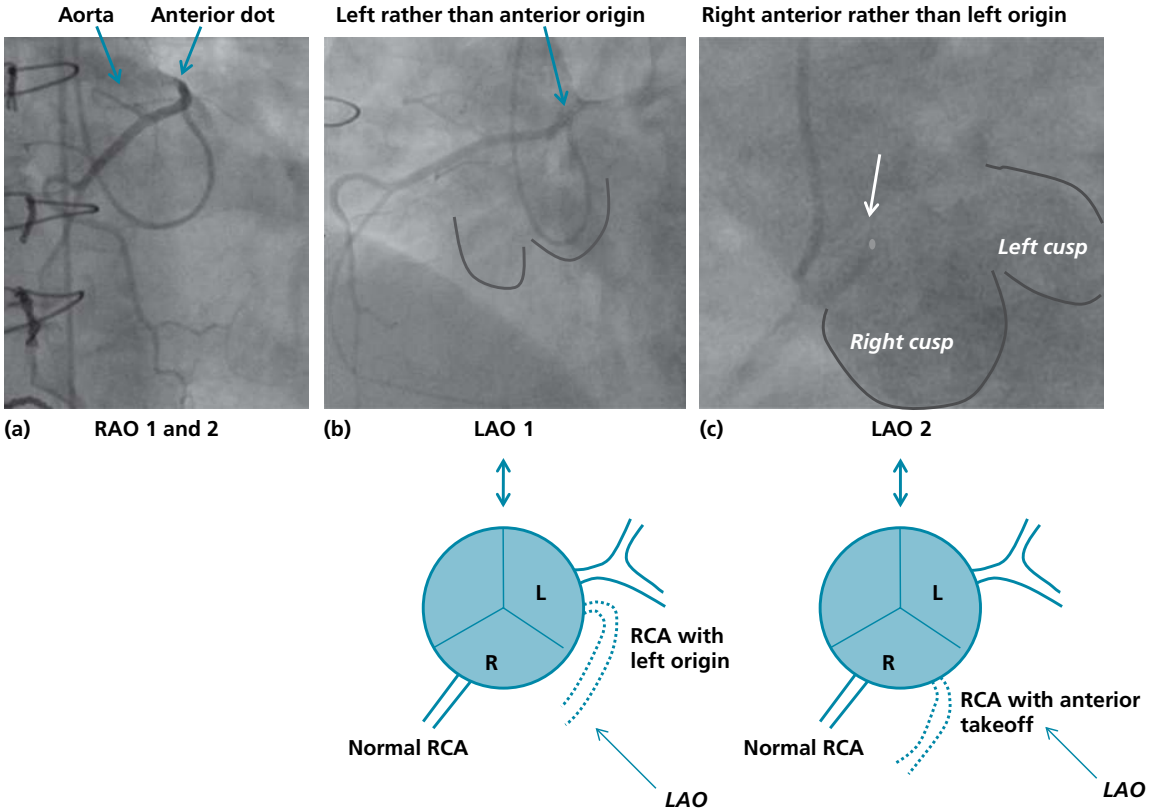

Figure 35.53 Anomalous RCA engaged with AL1. Two cases (1 and 2) are presented.

(a) *RAO view of both cases 1 and 2.* An anterior dot is seen, suggesting the possibility of an anomalous left RCA origin with interarterial course. However, in the particular case of RCA, this anterior dot (takeoff) does not necessarily imply an anomalous RCA origin and is, in fact, more commonly seen with a normal, anteriorly-displaced RCA origin. Before presuming that the RCA originates from the left cusp, ensure it is not just an anterior-origin RCA by imaging the cusps in a non-selective LAO 40° views; LAO splays out the left and right cusps and distinguishes a left origin from a right anterior origin.

(b) *On LAO of case 1*, the RCA is seen originating from the left cusp and the LM is seen filling next to it, implying a left-originating RCA rather than a right anterior RCA.

(c) *On LAO of case 2*, the RCA is seen originating from the anterior surface of the right cusp (*arrow*) rather than the left cusp, implying a right anterior RCA.

In the particular case of the RCA, a left RCA origin should be distinguished from the benign anterior RCA origin (Figure 35.53).

The sudden death or the exertional symptoms of chest pain or syncope typically manifest before the age of 25, if ever. The risk of sudden cardiac death with anomalous LM is unclear. In autopsy series, 27–80% of patients with anomalous interarterial LM had died suddenly, and up to 30% of patients with anomalous RCA had died suddenly. However, this does not represent the absolute risk of sudden death from an anomalous coronary artery; rather, it is the relative frequency of sudden death among patients with anomalous coronary artery who happened to have an unexplained death and receive an autopsy (selection bias). Stress testing is insensitive for the diagnosis of ischemia or prediction of sudden death related to an anomalous coronary artery and should not be used for risk-stratifying an anomalous LM. Surgery is indicated in patients with: (i) anomalous LM and high-risk anatomical features, regardless of symptoms or stress testing; or (ii) anomalous interarterial RCA with true exertional angina, or truly abnormal exercise stress test (not vasodilator test) (Table 35.1). ACC guidelines emphasize the long intramural course or the slit-like orifice as surgical indications rather than the classic interarterial course, but they do correlate. Also, younger age <35 is a strong incentive for surgical correction. Surgery typically consists of unroofing the coronary intramural course and relocation. Bypass surgery to the anomalous artery, preferably using a mammary graft, may be performed; since the artery is only obstructed

Table 35.1 Indications for surgical repair of an anomalous coronary origin.

True exertional angina, or truly abnormal exercise stress test (not vasodilator test), or VT:
Yes

Asymptomatic with no ischemia, but interarterial course or other high-risk features (slit-like, acute angle, intramural):
- Left main: yes (IIa)
- RCA: possibly (IIb) if <35. Surgery is rather reserved for true exertional angina, or a truly abnormal exercise stress test.

Asymptomatic with no ischemia, and no interarterial or other high-risk features:
- Left main: possibly? (IIb)
- RCA: no

during exercise, the mammary graft may not mature, hence ligation of the native artery is usually performed, the flow becoming totally dependent on the mammary graft.

B. Coronary artery fistula

A coronary artery fistula is a communication between a coronary artery and a cardiac chamber (*coronary cameral fistula*) or a vascular structure such as the PA or the coronary sinus (*coronary arteriovenous fistula*). Approximately 60% of these fistulas arise from the RCA, 30–40% from the LAD, and 5% involve both coronary arteries. They terminate most commonly on the right side of the heart (most frequently **RV** [41%], then RA and PA); only 3% terminate in the LV. ***LAO view*** looks at the septum and differentiates a left-sided vs. right-sided termination; ***RAO view*** looks at the AV groove and differentiates RV termination (anterior to the AV groove), RA termination (posterior to the AV groove), and PA termination (Figure 35.44).

Acquired fistula may be seen after a penetrating trauma, PCI, RV biopsy, or cardiac surgery. The origin and course of fistulas are delineated by coronary angiography, CT, or MRI. Congenital coronary fistulas are often small and benign; they are often diagnosed in adulthood as a result of a murmur, which is typically continuous but sometimes only heard in systole. However, a fistula is considered large if it has any of 3 major untoward consequences: (1) significant left-to-right shunting with O_2 step-up, pulmonary hypertension, and both right-sided enlargement (fistula to RA) and right- and left-sided enlargement (fistula to RV); (2) coronary steal, i.e., reduction in blood flow distal to the site of fistulization with myocardial ischemia (exertional angina, ischemia on stress test); (3) the proximal segment of the coronary artery attempts to compensate for the steal and undergoes progressive aneurysmal dilatation; atherosclerosis, thrombosis, and endarteritis may develop. By catheterization, (1) and (3) are the 2 features defining large fistula. Small fistulas have an excellent prognosis and ~23% close spontaneously. Fistula-related complications are present in 11% of patients younger than 20 years and 35% of patients older than 20 years. Many fistulas progressively enlarge over time and insidiously lead to symptoms at a later age.

Some fistulas are simple and consist of a single origin and a single track, whereas others are complex (multiple origins, distal coronary continuation in a cavity with no separate origin, or plexiform network). A large fistula should be closed: (i) any fistula with hemodynamic effect; or (ii) a fistula track that is 2× the caliber of the distal vessel in the case of a single fistula track. Surgical closure consists of ligating its origin or track, or, in case of multiple tracks, patching the distal termination from inside the cavity. Percutaneous closure is possible when a single large communication is identified (oversized coil embolization).

C. Anomalous coronary artery originating from the pulmonary artery

In this case, a coronary artery originates from the PA. This is different from coronary-to-PA fistula, wherein the coronary artery originates normally but communicates with the PA. A coronary artery originating from the PA is one of the most serious coronary anomalies and often leads to death in infancy if untreated, particularly since the coronary artery involved is often the left coronary artery. *The main issue is the low pressure in the main PA, which is more dreadful than its low oxygenation.* The low PA pressure explains why the flow in the aberrant coronary artery is directed retrogradely toward the pulmonary artery and is derived via anastomotic vessels from the contralateral, normally arising coronary artery. Severe myocardial ischemia is therefore present. The few patients who are diagnosed in adulthood have an RCA originating from the PA, or a left coronary artery arising from the PA with a relatively small left coronary system and abundant right-to-left collaterals.

D. Dilated Thebesian veins

In some patients, the left and/or right coronary artery seem to provide microfistulae draining into the LV. However, those are often dilated Thebesian veins rather than true fistulae. In fact, **the LV myocardial WALL and LV myocardial boundaries are delineated by a BLUSH or stain before the cavity is seen**, which indicates that those are not direct coronary-to-LV fistulae and are rather dilated myocardial veins (Figure 35.54).

Blood drains from the myocardial capillaries into the major coronary venous system, which eventually ends into the coronary sinus. But

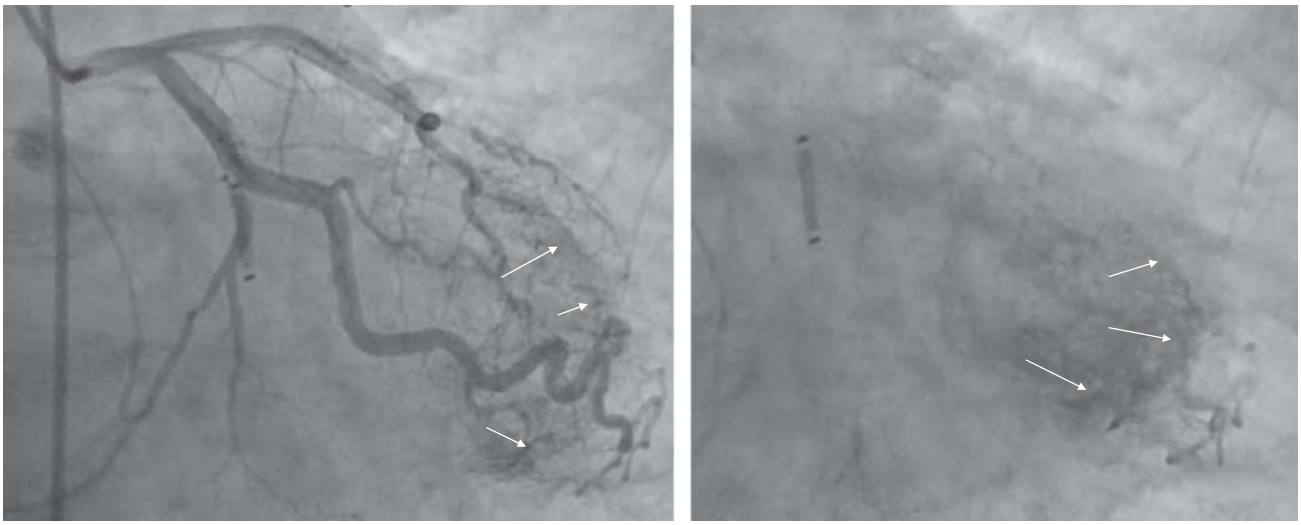

Figure 35.54 Dilated Thebesian veins (*arrows*) causing myocardial blush, then draining into the LV cavity. The blush of the LV boundary is more pronounced than the filling of the LV cavity. This is an RAO view; to differentiate LV vs. RV drainage, LAO view is necessary.

there is a smaller venous system, the Thebesian vein system, where the veins drain directly into a cardiac cavity, on the right or left, atrium or ventricle. When those veins are dilated, the appearance of Figure 35.54 is seen; this dilatation is more often seen in the LV. This is not a traditional coronary-cameral fistula, as the artery does not communicate directly with the cavity. The artery feeds the myocardium, which therefore does not get ischemic; then, it is the venous blood that drains into the cavity. That is why dilated Thebesian veins are not hemodynamically significant. The proof of hemodynamic insignificance is 2-fold: (i) the upstream coronary artery is not usually significantly dilated, contrary to what would happen in a truly severe fistula; (ii) LV is not dilated: if a coronary to LV fistula is significant, there would be left-to-left shunting, and, consequently, LV dilatation that is otherwise unexplained.

XIV. Lower extremity angiography

A. Anatomical tips (see Figures 35.55–35.57)

B. Technical tips

Angiography of the abdominal aorta is performed using a 4–5 Fr multihole pigtail catheter or pigtail-like catheter (e.g., OmniFlush). The catheter is positioned at the level of L1, which coincides with the level of the renal arteries. Angiography is obtained using a 10–12 ml/s injection for a total of 20–24 ml (4 Fr OmniFlush catheter allows the injection of this volume).

If bilateral iliofemoral runoff is performed using a bolus-chase technique, the contrast dose is 7–8 ml/s for 60–70 ml. The bolus fills the patient's aorta and iliac arteries, and the use of 7 ml vs. 8 ml depends on the size of these vessels. The duration of the injection depends on the patient's height; less than a 10-second injection may be done in small patients.

Alternatively, one may selectively engage a contralateral iliac artery using the OmniFlush or IMA catheter with the help of a slippery wire (Glidewire): (1) from a right femoral access, the OmniFlush catheter is torqued toward the left iliac, (2) the Glidewire is then advanced beyond the OmniFlush catheter tip, then torqued and advanced into the left iliac, (3) the catheter and wire are then slightly pulled until the catheter perfectly embraces the aortoiliac bifurcation; the catheter is then advanced over the wire more distally (Figure 35.58). For selective unilateral iliofemoral runoff, the contrast dose is 5 ml/s for a total of 30 ml (alternatively, as low as 4 ml/s for 20 ml may be used in short patients with small arteries). *The per-second dose is adjusted according to the diameter of the vessels (a large vessel needs a large bolus to fill it); the total duration, and thus the total dose, is adjusted according to the height of the patient.*

C. Angiographic tips

The runoffs are typically performed in AP view. In *iliac* imaging, a *contralateral* view is helpful in opening up the bifurcation of the common iliac artery into the external and internal iliac arteries and removing any overlap (20° contralateral oblique ± 20° caudal). In *femoral* imaging, a 30° *ipsilateral* view is helpful in opening up the common femoral bifurcation and identifying the ostium of the SFA; the SFA is more anterior and medial than the profunda and directed away from the femur. A more oblique view may help open the femoral bifurcation when the profunda is overlapped with the SFA on a shallow oblique view.

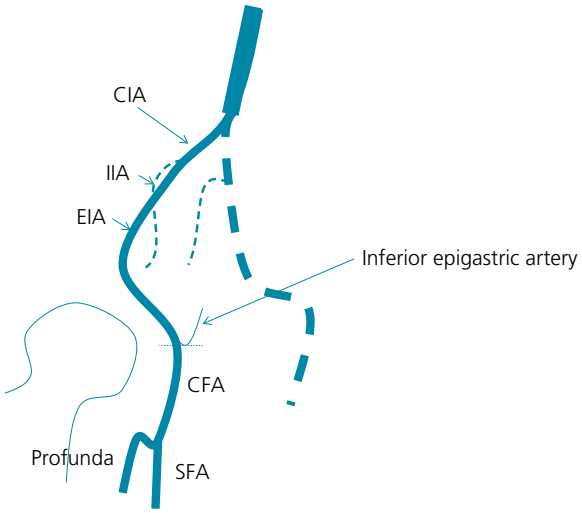

Figure 35.55 Right oblique view of the aorta, iliac, and femoral arteries. Note how the iliac arteries dive posteriorly, then emerge and become superficial at the level of the inguinal ligament to form the CFA over the head of the femur. The lower loop of the inferior epigastric artery corresponds to the inguinal ligament, and thus defines the point where the deep external iliac artery emerges to the surface and becomes the CFA. A femoral stick above the loop of the inferior epigastric artery is a deep stick in the pelvic area, at a level where the artery cannot be appropriately compressed for hemostasis and where bleeding can seep through loose, non-concealing pelvic tissue.

The internal iliac artery gives gluteal branches to the thigh and deep pelvic branches, and may receive collaterals from the inferior mesenteric artery and the median sacral artery in case of common iliac occlusion. The CFA gives the *profunda femoris*, which sharply dives posteriorly and laterally in the thigh *close to the femur*, and the *SFA, which continues anteriorly and medially, away from the femur,* and is almost as anterior as the CFA early on. The CFA and profunda give circumflex branches to the hip, and the profunda gives perforating branches to the thigh throughout its course. The SFA only gives distal geniculate branches to the knee area. CFA, common femoral artery; CIA, common iliac artery; EIA, external iliac artery; IIA, internal iliac artery; SFA, superficial femoral artery.

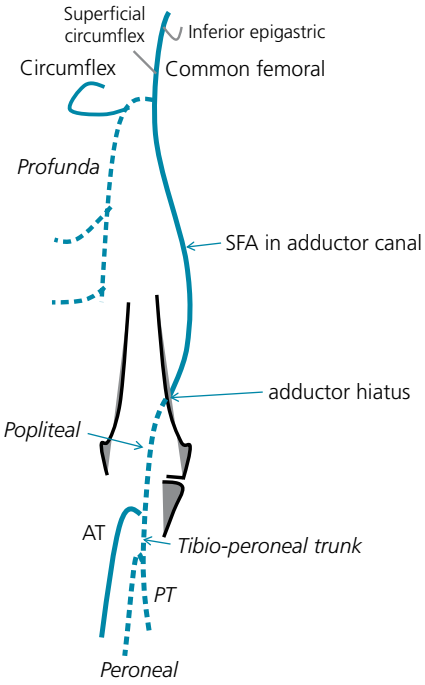

Figure 35.56 Femoropopliteal anatomy. A right lower extremity is shown. *Dashed arteries* are posterior arteries. SFA runs in the *adductor canal*, between the sartorius muscle anteriorly and the adductor muscles posteriorly. It dives posteriorly into the popliteal fossa behind the femur at the level of the *adductor hiatus*, which, in terms of fluoroscopic bony landmarks, coincides with the point at which the SFA intersects with the femur in an AP view. *SFA becomes popliteal artery at this adductor hiatus level*. Thus the popliteal artery starts much higher than the knee joint space (*dashed artery)*. The popliteal artery is a posterior artery; below the knee, it gives the anterior tibial (AT) artery then continues straight in the posterior leg compartment as the tibioperoneal trunk. The AT artery is an anterior branch that emerges anteriorly by bending below the fibula head (AT genu), lies deep in the anterior leg compartment over the interosseous membrane (deeper than the anterior tibial muscle), supplies the anterior leg compartment, then emerges superficially as the dorsalis pedis artery and the lateral tarsal artery at the foot level. The tibioperoneal trunk gives rise to the posterior tibial (PT) artery and the peroneal artery, both of which supply the posterior compartment of the leg. The peroneal artery ends at the lateral malleolus and communicates with the AT through the anterior perforating branch; the PT runs to the medial malleolus and continues to the plantar foot.

Laterally to medially, the infrapopliteal vessels encountered are: AT, peroneal, then PT (distally, the peroneal becomes more lateral than the AT).

There are several anatomical variants. Some patients have a trifurcation of AT, PT, and peroneal artery (as opposed to 2 bifurcations). Other patients have a very high takeoff of the AT close to the knee joint.

In ~8% of patients, the AT ends early and the peroneal artery provides the dosalis pedis artery through an anterior perforating branch. In another small proportion of patients, there is no anatomical large dorsalis pedis artery at the level of the foot; the AT ramifies early on and ends as a lateral tarsal artery that supplies the foot.

Note about the femoral vein: in contrast to the groin/CFA level, where the vein is medial to the artery, the femoral vein quickly crosses under and becomes lateral to the SFA and to the popliteal artery, up until the mid-popliteal level at the knee joint level, where the vein becomes posterior to the popliteal artery. Thus, when attempting retrograde popliteal arterial access, the needle should be positioned 3–4 cm above the knee joint to enter the artery 6–7 cm above the knee joint, where the artery and vein are not overlapped.

Below the knee, every infrapopliteal artery is surrounded by two veins.

When the common iliac artery is occluded, collaterals develop through the contralateral internal iliac artery, the inferior mesenteric artery (which anastomoses with the internal iliac artery), or the median sacral artery. *When the external iliac artery is occluded*, collaterals develop through the ipsilateral internal iliac artery but also the mammary artery (as it goes down from the chest and anastomoses with the inferior epigastric artery) (Figure 35.59). *When the SFA is occluded*, the profunda, which is rarely diseased, supplies collaterals to the popliteal artery through the geniculate branches and reconstitutes the SFA distally (Figures 35.60, 35.61).

Beware of confusing the profunda with the SFA in a case of ostial SFA occlusion. Unlike the SFA, the profunda provides branches at the thigh level. A medial profunda branch segment may still be mislabeled as proximal SFA when the true SFA is totally occluded; in this case, use a steep ipsilateral oblique view at the common femoral level to see whether this branch has a posterior course directed toward the femur (profunda), or an anterior course that curves away from the femur (SFA). A path too close to the femur on the AP or oblique view indicates that the artery is a profunda rather than SFA (Figures 35.62, 35.63).

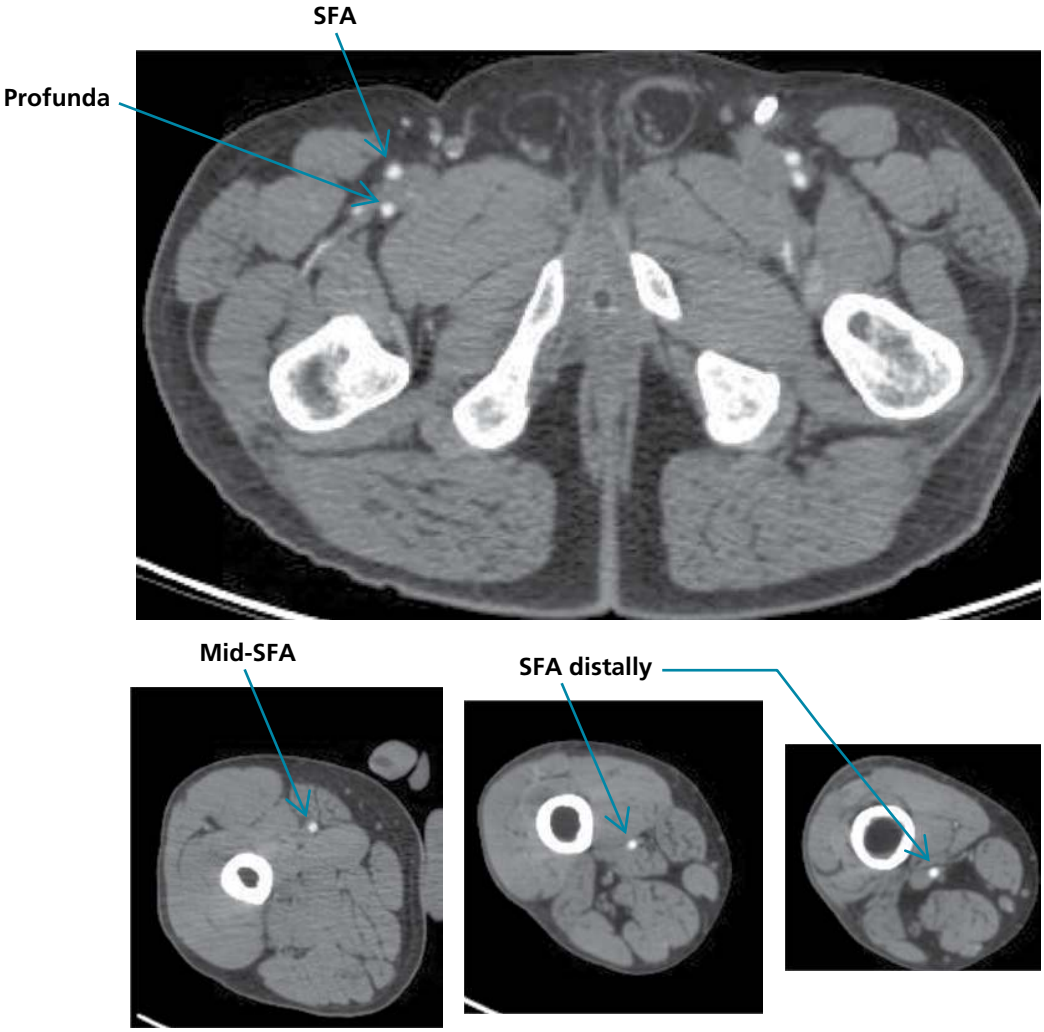

Figure 35.57 Axial CT scan images showing the SFA anatomy.
Top: note the anteroposterior relationship between SFA and profunda.
Bottom left: SFA in the adductor canal, anterior to the adductor muscles. It becomes progressively more posterior as it goes down the thigh.
Bottom right: SFA just proximal then distal to the adductor hiatus.

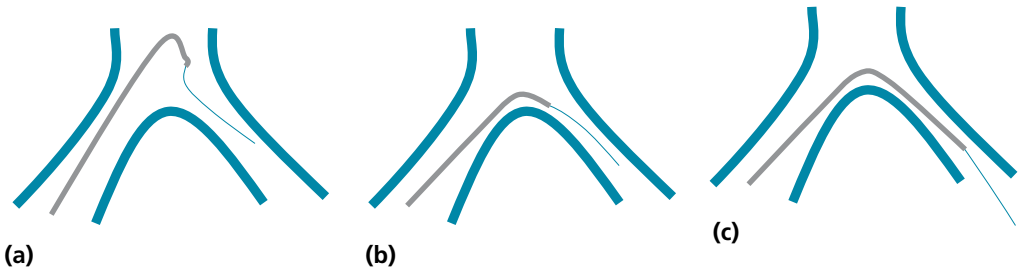

Figure 35.58 OmniFlush or IMA catheter used to selectively engage the left iliac/femoral artery through a right femoral access. **(a)** The left iliac is wired through a properly directed OmniFlush catheter, albeit not selectively engaged. A slippery wire (Glidewire) is used. **(b)** After the wire gains some distance into the left iliac, the whole system (catheter + wire) is pulled back to embrace the aortoiliac curvature, providing support for further wire and catheter advancement, as seen in **(c)**.

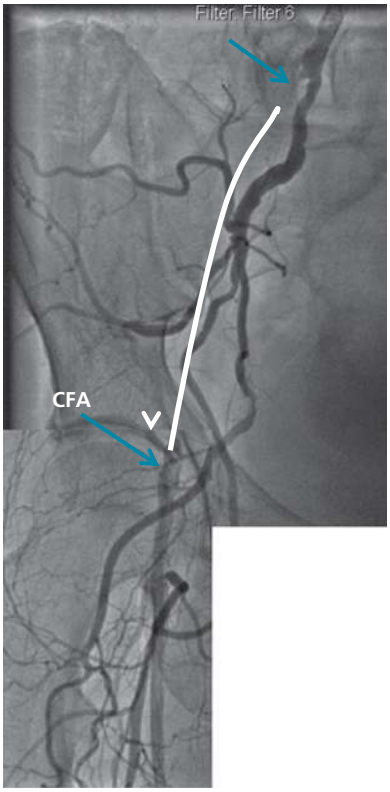

Figure 35.59 External iliac occlusion extending into the common femoral artery (CFA), with reconstitution from the internal iliac artery at the level of the CFA. **The reconstitution partly occurs through the *superficial circumflex artery*** (*arrowhead*), a lateral artery lower than the inferior epigastric artery. The *white line* indicates the path of the occlusion.

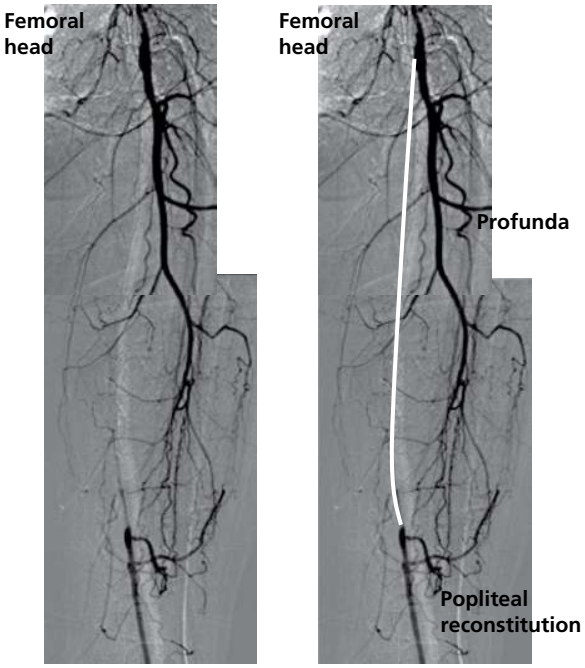

Figure 35.60 Totally occluded left SFA from the ostium to the popliteal level. It reconstitutes through profunda collaterals. The *right panel* shows the path of the occluded SFA (*white line*).

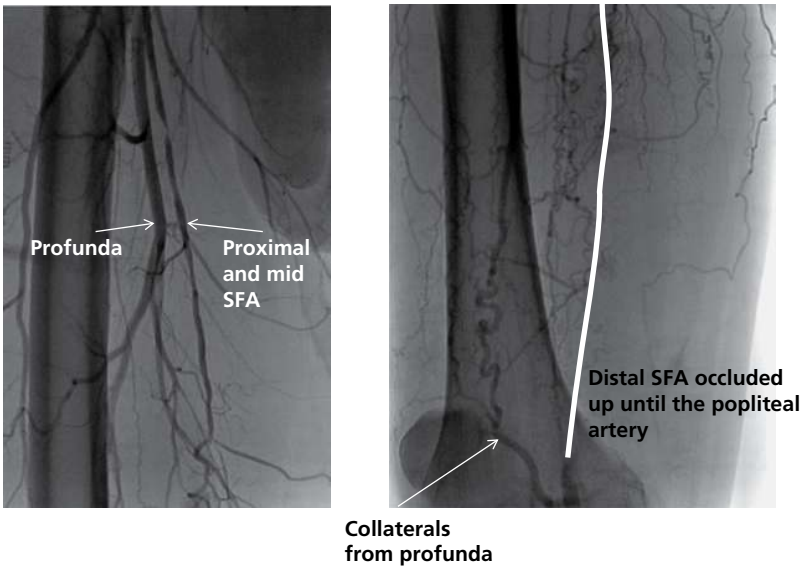

Figure 35.61 Totally occluded right distal SFA with collaterals mostly originating from the profunda; additionally, some bridging collaterals are seen.

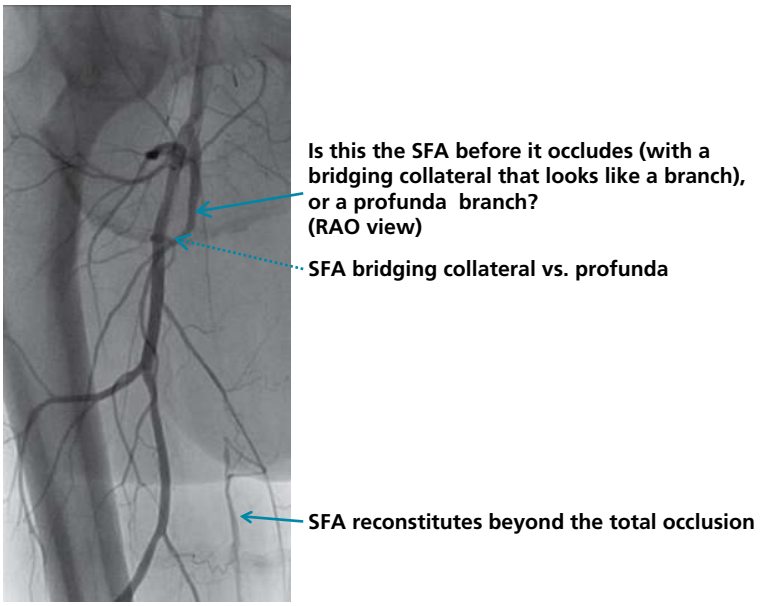

Figure 35.62 Differentiate SFA from profunda in the case of SFA occlusion.

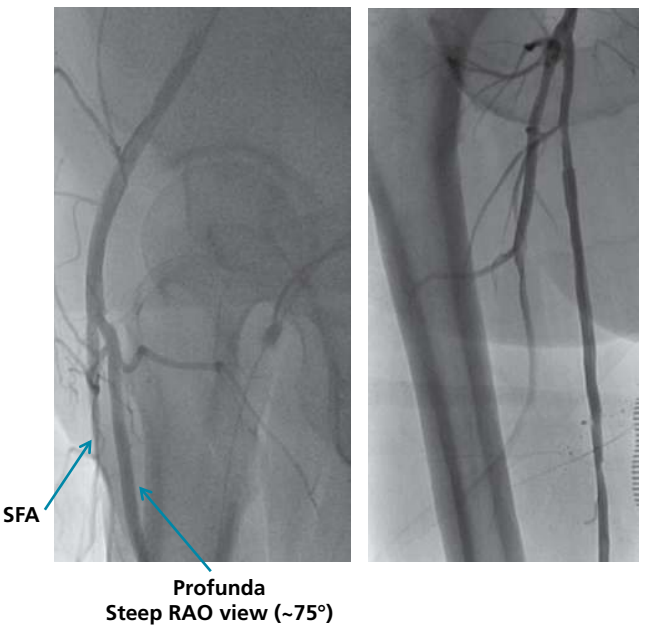

Figure 35.63 Same patient as Figure 35.62. An almost lateral view (*left panel*) shows that the branch in question is actually SFA not profunda, as it is anterior and directed away from the femur, whereas the profunda dives toward the femur. Successful revascularization of this SFA was performed (*right panel*).

In moderate iliac or common femoral disease, pressure gradients should be obtained across the stenosis. A significant pressure gradient is a peak-to-peak gradient > 20 mmHg at rest or with vasodilators (nitroglycerin). Pressure gradients may be obtained by catheter pullback; however, owing to respiratory fluctuations in arterial pressure, this method is often inadequate in assessing moderate instantaneous gradients; in addition, the catheter itself may create an obstruction and worsen the gradient, or a curved catheter may abut the arterial wall and falsely create a damped pressure past a stenosis. The best technique consists of advancing a 0.014″ coronary pressure wire through a catheter and positioning it distal to the lesion, followed by simultaneous pressure measurements distal to the lesion (pressure wire transducer) and proximal to the lesion (using any catheter ≥ 5 Fr or a long 4 Fr sheath advanced close to the lesion). Alternatively, simultaneous pressure measurements may be performed using a 6 Fr sheath positioned proximal to the lesion and a straight 4 Fr catheter (e.g., Glidecath) advanced beyond the lesion. Make sure both transducers are zeroed at the same level.

XV. Carotid angiography

A. Anatomical and technical tips

Aortic arch angiography is performed in the view that opens up the aortic arch, that is, the LAO view (20 ml/s for a total of 40 ml). The aortic arch is classified as type I–III, depending on how steep it is, i.e., depending on the distance between the peak of the aortic arch and the origin of the right innominate trunk (Figure 35.64).

A true *bovine arch* is characterized by a left common carotid artery that comes off the innominate artery at least a few millimeters beyond its origin, and is seen in 9% of the population. The left common carotid and innominate arteries may share a common bifurcating origin from the aortic arch; this is sometimes erroneously called bovine arch. While vertebral arteries usually originate from the subclavian arteries, the *left vertebral artery originates from the aortic arch in 5% of patients.* The aortic arch angiogram defines the arch's anatomy and any disease in the proximal portions of the 4 major vessels.

In aortic arch types I, II, and sometimes III, a JR4 catheter may be used to selectively engage the innominate and the left carotid arteries, in an LAO view. After being positioned in the ascending aorta, the JR4 catheter is pulled with a ***counterclockwise rotation*** to selectively engage the innominate artery then the left common carotid artery. On the right, after selectively engaging the innominate artery, a Wholey wire or a Glidewire is used to selectively enter the right common carotid artery, followed by advancement of the JR4 catheter over the wire (Figure 35.65). Beware of advancing the Wholey wire distally into the internal carotid artery. Other catheters with tips longer and straighter than JR4 are preferably used (e.g., JB1 catheter, HeadHunter). RAO caudal view (20°, 20°) opens the right innominate bifurcation into the right common carotid artery and guides selective wiring of the common carotid artery.

In a type III arch, the curved catheters (Simmons or Vitek) may need to be used to engage both common carotid arteries. In a bovine arch, the curved catheters may be needed to engage the left common carotid artery (Figure 35.66). The wire is advanced until it is looped over the aortic valve, then the catheter is advanced until its base is on the aortic valve. Subsequently, the wire is removed and the catheter is allowed to take its shape in the ascending aorta over the aortic valve; the catheter is then pulled back until it engages the vessel of interest.

B. Angiographic tips

Once a common carotid artery is selectively engaged, the carotid bulb and the internal carotid artery (ICA) are positioned in the field of view; typically, the carotid bulb is located at the angle of the jaw. The carotid is then imaged in two views, using a 4–5 ml/s injection for a total of 10 ml per view: 30° ipsilateral oblique and 90° lateral view. A contralateral oblique view and an AP view may be used in case of overlap or unclear lesion severity. Note that the external carotid artery (ECA) is differentiated from the ICA by the fact that the ECA provides branches at the extracranial level, and that the ECA is actually internal to the ICA on an AP view (opposite to what the names may suggest). The ICA does not provide any branch at the cervical level. The right vertebral artery, if accidentally engaged, is distinguished from the right common carotid artery by its smooth straight course in the neck without branches and by the loop it makes at the level of C1.

The intracerebral circulation is also imaged in 2 views: lateral view and AP cranial view (Town view). *The first large ICA branch is the ophthalmic artery*, seen at the intracerebral level. In unilateral carotid disease, collaterals may be provided by: (i) contralateral ICA (crossover of

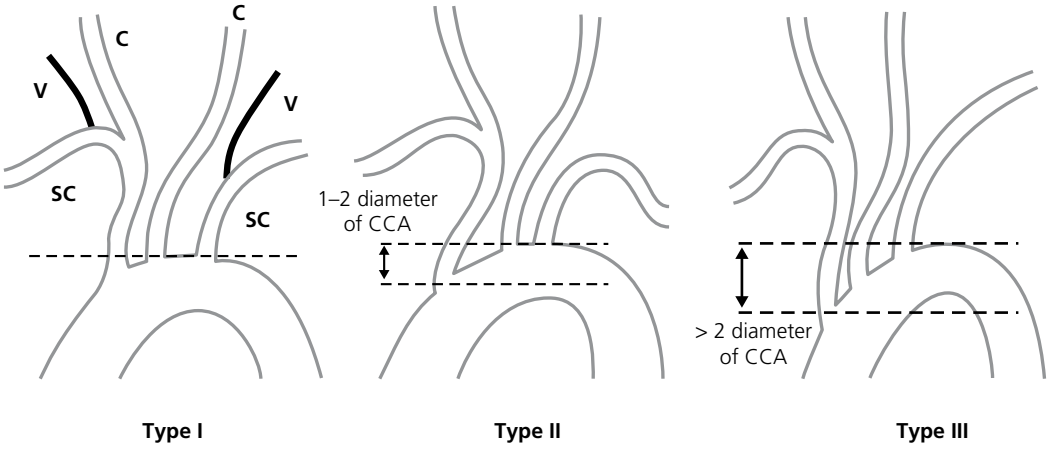

Figure 35.64 Aortic arch types I, II, and III. The distance between the top of the aortic arch and the right innominate is referenced to the diameter of the common carotid artery (CCA). C, carotid; SC, subclavian; V, vertebral. Reproduced with permission of HMP Communications from Madhwal S, Rajagopal V, Bhatt D, et al. Predictors of difficult carotid stenting as determined by aortic arch angiography. J Inv Cardiol 2008; 20: 200–4.

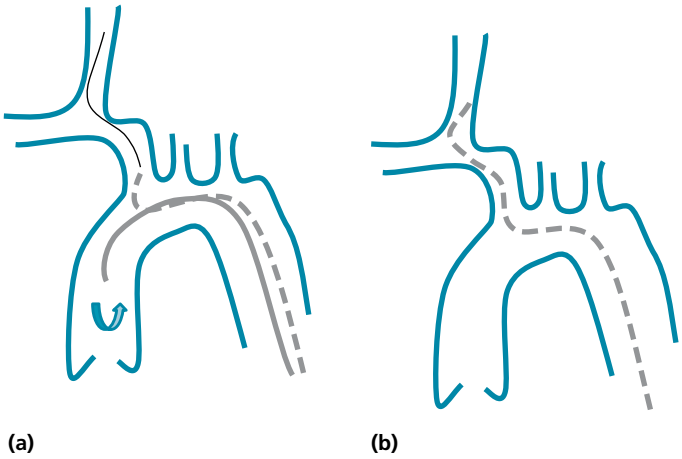

Figure 35.65 **(a)** On an *LAO view*, the JB1 catheter is torqued counterclockwise until it engages the right innominate trunk (goes from *solid to dashed*). Then a Wholey wire is advanced through the JB1 and torqued into the right common carotid artery; *RAO caudal view* may help open the common carotid–subclavian bifurcation. Occasionally, the wire may be going up the vertebral artery rather than the carotid artery. The vertebral artery originates more laterally than the carotid artery. **(b)** The JB1 catheter is subsequently advanced over the Wholey wire to selectively engage the common carotid artery.

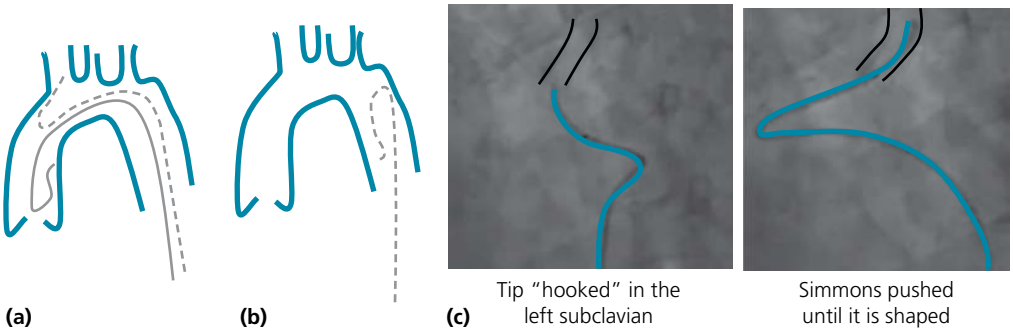

Figure 35.66 Simmons catheter used to engage the innominate and carotid arteries. There are several techniques to shape it: **(a)** it may be advanced over the wire until it is shaped over the aortic valve (*solid gray*), then pulled back with a counterclockwise rotation until it engages the innominate artery (*dashed gray*). **(b)** Alternatively, the Simmons catheter can be shaped in the descending aorta then advanced to engage the vessel of interest. **(c)** The tip of Simmons may be hooked into the left subclavian artery, then pushed until it is shaped in the aortic arch; a figure of eight may be seen before full shaping of the catheter.

flow from one ICA side to another through the circle of Willis may be visualized); (ii) ECA (through a communication between the superficial temporal artery and the ophthalmic artery); (iii) vertebral artery (through the circle of Willis and the posterior communicating artery). On the other hand, in a patient with severe vertebrobasilar disease, the posterior circulation may be provided by the ICA through the posterior communicating artery. Non-selective imaging of the vertebral arteries is necessary in severe carotid disease to assess the risk of an intervention.

QUESTIONS AND ANSWERS

Question 1. On RAO caudal view, in the LAD area, one artery is seen at the border of the heart shadow, another is seen over the heart shadow. Which one is the LAD?

Question 2. On RAO caudal view, in the LAD area, one large artery is seen running at the border of the heart shadow. No other large artery is seen. What is the large artery seen? And what is the likely status of the LAD?

Question 3. How would you confirm the findings of Question 2?

Question 4. On LAO caudal view, the distal LM, proximal LAD, and LCx are overlapped. Is this situation more likely to happen with a vertical or a horizontal heart? How would you open up the LM bifurcation in this case?

Question 5. Is there a situation where a cranial view may show well the proximal LAD and even the distal LM bifurcation?

Question 6. A cranial view shows a lot of overlap in the proximal and mid-LAD area. How can the image be improved?

Question 7. A patient has an occluded proximal LAD and a large proximal diagonal branch originating before the occlusion. On LAO cranial view (or any cranial view), how would you avoid miscalling this large diagonal LAD?

Question 8. On RAO caudal view, which branches run on the border of the heart shadow? On LAO cranial view and other cranial views, which arteries run on the border of the heart shadow?

Question 9. On RAO caudal view, the proximal LCx is foreshortened and overlapped with the distal LM. How can you open the distal LM and proximal LCx?

Question 10. A patient has a borderline ostial LM stenosis on the caudal views. What other views allow good delineation of the ostial LM?

Question 11. In which case is a cranial view a valuable view for the LCx?

Question 12. What is the single best RCA view?

Question 13. What part of the RCA is not well seen on the LAO straight view?

Question 14. What are, in order, the best views for the distal RCA, i.e., the views that open the distal RCA bifurcation?

Question 15. On LAO cranial view, RCA appears to course distally in a straight line, without any bend (Figure 35.33a). What can be said of this RCA?

Question 16. Which RCA view looks at the AV grove from its side rather than en face, only allowing assessment of the mid-RCA, while foreshortening the proximal and distal RCA?

Question 17. On LAO straight view, a venous graft appears attached to an artery running on the heart border. What is the grafted artery?

Question 18. On RAO straight view, a venous graft appears to be attached to an artery running on the heart border. What is the grafted artery?

Question 19. On RAO straight view, a venous graft appears to be attached to an artery running on the lower part of the heart. What is the grafted artery?

Question 20. What 3 views need to be obtained for a LIMA graft?

Question 21. In order to assess MR by LV angiography, what view should be used, and how much contrast should be injected?

Question 22. In order to diagnose the course of an anomalous LM (originating from the right sinus) or RCA (originating from the left sinus), aortography should be performed in what view?

Question 23. RCA appears to be originating from the left sinus. What is the other anomalous RCA origin that is sometimes confused with a left-originating RCA? Which view allows the distinction?

Answer 1. The diagonal branch runs on the border of the heart shadow. The artery that is more centered is the LAD (Figures 35.10–35.12).

Answer 2. The artery seen is likely a large diagonal branch. The LAD is likely occluded.

Answer 3. Obtain LAO cranial view (Figure 35.13).

Answer 4. This scenario is more likely to happen with a vertical heart. LAO caudal looks at the heart from underneath it and displays it better if it is horizontal. To open up the LM bifurcation, the LCx needs to be pulled farther down and to the right. Thus, change the view to a more caudal and less leftward angle (Figures 35.16, 35.18).

Answer 5. Vertical heart.

Answer 6. The LAD moves in an opposite direction to the image intensifier. Going more cranial will push the LAD down and separate it from the LCx. Also, imaging in deep inspiration will make the heart more vertical and provide a better cranial view (less overlap) (Figure 35.24).

Answer 7. The LAD stays in the center of the heart shadow, and in the LAO cranial view, it runs parallel to the spine. Conversely, the diagonal branch takes a turn and aims toward the border of the heart shadow (Figures 35.13, 35.26). Also, the LAD gives septal branches that are characteristically straight and do not torque in systole.

Answer 8. On the *RAO caudal* view, branches running on the border of the heart shadow are diagonal branches. On the *LAO cranial* view, branches running on the border of the heart shadow are OM branches; diagonal branches loop and aim toward the heart border, but do not usually run over it. On *other cranial* views, branches running on the border of the heart shadow can be either OM or diagonal branches (Figures 35.20, 35.21, 35.27).

Answer 9. Angle the image more caudally.

Answer 10. Cranial views are good for ostial LM. Also, LAO straight and AP straight are good views for ostial LM.

Answer 11. When the LCx is dominant, the cranial views show the LCx looping proximally then continuing distally and giving left PLBs and a PDA. The distal LCx, in this case, is well seen on cranial views. If the LCx is not dominant, it is only seen looping proximally without a deep distal continuation. In fact, whenever the LCx is well seen distally beyond its loop on a cranial view, suspect a dominant LCx. On LAO cranial view, the left PDA runs parallel to the LAD.

Answer 12. LAO cranial (30° LAO, 15° cranial).

Answer 13. The distal RCA bifurcation is not well seen on LAO straight (PDA and PLBs are overlapped). LAO cranial, on the other hand, opens the distal RCA bifurcation.

Answer 14. (1) AP cranial; (2) LAO cranial.

Answer 15. This RCA is either occluded in its mid-segment or non-dominant. A dominant, patent RCA should have 2 distal bends on the LAO straight, LAO cranial, and AP cranial views.

Answer 16. RAO straight view (Figure 35.35).

Answer 17. OM branch (Figure 35.38). In left coronary imaging, LAO straight resembles LAO cranial.

Answer 18. Diagonal branch.

Answer 19. OM branch. In left coronary imaging, RAO straight resembles RAO caudal.

Answer 20. (i) Straight view for the LIMA body (AP or RAO usually); (ii) cranial view for the native LAD (the cranial view may also show the LIMA–LAD anastomosis); (iii) 90° left lateral view for the LIMA–LAD anastomosis.

Answer 21. MR should be assessed in an extreme RAO view (e.g., 45–60°), which allows the separation of the large LA from the descending aorta. LAO cranial may also be used. A large injection is used and sustained over 4 seconds, to allow a steady-state filling of the LV and LA (12–13 ml/s for a total of 48–52 ml).

Answer 22. RAO view, which shows the "dot" and "eye" signs.

Answer 23. Anterior RCA takeoff from the right sinus may be confused with left RCA takeoff. LAO view allows the distinction. Anterior takeoff is benign, while left takeoff may lead to ischemia (Figure 35.53).

I. Design of the Judkins catheters (Figure 36.1)

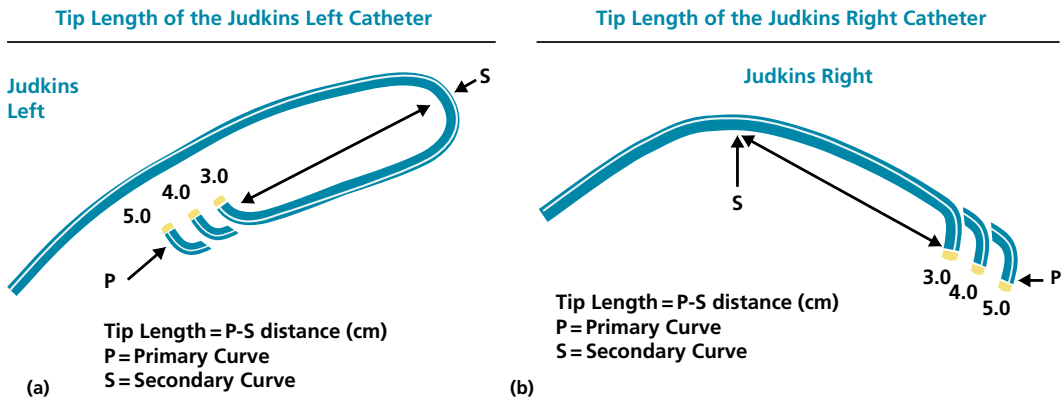

Figure 36.1 **(a)** Judkins left (JL) catheter. The *arm* or *size* of the Judkins catheter is the distance between the primary and secondary curves, in centimeters (JL3 → 6). The secondary curve is what sits on the contralateral aortic wall. **(b)** Judkins right (JR) catheter. Courtesy of Mark Freed and Robert Safian, Physician's Press, Royal Oak, MI.

II. Coronary cusps anatomy and view for the engagement of the native coronary arteries: LAO vs. RAO (Figure 36.2)

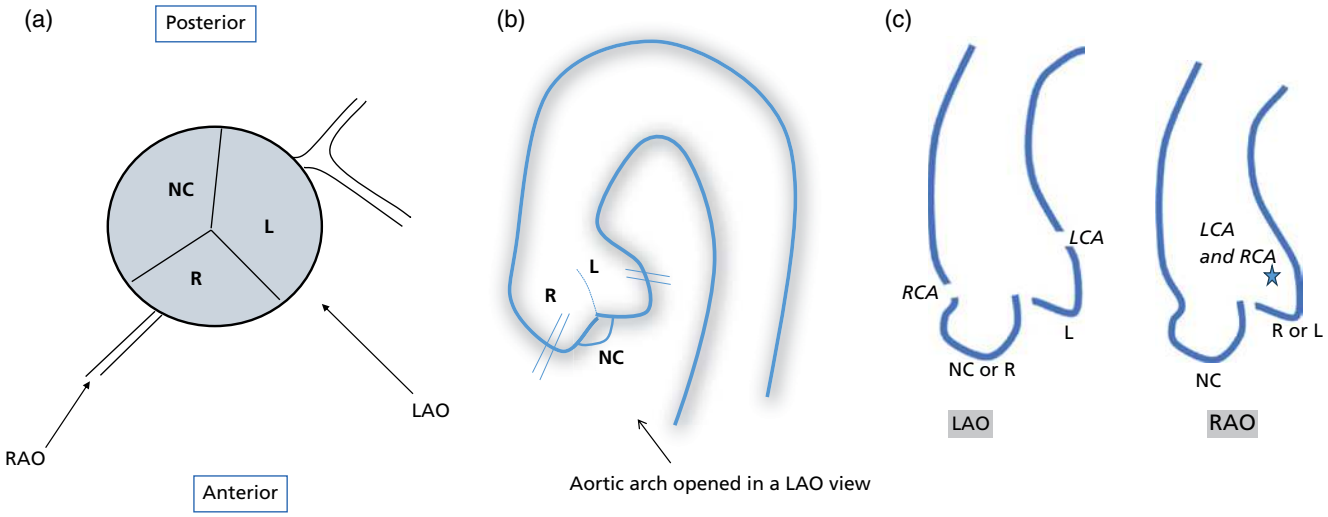

Figure 36.2 **(a)** Axial cut at the level of sinuses of Valsalva. R is the right cusp, L is the left cusp, and NC is the non-coronary cusp. RCA ostium is at ~7 o'clock, LCA ostium is at ~2 o'clock; on the flipped CTA images (anterior on top), RCA is at 11 o'clock and LCA at 4 o'clock. LAO view is orthogonal to the ostia and therefore displays the coronary arteries in front of the operator, permitting the catheters to be torqued toward the appropriate plane. Conversely, RAO is in-line with the coronary takeoffs and superimposes them. Hence LAO is used for coronary engagement. **(b)** Aorta opened in LAO view. NC is the most posterior cusp, and as such, it is also the lowest cusp (the aorta tilts posteriorly after its takeoff, which makes its posterior aspect lower than its anterior aspect). R is the second lowest cusp. When you see a catheter "fall down," it is either in the R or NC cusp. R is also the most anterior cusp (toward the RV). **(c)** LAO view separates L and R cusps (NC may be superimposed on R cusp); RAO separates NC cusp posteriorly, and R + L cusps more anteriorly.

III. Difference in left coronary artery (LCA) catheter elongation between femoral and radial access

(Figures 36.3, 36.4)

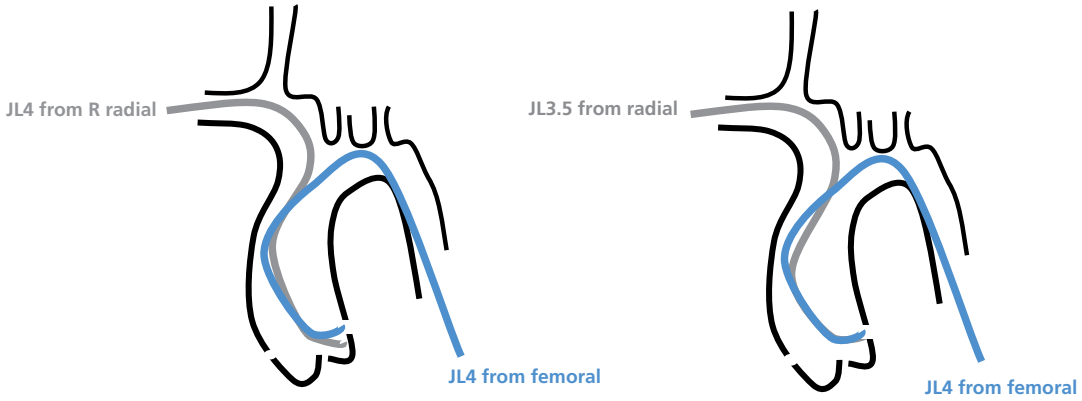

Figure 36.3 Right radial access elongates Judkins left (JL) catheters and makes them point down → hence a shorter JL arm is required from a radial access compared to femoral access (JL 3.5 from radial, JL 4 from femoral access). In addition, compared to femoral access, both left and radial accesses create an additional catheter twist at the level of the sharp innominate-aorta junction. This creates a catheter tendency to prolapse out into the aortic arch and reduces Judkins catheter support by up to 40%.

In general, from any approach, when a Judkins catheter is straightened and elongated, with its tip pointing down, as in the gray catheter of the left image → a shorter JL arm is needed to make the catheter point up.

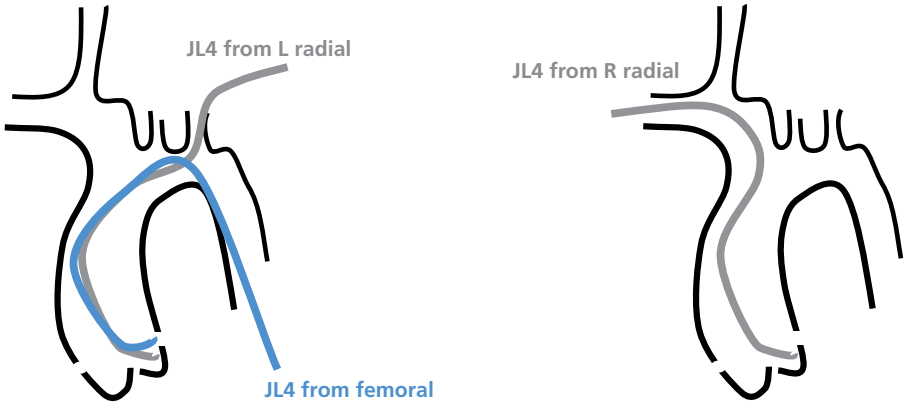

Figure 36.4 Left transradial access has a less sharp turn into the ascending aorta than right transradial access, yet it elongates catheters somewhat similarly to right transradial access (less than right transradial in some cases). Usually, a similarly shorter arm is required for both right and left transradial accesses (JL 3.5).

IV. From any approach, how to switch a Judkins left (JL) catheter that is fully falling down below the LCA and a JL catheter that is elongated (Figure 36.5)

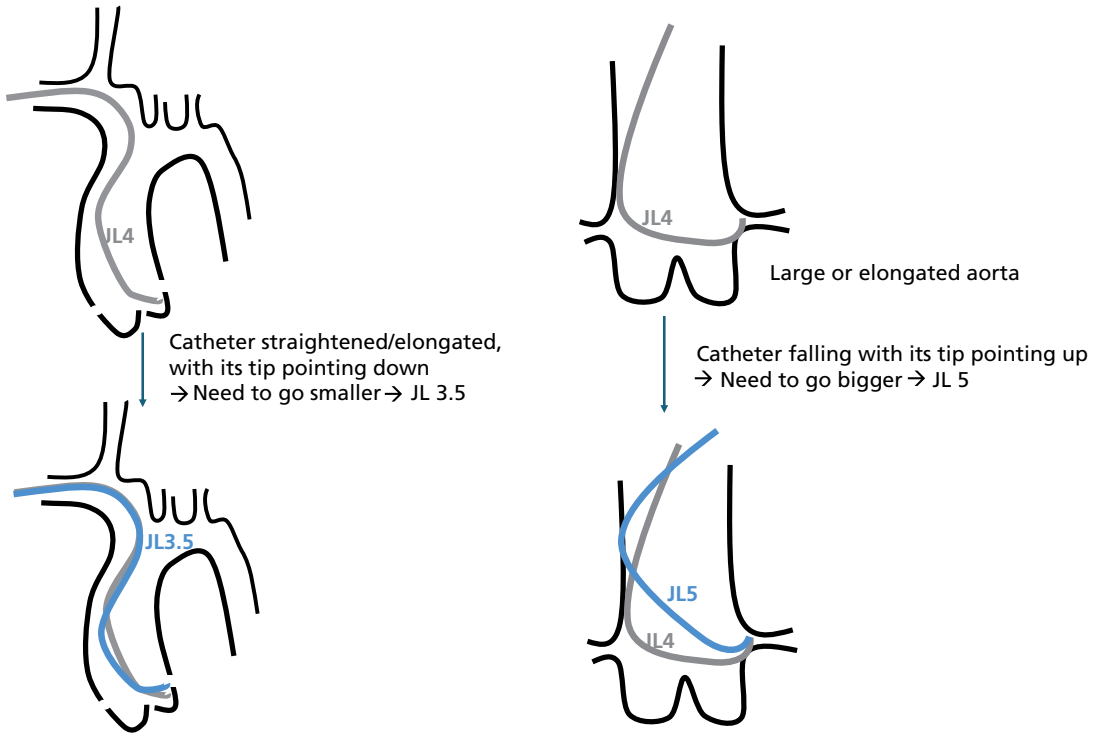

Figure 36.5 From any approach, when you see a catheter straightened and elongated, with its tip pointing down → a catheter with a shorter arm is needed. When you see a catheter falling and shortened/looped, with its tip pointing up → a catheter with a longer arm is needed.

In general, ***a longer arm is needed when aorta is dilated at the sinuses level >4.2 cm: for aortic sinuses of ~4.2–4.5 cm, use JL 4 from radial access*** instead of JL 3.5, ***JL 4.5 from femoral access***, and ***EBU 4–4.5*** from either access. Increase JL size by 0.5 for every 0.5 cm further aortic dilatation. The EBU arm and the transradial JL arm are generally sized 0-0.5 cm less than the aortic diameter. The size at the aortic sinuses is more relevant than the size of the higher, tubular aorta, which also dictates larger catheter arms but only with more significant dilatations (>4.5 cm).

V. Additional, specific radial catheters and Amplatz catheters (Figures 36.6–36.8)

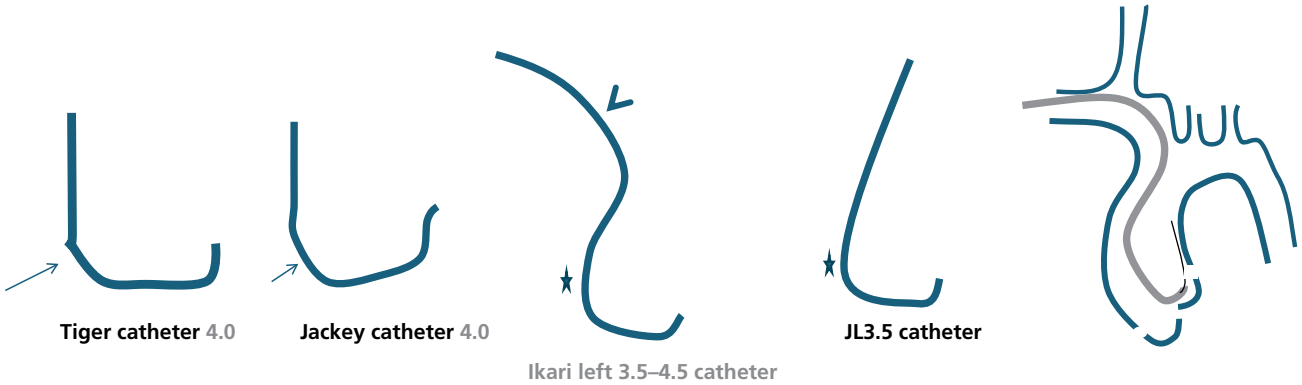

Figure 36.6 Specific radial catheters, Tiger and Jacky, may be used for both left coronary and RCA engagement from radial access. Note the long secondary curve that allows the catheter to rest over the contralateral aorta for support (*arrows*). Tiger tends to point up, while Jackey's tip may point down. However, the 4-cm arm is a disadvantage for those catheters, making their left coronary engagement less stable than JL 3.5 in standard cases.

Ikari left is radial PCI guide catheter that is easier to engage than standard left coronary guides, such as XB/EBU catheter: (i) it has a bend that sits at the innominate and prevents prolapse; (ii) it has a plateau that sits at the valve or the opposite aorta, unlike the JL bend (*star*); (iii) it is also more upward pointing and slippery, making it favorable for transradial engagement.

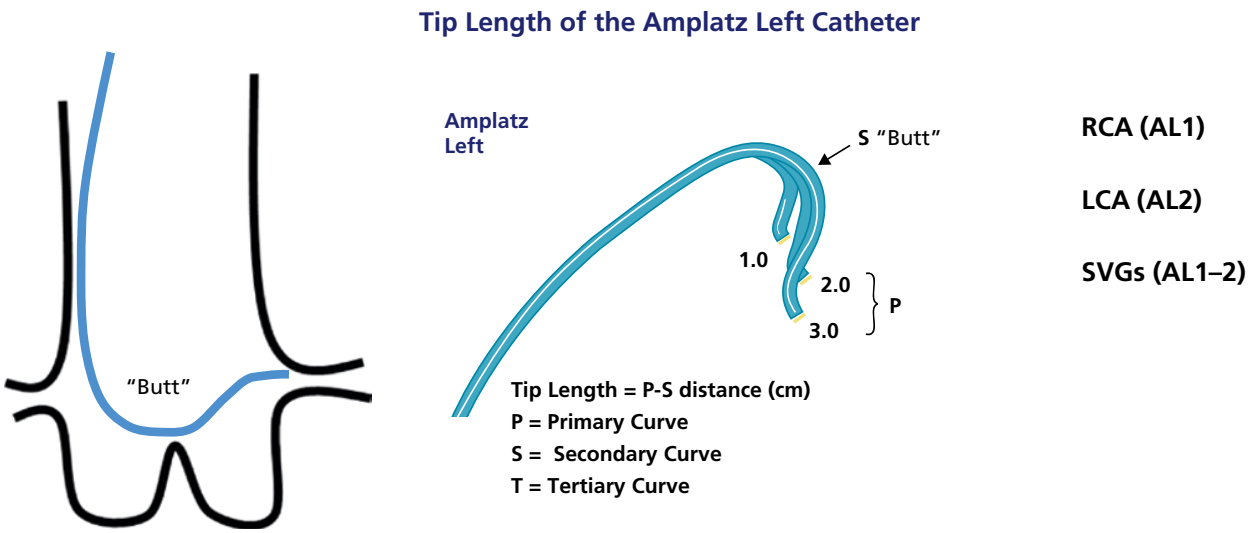

Figure 36.7 Amplatz left (AL) catheter has a duck shape with a large secondary curve, the so-called large "butt." It is used for both left coronary (AL2), right coronary (AL1), and SVG engagement (AL1 or AL2). The "butt" sits both on the back wall of the aorta and on the aortic valve, and thus provides robust support from both the opposite wall of the aorta and from the cusp. It is the most supportive catheter for RCA engagement and RCA PCI. AL ***points up*** but may point down if the AL curve is small relatively to the aorta. In addition, if the AL curve is small, the AL may not sit on the aortic valve and may not provide the support needed. ***Unlike Judkins, a larger curve makes it point further up.***

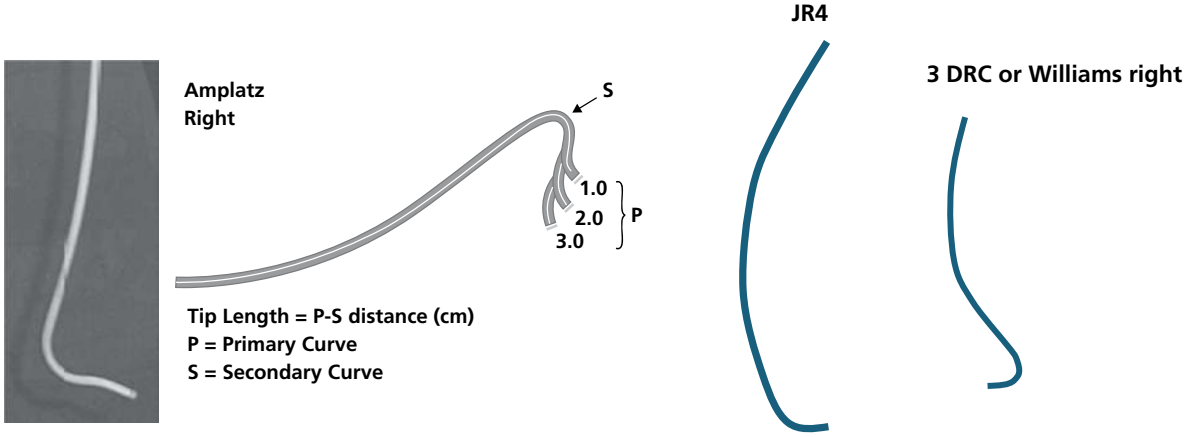

Figure 36.8 Amplatz right (AR) catheter. The size of the secondary curve (S), i.e., the "butt," distinguishes AR catheter from Amplatz left (AL) catheter. AR has a much smaller "butt" than AL. The P-S distance distinguishes between AR1 and AR2. AR2 has a longer tip than AR1 but is still a much smaller catheter than AL1. Therefore: (1) as opposed to AL, AR does not provide support from the back wall of the aorta or from sitting on the aortic cusps; (2) as opposed to AL, AR points down, even more so than JR 4.

Additional catheter: *No-torque catheter* (3DRC or Williams right catheter) that is, in a way, a JR4 catheter that is already torqued. It requires less torque or no torque for RCA engagement. For experienced operators, this catheter does not offer any advantage over the JR4 catheter, including no advantage in difficult RCA takeoff.

VI. Difference in RCA catheter elongation between femoral and radial access (Figure 36.9)

From radial, when aiming to the right, as opposed to the left, catheters are more looped, shortened, and upward-looking

→ Hence JR4 should be used in radial, like femoral

Figure 36.9 Radial access elongates left coronary catheters. Conversely, catheters are more looped, shortened, and upward-looking when aiming to the RCA. Hence Judkins right (JR) arm does not need to be shortened from a radial approach compared to a femoral approach (use the same JR4).

VII. Summary of diagnostic and guiding catheters used for left coronary and RCA engagement from femoral and radial accesses (Figure 36.10)

		Diagnostic		Guide
Femoral	LCA	JL4		EBU 3.5 (CLS, XB)
	RCA	JR4-AR		JR4, AL0.75
Radial	LCA	JL3.5	Tiger/Jackey	EBU 3.5-4 (CLS, XB) Ikari L 4-4.5
	RCA	JR4-AR	Tiger/Jackey	AL1, Ikari L or R

Amplatz left

Figure 36.10 Typical catheters and catheter sizes from radial and femoral approaches. The differences between radial and femoral approaches are highlighted in blue. Note that for left coronary engagement, a smaller JL diagnostic catheter is used transradially, vs. same-size or longer-arm guiding catheter (EBU 3.5–4 vs. 3.5). This is because guiding catheters often need to have a longer tip to sit on the aortic valve and provide the extra support needed in transradial PCI (they do not necessarily have to sit on the aortic valve in transfemoral PCI). AL catheter may be used for left and right coronary engagement, radially or femorally, and is particularly useful when robust support is needed or when engagement difficulties are encountered.

VIII. Steps in LCA engagement, tips and tricks (focused on transradial access)

The steps described herein mainly apply for transradial LCA engagement with JL or Tiger/Jacky. While they may also apply to transfemoral engagement, the latter is generally straightforward: the JL catheter usually directly and easily jumps onto the left coronary cusp and ostium upon wire removal; maneuvering from right to left cusp, similar to radial access, is occasionally needed. In case of difficult JL left coronary engagement from a femoral access, the reflex is that the JL catheter is either too short or too large, and different arm length is required (as in Figure 36.5).

The following are the standard steps in LCA engagement (Figures 36.11–36.15). LAO view is used to lay out the right cusp (lower) and left cusp (higher). Throughout the maneuvers, always imagine the left cusp (L), which is highest, and right (R) and non-coronary (NC) cusps, which are lower.

Step 0, base of operation: Advance the wire and loop it over the right cusp. The wire almost always goes to the lower, R or NC cusp.

Step 1. Advance the catheter over the wire, onto the R cusp. If needed, use ***deep breath*** and slight clockwise torque (10°–20°) to embrace the aortic curve. Do not just forcefully "shove" the catheter while it is scraping the convexity of the aorta: the catheter may loop on itself and prolapse out of the ascending aorta.

Step 2. Pull the wire but keep it inside the catheter. Clockwise torque the catheter to make it flat, i.e., well laid out and pointing toward the LCA. Then **pull the catheter to see it jump from R or NC onto L cusp (the JUMP)**. Pull straight but **be ready to readvance the catheter if it is about to fly out:** in this case, readvance the catheter, give it a slight torque, then reattempt to jump again. A ***deep breath*** helps with the jump as well. Keep the wire inside the catheter during the last step, both to enhance torquability but also to readvance the catheter if it flies out. If the catheter flies out in the ascending aorta, do not just readvance it. Rather, readvance the wire promptly and start over.

Step 3 of left coronary engagement: After the right-to-left cusp jump, the JL catheter may jump straight into the LCA. Frequently, however (~ half the time), it falls below the LCA, in which case there are 2 methods of LCA engagement (Figure 36.12):

3A. Engagement by **pulling** the catheter, the "direct technique": **Slightly pull** the catheter with a **slight clock** (10°–20°), but react to the catheter behavior: if the catheter starts to jump out → immediately counterclockwise torque and readvance. For CLS/EBU, it is often counterclockwise torque that works. A ***deep breath*** helps, as it pushes the LCA down toward the catheter.

3B. Engagement by **pushing** the catheter from below the LCA, the **"below technique"**: After the catheter tip falls onto the left cusp, push it from below until it catches the left main. If the catheter feels stuck and cannot be pushed, pull slightly to free the tip, torque the catheter, then readvance it; if the catheter tip does not catch the LCA and rather arrives adjacently, pull the catheter, torque it to move it in a different plane, then readvance again. Once the catheter catches the LCA, pull it slightly to make it more coaxial and less upward pointing into the LM. This technique (3B) may occasionally be done from the right cusp if the catheter flies out each time one tries to jump to the left cusp, in patients with short and sharp angled aorta.

For technique 3A, **this triple combination** often works: (i) slight pull with (ii) a slight clock and (iii) a deep inspiration. Toward the end, as the catheter goes in the LCA, be ready to advance it to lock it in, as a deep breath eventually makes it fly out.

The wire is kept inside the catheter tip during LCA engagement, to allow readvancement in case the catheter flies up in the aorta.

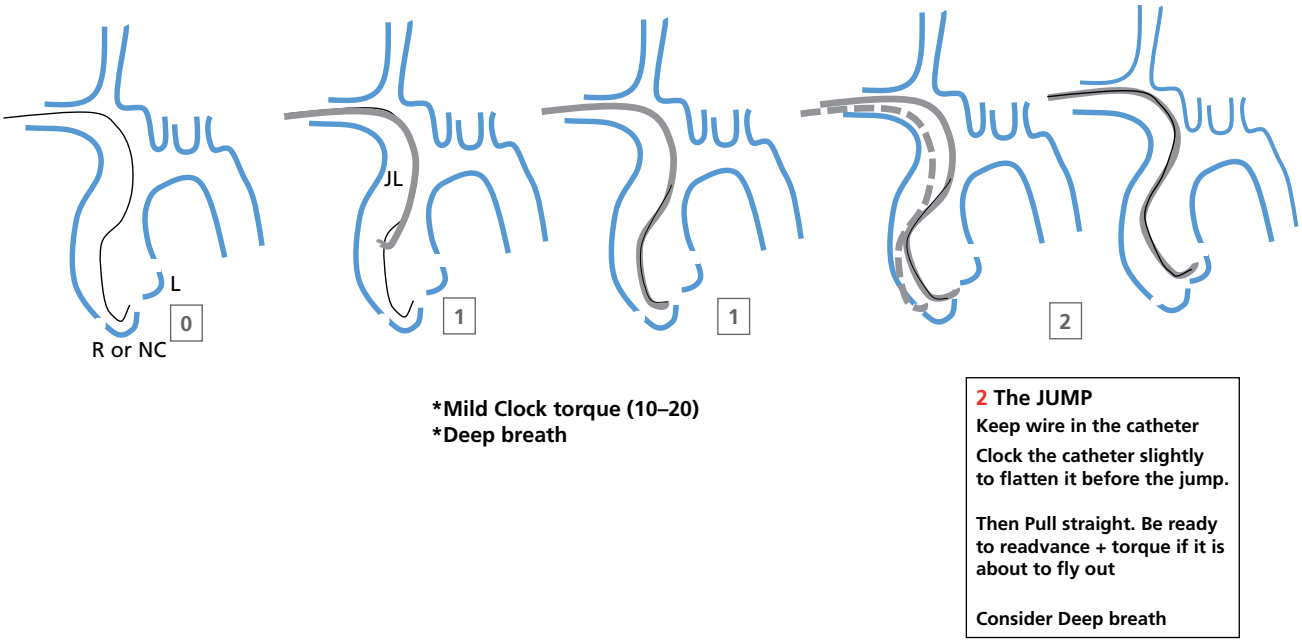

Figure 36.11 Basic steps of radial left coronary engagement, which apply for diagnostic and guiding catheters. LAO view is used to lay out the right cusp (lower) and left cusp (higher). Throughout the maneuvers, always imagine the left cusp (L), which is highest, and right (R) and non-coronary (NC) cusps, which are lower.

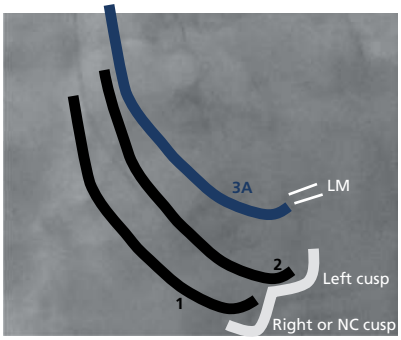
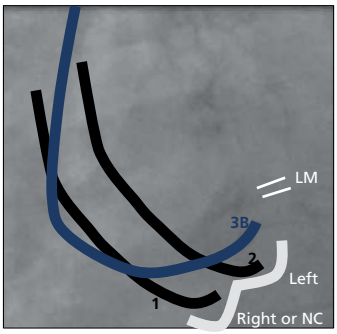
Step 0. ***Base of operation***: Advance the wire and loop it over the right cusp. The wire almost always goes to the lower, R or NC cusp.

Step 1. Advance the catheter over the wire, onto the R cusp. If needed, use a ***deep breath*** and slight clockwise torque (10°–20°) to embrace the aortic curve. Do not just forcefully "shove" the catheter while it is scraping the convexity of the aorta: the catheter may loop on itself and prolapse out of the ascending aorta.

Step 2. Pull the wire but keep it inside the catheter. Clockwise torque the catheter to make it flat, i.e., well laid out and pointing toward the LCA. Then **pull the catheter to see it jump from R or NC onto L cusp**. Pull straight but **be ready to readvance the catheter if it is about to fly out**: in this case, readvance the catheter, give it a slight torque, then reattempt to jump again. A deep breath helps with the jump as well. Keep the wire inside the catheter tip (*black line* inside the gray catheter), both to enhance torquability but also to readvance the wire and the catheter if it flies out. If the catheter flies out in the ascending aorta, do not just readvance it. Rather, readvance the wire promptly and restart over. At times, it is possible to get back down to the left cusp with a torque (typically clockwise) and deep breath.





3A: Pull or Direct technique
Pull with gentle clockwise 10°–20°torque (or counterclock)
If catheter is flying out, immediately push and reverse torque

3B: Push technique, from below (U technique) : Push with or without torque (clock > counterclock for JL)
Better technique when catheter unstable and when engagement difficult

Apply to any of the typical radial catheters:
***JL3.5, Tiger: 3A or 3B**
***Ikari L 4–4.5: often 3B**
***EBU/CLS 3.5–4.5: 3B**

May switch back and forth between 3A and 3B

Figure 36.12 Step 3 of left coronary engagement: After the right-to-left cusp jump, the JL catheter may jump straight into the LCA. Frequently, however (~ half the time), it falls below the LCA, in which case there are 2 methods of LCA engagement: **3A (direct pull)** and **3B (push, from below)**.

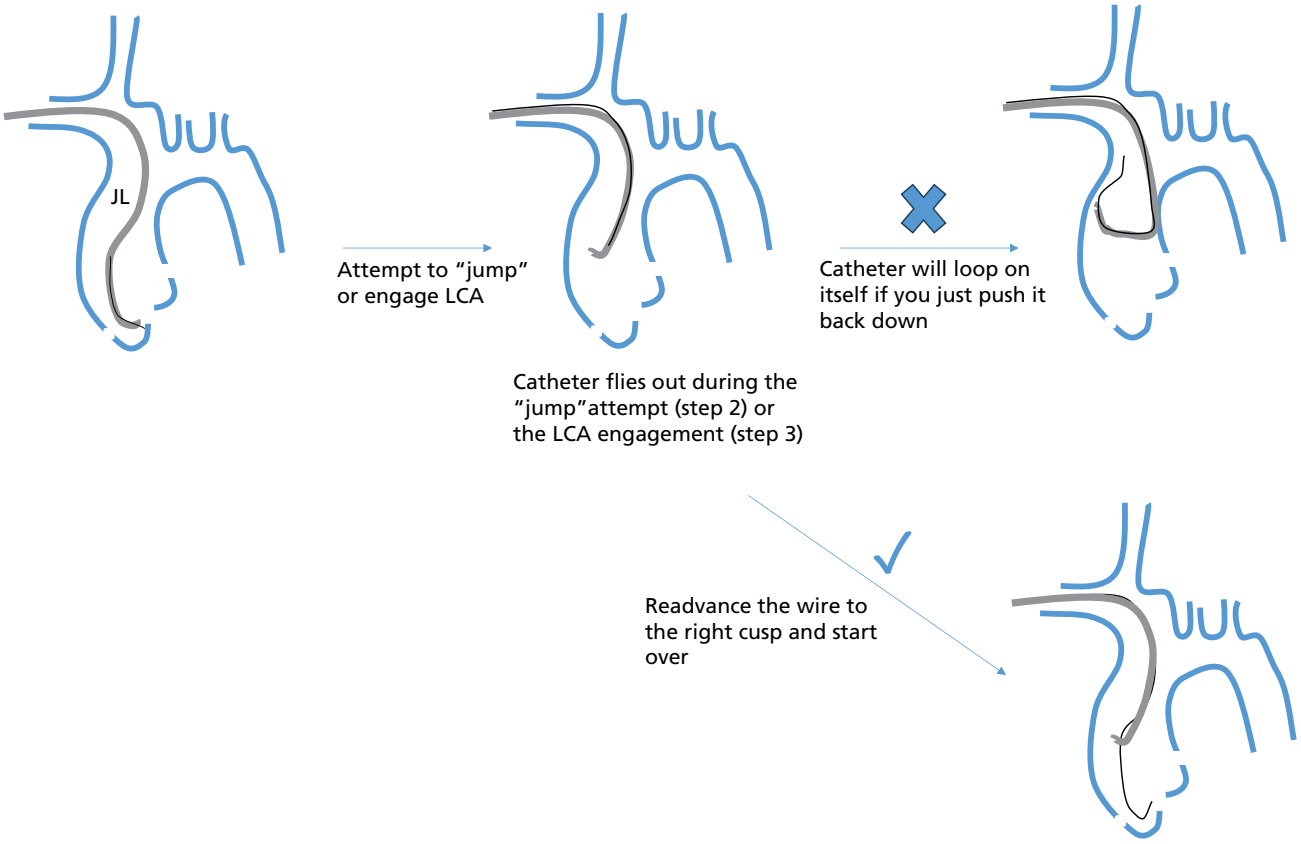


Figure 36.13 This is what we call "catheter flying out" during steps 2 (the jump) and 3. The catheter jumps onto the outside curvature of the ascending aorta, close to the arch. Do not just push the catheter in those cases, it will end up looping on itself. Rather, readvance the wire to the right cusp (base of operation) and start over. Occasionally, after the catheter flies out, *one may be able to get back down to the left cusp with a torque maneuver, typically clockwise torque, along with a deep breath*.

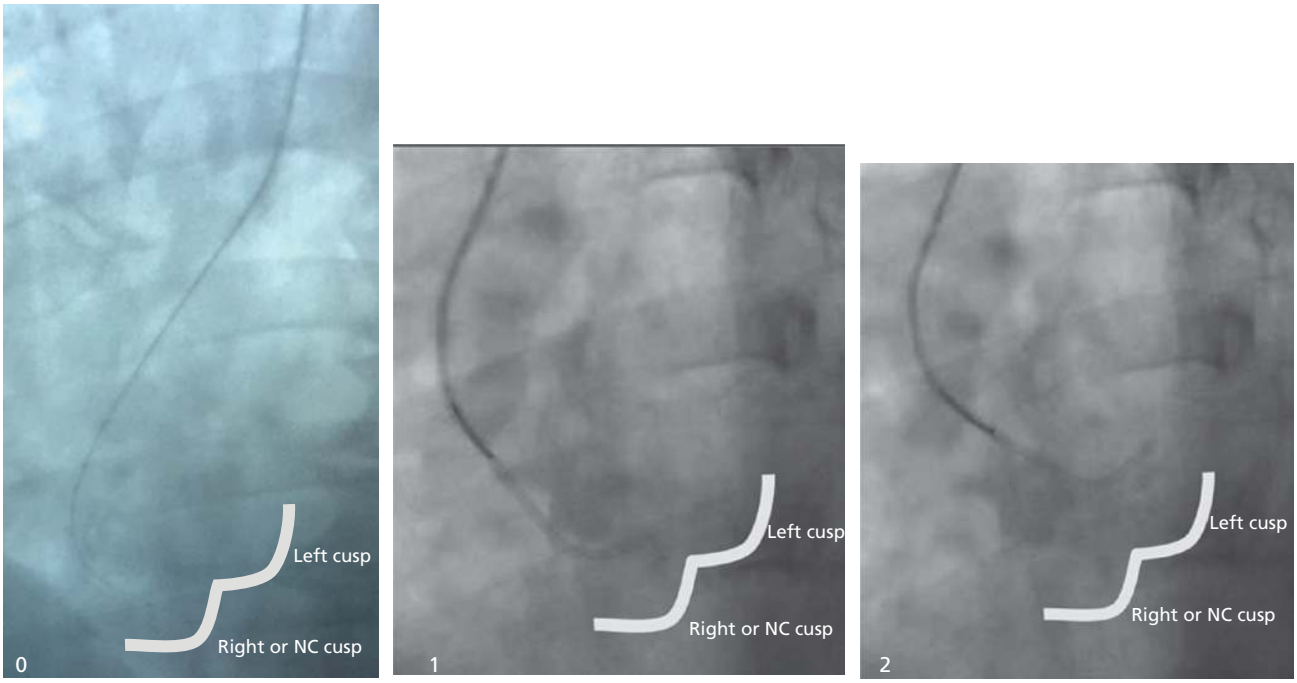

Figure 36.14 Illustration of steps 0, 1, and 2 (the jump). In this patient, during the jump, the Judkins left (JL) catheter jumped straight into the left coronary ostium. Note that the wire is kept inside the catheter during left coronary engagement, to allow readvancement in case the catheter flies up in the aorta during the pull; the wire does not protrude outside the tip.

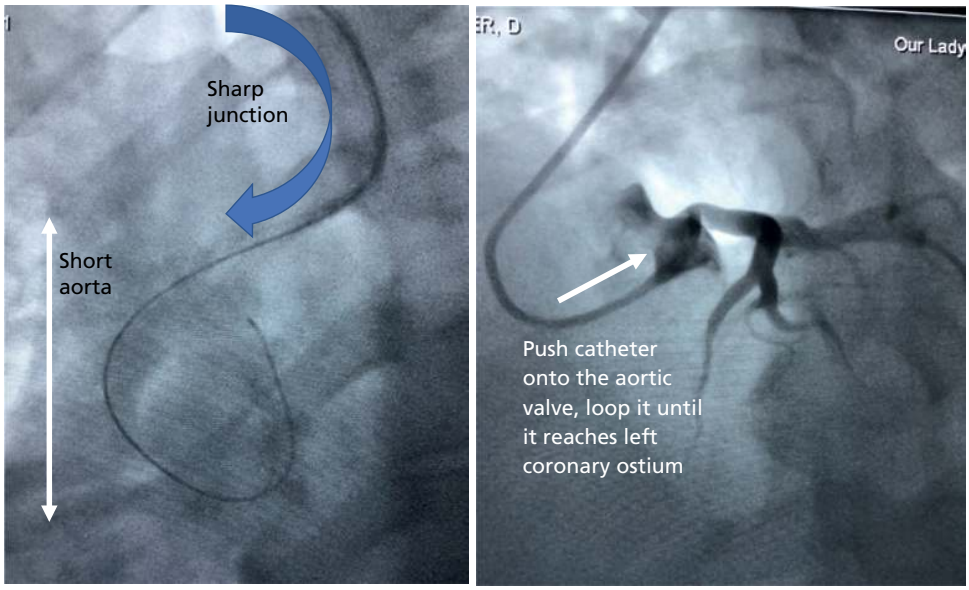

Figure 36.15 Right transradial engagement of the left coronary artery in a patient with **a difficult double combination: (1) sharp innominate-aorta angle, (2) short ascending aorta. (i)** Advance the catheter to the right cusp **while the patient is taking a deep breath**, (ii) make it jump onto the left cusp during deep inspiration as well (most difficult step), (iii) then loop it from below and make it reach up the left main. Occasionally the catheter may be pushed and looped up from the right cusp. A simple catheter pull (technique 3A) is unlikely to engage the left main and will likely cause the catheter to prolapse out of the ascending aorta.

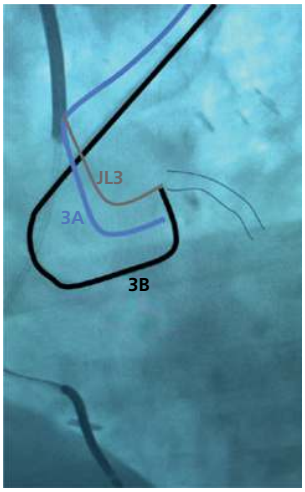
In patients with a short and sharply angled ascending aorta, where the catheter risks prolapsing out of the ascending aorta with the pull technique, the technique 3B is more likely to be successful. In patients with heavy tortuosity and poor torquability, technique 3B is also more favorable. Conversely, in patients with long ascending aorta, technique 3A is easiest and most successful.

These technical steps (0–3) apply to the common catheters (JL3.5, Tiger) and to guides like Ikari and EBU/XB-type of guides. Regarding EBU catheters, their tip is long and bulky, and points farther down compared to JL, hence only the 3B technique is used for their transradial engagement, i.e., push the catheter tip from the left cusp until it catches the left coronary ostium.

IX. When JL tip falls below the LCA ostium after the cusp jump: techniques 3A, 3B, and beyond

(Figure 36.16)



When JL3.5 catheter tip falls below the left coronary ostium after the jump, there are 4 techniques to hook the coronary ostium:

- Engage by pulling + clock torque (3A)
- Engage by pulling + clock torque + DEEP INSPIRATION
- Push to engage from below with JL 3.5 (3B)
- Engage by pulling using JL3

Figure 36.16 The JL 3.5 catheter tip frequently jumps into the LCA ostium after the right-to-left cusp jump, but it may fall below it. When this happens, there are 4 techniques to hook the coronary ostium. Often, what works best is this triple combination: (i) **slight clock** (10°–20°) with (ii) a **slight pull**, (iii) while the patient is taking a **deep breath.** Deep breath elongates the aorta and pushes the left main down to the level of the catheter. At the end of this maneuver, after the pull and clock, ***be ready to push/advance the catheter, to lock it in the ostium*** and prevent it from flying out with the deep breath.

If this technique and technique 3B fail, consider switching to a shorter JL3, particularly if JL3.5 appears too elongated with its tip pointing too much down.

X. Case illustrations and 2 additional transradial and LCA engagement tips

- Deep breath is very helpful throughout steps 1–3 (Figures 36.17–36.19).
- From a right radial access, if the catheter falls in the descending aorta, a pull with a ***counterclockwise*** torque moves it in the ascending aorta. From a left radial access, a pull with a clockwise torque moves it in the ascending aorta (Figure 36.20).

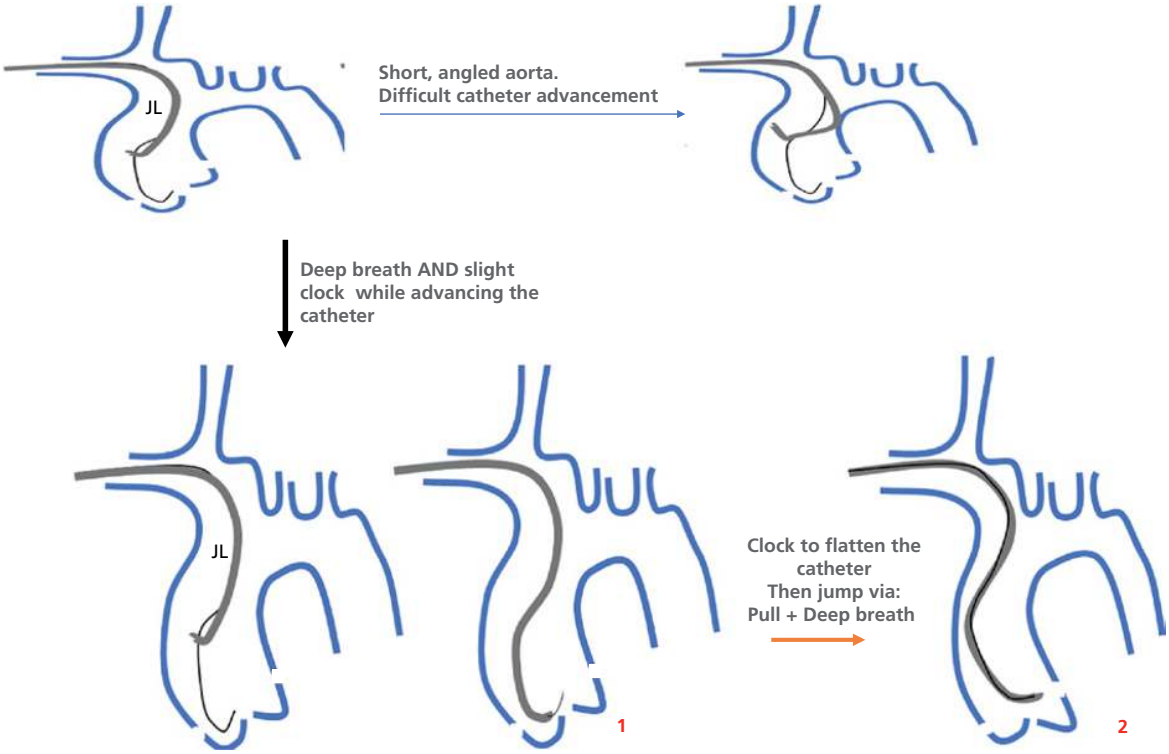


Figure 36.17 Deep breath and slight clockwise torque (10°–20°) are particularly helpful in the case of a short aorta or a sharp innominate angle. Deep breath elongates the aorta-innominate angle and the aorta, allowing the catheter to descend with less resistance (step 1). It also allows it to more easily jump to the left cusp (step 2), and eventually jump in the left coronary ostium (3A).

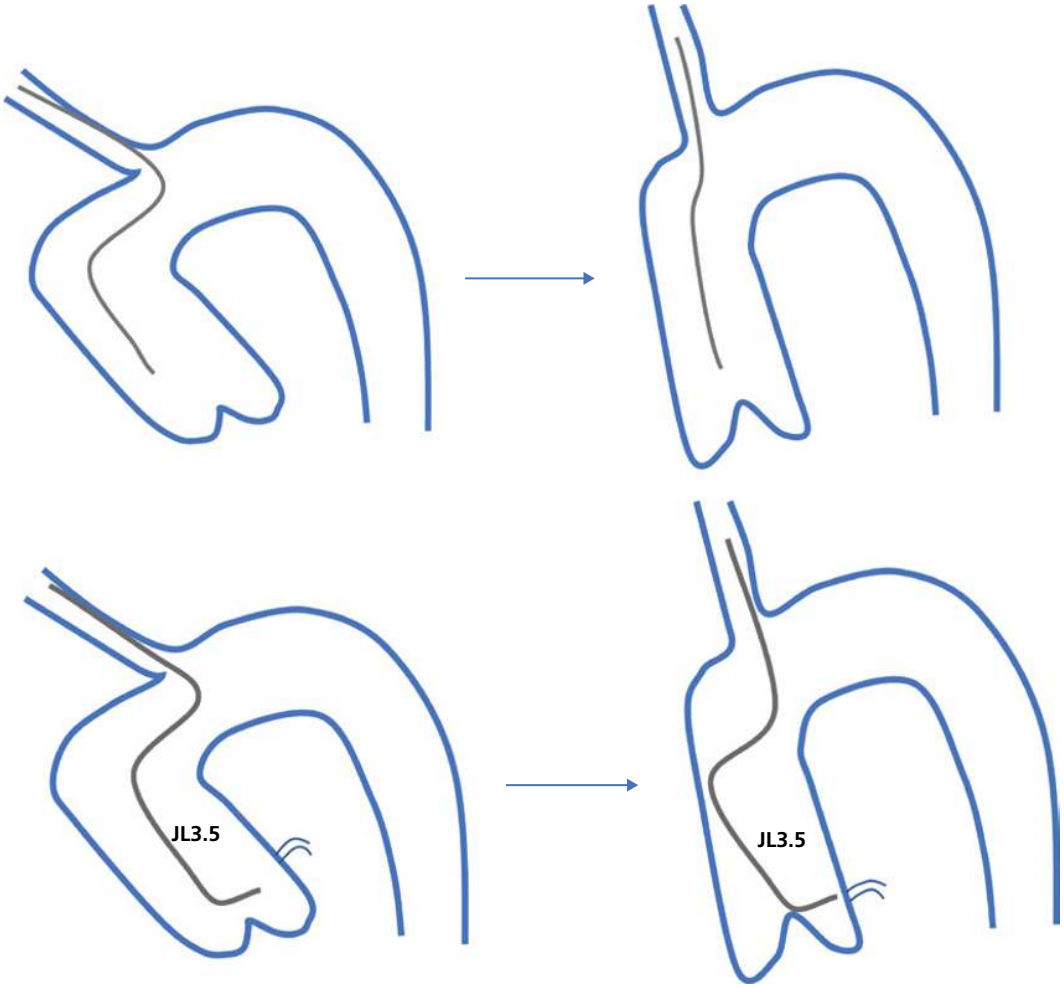

Figure 36.18 The valuable effect of **deep inspiration**. (*Upper image*) Deep inspiration elongates the aorta-innominate angle, which helps getting the catheter down without prolapse (step **1**). Elongating the aorta also facilitates the **JUMP** (step **2**), as it makes it less likely for the catheter to fly out into the high aorta and levels the right and left cusps.

(*Lower image*) Deep breath also helps with step **3A catheter engagement**. With a deep breath, not only is the aorta elongated, but also the left main gets pushed down and changes from being superior to more horizontal, so the catheter that is below it and pointing down will hook it. At the end of this deep breath +/– pull and clockwise maneuver, be ready to push/advance the catheter, to lock it in the ostium and prevent it from flying out with the deep breath. **ALWAYS, with deep breath, when it is used in any step, one has to be ready to readvance the catheter to prevent it from flying out.**

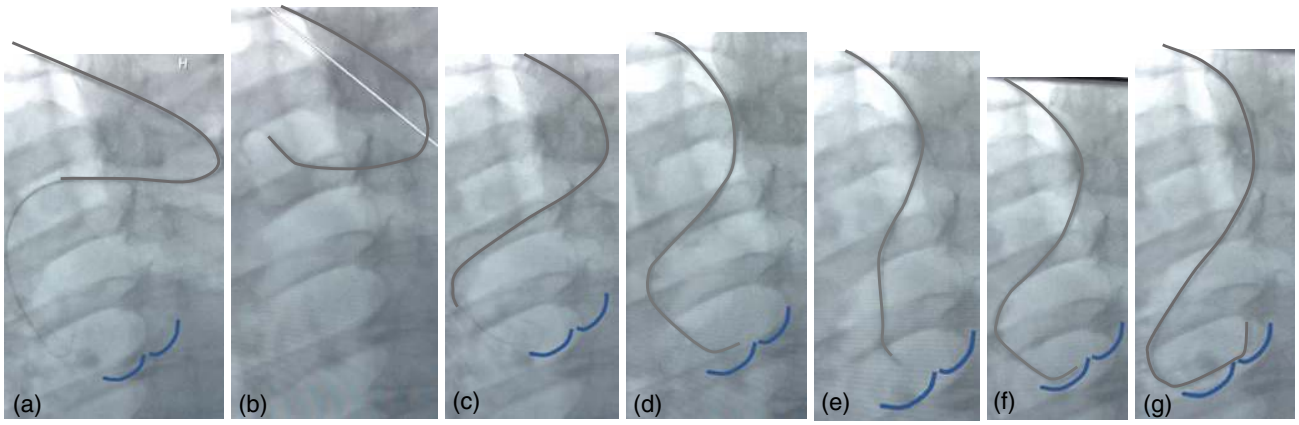

Figure 36.19 Difficult LCA engagement in a patient with sharp innominate-aorta angulation. **(a, b)** As the JL 3.5 catheter is being advanced through the sharp angulation (step 1), it tends to prolapse out of the ascending aorta, particularly if it is "shoved" over the wire, and indeed it did **(b)**. **(c, d)** The catheter is readvanced with 2 tricks: **deep breath** *and* slight torque to make it embrace the inner aortic curvature. **(e, f)** During the jump attempt (step 2), the catheter is about to fly out (e), so it is quickly readvanced (f). **(g)** After a torque and with **deep breath**, the jump was successful, and the LCA was engaged using the "below technique" 3B, which is preferred in such a complex case wherein the catheter has a propensity to fly out with the 3A pull technique.

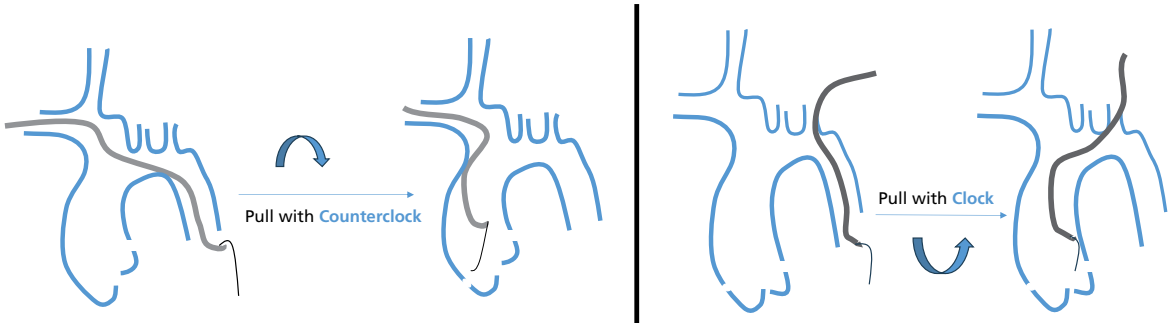

Figure 36.20 From a **right radial** access, if the catheter falls in the descending aorta, advance it deeply in the descending aorta. Then, after pulling the wire inside the catheter, pull the catheter with a ***counterclockwise*** maneuver. A jump will be seen from the descending to the ascending aorta, at which point the wire is advanced onto the right cusp. When this maneuver does not work, it is usually because the catheter was already too high in the arch when the pull maneuver was initiated. The catheter must be advanced deeply in the descending aorta before getting pulled.

From a **left radial** access, a clockwise maneuver moves the catheter from descending to ascending aorta.

XI. Management of a JL catheter that is sub-selectively engaged in the LAD or LCx

If the JL3.5 catheter keeps selectively engaging the LCx in a patient with a short LM or separate ostia for the LAD and the LCx, how can the catheter be directed toward the LAD? The LAD is more superior pointing than the LCx, and more anterior. The following techniques may be used to move the catheter from LCx to LAD (Figures 36.21, 36.22):

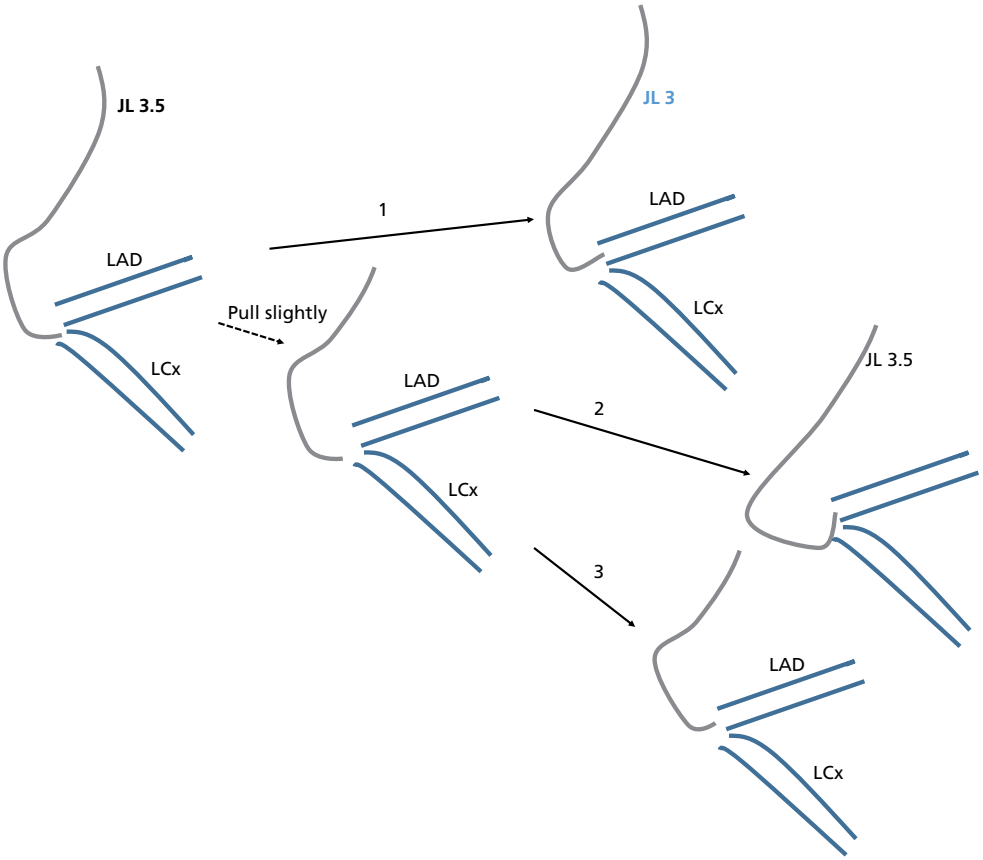

Figure 36.21 To move the JL 3 catheter from LCx to LAD:

1. Try a smaller, more upward-pointing catheter (JL 3);
2. OR disengage slightly then push to the valve and re-engage from below;
3. OR disengage slightly then clockwise or counterclockwise torque and readvance (torquing aims the catheter in a different anteroposterior plane);
4. OR disengage slightly, ask for deep inspiration, then readvance the catheter during deep breath. A deep breath pushes the LAD down to the level of the down-pointing catheter.

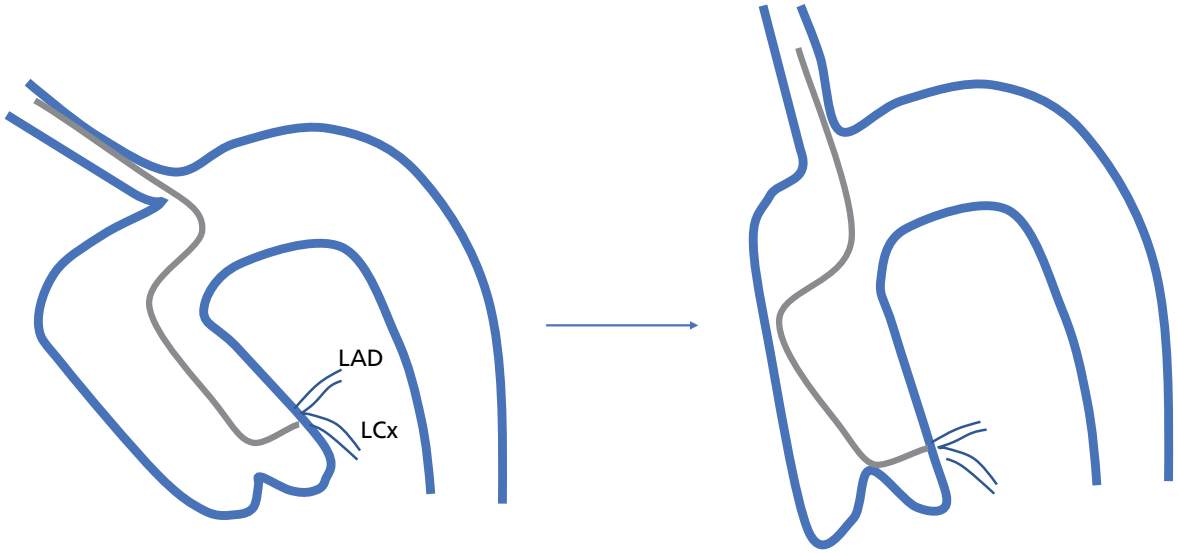

Figure 36.22 Deep breath may also be used not just to get into the left main, but for selective LAD engagement in case of separate LAD/LCx ostia. LAD has a superior takeoff, and deep breath makes it more horizontal or down looking. If the catheter is in the LCx, slightly pull out of the LCx, ask for a deep breath, then quickly push and re-engage while holding the deep breath. The opposite, deep exhalation, may be done to push the LAD and LCx up and engage LCx from a catheter selectively engaged in the LAD.

1. Switch to smaller JL, JL3, to point more up.
2. Slightly pull to disengage the catheter, then quickly push it onto the valve, then push it to engage the LCA from below (3B). Engaging from below makes the catheter point more upward compared to straight engagement, making it more likely to hook the LAD.
3. If JL has a hinge on the aorta, slightly disengage it, then readvance it with *counterclockwise* torque, as this points JL more anteriorly. When the JL secondary curve does not sit on the aorta, clockwise torque moves it anteriorly, similarly to the behavior of a JR catheter, which has no hinge on the aorta. *Clockwise* torque may also succeed as it points the catheter more superiorly.
4. DEEP INSPIRATION: slightly pull out of the LCx, ask for a deep breath, then quickly push and re-engage while holding the deep breath. A deep breath pushes the LAD down to the level of the down-pointing catheter.
5. Long-arm AL2 catheter, which points up.

To move the catheter from LAD to LCx, the opposite may be done (larger catheter JL4, disengage–clock–then readvance, deep exhalation, shorter-arm AL1 to point down). *A short-arm AL tends to point down (opposite of short-arm JL)*, and thus would selectively point toward the LCx. A long-arm AL points up to the LAD.

XII. Engagement of the RCA

The RCA is ~1.5 cm above the right coronary cusp, at the top of the right sinus of Valsalva, close to the sinotubular junction. To engage the RCA, advance the ***JR4 or AR1–2 catheter*** to the right cusp, similarly to the JL catheter in step 1. Touch the cusp with the catheter, to ensure you have reached it. The right cusp is the base of operation for LCA and RCA engagement and must be the starting point for engagement; this avoids starting the maneuvers too high in the aorta. Then, pull and clockwise torque 90°–180° in one motion (both the pull and clockwise motions must be coordinated) (Figure 36.23). The torque is not transmitted to the tip unless the catheter is pulled/pushed by the operator. Torquing the catheter without pull/push does not lead to any torque transmission to the tip; then, immediately as the catheter is pulled, all the excessive torque is transmitted. The key to a successful RCA engagement is a ***coordinated and simultaneous pull and torque*** (90°–180°). **Do not keep torquing the catheter if the tip remains immobile, meaning if the torque is not getting transmitted: torquing >90°–180° while the tip remains immobile causes a catheter kink** at the bend that is stopping the torque transmission. Rather, if torque transmission proves difficult, torque slowly (<90°–180°) while the left hand at the sheath level is doing a lot of short back-and-forth, pull-and-push movements (a few millimeters) to gradually transmit the torque.

Femoral vs. radial access – From femoral access, the catheter tip tends to dive down when the torque gets transmitted, hence the importance of keeping a pulling tension on the catheter as the torque is transmitted. From radial access, the catheter is much less likely to dive with torquing; in fact, the main concern is pulling the catheter out into the high ascending aorta. Thus, a slighter pull is required from radial access.

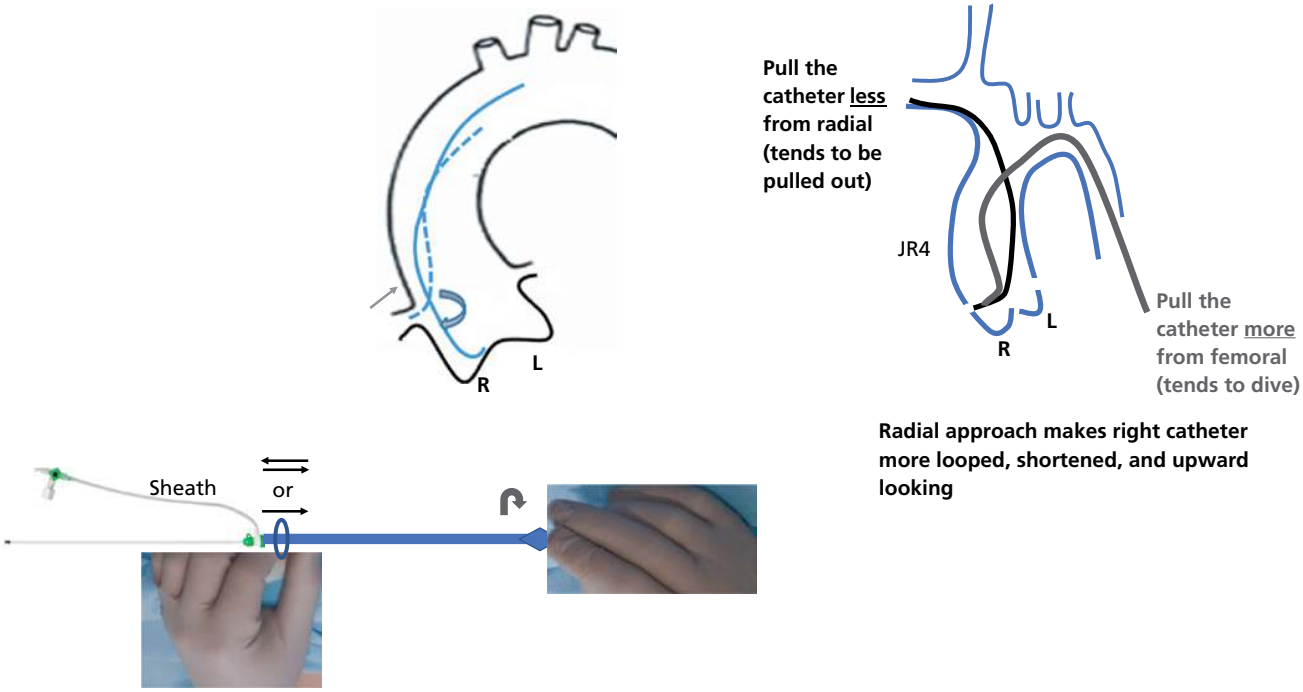

Figure 36.23 RCA is at the top of the right sinus of Valsalva, close to the sinotubular junction, ~1.5 cm above the right cusp. When engaging the RCA, start at the right cusp (lower cusp), touch it with the catheter, then pull with a clockwise torque, 90°–180°, using both hands. The right catheter tends to dive with a femoral approach, so *keep a pull tension on it during transfemoral engagement*. This is not the case with a radial approach; hence the catheter is pulled less transradially vs. transfemorally. (*Lower image*) Note the hand positioning: one hand is at the sheath level, the other hand is at the back end, and both hands are torquing and pulling. Note that *180° torque in one direction reaches a different point than 180° in the other direction*, as the movement is not linear but 3-dimensional through arterial bends. Clockwise JR4 torque tilts it and elongates it anteriorly, while counterclockwise torque tilts it posteriorly.

Tips: **(i)** If contrast puffs show the convexity of the aorta (*arrow*), the catheter is already too high, above the ostium; **(ii)** If contrast puffs show the nest of the sinus of Valsalva, the catheter is too low below the ostium; **(iii)** If the torque does not easily transmit, do not keep torquing >90°–180°: the left hand may do short pull and push maneuvers at the sheath level to transmit the torque (*arrows* in the bottom image).

XIII. The 11 pitfalls of RCA engagement

These are the 11 forms of failure to engage the RCA. They will be discussed in the next sections.

1. Catheter tip is too low below the RCA after torque transmission
2. Catheter tip lands too high above the RCA
3. Catheter is in the left cusp and you are starting your maneuvers from the left cusp, which is higher than the right (if you torque from the left cusp, the catheter will land too high above the RCA)
   OR, while torquing from the right cusp, you jump to the left cusp
4. Elongated horizontal aorta
5. Anterior RCA takeoff, especially when cusp injection does not show the RCA
6. Catheter falls in the NC cusp, especially when, similarly to (5), cusp injection does not show the RCA
7. JR4 keeps flying out after engagement, especially with breathing
8. JR4 gets over-torqued and keeps rotating 360° after engagement
9. Catheter is pointing up with pressure damping/ventricularization (conus branch engagement)
10. Severe aorto-innominate tortuosity and/or angulation with inability to transmit the torque
11. All RCA engagement attempts fail, and non-selective cusp injections in both LAO and RAO do not show the ostium: Anomalous RCA origin from the left cusp

Follow these **4 tips** whenever difficulty is encountered during RCA engagement:

- Go back down and touch the right cusp; start at this base of operation.
- The RCA is at the top of the right sinus of Valsalva. Thus, if on non-selective cusp angiography, a "nest" or "bulb" is seen, the catheter is too low; if aortic convexity is seen (tubular aorta), the catheter is too high.
- Perform non-selective cusp angiography in LAO view, to see if you are too low or too high. If RCA origin is not seen in LAO, consider cusp angiography in RAO. LAO sets apart the right (or NC) cusp vs. left cusp, while RAO sets apart anterior structures vs. posterior structures, including the NC cusp. RAO may show an *anterior RCA takeoff* missed on LAO, or may show the catheter to be in the *NC rather than the right cusp*.
- Do not keep torquing if the torque does not get transmitted to the tip, as this will cause catheter kink. Rather, torque slowly (<90°–180°) while the left hand at the sheath level is doing a lot of short back-and-forth, pull-and-push movements.

XIV. RCA pitfalls 1–3 management (Figures 36.24–36.26)

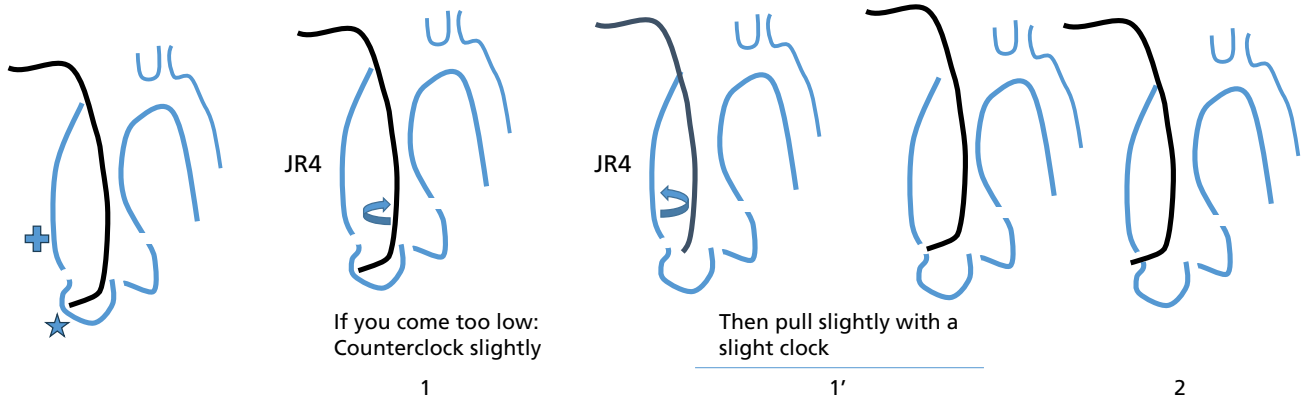

Figure 36.24 The RCA is at the top of the right sinus of Valsalva. If on non-selective cusp angiography, a "nest" is seen (*star*), the catheter is too low; if aortic convexity is seen (tubular aorta, +), the catheter is too high.

Pitfall 1: When the catheter lands too low below the RCA, do not just pull it while pointing rightward: it would fly up in the aorta. Rather, counterclock it slightly to make the tip look at you (*1*), then pull slightly with a slight clock (*1′*). After engagement, push the tip slightly to stabilize the catheter (*2*).

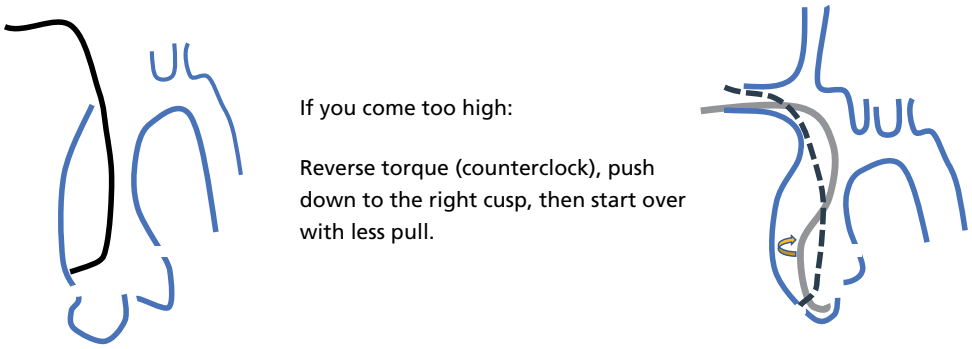

Figure 36.25 Pitfall 2. When the catheter lands too high above the RCA, do not just push it down. Rather, reverse the torque, then push it down and start over.

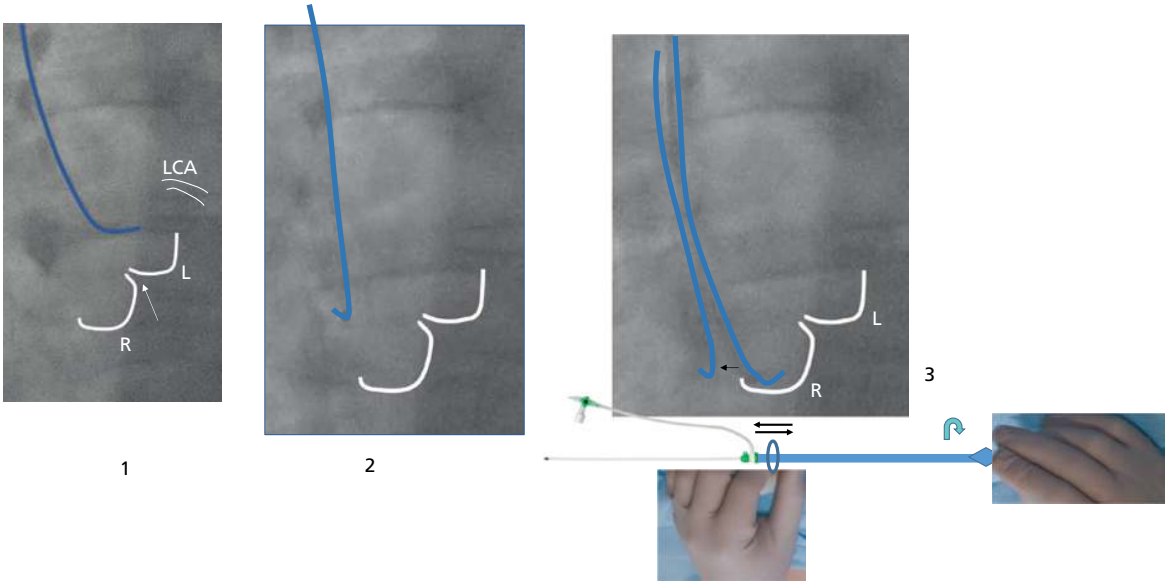

Figure 36.26 Pitfall 3. If, while torquing from the right cusp, the catheter jumps up to left cusp, what to do next?.

1. First, recognize that you landed in the left cusp, the hint being a catheter "jump" upward. This may be confirmed by a contrast puff, showing that a coronary artery (*LCA*) arises on the left of the catheter, and an inter-cusp ridge (*arrow*) on the right of the catheter. Do not try to engage from the left cusp, which is higher than the right cusp and as such, the catheter would land too high in the aorta.
2. Counterclock the catheter, making it point at you, then push it down to the right cusp, and ensure the catheter is down low touching the low right cusp.
3. Once low in the right cusp, if you clock and pull the catheter, it is likely to jump back up to the left cusp in such a patient. So, you have to ***clock and barely pull, clock while staying low, barely above the valve.*** To transmit the torque while staying low without much pulling, you may push and pull the catheter at the sheath level with your left hand (short back-and-forth movements of the catheter at the sheath level, as indicated by the *black arrows*).

Once the clockwise torque starts to transmit, and the catheter is pointing at you, then you may further clockwise torque and pull the catheter, as it is not going to jump to the left once it has built a momentum toward the right side.

XV. RCA pitfall 4: elongated horizontal aorta. How to gauge the level of the RCA origin in relation to the aortic valve level (Figures 36.27, 36.28)

In an old patient with **elongated** horizontal +/– dilated aorta: the distance between the aortic valve and the RCA origin is close to that of a normal aorta, but the level of the RCA is lower. RCA is in the same horizontal plane as the aortic valve; it is on the horizontal portion of the aorta. RCA seems to be displaced downward and is pointing more downward than usual. That is why, in those patients, one should seek the RCA origin low, at a level close to the plane of the aortic valve. *Once the catheter is at the outer curvature of the aorta* (in the vertical aorta), it is already too high above the RCA level; it should be readvanced to the aortic valve and pulled back more slowly.

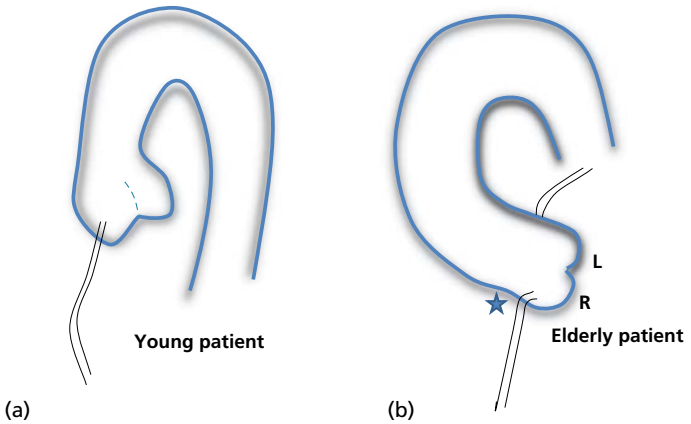

Figure 36.27 Pitfall 4. (a) Origin of the RCA in a young patient. **(b)** Origin of the RCA in an old patient with **elongated horizontal** +/– dilated aorta: the distance between the aortic valve and the RCA origin is nearly the same as in the young patient, but the RCA level is low and it seems to be displaced downward. RCA is nearly in the same horizontal plane as the aortic valve.

Tip: **The way the catheter body is shaped in the ascending aorta gives an idea about the shape of the aorta.** ***During the engagement attempt, once the catheter reaches the outer curvature of the aorta (*****star*****), it is already too high*****.***

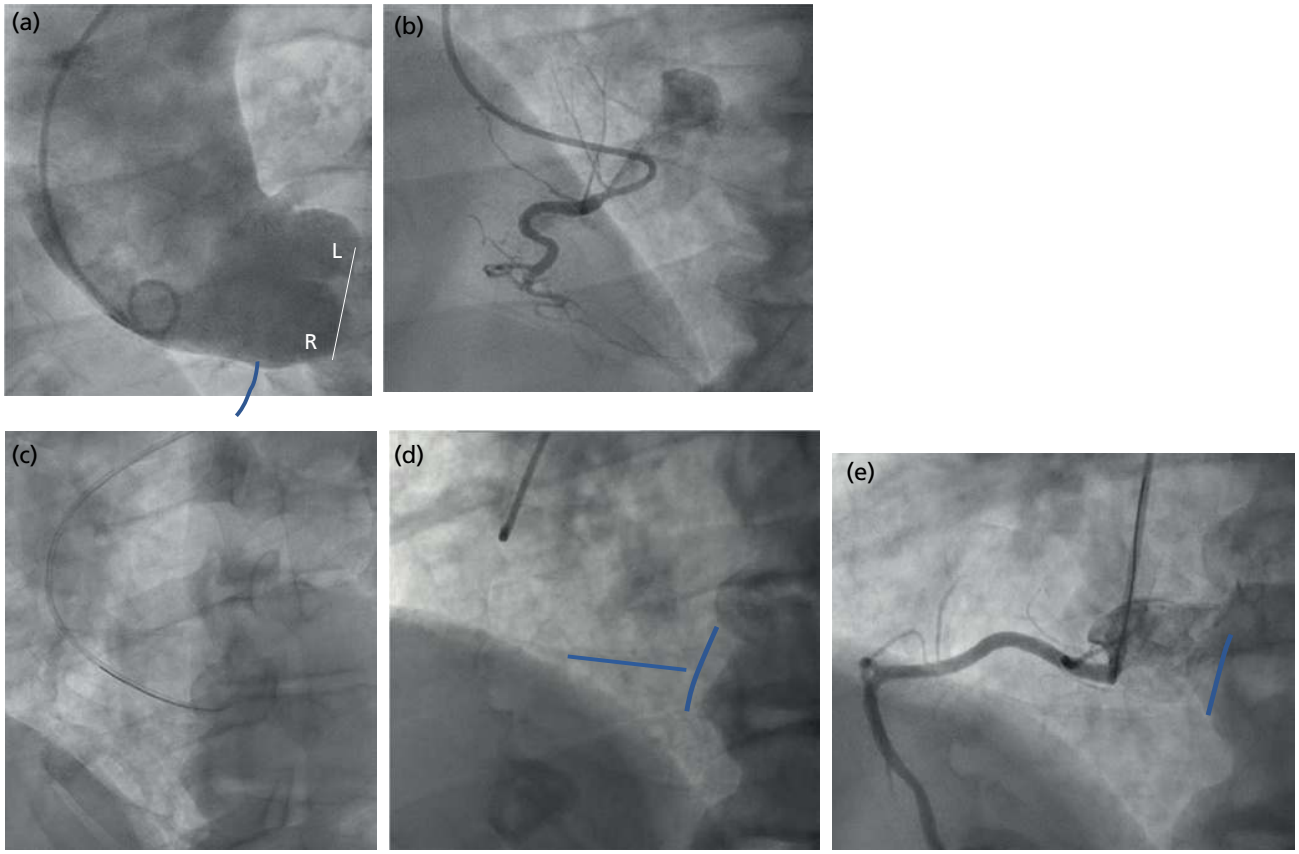

Figure 36.28 (a, b) Dilated, elongated horizontal aorta. RCA is still ~1.5–2 cm above the valve, so the catheter has to be pointed down and low on the horizontal portion of the aorta to engage the RCA. Note how the aortic valve becomes nearly vertical as the aorta elongates and falls down (*white line*).

(c–e) Another case of elongated horizontal aorta. The shape of the catheter in the ascending aorta **(c)** determines the morphology of the aorta without contrast injection. In **(d)**, the catheter level is very high relative to the horizontal portion of the aorta (*the blue lines* delineate the aortic valve and the horizontal aorta). Rather, the RCA should be sought at the bottom, close to the horizontal plane of the right cusp **(e)**. Depending the degree of aortic dilatation, an AL1 catheter may be needed to reach the RCA, as in Figure (b).

XVI. RCA pitfall 5: RCA engagement attempts fail, and non-selective right cusp injections do not clearly show the ostium. What is the most likely diagnosis, and how to manage it?

The most likely diagnosis is anterior RCA takeoff, wherein the RCA originates from the anterior right cusp, rather than the right side of the right cusp (Figure 36.29). In the LAO view, the origin of the RCA is pointing to the operator, rather than pointing to the right side of the cusp. Non-selective LAO puffs may totally miss the RCA or may show the anterior takeoff from the center of the cusp rather than its right edge. The next 2 steps are:

- Use the RAO view and point the catheter anteriorly; or, in the LAO view, make the catheter point to the center of the cusp toward the operator.
- Frequently, the JR4 catheter cannot reach the RCA origin. Switch to the AL1 catheter (or, occasionally, AR2 in patients with narrow aorta).

Notably, the same pitfall of anterior or even posterior takeoff applies to LCA engagement as well (Figure 36.30). Whenever issues are encountered in engaging the LCA (whether 3A or 3B technique) and non-selective puffs show that the ostium is close to the catheter, at the same level but in a different plane, yet multiple torque maneuvers fail to reach that plane, consider anterior or posterior LCA takeoff from the left cusp. Change the angle to RAO and sweep the cusp anteroposteriorly in the RAO view. The origin may be on the anterior side of the cusp, or the posterior side toward the inter-cusp ridge.

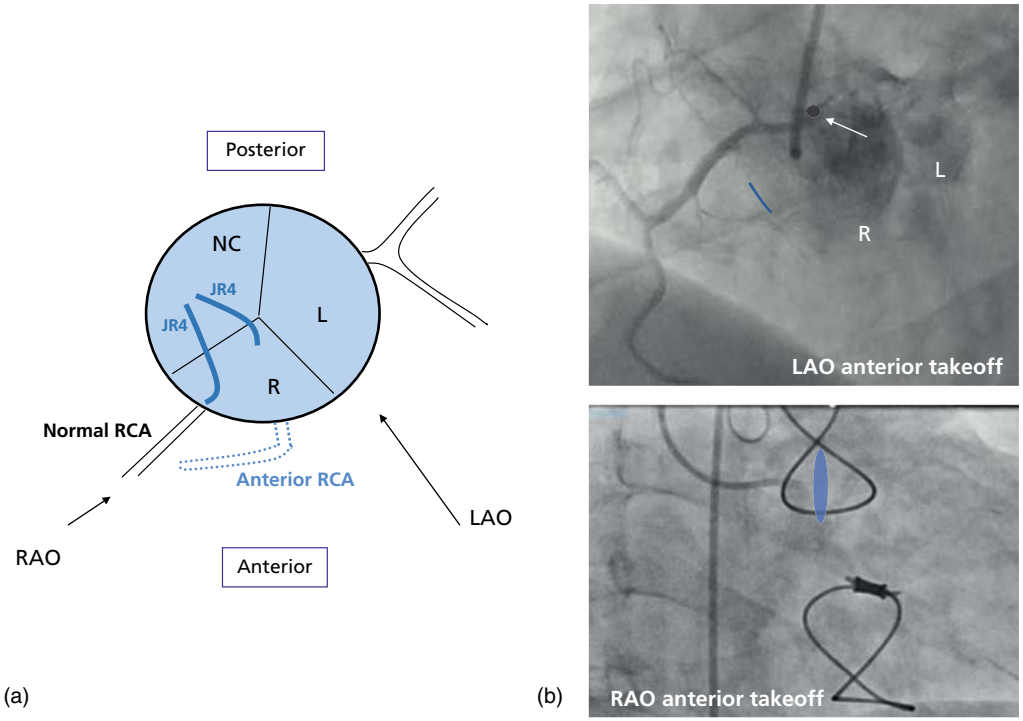

Figure 36.29 Pitfall 5, anterior RCA takeoff. **(a)** Axial cut at the level of the sinuses of Valsalva, showing anterior vs. standard RCA takeoff. Instead of LAO, RAO is orthogonal to the anterior RCA and allows easier engagement. To engage in a 30° LAO view, the catheter needs to be pointing toward the operator rather than to the right. Choose a catheter that is long enough to reach the anterior RCA. JR 4, when aiming in that direction, is too centered and short rather than elongated and eccentric. The AL1 catheter is often necessary to reach an anterior RCA, unless the aorta is narrow.

(b) In the LAO, see how the anterior takeoff is at the center of the cusp (*arrow*), rather than its edge (*blue line*), and see how the catheter needs to point toward the operator for proper engagement, i.e., toward the center of the cusp. Note how JR4 could not reach the anterior RCA ostium. The bottom image shows how the RAO view lays out the RCA origin on the anterior surface of the aorta (*blue oval*). The large AL1 is needed to reach it.

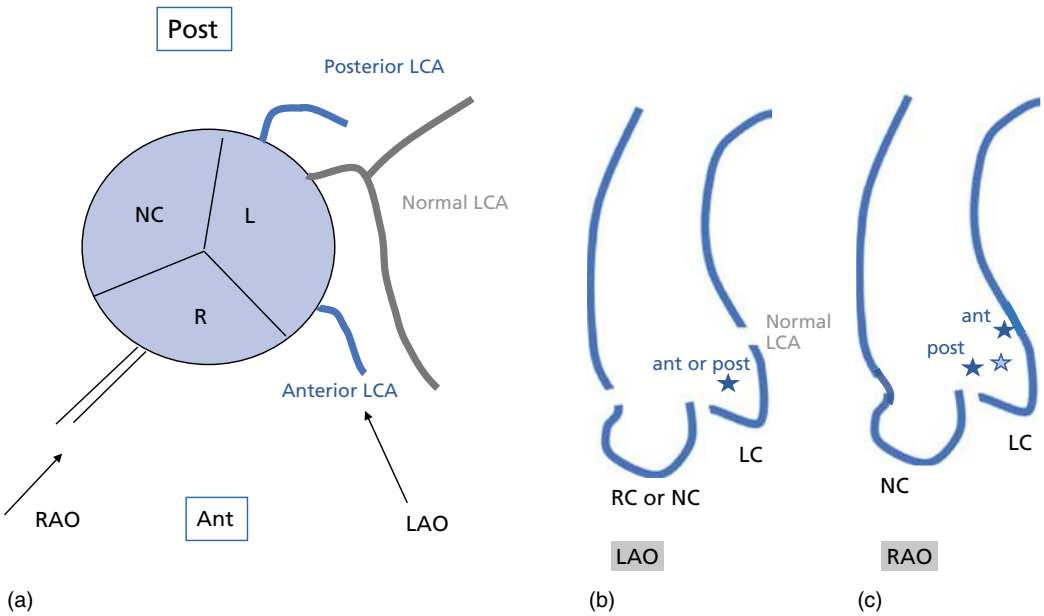

Figure 36.30 Pitfall 5 applied to the LCA. (a, b) The same pitfall of anterior or even posterior takeoff warranting the RAO view applies to the LCA takeoff as well. Whenever LCA engagement fails in the LAO view, and non-selective puffs keep showing that the ostium is near the catheter but in another plane, the takeoff is likely either anterior or posterior, pointing toward the operator or away from them in the LAO view, in the center of the cusp's projection (*star* in **b**). This is shown in **(a)** (axial cut at the level of the cusps) and **(b)** (aortic cusp configuration in LAO).

Switch to RAO and sweep the cusp antero-posteriorly in the RAO view **(c)**. LCA origin may be on the anterior side of the aorta (*ant*), or posterior (*post*) toward the ridge of the left coronary cusp, or may be in the center pointing away from the operator even in the RAO view (*lighter star*) (if it is only slightly anterior or posterior).

XVII. RCA pitfall 6: RCA engagement attempts fail, and non-selective right cusp injections do not clearly show the ostium. What is the second possibility, and how to manage it?

The 2 possibilities are: (i) anterior RCA takeoff; and (ii) the catheter, which is believed to be in the lower right cusp on LAO view, is in fact in the lowermost non-coronary (NC) cusp (Figure 36.31). To figure out this NC cusp possibility, move to RAO view and perform a non-selective puff: this would show the catheter in a posterior cusp (sinus nest and tubular aorta posteriorly, inter-cusp ridge anteriorly). Pull the catheter in RAO view to make it jump anteriorly onto the right cusp (the jump further confirms the catheter was in a posterior NC position). Then move back to LAO and confirm the catheter is indeed in the lower right cusp (not left), then engage the RCA with the standard maneuvers.

In summary, the RAO view and RAO puffs are useful in any difficult RCA engagement and sort out 2 major pitfalls: they help figure out if the catheter is in the NC cusp, or if the catheter is in the right cusp but the RCA takeoff is anterior.

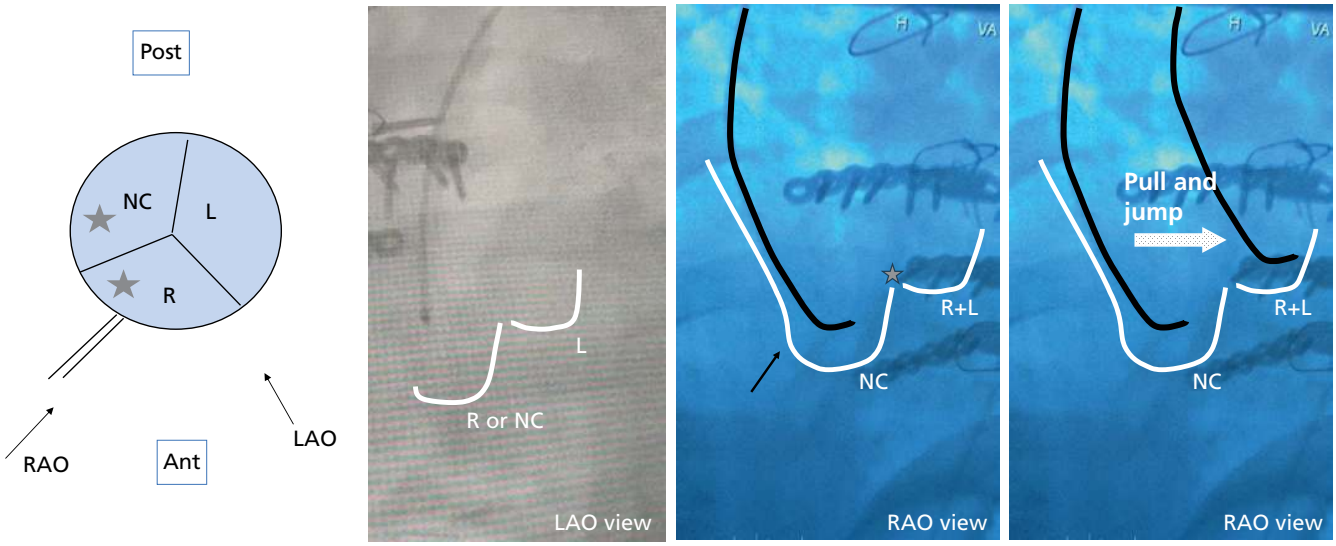

Figure 36.31 When RCA engagement fails and LAO puffs fail to show the RCA ostium, it is possible that the catheter is actually in the NC cusp rather than the presumed right cusp in LAO view. As implied on the axial cut, the **LAO view** frequently overlaps the 2 lower cusps, R and NC cusps, whereas **RAO** spreads apart the posterior NC cusp on one side, and the R and L cusps on the other side. In such a case, moving to the RAO view will confirm a posterior cusp: sinus nest and tubular aorta are seen posteriorly (*arrow*), while the inter-cusp ridge is seen anteriorly (*star*). Pull the catheter to jump anteriorly, then move back to the LAO view to ensure the catheter is still in a lower cusp (R) rather than L cusp.

XVIII. RCA pitfalls 7 and 8: unstable RCA engagement

Pitfall 7: in case JR4 keeps flying out after engagement, especially with breathing, there are 3 possibilities (Figure 36.32):

- The RCA has a standard takeoff and the catheter engagement was coaxial. Yet, the catheter flew out because it was barely in → upon re-engagement, slightly push the catheter to make it deeper and more stable.
- The catheter engagement was not coaxial and was pointing a bit anteriorly → upon re-engagement, slightly pull the catheter with a slight clockwise torque to make it coaxial, then push it deeply once coaxial.
- The RCA takeoff is anterior, hence JR4 is barely reaching the ostium → switch to AL1 catheter.

Pitfall 8: in case the JR4 is over-torqued, and keeps rotating 360° after engaging the RCA, re-attempt to engage with less torque. If a lot of torque has been used, be ready to counterclock the catheter once the torque gets transmitted and the catheter starts pointing to the right, to break the excessive catheter momentum.

Also, in cases where it is difficult to transmit the torque, rather than over-torquing, push and pull the catheter at the sheath level with the left hand while only slightly torquing (back-and-forth short movements of the catheter at the sheath level allow easier torque transmission and less risk of over-torquing) (Figure 36.23).

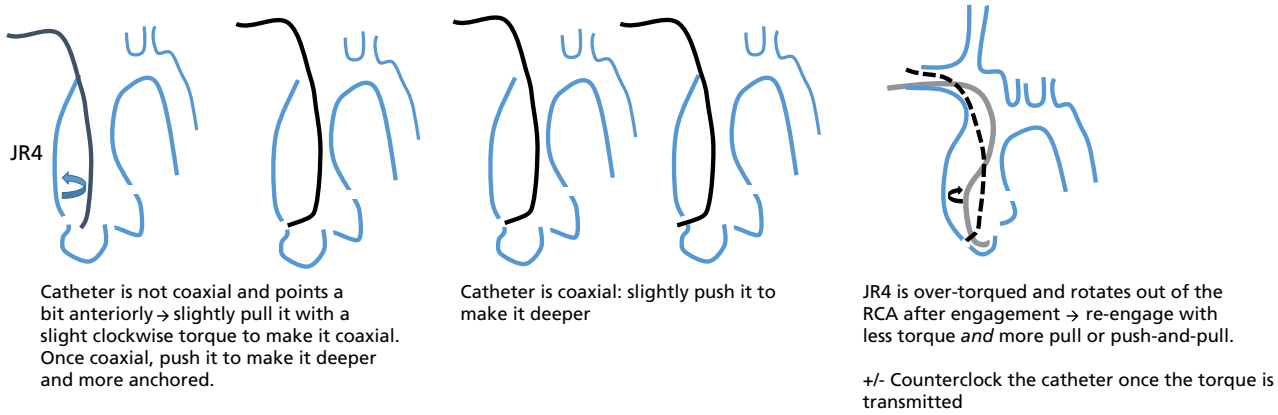

Figure 36.32 Pitfall 7: JR 4 keeps flying out after engagement. **Pitfall 8:** JR4 is over-torqued.

XIX. RCA pitfall 9: catheter is pointing up with pressure damping/ventricularization

This implies that the catheter is selectively engaged in the small conus branch and wedging it. The RCA origin is posterior and lower than the conus origin. As such, any of the following 3 maneuvers may be performed (Figure 36.33):

a. If the catheter tip is not too deep in the conus → **clock the catheter** to go posteriorly into the RCA, while simultaneously **pulling**. The extra pulling makes the catheter point down toward the RCA.

b. If the catheter tip is too deep in the conus, it is already stuck in it and further clocking is not helpful. Rather, counterclock the catheter to disengage, then engage while exerting:

- **i. more pulling on the catheter to elongate it and point it down**
- **ii.** AND **more clockwise torquing** to make it swing posteriorly

c. Get a catheter that points down: if JR4 was initially used → switch to **AR1 or JR5 or RCB** (right coronary bypass catheter)

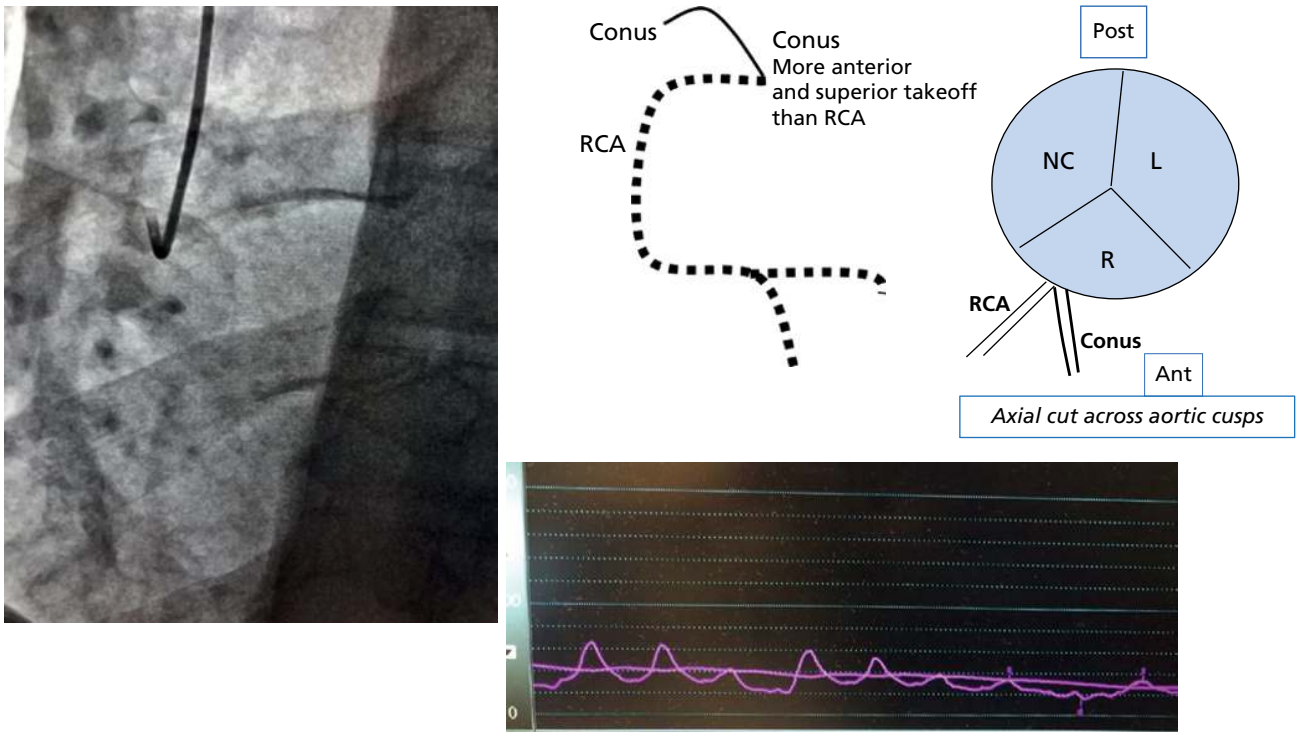

Figure 36.33 Pitfall 9. The JR 4 catheter is pointing up with catheter tip pressure damping. The catheter is in the conus branch, which is more anterior and superior-looking than the true RCA → (i) Disengage then attempt to engage the RCA with more clockwise torque and more pull on the catheter, to make it point more posteriorly and more inferiorly, or (ii) attempt engagement with a catheter pointing more downward, such as right coronary bypass (RCB) or JR5 or AR.

XX. RCA pitfall 10: severe aorto-innominate tortuosity and/or angulation (radial access) or severe aorto-iliofemoral tortuosity (femoral access), with inability to transmit the torque

To navigate the tortuosity or severe angulation, a soft polymer-coated wire (Glidewire) may be used, along with a deep breath to straighten the angulation and reach the valve level (Figure 36.34). Once at the valve level, follow these 4 tips for successful engagement of both RCA and LCA (Figures 36.35, 36.36):

- Use deep breathing throughout the maneuvers to attenuate the angulations.
- **Do not keep torquing if the torque does not get transmitted and the catheter tip does not move; this will cause a catheter kink.** Rather, torque the catheter gently with **a lot of pull and push by the left hand at the sheath level (short back-and-forth movements, a few millimeters).** Both hands should clockwise torque, while the left hand also pushes and pulls a few millimeters back and forth at the sheath level to transmit the torque. Keep doing so until the torque transmits.
- Keep the wire inside the catheter during the maneuvers, to improve stiffness and torquability, to straighten the innominate angle and allow torque transmission, and, very importantly, to prevent catheter kink. The wire remains inside the catheter but does not protrude outside the tip. Even after engagement, it is best to image while the wire is still inside the catheter: this is because when you take the wire out, the innominate angle that was straightened coils again and pulls up the catheter. A 0.035″ wire does not allow contrast injection through a diagnostic 6 French catheter, as there is not enough space inside it. Thus, it is best to **engage with a guide catheter or with a 0.018″ wire, and use a Tuohy device at the back of the catheter to inject while the wire is in place.** Administer heparin to prevent wire clotting.
- Carefully monitor the catheter pressure waveform. Any early deformation of the waveform indicates catheter kink and warrants catheter exchange. Do not wait until the waveform is too flat or distorted, at which point the catheter may have a knot and may be difficult to retrieve.

Fifth tip: In addition, consider exchanging the standard short sheath (11 cm) for a long sheath that lands in the aorta. In radial cases, switch to a **75-cm radial-to-peripheral (R2P) radial sheath** after crossing the tortuosity: this sheath keeps the tortuosity straightened and shields the catheters inside it, allowing torque transmission. In femoral cases, switch to a 45- to 55-cm Cook or Destination femoral sheath.

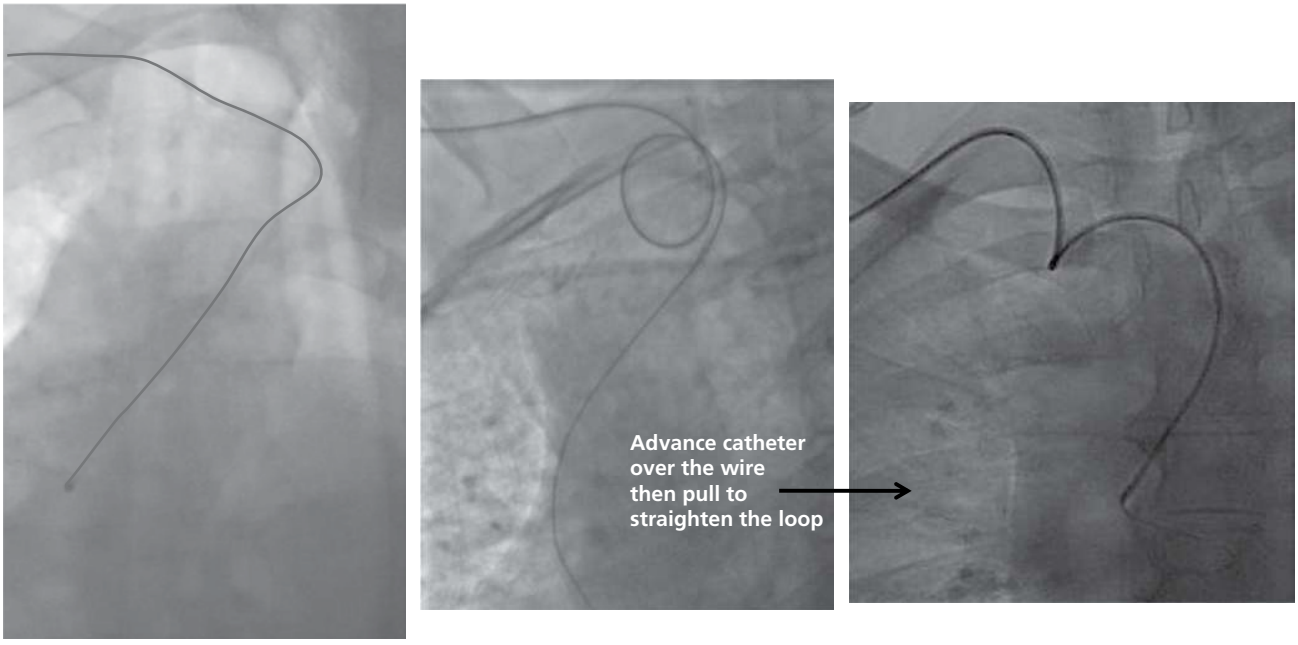

Figure 36.34 Cases of severe aorta-innominate angulation (*left image*) and tortuosity (*middle and right images*). Cross the tortuosity with deep breath, a *polymer-jacketed 0.035″ Glidewire, and a soft 4–5 Fr catheter. Exchange for a stiffer wire* (e.g., Rosen, or even stiffer, Amplatz) to allow advancement of larger catheters. Consider advancing a long hydrophilic radial sheath, such as the **75-cm radial-to-peripheral sheath**, to cross the tortuosity, keep it straightened, and allow torque transmission of catheters shielded inside the sheath.

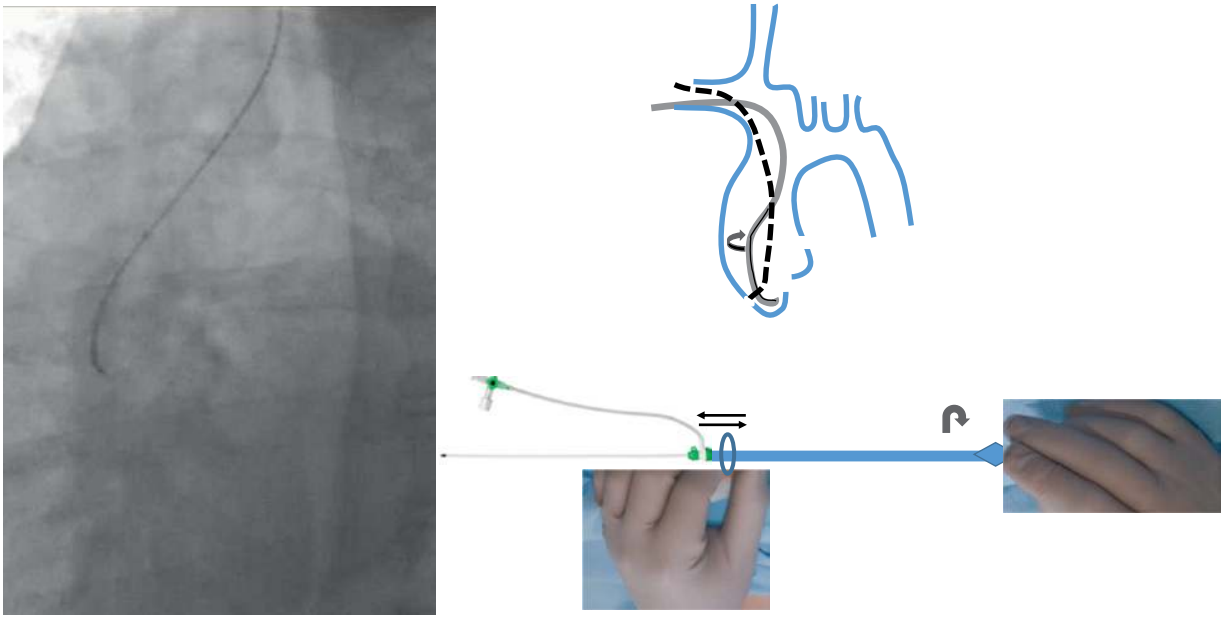

Figure 36.35 Pitfall 10. First major tip to transmit the torque in difficult cases: Do not keep torquing if the catheter tip remains in place; rather, gently torque with a lot of pull and push, short movements by the left hand at the sheath level. Both hands are clockwise torquing, while the left hand is also pushing and pulling a few millimeters back and forth to transmit the torque. Keep doing so until the torque transmits.

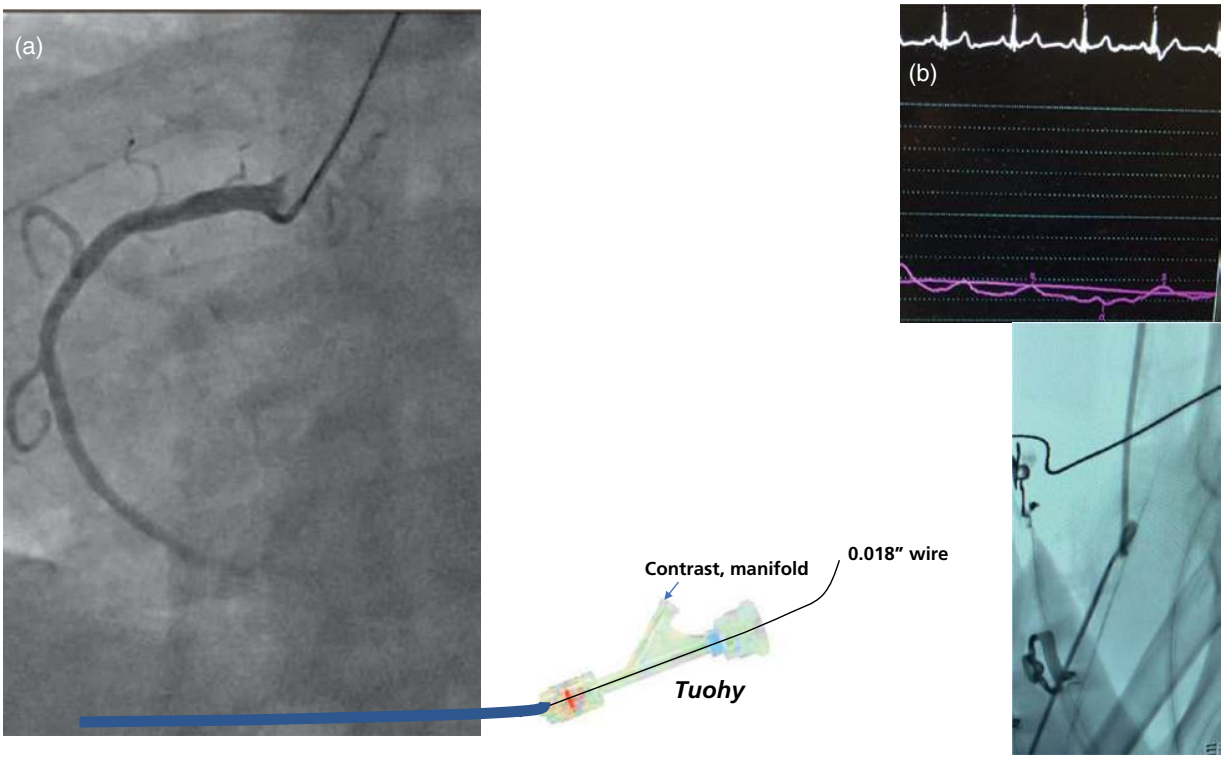

Figure 36.36 (a) Second major tip for torque transmission: engage with a guidewire inside the catheter, preferably 0.018″ or stiff 0.014″ wire that is kept inside the catheter during contrast injections. A Tuohy tool is placed at the back of the catheter to allow simultaneous contrast injection while the wire remains inside the catheter. **(b)** Carefully monitor the pressure waveform: early alterations indicate catheter kink. Stop torquing as soon as any mild pressure alteration is seen and exchange the catheter. Do not wait until the pressure is too erratic or flat as in this figure, at which time the catheter is too kinked or knotted and difficult to remove.

XXI. RCA pitfall 11: all RCA engagement attempts fail, and non-selective cusp injections in both LAO and RAO views do not show the ostium

In this case where RCA cannot be seen even after aiming for a potential anterior right cusp takeoff and using the RAO view, the final thought is anomalous RCA arising from the left cusp. Move the catheter to the left cusp and perform left cusp angiography in both the LAO and RAO views to figure out whether the ostium is: (i) close to the LCA and best seen in LAO view, in which case a hint of it is frequently seen during left coronary angiography; (ii) far from the LCA, over the anterior left cusp, and best seen in RAO view (Figures 36.37, 36.38).

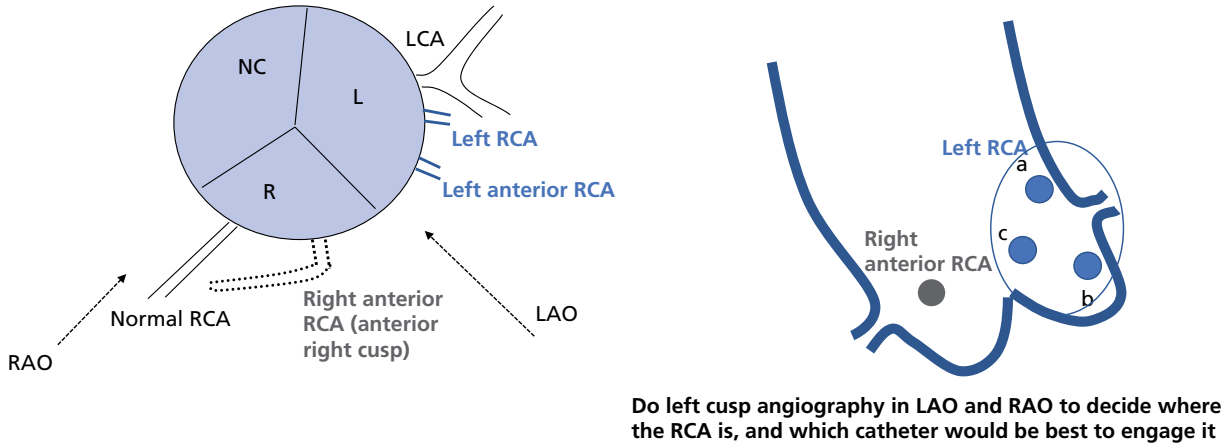

Figure 36.37 Pitfall 11. Anomalous RCA arising from the left cusp, on both axial and longitudinal cusps' view. Distinguish left-cusp RCA from right-cusp anterior RCA. The left-cusp RCA may be close to the LCA ostium and indirectly visible during LCA angiography (*a*, *b*), or may rather be anterior (*c*):

a. RCA that arises from the left cusp with a superior configuration is often best engaged with a **short Judkins left (JL) (e.g., JL3 or EBU 3) that is looped upward**.
b. The inferior configuration is often best engaged with **a short JL or EBU catheter, like (*a*)**, but looking straight down rather than looped upward.
c. The anterior configuration is often best reached with an AL catheter, often larger than AL1.

Those are general rules; reaching the superior configuration (*a*) may require looping of a larger JL (e.g., JL5) in some cases.

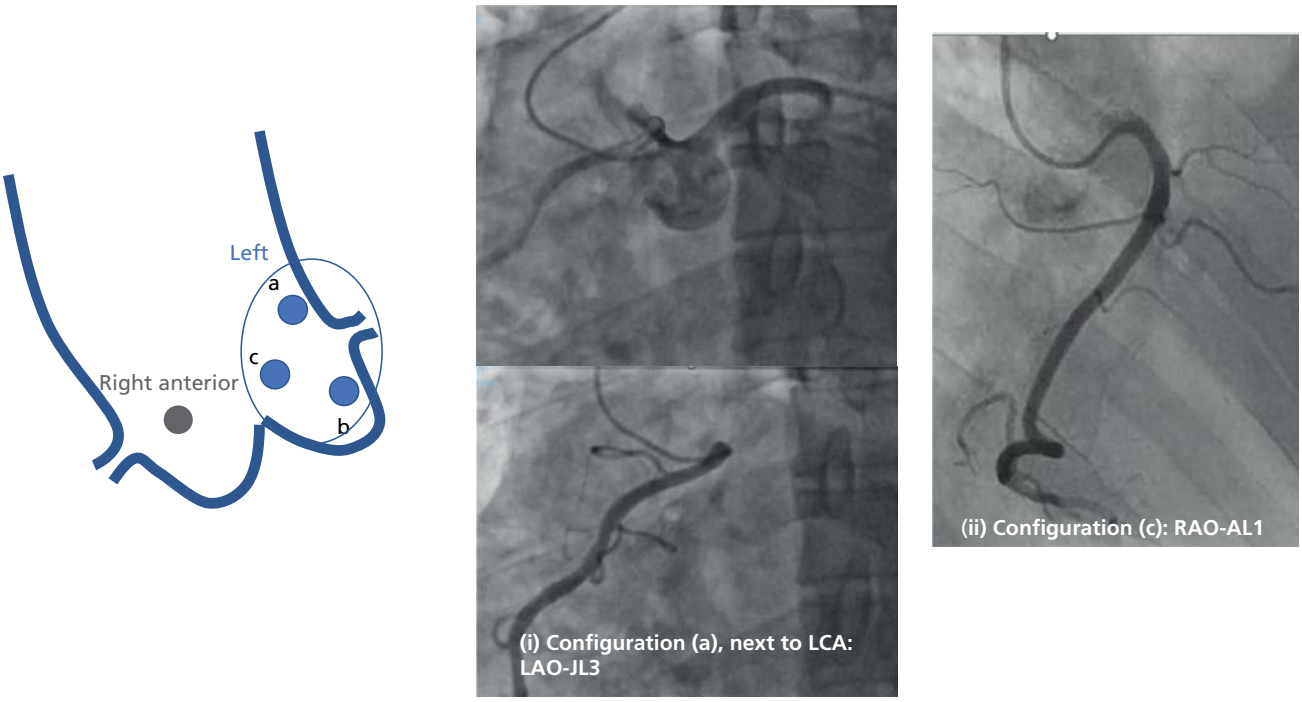

Figure 36.38 (i) Anomalous left-cusp RCA with left superior configuration (*a*), partially visualized during LCA angiography (*top image*). It is engaged in LAO view with Judkins left (JL) 3. **(ii)** Anomalous left-cusp RCA with anterior configuration (*c*), not seen during LCA angiography. The RCA takeoff is pointing toward the anterior aortic wall in the RAO view. The AL1 catheter is needed. In this RAO view, the left-cusp anterior RCA looks like the benign right-cusp anterior RCA. The LAO view distinguishes right cusp vs. left cusp origin (as on the *left image*).

XXII. Selective engagement of SVGs: general tips

It is important to obtain the surgical report and review prior grafts angiograms. At least review prior CXRs, to see whether the grafts have radio-opaque markers. Even in CABG patients with planned invasive angiography, pre-planning with CTA eliminates engagement efforts of occluded grafts and reduces procedural time, peri-procedural MI, access complications (via higher rate of radial artery access), and even the overall contrast volume (BYPASS-CTCA trial).

To engage SVGs, it is important to understand their locations and takeoffs (Figure 36.39).

a. From bottom to top, one finds SVG-to-RCA, then SVG-to-LAD or diagonals, then SVG-to-OM.
b. The SVG-to-RCA originates from the right surface of the aorta, above the RCA and often posterior to the plane of the RCA
The SVG-to-LAD or SVG-to-diagonal branch originates from the anterior surface of the aorta.
The SVG-to-OM originates from the left anterolateral surface of the aorta.
c. The SVG-to-RCA has a downward takeoff, whereas the SVGs to the left coronary branches have an upward takeoff (particularly upward in the case of SVG-to-OM).

Knowing these ideas of location and morphologies of SVGs, there are always 4 steps for every SVG graft angiography:

1. **Which view to engage** (Figure 36.40)
2. **How to torque**
3. **Which catheter (how it points)**
4. **Which views for imaging:** the view used to engage + another view that is good for the native target

The SVG-to-RCA is best engaged in an LAO view, which is orthogonal to this SVG takeoff. SVGs to the left coronary branches are best engaged in an RAO view, which is orthogonal to the takeoff of these SVGs (Figures 36.39, 36.40) (***R*ight SVG → *L*AO; *L*eft SVG → *R*AO).**

When rings are attached to the SVGs, engage each SVG in a view orthogonal to the ring, i.e., a view where the ring is seen as a straight column.

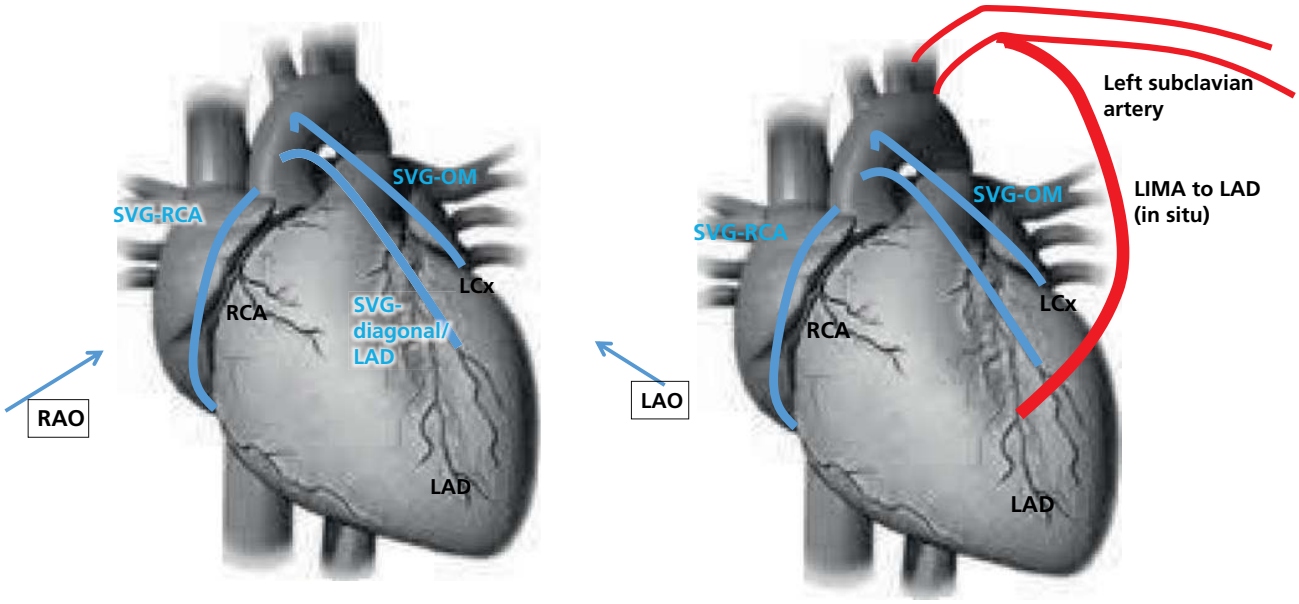

Figure 36.39 Three major anatomical ideas regarding SVGs:

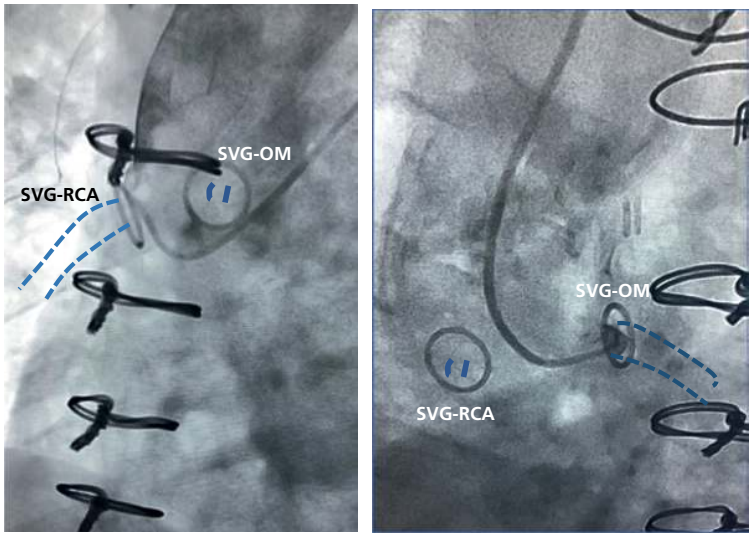
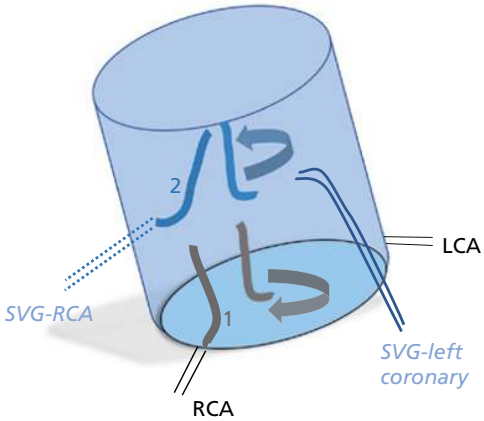
- Down to up: SVG-to-RCA, SVG-to-LAD or diagonal, then SVG-to-OM
- Right to left: SVG-to-RCA, SVG-to-LAD or diagonal, then SVG-to-OM
- Inferior takeoff for SVG-to-RCA. Superior takeoff for SVG-to-LAD or diagonal and, more so, SVG-to-OM

The LAO view is orthogonal to the takeoff of SVG-to-RCA, while the RAO view is orthogonal to the takeoff of SVG-to-left coronary branches. LIMA is an in situ graft that arises from the left subclavian.



LAO RAO



SVG-RCA vs. RCA

Figure 36.40 The *LAO view* is orthogonal to the marker of *SVG-to-RCA*, perfectly laying out the ostium as it comes off the aorta. The view may be angled further LAO until the marker becomes one line. In LAO, *SVG-to-OM* is looking at you, making it difficult to engage.

RAO view is orthogonal to the marker of SVG-to-OM. RAO is in line with the SVG-to-RCA.

(Right image) Clockwise torque of a standard catheter (e.g., JR4), tilts it anteriorly (→ toward the native RCA = 1), while counterclockwise torque tilts it posteriorly (→ toward SVG-to-RCA = 2). Clockwise torque may also tilt it anteriorly toward left SVGs. Note that 180° torque in one direction reaches a different point than 180° in the other direction.

XXIII. Specific torque maneuvers for engaging the SVGs

To engage the SVG-to-RCA, the catheter is positioned above the level of the RCA, then pulled with a counterclockwise rotation. As opposed to what may make intuitive sense, counterclockwise torquing is used to engage the SVG-to-RCA rather than clockwise torquing (this is opposite to native RCA engagement) (Figure 36.40).

Explanation: Counterclocking a catheter 180° does not reach the same point as clocking it 180°. Imagine the catheter movement three-dimensionally: counterclocking JR4 reaches a parallel but more posterior plane compared to clocking (Figure 36.40). SVG-RCA is on the right surface of the aorta but often posterior compared to the native RCA; only when it is anterior, clocking may successfully engage it.

To engage an SVG to a left coronary branch, advance the catheter down to the aortic valve, torque it counterclockwise, then pull up and torque clockwise around the expected level of the graft.

Overall, a *counterclockwise* torque is often necessary for right SVGs, and a *clockwise* torque around the graft level is necessary for left SVGs. However, this is not always the case, particularly for left SVGs: both counterclockwise and clockwise torques are often needed, while maintaining a catheter aim toward the anterior aortic wall in RAO view.

If, after engaging one SVG, the catheter keeps falling in this same SVG as one is trying to engage other SVGs, what should be done next?

The catheter needs to be moved out of the curvature that keeps leading it into the first SVG. The catheter should be pulled up a few centimeters above this SVG, torqued clockwise or counterclockwise about 90°–180° to get out of the same curvature, then advanced to the level where the other SVG is thought to be. Appropriate torquing is then performed at this level. For example, if the catheter keeps falling in the SVG-to-diagonal when one is trying to engage the SVG-to-OM, withdraw the catheter, torque it counterclockwise at a high level, then advance it and clockwise torque it at the expected SVG-to-OM level (above the SVG-to-diagonal level).

XXIV. Appropriate catheters for engaging SVGs (see Figures 36.41–36.44)

A. SVG-to-RCA

Since this graft has an inferior takeoff, a catheter pointing down is necessary for engagement:

1. A multipurpose catheter is the most appropriate catheter for this graft. It points down and has a long supportive tip that dives deeply and coaxially into the SVG.

2. AR1 and right coronary bypass (RCB) catheters are alternatives. The RCB catheter is somewhat similar to JR4, except that its short tip points down.

JR4 points slightly up and thus does not usually provide appropriate diagnostic images; the contrast may spill out and give the impression of a non-filling, occluded graft. Moreover, JR4 is certainly not an appropriate interventional guide for this SVG.

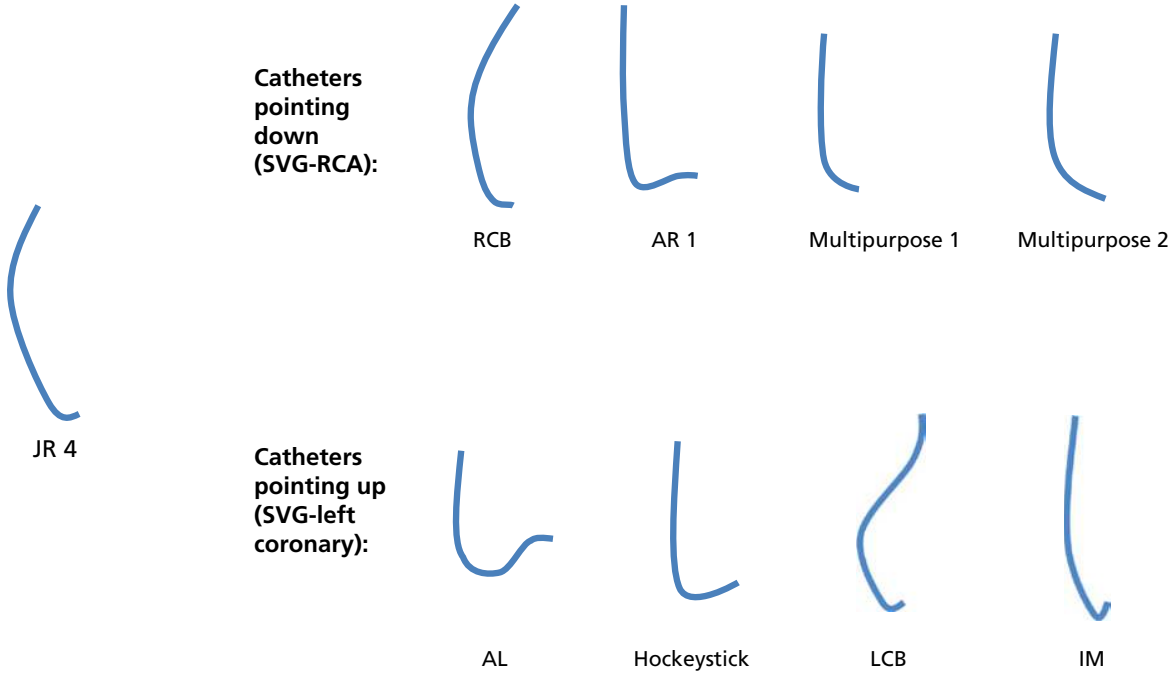


Figure 36.41 Shapes of various catheters.

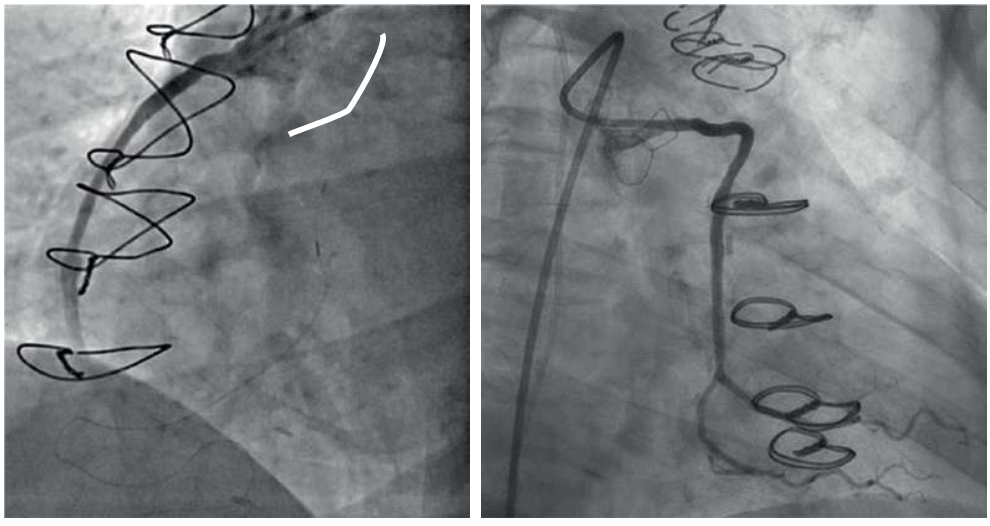

-MP guide for SVG-RCA
-RCB may also be used

Left SVG: -AL (1, 1.5, 2) is best guide
-JR4, LCB, IM are acceptable for diagnostic angiogram

Figure 36.42 *(Left)* Multipurpose (MP) catheter engaging SVG-to-RCA and pointing downward, providing deep coaxial support. It is pointing to the right surface of the aorta in LAO view. *(Right)* AL1 guide engaging SVG-OM, pointing to the anterior surface of the aorta in RAO view.

B. SVGs to the left coronary branches

JR4 is often an appropriate diagnostic catheter for the left-sided SVGs. However, since these SVGs have a superior takeoff, JR4 is not an appropriate interventional catheter. Guiding catheters pointing up are usually necessary for SVG intervention:

1. AL1.5 or AL2 (depending on the aortic size) is the preferred and most supportive catheter (Figures 36.42–36.44).
2. A left coronary bypass (LCB) catheter (short-tip catheter pointing up), a hockeystick catheter, or an internal mammary catheter may be used for the SVG-to-LAD or diagonal, which tends to have a less superior takeoff than the SVG-to-OM. However, for PCI, those catheters are less supportive than AL and less favored. The LCB catheter is somewhat similar to JR4, except that its short tip points up.

If whichever guide catheter is chosen is not supportive enough, add a Guideliner to create a large and supportive AL shape sitting on the opposite aorta.

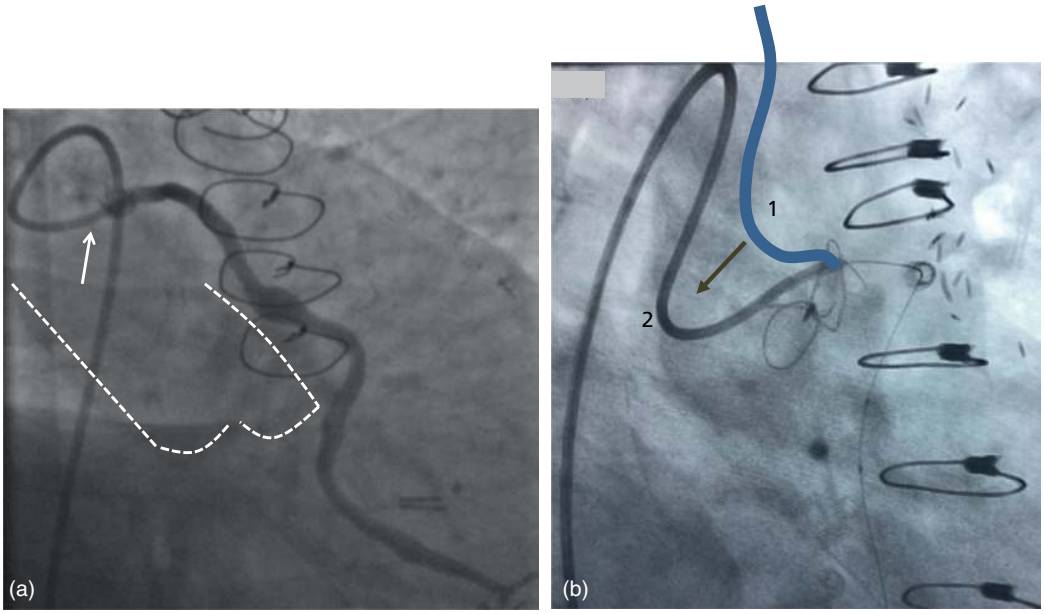

Figure 36.43 **(a)** A hockeystick-2 guide catheter is used to engage the SVG-to-OM graft in an RAO view. The long arm of the hockeystick-2 points slightly upward (*arrow*), which proves very useful in left-sided SVG interventions. It allows both coaxial and backup support. **(b) AL2 guiding catheter is used to engage SVG-to-OM** in an RAO view. (*1*) The AL2 is advanced in its flat, elongated shape into the ascending aorta, and the tip is geared toward the SVG ostium, high in the aorta (encircled by a graft marker). (*2*) After the tip catches the ostium, the catheter is pushed until it adopts its "duck" shape, with backup support from the opposite aortic wall (catheter moves from *1* to *2*).

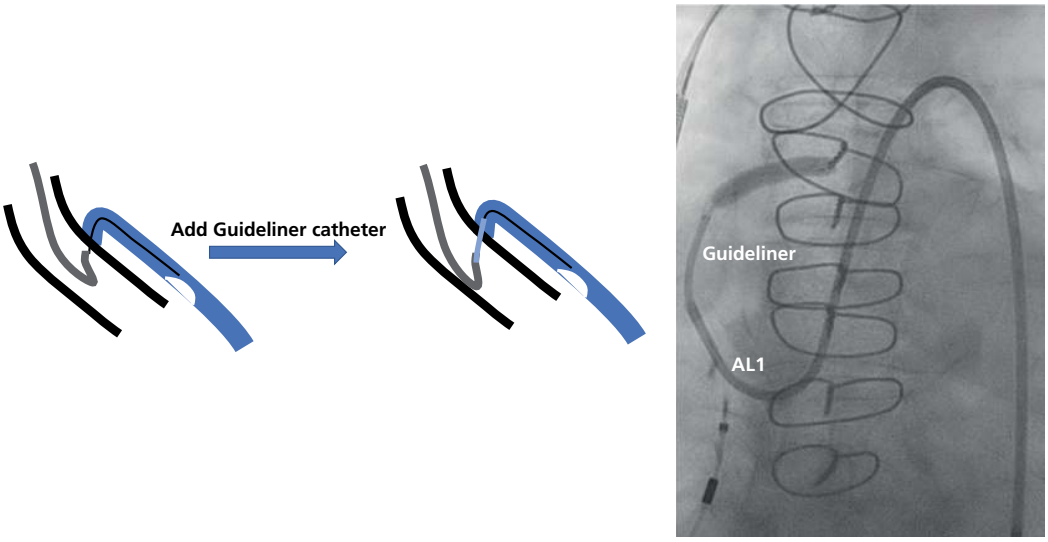

Figure 36.44 In difficult left SVG PCI, where the graft has a shepherd-crook upslope, use AL catheter for PCI. If AL is relatively small and does not abut the aorta, and if more support is needed, add a Guideliner catheter (*light blue, middle image*) to create a larger and more supportive AL shape sitting on the opposite aorta. *Guideliner converts a poorly engaged unstable guide into a large AL (middle and right images).*

XXV. Engagement of the left internal mammary artery graft from a femoral access

Left internal mammary artery (LIMA) engagement from femoral access requires 2 major maneuvers: left subclavian engagement followed by LIMA engagement. Following are the steps necessary to engage the LIMA graft from a femoral access (Figure 36.45):

1. Position a JR4 catheter in the aortic arch, then pull it back with a ***counterclockwise*** rotation until the left subclavian artery is engaged. This is performed in the LAO view, because the LAO view opens up the aortic arch and the origins of the major vessels.
2. Advance an exchange-length wire into the left subclavian artery with the support of JR4.
3. If the subclavian artery is very tortuous, a polymer hydrophilic wire (soft Glidewire) is used to maneuver through the left subclavian artery and JR4 tracks over it. Glidewire is then exchanged for a more supportive exchange-length wire.
4. JR4 catheter is exchanged for the more sharply bent internal mammary (IM) catheter. Advance the latter over the wire beyond the bend of the subclavian artery.
5. An AP or RAO view may be used to selectively engage the LIMA. The RAO view foreshortens the subclavian artery but is orthogonal to the LIMA takeoff. Pull the IM catheter with a slight ***counterclockwise*** torque until it engages the LIMA (*clockwise torque from left radial*). The aim is to point the catheter *down*. During this process, inject small puffs of contrast to identify where the LIMA originates. LIMA often originates *around the subclavian bend*, but it may originate a bit more distally or proximally before the bend. ***The LIMA is between the vertebral artery and the thyrocervical trunk***. Seeing the thyrocervical trunk during a puff injection indicates a need to pull the catheter *slightly* more and make it point farther down.

Occasionally, if the aorta and the subclavian artery are too tortuous, leave the 0.035″ wire inside the IM catheter during torque manipulations (but not outside the tip) to provide more stiffness and allow more torque transmission to the catheter. A 0.018″ wire with a Tuohy device at the back of the catheter may be used, as described under Section XX. Also, make sure a long 45- to 55-cm sheath is advanced in the aorta for support.
6. After obtaining the LIMA views, the catheter is disengaged and pullback pressure recorded across the ostium of the left subclavian artery. One of the most common causes of ischemia in the LIMA-to-LAD territory is left subclavian stenosis, hence this should be systematically checked.

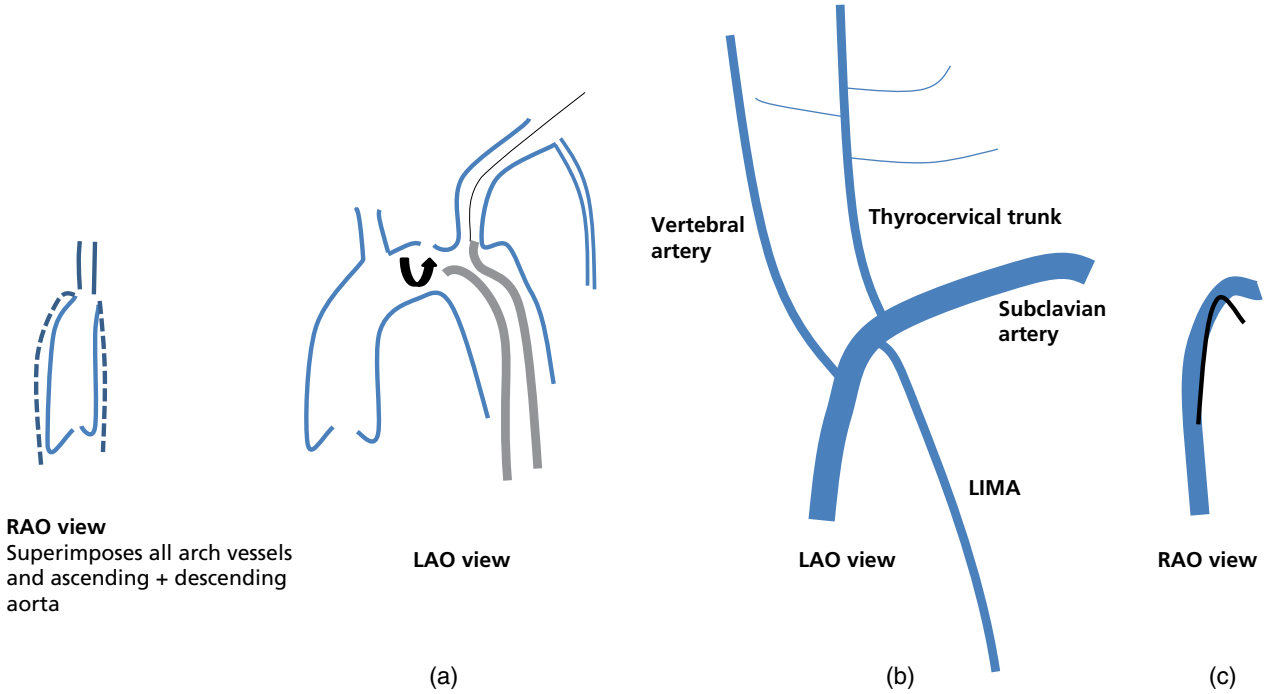

Figure 36.45 **(a)** Engagement of the left subclavian artery with a JR 4 catheter (*counterclockwise*), followed by wire advancement into the left subclavian artery, then catheter exchange for an IM catheter. This is done in LAO view, which opens the aortic arch, unlike RAO +/– AP view wherein all the arch branches are superimposed. **(b)** LIMA is between the vertebral artery and the thyrocervical trunk, at the subclavian bend. LIMA origin is usually very close to the thyro-cervical trunk, almost at the same level, but points down instead of up. **(c)** The engaged IM catheter is shown in an RAO view, which foreshortens the subclavian artery but opens the anterior ostium of the LIMA.

Additional tips:

- If the LIMA graft proves difficult to engage, do not persevere in the engagement attempts, as there is a risk of dissecting the LIMA ostium. Perform non-selective imaging near the LIMA ostium, with a relatively higher volume of contrast (e.g., 5 ml/s for 12 ml). In addition, inflate a blood pressure cuff across the left arm and perform the contrast injection at the peak cuff inflation. This diverts the non-selective contrast into the LIMA.
- If the left subclavian artery proves difficult to engage, perform an aortic arch angiogram to analyze its takeoff. It is likely that the aortic arch is a steep type III arch, with the left subclavian artery originating more proximally than thought, proximal to the aortic arch bend, *on the aortic upslope* (Figure 36.46).
- When the LIMA needs to be engaged for interventional purposes and difficulty is encountered, a 0.014″ hydrophilic or a soft coronary wire is used to selectively enter the LIMA, then the guide is gently tracked over this wire or over a ballon catheter.

The *right internal mammary artery (RIMA)* is engaged using the same steps as the LIMA, with a *counterclockwise* torque to enter the right innominate artery in an LAO view. However, afterward, an RAO caudal view may be needed to open the subclavian–carotid bifurcation and allow wiring of the right subclavian artery. Once the IM catheter is advanced into the subclavian artery, AP/LAO view is more appropriate to cannulate the ostium of the RIMA, and the catheter needs to be *clockwise* torqued rather than counterclockwise torqued.

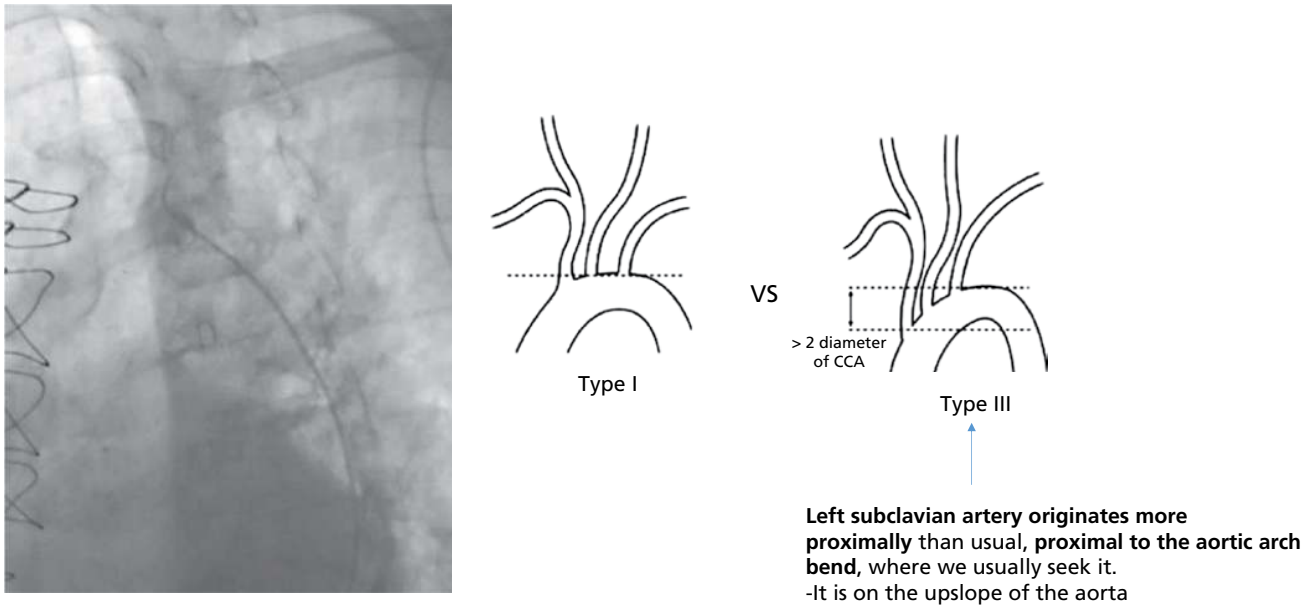

Figure 36.46 This left subclavian artery is arising on the upslope of the aorta, rather than the flat horizontal portion where we usually aim for it, in a patient with type III aortic arch. Whenever you fail with left subclavian engagement, seek it on the upslope of the aorta.

XXVI. Engagement of the left internal mammary artery graft from a left radial access

LIMA is generally easier to engage from a left radial access compared to the 2-step transfemoral engagement. A sharply angled BC catheter is directly advanced into the proximal left subclavian, then pulled back across the subclavian bend usually with a *clockwise* torque to make it point down (unlike the usual counterclockwise torque from a femoral access) (Figure 36.47). BC catheter has a narrower angle or hook than the IM catheter and is preferred to IM from a left radial access; as it is pulled, the catheter gets spread out and loses some of its tip acuity, hence the importance of starting with a very acutely angled tip, more so than the IM.

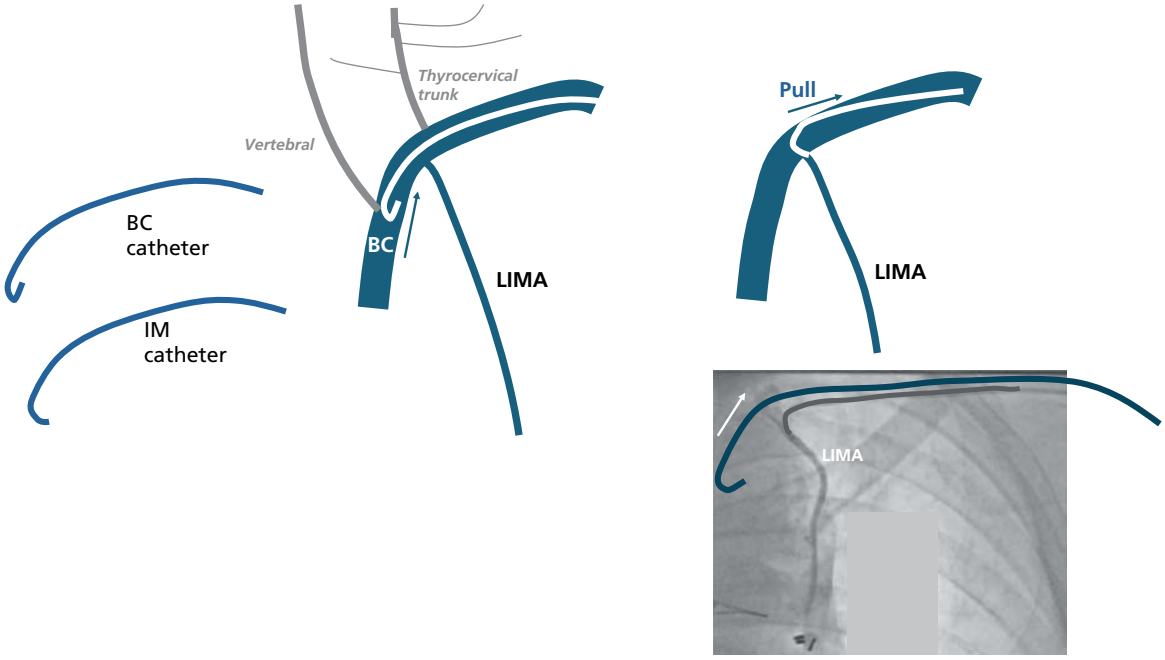

Figure 36.47 LIMA engagement from a left radial approach: a sharply bent BC catheter is advanced past the LIMA takeoff, in a bent way, then pulled back so it catches the takeoff. Generally, a *clockwise* maneuver is used; however, it is most important to use whatever torque is necessary to point the catheter tip down, away from the thyrocervical trunk, whose takeoff is very close but superior to the LIMA. From left radial access, a catheter that is more sharply bent than an IM catheter is needed, such as the BC catheter, as the catheter tip gets spread out during the pull. The IM catheter tip would end up getting spread too obtuse and flat from a radial access.

XXVII. Engagement of the SVGs from a left or right radial access

During transradial engagement of native coronary arteries, the ascending aorta provides a long supportive platform that prevents the catheters from flopping and falling in the aortic arch. This is not the case with short and sharply angled aortas, and not the case during SVGs engagement, as SVGs are placed higher up in the ascending aorta, close to the aorta-subclavian bend, with less of a supportive vertical platform. SVGs are engaged immediately after the sharp aortic bend, which creates more propensity for the catheter to straighten and fly out of the ascending aorta. The aorta provides better support and longer platform when engaging right grafts, which are lower on the aorta, compared to left grafts (Figure 36.48).

Left radial access presents nearly the same challenge as right radial access for SVGs engagement. In both accesses, the loss of support is even more relevant if one tries not just to image but to intervene.

The same catheters used transfemorally are also used to engage SVGs from a right or left radial access, especially RCB or MP for right grafts, and AL1–2 +/– JR4 or LCB for left grafts (large AL for left SVG PCI).

It is easier to engage the LIMA from a left radial access compared to a femoral access, but it may be slightly harder to engage SVGs. It is the author's preference to perform most graft studies using left radial access rather than femoral access, particularly when there are graft markers or the graft anatomy is known.

Note the 2 types of SVG markers (Figure 36.49).

XXVIII. Major tips in native angiography that assist with graft mapping. How to report graft cases

During native coronary angiography of patients with grafts, watch for the following 3 findings (Figure 36.50):

1. **Competitive flow** suggests patent graft (although it may be stenotic). However, the lack of competitive flow does not necessarily imply graft occlusion, as the graft to that region may be connected to a branch disconnected from the native system (e.g., another OM).
2. Upward lift on a major coronary branch suggests a graft is attached to that branch.
3. **Collateral flow.** A lack of collateral flow to a major, missing coronary branch or territory suggests that there is a patent graft to that territory.

In addition, during graft angiography: (1) analyze retrograde filling of the grafted branch (e.g., OM) and its major artery (e.g., LCx), besides antegrade filling of the branch; (2) superimpose native and graft anatomy to understand the perfusion of each of the 3 major coronary territories, i.e., map the global coronary perfusion.

As such, graft angiography cases are best reported in terms of perfusion of each of the 3 major territories, with particular attention to where retrograde graft perfusion stops and how many branches it feeds retrogradely (Figure 36.51, case illustration).

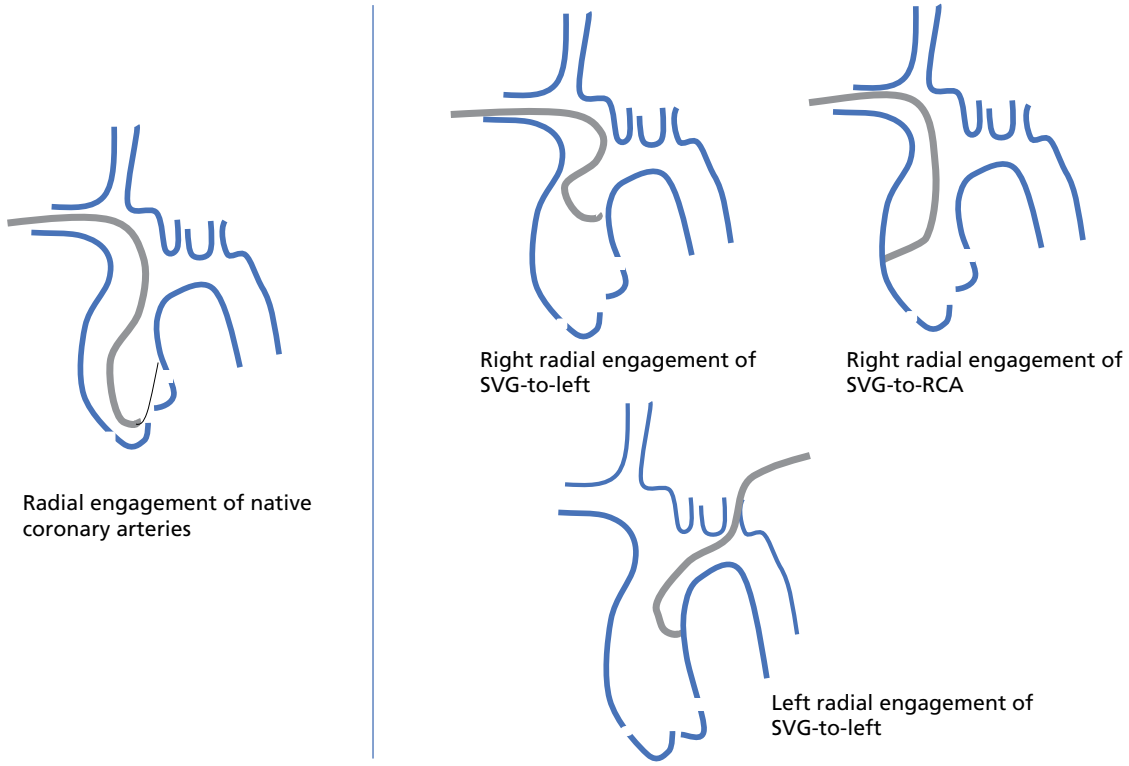

Figure 36.48 Radial access for SVGs. Compared to native coronary engagement, the ascending aorta no longer provides a long supportive platform during SVGs engagement, as SVGs are higher up in the ascending aorta, close to the aorta-subclavian bend. We try to engage the SVGs immediately after the sharp aortic bend, hence the vertical platform is shorter and less supportive. The ascending aorta provides better support and longer platform when engaging right grafts, which are lower on the aorta.

Left radial access presents nearly the same challenge as right radial access for SVGs engagement but facilitates LIMA engagement.

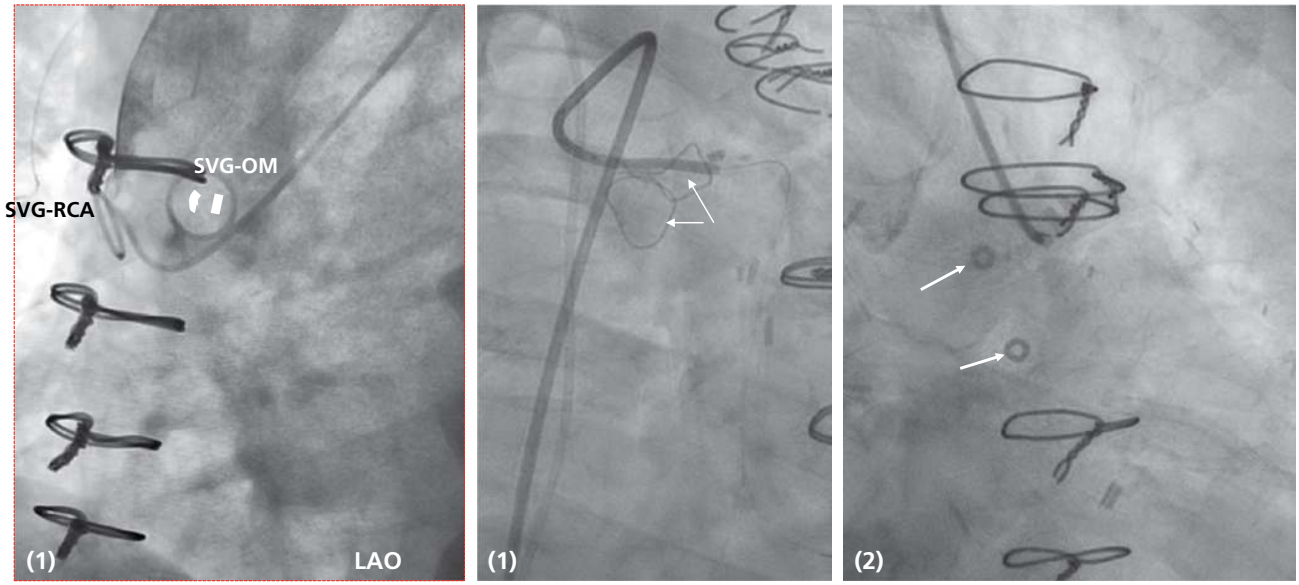

Figure 36.49 There are 2 major types of markers:

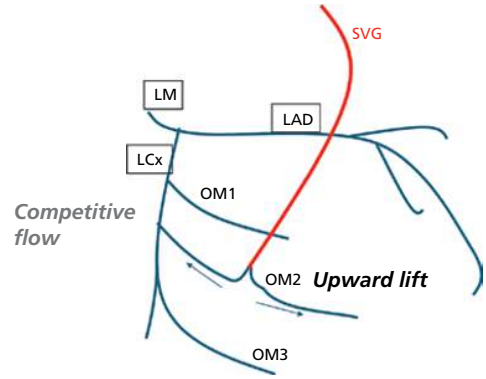
1. Large circles that surround the ostium and indicate exactly where the graft is. You need to make the catheter penetrate inside the circle, in an orthogonal view that makes the circle appear like a line (e.g., RAO for SVG-RCA in the *left image*). The circles may be sharp (*left image*), or less sharply demarcated (*middle image, arrows*).

2. Small circles (*arrows*). Those are not placed around the graft ostium, but rather in the neighborhood, in the same plane. They indicate the vertical level of the graft, not the exact location. It is necessary to sweep the aorta around this level to find the graft.

1. When you analyze the native angiogram, watch for competitive flow → competitive flow indirectly indicates graft is patent

But lack of competitive flow does not mean graft is occluded. Graft may be hooked to another OM disconnected from native circulation



2. If the native artery has upward lift → SVG hooked there
-If you see no competitive flow or retrograde SVG filling past the hook → SVG likely occluded

3. If there are collaterals to a large branch, and if you believe this branch is grafted → graft is likely occluded

If there is no collateral flow to a missing branch or territory (e.g., OM) on native and graft injections → graft to that branch is likely patent

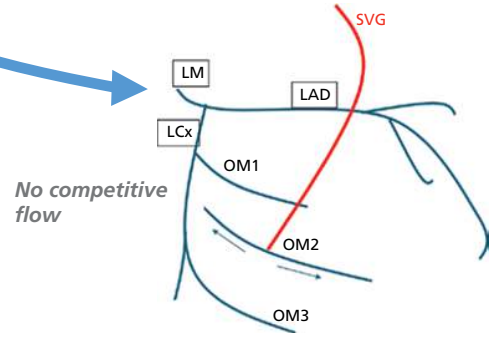


Figure 36.50 Graft angiography tips.

Write your report in terms of territory, and analyze where the retrograde filling from the graft ends:

LIMA-LAD patent, SVG-OM patent, SVG-PDA patent

1. LAD territory:
   -LIMA is patent and fills LAD antegradely to the apex, retrogradely to mid-LAD/ D2
   -Proximal LAD territory and D1 fill via native vessel and are impeded by 90% proximal LAD stenosis

2. LCx:
   -OM1 occluded and is not grafted
   -OM2: SVG-OM2 is patent but does not fill retrogradely the LCx
   -OM3 is fed by the native LCx, which has 80% stenosis

3. RCA:
   -SVG to PDA patent. Fills retrogradely the RCA via 90% retrograde stenosis
   -Native RCA feeds multiple PLBs and has 80% mid stenosis

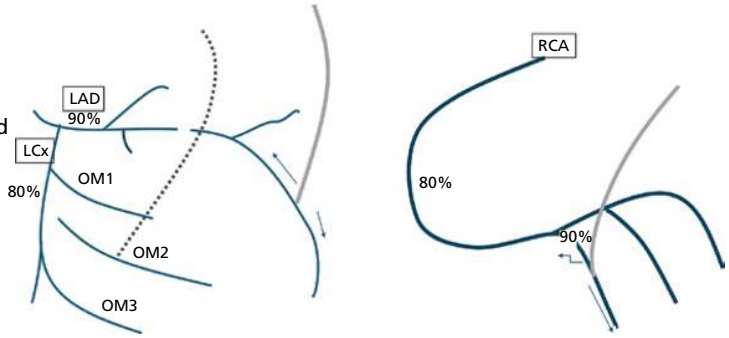

Figure 36.51 Example of a graft angiography report focusing on perfusion of the 3 major coronary territories. The images show the grafts filling antegradely and retrogradely coronary branches, and the coronary areas that are neither well perfused by the graft nor the native vessels.

XXIX. Guiding catheters for left coronary engagement

Guide catheters have a stiffer shaft but a larger internal diameter than diagnostic catheters. Guide catheters rely on 3 elements for support: (1) coaxial guide alignment with the coronary takeoff; this is the most important aspect of support and is achieved not just by advancing the catheter into the ostium but by clockwise (RCA guide) or counterclockwise torque; (2) deep engagement; (3) support from abutting the opposite aorta and/or the aortic valve (AL guides abut both the opposite aortic wall and the aortic valve, while the extra-backup guides abut the opposite aortic wall).

Guides useful for left coronary interventions

- ***Extra-backup guides*** (e.g., EBU, XB, CLS: all shaped somewhat similarly). Those guides have one bend and a long tip, longer than the JL tip, which allows more coaxial and deeper support than the angled JL tip. They also have a large plateaued secondary curve, unlike the bend of JL, which allows them to abut the opposite aorta on a stable long platform. When sitting on the opposite aorta, a shorter tip (3.5) points up while a longer tip points down. However, a longer tip (4.0) may be maneuvered to engage from below (3B) and sit across both the aortic valve and the opposite aorta and reach up and point up, providing more support than the short tip; this is commonly needed from a radial access to provide the extra support needed (Figures 36.52–36.54).

Figure 36.52 Extra backup guides (single bend with long tip) and AL guide for the left coronary artery.

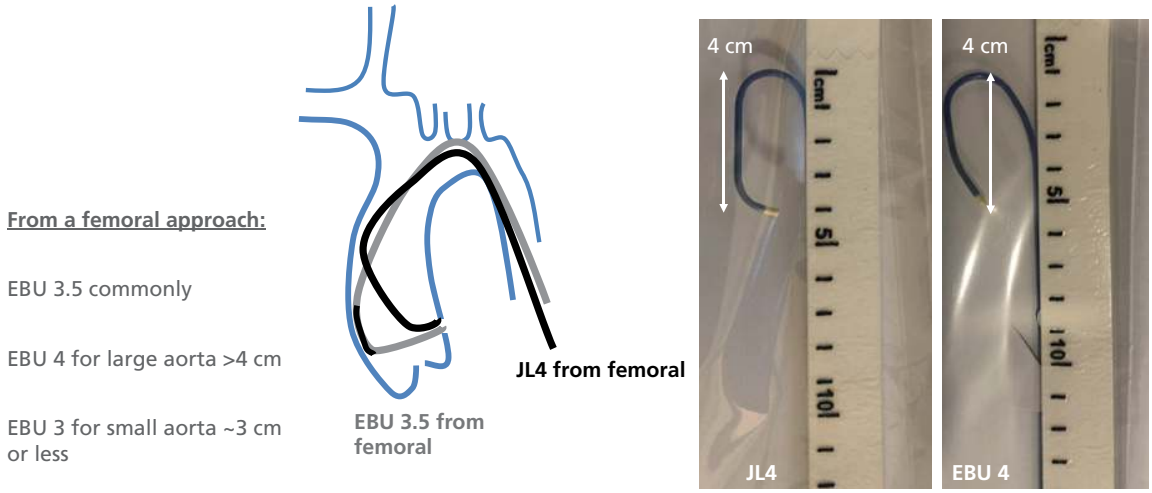

Figure 36.53 What size EBU should you use? The general wisdom is that EBU/XB/CLS points more downward than JL, as it does not have that extra upward-pointing distal tip. Thus, a size smaller than JL size is required to achieve equivalent superior orientation and to engage the same LCA. This is true if you want to engage transfemorally directly from above and sit loosely on the opposite aortic wall, wherein a curve slightly smaller than JL (0.25–0.5) is used: e.g., JL4 for diagnostic angiogram, EBU 3.5 for PCI. EBU 3.5 is often used from a femoral access, as it generally provides good enough support just from being coaxial +/– sitting on the opposite aortic wall (no need to deeply abut it against the aortic wall).

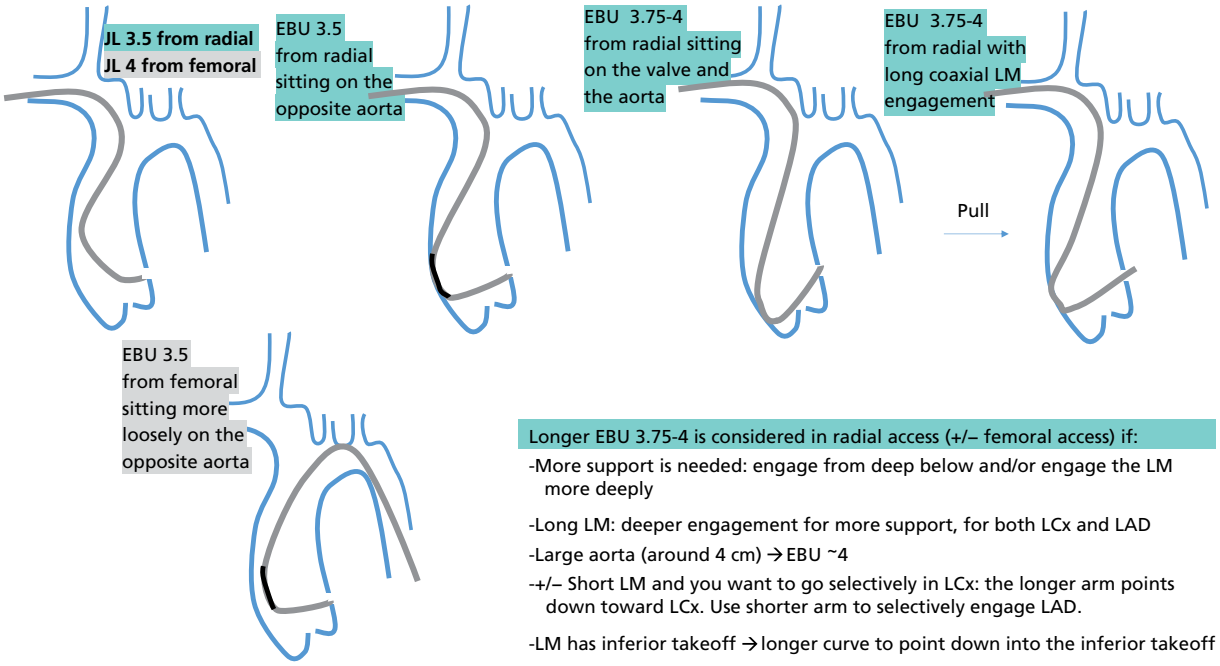

Figure 36.54 EBU size from radial access. Unlike the passive JL, EBU loses only up to 10% of its backup support transradially vs transfemorally. Yet, even this 10% loss implies that greater support is required transradially, esp. in complex cases. As such, although EBU is more elongated and down-pointing from radial access, an EBU arm as long as the femoral EBU arm, and sometimes longer, is needed radially to allow the catheter to engage from below and sit more tightly on the opposite aortic wall and even the aortic valve. This is unlike the downsizing of Judkins left (JL) catheter between femoral and radial approaches. The size of the radial EBU depends on whether support from the opposite aortic wall is enough (EBU 3.5) or more support is needed (EBU 3.75–4), in which case the catheter is "squeezed" more tightly in the aorta and onto the valve.

In general, JL4 and EBU 3.5 are used from a femoral approach, vs. JL 3.5 and EBU 3.5 or EBU 3.75–4 from a radial access. Up to 10% of the EBU backup support may be lost transradially. Thus, a relatively long or longer tip EBU 3.75–4 is required transradially to engage from below and provide the extra support needed in complex cases (Figure 36.54). Also, a longer tip is needed when:

- LM is long: EBU guide with long tip is used and advanced deep into the LM for more support and to reduce the non-supported distance before the sharp LM–LCx angle or LM-LAD angle
- Aortic sinuses are large, >4 cm. EBU arm is generally sized within 0.5 cm of the aortic diameter.
- LM is short and you want to selectively point into the downward-looking LCx (shorter tip if you want to point to the upward-looking LAD)

- ***Ikari left guide*** is a dedicated radial guide. It has a bend that sits at the innominate level and prevents catheter prolapse, and has a large plateau to sit on the aorta. It has a distal tip, not as sharp as JL but sharp enough to make it more upward pointing than EBU. All this makes it favorable for transradial engagement (Figure 36.55). It is also more slippery than EBU and dimpled, making it easier to maneuver than EBU. The downside of being lighter and more slippery is that it is less supportive than EBU. It must be U-shaped and tightly

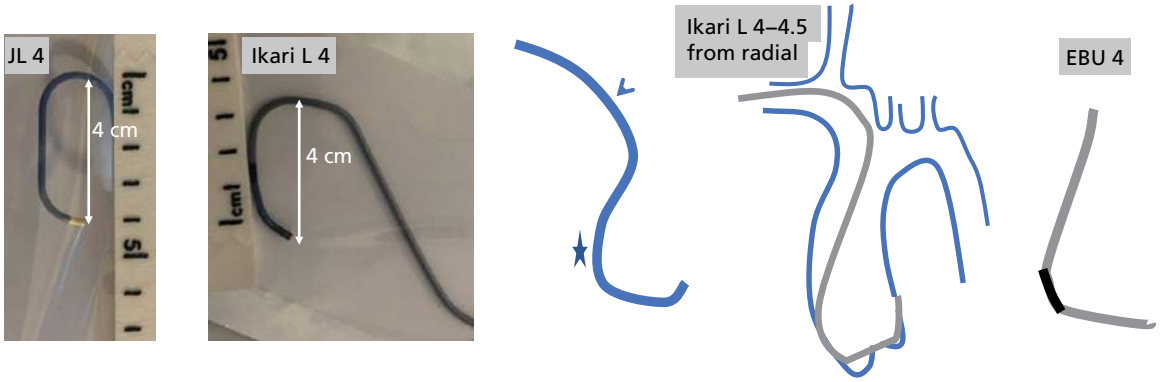

Figure 36.55 Ikari left guide. Ikari left has a bend that sits at the innominate level (*arrowhead*) to reduce catheter prolapse and has a large plateau to sit on the aorta (*star*). It has a distal tip, not as sharp as JL tip but sharp enough to make it **more upward pointing than EBU**. It is less supportive than EBU and must be U-shaped and tightly positioned over both the aortic valve and the opposite aorta to provide support. For that, a long arm is needed, longer than the JL in the same patient, typically Ikari L 4–4.5.

positioned over both the aortic valve and the opposite aorta to provide support. For that, a long arm is definitely needed, longer than the JL in the same patient, typically Ikari L 4–4.5; this long arm is even more important than with EBU, as EBU is more supportive and does not have to be seated on the aortic valve.

- ***AL guide:*** AL1.5 or 2 is useful in cases that require robust support and in transradial cases. An AL guide is also useful in case of a high coronary takeoff (use AL2 or AL3, depending on how high the takeoff is and how large the aorta is). For LCx interventions in patients with short LM, a short AL guide (AL1.5) may be used as it points down toward the LCx.
- ***JL guide*** does not usually provide adequate coaxial support because of the bend at its tip. It is useful for ostial LM intervention or interventions where extra support is not needed (e.g., LM is short and the LAD or LCx is neither calcified nor tortuous).

XXX. Maneuvering the EBU/XB/CLS guides and Ikari left guides for left coronary interventions

A. EBU/XB/CLS guides

After getting the EBU catheter to the right cusp, it is **paramount to use deep breath (+/– clock) to jump to the left cusp**. Deep breath is more critical than with JL catheter, as the EBU tip points more downward and away from the left cusp, making the jump (Step 2) more difficult.

Transradially, after the jump, EBU can only be engaged using the 3B technique (pushing the catheter from below, U technique, with a counterclockwise torque) (Figures 36.56, 36.57). On the other hand, transfemorally, technique 3B may be used, with clockwise torque instead of counterclockwise, but the 3A technique often succeeds (direct pull from the valvular level with clockwise torque). Also, transfemorally, EBU/XB may be engaged directly from above without having to start at the aortic valve level (3C technique); in fact, after removing the wire, EBU may curve up and jump straight into the LCA (Figure 36.58).

B. Ikari left guide

Ikari L is used only radially. Ikari L is jumped to the left cusp with the help of a deep breath and clockwise torque. Then, Ikari left may be engaged using the push from below technique 3B, but also the direct pull technique 3A (unlike EBU). Ikari L has a distal bend on its tip, which allows it to point more upward than EBU and successfully engage via the 3A maneuver. **Even if engaged by the pull maneuver, Ikari L must be pushed and looped over the valve, as it is less supportive than EBU and it is paramount for it to sit robustly on the valve for support (power position)** (Figure 36.59).

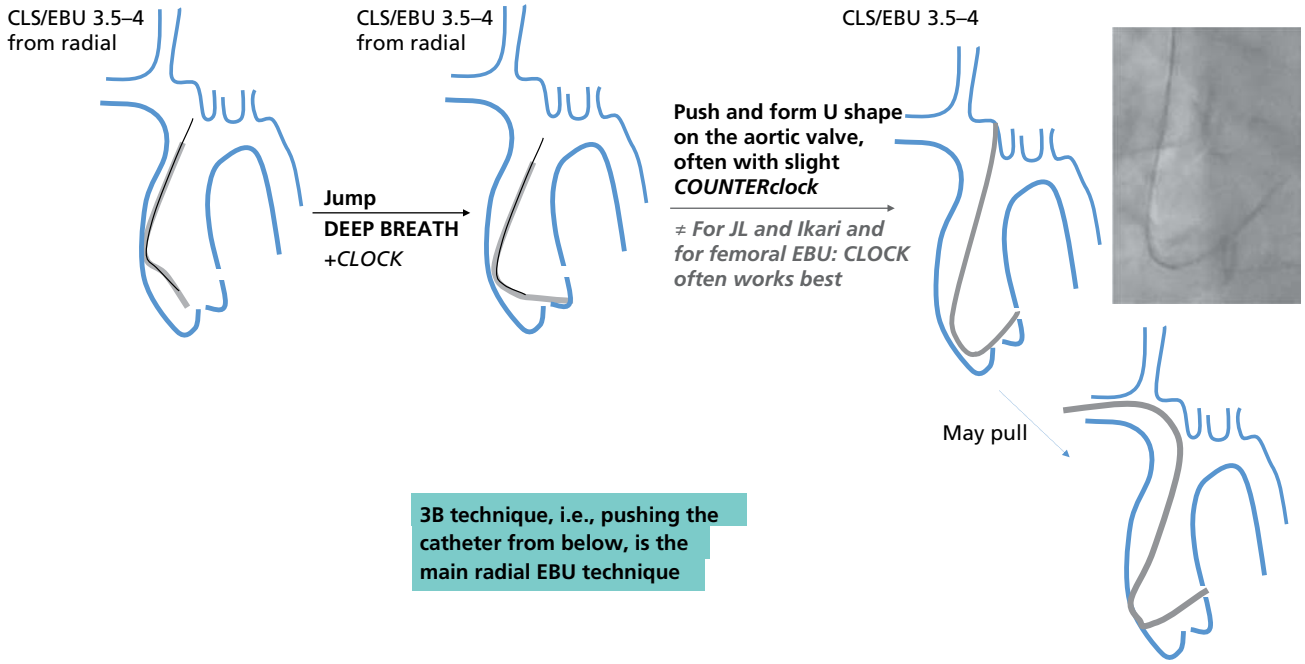

Figure 36.56 EBU engagement steps using 3B technique transradially (may also be used transfemorally):

- After reaching the right cusp, the jump is performed via **deep breath** and **clockwise torque**. The catheter points more downward than Judkins left (JL), hence the jump is more difficult than with JL. **Deep breath**, which lowers the left cusp, is paramount for allowing EBU to jump. Start with a slight clockwise torque and be ready to reverse the torque if the catheter is starting to flip up or rightward.
- After the jump into the left cusp, technique 3B is almost always required to engage the LCA, i.e., pushing the catheter to engage the LCA from below. The catheter tip being long and down-pointing, and more elongated and down-pointing radially than femorally, the pull maneuver (3A) is not successful radially. Typically, the catheter is pushed from below with a counterclockwise torque (although that depends on how much clockwise torque was performed while getting the catheter down and during the jump).

After catching the LCA ostium, EBU may be pulled to create deeper coaxial engagement, at the cost of potentially losing the abutment on the aortic valve. Even if you are not aiming to sit the catheter on the valve, you often must loop it from below to engage, then pull it to sit purely on the aorta.

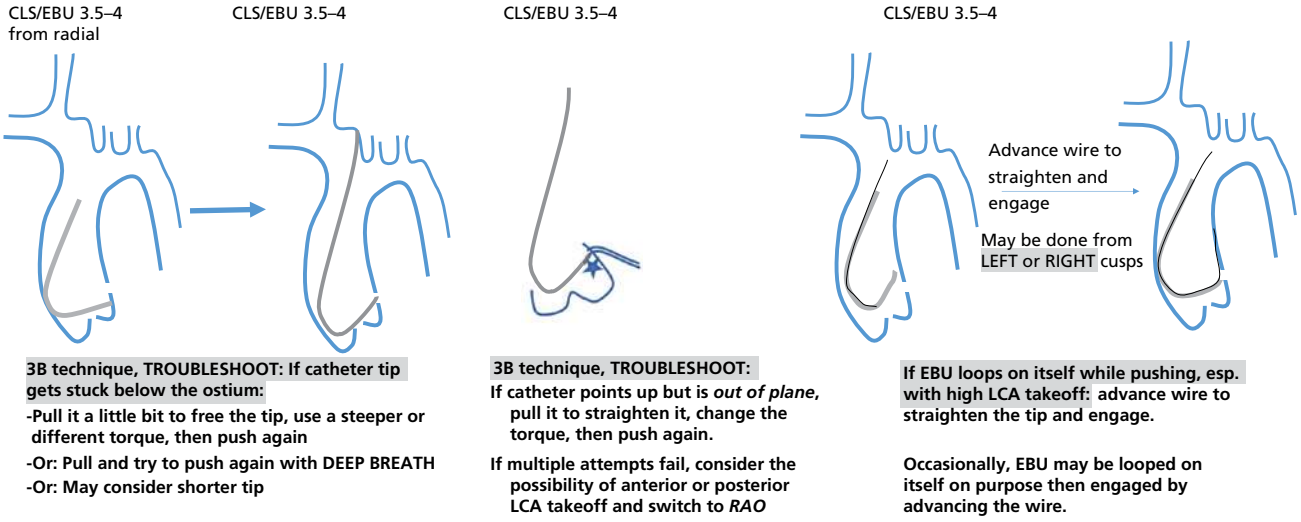

Figure 36.57 Troubleshooting EBU guide engagement.

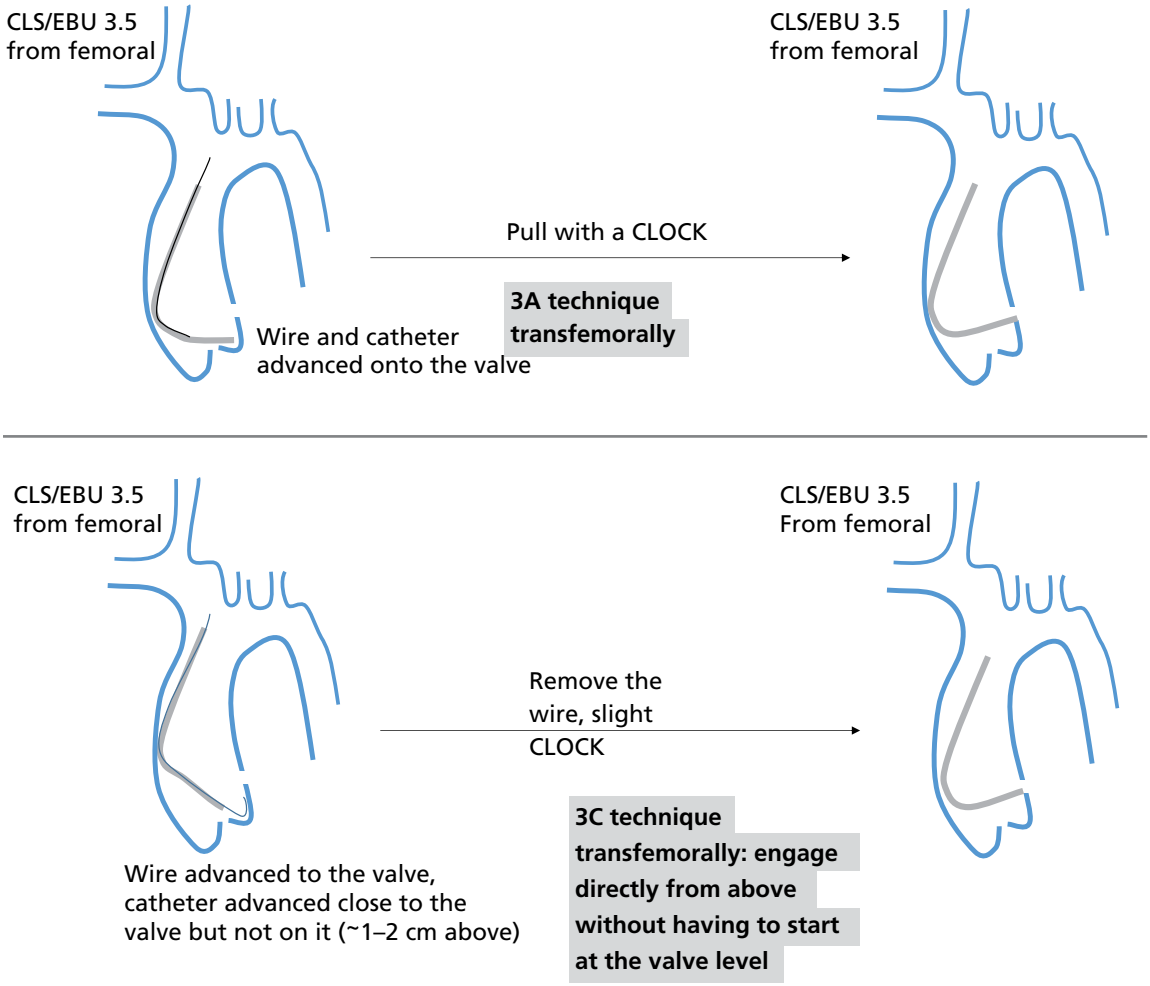

Figure 36.58 Additional EBU/XB/CLS techniques from a femoral approach. Simple pull (3A) often does not work with EBU guides transradially, as they have a long, stiff, and too down-pointing tip, which points even farther down from radial access. However, **3A** works transfemorally, as well as 3B. Even more, a direct engagement technique from above, not starting at the aortic valve, often works transfemorally (technique **3C**): the catheter may curl up into the LCA ostium upon wire removal.

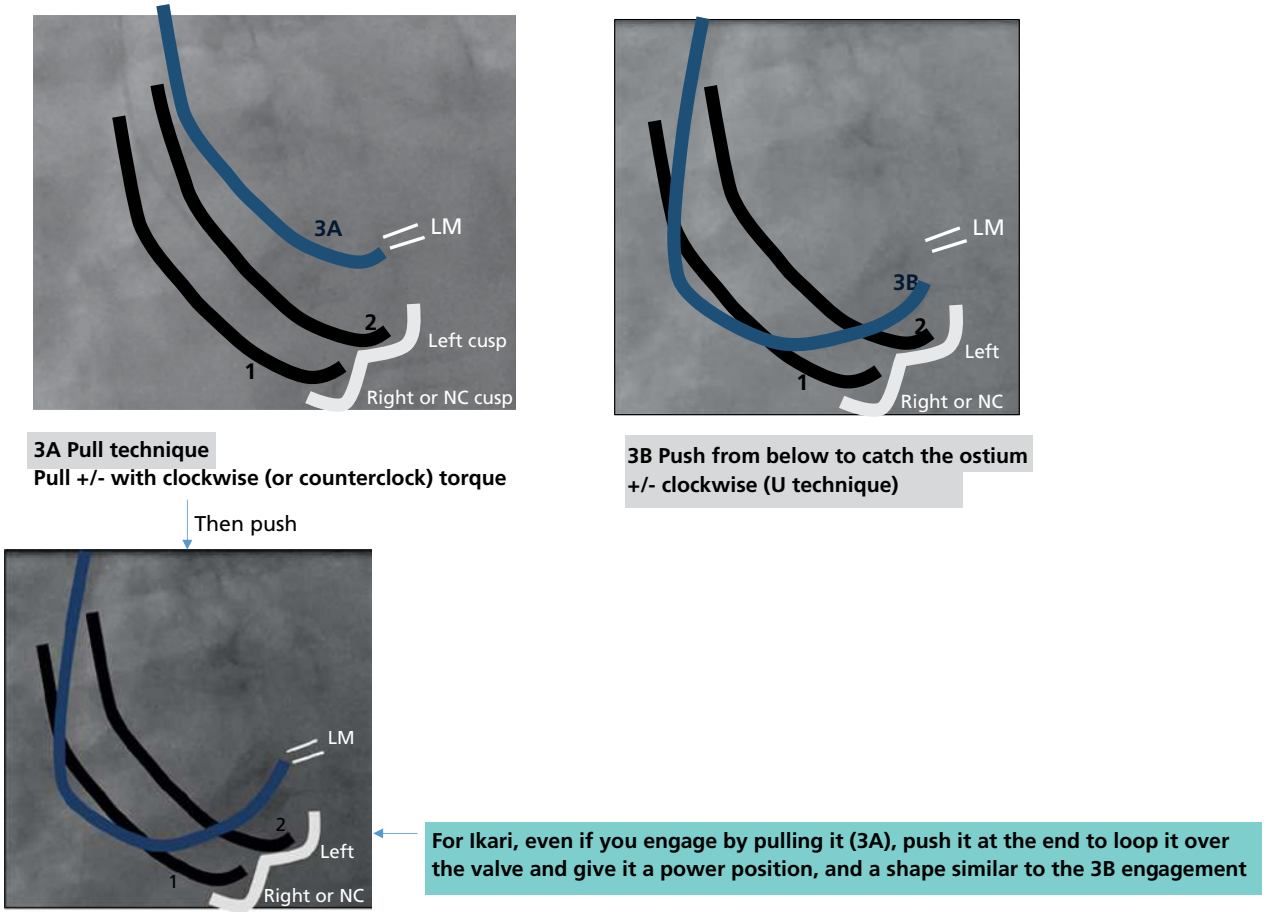

Figure 36.59 Maneuvers to engage **Ikari L** transradially. Ikari L is "jumped" to the left cusp with the help of a deep breath and clockwise torque. Then, Ikari left may be engaged using the push from below technique 3B, but also the direct pull technique 3A (unlike EBU). Ikari L has a distal bend on its tip, which allows it to point more upward than EBU and successfully engage via 3A maneuver. Even if engaged by the pull maneuver, Ikari L must be pushed and looped over the valve, as it is less supportive than EBU and must sit robustly on the valve for support.

XXXI. How to engage and maneuver Amplatz left catheter. Other guiding catheters for right coronary engagement: Ikari right and left

Avoid the use of JR4 guide transradially. It is unstable, may disengage with patient's respiration, and its short tip provides very little support, so much that a guide extension (Guideliner) would frequently be needed for deep coaxial support or to create an Amplatz left shape. JR4 guide may be considered transfemorally, as the femoral route is generally more supportive.

The following are the best transradial RCA guides:

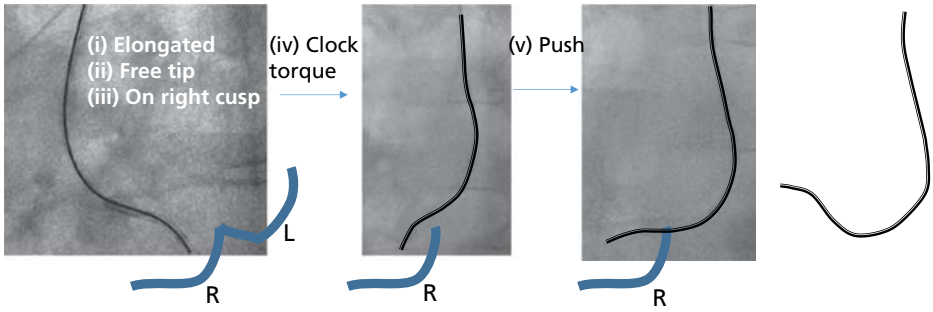
- **AL 1** (vs. AL 0.75 or AL1 transfemorally)
- **Ikari Left 4–4.5** or **Ikari Right 1–1.5**
- *For ostial RCA PCI*, the long and bulky AL1 may still be used, particularly in an elongated fashion, but is difficult to maneuver. The preferred catheters are: Ikari L or AL 0.75 (not in power position), Ikari R 1.0 (not in power position), or AR2.

A. How to engage AL catheter, whether for RCA or LCA

Advance a wire until it loops over the aortic valve, then advance the AL catheter over the wire onto the aortic cusp in an elongated fashion: the tip of the AL must catch the cusp of interest (right cusp for RCA). Then, while AL is **(i) elongated** with **(ii) free tip**, **(iii) on the aortic cusp of interest**, **(iv)** clockwise **torque it** (for RCA), THEN **(v) slightly push it around midway/latter half of the torque.** Those are the **5 key words** for AL engagement. It is best to keep the catheter elongated early on and not allow the big butt to be fully formed until the end of torque, close to engagement. This is because AL is a big and bulky catheter that would point too high in the aorta above the coronary ostium if the large butt and duck shape form too early before engagement (Figure 36.60).

When used to engage **SVG**, the AL catheter (1.5–2) is maneuvered similarly except that it is not advanced all the way down to the aortic valve level. The AL is advanced to the ascending aorta above the native coronary level, then, while in a *flat elongated shape, it is torqued until it* catches the appropriate SVG ostium (Figure 36.43). Once engaged, AL is pushed to adopt its duck shape.

Advance AL to the valve in an elongated fashion. Get the AL to be:
elongated with free tip, on the aortic cusp of interest



While the tip is elongated and free, on the cusp of interest:
torque (clock for the RCA) THEN slightly push around midway/latter half of the torque.

May need to pull if the duck shape (big butt) forms too quickly, i.e., if AL points too much up:
It is best to not make it fully duck shaped and looking up until engaged

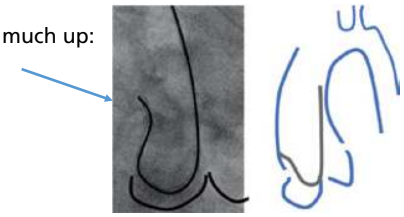


Figure 36.60 Amplatz left engagement of the RCA. Remember the 5 key words: Elongated, Free, on the Cusp of interest, Torque, then slightly Push midway.

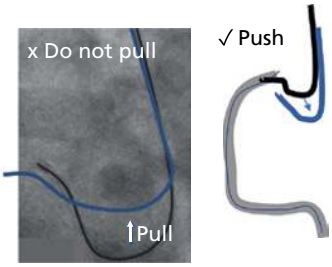
B. How to disengage AL catheter (Figure 36.61)
If a duck-shaped coaxial AL is pulled out, the tip has a tendency to be "sucked" in deeper and dissect the ostium if done abruptly. Thus, in order to disengage this AL shape, push it until it prolapses out of the ostium, then counterclock it out (push and counterclock). If the duck shape is not coaxial, or if AL is elongated, pulling it may successfully disengage. This is not always predictable, and therefore, gentle maneuvering under fluoroscopy with a change in strategy may be required. Also, it is best to disengage AL guide catheter while a balloon is protruding at its tip, to reduce the risk of ostial dissection.

How to disengage AL1:

-If it is perfect duck shape (big butt) AND coaxial :
Do not pull → it will dive deep
Rather, push then counterclock



- If elongated
  or if duck shaped but no coaxial → just pull

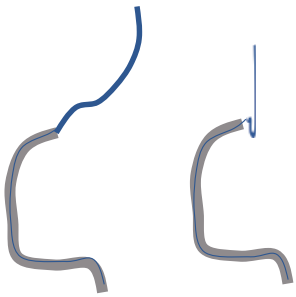


Figure 36.61 AL disengagement.

C. How to maneuver AL catheter during PCI
The issue with AL is that it may react unpredictably, which increases the risk of guide dissection: it may dive in when you pull it or prolapse out when you push it. AL provides support and stability in 2 ways: (i) the duck shape provides support from the aortic valve; and (ii) the elongated deep shape provides support from deep engagement. One shape may be chosen with alternation between the 2 shapes throughout the PCI (Figure 36.62):

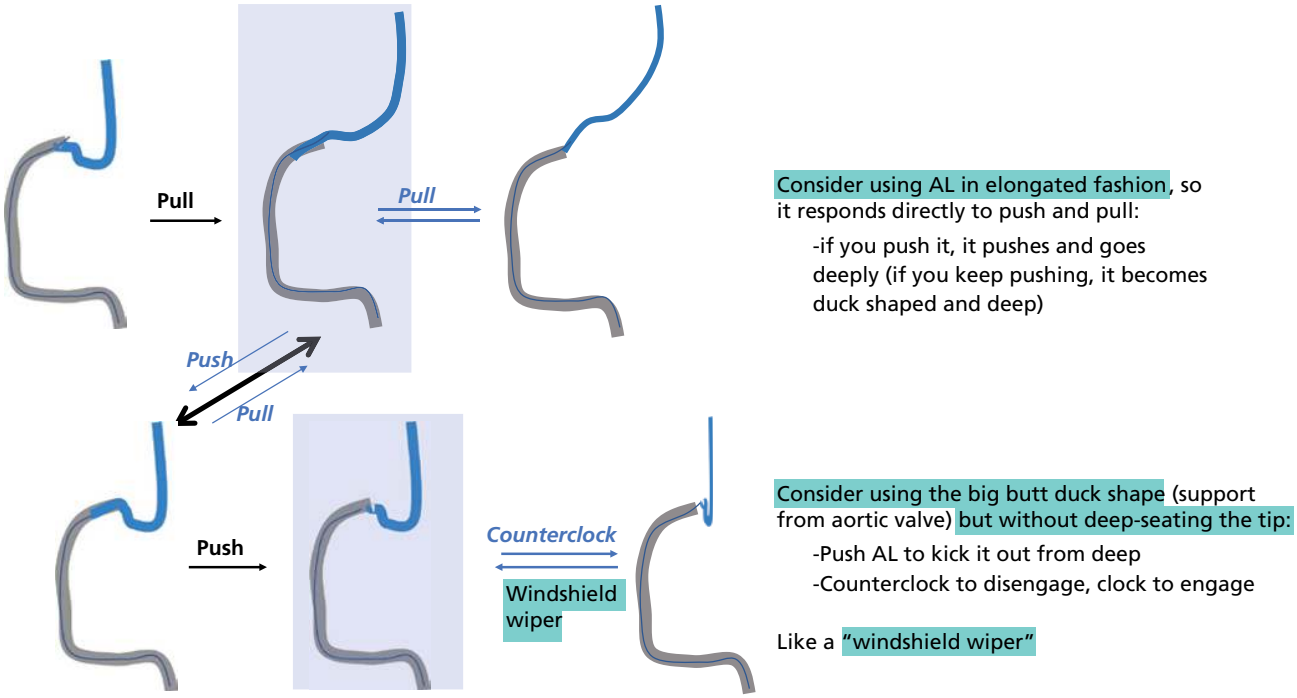

Figure 36.62 How to maneuver AL during the PCI case. AL may be used in 2 ways: (i) the **duck shape,** which provides support from the aortic valve; and (ii) the **elongated deep shape,** which provides support from deep engagement. One shape may be chosen with alternation throughout the PCI:

- If the elongated shape is chosen, pull the AL to make it elongated. The advantage of the elongated form is that it responds directly to push and pull
- If the duck shape is chosen, use a duck shape that is not too deep in the RCA. This reduces guide ischemia and allows the catheter to respond to torquing maneuvers: counterclockwise to disengage, clockwise to engage. A deep duck shape may intermittently be used when extra support is needed.
- You may alternate between the 2 shapes (*black double arrow*) by pushing the elongated form (→ becomes duck shaped, initially deep then shallower) or pulling the duck shape (→ becomes deep duck shape then elongated shape).

For ostial RCA PCI, the elongated form is preferred, along with a shorter AL tip (AL 0.75). A non-coaxial duck shape may also be considered.

- If the elongated shape is chosen, pull the AL to make it elongated. The advantage of the elongated form is that it responds directly to push and pull (if you push AL, it goes deeply, before becoming duck shaped; if you pull it, it pulls).
- If the duck shape is chosen, use a duck shape that is not too deep in the RCA. This reduces guide ischemia/ventricularization and allows the catheter to respond to torquing maneuvers: counterclockwise to disengage, clockwise to engage. A deep duck shape may intermittently be used when extra support is needed.
- You may alternate between the 2 shapes: (i) by pushing the elongated form (→ becomes duck shaped, initially deep then shallower), or (ii) by pulling the duck shape (→ becomes elongated).

For ostial RCA PCI, the elongated form is preferred, along with a shorter AL tip (AL 0.75). A non-coaxial duck shape may also be considered.

D. Ikari left guide for RCA (Figures 36.63, 36.64)

Ikari left may be used for both LCA and RCA engagement. It is a versatile catheter that may be used in 2 shapes for the RCA: (i) a straight shape that mimics a long and deep JR4; and (ii) a power position sitting in a U fashion on the aortic valve, mimicking AL. To engage the RCA, it is maneuvered similarly to JR4, with a pull and clockwise torque. It has a propensity to loop on itself, so more pull is required to keep it straight than with JR4 maneuvering, and the wire is generally maintained inside the catheter during engagement for straightening. **Once engaged, the catheter is pushed to create a more supportive power position, which may be as supportive as AL.** For ostial RCA PCI, use the straight shape.

With JR4, Ikari left, and Ikari right guides, deep coaxial support is not usually obtained by simply pushing. Rather, **clockwise torque the catheter to make it more coaxial and deeper**, ***with* a slight pull** to transmit the torque, and sometimes a **push after the torque is transmitted**. A counterclockwise torque with a pull may be used to slightly disengage the catheter, particularly in case of guide ischemia/damping.

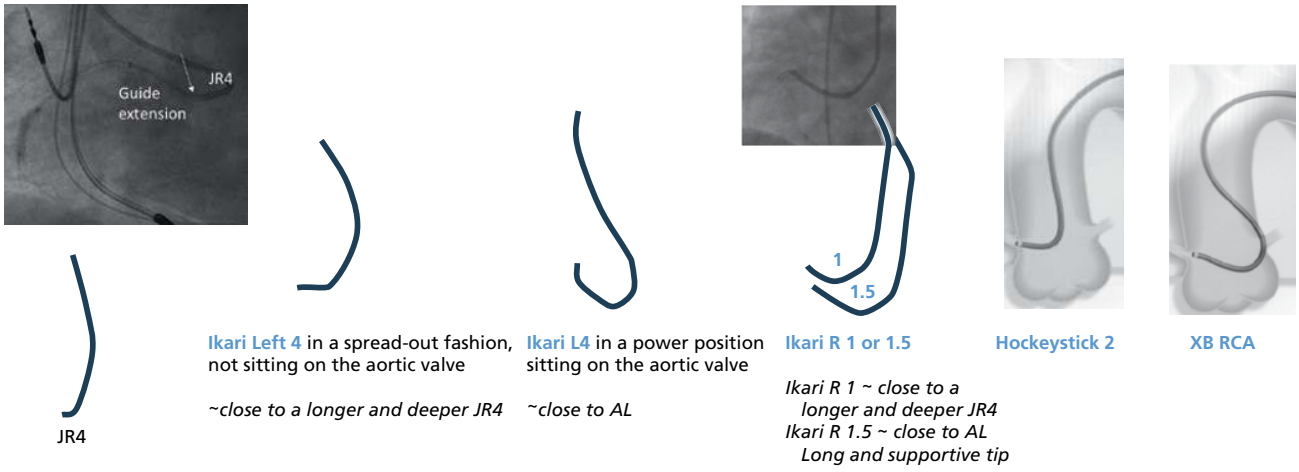

Figure 36.63 Other RCA guiding catheters:

1. Avoid using Judkins right (JR) 4 guide transradially. JR4 being poorly supportive, a guide extension is frequently needed to create an AL1 shape when JR4 is used as a guide catheter transradially, as shown in the top image.
2. Ikari left is a versatile catheter that may be used in 2 shapes for the RCA: (i) a straight shape that mimics a long and deep JR4; and (ii) a power position sitting in a U fashion on the aortic valve, mimicking AL.
3. Ikari right is a catheter with a wide curve that may act like a long and deep JR4 in case of Ikari R 1, or an AL1 in case of Ikari R 1.5, which tends to sit on the opposite aortic wall and be deeply seated with increased dissection risk.
4. A long tip Hockeystick-2 guide may be used, particularly transfemorally. XB RCA is another long-tip catheter, somewhat like Ikari R 1.5, that may be used transfemorally.

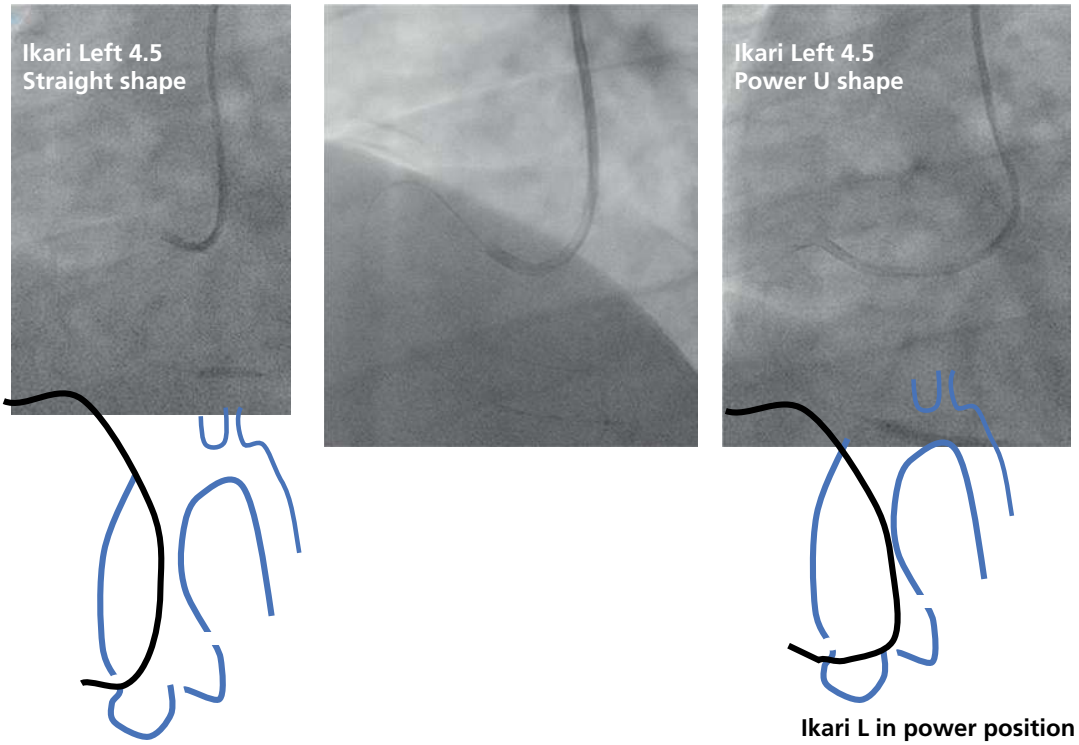

Figure 36.64 Ikari Left 4.5 initially engaged and used like a longer and deeper JR 4 (*left image*). It is **further clockwise torqued then pushed progressively into a power position** to provide the support needed for distal stent advancement (*middle image* then *right image*).

E. Ikari right guide 1–1.5

Ikari right is a catheter with a wide curve that may act like: (i) a long and deep JR4 in case of Ikari R 1; or (ii) an AL1 in case of Ikari R 1.5, which tends to sit on the opposite aortic wall and be deeply seated with increased dissection risk. It is engaged somewhat similarly to JR4 and Ikari left. Ikari R 1 is less supportive than Ikari R 1.5 but less risky and may be preferred to Ikari R 1.5 in most cases, except the most complex ones.

XXXII. Damping and ventricularization of the aortic waveform upon coronary engagement, and role of side-hole catheters

When a catheter engages a narrow coronary artery, the pressure at its tip may damp or ventricularize. Damping is characterized by flattening of the pressure tracing with a significant drop in the systolic and diastolic pressures; it indicates pressure reduction at the tip of the catheter (Figures 36.65, 36.66). Ventricularization is characterized by a change in pressure from an aortic to a "ventricular-like" tracing and reflects ostial narrowing. The engaged catheter restricts blood flow to the narrow ostium; *since coronary flow mainly occurs in diastole, the drop in pressure across the narrow ostium is mainly diastolic, causing a ventricular shape across this ostium from which the pressure is being recorded; also, the catheter wedges the coronary artery, occluding it, so that the pressure at its tip becomes a reflection of the downstream ventricular pressure*. Ventricularization may be obvious and may manifest as a severe drop in diastolic aortic pressure and a change from a triangular to a rectangular shape. ***Subtle or early ventricularization is more common and is identified by 2 features:*** *(1) diastolic pressure changes from downsloping (aortic) to upsloping (ventricular); (2) A waves appear on the tracing*. Also, in addition to the drop and change in diastolic pressure, the systolic pressure usually decreases during ventricularization.

Damping that occurs before engagement of a coronary artery usually alerts to the presence of air or a clot in the catheter, or to twisting of the catheter after excessive torquing. Damping or ventricularization upon coronary engagement has several causes: (1) severe ostial disease, with the catheter further reducing or occluding flow across the ostium and leading to reduced pressure in the coronary artery; (2) ostial spasm; (3) small coronary artery engaged with a large catheter that occludes it, particularly when a right coronary catheter selectively engages the small conus branch; (4) catheter against the arterial wall or against a plaque that damps the pressure at its tip (no ventricularization in this case). Since damping and ventricularization often signify occlusion of flow across the ostium, injecting contrast while damped or ventricularized replaces the remaining oxygenated blood with contrast. The latter is not quickly cleared because of reduced flow, which further reduces myocardial oxygen supply. ***Lack of contrast clearance from the coronary arteries or, worse, from the myocardium (myocardial stain) is a serious consequence of damping, which imminently leads to ischemia and ventricular fibrillation, and dictates immediate catheter disengagement.*** In addition, vigorous injection while damped or ventricularized may lead to coronary dissection, since the catheter is surrounded by ostial disease or is against the vessel wall.

Thus, one should not inject contrast or flush with saline while damped or ventricularized. Consider these 3 scenarios during which damping/ventricularization occurs:

1. RCA engagement with catheter tip pointing up → selective conus engagement. Attempt to engage the true RCA as explained in Section XIX.
2. LCA engagement, or RCA engagement with a catheter tip pointing horizontally or down: RCA or LCA ostium is narrow, small, or vasospastic. Administer intracoronary or sublingual nitroglycerin, and (Figure 36.67):
   a. **Try to barely disengage the catheter and be barely non-selective** (slight counterclock for RCA, slight pull for LCA). Improve the pressure, and be close enough to the ostium to obtain good non-selective images. Consider using a shorter tip catheter to prevent deep engagement (JL, JR, instead of Tiger or EBU).

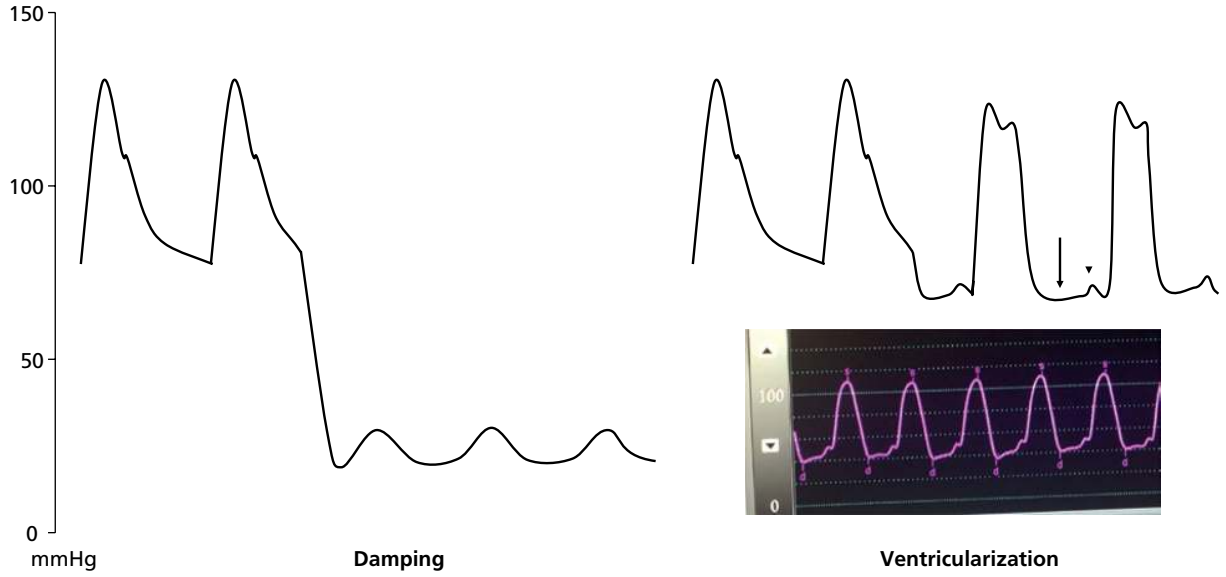

Figure 36.65 Examples of damping and ventricularization of the aortic pressure upon coronary engagement. In *ventricularization*, the diastolic pressure does not necessarily drop to levels that are as low as the left ventricular diastolic pressure, but the shape of the tracing changes from an arterial one to a ventricular one, i.e., the diastolic segment between the spikes is upsloping *(arrow)* and A wave is seen *(arrowhead)*.

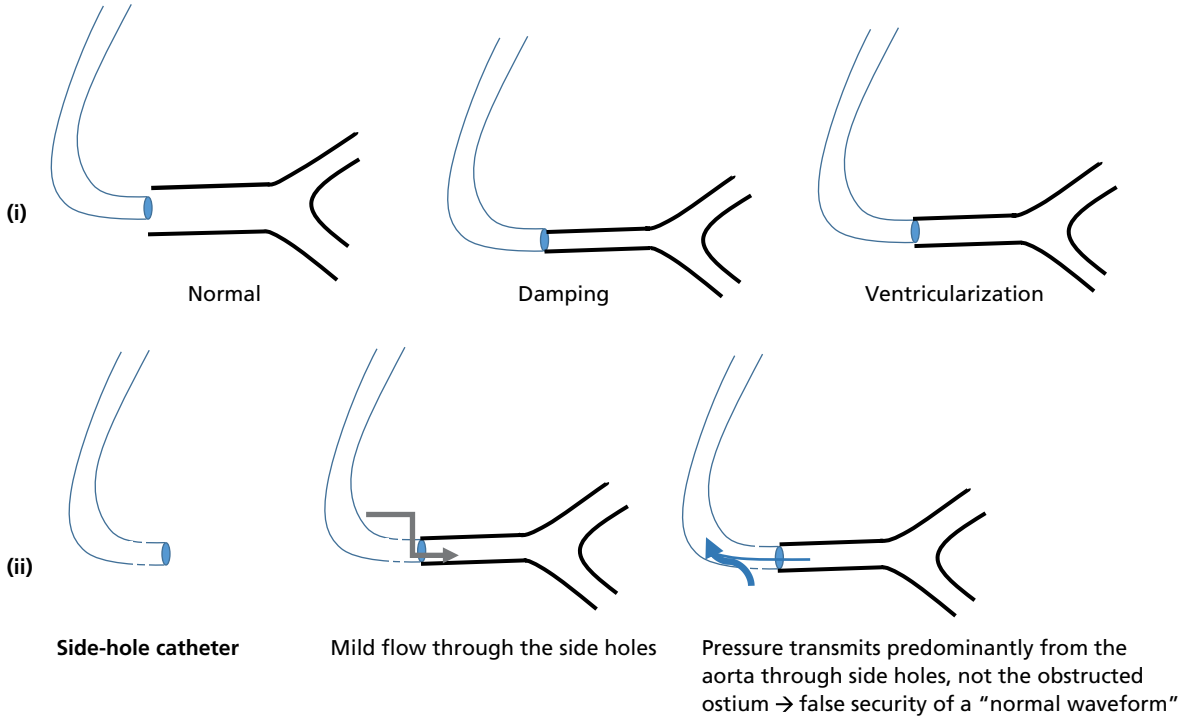

Figure 36.66 **(i)** How a catheter causes damping and ventricularization. The catheter fully wedges and occludes the ostium (pressure damping) or partially wedges and narrows the ostium (pressure ventricularization). The pressure is transmitted from the catheter tip, past the narrow ostium, hence the change in pressure waveform. **(ii)** Effect of side-hole catheters.

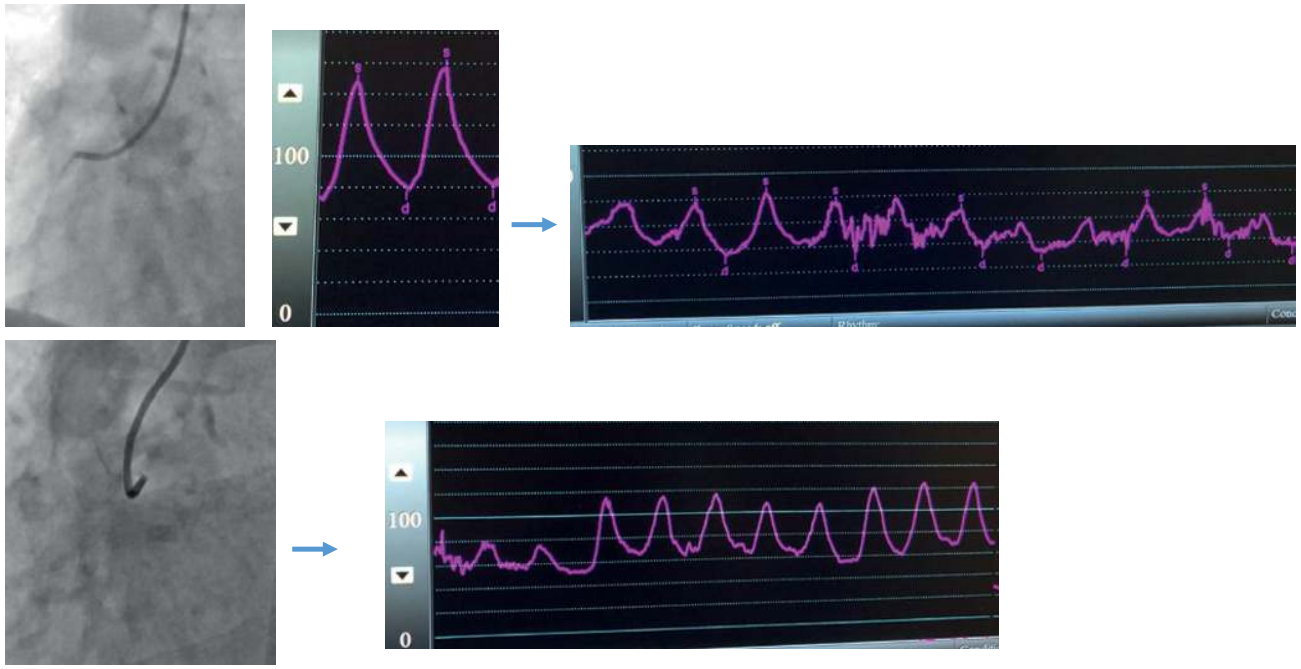

Figure 36.67 (*Top images*) A case of pressure damping upon RCA engagement with a JR 4 catheter. The catheter is pointing down, so this is not selective conus engagement. Suspect ostial disease or small RCA. (*Bottom images*) JR4 is counterclockwise-torqued while being slightly pulled, to make it less deep or to slightly disengage it (slightly non-selective). This improved the pressure waveform and allowed imaging.

b. The barely disengaged position may not be possible, and the catheter may keep flying out upon disengagement. As such, you may engage the coronary artery, **wire it** while the pressure is damped, then barely disengage the catheter and image the coronary artery (**hit and run wiring**). **The wire stabilizes the catheter in a barely disengaged position** (Figure 36.68).

c. **Hit and run injection**: inject 1–2 ml for RCA, ~3–4 ml for LCA, while withdrawing the catheter. However, re-engagement is required multiple times to obtain more images and is associated with a risk of ostial coronary dissection.

d. If ventricularization is mild, consider taking a couple of images while ventricularized.

3. During PCI, ventricularization often occurs when the guiding catheter is too deeply engaged. Slightly disengage with pullback and/or torque (e.g., counterclockwise for RCA). The guiding catheter may need to be stabilized in this disengaged position with double wiring.

A ***catheter with side holes*** allows contrast clearance, reduces the risk of ventricular fibrillation, and provides mild coronary perfusion while the catheter is seated in the coronary artery between coronary injections. Yet, it is important to realize the following limitations: (i) A catheter with side holes only minimally reduces catheter-related ischemia and does not prevent the dreaded risk of dissection. (ii) This catheter will transmit a normal pressure recording that is partly related to the transmission of pressure from the side holes positioned in the aorta, rather than from the tip positioned at the ostium, thereby providing a false reassurance (Figure 36.66). (iii) The spilling of contrast in the aorta results in lower image quality and greater contrast use. (iv) A side-hole catheter has no value with diagnostic catheters, which are sitting briefly in the coronary arteries. (v) ***A side-hole guide should not be used in left coronary interventions with small or diseased left main, as it causes left main ischemia while providing a false reassurance, which may lead to hemodynamic collapse;*** rather, PCI is mostly performed with a disengaged or less deeply engaged catheter to avert ischemia, with brief intermittent engagement when positioning stent/balloons (**"hit and run" maneuvering**). Double wiring may be necessary for support and stability. (vi) A side-hole guide may be used for RCA intervention when treating complex distal disease in a patient with small or moderately diseased ostium, as such distal disease requires the support of a well-engaged guide; it is not used while treating the ostium itself, as the catheter is only engaged during wiring and positioning of stent/balloons, and disengaged in between to lessen ischemia.

Interestingly, ***the administration of nitroglycerin may induce or worsen ventricularization early on***; the increase in flow induced by vasodilators may worsen the drop in pressure across the ostial obstruction, particularly diastolic pressure, leading to ventricularization (drop in pressure = flow × resistance). However, nitroglycerin may improve ventricularization later on, once spasm, a component of ostial obstruction, is relieved.

XXXIII. Coronary angiography in case of aorto-ostial stenosis

Perform coronary angiography with a catheter that is barely disengaged. Follow the 4 techniques described under Section XXXII and in Figures 36.67 and 36.68.

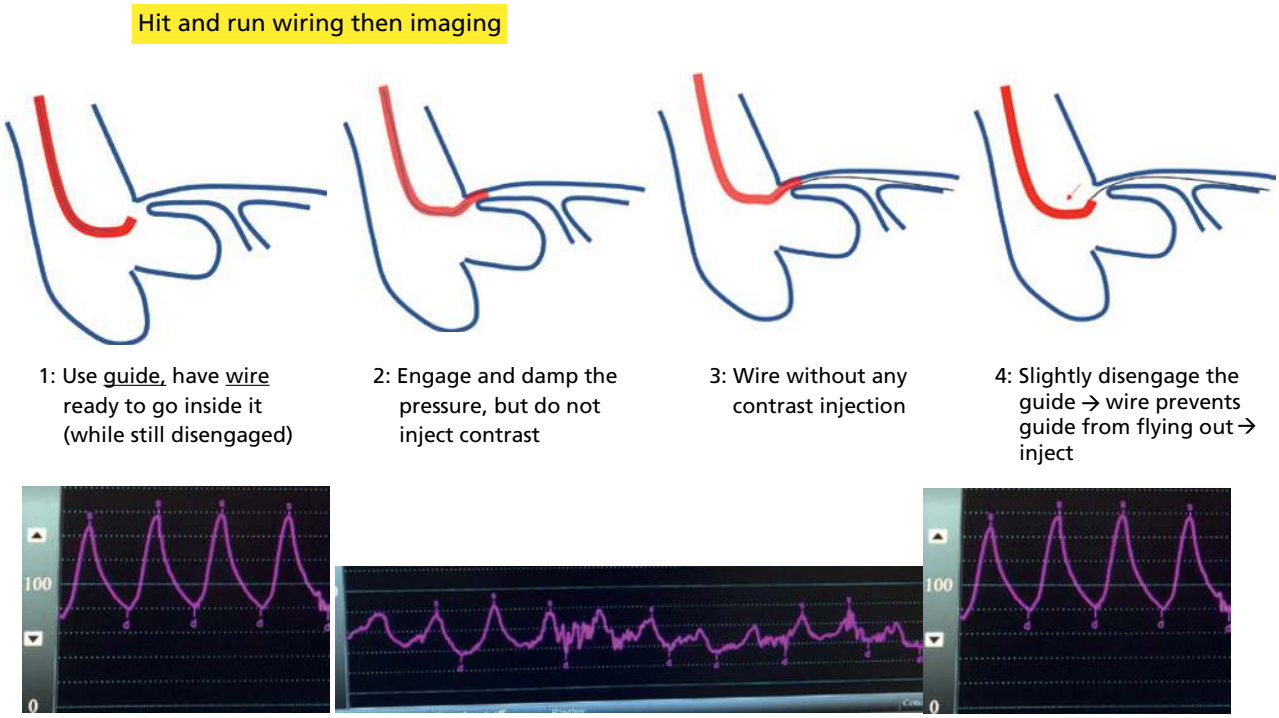

Figure 36.68 Hit-and-run wiring, followed by imaging while the catheter is barely disengaged. The wire stabilizes the catheter in a barely disengaged position, if such position could not be maintained.

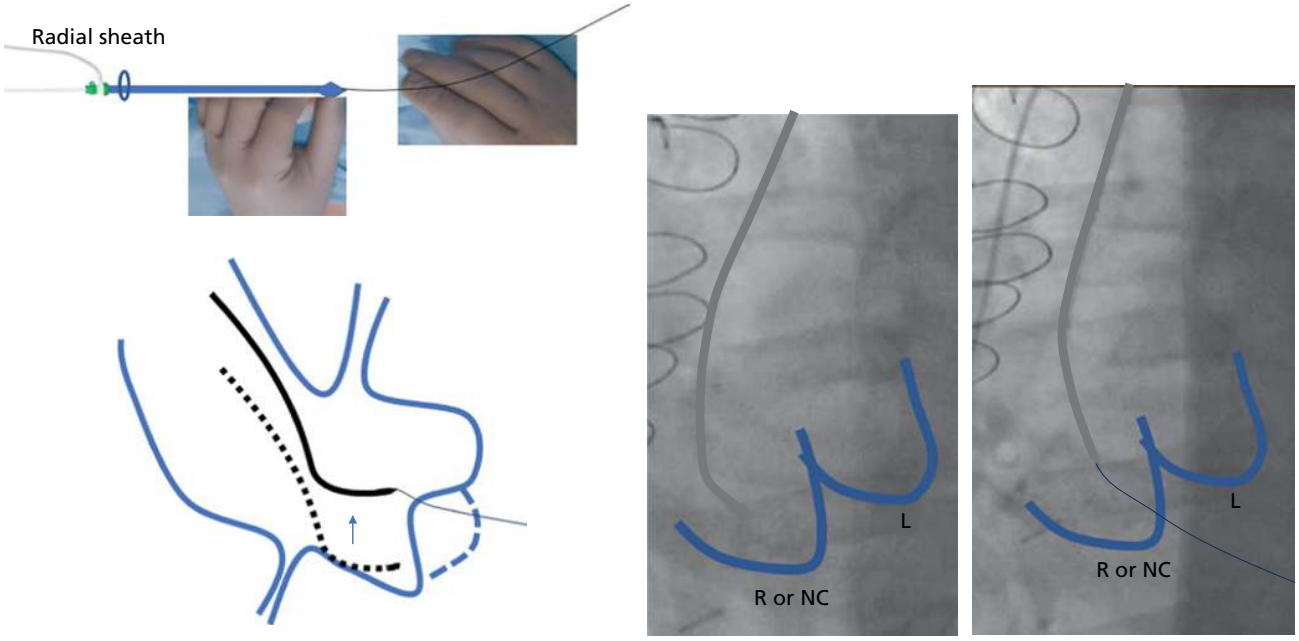

Figure 36.69 Technique of LV access. The catheter is torqued and pulled/pushed to direct the wire. Both hands are mostly on the back end of the catheter: the left hand maneuvers the catheter, while the right hand is on the wire advancing it on and off. There are **2 keys to successful LV crossing: (i) let the catheter jump out of the lower cusp, not be stuck in one cusp; (ii) know where the aortic orifice is and use a catheter configuration that aims toward the aortic orifice.** (iii) *Deep breath* also helps.

XXXIV. Left ventricular catheterization

The LV is routinely accessed for LVEDP measurement and for assessing LV-aortic pressure gradient. For that purpose, a standard end-hole catheter, e.g., JR4, is used. When left ventriculography is planned, the LV is instead crossed with a multi-hole pigtail catheter. With JR4, AL, Tiger, or any standard catheter, **the catheter is torqued *AND* pulled/pushed around the aortic orifice to direct a J-tip 0.035″ wire across this orifice. The aortic valve is crossed using this wire, and the directing catheter is then tracked over it** (Figures 36.69, 36.70):

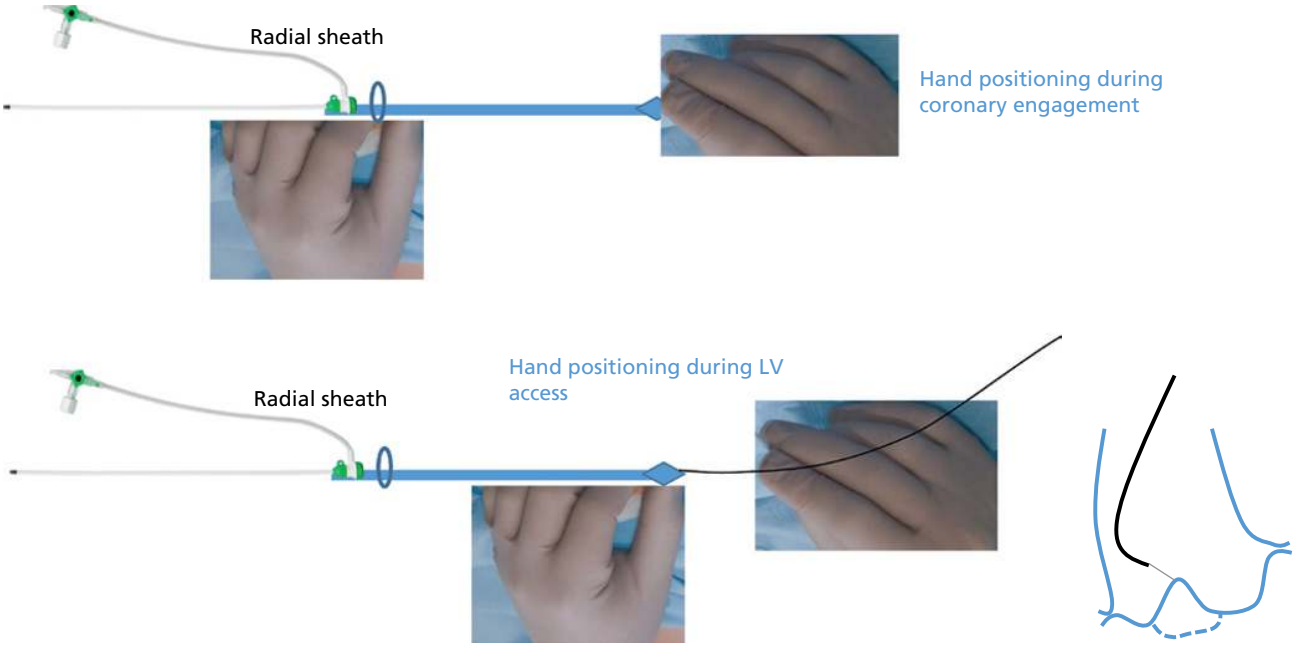

Figure 36.70 *(Upper images)* **Hand positioning** during coronary engagement: one hand is at the sheath level, the other hand is at the back end, both are torquing and pulling. (*Bottom images*) Conversely, during LV access, both hands are on the back end of the catheter: the left hand maneuvers the catheter, while the right hand is on the wire advancing it on and off. The left hand moves episodically to the front, i.e., the sheath level, each time the catheter needs to be advanced.

1. Use the LAO view, as it displays the right and left sinuses and the aortic orifice in between; it is also a useful view to ensure that the wire does not go into the coronary arteries.
2. Advance the catheter until it touches the aortic valve, typically at the level of the lower cusp. The wire is initially kept inside the catheter.
3. Know which cusp you are in: low position → right cusp or NC cusp. **Imagine the cusp anatomy and direct the wire in between the cusps using proper catheter configuration.** In AS, calcium or aortic angiography helps localize the orifice.
4. Jump out of the right cusp and aim the wire between the right and left cusps, as you are jumping.
5. If this fails, pull the wire back in the catheter, try different torques and heights on the catheter, while readvancing the wire on and off each time**. If the catheter is stuck in the lower cusp and has not jumped, recognize that and do not keep advancing and looping the wire in that low cusp** (common mistake).
6. During the maneuvers, both hands are mostly on the back end of the catheter: the left hand holds the catheter torquing it and pulling it as needed, while the right hand is on the wire advancing it on and off. Only when the catheter needs to be advanced is the left hand moved to the front of the catheter.
7. Use deep breath, which straightens the aortic-LV angle and straightens the trajectory of the wire into the LV.

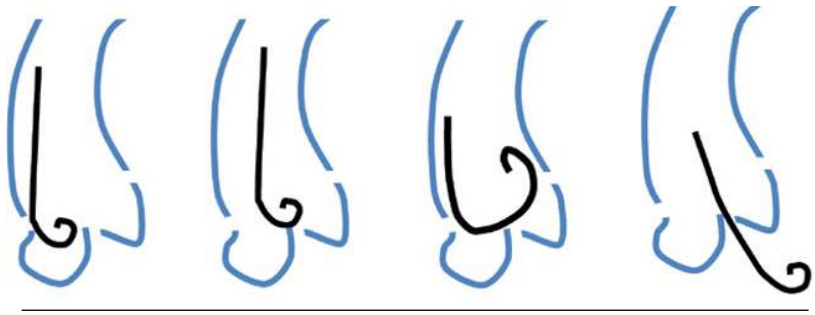
Pigtail catheter

To access the LV with a pigtail catheter, the pigtail itself may be used to cross into the LV without a wire (Figure 36.71). An angled pigtail catheter is typically used to better embrace the aortic curvature but also the LV. A wire may be used to provide stiffness and support to the catheter, particularly with a 4 Fr pigtail catheter, but the wire is kept inside the pigtail catheter all the way to the tip, not beyond the tip. The valve is crossed with the pigtail catheter itself:

- The pigtail is advanced over the lower cusp, then pulled to jump in between cusps.
- Then, it is pushed to loop over this between-cusp area (figure-of-nine). ***Avoid looping the pigtail in the lower cusp; some jump or movement out of the lower cusp must be seen before pushing it and looping it.***
- After looping it, it is pulled back with a slight clockwise or counterclockwise torque; it may fall into the LV during this pullback.
- If it does not, slightly torque the catheter to direct it in a different plane, then readvance it and pull it. This maneuver is repeated, each time with a slightly different torque.
- ***The loop has to be over the center of the valve, not eccentric over one cusp*** (most common cause of failure).
- *If the pigtail arm falls in the LV but the pigtail tip is still in the aorta, advance the wire beyond the tip*. This will invariably make the whole catheter fall in the LV.

If the pigtail repeatedly fails to fall into the LV, one may advance the wire beyond the pigtail tip and use it to access the LV, similarly to the technique with standard catheters (the wire is directed through catheter torque) (Figure 36.72).

Afterward, left ventriculography is typically performed in the RAO view, which shows the long axis of the LV, using **7–8 ml/s for a total of 20–24 ml. A larger volume (12 ml/s for 48 ml) and a steeper RAO angle is required to assess MR** (see Chapter 35).



Steps in pigtail catheter advancement

If the pigtail bend is in the LV but the pigtail tip is not → advance a wire → the whole system falls all the way in.

Figure 36.71 Pigtail catheter advancement. This is an LAO view. Advance a wire all the way to the tip of the catheter to stiffen it, then pull the pigtail to free it from the right cusp, and to jump higher up between the right and left cusps. Then advance the catheter and **loop it while making sure it is not stuck on one cusp, such as the lower right cusp** (if so, pull it until you see it jump). If the catheter does not fall in the LV, pull back with a torque (it may fall during the pull back). Then reattempt to push it and loop it after a slight clockwise or counterclockwise maneuver.

Aortic stenosis

In aortic stenosis, the LV is accessed using an Amplatz left (usually AL1), multipurpose, or JR catheter pointing toward the aortic valve orifice *and* a straight soft-tip 0.035″ wire (e.g., ADx), which is often more successful in crossing AS than J-tip wire. The steps are similar to the standard technique described earlier (Figures 36.69, 36.73). The catheter is torqued in the LAO view in a way that looks toward the aortic orifice; the catheter is used to direct the wire in various planes***. It is often best to start with an aortic cusp injection (6 ml/s for 12 ml) to localize the exact AS jet****, so that one can point the catheter/wire toward it*. The valve calcification seen on fluoroscopy may also help locate the aortic orifice. Serial catheter rotations and pull and push maneuvers with wire readvancement are performed until the wire

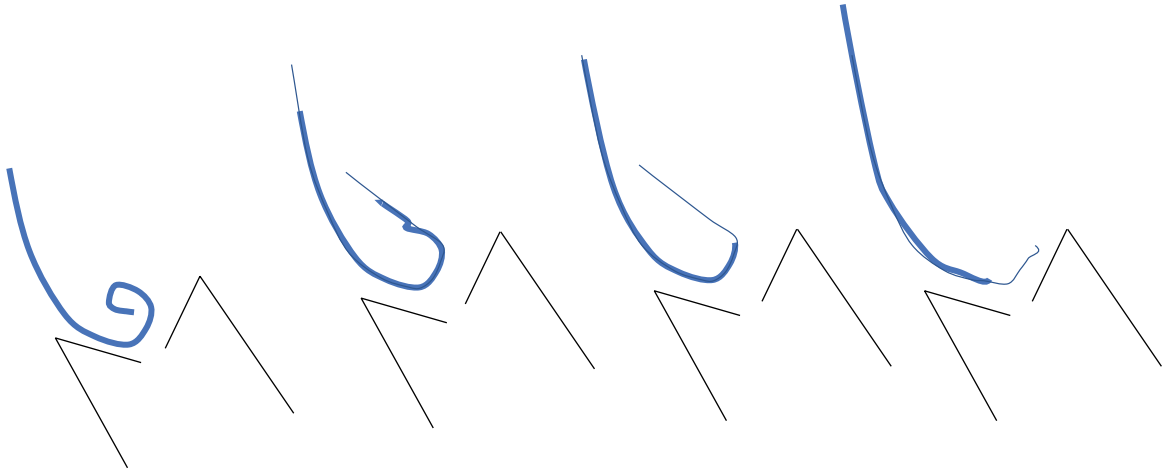


Figure 36.72 If direct crossing of the LV with the pigtail catheter fails, a wire may be advanced through it and used to cross. The wire is advanced while the catheter is pulled until the stiff body of the wire straightens the pigtail portion, making the catheter look like JR 4. This angled, "pseudo-JR4" catheter is now used to direct the wire across the aortic orifice, similarly to the JR4 maneuvers. Upon pulling the wire, e.g., after an unsuccessful attempt, the pigtail may form again: a significant wire length must be kept outside the catheter to keep it straightened by the stiff wire portion.

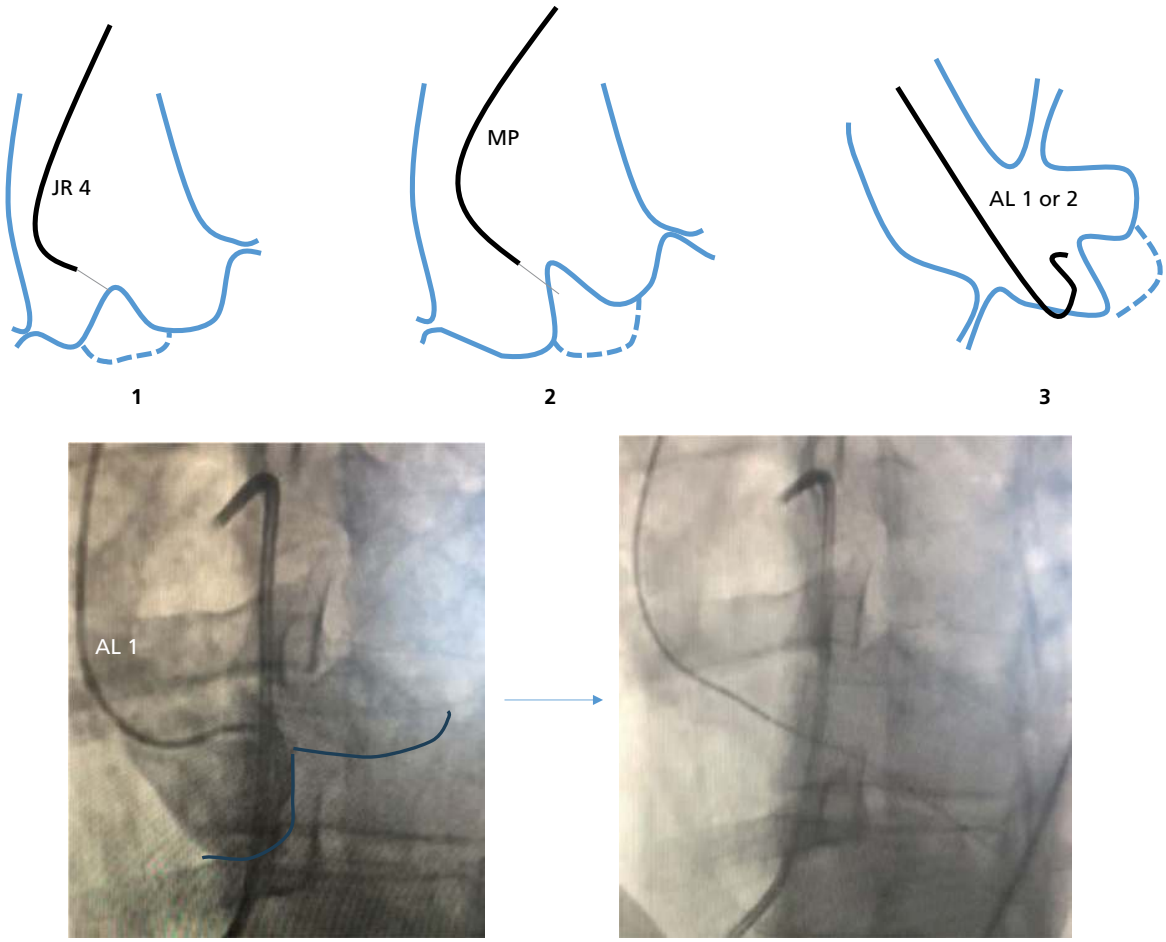

Figure 36.73 *(Top)* **Various aortic root shapes, with various locations of the aortic orifice on the LAO view.** A different catheter is necessary in each case to direct the wire into the aortic orifice: **(1)** JR 4, **(2)** multipurpose, **(3)** AL1 or 2. This aortic orifice is often indirectly localized using the aortic valve calcifications. *Moreover, an* ***aortic cusp injection (6 ml/s for 12 ml) helps localize the exact AS jet, so that one can point the catheter/wire toward it***. The aortic configuration **(3)**, wherein the aorta is elongated and horizontal while the aortic valve is vertical, is commonly seen in elderly patients. A soft, straight-tip wire is used to cross the valve in AS.

(*Bottom*) Crossing a stenotic aortic valve with AL1 catheter in the LAO view. Aortic root angiography done with AL1 delineates the aortic cusps and orifice. Subsequently, the catheter is properly directed to the aortic orifice, which is then crossed with a straight soft-tip wire.

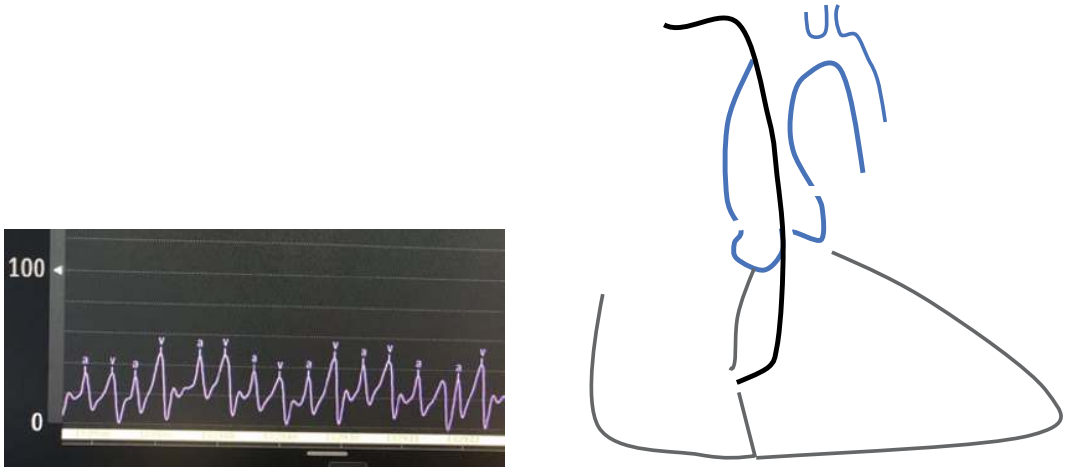

Figure 36.74 The JR 4 catheter presumably fell in the LV, yet the following tracing is obtained: atrial tracing with lower pressure and with A and V waves. Recognize that the catheter fell in the LA through the LV inflow.

crosses the aortic valve. The 2 keys to successful crossing of a stenotic valve are: **(i) to aim in the direction of the aortic orifice using proper catheter configuration** AND **(ii) to not be stuck onto one cusp (e.g., right cusp): in this case, the catheter is pulled up until a "jump" is seen** out of the cusp.

To reduce the risk of stroke during these manipulations, the catheter is flushed every 2 minutes and heparin anticoagulation is provided. After crossing the valve, the Amplatz catheter is exchanged for a double-lumen pigtail catheter using a long 260-cm J-tip wire (occasionally an Amplatz wire if the valve is very calcified).

Simultaneous LV and aortic pressures may be recorded in 2 ways: (i) through a 6 or 7 Fr double-lumen pigtail catheter positioned in the LV, or (ii) through a 4–5 Fr catheter positioned in the LV and a 6 Fr long sheath positioned close to the ascending aorta (e.g., 75-cm radial-to-periphery sheath). The cardiac output is simultaneously obtained through a Swan catheter that has been left in the PA, and the valve area is calculated.

Bicuspid AS

It is often more difficult to cross bicuspid AS than tricuspid AS, as the hole is eccentric. ~80% of bicuspid valves **have fusion of the right and left cusps**, and ~20% have fusion of the right and noncoronary cusps. In the first scenario: ***LAO view, which normally spreads apart the right and left cusps, is not likely to help, as the hole is rather in an antero-posterior plane, not right-left plane. The RAO view is instead orthogonal to the cusps*** and separates the anterior cusp (fused R + L) and the posterior cusp (NC). As such, perform aortic root angiography in RAO to delineate the aortic hole and consider further angulations, e.g., RAO caudal. In LAO, aortic root angiography will often show one domed cusp rather a separation between 2 cusps.

Note: From a radial access, the catheters tend to embrace the outer aortic curvature and may fall into the LA through the LV. Recognize this by the hemodynamic recording of LA pressure with A and V waves (Figure 36.74).

XXXV. Radial approach issues at the radial or brachial level (radial loop, high-branching radial artery)

When difficulty is encountered advancing a wire or a catheter around the forearm or arm, the issue may be mild radial-brachial tortuosity or angulation that is easily crossed with a soft-tip *non-polymer* Wholey wire under fluoroscopic guidance, without the need for angiography. Otherwise, when true difficulty is encountered and Wholey cannot be advanced, or the wire advances but it is difficult to advance the catheter over it, there are 3 anatomical possibilities (Figure 36.75):

- **Double radial artery**, with 2 branches: (i) a normal large radial artery that originates at the elbow; and (ii) a high-origin, small accessory radial artery. The wire may preferentially go in a straight line into the small straight branch. The wire may cross it easily, but the catheter cannot track over it at the elbow/arm level, or worse, if it does, the catheter may get entrapped and become difficult to remove.
- **Single high-branching radial artery *that is small***. A single high-branching radial artery, arising from the high brachial or axillary artery, is a common variant in 7% of patients and often goes unnoticed during our procedures as ***it is usually large***. This high radial artery only becomes problematic when it is small (particularly at the arm level), which is uncommon (<1%), or when its takeoff is too sharp.
- **Radial loop or sharp tortuosity**, seen in 2.3% of patients. All radial loops are associated with a small straight branch that arises from the apex of the loop. During blind advancement, the wire preferentially tracks the straight line of this small branch and may perforate it.

When the wire advances but the catheter cannot be advanced, the immediate consideration is usually arterial vasospasm. Administer vasodilators, but if the difficulty persists, immediately consider the 3 anatomical issues, particularly when the resistance is proximal, at the elbow or arm level.

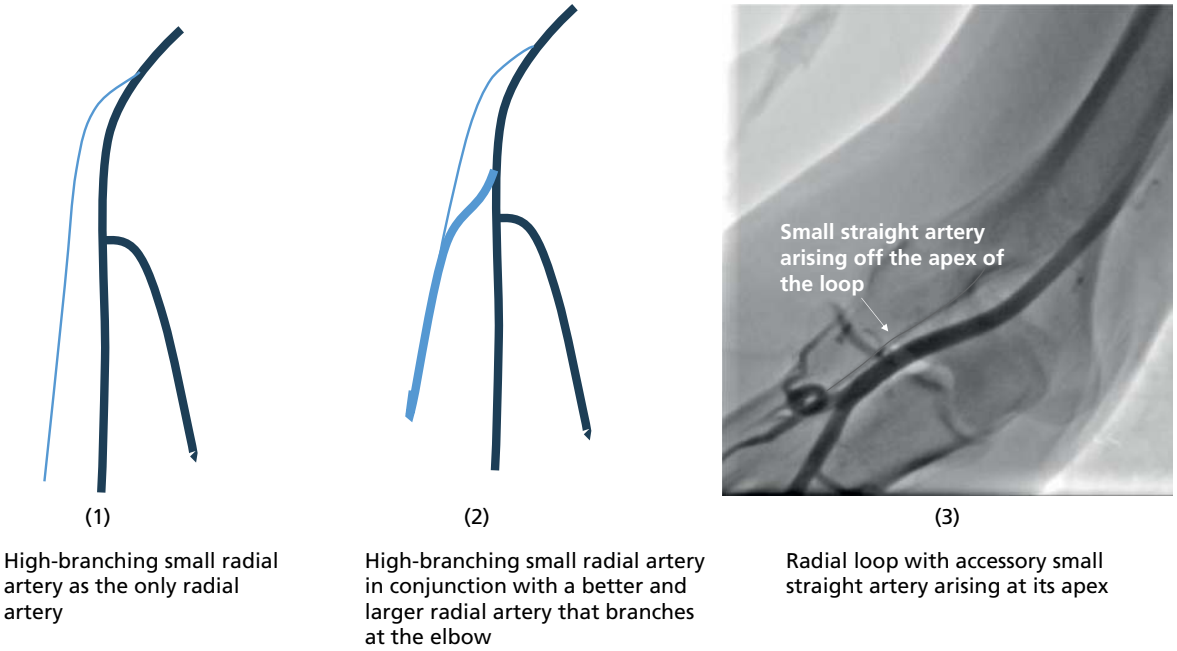

Figure 36.75 The 3 major anatomical issues at the radial or brachial level that prevent wire or catheter advancement. In **(1)** and **(2)**, the wire may advance easily in the small radial branch, but the catheter cannot track over it. In radial loops **(3)**, even the wire does not advance easily and may track and perforate the small straight artery. In all 3 cases, there is a small straight artery that the wire tends to follow and perforate or get stuck in.

When it is difficult to advance the wire or the catheter, obtain subtraction angiography via the radial sheath or catheter, then manage according to the finding:

- High-branching small radial artery as the only radial artery: administer vasodilators, and if difficulty persists, abort this access.
- Double radial artery: redirect the wire and catheter toward the large radial artery. Use an angled catheter, such as JR4, to direct the wire into this large artery.
- Radial loop: an ipsilateral angled view (e.g., RAO) may be needed to open up the loop, which may be underestimated in AP view. Direct a 0.014–0.018″ wire away from the small straight branch into the loop and cross it, then track over it a soft catheter, such as 4 Fr Glidecath.

On the angiography, look carefully for any small branch perforation that already occurred. ***Avoid using 0.035″ Glidewire at the forearm/arm level, as there are many small branches in the area and the Glidewire will easily enter them and perforate them***. Specifically, for radial loops, 2 major strategies may be employed (Figure 36.76):

- Cross the loop with **0.018″ or soft 0.014″ coronary wire**, then track over it a soft 4 Fr angled **Glidecath** catheter. Then, via the Glidecath, exchange the 0.014″ wire for 0.035″ wire, and try to straighten the loop by pulling the whole system with a counterclockwise maneuver (for the right radial access). If the loop straightens, advance a coronary diagnostic or guide catheter over the 0.035″ wire. If the loop does not straighten at some point with the 0.014″ or the 0.035″ wire, or if the patient complains of significant pain during the eventual catheter advancement, the access often needs to be aborted.
- *Balloon-assisted tracking* (BAT): cross the loop with 0.014″ coronary wire and directly track over it a 5-6 Fr coronary catheter with a monorail coronary balloon inflated at its tip and partially protruding outside the tip (1.5–2 mm × 15 mm balloon, inflated at ~5–6 atm, halfway inside the catheter tip, halfway outside it). This balloon serves as a dilator that facilitates movement of the catheter over the wire and prevents a razor effect on the arterial wall. The whole system is advanced along with the wire as a unit. BAT generally only works if the loop gets straightened with the 0.014″ wire.

XXXVI. Right heart catheterization (also review Chapter 37, *Hemodynamics*)

1. From jugular, subclavian, brachial, or femoral venous access, the right heart catheter is advanced to the RA while being connected to a pressure transducer (through the manifold, for example). It is flushed, and the RA pressure is recorded after ensuring proper zeroing at the mid-chest level

2. The catheter is then advanced to the RV, then the PA, while the balloon at the tip of the catheter is inflated and pressures are recorded. Special handling is required when femoral access is used, and any of the following 4 techniques may be applied (Figure 36.77):

i. At the base of the RV (bottom part of the cardiac silhouette), the catheter is pushed, then torqued *clockwise multiple 360° turns with a slight pull* until it points superiorly and falls into the PA. *Deep inspiration and cough may assist in crossing the pulmonic valve and advancing the catheter distally*.

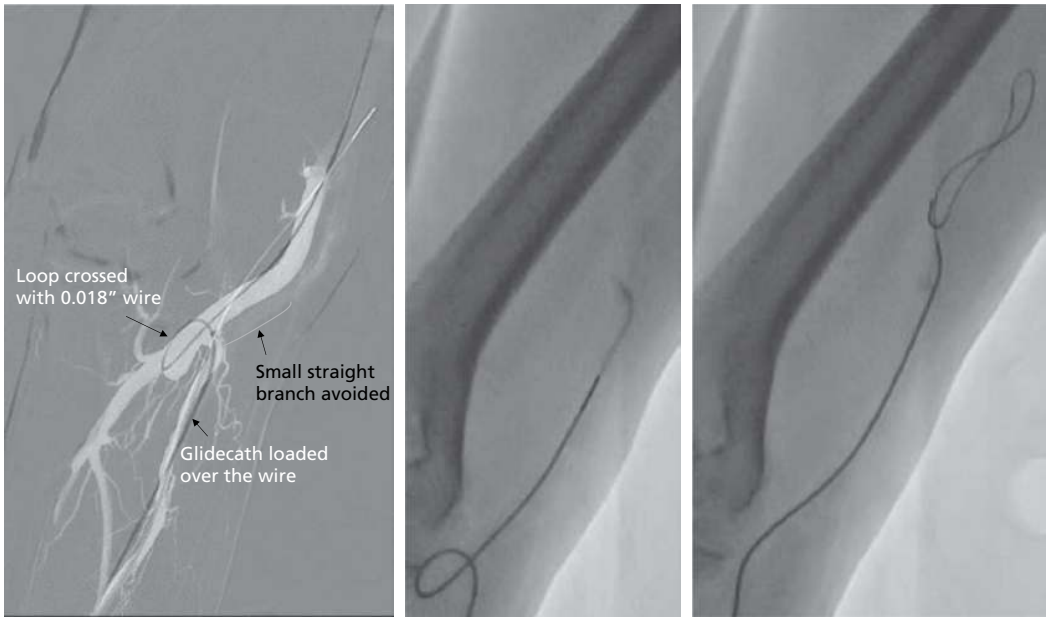

Figure 36.76 (*Left*) Radial loop crossed with 0.018″ wire and with the support of 4 Fr Glidecath, while avoiding the small straight branch at the apex of the loop. (*Middle*) 4 Fr Glidecath is then advanced over the wire and traverses the loop. The wire is then exchanged for a 0.035″ wire. The loop does not immediately straighten here. (*Right*) The whole system is pulled with counterclockwise torque to straighten the loop. A coronary catheter is then successfully advanced over the 0.035″ wire.

Notes:

- The loop is underestimated by angiography in this AP view and is better opened in RAO (ipsilateral oblique).
- A clockwise maneuver straightens the loop from left radial access.

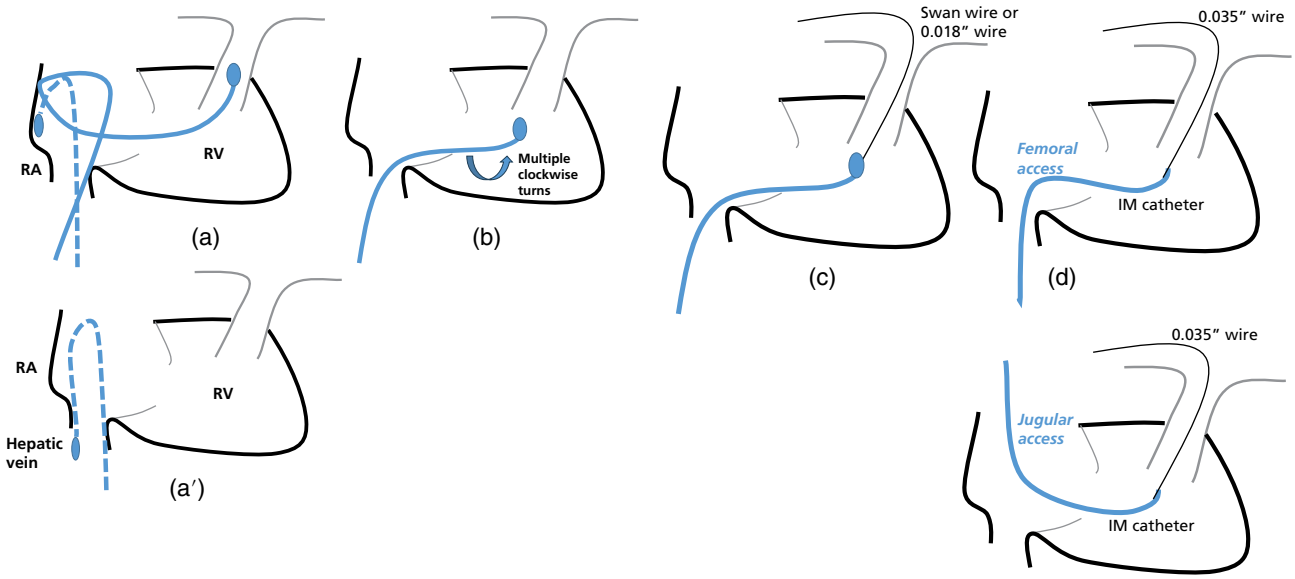

Figure 36.77 Swan catheter advancement from femoral access. (a) Catheter loop at the *lateral RA wall* allows advancement into the PA (*top*). **(a′)** The catheter tip may also be *hooked at the ostium of a hepatic vein* (*bottom*), pushed until it loops in the RA, then released with balloon deflation. In right HF with dilated hepatic veins, the catheter tends to dive deeply into the hepatic vein (unwanted effect) rather than be "stuck" at its ostium. **(b)** Alternatively, the catheter is kept straight, advanced at the bottom of the cardiac silhouette (RV), then torqued *multiple clockwise 360° turns with back-and-forth push and pull* until it points superiorly and falls into the PA. **(c)** Alternatively, a Swan wire is advanced through the Swan catheter and directed by catheter torque into the PA. This is especially useful in patients with dilated RV and/or TR: the wire helps the catheter access the PA, plus supports catheter tracking into the distal PA without prolapse in the RV. Remember that deep inspiration or cough/Valsalva followed by deep inspiration also allow easier catheter tracking into the PA. **(d) In cases of difficult Swan catheter advancement from a jugular or femoral access**, particularly in patients with dilated RV or tricuspid valve ring, use an angled 6 Fr coronary catheter, such as an IM catheter along with 0.035″ wire. Let the IM angle direct the wire into the RV then into the PA. After accessing the PA, the 0.035″ wire is exchanged for a stiff 0.014″ or 0.018″ wire, then the catheter is exchanged for the Swan catheter (Swan catheter cannot accommodate a 0.035″ wire).

ii. Alternatively, the catheter tip may be "hooked" in the ostium of a hepatic vein or directed toward the lateral RA with the balloon inflated. Then, when advanced, the catheter creates a loop in the RA. Once a loop is formed, further catheter push directs the tip of the loop toward the RV, then toward the RVOT and PA.

iii. A Swan wire or a supportive 0.014″–0.018″ wire may be advanced beyond the catheter tip, with the balloon inflated, and directed via catheter torque into the PA. This wire is particularly helpful in patients with dilated RV or TR. The wire also provides stiffness to the catheter and helps it track into the distal PA, preventing its prolapse into the RV. The catheter is advanced over the wire while the balloon is inflated, except in TR, where the inflated balloon may project the catheter backward, along the regurgitant flow.

iv. In the case of difficult Swan catheter advancement from jugular or femoral access, particularly in patients with dilated RV or tricuspid valve ring, use an angled 5 or 6 Fr coronary catheter, such as JR4 or IM catheter along with 0.035″ wire. Let the IM angle direct the wire into the RV then into the PA. After accessing the PA, the 0.035″ wire is exchanged for a stiff 0.014″ or 0.018″ wire, then the IM catheter is exchanged for the Swan catheter (Swan catheter cannot accommodate a 0.035″ wire).

3. After recording the PA pressure, the catheter is advanced with the balloon inflated until it wedges, i.e., the tip becomes immobile on fluoroscopy and one sees a change from PA pressure to PCWP on the monitor. PCWP is recorded, the balloon is then deflated and the catheter pulled back to the PA position. Avoid flushing in the PCWP position, as this may injure the pulmonary capillaries. Confirm wedge position by sampling O_2 saturation of the wedged catheter, which should be within 5% of the systemic O_2 saturation. This is particularly important in pulmonary hypertension or MS assessment.

4. An oxygen sample is obtained from the PA (both for CO calculation using the Fick equation *and* for detecting a shunt). Another oxygen sample is simultaneously obtained from the SVC via the side arm of the internal jugular sheath, to screen for left-to-right shunt.

In the case of a femoral access, SVC sampling is not readily possible, so oximetry shunt screen is left to the end. PA O_2 sample is obtained, then the Swan catheter is removed and SVC O_2 sample obtained with a multipurpose catheter. All O_2 samples should be collected within a few minutes in a calm steady state to avoid fluctuation of O_2 consumption and mixed venous O_2 saturation in the same patient. From femoral access, the SVC is easily engaged by advancing a multipurpose catheter over a 0.035″ wire into the SVC, immediately after removing the Swan catheter. The Swan catheter does not float easily into the SVC.

5. Cardiac output (CO) is measured using the thermodilution technique while the catheter is in the PA.

6. Left heart catheterization is performed afterward.

7. In special settings, simultaneous tracings may be necessary. During simultaneous recordings, "re-zero" both transducers simultaneously at the same level. After simultaneous recordings, switch catheter–transducer connections and ensure that the measurements and the pressure gradient remain unchanged (indirectly proving proper zeroing and proper/similar damping at the tubing level).

a. When suspecting constrictive pericarditis, standard right heart catheterization is initially performed. Afterward, the LV is accessed and simultaneous LV pressure and PCWP recordings are obtained, followed by simultaneous LV and RV pressure recordings.

b. When assessing for aortic stenosis, right heart catheterization is performed first and the right heart catheter is left in the PA. The left ventricle is then accessed, using the technique described in Section XXXII. Simultaneous LV–aortic pressure tracings are then recorded through a long 6 Fr sheath landing in the aorta and a 4 Fr catheter positioned in the LV. CO is simultaneously obtained through the Swan catheter that was left in the PA and the valve area is calculated.

c. When assessing for mitral stenosis, right heart catheterization is performed first and the right heart catheter is left in the PA. The left ventricle is then accessed and simultaneous LV pressure and PCWP recordings are obtained. CO is obtained (or repeated) after pulling the right heart catheter into the PA. In order to adequately calculate valve area, make sure the CO is performed close to the timing of gradient measurement. Some maneuvers may be performed if needed (e.g., handgrip, exercise), after which LV pressure, PCWP, PA pressure, and CO are evaluated again.

d. If pulmonary hypertension is not associated with an increased PCWP, and if pulmonary arterial hypertension is suspected, a vasodilator may be infused and PA pressure, PCWP, and systemic pressure reassessed at each up-titration. During the last titration of the vasodilator, measure CO and assess RA pressure on pullback.

Note: The right bundle being a slender bundle, the right heart catheter may produce a transient RBBB. In a patient with LBBB, this may lead to complete AV block. **Beware of AV block in any patient with LBBB undergoing right heart catheterization.** A temporary pacemaker should be readily available.

I. Right heart catheter (see Figure 37.1)

For catheterization technique, see Chapter 36, Section XXXV.

II. Overview of pressure tracings: differences between atrial, ventricular, and arterial tracings (Figures 37.2–37.4)

III. RA pressure abnormalities

Summary of RA pressure abnormalities (Figures 37.5–37.7):

- ***Deep X and deep Y descents:*** constrictive pericarditis, restrictive cardiomyopathy, and, most frequently, severe RV failure. Deep X and deep Y descents reflect loss of atrial and ventricular compliances, wherein atrial pressure goes sharply down and then up; they may also reflect the distension of the pericardium and the functional constriction seen in severe RV dilatation.
- ***Large V wave with deep Y descent:*** severe TR and/or RV failure. The X that precedes the V wave may be flattened and "carried up" by the large V wave (*flat X* = systolic flow blunting).
- ***Deep X and flat Y*** (blunting of diastolic flow): tamponade (mnemonic: **Flat Y Tamponade** = FYT). In tamponade, not only is chamber compliance impaired, but ventricular filling is totally impeded in diastole, explaining the flat Y. Y may also be flat with sinus tachycardia.
- ***Large V wave:*** severe TR and/or RV failure. In severe TR, the V wave is not only tall but wide and plateaus throughout systole, approximating the RV systolic pressure; this leads to a ***ventricularized*** RA pressure.
- ***Large A wave:*** impaired RV compliance.

IV. Pulmonary capillary wedge pressure (PCWP) abnormalities

PCWP is obtained by inflating the balloon-tipped catheter in a distal PA position until it occludes the PA branch. This leads to a stagnant column of blood beyond the balloon, the pressure of which equalizes with the downstream pulmonary venous pressure and thus the LA pressure. Similarly to LA pressure, PCWP has A, X, V, and Y waves. Mean PCWP is equal to mean LA pressure. However, PCWP is delayed ~50–100 ms in comparison to LA pressure because of the delay in retrograde pressure transmission from the LA through the

Companion website: www.wiley.com/go/hanna/cardiomedicine3e

pulmonary vasculature; therefore, PCWP's A and V waves peak later than LA's A and V waves. In addition, PCWP has a smoother contour with less steep and deep V downslope than LA pressure, as the pressure waveform gets damped while being transmitted from the LA through the pulmonary capillaries.

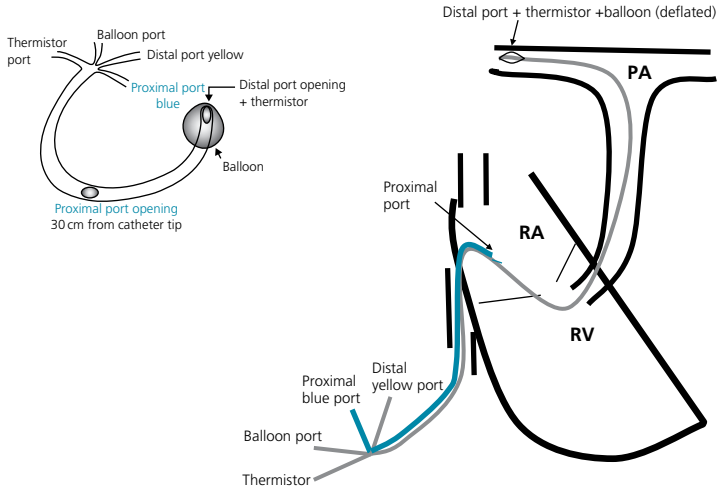

Figure 37.1 The Swan–Ganz balloon flotation catheter has 4 ports. (1) The ***distal yellow port*** communicates with the distal tip of the catheter; it is connected to the transducer and used to obtain pressures as the catheter is advanced through the right-sided chambers (RA → PA → PCWP). (2) The ***proximal blue port*** communicates with another lumen, 30 cm proximal to the tip. When the catheter tip is in the PA, the blue port opens in the RA; at this location, the blue port is used to inject saline into the RA and obtain cardiac output by the thermodilution technique. The blue port may also be used to record RA pressure simultaneously with PA pressure, particularly when a Swan–Ganz catheter is used for continuous monitoring in the cardiac unit. (3) The ***balloon port*** communicates with the distal balloon and allows wedging of the catheter tip (PA pressure → PCWP). (4) The ***temperature sensor port*** also communicates with the distal catheter tip; after cold saline is injected through the blue port (RA), the temperature sensor (PA) analyzes the temperature change over time and allows calculation of CO. Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

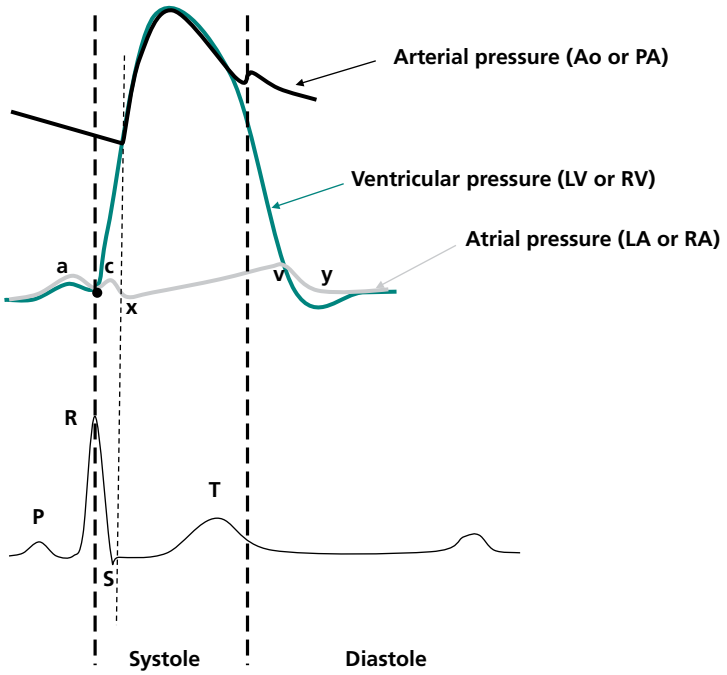

Figure 37.2 Timing of atrial, ventricular, and arterial pressures in relation to each other and to the ECG.

1. ***Atrial pressure*** has an A wave that follows the P wave, and **a V wave that peaks at or after the end of the T wave and almost intersects with the ventricular pressure descent (slightly precedes it).** Unlike the ventricular and arterial pressures, which peak during the ST–T segment, atrial pressure peaks before the ST–T segment (A wave) and after the ST–T segment (V wave).
2. ***Ventricular pressure*** increases in diastole and has an A wave.
3. ***Arterial pressure*** decreases in diastole, has no A wave, and has a dicrotic notch (the latter 3 features distinguish it from ventricular tracing).

Ventricular end-diastolic pressure (EDP) is the post-A ventricular pressure and corresponds to the peak of R wave (*black dot*).

Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

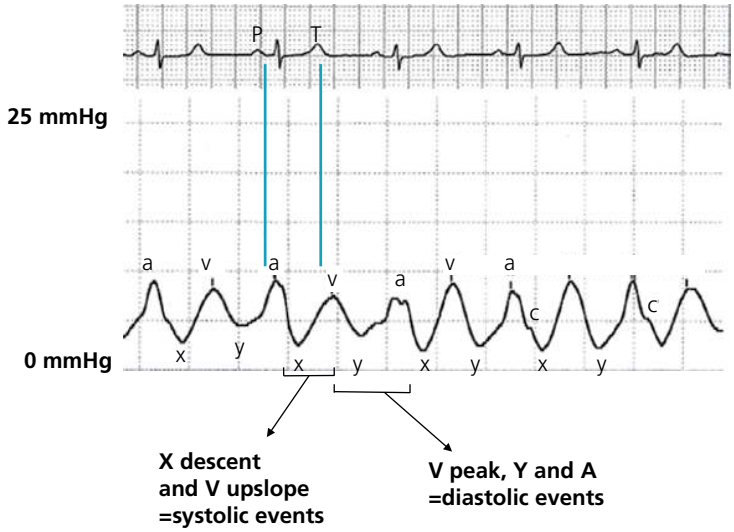

Figure 37.3 Atrial pressure tracing (RA or PCWP). A wave corresponds to atrial contraction and follows the electrocardiographic P wave. X descent corresponds to the atrial relaxation and to the downward pulling of the tricuspid annulus in early systole. V wave corresponds to atrial filling during ventricular systole while the tricuspid valve is closed. Y descent occurs in early diastole as the tricuspid valve opens and the RA rapidly empties. Thus, X descent and the upslope of V wave are systolic events (coincide with the pulse), whereas the peak of V wave, the Y descent, and the A wave are diastolic events.

V wave corresponds to atrial compliance (a large V wave implies a volume overload that overwhelms the atrial compliance). On the other hand, A wave corresponds to ventricular compliance. In normal individuals, RA pressure is characterized by A wave > V wave. LA is normally less compliant than RA, because it is constrained by pulmonary veins and it is thicker than RA, and thus LA V wave > A wave.

The C wave is a small positive deflection on the atrial tracing that interrupts the X descent and splits it into X1 and X2; it corresponds to the brief protrusion of the tricuspid valve into the RA in early systole during isovolumic ventricular contraction.

The A wave is only seen in sinus rhythm; it is not seen in atrial fibrillation (AF). However, a C wave may be seen in AF and may mimic the A wave.

Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

Figure 37.4 RA, RV, PA, and PCWP tracings obtained while advancing the catheter from RA to PA. LV pressure from LV catheterization is shown. In general, mean RA pressure is equal to RV diastolic pressure, and mean PCWP is equal to PA diastolic pressure and LV end-diastolic pressure. RA pressure and RV end-diastolic pressure are lower than PA diastolic pressure and PCWP, except in cases of "equalization of diastolic pressure" (tamponade, constriction, severe RV failure).

Concerning RA and PCWP pressures: note the A, X, V, Y waves and the timing of A and V waves (V peaks after ECG T wave).

Concerning PA: in contrast to the RV pressure, which increases throughout diastole (upsloping) and has A wave bump, PA pressure decreases throughout diastole (downsloping), does not have an A bump, and has a dicrotic notch. ***In contrast to the RA or PCWP tracing***, the systolic PA peak occurs during the ST–T interval and the PA pressure is downsloping in diastole.

Example of normal pressures (in mmHg):

RA pressure (mean) = 5; **RV** pressure = **25**/5; **PA** pressure = **25**/**12**; **PCWP** = **12**; **LV pressure** = 120/**12** (LVEDP = **12**)

Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

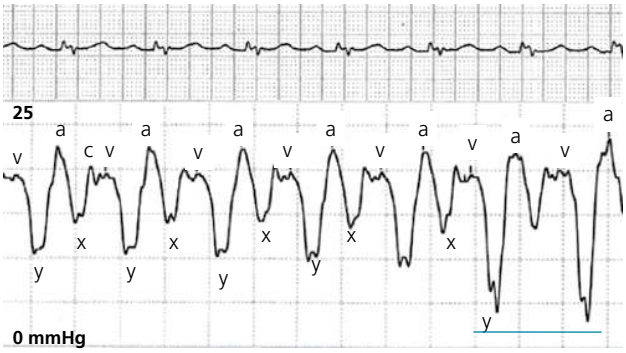

Figure 37.5 Typical deep X and deep Y descents on RA tracing, consistent with constrictive pericarditis but also with restrictive cardiomyopathy and severe RV failure. In severe RV failure, a large V wave with a flattened X descent may also be seen. V wave and Y descent become particularly prominent in inspiration (end of the tracing).

Normally, mean RA pressure declines with inspiration. A flat RA pressure without significant inspiratory drop of the mean, as in this case, is characteristic of RV failure and constriction. Only the depth of Y descent changes with inspiration. In severe RV failure, RA and RV compliances are severely overwhelmed, such that RA pressure may paradoxically rise with the inspiratory rise in preload, despite the direct transmission of negative intrathoracic pressure.

Reproduced with permission from Hanna and Glancy (2012).[1]

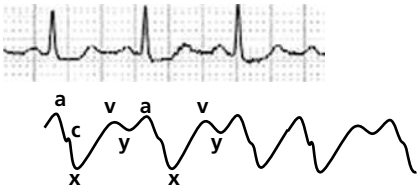

Figure 37.6 Deep X with flat Y on RA tracing, suggestive of tamponade. This may also be seen with sinus tachycardia, which shortens diastole and may thus attenuate Y descent. Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

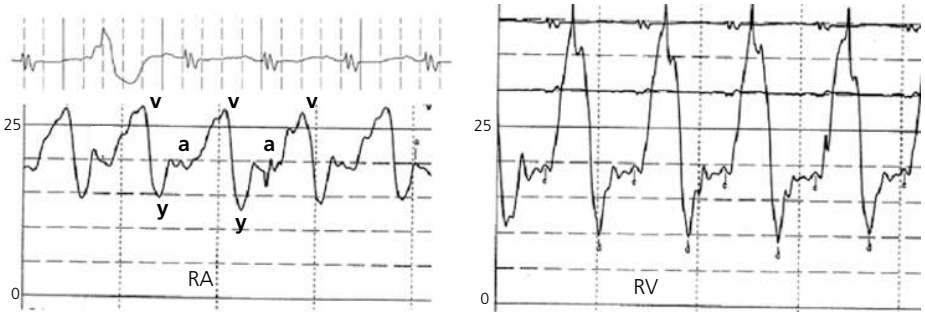

Figure 37.7 Ventricularized RA pressure in a patient with severe TR. The V wave is not only ample but wide and peaks during the ST–T segment, similarly to the RV systolic pressure. This is actually a large C-V wave, as C and V are merged: X2 is lost as regurgitant flow prevents the RA pressure drop during downward tricuspid pull. Note that Y descent is deep but X descent is flattened. Compare to RV pressure in the same patient. Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

A. Differential diagnosis of a large V wave

A large V wave is a V wave that is ≥ 50 mmHg or ≥ 10 mmHg larger than the mean PCWP, or, in its most severe form, ≥2× the mean PCWP. While classically associated with severe MR, ***a large V wave implies volume overload that overwhelms the LA compliance***. Thus, V wave may not be large in severe but compensated chronic MR (e.g., asymptomatic MR patients), and may, on the other hand, be large in decompensated HF even in the absence of MR. In fact, the causes of a large V wave are: (1) severe and decompensated MR; (2) decompensated LV failure; (3) mitral stenosis; (4) VSD. In one study, only 40% of patients with severe MR had a large V wave.[2] In practice, most large V waves are due to decompensated left HF, not MR. A gigantic V wave, i.e., a V wave that is ≥ 2–2.5× the mean PCWP, is usually secondary to MR.

B. Differentiate a large V wave from PA pressure

A large V wave may resemble PA pressure (Figures 37.8, 37.9). Five features help differentiate PCWP from PA pressure:

- V wave peaks after T wave, whereas systolic PA pressure peaks during T wave.
- V wave has a *gradual upslope and a sharp downslope*, which is opposite to the PA pressure (V wave has a more "peaked," narrow appearance).
- The segment between V waves is rather horizontal or upsloping and an A wave is usually seen, whereas on the PA pressure tracing the segment between the systolic peaks is downsloping, has a dicrotic notch, and does not have an A wave.
- Mean PCWP should be ≤ diastolic PA pressure and < mean PA pressure. *Upon balloon deflation and pullback of a wedged PA catheter, one should normally see a change in both the timing and the height of the pressure tracing corresponding to PA pressure*. However, a significant change is not sufficient to confirm true wedging.

- In difficult cases, particularly in PH or MS assessment, one should obtain a blood sample from the wedged catheter tip and check O_2 saturation. PCWP saturation = arterial saturation (≤5% difference). This is the best confirmatory method of appropriate wedging, as occasionally, A and V waves may be seen with a hybrid PA–PCWP tracing. It may be difficult to withdraw blood from a wedged Swan catheter when PCWP is low, but this is less problematic when V waves are large.

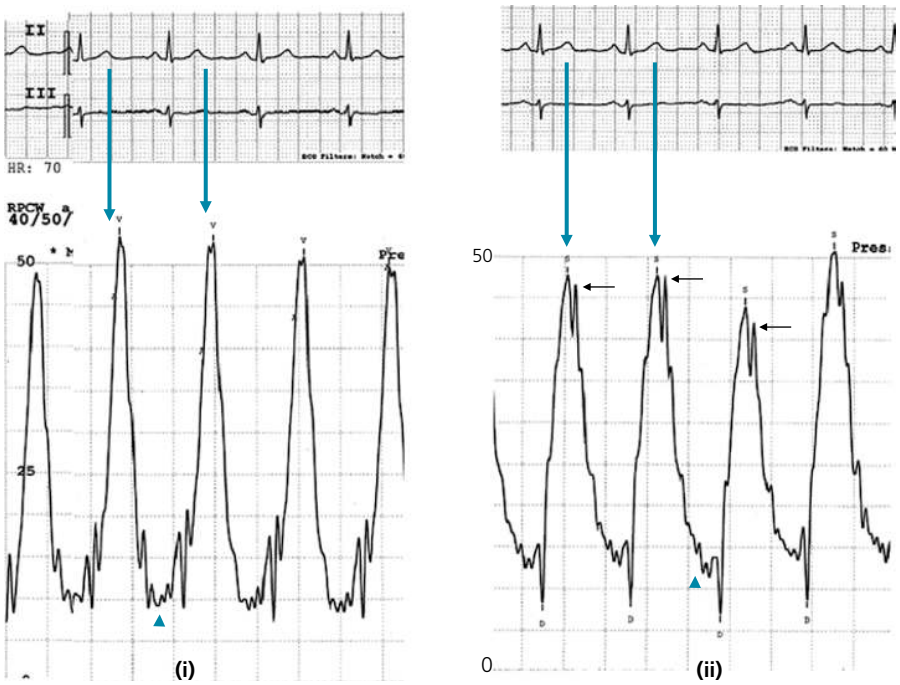

Figure 37.8 On gross inspection of both figures, they may seem similar. In fact, **(i)** is the PCWP tracing of a patient with severe MR and gigantic V waves, while **(ii)** is his PA pressure tracing. Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]
Keys to differentiate:

1. Timing: note that in (i) the V wave peaks *after the end of the ECG T wave*, whereas in (ii) the systolic PA pressure peaks *before the end of the T wave (down arrows).*
2. The segment between V waves is horizontal, whereas the segment between PA peaks, i.e., diastolic PA pressure, is downsloping (*arrowheads*).
3. PA pressure has a dicrotic notch. PA pressure has a sharp upslope and a slow downslope, which is opposite to the shape of a V wave ("peaky" shape).
4. PA pressure is double-peaked. The V wave is so large here that it matches the systolic PA pressure, a rare finding where PA flow will stop in end-systole, and PA pressure will display a second peak (*horizontal arrow*) that corresponds to the transmission of V wave to the PA pressure. This is also a rare case where *mean PCWP, driven by V, is higher than diastolic PA pressure*, but it remains lower than mean PA pressure.

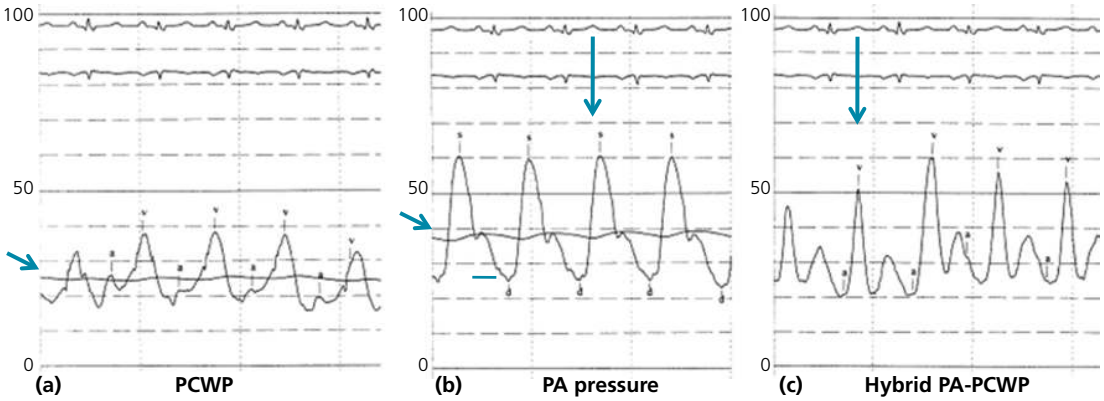

Figure 37.9 (a, b) PCWP tracing shows a large V wave of ~38 mmHg, with a mean PCWP of 26 mmHg. The mean PCWP (*left oblique arrow*) is lower than the mean PA pressure (*right oblique arrow*), and is equal to the PA diastolic pressure (*bar*), all of which is consistent with a true PCWP.

(c) Tracing is recorded after inflation of the PA catheter balloon. It may mimic a PCWP tracing with a large V wave. However, the mean of this pressure tracing almost approximates the mean PA pressure and exceeds the PA diastolic pressure. Also, the timing does not fit with PA pressure: the presumed V waves peak as early as the PA pressure peaks, during the ECG T waves (*vertical arrows*), and have a sharp upslope, similar to the PA pressure upslope; the presumed A waves precede the ECG P waves. Thus, this is not a true PCWP tracing. The PA catheter is "underwedged," which results in a hybrid PA–PCWP waveform.

C. Case of pulmonary hypertension: differentiate PCWP from a damped PA pressure

In severe pulmonary hypertension (PH), 2 issues arise. *First,* in severe PH, the segmental PA branches are dilated, which makes it difficult for the catheter to occlude these branches; thus, the wedged PA waveform may be a damped PA waveform and may overestimate the true PCWP (it is a hybrid PA–PCWP waveform with arterial rather than PCWP characteristics) (Figure 37.9). *Second,* a phasic PCWP depends on appropriate retrograde transmission of LA pressure through the pulmonary vasculature without any anatomical barrier; in case of severely elevated pulmonary arteriolar or venous resistance, retrograde transmission of LA pressure is attenuated, producing a damped and flattened PCWP that lacks distinct waves and descents. In the latter situation, mean PCWP may approximate mean LA pressure, but the waveform is flat and featureless and falsely creates or overestimates a transmitral gradient. ***In summary, the PCWP of PH may be a false PCWP (damped PA waveform), or a true PCWP that is, nonetheless, featureless (damped PCWP waveform).***

Beside the issue of PCWP–LA pressure correlation, a major pitfall of LA pressure itself is that it is not equivalent to LV preload, which is LV end-diastolic volume. Patients with a very steep LV pressure–volume relationship, such as patients with acute HF or severe diastolic HF, may have a relatively normal LV preload volume with a high LA pressure.

V. LVEDP

LV diastolic pressure slightly increases throughout diastole, and, except in AF, has an A wave that corresponds to the atrial A wave. LVEDP is located at the downslope of the A wave. In normal individuals with compliant LV, LV pressure increases only slightly after A wave, so that post-A LV pressure is not significantly higher than pre-A LV pressure. In *compensated LV dysfunction*, LV pressure is normal throughout diastole but increases only after A wave; similarly, LA pressure is overall normal and increases only after A wave, explaining why mean LA pressure better correlates with pre-A LV pressure than with LVEDP. In *decompensated LV dysfunction*, LV pressure is high throughout diastole and increases further after A wave (Figures 37.10 and 37.11, Table 37.1).

To identify LVEDP, search for a bump on the LV upstroke; the bump is A wave and the point that follows this bump is LVEDP (Figure 37.12). *While LVEDP varies with respiration, the most accurate LVEDP is obtained when the respiratory pressure is 0 mmHg, which, unless the patient actively exhales, corresponds to end-expiration and coincides with the highest recorded LVEDP point* (breath hold not recommended, due to the risk of inadvertent positive pressure strain). *This end-expiratory rule applies to all measured pressures.* Yet, in patients breathing deeply (e.g., obese), expiratory pressure is positive; the negative inspiratory and positive expiratory pressures cancel each other out, and averaging vascular pressures over several respiratory cycles is acceptable: mean pressure is often closer to the highest value, ~1/3 of the way between the highest and lowest values.

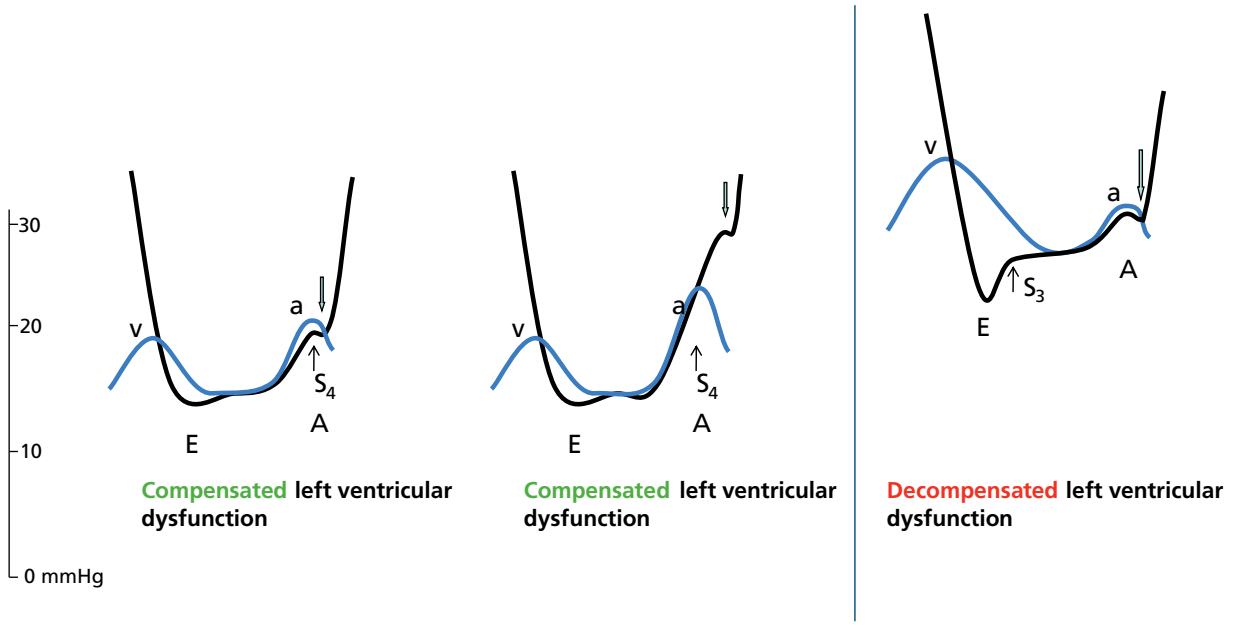

Figure 37.10 Diastolic superimposition of LA pressure (or PCWP, in *blue*) **and LV pressure** (in *black*). *Downward arrows* point to LVEDP.

In compensated LV dysfunction, LV pressure is normal before A wave but increases after A wave (LVEDP). On PCWP tracing, V wave is normal, A wave is increased, but mean PCWP is overall normal and better correlates with the pre-A LV pressure than the elevated LVEDP (PCWP < LVEDP). Post-A PCWP (X descent) is the best correlate of LVEDP.

In decompensated LV dysfunction, both pre-A and post-A LV pressures are elevated. On PCWP tracing, V wave is large, and mean PCWP is equal to LVEDP or larger than LVEDP, depending on how large V wave is.

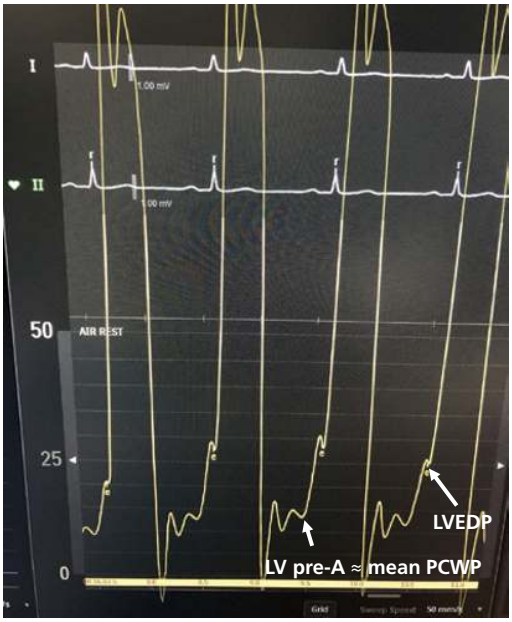

Figure 37.11 Whenever LVEDP is high but pre-A LV pressure is normal, mean PCWP correlates with the pre-A LV pressure rather than the LVEDP. PCWP is normal throughout most of the cardiac cycle, hence mean PCWP is normal; only end-diastolic PCWP shoots up, like end-diastolic LV pressure LVEDP. This is a sign of compensated LV dysfunction: LA is mostly normal throughout most of the cardiac cycle, but LV compliance only gets overwhelmed with the extra volume in end diastole. These patients are prone to decompensation with IV fluids or AF or strenuous exertion, but they are compensated now.

Conversely, when LV pre-A and post-A pressures are both high, mean PCWP correlates with LVEDP and may exceed it.

Table 37.1 Correlation between LVEDP and mean PCWP.

- Normally, LVEDP ~ mean PCWP
- LVEDP > PCWP: compensated LV dysfunction, AI
- LVEDP ≈ PCWP in decompensated LV failure
- LVEDP < PCWP: MS, MR with large V wave, decompensated LV failure with large V wave

  In MS, end-diastolic PCWP is higher than LVEDP, whereas in MR or LV failure with a large V wave, end-diastolic PCWP remains equal to LVEDP, but mean PCWP is larger than LVEDP (driven by the large V wave).

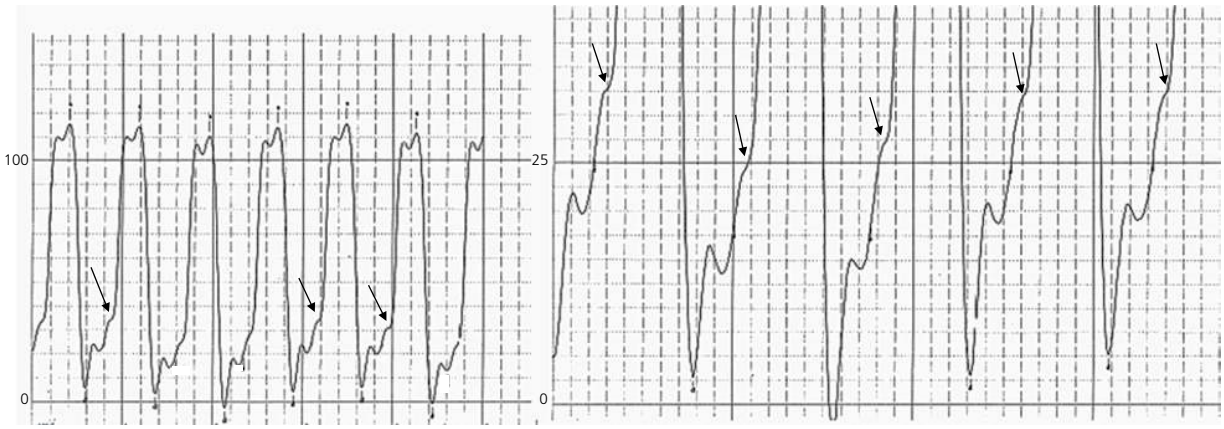

Figure 37.12 LVEDP corresponds to the bump seen on the LV upstroke (*arrows*), often coinciding with the peak of R wave on the ECG (LVEDP may be further delayed from R peak in case of long tubing between catheter and transducer). This bump is LV A wave. In this figure, LV pressure steeply increases during and after A wave, leading to a pronounced A wave and a high LVEDP of 32 mmHg. **LVEDP does not correspond to the flat/plateau portion of LV diastole.** Always look for these bumps when assessing LVEDP, as long as the rhythm is sinus. The pre-A LV pressure is only borderline increased (15–20 mmHg): in this scenario, it is a better correlate of mean LA pressure than LVEDP is. Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

Note: Normal hemodynamic values

- RA: mean ≤ 7 mmHg
- RV: ≤35/8
- PA: ≤35/12 (mean PA pressure ≤20 mmHg)
- LVEDP: ≤16 mmHg
- PCWP: mean ≤15 mmHg. Note that values of 15–18 mmHg may not lead to congestion in patients with chronic heart failure who have increased pulmonary capillary lymphatic drainage. However, PCWP of 15–18 mmHg corresponds to an unnecessary increase in LV volume preload and may be safely reduced to 12 mmHg, except in patients with poor LV compliance, such as new-onset acute heart failure or severe diastolic heart failure (see Chapter 5, Figure 5.6).

VI. Cardiac output and vascular resistances

The cardiac output may be measured using **3 different methods**: (1) true Fick method, which is the most accurate method; (2) assumed Fick method; (3) thermodilution. The simplified Fick equation is shown in Table 37.2.

Short of truly measuring it, O_2 consumption may be assumed to be 125 ml/min/m^2 of BSA or 3 ml/min/kg at rest. This assumption is subject to a large variation between individuals and within the same individual depending on the degree of wakefulness and anxiety at different times during the procedure. This assumption may be associated with discrepancies of 25% or more in comparison with the true Fick method. Thus, using 125 ml/min/m^2 of BSA may underestimate CO in a fully awake anxious or agitated young patient, or a septic patient with elevated O_2 consumption, and may overestimate CO in elderly patients, in heart failure patients who have reduced O_2 consumption, and in obese patients (the formula uses true body weight and surface area, which overestimates O_2 consumption of the obese). In HF, O_2 consumption is mainly limited during exercise, but may be limited at rest in severe class III/IV HFrEF, wherein the equation over- estimates CO by ≥25% in ~20% of patients.[3] Aside from O_2 consumption, the simplified Fick equation itself is subject to error in patients receiving excessive O_2 therapy, that is, if SaO_2 is >90% at baseline or becomes ~100% with O_2: this is because O_2 therapy increases SvO_2 disproportionately to SaO_2 and leads to overestimation of cardiac output (compared to SaO_2, SvO_2 is on a steeper portion of the O_2–hemoglobin dissociation curve, which explains the sharper rise with O_2 therapy). The excess of arterial O_2 cannot raise arterial Hb's SaO_2 beyond 100% and is instead carried in a dissolved fashion then unloaded onto the Hb of the venous system, raising SvO_2. Notably, arterial O_2 delivery increases with O_2 therapy, partly through this increase in the dissolved, non-hemoglobin-bound O_2 content that is trivial at baseline, but this is not reflected in SaO_2 and the simplified Fick equation.

Thermodilution is measured using a PA catheter that has a thermistor at its distal tip. After the catheter is positioned in the PA, 10 ml of cold (room temperature) saline is injected instantaneously through the blue RA port. The thermistor analyzes how quickly the temperature drops as blood reaches the PA and how quickly it recovers. The higher the cardiac output, the more brief and sharp the temperature change will be with a small area under the curve. The colder the injectate, and the more instantaneously it reaches the RA, the more accurate the measured cardiac output. Usually 3–5 measurements are obtained to average the slight variability of cardiac output (~10%) that occurs with respiration and various levels of wakefulness; the goal is to obtain 3 values within 10% of each other and average them. When used for valve area calculation, the cardiac output and pressure gradient should be measured almost simultaneously to account for this variation. *This method is valid in most cases, and has <5–10% error in comparison with the true Fick method, except in TR, low cardiac output, and right-to-left or left-to-right shunt:*

- *TR:* some data suggest that thermodilution underestimates CO by ~15% in moderate or severe TR, as the cold blood keeps recirculating and elongates the thermodilution curve. However, other data suggest a good correlation between true Fick and thermodilution in TR, as TR truly reduces CO.
- *Low cardiac output <3.5 L/min* (particularly <2.5 L/min): the injectate warms up excessively as it is traveling slowly through the RA and RV, before it reaches the PA, and gives the wrong impression of a slight and brief temperature change at the tip, hence the impression of a higher CO (up to 35% higher).
- *Shunts:* right and left cardiac outputs not being equal in shunt cases, thermodilution estimates the right rather than the left cardiac output, i.e., Qp rather than Qs. But even Qp is not adequately estimated in shunts. A large left-to-right shunt considerably dilutes the injectate and prevents any meaningful temperature change at the thermistor, or causes left-to-right recycling of the injectate and elongation of the curve.

Table 37.2 Simplified Fick equation.

O_2 consumption (ml O_2/min)	=	**Arterial O_2 delivery − Venous O_2 return**
	=	(**CO** × **arterial O_2 content**) − (**CO** × **venous O_2 content**)
	=	**CO** (liters blood/min) × **AV difference in O_2 content** (ml O_2/liters blood)
⇒ **CO** (liters blood/min)	=	**O_2 consumption** (ml O_2/min) divided by: **AV difference in O_2 content** (ml O_2/liters blood)
1. Arterial O_2 content (ml/L)	=	SaO_2 × Hb (g/dl) × maximal capacity of 1 g of Hb to carry O_2 (1.36 ml O_2/g of Hb) × 10
2. Venous O_2 content (ml/L)	=	SvO_2 × Hb × 1.36 × 10
⇒ **CO**	=	**O_2 consumption (ml/min) divided by: 1.36 × hemoglobin × (SaO_2 − SvO_2) × 10**

SaO_2 and SvO_2 are expressed as decimal fractions. ***In the absence of a left-to-right shunt, SvO_2 corresponds to O_2 saturation of the PA, where the venous blood achieves its best mixing from all sources*** (SVC, IVC, coronary sinus); sampling of the RA may selectively capture 1 of these 3 sources rather than their mixture. True arterial oxygen content is the amount of oxygen bound to hemoglobin *plus the amount of oxygen dissolved in arterial blood*. The latter equals 0.03× PaO_2 (ml/L); it is negligible (~1.5%) and is ignored in this simplified equation, unless under high flow of O_2 with high PaO_2. CO, cardiac output; Hb, hemoglobin; SaO_2, arterial O_2 saturation (transcutaneous O_2 saturation may be used instead of SaO_2 if an arterial sheath has not been placed); SvO_2, mixed venous O_2 saturation.

Mixed venous O_2 saturation (SvO_2) provides the best assessment of the adequacy of cardiac output. SvO_2 is determined by 3 factors: CO, Hb, and arterial O_2 saturation. *Given a normal hemoglobin level and a normal arterial O_2 saturation,* and in the absence of O_2 therapy, a normal SvO_2 of 65–78% corresponds to an adequate cardiac output that matches the peripheral O_2 demands. Patients with inappropriately reduced CO increase their peripheral extraction of O_2, thus reducing SvO_2. Patients who are sedated may have a low CO that, nonetheless, matches their peripheral demands, explaining the normal SvO_2 despite the low CO. On the other hand, heart failure patients exerting themselves or some patients with septic shock may have a normal or high CO that is, nonetheless, not high enough to match their peripheral demands; therefore, SvO_2 is low despite the high CO.

High-flow O_2 therapy increases O_2 delivery and raises SvO_2 disproportionately to SaO_2 if SaO_2 becomes ~100%. SvO_2 may exceed 65% despite a low CO. SvO_2 still correlates with the appropriateness of O_2 delivery, but less so with the appropriateness of CO.

In the absence of a left-to-right shunt, the oxygen saturation of the PA represents the best measurement of SvO_2, PA being the chamber where the venous blood achieves its best mixing from all sources. In the presence of a shunt, SvO_2 is O_2 saturation of the chamber just proximal to the shunt, i.e., proximal to the O_2 step-up.

Consider the following situations:

- Low PA O_2 despite a normal CO: severe anemia or hypoxemia
- Normal PA O_2 despite severe anemia: compensatory high CO that maintains O_2 delivery despite anemia
- Normal PA O_2 despite low CO: undiagnosed left-to-right shunt, high-flow O_2 therapy
- High PA O_2 >80%: high CO, undiagnosed left-to-right shunt, or high-flow O_2 therapy

The evaluation of systemic vascular resistance (SVR) is useful in assessing shock states, while the evaluation of pulmonary vascular resistance (PVR) is useful in assessing pulmonary hypertension. Vascular resistance is obtained by the general equation:

Resistance = Δ pressure/CO
→ SVR (in dyn.s.cm^{-5}) = (mean systemic arterial pressure – RA pressure) × 80/CO
→ PVR (in dyn.s.cm^{-5}) = (mean PA pressure – PCWP or LA pressure) × 80/CO
→ PVR (in Woods units) = (mean PA pressure – PCWP or LA pressure)/CO

Despite a potential discrepancy, LVEDP may be used as a surrogate of LA pressure when a proper PCWP tracing cannot be obtained.

Normal SVR = 700–1500 in dyn.s.cm^{-5}; normal PVR <2.5 Wood units

Cardiac power output (in Watts, or Joules/sec) = (flow × pressure) = (CO × mean systemic arterial pressure)/451. This is a variable that integrates CO but also the pressure generated by the heart, which is what the peripheral tissues "see". Unlike CO, it represents the *pumping ability of the heart* against systemic vascular resistance. Normal cardiac power output at rest is 1 Watt, and increases with stress or exercise up to 6 Watts. It is significantly abnormal when <0.6 and is the strongest predictor of mortality in cardiogenic shock (SHOCK registry). ***SvO_2 assesses how well CO matches peripheral O_2 demands; cardiac power output assesses how well CO matches systemic vascular resistance***.

VII. Shunt evaluation

A. Left-to-right shunt

Normally, $SvO_2 = O_2$ saturation of PA

$\approx O_2$ saturation of RV $\approx O_2$ saturation of RA

$\approx$ average O_2 saturation of SVC and IVC $\left(=[3\times SVC+1\times IVC]/4 \text{ or } [2\times SVC+1\times IVC]/3\right)$

O_2 saturation of the SVC is normally lower than O_2 saturation of the IVC by a few percentage points (~5%). The renal O_2 extraction being relatively low, the renal venous O_2 saturation is high and increases the IVC O_2 saturation at and beyond the level of the renal veins (the kidneys have high O_2 demands but receive a very high flow, ~20% of CO, hence their O_2 extraction is lower than most other organs, <15%). Mixed venous blood is a mixture of IVC (~55%), SVC (~45%), and coronary sinus blood (~5%). While the IVC flow is normally higher than the SVC flow (55% vs. 45% of cardiac output), mixed venous O_2 saturation more closely approximates SVC O_2 saturation than IVC O_2 saturation as a result of the very low O_2 saturation of the coronary sinus return (~30–40%). Note that, *in shock states,* blood is directed away from the splanchnic system, which increases splanchnic O_2 extraction, hence IVC O_2 saturation becomes lower than SVC O_2 saturation. Also, during running, the lower body increases its O_2 extraction: IVC O_2 becomes lower than SVC O_2. In any case, a low IVC sample, below the renal veins, will have a low O_2 saturation.

A significant left-to-right shunt is characterized by an O_2 step-up of 8% between SVC and RA, 7% between average SVC-IVC and PA, or 5% between RV and PA. During a routine right heart catheterization, 2 blood samples are typically acquired (PA and SVC). If a significant shunt is detected on this screen (8% between SVC and PA), a full oximetry run with sampling of all cardiac chambers needs to be performed. O_2 saturation of the RA is most subject to false measurement, depending on whether the sample is obtained close to the stream of the SVC, IVC, or coronary sinus. If the RA saturation is low on 1 sample only, it is likely that this sample was obtained close to the coronary sinus and represents a normal finding (e.g., 55% on 1 RA sample, while the remaining RA samples and the PA sample are 65%). Thus, try to collect multiple RA samples to avoid this sampling artifact, and preferably sample the RA at the mid-lateral level, with the catheter looking toward the border of the RA silhouette.

B. Right-to-left shunt

Arterial O_2 saturation ≥95% on ambient air rules out significant right-to-left shunt. Arterial O_2 saturation <95% may be secondary to a right-to-left shunt or, more commonly, lung disease or sedation. A right-to-left shunt is presumed present when arterial O_2 saturation is <95% and does not resolve with O_2 therapy and with taking a few deep breaths. In this case, pulmonary venous O_2 saturation (PV O_2) is considered 98% and the reduced arterial O_2 saturation is considered an O_2 step-down from shunting. On the other hand, if right-to-left shunt is deemed absent, PV O_2 is considered equal to the low arterial O_2 saturation.

Alternatively, if ASD or PFO is present, one may access the left upper pulmonary vein and directly measure PV O_2 and any potential O_2 step-down. Ideally, sampling all 4 pulmonary veins and averaging their O_2 saturations is required, but this is not usually feasible. Sampling 1 vein, the left upper pulmonary vein, through a defect is feasible, and in the right context, O_2 step-down from this 1 vein corroborates right-to-left shunting and is used in Qp calculation. However, O_2 step-down between 1 vein and SA O_2 does not, by itself, establish right-to-left shunting, as the other pulmonary veins may have low O_2 saturation with no step-down (the patient may have lung disease that is heterogenous, the left upper lobe being less involved and less hypoxic).

Isolated pathological right-to-left shunt is rare in adults. In adults with advanced left-to-right shunt causing PAH and shunt reversal, the shunt may not have fully reversed yet and **there is still usually left-to-right shunting (bidirectional shunting)**. Thus, a right-to-left shunt is usually diagnosed in a patient with a large defect, a concomitant left-to-right shunt, and O_2-refractory hypoxemia. Right-to-left shunting in adults may be seen in 3 clinical contexts (Chapter 18, Section 4).

C. Calculation of shunt flow ratios

In the absence of shunting, the pulmonary (right heart) blood flow is equal to the systemic (left heart) blood flow. A left-to-right shunt increases the pulmonary blood flow, which becomes equal to the sum of the systemic blood flow plus the shunt flow. The *net shunt flow ratio* is equal to:

$$\text{Pulmonary blood flow (Qp)} / \text{systemic blood flow (Qs)}$$

→ Using the Fick equation for flow:

$$Qp = O_2 \text{ supply by the lungs (ml/min) divided by } 1.36 \times \text{hemoglobin} \times (PV\ O_2 - PA\ O_2) \times 10$$

$$Qs = O_2 \text{ consumption divided by } 1.36 \times \text{hemoglobin} \times (SA\ O_2 - MV\ O_2) \times 10$$

$$Qp/Qs = (SA\ O_2 - MV\ O_2) \text{ divided by } (PV\ O_2 - PA\ O_2)$$

where SA O_2 is systemic arterial O_2 saturation, MV O_2 is mixed venous O_2 saturation obtained in the right-sided chamber just proximal to the O_2 step-up, PV O_2 is pulmonary venous O_2 saturation, and PA O_2 is pulmonary arterial O_2 saturation (Figure 37.13). The O_2 supply by the lungs is equal to the O_2 consumption systemically, hence the numerators cancel each other out in the ratio.

A Qp/Qs ratio of <1.5 signifies that the net left-to-right shunt is small. Qp/Qs of 1.5–2 and >2 signify intermediate and large left-to-right shunts, respectively, and are indications to repair the defect. Qp/Qs <1.0 signifies a net right-to-left shunt, i.e., reversal of a left-to-right shunt and typically contraindicates closure of the shunt.

Qp/Qs corresponds to the net shunt ratio. The patient may have large left-to-right and right-to-left shunts (bidirectional shunt) with hypoxemia and pulmonary hypertension, but a small Qp/Qs ratio as the ratio assesses the net shunting into the predominant direction, e.g., left-to-right. In the latter case, Qp/Qs underestimates the severity of shunting, which may be better assessed by echo or by the calculation of the absolute left-to-right and right-to-left shunts (see Appendix 1).

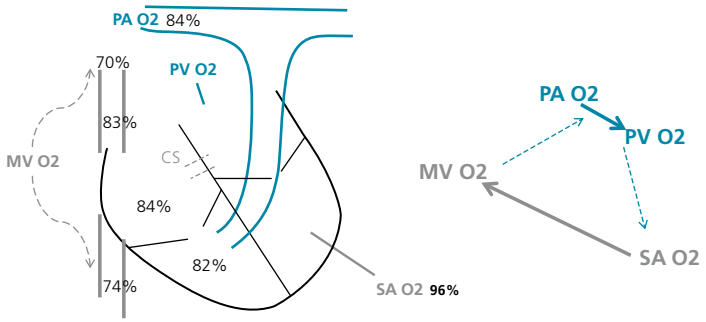

Figure 37.13 O_2 saturation at various levels. Note that MV O_2 and SA O_2 used as numerator in the Qp/Qs equation correspond to the "extreme" chambers (connected by *gray arrow*), while PA O_2 and PV O_2 used as denominator correspond to the in-between chambers (connected by *blue arrow*).

There is an O_2 step-up of ≥8% between the SVC and the PA. The O_2 step-up occurs at the level of the low SVC, signifying a possible sinus venosus ASD.

MV O_2 = (3 × high SVC + 1 × IVC)/4 = (3 × 70 + 74)/4 = 71

Qp/Qs = (SA O_2 – MV O_2)/(PV O_2 – PA O_2) = (96 – 71)/(96 – 84) = 2.1

In the absence of right-to-left shunt, PV O_2 = SA O_2. SA O_2 >95% on ambient air rules out any significant right-to-left shunt. For simplification, one may use SVC O_2 saturation (in this case, high SVC) as an estimation of MV O_2. ***In the absence of a R-L shunt, Qp/Qs may be calculated quickly as: (SA O_2-lowest value)/(SA O_2-highest value).*** Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

Other pitfalls of Qp/Qs

- The simplified Qp/Qs equation is not accurate in ***patients receiving O_2 therapy*** with induced SA O_2 or PV O_2 >90–92% for 3 reasons: (1) O_2 therapy increases the contribution of dissolved O_2 to the overall blood O_2 content, especially blood O_2 content of the pulmonary veins, where O_2 partial pressure is highest; (2) O_2 is a pulmonary vasodilator that may reduce PA pressure and the baseline right-to-left shunt; (3) the left-sided O_2 content, overloaded with O_2 therapy, gets shunted onto the mixed venous system, which has the lowest O_2 saturation and is on the steepest portion of the O_2 saturation–hemoglobin curve. As such, O_2 therapy excessively raises O_2 saturation past the shunt, i.e., PA saturation. Being on a flat portion of O_2-hemoglobin curve, PV O_2 rises less with O_2 therapy than the post-shunt PA O_2 saturation. Thus, O_2 step-up and Qp/Qs will be exaggerated with O_2 therapy if the induced PV O_2 is >90%. If PV O_2 is <90%, PV O_2 is on a steep portion of the O_2-hemoglobin curve as well, hence O_2 supplementation raises PV O_2 and PA O_2 somewhat symmetrically, so that the Qp/Qs denominator (PV O_2-PA O_2) does not change much, and the step-up remains appropriate. In sum, just enough supplemental O_2 may be used to raise SA O_2 to >90% (assuming SA O_2 = PV O_2, i.e., in the absence of a cardiac R-L shunt).
- ***High systemic CO*** causes SvO_2 to be higher than normal and lessens interchamber variability and O_2 step-up. A higher SvO_2 is on a flatter portion of the O_2 saturation–hemoglobin curve, so that a lot more O_2 is needed to increase O_2 saturation at the shunt level. If SVC O_2 is 85%, a 2:1 shunt is necessary to have an O_2 step-up of only 5–7%. In other words***, in the case of high cardiac output and high SVC O_2, a smaller O_2 step-up implies a larger shunt.*** Anemia, on the other hand, directly reduces SvO_2 but also increases CO and, overall, may not affect the degree of O_2 step-up.

D. How to calculate "cardiac output" and PVR in shunt cases

In the case of shunt, there is no longer a uniform "cardiac output," and it is best to avoid using this term. Rather, there are 2 cardiac outputs, Qp and Qs, that can only be measured using Fick equation, not thermodilution. **In every shunt case, both absolute Qp and Qs should be calculated, not just Qp/Qs ratio**. PVR is calculated using the Qp cardiac output: PVR = (mean PA-LA)/Qp.

Of note, thermodilution technique should be discarded in case of large shunts. Thermodilution is trying to measure Qp, not Qs, and it is an erroneous Qp, lower than the true Qp, as the thermodilution curve gets elongated with the recirculation of the cold injectate in left-to-right shunt (Qp > thermodilution measurement > Qs).

VIII. Valvular disorders: overview of pressure gradients

(A more detailed discussion of the hemodynamics of valvular stenosis and regurgitation is provided in Chapter 6.)

A. Transaortic pressure gradient

Aortic stenosis (AS) is assessed by simultaneously recording the LV and aortic pressures. Simultaneous recordings may be obtained by using a 6 Fr or 7 Fr double-lumen pigtail catheter, with 1 lumen communicating with the aorta and 1 lumen in the LV. Each lumen is connected to a transducer, and it is critical to calibrate and zero both transducers simultaneously at the same level and ensure none of the tracings is damped (aortic tracing has a dicrotic notch, LV tracing has an early diastolic dip and mid-systolic spiking). Moreover, it is important that the LV catheter is placed in the LV body, not in the LVOT. In fact, patients with AS may have a small subaortic gradient in addition to the transaortic gradient, which is part of the AS anatomy (flow acceleration upstream of the stenosis). Placing the catheter in the LVOT may underestimate the transaortic gradient by up to 30 mmHg.[4] In addition, the LV catheter with side holes must be fully inside the LV, without aortic contamination; if a few side holes are in the aorta, the peak LV pressure will be falsely reduced, and thus the gradient will be reduced.

The transaortic pressure gradient may also be measured with a 4 or 5 Fr catheter placed in the LV while the side arm of a long 6 Fr sheath measures the aortic pressure (the sheath should be significantly larger than the catheter inside it to allow adequate measurement of the aortic pressure). The sheath tip must land in the aorta: one may use a long 65-cm transfemoral sheath or 75-cm peripheral transradial sheath. Avoid using the side arm of a short femoral or radial 6 Fr sheath, as this has 2 shortcomings: (i) the femoral arterial tracing is delayed in comparison to the aortic tracing; (ii) due to a phenomenon of reflected pressure waves and systolic amplification in the periphery, the systolic femoral pressure is higher than the systolic aortic pressure, sometimes considerably higher (by 20–50 mmHg), particularly in young patients or in those with concomitant aortic insufficiency.

Alternatively, the transaortic pressure gradient may be obtained by catheter pullback across the aortic valve. This is followed by superimposition of the non-simultaneous tracings and calculation of the peak-to-peak and mean gradients. This method is useful in routine cardiac catheterization when AS is unsuspected and serves to rule out significant AS. In fact, in the absence of a gradient upon pullback, or if the peak-to-peak gradient is <15 mmHg, severe AS is almost excluded. In the assessment of severe AS, the pullback technique is less accurate than the simultaneous method. This method is particularly unreliable in AF, where significant beat-to-beat variability in pressure mandates simultaneous recordings.

Illustrations of transaortic pressure gradient are shown in Figures 37.14–37.16.

B. Transmitral pressure gradient (Figure 37.17)

Simultaneous LA–LV pressures should be obtained, and ideally LA pressure should be directly accessed through a trans-septal puncture. In practice, PCWP is sometimes used as a surrogate of LA pressure, and PCWP–LV simultaneous recordings are sometimes used to assess MS. There are 3 pitfalls in using PCWP, all of which lead to the overestimation of transmitral gradient (Figures 37.18–37.22):

i. PCWP tracing is delayed by 50–150 ms in comparison to LA pressure tracing.
ii. PCWP is more damped than LA pressure with less deep and steep Y descent.
iii. The obtained PCWP may not be a true PCWP and may rather be a damped PA pressure (hybrid PA–PCWP), as described in Section IV.

To correct for the phase delay, one may shift the PCWP leftward until the peak of V wave is bisected by the LV downstroke (or slightly precedes it). Two situations particularly exaggerate the PCWP pitfalls and affect its use as a surrogate of LA pressure in MS:

i. Large V wave, where the "spread-out," slow V downslope of PCWP creates a false gradient, not seen with the sharp V downslope of LA pressure (Figures 37.18–37.20).
ii. Pulmonary hypertension: pulmonary hypertension makes it difficult to wedge the PA and obtain a true PCWP. Even when PCWP is obtained, it is usually a damped, flat tracing that falsely suggests a high PCWP–LV gradient.

Typically, severe MS is characterized by the following 3 hemodynamic findings:

- LV and LA pressures do not equalize at the end of diastole (diastasis is not reached), even when the heart rate is controlled at <80 bpm and even after a pause of 1 second. This corresponds, on Doppler, to an E wave downslope that never touches the baseline.
- Mean transmitral gradient ≥ 10 mmHg at a heart rate <80 bpm.
- LA A wave may be prominent yet LV A wave is discrepantly absent (LV underfilling).

When mitral valve area is 1–1.5 cm^2 but the heart rate is slow (≤60 bpm) and the cardiac output is low, diastasis may be reached at the very end of diastole and the gradient may decline to 5–10 mmHg.

On the other hand, when the mitral valve area is >1.5 cm^2 but tachycardia (or heart rate >80 bpm), high-output state (e.g., anemia), or concomitant MR is present, diastasis may not be reached and the gradient may be >10 mmHg, as ***the gradient is highly dependent on cardiac output and heart rate.***

Outside MS, patients with elevated LA pressure and ample V wave, such as patients with severe MR or decompensated HF, have an early diastolic pressure gradient between LA and LV. As opposed to severe MS, LA and LV pressures equalize at mid-diastole (diastasis) and there is no LA–LV end-diastolic gradient (Figures 37.18–37.20).

Note: Pulmonary vein stenosis (prior AF ablation) creates a gradient between PCWP on the one hand and LA and LV on the other hand including in end-diastole, and is another condition that mimics MS on PCWP-LV recording. It is characterized by a flattened PCWP with no A and V waves, as LA waves do not get retrogradely transmitted to the pulmonary veins, but some PCWP peaking may be seen in systole. Sampling PCWP from multiple lung quadrants shows a discrepancy between various PCWPs.

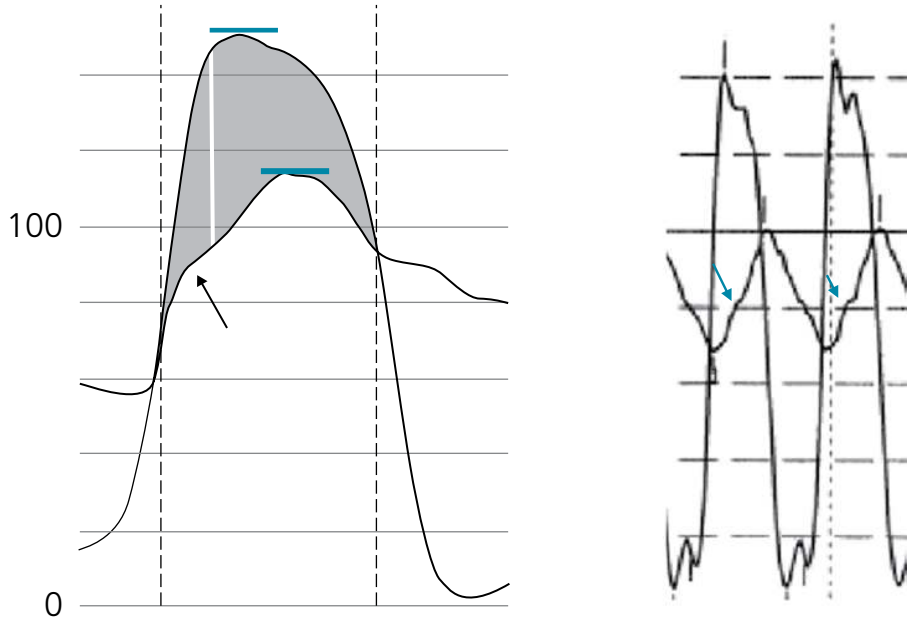

Figure 37.14 Aortic stenosis. ***Peak-to-peak gradient*** is the difference between the 2 *peaks (blue bars)*, ***peak instantaneous gradient*** is the largest difference between the 2 *curves (white vertical line)*, and ***mean gradient*** is the integration of all gradients (*gray area*). LV pressure peaks early and the aortic pressure peaks late, which is the opposite of what is found in HOCM.

Note the ***anacrotic notch*** beyond which the aortic upstroke is slowed (*arrows*). The aortic upstroke starts normally then is sharply impeded after the valve stops opening, creating this bend called an anacrotic notch. The aortic pressure has a *slow upstroke after the anacrotic notch and peaks late* (***pulsus tardus***). Also, the pulse pressure is reduced because of reduced stroke volume (***pulsus parvus***). In elderly patients with reduced arterial compliance, the pulse pressure may not be reduced and the anacrotic notch may be absent.

The mean gradient usually approximates the peak-to-peak gradient and is about 60–65% of the peak instantaneous gradient. *The peak-to-peak gradient is frequently slightly smaller than the mean gradient in mild/moderate AS with steep aortic upstroke. It is slightly larger than the mean gradient in severe AS with damped aortic upstroke.*

Note that, in AS, the aortic pressure upstroke is less steep than the LV pressure upstroke; if the LV and aortic upstrokes are superimposed, suspect subaortic obstruction or error in zeroing creating a false gradient (e.g., the LV and aortic transducers are zeroed at 2 different levels).

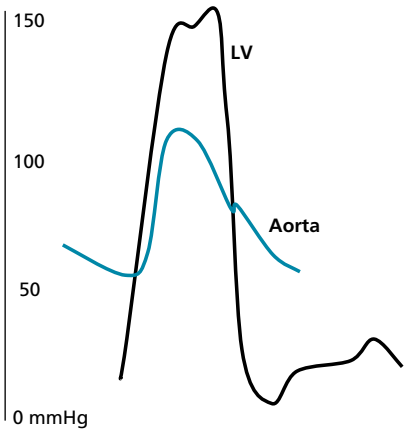

Figure 37.15 This simultaneous LV–aortic pressure recording simulates severe AS. However, the upstrokes of both tracings are parallel, which is unusual in AS, wherein the aortic upstroke is less steep than the LV upstroke and peaks late. This is a hint to an error in zeroing; in fact, the 2 transducers were zeroed at different levels.

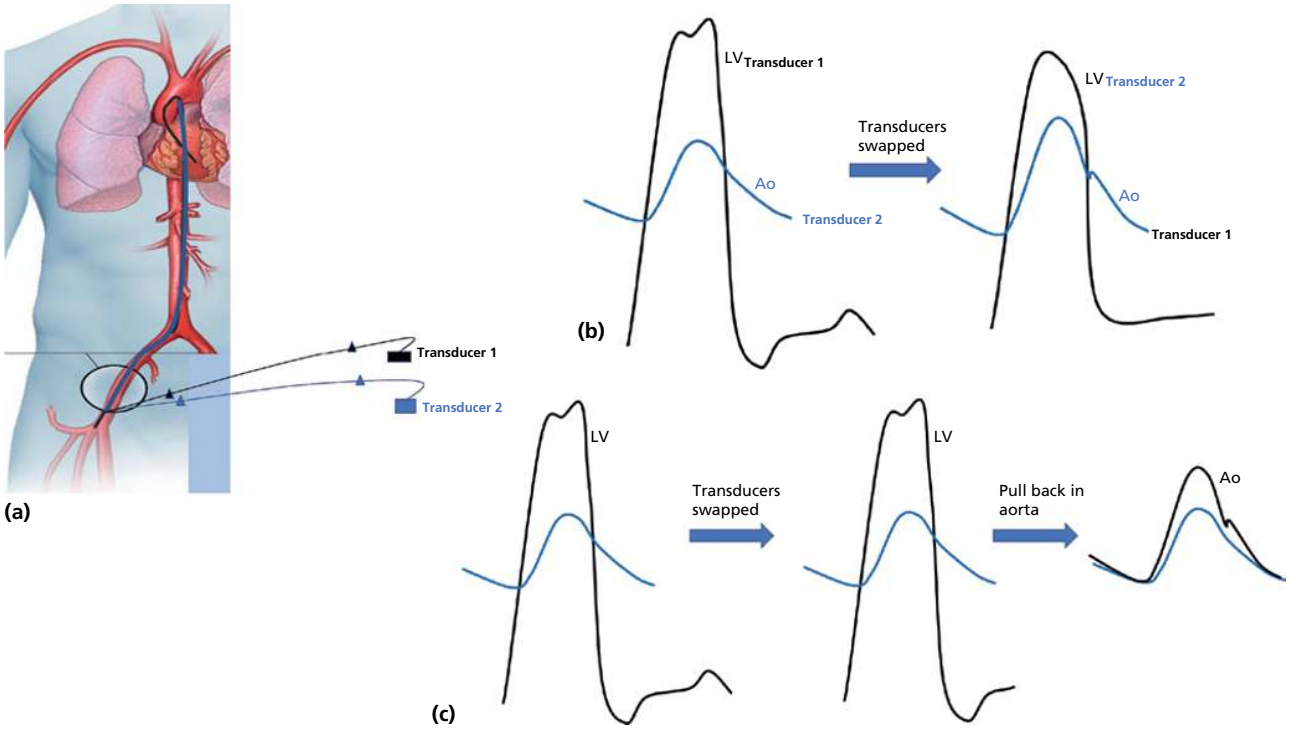

Figure 37.16 **(a)** A 6 Fr long sheath is in the aorta (*blue*), while a 4 Fr catheter is in the LV (*black*). Each one of the sheath and the catheter is connected to a separate tubing line and a transducer (*black and blue systems*). When performing simultaneous pressure recordings, there are 3 potential technical errors:

1. Error in zeroing.
2. Error in damping, i.e., the LV or aortic pressure tracing is overly damped or is underdamped. Damping can occur at any of the following 3 levels: (1) catheter (lumen too small, or air or clot), (2) tubing line (line too long, or air or clot), (3) transducer.
3. Error in positioning, i.e. the LV catheter is placed too close to the aliasing zone in the LVOT, or some of the side holes are in the aorta.

The following 5 technical tips unveil and correct potential errors:

(i) Place LV catheter in the LV body, not the LVOT. In patients with significant septal bulge on echo, use end-hole catheter.
(ii) Re-zero both transducers at the same level.
(iii) Ensure that both the LV and aortic tracings are properly damped: LV pressure should have mild systolic notching, early diastolic dip and A wave, and the aortic pressure should have dicrotic and/or anacrotic notch. If this is not the case, there is excessive damping of the LV or the aortic pressure either at the catheter level (lumen too small) or at the outside tubing/transducer level.
(iv) After the initial recordings, swap the catheter-tubing connections to verify that the gradient remains unchanged (a change implies error in zeroing, or excessive damping at the tubing/transducer level).
(v) Upon catheter pullback from the LV, verify that both pressures superimpose in the aorta. If they are not superimposed despite proper zeroing, the error is excessive damping of one measurement, whether at the catheter level or at the outside tubing/transducer level.
(b) Excessive damping and flattening of the aortic pressure, which falsely exaggerates the gradient. Swapping the catheter-tubing connections makes the LV pressure damped, which suggests that excessive damping is at the level of tubing 2 or transducer 2 → flush tubing 2, reduce its length, and consider changing transducer 2.
(c) Excessive damping of aortic pressure that does not change with swapping the transducers. This is due to damping at the catheter level (lumen too small) and is confirmed by LV catheter pullback showing a lack of tracings superimposition. In this case, you must repeat the case using larger catheters, e.g., 7 Fr aortic sheath with 5 Fr LV catheter, or use 2 separate 6 Fr accesses (e.g., radial for LV recording, femoral for aortic recording), or 7 Fr dual-lumen catheter instead of 6 Fr.

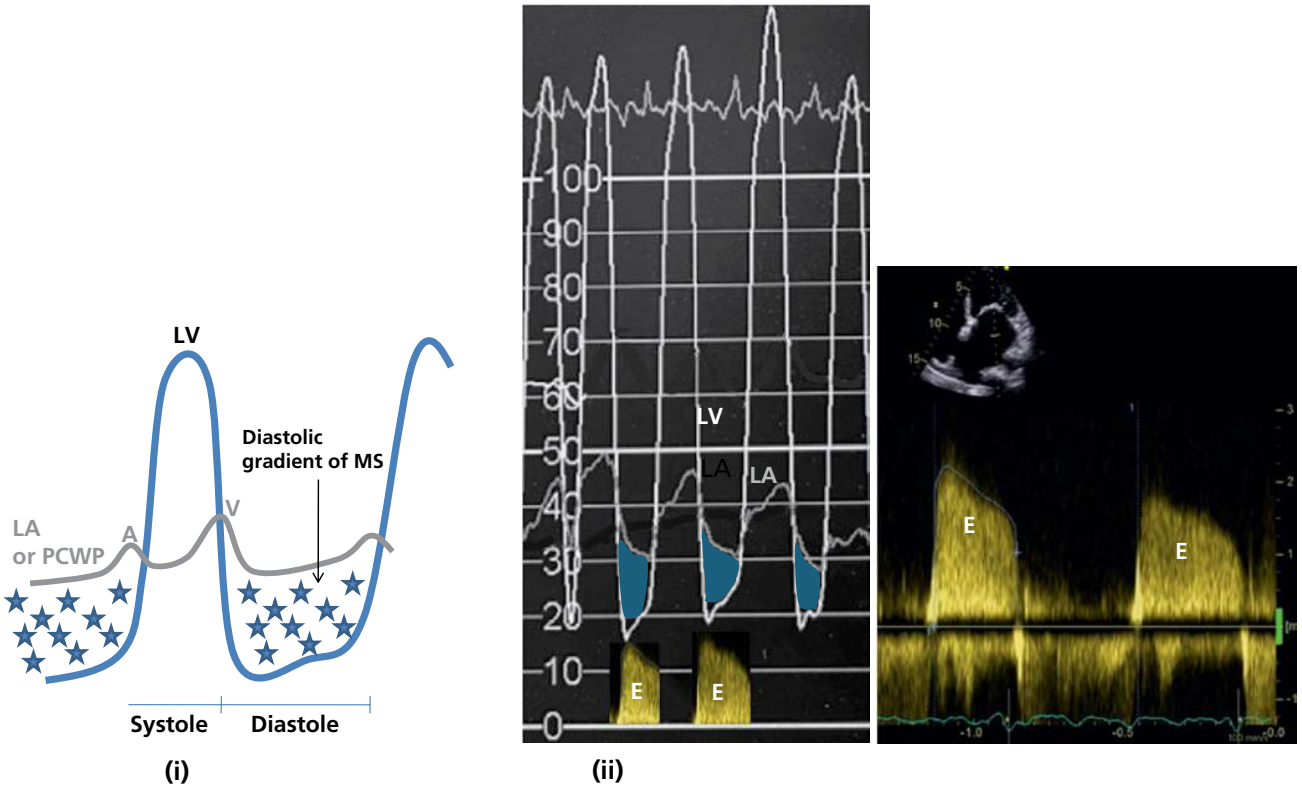

Figure 37.17 (i,ii) Two examples of mitral stenosis with a diastolic pressure gradient between LA and LV at a heart rate <80 bpm (*starred and blue filled areas*). If PCWP is used instead of LA pressure, its tracing should be shifted to the left so that the *peak of V wave is bisected by the LV downslope*. ***There is no LA–LV diastasis, i.e., LA pressure remains higher than LV pressure throughout diastole, despite a heart rate of <80 bpm, signifying severe MS.*** **(i)** LA A wave is pronounced but LV A wave is reduced because of ventricular underfilling (this is similar to the lack of S_4 in MS). **(ii)** The lack of diastasis translates into a slow E downslope on echo, which does not return to the baseline. In fact, **the Doppler E-A envelope corresponds almost exactly to the invasive LA-LV gradient area** (*blue*). This specific patient has AF with no A wave and with larger gradient at shorter R-R intervals.

In mild or moderate MS (valve area >1.5 cm^2), diastasis is reached at end-diastole. However, diastasis may not be reached if the patient is tachycardic (tachycardia converts a mild anatomic MS into a severe hemodynamic MS).

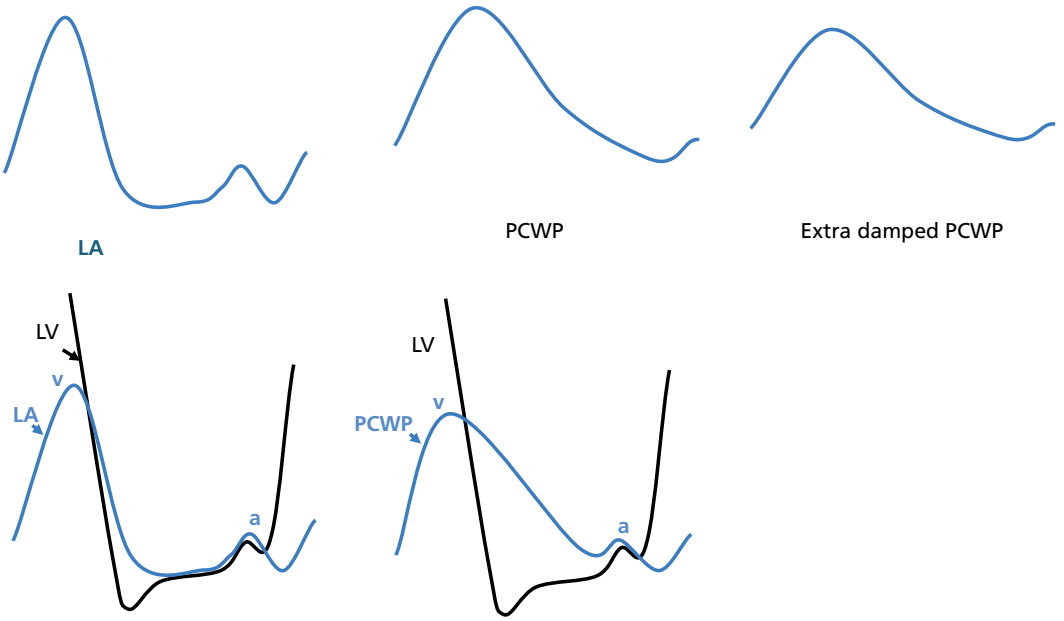

Figure 37.18 *(Top)* **Comparison of LA pressure and PCWP.** The mean PCWP approximates mean LA pressure, but PCWP waveform is a damped LA waveform, i.e., more elongated with shallower dips. Schematically, PCWP may be obtained by holding the ends of the LA tracing and pulling it sideways. The larger the V wave, the greater the discrepancy between LA and PCWP waveforms. Also, depending on how remodeled and constricted the pulmonary vasculature is, the retrogradely transmitted PCWP may be "extra damped."

(Bottom) **False impression of MS in a patient with large V wave.** When LA–LV pressures are simultaneously recorded, an early diastolic gradient is seen between LA and LV and is quickly followed by diastasis. However, when PCWP–LV pressure recording is performed, the damped and prolonged Y descent creates the impression of a large pressure gradient and a lack of diastasis, even when PCWP is appropriately shifted to the left, thus creating the impression of MS. Even in true MS, PCWP overestimates the transmitral gradient if V wave is large. Note that LV A wave is still present and prominent, arguing against severe MS.

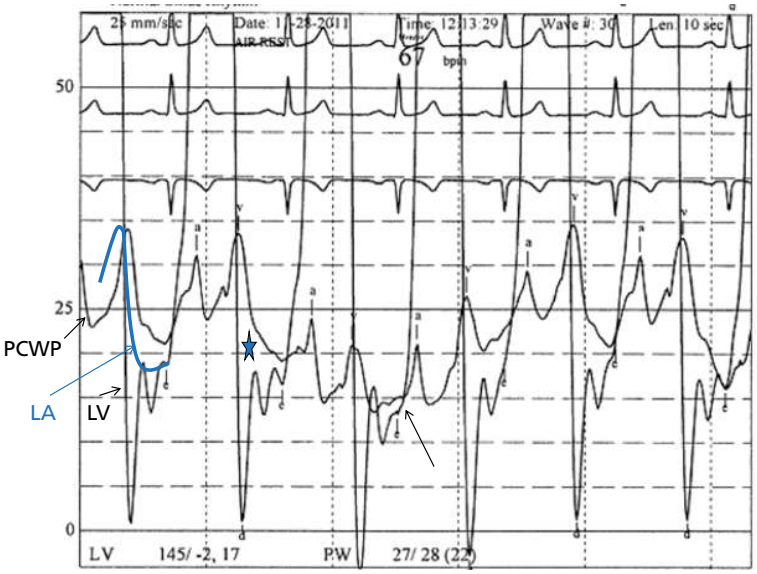

Figure 37.19 LA-LV recording vs. PCWP-LV recording. PCWP is a damped LA pressure: PCWP is more elongated than LA pressure with shallower Y descent, creating a falsely high gradient and false impression of MS in this patient with pronounced V wave.

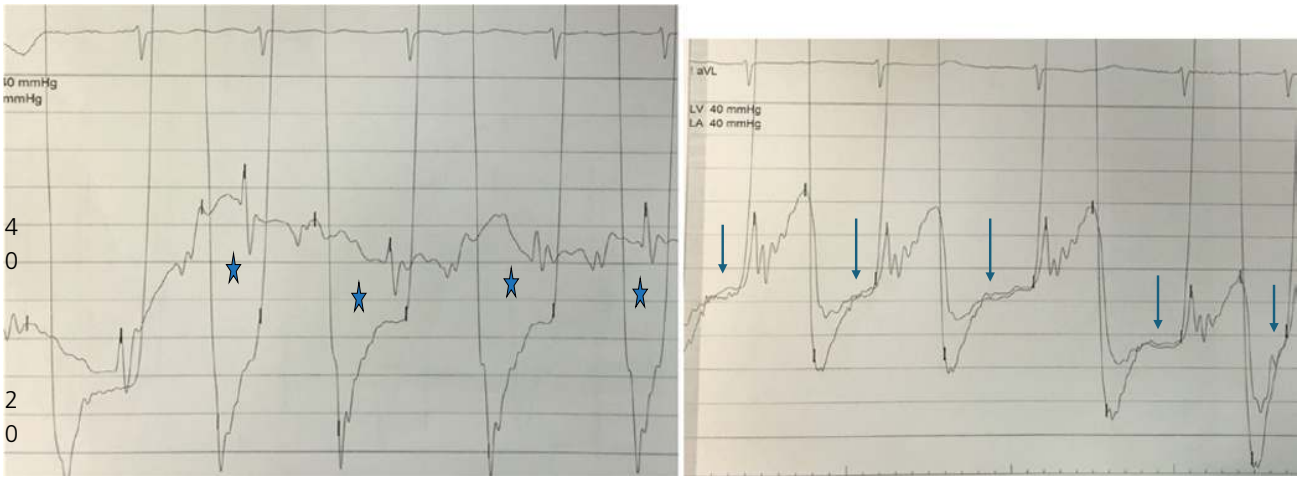

Figure 37.20 *(Left)* Simultaneous LV-PCWP recording of a 70-year-old man with AF and recurrent HF hospitalizations. Multiple prior echocardiograms are read as significant MS (heavy MAC and subvalvular calcium). PCWP is very damped and creates the illusion of a PCWP-LV gradient (*stars*).

(Right) Transseptal LA-LV recording shows full diastasis in early diastole, i.e., full equalization of LA and LV in early diastole, ruling out significant MS (*arrows*). The patient instead has MAC and restrictive cardiomyopathy with elevated LA pressure and LVEDP.

C. Transvalvular gradients in tachycardia and AF

AS – Tachycardia is associated with an increase in inotropism up to a certain rate (Bowditch phenomenon), which may raise the per-second transaortic flow and hence the aortic gradient. However, there are 3 pitfalls: (i) the rise in flow also depends on whether the preload and the stroke volume can be maintained despite the shorter diastole: they are more likely to be maintained during exercise (↑ venous return) compared to the inappropriate tachycardia of pacing or tachyarrhythmia. (ii) Bowditch is limited in LV dysfunction (inotropism and lusitropy do not ↑ beyond 110–120 bpm). (iii) CO is more specifically limited in AF. In fact, ***AF,*** even if rate controlled, directly reduces cardiac output and thus, AS gradient. Consider taking ***the highest gradient, instead of averaging gradients*** from multiple beats, to compensate for AF's low-flow state.

MS – The effect of heart rate on MS gradient is more clear and dramatic than AS. Transmitral **MS** gradient may strikingly increase after a short R–R cycle, as the diastolic time allowed for LA emptying is reduced and the per-second diastolic flow increases. *The increased gradient during tachycardia is relevant to the decision making and approximates MS gradient on stress testing* (gradient is actually higher during exercise testing than during the short R–R cycles of AF, because exercise not only increases heart rate but increases stroke volume and the overall cardiac output). ***It is always important to comment on heart rate in any MS study, as tachycardia can convert an anatomically mild MS into a physiologically severe MS with a high gradient.***

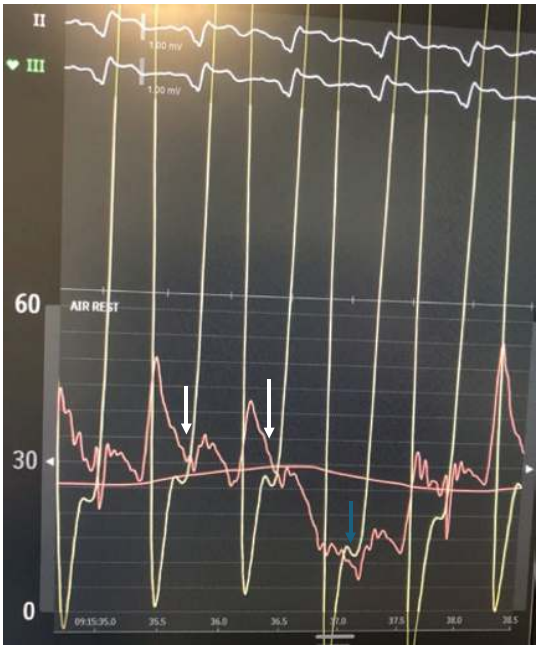

Figure 37.21 PCWP-LV recording ***can rule out significant MS*** if diastasis is present, such as in this case (particularly at a heart rate >60 bpm). Note the PCWP-LV equalization in end-diastole on most beats (*white arrows*) and even equalization in mid-diastole on one beat (*blue arrow*). Conversely, an apparent PCWP-LV gradient with lack of diastasis ***cannot rule in the diagnosis of MS***; instead, this requires direct LA-LV recording for confirmation.

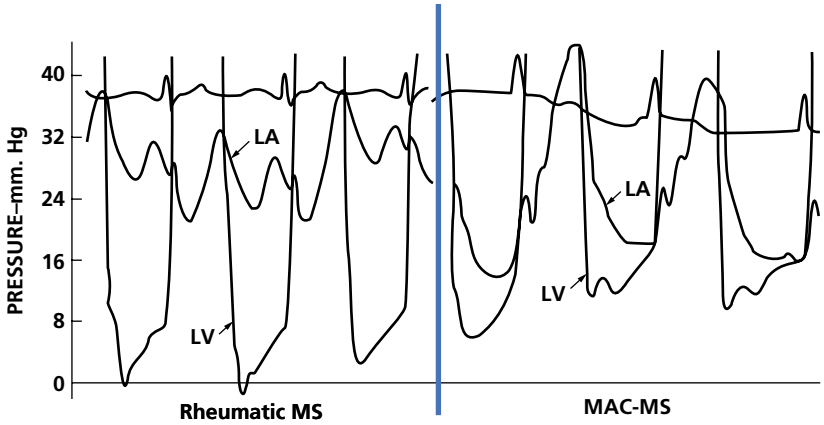

Figure 37.22 Illustration of the difference between rheumatic MS and MAC-MS. In MAC-MS, LV and LA per se are sick, with a large V wave reflective of poor LA compliance and a high LVEDP reflective of poor LV compliance; there is also AF in this case. LA pressure is high in both cases, but in MAC, it is related to LV and LA disease far more than valvular obstruction and relieving valvular obstruction may not help. **In rheumatic MS,** LVEDP is low and there is a true end-diastolic LA-LV gradient.

Note the brisk LA Y descent and the rapid equalization of LV and LA pressures in MAC-MS on a longer RR interval, suggestive of low valvular impedance. This corresponds to a *steep E descent* on Doppler, unlike the *slow E descent* of rheumatic MS. Had PCWP been used here, the false impression of significant MS would have been exaggerated. MAC, mitral annular calcification.

IX. Valvular disorders: valve area calculation

According to Gorlin, the valve orifice area is equal to:

$$\text{Flow across the valve}/(\text{constant} \times \sqrt{\text{pressure gradient}})$$

Flow across the valve is not continuous. In fact, the cardiac output expressed in liters per minute crosses the valve during the intermittent time it is open, i.e., in less than a minute. Therefore, the per-second flow rate across the valve is actually larger than the cardiac output. For the mitral and tricuspid valves, if the cardiac output is 5 L/min and if the diastolic duration is 35 s/min, the flow across the mitral and tricuspid valves is actually 5 liters per 35 seconds, or 0.14 L/s; thus, the flow across the valve is equal to the cardiac output divided by the diastolic filling time expressed in seconds per minute.

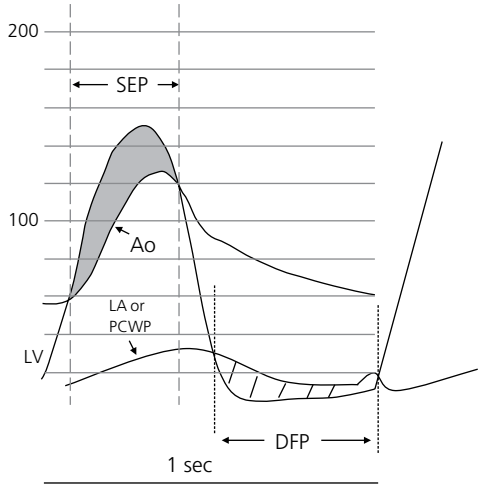

Figure 37.23 LV, aortic (Ao), and PCWP tracing in a patient with AS (LV–Ao gradient, *gray area*) and MS (PCWP–LV gradient in diastole, *dashed area*). Illustration of how to obtain SEP and DFP. Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

The diastolic filling time is the diastolic filling period (DFP) per each beat (expressed in seconds) multiplied by the heart rate, or the diastolic filling time of all beats occurring in a 10-second period multiplied by 6 (Figure 37.23).

$$\text{Thus, mitral valve area} = \frac{\text{CO (liters/minute)} \times 1000/\text{diastolic filling time (seconds/minute)}}{37.7 \times \sqrt{\text{mean transmitral gradient}}}$$

$$\frac{\text{CO} \times 1000/(\text{DFP [seconds/beat]} \times \text{HR [beats/minute]})}{37.7 \times \sqrt{\text{mean transmitral gradient}}}$$

For the aortic and pulmonic valves, the diastolic filling time and the diastolic filling period per beat are replaced by the systolic ejection time (expressed in seconds per minute) and the systolic ejection period per beat (SEP).

$$\text{Thus, aortic valve area} = \frac{\text{CO} \times 1000/\text{systolic ejection time (seconds/minute)}}{44.3 \times \sqrt{\text{mean transaortic gradient}}}$$

$$\frac{\text{CO} \times 1000/(\text{SEP [seconds/beat]} \times \text{HR [beats/minute]})}{44.3 \times \sqrt{\text{mean transaortic gradient}}}$$

A simpler equation (Hakki formula) has been validated for both mitral and aortic valves:

$$\text{Valve area} = \text{CO}/\sqrt{\text{gradient}}$$

In Hakki's equation, mean gradient is used for the mitral valve, while mean gradient or peak-to-peak gradient is used for the aortic valve. This formula is not well tested in patients with bradycardia (<40 bpm), tachycardia (>100 bpm), or atrial fibrillation.

These equations show that for a fixed valvular area, gradient is dependent on the square of the CO. Thus, a twofold increase in CO almost translates into a fourfold increase in gradient, while a low CO translates into a low gradient even if the stenosis is severe.

Calculation of valvular area in atrial fibrillation

In atrial fibrillation, average the mean valvular gradient over 10 beats. Then measure the systolic ejection time (or diastolic filling time) spent in a 10-second period throughout all the beats contained in these 10 seconds, and multiply this time by 6 to obtain the systolic ejection time in seconds/minute. Then apply Gorlin's equation. Hakki equation may prove particularly convenient in AF, as long as it is rate

controlled <100 bpm (although not validated in AF). In AS, the highest gradient better correlates with AS severity, but average gradient is used for AVA calculation, as average CO is measured.

Calculation of valvular area in the case of coexisting regurgitation of the same valve

In the case of severe regurgitation of the same valve being evaluated for stenosis, CO obtained by Fick or thermodilution cannot be used in Gorlin's or Hakki's equation. The latter CO is the net flow that reaches the systemic circulation, whereas at the level of the valve the flow is a summation of the net systemic flow and the backward regurgitant flow. Using the smaller net CO in Gorlin's equation *falsely decreases the valve area*. In this case, the angiographic CO ([LV diastolic volume – LV systolic volume] × HR) may be used, as it integrates all the ejected flow, including the flow that ultimately goes backward. Also, since the regurgitant flow in severe regurgitation is typically at least as large as the net forward flow, the total flow across the valve is at least twice the forward CO; therefore, twice the forward CO (thermodilution) may be used in Gorlin's equation. This allows a rough and conservative estimate of the valve area, as the regurgitant flow may be larger than the forward flow, and therefore the true valve area may even be larger than the corrected calculation.

A regurgitation affecting a valve other than the valve of interest does not impact upon valvular area calculation using Gorlin's equation but may lead to a low CO and a lower gradient across the valve of interest.

X. Low-gradient aortic stenosis

A. Low-gradient severe AS (Table 37.3) (see also Chapter 6, Section 4)

Table 37.3 Low-gradient AS with AVA <1 cm^2.

Low-gradient AS (AVA <1 cm^2, gradient <40 mmHg) with normal EF >50%[a] → 3 types:

1. **Echo mismeasurements (50%)**, especially falsely low LVOT diameter (*hint*: DI is in a non-severe range, >0.25); or pressure recovery
   - *→ Importance of careful echo measurements*
   - *Post-PVC gradient*
   - *Pick highest gradient in AF* (instead of averaging gradients)
   - *Catheterization to confirm*[a]
   - *Hybrid AVA calculation: pressure gradient by echo, CO by cath*
   - *Valve CT calcium scoring*
2. **Low-gradient true AS with *low flow* despite normal EF** (stroke volume <35 ml/m^2): low preload, high afterload, or AF
3. **Low gradient true AS with *normal flow:*** related to guidelines cutoff misalignment (AVA of 1 cm^2 corresponds to a gradient of ~30 mmHg if CO 5–5.5 L/min). Valve area ~ CO/$\sqrt{\text{P gradient}}$ → P gradient ~ CO^2/valve area^2

This is different from low-gradient AS (AVA <1 cm^2) with low EF[a]

The issue in low EF is contractility, but the issue in *normal-EF low-gradient AS* is not contractility, it is rather ***low flow from poor diastolic filling (low preload volume) and high afterload*.**

- **Dobutamine is used in low-gradient AS with low EF,** *but it does not definitely increase flow in low-gradient AS with normal EF and may paradoxically ↓ flow by ↓ diastolic time and preload.*
- **Rather, exercise or nitroprusside may improve flow in normal-EF low-gradient AS** *by ↓ afterload and ↑ preload*
- **Post-PVC gradient helps in both normal and low EF**

[a] Invasive AVA ≤1 cm^2 generally establishes severe low-gradient AS in normal EF, but AVA calculation may vary and be indecisive due to the following: slight changes in the gradient related to mild technical issues, use of peak-to-peak vs. mean gradient, variability of CO by thermodilution, or the use of Gorlin vs. Hakki equations.

B. Effects of PVC and AF in low-gradient AS

PVC – Preload and flow increase post-PVC and unveil the true severity of AS. In fact, during cath assessment of AS, induce PVC and see its effect on mean or peak-to-peak gradient:[5,6]

- Post-PVC gradient >40 mmHg nearly establishes the diagnosis of severe AS.
- Post-PVC gradient <40 mmHg: severe AS is still possible and is not ruled out.
- Post-PVC gradient rises >33%: likely severe AS.

AF – AF is a low-flow state and directly reduces AS gradient. Take the highest gradient (usually after a short-long sequence) instead of averaging gradients.[7]

XI. Valve area vs. gradient for defining stenosis severity: differences between AS and MS

In AS, a high gradient ≥40 mmHg is highly specific and diagnostic of AS, regardless of AVA calculation. Unlike AS, a high gradient is not specific enough for defining severe MS, for 2 reasons:

1. The 10-mmHg cutoff chosen in MS barely translates into MVA <1.5 cm^2 under normal flow conditions: MVA ~ CO/$\sqrt{\text{mean gradient}}$

   → for a CO of 5+ L / min and MVA of 1.5 cm^2 → mean gradient ~ 11+ mmHg

2. MS gradient is more labile with heart rate fluctuations than AS gradient: tachycardia reduces diastolic time while increasing systolic time; hence diastolic flow per second across the mitral valve (CO/diastolic time) increases, while systolic flow per second across the aortic valve (CO/systolic time) is much less affected (both CO and systolic time increase in tachycardia). Even mild MS may have a gradient >10 mmHg in case of tachycardia/high output.

As such, **MVA is more important than gradient for assessment of MS severity, whereas both AVA and gradient are important in AS, gradient being the most specific.** Because echo is highly accurate for assessing MS gradient but less so for MVA, and because cath assessment of gradient is difficult, a *hybrid method may be used: measure CO invasively and measure transmitral gradient simultaneously by echo*. Then apply Hakki equation: MVA = CO/$\sqrt{\text{gradient}}$. The LA and LV pressure behavior and diastasis cannot be directly assessed by this method, but may be indirectly gauged by the E slope on echo: a slow E downslope that does not return to the baseline correlates with the lack of LA–LV diastasis (Figure 37.17). Transseptal LA measurement and LA–LV recording remain the gold standard for MS assessment.

XII. Aortic insufficiency

Five findings are suggestive of severe aortic insufficiency (AI) (Figures 37.24, 37.25):

1. Widened pulse pressure is seen with chronic severe AI (enlarged LV with a large stroke volume). This is a very sensitive finding in chronic AI, but not specific (may be seen in non-compliant aorta).
2. Dicrotic notch is absent. This is particularly true when the aorta is non-compliant, as in acute AI or AI of the elderly; the dicrotic notch may persist in chronic AI of young patients.
3. LVEDP sharply rises while aortic diastolic pressure sharply falls → LV pressure and aortic pressure approximate in end-diastole (difference <30 mmHg or <25% of SBP). This is seen with acute or decompensated AI.
4. Peripheral systolic amplification of arterial pressure is exaggerated in AI.
5. LVEDP exceeds not only mean PCWP but end-diastolic PCWP. This leads to early mitral closure on echo and is a sign of acute or decompensated AI.

XIII. Dynamic LVOT obstruction

(See also Chapter 7.)

In the presence of a gradient between the LV and the aorta, and if LVOT obstruction is suspected, use an end-hole catheter, rather than a multihole catheter, and slowly pull back across the LVOT to localize the site of pressure drop. Once the site of pressure drop is localized, a double-lumen pigtail catheter may be used for simultaneous LV–aortic pressure recording and exact gradient determination. Unlike the fixed obstruction of AS, dynamic LVOT obstruction worsens throughout systole as the LV cavity becomes smaller. Thus, dynamic LVOT obstruction is worse in late systole and is characterized by 4 features (Figures 37.26–37.29):

1. Early and sharp aortic upstroke (spike), followed by a pressure drop (plateau)
2. Late dagger-shaped LV peak with a late LV–aortic gradient
3. Brockenbrough phenomenon after a pause
4. Gradient is dynamic with maneuvers

This dynamic LVOT obstruction may be secondary to HOCM or to a hypercontractile small LV cavity in a hypovolemic patient with a degree of hypertensive hypertrophy ("hypertensive obstructive cardiomyopathy").

In some patients with HCM, especially apical HCM, or thick hypertensive LV, the catheter may get entrapped and compressed intramurally with each LV contraction, which leads to a systolic pressure spike across the LV tracing simulating a pressure gradient between the LV and the aorta (**catheter impact artifact with false LVOT gradient**). This is distinguished from true obstruction by: (i) lack of aortic spike and dome morphology and lack of Brockenbrough phenomenon; (ii) the LV pressure tracing is damped and smooth in diastole with no diastolic dips or A waves.

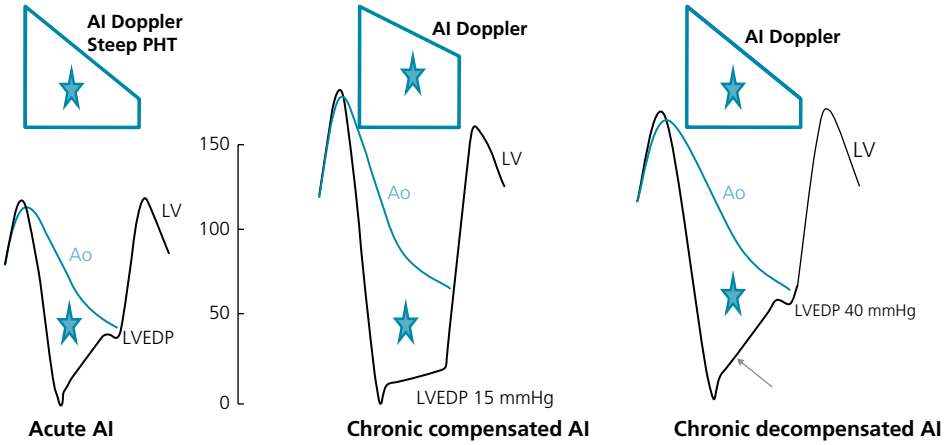

Figure 37.24 LV–aortic pressure tracings in acute AI and chronic AI. In acute and decompensated AI, the steep diastolic approximation of LV and aortic pressures (triangle, *star*) translates into a similarly steep AI Doppler. Conversely, in compensated AI, LV and aortic pressures do not approximate in end-diastole. Note the attenuation of the dicrotic notch, particularly with acute AI.

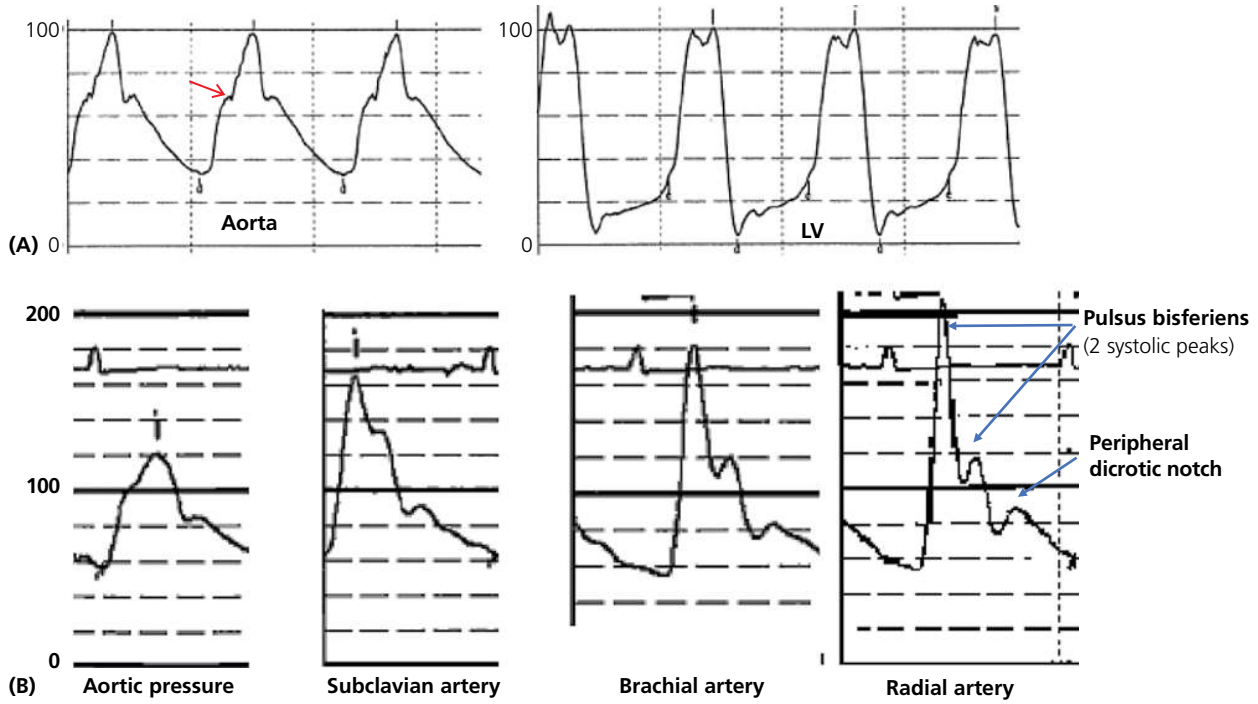

Figure 37.25 (A) On the aortic tracing, the aortic pressure drops precipitously in diastole, while the LV pressure sharply rises. LVEDP approximates aortic end-diastolic pressure. This suggests acute or decompensated AI. The fact that systolic aortic pressure is low implies either acute AI or chronic end-stage AI (with reduced EF and total stroke volume). *The dicrotic notch* may persist in chronic AI with compliant aorta. An *anacrotic notch* is noted here (*arrow*); anacrotic notch may be seen in AI even when the associated AS is not severe; because of the high flow crossing it, the aortic valve may become functionally obstructive. Unlike in severe AS, this anacrotic notch is high on the aortic upstroke and the aortic upstroke remains sharp rather than "tardus." **(B) Exaggerated peripheral systolic amplification in AI**. Catheter pull-back from the central aorta to the radial artery shows 2 features suggestive of AI:

(i) progressive and severe peripheral systolic amplification with a central aortic pressure of 120/55 mmHg and a radial pressure of 210/55 mmHg. This explains why it is difficult to control peripheral BP in AI.

(ii) peripheral upslope becomes steep (no anacrotic notch) with 2 systolic peaks. This is called pulsus bisferiens. The first peak is due to the large initial stroke volume percussing the less compliant, muscular peripheral arteries. This large percussion is followed by aftershock waves that get reflected in the periphery and cause a second systolic peak called tidal wave. Pulsus bisferiens is more clearly seen in peripheral arteries.

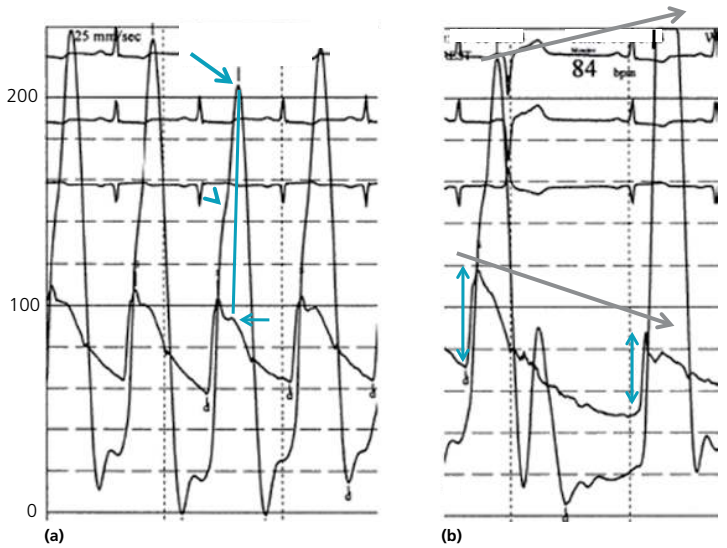

Figure 37.26 Dynamic LVOT obstruction.

(a) The LVOT obstruction worsens throughout systole as the LV becomes smaller, which explains why the aortic pressure drops and plateaus after an early peak (spike-and-dome appearance, *horizontal arrow*), and why the LV pressure peaks in late systole (*upper arrow*) and has a narrow, dagger shape. The LV pressure has a bend that corresponds to the point of worsened obstruction (*arrowhead*). The LV–aortic pressure gradient is a late gradient (*vertical line*); this is similar to the Doppler finding of a late-peaking dagger-shaped velocity across the LV. As opposed to AS, the peak-to-peak gradient approximates the peak instantaneous gradient in HOCM.

(b) The behavior of LV and aortic pressures after a premature beat helps corroborate the diagnosis. Following a pause, the increased myocardial contractility worsens the dynamic LV obstruction. Thus, while the LV pressure and the pressure gradient increase, the stroke volume decreases, which reduces the aortic pulse pressure and accentuates its spike-and-dome shape (*double arrows*) (= Brockenbrough sign). In AS, the obstruction is fixed and thus the increased contractility after a premature beat leads to increased stroke volume, and, consequently, an increase in the transaortic gradient (as per Gorlin's equation, the transaortic gradient increases with increased flow across the valve). As opposed to HOCM, the aortic pulse pressure increases as well.

Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

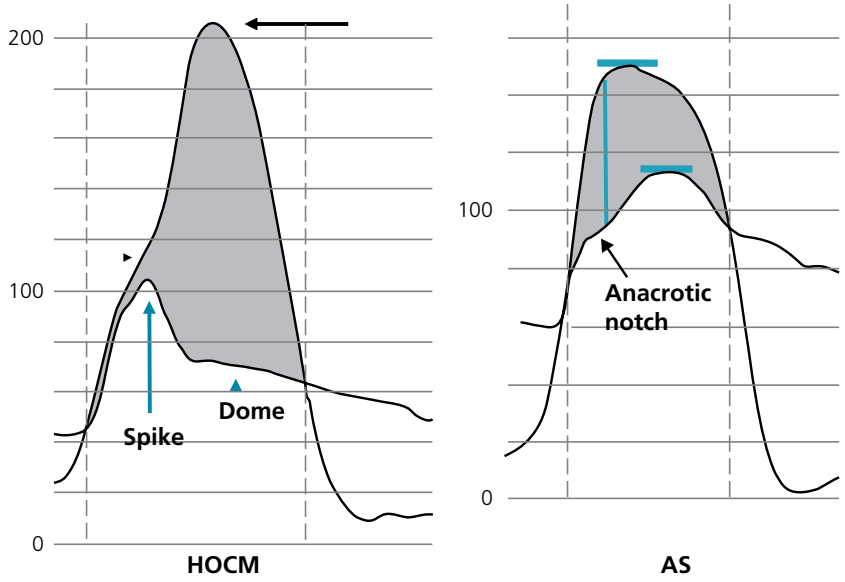

Figure 37.27 Contrast LV–aortic tracings in HOCM vs. AS. In HOCM, the aortic pressure peaks early while the LV pressure and the gradient peak late, after a bend (*arrowhead*). In AS, the LV pressure peaks early while the aortic pressure peaks late, after an anacrotic notch, with a round gradient contour. Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

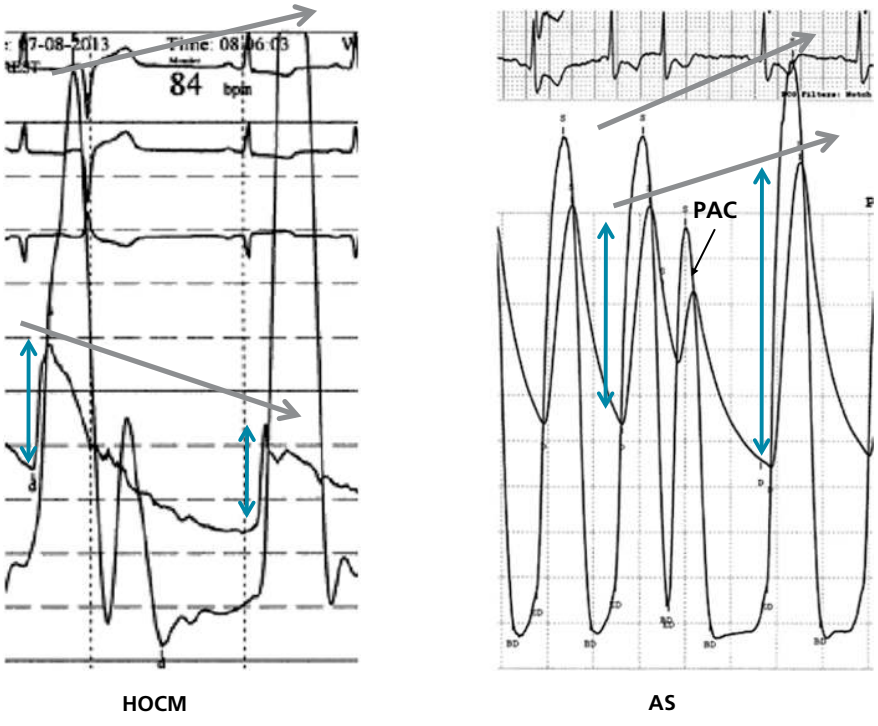

Figure 37.28 Brockenbrough phenomenon after a premature beat in HOCM. Note the increased pressure gradient but reduced aortic pulse pressure (*double arrows*) after a pause in HOCM, vs. the increased pressure gradient but also increased aortic systolic and pulse pressures in AS. The *arrows* indicate the change in LV pressure vs. aortic pressure. The pressure gradient increases much more markedly with HOCM than with AS after this pause. Also, because of the increased obstruction, *the LV dagger shape and the aortic spike-and-dome morphology become more apparent after a pause.* ***Not only the gradient is dynamic, but the LV and aortic morphologies are dynamic as well***.

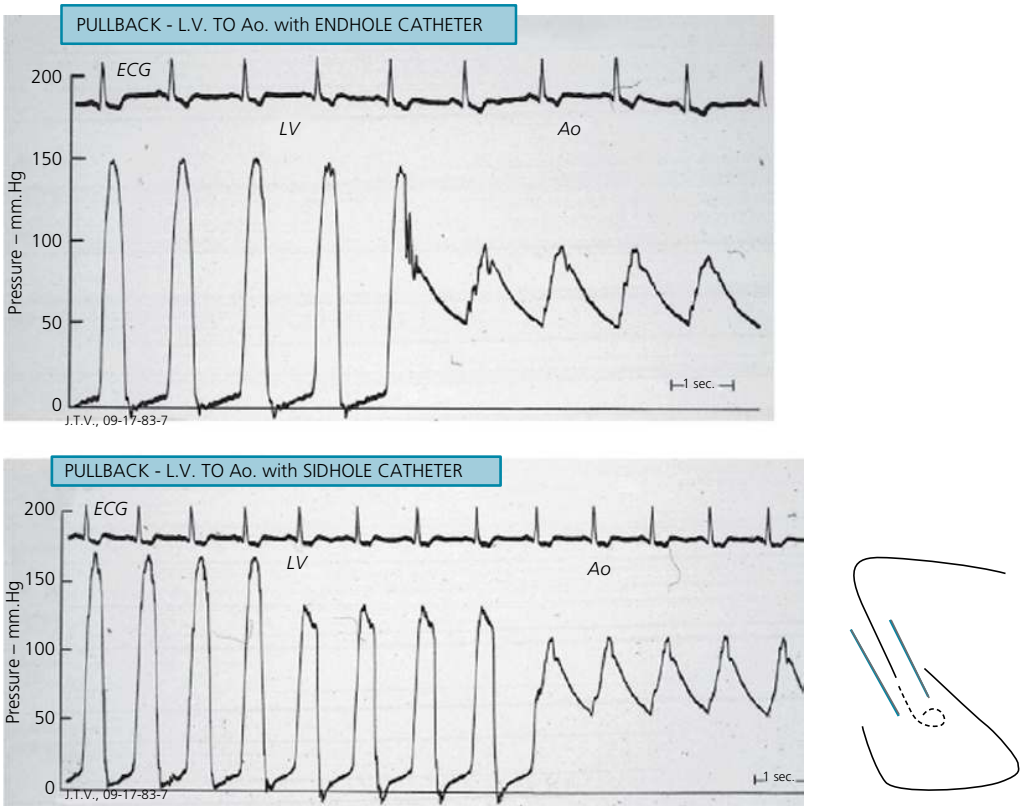

Figure 37.29 LV–aortic pullback using an end-hole catheter in a patient with severe AS (*upper tracing*). A pullback from the LV to the aorta using a catheter with side holes contaminates the LVOT pressure with aortic pressure and creates the impression of a drop in pressure across the LVOT rather than the aortic valve (*lower tracing*).

Conversely, in a patient with LVOT obstruction, a side-hole LVOT catheter may transmit the aortic pressure rather than the LVOT pressure, as holes are spread across both the LVOT and the aorta, which may create the impression of an aortic rather than an LVOT drop in pressure.

This illustrates the importance of an end-hole catheter in localizing the site of obstruction during a pullback maneuver. Once the obstruction is localized, a multihole LV catheter positioned at the apex (e.g., double-lumen pigtail) may be used for simultaneous pressure recordings, as in Figure 37.28.

Reproduced with permission of Demos Medical from Hanna and Glancy (2012).[1]

XIV. Pericardial disorders: tamponade and constrictive pericarditis (see Figures 37.30–37.32)

(See Chapter 17)

The diagnosis of constrictive pericarditis requires simultaneous right and left heart catheterization with simultaneous recording of LV and RV pressures. **Only the discordance between LV and RV systolic pressures is highly sensitive and highly specific (>90%)** for the diagnosis of constrictive pericarditis, and specific tips must be used for analysis (Figure 37.32).

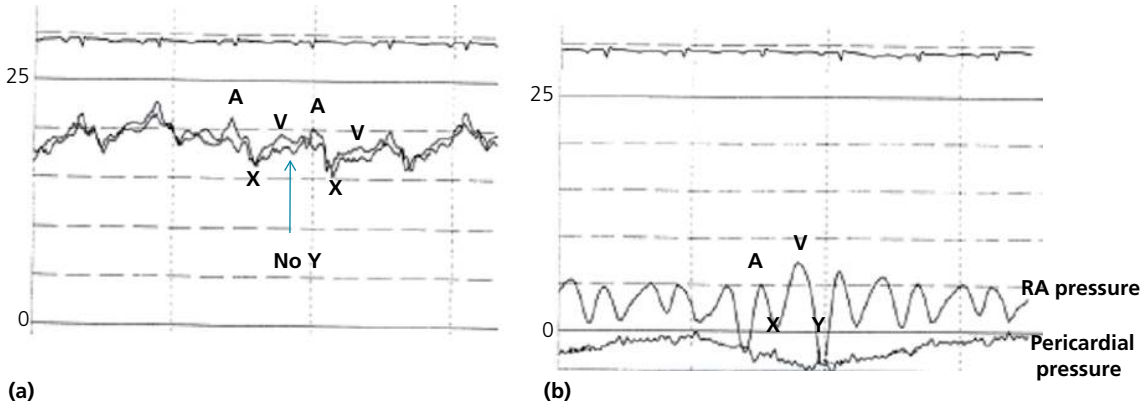

Figure 37.30 (a) Simultaneous pericardial and RA pressures are recorded in **tamponade**, before pericardiocentesis. **The RA and pericardial pressures are elevated and equalized** (~20 mmHg); this defines tamponade. The 2 tracings are actually superimposed. Furthermore, X descent is seen, but Y descent is flat (mnemonic: **Flat Y Tamponade = FYT**). V wave almost continues straight into A wave. **(b)** Post-pericardiocentesis, pericardial pressure becomes normal (negative pressure ≤ 0 mmHg). RA pressure is normal with clear V wave and Y descent. Had the pericardial pressure or RA pressure not normalized, or had these pressures remained equal, effusive–constrictive pericarditis would have been suggested.

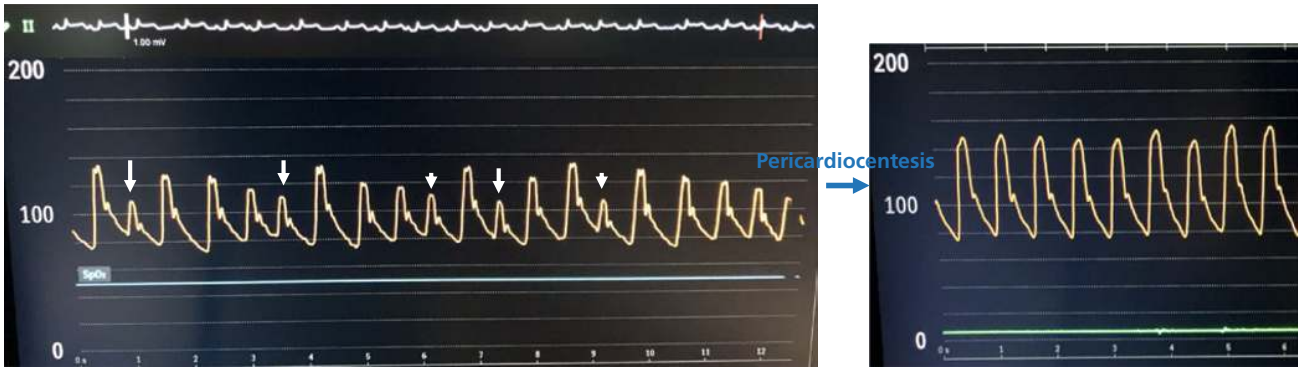

Figure 37.31 Pulsus paradoxus in a patient with tamponade. Note the collapse of the aortic waveform height and width during inspiration (*arrows*). After pericardiocentesis, the respiratory variations are attenuated, and the aortic waveform significantly expands in both height and width, as the stroke volume improves. In fact, the aortic waveform size closely approximates the stroke volume.

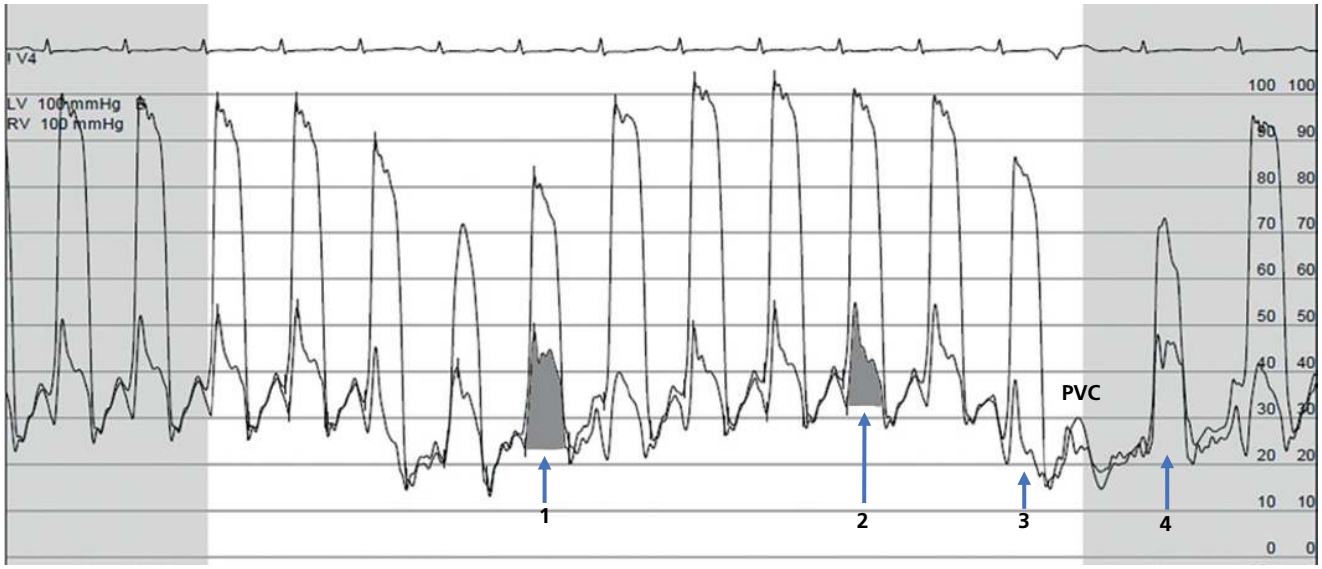

Figure 37.32 Simultaneous LV-RV recordings in a 61-year-old man with no past medical history who presents with anasarca. Diagnosis: constrictive pericarditis.

1. **There is equalization of RV and LV *diastolic* pressures.** This is not a specific finding, and may be seen in RV failure, restrictive cardiomyopathy or constriction.
2. **To assess for RV vs. LV *systolic* discordance, pick the peak inspiratory beat,** which is the beat preceded by the lowest diastolic dip, **and peak expiratory beat**, which is the beat preceded by the highest diastolic dip ***(beats 1 and 2).* It is more important to analyze the systolic areas, i.e., the bulk of the rectangular pressures, than to analyze peaks. The area is what corresponds to the stroke volume.** Peaks may be discordant as well, but less often than areas. The LV area declines with inspiration while the RV area dramatically rises with inspiration. The RV peak itself declines here, but the RV area, most importantly, rises.
3. Analyze post-PVC behavior *(beats 3 and 4)*: normally, and in cardiomyopathies, stroke volumes of both ventricles rise after a PVC with no dramatic discrepancy. Conversely here, RV area dramatically increases while LV area declines, which suggests marked ventricular interdependence. As the preload of one ventricle rises, the preload of the other ventricle must decline, as they are both fighting for room in a constrained space and expand at the expense of each other (rather than outward). This is a key value of PVC in constriction analysis. The post-PVC discordance may be analyzed regardless of the respiratory cycle.
4. The significant RV stroke volume variability implies good stroke volume reserve, which argues against restrictive cardiomyopathy or intrinsic RV failure.

Regarding the other invasive hemodynamic features, **equalization of LV–RV end-diastolic pressure indicates a major pathology but is very poorly sensitive and specific** as it may be seen in any cardiomyopathy. **Each one of the following 4 features, obtained by stand-alone right heart catheterization, is highly sensitive (93%) but poorly specific for constriction, meaning that the absence of one or especially several of them may rule out constriction**, but their presence does not rule it in, as they are, in practice, much more commonly reflective of cardiomyopathies and RV failure than constriction (see Questions 12, 13):

i. RA Kussmaul sign = lack of respiratory drop in mean RA pressure. Also: RA has deep X and Y descents, with Y deeper than X.
ii. PA systolic pressure <55 mmHg. PA pressure is unlikely to be >55 mmHg in constriction because RV stroke volume is low and LA pressure is not high enough to cause severe post-capillary PH.
iii. Dip-plateau RV and LV pattern with ≥7 mmHg height between the LV dip and the plateau, called rapid filling wave.
iv. RVEDP/RV systolic pressure ratio >1/3, a reflection of the high RVEDP and the relatively low RV systolic pressure <55, as well as the low RV stroke volume (narrow RV pulse).

XV. Exercise hemodynamics

In patients with unexplained exertional dyspnea and resting PCWP ≤15 mmHg, diastolic HF may be unveiled via exercise testing. Exercise may be performed on a supine cycle ergometer mounted on the catheterization table. Invasive PA pressure, PCWP, and CO are measured during exercise. This may unveil occult LV diastolic dysfunction as a cause of the patient's dyspnea. On the bicycle, the work is started at 25 watts (W) and increased by ~25 W every 2 minutes. Exercise is graded as follows: mild exercise ~50 W, heart rate 110 bpm; moderate exercise ~100 W, heart rate 130 bpm; maximal exercise ~150–200 W. At each stage, the patient must pedal at 60–80 rpm to achieve the estimated work.

During exercise, venous return increases and stroke volume increases as a result of the increased preload (Frank–Starling mechanism) and the inotropic reserve. Normally, in early exercise, LV end-diastolic volume increases (preload increases) while end-systolic volume decreases (EF increases). At high levels of tachycardia, as diastole shortens, the rising LV end-diastolic volume plateaus or even declines, while stroke volume continues to rise from the reduction of end-systolic volume.

Even in normal individuals, PCWP and PA pressure increase to some extent with exercise, and PCWP frequently exceeds 15 mmHg because of the high preload (Figure 37.33). PA pressure increases as a result of the increased cardiac output (similarly to the exertional rise of systemic arterial pressure). The normal values of exertional PA pressure and PCWP are shown in Table 37.4.[8]

A rise in mean PCWP to ≥25 mmHg is diagnostic of diastolic HF (if EF is normal). In diastolic HF, most of the rise of PCWP (≥80%) already occurs at a low level of exercise (at 1.5 minutes of 25 W).[9] PCWP will rise sharply early on, then continue the rise, but the early rise already gives a good idea of the final response. In fact, in diastolic dysfunction, PCWP already rises with passive leg elevation, before cycling (~40% of the eventual rise).[9] Two studies found that PCWP adjusted to the workload in W/kg provides a more accurate assessment of diastolic function (normal PCWP is <25 mmHg/W/kg).[10,11] PCWP declines quickly and returns to baseline within 2–3 minutes of recovery, as the preload sharply declines.

HF, including HFpEF, is characterized by an excessive rise of PCWP and PA pressure, beyond the numbers in Table 37.4, and a blunted rise of cardiac output. In fact, the capacity to increase LV diastolic volume is limited (limited preload reserve with limited capacity to use the

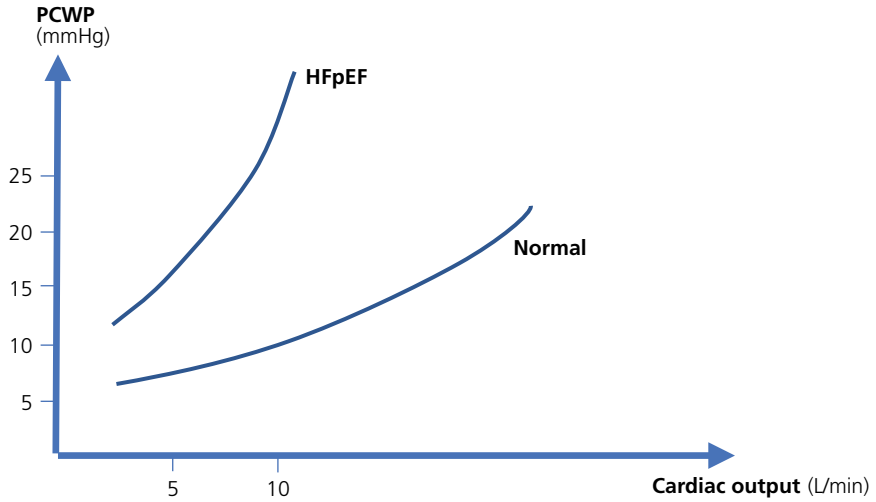

Figure 37.33 PCWP rise with exercise. *In normal individuals*, as preload and cardiac output rise during exercise, PCWP rises mildly and slowly (this is similar to the LV pressure-volume relationship in diastole). PCWP may reach 15-20 mmHg when cardiac output and venous return are markedly increased (e.g., 20 L/min), overwhelming LV compliance: this partially explains the breathlessness of normal individuals during heavy exertion. Conversely, in *HFpEF*, the same rise in PCWP occurs very quickly, even with passive leg raise, as the myocardium is non-compliant and cannot accommodate the venous return. This steep slope corresponds to ΔPCWP/ΔCO >2 mmHg/L/min and is *similar to the pressure-volume slope*. PCWP drops quickly after stopping exercise, as preload sharply declines.

Table 37.4 Normal exertional values of PCWP, PA pressure, and cardiac output, according to age.

Patients <50 years of age
- Mean PCWP <18–20 mmHg
- Systolic PA pressure <40 mmHg; mean PA pressure <30 mmHg

Patients ≥ 50 years of age
- Mean PCWP <25 mmHg
- Systolic PA pressure <50–55 mmHg; mean PA pressure <40 mmHg

In all patients, at peak exercise
- Cardiac output usually increases to >10 L/min, and cardiac index increases to >6 L/min/m^2 (even at low workloads)
- In relative terms, cardiac index more than doubles and stroke volume index increases 25–40%
- ΔPCWP/ΔCO <2 mmHg/L/min and Δmean PA/ΔCO <3 mmHg/L/min
- PA O_2 saturation declines up to a value of 30% as O_2 extraction increases

At rest, PCWP and PA pressure are measured at end-expiration, where the respiratory pressure is 0. However, during exercise, the end-expiratory pressure is a positive pressure (active exhalation), and thus the most representative exercise pressures average the inspiratory and expiratory numbers.[14] Yet, some studies have used the above pressure cutoffs in end-expiration.[9]

Frank–Starling mechanism), and the capacity to reduce LV systolic volume is limited (limited contractile reserve). This translates into a limited stroke volume reserve and a back-up rise in pressure. More specifically, in one study, the stroke volume index did not significantly rise in HFpEF patients (rose <20%, stroke volume index remained ~40 ml/m^2 vs. >60 ml/m^2 in controls).[10] As such, one study found that a steep PCWP-to-CO slope during exercise, i.e., ΔPCWP/ΔCO >2 mmHg/L/min, correlates with diastolic HF.[12] Also, mean PA/CO slope >3 mmHg/L/min suggests exertional pulmonary hypertension, pre- or post-capillary (ESC).

Other modalities of stress testing may be employed to unveil occult LV diastolic dysfunction and elicit a rise of PCWP and PA pressure (CO blunting cannot be properly assessed with these modalities): (1) 45° passive leg raising using a wedge or a supine bike to increase venous return (abnormal PCWP cutoff of ~18 mmHg, lower than exercise); (2) adenosine infusion (adenosine is an arterial but not a venous dilator; thus, it increases venous return and may increase PCWP); (3) fluid challenge with 500 ml of normal saline over 5 minutes. No healthy subject, regardless of age and sex, had PCWP >18 mmHg with this volume challenge in one study;[13,14] (4) sustained handgrip isometric exercise using a dynamometer, for 3 minutes (causes a reflex increase in BP, heart rate, and CO); (5) atrial pacing may increase CO and reduce LA pressure up to a certain point (~110-120 bpm), beyond which, in diastolic dysfunction, lusitropy is further impaired and LA pressure rises.

Note: Exertional PA saturation *in normal subjects vs. HF – In normal subjects*, O_2 consumption (VO_2), which is CO × (arterio-venous O_2 difference), increases ~13-fold from rest to peak exercise. This is related to an increase in O_2 delivery via increased CO (e.g., 4- to 5-fold increase), but also an increase in tissue O_2 extraction. This increase in O_2 extraction explains the significant decline in PA O_2 saturation at peak exercise even in normal individuals (PA O_2 saturation may decline to a value of 25–30%). ***In HF***, CO reserve is limited (usually <2-fold) and therefore, in an attempt to maintain O_2 delivery, tissue extraction is amplified, and PA saturation frequently drops to <20–25%. This muscular O_2 extraction is further exaggerated with exercise training, especially intense training, where PA saturation can drop to <15% and raise VO_2 (increased muscular capillarity and mitochondrial content).[15,16]

XVI. Additional hemodynamic caveats in AF

In AF, CO (HR × stroke volume) rises with increased HR, up to a certain rate wherein diastolic filling sharply drops (~R-R of 500 ms or rate >115 bpm). CO also drops at R-R >700 ms (<85 bpm), as diastolic filling does not rise enough to compensate for the HR drop. This is further compounded by rate irregularity. For the same heart rate, e.g., 90 bpm, the worst CO is seen when R-R varies between too long and too short. CO particularly drops with a long-short R-R sequence, causing at times a pulse deficit.

Thermodilution estimates cardiac output from a few cardiac beats and assumes steady flow. In irregular rhythms with beat-to-beat variability, the sampled beats may not represent the average cardiac output. Less CO variability is seen when all R-R intervals are within a rate range of 85–115 bpm, or when all R-R intervals correspond to <85 bpm, with *no long-short sequences*. Perform at least 5 measurements, and average the ones that are within 25% range. The same rate ranges are desired when assessing transvalvular gradients. **Note:** AF, even at a rate of 85–115, induces a **low-flow state** via rate irregularity and loss of atrial kick. This reduces AS gradient.

Appendix 1. Advanced hemodynamic calculation: a case of shunt with pulmonary hypertension

Case scenario

The following O_2 saturations are obtained (Figure 37.34**):**

Right circulation: SVC 58%, IVC 66%, RA 68%, PA 73%
Left circulation: pulmonary vein (PV) 93%, aorta 85%

The following pressures are obtained:

PA pressure = 75/21, mean 43 mmHg; PCWP = 16 mmHg; RA pressure = 13 mmHg; aortic pressure = 130/77 mmHg; hemoglobin (Hb) = 14 g/dl; body surface area (BSA) = 2.1 m^2

What is the direction of the shunt? Should this shunt be closed?

Answer

There is a significant O_2 step-up at the level of the RA, indicating a left-to-right shunt across an ASD (>8% O_2 step-up between SVC and PA, PA having the best mixture of shunted blood). There is a significant O_2 step-down between the PV and the aortic level, indicating a

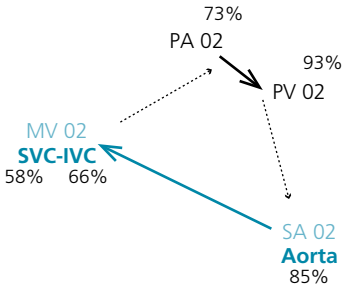

Figure 37.34 The numerator of the Qp/Qs is in blue (extreme chambers), while the denominator is in black (between chambers).

right-to-left shunt with hypoxemia. Thus, this patient has a bidirectional shunt with severe pulmonary hypertension, worrisome for Eisenmenger syndrome.

$$MV\ O_2 = (3\ SVC + 1\ IVC)/4 = 60\%$$
$$Qp/Qs = (SA\ O_2 - MV\ O_2)/(PV\ O_2 - PA\ O_2) = (85 - 60)/(93 - 73) = 1.25 \text{ (Figure 37.33)}$$

A Qp/Qs ratio in the 1–1.5 range does not imply that the shunt flow is small. Since the oximetry suggests significant bidirectional shunting, the patient may very well have large left-to-right and right-to-left shunts, the net shunt being slightly left-to-right. One must calculate the absolute Qp and Qs and the absolute shunt flow in each direction to address the true severity of the shunt in each direction, rather than solely rely on Qp/Qs.

$Qp = O_2$ consumption/ $(Hb \times 1.36 \times [PV\ O_2 - PA\ O_2] \times 10)$
$= (125\ ml/min/m^2 \times BSA)/(14 \times 1.36\ [0.93 - 0.73] \times 10) = 6.9\ L/min$
$Qs = O_2$ consumption/ $(Hb \times 1.36 \times [SA\ O_2 - MV\ O_2] \times 10)$
$= 5.5\ L/min$
Q effective = theoretical right- and left-sided flow had there not been any shunt, in which case $SA\ O_2 = PV\ O_2$ and $PA\ O_2 = MV\ O_2$
$= O_2$ consumption/$(Hb \times 1.36 \times [PV\ O_2 - MV\ O_2] \times 10)$
$= (125\ ml/min/m^2 \times BSA)/\ (14 \times 1.36 \times [0.93 - 0.60] \times 10)$
$= 4.2\ L/min$
Left-to right shunt = Qp – Q effective = 2.7 L/min
Right-to-left shunt = Qs – Q effective = 1.3 L/min

Note that, in the absence of a right-to-left shunt, $PV\ O_2 = SA\ O_2$ and thus, Qeffective=Qs.
Thus, there is a large left-to-right shunt (40% of Qp) and moderate right-to-left shunt. To appreciate the severity of this left-to-right shunt, **remember that in patients with isolated left-to-right shunt, a Qp/Qs of 1.5 corresponds to a shunt flow that is 33% of Qp (Qp = 1.5 units, Qs = 1 unit, and the shunt flow = 0.5 unit). A Qp/Qs of 2 corresponds to a shunt flow that is 50% of Qp (Qp = 2, shunt = 1, Qs = 1).**

One must additionally determine if the severe pulmonary hypertension is due to an Eisenmenger process or is simply due to the increased flow across the pulmonary arteries without much of an increase in PVR. For this purpose, one must measure PVR and see if PVR is >5 Wood units or >1/3 SVR, in which case PAH therapy is recommended, followed by later hemodynamic reassessment

$$PVR = (\text{mean PA pressure} - PCWP)/Qp = (43 - 16)/6.9 = 4 \text{ Wood units}$$
$$SVR = (\text{mean aortic pressure} - \text{RA pressure})/Qs = (95 - 13)/5.5 = 15 \text{ Wood units}$$

Note that Qp, rather than the cardiac output obtained by thermodilution, should be used to calculate PVR. The patient's PVR is only mildly elevated and is much lower than SVR, suggesting that the pulmonary hypertension is mainly related to the increased flow. Yet, since the shunt is bidirectional with Qp/Qs <1.5, vasodilator therapy should be started: attenuate the right-to-left shunt and raise Qp/Qs to >1.5 before considering closure (congenital ESC guidelines).

QUESTIONS AND ANSWERS: ADDITIONAL HEMODYNAMIC CASES

Question 1. The following oximetry run is obtained:
IVC 77%, high SVC 84%, low SVC 90%
High RA 88%, mid-RA 85%, low RA 78%, RV 84%, PA 86%
Left upper pulmonary vein 99%, aorta 96%
Is there a significant shunt? Calculate Qp/Qs.

Question 2. A simultaneous LV–LA recording is shown (Figure 37.35). What does it suggest?

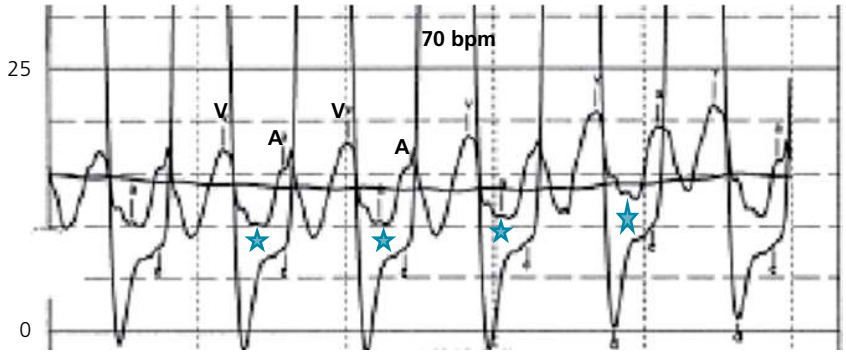

Figure 37.35

Question 3. The patient in Question 2 underwent mitral valvuloplasty. Which chambers are represented on this simultaneous recording (Figure 37.36)? Is there any residual MS? What else is suggested on this recording?

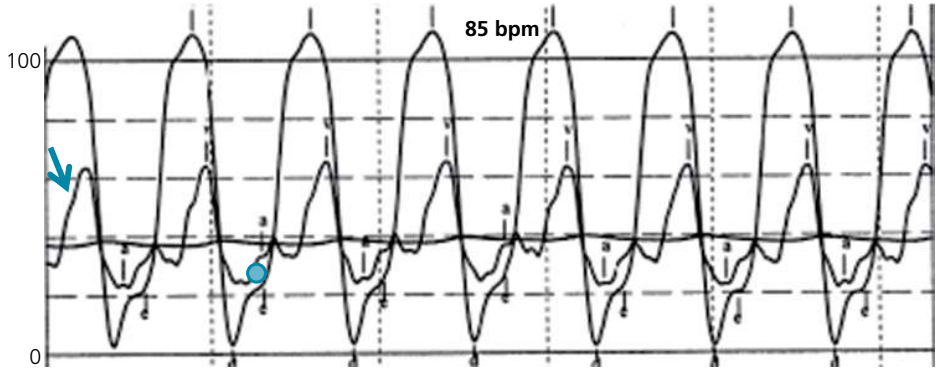

Figure 37.36

Question 4. What do these aortic and PA tracings suggest (Figure 37.37)?

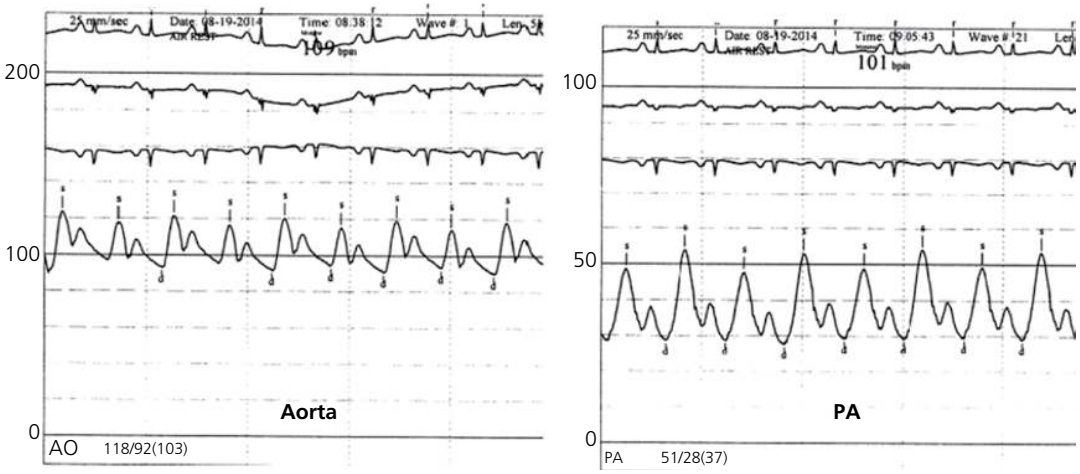

Figure 37.37

Question 5. A 69-year-old hypertensive, obese woman (BMI 35) with sleep apnea presents with dyspnea on exertion. Echo shows normal EF with mild LVH and grade 1 diastolic dysfunction. Pulmonary function testing is normal. A right heart catheterization is performed. Hemodynamics at rest: RA pressure 5 mmHg, PA 42/20 mmHg (mean 27 mmHg), PCWP 11 mmHg (with a prominent A wave of 16 mmHg > V wave). Cardiac output is 6.7 L/min with cardiac index 3.4 L/min/m^2. Stroke volume index = cardiac index/heart rate = 40 ml/min/m^2 (heart rate 85 bpm). Arterial O_2 saturation is 95% (ambient air), PA O_2 saturation is 75%. What is the diagnosis?

A. Mild pulmonary hypertension related to sleep apnea
B. HFpEF
C. Exercise hemodynamics are required to establish a diagnosis

Question 6. Exercise hemodynamics were performed on the patient in Question 5, using a supine bicycle. Hemodynamic parameters were measured upon leg raising, before cycling, then upon cycling (25 W to 150 W). Hemodynamics with leg raising, before cycling: PA pressure 55/28 mmHg, PCWP 15 mmHg (V = A = 22 mmHg).

Hemodynamics with peak exercise (150 W, 140 bpm): PA pressure 75/35 mmHg, mean 48 mmHg; PCWP 27 mmHg, prominent V = 36 mmHg; cardiac output by thermodilution = 12 L/min, with cardiac index 6 L/min/m^2; stroke volume index = 42 ml/min/m^2; arterial O_2 saturation 85%, PA O_2 saturation 30%.

At 2 minutes post-recovery, arterial saturation went up to 98%, PA saturation was 81%. Which of the following statements is (are) correct?

A. PA pressure and PCWP rose excessively with exercise, implying HFpEF (the cutoff for abnormal exertional PCWP is 25 mmHg, the cutoff for abnormal exertional systolic PA pressure is 55 mmHg)
B. The cardiac output rose with exercise but not enough, as manifested by the low PA O_2 saturation
C. The stroke volume rose <20–25%, implying a limited preload reserve

D. The pressure–volume relationshsip of the LV is steep
E. Exertional PA O_2 saturation is low because of the inappropriate cardiac output but also the low arterial O_2 saturation

Question 7. A 66-year-old man presents with a clinical picture of biventricular failure with hypoxemia, elevated jugular venous pressure, peripheral edema, and pulmonary edema on his chest radiograph. On auscultation, a 4/6 holoystolic murmur is heard on the left sternal border with a palpable thrill. Echocardiography shows a moderate size perimembranous ventricular septal defect (VSD) (1 cm in diameter), severe pulmonary arterial hypertension, mildly enlarged left ventricle with a preserved ejection fraction, severe left atrial enlargement, and significant biventricular hypertrophy. A hemodynamic study is done at rest and with inhaled nitric oxide (Figure 37.38). Thermodilution cardiac output is 2.5 L/min at rest. Hemoglobin is 10 g/dl and body surface area is 2 m^2.

Does he have a significant shunt, and in which direction? Estimate absolute values of Qp and Qs at rest, and Qp/Qs at rest. Calculate PVR at rest.

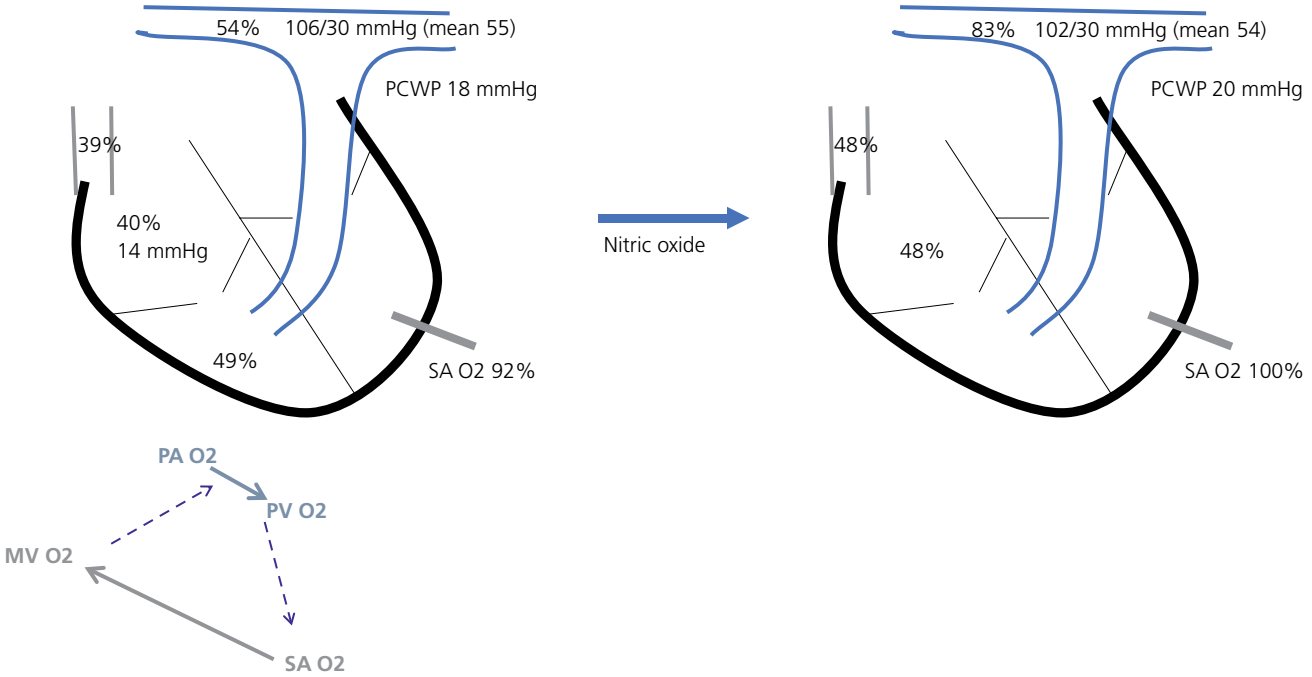

Figure 37.38

Question 8. In the case of Question 7, after nitric oxide, did the direction and severity of the shunt change and why? Why did arterial O_2 saturation normalize?

Question 9. Simultaneous pressure recording is obtained in the LV and another chamber (Figure 37.39). What is the diagnosis?

Figure 37.39

A. Constrictive pericarditis with equalization of end-diastolic pressures
B. Mitral regurgitation
C. Mitral stenosis
D. Aortic regurgitation
E. Tricuspid regurgitation

Question 10. A 72-year-old woman with severe hypertension undergoes pulmonary vein isolation for persistent AF. She continues to have exertional dyspnea, even though she is in sinus rhythm. Echo shows LVH and moderate LA enlargement, with no significant mitral valve disease. Right heart catheterization shows a PA pressure of 60/34 and a mean PCWP of 29 mmHg with an end-diastolic PCWP of 22 mmHg, after a marked A wave. Wedged PA saturation is 95%. Why is mean PCWP higher than end-diastolic PCWP, what do you expect LVEDP to be, and what is the diagnosis?
A. Large V waves (likely >40) explain the discrepancy. LVEDP=22 mmHg. Diagnosis: stiff LA syndrome
B. Large V waves (likely >40) explain the discrepancy. LVEDP=22 mmHg. Diagnosis: dynamic MR
C. Pulmonary vein stenosis. LVEDP likely <22

Question 11. A 42-year-old patient with no diastolic HF risk factors has exertional dyspnea. Echo shows RV pressure overload pattern with systolic PA pressure of 70 mmHg. He is suspected of having pre-capillary PH. During right heart catheterization, which of the following technical considerations is correct (multiple possible answers)?
A. An elevated PCWP should warrant confirmation by a wedged PA O_2 saturation (>90–95%) or LVEDP
B. Prominent V waves are suggestive of occult left heart disease even if mean PCWP is normal and should be reported
C. A normal PCWP should warrant saline loading or exercise to rule out left HFpEF
D. Pressure measurements are done at end-expiration (take the highest pressures), except in patients breathing heavily during exercise hemodynamics (average inspiration and expiration)
E. Pressure measurements may be performed during end-expiratory hold
F. Look for signs of overdamping (waveform too smooth with no notches) and underdamping, also called catheter ringing (excessive spikes)
G. Over- and underdamping change the amplitude of the waveform, but often do not affect the mean
H. Damping issues may be addressed by flushing and by shortening the tubing. Underdamping may be attenuated by aspirating a bit of blood in the catheter.

Question 12. A 68-year-old man presents with progressive peripheral edema, dyspnea, and 50-lb. weight gain. Diuresis attempts are limited by a marked rise in creatinine. The following hemodynamic study is performed (Figure 37.40):
- On the RA pressure recording, what is the deepest descent, and why does it get deeper at times?
- What are the 2 major characteristics of the RA pressure waveform, and what diagnosis do they suggest?
- Can such RA pressure be seen in tamponade?

Figure 37.40

Question 13. Regarding the patient in Question 12, which statement(s) is (are) true (multiple possible choices)?
A. RVEDP/RV systolic pressure ratio >1/3 strongly suggests constrictive pericarditis
B. The RA pressure M morphology strongly suggests constrictive pericarditis
C. RV/LV systolic pressures are discordant, which establishes constrictive pericarditis
D. The equalization of RV-LV end-diastolic pressures strongly suggests constrictive pericarditis

Question 14. What is the diagnosis suggested by the hemodynamic tracings of Figure 37.41?

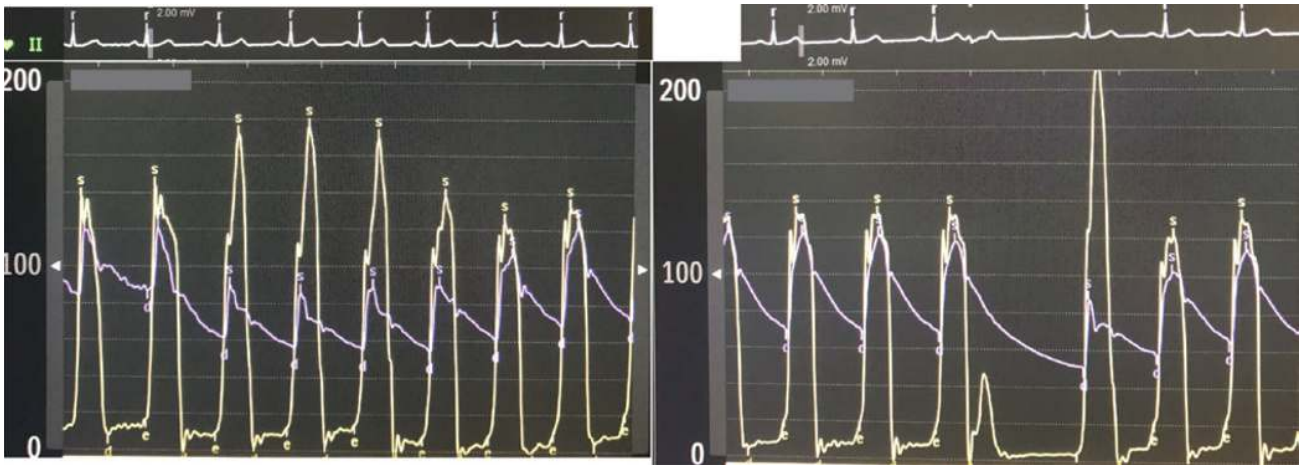

Figure 37.41

Question 15. The following recording (Figure 37.42) is obtained in the same patient as Question 14 at a later time. What explains the resolution of the LV-aortic gradient?
A. Mavacamten
B. The gradient is still present
C. Bisoprolol
D. Septal myectomy

Figure 37.42

Question 16. What is the diagnosis on the simultaneous LV-aortic pressure recording of Figure 37.43?
A. Severe AS
B. Dynamic LVOT obstruction
C. Severe AS and dynamic LVOT obstruction
D. Subaortic fixed AS

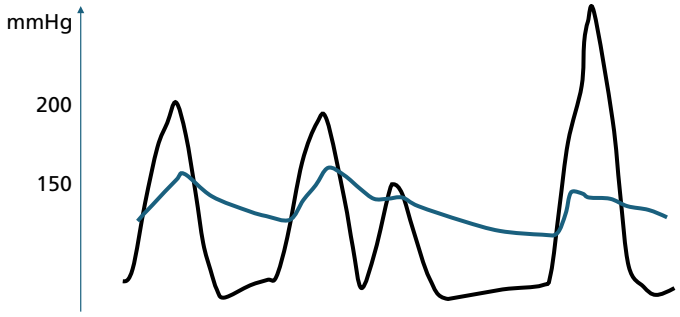

Figure 37.43

Question 17. The tracing of Figure 37.44 is obtained during RHC. What chamber does it represent: RA, RV, PA, or PCWP?

Figure 37.44

Question 18. Which diagnosis is suggested by the aortic pressure tracing of Figure 37.45?

Figure 37.45

A. Severe AI
B. Tamponade
C. Severe AS and significant AI
D. Dynamic LVOT obstruction

Answer 1. There is a step-up at the level of the low SVC, suggesting a shunt at this level, likely a sinus venosus ASD. Furthermore, the IVC O_2 being normally higher than the SVC O_2 (outside shock), even the high SVC sample is contaminated by a spillover of the left-to-right shunt. Thus, IVC O_2 is the best representation of the mixed venous O_2 in this case, rather than the average of IVC O_2 and high SVC O_2.

Note that the RA saturation is highly variable, depending on whether it is sampled next to the IVC (78%), SVC (88%), or in between (85%). The best mixture of all venous return is achieved at the PA level. Overall, the 9% O_2 step-up between the IVC and the PA suggests significant left-to-right shunt.

The left upper pulmonary venous O_2 is 99%, while aortic O_2 is 96%. Should pulmonary venous O_2 (PV O_2) be considered 99% in the Qp/Qs calculation? In the absence of right-to-left shunt and when aortic O_2 is >95%, PV O_2 is considered equal to aortic O_2, 96% in this case rather than 99%. The sampling of 1 out of 4 pulmonary veins may be affected by sampling contamination (not here) or by a better function of 1 lung quadrant.

Thus: Qp/Qs = (aortic O_2 – IVC O_2)/(PV O_2 – PA O_2) = (96 – 77)/(96 – 86) = 1.9.

Answer 2. Note the lack of LV–LA diastasis in end-diastole despite a heart rate of 70 bpm, implying severe MS (the diastolic gradient is marked by the *star*). Also, a mean gradient ≥10 mmHg at a heart rate <80 bpm suggests severe MS. The large V wave and the large A wave on the LA tracing are consistent with severe MS. MS often leads to prominent V and A waves; at an early stage A wave may be most prominent, at a late stage V wave may be most prominent. Note the lack of LV A wave despite the prominence of LA A wave: this is characteristic of MS, where the large LA A wave can barely fill the LV through the stenotic mitral valve.

Answer 3. Figure 37.36 is a simultaneous LV–LA (or LV–PCWP) recording. The large V wave may mimic PA pressure. Distinguish this LA tracing from PA tracing using the following:

1. The tracing is upsloping in diastole and has an A wave, implying LA pressure rather than PA.
2. Timing: the pressure peak occurs after the LV pressure plateau (rather than simultaneous with it), implying that it is not PA pressure. Rather, it almost intersects with the LV descent, implying it is a V wave.
3. The pressure peak has a gradual upslope and a sharper downslope, implying a V wave.

V wave has become gigantic after valvulopasty (~65 mmHg), definitely implying acute MR. A lack of diastasis is seen in diastole (*blue dot*). However, at this particular time, MS is likely mild, the diastolic gradient and the hemodynamic severity being exaggerated by the high transmitral flow initiated by MR and the faster heart rate.

Answer 4. Note the following 3 findings:

1. A very narrow aortic pressure: narrow in *height* (pulse pressure <25% of systolic pressure) and narrow in *width* in systole. This implies a low stroke volume/cardiac output. Clinically, a narrow pulse pressure is the best correlate of a low stroke volume. Invasively, the systolic area of the waveform correlates with the stroke volume.
2. The waveform morphology and height vary alternately between beats. This is called pulsus alternans and implies a low cardiac output. Differentiate this from pulsus paradoxus, wherein the pulse varies cyclically (with respiration), rather than alternately.
3. The dicrotic notch is very prominent on both the PA and aortic waveforms. In fact, the aortic and PA pulses are called dicrotic pulses. A prominent dicrotic notch results from severe peripheral vasoconstriction (conversely, the dicrotic notch is attenuated in cases of peripheral vasodilatation and extensive peripheral runoff). In a way, it also implies a low cardiac output.

In summary, this patient has severe low-output systolic HF. His PA saturation is very low at 40% and he has sinus tachycardia, further confirming the low-output state.

Answer 5. C. The prominent A wave on PCWP tracing is a hint to the presence of LV dysfunction, albeit a compensated LV dysfunction (mean PCWP is normal, but post-A PCWP and LVEDP are abnormal). In decompensated LV dysfunction, V wave becomes prominent, much more so than A wave (Figure 37.10). Even if mean PCWP is normal, a prominent A or V is a hint to LV dysfunction.

Answer 6. All are correct. The cardiac output did not rise enough and the stroke volume almost did not rise at all. The LV cavity is small and stiff, and is unable to dilate and accept the increased venous return (limited preload reserve). It is unable to use the Frank–Starling mechanism, wherein a higher preload would raise the stroke volume. It does not accept preload, which backs up in the pulmonary circulation. Filling pressures rise despite a lack of change of preload, a sign of a steep LV pressure–volume relationship in diastole. Note that some abnormalities already manifest with leg raising, before exercise.

Answer 7. The patient has a significant O_2 step-up on the right (39% to 54%), suggestive of left-to-right shunt. The arterial hypoxemia (92%) is assumed to be related to right-to-left shunting in this context, and PV O_2 is assumed to be 98% (significant O_2 step-down on the left). For Qp calculation, use the O_2 saturations of the in-between chambers, PV O_2 and PA O_2; for Qs calculation, use the extreme chambers:

Qp= 125 ml/min/m^2 × BSA/ (Hb×1.36 × [PV O_2–PA O_2)×10) =250/(11×1.36×[0.98–0.54]×10) = 3.8 L/min

Qs= 125 ml/min/m^2 × BSA/ (Hb×1.36 × [SA O_2–SVC O_2)×10) =250/(11×1.36×[0.92–0.39]×10) = 3.15 L/min

Qp/Qs=1.2→ Qp/Qs underestimates the severity of the left-to-right shunt in patients with bidirectional shunts.

PVR is calculated using Qp, not Qs and not thermodilution CO, which is meaningless in shunt cases. PVR = (mean PA-PCWP)/Qp ~10 Wood units.

Answer 8. With NO, PVR dramatically declines, which "sucks" more flow to the right circulation, thereby sharply increasing the left-to-right shunt and abolishing the right-to-left shunt. Hence arterial O_2 saturation normalizes. This change in shunt flow can only be explained by a dramatic reduction of PVR:

-Right-sided O_2 step-up is much more pronounced: 48% to 83%, with Qp/Qs: (100–48)/(100–83)=3.

-Qp becomes ~10, and PVR becomes ~3.4 Wood units. Qs does not change significantly (LV increases its overall output, but most of it goes toward the PA, increasing Qp, while Qs remains unchanged)

-PA pressure does not change as Qp ×PVR remains unchanged (PVR declines but Qp rises)

Eisenmenger is ruled out as PVR is reversible and shunt becomes directed left-to-right with vasodilators.

This case is unique in that the patient presents with a hemodynamically significant VSD at the age of 66. This late hemodynamic decompensation may be related to increased left ventricular systolic and diastolic pressures as the patient ages, leading to progressively more left-to-right shunting despite a small or moderate-size defect; his Qp/Qs was probably in the moderate range at a younger age (1.4–1.9).

Answer 9. B. Identify the bottom waveform: pressure is upsloping in diastole with A wave, hence it is not an arterial waveform. This is LA waveform with a large V wave: it peaks late compared to ventricular systole, after T, and is almost bisected by LV descent (slightly precedes it in MR); it has a slow upslope and a sharp downslope. The large V wave suggests decompensated MR. In diastole, LA pressure immediately meets the LV pressure and is superimposed on it, ruling out any degree of MS.

Answer 10. A. LVEDP typically corresponds to the end-diastolic PCWP, which is PCWP at the C wave (post-A PCWP, in the middle of the A descent). Often, LVEDP ~ end-diastolic PCWP ~ mean PCWP. However, mean PCWP exceeds LVEDP when V wave is large (Figure 37.10). In this patient, V wave is large because of a *stiff LA syndrome*. Dynamic MR is possible, but is likely to be unveiled during exercise hemodynamics, not at rest. A hybrid PA-PCWP waveform should be considered when mean PCWP exceeds LVEDP: a wedged PA saturation >90–95% reduces this possibility.

Pulmonary vein stenosis may be considered when dyspnea occurs after pulmonary vein isolation; the key characteristic is a gradient between PCWP and LA pressure, or indirectly, between end-diastolic PCWP and LVEDP like in mitral stenosis. The PCWP tends to be flat and featureless, with no A wave and no classic V wave, as LA waves are not retrogradely transmitted through the obstructed vein. PCWP may have some phasicity and a small peak in systole from the systolic filling of the pulmonary venous compartment, with the morphology of a damped artery rather than an atrial V morphology. Sampling multiple lung quadrants may show discrepancy between PCWP in stenotic vs. non-stenotic quadrants.

Answer 11. A, B, D, F, G, H. When the PCWP waveform does not have clear distinct waves that are properly timed, and particularly when PCWP is paradoxically elevated in a patient with suspected precapillary PH, it is important to confirm PCWP by checking the O_2 saturation of the wedged PA catheter. PCWP saturation >90–95% suggests true PCWP. In this patient with normal PCWP that is consistent with the clinical suspicion, provocative testing is not warranted. Conversely, provocative testing is warranted whenever there is a high clinical suspicion of occult left diastolic HF, particularly when PCWP is 13–15 mmHg or when V wave or A wave is prominent, even if mean PCWP is normal. Pressure measurements are performed, when possible, during quiet breathing at end-expiration (at which time respiratory pressure is 0 and does not alter the true intracavitary pressure). Avoid breath-holding maneuver, as the latter may inadvertently create a positive chest pressure.

Answer 12. The RA pressure is severely elevated (mean RA >15 mmHg). This indicates decompensated right heart failure, whether intrinsic (RV failure, restrictive cardiomyopathy) or, much less commonly, from a constrictive process. Whenever RA pressure is >15 mmHg, 2 features are inherently seen on the RA contour, regardless of the underlying cause:

- Deep Y descent, sometimes with deep X as well (M contour). Deep Y is related to the overwhelmed RA compliance and the high V wave. Y gets deeper with inspiration, as venous return increases and enlarges V wave and its Y descent. The ECG confirms Y descent (it occurs after T wave), but this is not even necessary as one can assume the deepest descent is Y whenever RA pressure is severely elevated.
- RA Kussmaul sign, wherein RA mean line minimally varies with respiration (<3 mmHg) or paradoxically rises with inspiration, around the deepest Y descent, as is the case here. The inspiratory increase in venous return overwhelms the RA compliance and raises its pressure enough to counteract the direct negative respiratory pressure.

These 2 features are not specific and most frequently reflect decompensated intrinsic RV failure. ***The only case of severe RA pressure elevation without these 2 findings is tamponade***, wherein Y is flattened, and wherein mean RA pressure usually displays respiratory variability.

Answer 13. C. The patient has 4 findings that are very sensitive and nearly universal in constriction but are more commonly seen in practice with severe RV failure and restrictive processes and, thus, do not rule in constriction: (i) RA pressure Kussmaul sign, and deep X and Y descents; (ii) RV large and rapid early diastolic filling wave; (iii) RV systolic pressure <55 mmHg; (iv) RVEDP/RV systolic pressure >1/3, a reflection of the low RV stroke volume and high RVEDP. There is also intermittent equalization of RV and LV end-diastolic pressures, which is pathological but poorly specific for any etiology. This patient indeed has constrictive pericarditis, but this is based on RV/LV systolic discordance (Figure 37.46). He also has dramatic fluctuations of the RV and LV pulse volumes with respiration, implying good stroke volume reserve despite the very low pulse volume (i.e., very low stroke volume); this argues against myocardial disease and further suggests constriction.

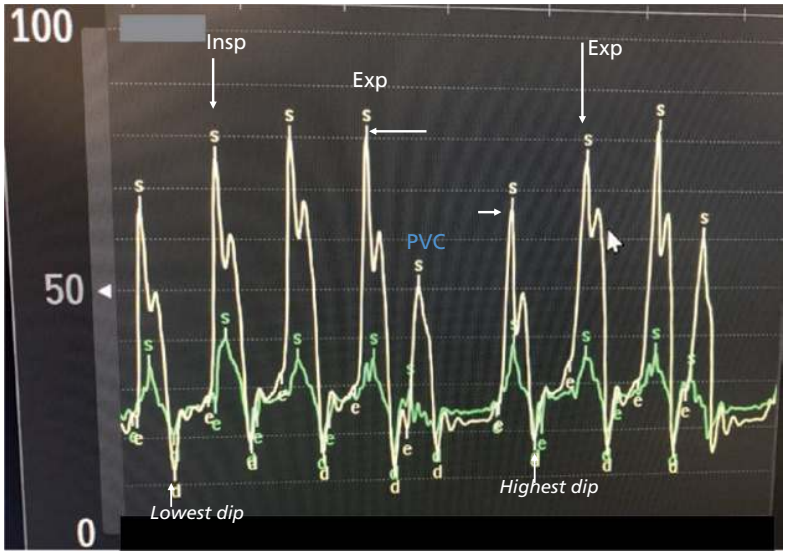

Figure 37.46 Analysis tips for assessing RV–LV systolic discordance:

1. Pick the peak inspiratory beat, which is the beat preceded by the lowest diastolic dip, and peak expiratory beat, which is the beat preceded by the highest diastolic dip, as marked by the *arrows*. Repeat recordings during deep breathing to accentuate discordance.
2. It is paramount to analyze the systolic areas, i.e., the bulk of the rectangular pressures, rather than the peaks. The area is what corresponds to the stroke volume. In this patient, the RV area shrinks while the LV area augments in expiration.
3. Analyze post-PVC behavior. A well-timed PVC may accentuate discordance and further corroborate the diagnosis, as in this case, where LV pressure area shrinks after PVC, while RV area bulks up.

Answer 14. A variable, and therefore dynamic LV-aortic pressure gradient is seen. Dynamic LVOT obstruction is suggested by the following:

- Gradient is dynamic and varies even spontaneously between beats (likely because of respiratory effect).
- The morphology: on beats with the worst obstruction/gradient, the LV pressure has a late-peaking dagger shape, while the aortic pressure has a spike-and-dome morphology. **Not only the gradient is dynamic, but the LV-aortic morphologies are dynamic as well, which further suggests dynamic LVOT obstruction.**
- Brockenbrough phenomenon: following a PVC, the LV-aortic gradient increases and, most importantly, the aortic pressure waveform collapses (unlike in fixed obstruction or in normal individuals with no obstruction, where the aortic waveform bulks up after a pause). Not only the gradient rises, but the LV waveform becomes more "peaky" and dagger-shaped while the aortic waveform becomes more spike-and-domed.

Answer 15. B. At first glance, it seems that there is no LV-aortic pressure gradient. However, after the PVC, the aortic and LV pressures collapse, and the aortic pressure acquires a spike-and-dome morphology. If this patient's obstruction was relieved, the aortic pulse pressure and waveform would bulk up after a pause. Thus, this recording is in fact obtained in the LVOT past the point of obstruction, where LVOT and aortic systolic pressures and shapes match. This explains why after a PVC, the aortic pressure becomes spike-and-domed, and the LV pressure changes in a similar fashion, with early LV spiking (unlike the late-dagger LV morphology proximal to the obstruction). **In fact, dynamic LVOT obstruction may be suggested solely by analyzing the aortic pressure morphology and its behavior after a PVC, without simultaneous LV-aortic recording.**

Answer 16. C. The first 2 beats show an aortic morphology consistent with severe fixed obstruction, typically AS (or occasionally fixed subaortic AS): slow, late-peaking aortic upslope, not parallel to the LV upslope, with an anacrotic bend on the second beat. The peak-to-peak gradient is ~50 mmHg, consistent with severe AS. *After PVC*, the aortic and LV morphologies change: the aortic upslope is now sharp and parallel to the LV, with a spike-and-dome morphology, while the LV has a late-dagger shape. Also, a classic Brockenbrough phenomenon is seen: the aortic pulse pressure drops while the gradient dramatically rises. Thus, this patient exhibits *2 concurrent processes: severe AS and an associated severe dynamic LVOT obstruction* (possibly from a severe septal bulge secondary to AS). Both processes need to be treated during surgery.

Answer 17. This tracing is PCWP with a massive V wave of 65 mmHg. It is not PA (Figure 37.47): (i) PCWP is upsloping between the peaks with an A wave, while PA would be downsloping with dicrotic notch; (ii) PCWP's V wave is "peaky" and narrow, while PA would be wider (PA plateaus throughout the T wave) with a sharp upslope but slow downslope. It is not RV: the upsloping morphology in diastole could be consistent with RV, but again the RV is not peaky and is rather rectangular. Figure 37.46 shows PA vs. PCWP in this patient. A large V wave, i.e., >50 mmHg, or >10 mmHg higher than mean PCWP, most commonly reflects severe HF. But when very large, over 2–2.5× the mean

Figure 37.47 Note the difference in morphology between PA and PCWP: note the different slope between the peaks (downslope for PA, upslope for PCWP), and the different shape of the peaks ("peaky" PCWP).

PCWP, it suggests decompensated severe MR. The V wave is so large here that it matches the systolic PA pressure, a rare finding where the PA flow will stop in end-systole, and PA pressure may display a second peak, the V wave transmission to the PA (Figure 37.8). This is also a rare case where *mean PCWP, driven by V, is higher than diastolic PA pressure*, but it remains lower than mean PA pressure (otherwise, blood cannot flow forward). The diastolic PCWP remains lower than diastolic PA pressure, so there is forward flow in diastole as well.

Answer 18. C. The aortic tracing displays a low-lying anacrotic notch on its upslope along with late peaking, which is suggestive of AS. However, the pulse pressure is wide (153/74), which is unusual in AS. This may suggest mixed severe AS-AI or severe AS in an elderly patient with very stiff non-compliant arteries. It is unlikely to be a pure severe AI with functional AS from the high flow across the aortic valve, as in this case, the anacrotic notch would be high on the aortic upslope. The most likely diagnosis is severe AS with non-compliant arteries or with moderate AI.

I. Image basics

The arterial wall has 3 layers: (1) intima, typically white (echodense); (2) media, a thin black band; (3) adventitia, a thick, white, onion-skin external layer. The lumen is black (echolucent). In normal vessels, the intima is very thin, thinner than the media. In atheromatous arteries, the intima is essentially composed of atheroma, and its thickness corresponds to the plaque thickness; the media undergoes atrophy and becomes thinner than the intima. **When one is looking at an IVUS image, the first step is to find the black band inside the arterial wall. This black band is the media; inside it are the intima and the lumen** (Figures 38.1, 38.2).

Because of a blood stasis artifact, the lumen may look white and "foggy" and the lumen–intima boundary may be blurry, making luminal measurement difficult. In addition, the "foggy" lumen may be confused with a thrombus or with an echolucent intima, e.g., lipid-rich intima or intima with a necrotic core, falsely suggesting unstable disease. In order to improve blood stasis artifact, flush the coronary artery with contrast or saline whenever there is luminal blurriness (Figure 38.3). One may also use the color signal feature available with the Volcano system, wherein blood echogenicity is assigned a red color.

Vascular structures seen in the surroundings of the imaged artery may be arterial branches (e.g., septal, diagonal branches) or coronary veins. If, upon pullback, the structure enters the intima and joins the main vessel, the structure is a branch. Otherwise, it is a vein. Arterial branches are useful landmarks that identify the disease location and correlate it with angiography (Figures 38.4–38.6). Also, in the case of dissection, if the wire position is in question (true lumen vs. false lumen), seeing branches that join the lumen confirms the true luminal position of the wire.

In the presence of atherosclerosis, the media undergoes expansion in such a way that the luminal area remains normal. This is called **positive remodeling** or the Glagov phenomenon (Figures 38.7, 38.8). When the plaque area occupies more than 40% of the total vessel area (external elastic membrane area), luminal narrowing is seen. However, ~10–20% of atherosclerotic vessels undergo **negative remodeling**, wherein the media constricts and further narrows the lumen beyond what is expected from atherosclerosis. Thus, ***luminal narrowing depends on the amount of atherosclerosis but also the type and extent of remodeling***.

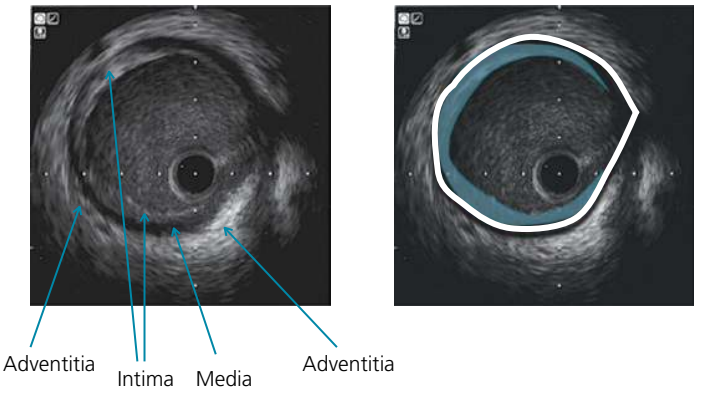

Figure 38.1 The left image is duplicated on the right with blue shading highlighting the intima and a white line highlighting the media.

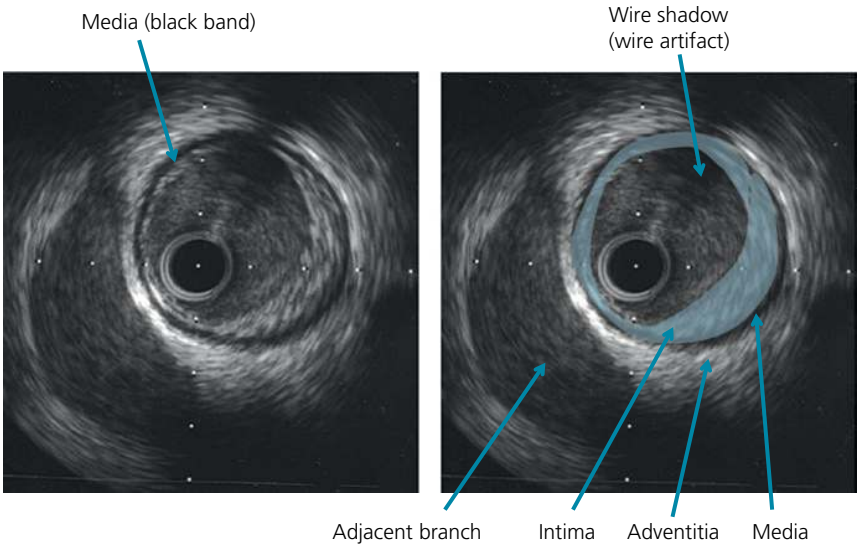

Figure 38.2 The left image is duplicated on the right with blue shading highlighting the intima. A wire artifact is seen as a black shadow. An adjacent vessel is seen. The imaged vessel is the proximal LAD and the adjacent vessel is the ramus.

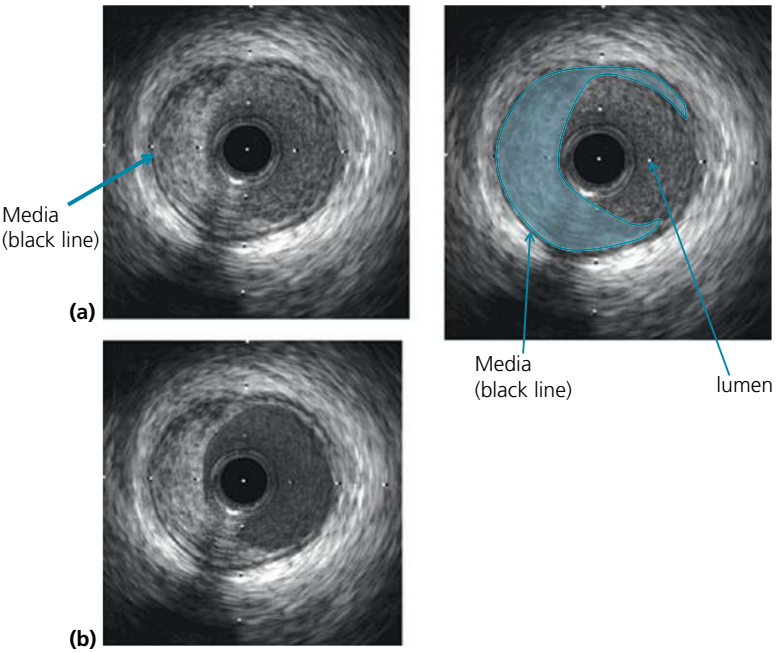

Figure 38.3 **(a)** Intima is marked in blue in the right-hand image. Note that the lumen is hazy, and one cannot definitely rule out echolucent (dark) plaque within this lumen. **(b)** After flushing the lumen, its boundaries become sharper, which makes luminal and intimal calculations easier and rules out echolucent plaque or intraluminal thrombus.

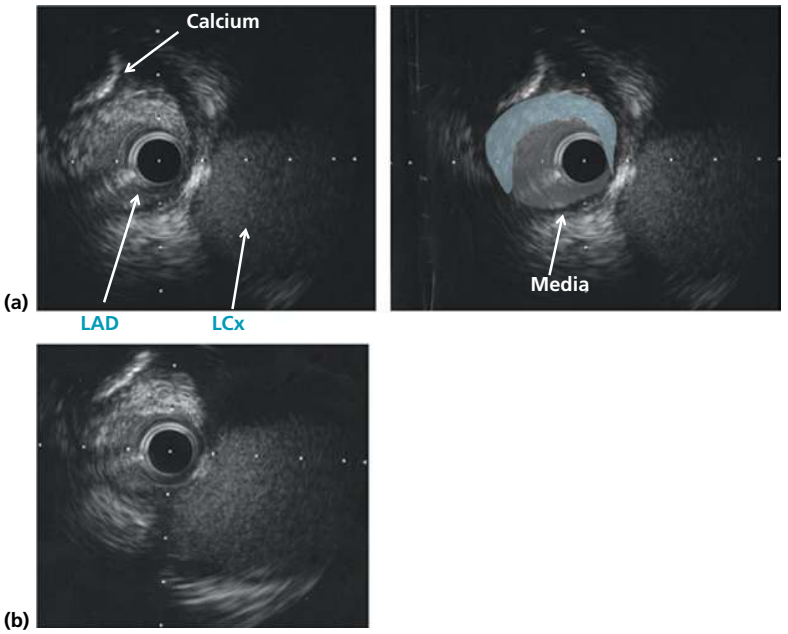

Figure 38.4 **(a)** Ostial LAD with LCx adjacent to it. The blue shading marks the intima, the gray shading marks the lumen. The black line surrounding the intima is the media. Always start by identifying the media, then identify the intima and lumen. **(b)** The severe LAD disease with constrictive remodeling extends until the very ostium, just as the LCx meets the LAD. The LAD lumen is narrow as a result of atherosclerosis but also as a result of vessel constriction. In fact, the media-to-media diameter of this ostial LAD (external elastic membrane [EEM] diameter) is only 3 mm (the distance between 2 dots being 1 mm).

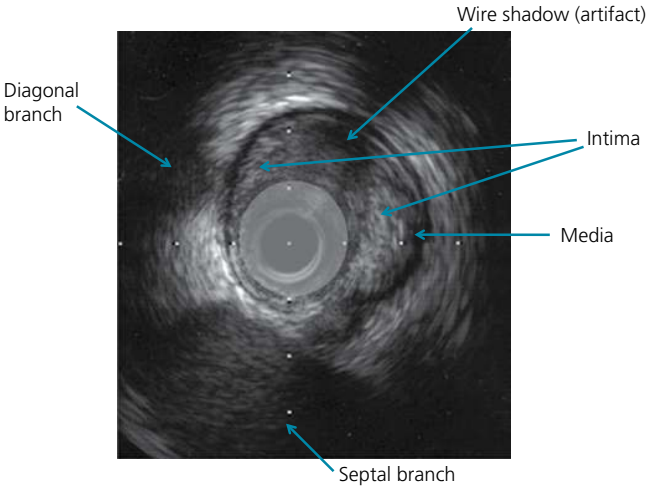

Figure 38.5 Diseased LAD at the level of first septal and first diagonal branches. The gray shading marks the lumen.

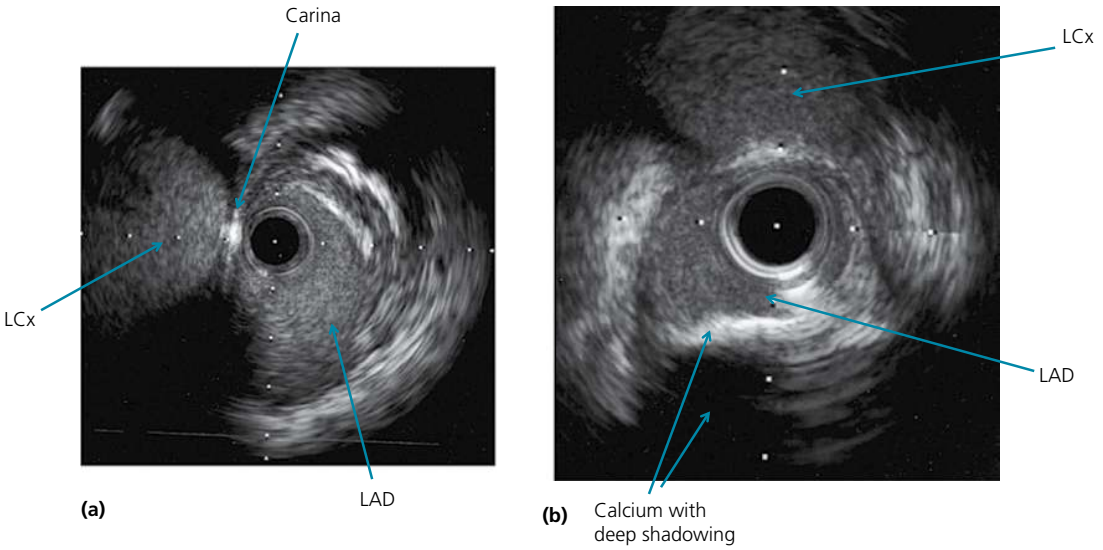

Figure 38.6 (a, b) Two IVUS images of a left main bifurcating into LAD and LCx. In **(b)**, note that the ostial LAD is heavily calcified with a luminal area of 4 mm^2.

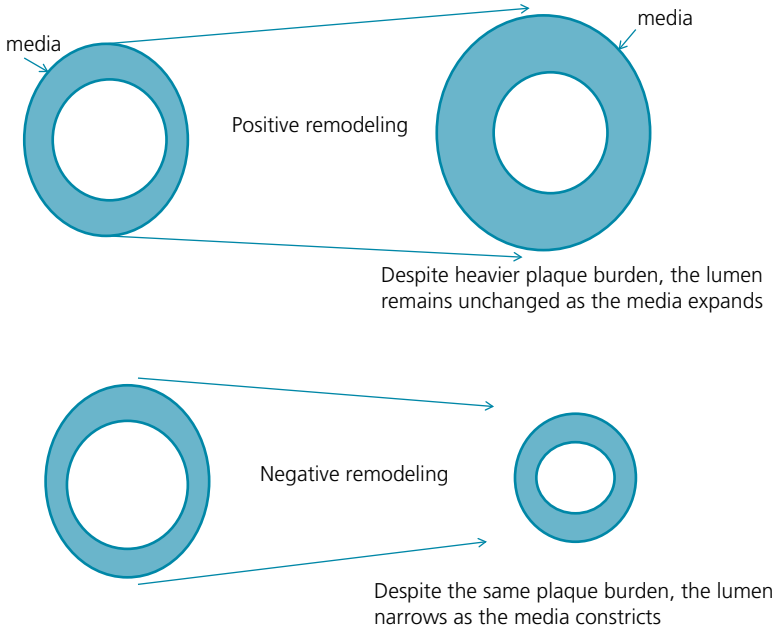

Figure 38.7 Positive and negative remodeling.

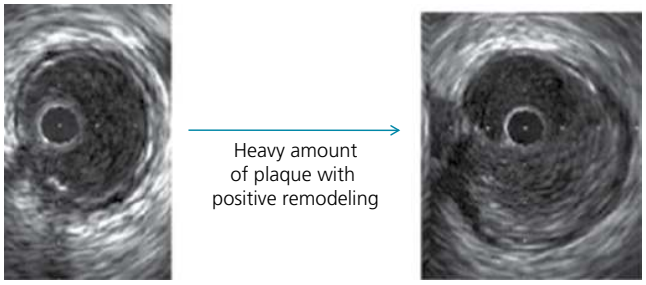

Figure 38.8 Example of positive remodeling (EEM area has expanded to accommodate atherosclerosis). Remodeling index = EEM area at the level of the lesion (*right*)/EEM area at the level of the reference (*left*).

II. Plaque types

IVUS identifies 3 types of plaques, i.e., 3 types of intima:

- *Echolucent, soft intima* is less echogenic (less white) than the adventitia. A soft plaque may be hard to differentiate from a foggy lumen.
- *Echodense, fibrous intima* is as bright as or brighter than the adventitia. Most atherosclerotic lesions are fibrous.
- *Calcified intima* is brighter than the adventitia and has deep shadowing (Figures 38.4, 38.6). The calcium is quantified by the arc it encompasses (e.g., 90°, 180°) and its depth. Superficial calcium is defined as calcium in the top half of the intima and is particularly adverse to stent expansion.

In addition, one should look for signs of plaque instability (Figures 38.9–38.12):

a. *A ruptured or ulcerated plaque* is a plaque that has been split. It contains a cavity that communicates with the lumen, with a variable amount of overlying, ruptured fibrous cap.
b. *A dark, echolucent area* within a plaque represents a soft lipid-rich component, a necrotic core, intra-plaque hemorrhage, or an intra-intimal thrombus.
c. *A thrombus* is an intraluminal or intra-intimal echolucent mass having a layered or lobulated appearance (± speckled texture). It is sometimes hard to differentiate from soft echolucent plaque or necrotic or lipid-rich areas. Also, blood stasis artifact may hide a thrombus or create the impression of a thrombus. When in doubt, flush the coronary artery to clear blood stasis.

In addition, heavy atheroma with positive remodeling is often seen in ACS and is a marker of instability. While positive remodeling reduces the severity of coronary stenosis, it is a marker of heavy atherosclerosis and plaque progression, frequently through prior plaque ruptures, and is thus a negative prognostic marker.

When measuring the luminal area in a ruptured/ulcerated plaque, exclude the ulcerated area, as it is not true lumen. The lesion may not look severe on angiography because the ruptured cavity fills with contrast, concealing the tightness of the true lumen.

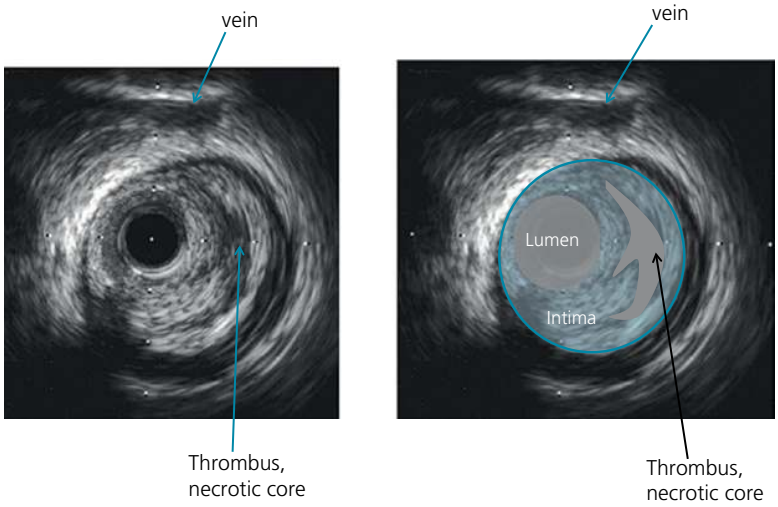

Figure 38.9 Lesion with necrotic core. Intima and necrotic core are highlighted in the right-hand image.

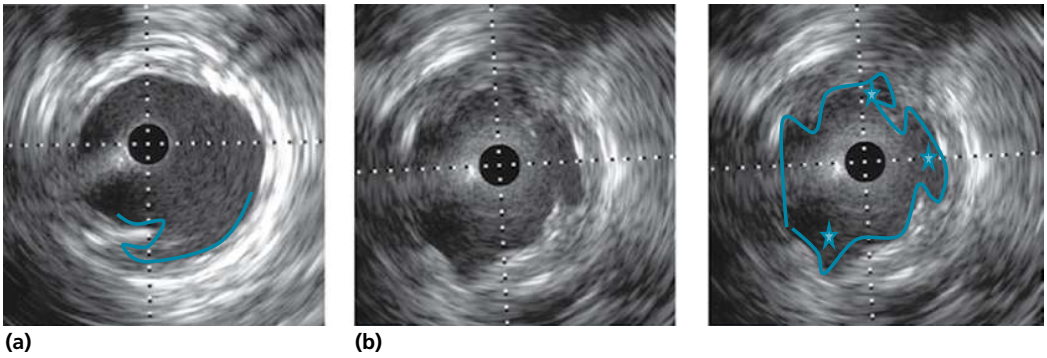

Figure 38.10 Ulcerated lesions. **(a)** Ulcer demarcated at 6 o'clock. **(b)** Stenosis with multiple ulcers demarcated at 12, 3, and a little after 6 o'clock (*stars* in right-hand image). The blue line delineates the intima–lumen boundary.

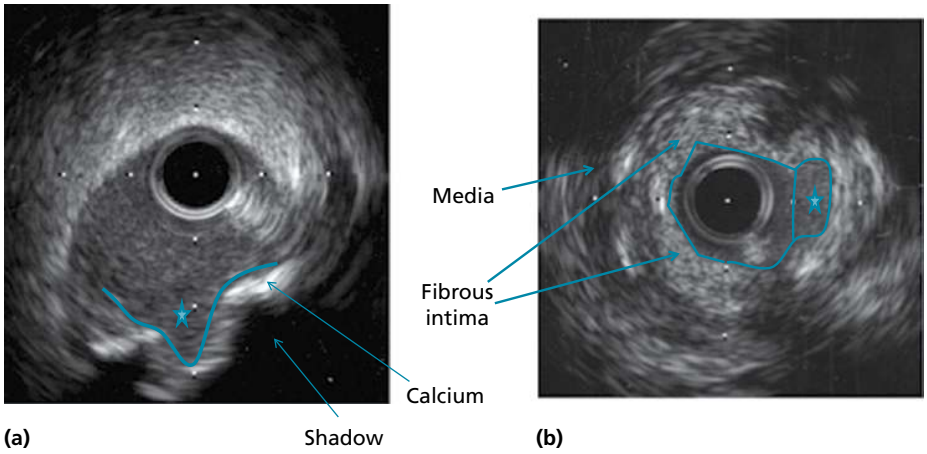

Figure 38.11 Further examples of ulcers. **(a)** LAD ulcer at 6 o'clock (*star*). Also, a superficial calcified arc of 45° is seen with deep shadowing. **(b)** Crater/ulcer at 3 o'clock (*star*). Lumen area measures ~2.5 mm^2, excluding the crater (using the imaginary vertical line).

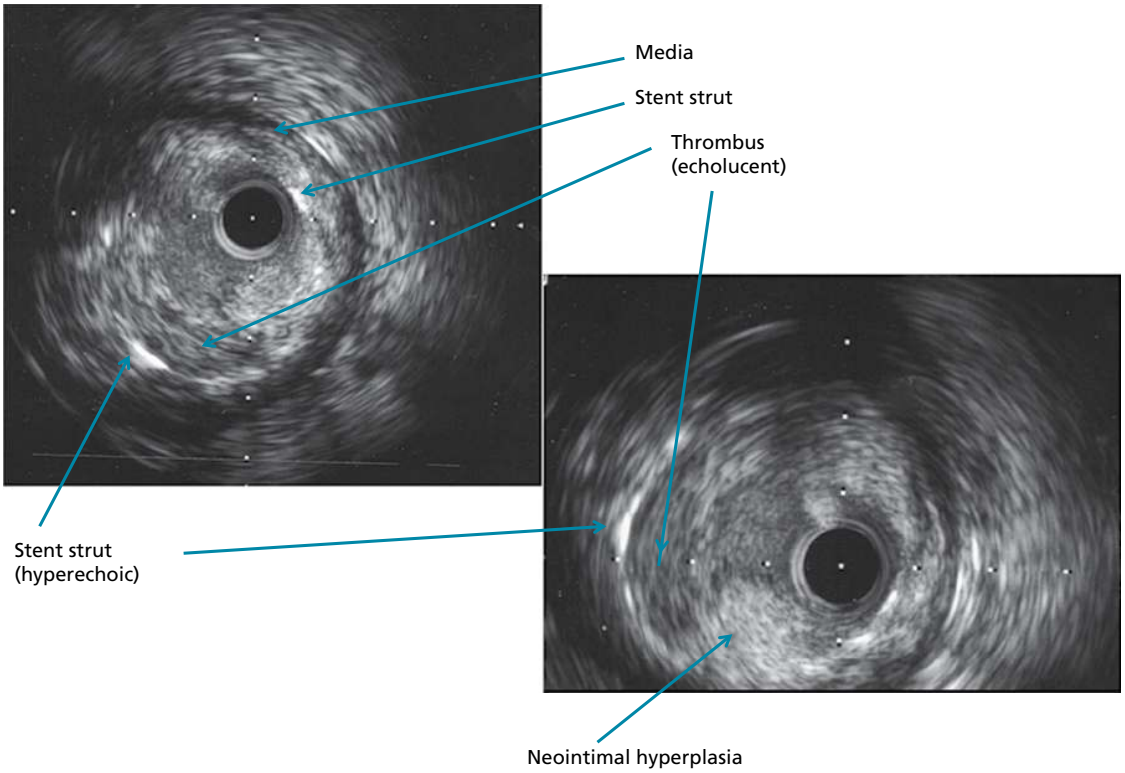

Figure 38.12 Stent thrombosis and neointimal hyperplasia.

III. Basic IVUS measurements

The following are basic IVUS measurements (Figure 38.13):

a. *External elastic membrane (EEM)* cross-sectional area (CSA), also called total vessel CSA: EEM corresponds to the outer boundary of the media. This is the boundary between the black band (media) and the outer adventitia.
b. *Lumen CSA* at the level of the stenosis (*minimal luminal area [MLA]*): this is the most important measurement and the one correlating the most with outcomes.
c. *Intima + media CSA* = atheroma CSA = EEM area minus lumen area.
d. *Area of stenosis*: contrary to a common misconception, the area of stenosis does not reference the stenosis to the EEM area. As a result of positive remodeling, the EEM area is larger than the original non-diseased vessel area, and thus ***MLA should be compared to the most normal surrounding lumen rather than the EEM area.*** The reference lumen is the most normal-looking lumen, i.e., the largest lumen with the smallest plaque burden (<40% burden) adjacent to the lesion. One may average the proximal and distal references.

Conversely, referencing the plaque to the EEM area is called *plaque burden* or *percent cross-sectional narrowing* and is dependent on the amount of atheroma.
e. In patients with a stent, the *stent area* is the area bounded by the stent struts, while the *neointimal hyperplasia area* is equal to stent area minus lumen area (Figures 38.14, 38.15). ***The stent should be sized to the reference lumen area, not the EEM area***. The stent should be sized to 100% of the distal reference or 90% of the average proximal and distal references. Sizing the stent to the EEM area results in stent oversizing with a risk of perforation or edge dissection. A stent is underexpanded when (Figure 38.14):

- The minimal stent area (MSA) (i.e., the stent area in the tightest spot) is less than the reference lumen area.
- The diameter of the stent is less than the nominal stent diameter (e.g., a 3-mm stent is only expanded to 2.5 mm).
- It is asymmetric with a minimal-to-maximal stent diameter <0.7.

Underexpansion is typically focal in calcified or fibrotic spots.

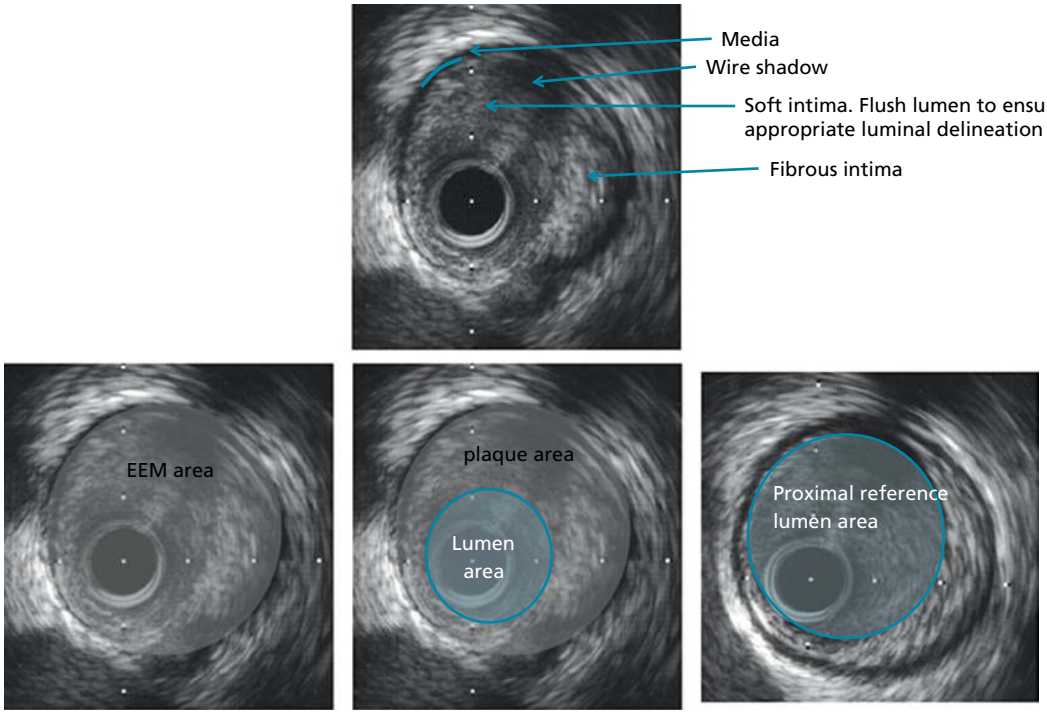

Figure 38.13 Illustration of various IVUS-determined areas. The luminal diameter across the stenosis is ~2 mm, with a minimal luminal area (MLA) of 3.5 mm^2 (1-mm grid). The EEM diameter is 4 mm, with EEM area (total vessel area) of ~12.5 mm^2. The proximal reference lumen diameter is 3 mm, with a proximal reference lumen area of 7 mm^2.

The area of stenosis is MLA in reference to the reference lumen area, not vessel area. Thus, the area of stenosis is equal to (reference lumen – stenotic lumen)/reference lumen = (7 – 3.5)/7 = 50%.

The plaque burden is: plaque area/EEM area = (EEM area – stenotic lumen)/EEM area = (12.5 – 3.5)/12.5 = 72%.

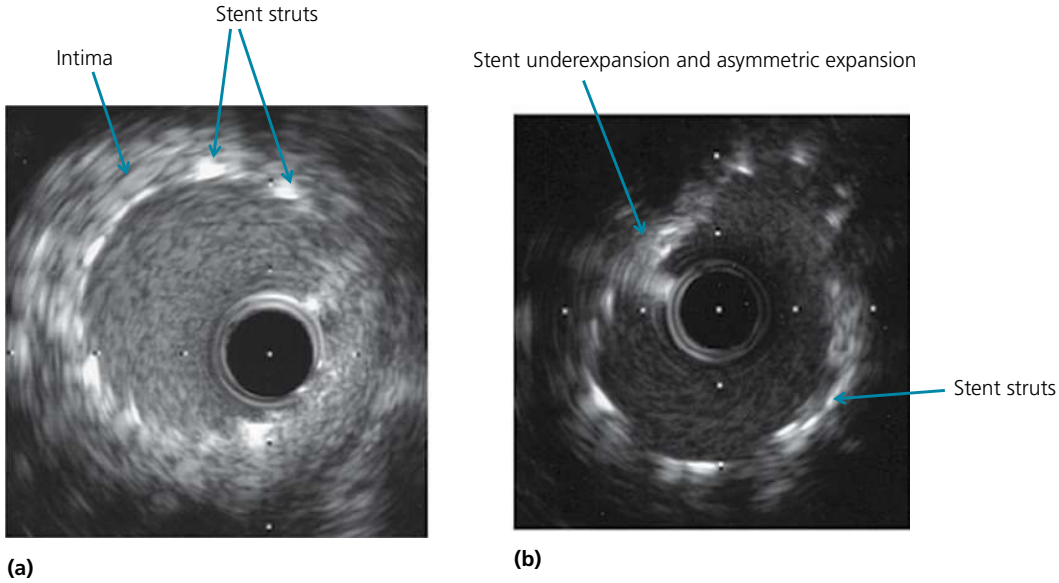

Figure 38.14 Stents. **(a)** Ostial LM stent with intima seen underneath the struts. **(b)** Stent underexpansion and asymmetric expansion. The minimal stent diameter is 2.5 mm, while its maximal diameter is 4 mm.

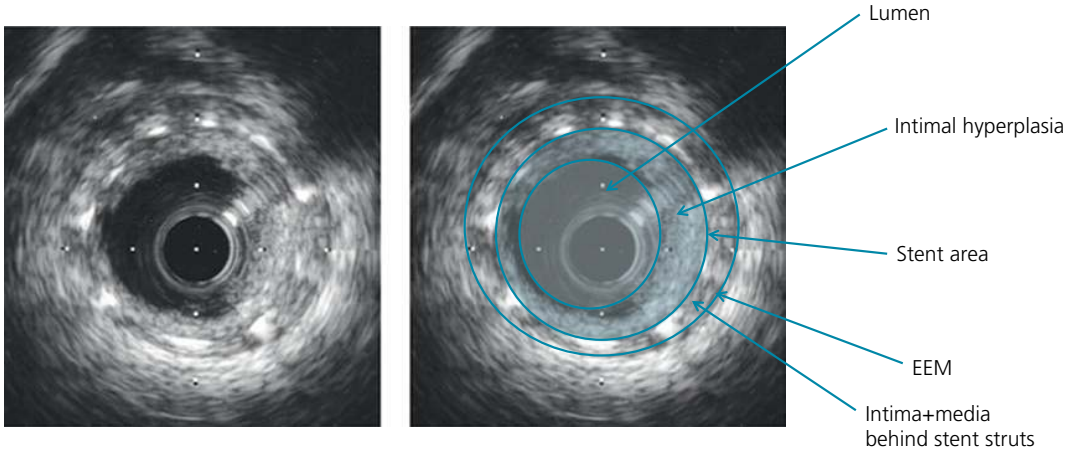

Figure 38.15 Stent with neointimal hyperplasia. In-stent restenosis percent is equal to neointimal hyperplasia area/stent area.

IV. Interpretation of how a severe stenosis may look mild angiographically, yet severe by IVUS; significance of lesion haziness (see Figure 38.16)

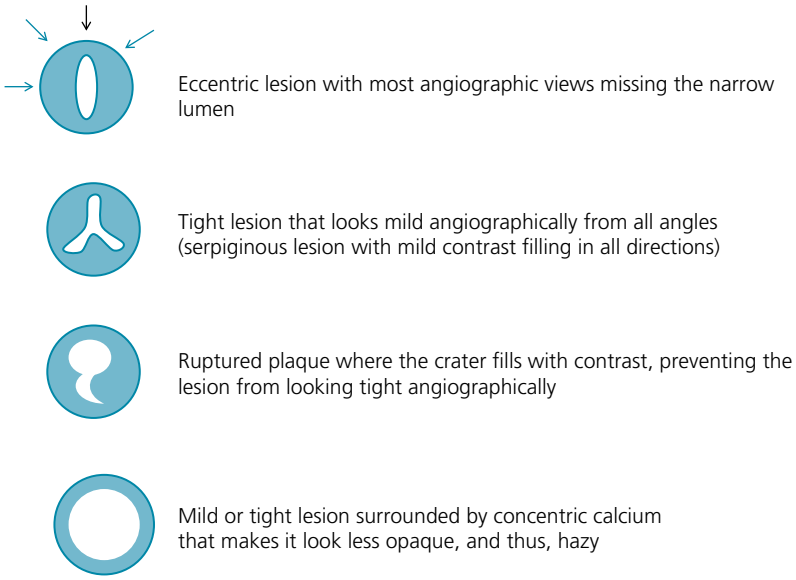

Figure 38.16 Causes of lesion haziness. Interpretation of how a severe stenosis may look mild angiographically, yet severe by IVUS.

V. Assessment of lesion significance by IVUS

Several studies have tried to associate ischemia with a single minimal luminal area cutoff by IVUS. MLA <3 mm^2 for non-left main arteries had a good correlation with FFR <0.75 in one study, whereas MLA <4 mm^2 had a good correlation with ischemia determined by coronary vascular reserve in another study.[1,2] More specifically, cutoffs of 2.4 mm^2 for any epicardial vessel, 3 mm^2 for the proximal LAD, and 2.75 mm^2 for the mid-LAD were found to have the best correlation with FFR ≤ 0.80.[3,4] In the modern FLAVOUR trial of IVUS vs. FFR for intermediate lesion assessment, a cutoff of 3 mm^2 was used to call a lesion significant, or 3–4 mm^2 with plaque burden >70%.[5] These IVUS cutoffs proved non-inferior to FFR guidance. In the PREVENT trial of patients with somewhat similar IVUS criteria, PCI slightly reduced target vessel revascularization compared to medical therapy.[6]

However, the use of a single anatomical cutoff clearly has issues: a 4-mm^2 MLA may limit flow in a large proximal vessel, but not in a distal small vessel. In fact, the area of a normal 2.5-mm vessel is 4.9 mm^2; thus a stenosis with MLA 4 mm^2 corresponds to a 28% area of stenosis and should not be considered functionally significant. Even in a 3-mm vessel (7.12 mm^2 area), a 4 mm^2 MLA corresponds to a 44% area of stenosis, unlikely to be significant.[7] Furthermore, the drop in flow across a lesion correlates with length as well as diameter, i.e., a focal 4 mm^2 stenosis may not be significant. Deferral based on IVUS MLA >4 mm^2 is appropriate and associated with excellent clinical outcomes; however, the decision to treat a lesion with MLA <4 mm^2 is less appropriate.[8] An intermediate lesion is better assessed functionally, while IVUS is still useful for lesion assessment in ACS. IVUS is useful before lesion stenting for sizing and for evaluation of some unstable morphological features (e.g., plaque rupture, circumferential calcifications that dictate rotational atherectomy), and is useful after stenting to assess stent expansion, apposition, and distal edge dissections.

VI. Pre-stent IVUS or OCT sizing and calcium assessment. Post-stent IVUS or OCT assessment

Two major randomized trials proved the value of intravascular imaging in reducing target vessel failure, mainly target vessel revascularization, target vessel MI, and stent thrombosis: ULTIMATE trial, which used IVUS in all PCI comers (JACC 2018) and RENOVATE-COMPLEX PCI trial, which allowed both IVUS (~75%) and OCT (~25%) in complex PCI (NEJM 2023).[9,10] The sizing methods described herein are derived from those 2 trials.

A. PRE-STENT sizing

Stent is typically sized according to the distal REFERENCE LUMEN (100% the distal reference lumen diameter or 90% the average proximal + distal reference lumen diameters). The proximal and distal references are defined as segments with <40% plaque burden ideally.

A more aggressive approach consists of using the distal REFERENCE EEM or the average EEM of the proximal and distal references, downsized ~0.25 mm. This method was adopted in the COMPLEX-RENOVATE trial for both OCT and IVUS, as well as in other OCT and IVUS trials (Ilumien and iSIGHT trials). **DO NOT use the LESION EEM.** Sizing by the REFERENCE EEM carries less risk of oversizing than sizing by the larger and more positively remodeled LESION EEM.

So, for initial stent sizing (IVUS pre-PCI), you may use REFERENCE LUMENs or REFERENCE EEMs.

B. Pre-stent calcium assessment and calcified nodules

Severe coronary calcification is defined fluoroscopically as long (>15 mm) calcium present on both sides of the vessel AND seen even without cardiac motion and before contrast injection. By IVUS and OCT, severe calcium is defined as any of the following and may dictate calcium modification by atherectomy or lithotripsy balloon (SCAI 2024): arc of calcium **>270°** or calcified nodule. A calcified nodule is an eccentric piece of calcium **protruding** into the lumen. As opposed to calcified sheets or plates, the key defining feature is the **bulge** into the lumen, likely from fracture of the calcium sheets; hence it is flanked proximally and distally by hard, collagen-rich calcified sheets, and it is more likely to occur: (i) at hinge points, such as in the ostial or middle RCA; and (ii) in areas of high lipid content and necrotic core within the calcium (which makes it prone to rupture), such as left main bifurcation and proximal coronary tree (Figure 38.17). *Even if localized, a calcified nodule significantly impairs stent expansion* compared to calcified lesions without nodules and may warrant calcium modification with lithotripsy balloon; being eccentric, even rotational atherectomy may not affect it, unless the wire hugs the calcium (i.e., wire bias into the nodule). *An eruptive calcified nodule is a calcified nodule that, in addition, ruptures the cap and often causes thrombus* formation and ACS. A calcified nodule accounts for 4–8% of MI culprit lesions, but is much more prevalent in heavily calcified lesions with >180°–270° arc of calcium or lesions considered for calcium modification therapies (40s%).

C. POST-STENT IVUS or OCT

1. For assessment of **stent expansion**, only REFERENCE LUMENS have been used in both landmark trials: a stent is considered well expanded if minimal stent area (MSA) ≥90% of the distal reference LUMEN or ≥80% of the average reference lumens. In long stenting >28–30 mm or stenting across bifurcation/large side branch with vessel stepdown, proximal stent MSA should be ≥90% of the proximal reference lumen, while distal stent MSA should be ≥90% of the distal reference lumen (Figure 38.18).

Absolute values for stent expansion were also allowed as an alternative in both trials: non-left main MSA >5.5 mm^2, left main stent MSA >7 mm^2 (distally) or 8 mm^2 (proximally), or 11 mm^2 per European data. The 2 trials considered the stent properly expanded if either the relative or absolute value is met, not necessarily both, but the relative value is more relevant. Stent underexpansion is treated with high-pressure balloon dilatation, using a non-compliant balloon sized up to: (i) the reference EEM diameter; (ii) 0.5 mm or 10% larger than the reference lumen diameter.

2. Regarding **edge dissection**, to be considered significant and to warrant further therapy, both trials mandated that the dissection extends deep to the media, AND is additionally either longer than >3 mm or has an arc >60°. A shallow dissection at the intima level did not warrant further stenting.

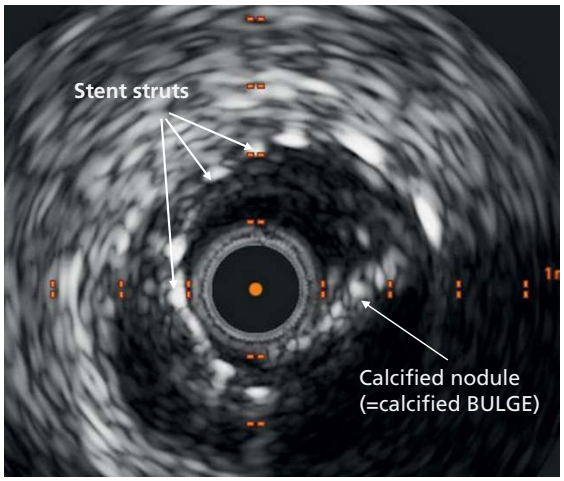

Figure 38.17 Calcified neoatheroma inside a stent with calcified nodule BULGING into the lumen.

3. Regarding **edge disease**, ULTIMATE recommended that stent edges have <50% plaque burden (plaque area/EEM <50%). For >50% residual plaque burden, repeat ballooning was recommend using an undersized balloon, not stenting. In general, it may be best to avoid further ballooning or stenting based on an absolute MLA of the edge. One pitfall of ILUMIEN IV trial of OCT guidance, which failed to meet its primary clinical endpoint, is the recommendation to add a stent at the edge if the edge's lumen is <4.5 mm^2.

4. Stent apposition is the least important target and is a far less predictor of stent restenosis and thrombosis than stent malexpansion. In RENOVATE, major malapposition warranting further dilatation was defined as ≥0.4 mm gap between the stent and the underlying intima (Figure 38.19).

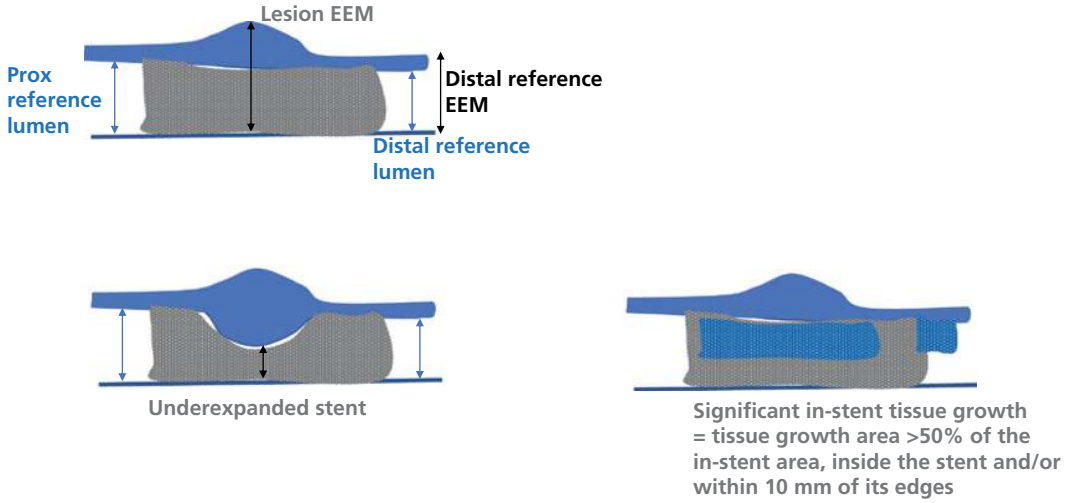

Figure 38.18 Before stenting, the distal and/or proximal reference lumen of the healthiest vessel segment is used to size the stent (the reference segment ideally has <40% plaque burden). The reference EEM of this healthy segment may alternatively be used. The stent is sized to 100% of the distal reference lumen, or downsized ~0.25 mm from the distal reference EEM. Whether for the distal reference lumen or the distal EEM, the mean of the maximal and minimal diameters on the cross-section is used.

After stenting, proper stent expansion is defined as stent expansion ≥90% of the distal reference luminal area or ≥80% the average proximal + distal lumen. Reference EEM is not used.

In-stent tissue growth is significant if it occupies >50% of the in-stent lumen. It may be neointimal hyperplasia in the first 1–3 years and neoatherosclerosis beyond 1–3 years after stenting. The *gray cage* is the stent deployed across the lesion, the *blue shade* is in-stent tissue growth.

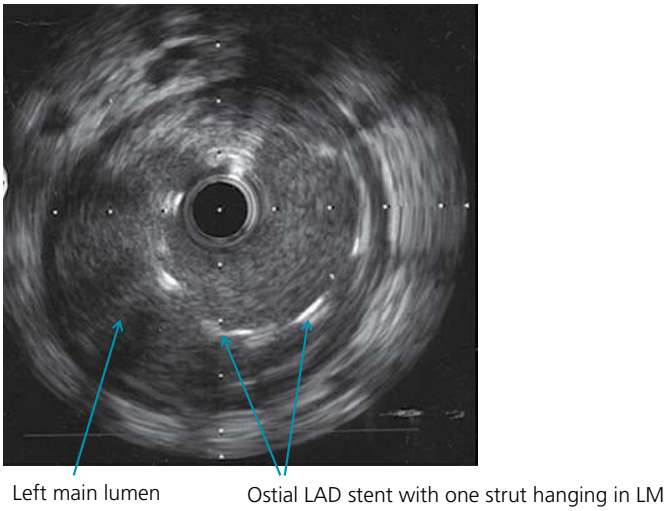

Figure 38.19 The stent is well expanded in the ostial LAD with one strut hanging in the left main (standard ostial stenting technique). Had this been a left main stent, a major stent malapposition would have been diagnosed (stent not touching the vessel wall).

VII. Assessment of left main by IVUS

See Chapter 40, Section 1.

2. OPTICAL COHERENCE TOMOGRAPHY (OCT)

OCT uses infrared light. An optical beam is directed at the tissue, and the small portion of light that reflects from subsurface tissues is collected. Since it uses light, OCT has a much higher resolution than ultrasound/IVUS, an almost microscopic resolution (10 micrometers with OCT vs. 150 micrometers with IVUS).

On OCT, the intima is yellow, the media is dark lucent, and the adventitia is often not visualized (when visualized, adventitia is dark red). The morphology of various lesion types is shown in Figures 38.20 and 38.21.

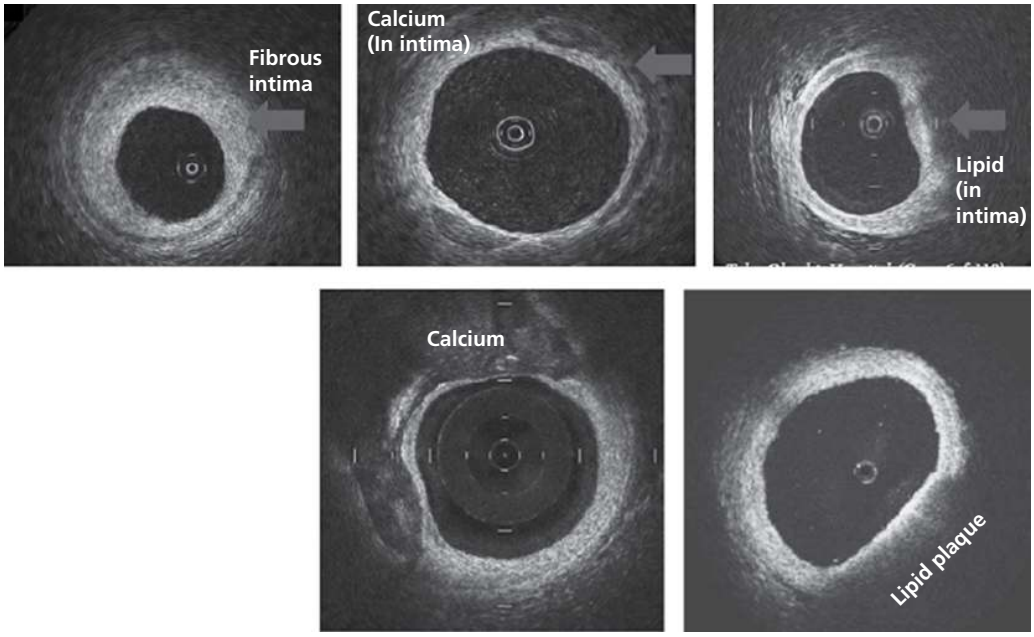

Figure 38.20 OCT. *Fibrous plaque* is characterized by being bright (high signal). As opposed to IVUS, *calcium* on OCT is dark (low signal) and is well demarcated with low attenuation of light, allowing deeper imaging. *Lipid plaque* is also dark but attenuates light more than calcium does, which explains the loose edges and the shadowing; it is homogeneous. Courtesy of St. Jude Medical.

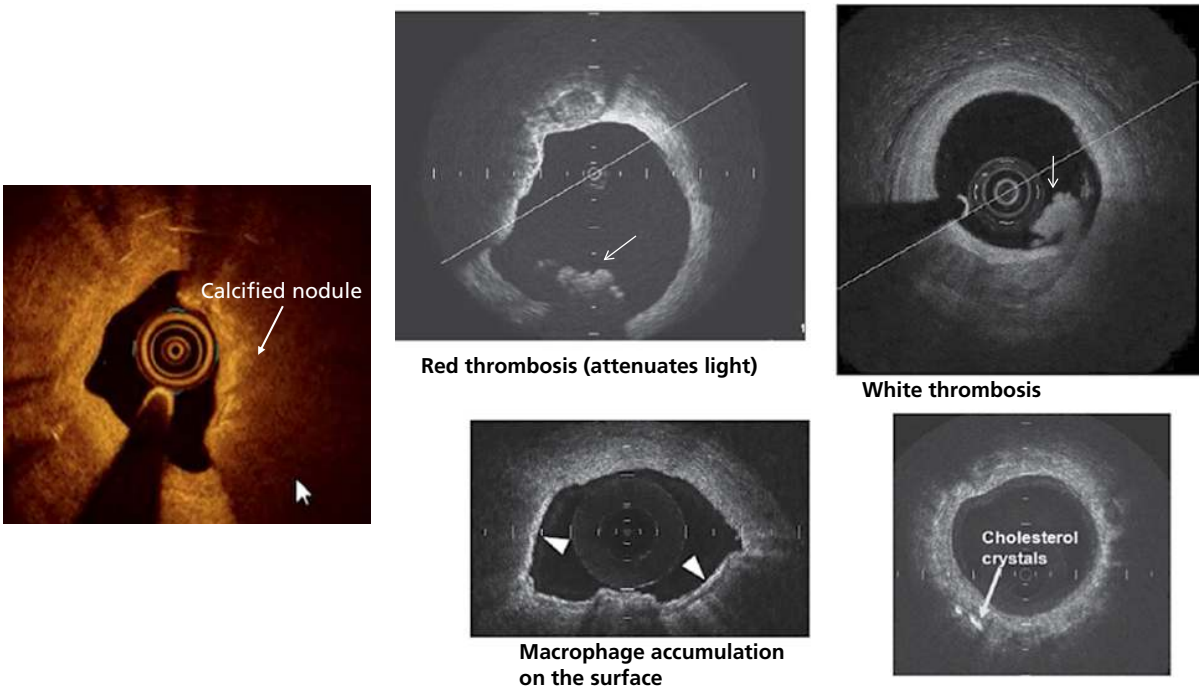

Figure 38.21 Calcified nodule, thrombus, macrophage accumulation, and cholesterol crystals imaged by OCT. A *calcified nodule* is a piece of calcium BULGING into the lumen: **while calcium is usually well demarcated on OCT, a calcified nodule is not well demarcated and causes attenuation** as it tends to have a necrotic and lipid core. This calcified nodule is non-eruptive, as there is no thrombus or cap rupture over the calcium. *Macrophage accumulation* appears as a bright line on the surface of the plaque and is associated with shadowing. Macrophages usually accumulate superficially within the fibrous cap and are a sign of instability. In fact, macrophages are the cells that rupture the cap. Cholesterol crystals look like bright dots. *Red thrombi*, rich in red blood cells, attenuate light, while *white thrombi*, rich in platelets, exhibit low light attenuation. Courtesy of St. Jude Medical.

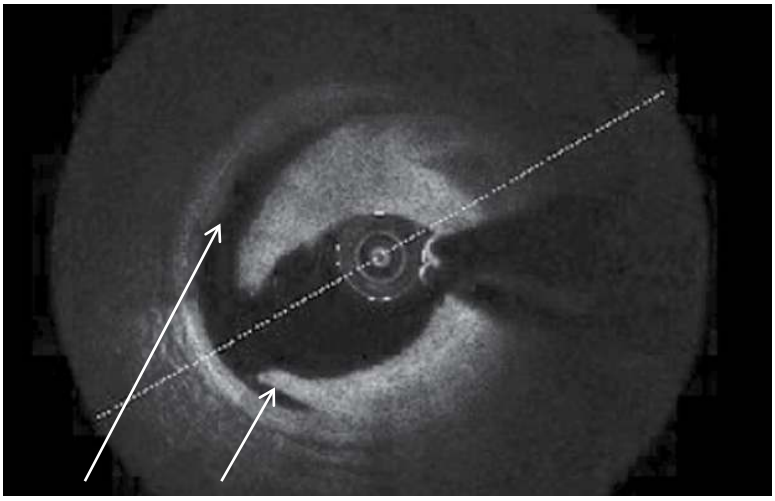

Figure 38.22 Stent edge dissection. Arrows show the dissection planes. The dissection is deep (reaches the media between 10 and 12 o'clock) and extends more than 1 quadrant. This dissection is thus clinically significant. Courtesy of St. Jude Medical.

Advantages of OCT include:

1. Greater definition of the lumen boundaries than IVUS, allowing a more accurate calculation of lumen CSA. Also, it allows better assessment of stent expansion and stent apposition to the intima.
2. Visualization of the thin fibrous cap and diagnosis of cap rupture. A thin cap is defined as a cap thinner than 65 micrometers. Most plaque ruptures (80%) occur over a thin-cap fibroatheroma.
3. Better assessment of plaque composition than IVUS (lipid-rich plaque vs. fibrous plaque). OCT is as good as IVUS for the assessment of calcifications and better than IVUS at measuring the calcium thickness and at distinguishing eruptive vs. non-eruptive calcified nodule (Figure 38.21).
4. Better visualization of thrombus than IVUS (Figure 38.21).
5. Better visualization of stent edge dissections (Figure 38.22). While edge dissections are seen by angiography in 5% of stenting procedures, they are seen by IVUS and OCT in 10% and 30% of stenting procedures, respectively. However, small edge dissections (<1 quadrant and <3 mm in length, or longer but not extending to the media) do not need to be stented.

Disadvantages of OCT include:

1. Poor tissue depth penetration of 1–2.5 mm, as opposed to 10 mm with IVUS. Thus, OCT may not visualize the full depth of the intima and may not be able to measure the plaque burden.
2. Requires a blood-free medium for imaging. OCT imaging is performed quickly to allow imaging during a single contrast injection (e.g., 4 ml/s for 16 ml). Blood that has not cleared from some areas may lead to swirls or to speckle artifacts that simulate thrombi. This also implies that OCT cannot be used to assess the ostial left main or the ostial RCA, as the guide catheter has to be appropriately engaged beyond the ostium to allow coronary contrast filling, which prevents the imaging of that ostium.
3. The imaging depth is lower than with IVUS. OCT penetrates ~3.5–4 mm of the blood-free medium, which means that OCT is suboptimal for large vessel imaging.

I. Major coronary interventional devices

A. Balloon angioplasty

1. Mechanisms of action

Angioplasty expands the external elastic membrane of the stenotic segment, creating a larger total vessel area that compensates for the intimal plaque; this is similar to the positive remodeling phenomenon (Figure 39.1). Some axial plaque redistribution, proximally and distally, may also reduce the stenosis, at the expense of creating edge stenoses.

2. Pitfalls

a. Angioplasty fractures the intimal plaque, allowing it to yield for vessel expansion. ***Dissection*** of the intima (coronary plaque) is, thus, a normal finding with angioplasty. In heavily fibrotic or calcified stenoses, dissections are necessary to allow the plaque to yield and prevent early recoil. The dissection plane may extend deep into the media, at which time it is considered true dissection with more hazard of blood flow compromise. Overall, dissections are angiographically seen after ~30% of balloon angioplasties. Mild and shallow dissections (angiographic type A or B dissections) are not associated with worsened long-term outcomes; to the contrary, the well-expanded, fractured vessel may be associated with less long-term constriction/restenosis. However, a severe dissection may obstruct the lumen and impair flow. Also, dissection may lead to abrupt vessel closure within minutes to 24 hours after angioplasty; this occurs in 5–10% of plain balloon angioplasties and is treated with bailout stenting.

b. ***Elastic recoil*** is the immediate vessel constriction that occurs after angioplasty. After the vessel appropriately yields to balloon inflation, it may quickly constrict upon balloon deflation (within 10 minutes). More prolonged inflation of the vessel with an appropriately sized balloon (sized 1:1 to the reference luminal diameter) at a high pressure reduces this phenomenon.

c. ***High risk of restenosis*** (~40%). Restenosis starts beyond the first month and is mainly due to ***negative remodeling***, which is a form of late vessel constriction (as opposed to elastic recoil, a form of early vessel constriction).

3. Compliant vs. non-compliant balloons

Non-compliant (NC) balloons do not expand much beyond their nominal size even at high pressures (<10% overexpansion), allowing one to exert high pressure across a calcified, unyielding lesion without balloon overexpansion across the soft spots. They are thicker than compliant balloons and harder to deliver (higher profile).

4. Balloon angioplasty with a balloon that is scored with blades (cutting balloon) or wires (Angiosculpt) allows the plaque to yield more easily, at lower inflation pressures. Theoretically, this increases the success of angioplasty and may be associated with less severe dissections. Also, a scored balloon is less likely to slip during balloon inflation. Standard, non-scored balloons tend to slip when inflated across a heavily fibrotic stenosis ("watermelon seeding"). Longer balloons, slower inflation, and scored balloons reduce this phenomenon.

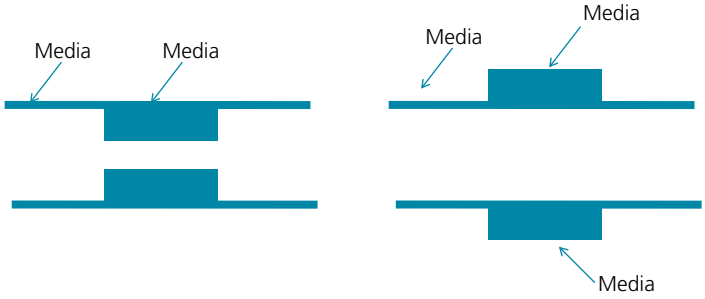

Figure 39.1 Main mechanism of action of balloon angioplasty. Angioplasty pushes the plaque and its media out, making the media larger at the treatment site. In order for this to happen, the plaque has to yield; it frequently fractures, sometimes deeply into the media (dissection).

5. Cases where plain balloon angioplasty is sometimes performed, without stenting

- Vessels <2.5 mm may be considered for standalone drug-coated ballooning
- Bifurcation lesions, in which a diseased side branch is dilated while the main branch is stented
- Treatment of DES restenosis
- Femoral and tibial interventions

B. Bare-metal stents (BMSs)

A stent addresses all 3 balloon angioplasty pitfalls. It covers and seals the dissection planes or, at least, prevents them from expanding and promoting abrupt vessel closure. It has enough radial strength to prevent early (elastic recoil) and late (restenosis) vessel constriction. Stenting improves the immediate and late PCI result, but has its own pitfalls:

i. *Stent thrombosis:* while preventing abrupt vessel closure, stenting is associated with a risk of stent thrombosis, mainly in the first month. This risk is 0.5–1% in patients receiving dual antiplatelet therapy (DAPT) with aspirin and clopidogrel, and 5–10% in patients receiving single antiplatelet therapy with aspirin.

ii. *In-stent restenosis (ISR):* restenosis is reduced to 20–25% with BMS stenting. Overall, stenting *eliminates the late negative remodeling* seen after plain angioplasty*, but increases the degree of neointimal hyperplasia*, which starts 1 month after stenting and progresses for up to 6–8 months.

Note on technical aspects

The stent is mounted on a compliant balloon and is apposed to the vessel wall through balloon inflation. Prior to advancing a stent, lesion pre-dilatation with a slightly undersized balloon breaks the fibrosis and calcium, which allows stent delivery and expansion. Sometimes, "direct stenting" not preceded by balloon angioplasty may be performed. Factors favoring successful direct stenting are: absence of calcium at the target and in other coronary vessels, absence of severe proximal tortuosity, non-critical stenosis, and age <70 years. Conversely, for severely calcified disease, pre-dilate with an NC balloon sized 1:1 to the reference and inflated at high pressure ≥18 atm, and ensure proper expansion in 2 orthogonal views before stenting. If the lesion does not yield, prepare it with any of the following: atherectomy, lithotripsy balloon (sized 1:1 to the reference vessel), or OPN or cutting balloons (sized 0.5 mm smaller than the reference vessel).

The stent is usually deployed at a pressure ≤16 atm to prevent edge overinflation by the compliant stent balloon and the risk of edge dissection. After stent deployment, further stent dilatation may be performed with a shorter non-compliant balloon placed within the stent and inflated at a higher pressure to ensure proper stent expansion. *The post-dilatation pressure is ≥18 atm* (18-22 atm) based on the recommendations of ULTIMATE, IVUS-CHIP, and COMPLEX-RENOVATE PCI trials. This balloon is initially sized 1:1 to the stent diameter or the reference lumen diameter. In the case of underexpansion, it may be sized 1:1 to the reference vessel EEM diameter or *up to 0.5 mm or 10% larger than the reference lumen diameter* (ULTIMATE, COMPLEX-RENOVATE PCI, ILUMIEN IV trials).

C. Drug-eluting stents (DESs)

(*First-generation DESs:* sirolimus [Cypher] and paclitaxel [Taxus, Ion]; *second-generation DESs:* everolimus [Xience V, Promus, Synergy], zotaralimus [Resolute]).

A DES consists of a stent platform similar to a BMS, with 2 additional components: a drug, and a polymer that controls the local drug delivery over 3–6 months. The drug inhibits cell proliferation and thus neointimal hyperplasia, with a restenosis rate of ~5–10%. On the other hand, by delaying stent strut coverage, the risk of stent thrombosis used to persist beyond the first month. With the first-generation DESs, this risk of stent thrombosis remained significant for the first 12 months and mandated DAPT for 12 months. The second-generation DESs are associated with a dramatic reduction in the risk of stent thrombosis and target vessel MI (vs. first-generation DESs); the risk of stent thrombosis is very low even after clopidogrel interruption at 1–6 months.

The risk of stent thrombosis with current-generation DES is similar to BMS, as long as clopidogrel is used ≥1 month (ZEUS, SENIOR, and Leaders free trials, and registry analyses). The proper duration of dual antiplatelet therapy with second-generation DES is: (i) 6 months in the setting of stable CAD PCI, with a possible reduction to 1–3 months if needed (class IIb); (ii) 12 months in the setting of ACS, with a possible reduction to 1–3 months if needed (class IIb).

While DES does not clearly reduce mortality or MI in comparison to BMS, it dramatically reduces restenosis and repeat revascularizations. Yet, the risk of restenosis with DES remains elevated *in the following cases*:

a. One of *5 features* indicative of a high risk of restenosis: diabetes, long lesions >20 mm, small vessel <3 mm, bifurcation stenting, chronic total occlusion (CTO).
b. In-stent restenosis.
c. More extensive, multivessel stenting
In complex lesions with several of those features, the restenosis rate remains high even with DES, ≥10%, with an even higher rate of target vessel revascularization related to disease progression outside the stented area.

BMS is no longer used nowadays in any lesion subset as it has no advantage over DES, not even an earlier interruption of clopidogrel. Studies have shown the safety of 1- to 3-month DAPT vs. longer DAPT with DES (STOP-DAPT2, MASTER DAPT, HOST-BR trials).

D. Drug-coated balloons (DCBs)

DCB is a special balloon that is coated with paclitaxel. Paclitaxel gets delivered to the vessel wall, the media specifically, which inhibits neointimal smooth muscle cell proliferation. It is a particularly useful treatment for in-stent restenosis, where the outcome at 1–2 years nearly matches that of repeat DES: the 2-year recurrent ISR for DES vs. DCB vs. standard balloon is ~10–15% vs. 15–20% vs. ~50% (those numbers are better in focal ISR and worse in diffuse ISR: ~25% with DES or DCB). It may also be used for native coronary disease where stenting needs to be avoided, such as diffuse small vessel disease or ostial side branch in bifurcation stenting. In native coronary disease, DCB was non-inferior to DES in small vessels <3 mm (BASKET-small-2 and PICCOLETO-II trials and REC-CAGEFREE1 trial, <3 mm subgroup), but was inferior to DES in vessels >3 mm (REC-CAGEFREE1 trial, >3 mm subgroup). The overall 1-year event rate with DCB appeared much lower than with plain angioplasty, including in large vessels, and was <10% in both trials. In a meta-analysis of DCB vs. DES for small vessel disease <3 mm, DCB appeared safer than DES with lower MACE, target lesion thrombosis, target vessel revascularization, and MI at 3 years (as DCB avoids the thrombotic risk of uncovered stent struts and of destabilized neoatherosclerosis) (ANDROMEDA analysis[1]). Only 6–20% of patients required bail-out stenting for poor angioplasty result, which is defined as: major flow-limiting dissection type D–F or elastic recoil with residual stenosis >30%. Although the immediate luminal gain is better with DES, DCB is associated with late positive vessel expansion in 60% of de novo lesions, instead of the traditional negative vessel shrinking seen with plain balloon angioplasty. This happens even in lesions with residual mild dissections (A–C).[2] It is even believed that dissections may improve the efficacy of DCB, as they allow paclitaxel to penetrate the media and prevent smooth muscle cells from migrating and forming the neointima.

Paclitaxel is carried onto the balloon mixed with an excipient (drug carrier) and shielded by balloon folds. During balloon inflation, the balloon unfolds, and the *hydrophilic excipient* delivers the *hydrophobic paclitaxel* to the vessel wall. Some of the drug gets lost en route during DCB travel through the guide, then in the coronary vasculature during balloon inflation. ~10–20% of the drug gets delivered to the vessel wall. Paclitaxel is more favorable for DCB drug delivery than sirolimus, as paclitaxel is: (i) hydrophobic, hence it repels water and delivers well from balloon to vessel wall during balloon inflation instead of getting washed away by blood; (ii) lipophilic, hence it has a high affinity for the coronary wall/cell membranes and good cell absorption (higher affinity for tissue binding than for blood, thereby decreasing washout); and (iii) once in the vessel wall, the crystalline formulation and the low dissolution rate allow the drug to retain in the vessel wall for ≥2–3 months, maintaining the antiproliferative efficacy during the critical phase of neointimal hyperplasia. The excipient is hydrophilic and necessary to carry the hydrophobic paclitaxel from the balloon to the vessel wall during balloon inflation. ***Sirolimus*** is less lipophilic and more hydrophilic than paclitaxel. Yet, a sirolimus DCB (Selution) was successfully designed using microspheres to encapsulate sirolimus and shield it from blood during transit and after transfer to the vessel wall, ensuring sustained drug release for 90 d. Within the microspheres, phospholipid coating allows sirolimus transfer inside the cells. This DCB proved non-inferior to DES in native-vessel PCI, with a trend toward more TVF, esp. in vessels >3 mm (SELUTION trial).

In stable CAD, the natural progression of a significant but non-critical stenosis (50–80%) is likely slower than the progression of in-stent processes, particularly in long stents. This suggests deferring moderate disease PCI, even if functionally significant, unless angina is severe + refractory:

- Natural progression of a stenosis >50%: <10% risk of progression of this stenosis over 1.5–2 years per COURAGE trial, with <2–3% individual risk of MI (at least as many events arise from areas of non-significant disease)
- Within stents:
  - At 1 year: ~10% in-stent restenosis with ~1% stent thrombosis and 1–2% stent-related MI
  - Beyond 1 year: ~1–2% severe in-stent tissue growth per year (neointimal hyperplasia or neoatherosclerosis) and 0.2–0.9% stent thrombosis/year

E. Rotational atherectomy (Rotablator), orbital atherectomy, lithotripsy balloon, cutting and OPN balloons

The atherectomy devices consist of a burr mounted over a catheter. As opposed to angioplasty, which expands the media without affecting plaque volume, atherectomy acts by removing plaque; it cuts the atheroma into small microparticles that are subsequently eliminated by the reticuloendothelial system. Those microparticles are typically very small, smaller than the red blood cells, and thus do not usually plug the microcirculation, as long as each atherectomy pass is limited to <20 seconds and the lesion is gradually crossed through multiple short passes instead of a single one. The Rotablator achieves better immediate results than angioplasty but is associated with a similar rate of late restenosis; the heat injury initiates both negative remodeling and neointimal hyperplasia. Atherectomy is useful in heavily calcified lesions that do not yield with high-pressure balloon angioplasty, meaning that the balloon never fully expands across the lesion (*balloon undilatable lesion*), or when no balloon can cross the lesion (*balloon uncrossable lesion*). The lack of full balloon expansion is different from the more common elastic recoil, wherein the balloon expands but the vessel quickly collapses back. **A stent should never be used for an unyielding lesion**, i.e., a lesion where the balloon does not fully expand, as the stent will fail to appropriately expand and a catastrophic stent thrombosis may occur.

Rotational atherectomy is not performed in a patient with major dissection planes (grade ≥C) soon after angioplasty, as a major perforation may be created by atherectomy. If flow is impaired by the dissection, try to re-establish flow with further angioplasty; then perform balloon lithotripsy instead of atherectomy, or bring the patient back 4–6 weeks later for rotational atherectomy.

Lithotripsy balloon (Shockwave) is a specialty balloon that delivers electric energy, which vaporizes the liquid inside the balloon and creates acoustic shock waves. Those waves crack the arterial wall calcium, superficially and deeply. It is an alternative to atherectomy in severely calcified lesions that can be crossed with a balloon and is particularly helpful in eccentric calcium, which may not be properly modified by atherectomy, and in distal or tortuous disease, where atherectomy is more risky. The main limitation of lithotripsy balloon is that it may not cross a severely calcified lesion, as its profile is larger than the profile of non-compliant balloons. Thus, extensive vessel preparation may be required: pre-dilatation is performed in most cases, and rotational or orbital atherectomy is required for *balloon uncrossable lesions*. Also, lithotripsy involves up to 12 balloon inflations of 10 seconds each to deliver the sonic pulses; this prolonged balloon dilatation may not be tolerated in the LM of hemodynamically tenuous patients.

Two trials showed that ***cutting balloon*** or ***OPN balloon*** may alternatively be used in severely calcified stenoses, including the *balloon undilatable stenoses* (not yielding with 1:1 NC balloon at >18 atm). While lithotripsy is sized 1:1 to the reference EEM diameter and inflated at 6 atm, cutting balloon and OPN are sized 0.5 mm smaller than the reference EEM and inflated at ~18 atm and 35-40 atm, respectively. OPN is a super NC balloon with double NC layers limiting its expansion and rupture at very high pressure (a 3 mm OPN balloon expands to ~3.4 mm at 35 atm). OPN is often more deliverable than lithotripsy balloon.

F. Aspiration thrombectomy and distal embolic protection

As an adjunct to balloon and stenting, aspiration thrombectomy catheters (suction catheters: Penumbra, Pronto catheters) can be used to aspirate thrombi. Large STEMI trials (TASTE and TOTAL) did not show any clinical benefit from the systematic use of thrombectomy, and there was a small stroke hazard. The selective use of thrombectomy in STEMI patients with a large thrombus burden may still be justified, particularly Penumbra with its strong engine aspiration.

Wires with a distal basket, called *distal embolic protection devices*, are mainly useful during PCI of venous grafts, where they reduce no-reflow and peri-PCI MI, not mortality (SAFER trial), and during femoro-popliteal atherectomy. They have not shown a benefit in acute MI: native coronary arteries have numerous side branches, such that a distal basket will prevent embolization into the distal vessel but will favor embolization into side branches, some of which are large. Also, the basket may move during device manipulations and injure the artery.

II. Stent thrombosis, restenosis, and neoatherosclerosis

A. Thrombosis

Stent thrombosis usually occurs within 1 month of stent placement but can occur later with DES or BMS. It is prevented with dual antiplatelet therapy and adequate stent expansion. Stent thrombosis typically leads to STEMI, the prognosis of which is much worse than that of spontaneously occurring STEMI (high clot burden), with a 15–45% risk of mortality.

Timing of stent thrombosis: acute (within 24 hours), subacute (between 1 and 30 days), late (between 1 and 12 months), and very late (>12 months). Late and very late stent thromboses are rare, but may be seen with DES or BMS, especially if both antiplatelet agents are discontinued. The risk of late stent thrombosis is probably similar with second-generation DES and BMS (0.2–0.4% per year) (DAPT trial). After the first month, stent thrombosis usually occurs ≥ 7 days after clopidogrel discontinuation, implying that brief clopidogrel interruption for non-cardiac surgery may be safe.

There are 3 categories of risk factors for stent thrombosis (Table 39.1).

Table 39.1 Risk factors for stent thrombosis.

a. Mechanical

Stent underexpansion, stent malapposition, edge dissection, edge plaque shift (especially if the plaque is necrotic and active)

b. Pharmacological

Acutely, a delayed loading of ADP receptor antagonist is a risk factor for acute thrombosis. Non-compliance with the recommended duration of DAPT is the most important risk factor for subacute and late stent thrombosis. Clopidogrel non-responsiveness increases the risk of stent thrombosis, which remains low, in absolute terms, in stable CAD PCI. The latter is rarely a standalone factor in stent thrombosis

c. Underlying patient and lesion

- ACS presentation, particularly STEMI, is by far the most important predictor of stent thrombosis in this category
- Other factors: diabetes, renal failure, small vessel, long lesion, poor runoff, and bifurcation PCI (especially dual stenting)

B. Restenosis (Figures 39.2, 39.3)

1. Mechanisms

a. *After plain balloon angioplasty*, 2 processes lead to restenosis:

- Negative arterial remodeling (arterial constriction).
- Neointimal hyperplasia.

Both processes start beyond 1 month (1–6 months). As opposed to stenting, the main mechanism of restenosis after angioplasty is negative remodeling, which peaks earlier than neointimal hyperplasia. Both processes are inhibited by DCB.

b. *After stenting*:

- Stent underexpansion (suboptimal stent deployment).
- Focal or diffuse in-stent tissue growth (neointimal hyperplasia or neoatherosclerosis). *Neointimal hyperplasia* refers to smooth muscle cell and macrophage migration from deep in the vessel wall (media) to the surface of the struts. This is followed by cellular proliferation and production of extracellular matrix (fibrosis). Neointimal hyperplasia leads to a "fibrotic" narrowing of the stent lumen, different from thrombosis, and different from atherosclerosis.

When the stent is underexpanded, even a mild degree of neointimal hyperplasia may lead to significant restenosis. Underexpansion is a major factor in up to 50% of DES restenosis, where neointimal hyperplasia is milder than with BMS.

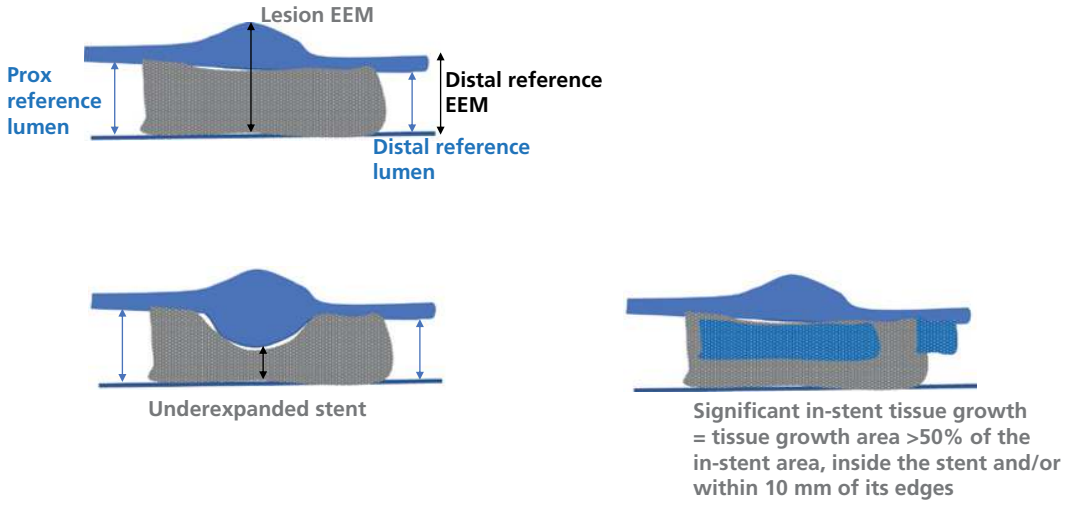

Figure 39.2 Stent sizing, stent underexpansion, and in-stent tissue growth (the *gray cage* is the stent deployed across the lesion). **Before stenting**, the distal and/or proximal reference lumen of the healthiest vessel segment is used to size the stent (the reference segment ideally has <40% plaque burden). The reference EEM of this healthy segment may alternatively be used. The stent is sized to 100% of the distal reference lumen, or downsized ~0.25 mm from the distal reference EEM.

After stenting, proper stent expansion is defined as stent expansion ≥90% of the distal reference luminal area (demonstrated by IVUS or OCT) (ULTIMATE IVUS trial, RENOVATE Complex PCI), or ≥80% the average proximal + distal lumen areas (iSIGHT and ILUMINEN trials). In case of a long stented area, such as across a major bifurcation, proper stent expansion is defined as distal stent area ≥90% of the distal reference lumen, or proximal stent area ≥90% of the proximal reference lumen. Reference EEM is not used.

Absolute stent areas may also be used as expansion targets: non-left main minimal stent area >5.5 mm^2, left main stent >7 mm^2 (distally) and 8 mm^2 (proximally).

In-stent tissue growth is significant if it occupies >50% of the in-stent lumen. It may be neointimal hyperplasia in the first 1–3 years and neoatherosclerosis beyond 1–3 years after stenting. Neoatherosclerosis may calcify beyond 1–3 years, or native calcium may protrude through the stent cells, especially when a calcified nodule is stented.

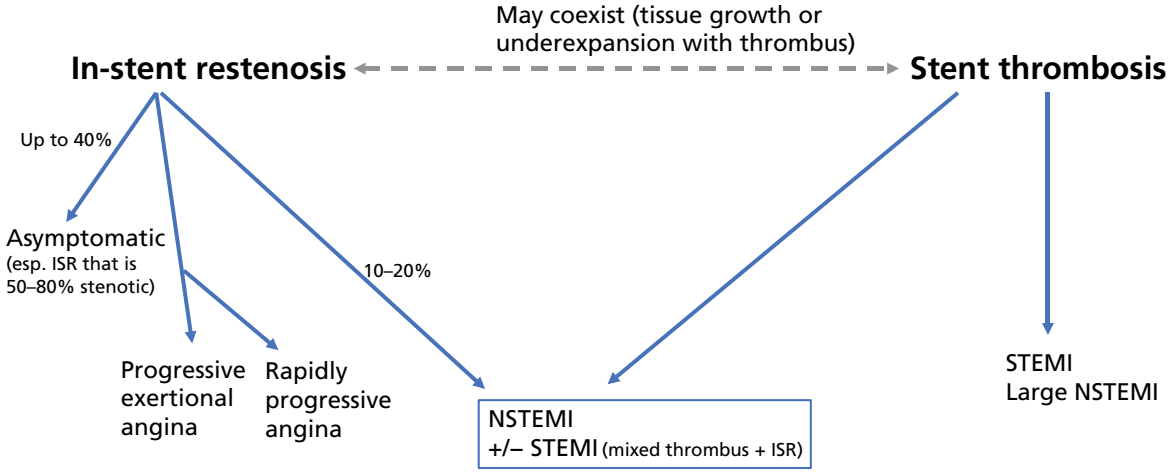

Figure 39.3 While stent thrombosis is clinically more dramatic than stent restenosis and often presents as STEMI and large NSTEMI, there is overlap in their clinical presentations. Specifically, ISR may present as NSTEMI in 10–20% of ISR cases, and ISR and stent thrombosis may coexist in many STEMI and NSTEMI cases. Therefore, it is important to look for both stent thrombosis and in-stent tissue growth in any patient with stent obstruction and MI. Another note: In-stent restenosis is asymptomatic in up to 50% of patients.

2. Neointimal hyperplasia

Neointimal hyperplasia starts to develop 1 month after angioplasty or stent placement, peaks at 3–6 months, and does not progress beyond 6–8 months with BMS or 12 months with DES. After DES, neointimal hyperplasia is milder but also more delayed than after BMS. Either way, neointimal hyperplasia does not usually progress beyond 1–3 years. However, progression of atherosclerosis in the nearby segments and neoatherosclerosis over the neointima may occur beyond those timelines (even more so with SVG stenting).

3. Neoatherosclerosis

Beyond 1 year, atherosclerosis starts to grow over the stent neointima; this is referred to as neoatherosclerosis. As opposed to neointimal hyperplasia, neoatherosclerosis is characterized by a lipid-laden plaque with foamy macrophages and a fibrous cap. It tends to appear earlier and more frequently with DES (30–50% at 1–2 years) than BMS (16% at 5 years). It explains *late restenosis* and partly explains the *very late stent thrombosis* seen with both types of stents. Neoatherosclerosis progresses over months to years and demonstrates an accelerated course in comparison to de-novo atherosclerotic CAD. This is secondary to the dysfunctional endothelial coverage of the stented segment.

4. Patterns of restenosis

Restenosis may be focal (42% of cases of BMS restenosis), diffuse (21%), proliferative (extends beyond stent margins; 30%), or totally occlusive (7%). With DES, restenosis is often focal (~60%), sometimes purely at the edges, in relation to uncovered progressive edge disease, or neointimal hyperplasia and negative remodeling at the edges. High-pressure inflation of the compliant stent balloon may also induce edge injury and restenosis. Stenosis within 10 mm of the edge of the stent is considered in-stent restenosis (called "in-segment in-stent restenosis").

5. Clinical presentation

Restenosis usually leads to recurrence of stable angina, but it may lead to MI presentation in ~10% of patients (usually NSTEMI), from the instent tissue growth itself or from a mixture of tissue growth and thrombus. Therefore, while it is less catastrophic than stent thrombosis, restenosis is not always benign.

In-stent restenosis is asymptomatic in up to 50% of patients. Asymptomatic restenosis is associated with favorable long-term outcomes, with no clear effect on mortality or MI (compared to no restenosis). In DES trials, routine angiography and PCI of restenosis was not associated with improved outcomes (vs. clinically driven PCI). Likewise, routine stress testing after high-risk PCI did not improve outcomes (POST-PCI trial, which included LM, multivessel CAD, and long and complex CAD). Thus, after PCI, neither surveillance stress testing or angiography nor treatment of asymptomatic restenosis is indicated.

Also, FFR may be used to safely defer treatment of restenosis >50% at >6 months after the index PCI.

C. Mechanisms of recurrent target vessel disease after stenting (Table 39.2)

Table 39.2 Recurrent target vessel disease/angina after stenting.

1. **First 1–2 months**
   - ***Mechanical issues*** leading to subacute stent thrombosis (acute severe presentation). Or residual stenosis (insidious presentation): stent underexpansion, edge disease or edge dissection, failure to cover the entire target lesion
2. **1–12 months: ~10% target lesion revascularization at 1 year, including ~1–2% stent-related MI** and ~1% stent thrombosis. ~10–20% of in-stent restenoses may cause MI, usually NSTEMI
   - ***Stent restenosis:*** (1) neointimal hyperplasia and/or (2) stent underexpansion
   - ***Late stent thrombosis*** from stent underexpansion[a]
   - ***Disease progression*** outside the stented area, especially at the edges (more so in ACS)
3. **Over 1 year:** ~1–2% target lesion revascularization per year, including 0.2–0.9% stent thrombosis per year
   - ***Neoatherosclerosis***
   - ***Late presentation of neointimal hyperplasia***
   - ***Disease progression*** outside the stented area. At least ~50% of total events (<1 year and >1 year) are plaque progression outside the stented area.

[a] Also, necrotic plaque protrusion through the stent (more so in ACS) may predispose to restenosis or thrombosis.

III. Peri-PCI antithrombotic therapy (see Table 39.3)

Table 39.3 Peri-PCI antithrombotic therapy.

Stable CAD PCI

Planned PCI

1. Aspirin 325 mg >2 h before PCI if aspirin-naïve (otherwise, aspirin 81 mg the day of the procedure)
2. Clopidogrel 600 mg ≥ 2 h, 300 mg ≥ 24 h, or 75 mg ≥ 7 days before PCI
3. GPI for PCI complications (bailout)
4. UFH or bivalirudin:

   Bivalirudin: no clear reduction in bleeding vs. UFH in modern trials, possibly more acute stent thrombosis

   Dose of UFH: 70–100 units/kg to a goal ACT 250–300 s if GPI is not used
   50–70 units/kg to a goal ACT 200–250 s if GPI is used

Ad-hoc PCI

- Preloading all patients undergoing coronary angiography with clopidogrel, for the possibility of PCI, has not been shown to be superior to in-lab loading in stable CAD. Thus, clopidogrel 600 mg is administered during the procedure, once a decision is made to proceed with PCI

(*Continued*)

Table 39.3 (Continued)

NSTE–ACS

Antiplatelet therapy

1. Aspirin 325 mg on admission, then 81 mg daily
2. Clopidogrel 300 mg or ticagrelor 180 mg may be considered on admission This upstream use before PCI is of questionable benefit and is not recommended by ESC or ACC when cath is anticipated at<24 h; class IIb when cath >24 h
   Definitely withhold in patients with a high probability of needing CABG
3. Upstream GPI *is not indicated*
4. After coronary angiography, if PCI is to be performed:
   - Add 300 mg of clopidogrel if 300 mg has already been given
     or load with 600 mg of clopidogrel in the cath lab if no clopidogrel has been given
     or load with prasugrel 60 mg in the cath lab (even if clopidogrel has been given)
     or load with ticagrelor 180 mg in the cath lab (even if clopidogrel has been given)
   - GPI if PCI complications (bailout use of GPI)
   - Cangrelor infusion for at least 2 hours may be considered in high-risk cases not pretreated with an ADP-receptor antagonist

Anticoagulant therapy

UFH pre-catheterization and during PCI
or UFH pre-catheterization and switch to bivalirudin during PCI
or Fondaparinux 2.5 mg SQ QD pre-catheterization with standard-dose UFH or bivalirudin during PCI
or Enoxaparin pre-catheterization. If the patient received 1 mg/kg SQ enoxaparin within 8 h of PCI and has already received 2 doses of enoxaparin, no additional anticoagulation is needed during PCI. If enoxaparin was given 8–12 h ago or only 1 SQ dose was given, add 0.3 mg/kg IV bolus during PCI
Avoid switching between UFH and enoxaparin. The switch to bivalirudin is, however, acceptable

STEMI

1. Aspirin 325 mg in the emergency room
2. Clopidogrel 600 mg, prasugrel 60 mg, or ticagrelor 180 mg *upstream* in the emergency room
3. No upstream GPI before PCI regardless of PCI delay (if PCI delay, give fibrinolytics rather than GPI)
4. Upstream UFH (60 units/kg, up to 4000 units)
5. During PCI:
   - May use UFH or bivalirudin
   - GPI if high thrombus burden

GPI, glycoprotein IIb-IIIa inhibitors.

IV. Sheath management

If heparin is used during PCI, the femoral sheath is removed when ACT <170 seconds (~2–3 hours after PCI).

If bivalirudin is used, the sheath is removed 1.5 hours after the infusion is discontinued, the half-life being 25 minutes in patients with normal renal function; wait 2–3 hours in advanced renal failure (GFR <30 ml/min), where the half-life is ~1 hour.

If enoxaparin is used, remove the sheath 6–8 hours after the last SQ dose of enoxaparin.

General duration of manual pressure over the femoral artery: 10 minutes if a 4 Fr sheath is used and 5 more minutes for each higher French size. 4–6 Fr sheaths are usually used for diagnostic coronary angiography; ≥5 Fr sheaths are used for PCI.

In general, the patient is maintained flat in bed 4 hours after 4 Fr sheath removal and 6 hours after 6 Fr sheath removal. A vascular closure device may be used (polyethylene glycol [Mynx], collagen [Angio-Seal], or suture-based device [Perclose]). When a closure device is used, the sheath is pulled out immediately after PCI, even while anticoagulation with heparin or bivalirudin is therapeutic; prolonged occlusive manual compression is not needed and the patient can ambulate 2–4 hours later. ***However, while convenient, closure devices do not reduce local vascular and bleeding complications***. They may, in fact, increase local vascular complications (small risk of arterial occlusion). It is safe to restick the same artery immediately after Mynx or Perclose closure. It is preferred to wait 3 months after Angio-Seal deployment, but, if needed, a restick may be performed 24 hours after deployment, 1 cm proximal to the initial stick.

If a radial access is used, heparin is given regardless of PCI to prevent radial occlusion, which occurs in ~3–5% of cases (UFH 5000 units or 50 units/kg). If an intervention is performed, additional UFH is supplemented to achieve a total of 70–100 units/kg. The sheath is removed at the end of the procedure and hemostasis achieved with the use of an inflatable transradial band. *Patent hemostasis* should be used, meaning that the transradial band is only inflated with enough volume to stop the bleeding, not more (the transradial band is only inflated with 1 ml of air beyond the occlusive volume); pulse oximetry should continue to show a waveform even with manual ulnar occlusion, confirming antegrade radial flow. The band is kept untouched for 60–90 minutes then deflated progressively (~3 ml every 15 minutes).

Patients may be hospitalized for 1 day after PCI, during which they are monitored for access complications, contrast nephropathy, and periprocedural MI. Low-risk patients without major comorbidities (HF, renal failure) undergoing a non-complex elective PCI through a radial access may be discharged on the day of the procedure; this may be extended to transfemoral procedures with no access complication (EPOS trial). Beyond 6 hours after PCI, the likelihood of complications is very low.

V. Post-PCI mortality and coronary complications

A. Mortality

Mortality after diagnostic angiography is ~0.1%, but this increases significantly in ***severe AS*** or ***left main disease*** (up to 0.5%), where any transient arrhythmia or hypotension, sometimes induced by sedation, may initiate an irreversible, vicious circle of myocardial ischemia and further hypotension. Also, in left main disease, the catheter abutting a left main plaque may create a left main dissection.

Mortality after PCI is <1% (~0.5%). Complications and mortality after PCI are related to both the patient and the lesion characteristics:

a. *Patient characteristics:* ACS presentation, unstable hemodynamics/emergent case, severe HF or severe LV dysfunction, older age, CKD
b. *Lesion characteristics:* severe calcifications, tortuosity, multivessel CAD, CTO, degenerated venous graft (especially left venous graft, where guide support is difficult)
Patient characteristics are a stronger determinant of complications than lesion characteristics.

B. Coronary dissection

A coronary dissection is seen after 30% of balloon angioplasties. It may also occur at the edges of a stent, when overinflation of the stent's balloon damages the edges. The frequency of stent edge dissection is 5% angiographically, 10% by IVUS, and 30% by OCT (the latter frequently detects some small and clinically insignificant dissections). Coronary dissection is more common in diffuse or calcified disease. Coronary dissection may also result from wire manipulations or from a deep-seated guiding catheter. Dissections typically propagate distally (antegradely).

1. Angiographic types of coronary dissection

- Type A: luminal haziness that does not persist after dye clearance.
- Type B: parallel tract or double lumen seen during dye injection, does not persist after dye clearance.
- Type C: extraluminal dye stain that persists after dye clearance (different from thrombus, where the stain is intraluminal). It looks angiographically similar to a type 1, localized perforation.
- Type D: spiral luminal filling defect that *significantly narrows* the true lumen. Flow may be slow but completely fills the artery.
- Type E: luminal filling defect with incomplete distal flow.
- Type F: total occlusion.

2. Treatment

When occurring after plain balloon angioplasty or DCB, types A and B dissections are often benign and do not affect outcomes; they may be treated with prolonged low-pressure balloon dilatation (balloon sized 1:1 to the vessel). After stenting, any angiographic edge dissection (except possibly type A or B) is worrisome as it increases the risk of stent thrombosis. Further edge stenting—using a smaller stent deployed at lower pressure—is warranted for dissections types C–F, and at least intracoronary imaging is performed for types A and B.[3] On IVUS or OCT, superficial dissections that do not reach the media, or extend to less than one quadrant and are <3 mm in length are benign. Edge dissections are frequently seen on OCT and do not necessarily warrant further stenting if they have benign features.

Whether with angioplasty or stenting, angiographic dissections types C through F carry an increased risk of thrombosis and vessel closure and are treated with further stenting. Stent distally to stop the propagation of the dissection, then proximally to seal the source of dissection. However, if the dissection is occlusive and unclear where it ends, or if it extends very distally in a spiral fashion, start by stenting the proximal entry point to stop the expansion of the false lumen and collapse it; the distal extent of the dissection may then be stented if not too long. When the guide dissects the ostial left main or RCA and leads to hemodynamic compromise, proximal stenting typically needs to be performed first to relieve the extent of ischemia. In small or severely tortuous vessels where stenting is not possible, perform prolonged low-pressure balloon inflation with a well-sized balloon (not undersized).

Since type C dissection may, in fact, be a localized perforation that manifests 24–48 hours later, the patient needs to be carefully monitored and an echo needs to be obtained ± repeated 24 hours later, looking for hemopericardium.

3. Intramural hematoma is a bleeding inside the media that displaces the internal elastic membrane inward without a dissection entry or exit point. It may be iatrogenic, post-stenting, or spontaneous (SCAD). On IVUS, it appears like an echolucent crescent behind the intima/plaque, sometimes giving the impression of an echolucent plaque. Angiographically, it may simulate a dissection or may appear smooth, ***simulating a refractory spasm***. It is usually treated with further stenting, using a smaller stent at a low pressure.

C. Guide catheter-induced ostial dissection (ostial RCA or left main)

The tips described herein apply not only to guide dissection but to any coronary dissection type C–F.

1. If you already have a wire across the coronary artery → stent proximally to tuck the origin of the dissection (entry site) and collapse the hematoma, then treat the distal disease afterward (Figure 39.4). Use a relatively long stent, to ensure covering as much of the dissection as possible, properly sized or slightly undersized to avoid propagating the intramural hematoma. Stop injecting contrast or limit it as much as possible (<1–2 ml per injection when needed, e.g., when positioning the stent). Starting with distal stenting may be less effective in re-establishing flow than proximal stenting and is less often feasible, as the distal edge is not visible in occlusive or long spiral dissections.

i. If you see where the dissection ends → try to cover the distal and the proximal edges of the dissection. Also, if you start with proximal stenting, inject contrast after stenting and assess the distal vessel. If there is residual dissection distally that is not too long → tuck it with another stent overlapping with the proximal one. *Note:* An angiographic flap may persist behind the stent and will heal with time; aggressive post-dilatation to further appose the stent is a wrong reflex, as it risks further propagating the subintimal hematoma.
ii. If there is no flow/poor flow, or if the dissection has spiraled extensively distally → just cover the entry site of the dissection; this will likely collapse the extensive distal propagating hematoma and re-establish flow. *Occasionally, if TIMI flow remains <3 despite proximal stenting of a long spiral dissection →*

- *Do distal undersized ballooning to re-establish flow +/– cutting balloon to decompress the subintimal hematoma.*
- *If rewiring was performed, it is possible that the wire is in the false lumen and the false lumen got stented. Perform IVUS and consider gentle distal dye injection via a dual lumen catheter.*

iii. If dissection extends in branches → just covering the entry site of the dissection and the main vessel will likely collapse the hematoma propagation into branches.

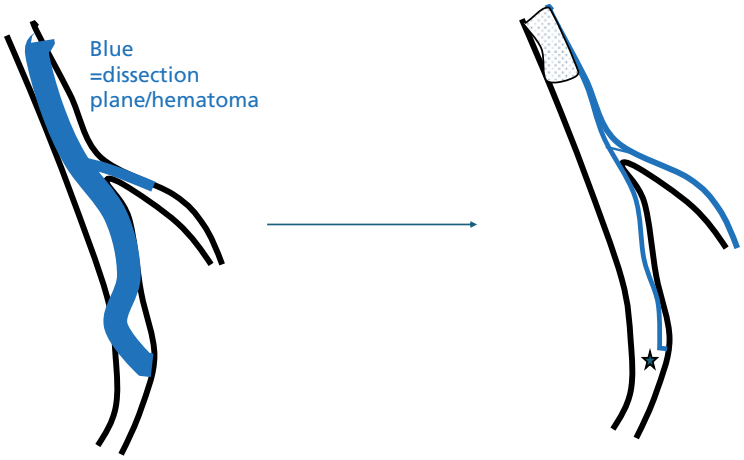

Figure 39.4 Proximal stenting of a long dissection tucks the dissection's entry site and collapses the hematoma, often re-establishing flow distally and into branches. After re-establishing flow, if there is residual dissection distally that is not too long, it may be tucked with a distal overlapping stent. In the case shown, the distal dissection is too long (*star*) but has collapsed thanks to proximal stenting, so further stenting is not definitely needed.

2. If you do not have a wire across the coronary artery →

i. The first step is to change the guide to a guide pointing in a different direction, away from the dissection plane, unless it was difficult to engage and multiple guide exchanges were necessary, e.g., difficult takeoff or difficult transradial or aortic anatomy.
ii. The second step is to wire the true lumen. Try to wire without contrast injections. Here are tips for avoiding the false lumen:

- Avoid wire buckling and wire knuckle, which suggest that the wire is in the subintimal plane. In this case, pull back the wire and keep flipping it like a "helicopter" as you are advancing it.
- Use a soft workhorse wire (e.g., BMW) or, occasionally, a soft polymer wire.
- Twirl the tip like a "helicopter."
- Going in and out of side branches suggests true lumen wiring.
- The occurrence of PVCs implies deep subintimal wiring.
- Consider distal contrast injection via a dual-lumen catheter to confirm true lumen wiring. This is done after the wire has been advanced distally and seems to move freely (true luminal position). However, it may extend the subintimal dissection if the wire is actually in the subintima.
- Consider IVUS. Subintimal hematoma looks like a circumferential or banana-shaped dark structure, sometimes with white speckles.

iii. If you fail to wire the true lumen and the vessel is compressed by the dissection's intramural hematoma, consider parallel wiring: keep the subintimal wire in place plugging the subintima and advance another wire. You may need to advance a microcatheter over the subintimal wire, such as an over-the-wire catheter or a dual lumen catheter, and aspirate through it to decompress the false lumen and allow the second wire to succeed (STRAW technique) (Figure 39.5).

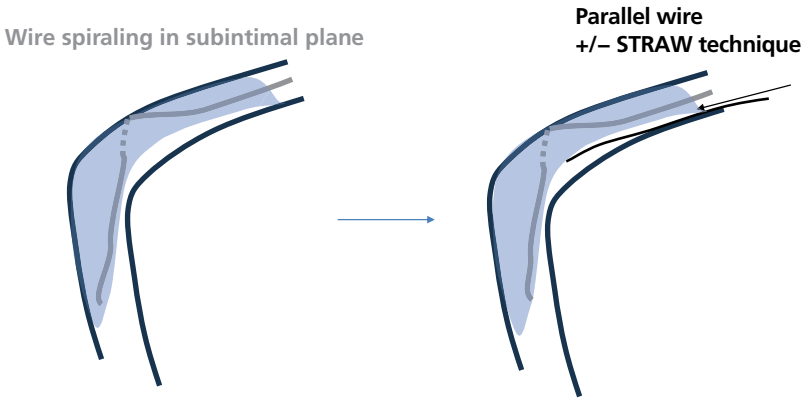

Figure 39.5 Coronary dissection with inability to wire the true lumen. If it is not possible to get in the true lumen and the vessel is fully compressed by the hematoma:
- Try workhorse then soft polymer wire to slip in the true lumen, while avoiding wire buckling and wire knuckle, which imply the wire is in the subintimal plane. Keep flipping the wire like a "helicopter" as you are advancing it.
- Consider parallel wiring: keep the subintimal wire in place plugging the subintima and advance another wire. A microcatheter may be advanced over the subintimal wire and aspiration done through it to decompress the false lumen and allow the second wire to succeed (STRAW technique).

D. Periprocedural MI

Two types of periprocedural MI may be seen:

a. Q-wave transmural MI occurs in ~1% of PCIs. It is often the result of abrupt vessel closure, thrombus formation, or occlusion of a major side branch.

b. Non-Q-wave MI is usually due to either:

- **i.** Distal microembolization, microvascular spasm, and microcellular reperfusion injury in a successfully opened vessel. A sluggish flow in spite of a patent epicardial artery (TIMI 2 flow or less) is called *no reflow*.
- **ii.** Loss of small side branches.
- **iii.** Transient procedural complications, such as thrombus or flow-limiting dissection.

No reflow is reduced with the use of IIb–IIIa inhibitors in cases of large thrombus, and with the use of filter devices during venous graft interventions. Once it occurs, it is treated with: (i) intracoronary adenosine, verapamil, or nitroprusside; (ii) then, if it persists, IIb-IIIa inhibitors.

Before saying that the patient has "no reflow," always make sure there is no mechanical obstruction or dissection (angiographically or on IVUS).

According to the 2018 ACC universal MI definition, periprocedural non-Q-wave MI is defined by an increase in troponin I to >5× the upper limit of normal, along with: (1) prolonged chest pain, or (2) ischemic ST changes or new Q waves, or (3) new wall motion abnormality, or (4) angiographic evidence of procedural, flow-limiting complications. However, as opposed to the more recognized prognostic value of post-PCI CK-MB elevation (>3–10× normal), the degree of troponin rise used in the definition does not clearly carry an independent negative prognostic value. Therefore, an expert consensus document has suggested the use of CK-MB elevation ≥ 10× normal or troponin I elevation ≥ 70× normal to define periprocedural MI. Lesser degrees of CK-MB elevations, as well as isolated troponin elevation post-PCI, are of questionable prognostic value.

The above definition applies for patients with normal baseline biomarkers. If the biomarker values are elevated but stable or falling, periprocedural MI is diagnosed by ≥ 20% reincrease of a previously downward trending troponin or CK-MB value. In patients who present with elevated biomarkers that are on the rise and who undergo PCI within 24 hours of presentation, periprocedural MI is defined by the occurrence of procedural thrombotic/occlusive complications, prolonged ischemic symptoms ≥ 30 minutes, or new ischemic ST abnormalities or Q waves after PCI, along with an increase of the next troponin I or CK-MB by at least 50% (this is the definition used in trials, e.g., ACUITY, EARLY ACS, CHAMPION Phoenix trials).

The increase in biomarkers reflects a more extensive and unstable atherosclerotic burden that predisposes to future ischemic events. The latter partly contributes to the mortality associated with periprocedural MI, besides the injury itself. This explains why the unadjusted increase in mortality with periprocedural MI is more striking than the adjusted increase in mortality, and why only marked biomarker rise post-PCI carries an independent prognostic value.

Note that *spontaneous NSTEMI carries a much stronger independent prognostic value than periprocedural MI*, despite less biomarker elevation (3× higher mortality, according to ACUITY trial data). In fact, in NSTEMI, the adverse outcome is related not only to the minor myocardial injury but to the ruptured active plaques that carry a high risk of a large infarction, which is not the case in controlled periprocedural MI.

Large periprocedural MI (CK-MB > 5–10× normal) currently occurs in ~2.5% of PCI cases, and the incidence is reduced with the current antiplatelet regimens. Most periprocedural MIs are clinically silent. Cardiac markers should be checked 12–24 hours after all complicated PCIs and in patients with ischemic symptoms during or after PCI. Cardiac markers may also be checked routinely, 12–24 hours after any PCI (class IIa recommendation).

Chest pain is relatively common after PCI (~30%) and should be immediately evaluated with an ECG. A mild pain may simply be secondary to the continuous stretch of the treated vessel segment by the deployed stent. On the other hand, pain may be related to distal microembolization, coronary spasm, coronary dissection, or loss of small side branches, and may be associated with periprocedural MI.

Pain is initially treated with nitroglycerin. If pain is severe and persistent or associated with new ST-segment abnormalities or hemodynamic changes, coronary angiography is repeated and PCI performed urgently if needed (coronary thrombosis, dissection, large side branch occlusion). *An increase in cardiac markers is an adverse prognostic sign that does not dictate, per se, a repeat coronary angiography*.

Chest pain that occurs during PCI has similar causes. In addition, guide catheter dissection of the left main or ostial RCA should be considered and carefully assessed by angiography.

Differential diagnosis of post-PCI hypotension

- Access site complications: hematoma, retroperitoneal bleed
- Coronary perforation with tamponade
- Acute stent thrombosis or occlusive edge dissection → diagnosis by ECG
- Left main or RCA dissection (induced by the guiding catheter) → diagnosis by ECG
- Vagal shock from pain or sheath removal
- Excessive use of sedatives or antihypertensives in HF; or hypovolemia

E. Coronary perforation

1. Causes of coronary perforation

A coronary perforation may be secondary to:

a. Wire tip tearing the distal end of a branch, especially when a polymer wire is inadvertently advanced too deeply. Wire perforations are usually limited, type 1 or 2 perforations.
b. Balloon or stent inflation, in which case the perforation is a large, type 2 or 3 perforation. This is more common with an oversized balloon, especially in a calcified vessel.
c. Rotablator perforation, usually the largest perforation.

2. Classification of coronary perforations

- **Contained perforation (Ellis type 1)** manifests as an extraluminal stain. It requires no specific treatment except monitoring. Both type 1 perforation and type C dissection manifest as an extraluminal stain and may be indistinguishable angiographically. In the former, the stain is periadventitial, whereas in the latter, the stain is in the media.
- **Limited perforation (type 2)** manifests as a myocardial or epicardial blush without jetting. This means active persistent contrast filling of a localized area, but contrast does not clear. It can usually be managed with prolonged balloon inflation (≥5 minutes) at the perforation site or just proximal to it. An echo is performed and repeated 24 hours later.
- **Free-flowing, jet-like dye streaming through a clear hole, with quick contrast filling and quick clearing (type 3)**. The streaming may be pericardial, leading to immediate tamponade, or ventricular, better tolerated hemodynamically.

There are **2 major categories** of coronary perforations:

- *Small vessel perforation*, usually a wire perforation of the distal vessel or of a side branch. It is usually a type 1 or 2 perforation with less immediate hemodynamic effect.
- *Large vessel perforation*, related to balloon/stent/rotablation. It is a type 3 perforation with major hemodynamic compromise.

Note that a stain/blush that does not clear (type 2 perforation) implies a degree of sealing of the perforation and is, thus, less threatening than a blush that quickly flows and clears.

3. Management

Two procedures are to be immediately and concomitantly performed in any perforation, and this may require 2 physicians: (i) prolonged balloon inflation proximal to the perforation site; (ii) pericardiocentesis (especially with large vessel type 3 perforation).

Large vessel perforation (Figures 39.6, 39.7). While the balloon is still inflated, the artery is wired with an additional wire and a covered Papyrus stent advanced, the balloon being deflated only briefly and intermittently during wire and stent delivery to the perforation site. Even short periods of balloon deflation may lead to hemodynamic compromise. Because the Papyrus stent has a low profile and may be advanced through a 5 Fr guide, a single 6 Fr guide may fit both the blocking balloon and the Papyrus stent, obviating the need for double guides. However, if a larger Papyrus stent is needed or a Graftmaster stent is used and the guide is 6 Fr, a second femoral access (6 or 7 Fr) is obtained and a second guiding catheter is used to double-engage and double-wire the perforated coronary artery. The covered stent is advanced through the second guiding catheter while the balloon is maintained inflated through the first guiding catheter.

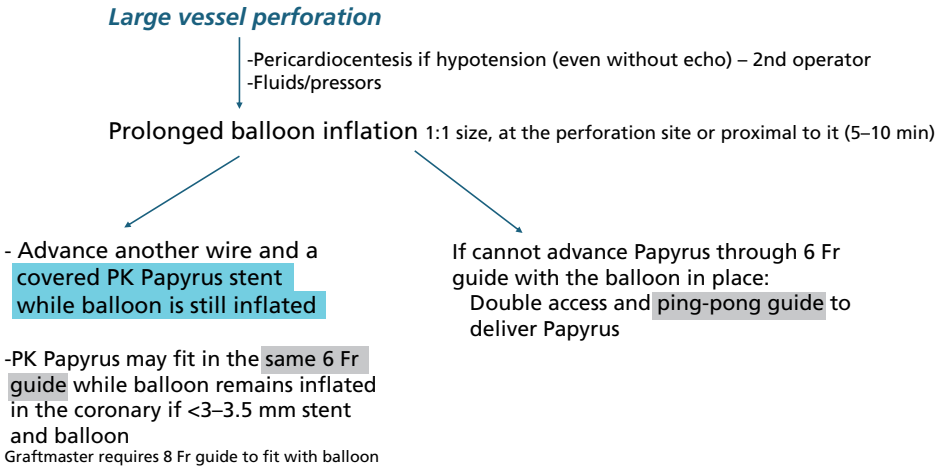

Figure 39.6 Management of large vessel perforation. It is not common for prolonged inflation to stop the bleeding. We typically advance the covered stent while the blocking balloon that is controlling the bleeding is in place. So, we must deliver another wire and advance Papyrus next to the balloon, and have simultaneous stent and balloon in the guide. This may be done via 6 Fr guide with Papyrus stent ≤3.5 mm, otherwise 7 Fr guide.

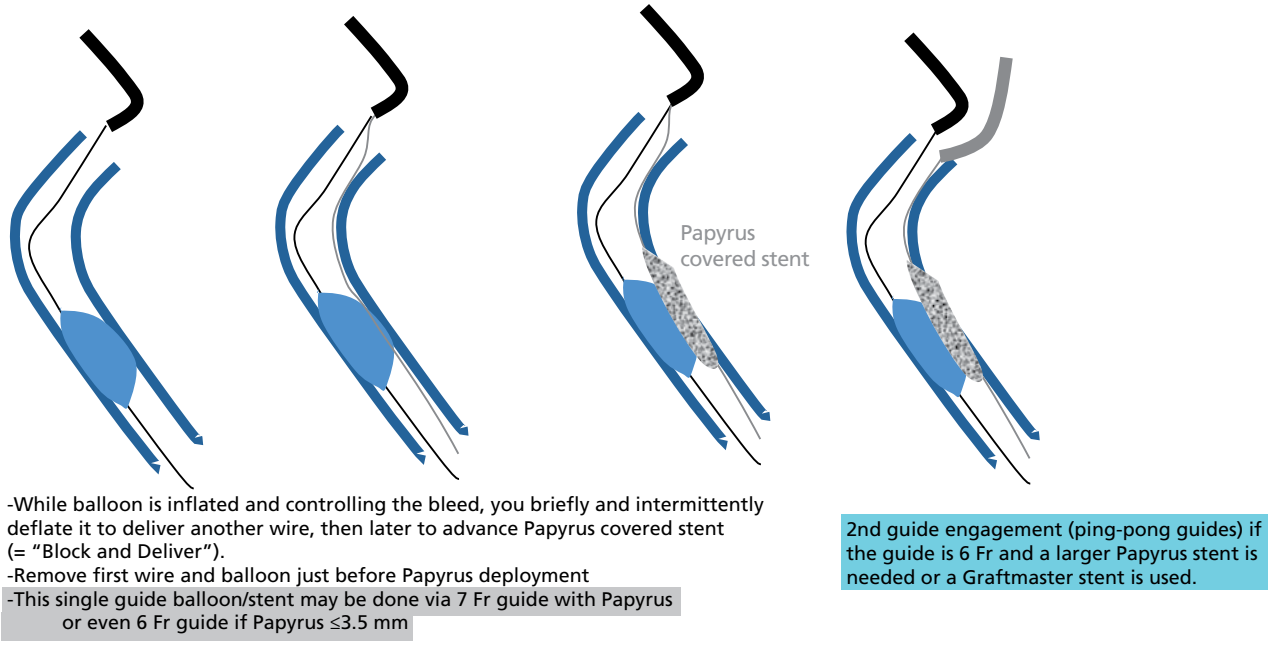

Figure 39.7 While a balloon is inflated and controlling the bleed, we briefly and intermittently deflate it to deliver the additional wire, then later to advance the Papyrus covered stent. This is the "Block and Deliver" technique and may be done via 6 Fr guide if Papyrus ≤3.5 mm. If the guide in place is 6 Fr and a larger Papyrus or Graftmaster stent is required, a second guide engagement is required (2 guides engagement).

Small vessel perforation (Figure 39.8). After prolonged balloon inflation, a non-sealing perforation of a branch or distal vessel, which is usually a wire-induced perforation, may be treated by distal injection of: *(i) small coils or (ii) fat particles*. An over-the-wire microcatheter is advanced distally into the perforated branch. Negative suction is applied to the lumen of this catheter, using a 20 ml syringe; this negative suction may seal the perforation. If not, coils or fat particles are advanced through the catheter. Fat particles are harvested from a cut made in the groin area (fat is cut into pieces <1 mm and mixed with saline then contrast to make it visible).

Anticoagulation is not immediately reversed during the above maneuvers (e.g., prolonged balloon inflation), as this may lead to extensive coronary thrombosis.

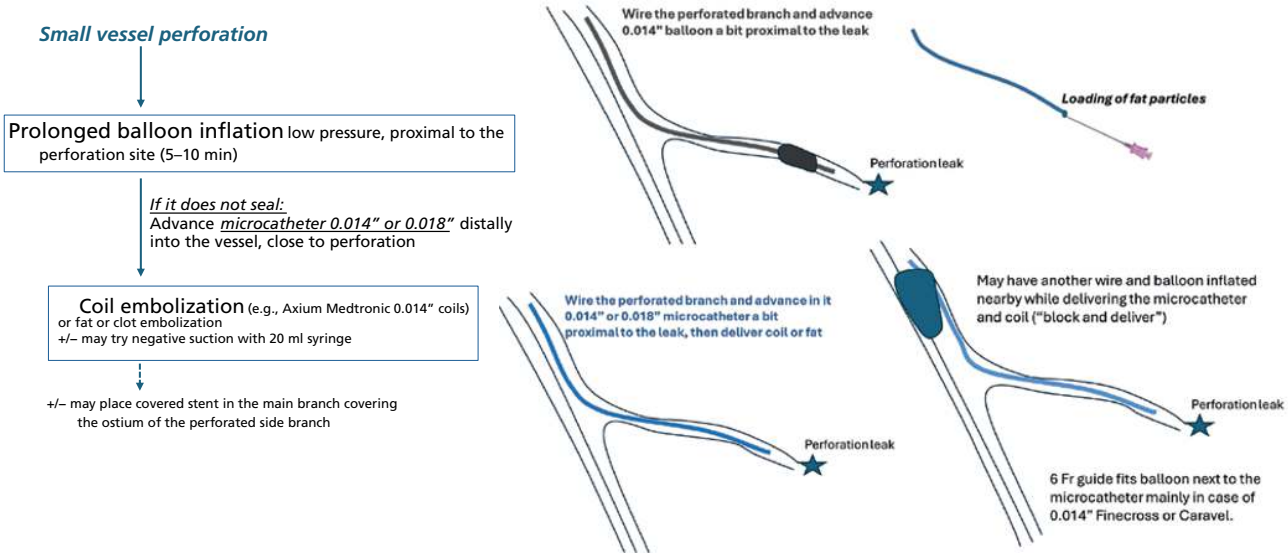

Figure 39.8 Small vessel perforation management. Finecross 0.014″ microcatheter is preferred as: (i) it accommodates more coils than other 0.014″ microcatheters, including some 0.018″ coils; (ii) it has a lower profile and may allow simultaneous, parallel balloon inflation within the 6 Fr guide during coil delivery. Coils may be *pushable* or preferably *detachable*. Examples of 0.014″ coils: Medtronic *detachable* Axium neurovascular coils or Concerto coils. Terumo Azur coils, pushable or detachable, generally require 0.018″ microcatheter.

VI. Femoral access complications

All femoral bleeding complications are increased with PCI (vs. diagnostic catheterization), female sex, higher anticoagulant dose, GPI therapy, and HTN.

A. Groin hematoma

A large hematoma is a hematoma that is associated with a significant drop in hemoglobin, a requirement for transfusion, or hemodynamic compromise. In addition, it may lead to nerve compression and neurological symptoms (femoral or lateral cutaneous nerve).

B. Retroperitoneal hematoma (~0.7% of PCIs)

While the common femoral artery is a superficial compressible artery, the external iliac artery dives deeply in the loose pelvis and is not compressible, even at its distal part (Figure 39.9). Thus, an iliac stick, i.e., a high stick above the inguinal ligament, has a 5× higher risk of a free-flowing, deep bleed called retroperitoneal bleed. Retroperitoneal bleed may, however, occur with a lower stick. It may also be due to inadvertent puncturing or cannulation of a small branch during access, such as the inferior epigastric artery.

Such a bleed does not usually cause superficial hematoma. It should be immediately considered in a patient with flank or back pain, flank fullness or swelling, unexplained bradycardia or vagal shock, or unexplained tachycardia or hypotension that does not quickly improve—and remain stable—with fluid administration and atropine (if appropriate). Perform quick initial fluid resuscitation and high groin compression, and consider protamine. RP bleed may stop via "self tamponade," and the patient may stabilize with this initial fluid resuscitation, eventually requiring transfusion based on subsequent Hb levels. Most patients (84–95%) quickly stabilize and do not require invasive management.[4] If hypotension persists after ~20 minutes of the initial measures, the patient is urgently taken back to the cath lab and a contralateral access is obtained (Figure 39.10). Iliac angiography is obtained and, if contrast extravasation is seen, a

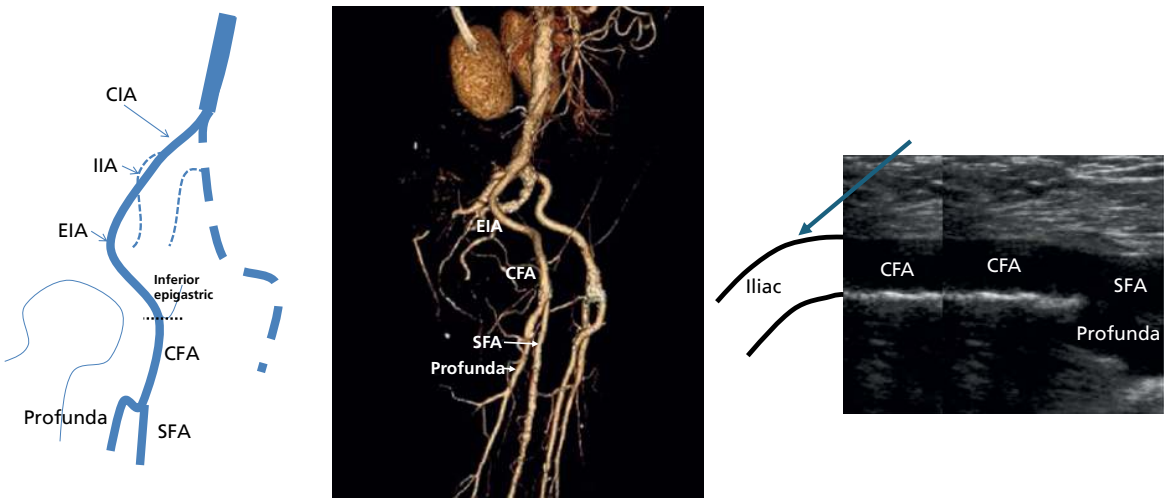

Figure 39.9 Anatomy of the femoral and iliac arteries. The high common femoral artery (CFA) becomes external iliac artery (EIA) at the level of the inguinal ligament, which corresponds to the bottom loop of the inferior epigastric artery (*interrupted black line, left image*). While the CFA is a superficial and compressible artery, the **EIA dives sharply and deeply in the loose pelvis** and is not compressible, even at its early part. This is underestimated in frontal angiography and best appreciated on lateral illustrations. Heavy bleeding can seep through loose, non-constraining pelvic tissue. Thus, an iliac stick, i.e., a high stick above the inguinal ligament, has a 5–17× higher risk of a free-flowing, deep bleed called retroperitoneal bleed. On ultrasound, during access, the point of deep deflection of the CFA is the point where it becomes iliac artery (*arrow*): avoid sticking at this level.

The **profunda sharply dives posteriorly and laterally in the thigh** and is loose and unsupported by any bone structure. This may not be well appreciated on 2D frontal angiography. Even a stick in the proximal profunda is already too deep in the thigh and cannot be compressed; it may bleed incessantly.

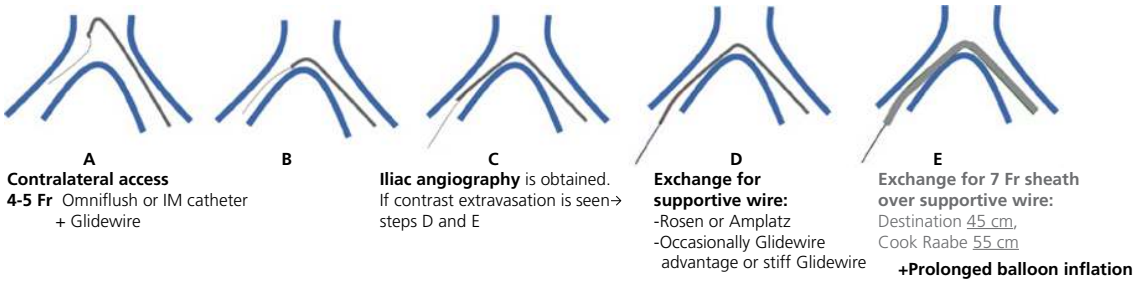

Figure 39.10 Treatment of iliac perforation. After advancing crossover contralateral sheath, perform prolonged balloon inflation with a peripheral balloon, at or just upstream of the bleed (~6- to 8-mm balloon, sized 1:1, >10 minutes). Next:

1. If bleeding persists and the leak is iliac → Place Viabahn self-expanding covered stent (flexible, nitinol) or iCAST balloon-expandable covered stent. The size is ~6–8 mm, upsized by 1 mm in case of self-expanding stent. Covered stents typically require 7 Fr sheath, except for the newer Viabhan VBX 6–7 mm stent and Bentley balloon-expandable 6- to 8-mm stent, which may be advanced via a 6 Fr sheath.
2. If bleeding persists and the leak is common femoral: urgent surgical correction is typically required, while keeping the sheath in place and the balloon inflated during transport for surgery. Alternatively, a short self-expanding Viabahn 25-mm stent is deployed.

prolonged balloon inflation is performed. This may be followed by placement of a covered stent across the perforation if it is iliac. If the perforation is common femoral, stenting is better avoided and prolonged balloon inflation alone, very short stenting, or surgical correction may be performed. If the perforation results from the puncture of a small branch, this branch may be wired then coiled; alternatively, an over-the-wire balloon may be advanced into it, followed by thrombin injection through the balloon lumen.

When retroperitoneal hematoma is suspected with any degree of sustained hemodynamic compromise, iliac angiography through a contralateral access is urgent. **CT scan is not necessary to confirm the diagnosis in a persistently hypotensive patient, nor should the diagnosis rely on a drop in hemoglobin level**. The patient may fall into a progressive irreversible shock with unnecessary delay. Besides delaying treatment, CT may further destabilize the patient during movement and straining. A CT scan is justified only in a hemodynamically stable, non-tachycardic, comfortable patient who has an unexplained drop of a routinely checked hemoglobin, sometimes preceded by a transient hypotension that has quickly stabilized. This patient likely had a self-limited retroperitoneal bleed that spontaneously clotted. CT scan serves to confirm the diagnosis in this particular case, many hours later.

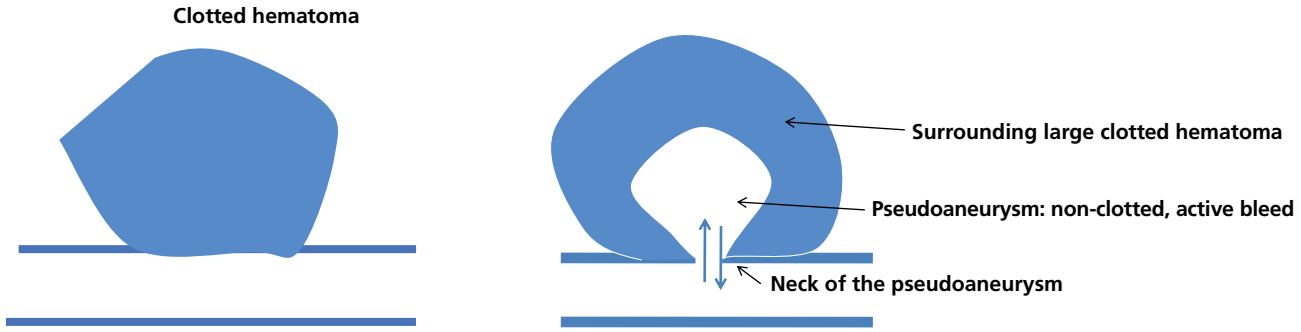

Figure 39.11 A pseudoaneurysm is characterized by a non-clotted active bleed and may be surrounded by a clotted, larger area of hematoma. A to-and-fro flow is seen from the arterial lumen. A large hematoma may evolve into a pseudoaneurysm: the hematoma may initiate intrinsic fibrinolysis, which may dissolve the clot that initially plugs the arteriotomy site.

C. Pseudoaneurysm

A pseudoaneurysm is an expansile collection of blood that has 2 features differentiating it from a hematoma: (i) it is not clotted, and (ii) it remains in communication with the arterial lumen, i.e., there is active bleeding (Figure 39.11). In contrast, a hematoma is clotted blood without active bleeding. A pseudoaneurysm must be distinguished from a hematoma (exam, ultrasound), as it is an active bleed that will continue to expand.

A hematoma may initiate intrinsic fibrinolysis, which may dissolve the clot that initially plugs the arteriotomy site; thus, *a hematoma may evolve into a pseudoaneurysm*.

A bruit is heard on exam and a pulsatile mass is felt. The diagnosis is made by ultrasound Doppler, which shows a mass that communicates with the femoral artery through a *to-and-fro, high turbulence mosaic flow*.

The risk is higher with a low superficial femoral or profunda stick, as those arteries are not supported by bony structures and are difficult to compress; the profunda, in particular, dives posteriorly and deeply into the thigh, immediately upon takeoff, making it particularly prone to uncontrollable bleed or pseudoaneurysm.

Femoral pseudoaneurysm management:

- <2 cm: very often closes spontaneously at a mean of 23 days (88%).[5] Consider serial ultrasounds (Q1–2 weeks), then active treatment if it does not close at 1 month.
- >2 cm with a favorable neck, i.e., a narrow and tall neck (width <0.5–1 cm, height >0.5 cm), is treated with:
  1. Ultrasound-guided focal and directed compression (45 minutes): ~75–90% efficacy
  2. Or ultrasound-guided thrombin injection (1000 units/ml thrombin, 0.2–0.5 ml injection into the sac)
- Surgical correction is needed if the pseudoaneurysm has a wide neck (>0.5–1 cm) or short neck (<0.5 cm), or if it is very large >4–5 cm with compressive symptoms (neuropathy), or if it fails thrombin therapy.

Radial pseudoaneurysm may occur in up to 0.2% of transradial PCIs. Most small pseudoaneurysms <1 cm close spontaneously. Treatment of pseudoaneurysms >1 cm:

- Transradial band compression for ~3 hours, with patent hemostasis, often successfully occludes it.
- Small superficial thrombin injection (far away from the neck) may be performed. Avoid thrombin in pseudoaneurysm with a large (>1 cm) or short neck (<0.5 cm) (risk of thrombin migration into the radial artery and the hand).
- Surgical correction, which is straightforward as the artery is superficial.

D. Arteriovenous fistula

The risk is increased when the access is low, at the superficial femoral or profunda level, or when a venous sheath is used along with the arterial sheath. Below the femoral bifurcation, the femoral veins cross under to become posterior then lateral to the arteries, rather than medial, and risk getting punctured during arterial access if the stick is posterior (Figure 39.12).

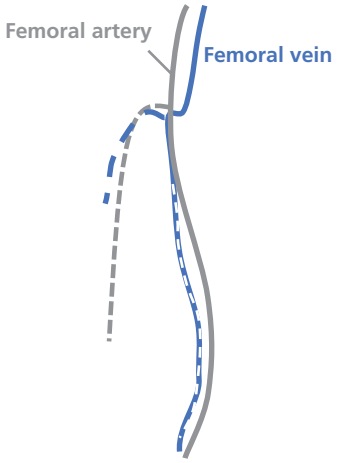

Figure 39.12 At the groin/CFA level, the femoral vein is medial to the artery, but then it quickly crosses under and becomes posterior then lateral to the SFA and to the popliteal artery. At the high SFA and profunda level, the artery and the vein are superimposed and a venous stick may go through the artery. A posterior wall SFA stick may touch the femoral vein wall. AV fistula particularly happens with venous sheath placement, or low arterial stick that goes through the posterior wall of the SFA or profunda.

A continuous femoral bruit is heard. At least one-third of fistulas close within 1 year, mostly within 4 months. The remaining fistulas tend to remain stable without complications on 1-year follow-up, as these fistulas are usually small.[6] Another series suggested that 81% close spontaneously.[7]

Monitoring is usually the first line of therapy, with serial clinical and ultrasound follow-ups (Q1 month for 3 months, then Q3 months). Surgical correction is indicated in the case of progressive growth or complications (limb ischemia, DVT, right or left HF). Ultrasound-guided compression may be tried, but generally has a low success rate (less than pseudoaneurysm, ~1/3). The shunt flow across the fistula being much less than 30% of the cardiac output (Qp/Qs <<1.5) and less than a dialysis AV fistula flow, most AV fistulae (>90%) are asymptomatic and do not require repair.

E. Limb ischemia

Limb ischemia may be related to impairment of flow by the sheath itself in patients with a small or diseased femoral artery. Also, the sheath may further impair the already reduced baseline flow of any severe PAD. If limb ischemia is not promptly corrected by sheath removal, a femoral dissection, thrombus, or distal embolization should be suspected. Heparin is administered and a femoral ultrasound is urgently performed, followed by urgent vascular surgery (for exploration and thrombectomy) or percutaneous intervention through a contralateral access.

Retrograde iliac dissection may occur with wire advancement. Being retrograde, it is generally benign and seals with the antegrade flow.

When forearm compartment syndrome occurs in a patient with radial access, what is the usual mechanism? It is not usually due to bleeding from the access site itself; rather, it is due to *perforation of a branch at the forearm level, especially perforation of a small recurrent branch arising from a radial loop*.

It should be recognized and diagnosed by angiography early, before the stage of hematoma. If diagnosed early, it is treated by crossing the main radial artery and its loop with a catheter and keeping it 20+ minutes (which reduces flow across the bleeding branch), or inflating a BP cuff over the forearm, or, if needed, inflating a coronary balloon at the takeoff of the bleeding branch.

VII. Renal, stroke, and atheroembolic complications

A. Contrast nephropathy. *Traditional definition:* ↑ creatinine ≥0.5 mg/dl or ≥25%. *KDIGO:* ↑ creatinine ≥0.3 mg/dl.
The incidence is ~3–5%, but is higher, ≥10%, in the case of a pre-existing renal failure, HF (or worse, shock), dehydration, or diabetes with renal failure (diabetes alone is not a risk factor). A high contrast load (>3× the GFR in ml/min) or multiple contrast studies within 72 hours are major risk factors. In patients with pre-existing GFR < 40 ml/min, the risk is ~10–25%. In patients with a baseline creatinine >4–5 mg/dl, the risk is >50%. In the absence of risk factors, the risk is <2%. The risk of severe renal failure requiring dialysis or irreversible renal failure is, however, ~5× lower. Most contrast nephropathies eventually improve and renal function returns to baseline. However, 18% are left with some irreversible impairment of renal function. **Contrast nephropathy is one of the most powerful predictors of post-PCI mortality (3–8 times increased mortality** at 30 days and 1 year).

Creatinine starts to rise 24–48 hours after PCI, peaks at 3–5 days, and improves at 1 week. Creatinine often declines the day after the procedure because of dilution/hydration; a slight rise in creatinine at 24 hours may be an early sign of contrast nephropathy.

Prevention of contrast nephropathy:

- Hydration with normal saline (better than 0.45% saline), ***in the absence of HF***: 100 ml/h for a few hours before the procedure and 4–12 hours after the procedure. *In HF with clinical or hemodynamic congestion, hydration aggravates volume overload and may potentially worsen the risk of renal impairment*.
- As in the POSEIDON trial, LVEDP may be used to guide a brief, 4-hour post-procedural hydration: LVEDP <13 mmHg → 5 ml/kg/hr; 13–18 mmHg → 3 ml/kg/hr; >18 mmHg → 1.5 ml/kg/hr. Before the procedure, 3 ml/kg is administered over 1 hour.

- Data from REMEDIAL trials suggest that maintaining a high urinary flow ≥300 ml/hr for 4 hours post-procedurally, rather than mere hydration, significantly reduces renal injury. This was achieved via the paradoxical combination of high volume of intravenous fluids as well as furosemide. This combined strategy seems particularly attractive in patients with elevated LVEDP, in whom standalone hydration may lead to pulmonary edema. In the REMEDIAL III trial, which included a large proportion of patients with high LVEDP, standalone hydration was not clearly beneficial and the risk of renal injury was double that of hydration + furosemide.
- Use the smallest amount of contrast (<30 ml for a diagnostic coronary angiogram, if possible; <2–3× GFR for PCI, preferably <1x).

B. Stroke

Periprocedural incidence: 0.07% after routine diagnostic cardiac catheterization, up to 1% after crossing the aortic valve in severe AS, up to 0.6% after complex PCI (SYNTAX and EXCEL trials).

Ischemic stroke is related to atheroembolization of aortic plaques (as the catheters scrape the aorta), embolization of thrombi formed on the wires/catheters, or embolization of an LV thrombus. This risk increases with age, peripheral arterial disease, or venous graft interventions. Patients with prior CABG generally have heavy aortic atherosclerosis; in addition, difficult left venous graft engagement and retrograde embolization during ostial venous graft intervention may lead to stroke.

Hemorrhagic stroke is rare and may be related to anticoagulation.

C. Cholesterol atheroembolization

Atheroembolization may occur in patients with severe aortic or iliac atherosclerosis, who slough off cholesterol debris during the procedure. This may lead to distal cyanosis (blue toes), livedo reticularis, subacute progressive renal failure (occurring >1 week later, with eosinophiluria), and mesenteric ischemia.

VIII. Intra-aortic balloon pump (IABP) or intra-aortic balloon counterpulsation

A. Overview of IABP

An IABP is a balloon mounted on a catheter, inserted through a femoral artery (7–8 Fr sheath). It is placed just distal to the left subclavian artery (at the level of the *tracheal carina* fluoroscopically) and extends proximal to the renal arteries. It has 2 lumens: (i) a helium gas line connected to the balloon, and (ii) a central arterial lumen attached to the arterial monitor (Figure 39.13). Newer IABP catheters have a fiber-optic line that allows arterial pressure monitoring without the need for the arterial lumen; the arterial lumen (line) is just connected to a flushing solution to prevent catheter tip clotting. If the fiber-optic port becomes dysfunctional, the arterial line may be connected to the arterial port on the IABP console. If the arterial line clots with a functional fiber-optic port, it is not a major issue. But if the IABP catheter does not have a fiber-optic port, arterial line clotting prevents monitoring of the arterial waveform and may dictate balloon removal; alternatively, the arterial port of the IABP console may be connected to a suboptimal radial line.

The IABP inflates in early diastole, just at the dicrotic notch. It deflates at end-diastole, just at the isovolumic contraction phase before the aortic upslope: this creates a negative pressure in the aorta that "sucks" flow from the LV, thus reducing afterload and myocardial wall stress. This increases cardiac output by ~20%, up to 0.5–1 L/min, and decreases LV filling pressure and PCWP by ~20%. Furthermore, the reduction in afterload decreases myocardial O_2 demands, which reduces myocardial ischemia.

Note that an IABP reduces systolic and end-diastolic BP, but creates a third component to BP, called *augmented BP*, that is higher than the unassisted systolic BP (Figures 39.14–39.16).

Assisted systolic and end-diastolic pressures are reduced in comparison to the corresponding unassisted pressures.

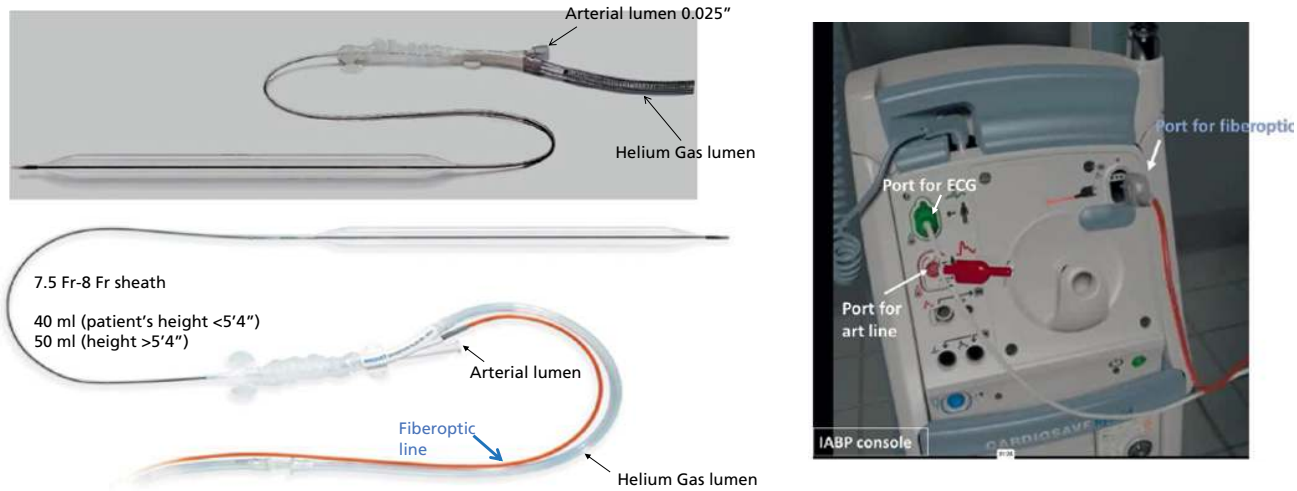

Figure 39.13 IABP catheter has 2 or 3 lines: arterial lumen, gas lumen, and +/– fiber-optic line. Both the latter 2 allow aortic pressure monitoring, but the IABP defaults to the fiber-optic line. The arterial lumen is connected to a transducer and a pressurized saline bag to keep it patent. If the fiber-optic line is dysfunctional, pressure monitoring may be switched to the IABP arterial lumen or even a radial line: the tubing from the arterial lumen's transducer is connected to the arterial port on the console. In order to get the input from the arterial port, open the "pressure source" on the IABP screen and move from fiber-optic to pressure sensor. Courtesy of Maquet.

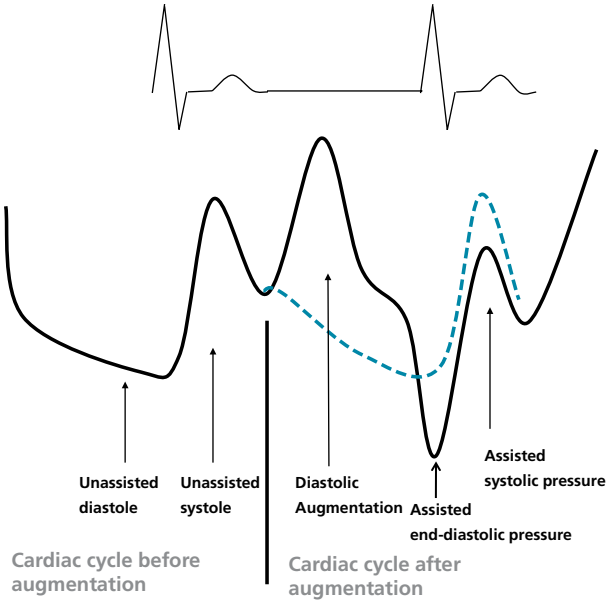

Figure 39.14 Unassisted and assisted aortic pressure. Balloon inflation occurs at the dicrotic notch, which corresponds to the end of T wave on the ECG (***end of T inflation***); balloon deflation occurs at the isovolumic contraction, which corresponds to the peak of R wave (***R-wave autodeflation***). The timing of balloon inflation/deflation is fine-tuned **until the dicrotic notch is concealed within the balloon inflation and until the nadir diastolic pressure is 10–15 mmHg lower than the unassisted diastole.** Note that the assisted end-diastolic pressure is lower than the unassisted end-diastolic pressure, the assisted systolic pressure is lower than the unassisted systolic pressure, and the augmented pressure is higher than the systolic pressure. The *blue tracing* corresponds to the aortic tracing had there not been balloon augmentation. Compare the diastolic and systolic pressures before and after augmentation.

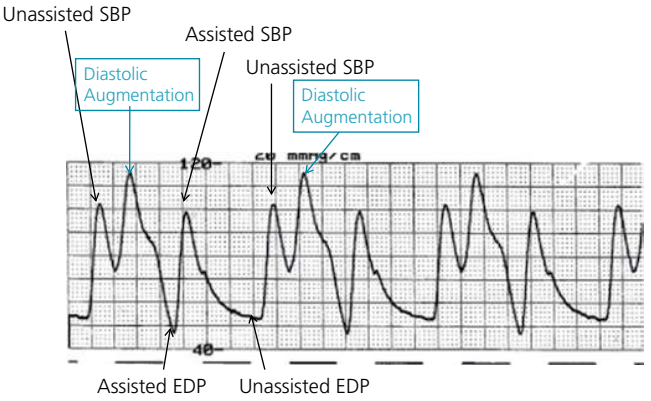

Figure 39.15 1:2 IABP inflation. Note that in a 1:2 or 1:3 mode, the SBP that immediately precedes augmentation is actually the unassisted SBP. **The 2 pressures to the left of augmentation are the unassisted pressures, while the pressures to the right are the assisted pressures.** EDP, end-diastolic pressure. Courtesy of Maquet.

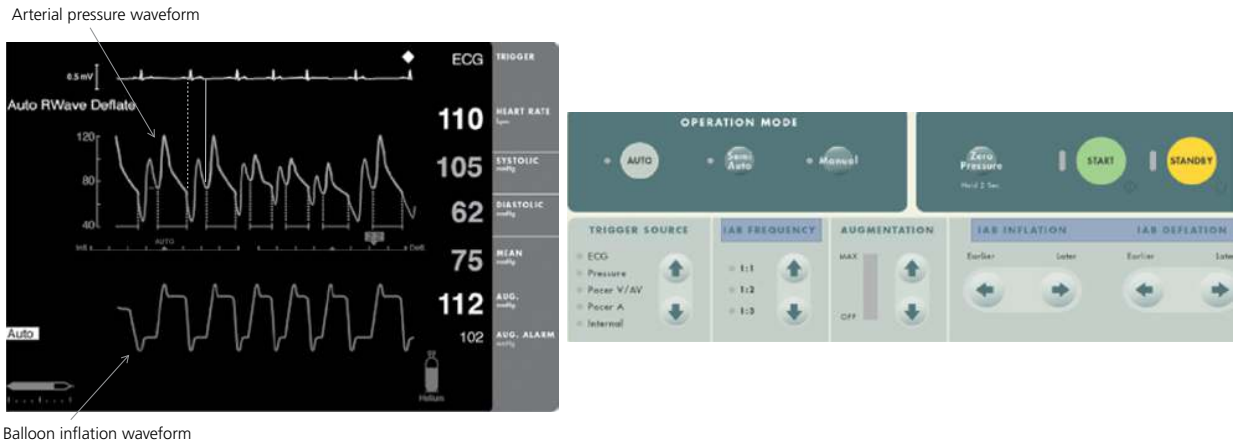

Figure 39.16 IABP monitor showing the ECG, the arterial pressure waveform, and the balloon inflation waveform. The IABP is inflating in a 1:1 mode. Note that the IABP deflates at the peak of R wave (*top dashed line*) and inflates at the end of T wave (*solid line*). Note that during shorter R–R intervals there is less augmentation in pressure (balloon inflates well, as well as during long R-R cycles, but for a shorter duration). *On the right*, IABP console buttons are shown. These buttons may change the trigger source (e.g., from ECG to pressure), IABP frequency, and inflation/deflation timing under semi-auto mode. Courtesy of Maquet.

The end-diastolic pressure should generally be reduced by ~10–15 mmHg in comparison to the baseline end-diastolic pressure to ensure proper support. The mean arterial pressure increases, and more importantly cardiac output and tissue perfusion increase even if the mean arterial pressure is unchanged. Systemic pressure is not a parameter by which the efficacy of IABP should be gauged. The organs below the balloon level are not adversely affected, because they still receive the enhanced cardiac output during systole.

B. Effect of IABP on coronary flow

IABP inflation in diastole increases aortic diastolic pressure. In addition, IABP reduces LVEDP. Thus, IABP improves the gradient that drives coronary flow (aortic diastolic pressure minus LVEDP), which improves coronary flow in low-output states with non-obstructed coronary arteries. In the case of a critical coronary stenosis, coronary flow increases upstream of the stenosis but does not increase distal to the critical stenosis, even in shock. In fact, one landmark study by Kern et al. positioned a Doppler wire past critical coronary stenoses and demonstrated that ***IABP does not increase coronary flow velocity, a surrogate of flow, in a coronary artery beyond a critical stenosis*** (flow-limiting stenosis). Once the stenosis is treated with angioplasty, IABP increases distal coronary flow in comparison to no IABP augmentation. Another study demonstrated that coronary pressure is not increased by IABP distally to a severe stenosis (>70–80% stenosis). ***Thus, IABP improves myocardial ischemia distal to a severe stenosis through the reduction in O_2 demands rather than through an increase in coronary flow or pressure.*** Only when a non-obstructed artery supplies large collaterals (grade 2 or 3) to the occluded site can IABP increase flow distal to the coronary occlusion. Conversely, after PCI, IABP consistently increases coronary flow and plays a great role in relieving ischemia related to microvascular obstruction and no reflow, and thus, in relieving persistent ST elevation.

C. Triggering and timing

The IABP is often timed and triggered to the surface ECG. It inflates at the end of T wave, which corresponds to the dicrotic notch and beginning of diastole, and deflates at the peak of R wave, which corresponds to the beginning of the isovolumic contraction (Figures 39.14–39.16). The device can be triggered every beat/every QRS (1:1 inflation) or every other beat/QRS (1:2, 1:3). Timing is adjusted to achieve the optimal waveform and is best done under 1:2 or 1:3 pumping mode, so that arterial tracings from consecutive beats with and without assistance can be compared. Adjustment of timing is rarely necessary with the current IABP systems, as these systems look at the aortic pressure and automatically fine-tune the timing to achieve the best arterial waveform.

The arterial waveform can also be used for triggering and timing but should not be used in irregular rhythm, as the balloon may remain inflated between cardiac cycles. Ventricular pacing spikes may be used for timing of patients who are 100% ventricular-paced and who do not have a good-amplitude QRS. In fact, even in patients who are paced, it is preferred to use the ECG for timing. If the arterial lumen is thrombosed, a radial line may be connected to the IABP console to monitor the arterial waveform but not to adjust the timing, as balloon inflation and deflation are seen relatively later on the radial waveform than on the aortic waveform.

D. Troubleshooting and lack of appropriate augmentation (Table 39.4)

If there is no pressure augmentation and the helium balloon inflation waveform is flat or abbreviated, consider gas leak (check tubing connections, check for blood in the gas lumen). Also, consider catheter kink and ensure that the balloon is fully out of the sheath.

A **helium balloon inflation waveform that is overexpanding** suggests impaired balloon deflation (catheter is kinked or balloon is partially in the sheath).

Table 39.4 Causes of poor diastolic augmentation.

Patient-related factors:

1. **Very poor LV function and stroke volume:** (i) Lower stroke volume → less volume ejected in the aorta → less volume can be displaced by the IABP to create augmentation → less augmentation. (ii) Also, a poor LV has a poor stroke volume reserve.
2. **Tachycardia >120 bpm** reduces stroke volume, which hinders IABP augmentation as explained under (1). Tachycardia also reduces *diastolic time*, which reduces the time allowed for IABP to displace blood volume in diastole, hence diastolic augmentation is reduced for the same volume of helium inflation. Helium gas is light and circulates quickly, hence the balloon is maximally inflated even at high rates: the issue is not circulating helium gas or inflating the balloon. The issue is rather in maintaining the inflation for long enough to move enough blood for augmentation. Switching to 1:2 does not help and rather cuts the support in half.
3. **Shock state that is not cardiogenic** in nature, such as hypovolemic shock or septic shock. In septic shock, afterload is already reduced and IABP does not further increase stroke volume. IABP inflation cannot ↑ the pressure of a dilated circulation, i.e., a large compartment (vs. small compartment in vasoconstricted HF) (see Appendix, Section XIII, Question 19).
4. Very low BP: implies an already low afterload pressure and/or stroke volume, hence inability to augment (esp. when mean BP < 40).

Catheter-related factors:

1. **Balloon kinking** may lead to poor inflation or, if less severe, to poor deflation with an overexpanding balloon inflation waveform. Kinking may occur:
   - Inside the body across a calcified aortoiliac tortuosity, esp. if the balloon migrates down to the iliac artery
   - *Or* outside, especially at the groin level, if patient's upper body is elevated >30° or hip/groin is bent
   - *Or* in the sheath if the balloon is partially in the sheath

   → Check the catheter and tubing for a visible kink, position the patient flat, and ensure the balloon has fully exited the sheath and the iliac artery + get an X-ray of chest/abdomen.
2. **Gas leak due to loose connections** (tubing or console connections) **or balloon leak/rupture.** The latter may result from inflation against calcified aortic plaques and may lead to clotting inside the balloon and balloon entrapment. The blue balloon inflation waveform is abbreviated, and **blood is seen coming out of the gas lumen.** IABP should be placed on standby and **removed quickly** (<30 min), to prevent balloon clotting and entrapment.

Pump inflation timing:

1. **Late inflation or early deflation:** leads to suboptimal increase in coronary perfusion and suboptimal sucking effect.
2. **Late balloon deflation or early inflation:** balloon is partially inflated in systole and increases afterload.
3. **With these dysfunctional timings,** one of the dips of Figure 39.14 widens or gets effaced. Changing the timing corrects this.

E. Indications for IABP

1. Cardiogenic shock due to acute ischemia/infarction: IABP is used in conjunction with PCI, placed before or after PCI, and kept until the patient stabilizes (IABP used as a bridge to recovery). Yet, the IABP-SHOCK II trial failed to show a benefit of IABP in MI patients with cardiogenic shock. The failure of the IABP-SHOCK II trial may be due to the heterogeneity of shock patients included (45% had post-cardiac arrest shock). IABP is still justified in patients who continue to decline and require increasing inopressor doses, yet are not in extremis. Outside shock, IABP is also useful in patients with a large STEMI who have persistent ischemia or ST elevation after primary PCI (IABP improves microvascular no reflow).

2. Mechanical complications related to MI (ventricular septal rupture, papillary muscle rupture): IABP is used as a bridge to surgical surgery.

3. Decompensated chronic cardiomyopathy with shock. IABP is superior to inotropes in improving SvO2 (+17% vs. +5%) and cardiac power output (+0.27). It may be inserted via the axillary artery for long-term ambulatory support (weeks) while awaiting LVAD or transplant.

4. Patients with low EF undergoing multivessel or left main PCI. In patients with extensive multivessel disease and EF <30% undergoing PCI, planned IABP placement was associated with a significant 34% reduction in 4-year mortality compared with no IABP or bailout IABP (BCIS-1 trial). IABP did not reduce the 30-day mortality. Rather, the mortality benefit started to emerge beyond 3 months of follow-up and was significant at 4 years.

5. Coronary complications occurring during PCI and leading to ischemia/shock: IABP as a bridge to recovery.

6. Prophylactically, pre- and post-cardiac surgery in the following high-risk cases: severe LV dysfunction, ongoing ischemia, high-grade left main stenosis, decompensated AS. The pre-operative placement allows the heart to tolerate anesthesia induction and withstand the myocardial stunning that is unveiled during weaning from the pump. IABP may also be placed post-cardiac surgery for cardiogenic shock.

7. Refractory ischemic arrhythmias: IABP is placed during revascularization, or after revascularization if these arrhythmias persist.

IABP is a temporizing measure, a bridge to a more definitive therapy (CABG, PCI). It is also a supportive measure pending an expected recovery after MI or complicated PCI or CABG with transient ischemia and stunning.

F. Contraindications

IABP is contraindicated in moderate or severe AI and in HOCM (since intracavitary obstruction increases with afterload reduction). Severe peripheral arterial disease is a relative contraindication. Rather than being due to the balloon itself, *limb ischemia is related to the sheath* occluding flow to the ipsilateral limb. The use of a sheathless IABP limits limb ischemia, but sheathless insertion is contraindicated in severely obese patients because of the risk of subcutaneous catheter kink. Ipsilateral iliac angioplasty should be performed before IABP insertion in patients with iliac disease.

G. Care, follow-up, and weaning

- Daily chest X-rays are performed to check the catheter position. If needed, the catheter may be manipulated and repositioned through the sheath.
- IV therapeutic doses of heparin (goal PTT 46–70 seconds) are provided to: (i) prevent limb ischemia from the large sheath, (ii) prevent thrombosis over the balloon.
- Daily CBC, as IABP may lead to hemolytic anemia and mild thrombocytopenia. *Severe thrombocytopenia is not* secondary to IABP.
- The IABP is weaned off when the patient is stable, usually 24–48 hours after placement, and after appropriate therapy of the underlying cardiac condition. The patient must be:
  - Stable from the hemodynamic standpoint, i.e., have a stable systemic pressure and peripheral perfusion with or without small doses of inotropes/vasopressors, and possibly with the support of small doses of vasodilators that will simulate the IABP effect, if the blood pressure allows (nitroprusside, nitroglycerin).
  - Stable from the ischemic standpoint.
- When the patient is ready to be weaned off, IABP inflation is changed from 1:1 to 1:2 then 1:3 over the course of one to several hours to ensure tolerability. If the patient tolerates weaning, IABP may be removed. Heparin is held for ~2 hours and 1:1 pumping is resumed during these hours to prevent balloon clotting. The pump is shut off and IABP removed when ACT <160 seconds or PTT <50 seconds.

IX. Percutaneous LV assist device: Impella mechanism, troubleshooting, and weaning

A. Impella general features and mechanisms

Impella is the prototype transvalvular LV assist device. It is a microaxial rotatory pump that expels blood from the LV to the aorta. The flow is continuous rather than pulsatile. Impella CP can provide up to 3.5 L/min of flow support, with P2 to P9 levels of support, and is inserted percutaneously, typically via the femoral artery. The pump segment diameter is 14 Fr, while the catheter is 9 Fr (Figures 39.17, 39.18). A 14 Fr sheath is used for insertion. If Impella is kept in place after PCI, the 14 Fr sheath is peeled away and replaced with the tapered 13 Fr repositioning sheath stationed at the back end of the Impella catheter. Impella 5.5 can provide up to 5.5 L/min of support and is inserted surgically via axillary access (21 Fr). In addition to increasing cardiac output, ***Impella reduces the end-diastolic volume (preload) and the end-systolic volume (wall tension or afterload), which reduces O_2 demands***. The reduction in end-diastolic pressure also improves subendocardial perfusion and microcirculatory flow.

Impella reduces afterload differently from IABP: the former reduces LV volume (flow device) while the latter reduces aortic resistance (pressure device). However, the 2 devices should not be combined. The diastolic augmentation of IABP increases the diastolic afterload of Impella, which is a continuous pump, and counteracts the Impella flow in diastole. This drastically reduces the diastolic and overall Impella flow. Besides, significant hemolysis may occur as the Impella pumps against an inflated balloon.

Impella provides a constant axial flow, and, as opposed to IABP, there is no need for ECG or pressure waveform synchronization. The arterial pressure increases but the pulse pressure narrows since most of the cardiac output is provided by this non-pulsatile pump. ***The more Impella contributes to the cardiac output, the less pulsatile the blood flow is.*** For example, during coronary balloon inflation in high-risk coronary intervention, the pulse pressure is severely reduced and the aortic pressure may become a flat pressure line provided by Impella.

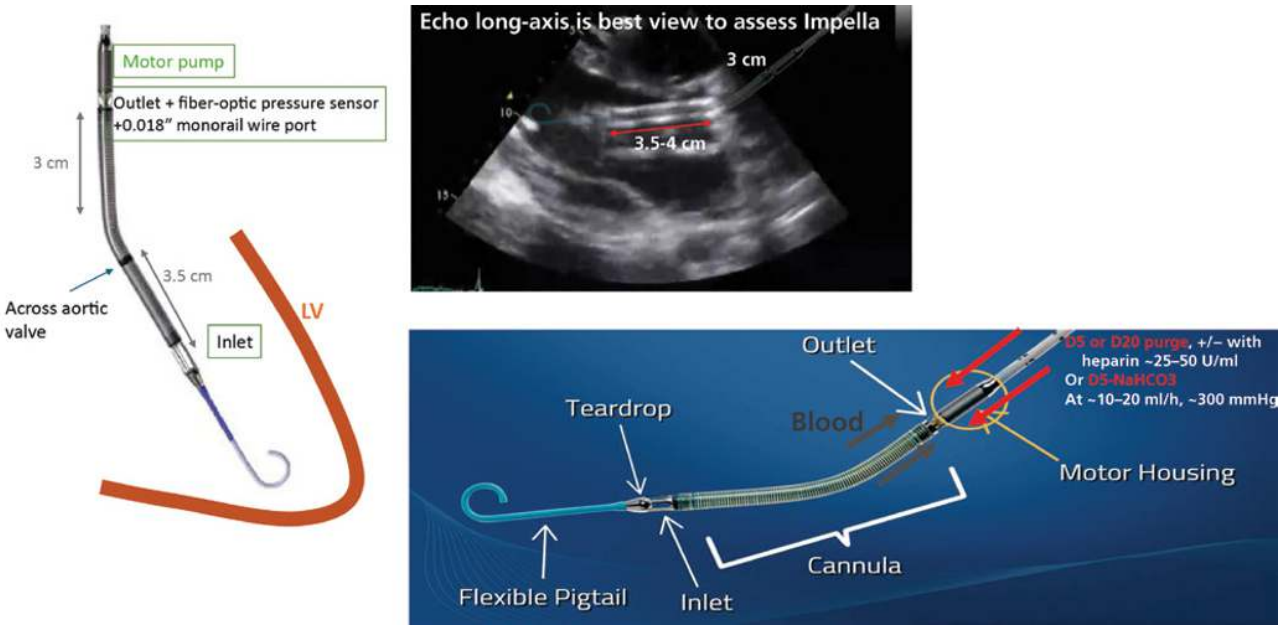

Figure 39.17 Impella CP assist device. Blood is pulled from the LV through the *inlet area* and pumped into the ascending aorta through the *outlet area*. The motor is above the outlet area, and purging prevents it from being contaminated with blood. The *arterial fiber-optic sensor*, which senses the arterial waveform, and the monorail *wire exit port* are all in the outlet area. The catheter bend is positioned across the aortic valve. The distance from the aortic valve to the inlet area, well seen on echo, should be ~3.5–4 cm, while the distance from the aortic valve to the outlet area (seen as mosaic of flow) should be 3 cm. If the aortic sensor displays LV waveform, Impella is too deep and needs to be pulled 3 cm (3 cm being the distance between the outlet/aortic sensor and the Impella bend).

Purge solution flows in opposite direction to blood at a high pressure of ~300 mmHg, to prevent motor corrosion with blood. Dextrose D5 or D20 is used, not saline, as saline may cause motor corrosion. Purge flow is variable as it depends on the systemic BP and viscosity of the solution. D20 is more viscous than D5, resulting in a 30–40% slower purge flow rate and less local UFH infusion but increased risk of purge obstruction. Sodium bicarbonate (25 mEq/L) may be used and reduces the risk of pump thrombosis.

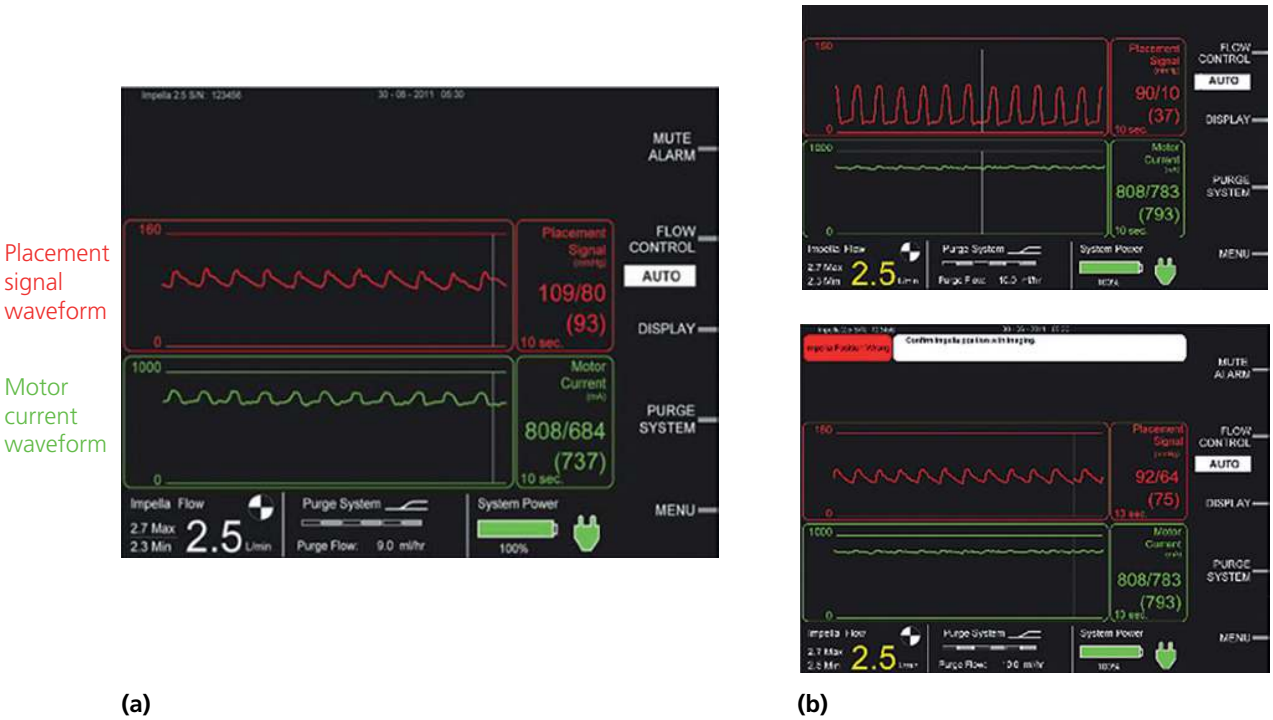

Figure 39.18 **(a)** The Impella console shows 2 waveforms: the aortic waveform (*on top*) captured by the arterial port above the motor, and the motor current waveform (*bottom*). The Impella flow is an estimate derived from the motor current. While the pump is continuous, the current and flow are higher in systole than diastole because of the higher delta pressure between the LV and the aorta.

(b) There are 2 situations wherein the motor current waveform becomes flat (but not low) despite a pulsatile pressure waveform: the inflow and outflow ports are both in the LV (*top*) or both in the aorta (*bottom*). If they are both in the LV, the aortic port displays a ventricular waveform (*top*).

If the LV is underfilled and gets sucked by Impella, the flow will be lower than the programmed flow and the motor current may dampen and decline but is not flat. Courtesy of Abiomed.

With IABP, the absolute increase in cardiac output depends on the baseline cardiac output; thus, in the sickest patients with severe heart failure and limited cardiac reserve, cardiac output may only increase by 0.2 L/min, which necessitates the adjunctive use of inotropic agents. The benefit of IABP in this context is mainly in reducing myocardial ischemia. Impella CP, on the other hand, increases cardiac output by 3.5 L/min in the most severe cases of heart failure. For example, if an Impella is applied to a patient with a cardiac output of 5.5 L/min, the preload reduction reduces the native stroke volume and cardiac output to 4 L/min, but Impella provides 2.5 L/min of extra flow, making the new cardiac output 6.5 L/min, i.e., providing a total increase in cardiac output of 1 L/min. If Impella is applied to a patient with a cardiac output of 2 L/min, the preload reduction barely reduces the native cardiac output to 1.7 L/min, as the failing LV is not preload-dependent, and Impella provides the full 3.5 L/min of extra flow, making the new cardiac output 5.2 L/min, i.e., providing a total increase in cardiac output of 3.2 L/min. The SBP is lower in the second case compared to the first one, allowing Impella to pump the full 3.5 L/min. In fact, ***the more depressed the aortic pressure (low afterload), the higher the flow provided by the Impella pump in both systole and diastole*** (Figure 39.19). Thus, ***Impella further improves cardiac output in severe LV failure while unloading the LV and reducing O_2 demands*** (Figure 39.20). The patient is less likely to require inotropic agents with Impella than with IABP support. It is important to maintain adequate preload during Impella therapy, as a low preload reduces the benefit from Impella and its potential to increase the overall cardiac output. It is also important to maintain a low arterial afterload (mean BP <90 mmHg), as the axial Impella pumping is impeded by a high upstream, aortic pressure.

Figure 39.19 Both the motor current and the pressure waveform are flat, which implies very poor LV function with full reliance on the axial flow of Impella and, as a result, no pulsatility.

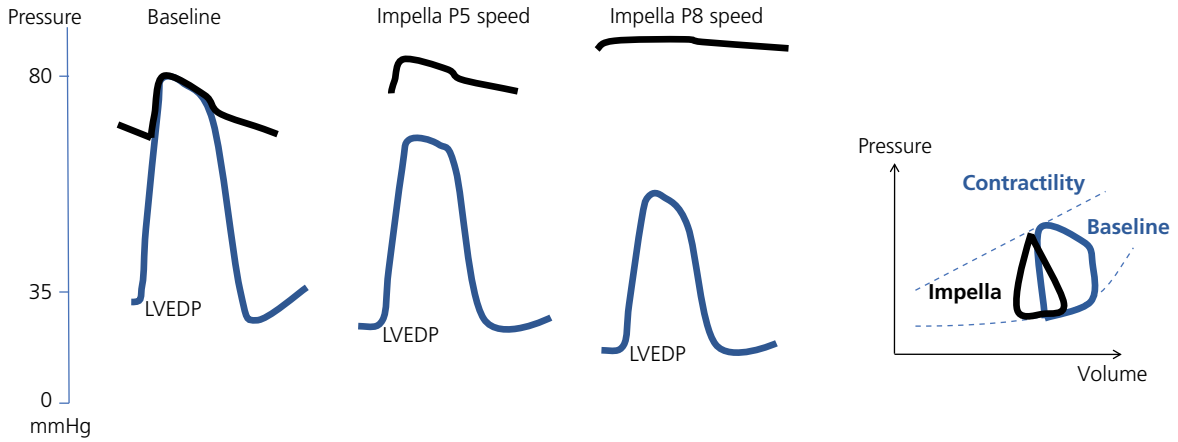

Figure 39.20 Simultaneous LV-aortic pressure waveforms in a patient with severe LV failure. With poor LV flow and increased Impella support, aortic pressure progressively becomes flatter and higher than LV pressure (uncoupling of aortic and LV pressures). LV systolic pressure but also LVEDP decline as the LV is unloaded by Impella.

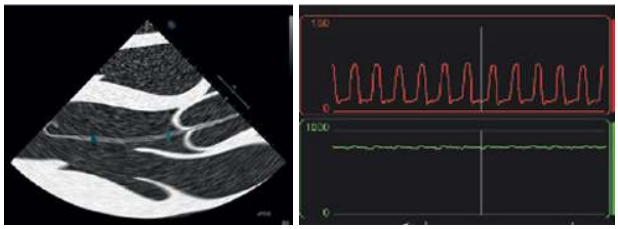
Impella support shifts the pressure-volume loop to the left (LV preload and afterload are reduced). The loop becomes triangular, as the continuous flow eliminates isovolumic LV contraction and relaxation.

Effect on coronary flow: In an animal study of cardiogenic shock, *Impella improved coronary flow in unobstructed coronary arteries by up to ~45%*, significantly more than IABP (~15%) (Sauren et al.). Impella improves coronary flow through the increase in mean arterial pressure but also through the reduction of LVEDP and microvascular resistance. Moreover, ***Impella unloads the LV and reduces O_2 demands more dramatically than IABP.*** In *obstructed coronary arteries*, one study addressed coronary pressure distal to the stenosis at low vs. high Impella power, and found a 17% increase in that pressure. This, along with a reduction of LVEDP, increased coronary perfusion pressure (distal coronary pressure minus LVEDP). This is in contrast to IABP, which does not increase coronary pressure past a stenosis.

Clinical data: ***(i) Protected PCI-*** In PROTECT II, Impella did not improve death/MI in elective, high-risk PCI. Worse, in the CHIP-BCIS3 trial of ***high-risk, highly complex PCI***, *Impella was associated with an absolute 12.2% higher CV mortality at 22 months* (26.7% vs 14.5%), yielding a number needed to kill of 8! This was partly related to bleeding complications, but also to more extensive and prolonged PCI in Impella-supported patients, and as a result, more peri-PCI myocardial injury.

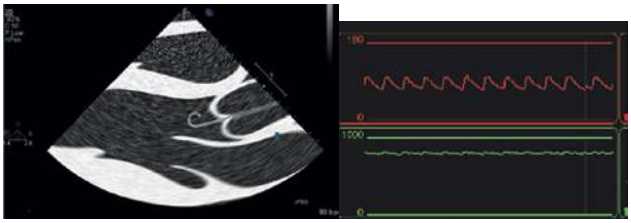
(ii) Cardiogenic shock- Conversely, Impella CP dramatically improved mortality in ***select STEMI-related cardiogenic shock***. The DanGer trial randomized very select STEMI patients with cardiogenic shock <24 hours (median 4 hours) and lactate >2.5 mmol/L (median 4.6 [3.4–7]), undergoing primary PCI to Impella CP vs. standard therapy (PCI and inopressors). Median age was 67 (58–76). By very selectively choosing STEMI-shock that is recent and severe, not late/prolonged severe and not post-prolonged cardiac arrest (U-shape concept), Impella CP reduced 6-month mortality from 58% to 45%. No benefit was seen in women, and significant harm was noted in patients older than 77. While it reduced death, Impella CP was associated with more complications (major bleeding: 22% vs. 12%, limb ischemia: ~5.5% vs. 1%, and more sepsis).

B. Impella position troubleshooting (Figure 39.21)



If Impella is too deep with ventricular tracing

→ Pull back until the inlet is 3.5–4 cm below the aortic valve and the outlet is 3 cm above it. Avoid entanglement with papillary muscles:
1. Lower P level to P2 to reduce suction with deep position
2. Pull back 1 cm at a time while monitoring Impella waveform
3. Once aortic waveform is displayed, pull another **3 cm** so that the bend of the Impella is across the aortic valve and the **inlet is 3.5 cm** below it



If Impella is pulled out fully in the aorta, a wire cannot be advanced through it to reposition it in the LV (monorail system)

→ -May maneuver it under fluoro without a wire
-May need to take Impella out, reinsert a catheter/wire in the LV, then readvance Impella over the wire
-But Impella cannot be taken out through the tapered 13 Fr repositioning sheath→Take the sheath + Impella out while maintaining side-port wire access

Figure 39.21 Troubleshooting Impella position (too deep in the LV, or withdrawn out in the aorta). The *blue* markers indicate the inlet and the outlet.

C. Impella clinical scenarios: troubleshooting (Table 39.5)

Table 39.5 Impella troubleshooting: clinical scenarios

1. Cardiogenic shock, Impella CP in place. Lactate keeps rising and PA saturation is declining. Cardiac output is only 3 L/min and <u>pump flow is 1.8 L/min (lower than expected at maximum pump speed)</u>, with intermittent <u>suction alarms</u>. CPO 0.55 W. What is the diagnosis?
- Poor position (Impella has migrated too deeply or is stuck in the mitral apparatus)
- Low LV preload from hypovolemia or bleeding
- Low LV preload from RV failure
- Tamponade
- Fast AF (especially impairing the RV)

Assess and perform the following:
- Echo for:
  (i) Impella position, (ii) RV dilatation (septum pushed toward LV), and (iii) tamponade
- RA and PCWP:
  - If both are low (RA < 10), consider fluid challenge (responsive if CO ↑ >10%, RA ↑ <3 mmHg)
  - If RA elevated, with RA/PCWP > 0.7–1 <u>or</u> PAPi <1 <u>or</u> poor RV by echo → RV failure
- For RV failure →
  1. Increase inotropes + <u>diurese</u>
  2. Optimize ventilation settings to reduce RV afterload (lower PEEP, low tidal volume)
  3. Inhaled pulmonary vasodilators (inhaled NO, iloprost)
  4. <u>If all fails, or very severe</u> failure → <u>RV mechanical support</u> (RP Impella, VA ECMO)

(*Continued*)

Table 39.5 (Continued)

2. Cardiogenic shock, Impella CP in place. BP remains low (mean 60) and lactate keeps rising, although PA saturation is stable or rising. Cardiac output is 5 L/min, and pump flow is as expected (3.3 L/min). CPO is low because of low BP (0.58 W). What is the diagnosis?

Insufficient support with insufficient CO even at 5 L/min (large body habitus, high demands)
vs. vasoplegia (sepsis, SIRS).

In vasoplegia, (i) SVR is relatively low (<1000) and (ii) SvO2 is not too low (microvascular shunts in sepsis). In this patient,
SVR = (mean BP – RA) × 80/CO = 800
→ Focus on vasopressors +/– 500 ml fluid challenge if BP and CO are fluid responsive to dynamic maneuvers.
No need to escalate support unless cardiac index is low in absolute value AND lactate continues to rise despite SVR correction.

3. Hemolysis (defined as plasma-free Hb > 40 mg/dl, or sudden rise >27 mg/dl, or LDH > 2.5 ULN with high bilirubin)
>8% of Impella CP cases (8–63%), much less with Impella 5.5 (larger inlet-outlet path)

Causes:
- Position too deep (pull back under echo guidance)
- Low LV preload from hypovolemia (check RA-PCWP and if low → give fluids)
- Low LV preload from RV failure
- Rarely: pump thrombosis (as in surgical LVAD)

→ Reduce pump speed until position + preload are treated

Hemolysis causes and management are ~ similar to poor pump flow and suction alarm (scenario 1), except for the additional pump thrombosis

4. Cardiogenic shock, Impella CP in place. Lactate and ALT keep rising, and PA saturation is declining (42%). Cardiac output is 3.6 L/min (index 1.5 L/min/m^2, obese patient), and pump flow is 3.1 L/min. CPO 0.55 W. No suction alarms. What is the diagnosis?

Consider:
- Slightly suboptimal Impella CP performance from deep position or low preload (→ check position, check RA/PCWP, check RV)
- **vs.** Progressive shock despite proper Impella CP function, especially in cases of large body habitus, or profound shock, or high metabolic demands. For example, in a large patient with BSA of 2.7 m^2, CO should be >2.2 L/min/m^2 × 2.7, i.e., >6 L/min → Impella CP is not enough for profound shock. This is a case of insufficient Impella CP support

→ Need to escalate
→ If PCWP is high → need higher flow device: Impella 5.5 or VA-ECMO (+/– escalation of inotropes)
→ If PCWP is near normal but RA is elevated (RA/PCWP >0.7) or PAPi < 1 → add RV support: VA-ECMO or RP Impella (+/– escalation of inotropes and inhaled NO)

5. High motor current and Impella flow (per console), yet low Swan cardiac output that does not match the displayed Impella flow

The diagnosis is likely pump thrombosis. Pump thrombosis is suggested by:
Motor current high or unstable + fluctuant (similar to the high power in LVAD thrombosis)
+ Hemolysis (despite no suction alarms)
+ High pressure in the purge system. Purge flow rate declines (esp. <3 ml/hr) as a result of thrombosis

Treatment: Pump exchange (+/– local tPA through the purge fluid)

6. Anticoagulation with Impella and how to manage anticoagulation in a bleeding patient
- The purge solution runs around the motor and is meant to keep blood away from the motor. D5W or D20W solution is used and runs at ~10–20 ml/hr.
- Purge flow is variable as it depends on systemic pressure and viscosity of the solution.
- UFH may be mixed in the purge solution (~25–50 units/ml ×10–20 ml/hr) and supplemented with a peripheral UFH infusion (for a total of ~12 units/kg/hr). The PTT goal is 60–80 seconds and anti-Xa goal is 0.3–0.5. To simplify UFH titration, all the UFH may be given as a peripheral infusion (no UFH in the purge).

In the case of bleeding:
- One study suggested that a lower PTT target may be as safe as a higher target with lower bleeding risk (40–50 seconds and anti-Xa level 0.2–0.3).
- Also, fully stopping UFH and changing the purge solution to NaHCO3 (25 mEq/L in D5W) may be considered, as the latter is hypothetically associated with less pump thrombosis than pure dextrose. But beware of the risk of limb ischemia from femoral thrombosis around or below the large Impella sheath in patients who are not anticoagulated.

D. When and how to wean Impella and other mechanical circulatory support

1. Criteria to wean

Three categories of hemodynamics are followed closely in any shock patient:

i. Systemic perfusion (lactate), which is initially checked every 1–2 hours during escalation. Once it is trending down and hemodynamics have stabilized, lactate is checked every 12–24 hours. Goal lactate <2 mmol/L, urine >30 ml/hr.
ii. Systemic hemodynamics: goal SBP > 90 mmHg and BP pulsatility > 20–30 mmHg.
iii. Invasive right heart cath hemodynamics: goal SvO_2 >55%, cardiac index >2.2, CPO >0.6, RA and PCWP only mildly abnormal (<12 and <18 mmHg, respectively).
iv. Echo may help and may be used as fourth parameter (improvement of LV/RV sizes and contractility, MR/TR improvement).

When the patient meets the 3 axes of hemodynamic criteria on small doses of 1 ± 2 inopressors, the MCS support may be weaned down. If the favorable hemodynamic criteria continue to be met on P2 support for 2 hours, the device is ready to be explanted.

2. Protocols of weaning Impella

There are 2 Impella weaning methods: (i) slow weaning, wherein the power P level (e.g., P8) is reduced by ~2 P levels every 2–4 hours to reach P2; (ii) fast weaning, wherein support is reduced by ~2 P levels every 5–10 minutes quickly to P2. Slow weaning is most used and is best for advanced HF shock, or MI shock without good LV recovery on echo. Fast weaning may be considered in acute MI with excellent LV recovery on echo.

At each level of weaning, recheck the 3 major hemodynamic categories (lactate, BP pulsatility, invasive CO/SvO_2/PCWP/RA). If they deteriorate, resume full support for 24 hours and reattempt weaning 24 hours later; address the cause of failure (e.g., administer more diuresis or small vasodilator dose). If hemodynamics remain stable at low support level, the device may be explanted. Stop anticoagulation and explant Impella once ACT <160 seconds. While Impella is in the LV, do not reduce P support to P0 or P1 at any time as this would prevent the motor from generating enough power, hence retrograde outlet-to-inlet flow would occur toward the LV, a form of severe AI. Once it is decided to explant, Impella may be pulled into the descending aorta, at P2 power, then turned down to P0 just before explant.

Impella contraindications

Impella is contraindicated in critical AS (aortic valve area <0.6 cm^2), as the Impella catheter may worsen the aortic obstruction. It is also contraindicated in moderate or severe AI, and in the presence of LV thrombus. Severe peripheral arterial disease is a relative contraindication.

E. TandemHeart LV assist device

TandemHeart is a left atrial-to-iliac artery bypass. It consists of an extracorporeal centrifugal pump that withdraws blood from the left atrium via a 21 Fr trans-septal cannula and pumps it into the iliac artery (15–17 Fr cannula) at a continuous flow rate of up to 3.5 L/min (15 Fr outflow cannula) or 5 L/min (17 Fr outflow cannula). The iliac flow retrogradely supplies the systemic circulation. The left atrial cannula is inserted trans-septally through the femoral vein. The maximum output depends on the diameter of the outflow cannula. In order to prevent limb ischemia from the large arterial cannula, a sheath is placed antegradely in the femoral artery below the outflow cannula and connected in a Y fashion with this cannula. Similarly to Impella, this percutaneous LVAD unloads the LV and improves subendocardial perfusion, with a potential for more cardiac output increase than Impella CP. While Impella directly unloads the LV volume and pressure, TandemHeart unloads the LV volume but increases the pressure afterload, and is, therefore, less effective in reducing O_2 consumption. Thus, while both devices provide good hemodynamic support and myocardial ischemic protection, Impella is more suited for high-risk PCI or MI, where ischemic protection is the primary concern, whereas TandemHeart is suited for cardiogenic shock, where hemodynamic support is the primary concern. Impella 5.5, which provides both ischemic protection and large flow rate, has lessened the need for TandemHeart.

X. Extracorporeal membrane oxygenation (ECMO)

Peripheral venoarterial ECMO consists of a femoral venous cannula (~23 Fr), a femoral arterial cannula (~17 Fr), an extracorporeal pump (non-pulsatile, e.g., Cardiohelp pump), and an oxygenator. ECMO drains unoxygenated blood from the IVC and returns oxygenated blood through the femoral artery. In the absence of any forward cardiac output, blood will retrogradely flow from the femoral artery toward the upper body. Peripheral ECMO provides a cardiopulmonary bypass wherein oxygenation and flow are *almost* fully provided by the machine (see below why peripheral ECMO should not provide *full* support). ECMO provides flow at ~4–5 L/min. ECMO is particularly useful in:

1. Patients with witnessed VF cardiac arrest who had an immediate start of cardiopulmonary resuscitation, yet a lack of return of spontaneous circulation despite ongoing resuscitation >10 minutes but <45 minutes. *ECMO may be placed at the bedside in a patient with cardiac arrest and ongoing chest compressions, using groin access*.

2. Patients with profound cardiogenic shock and biventricular failure, where LV support alone with Impella may not be enough. This may apply to patients with MI, decompensated-HF shock, or severe myocarditis.

Femoral–femoral ECMO has several caveats that explain why some intrinsic LV output should be maintained:

1. The LV continues to receive venous return from the bronchial and thebesian veins, and thus may overdistend in the absence of some intrinsic LV function. ECMO increases pressure afterload and may make it harder for the intrinsic LV to open the aortic valve and decompress. LV overdistension may lead to coronary compression, irreversible myocardial injury, and pulmonary edema and hemorrhage. The LV needs to be monitored by echo and vented if necessary: this is performed using adjunctive IABP, Impella, or inotropes. LA atrial septostomy may also be used to vent the left heart. While ECMO flow is non-pulsatile, the maintenance of intrinsic LV function leads to a perceptible pulse on the arterial waveform. Some arterial pulsatility (e.g., >10 mmHg), aortic valve opening, and lack of progressive LV dilatation on echo are desired (as in the ECLS-SHOCK protocol).

2. While necessary, the preservation of LV pumping means that the upper body is partly supplied by the LV and lungs rather than the ECMO. Competition between ECMO flow (coming retrogradely through the descending aorta) and intrinsic LV flow may lead to deoxygenation of the brain, coronary arteries, and upper body, especially the right side (Harlequin syndrome). This mainly occurs if the LV function is recovering or well supported while the pulmonary function remains severely impaired. It is monitored by checking the arterial O_2 saturation of the right radial artery (furthest away from ECMO flow). It is treated by optimizing the mechanical ventilation or by switching to a veno-arterial-venous (VAV) ECMO. In VAV ECMO, an additional, smaller oxygenated blood return cannula is inserted into the right internal jugular vein; this directs part of the outflow toward the RA and, consequently, the pulmonary vasculature, which allows more efficient oxygenation of the upper body.

After a few days, ECMO is weaned off by progressively reducing its flow to 1.5 L/min while monitoring systemic perfusion and LV function by echo. Before removal, the cannulae are clamped for 15 minutes to ensure hemodynamic stability. Vasopressors may need to be up-titrated during the weaning process. Pulmonary edema may worsen as venous return increases.

As an alternative to ECMO in patients with biventricular failure and shock requiring temporary support, an ***extracorporeal biventricular assist device*** may be used (CentriMag BiVAD). The cannulae of the right assist device are surgically placed in the RA and PA, while the cannulae of the left assist device are surgically placed in the LV (or LA) and the aorta. The CentriMag pumps, and the optional oxygenator, are outside the body. Alternatively, a single CentriMag pump may be connected to arterial and venous cannulae to form an ECMO circuit. Using a magnetically levitated pump, CentriMag BiVAD or ECMO may be maintained for 30 days and may be more durable and hemocompatible than the portable Cardiohelp ECMO pump.

Veno–venous ECMO drains blood from a femoral venous access and returns it after oxygenation into a jugular access. It is used in patients with preserved circulation but severe respiratory failure, such as acute respiratory distress syndrome. It has shown a mortality reduction during the H1N1 epidemic.

QUESTIONS AND ANSWERS

Question 1. Which of the following is *untrue*?
A. Thrombosis mostly occurs the first month after stent implantation
B. In-stent restenosis mostly occurs 1–12 months after stent implantation
C. Neoatherosclerosis occurs >1 year after stent implantation
D. Risk factors for stent thrombosis are twofold: mechanical or pharmacological issues

Question 2. A patient has 90% mid-LAD stenosis at a bifurcation with a large diagonal branch. The diagonal branch also has 90% stenosis. What is the best PCI strategy?
A. Wire both LAD and diagonal, dilate the LAD, then dilate the diagonal, then stent the LAD while jailing the diagonal wire. Redilate the diagonal only if it has impaired flow post-stenting. No need to stent the diagonal
B. Plan for an upfront 2-stent technique using crush or culotte technique

Question 3. After mid-LAD stenting, a spiral dissection is seen at the edge and is spiraling down distally to the apical LAD, impairing flow across the artery. The patient has chest pain. What type of dissection is this?

Question 4. The dissection of Question 3 becomes subtotally occlusive. What is the next step?
A. Stent distally
B. Stent proximally, at the edge of the stent

Question 5. A patient has an 80% mid-LCx stenosis. The reference vessel diameter is ~3 mm. The lesion is treated with a 3-mm compliant balloon at a high pressure of 19 atm, but the balloon never fully expands and the lesion does not yield. What is the next step?
A. Dilate the lesion with 3-mm non-compliant balloon
B. Dilate the lesion with 2.75-mm non-compliant balloon
C. Use rotablation
D. Use cutting balloon
E. Stent the lesion

Question 6. In patients with multivessel CAD involving the LAD, PCI is an alternative to CABG when:
A. SYNTAX score is ≤22 without diabetes
B. SYNTAX score is <32 without diabetes
C. SYNTAX score is ≤22 regardless of diabetes

Question 7. A patient has CTO of the mid-RCA that is ~5 cm long with heavy calcium. It reconstitutes distally before the bifurcation, through LAD septal collaterals. There is a cap at the occlusion site and the distal reconstitution has a 2.5-mm caliber. What is the first recanalization strategy?
A. Antegrade recanalization with polymer wire escalation
B. Antegrade recanalization with heavy-tip wire escalation
C. Antegrade recanalization with subintimal tracking followed by reentry
D. Retrograde recanalization through the septal collaterals

Question 8. A patient underwent an uneventful PCI of the mid-RCA through a femoral access. The femoral access is closed using a closure device. One hour after the procedure, the patient is noted to be diaphoretic and hypotensive (BP 90/65), with a rise in pulse (from baseline 60 to 90 bpm). On exam, his access site is soft without hematoma. He does not complain of chest pain and ECG is unremarkable. Hypotension does not improve with a quick fluid bolus. What is the next step?
A. Continue fluid administration and check hemoglobin
B. Continue fluid administration, check hemoglobin, and obtain a stat CT scan of the abdomen
C. Take the patient urgently to the catheterization laboratory, perform contralateral femoral access, and obtain iliofemoral angiography

Question 9. Concerning differences between groin hematoma and pseudoaneurysm, which of the following is *untrue*?
A. Hematoma is a clotted blood collection, wherein the bleeding has already stopped (no communication with the lumen)
B. Pseudoaneurysm is a non-clotted blood collection that continues to communicate with the true lumen through the arteriotomy (the arteriotomy is the neck of the pseudoaneurysm)
C. Pseudoaneurysm consists of active bleeding into the blood collection
D. On ultrasound, a hematoma is characterized by a to-and-fro, high-turbulence mosaic flow
E. A hematoma may evolve into a pseudoaneurysm through intrinsic thrombolysis

Question 10. A patient undergoes mid-RCA stenting. At the end of the procedure, it is noted that the ostium of the RCA has been dissected by the guiding catheter. The dissection extends into the right coronary cusp. What is the next step?
A. Refer to cardiac surgery (aortic dissection)
B. Stent the ostium of the RCA and treat the cusp dissection conservatively with clinical and CT monitoring

Question 11. A mid-RCA stenosis has been treated over a polymer wire. The polymer wire has been inadvertently advanced into a small PDA branch. At the end of the procedure, it is noted that the polymer wire tip has perforated the small PDA branch. There is a small myocardial blush in the septum at the level of the branch. This blush only slowly clears. What type of perforation is this?

Question 12. How should the perforation of Question 11 be managed? (choose the false answer)
A. Prolonged balloon inflation distally (~3–5 minutes), close to the level of the perforated branch
B. Rewire the small branch and advance a microcatheter into it. Afterward, remove the wire and inject coils, clot, or fat particles into the excluded branch
C. Reverse anticoagulation

Question 13. A patient has a proximal LAD stenosis and a mid-LAD stenosis. A pressure wire is placed between the 2 stenoses. The FFR number is 0.85. Which of the following statements are true (multiple options)?
A. This number is an adequate representation of the significance of the proximal LAD stenosis
B. Had there not been a mid-LAD stenosis, the FFR number at this level would be >0.85
C. Had there not been a mid-LAD stenosis, the FFR number at this level would be <0.85
D. 0.85 is not a true FFR across the proximal stenosis, as the mid-LAD stenosis prevents the achievement of maximal hyperemia across this proximal stenosis

Question 14. A patient has mid-LAD stenosis of 70%. A pressure wire is advanced in the LAD for FFR. The patient has a small left main with mild ostial disease, which makes the guiding catheter obstruct the ostium and leads to ventricularization of the guiding catheter pressure during engagement. The FFR measured across the LAD while the catheter is engaged is 0.82 (under maximal hyperemia). How will this FFR number change if the catheter is disengaged?
A. FFR will rise (e.g., 0.87), as the guiding catheter was creating additional ostial obstruction
B. FFR will drop (e.g., 0.75)

Question 15. On Figure 39.15, during 1:2 IABP balloon augmentation, identify the assisted systolic and diastolic pressures, as well as the unassisted pressures.

Question 16. Compared to manual compression, femoral access closure devices are associated with all of the following except:
A. Reduced time to ambulation
B. Reduced time to discharge
C. More patient comfort
D. Lower vascular complications
E. Higher bleeding risk

Question 17. Identify the support devices that explain the shift in pressure-volume loop from blue to gray in cases A, B, C, and D (Figure 39.22). For each case, choose between ECMO, IABP, Impella, or TandemHeart.

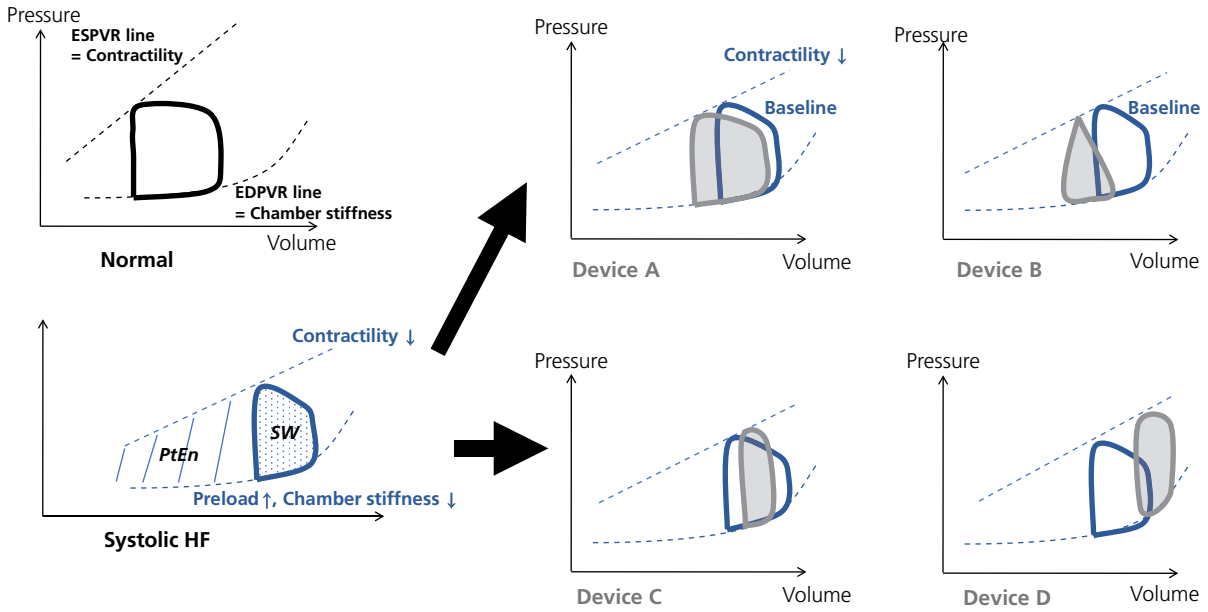


Figure 39.22

Answer 1. D. Risk factors for stent thrombosis are threefold: mechanical, pharmacological, and patient/lesion characteristics.

Answer 2. A. Provisional stenting is preferred to a 2-stent strategy. In a true bifurcation, a critically stenosed diagonal may be dilated before LAD stenting, to reduce the risk of post-stent occlusion. After LAD stenting, the diagonal is only dilated if flow is impaired (NORDIC 3), or, possibly, if it is left with a stenosis >75–90% (EBC-II and PERFECT trials).

Answer 3. Type D dissection.

Answer 4. B. The dissection may initially be stented distally to prevent further propagation, then proximally. However, in cases where the dissection extends too far distally or the distal extent cannot be properly assessed, it is reasonable to stent proximally to collapse the false lumen and block its expansion. This may also be done in unstable patients or in left main or guide-induced dissection.

Answer 5. C. A lesion that does not fully yield during balloon inflation should not be stented. The lack of full balloon expansion is different from the more common elastic recoil, wherein the balloon expands but the vessel quickly collapses back. A stent treats elastic recoil and dissections that occur after balloon angioplasty, but will not be able to expand a lesion that does not yield to balloon angioplasty. The stent will fail to appropriately expand, and a catastrophic stent thrombosis may occur. Rotablation should be used in this case, and one may have to wait 4–6 weeks after balloon angioplasty attempt if a dissection is seen. The pressure of balloon angioplasty is what makes the lesion yield, not the type of balloon. A non-compliant balloon allows high inflation pressure without much of a growth in balloon size and is safer to use for high-pressure inflation >14 atm (i.e., a 3-mm balloon stays close to 3 mm in size). However, the yielding power of high pressure, 19 atm in this case, is the same with either balloon.

Answer 6. A. This is based on the SYNTAX and FREEDOM trials. If SYNTAX score is >32 or diabetes is present, CABG is associated with a mortality reduction in comparison to PCI. If SYNTAX score is 23–32, CABG is associated with a reduction of MI and repeat revascularizations.

Answer 7. C. The "hybrid CTO algorithm" has been developed to allow quick recanalization of difficult CTOs:

1st step: does the CTO have: (i) a clear proximal cap, tapered with no bridging collaterals, and (ii) a robust distal reconstitution target away from a bifurcation point? If so, antegrade recanalization should be attempted.

2nd step: if, in addition, the CTO is <20 mm, especially without calcification or angulation at the CTO level, antegrade recanalization may be performed through the true intima using wire escalation technique. If several adverse features are present, subintimal wiring with a knuckled polymer wire may be performed, followed by distal reentry.

3rd step: in the absence of a clear proximal cap or a robust distal target that provides space for antegrade reentry, retrograde recanalization may be performed.

Answer 8. C. The patient has unexplained hypotension, without major groin hematoma and without suspicion of any cardiac issue (MI, tamponade). The top diagnosis is retroperitoneal hematoma. CT scan should not be performed in an unstable patient as the patient may quickly go into a full-blown shock during the waiting time. A quick bedside echo may be performed before taking the patient to the lab, to rule out tamponade from coronary perforation.

Answer 9. D. A pseudoaneurysm is characterized by to-and-fro flow.

Answer 10. B. Retrograde cusp dissection is generally benign and heals spontaneously, as long as the ostium is stented to seal the dissection entry site. It does not require aortic surgery. CT scan may be performed and repeated to ensure the dissection does not antegradely extend into the ascending tubular aorta, in which case surgery may be needed. Surgery is particularly indicated when the dissection extends >4 cm in the ascending aorta or if the cusp dissection is causing severe AI. Ostial coronary dissection induced by a guide is a major coronary dissection that readily progresses to occlusion. The coronary ostium should be treated with stenting.

Answer 11. Type 2 perforation.

Answer 12. C. If, after prolonged inflation, myocardial blush continues to be seen during contrast injections, distal delivery of coil or fat is the next therapy. Reversing anticoagulation is not initially necessary, and may lead to extensive thrombus formation during prolonged balloon inflation.

Answer 13. C and D. Local FFR across each stenosis is not a true FFR and is a higher number than the true FFR, as maximal flow cannot be achieved across each stenosis, and thus maximal pressure drop cannot be achieved. Only the summation FFR, obtained by placing the wire past all stenoses, is an adequate representation of the significance of the overall disease. The true local FFR across the proximal stenosis may be obtained after treating the mid-LAD stenosis.

Answer 14. B. When the guiding catheter creates an ostial obstruction, it prevents maximal hyperemic flow and thus maximal pressure drop at the level of the lesion (serial stenoses concept). FFR at the level of the lesion is, thus, falsely increased. Guide pressure (Pa) ventricularization at rest or with hyperemia is a hint to this phenomenon. The guide needs to be withdrawn in the aorta during FFR measurement, allowing a proper drop of the FFR number.

Answer 15. In 1:2 mode, the assisted pressures are the 2 pressures that immediately follow augmentation, while the *unassisted* pressures are the 2 pressures that immediately precede augmentation (*to the left* of it). The systolic pressure over which the balloon inflates is actually an unassisted pressure. The assisted systolic and diastolic pressures are lower than the unassisted systolic and diastolic pressures, respectively.

Answer 16. D. According to a large meta-analysis of randomized trials (Koreny M et al, JAMA 2004),[8] closure devices are associated with increased risk of hematoma, pseudoaneurysm, and limb ischemia. The effect was neutral in the more modern ISAR-Closure trial.

Answer 17. A is IABP, B is Impella, C is TandemHeart, and D is ECMO. On the baseline pressure-volume loop, stroke volume corresponds to the width of the loop, while stroke work (SW) corresponds to the area of the loop. ESPVR slope (also called Ees slope) corresponds to contractility, while points along this slope correspond to afterload (a lower point means less afterload). Besides stroke work, the area contained to the left of the loop also affects myocardial oxygen consumption and is called potential energy (PtEn): it represents the residual tension of the myocardium after ejection. Imagine pushing an object and keeping your arms up at the end of the push: residual energy is required to keep the arms up, and this corresponds to PtEn. The *summation of the potential energy area and the stroke work area is called pressure-volume area (PVA)* and is the best indicator of myocardial O2 consumption per beat. As such, a leftward shift of isovolumic contraction reduces O2 consumption. The following effects are noted:

- ***IABP*** reduces afterload on the ESPVR line, reduces preload on the EDPVR line, and increases stroke volume; but the myocardium itself is increasing its stroke work, hence the reduction in O2 consumption is limited.
- ***Impella*** dramatically reduces preload but also afterload, as the LV systolic pressure becomes uncoupled and lower than aortic pressure (work is carried by Impella); this dramatically shrinks SW and PtEn.
- ***TandemHeart*** reduces preload, as it empties the LA, but increases LV afterload, as it "dumps" pressure retrogradely in the aorta. It lowers the EDPVR point but raises the ESPVR point: it reduces stroke work, but the potential energy is increased. As such, it reduces O2 consumption, but less effectively than Impella.
- ***ECMO*** increases preload as it does not directly empty the LV, which continues to receive bronchial venous return, and increases afterload. ECMO provides the fullest support of the systemic circulation, yet increases PVA and O2 consumption the most. This is attenuated by venting the LV (combining ECMO with Impella or IABP).

1. FRACTIONAL FLOW RESERVE (FFR)

A. FFR concept and application

FFR is measured using a 0.014" coronary pressure wire that has a micromanometer 3 cm from its floppy tip (at the junction of the radiopaque distal tip and the radiolucent part of the wire). This wire is advanced into the coronary artery and measures pressure distal to the stenosis (Pd). This pressure is compared to the aortic pressure (Pa) obtained through the guiding catheter. In a simplistic way, FFR compares pressure distal to the stenosis to pressure in the aorta (Pd/Pa) under maximal hyperemia. However, FFR actually aims to evaluate the ratio of maximal myocardial flow in the presence of a stenosis to the theoretical maximal myocardial flow had there not been a stenosis. Since myocardial flow = microvascular flow = pressure/microvascular resistance, maximal microcirculatory vasodilatation needs to be achieved in order to make pressure correlate linearly with flow (Figure 40.1). In a patient with a significant stenosis, flow may be normal at rest but does not increase enough with maximal vasodilatation; thus, vasodilatation allows the calculation of the maximum achievable flow ratio (corresponding to exertional flow).

The drop in flow across a stenosis corresponds to the severity of luminal narrowing, the length of stenosis, the extent of viable myocardium supplied by the artery, and the presence of collaterals (Figure 40.2). A 75% mid-LAD lesion supplying a normal anterior wall is more likely to be significant than a 75% small diagonal stenosis or 75% mid-LAD stenosis supplying an infarcted anterior wall.

The preferred hyperemic stimulus is intravenous adenosine administered through a central venous line or a large antecubital vein. The FFR number obtained before adenosine administration is simply a drop in pressure across a stenosis and does not correspond to a drop in flow; "baseline FFR" or "pre-adenosine FFR" are inappropriate descriptions, "baseline pressure ratio" being the appropriate characterization of the ratio obtained before adenosine administration. After adenosine infusion, the myocardial flow increases because of microcirculatory dilatation, the pressure further drops across the lesion (Figure 40.2), and, more importantly, this additional pressure drop correlates with an actual flow drop, i.e., FFR.

Systemic hemodynamics such as heart rate or blood pressure do not affect the drop in myocardial flow secondary to a coronary stenosis, and therefore FFR remains accurate in these circumstances. Moreover, FFR is more likely to be significant if the stenotic artery provides collaterals. FFR <0.75 is hemodynamically significant and accurately identifies ischemia on non-invasive stress testing with 100% specificity. When FFR is between 0.75 and 0.80, ischemia is generally present but clinical variables are necessary to guide revascularization, whereas FFR>0.80 reliably excludes stenosis-related ischemia (>90% NPV). *Yet, a stenosis may be associated with ischemia despite an FFR>0.80 in the case of microvascular dysfunction* (which causes ischemia per se, and which ↓ the relative significance of the stenosis by ↓ hyperemic flow and the pressure drop across it).

As per ISCHEMIA trial, all 50-80% stenoses require objective documentation of significance by FFR/iFR before PCI, or less favorably by IVUS, unless stress imaging is unequivocally positive in that territory. This requirement may extend to stenoses of up to ***90%*** per FAME trial. Of note, FLAVOUR trial validated IVUS vs FFR in the assessment of moderate disease (Chapter 38.V).

When FFR is <0.80, the distal coronary pressure becomes ventricularized and loses its dicrotic notch (Figure 40.3). In fact, blood flows in the left coronary artery predominantly during diastole. If a stenosis is present, the diastolic drop in pressure is larger than the systolic drop

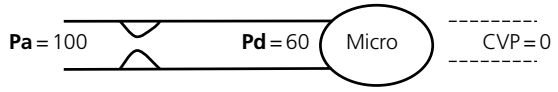
Myocardial flow in the absence of stenosis= Flow 1= (Pa-CVP)/microvascular resistance



Myocardial flow in the presence of stenosis= Flow 2=(Pd-CVP)/microvascular resistance

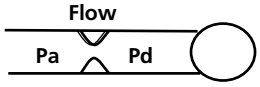
$$\text{FFR} = \frac{\text{Flow 2}}{\text{Flow 1}} = \frac{\text{(Pd-CVP)/microvascular resistance}}{\text{(Pa-CVP)/microvascular resistance}}$$

During maximal hyperemia, microvascular resistance is low and equal in both conditions (in the absence of microcirculatory impairment or in the presence of microcirculatory impairment that is steady over time)

→ Flow and pressure are linearly related

→ FFR= (Pd-CVP)/ (Pa-CVP)~ Pd/Pa

Figure 40.1 Concept of FFR. FFR evaluates the ratio of maximal myocardial flow in the presence of a stenosis to the theoretical maximal myocardial flow had there not been a stenosis. Reproduced with permission of Demos Medical from Hanna EB. Fractional flow reserve. In: Hanna EB, Glancy DL. Practical Cardiovascular Hemodynamics. New York, NY: Demos Medical, 2012, p. 193.



(Pa-Pd)= Flow /resistance across the stenosis

If flow ↑ → More drop in pressure past the stenosis
At maximal hyperemia, flow ↑ and thus Pd further drops.

This further drop in Pd represents a relative drop in flow at maximal hyperemia. Flow rises, but less than the potential rise had there not been a stenosis: e.g., flow ↑ x2, instead of x4 without a stenosis (flow ratio = 0.5)

Figure 40.2 The drop in pressure and thus the drop in flow across a stenosis is dependent on the proximal flow, which depends on the amount of viable myocardium supplied by the artery. Thus, for the same stenosis severity (e.g., 80%), a proximal left anterior descending artery stenosis is more likely to be significant than a small diagonal stenosis (e.g., FFR 0.65 in the former and FFR 0.90 in the latter).

Also, for the same stenosis severity, length increases the significance of a stenosis. According to the Poiseuille law, resistance across a stenosis correlates with (viscosity × length)/radius^4.

in pressure (drop in pressure across a stenosis = flow/ resistance → larger diastolic flow translates into a larger diastolic pressure drop). Therefore, the shape of the pressure curve recorded by the wire is different from the aortic pressure curve, with a flat or ventricularized diastole. During hyperemia, diastolic blood flow increases with a lesser increase in systolic flow, further accentuating the ventricularized shape of the distal pressure signal. FFR <0.80 without distal pressure ventricularization suggests an error in zeroing or error in equalization of both transducers at the aortic level. Pull back the wire to the tip of the guide and verify appropriate equalization.

B. Instantaneous wave-free ratio (iFR) + the nearly similar diastolic wave-free ratio (dFR) + Angiographic FFR

As noted above, microcoronary resistance has to be low and constant in order for Pd and Pa pressures to correlate with flow. iFR and dFR use the concept that microcoronary resistance is lowest and flow is highest in diastole; therefore, in diastole, Pd/Pa ratio drops the most and approximates flow ratio, even without using adenosine. dFR measuress Pd/Pa ratio during the entire diastole, while iFR measures this ratio during the latter ~75% of diastole, where resistance is most stable and lowest. *The cutoff of iFR and dFR significance is 0.89.* Two large trials showed that iFR-guided PCI was associated with long-term outcomes similar to FFR-guided PCI, with slightly less lesions considered significant and stented (29% vs. 37%).

iFR may underestimate the stenosis severity of arteries with very large territories or healthy microcirculation, because the increase of flow in those lesions with hyperemia is massive and FFR would drop far more than a resting ratio. Hence more lesions are significant by FFR than by iFR, but iFR guidance still produces similar long-term outcomes to FFR, including similar rates of MI, TLR, and unplanned revascularizations.

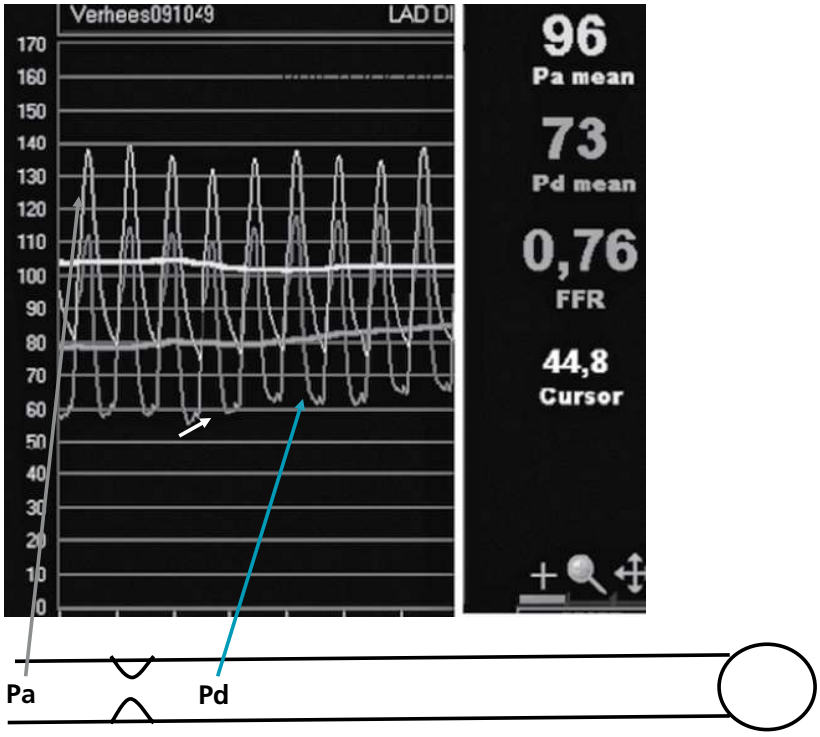


Figure 40.3 The upper tracing illustrates Pa, the pressure at the guide catheter tip, while the lower tracing illustrates Pd, the pressure obtained through the wire sensor. When the lesion is significant with FFR <0.80, the distal pressure takes a ventricularized morphology, wherein the pressure is horizontal or upsloping in diastole (*white arrow*), sometimes with A wave. Reproduced with permission of Demos Medical from Hanna EB. Fractional flow reserve. In: Hanna EB, Glancy DL. Practical Cardiovascular Hemodynamics. New York, NY: Demos Medical, 2012, p. 196.

Based on the Figaro study, FFR+/iFR– discrepancy occurs in 14% of lesions, more so the RCA (25%), where maximum coronary flow can occur during late systole or early diastole, instead of mid-diastole where iFR is measured. The discrepancy FFR–/iFR+ may occur less commonly, in 6% of lesions, particularly in arteries with dysfunctional microvasculature and less hyperemic response to adenosine (e.g., diffuse disease, elderly, CKD, diabetes).

An angiographic FFR (FFR-angio) may be estimated without a pressure wire by computational fluid dynamics, using at least 2 angiographic views of the coronary artery with automatic software-based 3D reconstruction. FFR-angio proved non-inferior to wire-based FFR regarding 1-year CV events in 2 large randomized trials (FAST III, ALL RISE). However, more lesions were deemed significant and stented based on FFR-angio (~44% vs 35%). Also, angiographic FFR using QFR software, which is less automated and more manually intensive, was associated with higher MACE vs. wire-based FFR, particularly overcalling LCx disease.

C. Special situation: serial stenoses (Figure 40.4)

Place the wire distal to all lesions and assess the summation FFR. If FFR ≤0.80, perform a wire pullback maneuver under steady-state hyperemia (intravenous adenosine infusion) and assess the local pressure drop across each lesion. Treat the lesion with the highest focal drop, then reassess FFR to see if the remaining lesion is focally significant. **After treating lesion 2, the flow increases, which leads to further pressure drop across lesion 1, and as a result the true FFR across lesion 1 will be lower than initially expected.**

Serial stenoses crosstalk is exaggerated by hyperemia/high flow. **As such, it may be better to use static non-hyperemic parameters, like iFR**, to assess which lesion is most significant: when you fix lesion 2, flow rises and iFR further drops across lesion 1, but not as much as if you had given adenosine and further increased flow. Thus, the baseline local iFr drop at lesion 1 is closer to the eventual iFr measured after fixing lesion 2. Yet, if one stenosis is very severe, >90%, crosstalk is likely to remain pronounced across the other stenosis even with iFR.

D. Special situation: diffuse disease

If FFR ≤0.80 but pressure pullback reveals a gradual decline in pressure without a focal drop, the patient may not be served by revascularization. This may be seen in patients with mild or moderate diffuse disease and small coronary arteries. In fact, 8% of arteries with mild diffuse coronary atherosclerosis and without a focal stenosis have a graded continuous fall in pressure along the arterial length with FFR <0.75, explaining myocardial ischemia and angina without angiographically obstructive disease.

E. Special situation: ostial disease

If the guiding catheter is too deeply engaged in a patient with ostial disease, the pressure at its tip corresponds not to the aortic pressure but to the pressure distal to the lesion. In this case, both the guiding catheter tip and the pressure wire sensor are distal to the stenosis. The guiding pressure (false Pa) and the sensor pressure (Pd) correlate closely and the FFR is falsely increased.

Thus, while the guide may be temporarily engaged during wiring, it must be disengaged when FFR measurements are obtained. Damping or ventricularization of the guide pressure upon engagement, if present, may be used to confirm engagement then to confirm disengagement as damping resolves.

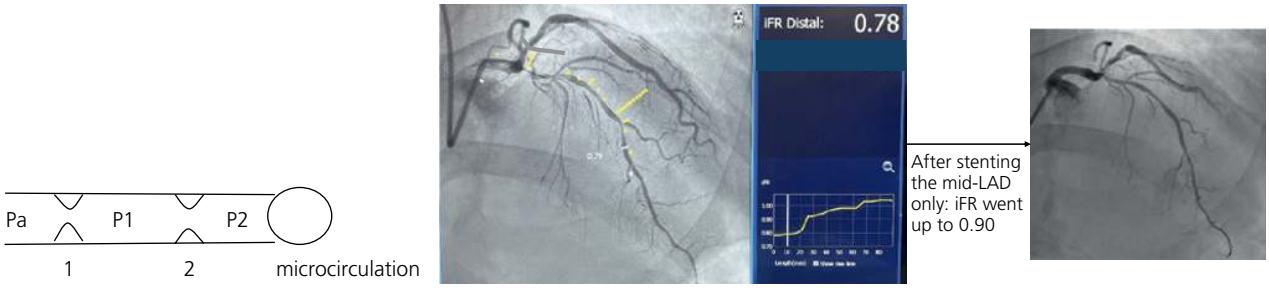

Figure 40.4 (a) Serial stenoses. The calculation of local FFR across each stenosis under maximal hyperemia, i.e., P_1/Pa and P_2/P_1, underestimates the true severity of each lesion; had there not been another lesion, the local flow across each lesion would be higher and the pressure drop across each lesion would be higher than estimated by the local FFR. In fact, P_1 does not have a linear correlation with the myocardial flow past lesion 1, as the presence of lesion 2 prevents maximal hyperemia past lesion 1, and thus, P_1/Pa and P_2/P_1 are not true FFR values. P_2, the summation of pressure drop across both stenoses, linearly correlates with myocardial flow past lesion 2, and P_2/Pa is an adequate estimate of myocardial flow drop across all lesions.

Because iFR is not reliant on maximal hyperemia, the cross interactions between lesions and the effect of each lesion on the iFR of the other is not as dramatic. The local iFR drop past each lesion is a more reliable estimate of severity than local FFR: local iFR2 (P_2/P_1) more closely approximates the eventual true iFR2 measured after fixing lesion 1.

(b) "iFR coregistration" software allows an overlay of the local iFR values onto the angiogram during pullback. Each dot corresponds to 0.01 drop in iFR. One can measure which lesions need to be covered with stenting to get a final iFR >0.89. In the patient shown, the mid-LAD got stented and the proximal LAD was left untreated: iFR went up as predicted by the local mid-LAD iFR drop pre-PCI.

On the other hand, when assessing a downstream coronary lesion in a patient who has moderate ostial disease or a small ostium that damps upon guide engagement, deep guide seating creates an ostial obstruction and prevents maximal hyperemic flow, and thus maximal pressure drop at the level of the lesion (serial stenoses concept). ***FFR at the level of the lesion is, again, falsely increased. Guide pressure (Pa) ventricularization at rest or with hyperemia is a hint to this phenomenon.*** The guide needs to be withdrawn in the aorta during FFR measurement.

F. Artery supplying an old infarcted myocardium: value of FFR in assessing residual ischemia and viability

When part of the territory supplied by a coronary artery is infarcted, this territory receives reduced myocardial flow, and thus the maximal achievable flow across this myocardial territory is reduced. Also, the hyperemic microcirculatory response of a chronically infarcted myocardium is impaired. Thus, suppose that a patient with no history of anterior myocardial infarction has a 70% mid-LAD stenosis and FFR 0.70. If that same patient with the same LAD stenosis has a history of myocardial infarction with necrosis of three-quarters of the supplied territory, FFR may end up being ~0.85, and *there may not be a significant difference between the resting and hyperemic pressure ratio (impaired microcirculation)*. It has been shown that patients who are positive for residual ischemia after myocardial infarction, as assessed by nuclear imaging, have lower values of FFR compared to patients without residual ischemia. In the infarcted territory, FFR <0.75 identifies residual ischemia that is completely reversible with stenting with a specificity of 100% and a sensitivity of 87%. In another study, FFR ≤0.71 had an 88% positive predictive value for significant myocardial recovery after revascularization.

G. FFR vs. nuclear perfusion imaging in multivessel disease

Myocardial perfusion imaging (MPI) techniques are based on the concept of relative flow reserve (i.e., comparison of hyperemic flow in a stenotic artery vs. hyperemic flow in a non-stenotic artery) and require the presence of at least one normal vascular bed to demonstrate ischemia. In one study, despite angiographically severe 3-vessel coronary artery disease, myocardial perfusion imaging showed no defect in 18% of patients and a single-vessel disease pattern in 36% of patients.

A nuclear substudy of the FAME trial found that in patients with angiographic multivessel disease, ~50% of vessels with FFR <0.80 were not identified on nuclear imaging, and *34% of patients with ischemia by FFR had a negative nuclear scan*.

H. Left main disease: FFR and IVUS

The assessment of left main lesion severity by angiography is subject to large inter- and intra-observer variability, particularly for 30–60% stenoses. In left main disease, several prospective studies have shown that deferral of coronary artery bypass grafting (CABG) based on FFR >0.80 is associated with good long-term outcomes, similar to the outcomes of patients with left main FFR ≤0.80 who receive CABG.

IVUS may be used to guide left main revascularization. However, various studies have provided various cutoffs for what should be considered significant left main disease. While one retrospective study found that the lack of revascularization of a stenotic left main artery with a minimal lumen area <7.5 mm^2 was associated with poor outcomes, other studies have found different cutoffs, such as a minimal lumen area <6 mm^2, or a minimal lumen diameter <2.5 mm. The functional significance also depends on the patient's original left main diameter and the presence of branch vessel disease (LAD or LCx disease). In fact, a cutoff of 4.5 mm^2 best correlated with functional significance in a Korean study. Additionally, the lack of coaxiality and the potential oblique luminal distortion may overestimate the minimal luminal area. Hence, IVUS of the LM should be performed from 2 different angles, one through an LAD wire and the other through an LCx wire.

FFR seems to provide a more uniform and reproducible assessment of the significance of left main disease, but FFR has limitations as well: the frequent presence of concomitant lesions in the LAD, LCx, or both interferes with an isolated evaluation of the left main lesion. ***Left main FFR is falsely increased in the presence of severe LAD or LCx disease (serial stenoses concept)***. Let's take the example of a patient with proximal LAD stenosis: even if the wire is placed in the LCx, the maximal flow across the left main continues to be impaired by the LAD stenosis, and FFR is underestimated. Placing the FFR wire in the mid-LAD provides an adequate assessment of the

summation flow drop across the left main plus LAD, and may justify CABG without knowing the exact significance of the left main disease. Isolated assessment of the left main is more critical in patients with proximal LCx disease and no LAD disease, in whom the referral to CABG is based on left main disease. One study has shown that *if the composite FFR of the LM plus the downstream LAD or LCx disease is ≥ 0.65, i.e., not too severe, the isolated LM FFR is adequately approximated by placing the pressor sensor between the LM and the downstream disease*. If the summation FFR is <0.65, the intermediate wire placement will overestimate the true, isolated LM FFR (by an average of ~0.08). Therefore, both FFR and IVUS modalities may be needed in left main assessment.

Since iFR is more helpful than FFR for predicting focal lesion significance in serial disease, iFR may appear logical in assessing LM with downstream disease and has been validated in multiple registries (Define LM, iLITRO). The downside is that LM has a large flow and may get a pronounced pressure drop with hyperemia, making iFR less suitable than FFR from that point of view. In fact, 10% of intermediate LM stenoses are FFR+/iFR-, and 10% are FFR-/iFR+ (iLITRO). As such, the iLITRO registry suggests that in difficult cases, indeterminate LM may be best assessed by IVUS, iFR, and FFR, and considered significant when 2 of the 3 are abnormal.

2. COMPLEX PCI LESION SUBSETS

I. Bifurcation stenoses

A. Classification

Bifurcation stenoses are classified according to the Medina classification (Figure 40.5). Most importantly, distinguish **true bifurcation** from **non-true bifurcation**: true bifurcation means ≥50% stenosis involves both the main branch (MB, proximally and/or distally) and the side branch (SB).

Then classify true bifurcation in 2 subtypes: (i) **simple true bifurcation**; (ii) **complex true bifurcation** wherein the disease involving the SB is not just ≥50%, but ≥90% in non–left main bifurcation and ≥70% in left main bifurcation (such as ≥70% LCx) AND is long ≥10 mm, AND has additional complex features (calcifications, heavy plaque burden or small diameter of the MB, angle <45° or >70°) (DEFINITION study and DK-crush V criteria).

B. Risk of SB occlusion

If the SB originates from a lesion in the MB but is normal or has <50% stenosis (non-true bifurcation), the risk of SB occlusion is very low (<2–3% per NORDIC 3 and CROSS and V-Resolve study).

When the SB ostium has >50% stenosis AND arises from the MB lesion (as in true bifurcation), the risk of SB occlusion is high (4–18%, up to 18% in complex true bifurcation with a small MB diameter close to that of the SB [V-Resolve study]).

C. MB stent sizing – Mechanisms of SB narrowing after MB balloon or stenting (Figure 40.6) – Carina shift and prevention by proximal optimization technique (POT) (Figure 40.7)

The MB stent is sized to the distal MB and extended >6–8 mm proximal to the carina. Based on Finet's law, the diameter of the proximal main vessel is ~2/3 the sum of its 2 branches. Accordingly, POT involves proximal dilatation of the MB stent, proximal to the carina, with a larger balloon that equals 2/3 of (distal MB diameter + SB diameter). The POT balloon is positioned just proximal to the carina. It is a larger balloon (~0.5–1 mm larger), but does not inherently mandate a higher inflation pressure. Stents can typically be overexpanded by 1–1.5 mm beyond their nominal sizes using POT (refer to specific manufacturers' stent charts).

D. Treatment approach

There are 2 major treatment strategies:

1. **Stepwise provisional strategy: a planned 1-stent strategy in the main branch**
   - Followed by provisional SB ballooning if needed
   - Followed by provisional SB stenting if needed

   Within the provisional strategy, there are 2 sub-strategies:

   1′. **Leave-it-alone technique:** SB is wired but otherwise is not touched at all unless it occludes. No pre- or post-ballooning is performed.

   1″. **Provisional technique with SB ballooning after MB stenting** (± SB ballooning before MB stenting)
2. **Planned (upfront, systematic) 2-stent strategy**

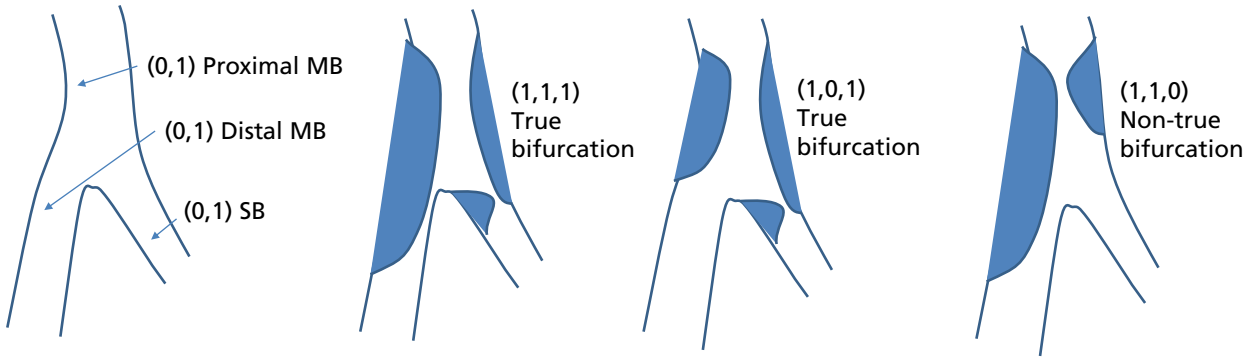

Figure 40.5 Medina bifurcation classification. A score of 0 (<50% stenosis) or 1 (≥50% stenosis) is assigned to proximal MB, then distal MB, then SB. In a true bifurcation stenosis, there is disease in both MB (proximal and/or distal) and SB. (1,1,1), (1,0,1), and (0,1,1) are true bifurcation stenoses, while (1,1,0), (1,0,0), or (0,1,0) are non-true bifurcations stenoses.

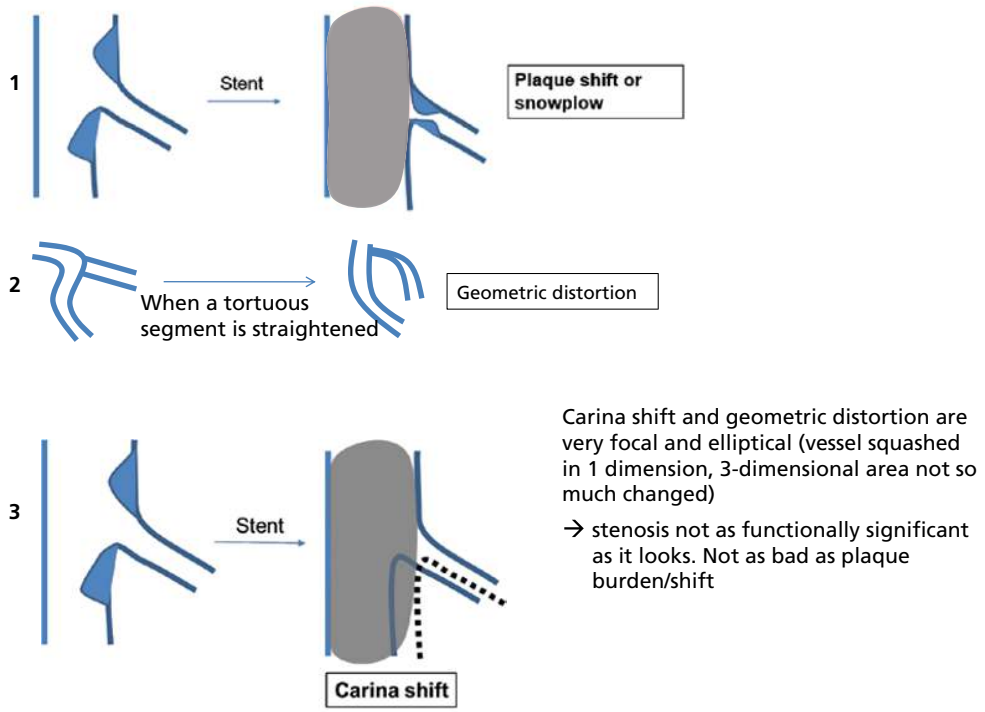

Figure 40.6 Three mechanisms of SB narrowing after MB stenting:

1. Plaque shift, which depends on MB plaque burden.
2. When MB is straightened, the carina gets shifted up, and this may create SB pinching.
3. Carina shift: moving the distal vessel forward narrows the SB, particularly when the stent in the distal MB is oversized. This is at least as important as plaque shift in causing SB narrowing.

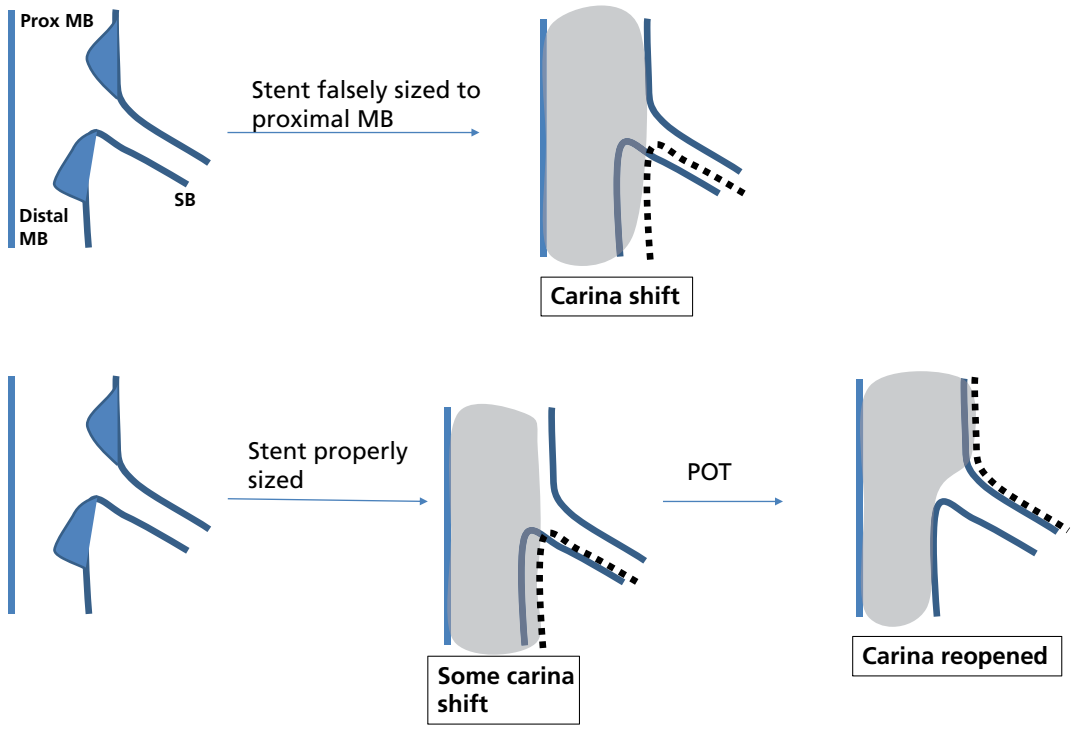

Figure 40.7 Mechanisms of carina shift. The proximal MB diameter normally = 2/3 (distal MB + SB). This is the fractal law; for example: proximal MB ~3.5 mm, distal MB 3 mm, SB 2.5 mm. The MB stent is sized based on distal MB, then the proximal portion is post-dilated with a balloon sized to the proximal MB: this is called the proximal optimization technique (POT). Oversizing the stent distally narrows the SB via carina shift. On the other hand, POT of MB enlarges the SB ostium, as it expands the upper portion of the SB and opens the stent struts into the SB. SB stenosis can improve after POT, even without touching the SB.

Non-true bifurcation is generally treated using the provisional (1′) leave-it-alone strategy. In this case, SB narrowing is usually caused by carina shift, is often not hemodynamically significant, and does not warrant any intervention unless SB flow becomes impaired, or SB stenosis becomes >75% in LM bifurcation stenting (LCx usually) (Figure 40.8). Data suggests that *in non-true bifurcations and even some simple true bifurcations, dilatation of the uninvolved SB is not beneficial* and may even worsen MB outcomes, unless the SB TIMI flow becomes <3. *Even severe (>75%) SB stenosis developing after MB stenting is accepted*. This was shown in CROSS, NORDIC III, and KISS trials for non-LM disease; SMART-STRATEGY trial and COBIS registries for both LM and non-LM; and EXCEL analysis for LM disease. In these studies, SB dilatation/final kiss provided no benefit in 1-stent strategy, with a trend toward more stent thrombosis (EXCEL), more peri-PCI injury (SMART), or more MB restenosis (SMART, CROSS, COBIS I registry).

Simple true bifurcation is generally treated using the provisional (1″) strategy. After MB stenting, SB ballooning is sometimes performed (for >75% stenosis), but SB stenting is reserved only for persistent >90% SB stenosis despite ballooning (Figures 40.9, 40.10). FFR studies have shown that SB narrowing that occurs or worsens after stenting is often functionally non-significant (~75% of the time), particularly when the narrowing is <90%. Planned 2-stent strategy increases procedural time, with a trend toward more periprocedural MI, without improving outcomes in this group (LM trials: EBC main, DK-CRUSH V LM simple subgroup; non-LM trials: PERFECT, NORDIC IV, EBC II, DK-CRUSH II Trials). In modern trials, ~20–25% of stepwise provisional cases eventually receive a provisional second stent.

Complex true bifurcation is generally treated with planned upfront 2-stent strategy, which, in this group, reduces future target vessel failure and MI (mainly in relation to SB), and even periprocedural MI as it reduces acute SB occlusion (DEFINITION II Trial, DK-CRUSH V LM complex subgroup). However, mortality is comparable to a provisional strategy, which may remain acceptable in technically difficult cases.

Two ideas apply to all bifurcation stenting:

- POT: larger balloon dilatation of the proximal MB in all strategies, provisional or 2-stent.
- Final kissing balloon inflation in any 2-stent strategy and in provisional strategy when SB post-dilatation is performed. Avoid final kissing inflation in the leave-it-alone strategy.

There are 3 major 2-stent strategies, which may be used in a planned fashion or provisionally: TAP technique, mini-crush technique (single-kiss or double-kiss [DK] mini-crush), and culotte technique (Figure 40.11). These techniques may be used in provisional stenting approaches when the SB result is poor despite ballooning: >90% residual stenosis or impaired flow.

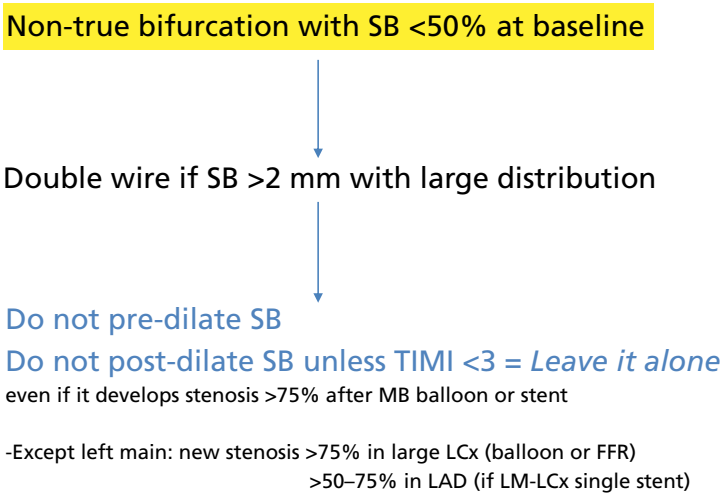

Figure 40.8 Management of non-true bifurcation disease. Derived from SMART-STRATEGY, NORDIC III, and CROSS trials. LM subset numbers derived from SMART-STRATEGY and EXCEL trial design.

Bifurcation with SB >50% (true bifurcation) + SB >2.25–2.5 mm with significant territory

Simple true bifurcation

Stepwise provisional stenting

-Predilate SB if critical or heavy Ca, just before MB stenting
-Stent MB
-Dilate proximal MB with larger balloon (**POT**)

Residual or worsening SB >75–90%?

yes

-Rewire SB (distal strut) with *non-polymer* wire, while keeping the jailed wire
-Post-dilate SB *vs. FFR*
-**Kissing balloon** and +/– re-POT of MB

SB TIMI <3 *or* severe dissection *or* persistent SB >75–90%?

yes

-Provisional T and Protrusion (TAP)
+/– culotte
+/– reverse crush

Complex true bifurcation:

*SB >90% (non-LM) or >70% (LM)
+
*lesion >10 mm
+
*heavy calcium, angle>70 or <45, long MB disease>25 mm, small MB<2.5 mm

Consider 2-stent strategy:

-Crush: SK mini or nano
Crush: DK mini
-Culotte
-TAP stent
-Perfect T~Nanocrush

Rewire stent twice

Figure 40.9 CENTRAL illustration. Management of true bifurcation disease. Only *complex* true bifurcation warrants upfront 2-stent strategy. This implies true bifurcation with several additional features: very severe SB narrowing (>90% in non-LM), long >10 mm, and with additional complexity features (e.g., calcifications, small MB that approximates SB diameter or has long plaque burden).

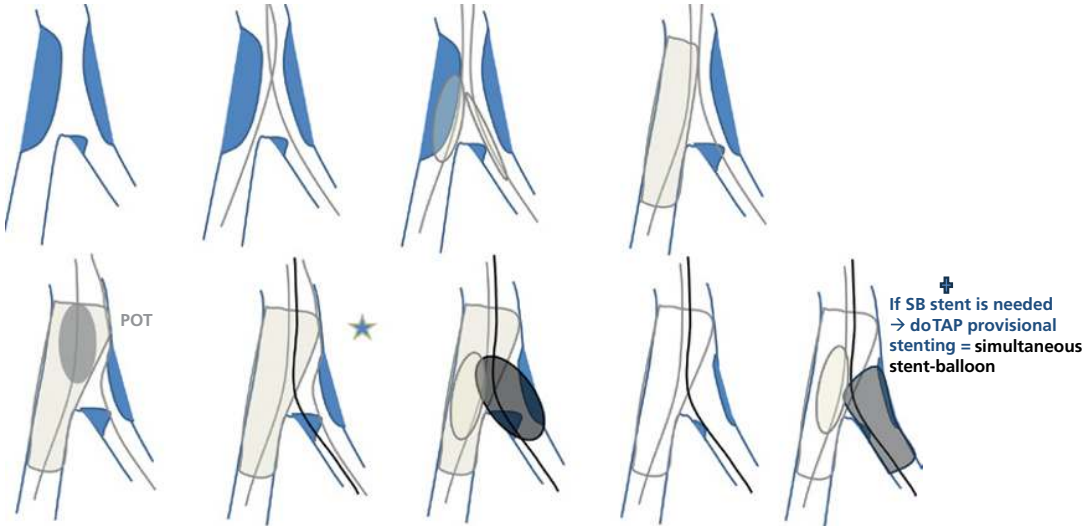

Figure 40.10 Steps of provisional stenting technique, which may be done in a 6 Fr guide:

- Double wire MB and SB, then dilate MB +/– SB.
- Stent MB with a stent sized to the distal MB, undersized proximally.
- POT the stent with a larger balloon that equals 2/3 of (distal MB + SB): The POT balloon is positioned just proximal to the carina. It is a larger balloon (~0.5–1 mm larger), but it is not necessarily inflated at a higher pressure.
- Rewiring is the single most difficult step (*star*). POT helps rewiring in 3 ways: (i) it apposes the proximal stent and prevents the wire from going behind the struts; (ii) by stretching the stent at the carina, it opens the stent cells and improves SB access; (iii) it opens the SB ostium and reduces SB stenosis. Rewire through the distal MB struts preferably. After rewiring, remove the jailed wire.
- Balloon SB, then do simultaneous kissing balloons, using an MB balloon sized to the distal MB. The 2 balloons overlap in the proximal MB, and their summation in the proximal MB is equal to 2/3 of their size summation (e.g., the size of two 3-mm overlapping balloons is 4 mm, not 6 mm).
- If provisional SB stenting is needed, TAP technique may be used (SIMULTANEOUS STENT-balloon technique): (i) position a stent in the SB and deploy it while a balloon is simultaneously stationed in the MB; the SB stent protrudes minimally in the MB, ~1–2 mm, enough to cover the upper, non-carina arm; (ii) the stent's balloon is then pulled back slightly and inflated at high pressure; (iii) the MB balloon and the stent's balloon are then simultaneously inflated. This may be done in a 6 Fr guide, as long as the simultaneous stent and balloon are ≤3 mm.

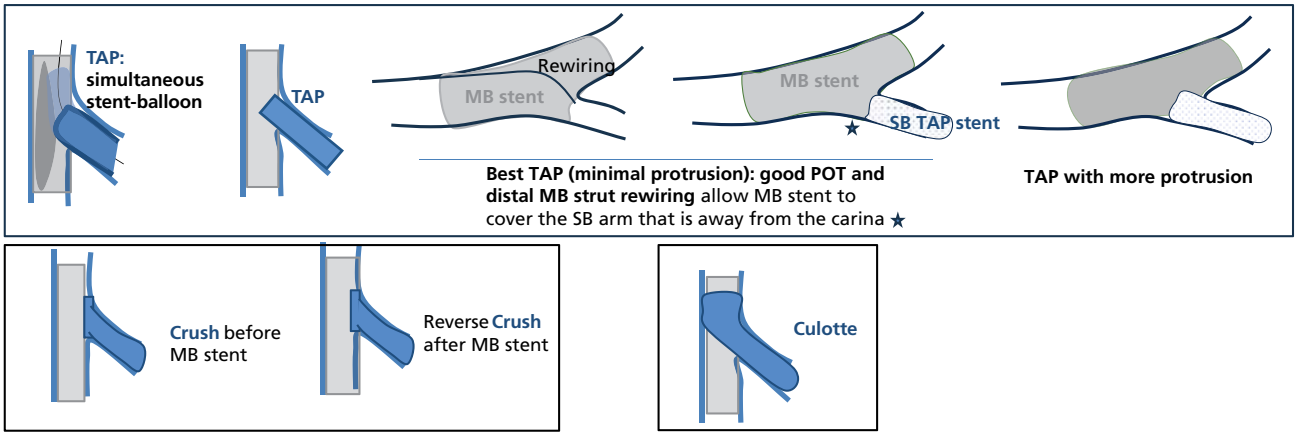

Figure 40.11 Illustration of 2-stent techniques, which may be used in a planned fashion or in a provisional fashion when the SB becomes severely impaired with poor balloon result (>90% stenosis or impaired flow):

- TAP leaves a small neocarina, which is a piece of metal hanging in the middle of the MB. The neocarina is minimized if *one makes the MB stent cover the non-carina arm of the SB*, the arm that is most difficult to cover (*star*): this is achieved with a proper POT and with rewiring the SB via distal MB struts, allowing those struts to get lifted toward the non-carina arm during balloon inflation. In such case, the SB stent does not need to significantly overhang in the MB lumen.
- Crush → SB stent is smashed to the wall, with no neocarina in the lumen. SB is stented before MB in the planned 2-stent mini-crush (single kiss or double kiss [DK] mini-crush). SB is stented after MB in provisional SB crush stenting (reverse mini-crush). Mini-crush means <2–3 mm of the SB stent is overhanging and crushed in the MB.
- Culotte: SB stent goes all the way back and touches the opposite MB wall. The full circumference of the SB stent partially overlaps with the full circumference of the MB stent. There are 2 full circumferential layers of stents against the MB wall. Keep the overlapped area as short as possible (mini-culotte).

II. Isolated ostial branch disease, ostial LAD, ostial LCx

For isolated branch disease, such as diagonal or OM, the narrow angle is not usually favorable for a perfect T or nail-the-ostium technique. To avoid either missing the ostium, or the converse, leaving excessive stent struts protruding into the middle of the main vessel (e.g., LAD), the best technique is usually stent crossover from the main artery (LAD) into the branch (diagonal)—resembling a semi-culotte—followed by POT of the proximal MB. Rewiring and ballooning the distal MB depends on the degree of carina and plaque shift, and it is suggested for a stenosis >50–75% (Figure 40.12).

Regarding isolated ostial LAD or LCx disease, the bifurcation angle is more commonly steep 70°–90° than isolated diagonal or OM disease. Hence 2 strategies may be applied: (1) nail the ostium strategy (~ isolated T stenting of the LAD or LCx ostium); (2) crossover stenting from the LM into the LAD or LCx (Figures 40.13, 40.14).

With crossover stent strategy from the LM into the LAD, try to not even touch at all the LCx (wire it but do not pre-dilate it and do not necessarily post-dilate it). There is no evidence that leaving a grid of metal (thin struts) across the LCx ostium is harmful. This likely applies for crossover stenting from LM to LCx in the case of a non-diseased LAD. Such an approach is suggested by the same studies supporting the "leave-it-alone strategy" in non-true and some simple true bifurcations, where SB dilatation/final kiss provided no benefit and was possibly harmful even in the LM position: NORDIC 3, SMART-STRATEGY, COBIS 3 (all of which included LM), and EXCEL. Consequently, provisional LCx dilatation is justified mainly if it develops a >75% stenosis (SMART-STRATEGY).

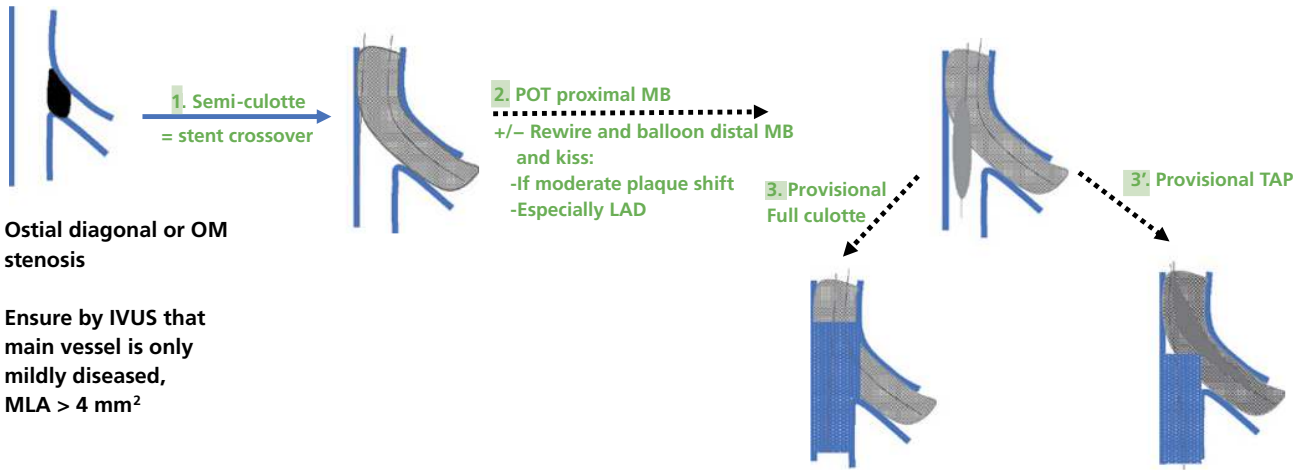

Figure 40.12 Isolated ostial diagonal disease treated with single-stent crossover from the proximal LAD into the diagonal. The stent would extend ~6–10 mm in the LAD to ensure the possibility of POT of the proximal LAD stent. The same approach applies to isolated ostial OM disease. After stenting, the distal MB is rewired and ballooned if it develops >50–75% stenosis (50% for LAD); it is stented if it remains >50–75% stenotic despite ballooning.

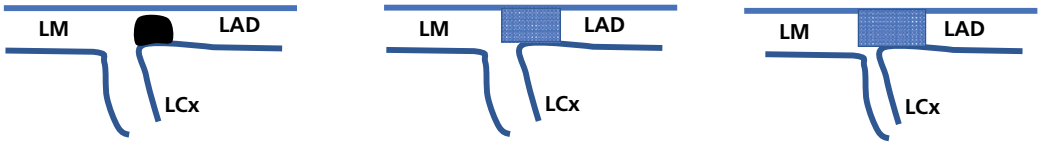
Isolated ostial LAD or LCx:
1.“Nail the ostium” strategy or “floating stent technique”



In true ostial LAD disease with normal LM *AND* LAD-LCx angle ~70°–90°

-Position the stent at the LAD ostium
and
-Make **~1–2 struts (~2–3 mm) hang across the LCx (ideally slightly or halfway through its ostium) or occasionally ~1–2 mm into the LM (if LCx small).**

~Perfect T positioning as 1-stent strategy

Figure 40.13 Nail the ostium technique for ostial LAD disease. Make ~ a couple of struts hang across the LCx or into the LM, to ensure full coverage of the ostium, especially as the heart moves with the cardiac cycle and respirations during stent deployment. Before adopting this strategy, check LM by IVUS and ensure it is not moderately diseased or small and diffusely diseased (<6 mm², +/– even <7.5 mm²), in which case there is a significant risk of longitudinal plaque shift at the edge into the LM. In the latter case, LAD is stented into the LM followed by LM POT. The same technique applies to isolated ostial LCx disease.

Isolated ostial LAD or LCx:
2. Provisional steps of crossover LM-LAD stent (stepwise provisional bifurcation strategy)

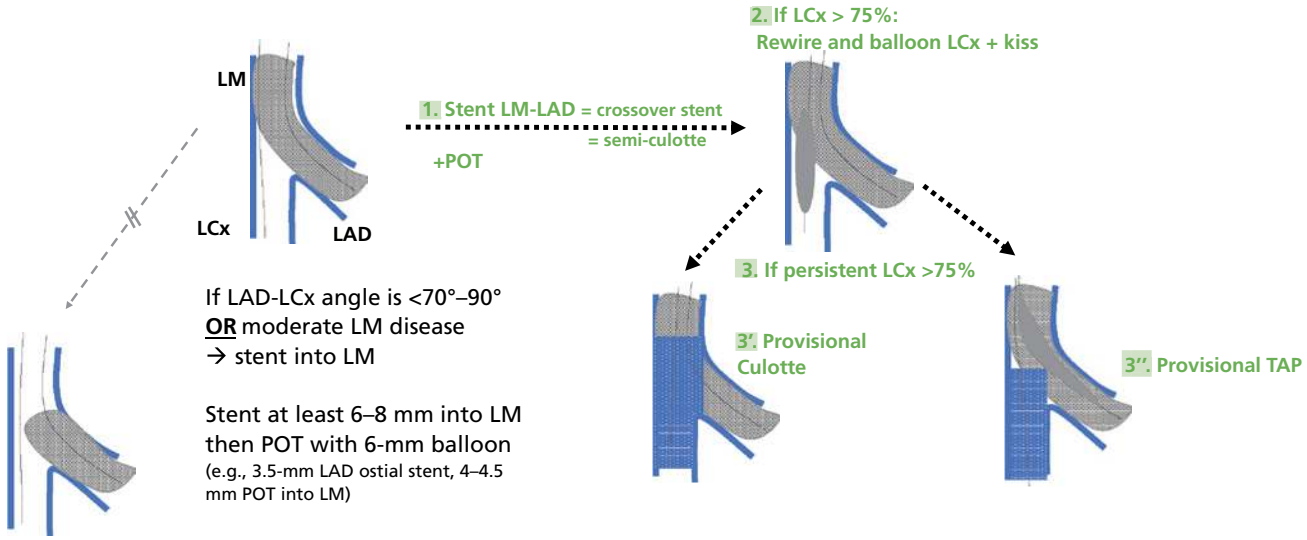


Figure 40.14 Stent crossover strategy for isolated ostial LAD disease. Even if the LM is only moderately diseased (6–8 mm²), there is a risk of longitudinal plaque shift at the edge into the LM, hence the preference for upfront stenting into the LM. The same technique applies to isolated ostial LCx disease: perform crossover LM-LCx stenting, and consider a lower cutoff for provisionally ballooning and stenting the LAD (~50–75%).

III. In-stent restenosis management (Figure 40.15)

Define the mechanism by IVUS/OCT and stent boost: (i) stent underexpansion vs. (ii) in-stent tissue growth. Stent underexpansion may require: *lithotripsy* to fracture the calcium behind the stent, or *laser* to create explosive bubbles that fracture calcium behind the stent (particularly laser passes done *with simultaneous contrast injection*), or rotablation to heat the stent metal and allow the heat to break the calcium behind it.

For in-stent tissue growth, the treatment options are:

- Sandwich DES (=DES inside DES restenosis): this is associated with ~10–15% risk of recurrent restenosis and TLR at 1–2 years (but up to 25% if diffuse ISR and 30s% if occlusive ISR).
- vs. DCB: ~18–20% TLR at 1–2 years
- vs. standalone balloon POBA: ~50% TLR (but ~20–30% if focal ISR)

Either repeat DES or DCB is an option for DES restenosis: Consider DCB for focal ISR, including edge ISR, vs. DES for diffuse ISR.

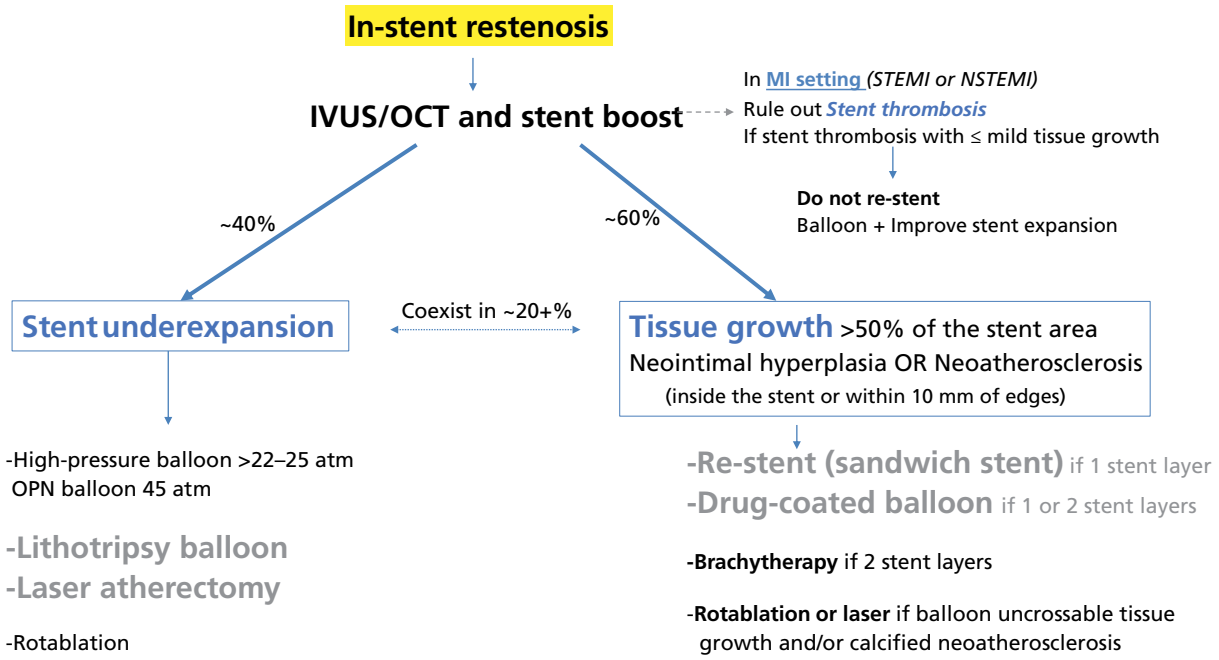

Figure 40.15 Treatment of in-stent restenosis. Do not re-stent a predominant stent underexpansion or a stent thrombosis with <50% in-stent tissue growth.

IV. Long and diffuse disease

Normally, the stent should be implanted from normal reference to normal reference if possible (starting 2 mm before and 2 mm after the lesion); this will avoid edge dissections and edge plaque shift. The reference should have <40% plaque burden on IVUS. In case of diffuse disease with tandem lesions in series, the most severe lesions are stented (spot stenting), while the intermediate ones may be left untreated, although edge plaque burden >50% is suboptimal according to IVUS/OCT studies. FFR or, better yet, iFR may be used to guide PCI in diffuse disease: stent the areas where the pressure drop is largest, as assessed by iFR pullback tracing. If possible, the distal lesion should be stented first, followed by the proximal lesion; this obviates the need to cross the proximal stent with the distal stent. Because iFR is not reliant on maximal hyperemia, the cross interactions between lesions and the effects of each lesion on the local iFR drop of the other are less than with FFR.

While DES length does not increase restenosis rate as strongly as BMS length, very long stenting ("full metal jacket"), even with DES, is associated with a high risk of restenosis and SB compromise and is preferably avoided. Furthermore, long stenting may compromise future placement of bypass grafts and is preferably avoided, especially in the LAD.

The natural progression of stable CAD that is significant but non-critical (50–80% stenoses) is likely slower than the progression of in-stent processes: <10% risk of progression of this stenosis over 1.5–2 years per COURAGE trial, with <2–3% individual risk of MI. This is likely slower than the progression of in-stent processes in long stents: >10% in-stent restenosis at 1 year with ~1–2% stent-related MI, and ~1–2% severe in-stent tissue growth per year beyond 1 year. Hence, in moderate diffuse disease, focal stenting of critical disease may be justified, while medical therapy may be used for moderate disease.

V. Chronic total occlusion (CTO)

CTO implies a total coronary occlusion that is >3 months old. An occlusion may develop progressively over time and lead to an insidious, chronic angina presentation. It may also develop or progress acutely/subacutely leading to STEMI or NSTEMI; when this acute occlusion is not treated early on, it enters the category of CTO 3 months later. Well-developed collaterals may provide flow equivalent to a 50–90%

stenosis, which helps maintain myocardial viability and prevents resting myocardial ischemia. When the coronary occlusion develops progressively rather than abruptly, the myocardial function may be normal at rest or depressed, but not infarcted (hibernating rather than necrotic myocardium). Hibernation is distinguished from infarction by any of the following: persistence of angina, lack of Q waves, or ischemia or >50% tracer uptake on nuclear imaging. Angina status *and* Q waves are most important: **akinesis with *Q waves and without angina often implies infarction*** *and is unlikely to benefit from revascularization*. MRI may be used when viability is questionable.

CTO PCI is indicated in symptomatic patients whose angina is refractory to medical therapy. Four randomized trials have shown that CTO recanalization does not reduce the long-term risk of death or MI. It does not improve overall wall motion or EF (Explore trial), and does not clearly improve the segmental motion of dysfunctional segments (REVASC trial). **It improves only angina and quality of life, as per the Euro-CTO trial**. In addition, opening an occlusion that was associated with a large transmural infarct (STEMI or Q-wave MI), and with a myocardium that is now akinetic and minimally ischemic, is not beneficial and is not indicated (OAT trial). The success rate of CTO PCI can exceed 80% when using a hybrid algorithm, with mortality rates of 0–2% (see Chapter 39, Question 7). The restenosis rate is markedly reduced with DES (~10%).

Six main features predict failure of the antegrade approach to CTO PCI (the first 5 are J-CTO score):

- Any visible calcification across the CTO.
- Sharp angle/tortuosity >45° within the CTO site.
- Presence of an SB at the occlusion point without any stump (the wire will preferentially go into the SB). This, or the presence of thin bridging collaterals, defines an "ambiguous proximal cap."
- Long CTO >2 cm.
- Failed prior PCI attempt.
- Presence of a network of thin bridging collaterals around the occlusion (caput medusa). These are sometimes hard to distinguish from intralesional microchannels, which, by contrast, predict a high success rate. CTO with antegrade, microchannel flow is called functional CTO; the vessel continues to opacify past the CTO in an antegrade fashion.

Polymer-coated wires may be used in a functional CTO to slide through the microchannels. Otherwise, drilling wires with progressively heavier tips are used, with the support of a catheter advanced to the occlusion site. Subintimal passage followed by reentry into the true lumen distally is the preferred technique when multiple adverse features are present, especially long calcified CTO or J-CTO score ≥2. Double arterial access with engagement of the contralateral coronary artery is usually necessary. Contralateral injections allow collateral retrograde filling of the index vessel and thus proper visualization of wire progression. Antegrade vessel opacification via ipsilateral collaterals usually ceases once the wire and catheter are advanced to the CTO site, making contralateral guidance critical in most cases.

VI. Aorto-ostial stenting

Choose a **view** that lays out the junction between the cusp and the ostium, setting them apart, rather than a view where the ostium is partially covered by the cusp (e.g., LAO cranial or straight LAO 15° for the LM, and LAO 40s° for the RCA). Several issues need to be addressed while performing ostial LM or RCA stenting:

1. Guide-induced ischemia and ventricularization on engagement. PCI should be done while limiting the ischemic time, i.e., limiting duration of engagement. This is achieved via **hit-and-run maneuvering of the balloon and stent:** engage and slightly disengage the guide off and on. Engage the guide to wire the lesion and advance balloons and stents, then slightly disengage it between gear positioning and during imaging. If the guide can be stable in a barely disengaged position, wire and stent the lesion while the guide is partially out, without needing the hit and run.

2. Which guides? Use a guide that does not deeply cannulate the coronary origin. For the LCA, JL or Ikari L guides are favored over EBU guides. For the RCA, JR4 may be used, although it is poorly supportive from radial access; hence Ikari R 1, Ikari L ~4, or AR2 guides are generally favored. AL 0.75 may also be used by experienced operators: use it in an elongated fashion rather than a coaxial "duck" shape.

3. Avoid geographic miss. Avoid missing the ostium, and conversely, avoid extending the stent too much in the aorta. The stent should extend ~2–3 mm in the aorta/aortic cusp, beyond the lower edge of the ostium. The lower ostial edge is used as the landmark for stent positioning (Figure 40.16).

4. What maneuvers are required to position the stent exactly at the desired location 2–3 mm into the aorta? The challenge when positioning the ostial stent is the opposite actions and reactions of the guide, stent, and wire (Figure 40.17). This is besides the second major issue, which is stent movement with respiration. To limit these effects:

- Advance the stent in the coronary artery, potentially while the guide is engaged. Then disengage the guide slightly with the left hand while the right hand keeps a back tension on the stent to prevent it from diving in.
- Then pull the stent and position it at the desired position. The stent is pulled with the right hand, while **the palm of the left hand is holding a back pull on the guide**, and the **fingers of the left hand** are not only holding the wire but keeping a back pull on it (to prevent the wire from diving as well). This is the "palm of the left hand" technique (Figure 40.18).

5. Always verify by IVUS that the stent covers the ostium into the cusp (Figure 40.19).

6. The floating wire technique is not generally helpful. It consists of placing a second wire through the guide into the aortic cusp, to delineate the ostium and prevent the guide from diving too much in while pulling the stent; hence it may prevent missing the ostium. However, it may float too far out in the aorta, hence making you position the stent too far out in the aorta. Also, it adds another element to watch, beside the guide and stent; it takes away from the focus on what matters the most.

This limitation of floating wire extends to the Szabo technique, which is a floating wire hooked to the proximal stent strut.

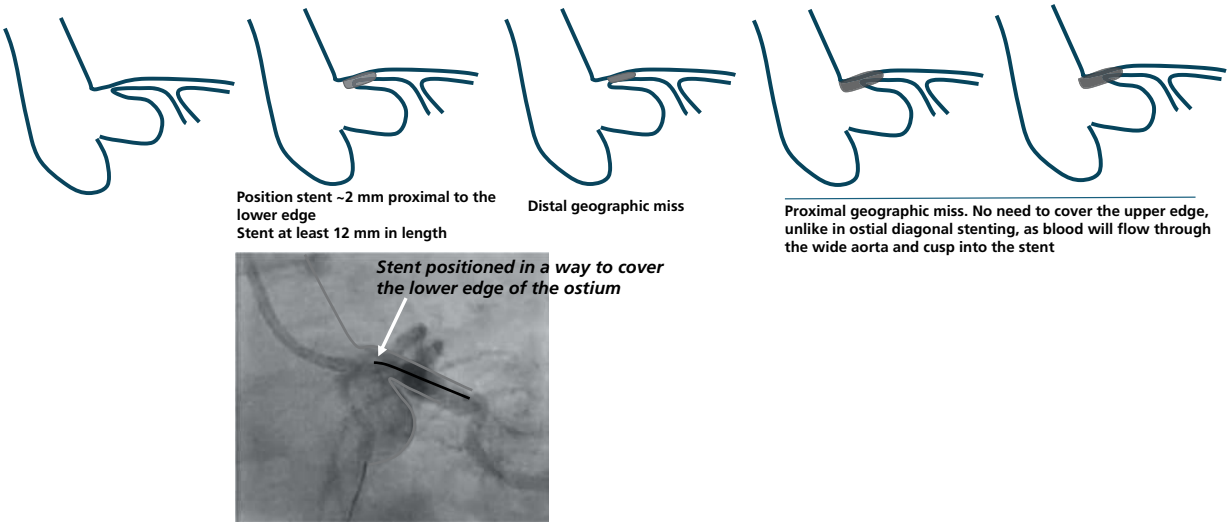

Figure 40.16 In most ostia, whether LM, RCA, or right graft, the lower edge is shorter than the top edge, as the lower edge is at the cusp, while the upper edge is close to the tubular aorta. Perfect positioning is ~2–3 mm proximal to the lower edge, covering the cusp. There is no need to cover the upper edge (unlike in ostial branch stenting), as blood will flow through the wide aorta and cusp into the stent, as long as the stent covers the cusp. Note how the cusp-ostium boundary is well delineated in this view and *can be traced in one line*.

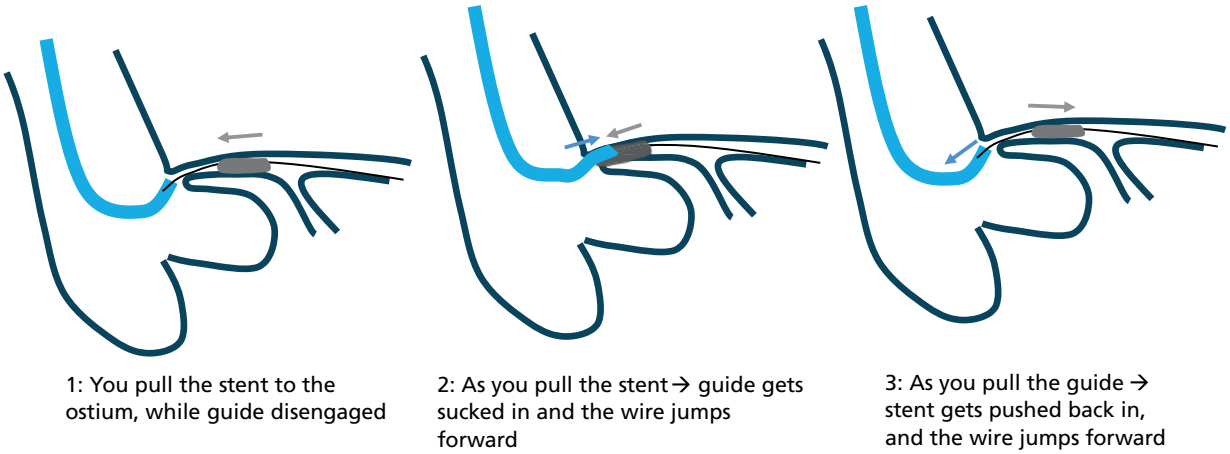

Figure 40.17 Demonstration of the opposite actions and reactions of the 3 elements—namely, guide, stent, and wire—during maneuvering the guide or the stent.

Figure 40.18 Right- and left-hand maneuvers while positioning the ostial stent. Focus on the palm of the left hand, which exerts a back pull on the guiding catheter while the right hand pulls the stent.

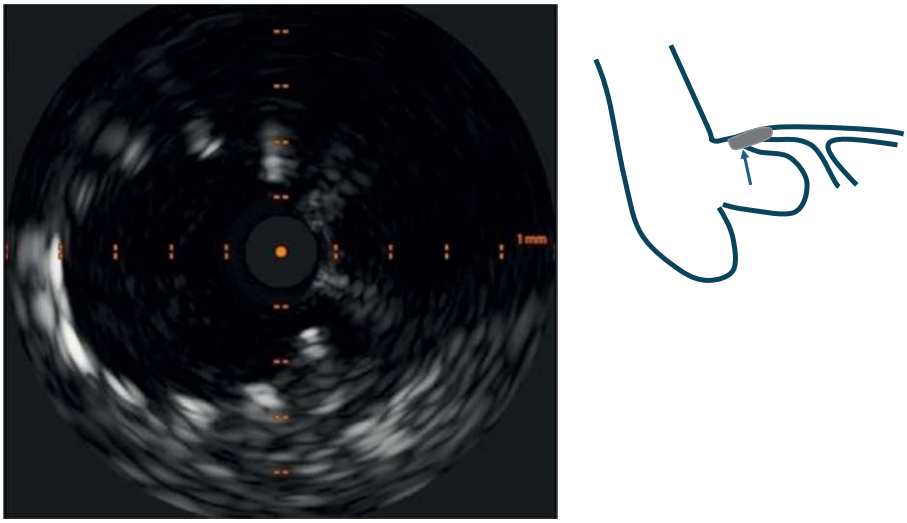

Figure 40.19 IVUS of a properly positioned ostial stent: one part of the stent is touching the wall (this must be the upper ostial border), while another part is in the aorta (this must be the lower ostial border). This means the stent fully covers the lower border and extends beyond it, protruding into the aorta (*arrow*).

VII. Severe coronary calcification

A. Severe coronary calcification is defined fluoroscopically as:

Long (>15 mm) calcium present on both sides of the vessel and obvious on still images, even without cardiac motion and before contrast injection.

By IVUS and OCT, severe calcium is defined by any of the following 3 criteria and *may* dictate calcium modification by atherectomy or lithotripsy balloon (SCAI 2024):

- Arc of calcium 360°
- Arc of calcium **>270° over >5 mm**
- Or calcified nodule (CN). A CN is an **eccentric** piece of calcium **protruding** into the lumen

Additional features that further favor calcium modification, on top of the 3 major criteria above:

- The longer the calcium, the worse it is
- Negative vessel remodeling (lesion EEM < distal EEM) or EEM diameter <3.5 mm. It is harder to fracture the calcium of a smaller vessel as the smaller balloon that gets inflated exerts less wall tension on the lesion. Also, calcium tends to be superficial in a small vessel
- Superficial calcium (top 50% of the intima) is harder to disrupt than deep calcium, as it is more solid and less mingled with soft tissue.
- Minimal calcium thickness >0.5 mm by OCT

B. Calcified nodule, non-eruptive and eruptive

A calcified nodule (CN), whether eruptive or not, is an eccentric piece of calcium **protruding** into the lumen. As opposed to calcified sheets or plate, the key defining feature is the **bulge** into the lumen, likely from fracture of the calcium sheets, hence it is more likely to occur at hinge points and in the mobile RCA, and in areas where calcium has necrotic or heavy lipid core (Figure 40.20). *Even if localized, a CN significantly impairs stent expansion* compared to calcified lesions without nodules and may warrant calcium modification. This is because the calcium is not simply eccentric but high and thick like a "mountain", and because its rounded surface prevents the balloon from gripping it; instead, the balloon rolls around the nodule, overexpanding the softer parts of the vessel. *An eruptive CN is a CN that, in addition, ruptures the cap and often causes thrombus* formation and ACS. Since it causes ACS, eruptive CN is associated with worse long-term outcomes but better stent expansion than non-eruptive CN, as the nodule forms more acutely and has soft elements (thrombus, hemorrhage). Non-eruptive CN bleeds at its base after it fractures the sheets of calcium, and the bleeding calcifies with time, which increases the lesion's calcium burden and rigidity and further impedes stent expansion. OCT is superior to IVUS for defining eruptive vs. non-eruptive nodule:

- Non-eruptive nodule = protruding calcium with thick cap covering the bulge AND no thrombus
- Eruptive = protruding calcium with ruptured cap AND thrombus

A calcified nodule accounts for 4–8% of MI culprit lesions but is much more prevalent in heavily calcified lesions with >180°–270° arc of calcium or lesions considered for calcium modification therapies (40s%). CNs are flanked proximally and distally by calcified sheets and arise from fracture of those calcified sheets, hence they are more frequently found at:

- Sites of hinge motion of severely calcified coronary lesions, such as in the ostial or middle RCA or calcified bends
- Areas of high lipid burden and necrotic core, such as the left main coronary bifurcation and proximal coronary tree. This is because a soft necrotic core inside the calcium facilitates fracture; in fact, CNs have a higher prevalence of necrotic core compared to adjacent calcified regions.

After stenting CNs, re-protrusion or re-growth of CNs inside the stent may happen, and this is likely the predominant reason for target lesion revascularization (TLR) in patients with CNs, besides stent underexpansion. In-stent calcium and in-stent CN may develop *early after stenting* and often culminate in poor outcomes.

Being eccentric, *a CN may not be modified at all by rotational atherectomy if the rotational wire and burr hug the opposite arterial wall* (i.e., wire bias toward the opposite arterial wall); as such, it frequently requires a larger burr. Orbital atherectomy orbits eccentrically, away from the center of the catheter, and is more likely to modify eccentric calcium even if the wire does not hug the calcium; unfortunately, it may also orbit excessively at the noncalcified opposite arterial wall and cause deep dissection or perforation. Even high-pressure balloon is riskier than in other lesions as it may expand excessively toward the opposite arterial wall. Lithotripsy is the best modality for treating eccentric calcium, including CN, if it can cross the lesion.

C. Which severe calcifications mandate calcium modification with atherectomy or lithotripsy

Calcium modification is particularly justified in the following 3 situations:

1. Balloon uncrossable lesion (→ atherectomy) or balloon **undilatable** lesion (→ atherectomy, or lithotripsy balloon if it can cross). A lesion is considered balloon undilatable when a 1:1 sized balloon inflated at high pressure ≥18 atm does not fully expand in 2 orthogonal angiographic views.

2. Within the severely calcified lesions, **the denser and thicker the calcium, and the longer the calcium, the more likely that calcium modification is necessary before stenting** (vs. high-pressure ballooning).

3. The presence of multiple IVUS/OCT severe calcium features: long calcium >270° with spots of 360° calcium, or spots of CN, or negative vessel remodeling. Also, longer severe calcium more readily requires modification.

D. Three questions must be addressed during PCI of severe coronary calcium (Figure 40.21):

1. Does calcium require calcium modification (atherectomy or lithotripsy)? Vs. high-pressure NC balloon ≥20 atm +/– cutting balloon?

2. Which modality: (2) lithotripsy vs. (3) atherectomy (rotational or orbital or laser). The main downside of lithotripsy is its high crossing profile, higher than that of standard balloon and even non-compliant balloon. It may not cross a calcified critical stenosis and requires balloon dilatation and sometimes atherectomy before its application. The *combination atherectomy-lithotripsy* is particularly useful in difficult-to-cross thick or eccentric calcium, where atherectomy shaves the superficial calcium and allows the advancement of lithotripsy, which then disrupts calcium superficially and deeply, in a more concentric and homogeneous way.

3. If atherectomy is chosen: (3) rotational vs. (3′) orbital? When to use laser?

Calcified stenoses that are balloon uncrossable despite proper guide support generally require rotational or orbital atherectomy. A standard or polymer wire is used to cross the lesion and then exchanged for an atherectomy wire via a microcatheter (Rotawire or orbital Viperwire). But what is done if a standard wire crosses the lesion but the microcatheter cannot cross, i.e., the wire cannot be exchanged for the atherectomy wire? Advance the microcatheter to the mouth of the lesion, then directly wire it with the atherectomy wire. If this fails, laser atherectomy may need to be done first, as laser may be advanced over any wire. Laser vaporizes and softens the lesion enough to allow the later advancement of a microcatheter, followed by the exchange for a Rotawire or Viperwire, and finally atherectomy. In balloon uncrossable lesions, orbital atherectomy is a double-edged sword: orbital atherectomy's Viperwire is more maneuverable than Rotawire and may more readily cross the lesion (Viperwire flex 0.012″ body/0.014″ tip, vs. Rotawire 0.009″ body/0.014″ tip); however, the orbital burr itself has a 5-mm nose cone that may prevent it from engaging the lesion, while the rotational burr directly engages and penetrates the lesion.

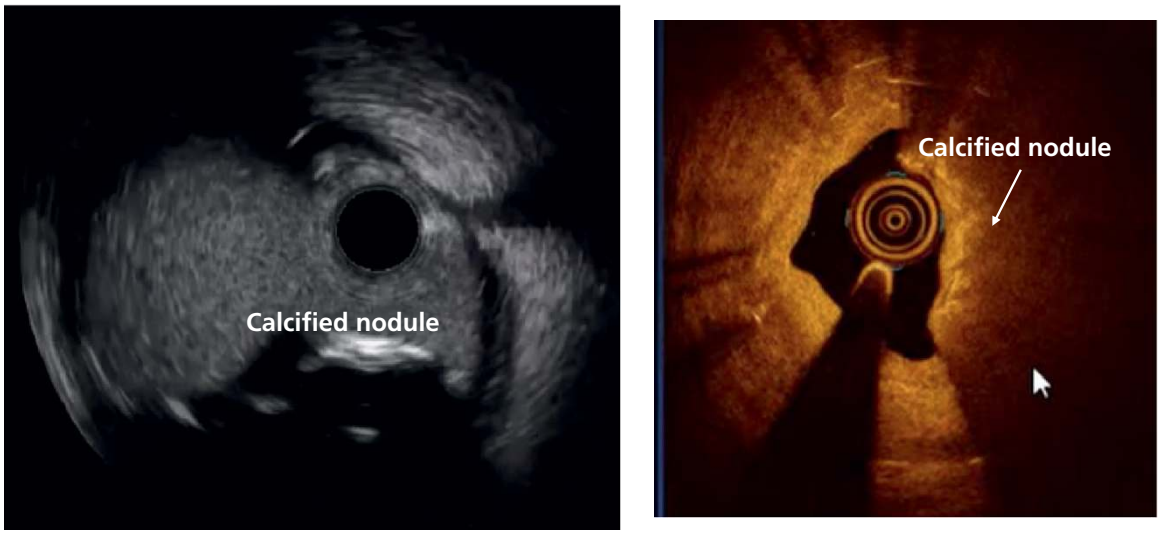

Figure 40.20 Calcified nodule (CN) on IVUS and OCT. **On OCT, unlike general calcium, a CN causes attenuation because it tends to have a necrotic and lipid core within the calcium** (+/– clot and RBC in eruptive CN). This necrotic core is what facilitates the fracture of calcium and the bulge.

Severe coronary calcium

Fluoro: long (>15 mm) calcium present on both sides of the vessel and obvious on still images
IVUS/OCT: -arc of calcium 360°
-arc of calcium **>270° over >5 mm**
-or calcified nodule. A calcified nodule is an **eccentric** piece of calcium **protruding** into the lumen
+ Additional:
-The longer the calcium, the worse it is
-Negative vessel remodeling (lesion EEM < distal EEM) or EEM diameter <3.5 mm
-Minimal calcium thickness >0.5 mm by OCT

1-Calcium modification (atherectomy or lithotripsy) if:

1. Balloon uncrossable lesion (→ atherectomy) or undilatable lesion (atherectomy or lithotripsy)
2. Within the severely calcified lesions, **the denser and thicker the calcium, the more likely that calcium modification is necessary before stenting** (vs. high-pressure ballooning)
3. Multiple IVUS features: long calcium >270° with spots of 360° calcium, or spots of calcified nodule, or negative vessel remodeling

2-Lithotripsy:

1. Eccentric or calcified nodule
2. Thick dense + deep calcium (+/– preceded by atherectomy)
3. Severe tortuosity or angulation
4. Distal disease
5. Small vessels ~2.5 mm
6. Dissection planes (vs. bring the pt back 4–6 weeks later for atherectomy)
7. MI with mild thrombus burden (vs. bring the pt back 1–2 days later)
8. Stent-related calcium: (i) behind the stent [underexpanded stent] or (ii) inside it

3-Rotational:

1. Balloon uncrossable lesion
2. Balloon undilatable lesion
3. Thick dense proximal calcium + critical stenosis, likely balloon uncrossable or poorly crossable
4. Stent-related calcium: behind the stent or inside it

3'-Orbital:

1. +/– Large vessels > 3.5–4 mm
2. Balloon uncrossable lesion: orbital wire better than rotawire, but orbital burr has nose cone that may hinder crossing
3. Balloon undilatable lesion
4. Thick dense proximal calcium + critical stenosis

Laser:

-Underexpanded stent
-Balloon uncrossable lesion with inability to exchange for *or* advance atherectomy wire

Figure 40.21 Approach to severe coronary calcium.

VIII. Balloon uncrossable lesions and how to improve guide support

A balloon may not be able to cross a lesion for 2 major reasons (Figures 40.22–40.25):

1. Poor support, particularly poor guide support while stenting a distal lesion with calcified angles and tortuosities along its path: this is improved with better guides, the use of guide extension (GuideLiner), and the use of a microcatheter (e.g., Corsair) or a small 1- to 1.25-mm balloon to cross and start dilating the lesion.
2. Heavily calcified critical stenosis that requires atherectomy

A guide extension (e.g., GuideLiner or Guidezilla) is a monorail catheter advanced inside the guide: it is ~25 cm in length and ~1–1.5 Fr size smaller than the guide. It provides extra support by giving extra weight to the guide, by deeply penetrating the coronary artery, and/or by allowing the creation of an Amplatz left guide shape that sits on the aortic valve. In fact, when it is difficult to deliver a stent, a GuideLiner may be advanced through the lesion using the balloon anchoring technique, then the stent is advanced inside it and positioned across the lesion, then the GuideLiner is pulled back. Of note, 6 Fr GuideLiner has the inner lumen of a 5 Fr guide, 7 Fr GuideLiner has the inner lumen of an ~5.7 Fr guide, and 8 Fr GuideLiner has the inner lumen of an ~6.2 Fr guide. Thus, simultaneous kissing balloons cannot be advanced through a 6 Fr GuideLiner; they can be advanced through a 7 Fr GuideLiner, particularly for small balloons ~2 mm.

Support:
-GuideLiner
-Buddy wire in SB
Buddy wire in main branch (coaxial)
-GuideLiner over 2 wires (buddy wires)

-Anchor balloon in SB
Anchor balloon in main branch (coaxial distal balloon to support stent delivery)
-Anchor balloons require 7 Fr GuideLiner, not 6 Fr
-7–8 Fr Guide with 7–8 Fr GuideLiner
-Femoral access

Microcatheters low tip profile and/or more penetration:
-Balloons: Sapphire Pro 1 mm *or* Threader 1.2 mm *or* Glider balloon
-Balloon rupture at the mouth of the lesion may fracture the lesion (Grenadoplasty)

-Mamba, Corsair
-Mamba Flex, Corsair XS
-Finecross, Caravel

Atherectomy:
-Laser
-Rotational or Orbital

Unable to cross the balloon through stent cells
→ consider the wire is behind stent struts →
Rewire using:
-Non-polymer wires
-Tip shape: large J or umbrella shape. Hook the SB ostium on the way back
-Parallel wiring
-Supercross angled cath
-Dual lumen cath

Figure 40.22 Balloon uncrossable lesions: 3 modalities to allow balloon crossing, plus an additional modality for crossing stent struts.

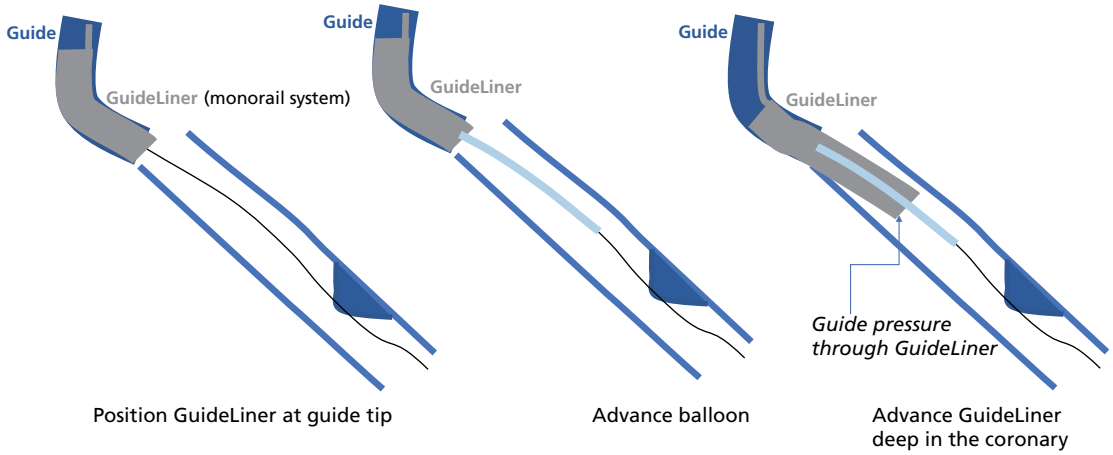

Figure 40.23 A guide extension is a monorail catheter advanced inside the guide: it is ~25 cm in length and 1 Fr size smaller than the guide. It is advanced inside the guide until the guide's tip. Then a balloon is introduced from outside the body through the GuideLiner deep inside the coronary artery, then the GuideLiner is advanced over the balloon deep in the coronary artery; a GuideLiner is not advanced inside the coronary artery in a "bare" fashion, without a balloon catheter inside it. After its advancement, the invasive pressure displayed on the monitor is now transmitted through the GuideLiner tip, not the guide tip, because the guide is wedged by this GuideLiner. So, a damped or ventricularized pressure implies that the GuideLiner is occlusive and causing ischemia, not necessarily the guide itself.

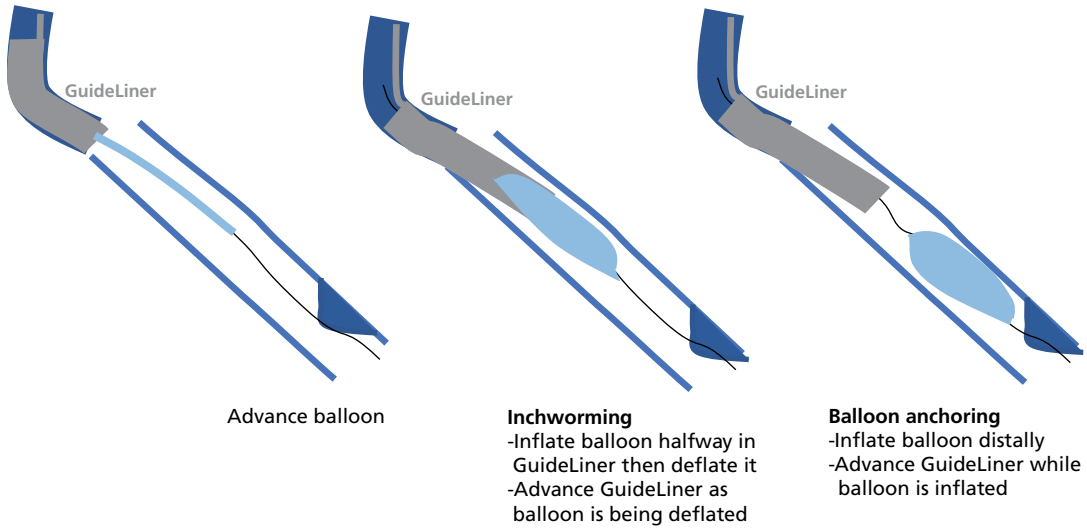

Figure 40.24 How to advance GuideLiner in difficult cases: inchworming and balloon anchoring techniques.

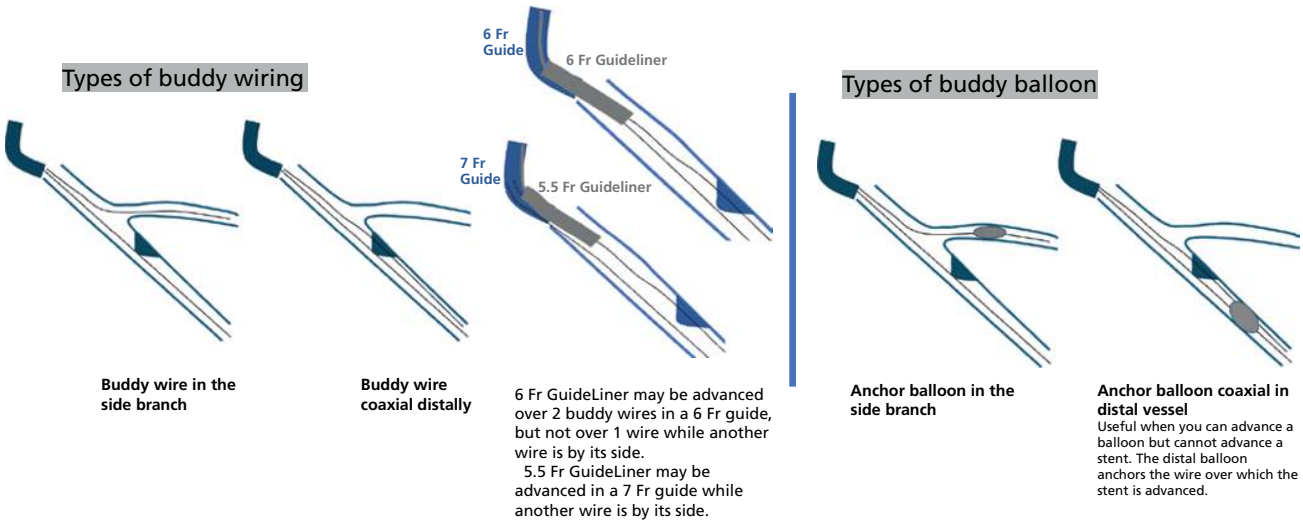

Figure 40.25 Improving guide support and device deliverability using buddy wiring and buddy balloon (also called anchor balloon). If the main issue is delivering devices to the lesion itself, distal buddy is best to improve balloon or stent delivery. If the issue is maintaining the guide engaged, side buddy is an acceptable option.

IX. Brief on coronary guidewires (Figures 40.26–40.30)

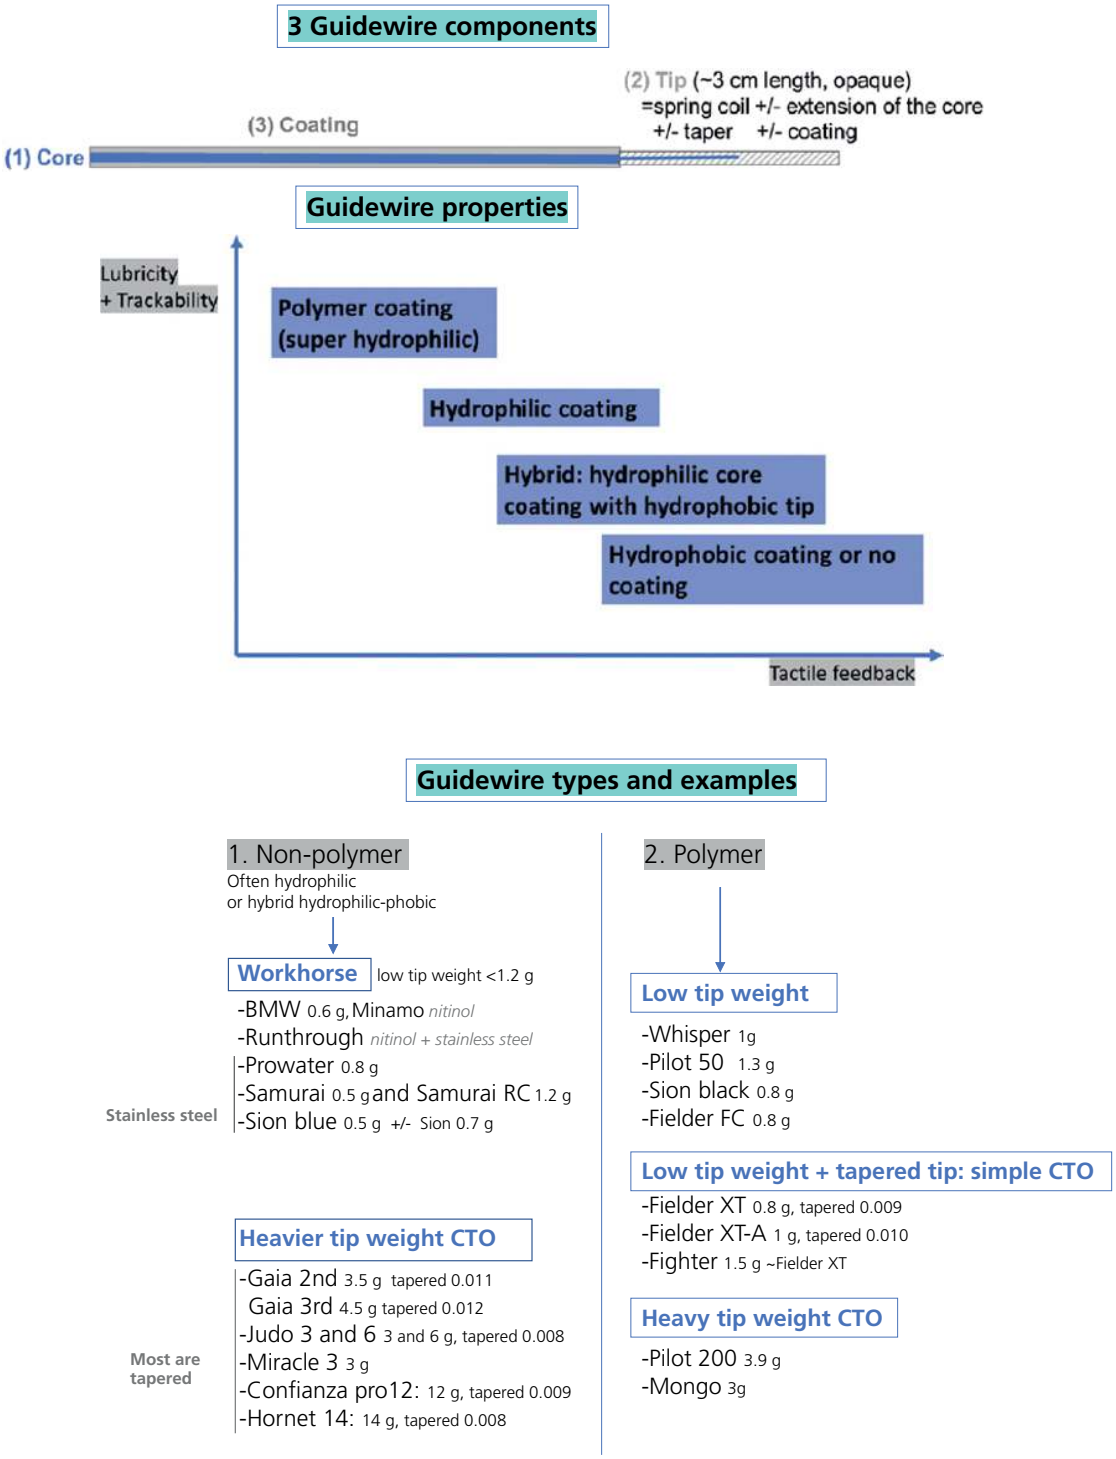

Figure 40.26 Coronary guidewires. A coronary guidewire has 3 components: core, spring coil tip, and coating (hydrophobic vs. hydrophilic vs. polymer). The core may or may not reach the tip: if it does not, a shaping ribbon allows the tip to retain its shape.

There are 2 major types of guidewires (right image): **polymer-coated** and **non-polymer coated**. The terms *hydrophilic* and *polymer-coated* are often confused; polymer is an extreme form of hydrophilic coating that makes the wire slippery, more flexible, and trackable through calcium, severe tortuosity, and total occlusions. Most wires are hydrophilic but not polymer coated; the disadvantage of polymer coating is the risk of slipping subintimally with no resistance or tactile feedback.

The wire material is usually *stainless steel* but may be *nitinol*. Nitinol is more elastic and flexible, torques better in tortuous anatomy, and is more durable (kink resistant, retains its shape).

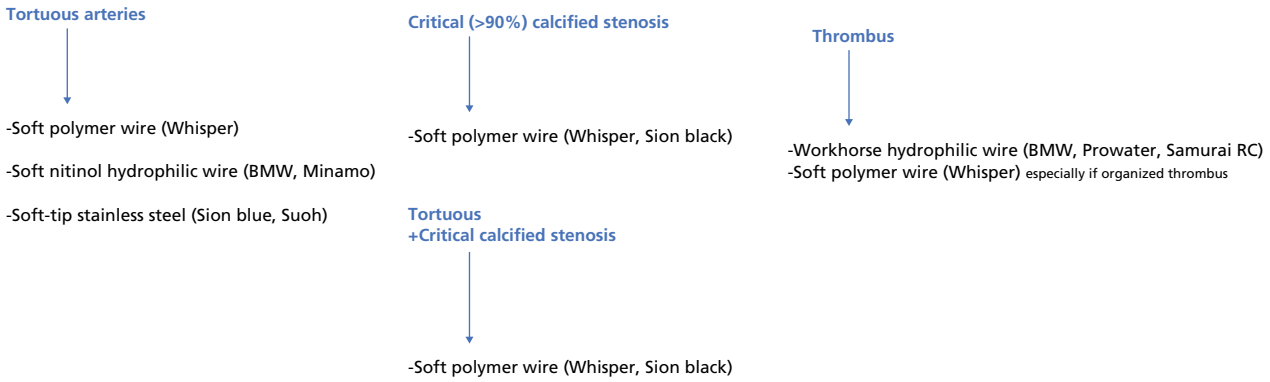

Figure 40.27 Guidewires for various types of coronary lesions, with brand examples.

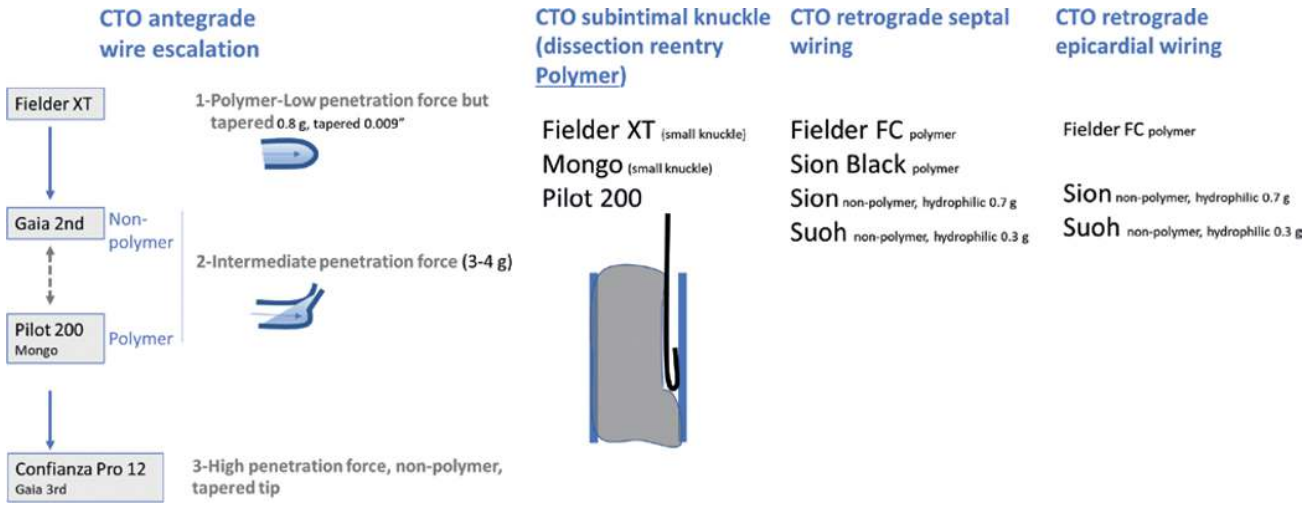

Figure 40.28 CTO guidewires: guidewires for antegrade wire escalation, subintimal tracking, and retrograde collateral navigation. In antegrade wire escalation, the tapered low-weight polymer wires are most suited for the tapered stump, while heavier-tip wires are more suited for the blunt stump (*blue images*). Suoh wire has a flexible and ultra-low tip load that improves navigation of angulated and tortuous collaterals (but it is so flimsy that it should not be torqued).

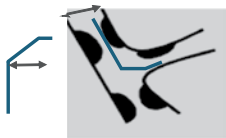
To cross the distal occlusion cap after crossing a retrograde channel, reverse CART technique may be used, or retrograde wire escalation may be attempted as in the proximal cap (Fielder FC or XT, then Gaia or pilot 200, then Confianza).

- First standard technique is to use sharp wire shape, polymer wire

  -Length of the bend depends on the caliber of the main branch
  -Angle of the bend depends on the sharpness of the side branch



- If this fails, the 3 best techniques are, in order of progression:

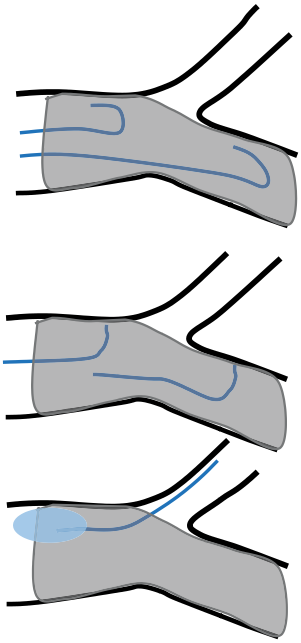
  1. Sharp or Umbrella U shape on the wire, even without a microcatheter or dual lumen catheter. *Hook the branch, then spin the wire with slight pull, then push*

  2. Dual lumen catheter, *along with sharp or U bend on the wire*
     Dual lumen catheter is preferable to microcatheter because it stays more robustly centered, providing more support for wire push into the SB and less risk of wire prolapse after hooking this SB
  3. "Blocking balloon": inflate a balloon in the LAD just past the diagonal branch to occlude the LAD lumen. This redirects the wire preferentially into the diagonal branch. Risks: (i) LAD injury, (ii) plaque shift and occlusion of the diagonal

  +/– Reverse hairpin wire bend (3- to 5-cm U-shape bend): requires microcatheter or dual lumen catheter for advancement of the large-bend wire

  +/– Supercross angled catheter

Figure 40.29 Techniques for wiring difficult side branch angulations. Remember the ***4 sequential wire maneuvers:*** Hook-Spin with slight Pull-Push.



Key ideas for rewiring side branch through main branch struts:

1. Proper POT
2. Sharp double bend on the wire tip, long (length matches MB size)
3. Advance the wire through the stent in 1 of 2 ways:
   (i) **knuckle it** from the beginning, before entering the stented area. The long tip helps create a knuckle. Get the knuckle past the SB, then try to direct it to the SB and hook it on the way back.
   (ii) or **constantly "helicopter" spin** the wire tip. Keep the wire tip constantly "dancing and free." In case of buckling, pull back and re-spin the wire to make sure its tip remains free. You may directly cross the carina, or go past it and hook it during the pullback.
4. After hooking the carina, you may push with directionality without much spin at the carina level (accept some resistance or buckling at that level). Then immediately re-spin or knuckle
5. Advance a small compliant 2-mm balloon. If the balloon gets stuck at one point → it is the point where the wire went behind struts → keep the balloon at that point, pull back the wire, and redirect the wire at that point

Figure 40.30 Tips for rewiring a side branch after main branch stenting. Rewire through the stent cells rather than behind the stent struts.

3. WHEN TO USE LV SUPPORT DURING COMPLEX PCI – PRE-PLANNING LEFT MAIN PCI

A. Criteria used to decide about LV support

In complex and prolonged PCI, hemodynamic compromise may occur for the following reasons: (i) supine positioning and contrast loading increase preload, LVEDP, and myocardial ischemia; (ii) procedural sedation blunts compensatory vasoconstriction and tachycardia in HF; (iii) PCI causes intermittent myocardial flow impairment from balloon inflations, difficult stent delivery, no reflow, SB loss, or reperfusion injury. This is particularly pronounced if the guiding catheter partially occludes the coronary ostium with ventricularized pressure, and it will not be tolerated if LVEDP is elevated or BP is borderline.

LV support is considered during some left main interventions. It is not usually considered for non-LM interventions, including triple-vessel CAD, except in acute shock. The following is the author's approach, noting that Impella CP support was associated with higher CV mortality in high-risk complex PCI (CHIP-BCIS3 trial), partly due to longer and more extensive PCI in supported patients. Thus, it should be reserved for very select cases, and it should not provide false reassurance: PCI must remain targeted, quick, and efficient. The decision to use support in left main interventions depends on **2 major factors and 7 other, less critical factors** (Figures 40.31–40.33). The top 2 major factors are: (i) impaired hemodynamics (of varying severity); and (ii) technical complexity and duration of the PCI, mainly if distal left main atherectomy or lithotripsy is required *and* 2-stent crush or culotte strategy is planned:

- If both (i) and (ii) are present and LM PCI needs to be done before hemodynamic stabilization, or hemodynamic stabilization is not possible without a support device → a support device, likely Impella CP, is required during PCI.
- If only (i) is present (impaired hemodynamics), the decision for LV support depends on: (a) how many hemodynamic features are present and how severe they are (e.g., SBP of 90–100 mmHg and LVEDP of 16–25 are mild hemodynamic features); (b) whether it is possible to delay PCI until diuresis is achieved; (c) whether shock, if present, improves quickly with inopressor support only (shock stage C); otherwise, LV support device is needed for shock stabilization, not just for PCI support; (d) also, account for the additional 7 factors.
- If only (ii) is present with minimal/mild hemodynamic impairment, LV support may not be needed but use the additional 7 factors to decide (multiple of those + either (i) or (ii) favors LV support). Note that LVEF is not a major factor in deciding about LV support; hemodynamics are far more important.

B. Questions to ask when planning LM PCI

Six major questions need to be addressed before LM PCI:

1. Assess whether the lesion is severely calcified: long calcium >15 mm seen on both sides of the vessel fluoroscopically even on still images, or >270° arc of calcium on IVUS, or CN bulging inside the lumen (even if localized). If so, **does calcium require modification**, using atherectomy or lithotripsy? Within the severely calcified lesions, the denser and thicker the calcium, the more likely that calcium modification is necessary before stenting (vs. high-pressure ballooning). Atherectomy may be favored over lithotripsy for densely calcified and critically stenosed LM, where it may be difficult to deliver a lithotripsy balloon. Also, short and careful atherectomy runs are often associated with less hemodynamic compromise than the repeated balloon inflations of lithotripsy.

2. Is there a **complex true distal left main bifurcation disease requiring a planned 2-stent strategy**, such as mini-crush, culotte, or planned TAP? Planned crush and culotte involve many steps and increase the chance of hemodynamic compromise compared to a single-stent strategy.

Top 2 factors predicting hemodynamic compromise during PCI and LV support

1-Hemodynamics: **low or borderline BP<90-100**, sinus **tachycardia**
Multiple +Severe +LM PCI
Clinical HF, orthopnea, hypoxemia (esp. requiring O2)
PCWP or **LVEDP>25-30**, RA>15, CI <1.5-1.8
More advanced: lactate>2, PA sat <50%

→ **Diurese the patient, then bring back for PCI**

In case of *full-blown shock but no ongoing* ST elevation or profound ST depression → Don't intervene yet → Give ino-pressors + diuresis, then bring back for PCI once tissue perfusion and hemodynamics have improved. If *shock is unresponsive* → place IABP or Impella CP *and* perform PCI urgently

In case of *full-blown shock with ongoing* profound ST abnormality → place support device *and* perform PCI emergently

2-Complexity and length of left main PCI: distal LM with atherectomy *and* planned 2-stents, esp. DK crush or culotte (many lengthy steps)
vs. a much shorter provisional stenting, or T, or TAP. Do the latter if you want to avoid support.

In non-LM PCI, consider support if full blown cardiogenic shock OR Complex and long PCI of last functional territory : eg, PCI of long and calcified RCA or long and calcified dominant LCx in a patient with extensive anterior akinesis and EF 20%.

→ **-In complex distal LM not candidate for Impella, *consider* using provisional technique and accepting suboptimal result across the ostial LCx, especially if the LCx is small, OR consider TAP of the LCx (simpler with fewer steps).**

-Do shorter inflations, short Rotablation runs of 10s with a lot of time for recovery between runs. Same with lithotripsy balloon, which tends to be less tolerated than rotablation as it dictates multiple balloon inflations.

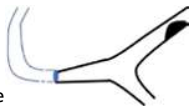
Figure 40.31 The top 2 factors that predict hemodynamic compromise during PCI and dictate LV support, and how to lessen them insomuch that LV support is less likely to be required.

Other 7 factors:

-EF<30-35% *OR* severe AS even if EF normal *OR* severe MR

-LM PCI with diseased RCA. This does not mean RCA PCI should be done before LM PCI;. It is often appropriate to start with LM PCI, as per EXCEL trial. Start with RCA PCI only if it is large *and* critical >90% *and* perceived to be culprit of acute presentation (MI), while LM is only moderate <70%

- **Distal PCI through a diseased ostial LM with guide ventricularization=** Prolonged periods of off-and-on LM ventricularization. Stent the LM first in those cases. Stent distally later (in the same or different setting). It is easier to intervene *on* ostial LM (quick) than to intervene *through* a diseased ostial LM, as this mandates a longer procedure with more prolonged guide seating and LM ischemia to deliver wire and stents.



-**Anesthesia**: moderate sedation < deep sedation with MAC < intubation.
Try deep sedation (e.g., IV Precedex drip) with high flow O_2 and anesthesiology assistance (MAC), rather than intubation with deeper sedation (deeper sedation → more hemodynamic compromise)

-**PCI on a territory that is already akinetic**: PCI of mid-LAD in a patient with akinetic anterior wall is well tolerated with no need for support. Patients with low EF tolerate PCI on the akinetic area, but very poorly tolerate intervention on the properly contractile or hypercontractile area. If the base is hypercontractile and you need to maneuver (rotablation, stent) proximal to the first septal or in the RCA → poorly tolerated hemodynamically.
If multivessel PCI: consider starting with the akinetic territory, the most tolerated
~Similarly, PCI on a subtotally occluded artery with collaterals is often well tolerated

-**PAD/femoral-iliac disease**, femoral size (<5 mm), heavy calcium and tortuosity

+/– Difficult LM wiring +critical stenosis >95%: flow expected to shut during wiring

Figure 40.32 The other factors that predict hemodynamic compromise during PCI and may favor LV support. The 6th one, severe PAD, argues against or complicates LV support. Notes: (i) low EF with stable hemodynamics is not a major factor, as it implies the LV, LA, and peripheral tissues have adapted. (ii) Regarding concomitant distal LAD or LCx disease in a patient with severe LM disease, particularly ostial LM with intermittent guide ventricularization: it may be best to just treat the left main, then stent the LAD afterward, possibly in a separate setting. Try to keep the procedure simple and quick and minimize LM ventricularization, even if LV support is in place (this does not compensate for the massive ischemia ensuing from ventricularization).

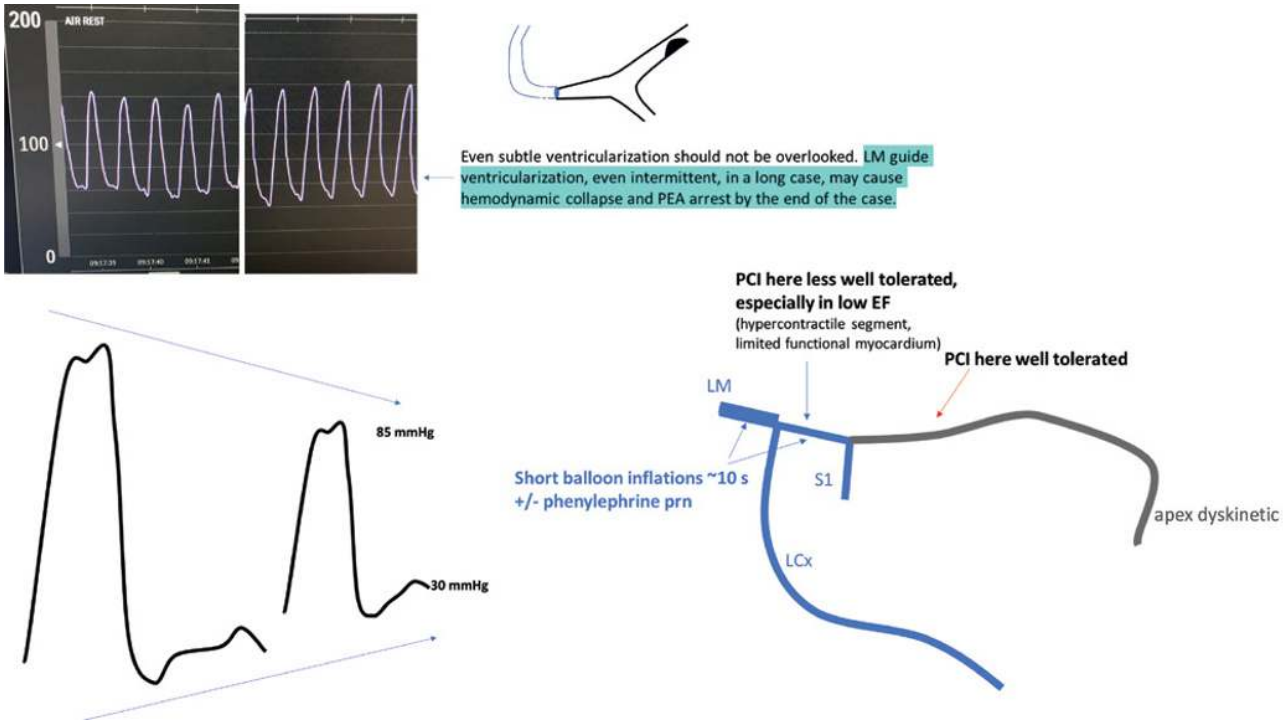


Figure 40.33 Illustration of some factors predicting hemodynamic compromise during PCI. (i) LM guide ventricularization, which implies LM occlusion by the guide and global LV ischemia, should be avoided at all times (do not tolerate more than a few seconds of intermittent ventricularization, even if LV support is in place); (ii) a shrunk LV pressure waveform, with low systolic pressure and high LVEDP, foreshadows cardiogenic shock; (iii) PCI of mid-LAD in a patient with akinetic septum is well tolerated with no need for support, but PCI proximal to the first septal is poorly tolerated.

3. Is there distal downstream disease that needs to be treated (LAD, LCx)? *Treat distal disease first, unless LM disease is ostial or critical and the patient develops ischemia early during PCI*. In this case, LM may be stented first to relieve guide ventricularization and relieve LM ischemia that occurs each time balloon/stent catheters are advanced through the LM, further narrowing its flow. Try to simplify and at times delay the treatment of distal disease, especially if hemodynamics are tenuous and the distal disease is not critical or its territory is not large. *Impella support should not provide a false sense of security and ventricularization should always be minimized*.

4. Sedation plan: anesthesiology support is required in the following cases: (i) PCI is expected to be long, >2–3 hours, and the patient is old and agitated; or (ii) impaired baseline hemodynamics or oxygenation, which inherently worsen during sedation, supine positioning, and PCI-induced ischemia. The best anesthesia plan in these cases is deep sedation (e.g., IV dexmedetomidine) with high-flow O2, preferably without intubation and its more profound sedation requirement.

5. Concomitant RCA disease: LM PCI is usually done before RCA PCI, as in the EXCEL trial, unless RCA is large with critical disease >90% deemed to be a culprit of the patient presentation, while LM disease is moderate <70%.

6. Need for LV support: LV support is decided based on (i) baseline hemodynamics, and (ii) the complexity of PCI as dictated by the above features 1–5.

Abdel-Wahab M, Richardt G, Joachim Büttner H, et al. High-speed rotational atherectomy before paclitaxel-eluting stent implantation in complex calcified coronary lesions: the randomized ROTAXUS trial. JACC Cardiovasc Interv 2013; 6(1): 10–9. *Same clinical outcomes with rotablation vs. balloon, more late lumen loss with rotablation despite better acute luminal gain. Rota was required in 12% of the standard PCI arm: because of failure of balloon or stent delivery or suboptimal balloon expansion despite the use of a noncompliant balloon (uncrossable or undilatable lesions)*.

Abdel-Wahab M, Toelg R, Byrne RA, Geist V, El-Mawardy M, Allali A, Rheude T, Robinson DR, Abdelghani M, Sulimov DS, Kastrati A, Richardt G. High-speed rotational atherectomy versus modified balloons prior to drug-eluting stent implantation in severely calcified coronary lesions. Circ Cardiovasc Interv 2018; 11(10): e007415. *Again, ~17% more success with rotablation vs. balloon in severely calcified stenoses, but outside that, the same outcomes, a bit more late lumen loss in the rota arm. Crossing over to rotablation was most commonly because of uncrossable (n = 8) or undilatable (n = 6) lesions*.

Kirtane AJ, Genereux P, Lewis B, et al. Orbital atherectomy versus balloon angioplasty before drug-eluting stent implantation in severely calcified lesions eligible for both treatment strategies (ECLIPSE): A multicentre, open-label, randomised trial. Lancet 2025; 405(10486): 1240–51. *In the ECLIPSE trial, patients with severe calcium by fluoroscopy or by IVUS/OCT criteria were randomized to orbital atherectomy vs. conventional PCI without atherectomy or lithotripsy → no clinical benefit of atherectomy, more cardiac death at 30 days 0.8% vs. 0%, p = 0.005, no improvement of TVR. Only 5% needed to cross over to atherectomy in the conventional PCI arm. The extremely calcified or the uncrossable lesions were excluded, as patients were eligible for enrollment if the operator felt there was treatment equipoise. That still tells us that using the severe calcium criteria by IVUS/OCT does not mandate atherectomy. A good proportion of these patients will do as well without it*.

2. Answers

QUESTIONS

I. NSTEMI and STEMI (Answers on pages 1080–1082)

Question 1. A 62-year-old man with a history of CABG presents with persistent chest pain for the last 2 hours. ECG shows diffuse ST depression, most pronounced in V_1-V_3 (~3–4 mm in V_1-V_3, 1 mm in other leads). Hs-troponin is detectable but below MI cutoff. What is the next step?

A. Aspirin and heparin
B. Serial troponin measurements
C. Aspirin and fibrinolytic

Question 2. A 62-year-old hypertensive man presents in the late evening with a prolonged episode of chest pain that occurred at rest and lasted 1 hour. Chest pain resolved in the emergency department after initiating heparin, metoprolol, and nitroglycerin drip. ECG shows mild lateral ST depression, and initial troponin I is 0.08 ng/ml. The nurse notes a 30-second run of VT on telemetry that resolves spontaneously. He is comfortable, chest-pain free, with BP of 132/82 and a heart rate of 75 bpm. What is the timing of cardiac catheterization?

A. Within 2 hours
B. Within 24 hours (next morning)
C. Within 72 hours

Companion website: www.wiley.com/go/hanna/cardiomedicine3e

Question 3. A healthy 47-year-old woman presents with chest pain that started during kickboxing and lasted 5 hours (not ongoing). ECG shows inferolateral ST depression, troponin I is 2.3 ng/ml. Coronary angiography is performed (Figure 1). What is the next step?

A. Conservative management
B. Bifurcation dual stenting of the PDA and PLB
C. Stenting of the PDA with balloon angioplasty of the PLB
D. Eptifibatide therapy and repeat angiography in 24 hours
E. OCT of the lesion

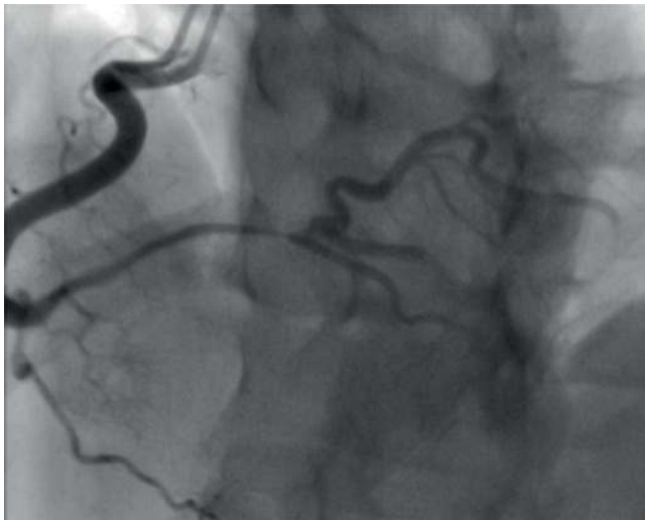

Figure 1

Question 4. A 52-year-old woman presents with ACS and is diagnosed with SCAD of the mid-LAD (95% stenosis). She is treated conservatively, and chest pain resolves. Which of the following is true?

A. Risk of recurrence is ~10% at 5 years
B. CT angiography of head and neck needs to be performed
C. Coronary angiography needs to be repeated in 6 weeks, to document healing
D. IVUS or OCT is needed to confirm the angiographic suspicion

Question 5. A 62-year-old man, with a history of single-vessel CAD (occlusion of the left circumflex artery several years ago), presents with episodes of severe dizziness and palpitations over the last 24 hours, followed by a fall and near syncope. Emergency medical personnel successfully cardioverted him (Figure 2). Subsequent ECG shows anterolateral ST depression that resolves 5 minutes later. He denies any chest pain. Troponin level is 7 ng/ml, and creatinine and liver tests are acutely elevated. Emergent coronary angiography shows no left main or LAD disease, 100% proximal LCx occlusion involving a high and large OM branch, and 80% mid-RCA smooth stenosis. What is the next step?

A. PCI of RCA. No need for ICD placement
B. PCI of RCA followed by ICD placement
C. ICD placement. No need for RCA PCI
D. FFR of RCA
E. PCI of LCx

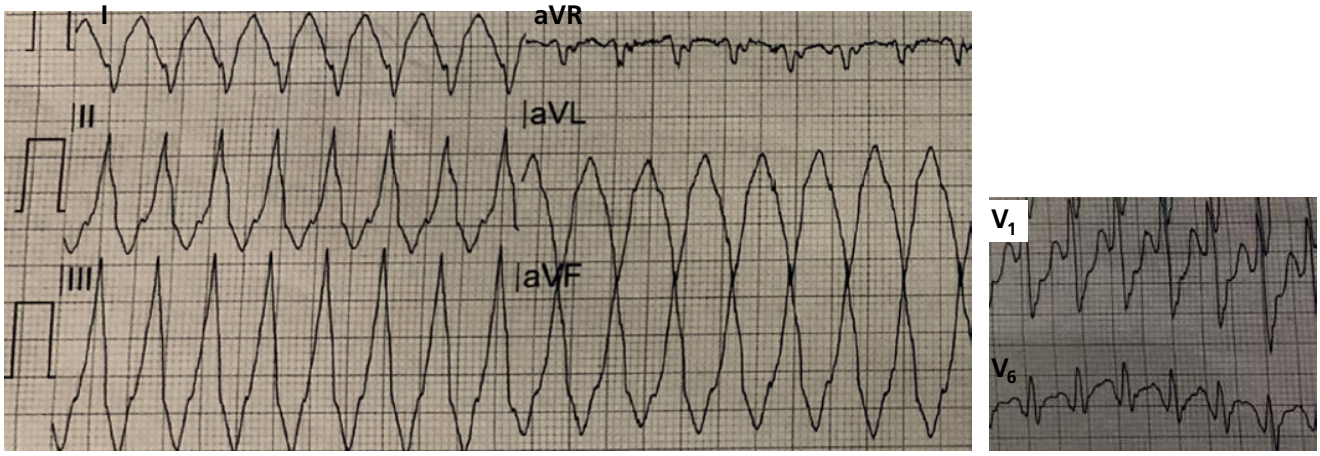

Figure 2

Question 6. A 60-year-old man presents with progressive dyspnea and is found to have decompensated HF (EF 30%). BNP is 1800 ng/L; his initial hs-troponin is 50 ng/L (99th percentile for men 15 ng/L) and rises to 80 ng/L. ECG shows LVH with no ischemic ST abnormality, and echo shows global LV dysfunction without segmental wall motion abnormality. Define the elevated troponin value:

A. Type 1 MI
B. Type 2 MI
C. Acute myocardial injury
D. Chronic myocardial injury
E. False positive (hs-troponin has a high false-positive rate)

Question 7. A 78-year-old woman presents with anterior STEMI. She undergoes primary PCI of a 100% occluded proximal LAD. She continues to have persistent ST elevation post-PCI, along with Q waves. Echo shows extensive anterolateral akinesis with EF ~25%. Telemetry shows frequent polymorphic PVCs, with occasional couplets and triplets. Besides β-blockers and aldosterone antagonists, which of the following has been shown to reduce the early risk of arrhythmic death post-MI?

A. LifeVest
B. Amiodarone
C. Both LifeVest and amiodarone

Question 8. In regard to LV free wall rupture, which statement is false?

A. It is the most common STEMI mechanical complication
B. Early thrombolysis <12 hours reduces its incidence
C. Late thrombolysis >12 hours increases its incidence
D. It is more common in men, first MI, or severe hypertension
E. It is the second most common cause of in-hospital STEMI death, after cardiogenic shock
F. Thrombolysis increases the risk of free wall rupture in the elderly (>75 years old)

Question 9. A 55-year-old man presents with shock and severe pulmonary edema. His wife notes that he complained of chest pressure for several hours 4 days previously. ECG shows inferior Q waves. No murmur is heard on exam. Echo shows inferior akinesis with mild MR. What is the next step?

A. Coronary angiography and PCI
B. TEE
C. Right heart catheterization and supportive treatment

Question 10. A 69-year-old man presents with progressive dyspnea and a mild degree of pulmonary edema. He has a 3-week history of off and on chest pain. ECG shows lateral and inferior Q waves, with T inversion and mild, 1 mm ST elevation. He had chest discomfort earlier today, but he is not currently having chest pain. Echo shows inferolateral and lateral wall dyskinesis with a questionable layering thrombus (4-chamber view shown, Figure 3). A CT is performed (Figure 3). What is the next step?

A. Heparin and diuresis
B. Avoid heparin, emergently consult cardiac surgery
C. Heparin and urgent PCI

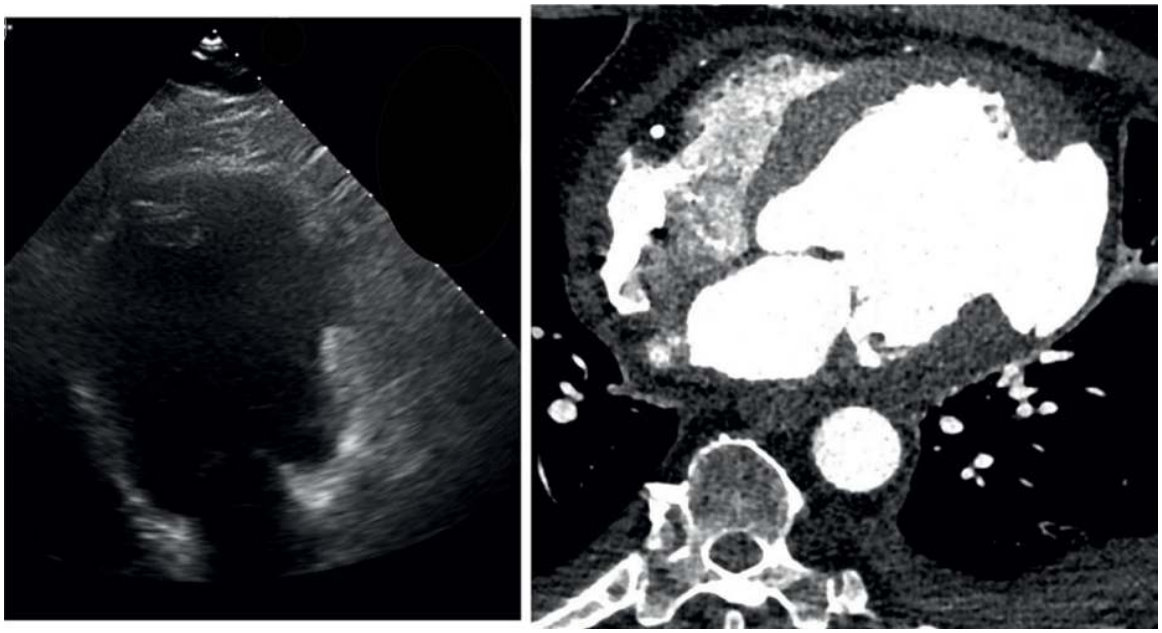

Figure 3

Question 11. An 80-year-old man presents to a rural hospital with STEMI. He receives tenecteplase and is getting transferred to a PCI facility for catheterization. What drugs should he receive before transfer?
A. Clopidogrel 75 mg
B. Clopidogrel 300 mg
C. Clopidogrel 600 mg
D. Prasugrel 10 mg

Question 12. A patient presents with anterior STEMI. He undergoes PCI of mid-LAD with no issues. He is found to have 90% proximal RCA stenosis. What option is supported by the most robust randomized data?
A. PCI of RCA in the same setting
B. PCI of RCA before discharge only if angina is present
C. Perform nuclear stress testing
D. PCI of RCA in 2 weeks

Question 13. A 79-year-old man presents to a rural hospital with inferior STEMI. He receives tenecteplase then is transferred to your facility. On arrival, ST elevation has resolved, but the patient is dyspneic and distressed. BP is 90/70, JVD is present, lungs are clear, and heart sounds are distant. Which hemodynamics are consistent with this clinical picture?
A. RA pressure 18, PA 30/18, PCWP 17 mmHg
B. RA pressure 18, PA 28/13, PCWP 13 mmHg
C. RA pressure 8, PA 50/23, PCWP 23 mmHg
D. RA pressure 18, PA 50/23, PCWP 23 mmHg

Question 14. A patient with anterior STEMI receives primary PCI of the mid-LAD. Which of the following new findings more readily indicates a temporary transvenous pacemaker?
A. RBBB
B. LBBB
C. RBBB + LPFB
D. RBBB with increased PR interval

Question 15. A 71-year-old man presents with inferior STEMI and hypotension. He receives primary PCI, but he remains hypotensive with SBP 75 mmHg, despite 2 liters of normal saline. Right heart catheterization is done: RA pressure 25 mmHg, PCWP 22, PA pressure 45/22, and cardiac index 1.5 L/min/m^2. What is the next step?
A. Additional saline boluses
B. Dobutamine
C. IABP
D. Right-sided Impella
E. ECMO

Question 16. What is the mode of action of reteplase?
A. Reduces thrombin
B. Increases plasmin
C. Increases plasminogen
D. Increases PAI-1

Question 17. A patient with inferior STEMI just underwent primary PCI of the proximal RCA. In the cardiac care unit, his monitor shows complete AV block with a junctional escape rhythm of 40 bpm for ~5 min, which subsequently resolves. He felt dizzy but did not experience chest pain recurrence. What is the next step?
A. Continue to monitor
B. Place a transvenous pacemaker
C. Administer atropine

Question 18. A patient with anterior STEMI just underwent primary PCI of the proximal LAD. In the cardiac care unit, his monitor shows complete AV block with a slow escape for 15 sec, which subsequently resolves. He feels well. His ECG shows RBBB and residual anterior ST elevation with Q waves. What is the next step?
A. Continue to monitor
B. Place a transvenous pacemaker
C. Administer atropine

Question 19. A 68-year-old woman presents with dyspnea and syncope. Her ECG shows anterior ST elevation and Q waves. Her SBP is 90 mmHg, and she appears obtunded and in distress. Dobutamine is started, but her SBP drops to 78 mmHg. Emergent coronary angiography is done and shows patent coronary arteries with minimal luminal irregularities. Left heart catheterization is performed: LV pressure is 160/35 (LVEDP 35 mmHg), and upon pull back, aortic pressure is 78/58 mmHg. What is the next step?
A. Diuresis
B. Switch from dobutamine to phenylephrine
C. Switch from dobutamine to norepinephrine
D. IABP
E. Impella
F. Echo and consider aortic valvuloplasty

Question 20. A 68-year-old man presents with anterior STEMI and receives primary PCI of the LAD. EF is 40%. On day 3, he collapses while walking in the hospital hall and is found to have a monomorphic wide complex tachycardia, which is successfully DC cardioverted. Post-cardioversion ECG is unchanged (anterior Q waves, no ST abnormality). How should this patient be managed?
A. Repeat coronary angiography
B. Amiodarone
C. ICD placement
D. EP study
E. LifeVest

Question 21. A 48-year-old man, smoker, reports an episode of chest pain of 1 hour duration 6 hours previously. ECG is unremarkable. Admission hs-troponin is 500 ng/L. Coronary angiography shows mild diffuse atherosclerosis with 30% lesions in the LAD and RCA. OCT of the LAD is performed. Which of the following is true?
A. OCT would reveal plaque disruption in 20% of such cases
B. Plaque erosion, in situ thrombosis, or SCAD type 3 is possible
C. Cardiac MRI is more likely to detect an ischemic mechanism than OCT
D. Medical therapy (DAPT and statin) is recommended regardless, hence OCT has limited value

Question 22. A 60-year-old man presents with shock, SBP of 75 mmHg, pulmonary edema, and diffuse 1-mm ST depression on ECG. He is intubated, started on norepinephrine, and undergoes emergent coronary angiography, which shows the following: thrombotic total RCA occlusion, mid-LAD 90%, proximal LCx 80%. What is the next step?
A. PCI of RCA
B. PCI of RCA and LAD
C. PCI of RCA, LAD, and LCx

Question 23. For the patient of Question 22, based on randomized controlled trials, which mechanical support device is appropriate?
A. IABP
B. Impella
C. VA-ECMO
D. None of the above

II. Stable CAD (Answers on pages 1082–1084)

Question 1. A 60-year old man with exertional angina is found to have distal left main bifurcation disease with a SYNTAX score of 25. The patient asks about PCI vs. CABG. What is the best answer?
A. CABG consistently reduces mortality compared to PCI
B. CABG consistently reduces spontaneous MI and future need for revascularization
C. CABG consistently leads to higher early stroke but lower periprocedural myocardial infarction
D. All of the above

Question 2. A 45-year-old woman with family history of breast cancer presents with chest pain. She is concerned about radiation exposure and the carcinogenic risk. Which of the following tests has the highest mean effective total body radiation dose, and which one has the lowest radiation dose?
A. Coronary angiography
B. 64-slice cardiac CTA
C. 64-slice cardiac CTA with prospective gating
D. Rest/stress Technetium sestamibi SPECT
E. Thallium SPECT stress-redistribution
F. Rest stress ^{13}N cardiac PET

Question 3. A 61-year-old obese, diabetic woman has atypical, episodic rest chest pain, as well as exertional angina. She undergoes ^{13}N stress-rest cardiac PET scan. PET shows no stress-induced perfusion defect. On quantitative PET measurements, myocardial blood flow was 1.5 ml/mg/min at rest, and 2.8 ml/mg/min with stress. What is the diagnosis?
A. Balanced myocardial ischemia suggestive of 3-vessel CAD
B. Obstructive CAD with microvascular dysfunction
C. Microvascular dysfunction with no CAD
D. Normal microvascular function and no CAD

Question 4. A 55-year-old man has angina with strenuous activity. He takes amlodipine for hypertension. EF is normal on echocardiography with questionable inferior hypokinesis, and coronary angiography shows a mid-RCA chronic total occlusion (CTO) without any left coronary disease and with grade 3 left-to-right collaterals. Which of the following is true?
A. Check for inferior wall viability before PCI of CTO
B. Attempt PCI of CTO if severe ischemia is demonstrated on stress testing
C. PCI of RCA CTO only reduces angina
D. Randomized CTO trials have shown that CTO PCI reduces mortality compared to medical therapy
E. Randomized CTO trials have shown that CTO PCI improves EF and wall motion compared to medical therapy

Question 5. Which of the following is *false*?
A. Most MIs arise from a non-obstructive plaque
B. Most plaque ruptures are asymptomatic
C. Stable CAD stenoses are frequently layers of healed plaque ruptures
D. In a patient with prior PCI, half of the long-term events are related to the non-stented areas (frequently non-obstructive)
E. The individual risk of MI from a stenosis <50% is lower than stenosis >50–70%
F. Positive remodeling correlates with reduced MI risk

Question 6. Which of the following is characteristic of coronary endothelial dysfunction?
A. Impaired vasodilatory response to adenosine
B. Vasoconstrictive response to acetylcholine
C. Impaired vasodilatory response to nitroprusside
D. Impaired vasodilatory response to nitroglycerin

Question 7. Which of the following is an endothelium NO-dependent coronary vasodilator (multiple possible answers)?
A. Acetylcholine
B. Serotonin
C. Nitroglycerin
D. Adenosine
E. Nitroprusside

Question 8. A 60-year-old man with a history of diabetes, obesity and hypertension presents with episodes of chest burning that occur each time he carries a heavy load or shovels the snow in the cold. They occur about twice a week and resolve within a couple of minutes of rest. He takes lisinopril, HCTZ, metformin, and glipizide. ECG shows non-specific mild ST-T abnormality. Creatinine is 1.1 mg/dl. What is the best next step?
A. Medical therapy with statin and anti anginal drugs
B. Coronary CTA
C. Coronary angiography
D. Exercise stress imaging

Question 9. A 60-year-old man with a history of diabetes, obesity, and hypertension presents with episodes of chest burning that occur each time he walks to his mailbox and almost every evening as he gets ready for sleep. They occur daily, sometimes twice in a day. He takes lisinopril, HCTZ, metformin and glipizide. ECG shows non-specific mild ST-T abnormality. Creatinine is 1.1 mg/dl. Troponin is negative. What is the best next step?
A. Medical therapy with statin and antianginal drugs
B. Coronary CTA
C. Coronary angiography
D. Exercise stress imaging

Question 10. A 61-year-old man is referred to you for cardiovascular screening. He does not smoke, LDL is 155, and his hypertension is controlled with amlodipine. He requests to undergo a screening stress test or coronary CTA. Which of the following statement(s) is (are) true (may select one or multiple answers)?
A. Stress testing of asymptomatic patients does not improve cardiovascular outcomes
B. Stress testing has a high false positive rate in asymptomatic patients
C. In asymptomatic patients, ~75% of future MIs arise from non-significant plaques, hence the limited value of CAD screening
D. In patients with a history of CAD, 50–66% of MIs arise from non-significant plaques
E. If a silent significant CAD is found through screening, revascularization will improve outcomes

Question 11. The AHA risk score for the patient from the prior question is 11% at 10 years. What is his best cardiovascular preventive option?
A. Screening with stress testing or CTA
B. Statin. If he is reluctant about statin use, screen with coronary calcium CT
C. Statin. Coronary calcium CT does not help with decision-making at his level of risk
D. Statin and aspirin

Question 12. A 63-year-old man presents with exertional chest pain. Nuclear stress test is performed using Bruce protocol: the patient exercised for 8 minutes and developed 1-mm ST depression at 6 minutes of exercise followed by chest pain toward the end. Nuclear images show moderate inferior ischemia. Metoprolol is prescribed, and exertional chest pain subsequently resolves. What is the next step?
A. No further workup
B. Coronary angiography
C. Coronary CTA
D. Coronary calcium scoring

Question 13. A 63-year-old man presents with exertional chest pain. Nuclear stress test is performed using Bruce protocol: the patient exercised for 5 minutes and developed 1.5-mm ST depression and chest pain at 5 minutes of exercise. Nuclear images show large anterior ischemia. Metoprolol is prescribed, and exertional chest pain subsequently improves and only occurs with heavy activity. What is the next step?
A. No further workup
B. Coronary angiography
C. Coronary CTA
D. A or C

Question 14. A 63-year-old man presents with exertional chest pain. Nuclear stress test is performed using Bruce protocol: the patient exercised for 5 minutes and developed 1.5-mm ST depression and chest pain at 5 minutes of exercise. Nuclear images show large anterior ischemia. Metoprolol is prescribed, and exertional chest pain subsequently improves and only occurs with heavy activity. His creatinine is 1.9 mg/dl and GFR is 40 ml/min. What is the next step?
A. No further workup
B. Coronary angiography
C. Coronary CTA

Question 15. A patient with stable angina is found to have a 75% mid-LAD stenosis. What is the likelihood of significant progression of this lesion (to a more severe lesion, more symptomatic lesion, or to MI) in the next 1.5–2 years?
A. 5–10%
B. 15–20%
C. 25%
D. >25%

Question 16. A patient with NSTEMI is found to have a 75% mid-LAD stenosis with overhanging edges. If untreated, what is the likelihood of significant progression of this lesion (to a more severe lesion, more symptomatic lesion, or to MI) in the next 2 years?
A. 5–10%
B. 15–20%
C. >25%

Question 17. Compare a 75% lesion with low FFR to a 75% lesion with insignificant FFR.
A. The low FFR lesion has a higher risk of MI
B. The low FFR lesion is more likely to have features of plaque vulnerability
C. Low FFR lesion increases shear stress, thrombogenicity, and oxidative stress compared to high FFR lesion
D. Stenting low FFR lesion reduces spontaneous MI and the overall MI risk
E. All of the above
F. A, B, C
G. None of the above

Question 18. A 50-year-old woman has episodes of chest pain at rest and particularly at night. Stress SPECT shows questionable anterior defect. Coronary angiography shows 50% mid-LAD stenosis, which is not significant by FFR (0.85). She continues to have chest pain and an ambulatory ECG monitor shows ST changes coinciding with her chest pain. What is the next step?
A. Amlodipine
B. Ranolazine
C. β-Blockade
D. PCI of mid-LAD

Question 19. A 48-year-old woman presents with episodes of dull chest pain, sometimes exertional. Her coronary angiogram shows 60% proximal RCA stenosis and no other disease. What is the next step?
A. Stenting of RCA
B. FFR of RCA
C. Assess nitroglycerin response
D. Assess acetylcholine response

Question 20. A 48-year-old woman presents with exertional chest pain. On SPECT stress imaging, she has a lateral defect, with no ischemia on stress ECG. Coronary angiography is then performed and shows 30% LCx stenosis. What are the expected findings on CFR and FFR?
A. CFR 2.1, FFR 0.86
B. CFR 2.9, FFR 0.86
C. CFR 2.1, FFR 0.73
D. CFR 2.9, FFR 0.73

Question 21. Regarding the natural history of CAD, which of the following is true (multiple possible answers)?
A. The most common presenting complaint of CAD in women is angina
B. The most common presenting complaint of CAD in men is MI
C. The most common presenting complaint of CAD in young patients is MI
D. Most MIs (up to 75%) are first cardiac presentation
E. Up to 50% of sudden cardiac deaths are first cardiac presentation
F. 50% of cardiac deaths are sudden
G. Up to 20% of STEMI patients die suddenly in the first few hours, before hospital presentation

Question 22. A patient with stable chest pain concerning for angina is undergoing coronary angiography. He read about the benefits of stents and is concerned about periprocedural MI should he undergo PCI. Which pre-treatment most clearly reduces peri-PCI MI?
A. High-dose atorvastatin
B. Clopidogrel
C. Carvedilol
D. Nitrate therapy

Question 23. A 68-year-old man with a long-standing history of diabetes and CKD stage 3 presents with severe progressive angina. EF is normal. Coronary angiography shows severe calcified 3-vessel CAD with a SYNTAX score of 28. On fluoroscopy, it is noted that his aortic arch and part of the ascending aorta are heavily calcified. Regarding CABG vs. PCI in this patient, which is incorrect?
A. CABG reduces the need for repeat revascularizations at 1 year and 5 years
B. CABG reduces 5-year MI and mortality based on SYNTAX trial, 3-vessel CAD analysis
C. CABG reduces 5-year MI and mortality based on FREEDOM trial
D. CABG mildly increases the stroke risk, but this is counteracted by the mortality benefit

III. Heart failure and cardiomyopathies (Answers on pages 1084–1088)

Question 1. A 77-year-old woman presents with progressive dyspnea over the last week. Chest X-ray demonstrates pulmonary edema, and ECG shows extensive anterior (V_1-V_6) and inferior Q waves with no ST abnormality. Echo shows anteroapical akinesis with EF ~30% and no LV dilatation. Troponin is negative. A 90% mid-LAD stenosis is found on coronary angiography. What is the next step?
A. PCI of mid-LAD
B. Viability testing of anterior wall. If viable, proceed with LAD PCI
C. Stress testing of the anterior wall
D. Standalone medical therapy

Question 2. A 68-year-old asymptomatic man undergoes a preoperative ECG (hernia surgery) (Figure 4). He is very active, bikes several miles a day without dyspnea or chest pain. Echo shows anteroapical dyskinesis with an EF of 25%. Coronary angiography is performed and demonstrates 100% proximal LAD occlusion with bridging collaterals and no other disease. LVEDP is 10 mmHg. What is the next step?
A. PCI of proximal LAD
B. Viability testing, followed by PCI of LAD if anterior wall is viable
C. Standalone medical therapy

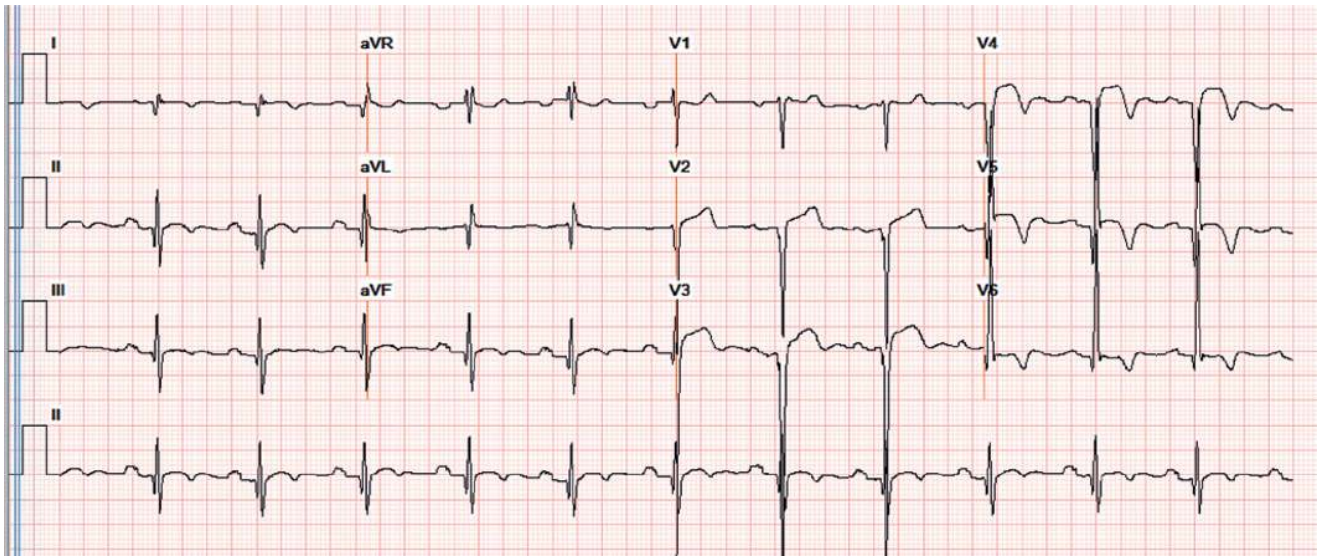

Figure 4

Question 3. Which of the following is incorrect regarding CABG vs. medical therapy in ischemic cardiomyopathy (STICH trial)?
A. CABG significantly reduced 5- and 10-year mortality
B. CABG significantly reduced 5- and 10-year rates of HF hospitalizations
C. CABG significantly reduced the number of hospitalizations in an individual patient
D. An early hazard was seen with CABG and survival benefit was mild and late

Question 4. Which of the following is incorrect regarding CABG vs. medical therapy in ischemic cardiomyopathy (STICH trial)?
A. Viability predicted EF improvement with CABG
B. Viability predicted EF improvement with standalone medical therapy
C. EF improved to a similar magnitude with CABG vs. medical therapy if viability+
D. Viability did not predict the survival benefit from CABG
E. Ischemia testing predicted the survival benefit from CABG
F. Patients with the worst LV dimensions, worst EF, and most extensive CAD derived the most benefit from CABG
G. A lack of viability was associated with higher mortality at 5 years

Question 5. A patient with known HF with reduced EF presents with severe volume overload. His BP is 130/85, pulse is 85 bpm. Creatinine is 1.5 mg/dl, and blood urea nitrogen is 40 mg/dl. He takes furosemide 60 mg twice daily on a chronic basis, lisinopril, and spironolactone. He is hospitalized and treated with intravenous furosemide 120 mg 3 times daily. Urine output is 2 liters per day, and the negative fluid balance is 0.5 liter. What explains the limited urine output?

A. Urine output is not limited, it is appropriate
B. Excessive distal tubular reabsorption
C. Impaired renal function
D. Impaired renal perfusion from HF
E. Inadequate dose of IV furosemide

Question 6. For a patient hospitalized with HF and receiving intravenous furosemide, how should the diuretic response be assessed?

A. Urine output at 24 hours
B. Urine output at 48 hours
C. Urine output at <6 hours
D. Weight at 24 hours
E. Dyspnea at 24 hours

Question 7. A 65-year-old woman has chronic HF with reduced EF and takes furosemide 80 mg once daily. She has mild worsening of dyspnea, 6 pounds weight gain, and mild orthopnea. She has increased her furosemide to 80 mg twice daily for the last 3 days with no improvement. What is the next step?

A. Increase furosemide to 120 mg twice daily
B. Add spironolactone
C. Give one dose of intravenous furosemide in the clinic then keep same furosemide dose
D. Add metolazone for 2 days, then as needed
E. Switch to torsemide
F. Any of the above

Question 8. A 72-year-old woman, non-smoker, with a history of HTN and mild CKD presents with severe exertional dyspnea for the last year. On exam: SBP = 144 mmHg, BMI = 25, mild systolic apical murmur, normal JVP, and no peripheral edema. Echocardiography shows normal EF, mild septal hypertrophy with no LVOT obstruction at rest, grade 1 diastolic dysfunction, LA enlargement, and mild MR. BNP is 45, chest X-ray is clear, and hemoglobin is normal. What is the next step?

A. TEE
B. Auscultation with dynamic maneuvers
C. Nuclear stress test
D. Diastolic echo stress test
E. Right heart catheterization

Question 9. The patient from the prior question undergoes right heart catheterization. PA pressure at rest: 32/15, PCWP 14 mmHg. Within 1 minute of supine cycling: PA pressure rises to 75/40, and PCWP is shown (Figure 5). What is the next step?

A. Initiate diuretic therapy
B. Perform echocardiography during exercise
C. Initiate bosentan + sildenafil
D. Perform coronary angiography
E. Repeat PCWP measurement (this is a mixed PA-PCWP waveform)

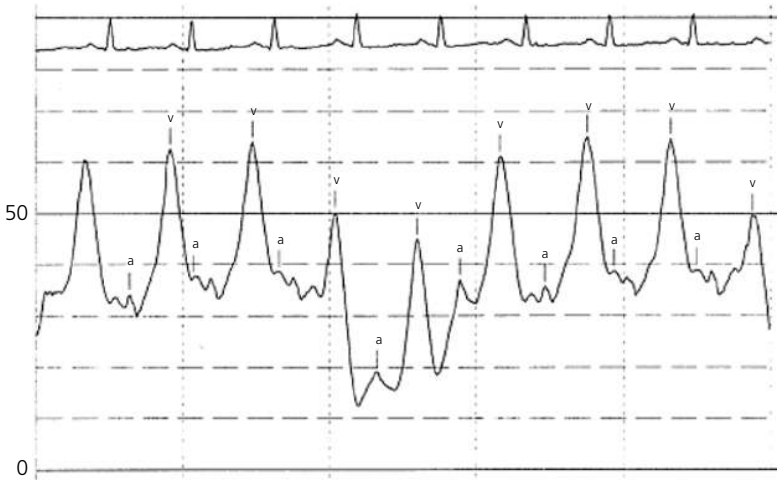

Figure 5

Question 10. A 67-year-old man with TTR amyloidosis presents with weakness and dizziness. He is found to have AF, at a rate of 140 bpm, with SBP of 105 mmHg. Which one of the following agents should be used?
A. Digoxin
B. Metoprolol
C. Amiodarone
D. Diltiazem

Question 11. Which of the following is false?
A. Conduction disease of the His-Purkinje is highly prevalent in senile amyloidosis, more than AL amyloidosis
B. 40% of patients with senile amyloidosis have LBBB and 40% require permanent pacing
C. MRI shows global subendocardial LGE mainly in TTR amyloidosis
D. Senile and genetic TTR amyloidosis are more slowly progressive than AL amyloidosis
E. Senile and genetic TTR amyloidosis have more severe ventricular thickening and echo findings than AL amyloidosis

Question 12. A 52-year-old black man has occasional palpitations lasting up to 20 seconds, with lightheadedness. His exam and baseline ECG are normal, and his echo is grossly normal. Holter monitoring shows frequent unifocal PVCs, with one 5-beat run of monomorphic NSVT. Stress SPECT shows a moderate fixed inferolateral defect with no wall motion abnormality. Coronary CTA shows mild atherosclerosis. What is the next step?
A. No further testing. Benign idiopathic PVCs
B. Prolonged rhythm monitoring
C. Cardiac MRI
D. EP study
E. PET perfusion study

Question 13. Which of the following is a load-independent measurement of LV contractility?
A. EF
B. 2D echo strain
C. End-systolic elastance Ees on the pressure-volume curve (=systolic BP/end-systolic volume)
D. Systolic LV dp/dt on MR Doppler envelope

Question 14. A 35-year-old man with no prior cardiac history presents with palpitations and is found to have frequent unifocal PVCs on Holter monitoring. ECG is normal. A 2-chamber echo view is shown (Figure 6). What is the diagnosis?
A. Idiopathic PVCs
B. Sarcoidosis
C. Amyloidosis
D. ARVD
E. LV noncompaction

Figure 6

Question 15. Two men in their 40s present with HF and anasarca. They are both found to have ventricular thickening with restrictive filling. Figure 7(i) corresponds to the echo strain imaging from patient (i), while Figure 7(ii) corresponds to MRI late gadolinium enhancement from patient (ii). Associate patients (i) and (ii) with the corresponding diagnoses.

A. i: hypertrophic cardiomyopathy, ii: sarcoidosis
B. i: amyloidosis, ii: Anderson-Fabry disease
C. i: hypertensive cardiomyopathy, ii: Anderson-Fabry disease
D. i: amyloidosis, ii: sarcoidosis
E. i and ii: amyloidosis

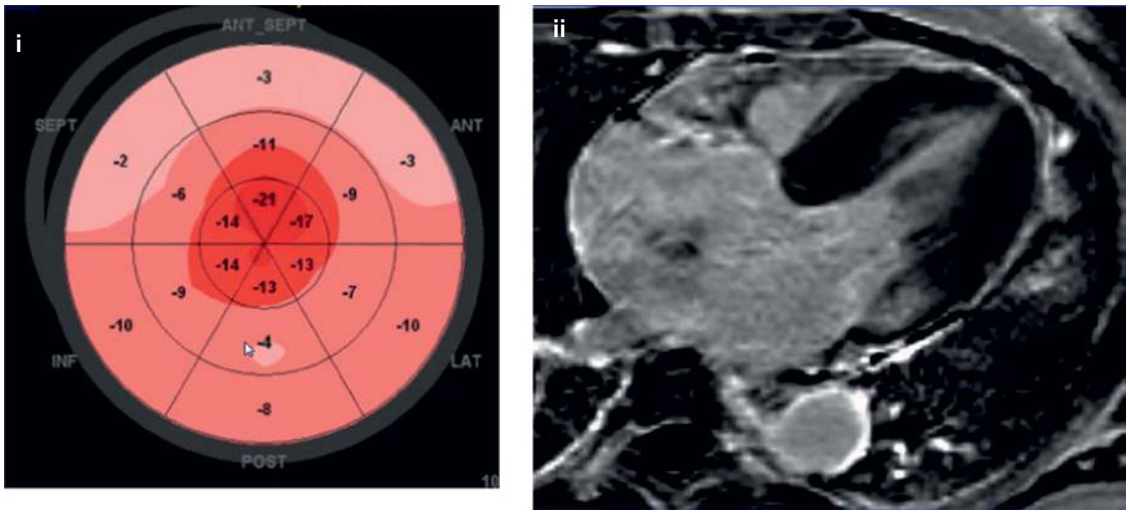

Figure 7

Question 16. A dyspneic patient has the following hemodynamic tracing, obtained in one chamber during right heart catheterization (Figure 8). What do you expect on physical exam?

A. S_3
B. S_4
C. Loud holosystolic murmur
D. Loud P_2 and split S_2
E. Severe JVP elevation and ventricularized waveform

Figure 8

Question 17. A 50-year-old man presents with anasarca. His external jugular vein is dilated and appears to pulsate simultaneously with the carotid pulse. RA waveform is shown (Figure 9). What is the diagnosis?

A. Severe TR
B. Constrictive pericarditis
C. Restrictive cardiomyopathy
D. Left-to-right shunt

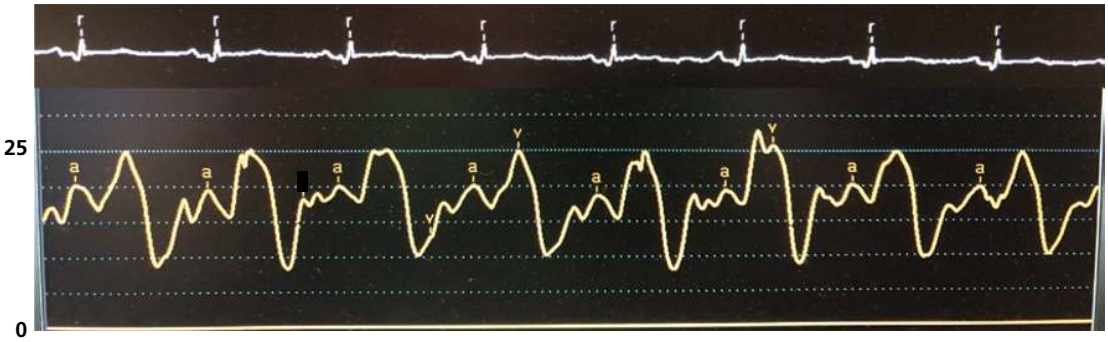

Figure 9

Question 18. A 50-year-old morbidly obese woman presents with anasarca. A right heart catheterization is performed and shows the following RA and PA tracings (Figure 10). The tracings indicate:

A. Constrictive pericarditis
B. Kussmaul sign
C. Restrictive cardiomyopathy
D. Severe TR
E. RV failure

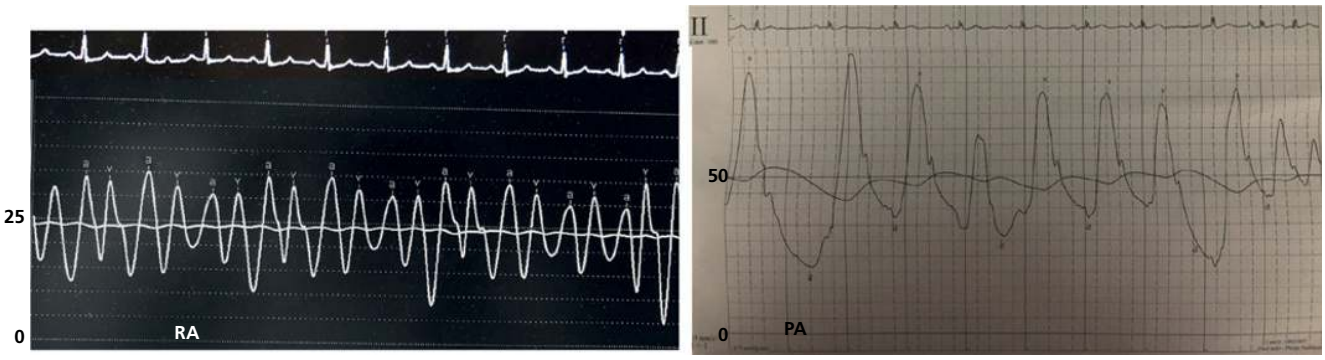

Figure 10

Question 19. A 42-year-old woman has a history of Lyme disease. Her sister died 2 months ago, and she has been grieving. She had emigrated from Ecuador 10 years previously. She presents with chest pain, dyspnea, and inferior ST elevation. Emergent coronary angiography shows no significant CAD. Troponin peaks at 12 ng/ml, and echo shows inferior akinesis. Cardiac MRI shows inferior subepicardial late gadolinium enhancement (LGE). What is the diagnosis?

A. Recanalized coronary thrombosis
B. Lyme carditis
C. Chagas disease
D. Takotsubo cardiomyopathy

Question 20. A patient with dysfunctional anterior myocardium undergoes a low-dose dobutamine stress echocardiography. Which of the following responses is most suggestive of a potential benefit from PCI?

Dobutamine dose	*0*	*5 mcg/kg/min*	*10 mcg/kg/min*
A	Akinetic	Hypokinetic	Normal
B	Akinetic	Hypokinetic	Akinetic
C	Hypokinetic	Hypokinetic	Hypokinetic
D	Dyskinetic	Akinetic	Dyskinetic

Question 21. A patient with dysfunctional anterior myocardium undergoes *resting* metabolic-perfusion PET nuclear scan. Which of the following responses is most suggestive of a potential benefit from PCI?

	Perfusion scan (N^{13} tracer)	**Metabolic uptake scan (FDG [fluorodeoxyglucose])**
A	Impaired	Impaired
B	Impaired	Preserved
C	Preserved	Preserved
D	Preserved	Impaired

Question 22. A patient with dysfunctional anterior myocardium undergoes *stress* SPECT imaging. Which finding is most predictive of myocardial recovery?
A. Reversible defect
B. Fixed defect with tracer uptake >50–60%
C. Fixed defect with tracer uptake <50%

Question 23. A 33-year-old woman develops progressive dyspnea. She had an uneventful pregnancy and delivery 1 year ago. Echo shows severe LV dysfunction (Figure 11). What is the diagnosis?
A. Peripartum cardiomyopathy
B. Genetic cardiomyopathy
C. Myocarditis

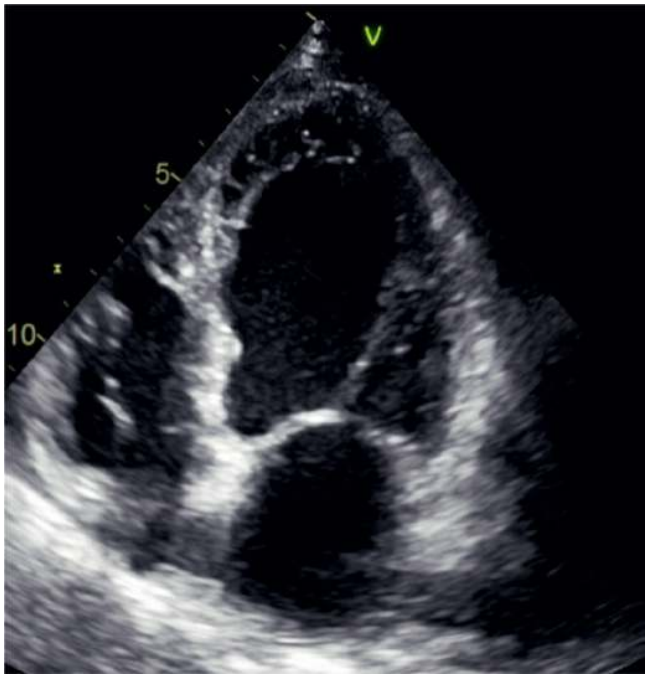

Figure 11

Question 24. A 76-year-old man has a history of HTN, and no other medical history except for carpal tunnel operation. He has developed progressive dyspnea over the last 6 months. On exam: SBP 110 mmHg, elevated JVP, S_3, 2+ edema, and hepatomegaly. ECG shows sinus rhythm with nonspecific ST-T abnormalities. Echo shows moderate LVH with preserved EF. What is the next step?
A. Cardiac MRI
B. Coronary angiography
C. Technetium pyrophosphate cardiac scan
D. Stress testing

Question 25. A 32-year-old woman has a history of HTN with end-stage renal disease and hemodialysis for the last 3 years. She has been getting progressive dyspnea over the last 6 months. ECG shows LVH. Echo shows severe LV hypertrophy (septal thickness 16 mm), with severe bi-atrial enlargement, moderate pulmonary hypertension, and elevated LA and RA pressures. What is the next step?
A. Technetium pyrophosphate myocardial scan
B. Genetic testing

C. Endomyocardial biopsy
D. Cardiac MRI
E. No further testing, aggressive hypertension control

Question 26. A 53-year-old woman had urinary tract infection for which she was prescribed norfloxacin 1 week ago. However, since then, she has been dyspneic. On exam, she has 1+ edema, elevated JVP, and crackles. Temperature is 38.1°C, SBP is 80 mmHg. Troponin is 2.1 ng/ml, BNP is 450 ng/L, creatinine is 1.6 mg/dl, and CBC shows elevated white cell count. ECG shows diffuse ST elevation. Echo shows severe biventricular systolic dysfunction with thick and small cavities and a thrombus at the apex. MRI shows diffuse subendocardial LGE. What is the next step?
A. LVAD
B. Intravenous glucocorticoids
C. Dopamine
D. Emergent coronary angiography
E. ECMO

Question 27. A 37-year-old woman presents with urinary tract infection, bacteremia and septic shock. She has ARDS and is intubated. Her shock is refractory to fluid resuscitation and is requiring vasopressor support. Two days later, her shock continues to progress and she is now requiring high doses of 2 vasopressors. PaO_2 is 60 mmHg on 100% FiO_2. Echo shows severe biventricular failure, and right heart catheterization shows:
RA 12 mmHg, PCWP 18 mmHg, and cardiac index of 1.5 L/min/m^2.
What is the next step?
A. Add a third inopressor
B. ECMO
C. Impella
D. IABP
E. Attempt a fluid challenge

Question 28. A 51-year-old man has developed progressive dyspnea over the last 3 months. He has ascites, JVD, 3+ peripheral edema, and BP of 95/70. His echo shows normal LVEF and enlarged atria. He has no prior cardiac history and no prior chest radiation. His brother died of severe HF at the age of 55. A simultaneous RV-LV pressure recording is obtained (Figure 12). What is the next step?
A. Technetium pyrophosphate cardiac scan and serum and urine protein immunofixation
B. Genetic testing for transthyretin amyloidosis
C. Pericardiectomy
D. Cardiac MRI

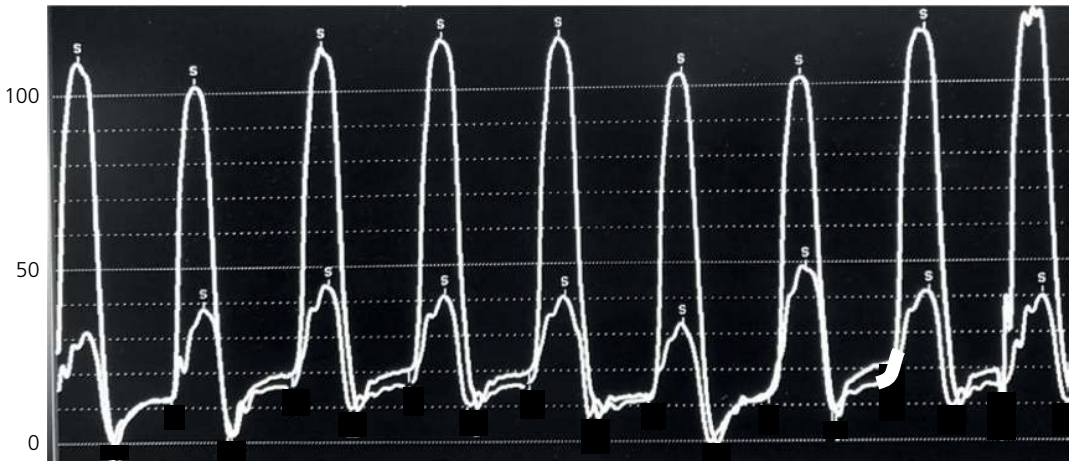

Figure 12

Question 29. A 74-year-old African American man presents with a picture of HF and anasarca. He has also been falling frequently. Exam: SBP 105, falls to 70 upon standing with unchanged pulse. Echo shows preserved EF, severe asymmetric LVH (17-mm septum) with pulmonary hypertension and significant RV dilatation. ECG shows anterior Q waves and normal QRS voltage. Troponin is 0.4 ng/ml (it was 0.3 2 months ago). BNP is 1600 ng/L. What is the next step?
A. Cardiac MRI
B. Coronary angiography
C. Technetium pyrophosphate cardiac scan
D. No further testing needed

Question 30. A 68-year-old woman, morbidly obese, has a history of HFpEF and is receiving chronic furosemide therapy. She presents with severe exertional dyspnea, functional class III, progressive over the last year. Echo shows normal EF, grade 1 diastolic dysfunction, mitral regurgitation of questionable severity, and a small pericardial effusion. A hemodynamic study is done, and simultaneous PCWP-LV recording is shown (along with the waveform of a respirometer) (Figure 13). What pathophysiological process does this recording suggest?

A. Mitral stenosis
B. Mitral regurgitation
C. Dissociation between intracardiac and intrathoracic pressures
D. Decompensated HF
E. Ventricular interdependence

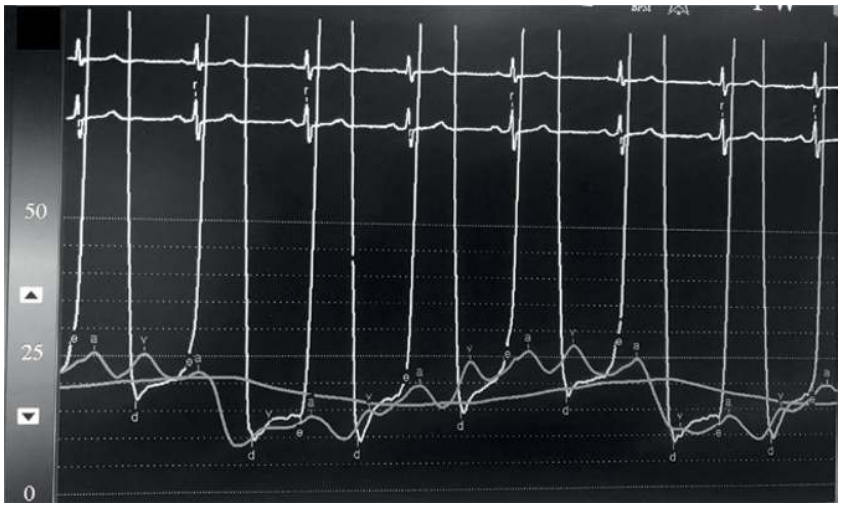

Figure 13

Question 31. Which condition is associated with reverse pulsus paradoxus?

A. COPD
B. Aortic stenosis
C. Hypertrophic obstructive cardiomyopathy (HOCM)
D. Tamponade
E. Mitral regurgitation

Question 32. A 67-year-old hypertensive man is started on lisinopril and HCTZ. Since initiation of the latter medications, he has developed exertional dyspnea. Exam findings: BP 132/80 mmHg, pulse 75 bpm; mid-systolic murmur at the left lower sternal border that increases with standing; increased PMI with double impulse. Exercise stress echo shows turbulent flow across the LVOT and severe MR. His septal thickness is 16 mm. What is the next step?

A. Mitral valve surgery
B. Stop lisinopril and HCTZ and initiate metoprolol
C. Myectomy + mitral valve surgery
D. Alcohol septal ablation

Question 33. A 66-year-old man presents with severe exertional dyspnea, paroxysmal nocturnal dyspnea, and 2+ peripheral edema. He has a history of non-Hodgkin lymphoma treated with chest radiation 26 years previously. Echo shows septal thickness of 31 mm, and LVOT gradient of 65 mmHg, which increases to 110 mmHg with Valsalva. His pulse is 55 bpm on metoprolol therapy. His chest wall skin is noted to be thin with telangiectasias and small erosions. He could not tolerate mavacamtem. What is the next step?

A. Increase β-blocker therapy
B. Alcohol septal ablation
C. Septal myectomy
D. Pericardiectomy

Question 34. A 45-year-old man presents with exertional dyspnea on activity of daily living, such as climbing 2 flights of stairs or walking briskly. He has a dynamic midsystolic murmur at the left lower sternal border, which increases with Valsalva strain and decreases with hand-grip. A 75-mmHg resting pressure gradient is observed across the LVOT, with a septal thickness of 23 mm. He is given metoprolol 50 mg BID; 3 weeks later, his dyspnea has improved, and he can now perform most of his activities with no dyspnea. He has mild dyspnea when he carries heavy loads upstairs. Echo now shows a LVOT gradient of 100 mmHg at rest. What is the next step?

A. Continue current therapy
B. Septal myectomy
C. Alcohol septal ablation (reduces symptoms, gradient, and mortality)
D. Alcohol septal ablation (reduces symptoms and gradient, not mortality)
E. Add mavacamtem
F. ICD

Question 35. A 65-year-old woman with a history of hypertension presents with exertional dyspnea. Her home SBP runs 150s–160s. She receives metoprolol and her pulse rate is ~60 bpm. On exam, she has a mild mid-systolic murmur at the base, which does not significantly change with maneuvers. Echo shows moderate concentric LVH with a septal thickness of 15 mm, and a calcified aortic valve with a mild gradient across it. Hemodynamic recordings are obtained (Figure 14).
What is the next treatment step?
A. Antihypertensive drugs
B. Increase the metoprolol dose
C. Aortic valve replacement
D. Septal ablation
E. Mavacamtem

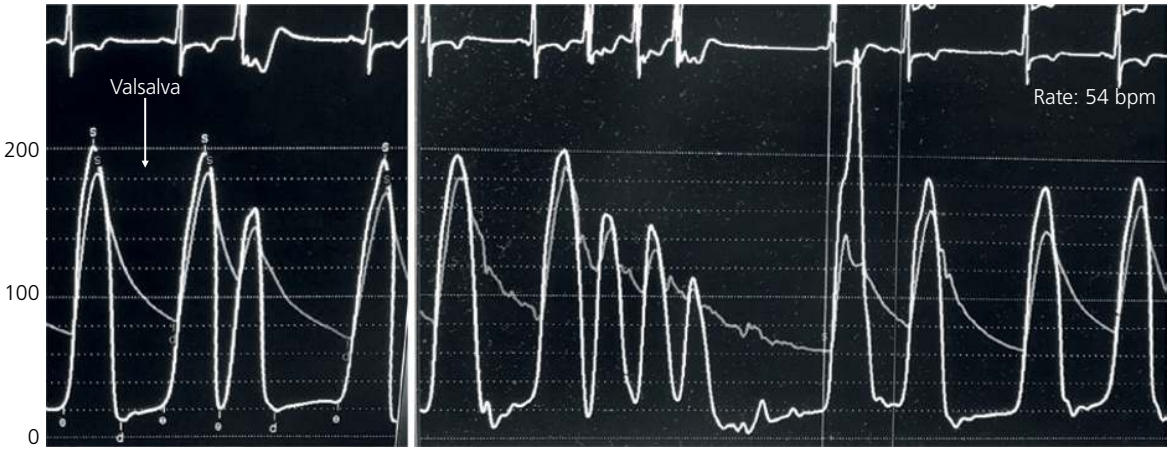

Figure 14

Question 36. A 51-year-old woman presents with class III exertional dyspnea. BP is 150/85. Echo reveals asymmetric septal hypertrophy of 18 mm and a resting LVOT gradient of 80 mmHg, with anteriorly directed severe MR. Her dyspnea is refractory to metoprolol. What is the best treatment strategy?
A. Alcohol septal ablation
B. Surgical myectomy
C. Surgical myectomy with mitral valve repair
D. Add disopyramide then reassess the need for septal reduction
E. ICD

Question 37. A 50-year-old man presents with palpitations. His father died suddenly at the age of 41. ECG shows LVH with strain, and echo reveals an apical aneurysm. Coronary angiography shows 30–40% disease in the LAD. What is the diagnosis?
A. Familial dilated cardiomyopathy
B. Hypertrophic cardiomyopathy
C. LV non-compaction
D. Prior coronary vasospasm and apical infarct
E. Prior coronary plaque rupture/thrombosis and apical infarct

Question 38. A 65-year-old man undergoes Heart Mate 3 placement for HFrEF. He develops postoperative RV failure requiring right Impella support, but this improves few weeks later. He presents a year later with fatigue and dyspnea. Mean BP is 60 mmHg, he has JVD, ascites, and anasarca. Echo shows enlarged LV and RV; LVAD interrogation reveals high power and high flow. Cardiac index is 1.8 L/min/m^2 by Swan. INR is 3 and urine is dark. Echo shows that the inflow cannula has a damped velocity. What is the diagnosis?
A. RV failure
B. Pump thrombosis
C. Outflow cannula thrombosis
D. Inappropriately low pump speed

IV. Valvular disorders (Answers on pages 1088–1092)

Question 1. A 46-year-old woman presents with an asymptomatic murmur. BP 155/60, pulse 75. On exam: S_1 and S_2 are normal. A mild early diastolic murmur (2/6) is heard at the LUSB, mainly in expiration; an early systolic sound and a soft diastolic murmur are heard at the apex. What is the diagnosis?
A. Mitral valve prolapse + MS
B. AI + MS
C. Bicuspid aortic valve with AI
D. MS + Graham Steell murmur

Question 2. In a patient with aortic stenosis and moderate aortic regurgitation, what is the best method of calculating aortic valve area?
A. Standard Gorlin equation by catheterization
B. Continuity equation by echo
C. Both A and B

Question 3. A patient has a heavily calcified aortic valve with a high aortic valve velocity of 4 m/s. He also has a hypertrophied septum with elevated LVOT velocity of 2 m/s by pulsed wave Doppler. What is the best method of estimating AVA and AS severity?
A. AVA by continuity equation
B. Dimensionless index
C. AVA by Gorlin equation (cath)
D. Pull back gradient across the LVOT and aortic valve

Question 4. This continuous wave Doppler envelope is obtained across a calcific aortic valve with a degree of impaired mobility (Figure 15). What does it suggest?
A. Severe AS
B. Severe LVOT obstruction with mild AS
C. Severe AS with mild LVOT obstruction

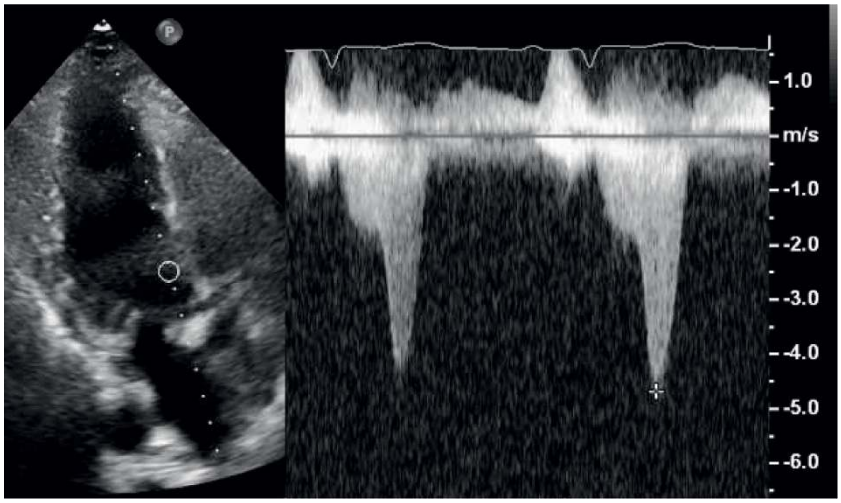

Figure 15

Question 5. A 45-year-old patient has symptomatic MS with a mean gradient of 11 mmHg and a pressure half-time of 190 ms (which translates into MVA of 1.1 cm^2). He undergoes PMBV. Next day, he is comfortable, and his diastolic rumble is briefer than preoperatively. Echo shows reduced mitral gradient of 5 mmHg, but pressure half-time is 185 ms. Heart rate is 72 bpm. Can you calculate MVA, and what is the next step?
A. Refer to mitral valve surgery
B. Increase β-blocker therapy
C. Continue to observe and repeat echo in 2 weeks

Question 6. A 78-year-old man has chronic HFpEF with right-sided dilatation and severe TR. He has had multiple HF hospitalizations. What is the 1-year mortality of uncorrected, symptomatic severe TR?
A. 10%
B. 20%
C. 30%
D. 40%

Question 7. A 70-year-old woman presents with recurrent near syncope on exertion. She has a history of radiation for left breast cancer 15 years prior. Echo shows mild AS and heavy MAC. ECG shows sinus bradycardia (55 bpm), incomplete RBBB, and LVH with 1 mm ST depression. What is the next step?
A. Coronary angiography
B. Hemodynamic study to assess the severity of MS and AS
C. Exercise stress ECG
D. Exercise nuclear testing
E. 30-day event monitoring

Question 8. A 65-year-old man presents with severe exertional dyspnea and near syncope. He has a history of chest radiation for lymphoma 20 years prior. Echo shows high velocity across the aortic valve (5 m/s) with a calculated aortic valve area of 0.75 cm^2. He has severe

calcifications of the mitral annulus, including the anterior mitral annulus and the mitro-aortic curtain; the aortic valve appears to be opening adequately on echo images. What is the next step?

A. Surgical AVR
B. TAVR
C. Cardiac CTA
D. Invasive catheterization to assess the true severity of AS and MS

Question 9. Which of the following is false regarding radiation heart disease?

A. Pericardial complications may occur within 1 year
B. The tricuspid valve is the valve most commonly affected, as it is anterior
C. Radiation may cause recurrent pleural effusions requiring prolonged drainage, further aggravated by cardiac surgery
D. Younger age <60 years is a risk factor for radiation heart disease
E. The concomitant use of anthracyclines increases the risk of radiation heart injury

Question 10. A 48-year-old man is referred for chest pain, He has had a murmur for decades. He works a physical job and has not noted any functional limitation or dyspnea. He had nocturnal chest pain a couple of times, which awakened him from sleep and resolved with acid buffers but feels well overall. On exam, he has a loud midsystolic murmur and a holodiastolic murmur at the left and right upper sternal borders, with attenuated A_2. BP is 150/70 mmHg, and pulse is 60 bpm. Echo shows a bicuspid aortic valve with eccentric AI, that is mild to moderate, with moderate AS (peak velocity 3 m/s). LV is mildly dilated (LVEDD 6 cm, LVESD 4.4 cm), and the aortic sinuses are dilated at 4.4 cm. TEE is performed and similarly suggests mild-to-moderate AI. What is the next step?

A. Repeat echo in 1 year
B. Repeat echo in 2 years
C. Cardiac MRI
D. Nuclear stress testing
E. Coronary angiography

Question 11. A patient has the following simultaneous pressure recording (Figure 16). What do you expect to find on physical exam?

A. Late peaking systolic murmur with absent A_2
B. Holodiastolic blowing murmur at the left upper sternal border
C. Diastolic rumble with presystolic accentuation and S_4
D. Diastolic rumble with presystolic accentuation and no S_4
E. Holosystolic blowing murmur

Figure 16

Question 12. A 78-year-old woman is admitted with HF. She has a late peaking mid-systolic murmur with attenuated A_2. BP is 130/60 mmHg, and body surface area is 1.7 m^2. Echo shows EF of 68%, a small LV cavity with moderate concentric LV hypertrophy, and severe diastolic dysfunction. The aortic valve is calcified and poorly mobile. The peak velocity across the aortic valve is 3 m/s in the right parasternal view (2.8 m/s in the apical view) with a mean gradient of 22 mmHg and an aortic valve area of 0.8 cm^2. Cardiac catheterization is performed and shows the following tracing (Figure 17) with a cardiac output of 3.9 L/min. What is the diagnosis?

A. Diastolic HF with moderate AS and erroneous echo AVA calculation
B. Truly severe AS with low gradient related to severely restricted diastolic filling
C. Truly severe AS with low gradient related to hypovolemia (overdiuresis)
D. AS of indeterminate severity. Perform calcium scoring
E. Severe AS vs. pseudo-severe AS. Perform dobutamine testing
F. Pressure recovery phenomenon

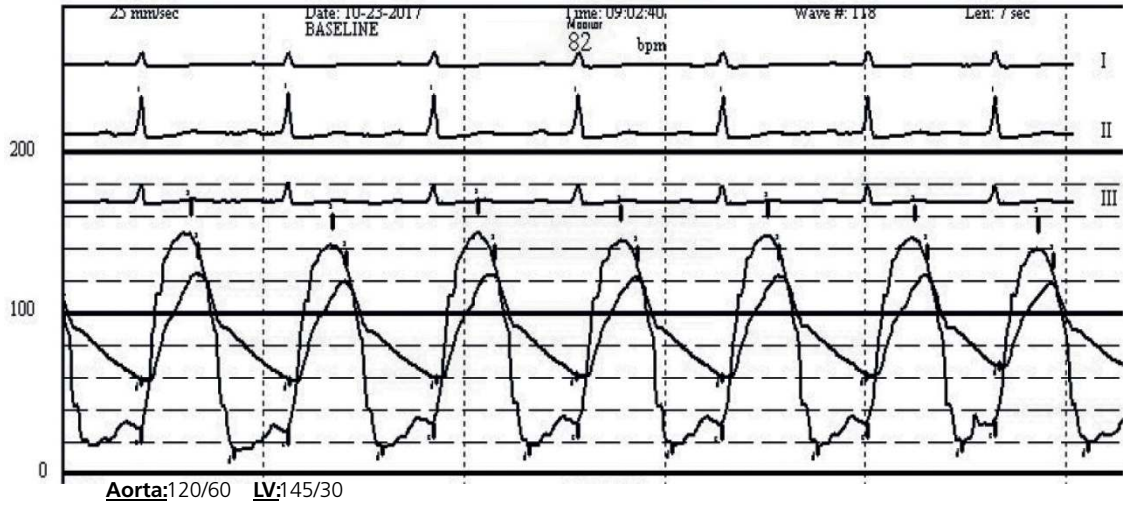

Figure 17

Question 13. A 78-year-old man is admitted with HF. He is debilitated, partly from spinal stenosis, and partly from chronic orthostatic hypotension. He has a late peaking mid-systolic murmur with attenuated A_2. BP is 90/60 mmHg. Echo shows EF of 60%, a small LV cavity with severe concentric LV hypertrophy (septal thickness 17 mm, asymmetric), and severe diastolic dysfunction. The aortic valve is calcified and poorly mobile. The peak velocity across the aortic valve is 2.8 m/s with a mean gradient of 22 mmHg and an aortic valve area of 0.8 cm^2. Stroke volume is 60 ml with a stroke volume index of 29 ml/m^2. ECG shows anterior Q waves.
What is the next step?
A. Perform scintigraphy with technetium pyrophosphate
B. AS of indeterminate severity. Perform calcium scoring then TAVR if severe
C. AS of indeterminate severity. Perform dobutamine testing then TAVR if severe.
D. Truly severe AS with low gradient from hypertensive cardiomyopathy. Perform TAVR
E. HOCM. Perform alcohol septal ablation

Question 14. A 76-year-old man has a history of chronic hypertension. He has been having mild exertional dyspnea for the last 2 years but remains active and plays ping-pong daily. Echo is performed. It shows a normal EF, a poorly mobile and calcified aortic valve, with peak velocity of 3.2 m/s and a mean gradient of 23 mmHg (Figure 18). Two LVOT velocities are recorded. The dimensionless index is measured at 0.45, and the AVA is calculated at 1.5 cm^2 (LVOT diameter 2.1 cm). What is the next step?
A. This is moderate AS by both AVA and gradient. Repeat echo in 1–2 years
B. This is low-gradient AS with AVA ≤1 cm^2. Perform aortic valve CT calcium scoring
C. AS of indeterminate severity. Perform cardiac catheterization
D. AS of unclear symptoms. Perform exercise stress testing for functional assessment
E. This is HOCM with LVOT obstruction

Question 15. A 76-year-old man has a history of chronic hypertension. His height is 185 cm and his weight is 240 lbs. He has been having mild exertional dyspnea for the last 2 years but remains active and plays ping-pong daily. Echo is performed. It shows a normal EF, thick LV with small cavity and low E′ velocity; a poorly mobile and calcified aortic valve, with peak velocity of 3.1 m/s, a mean gradient of 20 mmHg, and mild AI. Cardiac catheterization shows a mean transaortic gradient of 22 mmHg, a cardiac output of 5 L/min, and AVA of 1.1 cm^2. Heart rate is 72 bpm. Which of the following is true?
A. Severe low-gradient AS related to low flow from impaired diastolic filling
B. Severe low-gradient AS with normal flow, related to the misalignment of the guidelines' severe AS cutoffs
C. Moderate AS
D. Mild AS with exaggerated gradient related to AI

Question 16. A 55-year-old man has severe primary MR and functional dyspnea NYHA class II. He is inquiring about the risk of postoperative HF. What is the most important predictor of postoperative HF?
A. Preoperative NYHA
B. Preoperative EF ≤60%
C. Preoperative AF
D. Concomitant CAD
E. Valve repair vs. replacement

Question 17. A 55-year-old man has exertional dyspnea (NYHA functional class II). Echo shows severe bicuspid AS with preserved EF. His largest aortic size at the sinuses of Valsalva is 4.2 cm. He is a smoker, has mild lung disease and CKD stage 3. What is the preferred treatment strategy?

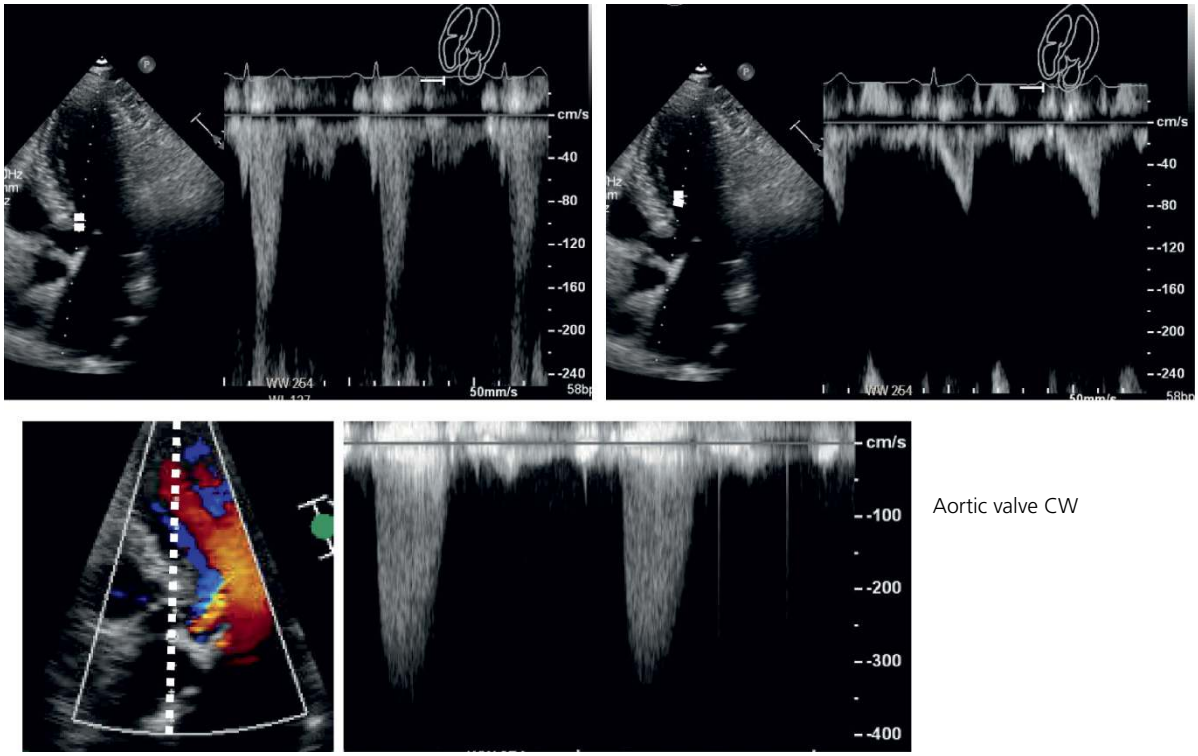

Figure 18

A. TAVR
B. Surgical bioprosthetic AVR
C. Surgical mechanical AVR
D. Mechanical AVR and aortic root replacement using Bentall procedure

Question 18. A 55-year-old patient presents with exertional dyspnea and angina. He has the following hemodynamic tracing upon pull back of the LV catheter into the aorta (Figure 19). What do you expect to find in this patient?
A. Dynamic mid-systolic murmur
B. Slow, late-peaking mid-systolic murmur
C. Coronary diastolic flow reversal on angiography
D. Early diastolic rumble at the apex

Figure 19

Question 19. A 50-year-old woman has a history of bicuspid aortic valve and AVR 13 years prior, using a St Jude bileaflet mechanical valve. She is morbidly obese (BMI 46) and smokes. There have been gaps in her INR monitoring. She presents with dyspnea on mild exertion. Echo shows an increased velocity of 5.5 m/s across the aortic prosthesis. She is receiving warfarin and her INR on presentation

is 2.4. Cardiac CT shows a 1.5 × 0.9 cm hypo-attenuated mass on the valve. The leaflets' motion is assessed by gated cardiac CT as well as by fluoroscopy (Figure 20). What is the next step?

A. Refer for redo aortic valve surgery (redo AVR or thrombus aspiration)
B. Thrombolytic r-tPA infusion, 25 mg over 25 hours, to be repeated as needed
C. Thrombolytic r-tPA bolus, 100 mg over 2 hours
D. Heparin infusion and echo monitoring

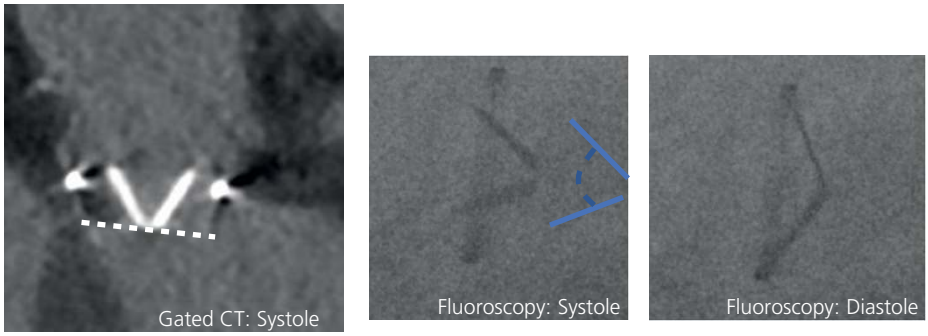

Figure 20

Question 20. A 68-year-old man has exertional dyspnea (NYHA functional class II). Echo shows severe AS with preserved EF; the aortic valve is tricuspid. His largest ascending aortic size, at the sinuses of Valsalva is 4.2 cm. He has a low surgical risk (STS score 2%). What is the preferred treatment strategy?

A. TAVR
B. Surgical bioprosthetic AVR
C. Surgical mechanical AVR
D. Surgical bioprosthetic AVR and aortic root replacement using Bentall procedure
E. A or B
F. A, B, or C

Question 21. A 70-year-old man underwent mitral valve replacement for severe MR 10 years prior. He is presenting now with exertional dyspnea and fatigue, as well as ascites and peripheral edema, and progressive renal injury (creatinine increased from 1.2 to 2.4 mg/dl over the last 6 months). He is on high diuretic doses. Echo shows a competent mitral valve and severe TR with dilated and dysfunctional RV. What is the best treatment option?

A. Tricuspid valve percutaneous correction (improves symptoms and survival)
B. Tricuspid valve percutaneous correction (e.g., MitraClip, improves symptoms)
C. Hospitalization and high-dose IV diuresis + paracentesis
D. Tricuspid valve surgical correction

Question 22. A 65-year-old man is hospitalized with HF (pulmonary edema, elevated JVP). He is found to have severe MR with EF of 55% and will be undergoing mitral valve repair after proper diuresis. He also has mild AS (peak velocity 2.5 m/s, AVA 1.8 cm^2) and mild TR. How should he be treated?

A. Isolated mitral valve repair
B. Mitral valve repair and AVR
C. Mitral valve repair and tricuspid repair
D. Mitral valve repair and tricuspid repair if severe pulmonary hypertension is present
E. Mitral valve repair, aortic valve replacement, and tricuspid repair

Question 23. A 70-year-old man with EF 30% and functional severe MR undergoes MitraClip placement. Which of the following is true?

A. MitraClip is only indicated in functional MR, not degenerative MR
B. MitraClip often improves EF
C. MitraClip improves cardiac output by ~20% and reduces afterload
D. MitraClip improves cardiac output by ~20% with no effect on afterload
E. MitraClip improves cardiac output by ~20% and increases afterload

Question 24. A 56-year-old woman has a history of severe bicuspid AS and aortic valve replacement with 21-mm St Jude bileaflet mechanical prosthesis 10 years previously. Her INR target has been difficult to maintain, and she has noticed progressive dyspnea over the past year with peripheral edema. TTE and TEE show a mean gradient of 36 mmHg across the aortic prosthesis with no clear prosthetic mass. Aortic valve fluoroscopy shows that the leaflets open with an in-between angle of 10°. The aortic prosthesis was crossed with a 5 Fr catheter and pull back pressures were recorded: LV 155/30 mmHg, LVEDP 30 mmHg, aorta 155/80 mmHg. What is the diagnosis?

A. Patient prosthesis mismatch
B. Pannus formation missed by TEE
C. Pressure recovery
D. Low-output severe mechanical AS
E. False echo measurement

Question 25. A 64-year-old hypertensive man has severe AS. What is the most likely etiology?
A. Degenerative
B. Bicuspid
C. Rheumatic

Question 26. A 45-year-old man has a history of congenital AV block with pacemaker placement 20 years previously and multiple lead fractures and lead revisions over the years. He presents with anasarca, hepatomegaly, ascites, elevated JVP with large A wave. A soft diastolic murmur is heard over the left lower sternal border. There is no RV lift and S_2 is normal. What is the diagnosis?
A. Tricuspid regurgitation
B. Tricuspid stenosis
C. Mitral stenosis
D. Pulmonic regurgitation

Question 27. A 72-year-old man has severe mitral regurgitation secondary to posterior mitral valve prolapse with EF of 55%. He undergoes mitral valve repair with mitral ring placement. Postoperatively, the patient develops progressive severe HF, and echo shows severe eccentric, anteriorly directed mitral regurgitation with decline of EF to 30%. He is anemic (hemoglobin 7 g/dl) with schistocytes on blood smear. What is the next step in management?
A. MitraClip repair
B. Open mitral valve replacement
C. Open repeat mitral valve repair

Question 28. A 60-year-old woman has a history of St Jude mechanical aortic valve. She is physically active and has no complaints. She takes warfarin and lisinopril. Her BP is 128/78 and INR is 2.4. What do you recommend?
A. Increase warfarin. Aim for INR 2.5–3.5
B. Continue the same regimen
C. Add aspirin 81 mg daily
D. Increase warfarin (INR 2.5–3.5) and add aspirin 81 mg daily

Question 29. A 56-year-old man received a mechanical aortic valve prosthesis 4 years ago. At baseline, prosthetic gradients were: peak 18 mmHg, mean 10 mmHg. He develops pneumonia with fever, and it is noted that the intensity of the systolic murmur increases. His PMI is hyperdynamic and pulses are bounding. Echo now shows the following prosthetic gradients: peak 36 mmHg, mean 22 mmHg. What is the next step?
A. TEE
B. Fluoroscopy
C. No further workup

Question 30. A 64-year-old man has a midsystolic murmur suggestive of AS. Which physical exam finding rules out severe AS?
A. Normally split S_2
B. 2/6 murmur severity
C. Lack of radiation to the carotids

Question 31. Which murmurs do not increase after a pause (multiple answers allowed)?
A. HOCM
B. AS
C. MR
D. TR
E. VSD

Question 32. What is a normal finding across a prosthetic valve?
A. Soft diastolic rumble across a mitral prosthesis
B. Peak velocity of 4 m/s across an aortic prosthesis
C. Peak velocity of 3 m/s across a mitral prosthesis
D. Soft systolic apical murmur across a mitral prosthesis

Question 33. Which diagnosis is suggested by this hemodynamic tracing (LV-aortic pressure recording, Figure 21)?
A. Aortic stenosis
B. Hypertrophic obstructive cardiomyopathy
C. Subaortic membrane

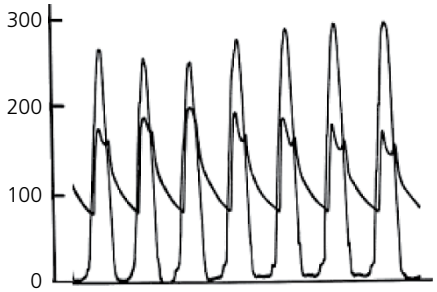

Figure 21

V. Arrhythmias (Answers on pages 1092–1095)

Question 1. A 62-year-old man had symptomatic AF that was successfully cardioverted (on first attempt) but recurred 1 week later. He is given an antiarrhythmic drug and DC cardioversion is reattempted. DC cardioversion fails to re-establish sinus rhythm this time. What was the antiarrhythmic agent?

A. Sotalol
B. Flecainide
C. Dofetilide
D. Dronedarone
E. Propafenone

Question 2. DC cardioversion is attempted for AF in an obese patient, but fails to re-establish sinus rhythm, not even for one beat. How to improve the chance of successful DC cardioversion? (multiple possible answers)

A. Prepare the patient with amiodarone for 3 weeks, then reattempt DC cardioversion
B. Give IV procainamide over 30 min, then reattempt cardioversion
C. Give IV ibutilide, then reattempt cardioversion
D. Change pad positions
E. Hold heavy pressure over the pads to reduce insulation

Question 3. Which of the following is the most potent sodium channel blocker?

A. Flecainide
B. Procainamide
C. Lidocaine
D. Amiodarone

Question 4. A patient presents with regular, wide complex tachycardia at a rate of 180 bpm with a typical LBBB morphology. AV dissociation is noted. SBP is 110 mmHg. Which of the following is true?

A. This is idiopathic RVOT VT. Chronically treat with verapamil or metoprolol
B. This is bundle branch reentrant tachycardia, in a patient with no underlying heart disease. Chronically treat with verapamil
C. This is bundle branch reentrant tachycardia in a patient with severe cardiomyopathy. The best treatment is ICD
D. This is bundle branch reentrant tachycardia in a patient with severe cardiomyopathy. The best treatment is ablation of the right bundle
E. This is idiopathic fascicular VT. Chronically treat with verapamil

Question 5. A 63-year-old man with prior MI presents with sustained monomorphic VT. It is upright in V_1 with an atypical RBBB morphology, with a transition in V_2, and negative QRS with no R wave in V_3-V_6. The frontal axis is right superior. Where is the location of his prior infarct?

A. Inferior wall
B. LV apex
C. Lateral wall
D. Basal septum
E. RV

Question 6. A 41-year-old man has a history of palpitations. An even monitor is placed and reveals the following (Figure 22). What is the diagnosis?

A. VT
B. Atrial flutter
C. AVRT
D. AVNRT
E. AF

Figure 22

Question 7. A patient develops VT after acute STEMI. VT is successfully cardioverted and he is started on a new drug. Unfortunately, he continues to have VT breakthroughs that are now more difficult to DC cardiovert. What new drug has been started?
A. ACE inhibitor
B. Lidocaine
C. Metoprolol
D. Procainamide

Question 8. What is the most common cause of syncope in sinus node disease?
A. Sinus bradycardia
B. Chronotropic incompetence
C. Tachy-brady syndrome

Question 9. A 81-year-old man presents with recurrent falls. His ECG shows sinus rhythm at a rate of 65 bpm. He has a history of AF and is not on any rate-controlling drug. He is admitted for observation, and telemetry rhythm is shown (Figure 23). What is the cause of this patient's falls?
A. Sinus bradycardia
B. Paroxysmal AF
C. AF pause
D. Pause at the transition between AF and sinus rhythm
E. Prolonged sinus pause

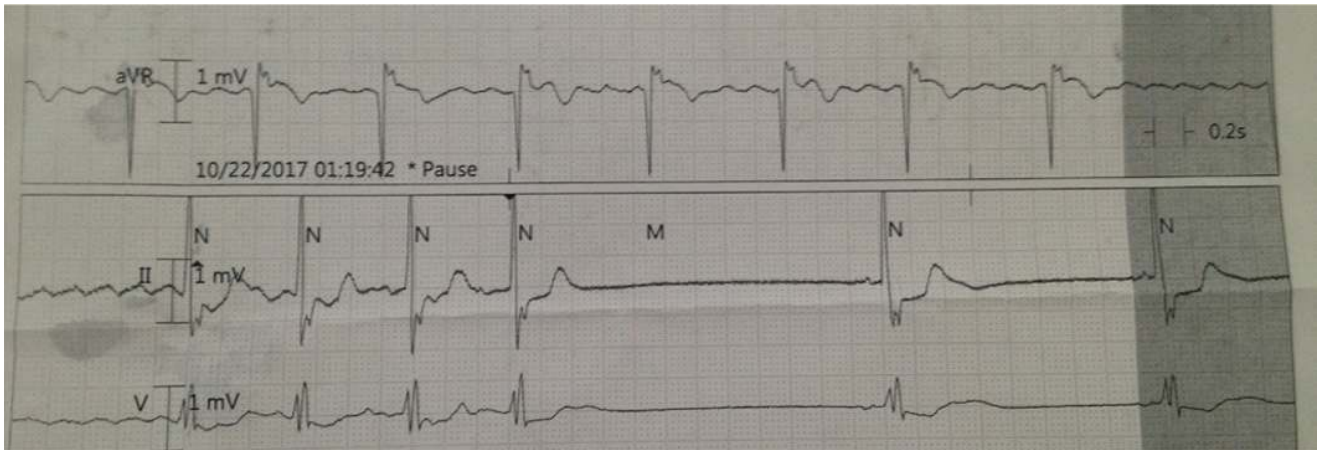

Figure 23

Question 10. Which medication, if not contraindicated, may reduce the falls of the preceding patient?
A. Amiodarone
B. Dofetilide
C. Dronedarone
D. Sotalol
E. Flecainide

Question 11. Regarding invasive EP assessment of the conduction system, which of the following is incorrect?
A. EP study may be indicated in patients with Mobitz 1 AV block and symptoms of near syncope
B. Infra-His block on EP study dictates permanent pacemaker placement, regardless of symptoms
C. A normal sinus node recovery time rules out sinus node disease
D. Ambulatory rhythm monitoring is more helpful in the diagnosis of sinus node disease
E. On incremental pacing, HV prolongation followed by V drop indicates infra-His block

Question 12. A 65-year-old diabetic man, asymptomatic from a cardiac standpoint and with no functional limitation, undergoes a preoperative ECG before colonoscopy. ECG shows complete LBBB with QRS of 160 ms. Echo is performed and shows EF of 35%, with abnormal septal motion and preserved apical function. Which of the following is true?

A. EF is expected to super respond to CRT
B. CRT placement is indicated
C. CRT-ICD placement is indicated
D. EF is expected to improve with ACE inhibitors and carvedilol
E. This is likely an ischemic cardiomyopathy. Perform coronary angiography

Question 13. A 40-year-old woman presents with severe tiredness that started over the last 3 months. She gets fatigue, dyspnea, and dizziness while walking or performing simple daily tasks. On exam, her pulse is 108 bpm and BP is 105/65 mmHg in the supine position; the pulse rises to 118 bpm upon standing, and BP remains unchanged. No murmur is heard. ECG shows sinus tachycardia, and echo shows hyperdynamic ventricular function with no abnormalities. A Holter monitor shows an average sinus rate of 99 bpm. TSH is normal, and basic laboratory tests are normal. What is the treatment?

A. Metoprolol 25 mg BID
B. Ivabradine 2.5 mg BID
C. Lifestyle measures (exercise, hydration)
D. Sinus node modification

Question 14. A 40-year-old woman presents with severe tiredness that started over the last 3 months, after a brief viral illness. She used to be athletic. She now gets fatigue, dyspnea, and dizziness while walking or performing simple daily tasks. On exam, her pulse is 95 bpm and BP 110/65 in the supine position; after 5 minutes of standing, pulse rises to 130 bpm, and BP becomes 105/60, along with dizziness. No murmur is heard. ECG shows sinus tachycardia, and echo shows hyperdynamic ventricular function with no abnormalities. A Holter monitor shows an average sinus rate of 99 bpm. TSH is normal, and basic laboratory tests are normal. What is the treatment?

A. Metoprolol 25 mg BID
B. Ivabridine 2.5 mg BID
C. Lifestyle measures (exercise, hydration)
D. Droxidopa
E. Midodrine

Question 15. A patient has a regular atrial rhythm with an atrial rate of 180 bpm and 2:1 AV conduction. The medical student asks if it is important to distinguish atrial flutter from atrial tachycardia (AT). Which of the following is true?

A. Both AT and atrial flutter are responsive to class I antiarrhythmics
B. The biggest ECG distinguishing feature is atrial rate (<200: AT; >200 atrial flutter)
C. β-Blockers and calcium channel blockers may break AT or MAT
D. AT is easy to induce and to successfully ablate, like atrial flutter
E. AT is often responsive to DC cardioversion

Question 16. A 41-year-old man collapses while sitting and resting and is found to have VT storm. His ECG between VT episodes is shown (Figure 24). What is the best intravenous treatment?

A. Amiodarone
B. Isoproterenol
C. Lidocaine
D. Procainamide
E. Quinidine

Figure 24

Question 17. An 85-year-old man has a history of dual-chamber pacemaker placed for sick sinus syndrome 10 years prior. He presents with syncope that occurred during defecation. His ECG shows A-paced, V-sensed rhythm with an intrinsic PR interval of 180 ms and a narrow QRS complex. His device interrogation shows: V pacing 70% of the time, with a paced AV delay of 250 ms; intermittent rise in V lead impedance from 400 to 1200 Ohms; and frequent arrhythmia episodes with marker recordings shown (no EGM recording available) (Figure 25). What is the diagnosis?

A. VT
B. Ventricular oversensing
C. Ventricular undersensing
D. Ventricular over- and undersensing
E. Atrial oversensing

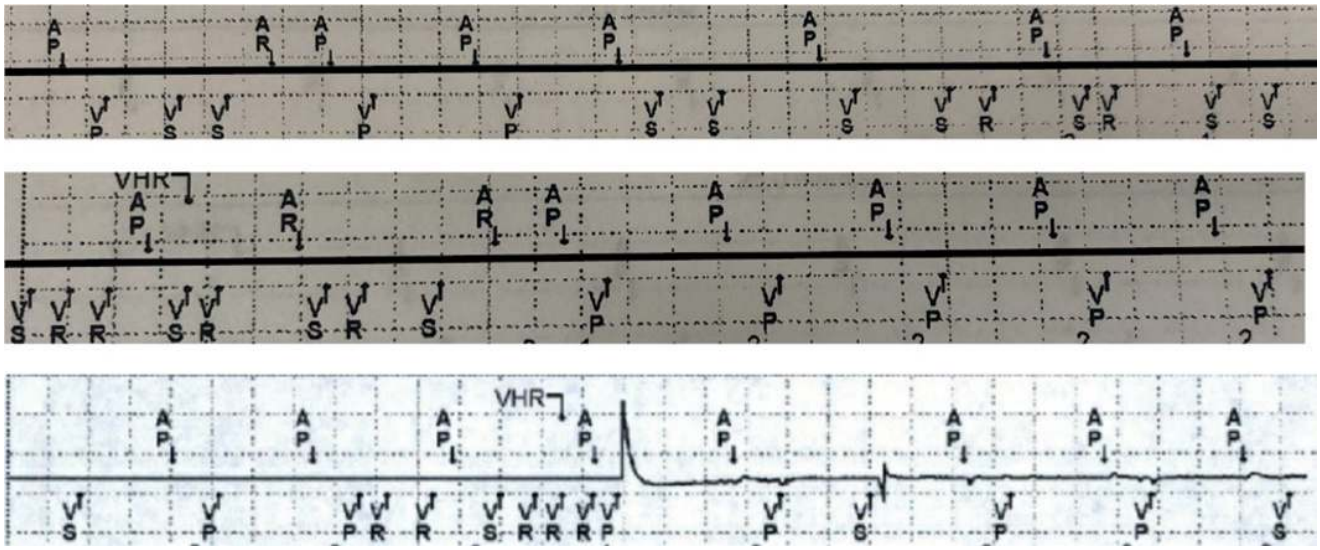

Figure 25

Question 18. For the prior patient, what is the next management strategy?

A. Upgrade to ICD
B. Revise the ventricular lead
C. Change the V lead configuration to unipolar
D. Revise the atrial lead

Question 19. A 22-year-old black college basketball athlete is referred for cardiac screening. He trains and competes for several hours daily with no symptoms. He has no family history of sudden death and his exam is normal. An ECG is performed (Figure 26). Echocardiography shows a septal thickness of 11 mm, mild LV dilatation at 5.8 cm, and normal findings otherwise. What is the next step?

A. No further testing. Allow competitive exercise
B. Cardiac MRI
C. Genetic testing for hypertrophic cardiomyopathy
D. Genetic testing panel for all cardiomyopathies, including LV non-compaction
E. Genetic testing for long QT syndrome

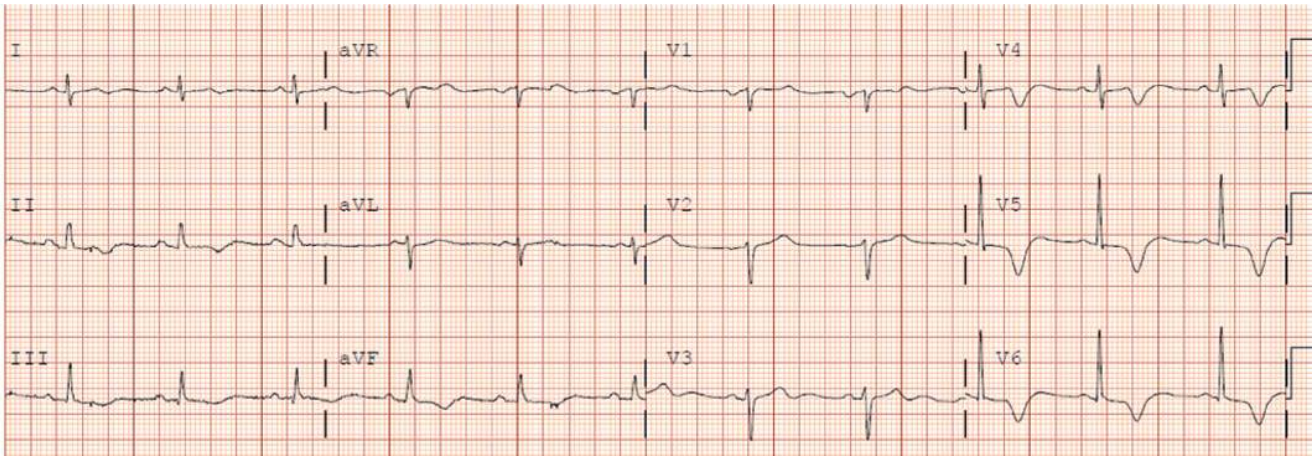

Figure 26

Question 20. A septic patient in the intensive care unit develops the following rhythm (Figure 27). What is the next step?
A. Overdrive pacing
B. Defibrillation followed by overdrive pacing
C. Isoproterenol
D. Amiodarone

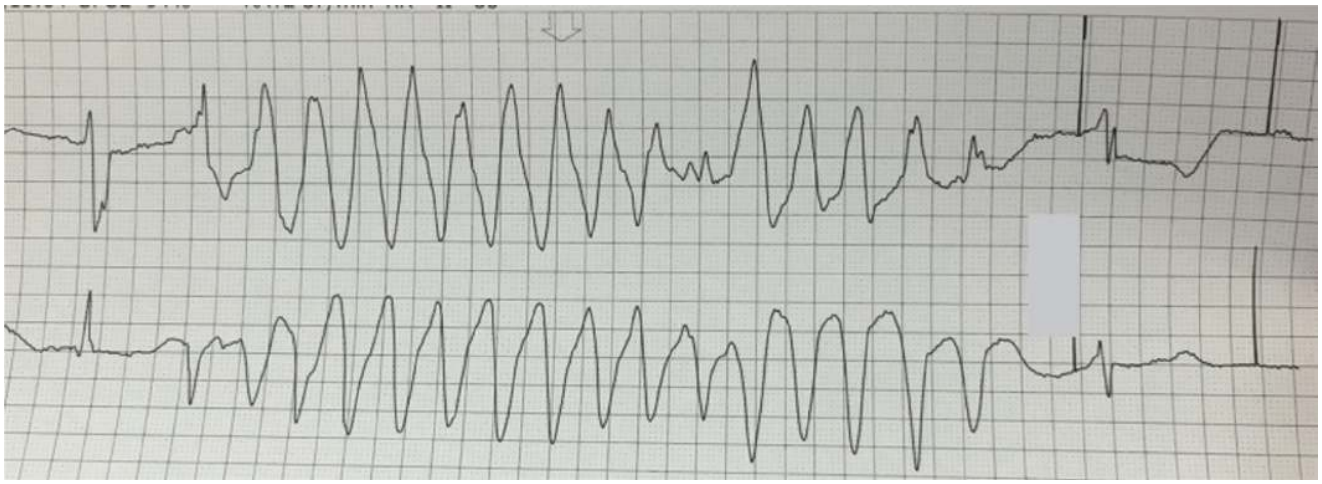

Figure 27

Question 21. A septic patient in the intensive care unit develops the following rhythm (Figure 28). What is the next step, after defibrillation?
A. Fast ventricular pacing
B. Isoproterenol
C. Procainamide

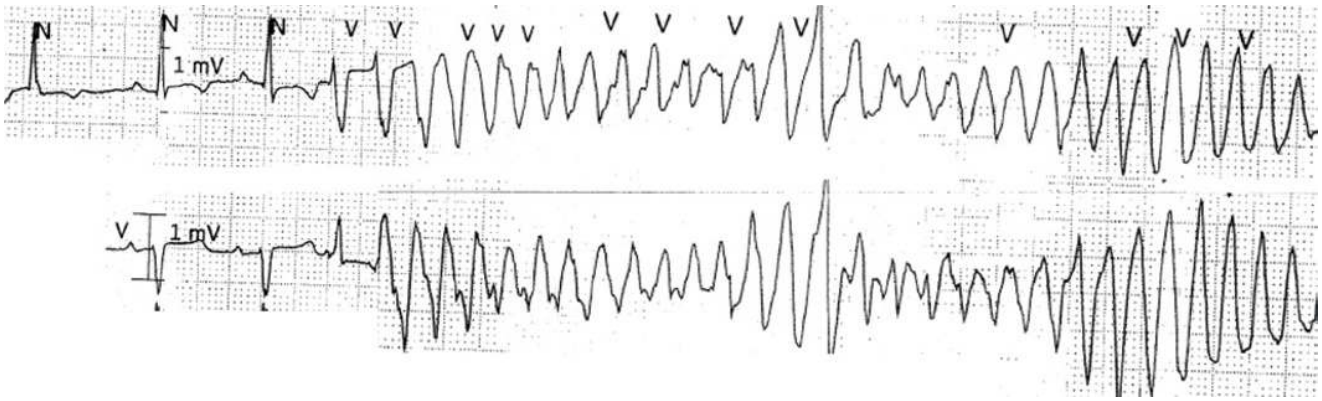

Figure 28

Question 22. A 45-year-old black woman has had palpitations for several months. She eventually collapses; emergency medical personnel found her to be in VF and successfully defibrillated her. Coronary angiography shows no CAD. ECG shows RBBB with intermittent 2:1 AV block on telemetry. Echo is normal. Chest X-ray is unremarkable. What is the next step?
A. Dual chamber pacemaker
B. Dual chamber ICD
C. Cardiac MRI
D. Chest CT

Question 23. A 22-year-old man is referred to you because of an abnormal ECG. ECG shows elevated J point of ~2 mm in the inferior and lateral leads, with slurred J morphology. His family history is insignificant, except for a brother who died at the age of 25 from a car accident. What is the next step?
A. No further workup
B. ICD placement
C. EP study
D. Genetic testing

Question 24. A 26-year-old man tripped and got injured while playing soccer and started to have chest pain afterward. He did not lose consciousness at any time. ECG shows coved, downsloping ST elevation in leads V_1-V_3 with true complete RBBB. The patient's family history is unknown. What is the next step?
A. ECG provocation with procainamide
B. ICD placement
C. Continue to observe
D. Quinidine

Question 25. A 30-year-old patient collapses while playing basketball; he is successfully cardioverted. His ECG shows WPW pattern. He absolutely refuses ablation. What is the best treatment?
A. Flecainide
B. Amiodarone
C. Metoprolol
D. Digoxin

Question 26. A patient presents with palpitations (Figure 29). He is stable hemodynamically, SBP 115 mmHg. What is the best intravenous treatment?
A. Amiodarone
B. Ibutilide
C. Metoprolol
D. Diltiazem
E. DCCV

Figure 29

Question 27. A 71-year-old woman with HFrEF and CRT has been doing well until recently. She developed AF that recurred after cardioversion and could not be rhythm controlled. AF is rate controlled on metoprolol 25 mg BID, but she is still feeling tired and more dyspneic than usual. ECG shows AF with a ventricular rate of 85 bpm. The CRT interrogation shows:
Lower rate 75, upper rate 120, LV pacing 25%, RV pacing 25%. What is the best option?
A. Increase LV output for better capture
B. Increase LV and RV outputs
C. Increase metoprolol to 50 mg BID
D. Increase the upper rate to 130 bpm
E. Reattempt to cardiovert AF

Question 28. A 60-year-old woman has HF with reduced EF of 25%. She develops AF and fails attempts of rhythm control with dofetilide. She takes lisinopril, carvedilol, and furosemide. BP is 106/70 and she appears euvolemic on exam. ECG shows atrial fibrillation with a ventricular rate of 65 bpm and LBBB with a QRS of 120 ms. She continues to be tired. What is the best management?
A. Rhythm control with amiodarone
B. Reduce the dose of carvedilol
C. Refer to AF ablation
D. CRT
E. AV nodal ablation + CRT

Question 29. A 64-year-old man has a history of paroxysmal AF treated with flecainide. He has been having exertional dyspnea and recurrent palpitations. During exercise stress ECG, he has sinus rhythm at baseline, but develops a wide complex tachycardia during exercise (rate ~280 bpm), hence the test is immediately stopped. This tachycardia becomes narrow complex at a nearly similar rate, then progressively slows down with an irregular rate. What is the likely rhythm?
A. VT
B. Atrial flutter with 1:1 AV conduction
C. AF with aberrancy
D. AF with QRS widening from flecainide

Question 30. A 70-year-old man with a history of AF receives chronic warfarin therapy. He has HTN and diabetes, with no prior stroke or HF. His baseline INR is 2.6. He is about to undergo cataract surgery. What is the best strategy?
A. Hold warfarin for 2 days. Bridging is not needed
B. Continue warfarin with no interruption
C. Hold warfarin for 5 days, initiate enoxaparin bridge 2 days after the last warfarin dose
D. Hold warfarin for 4–5 days. No bridging is needed

Question 31. A patient's ICD interrogation shows a lot of noise on both the A and V leads electrograms. What is the diagnosis?
A. Lead fracture
B. Myopotentials
C. Far-field artifact
D. Electromagnetic interference

Question 32. A patient presents with syncope. He has a narrow QRS on ECG and the following His recording during EP study (Figure 30). Which of the following is true?
A. Complete AV block
B. Infranodal AV block below the His level
C. Nodal AV block
D. This block worsens with atropine and exercise

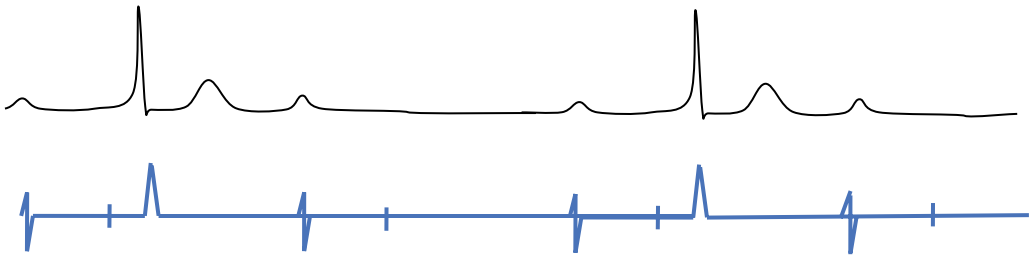

Figure 30

Question 33. Which of the following ECG findings in an athlete warrants further investigation?
A. RBBB with QRS 120 ms
B. LVH voltage
C. Deep T inversion in V_1-V_4 preceded by ST elevation in a black athlete
D. 2 PVCs on ECG
E. RVH voltage
F. QRS axis +110°

VI. Congenital heart disease (Answers on pages 1095–1097)

Question 1. A 30-year-old patient with uncorrected VSD and Eisenmenger syndrome presents with fatigue. Hemoglobin is 18, hematocrit is 58, and MCV is 70. What is the next step?
A. Phlebotomy
B. Iron studies
C. Phlebotomy with saline hydration

Question 2. Concerning TGA:
A. The atrioventricular valves are concordant with their respective ventricles (tricuspid valve is always with RV)
B. On echo, in both l-TGA and d-TGA, the RV is identified by being the ventricle with the lower-most valve
C. In both l-TGA and d-TGA, the aorta has an anomalous origin
D. A and B
E. A, B and C

Question 3. A healthy 26-year-old male diver is referred for consultation. He is a recreational diver and has never experienced significant symptoms after diving, and only has occasional migraines. He wants to train for commercial diving. Echo with bubble study was performed by another physician and suggests PFO with right-to-left bubble shunting. Exam and remainder of echo are normal. What is your recommendation regarding PFO and diving in this patient?
A. Avoid diving commercially to a depth >20 m indefinitely
B. May dive commercially using standard precautions
C. PFO closure
D. Measure Qp/Qs and decide about closure accordingly

Question 4. An adult patient with repaired tetralogy of Fallot is presenting with dyspnea. Echo shows an elevated TR jet velocity. This may correspond to which of the following (multiple possible answers)?
A. Residual pulmonic stenosis
B. Severe TR
C. Severe pulmonic regurgitation
D. Gerbode defect
E. Pulmonary arterial remodeling
F. Peripheral pulmonic stenosis

Question 5. Which congenital heart disease is suggested by the following MRI image (Figure 31)?
A. Situs inversus
B. D-transposition of the great arteries (D-TGA)
C. L-transposition of the great arteries (L-TGA)
D. Normal
E. Right-sided aortic arch

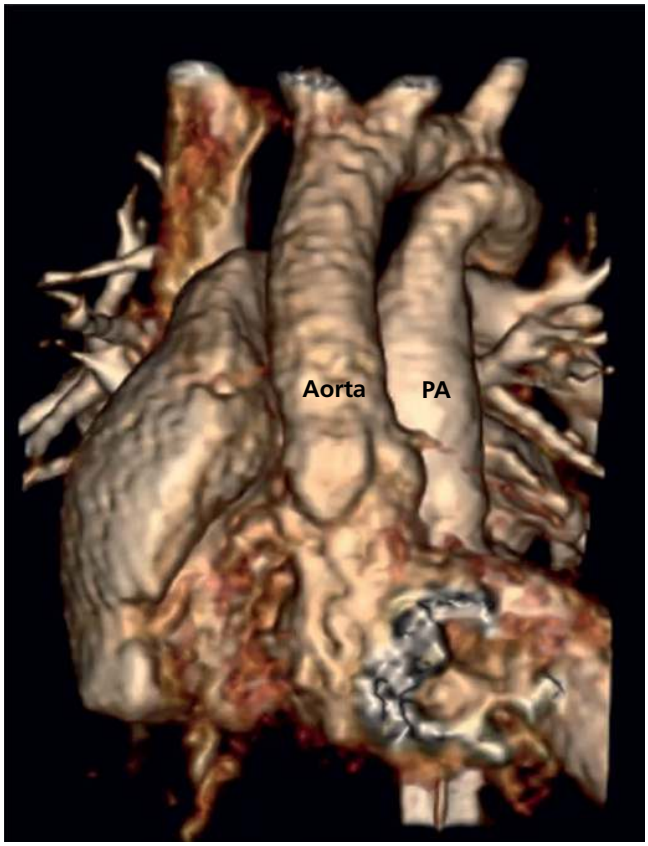

Figure 31

Question 6. A 25-year-old man has a known history of restrictive small VSD with previously normal LV and RV sizes. He has developed exertional dyspnea and fatigue with near syncope. His systemic O_2 saturation is normal at rest. Echo is repeated, and shows significantly attenuated velocity across the VSD of 1.5 m/s. His TR jet velocity is 6 m/s. Right and left heart catheterizations are performed and show the following:

RA 8 mmHg, RV 125/10 mmHg, PA 25/10 mmHg (mean 15), LV 125/14 mmHg
SVC O_2 saturation 65%, PA O_2 saturation 69%, arterial O_2 saturation 95%

What is the diagnosis?
A. Eisenmenger syndrome
B. Pulmonic stenosis
C. Double-chambered RV
D. Large VSD shunt
E. Severe TR

Question 7. Identify the anomaly on this RV angiography, obtained using a balloon tipped multi-hole Berman catheter (Figure 32):
A. Pulmonic stenosis
B. Supra-pulmonic stenosis
C. Double-chambered RV
D. VSD

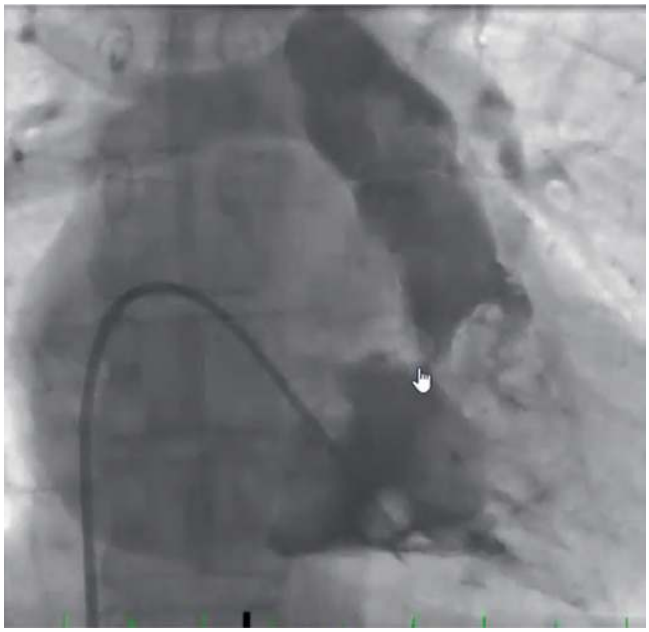

Figure 32

Question 8. A 39-year-old man has the following chest X-ray, obtained during pre-employment evaluation (Figure 33). Transfemoral vein catheterization is shown. What do you expect in this patient?

A. O_2 step-up in the IVC (IVC O_2 much higher than the SVC)
B. O_2 step-up at the RA level
C. Right-to-left shunt
D. Severe dyspnea

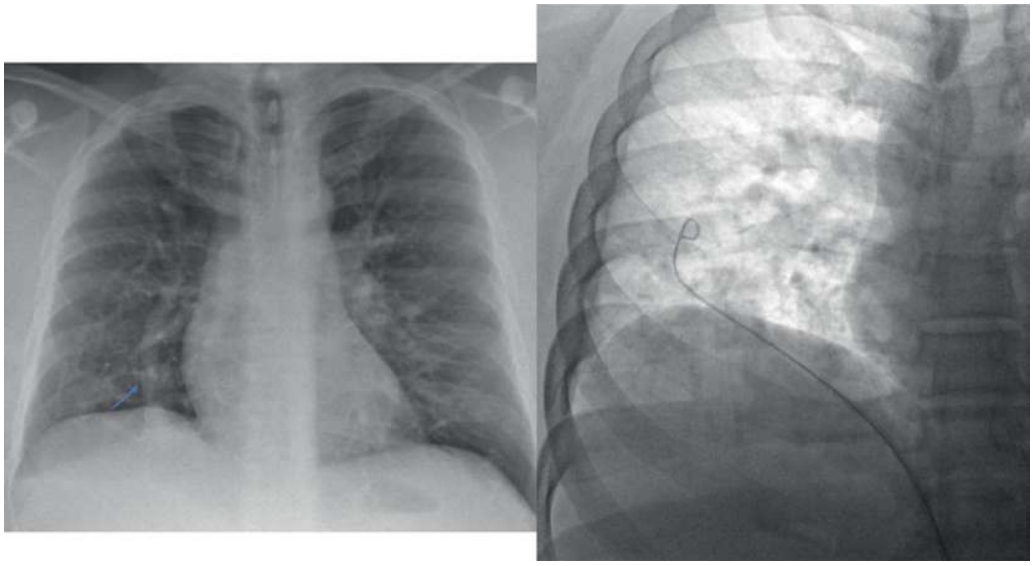

Figure 33

Question 9. A 23-year-old man is getting evaluated for a murmur. He has mental retardation, short stature, and a large forehead. He has a loud systolic ejection murmur, crescendo-decrescendo, on the left third intercostal space, with a widely split S_2 and increased A_2 intensity. The murmur radiates to the right carotid only, with suprasternal thrill. BP is 140/80 and chest X-ray shows cardiomegaly. What is the diagnosis?

A. Holt-Oram syndrome
B. Williams syndrome
C. Down syndrome
D. Bicuspid aortic valve

Question 10. A patient with Eisenmenger syndrome undergoes general surgery. He has postoperative dyspnea and is given furosemide. His dyspnea worsens. What is the best treatment?
A. Neosynephrine
B. Metoprolol
C. Intravenous fluids

Question 11. A right-sided aortic arch is more commonly seen in which of the following?
A. ASD
B. Tetralogy of Fallot
C. Transposition of the great arteries
D. Coarctation of the aorta

Question 12. A child is undergoing surgical repair of tetralogy of Fallot. Which coronary anomaly is most common and needs to be recognized pre-operatively?
A. Anomalous left main from the RCA, interarterial course
B. Anomalous LAD from the RCA, anterior course
C. Anomalous RCA from the left main

VII. Peripheral arterial disease—Pulmonary embolism—Pulmonary hypertension (Answers on pages 1097–1098)

Question 1. A 34-year-old pregnant woman with a history of bicuspid aortic valve and mild AS is presenting to the cardiology office. She is at 18 weeks of gestation. Echo shows mild AS and dilated aortic sinuses at 4.3 cm. What do you recommend?
A. Therapeutic abortion
B. Regular echo surveillance and cesarean delivery if aorta remains 4.3 cm
C. Regular echo surveillance and vaginal delivery if aorta remains 4.3 cm
D. Regular echo surveillance and pre-term delivery if aorta becomes >4.5 cm with quick growth, regardless of fetal viability

Question 2. A 37-year-old woman with Turner syndrome is planning to conceive using donor oocytes. She does not have aortic coarctation. Echo shows a bicuspid aortic valve with no stenosis or regurgitation, and an aortic diameter of 3.3 cm at the level of the sinuses of Valsalva (2.2 cm/m^2 of body surface area). What is your recommendation regarding her pregnancy?
A. Proceed with pregnancy, no follow-up is needed
B. Proceed with pregnancy, with regular echo follow-ups
C. Avoid pregnancy and perform aortic surgery
D. Avoid pregnancy, and continue to observe

Question 3. A 25-year-old patient has a dilated aorta, a bifid uvula, and hypertelorism. A second 25-year-old patient has dilated aorta, average height, long fingers and long upper extremity span, with pectus excavatum. What are the corresponding genetic mutations?
A. Patient 1 → TGFBR 1 or 2 gene Patient 2 → FBN 1 gene
B. Patient 1 → COL gene Patient 2 → TGFBR 1 or 2 gene
C. Patient 1 → FBN 1 gene Patient 2 → TGFBR 1 or 2 gene

Question 4. A 55-year-old smoker with no known cardiovascular disease undergoes ABI screening.
The following measurements are obtained:
- Right arm BP 130/80, left arm BP 120/75
- Right DP systolic pressure 65 mmHg, right PT 100 mmHg
- Left DP systolic pressure 110 mmHg, left PT 80 mmHg

Select the correct statement:

A. Right ABI = 0.54, left ABI = 0.66. He qualifies for aspirin and statin
B. Right ABI = 0.77, left ABI = 0.85. He qualifies for aspirin and statin
C. Right ABI = 0.5, left ABI = 0.61. He qualifies for aspirin and statin
D. Right ABI = 0.77, left ABI = 0.85. He qualifies for statin, not aspirin
E. Right ABI = 0.5, left ABI = 0.61. More information is needed to decide about aspirin and statin

Question 5. A 72-year-old man, smoker, presents with severe right lower extremity claudication, along with rest foot pain at night. On exam, right toes have delayed capillary refill and dark red discoloration. CTA shows a 4.5-cm abdominal aortic aneurysm and a total occlusion of the right common iliac artery. What is the next step?
A. Open repair of the aortic aneurysm with aortofemoral grafting
B. Stenting of the right iliac artery
C. Endovascular aortic graft placement with stenting of the right iliac artery

Question 6. A 57-year-old woman, morbidly obese (BMI 48) is referred for evaluation of severe RV failure. PA pressure could not be measured by echo. A hemodynamic study shows:
-PA pressure 120/30 mmHg (mean 63), PCWP 13 mmHg, arterial O_2 saturation 83% on ambient air, PA O_2 saturation 68%, SVC 62%, IVC 64%.
-Adenosine study is performed: mean PA pressure declines to 53 mmHg, PCWP 15 mmHg, arterial O_2 saturation increases to 96%.

What do you expect this patient's resting cardiac output to be?
A. Elevated (>3.5 L/min/m^2)
B. Normal
C. Low (<2.2 L/min/m^2)

Question 7. Concerning the patient in the preceding question, should she be treated with pulmonary vasodilators?
A. She is not responsive to vasodilator challenge by universal criteria. She should not be treated with pulmonary vasodilators
B. She is not responsive to vasodilator challenge by universal criteria. She should be treated with pulmonary vasodilators
C. She is responsive to vasodilator challenge by universal criteria. She should be treated with pulmonary vasodilators

Question 8. Why is the patient of the preceding question hypoxemic, and why did O_2 saturation improve with adenosine?
A. V/Q mismatch from lung disease
B. Right-to-left shunt
C. Obesity-hypoventilation
D. Reduced lung diffusion capacity from severe pulmonary hypertension
E. C and D

Question 9. A 61-year-old obese man (BMI 41) who smokes presents with dyspnea, hypoxemia (arterial O_2 saturation 80% on ambient air) and hypercapnia (pCO_2 = 79 mmHg). He has severe JVD, and echo shows RV dilatation with PA pressure of 70 mmHg and normal LV EF. He is treated with diuretics, then right heart catheterization is performed: RA pressure = 12 mmHg, PA pressure 60/28 mmHg (mean 39), PCWP 14 mmHg, cardiac output 8 L/min by thermodilution, and PA saturation 79% (arterial saturation 93% on 3 L of O_2). Answer the following: (i) What is the immediate next step? (ii) Based on current values, classify the mechanism of his pulmonary hypertension:
A. Pulmonary arterial hypertension, WHO group 1
B. Post-capillary pulmonary hypertension, WHO group 2
C. Combined pre- and post-capillary pulmonary hypertension
D. Pulmonary hypertension related to high cardiac output

Question 10. A 48-year-old presented with pulmonary embolism 3 months prior. At that time, his RV was dilated, and systolic PA pressure was 45 mmHg. Anticoagulation was initiated, but his dyspnea persisted, and he still cannot perform moderate activities of daily living. Echo is repeated: PA pressure cannot be measured, but RV has a D shape in systole and the pulmonic valve spectral Doppler shows a notched peak (W shape). Right heart catheterization shows PA pressure of 65/35 mmHg (mean 47), with PCWP of 12 mmHg, and reduced cardiac output of 3.5 L/min. A pulmonary angiogram is performed (Figure 34). Calculate PVR and choose a treatment strategy:
A. Systemic thrombolysis
B. Catheter thrombectomy
C. Surgical thromboendarterectomy
D. Bosentan + riociguat
E. Give anticoagulation for 3 more months then reassess

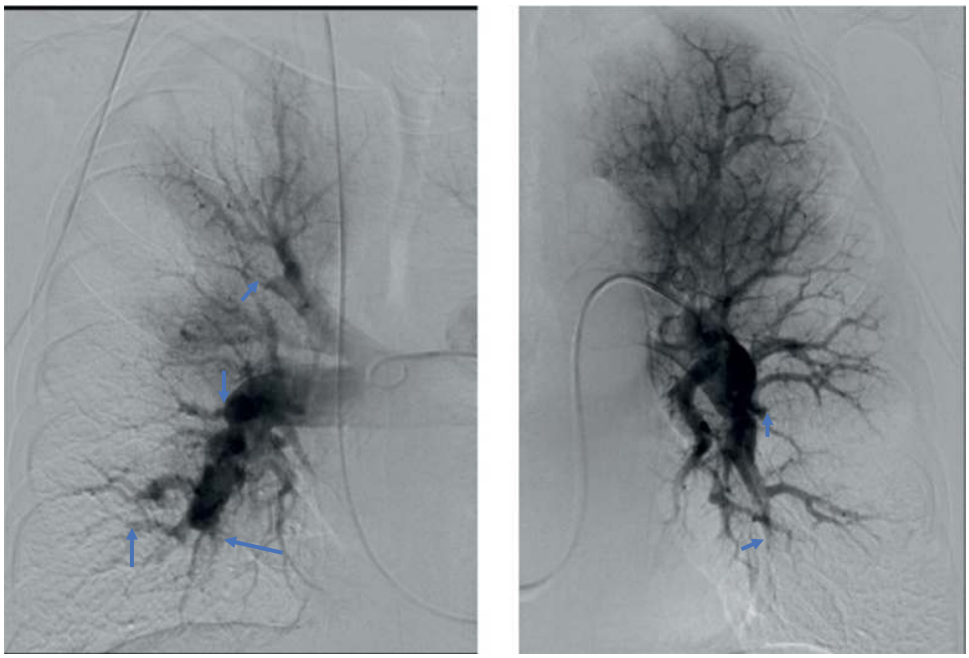

Figure 34

Question 11. A 40-year-old man goes to Utah to ski (altitude ~10,000 feet). He develops dyspnea with moist crackles and transcutaneous O_2 saturation of 83%. Besides O_2 administration, what is the best therapy?
A. Rapid descent of 3000 feet
B. Nifedipine
C. Dexamethasone
D. Acetazolamide
E. Furosemide

Question 12. A 64-year-old man with a history of HTN and no other major medical history develops right leg pain and dyspnea after a flight. On exam: O_2 saturation 94% on ambient air, pulse 85 bpm, BP 130/85, respiratory rate 18, normal JVP. CT chest shows right lower lobe PE. What is the best treatment?
A. Outpatient apixaban
B. Outpatient warfarin
C. Inpatient heparin followed by warfarin
D. Inpatient enoxaparin followed by apixaban

Question 13. A 40-year-old woman develops femoral deep vein thrombosis after tibial fracture. Work up reveals factor V Leiden. Which of the following is true?
A. She needs indefinite anticoagulation
B. Factor V Leiden has a 0.5% prevalence in Caucasians and a high lifetime risk of PE/DVT
C. Family members must be screened
D. Aside from cancer, antiphospholipid syndrome is the highest risk chronic thrombophilia
E. Antiphospholipid syndrome may be treated with warfarin or NOAC

VIII. Hypertension and syncope (Answers on pages 1098–1099)

Question 1. Which of the following anti-hypertensive agents is best avoided in patients with long QT syndrome?
A. ACE inhibitors
B. Hydrochlorothiazide
C. Spironolactone
D. Amlodipine

Question 2. A patient presents with recurrent syncope that appears vasovagal in nature. What is the expected sequence of events on tilt-table testing?
A. Sinus tachycardia followed by abrupt BP drop followed by abrupt sinus bradycardia
B. Progressive BP drop followed by sinus bradycardia
C. Sinus bradycardia followed by BP drop

Question 3. A 32-year-old woman was previously healthy and athletic. She developed a viral illness 6 months ago and since then, she has tiredness with walking and standing, along with dizziness and palpitations. Tilt-table testing shows the following response:

Time	BP	Pulse	Symptoms
0	110/70	85	
1 min	105/70	105	Mildly dizzy
5 min	100/75	130	
10 min	100/75	140	Severely dizzy

What is the diagnosis?
A. Orthostatic hypotension
B. POTS
C. Vasovagal syncope

Question 4. The patient from the prior question fails lifestyle measures. What is the best treatment at this point?
A. β-Blockade
B. Ivabradine
C. Midodrine
D. Droxidopa

Question 5. A 75-year-old man presents with frequent falls. He does not take anti-hypertensives. On exam:
-Supine: SBP 165 mmHg, pulse 70 bpm
-Standing: SBP 90 mmHg, pulse 73 bpm
Cortisol testing is normal. What is the treatment?
A. Midodrine
B. Fludrocortisone
C. Droxidopa

D. Pacemaker
E. Lifestyle measures

Question 6. A 75-year-old man frequently gets dizzy upon standing, with no falls. He takes lisinopril for HTN. On exam:
-Supine: SBP 148 mmHg, pulse 72 bpm
-Standing: SBP 120 mmHg, pulse 72 bpm
What is the treatment?
A. Lifestyle measures
B. Discontinue lisinopril
C. Midodrine
D. Droxidopa

Question 7. How often and at what times should home blood pressure measurements be performed?
A. Morning before breakfast and before medications, and evening before dinner
B. Morning after breakfast and medications, and evening before dinner
C. Morning before breakfast and medications, and bedtime
D. Morning after breakfast and medications, and bedtime

IX. Pregnancy—Chemotherapy and heart disease—Miscellaneous (Answers on pages 1099–1100)

Question 1. A 29-year-old woman is 12 weeks' pregnant, first pregnancy. She has long and slender fingers and her sister has Marfan syndrome. Echo shows aortic diameter of 4.1 cm at the aortic sinuses. What is the next step?
A. Therapeutic abortion
B. Echo surveillance and β-blockade. Vaginal delivery
C. Echo surveillance and β-blockade. Cesarean delivery
D. Aortic surgery during pregnancy
E. Genetic testing

Question 2. A 33-year-old woman, Mexican immigrant, is asymptomatic. She has a cardiac murmur and is found to have mitral stenosis with a mitral valve area of 1.3 cm^2 and mean pressure gradient of 10 mmHg at rest, with PA pressure of 45 mmHg. The valve appears pliable and the subvalvular apparatus is not severely thickened. ECG shows sinus rhythm with a rate of 75 bpm. She is planning to conceive. What should you recommend?
A. Allow pregnancy with close cardiac monitoring
B. Initiate metoprolol and allow pregnancy with close monitoring
C. Perform percutaneous mitral balloon valvulotomy (PMBV) before pregnancy
D. Perform mitral valve replacement before pregnancy

Question 3. A 32-year-old woman is considering pregnancy. She has been referred by her gynecologist because of a cardiac murmur. She is asymptomatic, exercises routinely with no limitation. Her echo is shown (Figure 35). PA pressure is normal. What is the next step?
A. Percutaneous balloon mitral commissurotomy
B. Mitral valve repair
C. Proceed with pregnancy without any therapy
D. Mitral valve replacement with a bioprosthesis
E. Mitral valve replacement with a mechanical prosthesis

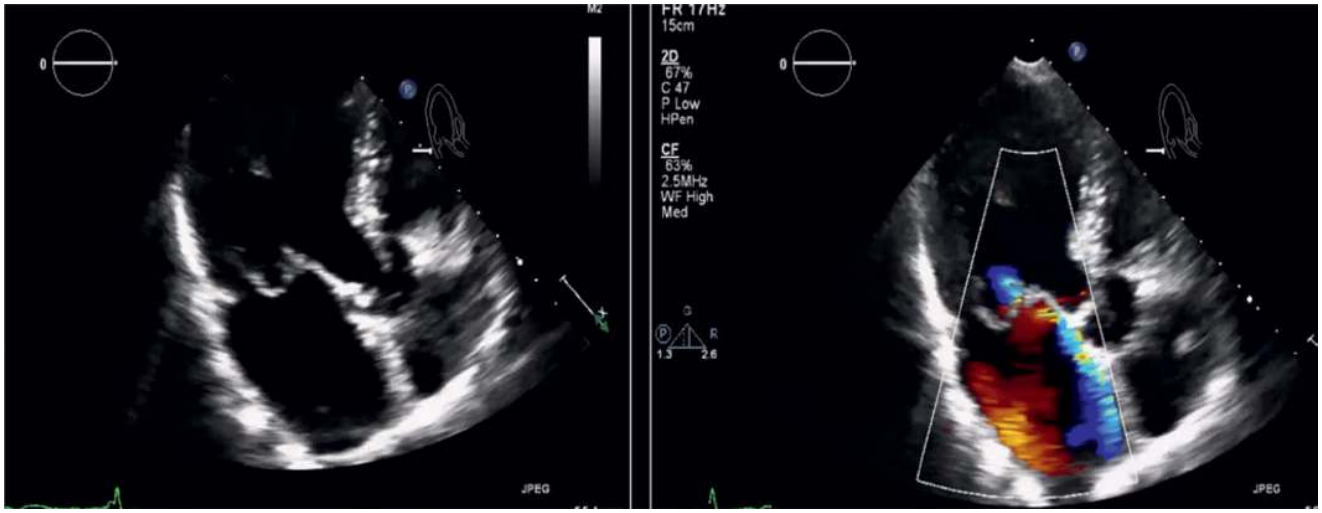

Figure 35

Question 4. A 28-year-old pregnant woman (26 weeks) is referred for mild exertional dyspnea and a murmur. Echo reveals pulmonic stenosis with a peak pulmonic valve velocity of 4 m/s. What do you recommend?
A. Pregnancy termination
B. Pulmonic balloon valvuloplasty now, during pregnancy
C. Continue pregnancy (high risk of complications)
D. Continue pregnancy (low risk of complications)

Question 5. A 45-year-old woman has breast cancer and is receiving chemotherapy with doxorubicin. At baseline, her echo showed EF of 55% and echo strain was normal with global longitudinal strain (GLS) of −19%. After 2 cycles of chemotherapy, EF is 53% and GLS is −14%. Which of the following is true?
A. She should stop doxorubicin and switch to another regimen
B. GLS change is considered significant when it exceeds 25%
C. Doxorubicin may be continued
D. Doxorubicin should be halted, then resumed once GLS recovers
E. A decline of GLS is more worrisome than an abnormal baseline GLS (>−16%)

Question 6. Correlate each of the following chemotherapeutic agents (A–D) with its main cardiac side effect (i–v):
A. Bruton and BCR-ABL tyrosine kinase inhibitors
B. Immune checkpoint inhibitors
C. VEGF inhibitors
D. 5-FU
i-Coronary thrombosis, ii-coronary vasospasm, iii-AF, iv-fulminant myocarditis, v-HTN

Question 7. A 60-year-old woman with metastatic breast cancer starts trastuzumab therapy. Pre-treatment echo shows mild LVH and EF of 65%. At 3 months, echo shows EF of 45%. Patient has no cardiac symptoms and no HF on exam. What is the next step?
A. Continue trastuzumab + add carvedilol
B. Continue trastuzumab + add ACE-I and carvedilol
C. Hold trastzumab for 1 month, then restart it if EF normalizes
D. Stop trastuzumab indefinitely

Question 8. A 62-year-old man is scheduled for elective hip replacement. He takes metoprolol and lisinopril chronically for HTN, and his home BP runs around 120/80 mmHg. He has no cardiac disease and no cardiac symptoms. What would you recommend?
A. Stop metoprolol and lisinopril the morning of surgery
B. Continue metoprolol and lisinopril throughout surgery
C. Continue metoprolol, hold lisinopril the morning of surgery
D. Continue metoprolol, hold lisinopril for 24 hours before surgery
E. Continue metoprolol, hold lisinopril for 48 hours before surgery

Question 9. In which of the following patients is the continuation of aspirin perioperatively likely beneficial?
A. Patients undergoing aorto-bifemoral bypass surgery
B. Stable CAD
C. Prior PCI with bare-metal stents
D. Diabetes
E. All of the above
F. None of the above

Question 10. A 35-year-old woman presents with arthralgias and facial skin rash. Anti-nuclear antibodies are positive. Echo shows a small mass on the posterior mitral leaflet, on the upstream (LA) side. What is the treatment?
A. Mitral valve surgery
B. Corticosteroids
C. Intravenous antibiotics

Question 11. A 57-year-old man has dyslipidemia, with LDL of 160 mg/dl and triglycerides of 310 mg/dl. He received a medication that reduced LDL to 128 mg/dl, but increased triglycerides to 400 mg/dl. Which medication did he receive?
A. Ezetimibe
B. Cholestyramine
C. Rosuvastatin
D. Pravastatin

Question 12. A 37-year-old man developed acute pericarditis and was placed on high-dose ibuprofen and colchicine. His symptoms improved but a mild chest pain persisted and precluded full tapering of ibuprofen. Four months later, he presents with worsening dyspnea, orthopnea, and JVD on exam. Echo shows a new moderate circumferential pericardial effusion (1.5 cm), along with a dilated IVC, respiratory E velocity variations, and abnormal septal motion. What is the next step?
A. Pericardiocentesis
B. Prednisone therapy (0.25–0.5 mg/kg daily) along with colchicine and furosemide
C. Surgical referral for pericardiectomy
D. Cardiac MRI

Question 13. A dyspneic patient has elevated JVP with flay Y descent and pronounced X descent. What is the diagnosis?
A. Severe RV failure
B. Tamponade
C. Constrictive pericarditis

Question 14. A 70-year-old man, heavy smoker, has persistent AF. He undergoes AF ablation after holding one dose of rivaroxaban. Later that evening, he develops dyspnea, a drop in BP to 100/70, and JVD. He has no pulsus paradoxus on exam. Echo shows large pericardial effusion. Why is pulsus paradoxus absent?
A. COPD
B. Interatrial communication from transseptal puncture
C. Hypervolemia from periprocedural fluid administration

X. ECG (Answers on pages 1100–1101)

Question 1. What is the top abnormality suggested by this ECG (Figure 36)?
A. Ischemia
B. Hypokalemia
C. Congenital long QT type 1
D. Congenital long QT type 2
E. Amiodarone toxicity

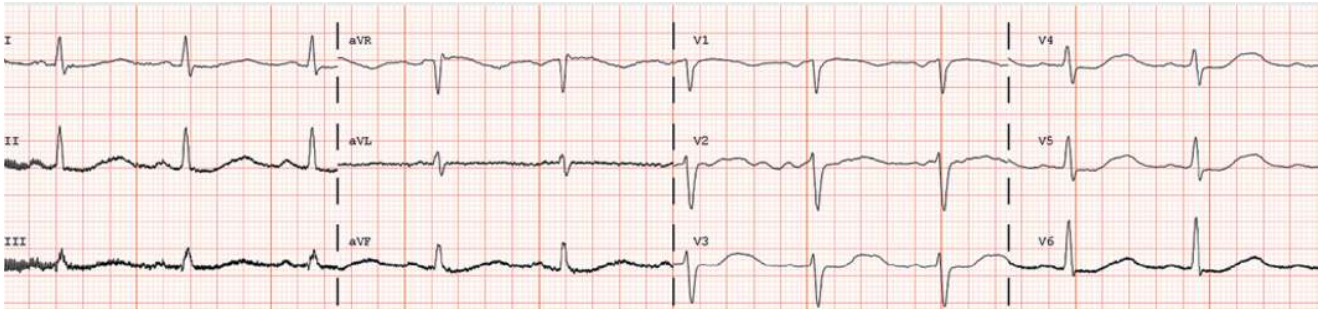

Figure 36

Question 2. Identify the abnormalities of the following ECG (Figure 37):

Figure 37

Question 3. What is the top abnormality suggested by this ECG (Figure 38)?
A. Anterior STEMI
B. Brugada syndrome
C. Hyperkalemia
D. Pulmonary embolism

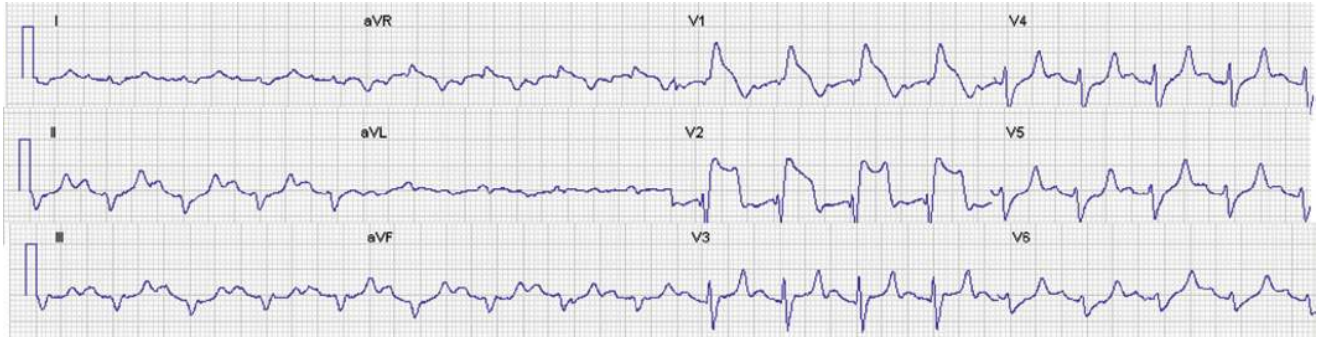

Figure 38

Question 4. What is the diagnosis on this ECG (Figure 39)?
A. VT of anterior LV origin
B. VT of inferolateral origin
C. SVT with aberrancy
D. SVT with pre-excitation

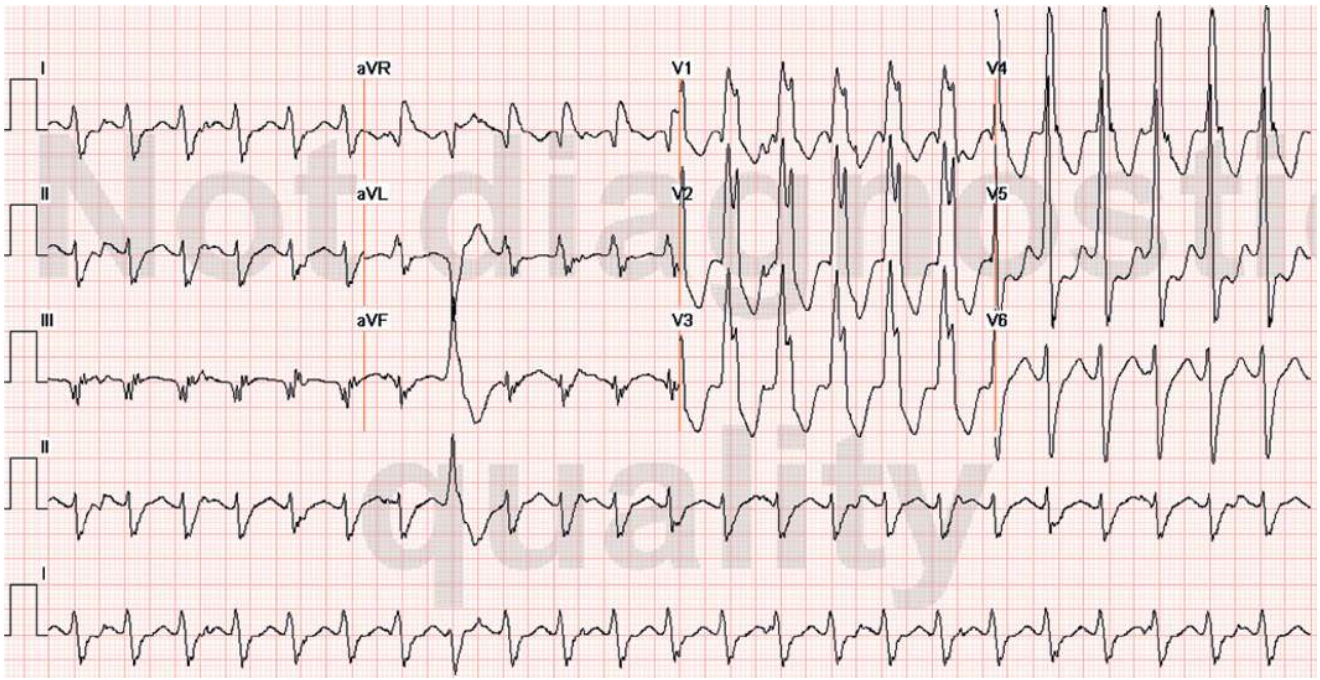

Figure 39

Question 5. What diagnosis is suggested by this ECG (Figure 40)?

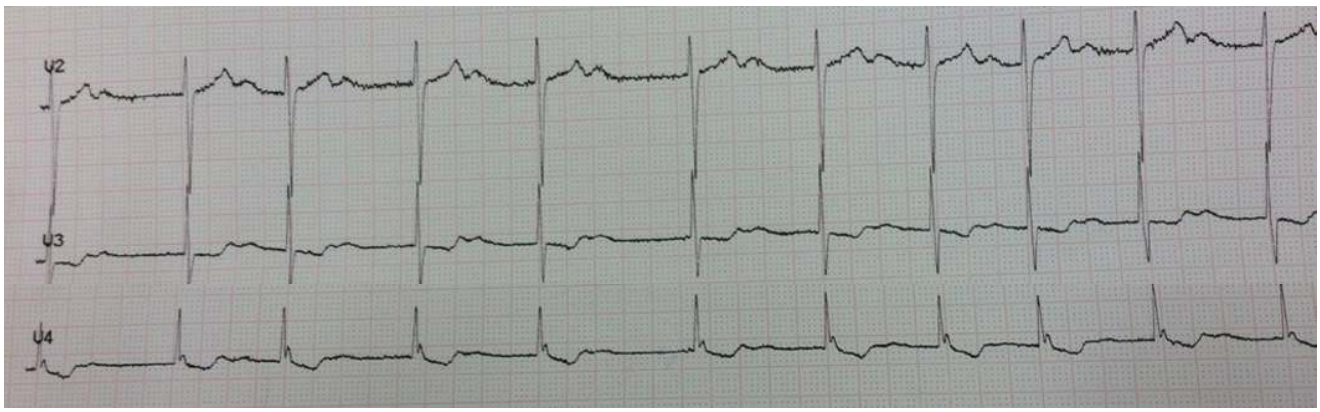

Figure 40

XI. Echocardiography (Answers on pages 1102–1103)

Question 1. What is the anomaly depicted by this image (Figure 41)?
A. Mitral valve prolapse
B. SAM of the mitral valve
C. Mitral stenosis
D. Aortic stenosis
E. Constrictive pericarditis

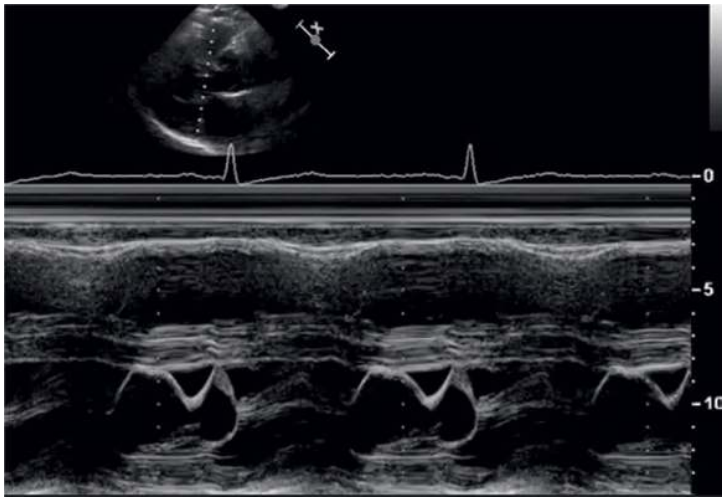

Figure 41

Question 2. A 59-year-old man presents with hemodynamic collapse. ECG shows lateral and posterior STEMI. No murmur is heard on exam, but echo is performed emergently (Figure 42). What is the diagnosis?
A. Anterolateral papillary muscle rupture. Left circumflex (OM) culprit
B. Posteromedial papillary muscle rupture. RCA or dominant LCx culprit
C. Anterolateral papillary muscle rupture. RCA or LCx culprit
D. Posterior leaflet tethering with functional eccentric MR

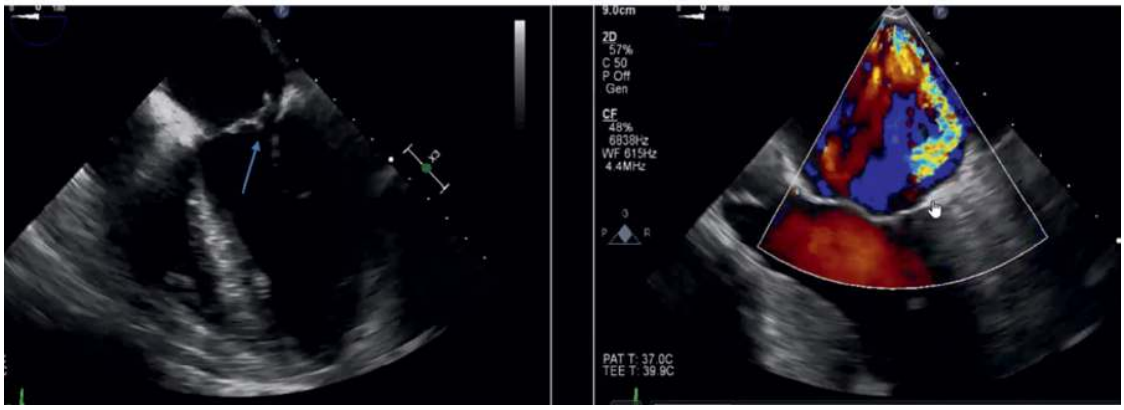

Figure 42

Question 3. A mitral valve surgeon's view is shown on 3D TEE, illustrating how the mitral valve looks from inside the LA (Figure 43). The aortic valve is seen, separated from the anterior leaflet by the aorto-mitral curtain. What are the aortic cusps C1 and C2?

A. C1 is the noncoronary cusp, C2 is the right coronary cusp
B. C1 is the left coronary cusp, C2 is the noncoronary cusp
C. C1 is the left coronary cusp, C2 is the right coronary cusp
D. C1 is the right coronary cusp, C2 is the left coronary cusp

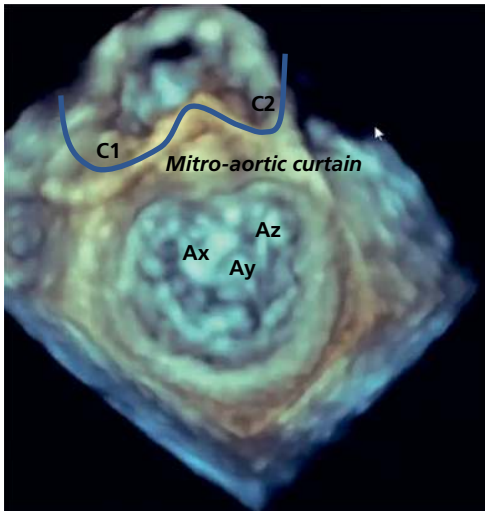

Figure 43

Question 4. Regarding Figure 43, what are the mitral scallops Ax, Ay, and Az?

A. A_1, A_2, A_3 (respectively)
B. A_3, A_2, A_1 (respectively)

Question 5. On this 3D TEE surgeon's view, identify the anterior, posterior, medial, and lateral positions (Figure 44). Also, identify the scallops Ax and Px.

A. 1 = anterior, 2 = posterior, 3 = lateral, 4 = medial
B. 1 = anterior, 2 = medial, 3 = posterior, 4 = lateral
C. 1 = anterior, 2 = medial, 3 = lateral, 4 = posterior

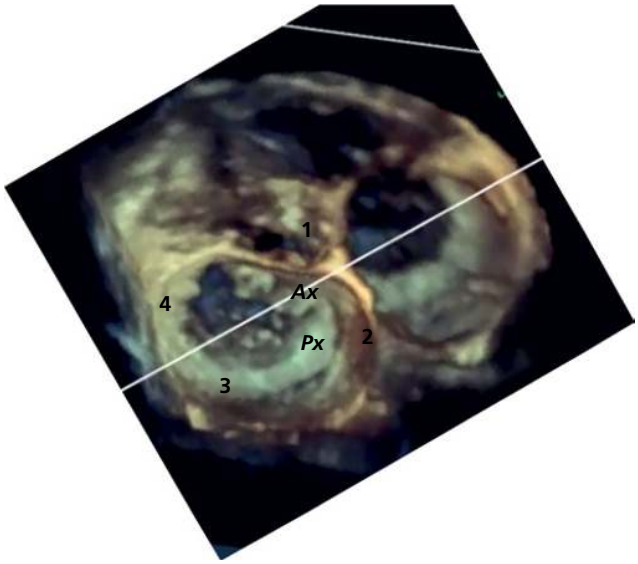

Figure 44

Question 6. On the RV inflow view, identify the tricuspid leaflets 1 and 2, and identify the structures 3 and 4 (Figure 45).

A. 1 is septal leaflet, 2 is posterior leaflet, 3 is IVC, 4 is coronary sinus
B. 1 is anterior leaflet, 2 is posterior leaflet, 3 is coronary sinus, 4 is IVC

C. 1 is anterior leaflet, 2 is septal leaflet, 3 is IVC, 4 is coronary sinus
D. 1 is anterior leaflet, 2 is septal leaflet, 3 is coronary sinus, 4 is IVC
Also, answer the following: which tricuspid leaflet is only seen on one echo view, and what is this view specifically?

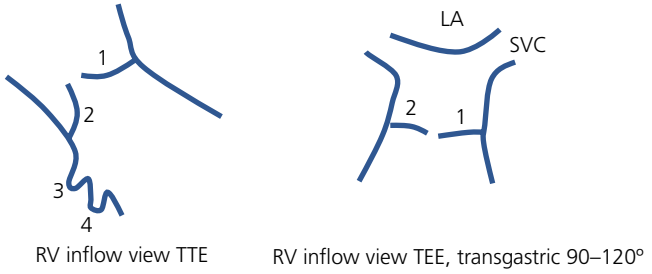

Figure 45

Question 7. A patient has mitral regurgitation (MR) that is at least moderate, with no significant aortic insufficiency (case 1, Figure 46). You decide to perform quantitative, volumetric assessment of his MR. Measure the MR regurgitant volume, MR regurgitant fraction, and ERO area.

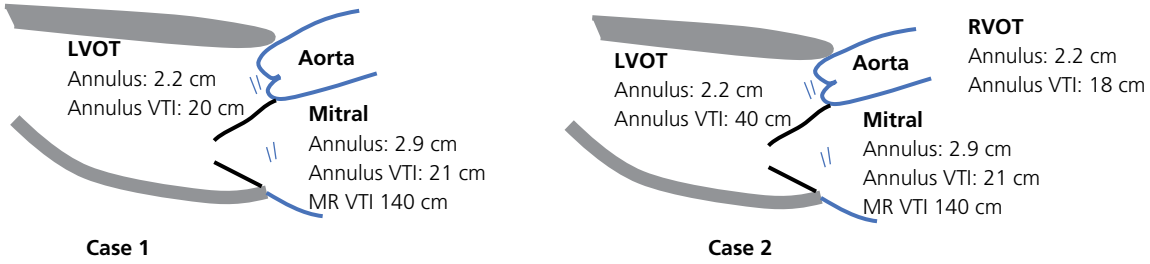

Figure 46

Question 8. A patient has significant MR, and unlike the prior question, he also has significant AI (case 2, Figure 46). You decide to perform quantitative volumetric assessment of MR and AI. Measure the MR regurgitant volume and fraction and AI regurgitant volume and fraction.

Question 9. A 48 year-old woman presents with chest pain. Echo shows a flail posterior leaflet with a small piece of torn chord. There is eccentric MR with PISA radius of ~0.7 cm and ERO area of 0.25 cm^2. The regurgitant volume is measured using ERO area × mitral regurgitant VTI, and measures 40 ml. The MR envelope on spectral Doppler is triangular with early peaking. The ejection fraction is 60%, and the LV end-diastolic volume is 130 ml. What is the MR severity (mild, moderate, or severe, or indeterminate)?

Question 10. A patient with mid-systolic murmur undergoes echocardiography. Aortic valve area measures 0.85 cm^2, with a mean gradient of 22 mmHg and a dimensionless index of 0.4. EF is normal and E/A is reversed. What is the diagnosis?
A. Low-gradient severe AS related to low flow (poor diastolic filling)
B. Moderate AS with under-measurement of LVOT diameter
C. Unclear AS severity. Perform CT calcium scoring of the aortic valve
D. Severe AS with underestimation of true aortic valve velocity

Question 11. A 70-year-old hypertensive patient presents with severe dyspnea. Echo shows LVH, LA enlargement, normal EF, and a flow between the LA and RA. Continuous wave Doppler across this jet shows a peak velocity of 2.5 m/s. His RA pressure is estimated at 10 mmHg. Which of the following is true?
A. Peak LA pressure is 35 mmHg
B. Mean LA pressure is 25 mmHg
C. Qp/Qs should be calculated and closure of the shunt considered
D. All of the above

Question 12. A 20-year-old man undergoes echo for continuous murmur. The latter shows PDA, with the following measurements: LVOT 2.1 cm, LVOT VTI 27 cm, RVOT 2.5 cm, RVOT VTI 12 cm. Heart rate is 85 bpm. What is true?
A. Qp/Qs = 0.64. Shunt is right-to-left, expect the patient to have lower body cyanosis
B. The patient's systemic cardiac output is 8.8 L/min
C. Qp/Qs is 1.55

Question 13. Is TEE superior to TTE for the assessment of AS severity? Which TEE view is best for the assessment of AS gradient?

Question 14. Which of the following is false regarding echo assessment of LVAD?
A. High velocity >1.5–2 m/s in the inflow or outflow graft suggests obstruction
B. Low inflow velocity with no diastolic signal suggests pump thrombosis

C. Outflow cannula is easy to interrogate
D. LVAD speed is increased to shrink LVEDD, up until the septum is in a neutral position (just before it bows to the left)

Question 15. The following measurements are obtained in a patient with AI of questionable severity (BP 140/55 mmHg)
-On spectral Doppler, peak diastolic AI velocity 4 m/s, end-diastolic AI velocity 2 m/s, peak systolic velocity 2 m/s
-On color Doppler: PISA radius 0.8 cm at an aliasing limit of 40 cm/s
Calculate ERO area of AI and calculate LVEDP.

XII. Additional hemodynamics (Answers on page 1104)

Question 1. An asymptomatic patient has the following oximetry run during right heart catheterization:
High IVC 83%, low IVC 85%, right iliac vein 87%
High SVC 80%, low SVC 82%
High RA 84%, PA 87%
Arterial O_2 saturation is 100% on ambient air.
Is there a shunt?
A. Yes, at the level of the IVC. Qp/Qs ~1.5
B. Yes, at the level of the IVC. Qp/Qs ~1.3
C. Yes, at the level of the SVC. Qp/Qs ~1.5
D. Yes, at a level beyond the RA. Qp/Qs ~1.3
E. No significant shunt

Question 2. Which diagnosis is suggested by the following aortic tracing (Figure 47)?
A. Tamponade
B. Constrictive pericarditis
C. HOCM
D. Severe heart failure

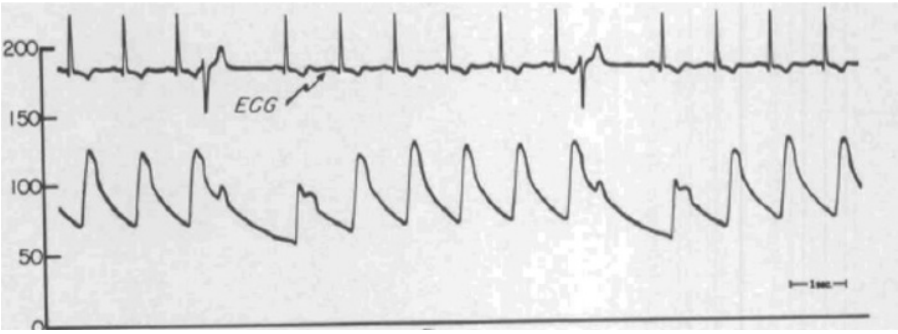

Figure 47

Question 3. Associate each of the arterial tracings A, B, C, and D (Figure 48) with one of the following diagnoses: severe heart failure, AS, AI, HOCM.

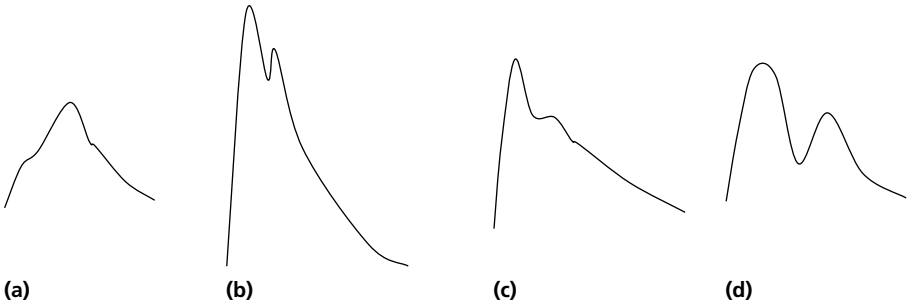

Figure 48

Question 4. What diagnosis is suggested by the following LV-femoral artery pressure recording (Figure 49)?
A. Severe AS
B. Severe AS and severe AI
C. Severe AS and moderate AI
D. Severe AI and moderate AS
E. HOCM

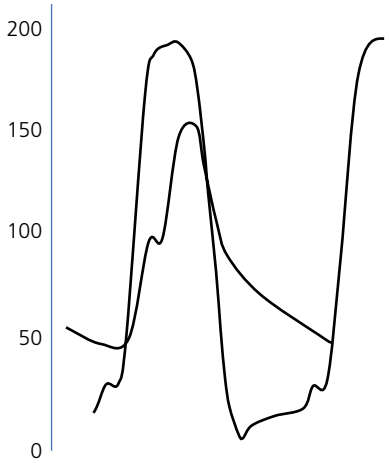

Figure 49

Question 5. In a patient with severe AI and moderate AS gradient of 30 mmHg, thermodilution cardiac output is 4 L/min. What is AVA by Hakki's equation and what is AS severity?

A. AVA 0.75 cm^2. AS is severe
B. AVA >1.5 cm^2. AS is mild
C. The severity of AS cannot be assessed with the above data

Question 6. What diagnosis is suggested by the following RA pressure tracing and simultaneous RA-RV pressure tracings (Figure 50)?

A. Constrictive pericarditis
B. Torrential tricuspid regurgitation
C. Severe RV failure with moderate tricuspid regurgitation
D. ASD

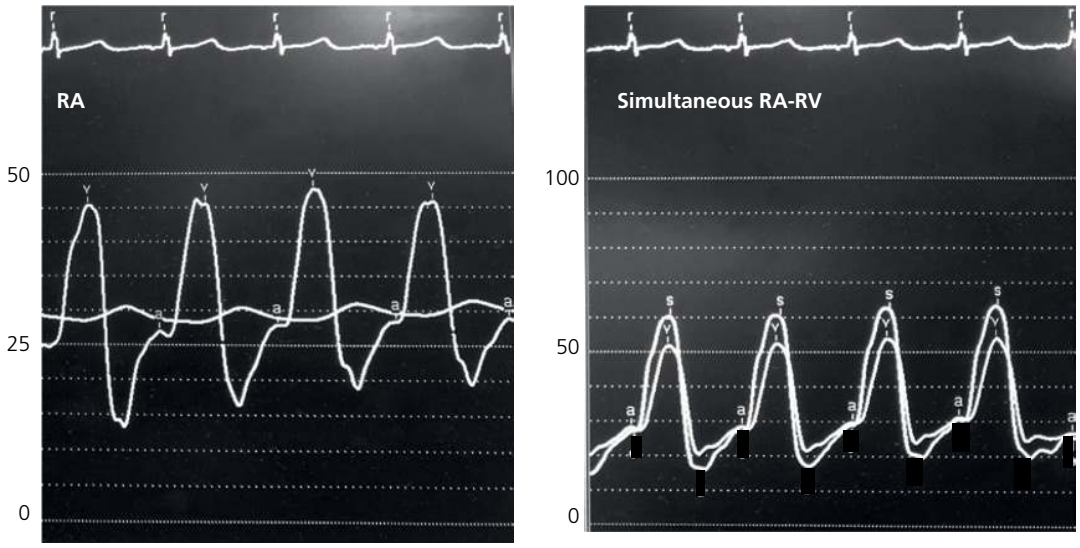

Figure 50

Question 7. A patient with a history of mechanical mitral valve replacement 1 year prior presents with a HF picture. Echo suggests moderate TR, and the mitral valve appears well seated with no significant MR. A hemodynamic study is performed: PCWP and simultaneous RA-PCWP recordings are shown (Figure 51). They suggest which diagnosis(es)?

A. Mitral prosthesis thrombosis and severe TR
B. Mitral prosthesis dehiscence and severe TR
C. Severe left and right HF
D. Postoperative constrictive pericarditis
E. Severe MR and moderate TR

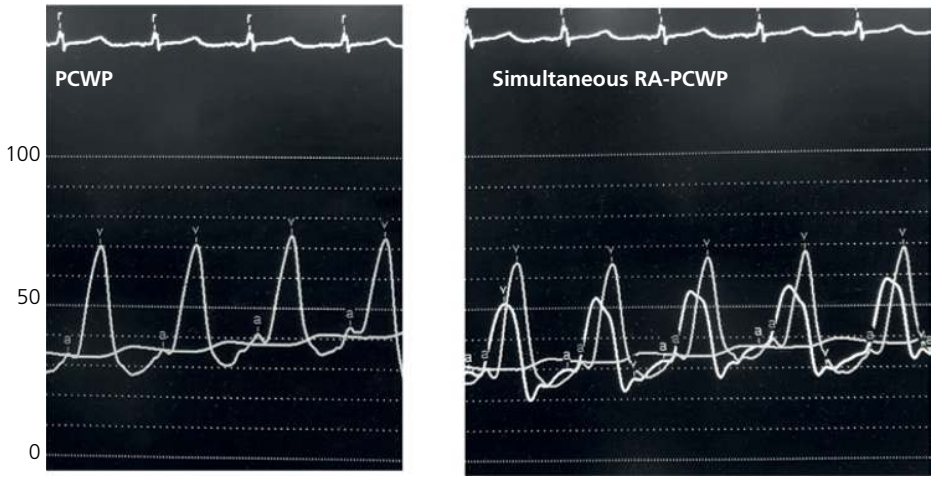

Figure 51

Question 8. A 70-year-old woman is evaluated for dyspnea. She has normal EF and no significant valvular disease. This is a simultaneous pressure recording of the LV and another chamber during supine biking in the cath lab (Figure 52). What is the other chamber, and what is the differential diagnosis suggested by this tracing?

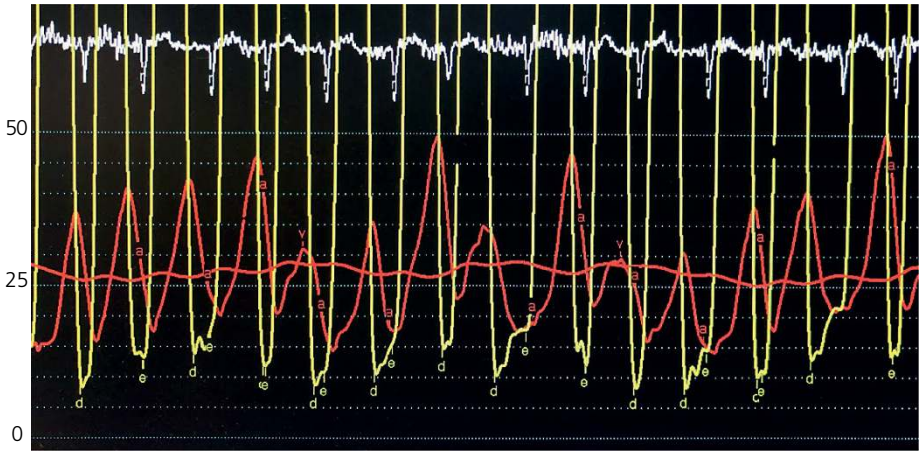

Figure 52

Question 9. A hemodynamic study is done in a 64-year-old patient with dyspnea on heavy exertion. All the numbers are normal (RA 5 mmHg, PA 20/8 mmHg, PCWP 7 mmHg). RA tracing is shown (Figure 53). What is the diagnosis?

A. Normal hemodynamic study at rest. Perform diastolic stress testing
B. Severe primary TR
C. Severe TR, primary or functional
D. Constrictive pericarditis

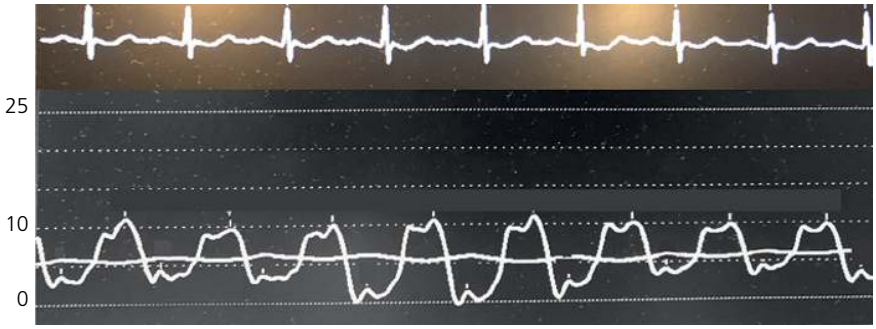

Figure 53

XIII. Percutaneous coronary intervention and shock (Answers on pages 1105–1108)

Question 1. Upon attempting to engage the RCA from a radial access using 5 Fr Tiger catheter in an LAO view, the pressure recording from the catheter tip shows the following change (Figure 54). What is the next step?

A. The catheter is in the conus branch, disengage and change to a downward-looking catheter
B. Disengage and try to obtain non-selective image with the same catheter
C. Disengage and change to a catheter with a shorter tip or a 4 Fr catheter
D. Image the RCA using the "hit and run" technique
E. Disengage and obtain diagnostic images with a side-hole catheter

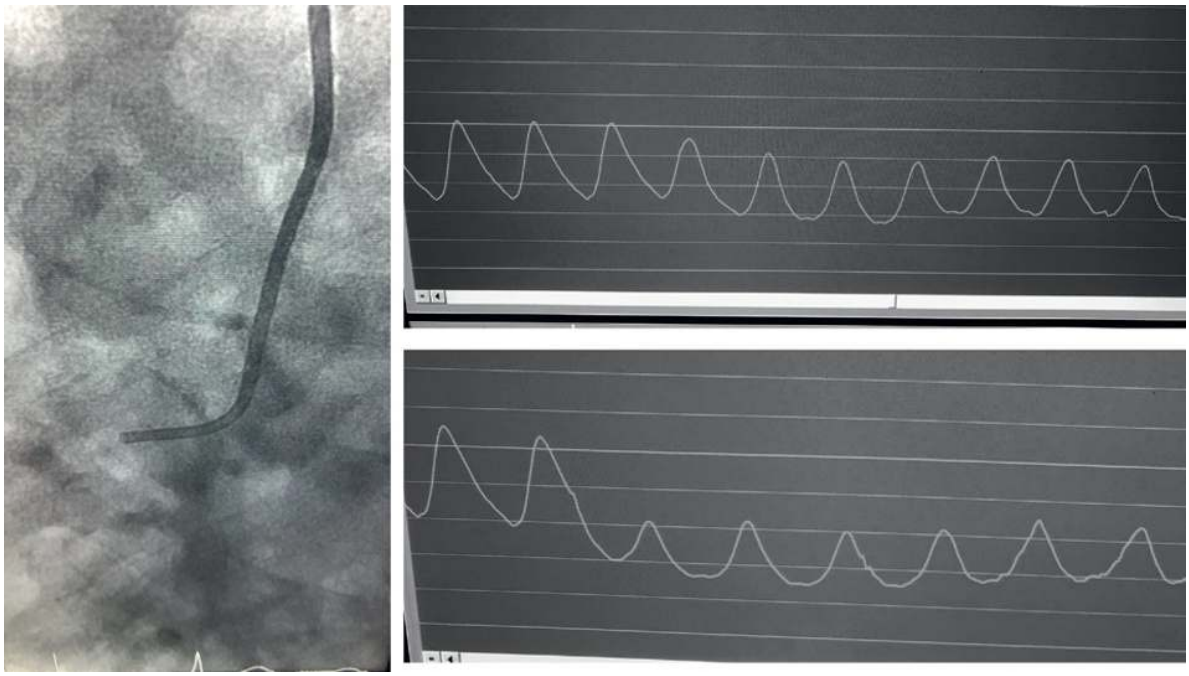

Figure 54

Question 2. A 55-year-old man presents with a newly diagnosed biventricular failure. He undergoes coronary angiography. The left coronary artery is normal, and the RCA is shown (Figure 55). What is the diagnosis?

A. Coronary cameral fistula to the RA
B. Coronary cameral fistula to the RV
C. Coronary cameral fistula to the LV
D. Coronary fistula to the PA

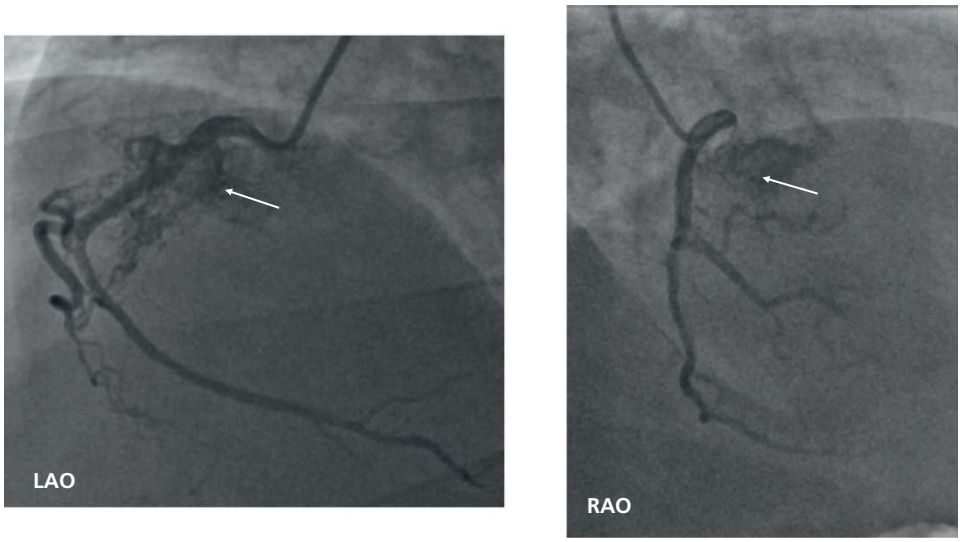

Figure 55

Question 3. Regarding the patient from the prior question, what is the next step?
A. The fistula is causing HF, refer for fistula closure
B. The fistula is benign, closure is not needed
C. Perform cardiac CTA

Question 4. Concerning drugs used in drug-eluting stents and balloons, which of the following is incorrect?
A. Everolimus inhibits cell cycle past G_1
B. Paclitaxel inhibits tubulin polymerization
C. Both everolimus and paclitaxel have potent anti-inflammatory effects
D. Both everolimus and paclitaxel inhibit smooth cell muscle proliferation
E. Everolimus, zotaralimus, and sirolimus have similar effects

Question 5. An 81-year-old man presents with anterior STEMI and severe HF. His GFR is 19. He undergoes emergent PCI. What is his risk of contrast-induced nephropathy?
A. 10%
B. 20–30%
C. >50%

Question 6. A 61-year-old man presents with stable angina and undergoes long proximal RCA stenting. After PCI, he develops mild persistent chest pain. ECG shows broad positive anterior T waves in leads V_1-V_3 with subtle ST elevation of 0.5 mm. These findings are new compared to pre-PCI ECG. What is the next step?
A. Continue to observe
B. Repeat coronary angiography. Stent thrombosis with posterior infarct suspected
C. Repeat coronary angiography. Left main dissection suspected
D. Administer nitroglycerin

Question 7. A femoral access is used to perform a planned PCI. Difficulty is encountered during iliac wiring; femoral angiography shows that the sheath is properly positioned in the true common femoral lumen, but the external iliac artery is tortuous and has a retrograde, non-flow limiting dissection. What is the next step?
A. Abort the procedure, remove the sheath and hold manual pressure
B. Attempt to wire the true lumen using JR4 catheter, and proceed with PCI as planned
C. Remove the right femoral sheath, then perform the procedure through a left femoral or radial access
D. Stent the external iliac artery

Question 8. A right radial access is used for coronary angiography. The radial artery is tortuous, and there is difficulty advancing the catheter. Contrast injection shows a perforation at the level of the proximal radial artery. What is the next step?
A. Abort the procedure and call vascular surgery
B. Continue the procedure, and try to advance 0.014" wire beyond the perforation
C. Continue the procedure, but do not perform PCI/anticoagulation
D. Abort the procedure, and control the bleeding with prolonged balloon inflation
E. Abort the procedure, and control the bleeding with inflation of a BP cuff

Question 9. A patient with anterior STEMI develops cardiogenic shock and requires Impella placement. Over the next 48 hours, the nurse notices dark urine and reduced urine output. His bilirubin is rising (3 mg/dl), hemoglobin is declining (11 to 9 g/dL), and creatinine is rising (1.8 mg/dL). What is the next management step?
A. Remove Impella
B. Reduce Impella power level
C. Check Impella position by echo
D. Continue to monitor
E. Fluid administration

Question 10. A patient presents with anterior STEMI and cardiogenic shock. Left ventriculography is performed in the RAO view and shows contrast swirling outside the LV shadow with no persistent stain. What is the diagnosis?
A. Ventricular septal rupture
B. Myocardial free wall rupture
C. Papillary muscle rupture

Question 11. A 55-year-old diabetic man presents with stable angina. Coronary angiography shows severe mid-LAD stenosis, which is then stented with one drug-eluting stent. Platelet function testing is done and shows high on-clopidogrel platelet reactivity (>208 P2Y12 reaction units by the VerifyNow test). Besides aspirin, what antiplatelet therapy should he receive?
A. Clopidogrel 75 mg daily
B. Clopidogrel double dose
C. Prasugrel
D. Ticagrelor
E. C or D

Question 12. A 74-year-old diabetic man presents with NSTEMI. Coronary angiography shows severe mid-LAD stenosis, which is stented with one drug-eluting stent. Genotype testing is done and shows CYP2C19 loss-of-function gene. Besides aspirin, what antiplatelet therapy should he receive?

A. Clopidogrel 75 mg daily
B. Prasugrel
C. Ticagrelor
D. B or C
E. A, B, or C

Question 13. A 65-year-old man presents with severe respiratory distress and collapse. His SBP is 75 mmHg, and ECG shows anterior ST elevation. He is taken urgently to the cath lab. LAD is occluded proximally, with 80% OM1 disease and 80% proximal RCA. PCI of LAD is performed but is complicated by slow flow phenomenon, and progressive requirement for higher doses of norepinephrine. Right heart catheterization is performed and shows:

RA: 20 mmHg, RV 50/20 mmHg, PA 45/30, PCWP 30, SVC saturation 48%, PA saturation 74%, thermodilution cardiac output 3 L/min, cardiac power output 0.4 W.

What is the next step?

A. PCI of OM1 and RCA
B. IABP
C. Urgent echo
D. Impella
E. ECMO

Question 14. A 44-year-old man presents with episodic chest and back pain that occurs with certain heavy activities, but not consistently, and may occur with rest. A coronary angiogram is performed and is shown (Figure 56). What is the anomaly and the next step?

A. RCA has anomalous left origin, with interarterial course. He needs surgical correction
B. RCA has anomalous left origin, with anterior course. No need for surgery
C. RCA has anomalous left origin, with interarterial course. He needs cardiac CT
D. RCA has anomalous left origin, with interarterial course. He needs exercise stress imaging
E. RCA has anterior right origin. No further workup needed.

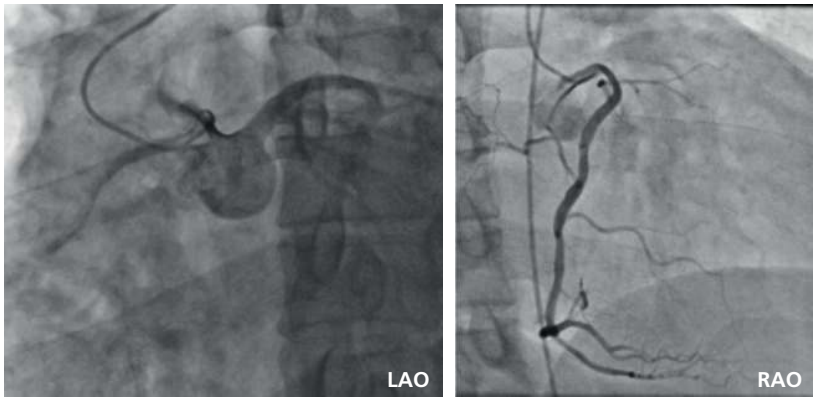

Figure 56

Question 15. A patient with severe LV failure and a baseline LV pressure volume-loop, shown in blue, undergoes 3 different interventions, (i), (ii), and (iii) with a change to the gray pressure-volume loop (Figure 57). Identify the 3 interventions.

A. (i)=Tandemheart, (ii)=IABP, (iii)=Impella
B. (i)=Tandemheart, (ii)=IABP, (iii)=ECMO
C. (i)=Norepinephrine, (ii)=IABP, (iii)=Impella
D. (i)=ECMO, (ii)=IABP, (iii)= Impella

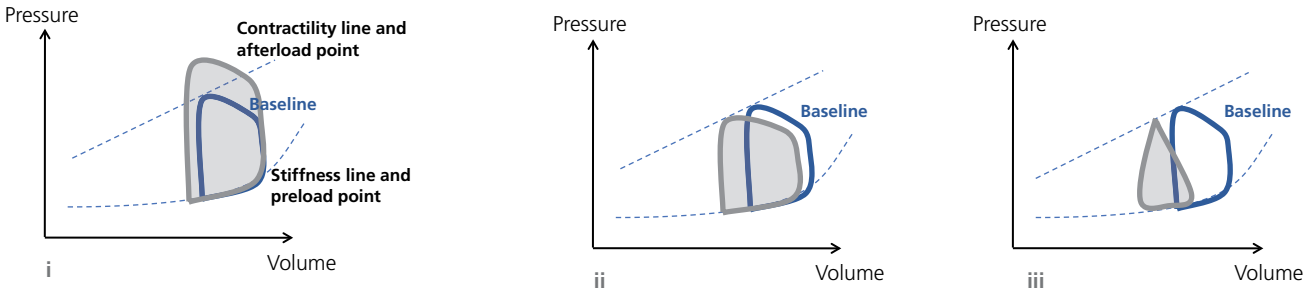

Figure 57

Question 16. A coronary angiogram shows ostial left main stenosis of 55%, and diffuse, moderate, calcified distal left main and proximal LAD disease (~40–50%). The RCA is occluded and receives collaterals from the LAD. EF is 60%. IVUS of the left main shows a minimal lumen area of 4.6 mm^2. iFR of the LAD is performed (wire placed in the distal LAD) and measures 0.93.

Which of the following is true?

A. Significant left main disease, insignificant LAD disease. Perform left main stenting
B. Hemodynamically insignificant left main and LAD disease
C. False iFR measurement related to calibration error
D. False iFR measurement related to guide position
E. iFR is not appropriate in left main disease. Perform FFR

Question 17. A 42-year-old man undergoes coronary angiography for chest pain. He has no obstructive CAD, but the RCA is large and aneurysmal. What is the most likely process?

A. Atherosclerosis
B. Kawasaki disease
C. Coronary-cameral fistula
D. Congenital
E. Marfan syndrome
F. Cocaine abuse

Question 18. A 62-year-old man presents with stable angina for 6 months, on moderate activity of daily living, despite metoprolol and isosorbide mononitrate. Coronary angiography shows mid-LAD 50% stenosis and proximal RCA CTO with collaterals from the LAD septal branches (occlusion is 4 cm in length, not heavily calcified, clear proximal cap, good-size distal reconstitution). LAD FFR is 0.76. What is the best next step?

A. CABG
B. PCI of LAD. If symptoms persist, perform RCA PCI
C. PCI of RCA CTO, then reassess LAD FFR
D. Add a third antianginal drug

Question 19. A balloon pump waveform changes from 1 to 2 (Figure 58). What explains the change (multiple possible answers)?

A. Balloon kink
B. Balloon rupture
C. Moving from cardiogenic shock (1) to LV recovery (2)
D. Moving from cardiogenic shock (1) to septic shock (2)

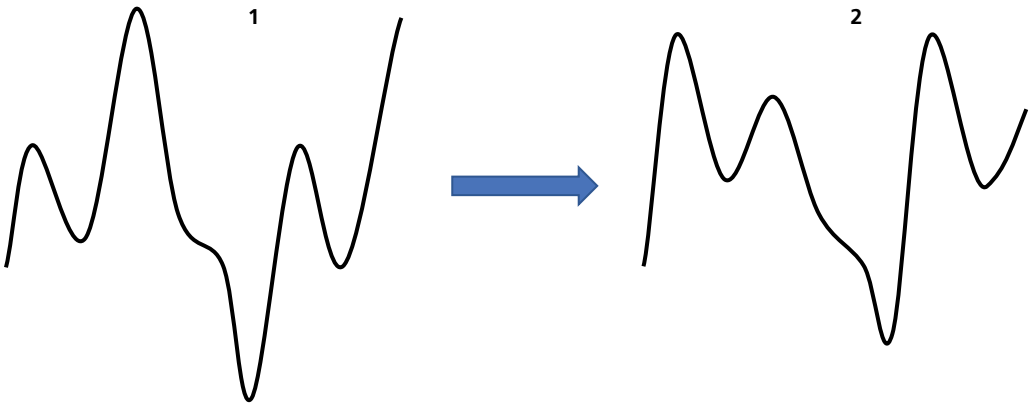

Figure 58

Question 20. A patient presents with NSTEMI and is managed medically after cardiac catheterization showed moderate disease. Besides aspirin, he is receiving clopidogrel but has high-on-treatment platelet reactivity. What is the next step?

A. Continue clopidogrel
B. Switch to prasugrel
C. Double clopidogrel dose to 150 mg daily
D. Perform genetic testing of CYP2C19, then decide about switching to prasugrel

Question 21. A 60-year-old diabetic man, smoker, presents with NSTEMI and undergoes PCI of the mid-LAD via a right radial access and is discharged on a standard regimen of metoprolol, atorvastatin, clopidogrel, and aspirin. One week later, he presents with diffuse rash and severe acute kidney injury with confusion. His hemoglobin is 8 g/dl (baseline 12 g/dl) and platelets are 40,000. What is the next step?

A. Hemodialysis
B. Corticosteroids and continue clopidogrel
C. Plasmapheresis
D. Corticosteroids and stop aspirin and clopidogrel
E. Argatroban

Question 22. Select the false answer regarding the pharmacology of antiplatelet agents.
A. Ticagrelor is a reversible, non-competitive P2Y12 ADP-receptor antagonist
B. The duration of effect of ticagrelor is brief (hours)
C. Cangrelor is an intravenous reversible competitive P2Y12 ADP-receptor antagonist
D. Cangrelor has a very short half-life (5 minutes) and duration of effect (30 minutes)

Question 23. Which statement(s) is (are) true? (multiple possible choices)
A. Prasugrel and clopidogrel are irreversible antagonists of P2Y12 with a half-life of ~5 days
B. Prasugrel and clopidogrel cannot be given during cangrelor infusion; ticagrelor can
C. Cangrelor, ticagrelor, and prasugrel act directly on the P2Y12 receptor, vs. clopidogrel is metabolized into an active metabolite that acts on the receptor
D. P2Y12 receptor reduces intraplatelet cyclic AMP, which causes activation of IIb-IIIa receptors

Question 24. Select the correct answer(s) regarding the pharmacology of anticoagulant agents (multiple possible choices):
A. Bivalirudin is a direct, reversible competitive inhibitor of thrombin
B. Bivalirudin is a direct, reversible noncompetitive inhibitor of thrombin
C. Unfractionated heparin inactivates thrombin and Xa via enhancing AT III
D. Unfractionated heparin inactivates thrombin, Xa, + IXa, XIa, XIIa
E. Enoxaparin inactivates thrombin and Xa (Xa>thrombin) via enhancing AT III
F. Unfractionated heparin is eliminated renally
G. Enoxaparin is eliminated renally

Question 25. Regarding transradial PCI vs. transfemoral PCI, which of the following statements is (are) true (multiple possible choices)?
A. Reduction of major bleeding and major vascular complications by >50% in all settings
B. Reduction of mortality in all ACS
C. Reduction of mortality in STEMI
D. Reduction of mortality in stable CAD
E. Reduction of MI
F. Reduction of major adverse cardiovascular events (MACEs) (MI, stroke, mortality) in all ACS
G. Reduction of MACEs in STEMI
H. Higher radiation dose with radial access, even among experienced operators
I. Higher acute kidney injury with radial access

Question 26. An anomalous RCA originating from the left coronary cusp may arise above the left coronary artery (Figure 59.a), below it (Figure 59.b), or more anterior to it, close to the midline (Figure 59.c). Which catheter is most appropriate for engagement in each configuration?
A. (a)→JL3; (b)→JL5; (c)→AL2
B. (a)→JL3; (b)→JL3; (c)→AL2
C. (a)→AL2; (b)→JL3; (c)→AL2
D. (a)→AL2; (b)→JL5; (c)→JL3

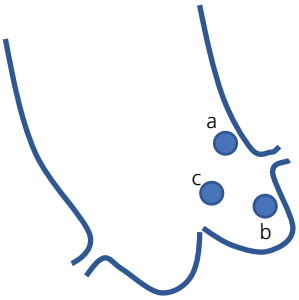

Figure 59

Question 27. A patient with distal left main disease undergoes stenting of the left main into the proximal LAD using a 4-mm single stent (Figure 60). The ostium of the left circumflex develops a tight ostial stenosis after stenting. An attempt to rewire it after left main stenting, using a standard workhorse wire, fails. What is the next step?
A. Perform balloon dilatation of the left main stent with 4.5-mm balloon
B. Use an angled microcatheter
C. Use a double-lumen catheter, with a side lumen to aim into the LCx (e.g., Twin Pass)
D. Use a polymer-jacket hydrophilic wire

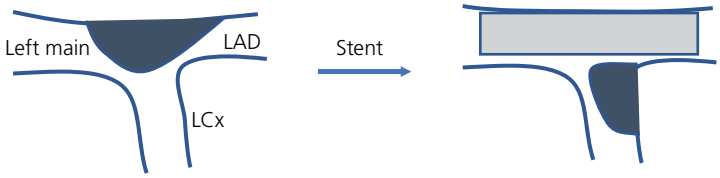

Figure 60

XIV. Radiation in the cardiac catheterization laboratory (Answers on pages 1108–1109)

Question 1. Regarding radiation in the catheterization lab, which of the following is false?
A. Skin dose (or absorbed dose, in mGy) correlates with the deterministic effect
B. Effective dose (in mSv) correlates with the stochastic effect
C. Air Kerma is an estimate of the skin dose
D. Dose-area product correlates with deterministic and stochastic effects
E. Radiation to the operator comes directly from the X-ray tube, hence the shield should be placed between the tube and the operator

Question 2. Which of the following statements is incorrect? To protect the operator and others from radiation:
A. Move 1–2 feet back from the patient and avoid leaning over
B. LAO and LAO cranial views lead to more scatter to the operator than RAO view, particularly the face/eyes
C. The shield should be positioned between the patient's body and the operator's face
D. To protect a fetus of a pregnant woman undergoing coronary angiography, place a shield on her abdomen

Question 3. Which of the following answers is incorrect?
A. Steep double angulation of 30° (e.g., LAO cranial) increases radiation 3- to 5-fold
B. Doubling the magnification doubles the skin dose
C. Obesity increases radiation, 3–4 times for 5 cm of extra body thickness, and more exponentially with steep angles
D. Lowering the frame rate from 15 to 7.5 frames per second reduces radiation exactly in half

Question 4. Which of the following answers is incorrect?
A. Collimation of half of the field reduces the dose-area product and body dose in half, but skin dose remains the same
B. Collimation reduces radiation dose while increasing image quality
C. Raising the X-ray detector 1 foot away from the patient increases radiation ~3 times
D. Lowering the table increases the skin dose
E. Cinefluoroscopy delivers 10–20 times higher dose than fluoroscopy
F. Lower extremity vascular procedures are associated, on average, with higher skin doses

Question 5. A patient undergoes a complex CTO PCI. The total skin dose at the end of the procedure is 6 Gy. The patient is obese, and most of the work was done in LAO caudal view (30°, 30°) at a 22-cm field of view. The fluoroscopic time was 50 minutes, and 5 cine-fluoroscopy runs were performed. Which of the following interventions would have reduced the skin dose the most?
A. Working in straight AP rather than LAO caudal view
B. Reducing the magnification from 22 cm to 32 cm
C. Obtaining less cine images
D. Reducing the frame rate from 15 to 7.5
E. Collimating half the field
F. Raising the table

Question 6. While imaging a morbidly obese patient in a LAO caudal view, it seems the image contrast is reduced; despite proper catheter engagement and good amount of contrast injected, the image is washed out and it is hard to delineate the coronary stenosis. What is the explanation for this?
A. Automatic brightness control increases mA
B. Automatic brightness control reduces KVp
C. The iodine peak absorption is at 33 KeV

Question 7. Which of the following safety cutoffs is correct?
A. The limit stochastic (effective) whole-body dose for physicians is 50 mSv (5 rem)/year, and 500 mSv per lifetime
B. For the operator: the limit deterministic dose for the eyes is 150 mGy (15 rem)/year, and for other organs, 500 mGy/year
C. The limit effective dose during the whole pregnancy is 5 mSv
D. The deterministic skin risk starts at 2,000 mGy, and is dramatic at 15,000 mGy (sentinel event)
E. All are correct

ANSWERS

I. NSTEMI and STEMI

Answer 1. C. Persistent chest pain with ST depression that is isolated or predominant in V_1-V_3 indicates a posterior STEMI. Performing posterior-leads ECG increases the diagnostic yield, but regardless, this patient is managed as posterior STEMI, with fibrinolytic or, preferably, primary PCI.

Answer 2. A. This patient with NSTEMI has developed sustained VT, which is a sign of electrical instability, even if it has spontaneously resolved and has not recurred yet. In NSTEMI, the indications for catheterization within 2 hours are: persistent or recurrent chest pain or deep ischemic ST depression; hemodynamic instability; or electrical instability (=sustained VT).

Answer 3. A. Several features suggest SCAD type 2, which is a long spontaneous intramural hematoma, and argue against performing PCI: (1) long smooth disease >30 mm with no calcification; (2) tortuous, elongated coronary arteries; (3) distal disease; (4) woman <60 years. Data suggest ~50% failure or complication rate with PCI. Conversely, SCAD spontaneously heals in 70–97% of patients at 35 days, which favors conservative SCAD management in the absence of STEMI, TIMI 0 or 1 flow, profound ST depression on ECG, or shock with proximal SCAD. The diagnosis is often purely angiographic and may be confirmed prospectively by demonstrating spontaneous lesion healing on coronary CTA. IVUS/OCT is not routinely performed, as unnecessary lesion wiring may worsen SCAD, but is selectively performed when the angiographic findings are not typical. In this case, the flow is TIMI 2 and she is not having ongoing angina, so conservative management is adopted.

Answer 4. B. Coronary manipulations are typically avoided in SCAD, and the diagnosis relies on the angiographic features and clinical context. Thus, typically, OCT/IVUS is avoided and repeat angiography is avoided if chest pain resolves; coronary CTA may be performed for follow-up of vessels >2.5 mm. SCAD is associated with a high prevalence of intracranial aneurysms (15–20%) and of peripheral fibromuscular dysplasia, sometimes involving the carotids (50%), justifying screening with a head and neck CTA.

Answer 5. C. The patient has monomorphic VT secondary to a scar from a prior LCx/ramus anterolateral infarct rather than acute RCA ischemia. Monomorphic VT is secondary to scar rather than acute ischemia, and the known history of occluded LCx is further suggestive of that. The patient's echo confirmed the presence of a thin and akinetic high lateral wall. PCI of RCA is only helpful in the setting of *polymorphic VT with ongoing signs of ischemia*, such as persistent chest pain or ST abnormality.

Origin of this VT: anterior (positive in the inferior leads, i.e., looking toward the inferior leads), lateral (negative in the lateral leads, i.e., looking away from the lateral leads), and basal (positive in lead V_6, i.e., it is looking toward the apex).

Troponin rise and transient ST depression are rather secondary to VT and prolonged hemodynamic compromise, not the other way around. The same hemodynamic compromise explains acute renal injury and shock liver.

The only specific VT treatment here is ICD (+/– amiodarone). RCA stenting is unhelpful and may hinder ICD placement as insurance payers may not cover ICD costs in the 90 days following PCI.

Beware of coronary angiographic findings in the setting of monomorphic VT. A coronary stenosis in a patient with monomorphic VT is frequently an incidental stenosis, the treatment of which does not affect VT recurrence.

Answer 6. C. To define MI, troponin must rise and/or fall *along with* at least one of the following c*linical features of ischemia*: (1) chest pain, (2) ischemic ST abnormality or new Q waves, (3) new wall motion abnormality. Without the latter, the troponin elevation is called myocardial injury, or non-MI troponin elevation, even if there is a rise and fall pattern, and often has a mechanism similar to type 2 MI; it is not a false positive troponin elevation. The rise-and-fall pattern (>20%) suggests that the myocardial injury is acute, a very common process in acute HF and the critically ill. A steady-state elevation suggests chronic myocardial injury, as in chronic severe HF or advanced CKD. False-positive troponin is rare (regardless of high-sensitivity or conventional assays): it may be seen in patients with heterophile antibodies that agglutinate with the murine antibodies used in the troponin assay, myositis (troponin T), rheumatoid factor, and hemolysis.

Answer 7. B. This patient has an increased risk of arrhythmic death, including in the first 40 days (large infarct size, persistent ST elevation suggestive of an irreversible myocardial injury, frequent PVCs). In both EMIAT and CAMIAT trials, amiodarone initiation in the early post-MI period (<40 days) significantly reduced the risk of arrhythmic death by ~35%; overall death was not reduced. Amiodarone is not routinely used after MI but may be used selectively in patients with the highest sudden death risk in this early period, such as this patient, while awaiting the eventual ICD implantation 40 days later.
In VEST trial, the use of LifeVest early after MI reduced arrhythmic death by ~35% as well, but the reduction was not statistically significant ($p = 0.18$). LifeVest reduced overall death, by ~35% as well, and this was borderline significant.

Answer 8. D. LV free wall rupture is more common in women, first MI, or severe hypertension.

Answer 9. B. The patient likely has severe acute MR from papillary muscle rupture, with eccentric jet missed by TTE. It is unlikely for an inferior MI, per se, to lead to such severe hemodynamic compromise. TEE should be followed by IABP, coronary angiography, and emergent surgical repair.

Answer 10. B. The echo and CT suggest lateral LV aneurysm or LV pseudoaneurysm. It is important to distinguish those 2 entities, as LV pseudoaneurysm is a sealed rupture that requires surgical therapy. Compare the neck to the bottom of the pocket: a ratio <0.5 implies pseudoaneurysm. In this case the ratio is 0.5–1, which may suggest true aneurysm; however, on CT, the whole myocardial thickness is interrupted at the level of the pocket, and only a thin layer of pericardium is seen. This is a sealed LV rupture = LV pseudoaneurysm. Even if the patient did not have LV rupture, he does not qualify for PCI per the OAT trial (>24–48 hours after his infarct, with an akinetic or dyskinetic wall).

Answer 11. A. A patient older than 75 treated with fibrinolytic therapy should only receive 75 mg of adjunctive clopidogrel. Should he eventually undergo PCI, 300 mg of clopidogrel may be loaded. Prasugrel is contraindicated in the first 24 hours after fibrinolytics. A clopidogrel 600 mg dose or a ticagrelor load is likely safe during a later PCI, particularly several hours after fibrinolysis in patients <75 years (based on the TREAT trial).

Answer 12. D. Based on the large COMPLETE trial, PCI of non-culprit disease reduces MI risk when performed in a separate procedure before discharge, or within 6 weeks of discharge. PCI may also be performed during the same acute procedure, based on smaller studies (PRAMI, Cvlprit), but was associated with worse outcomes in the OPTION-STEMI trial. Thus, A is an acceptable option, but D is the best option. B is incorrect because, unlike stable CAD, non-culprit lesions in an ACS setting are preferably treated regardless of angina.

Answer 13. A. This patient likely has tamponade from LV free wall rupture, precipitated in an elderly patient (>75) by thrombolysis. In tamponade, RA~PCWP~PA diastolic pressure (equalization of diastolic pressures). RV infarct is possible but less likely in a patient who achieved successful reperfusion. Moreover, RV infarct frequently leads to equalization of diastolic pressures as well; PCWP is expected to increase in an elderly patient with concomitant LV infarct. D is consistent with a predominant left heart failure, not the case here.

Answer 14. D. Standby transcutaneous pacing pads are indicated in all those scenarios. The same pads also provide defibrillation when needed; patients with new bundle branch blocks have larger infarcts and an increased risk of VF as well. A transvenous pacemaker is more readily indicated for acute bundle branch block with increased PR interval (class IIa) than for acute BBB or bifascicular block with normal PR (IIb). This was only detailed in the 2004 ACC STEMI guidelines.

Answer 15. B. This patient has the hemodynamic profile of RV shock. In RV shock, PCWP may increase because of ventricular interdependence (RV pushing against the LV and forcing equalization of diastolic pressures); PA pressure subsequently increases mildly. In fact, in SHOCK registry, PCWP was equally elevated in LV shock as in RV shock. The first treatment is fluid administration until a RA pressure of ~10–14 mmHg; then inotropic therapy is started (2nd treatment). IABP may improve RV shock by improving diastolic RCA flow and RV perfusion. Yet, IABP is reserved for RV shock refractory to inotropes, or RV shock with clinical left HF (3rd treatment). Right-sided Impella and ECMO are reserved for RV shock refractory to all the prior measures (4th treatment). RV fully recovers by 24 hours in most reperfused MIs.

Answer 16. B. Fibrinolytics activate plasminogen, leading to more plasmin formation. Plasmin degrades fibrin. On the other hand, thrombin works on generating fibrin from fibrinogen, and is not affected by fibrinolytics or plasmin.

Answer 17. A. Complete AV block in the setting of inferior STEMI is usually well tolerated and does not require pacing, unless persistent and associated with severe symptoms or hemodynamic compromise (usually with RV shock).

Answer 18. B. Complete AV block in the setting of anterior STEMI requires transvenous pacemaker placement, even if transient. It is a high-risk rhythm and is associated with a 4-fold increased mortality (GUSTO-1 trial), mainly related to the large size of the infarct and pump failure rather than AV block.

Answer 19. B. This patient has cardiogenic shock with what initially appeared to be anterior STEMI. The combination of a definite anterior STEMI on ECG, yet patent coronary arteries on angiography is highly suggestive of takotsubo syndrome, particularly in a post-menopausal woman. Q waves are uncommon in takotsubo but may be seen. There are 2 forms of cardiogenic shock in takotsubo syndrome: (1) classic shock from myocardial depression, (2) shock that results from LVOT obstruction (the hypercontractile LV base narrows the LVOT). This patient has the second form of shock, as evident by the fact that a positive inotropic agent has worsened her shock, via worsening of the LVOT obstruction; the gradient between LV and aorta is, in this case, a gradient across the LVOT, not the aortic valve, and further confirms the diagnosis. IABP reduces afterload and worsens LVOT obstruction. Alpha-agonists increase afterload and reduce LVOT obstruction. Impella reduces preload and worsens LVOT obstruction.

Answer 20. C. Monomorphic VT occurring any time after MI is a marker of a permanent substrate from a prior scar rather than acute ischemia. This, besides the fact that it is occurring >48 hours after MI, implies the need for ICD. Acute ischemia may facilitate the induction of monomorphic VT but is not usually the cause of it; since ECG is unchanged, coronary angiography is not needed.

Answer 21. B. The patient has classic type 1 MI presentation by ECG and troponin, yet no CAD. This is the so-called MINOCA. In 3 major cohort studies, at least 40% of patients with MINOCA exhibited plaque disruption on OCT or IVUS, at times in an angiographically normal coronary segment. MRI shows an ischemic mechanism in about the same number of patients, although not necessarily the same patients; MRI and OCT are complementary, and MRI diagnoses 3 other major causes of MINOCA: myocarditis, takotsubo, and myocardial infarction with no plaque disruption (suggestive of vasospasm). Medical therapy with DAPT and statin is not systematically indicated in MINOCA, as many such patients have the 3 latter diagnoses, hence the importance of OCT or MRI, +/- acetylcholine provocation of vasospasm (PROMISE trial). Beware that plaque rupture or erosion does not dictate stenting: it dictates secondary prevention with DAPT, statin, and HTN control. OCT is done in the suspected culprit artery, based on ECG and wall motion; alternatively, it may be systematically done in the proximal 6 cm of all 3 coronary arteries.

Unlike the long SCAD 1 and 2 that may be diagnosed purely based on angiography, SCAD type 3 is a focal or tubular stenosis that mimics atherosclerosis and can only be diagnosed by IVUS or OCT. It is rare and usually diagnosed in the setting of MINOCA's imaging.

Answer 22. A. The traditional teaching had been to only treat the culprit artery in hemodynamically stable MI patients, and to concomitantly treat culprit and non-culprit arteries in cardiogenic shock. Evidence now suggests the opposite: stable patients may safely undergo non-culprit PCI acutely, while cardiogenic shock patients with a clear culprit artery have a dramatic 8% absolute increase in mortality if non-culprit PCI is performed acutely (51% vs. 43%, CULPRIT-SHOCK trial, STEMI [62%] or NSTEMI). Non-culprit PCI increases procedural time and contrast load, leading to more LV volume overload and renal injury, and is hazardous in the hemodynamically compromised patient. Also, non-culprit PCI induces peri-PCI myocardial injury or side branch losses, unlikely to be tolerated in shock.

Answer 23. B. The IABP-SHOCK II trial failed to show a benefit of IABP in MI patients with cardiogenic shock. Impella improved the mortality of select STEMI-cardiogenic shock <24 hours. It may particularly benefit a shock receiving medium pressor dose and requiring escalation (SCAI stage C or early D).

II. Stable CAD

Answer 1. B. Compared to PCI, CABG has not reduced mortality in NOBLE, SYNTAX left main subgroup, and EXCEL at 3 years (mild mortality reduction at 5 years in EXCEL). CABG is associated with higher rates of early stroke (in all 3 trials, except NOBLE), and periprocedural myocardial infarction.

Answer 2. Highest = E; lowest = F. The total body radiation exposure, from highest to lowest is:
Dual Thallium-Technetium SPECT (~25–29 mSv) >Thallium SPECT (~20 mSv)
> Technetium rest-stress SPECT (~11–13 mSv)
> Coronary CTA with retrospective gating ~10–12 mSv
> Coronary angiography ~7 mSv (PCI ~17 mSv)

> Coronary CTA with prospective gating ~4 mSv
> ^{82}Rb rest-stress PET/CT imaging (^{82}Rb has a very short half-life) ~3–4 mSv (CT attenuation correction adds 0.5 mSv)
> Coronary calcium CT ~3 mSv > Coronary calcium CT with prospective gating ~1 mSv
> ^{13}N rest-stress PET imaging ~2 mSv

Answer 3. C. The myocardial blood flow normally increases >2.2–2.5 with stress, which corresponds to a coronary flow reserve (CFR) of >2.2–2.5; CFR may be measured invasively or via PET or MRI. The stress/rest ratio is abnormal at <2.2, which may indicate obstructive CAD or microvascular dysfunction. In the absence of defect, microvascular dysfunction is the most likely diagnosis. Extensive CAD with balanced ischemia may also explain the lack of significant focal defect, but there is no mention of findings that support balanced ischemia, such as TID or stress-induced ST abnormality.

Answer 4. C. This patient only has mild hypokinesis on echocardiography, and thus, viability testing has no role. Also, even if the inferior wall is dysfunctional, angina that can only be attributed to the CTO implies viability and may indicate PCI, regardless of viability testing. The only indication for CTO PCI is angina that is severe (e.g., daily, mild exertion) and refractory to 2 antianginal agents; the severity of ischemia on stress testing is less relevant. Three randomized trials (Explore, Euro-CTO, and Decision CTO) have not shown any improvement in hard outcomes with CTO PCI. In the EXPLORE trial of patients with recent STEMI, PCI of a non-culprit CTO did not improve EF and infarct size. Revasc trial specifically assessed, via cardiac MRI, the improvement of EF and segmental wall thickening after CTO PCI; no improvement was seen, the caveat being that half the patients did not have a segmental wall motion abnormality at baseline.

Answer 5. F. Several studies published in the 1990s analyzed MI patients who had a coronary angiogram in the preceding few years and found that the culprit stenosis was <50% obstructive in 70% of patients (<70% obstructive in 85% of patients). Similar data were replicated with prospective coronary CT follow-ups. The individual risk of MI from a stenosis <50% is <0.5% per year, lower than the risk of a stenosis >50%; yet the latter is not too high, ~2–3% per year (up to 25% progression to occlusion at 5 years in old studies from the 1990s). *The overall patient's risk is more driven by the multitude of non-significant lesions than by obstructive lesions*. The prediction of a coronary event by searching for vulnerable plaques is rendered even more difficult by the fact that most plaque ruptures are silent. At least 15% of asymptomatic patients with no known obstructive CAD have evidence of healed plaque ruptures on pathology or OCT; over 70% of stable CAD stenoses (stenoses >50%) have evidence of healed plaque ruptures (frequently 3 or 4 plaque ruptures in ~half the patients). In fact, plaque ruptures much more commonly cause no symptom at all, rather than MI; it is when plaque rupture coincides with blood vulnerability and thrombogenicity that MI is triggered. The heavier the amount of plaques (plaque burden), the more likely this is to happen. *Plaque burden is likely more relevant than individual plaque vulnerability features in predicting MI*.

Positive remodeling correlates with plaque burden and prior plaque ruptures and corresponds to higher lesion vulnerability. Atheroma is supplied by vasa vasora, which may not be enough in heavy atheroma, making it susceptible to necrosis and rupture. Also, positive remodeling stretches the plaque's cap, making it thinner and more susceptible to rupture.

Answer 6. B. Acetylcholine causes macro- and microvascular dilatation if the endothelium is intact and able to generate NO, whereas adenosine and nitroprusside vasodilate by directly acting on smooth muscle cells; nitroglycerin also vasodilates by directly acting on smooth muscle cells, but only at the macrovascular level. Acetylcholine tests "NO- or endothelium-dependent" vascular function, whereas adenosine, nitroprusside, and nitroglycerin test "endothelium-independent" function (nitroprusside and nitroglycerin get metabolized into NO, but they do not depend on the endothelium to generate intrinsic NO).

Answer 7. A and B. Serotonin and acetylcholine have a vasodilating effect on normal coronary arteries, as they induce the endothelium to produce intrinsic NO. When the endothelium is damaged or dysfunctional, serotonin and acetylcholine have a direct, unopposed vasoconstricting effect.

Answer 8. B. This patient has a very high likelihood of CAD (classic exertional angina, age, diabetes). CAD is stable and angina is not severe. Based on ISCHEMIA trial, ischemia on stress testing does not dictate coronary angiography or revascularization, and even severe ischemia is properly managed conservatively.

Only 2 factors argue for coronary angiography and revascularization: (1) left main disease (+/– critical 3-vessel CAD), and (2) severe and refractory angina. Coronary CTA is the preferred modality to rule out left main disease.

If CTA was not provided as an option, stress testing would be the best option in this patient with non-severe angina. If low risk, one may stop the workup. If high risk, CTA would be warranted as per ISCHEMIA trial, or coronary angiography may be performed to define left main anatomy. If CKD is present, especially severe CKD, the patient may be treated medically without any anatomic assessment, even after a high-risk stress test (the answer would be A, as per ISCHEMIA and ISCHEMIA CKD trials).

Answer 9. C. This patient has a very high likelihood of CAD. Unlike the previous question, he has severe and frequent angina with severe functional limitation and is not a typical ISCHEMIA or COURAGE patient. He qualifies for coronary angiography and revascularization of his CAD.

Answer 10. A, B, C, D. A is true based on DIAD and Factor-64 trials, which found no improvement in long-term outcomes after stress testing and CTA, respectively, in high-risk diabetic populations. C is true based on long-term follow-up of patients who have undergone a coronary CTA or coronary angiography at baseline. D is true based on PROSPECT and COURAGE trials, as well as follow-up of patients with prior stents.

E is false. If a silent, high-risk significant CAD is found through screening, revascularization does not improve outcomes (except for left main); this is based on ISCHEMIA trial.

Answer 11. B. For screening asymptomatic patients, CTA and stress testing have no value, as revascularization has limited value in asymptomatic patients (except for left main). Yet, coronary calcium scoring may provide clinical value, as it does not look for coronary obstruction and is not performed from the standpoint of seeking revascularization. It is rather a marker of the patient's atherosclerotic burden and a more sensitive indicator of the patient's cardiovascular risk. It provides a push toward statin use and more aggressive risk factor control, which are the only useful measures in primary prevention. Statin is favored but not immediately indicated for a patient with LDL < 190 and cardiovascular risk of 7.5–20% per ASCVD equations; calcium scoring (≥100 or >75th percentile for age) and other risk modifiers, such as metabolic syndrome or elevated triglycerides, favor statin therapy. Aspirin provides no net benefit in primary prevention (ARRIVE, ASCEND, ASPREE trials).

Answer 12. A. The patient has a moderate-risk stress test result by both imaging and ECG features (Duke treadmill score of –1). In stable CAD, the main indications for revascularization are uncontrolled angina or left main disease. It is reasonable to perform CTA and rule out left main disease before conservatively managing this patient, as in the ISCHEMIA trial. However, since angina is controlled with medical therapy and ischemia is moderate rather than severe, CTA is not absolutely necessary. In fact, the ISCHEMIA trial, which mandated CTA, mainly recruited high-risk stress test results; in order to qualify by ECG features, ST depression was required to be ≥1.5 mm at <6 minutes of Bruce protocol (before completion of stage 2), with angina.

Answer 13. C. This patient has severe ischemia by nuclear and ECG features. As per ISCHEMIA trial, such patients may be managed conservatively as long as angina can be controlled medically and CTA rules out left main disease.

Answer 14. A. This patient has severe ischemia by nuclear and ECG features. As per ISCHEMIA and ISCHEMIA-CKD trials, such patients may be managed conservatively as long as angina can be controlled medically. Those trials did not mandate CTA in patients with CKD (GFR < 60 ml/min): CKD patients with high-risk ischemia were managed conservatively even without any coronary imaging, as long as angina was controlled, and they fared as well as the invasive arm. Yet, coronary imaging is reasonable in individual cases, to rule out left main disease. As per the designs of the ISCHEMIA-CKD trial (GFR < 30 ml/min) and ISCHEMIA trial-CKD subgroup (GFR of 30–60 ml/min): "Exclusion of potential left main disease was left to site investigators based on clinical judgment using the stress test and hemodynamic findings."

Answer 15. A. In the COURAGE trial, ~20% of patients undergoing medical therapy received a second coronary angiogram during follow-up, mostly for symptom progression rather than ACS/MI (~5% for ACS/MI) (median follow-up 1.5 years). By comparing the second angiogram to the first, it was noted that 21% of lesions >50% have become culprits and progressed angiographically by ~10%. Considering that 80% of patients remained stable and did not undergo a second angiogram up to a median follow-up of 4 years, the measured frequency of 21% overinflates the true progression by up to 5 times. ***Stable stenoses >50% have <10% progression rate over 1.5–4 years of follow-up with <5% individual risk of ACS/MI.***

Answer 16. C. In MI, the progression of *culprit lesions >50%* is much faster than in stable CAD. In one old study, 25% of such lesions progressed on a second angiogram performed 8 months later, mostly to a total occlusion. Yet, this number may be lower in the modern era of aggressive statin and lipid management. Also, even in MI setting, non-culprit lesions <70% have a low risk of progression to MI, 1% at 3 years in the PROSPECT trial.

Chen M, Chester MR, Redwood S, et al. Angiographic stenosis progression and coronary events in patients with "stabilized" unstable angina. Circulation 1995; 91: 2319–24.

Answer 17. F. A low FFR lesion is associated with a higher risk of MI: it may cause plaque inflammation and shear stress or, alternatively, it may be the result of a vulnerable inflamed plaque that impairs coronary distensibility and FFR. In fact, a lesion with low FFR is more likely to have features of plaque vulnerability: positive remodeling, low attenuation, spotty calcification. Stenting a low FFR lesion marginally reduces the risk of spontaneous NSTEMI at 5 years (FAME trial), but this benefit is diluted by periprocedural MIs, stent-related MIs, and MIs arising from other lesions, with no overall effect on MI risk.

Answer 18. A. Insignificant FFR rules out significant epicardial disease, but the patient may still have ischemia from vasospasm (Prinzmetal) or microvascular dysfunction, as is the case in 50% of women with persistent chest pain and negative coronary angiogram. Acetylcholine

may be used to assess for vasospasm, while adenosine CFR measurement may be done to assess for microvascular dysfunction. Prinzmetal angina frequently occurs on top of moderate coronary plaques and frequently has a nocturnal pattern. Ranolazine is effective in microvascular disease, but this patient with nocturnal angina likely has epicardial vasospasm, hence amlodipine is preferred.

Answer 19. C. It is reasonable to routinely rule out a vasospastic component whenever any coronary lesion is seen, before performing PCI or FFR. In fact, in the landmark FFR DEFER trial, all coronary stenoses were reassessed angiographically after nitroglycerin administration, before proceeding with FFR. If no change occurs with nitroglycerin, FFR would be reasonable. If FFR is insignificant, acetylcholine testing may be performed in this symptomatic patient to see if vasospasm can be elicited.

Answer 20. A. This is a patient with classic exertional angina and objective ischemia on non-invasive testing, yet no obstructive CAD (<50% disease). Half of those patients have coronary vasomotor abnormalities, whether epicardial vasospasm or more so, microvascular dysfunction, particularly if angina is exertional. The latter is the most likely diagnosis. It is characterized by insignificant FFR (no significant epicardial obstruction) but impaired microvascular flow reserve (CFR < 2.5, or index of microvascular resistance [IMR] > 25).

Answer 21. All are true. In the Framingham long-term follow-up study, angina was more likely to be the presenting complaint of coronary disease in women (65%) than in men (37%). Only 23% of infarctions were preceded by angina. About 15% of MIs were silent or unrecognized. Thirty to 50% of sudden cardiac deaths are the first cardiac presentation, i.e., are not preceded by any CAD symptoms or cardiac history. All of this is related to the following facts: (1) most MIs (~75%) arise from plaques that are not significantly stenotic, so MI and sudden death are not preceded by any cardiac symptom; (2) coronary occlusion that is preceded by significant CAD is associated with a better prognosis, a lower likelihood of MI, a smaller-size MI, and less sudden death, as collaterals may have developed chronically (with stenosis >70–80%), and ischemic preconditioning may have occurred. MI that occurs in a patient with a recently normal stress test is more likely fatal than the one occurring after an abnormal stress test. The most severe hemodynamic compromise occurs in patients with LAD disease <50% who abruptly occlude it. While the individual risk of MI/death is higher in patients with positive stress tests, most MIs in the population (>75–80%) occur in subjects without underlying coronary obstruction; this is because they vastly outnumber patients with obstructive CAD, and mild stenoses are far more prevalent than obstructive ones—even in patients with obstructive CAD. While one may think that silent ischemia is one reason why MI and sudden deaths are often unheralded by angina, only 10–15% of patients truly have silent ischemia despite critical stenoses or infarcts. Most patients with silent ischemia on stress testing who develop MI actually progress to symptomatic ischemia as their stenosis progresses, before succumbing to death or MI (even a slight progression, from 70% to 80%, exponentially increases coronary resistance and may increase ischemia beyond the angina threshold); unlike patients with no ischemia, their MI is usually preceded by symptoms (70%) and they rarely die suddenly.

Answer 22. A. While clopidogrel preloading reduced peri-procedural MI in planned PCI in the CREDO trial, systematic preloading with ADP-receptor antagonist before coronary angiography, i.e., before it is certain the patient is undergoing PCI, has not shown benefit in Prague 8 and ARMYDA-5 Preload trials (clopidogrel preload in stable or unstable CAD), and in the ACCOAST trial (prasugrel preload in NSTEMI). High-dose statin preloading, in patients who are statin-naïve or chronically treated with low-dose statin, in the setting of stable CAD or ACS, has consistently reduced peri-PCI MI (NAPLES II, ARMYDA-ACS, SECURE-PCI trials and meta-analysis of randomized trials); this high dose has been mostly initiated 12–24 hours before PCI, or in the emergency department in the case of STEMI.

Answer 23. D. This patient has a porcelain aorta. CABG mildly increases the perioperative stroke risk compared to PCI in general (1.8% vs. 0.3% at 30 days in the FREEDOM trial); however, it will increase the stroke risk more dramatically in this patient with heavily calcified porcelain aorta. There is a high risk of athero-embolization during aortic cross-clamping or SVG suturing to the aorta. Only off-pump LIMA-to-LAD grafting with no aortic manipulation may attenuate the perioperative stroke risk.

III. Heart failure and cardiomyopathies

Answer 1. A. The presentation is consistent with either: (1) recent anterior infarct with late HF presentation, or (2) chronic anterior ischemia with hibernating myocardium. Despite the Q waves, this case is not an OAT trial case as the LAD is not totally occluded.

This should be treated as chronic CAD with cardiomyopathy. Q waves without persistent ST elevation do not rule out viability and may be seen with hibernation. In the STICH trial, neither viability nor ischemia testing predicted a revascularization benefit. Despite the REVIVED-BCIS trial, PCI remains reasonable when the dysfunctional segment is clearly subtended by a critical stenosis. Indeed, LAD PCI was performed in this patient and 3 months later, Q waves partially regressed (Q waves are now only seen in V_1-V_3), and the anterior wall significantly improved to mild hypokinesis (EF 45%).

Answer 2. C. Contrast this case with the previous question; in the previous question, PCI is performed as the LAD is not totally occluded and the patient is symptomatic. In this case, the total LAD occlusion, along with the anterior and anterolateral Q waves and the persistent

ST elevation/T inversion—which correlate with an even worse and more irreversible dysfunction than Q waves—make it unlikely for the LV to improve with revascularization. This argues against a complex LAD CTO PCI. CTO PCI has not improved EF or wall motion in EXPLORE and Revasc trials. If he had severe angina → revascularize LAD (no viability testing). If he had significant HF, viability testing might be considered to assess the anteroapex, followed by LAD PCI if viable; however, based on both OAT and REVIVED-BCIS trials, it is unlikely that PCI will yield any benefit or HF improvement, regardless of viability.

Answer 3. A. CABG significantly reduced 10-year mortality in the STICH trial, but only mildly. At 5 years, CABG was associated with a trend toward mortality reduction, but p value was not significant.

Answer 4. E. Neither viability nor ischemia testing predicted survival benefit from CABG. Patients with the most extensive CAD and the lowest EF derived the largest benefit from CABG. Viability predicted EF improvement with both CABG and medical therapy but was less clearly predictive of survival.

Answer 5. B. While impaired renal perfusion and impaired renal function are contributors to the limited diuretic response, the patient's BP and pulse pressure are not suggestive of a cold picture, and his renal function is not severely impaired. In this case, the distal tubular reabsorption of sodium and water is the main cause of diuretic resistance and may be counteracted by distal tubular blockade using metolazone or tolvaptan. He is receiving a proper furosemide dose (threefold his chronic oral dose).

Answer 6. C. After intravenous furosemide, peak diuresis occurs within 1 hour and lasts 2–3 hours. Diuresis should be assessed at 1–2 hours. If urination is <500 ml, a double dose should be administered at that time. After ensuring a dose is effective within a few hours, another assessment is made at 24 hours, the goal being 4–5 liters of daily urine output.

Answer 7. D. All the options presented are reasonable, but D is preferred. Her lack of response to furosemide may be due to the distal Na reabsorption past the loop of Henle (the most common cause of diuretic resistance), and it is reasonable to temporarily add metolazone. Yet, since this is oral furosemide, the lack of response may be due to reduced bioavailability in a congested patient. Torsemide may be tried, as it has better bioavailability, but it did not reduce HF hospitalizations and mortality compared to furosemide in a large trial (TRANSFORM-HF). Spironolactone is reasonable for mortality reduction but will not achieve the quick decongestion needed in this case. If she does not quickly improve with outpatient diuretic adjustment, she will require hospital admission and IV furosemide until she becomes euvolemic.

Answer 8. B. The differential diagnosis includes: (1) HFpEF (she has grade 1 diastolic dysfunction on echo, with normal LA pressure at rest; HFpEF is proven if LA pressure rises with stress); (2) functional atrial MR or ischemic MR that is dynamic; (3) septal hypertrophy with LVOT obstruction.
The immediate next step consists of murmur exam with maneuvers: supine position with leg raising, handgrip, and Valsalva. The first 2 maneuvers will aggravate functional MR and its murmur, by increasing venous return, while Valsalva attenuates functional MR. The opposite occurs in LVOT obstruction. Also, fast walk in the clinic will aggravate both functional MR and LVOT obstruction.
Afterward, diastolic stress echo or rest/exercise right heart catheterization is performed.

Answer 9. B. This is a true PCWP waveform with a large V wave (hints: slow upslope and sharp downslope, V peaks after T). The V wave rises sharply with minimal stress, to over 50 mmHg, which is suggestive of dynamic severe MR (in reality, V wave severely jumped just with leg raising). V wave rises with HF, but usually not to that degree. Pulmonary hypertension is secondary to PCWP, not pulmonary arterial disease; pulmonary vasodilator therapy will worsen PCWP (by increasing left preload) and induce flash pulmonary edema.

Thus, in this case, since dynamic MR is suspected, exercise right heart catheterization is not enough; echo images are still needed during stress to assess for MR, LVOT obstruction with SAM and MR, and ischemic wall motion abnormalities with dynamic MR.

Answer 10. C. Amyloid hearts very poorly tolerate CCB and β-blockers. Amiodarone may be the only option, even for rate control. Besides, a higher heart rate (up to 110–120 bpm) should be respected in restrictive cardiomyopathy with very limited stroke volume reserve, as cardiac output depends on it.

Answer 11. C. Global subendocardial LGE is seen in all types of cardiac amyloidosis. TTR amyloidosis has more marked echo abnormalities yet slower course.

Answer 12. C. The frequent PVCs and NSVT in the setting of a fixed defect are suggestive of a cardiomyopathy (sarcoidosis, ARVD, Chagas, prior myocarditis, prior infarct). The inferolateral location of the defect and the propensity for ventricular arrhythmia suggest cardiac sarcoidosis, although old myocarditis or infarct is also possible. MRI will differentiate ischemic scar from non-ischemic cardiomyopathy, and it will subclassify the latter; even if coronary arteries are currently patent, an ischemic scar may be the result of a prior coronary vasospasm or a recanalized coronary thrombosis. MRI is highly sensitive and specific for sarcoidosis, where it shows midwall or subepicardial LGE in a *basal septal or inferolateral location*; in this case, ICD would be indicated or, alternatively, EP study may be performed for further risk stratification. While the chest CT performed during coronary CTA is expected to show signs of sarcoid pulmonary/mediastinal involvement, cardiac sarcoidosis may be isolated. Metabolic PET, rather than standalone perfusion PET, is useful to assess active inflammation in sarcoidosis.

Answer 13. C. EF (stroke volume/end-diastolic volume) is highly dependent on loading conditions, preload and afterload, and is more a remodeling index than an intrinsic contractility index. The Ees point, on the end-systolic pressure-volume relationship, is the purest measurement of intrinsic myocardial contractility and is not affected by loading conditions (Chapter 5, Figure 5.7). Echo strain and dp/dt are mildly affected by loading conditions, markedly less than EF.

Answer 14. B. The patient has basal inferior thinning, and possibly an aneurysm at this level. This location is suggestive of sarcoidosis. Cardiac MRI will further support the diagnosis.

Answer 15. B. Figure 7 (i) illustrates the classic "sundae with cherry on top" echo strain, which may indicate amyloidosis. The apical echo strain, which corresponds to apical contractility, is preserved, while the basal echo strain is impaired, with an apex/base ratio of >2. This suggests

amyloidosis but has a limited sensitivity (<70%) and specificity (<65%) based on current data, as it may be seen in other cardiomyopathies (e.g., HTN, HCM). EF/GLS ratio >4.1 is more suggestive of amyloidosis. In this young patient, mutant TTR amyloidosis should be considered.

Figure 7 (ii) shows basal inferolateral LGE along with biventricular thickening. This is characteristic of Fabry disease, an X-linked glycosphingolipid accumulation. The other 2 main differential diagnoses are: (1) amyloidosis, characterized by global subendocardial LGE, and (2) HCM, characterized by patchy midwall LGE, particularly at the septum. Sarcoidosis leads to inferolateral LGE, but it does not cause diffuse or severe ventricular thickening; rather, it causes focal areas of thickening (active granulomas) and focal areas of thinning, typically in the basal inferolateral areas.

Answer 16. A. *Waveform identification:* The waveform is upsloping in diastole with A wave; thus, it is not arterial (not PA). It mimics ventricular waveform, but it is peaking after T wave, rather than plateauing during it; thus, this is not a ventricular waveform. It also has a peaked appearance with a relatively slow upslope, suggestive of atrial waveform with massive V wave of 50 mmHg. This is PCWP (LA pressure) with large V wave. RA pressure is unlikely, as RA pressure becomes ventricularized (plateaued) when V wave is very large.

Exam: Massive V wave directly leads to a loud S_3. It may be secondary to severe HF or severe MR. Even if severe MR is present, the murmur may not be holosystolic, as the rise in LA pressure in late systole, which is the actual V wave, attenuates the end-systolic portion of the murmur. The murmur may only be early systolic and soft, as the overall LV-to-LA gradient is reduced.

Answer 17. A. A JVP that pulsates is a ventricularized or arterialized JVP. This corresponds to a JVP with a pronounced V wave that peaks throughout systole, like the pulse, rather than peaks at the end of systole. The RA tracing mimics RV tracing and is pathognomonic for severe TR.

Answer 18. B. The patient has severe pulmonary hypertension. Being obese, she generates deep negative respiratory pressure, hence the pronounced respiratory fluctuations of PA pressure. Yet, despite deep breathing, mean RA pressure does not significantly drop with inspiration (~flat tracing): this is Kussmaul sign and suggests constriction but also severe RV failure, with or without severe TR. Y increases in depth with inspiration yet mean RA pressure minimally changes. In severe RV failure, RA compliance is severely overwhelmed, in a way that its pressure tends to paradoxically rise with the inspiratory rise in preload, which counteracts the direct transmission of negative intra-thoracic pressure. This creates a steady, invariable mean RA pressure; only the descents may deepen with the negative pressure. The W-shaped RA pressure (deep X and deep Y) is non-specific and may be seen in all options. Constrictive pericarditis is unlikely in the setting of severe pulmonary hypertension. The other options are plausible, but the most definitive answer is B.

Answer 19. B. The patient has classic type 1 MI presentation by ECG and troponin, yet no CAD. This is the so-called MINOCA (MI with non-obstructed coronary arteries). Recanalized coronary thrombosis is possible, but the MRI pattern is suggestive of myocarditis rather than MI. Several features argue against takotsubo: young age, troponin rise >5 ng/ml, and presence of LGE on MRI.

The likely diagnosis is focal myocarditis mimicking STEMI. Lyme carditis occurs in ~1–4% of Lyme cases, generally at 1–2 months after onset of infection (range, 1–28 weeks), and consists of conduction system disease with high-degree AV block in most cases (80–90%). Myocardial involvement with a myocarditis picture may infrequently occur with Lyme disease; even more rarely, valvular involvement may be seen. Chagas disease leads to chronic rather than acute cardiomyopathy. Chagas disease has an acute phase that is mild clinically; acute myocarditis is possible, particularly with oral transmission, but is infrequent and the incubation period is 1–2 weeks only.

Answer 20. B. A biphasic response is predictive of improvement with revascularization; it means the segment is viable, augments at low dobutamine dose, then becomes ischemic at higher doses and declines. A change from dyskinesis to akinesis is not considered a significant change. A uniphasic response argues against ischemia and against any benefit from revascularization: the myocardial segment is not ischemic, i.e., it is already receiving proper blood flow and would have recovered if that was possible. A uniphasic response suggests that subendocardial scarring is responsible for the lack of segmental improvement, rather than insufficient blood flow.

Answer 21. B. Preserved metabolic uptake implies viable tissue, while impaired perfusion implies ischemia. Perfusion-metabolic imaging, through its assessment of ischemia, is more predictive of myocardial recovery than isolated metabolic uptake imaging. The lack of ischemia means that the myocardial territory is already receiving enough blood supply and should be able to recover its function without revascularization if truly viable, which questions the value of revascularization.

Answer 22. A. A fixed defect with tracer uptake >50–60% may be an ischemic hibernating myocardium, but this is less predictive of ischemia than the presence of a reversible defect. Ischemic tissue is a viable tissue that readily improves its function with revascularization. This concept is similar to the biphasic response by dobutamine stress echo and to the perfusion-metabolic mismatch by PET imaging. Keep in mind that viability testing has not proven a useful revascularization guide in the the STICH trial and a REVIVED-BCIS trial analysis.

Answer 23. B. Peripartum cardiomyopathy develops in the first 5 postpartum months, not that late. The presence of heavy LV and RV trabeculations is suggestive of LV noncompaction. In the absence of another major explanation of LV dysfunction (CAD, severe HTN, infiltrative disease), LV hypertrabeculations in a young patient suggest a genetic cardiomyopathy.

Answer 24. C. This patient likely has senile (wild type) transthyretin amyloidosis. Elderly HFpEF with (1) moderate LV thickening ≥ 12 mm, plus (2) red flags, warrants amyloidosis investigation. This patient has several red flags: relatively low SBP (despite history of HTN), no LVH on ECG despite significant LV thickening on echo, and carpal tunnel syndrome. The best diagnostic test is Technetium pyrophosphate scan, which is highly sensitive >99% and specific for this diagnosis. Serum and urine immuno-electrophoresis and light chain ratio are also warranted to rule out AL amyloidosis. Cardiac MRI may also be performed, but is a bit less sensitive and specific, and does not distinguish transthyretin from AL amyloidosis; it may be reserved for restrictive cardiomyopathy with negative or indeterminate Technetium pyrophosphate scan.

Answer 25. B. A young patient with severe ventricular thickening and a pattern of restrictive cardiomyopathy is suspected of: (1) hypertrophic cardiomyopathy (restrictive phenotype), (2) mutant transthyretin amyloidosis, or (3) Fabry disease. Severe hypertensive cardiomyopathy secondary to renal disease is possible but less likely. The concomitant renal failure is strongly suggestive of Fabry disease; Fabry may be diagnosed via endomyocardial biopsy, but genetic testing is a safer method.

Answer 26. B. This patient developed a hypersensitivity reaction to norfloxacin with fever and leukocytosis. HF occurring in this context is suggestive of acute eosinophilic hypersensitivity myocarditis. The small and thick ventricles and the elevated troponin are suggestive of acute severe myocarditis. Endocavitary thrombus is seen in 20–30% of acute eosinophilic myocarditis and is suggestive of this condition. Eosinophils attack the endo-myocardium and cause diffuse endocardial damage that results in thrombi and subendocardial LGE on MRI. Persistent eosinophilia may progress to chronic eosinophilic myocarditis (Loeffler).

Answer 27. B. This patient has septic shock with ARDS, severe septic cardiomyopathy, and at this stage refractory biventricular cardiogenic shock. LV support (Impella) is not enough and will not solve the refractory hypoxemia or the RV failure. Like any LVAD, Impella may worsen RV failure by pulling the septum leftward, which further dilates the RV, and by pumping more flow in the systemic circulation, which increases the RV venous return. The only device that simultaneously supports the LV, RV, and pulmonary failure/oxygenation is ECMO. Guiding fluid administration to a higher PCWP target >12 mmHg or CVP target >8 mmHg has not proven useful in the ARDS net trial, even in shock patients, and resulted in worsening oxygenation and more prolonged ventilator requirement. PCWP >15–18 mmHg rarely provides any rise in cardiac output and is contraindicated in this patient with refractory hypoxemia.

Answer 28. C. There are 3 differential diagnoses for this presentation with predominant right heart failure: constrictive pericarditis, restrictive cardiomyopathy (particularly from genetic amyloidosis, considering his age and family history), and severe RV failure. Equalization of RV and LV diastolic pressures is seen at parts of the respiratory cycle, inspiration in this case, but this is not a specific finding, and may be seen in any of the latter 3 diagnoses.

Assess for *LV-RV respiratory systolic discordance*, which is highly sensitive and specific for constriction: compare *the peak inspiratory beat*, which corresponds to the beat preceded by the lowest diastolic pressure dip (2nd beat and 7th beat), and the *peak expiratory beat*, which corresponds to the beat preceded by the highest diastolic pressure dip and the most LV-RV diastolic separation (4th beat and last beat). It is most important to analyze the systolic areas, i.e., the bulk of the rectangular pressures, rather than analyze peaks. The area is what corresponds to the stroke volume. Peaks may be discordant as well, but less often than areas, and in fact, peaks grossly appear concordant here and are misleading. On the peak inspiratory beats, the LV area declines while the RV area dramatically rises. The RV peak itself is low on the 2nd beat but the RV area, most importantly, rises. This discordant behavior of RV and LV systolic areas is pathognomonic for constriction and may be exaggerated by recording the tracings during deep respiration. A cardiac CT or MRI may help consolidate the diagnosis by showing a thickened pericardium and may differentiate from amyloidosis; MRI is particularly useful to rule out inflammatory constriction, which may respond to an anti-inflammatory trial.

Answer 29. C. This patient likely has transthyretin amyloidosis; it may be wild type or genetic/mutant. Mutant transthyretin amyloidosis frequently has a late manifestation, particularly in African American patients. Elderly HFpEF with (1) moderate LV thickening ≥12–14 mm, plus (2) red flags, warrants amyloidosis investigation. This patient has several red flags: low SBP (while a truly severe LVH would suggest severe HTN), orthostatic hypotension, pseudo-Q waves on ECG, chronic troponin elevation (which in this case reflects the severity of the cardiomyopathy rather than CAD), and marked BNP elevation, more than the typical range of HFpEF.

Answer 30. C. This tracing is strongly suggestive of constrictive pericarditis. The patient is obese and generates deep breaths, which get transmitted to the pulmonary catheter and cause significant respiratory fluctuations of PCWP and V wave; as such V wave fluctuates between 10 and 25 mmHg. Conversely, the LV diastolic dip does not fluctuate as much, it varies between 10 and 18 mmHg. Along those same lines, the early diastolic gradient between LV and PCWP fluctuates excessively, between 0 and 10 mmHg, while normally both LV and PCWP should track respiration similarly with no dramatic change in this gradient (<5 mmHg). This is a landmark finding in constrictive pericarditis, wherein the constrictive shell shields the intracardiac structures, such as LV, from the effect of the respiratory pressure, while PA and PCWP recordings continue to be affected by the respiratory pressure. RV-LV systolic discordance on simultaneous RV-LV recording should be sought to corroborate this diagnosis.

There is no MS, as PCWP and LV pressures are equal and touch in mid- and end-diastole (diastolic diastasis). In decompensated severe MR, decompensated HF, and restrictive cardiomyopathy, V wave is expected to be larger than on this tracing.

Ventricular interdependence is diagnosed on simultaneous RV-LV recording: (i) equalization of end-diastolic RV-LV pressures suggests ventricular interdependence and is seen in both constriction and RV failure; (ii) respiratory discordance of systolic RV-LV pressures suggests ventricular interdependence with additional respiratory effect, a hallmark of constrictive pericarditis (not RV failure).

Answer 31. C. In HOCM, obstruction (or gradient) moves in an opposite direction to preload and afterload changes. Less known, gradient also varies with normal respiration, and deep breathing may be used to exaggerate a gradient. In inspiration, RV preload rises but LV preload declines from increased pulmonary vascular capacitance; more importantly, LV afterload rises during inspiration (LV transmural pressure) and it seems that HOCM patients are more afterload than preload sensitive. This afterload rise reduces the obstruction, causing less gradient, less murmur, and more pulse pressure (reverse pulsus paradoxus in HOCM).

Note: LV transmural pressure is the LV systolic pressure corrected for intrathoracic pressure (LV transmural pressure = systolic pressure – intrapleural pressure) and is considered a more accurate representation of cardiac afterload. LV transmural pressure increases with the negative inspiratory pressure.

Answer 32. B. The patient has HOCM with LVOT obstruction and secondary MR from SAM. LVOT obstruction and SAM are triggered by vasodilator and diuretic therapies. Discontinuation of the latter often suffices to improve symptoms and MR. If hypertension cannot be controlled with metoprolol, vasodilator or diuretic therapy may need to be slowly introduced, and mavacamtem or myectomy need to be considered if antihypertensive therapy is not tolerated.

Answer 33. B. The patient has severely symptomatic HOCM despite maximal β-blocker therapy (pulse ≤60 bpm) with marked septal hypertrophy ≥30 mm. As per ACC guidelines, alcohol septal ablation is generally discouraged in patients with septum ≥30 mm, and septal myectomy is particularly preferred in those patients. In fact, even a lesser septal thickness of 25–30 mm is associated with higher alcohol ablation failure rate and a persistently high mortality 7–10 years after ablation, which is not the case with surgical myectomy (Lu M et al,

Jensen MK et al). Yet, this patient has prior chest radiation with evidence of chronic radiation dermatitis, raising major concerns about postoperative healing. One registry data suggested that septal ablation was feasible in patients with severe septal thickening (>30 mm) and was associated, in this registry, with similar gradient reduction and similar failure rate as for septum <30 mm, although long-term mortality continues to be markedly increased after septal ablation and the number of reported patients is small (67).

Suggested readings:

Lu M, Du H, Gao Z, et al. Predictors of outcome after alcohol septal ablation for hypertrophic obstructive cardiomyopathy: an echocardiography and cardiovascular magnetic resonance imaging study. Circ Cardiovasc Interv 2016;9:e002675.

Voselka J, Jensen M, Liebregts M, et al. Alcohol septal ablation in patients with severe septal hypertrophy. Heart 2020;106(6):462–466.

Answer 34. A. The goal of medical therapy is to control symptoms, not necessarily to control the pressure gradient; in fact, β-blocker therapy blunts the provocable gradient but may have little effect on the resting gradient; it controls symptoms in ~50–60% of HOCM patients. This patient achieved symptom control to an acceptable degree and does not qualify for septal ablative therapies (which are used for NYHA III or IV). It is unclear whether alcohol septal ablation reduces mortality, particularly in patients <65 years old; septal myectomy may reduce overall mortality according to registry data, but even myectomy is mainly used for symptom control.

Answer 35. A. The baseline tracing shows mild LV-aortic gradient of <20 mmHg, with no change with Valsalva and with mild nonspecific increase after one PVC: this could be consistent with mild AS or mild LVOT obstruction. After a ventricular triplet, classic Brockenbrough phenomenon is seen with a dramatic rise in gradient to 120 mmHg, and a drop in aortic systolic and pulse pressure, implying dynamic LVOT obstruction. As importantly, the typical morphology of LVOT obstruction appears on the post-PVC beat: LV pressure is a late-peaking dagger, aortic pressure is a spike-and-dome. LVOT obstruction peaks late in systole, as the LV shrinks, which explains the late gradient, the late LV dagger, and the late drop in aortic tracing ("aortic dome").

While the inclination would be to treat the LVOT obstruction, it is important to note the following: (1) it was difficult to induce the LVOT obstruction, which only happened after a non-physiologic ventricular triplet and a long pause (it did not occur with one PVC or with Valsalva, which are the more physiologic maneuvers); (2) the septal thickness is only 15 mm; (3) severe arterial hypertension is noted on the tracing, with SBP of ~180 mmHg. Stress echo on a semi-reclined bike may be considered, to assess LVOT obstruction during physiological exercise and sort out what truly limits her (LVOT obstruction vs. HTN). Treadmill testing may also be performed with LVOT gradient assessment post-exertion. Short of that, a first step would be to cautiously try to control HTN, which is likely the driver of the patient's symptoms at this point. Treatment with diuretics or vasodilators, while generally harmful in dynamic LVOT obstruction, may improve symptoms if it controls HTN without worsening LVOT obstruction. The patient being already on the maximally tolerated β-blocker dose (pulse ~55–60), a small dose of thiazide, ACE-I, or amlodipine may be tried. If LVOT obstruction and symptoms worsen with HTN therapy, mavacamtem or myectomy is considered. Mavacamtem may also be initiated upfront, simultaneously to HTN therapy, in more typical cases of LVOT obstruction.

One report suggested nitroprusside challenge in the cath lab in hypertensive patients with LVOT gradient, with 2 potential scenarios: (1) HTN declines with no worsening of LVOT gradient, and with a reduction of PCWP, in which case standard HTN therapy may be initiated and expected to improve symptoms; (2) LVOT gradient dramatically worsens and hypotension occurs, in which case septal reduction therapy or mavacamtem is needed before initiating antihypertensive drugs.

Answer 36. C. In HOCM, severe MR that is anteriorly directed suggests intrinsic mitral valve disease, such as posterior leaflet prolapse. When MR is purely related to the systolic anterior motion of the mitral valve, the jet is directed posteriorly, as the relatively short posterior leaflet fails to meet the sucked anterior leaflet and simulates posterior tethering. In this patient, besides septal reduction, MR needs to be corrected. MRI or TEE helps define the mitral anatomy and surgical planning. ICD is not clearly indicated as no high-risk criteria are presented.

Answer 37. B. While D or E is possible, the most likely cause of apical aneurysm in a patient with non-obstructed coronary arteries, LVH with strain, and family history of sudden death (suggestive of a familial cardiomyopathy) is mid-cavitary hypertrophic cardiomyopathy with apical aneurysm. It is an HCM subset associated with a high risk of sudden death and apical thrombus formation, which indicates ICD as well as anticoagulation.

Answer 38. B. This patient with LVAD has marked LV failure and secondary RV failure, not isolated RV failure. The dilated LV on echo is a hint to that. A problem with LVAD is suspected: pump thrombosis or inflow or outflow obstruction. The high power is suggestive of pump thrombosis, and the high flow is a false calculation by the LVAD, discrepant with the Swan's CO; in the other conditions, the pump power is reduced because of reduced flow. The pump power is increased in pump thrombosis as it takes more energy to move the thrombotic rotor. On echo, a low velocity of the inflow cannula with a near-absent diastolic signal indicates inflow obstruction or pump thrombosis. Hemolysis is seen with elevated LDH and dark urine. The high INR does not preclude the diagnosis, as it may have only risen recently from liver congestion.

IV. Valvular disorders

Answer 1. C. The early systolic sound suggests the ejection click of a bicuspid aortic valve; conversely, the click of mitral valve prolapse is heard in mid-to-late systole, while the opening snap of MS is heard in diastole. The click of a bicuspid aortic valve is heard at the base but may be heard at the apex. The mild diastolic murmur at the base is AI; the other hint is the wide pulse pressure. The diastolic murmur at the apex is Austin-Flint murmur, which is heard in severe AI. Unlike this case, the diastolic murmur of pulmonic regurgitation (Graham Steell) increases in inspiration.

Answer 2. B. In the case of significant regurgitation of the same valve being evaluated for stenosis, CO obtained by Fick or thermodilution cannot be used in Gorlin equation. The latter CO is the net flow that reaches the systemic circulation, whereas at the level of the valve the flow is a summation of the net systemic flow and the backward regurgitant flow. Using the smaller CO in Gorlin equation falsely decreases the valve area (AVA = flow across the valve/constant × √pressure gradient). The AVA continuity equation is not affected by mixed valvular disease.

Answer 3. C. A patient with AS and elevated LVOT velocity that is, nonetheless, much lower than the aortic velocity, typically has severe AS with a secondary septal hypertrophy and LVOT flow acceleration. The high LVOT velocity is part of the AS flow acceleration (part of the AS anatomy), and should not be used in AVA or dimensionless index calculation (LVOT velocity/aortic velocity); rather, LVOT velocity should be derived from a more proximal LV area of laminar flow. In this case, when AS appears anatomically severe with poor valve opening, severity assessment should rather rely on the summation (LVOT + AS) peak velocity and summation gradient, not pull back gradient, or AVA calculation by invasive Gorlin equation. One exception is a high LVOT velocity that reflects a high-flow state, rather than AS flow acceleration, in which case the high LVOT velocity should be used in AVA and DI calculation.

Answer 4. B. This Doppler waveform shows the superimposition of 2 distinct waveforms (Figure 61): (i) an early, rounded one (AS, *solid line*), and (ii) a late-peaking dagger-shaped one (dynamic LVOT obstruction, *interrupted line*). Unlike the prior case, where aortic velocity was highest, LVOT velocity is highest here (5 m/s) and is this patient's primary, predominant pathology; he has severe LVOT obstruction and concomitant mild AS (peak velocity 2 m/s).

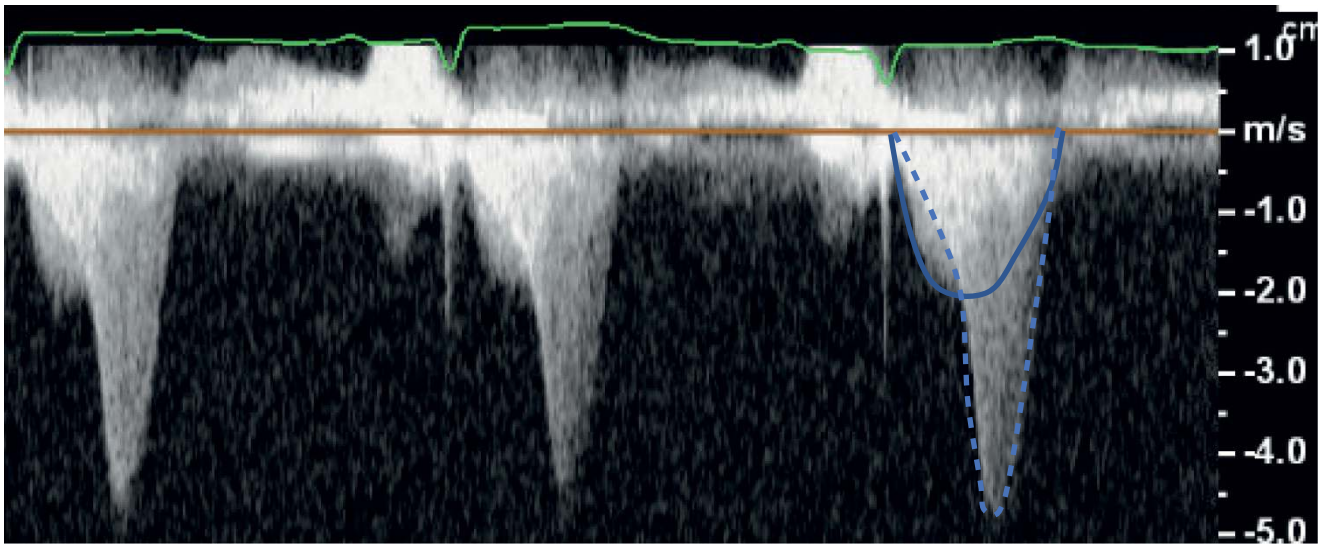

Figure 61

Answer 5. C. In the first few days after PMBV, pressure half-time is unreliable for MVA calculation and MS assessment. LA compliance continues to be impaired early on after PMBV, which creates a delayed drop in LA pressure (delayed pressure half-time) and a delayed E wave decay, despite improved MVA. Yet, the E wave will touch the baseline, implying diastasis, which is not the case pre-PMBV.

Answer 6. D. Like most uncorrected, symptomatic valvular disease, the mortality of severe symptomatic TR may approach 40% at 1 year (and more so in a patient with multiple HF hospitalizations).

Answer 7. C. This patient has radiation heart disease, as evident by the mitral and aortic involvement. She has calcification of the cardiac skeleton, and this frequently affects the His-Purkinje system and leads to infranodal block, which may be unveiled or aggravated by exercise. She may also have sick sinus syndrome with chronotropic incompetence, related to radiation, which will also be diagnosed by stress testing. Stress testing is here aimed to diagnose conduction disease, rather than CAD, hence nuclear stress testing is not warranted despite the baseline ST depression.

Answer 8. C. The findings are consistent with radiation-induced heavy calcification of the mitro-aortic curtain. While he may have AS, the aortic valve mobility rather suggests subaortic obstruction; the calcium of the mitro-aortic curtain is likely bulging in the LVOT and narrowing it. While catheter pull back across the LVOT may help localize the outflow obstruction, the best test is cardiac CTA, which defines the location and extent of calcium and helps guide corrective surgery.

Answer 9. B. Risk factors for radiation heart disease include: young age <60 years (more longevity to manifest the long-term sequelae of radiation), concomitant anthracyclines use, cardiac risk factors, high dose >30 Gy, and left chest radiation. Most of the manifestations occur late, except for pericardial effusion, which may occur early. The *left-sided valves* are more commonly affected than the right-sided valves, likely because the higher left-sided pressure makes them more prone to injury. The most anterior valve is the pulmonic valve, followed by the aortic valve, then tricuspid valve, then mitral valve (Figures 6.1 and 6.24).

Answer 10. C. When AI murmur is holodiastolic, severe AI is implied with a high specificity. The wide pulse pressure (>1/2 SBP) in this relatively young patient is also suggestive of severe AI. Nocturnal chest pain is related to further cardiac slowing at night, leading to significant reduction of DBP, significant rise of LVEDP, and an approximation of DBP and LVEDP. The driving pressure gradient for coronary perfusion is DBP minus LVEDP, and must ideally be maintained >30–40 mmHg. As such, DBP-LVEDP approximation causes functional ischemia. Functional

limitation may not be obvious as dyspnea develops insidiously, allowing patients to slowly adjust their activity. Echo frequently underestimates AI severity in eccentric, bicuspid AI, wherein the color abuts the mitral valve or the septum and quickly abates. TEE has a similar limitation. Color Doppler correlates with velocity more than volume; the regurgitant AI volume may be high, yet color may abate quickly. Indirect signs suggest severe AI, such as LV dilatation and the high velocity across the aortic valve, which is likely related to the high flow across the aortic valve from AI, rather than just moderate AS.

With this discrepancy between the exam and an inconclusive echo, cardiac MRI or invasive aortography is indicated: these 2 modalities assess AI volume (qualitatively for aortography, quantitatively for MRI). Cardiac MRI is the best modality in AI assessment.

Answer 11. D. First, identify the tracings based on their morphology. The top tracing is a rectangular tracing upsloping in diastole, likely LV.

Regarding the bottom tracing, is it ventricular, arterial, or atrial? Start by looking in diastole: the tracing is upsloping in diastole with A wave; thus, it is not arterial. It has a wave that follows T wave and intersects with the LV descent, which characterizes a V wave and implies an atrial tracing. Moreover, a ventricular or an arterial tracing would be peaking simultaneously to the LV, not the case here.

This is LV-LA recording. Normally, LV and LA pressures equalize in mid-diastole: the V wave descends all the way and touches the LV. This lack of diastasis despite a slow heart rate of 60 (<80) implies severe MS and corresponds to a diastolic rumble. Also, note how LA A wave is prominent, while LV A wave is absent (no S_4)— this discordance is another sign of severe MS.

Answer 12. B. On simultaneous LV-aortic pressure recording, the aortic pressure has a slow upslope with late peaking, consistent with AS. The peak-to-peak gradient is 25 mmHg. Using Hakki's equation, AVA = CO/√peak-to-peak or mean gradient = 3.9/√25 = 0.75 cm^2. Thus, catheterization confirms this is a truly low AVA rather than an echo mismeasurement. This is low-gradient truly severe AS; the flow is low, as the stroke volume index is <35 ml/m^2 ([CO ÷ heart rate] ÷ BSA = 28 ml/m^2). Dobutamine study is not recommended in normal EF with low-gradient AS; the issue is not contractility, rather it is low flow from impaired diastolic filling, i.e., low preload volume, and from high afterload. Dobutamine does not address the issue; in fact, it further reduces LV cavity size without increasing venous return and thus, reduces preload in patients with normal EF and small LV cavity. AS is truly severe if AVA is low by both echo and catheterization.

Aortic valve calcium scoring is an alternative modality that assesses the severity of AS in low-gradient AVA <1 cm^2 but is not needed if catheterization confirms severe AS. LVEDP is elevated at 30 mmHg, hence she is not overdiuresed. *Pressure recovery phenomenon* may be encountered in patients with small aorta, particularly small women: in this case the pressure gradient at the aortic valve partially recovers in the aorta and becomes attenuated downstream, the attenuated gradient being the true physiological gradient. Echo catches the exaggerated aortic valve gradient and exaggerates the true AS severity in this case; however, in our patient, echo gradient is not higher than cath gradient, hence pressure recovery is not a concern.

Answer 13. A. This patient has low-flow, low-gradient AVA ≤1 cm^2. He has features of amyloidosis: elderly patient with severe LV thickening ≥14 mm (may be asymmetric), low BP, spinal stenosis, orthostatic hypotension, pseudo-Q waves on ECG (in the absence of wall motion abnormality). Apical sparing on echo strain imaging and EF/GLS>4.1 would further suggest that. Amyloidosis is the underlying cardiomyopathy in 10–15% of low-gradient AS cases: AS is likely severe and the flow is reduced by the severely restricted diastolic filling, leading to a low gradient. Calcium scoring for the aortic valve and scintigraphy for amyloidosis should both be performed, and therapy of both conditions considered.

Answer 14. C. This echo has 2 measurement errors leading to underestimation of AS severity:

*The spectral Doppler line is not aligned with the aortic valve flow: it is angled over 20° compared to the transvalvular plane (*bottom left image*).

*The LVOT velocity that has been sampled, 1.6 m/s, is too close to the aortic valve and is capturing the flow acceleration just upstream of the aortic valve, which is actually part of AS (*top left image*). The mildly increased LVOT velocity is not a sign of LVOT obstruction, it is part of the AS flow acceleration. LVOT velocity should be captured farther away from the aortic valve, before the flow acceleration (*top right image*). The high LVOT velocity should not be used in AVA or DI calculation, as it reflects a focal process rather than a diffusely elevated LV velocity from a high flow state.

The true LVOT velocity is 0.9 m/s, and the dimensionless index is, thus, 0.28 (in the gray zone: 0.25–0.30). The aortic valve area measures 1 cm^2 (LVOT area × dimensionless index). Considering the poor echo measurements and the uncertain findings, it is best to obtain true transaortic pressure gradient and AVA invasively. The patient may have classic severe AS, with mean pressure gradient >40 mmHg, or low-gradient severe AS, or moderate AS. Exercise testing is reasonable to assess whether he has functional impairment from AS, but it is only considered once AS is proven to be severe. Calcium scoring is considered in low-gradient AVA ≤1 cm^2, not clearly the case here.

Answer 15. A. The AVA is >1 cm^2, but the patient is tall, and his indexed AVA is 0.5 cm^2/m^2, i.e., in the severe range (<0.6). Thus, by catheterization, he has severe low-gradient AS. His cardiac output appears normal, but the stroke volume index is low: (CO/heart rate)/BSA = 30 ml/m^2. Thus, the patient has severe, paradoxical low-flow, low-gradient AS. AI may exaggerate the AS gradient, but does not affect AVA calculation by echo continuity equation. Invasive AVA calculation is affected by AI when thermodilution or Fick CO is used in Gorlin equation; but the effect is minor and insignificant in mild AI.

Answer 16. B. Postoperative HF is common after mitral valve surgery performed for MR and occurs in ~25% of patients at 5 years. All answers A through E are predictive of a higher risk of postoperative HF, but EF is the strongest predictor (in absolute value and in statistical significance). A mildly reduced EF already indicates irreversible systolic dysfunction that may succumb to the postoperative rise in afterload, in ~25% of such patients. The risk of HF is >50% in patients with preoperative EF < 50%. Repair partially reduces the risk of postoperative HF.

Suggested reading:

Enriquez-Sarano M, Schaff HV, Orszulak TA, et al. Congestive heart failure after surgical correction of mitral regurgitation. A long-term study. Circulation 1995;92(9):2496–503.

Answer 17. C. TAVR is not considered for age <65, unless the patient has a prohibitive or a high surgical risk (STS score >8%), which is not the case here. Also, TAVR is not favored in a clearly bicuspid aortic valve. Either a mechanical prosthesis or a surgical bioprosthesis is acceptable in the aortic position for age 50–65 per ACC guidelines, but not per ESC guidelines, which use age 60–65 as a gray zone. Thus, a mechanical prosthesis is favored. The aortic root is replaced in conjunction with AVR when it is dilated to ≥4.5 cm.

Answer 18. C. This patient has severe aortic insufficiency as indicated by the following: (i) wide aortic pulse pressure with severely reduced aortic diastolic pressure of 40 mmHg; (ii) sharp rise of LVEDP after a pause, with LVEDP becoming equal to the aortic diastolic pressure. This LV-aortic diastolic diastasis is diagnostic of severe, decompensated AI. The coronary flow being driven by aortic diastolic pressure minus LVEDP, a gradient that approximates 0 mmHg translates into severe myocardial ischemia, even in the absence of CAD. Moreover, the aortic diastolic flow reversal seen in AI "sucks" blood from the coronary arteries and creates coronary diastolic reversal, which was visible on coronary angiography in this patient: this mimics myocardial bridging, except that the coronary artery is "milked" during diastole, not systole. AI may lead to premature closure of the mitral valve and late diastolic rumble (Austin-Flint), not early diastolic rumble.

Additional features suggestive of severe AI on this tracing:

– Dicrotic notch is absent
– Anacrotic notch is pronounced (notch on the upslope of aortic pressure). Anacrotic notch may be seen in AI even without severe AS; because of the high flow crossing it, the aortic valve may become functionally obstructive. Unlike in severe AS or mixed AS/AI, this anacrotic notch is high on the aortic upstroke and the aortic upstroke remains sharp rather than "tardus."

Answer 19. B. This patient has aortic valve thrombosis, as suggested by CT (hypo-attenuated mass) and by the leaflets' motion on fluoroscopy and CT. While her INR is currently at goal, this patient has a history of intermittent non-adherence to warfarin, which predisposes her to prosthetic thrombosis. Pannus growth is an alternative diagnosis but is less likely in the context of the CT finding and the history. Normally, during systole, both leaflets should open and become nearly vertical (>80°), with an in-between angle (marked in *dotted blue*), that is <20°. In this case, the in-between angle measures 55°, suggestive of restricted opening of both leaflets, but more so the right-sided one (toward the RV). This is treated either surgically or via thrombolytic therapy. The patient has NYHA <4, and she has increased surgical risk (redo cardiac surgery, obesity, smoking) and as such, low infusion of r-tPA is an appropriate first option (class I recommendation). The low infusion is associated with lower embolization and bleeding risk than the traditionally high bolus dose of 100 mg. Echo is repeated daily, and the low infusion may be repeated up to 6 times, until the gradient dramatically improves and the thrombus diminishes >75% in size. Standalone heparin therapy is only considered in subclinical leaflet thrombosis.

Answer 20. E. In the age range of 65–80 years with low or intermediate surgical risk, either TAVR or surgical bioprosthesis may be used (ACC guidelines, class I). For the age range 50–65 (or 60–65 per ESC), with low or intermediate surgical risk, TAVR is avoided, and either a mechanical or bioprosthesis is used. For age <50 (or 60 per ESC), a mechanical prosthesis is used. For age >80, TAVR is preferred.

Answer 21. B. The patient has severe TR that is likely functional and secondary to his prior mitral valve disease; he probably had baseline tricuspid annular dilatation that continued to progress over the years, leading to progressive TR, as in 25% of patients with mild TR at the time of left-sided valve surgery. Hence the tricuspid valve is best repaired during the initial mitral surgery whenever the annulus is significantly dilated >40 mm, even if TR is mild. At this point, isolated TR is the driver of his right HF; it qualifies for surgical or percutaneous repair if hepatic and renal dysfunctions are not too advanced (ESC class IIa recommendation for early intervention, including in patients with prior left heart valve surgery). The surgical mortality is traditionally high, >10%. Percutaneous clip devices (MitraClip placed in the tricuspid position, or PASCAL clip) and percutaneous valve replacement have been shown to be feasible and safe in high-surgical-risk patients, and significantly improve quality of life. Of note, neither surgical nor percutaneous therapies have demonstrated survival improvement in isolated TR, and their benefit is questionable when advanced liver or renal failure has already occurred (high Tri-SCORE). Diuresis is typically not efficacious for reversing annular dilatation and TR at the severe stage: the effect tends to be limited and transient, as the less fibrous tricuspid annulus (vs. mitral) loses its elastic recoil more easily.

Suggested reading:

Montalto C, Sticchi A, Crimi G, et al. Functional and echocardiographic improvement after transcatheter repair for tricuspid regurgitation: a systematic review and pooled analysis. JACC Cardiovasc Interv 2020;13(23):2719–2729.

Answer 22. C. During mitral valve surgery, even mild TR warrants concomitant surgical correction if the tricuspid annulus is dilated. Otherwise, tricuspid annular dilatation begets more annular dilatation, progressive TR, and RV dilatation over time. Concomitant tricuspid repair is indicated if the annulus is >4 cm or if prior clinical right HF has occurred (class IIa), as is the case here (elevated JVP).

Answer 23. D. MitraClip is studied and approved in both degenerative MR (EVEREST trial) and functional MR (COAPT trial). MitraClip improves forward CO and stroke volume by ~20–25%, reduces LV end-diastolic volume (preload) and LVEDP, and as a result of the increased CO, reduces systemic vascular resistance (EVEREST trial analysis). On average, LV afterload (LV systolic radius × LV systolic pressure) is not affected (as per an EVEREST trial analysis and a series of functional MR/low EF by Melisurgo et al). On average, EF slightly but significantly declines (EVEREST, Melisurgo et al, and COAPT analyses). *However, a substantial proportion of patients (26%), develop afterload mismatch*, wherein LV afterload increases after eliminating the low-impedance leak into the LA, LV "balloons," and EF dramatically declines; this is particularly true in patients with the most dilated and dysfunctional LV at baseline. In the remaining patients, EF is unchanged or slightly declines, and afterload is unchanged as the reduction in LV diastolic size and SVR adjust for the propensity of LV systolic pressure and diameter to rise, the latter remaining unchanged as a result. Importantly, EF, preload and afterload are stable over time with MitraClip compared to control patients, whose EF continues to decline and preload and afterload continue to rise over time (COAPT analysis).

Answer 24. C. The echo shows elevated mean gradient across the aortic prosthesis, which suggests patient-prosthesis mismatch (most common cause) or prosthetic obstruction by thrombus or pannus. Yet, catheterization shows no gradient at all, which is unusual, as echo tends to underestimate the true gradient by not being perfectly aligned with the highest velocity, not overestimate it. ***Only one process***

can cause the echo gradient to be significantly higher than the catheterization gradient, which is the true pressure gradient: pressure recovery phenomenon, whether across a bileaflet mechanical valve or across a native aortic valve. The smaller central orifice of the bileaflet valve gives rise to a localized obstruction and a localized pressure drop that is largely recovered once the central flow joins flow originating from the 2 lateral orifices. In native aortic valve with a small aortic root <3 cm, pressure drops across AS but partially recovers once flow hits the narrow aorta. In this patient, the opening angle between the leaflets is normal (<20°), which further suggests that the prosthesis is normal. The patient's dyspnea is caused by diastolic HF (high LVEDP).

Answer 25. B. Bicuspid valve is the most common form of AS (50%) at age <70.

Answer 26. B. TR leads to elevated JVP with large V wave; a large A wave is more indicative of tricuspid stenosis or RV pressure overload. Also, the lack of RV dilatation, of wide S_2 split (RV failure), and of pulsatile hepatomegaly argue against TR. The multiple leads across the tricuspid valve create adhesions and scar tissue over the valve, particularly when the leads have loops. This is a rare but well-described complication of multiple lead revisions.

Answer 27. A. Severe hemolysis with schistocytes is traditionally seen with large paraprosthetic leaks, particularly in a mechanical valve, but may be seen with patient-prosthesis mismatch (high transvalvular velocity), bioprosthetic valve degeneration, and with failed mitral valve repair (as the regurgitant blood strikes the endocardial ring). A mild degree of subclinical hemolysis is also common with the shear stress of normally functioning mechanical prostheses (25–50%). For a failed mitral valve repair, MitraClip may be performed if the valvular anatomy remains favorable on TEE, i.e., MR is related to a leaflet prolapse without excessive flail (gap between leaflets <10 mm in height).

Answer 28. B. She has aortic bileaflet prosthesis with no thromboembolic risk factors noted (no AF, no LV dysfunction, no prior stroke). Her INR goal is 2–3. If this was a mitral prosthesis, the risk of thrombosis would be higher, and the recommended INR would be 2.5–3.5 regardless of thromboembolic risk factors. Aspirin used to be recommended in all mechanical prostheses by the ACC. But now, neither ACC nor ESC guidelines favor routine aspirin use, as data supporting its use are outdated and did not analyze current-generation prosthetic valves (class II indication if associated atherosclerotic disease and low bleeding risk).

Answer 29. C. The pressure gradients are expected to increase in a high-flow state (fever, sepsis, bounding pulses) and do not reflect prosthetic valve obstruction. Pressure gradient is proportional to the square of the flow, as per Gorlin equation. Dimensionless index remains unchanged.

Answer 30. A. In severe AS, A2 is attenuated (or absent) and delayed, meaning S2<S1 at the RUSB.

Answer 31. C, D, and E. MR/VSD murmurs do not generally increase after a pause as DBP ↓ and forward flow into the aorta relatively ↑.

Answer 32. A. A soft diastolic flow murmur is normal across a mitral prosthesis, while a soft systolic flow murmur is normal across an aortic prosthesis (forward flow murmur). Velocity may be normally elevated across a prosthesis, especially when a degree of patient-prosthesis mismatch is present; it may normally be up to 3 m/s across an aortic prosthesis, and 1.9 m/s across a mitral prosthesis (ASE guidelines).

Answer 33. B. LV-aortic pressure gradient is present, with the following characteristics suggestive of dynamic LVOT obstruction:

- LV and aortic upslope are superimposed (aortic pressure is not tardus)
- Late-peaking, narrow, "peaky" LV pressure
- Early peaking aortic pressure with spike and dome appearance
- Gradient varies dramatically with respiration, which indicates a dynamic obstruction. In inspiration, afterload increases, LVOT obstruction improves, gradient declines, and aortic pulse pressure increases (reverse pulsus paradoxus).

V. Arrhythmias

Answer 1. B. All class I antiarrhythmic drugs increase defibrillation threshold (the effect of propafenone is less pronounced than flecainide). As such, it is best to initiate flecainide soon after successful DC cardioversion. Except for chronic oral amiodarone, class III drugs do not increase the atrial or ventricular defibrillation threshold and may actually decrease it (this includes dronedarone).

Answers 2. C, D, E. Procainamide and oral amiodarone may be used to pharmacologically cardiovert AF or to sustain sinus rhythm after electrical cardioversion (prevent immediate recurrence), but they do not increase the success of electrical cardioversion; in fact, they increase the atrial defibrillation threshold and make it harder to electrically cardiovert AF. Conversely, ibutilide and sotalol reduce the defibrillation threshold and facilitate electrical cardioversion.

Answer 3. A. Class Ic drugs are the most potent sodium channel blockers, followed by class Ia then class Ib.

Answer 4. D. AV dissociation implies this is VT, rather than SVT with aberrancy. VT with a typical LBBB morphology is mainly bundle branch reentrant VT, a VT that spreads down across the right bundle, then up across the left bundle, leading to a typical LBBB morphology. This VT is generally very fast. RVOT VT has an *atypical* LBBB morphology (vertical axis), and idiopathic fascicular VT has a typical RBBB + LAFB morphology. Bundle branch reentrant tachycardia is rarely seen with structurally normal hearts and is rather initiated by ischemic or non-ischemic cardiomyopathy with scar across the Purkinje system. While these patients frequently need an ICD, the direct and most effective therapy is ablation of the circuit across the right bundle.

Answer 5. B. The QRS of the VT looks away from where it originates, hence its QRS is negative in the zone of origin. An apical VT is negative in the apical leads, V_4 through V_6; since it originates from the LV, it is slurred and upright in V_1 (atypical RBBB), but being apical, it quickly transitions to negative by V_3. The apex being leftward, the VT looks to the right and superiorly in the frontal plane, hence the northwest axis. It is also negative in the inferior and lateral leads I and aVL. A VT that originates from the basal septum or even the basal lateral wall is upright beyond V_3 and may be upright or discordant in the inferior leads.

Answer 6. C. A sinus beat is followed by a tachycardia that is initially wide then becomes narrow. The R-R interval is longer during the wide portion than the narrow portion, which is unusual and suggestive of orthodromic AVRT with intermittent aberrancy. The accessory pathway must be on the same side as the aberrancy (e.g., left pathway and LBBB aberrancy). The reentry normally goes down the AV node and septum, then up the left AP; in case of LBBB, the reentry will have to make a detour (go down the right bundle, then septum then accessory pathway), which makes the tachycardia cycle longer.

Answer 7. B. Lidocaine increases the defibrillation threshold; while it reduces VT recurrence, it makes it harder to cardiovert it. Procainamide is a class Ia antiarrhythmic that may also increase the defibrillation threshold, but minimally and less noticeably than lidocaine.

Answer 8. C. Sinus node disease is commonly associated with atrial arrhythmias. Syncope in a patient with sinus node disease is most commonly related to the transition from paroxysmal AF to sinus rhythm. A sinus pause is seen at the transition, and that pause can cause syncope. Chronotropic incompetence usually leads to fatigue, not syncope. Sinus bradycardia is rarely symptomatic, per se, unless <40 bpm.

Answer 9. D. This patient developed paroxysmal AF and a pause at the conversion of AF into sinus rhythm, which is the most serious pause in AF patients. In a way, it is better for this patient to remain in AF than to alternate between AF and sinus rhythm and be exposed to long transition pauses. The most typical treatment is PPM. Rhythm control via AF ablation, if viable, may be considered, particularly in younger patients.

Answer 10. B. All antiarrhythmic drugs affect the sinus node, but dofetilide exhibits the least impact. It may be used to prevent AF and consequently reduce the AF-to-sinus conversion pause, but AF ablation or PPM remains the superior option.

Answer 11. C. For the diagnosis of sinus node disease, the sensitivity and specificity of sinus node recovery time are 70%. Correlation of symptoms with sinus pauses on ambulatory monitoring more reliably diagnoses sinus node disease.

Answer 12. A. This is LBBB-induced cardiomyopathy, as evidenced by the following: (i) the LV motion abnormality predominates at the septum, while the apex is preserved, which argues against LAD disease; (ii) QRS is very wide >150 ms, enough to cause pronounced dyssynchrony and cardiomyopathy. In a substudy of the MADIT-CRT trial, patients with LBBB ≥150 ms tended to be super-responders to CRT. A long-term follow-up of patients with LBBB and normal EF at baseline showed that those who later developed cardiomyopathy had a progressive QRS prolongation ≥150 ms and a super-response to CRT. One study suggested that in cardiomyopathy with LBBB, EF does not significantly improve with standard HF therapy. The patient will likely super respond to CRT, yet, being asymptomatic, such therapy is not indicated. Rather, routine follow-up is required, ACE-I/ARB and carvedilol are still prescribed for their proven benefit on mortality and HF decompensation, and CRT is implanted once symptoms occur. CRT may be considered without ICD, as EF will likely dramatically improve with standalone CRT.

Sze E, Samad Z, Dunning A, et al. Impaired recovery of left ventricular function in patients with cardiomyopathy and left bundle branch block. J Am Coll Cardiol 2018; 71: 306.

Answer 13. B. This patient has symptomatic inappropriate sinus tachycardia (IST), with no anemia or hyperthyroidism. She does not have POTS, as her sinus tachycardia is not orthostatic, i.e., it is present in a sitting or lying position and does not dramatically rise with orthostasis. POTS is mainly related to cardiovascular deconditioning, hence the importance of exercise and lifestyle measures. IST could be partly related to cardiovascular deconditioning but unlike POTS, is mostly related to dysautonomic activation of the sinus node. Ivabradine blocks this sinus node activation (class IIa recommendation for IST). Metoprolol may be used (class IIb), but may cause or worsen fatigue and drop BP.

Answer 14. C. Unlike the prior question, this patient has POTS with severe orthostatic rise in sinus rate >30 bpm. Sinus tachycardia compensates for (i) cardiac deconditioning (low stroke volume), (ii) vascular deconditioning (low renin-angiotensin activation, low volume), and (iii) peripheral autonomic neuropathy (lack of vasoconstriction). Slowing the sinus rate will aggravate symptoms, except in hyperadrenergic POTS, proven by high norepinephrine levels at 5 minutes of standing. Lifestyle measures are the mainstay POTS treatment: (1) hydration and liberal salt use in the absence of supine HTN, (2) sleeping in a semi-recumbent position (a form of orthostatic training), (3) waist-high compression stockings and abdominal binders, (4) and most importantly, supine exercises to improve the cardiovascular deconditioning. Droxidopa may be used in autonomic orthostatic hypotension, not POTS. Midodrine or fludrocortisone may be used in severe POTS cases refractory to initial measures.

Answer 15. C. AT is often responsive to class I antiarrhythmics, unlike atrial flutter, which may be perpetuated by them. The biggest distinguishing feature is the presence of an isoelectric line in AT, indicative of its focal origin, vs. a lack of isoelectric line in atrial flutter (=macroreentry). Atrial rate, as described in B, also helps and is a second distinguishing feature. AT is frequently an automatic rhythm, particularly in young patients with no heart disease, hence it is difficult to induce and is non-responsive to DC cardioversion; reentrant or triggered activity AT responds to DC cardioversion. β-Blockers and calcium channel blockers may suppress automaticity and break AT or MAT, not atrial flutter.

Answer 16. B. This patient has Brugada syndrome type 1, as evidenced by the coved ST elevation in V_1-V_2. Quinidine is highly effective in Brugada VT but is not available intravenously. Unlike quinidine, other class I antiarrhythmics aggravate the dispersion of repolarization in Brugada and worsen VT. Brugada is one of several VT storms that are triggered by rest and low sinus rate, and can be improved with catecholamine therapy: Brugada VT, pause-dependent VT or acquired TdP, short QT syndrome, and early repolarization VF.

Answer 17. D. The high number of V on the marker channels suggests ventricular arrhythmia vs. oversensing; EGM analysis would have helped distinguish between the 2. The erratic and very short VV intervals suggest V oversensing from lead fracture.

Also, the patient is frequently V paced, despite the lack of AV conduction disease, which suggests episodic undersensing of the intrinsic QRS, causing V overpacing.

The combination of undersensing and oversensing and the high lead impedance are suggestive of lead dysfunction.

Answer 18. C. The patient has V lead fracture. The initial inclination is to upgrade the V lead, yet 2 ideas indicate that this is not immediately necessary in this elderly patient: (i) V oversensing leads to V underpacing, but this is mainly consequential in a patient who is dependent on V pacing, which is not the case here, as he appears to only be dependent on A pacing; (ii) V oversensing leads to inappropriate shocks in a patient with ICD, not the case here.

V oversensing may also delay atrial pacing, as V sensing resets all pacing intervals including the atrial escape interval (V-to-A interval), and may be harmful in this patient; this explains why the interval between the paced A deflections is longer at times, and it may have contributed to his syncope. The V configuration was eventually changed in this patient from bipolar to unipolar, and this immediately reduced the lead impedance and improved sensing, reducing the burden of V pacing to <0.5% over the next day. A bipolar lead has a ring wire and a tip wire; lead fracture is likely partial here, involving the ring wire only; in this case, sensing issues are halted by sensing between the tip and the can, and avoiding the use of the ring (functionally converting the lead to a unipolar lead).

Changing from bipolar to unipolar configuration may also help in cases of undersensing related to a small QRS amplitude, or oversensing related to a large T-wave amplitude.

Answer 19. B. T-wave inversion beyond V_2 in white athletes and beyond V_4 in black athletes, as well as inferior T inversion, may indicate cardiomyopathy in up to 25% of athletes, sometimes occult or subtle and missed by echo, e.g., localized hypertrophic cardiomyopathy, including the apical variant, ARVD, or dilated cardiomyopathy. The septal thickness of an athlete's heart may normally be up to 14 mm, and 36% of professional US basketball players have LV dilatation; this dilatation frequently affects the RV and LA as well, which are dilated in ~20–30% of athletes. Thus, the echo findings presented in this case are compatible with a benign athlete's heart and would not be concerning per se; it is mainly the ECG that is concerning. Genetic testing only detects the known genetic mutations: those constitute <70% of genetic cardiomyopathies, hence a negative test is not helpful. The patient's QTc is ~460 ms (<470 ms, cutoff of male athletes). When suspected, exercise testing with exertional/recovery QTc measurement is the best assessment modality of long QT syndrome 1 (wherein QTc prolongs with exercise). In this patient, cardiac MRI is the best modality to assess subtle cardiomyopathy.

Answer 20. C. This is polymorphic VT with changing of the peaks' polarity and a prolonged baseline QTc, as evidenced on the beats preceding and following the VT run (QT~600 ms). Thus, this is torsades de pointe (TdP), triggered by a PVC falling over a long QT, i.e., over a long and dispersed repolarization. If TdP is persistent, it is defibrillated; if occurring in salvo, it is prevented by increasing the baseline ventricular rate, as to shorten QT and prevent PVC. This may be accomplished by fast ventricular pacing, which, however, is not called overdrive pacing: overdrive pacing means pacing the actual VT itself at a rate faster than the VT rate and is used as a treatment modality by an ICD (anti-tachycardia pacing during monomorphic VT). Isoproterenol may be used if pacing is not immediately available. Also, 2 grams of IV magnesium is immediately administered.

Answer 21. C. This patient has a polymorphic VT with a shifting peaks' polarity, but unlike the prior question, the baseline QTc is not prolonged: QT is <2 squares (<400 ms), at a heart rate of 80–90 bpm, which translates into a QTc < 450 ms (QTc = QT + 17.5 ms for every 10 beats above 60 bpm). Thus, this is not TdP, it is rather polymorphic VT. After defibrillation, amiodarone or procainamide may be started. Being initiated by a very short coupled PVC (<400 ms coupling, 2nd PVC), quinidine may also be effective.

Answer 22. C. A young patient with VT and conduction abnormalities is suspected of having sarcoidosis. Four additional diagnoses are possible: lamin A/C cardiomyopathy, ARVD, Chagas disease and myocarditis, but the echo and context do not suggest them here. Sarcoidosis may be diagnosed via: (a) specific pattern of inferobasal and inferolateral LGE on MRI, (b) hyperactive cardiac PET scan inferolaterally, (c) chest CT that shows hilar or pulmonary involvement in most, but not all, cardiac sarcoidosis cases. While she will need ICD regardless of the diagnosis, it is best to perform MRI before ICD placement.

Answer 23. A. While this patient has early repolarization with some adverse features (2 mm, inferior involvement), early repolarization remains an innocuous finding in >99.9% of individuals. ICD is only indicated for prior sudden death. Alone, a family history of sudden death does not dictate ICD, and genetic testing has not been found useful in early repolarization syndrome. EP study has not shown a definitive value in the risk stratification of early repolarization.

Answer 24. C. The patient has a type 1 Brugada pattern. This may be a true Brugada syndrome but is more likely RV contusion mimicking Brugada pattern on the ECG. In fact, multiple conditions can mimic a Brugada pattern: anterior MI, RV MI, PE. Procainamide may be used to induce type 1 Brugada in patients with the non-specific type 2 or 3 Brugada pattern, but this is not needed when type 1 Brugada is already present on the ECG. Even if this patient has a true Brugada syndrome, ICD and quinidine would not be indicated. ICD is only indicated in type 1 Brugada with prior sudden death or syncope; quinidine is indicated in symptomatic Brugada patients who refuse ICD or have ICD shocks.

Answer 25. A. Flecainide prolongs the AP antegrade refractory period and is the best treatment option (class IIa) (>amiodarone or sotalol, class IIb).

Answer 26. B. QRS morphology suggests VT, yet the rhythm is irregular and QRS is polymorphic and wider after longer R-R intervals: this is diagnostic of pre-excited AF. He is stable hemodynamically, thus IV antiarrhythmic treatment is tried first. Only procainamide or ibutilide may be used in pre-excited AF, per ACC guidelines. They prolong the AP refractory period.

Answer 27. C. A CRT patient who develops AF gets symptoms because of the following: (1) AF by itself, (2) even more importantly, the increased ventricular rate prevents ventricular pacing. The percent of biventricular pacing is reduced, and the patient loses the resynchronization benefit. Note that in AF, the pacemaker is placed in a non-tracking mode, such as VVI. The best options here are:
(1) Slow the intrinsic ventricular rate below the lower pacing rate (e.g., 70 here), so that the patient gets paced → block the AV node with metoprolol or digoxin, and if necessary, AV nodal ablation.
(2) Increase the lower VVI rate to 90 bpm, so that the pacemaker will overdrive the underlying V rate. The upper tracking rate is how fast the pacemaker can track fast P waves; this is not used in AF or in VVI mode switch (lower rate is what is important here).
(3) Attempt AF rhythm control. Since the patient has HF, and since she failed prior rhythm control attempts, the best option is AF ablation.

Answer 28. C. AF ablation is associated with a reduction of mortality and HF hospitalizations in HF with reduced EF, according to the CASTLE AF trial. Improvement in quality of life was noted in the PABA-CHF trial, and dramatic EF improvement was noted in PABA-CHF and CAMERA-MRI trials.

CRT, *for the purpose of HF control,* is avoided if QRS is <130 ms (Echo CRT trial, class III recommendation in ESC guidelines). AV nodal ablation + CRT, *for the purpose of AF control*, may be performed in AF with narrow QRS, but mainly when AF rate is uncontrolled, or +/- when HF is uncontrolled and AF ablation fails (esp. older patients, APAF-CRT trial).

Answer 29. B. This patient developed atrial flutter (1:1) with aberrancy, which then converted to AF in recovery. The very fast rate and flecainide therapy are suggestive of atrial flutter. While class Ic drugs (flecainide) prevent AF, they may facilitate the induction of atrial flutter or AF-to-atrial flutter conversion. Worse, they increase the AV conduction of AF and atrial flutter waves (through reducing the number of those waves and thus reducing the "bombardment" of the AV node and the duration of its refractoriness). Hence it is always important to give class I drugs with an AV nodal blocker. This is a classic complication of Ic drugs.

Answer 30. B. In anterior chamber eye surgery, such as cataract, the risk of bleeding is very low, and data suggest that warfarin does not increase the bleeding risk. Warfarin interruption is not recommended by the ACCP and ACC guidelines; the same applies to minor skin procedures and dental procedures (vs. 2-day interruption is an option in the latter). Conversely, glaucoma surgery and vitroretinal surgeries are associated with a higher bleeding risk and warfarin may need to be interrupted. Even if this patient needed warfarin interruption, bridging is only recommended for a CHADS2-VAS score of 7–9 *or* a prior history of TIA/stroke, not the case here. Of note, no clear data are available for NOAC continuation in cataract surgery: one dose may be held the morning of the procedure, i.e., the procedure is timed to the nadir of NOAC level.

Answer 31. D. Lead issues lead to high-frequency noise but are not likely to occur on both leads. A far-field artifact corresponds to V sensing the atrial pacing spike and is not an erratic high-frequency signal. Electromagnetic interference is the condition most likely to affect both A and V leads.

Answer 32. D. The recording shows the sequence: A-H-no V, which indicates infranodal AV block (Figure 62). Nodal AV block is characterized by A that is followed by neither H nor V and is more benign than infranodal AV block: nodal AV block could be a transient vagal AV block or Mobitz 1 AV block. This patient has infranodal AV block, which may be Hisian or infra-Hisian. The fact that QRS is narrow suggests a Hisian AV block (H wave may be prolonged, fragmented or split in Hisian block). Infranodal AV block may worsen with increased sinus node activity (e.g., atropine), as this increases the number of P waves "bombarding" the infranodal area, making it more refractory to subsequent P waves ("concealed partial conduction" of P waves prolongs the infranodal area refractory period).

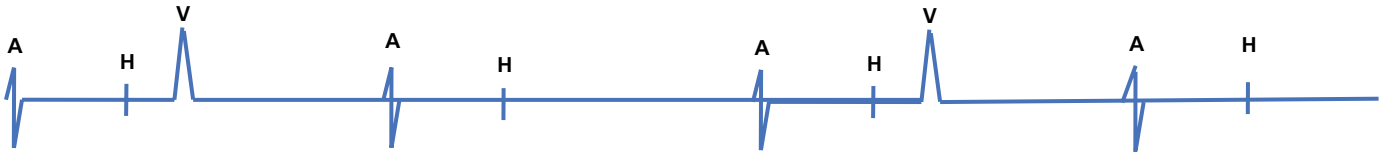

Figure 62

Answer 33. D. Frequent PVCs (>2000/day) are often benign but may reflect cardiomyopathy or channelopathy in up to 30% of athletes, particularly when they are triggered by exertion. Thus, in a patients with ≥ 2 PVCs on ECG, Holter is warranted to quantify PVCs, along with echo and stress testing. MRI is done if PVCs>2000/d or triggered by exertion. On ECG, the following is considered normal in athletes: LVH or RVH voltage; deep T inversion with J point elevation in V_1-V_4 in black athletes. The following abnormalities are considered borderline when isolated, and do not warrant any work-up per se: frank QRS axis deviations (note that +120 qualifies as right axis in an athlete, not 110), right or left atrial enlargement, complete RBBB.

VI. Congenital heart disease

Answer 1. B. Phlebotomy is not indicated solely for a high hemoglobin and requires the presence of hyperviscosity syndrome (neurological symptoms). Despite polycythemia, Eisenmenger patients are commonly iron deficient as a consequence of their frequent phlebotomies. Iron-deficient cells are stiffer and more likely to sludge and cause hyperviscosity.

Answer 2. E. Even in l-TGA, where the aorta supports the systemic circulation, the aorta has an anomalous origin that is left and anterior to the PA (unlike the normal origin that is right and posterior); there is no aortic knob on the right. In d-TGA, the aortic origin is right and

anterior to the PA. This is different from the description of the aortic arch, which is usually a left (normal) aortic arch in TGA; the aortic arch is commonly abnormal (right) in tetralogy of Fallot (Figure 18.14).

Answer 3. B. Normally, nitrogen is absorbed by the lungs and, being soluble (although 2× less than O_2), about 1 liter of it is dissolved in our tissues, mainly fat. As the pressure on the body rises during diving, more of the inhaled nitrogen dissolves in our body, sometimes in a high amount, and more nitrogen is absorbed from the lungs. This may occur with breathing compressed air from a machine, which is significantly denser and hence delivers a larger mass of nitrogen; this large mass dissolves into the blood at the dive's pressure. The increase in dissolved nitrogen causes nitrogen narcosis, mimicking NO anesthesia.

Upon rising, the pressure around the body decreases, which causes nitrogen to abruptly expand and come out of its solution in tissues and blood, forming bubbles (Boyle law, pressure of a gas × volume=constant) (like opening a bottle of champagne after shaking it). The lungs try to clear the extra nitrogen, but this is not possible if the rise is too rapid. The bubbles directly damage tissues, disrupt cells, and cause microvascular obstruction, tear, and ischemia. This is "decompression illness" (DCI) and manifests as bone and muscle pains, fatigue, and neurological and pulmonary signs in severe cases. It may also result in "arterial gas embolism": in most patients, only venous bubbles occur and are cleared by the lungs before reaching the arterial circulation (arterial system has a high pressure preventing bubble formation); if present, PFO may cause right-to-left shunting of bubbles during bearing down and further neurological effects. Right-to-left shunting may also occur at the lung level as the expanding lung gas ruptures alveoli.

Prevention mainly consists of avoiding >15 m depths (DCI almost never happens <15 m), ensuring a slow ascent and safety stops, and using enriched air with more O_2 and less nitrogen. Also, avoid air travel 24–48 hours after diving.

PFO and diving—(i) Overall, the risk of decompression illness is very low, and while PFO increases the relative risk up to 5 times, the absolute risk remains low at 1 per 2500 dives, and severe decompression illness and arterial gas embolism most often occur without PFO (2/3 of the time); (ii) PFO is not a contraindication to diving; (iii) safe diving measures reduce decompression illness more than PFO closure; (iv) across the population, the procedural risks of PFO repair outweigh the risks of diving. Thus, PFO screening is not recommended in recreational or commercial divers according to several British guidelines; the same applies to PFO closure. It is only suggested in patients with severe or repetitive DCIs, if they want to continue to dive commercially >15 m; if they agree to dive <15 m, then no PFO check is necessary.

Suggested reading:

Sykes O, Clark JE. Patent foramen ovale and scuba diving: a practical guide for physicians on when to refer for screening. *Extrem Physiol Med* 2013;2:10.

Answers 4. A, D, E, F. A high TR jet velocity does not imply severe TR; it rather implies a high RV systolic pressure. This may correspond to: (i) pulmonic stenosis, (iii) severe pulmonary hypertension (related, in a patient with tetralogy, to residual peripheral pulmonic stenosis or to pulmonary arterial remodeling related to a prior systemic-PA shunt), (iii) Gerbode defect with LV to RA shunting; the LV-RA jet may be mistakenly confused for TR jet.

Answer 5. B. The aortic origin is normally posterior and to the right of the PA. This aorta is anterior to the PA, suggesting TGA. It is to the right of the PA, suggesting D-TGA (D for dexter vs. L for left), with the aorta arising from the right-sided RV. In L-TGA, the aorta is anterior but to the left of the PA, arising from the left-sided ventricle, which in that case is the RV (aorta is connected to the RV in both types of TGAs).

Answer 6. C. Adult patients with a small restrictive VSD often live normally with no complication related to the VSD. A small proportion of patients get progressive worsening of VSD shunt with age, as LV pressure rises with age and causes more left-to-right shunting; this is particularly the case of patients with moderate baseline shunting. Another small proportion of patients develop hypertrophy of the RV at the site that is constantly struck by the high-velocity jet of VSD, particularly the moderator band, which creates an intra-RV cavitary obstruction (at the mid-RV or RVOT). This is what this patient has, and it can be demonstrated by careful catheter pull back across the RVOT, showing that the pressure gradient is within the RV: RV pressure 125/10, RVOT 25/10, PA 25/10. RV and LV systolic pressures are nearly equal because of this RV obstruction, which slows the VSD shunting. This complication usually happens in childhood but may happen in adults.

Eisenmenger is not the case here: in Eisenmenger, the patient is hypoxemic, and PA pressure, not just RV pressure, would equalize with the systemic pressure.

Answer 7. C. There is a tight obstruction within the RV, at the site marked by the cursor. Note that the RV has a cone-shaped infundibulum (RVOT) attached to it, and that the pulmonic valve is within that infundibulum, high up, significantly higher than the site of the narrowing, which appears to be at the mid-RV level. This is a double-chambered RV, likely in a patient with a high-jet, small restrictive VSD.

Answer 8. A. This chest X-ray is classic for Scimitar syndrome, in which the right inferior +/– right superior pulmonary veins drain in the IVC, instead of the LA. This inherently creates a left-to-right shunt, with O_2 step-up inside the IVC, which becomes significantly more oxygenated than the SVC. A characteristic chest X-ray is seen: the arrow indicates the right-sided inferior pulmonary vein draining in the IVC and forming the shape of a "sword," i.e., scimitar. The transfemoral venous catheter abnormally entered the right lung, more specifically a right pulmonary vein in this case.

These patients may additionally have right lung hypoplasia, and a fistula connecting the descending aorta to the hypoplastic lung/right PA (an additional source of left-to-right shunting). Isolated pulmonary venous-IVC shunt may be asymptomatic for a long time, but associated anomalies may lead to a more malignant course requiring surgical correction.

Answer 9. B. The murmur is consistent with supravalvular AS, in the setting of skeletal features of Williams syndrome. Aortic valve closure is early and accentuated because of the downstream obstruction. In bicuspid AS, A_2 is attenuated, a paradoxical split may be present, and a systolic opening click is often heard.

Answer 10. A. Dyspnea in Eisenmenger patients is due to conditions that increase right-to-left shunt via reduced SVR/PVR ratio (vasodilators and anesthesia), or conditions that reduce the marginal right-sided flow (e.g., diuretics). Vasodilatation is the original cause of the reduced pulmonary flow and dyspnea in this patient; this was exacerbated by furosemide but would not be reversed with fluids. Neosynephrine increases systemic pressure and reduces right-to-left shunt. Metoprolol is useful in tetralogy spells, not Eisenmenger.

Answer 11. B. In TGA, the anomaly involves the aortic origin rather than the aortic arch. In both L- and D-TGA, the aorta is connected to the RV and is anterior to the PA, rather than posterior to it and on its right. The aortic arch continues to be left-sided.

Answer 12. B. Coronary artery anomalies are seen in ~6% of tetralogy of Fallot patients, the most common anomaly being an anomalous LAD arising from the RCA and crossing the RVOT anteriorly. It is important to recognize this anomaly preoperatively, and to plan the surgical patch repair of the RVOT accordingly.

VII. Peripheral arterial disease—Pulmonary embolism—Pulmonary hypertension

Answer 1. C. Vaginal delivery is recommended for aortic size <4.5 cm, with epidural anesthesia and assisted second stage (ESC class IIa). Cesarean delivery is recommended when aorta is >4.5 cm. There is no indication for abortion: if the aorta is >4.5 cm *and* growing rapidly, prophylactic aortic surgery is recommended, after pre-term cesarean delivery if the fetus is viable, or while he remains in utero if he is not viable yet, at the cost of a high fetal mortality (ESC).

Answer 2. D. Patients with Turner syndrome have a high prevalence of bicuspid aortic valve (15–30%) and aortic dilatation. Considering the small body size of Turner patients, absolute aortic diameter underestimates the true severity of their aortic dilatation. As such, indexed aortic diameter is recommended by AHA guidelines to guide management:

- Turner syndrome with aortic size index ≥2.5 cm/m^2 (high risk) should undergo aortic surgery, particularly when bicuspid valve is also present, and avoid pregnancy.
- Turner with aortic size 2–2.5 cm/m^2 and additional risk factors, such as HTN, bicuspid aortic valve, or coarctation, is moderate-to-high risk: aortic surgery is not needed yet, but pregnancy is preferably avoided.
- Turner with aortic size 2–2.5 cm/m^2 and no additional risk factors is moderate risk: Conception and pregnancy are acceptable, with β-blockade and regular echo follow-ups during pregnancy.
- Turner with aortic size <2 cm/m^2 is low risk.

Aortic surgery is recommended for aortic size ≥2.5 cm/m^2. For less than that, repeat echo Q1–3 years, depending on risk factors.

Of note, even outside Turner, the normal indexed aortic diameter is <2.1 cm/m^2 at the aortic sinus and <2 cm/m^2 at the tubular aorta, and this should be applied to individuals of small stature.

Silberbach M, Roos-Hesselink JW, Andersen NH, et al. Cardiovascular health in Turner Syndrome: a scientific statement from the American Heart Association. Circ Genom Precis Med 2018;11(10):e000048.

Answer 3. A. Patient 1 has features of Loeys-Dietz syndrome, which is related to TGF beta receptors mutations. Patient 2 has Marfan syndrome, which is most commonly related to FBN1 gene mutation. FBN1 is a gene that affects the synthesis of *fibrillin*, a glycoprotein normally deposited in the extracellular matrix. COL is responsible for collagen synthesis and is mutated in Ehlers-Danlos syndrome. Lax joints, pectus, and kypho-scolios may be seen in all of them. Skin fragility and easy bruising are seen in Ehlers-Danlos and Loeys-Dietz. Loeys-Dietz, Marfan, and most Ehlers-Danlos syndromes are autosomal dominant.

Answer 4. D. ABI is calculated as the highest ankle systolic pressure (DP or PT), divided by the highest systolic arm pressure (right or left). Right ABI, in this case, is 100/130. The lowest value of DP or PT has a prognostic value and may be reported separately, but this is not the value recommended in the standard ABI equation.

This patient has asymptomatic PAD according to ABI, and thus qualifies for statin in secondary prevention of cardiovascular disease, regardless of his LDL levels. Yet, he does not qualify for aspirin. One trial randomized asymptomatic patients with low ABI to aspirin vs. placebo and found no benefit from aspirin. The ARRIVE trial, which was mainly an aspirin primary prevention trial, included nonetheless patients with low ABI and found no significant benefit from aspirin (Chapter 24, Section XI).

Answer 5. B. The patient's aortic aneurysm does not meet the indication for repair (≥5.5 cm). Common iliac occlusion is a TASC B lesion; percutaneous revascularization is the preferred strategy for TASC A and B disease and is an acceptable option for TASC C and D disease. Had there been signs of embolization (blue spots or patches on the toes), repair of the AAA would have been necessary.

Answer 6. A. The systemic arterial O_2 saturation is severely reduced, yet mixed venous O_2 saturation is normal, and in context, it is relatively high (68%). Mixed venous O_2 saturation is driven by how well O_2 delivery to the tissues matches O_2 demands, and thus, it is driven by the 3 determinants of O_2 delivery: cardiac output, hemoglobin, and arterial O_2 saturation. An elevated PA O_2 saturation despite low arterial O_2 saturation implies one of the following two diagnosis: (i) high cardiac output, (ii) left-to-right shunt (not the case here, as there is no O_2 step-up). The former is the case and is driven by this patient's obesity. This is also suggested by the wide PA pulse pressure. Cardiac output was measured at 7.7 L/min by thermodilution, with a calculated PVR of 7 Wood units.

Answer 7. B. The patient has significant hemodynamic improvement with pulmonary vasodilators, most notably improved arterial O_2 saturation. However, mean PA pressure must drop by >10 mmHg to <40 mmHg to fulfill the universal definition of responsiveness. That said, pulmonary vasodilators are effective in all patients, with or without pulmonary vasoreactivity; they may not reduce PA pressure, but they reduce PVR, improve cardiac output and right HF, and stabilize the pulmonary vascular process.

Answer 8. B. The most important cause of hypoxemia in severe PAH is right-to-left shunting. This may arise through a PFO: the high RA pressure forces the PFO to open and shunt from right to left, relieving the RV failure (it is a compensatory, appropriate shunting). Shunting may also occur through arterio-venous pulmonary anastomoses: normal individuals have pulmonary arterio-venous anastomoses with a very small degree of shunting (<5% of cardiac output). The anastomotic flow increases in PH, as an escape from the high PA pressure, and creates right-to-left shunting.

This is an isolated compensatory right-to-left shunting, with no left-to-right shunt (no right-sided O_2 step-up). This shunt is not pathological and is not the cause of PAH, rather it is a consequence.

The improvement of hypoxemia with pulmonary vasodilators further proves that hypoxemia is due to a baseline right-to-left shunt. Pulmonary vasodilators reduce PVR and improve forward pulmonary flow, thereby reducing the right-to-left flow. Conversely, V/Q mismatch's hypoxia worsens with pulmonary vasodilators, as they redirect pulmonary flow to hypoxic lung zones.

Answer 9. D. Post-capillary pulmonary hypertension (PH) is diagnosed when PCWP is >15 mmHg. In a patient with PCWP of 13–15 mmHg and diastolic HF risk factors, masked left HF is possible, particularly if he has been receiving diuretics. Diastolic LV function should be stressed by supine biking (PCWP rises to >25 mmHg), 500 ml volume challenge (PCWP rises to >18 mmHg), or passive leg raising. With the current values, PH is precapillary in nature, but has distinct features: PVR is only mildly elevated ([mean PA-PCWP]/CO = 3.2 Wood units), and CO is elevated. In fact, it appears that high output is the biggest driver of this PH (PA ~ CO × PVR). High output is caused by obesity but also lung disease: hypoxemia causes CO to rise and attempt to maintain systemic O_2 delivery, while hypercapnia causes vasodilatation. With the current values, PH is WHO group III, likely obesity-hypoventilation syndrome causing both a high CO and a mild precapillary PH component.

Answer 10. C. PVR is equal to (mean PA-LA)/CO = 10 Wood units, in the severely elevated range (normal being <3 Wood units). The notched RVOT spectral envelope (W shape) is indicative of precapillary pulmonary hypertension and is a useful echo sign when PA pressure cannot be calculated via TR jet. The patient has developed chronic thromboembolic pulmonary hypertension (CTEPH) after a submassive PE; some data suggest that acute thrombolysis reduces the occurrence of CTPEH, although this was not the case in the larger PEITHO trial. It is reasonable to consider thrombolysis, or catheter-based therapy, in submassive PE with persistent severe PH several days after anticoagulant therapy (up to 14 days), i.e., submassive PE with no catch-up phenomenon. Pulmonary obstruction and PA pressure do not generally improve beyond the first few weeks of anticoagulation, and a 3-month cutoff is used to define CTEPH.

The pulmonary angiogram is performed selectively for each lung, in an ipsilateral oblique view. It shows abrupt cutoffs of most lobar arteries (*arrows*): right upper, middle, and lower lobar arteries, as well as branches of the left lower lobar artery. Note that the right lung and the left lower lung are poorly perfused and have no perfusion blush; compare them to the perfused left upper lobe. This explains the large dead space and severe hypoxemia. The pulmonary obstruction is relatively proximal and surgical thrombo-endarterectomy should be considered. Pulmonary vasodilators are used for distal occlusions not amenable to surgical recanalization.

Answer 11. A. High-altitude pulmonary edema (HAPE) occurs upon rapid ascent or flight to altitudes >8,000 feet, in patients who are genetically predisposed. Low O_2 pressure, in a patient who does not properly increase his minute ventilation, leads to severe hypoxic pulmonary vasoconstriction, which leads to acute pulmonary hypertension. Pulmonary edema results from: (1) heterogeneous pulmonary vasoconstriction—some pulmonary areas are underperfused, while other areas are less vasoconstricted and become overperfused from the diverted blood, resulting in hydrostatic pulmonary edema; (2) besides pulmonary arterial constriction, pulmonary venous constriction occurs, leading to elevated pulmonary capillary pressure.

HAPE is prevented by gradual ascent to allow acclimatization and avoidance of exercise the first few days of high altitude (increased blood flow → more edema). O_2 may also prevent it, by preventing pulmonary vasoconstriction. Once HAPE happens, the best treatment is quick descent of 2000–3000 feet, for ~2 days, followed by gradual ascent of 1000 feet per day. Nifedipine may prevent HAPE (when used before ascent and for 2–3 days afterward) and is useful in treating it. In fact, patients with HAPE may be treated with O_2 and nifedipine while staying at altitude; HAPE will resolve in 1–2 days (but the best option is descent). Sildenafil may be used for prevention, but not therapy.

Another altitude illness is acute mountain sickness. It results from hypoxia-induced cerebral vasodilatation, which leads to headaches, fatigue, nausea, and dizziness. It may progress to high-altitude cerebral edema (HACE) with confusion and ataxia. Also, hypoxia leads to hyperventilation then acute respiratory alkalosis; the latter contributes to symptoms, both by itself and via a reflex that slows the adaptive hyperventilation. The kidneys excrete HCO_3 and adjust pH, but this takes ~4 days; acetazolamide accelerates this process. Besides O_2, acetazolamide and dexamethasone are effective therapies for acute mountain sickness, but not HAPE. Acetazolamide induces metabolic acidosis, which offsets hyperventilation-induced respiratory alkalosis and allows a continued hyperventilation response to hypoxia.

Answer 12. A. For a PE with no high-risk clinical features (simplified PE score index of 0) and no RV dilatation on CT, treatment may be initiated in the outpatient setting. In one randomized trial of outpatient PE treatment, enoxaparin was initially used and followed by oral anticoagulation with warfarin.
Note: Simplified PE score index (PESI) score (1 point for each): age >80, history of cancer, history of cardiopulmonary disease, O_2 saturation <90%, SBP <100, pulse >110.

Suggested reading:

Aujesky D, Roy PM, Verschuren F, Righini M, Osterwalder J, Egloff M, Renaud B, Verhamme P, Stone RA, Legall C, et al. Outpatient versus inpatient treatment for patients with acute pulmonary embolism: an international, open-label, randomised, non-inferiority trial. Lancet 2011;378:41–48.

Answer 13. D. Heterozygote factor V Leiden and prothrombin gene mutation are associated with only a mild increase in the lifetime risk of PE/DVT, and a mild increase in the risk of recurrence (up to 1.3×). They do not dictate, per se, indefinite anticoagulation. Factor V Leiden is highly prevalent (~5%) in the Caucasian population and is autosomal dominant. Neither Factor V Leiden nor higher risk thrombophilia dictate anticoagulation in an asymptomatic patient → Thus, screening family members is not routine and should be individualized: young female relatives may be screened, and if positive, counseled against oral contraceptives and about the increased DVT risk during pregnancy, as well as the lifestyle measures to mitigate it. Antiphospholipid syndrome must be treated with warfarin; rivaroxaban was inferior in one trial.

VIII. Hypertension and syncope

Answer 1. B. Hypokalemia is a hazard in patients with long QT, and thus HCTZ is preferably avoided.

Answer 2. A. The predominant response in vasovagal syncope is abrupt (not progressive) hypotension from a vagal reflex. Hypotension precedes bradycardia, explaining why pacemaker is not consistently an effective therapy in vasovagal syncope.

Answer 3. B. (1) POTS is characterized by peripheral autonomic denervation but also cardiovascular orthostatic deconditioning with reduced stroke volume and reduced renin-angiotensin activity. Upon standing, the only way to provide cardiac output is an increase in heart rate. Heart rate rises >30 bpm in the first 10 minutes of standing, preventing SBP from significantly dropping. (2) In orthostatic hypotension, SBP drops >20 mmHg in the first 10 minutes of standing, with or without a rise in pulse. The lack of a rise in pulse (<10 bpm) implies autonomic dysfunction (neurogenic orthostatic hypotension). (3) Vasovagal syncope is a more pronounced form of orthostatic hypotension wherein a vagal reflex kicks in and leads to a more pronounced and abrupt BP drop at >10 minutes of tilt, with bradycardia.

Answer 4. C. Since tachycardia is compensatory for the reduced stroke volume, β-blockade will aggravate POTS symptoms and lead to syncope, except in the subset of hyperadrenergic POTS. Norepinephrine may be tested in the upright position and propranolol or ivabradine is considered only if levels are >600 pg/ml (HRS class IIb). No medication is FDA-approved for POTS, but 3 medications that are approved for orthostatic hypotension may be temporarily used in POTS patients with severe symptoms preventing any exercise program (midodrine, fludrocortisone, or pyridostigmine) (HRS class IIb).

Answer 5. C. The patient has severe orthostatic hypotension with no rise in pulse, indicative of autonomic dysfunction (neurogenic orthostatic hypotension). Midodrine and fludrocortisone may be used, but droxidopa is the only medication specifically approved for neurogenic orthostatic hypotension. Droxidopa gets metabolized into norepinephrine at the level of the sympathetic ganglions, mainly when the sympathetic system is stimulated (as in a standing position); therefore, it is less likely to affect supine BP, as the sympathetic system is less active in the supine position. Supine HTN may need to be accepted in patients with profound orthostatic hypotension, such as this patient, and may be counteracted by sleeping semi-upright and by giving short-acting ACE-I/ARB at bedtime.

Answer 6. A. Like the prior question, this patient has neurogenic orthostatic hypotension, but not as severe and with no falls. The discontinuation of lisinopril will lead to a harmful supine HTN, which sometimes needs to be accepted in patients with more profound orthostatic hypotension, such as the patient of Question 5. ACE-Is/ARBs are the antihypertensives with the lowest risk of orthostatic hypotension. In this patient, the focus should be on: performing supine exercises to improve cardiovascular conditioning and thus, orthostatic responses; compression stockings; and sleeping in a semi-recumbent position (raise the bed's head posts 5–6 inches).

Answer 7. C. It is best to check BP twice a day. Measurement should be done in the morning before taking the medications, to ensure full 24-hour BP coverage, including during the trough effect. A is an acceptable option, but ACC recommends C.

IX. Pregnancy–Chemotherapy and heart disease–Miscellaneous

Answer 1. B. This patient has Marfan syndrome (autosomal dominant) with dilated aortic sinuses of 4–4.5 cm. Pregnancy with close surveillance is acceptable when aorta is 4–4.5 cm without rapid growth. Pregnancy is not recommended in patients with aortic size > 4.5 cm, yet if pregnancy occurs, abortion is not indicated: for an aorta >4.5 cm and growing rapidly (>3 mm), prophylactic aortic surgery is recommended during pregnancy, while the fetus remains in utero if he is not viable yet (high operative fetal mortality), or after pre-term cesarean delivery if he is viable (ESC). Vaginal delivery is recommended for aorta <4 cm, and suggested for aorta 4–4.5 cm. Cesarean delivery is recommended for aorta > 4.5 cm.

De Backer J, Haugaa KH, Hasselberg NE, et al. ESC Scientific Document Group. 2025 ESC guidelines for the management of cardiovascular disease and pregnancy. Eur Heart J 2025; 46(43): 4462–568.

Answer 2. C. Asymptomatic severe MS with PA pressure <50 mmHg does not generally require invasive therapy. However, when pregnancy is planned, PMBV is recommended before pregnancy even if the patient is asymptomatic (ACC and ESC class IIa recommendation in asymptomatic women). Severe MS has a high risk of hemodynamic decompensation with the high output and tachycardia that occur during pregnancy, particularly during the third trimester, justifying this aggressive pre-conception therapy. Asymptomatic patients with severe AS are also considered for aortic valve intervention before pregnancy (ACC class IIa), but less strongly than MS, and surgery is not needed if AS is truly asymptomatic with a normal pre-pregnancy stress testing (ESC, ACC).

If severe MS is found after the patient is already pregnant, the patient is managed medically (β-blockade and diuresis), and intervention is only considered during pregnancy if HF symptoms remain severe despite medical therapy.

Answer 3. C. This echo shows classic posterior leaflet mitral valve prolapse, with anteriorly directed MR. The leaflet is not flail, as the leaflet body is prolapsed but the tip itself continues to look in the LV rather than the LA. It is likely severe, considering the enlarged LA. Most patients with severe regurgitant valve disease, such as MR, with proper EF and PA pressure, tolerate the hemodynamic stress of pregnancy, as pregnancy reduces afterload. Mitral valve repair is generally appropriate in asymptomatic severe MR that results from posterior leaflet prolapse, as long as the likelihood of repair is high (class IIa); however, this is concerning in a young woman planning pregnancy and does not apply to her, as any failure will result in mitral valve replacement, with its inherent pregnancy risks (class IIb for pre-pregnancy repair).

Conversely, unlike regurgitant lesions, stenotic lesions such as AS and MS do not tolerate the hemodynamic stress of pregnancy; thus, treating asymptomatic severe AS and particularly severe MS is recommended before pregnancy, even when it is asymptomatic with no treatment indication outside pregnancy (class IIa).

Answer 4. D. PS, even severe, is usually well tolerated during pregnancy. Yet if found before pregnancy, severe PS is treated with valvuloplasty even if asymptomatic. In fact, this is indicated regardless of pregnancy planning. If found during pregnancy, monthly cardiac evaluations are advised, as there is a risk of RV failure or arrhythmias; pulmonary valvuloplasty is warranted during pregnancy only if severe right HF occurs.

Answer 5. C. GLS change is considered significant when it exceeds 15% in relative value, and in this case, it does (5/19 = 26%). A significant change indicates subclinical LV dysfunction and a higher risk of EF decline and future HF events; however, there is no evidence of increased mortality with GLS decline, and current data do not support interrupting doxorubicin or trastuzumab based solely on GLS decline. Abnormal baseline GLS is also predictive of future HF events, but again, it does not dictate halting chemotherapy. A significant EF decline is generally defined as ≥10% to an EF of 40–49%.

Answers 6. A→iii; B→iv; C→i and v; D→ii. VEGF inhibitors inhibit vascular healing and are associated with up to 4% risk of coronary thrombosis, >20% risk of HTN, including ~10% risk of severe HTN, and >10% risk of cardiomyopathy. The listed tyrosine kinase inhibitors are associated with a 5–10% risk of AF. 5-FU is associated with up to 20% risk of coronary vasospasm, during the infusion or within few days after it finishes. Immune checkpoint inhibitors have a double negative effect on the immune response, i.e., they boost the immune response and may cause of variety of autoimmune manifestations, including myocarditis.

Answer 7. C. Patients receiving trastuzumab therapy undergo a baseline echo and a repeat echo if symptoms occur and at routine intervals (e.g., every 3 months); routine echos are less needed in patients with metastatic cancer and limited options.

This patient developed *moderate asymptomatic CTRCD*, i.e., EF decline by ≥10% to an EF of 40–49%. Trastuzumab is held for 1 month, ACE-I and carvedilol are initiated, and EF is reassessed afterward. Trastuzumab may be restarted if EF normalizes. In select cases with moderate asymptomatic CTRCD and no other treatment options, trastuzumab may even be continued without interruption. *In moderate symptomatic CTRCD and in severe CTRCD (EF<40% or HF hospitalization)*, it is definitely interrupted until LV recovery.

Answer 8. C. Metoprolol is continued perioperatively in patients who chronically receive it. Holding ACE-I/ARB reduces intraprocedural hypotension but this did not translate into improvement of CV or renal outcomes in 2 trials (POISE-3, STOP-or-not). Thus, ACE-I/ARB is mainly held when BP is well controlled on preoperative assessment (e.g., SBP <110–120 mmHg), ALONG WITH either higher-risk surgery or high cardiac risk.

Answer 9. C. According to the POISE-2 trial and its subgroup analyses, patients with prior PCI are likely to benefit from aspirin perioperatively, but not other high-risk groups (e.g., PAD, stable CAD with no prior PCI). Also, carotid endarterectomy, which was excluded from POISE-2, likely benefits from perioperative aspirin.

Answer 10. B. Libman-Sacks endocarditis is a form of sterile, non-bacterial vegetation seen in 10–35% of systemic lupus and/or antiphospholipid antibody syndrome. It is a mixed mass of inflammatory cells and thrombi. *It is usually silent* but may lead to progressive valvular fibrosis and regurgitation. Systemic embolization is possible but rare. The treatment is unclear; corticosteroids are usually recommended, often with anticoagulation. Surgery is typically reserved for severe valvular regurgitation. Libman-Sacks endocarditis resembles another non-bacterial endocarditis seen in patients with metastatic malignancy (marantic endocarditis).

Answer 11. B. Cholestyramine reduces LDL by ~20–25% but raises triglycerides, particularly in patients whose baseline triglyceride level is >300 mg/dl.

Answer 12. B. This patient has effusive-constrictive pericarditis, which is inflammatory in nature, in the setting of persistent acute pericarditis. CRP and sedimentation rate are likely elevated and will confirm the inflammatory nature of this constrictive pericarditis. MRI may be used to confirm the diagnosis, but it is not mandatory; it will show heavy LGE of the pericardium. While prednisone is generally avoided in pericarditis, it is necessary in this refractory case as a third-line therapy (~25 mg/d), with a slow taper over months and close symptomatic and CRP follow-up. Rilonacept may also be used.

When a moderate or borderline large pericardial effusion is associated with pronounced hemodynamic compromise, always consider effusive-constrictive pericarditis rather than tamponade; pericardiocentesis is unlikely to help in this case. The following echo features will indicate effusive-constrictive pericarditis rather than tamponade: (1) medial E' > lateral E'; (2) more pronounced respirophasic septal shift.

Suggested reading:

Kim KH, Miranda WR, Sinakk LJ, et al. Effusive-constrictive pericarditis after pericardiocentesis: incidence, associated findings, and natural history. J Am Coll Cardiol Imaging 2018;11:534–541.

Answer 13. B. In tamponade, diastolic filling is fully impaired (flat D wave = flat Y descent). Conversely, in both constrictive pericarditis and RV failure, Y descent tends to be deep.

Answer 14. B. The presence of interatrial communication, such as iatrogenic ASD in this case, prevents pulsus paradoxus: with inspiration, the increase in venous return translates into more right-to-left shunt, which prevents the increase in RV filling and attenuates the RV-LV respiratory discordance.

X. ECG

Answer 1. B. This ECG shows a combination of ST depression, prominent upright T wave that is notched in some leads (V_3-V_6) and prolonged QT (QTc~600 ms). This combination is strongly suggestive of hypokalemia, and the *double-humped T is actually a T-U wave*. Potassium was 2.4 mEq/L in this patient. Less often, this ECG may reflect NSTEMI or congenital long QT2 syndrome (the notched T, in particular, is seen in long QT2).

Answer 2. This patient has VSD with biventricular failure clinically, and the following ECG abnormalities:

- Marked biatrial enlargement, with peaked and prolonged P wave in lead II and pronounced positive and negative P-wave deflections in lead V_1.
- Tall diphasic precordial QRS complexes (>50 mm) in V_4-V_6 indicative of biventricular hypertrophy and termed *Katz-Wachtel phenomenon*.
- Right bundle branch block with a fragmented rsR'S' pattern in lead V_1. In a patient with congenital defect, this fragmented pattern indicates a higher pulmonary arterial pressure than the classic rSR' pattern.
- Left ventricular hypertrophy (LVH) by various voltage criteria (R wave in aVL + S wave in V_3 > 28 mm in a man; and R wave in V_5 and V_6 >26 mm).
- In the setting of LVH, right ventricular hypertrophy and hence biventricular hypertrophy are suggested by: the fragmented right bundle branch block pattern, the Katz-Wachtel phenomenon, the large R wave (>5 mm) in lead aVR, the unusual northwest QRS axis, the paradoxically small S and S' in lead V_1 (<2–3 mm), discrepant with LVH, and the ST depression in the right precordial leads (a form of right ventricular strain).
- Diffuse ST-segment depressions and T-wave inversions in the precordial and limb leads: this is secondary to a combined ventricular strain.

Answer 3. C. This ECG shows sinus rhythm with prolonged PR, atypical RBBB, ST elevation in V_1-V_2, and narrow and peaked T waves in V_3-V_6, which, despite being <10 mm, are concerning for hyperkalemia. S wave as well as the ST segment in V_3–V_6 seem to be "pulled" by T, which is characteristic of hyperkalemia. Hyperkalemia also explains the QRS widening, the PR prolongation, and the ST elevation, as hyperkalemia may lead to an injury pattern.

The ***coved ST elevation morphology*** seen in V_1 may also be seen in *Brugada, PE, and STEMI.* Thus, other possible but less likely ECG diagnoses are:

- PE (sinus tachycardia and RBBB fit with PE): massive PE may lead to an injury pattern in V_1–V_2, as in this case, and to inferior Q waves.
- Anterior MI: less likely because of the narrow T and the absence of ST elevation in V_3.
- Brugada syndrome: the ST shape in V_1–V_2 simulates Brugada syndrome (coved ST elevation in V_1, saddleback shape in V_2). T inversion in V_1–V_2 and long PR also fit with Brugada.

Answer 4. B. This ECG reveals a wide-QRS-complex tachycardia that is mainly regular, with a QRS duration of ~180 msec. The differential diagnosis includes 3 entities: VT, SVT with bundle branch aberrancy, and SVT with pre-excitation (i.e., SVT with antegrade conduction over an accessory pathway). In this patient, each of the following features is diagnostic of VT, as opposed to SVT with aberrancy:

i. Atrioventricular dissociation. P waves are seen as small deflections that fall over the ST/T segments and have a *consistent morphology* and *timing,* i.e., those deflections are regular and can be marched out (Figure 63, *arrows*). P waves are generally best seen in leads with the smallest QRS complex; in this case, they are best seen in leads I and II. P waves are only intermittently seen, as many of them fall close to or within the QRS complexes. The visualized P waves should be separated by the same interval or by a multiple of the same interval: in this case, the interval between the first and second arrows is double the interval between the second and third, third and fourth, and fourth and fifth arrows. P waves do not have a consistent relationship with the QRS complexes and are less numerous than the QRS complexes, implying VT.

ii. QRS morphology is not consistent with RBBB or LBBB. The upright QRS complex in lead V_1 is reminiscent of RBBB. However, the wide initial R wave, which is wider and larger than R', is not characteristic of RBBB and suggests that the QRS complex is originating from a ventricular focus.

iii. Other QRS morphological features suggestive of VT:

*In leads with an RS pattern, such as leads I, aVL, and V_6, the wide initial R wave is suggestive of VT. This contrasts with SVT with aberration, where the QRS has a narrow initial deflection corresponding to the septal depolarization, followed by widening of the terminal portion of the QRS.

*Atypical notching of the QRS complex (seen in leads III and aVF). In fact, in scar-related VT, the electrical impulse spreads over a diseased, fibrotic myocardium and meets "bumps on the road," creating atypical notching of the QRS complex.

* Northwest QRS axis. The typical forms of aberrancy, including right bundle branch block, are not usually associated with a right axis or a northwest axis. On the other hand, VT most frequently originates from the left ventricle, i.e., the ventricle with the largest mass, and therefore frequently has a right axis or a northwest axis.

*QR pattern in lead aVR with a wide Q wave (>40 ms). In lead aVR, an initial R wave (large or wide) or a QR pattern with a wide Q wave suggests VT.

In addition to distinguishing VT from SVT with aberrancy, atrioventricular dissociation distinguishes VT from SVT with pre-excitation. Conversely, the VT morphological features described under paragraphs (ii) and (iii) may be seen with pre-excitation and do not generally distinguish VT from SVT with pre-excitation. Only one morphological feature, the predominantly negative QRS complex in lead V_6, argues against pre-excitation; the insertion of the accessory pathway being usually basal, a pre-excited QRS is upright in lead V_6.

The ECG also helps localize the origin of VT. The QRS is upright in lead V_1, implying that VT originates from the left ventricle. The QRS is negative in the inferior leads, implying that VT originates from the inferior wall. The QRS is negative in the lateral leads I and aVL, implying that VT originates laterally. Thus, VT originates from the inferolateral left ventricular wall.

Note that one QRS complex of a different morphology is seen (*star*). It is very wide and is likely an ectopic ventricular complex originating from a different ventricular focus, rather than a fusion complex. It does not reset the VT, which keeps looping at its own pace.

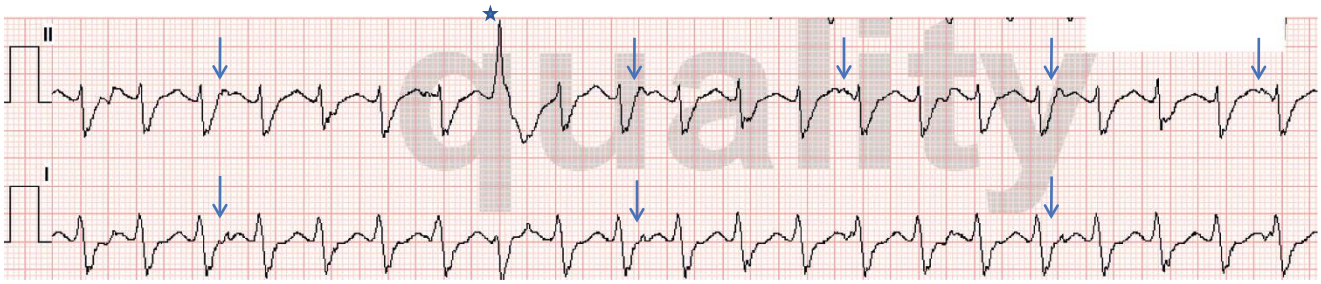

Figure 63

Answer 5. Digoxin effect. This ECG shows AF with ST depression and a U wave, well separated from the T wave. The overall ST–U shape mimics hypokalemia, but unlike the double-humped T wave seen in hypokalemia, this is a true U wave, well separated from T wave, and the QT is short. The T wave returns to baseline before the U wave.

XI. Echocardiography

Answer 1. B. This M mode is tracking the mitral valve motion. The mitral valve opens properly, with proper E and A. In systole, mainly mid-to-late systole, the leaflets are not fully apposed, which suggests MR. More specifically, the anterior leaflet is moving toward the septum and creating this gap. This is SAM of the mitral valve, in a patient with HOCM. Of note, the fact that the anterior leaflet abuts the septum in diastole is also an indirect hint to this process, as it suggests how small the LV cavity is at the base, making it prone to high velocity and anterior leaflet drawing in systole.

Answer 2. A. On this 4-chamber view, the anterior leaflet is prolapsed and over-riding the posterior leaflet (*arrow*), with posterior MR jet. In the setting of MI, this is suggestive of papillary muscle rupture, specifically the anterolateral papillary muscle. In fact, a piece of papillary muscle is seen flopping next to the leaflet (top image, *hand marker*). Papillary muscles connect to both leaflets, so prolapse of both leaflets may be seen, but the most adjacent leaflet prolapses the most, as it has the most acute papillary muscle-to-leaflet angle. The anterolateral papillary muscle has dual supply from the LAD (diagonal system) and LCx. In this patient with posterior and lateral STEMI, LCx is the likely culprit, and it is likely that the LAD system has chronic disease, affecting the dual system collateralization. The posterior papillary muscle has a single supply (RCA or distal LCx, depending on dominance).

Answer 3. B. The aortic valve is anterior, and the septum must be on the right side on this image (the LA is entered through the RA, and the mitral valve is looked at from above, through the LA). C2 is thus riding the septum, and as such, must be the non-coronary cusp. The anterior-most portion of the aorta looks toward the RVOT; as such, the anterior-most cusp is the right coronary cusp. Since this view focuses posteriorly on the mitral valve, it shows the non-coronary cusp C2 (most posterior) and left coronary cusp C1 (see Chapter 6, Figures 6.1 and 6.24).

Answer 4. A. The septum is on the right side on this image (the LA is entered through the RA). The mitral scallops closest to the septum (most medial) are A_3 and P_3, while those that are most lateral are A_1 and P_1

Answer 5. B. The scallops Ax and Px are medial and are A_3 and P_3, respectively. Considering the heart position in the chest, what is anterior is close to medial, and what is posterior is close to lateral. 1 is the anterior position, 2 is the septal position. 1 and 3 are linearly opposite to each other in a sagittal plane, while 2 and 4 are linearly opposite to each other in a coronal plane. The anterior mitral leaflet is convex, while the posterior mitral leaflet is crescentic.

Answer 6. D. The RV inflow view typically cuts through the septal leaflet when the CS is seen. When only the IVC is seen without the CS, the view cuts through the posterior leaflet. Often, only one view shows the posterior leaflet, the aortic short-axis view (Figure 64).

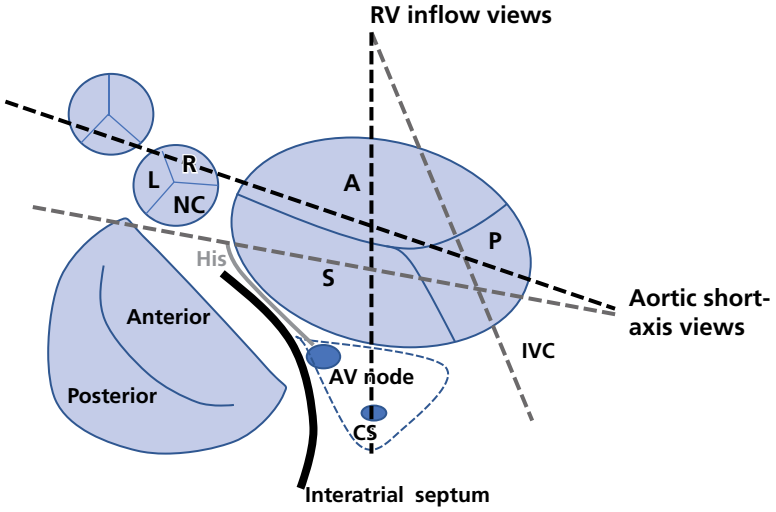

Figure 64 Surgeon's view of the tricuspid and mitral valves. Note their relationships with the aortic cusps and the conduction system. Note how TTE cuts through the tricuspid valve (RV inflow and aortic short-axis views). The RV inflow traditionally cuts through the A and S leaflets (*coronary sinus well seen*), but may cut through the A and P leaflets (IVC well seen). The aortic short-axis traditionally cuts through the A and P leaflets but may cut through the S and P leaflets if the plane is more inferior, at the LVOT level. Traditional cuts are shown as ***black lines***, alternative cuts are shown as ***gray lines***.

Answer 7. The volumetric evaluation of MR or AI consists of measuring the stroke volume at both the mitral annulus and the LVOT, using the continuity equation (volume = area × VTI velocity). The difference between the 2 corresponds to MR regurgitant volume (in which case mitral annular volume is higher) or AI regurgitant volume (in which case LVOT volume is higher). This calculation is only appropriate in the absence of mixed MR-AI. In this case:

- *Mitral annulus stroke volume* = 0.785 × diameter^2 × annulus VTI = 138 ml
- *LVOT stroke volume* = 0.785 × diameter^2 × LVOT VTI = 76 ml

As such:

- *MR regurgitant volume* is 138–76 = 62 ml.
- *MR regurgitant fraction* = MR volume/total volume entering the mitral annulus = 62/138 = 0.45 or 45%
- *MR regurgitant volume* = *Effective regurgitant* orifice (ERO) × MR VTI
  → *ERO* = MR volume/MR VTI = 62/140 = 0.44 cm^2

This MR is severe based on ERO > 0.4 cm^2 and regurgitant volume >60 ml, not based on regurgitant fraction (>50% for severe). Additional notes:

- The mitral annular cursor is placed at the level of the annulus, as shown by the double line, upstream of the valve leaflets and upstream of the standard mitral inflow Doppler.
- ERO is more often calculated using the *PISA method*, where the continuity equation is done at the mitral valve using PISA and peak velocities instead of VTI:
  MR flow = *ERO* × MR peak velocity = PISA hemisphere area × aliasing velocity
  MR regurgitant volume is then calculated via VTI: *ERO* × MR VTI

Answer 8. The mitral annulus stroke volume is the net forward stroke volume + MR, and the LVOT stroke volume is the net forward stroke volume + AI. The difference between the two does not give MR or AI volume in patients with mixed MR-AI. One has to use a valve with no regurgitation, at which level the stroke volume is a net forward stroke volume: RVOT stroke volume may be used here in the absence of shunt, and represents the net input flow into the mitral annulus (before MR) and the net output across the aortic valve (beyond AI).

- *Mitral annular stroke volume* = $0.785 \times 2.9^2 \times 21$ = 138 ml
- *LVOT stroke volume* = $0.785 \times 2.2^2 \times 40$ = 152 ml
- *RVOT stroke volume* = $0.785 \times 2.2^2 \times 18$ = 68 ml

As such:

- *MR regurgitant volume* = 138 – 68 = 70 ml; MR regurgitant fraction = 70/138 = 51%
- *AI regurgitant volume* = 152 – 68 = 84 ml; AI regurgitant fraction = 84/152 = 55%

For both MR and AI, the regurgitant volumes are >60 ml, and the regurgitant fractions are >50%, implying severe MR and severe AI.

MRI uses a similar volumetric principle to calculate MR regurgitant volume. MRI directly measures the total forward stroke volume across the aortic root (using pixel velocity) and the reverse aortic volume AI. LV stroke volume may also be calculated (end-diastolic and end-systolic volumes). MR volume is LV stroke volume minus total forward aortic volume. In isolated MR or AI, the regurgitant volume may be calculated as LV stroke volume minus RV stroke volume.

Answer 9. MR is severe. While ERO area (<0.4 cm^2) and regurgitant volume (<60 ml) fall within the moderate range, those values may underestimate eccentric MR severity as PISA may be underestimated. Also, in acute MR with non-dilated LV, MR volume may be <60 ml even if severe. A flail leaflet on echo imaging, with a leaflet tip that not just prolapses but tilts reversely and looks in the LA (+/– ruptured chord visualized), implies severe MR. The Doppler envelope that is early peaking rather than round suggests V-wave cutoff, i.e., an attenuation of LV-LA gradient in late systole because of a large V wave, and implies severe MR. The total stroke volume is LVEDV × EF = 78 ml. Thus, even with using the 40 ml regurgitant volume, the regurgitant fraction is = MR volume/total stroke volume = 51% (>50%), which is in the severe range.

Answer 10. B. A low AVA with a low gradient may result from echo mismeasurement (~50% of the time), or may be a truly severe AS with low flow or low-normal flow. A low dimensionless index <0.25–0.3 is consistent with truly severe AS but does not prove it (may be the result of pseudo-severe AS or underestimation of LVOT velocity because of misalignment); conversely, a high dimensionless index >0.3 often rules out severe low-gradient AS and suggests underestimation of LVOT diameter (AVA = dimensionless index × LVOT area). The next step consists of re-measuring the LVOT diameter at the annulus level (rather than below it).

Answer 11. A. The peak instantaneous pressure gradient between LA and RA is equal to $4 \times V^2$ → 25 mmHg. Peak LA pressure is, thus, 25 + 10 = 35 mmHg. This peak pressure corresponds to V wave in a patient with decompensated left HF. Mean LA pressure cannot be measured by this method. In an elderly patient with decompensated left HF, the shunt is most commonly through a PFO, and it is a benign compensatory shunt relieving the elevated LA pressure. An interatrial shunt, even large ASD, does not cause left HF; it rather relieves it (it may cause right HF). In context, this shunt does not need to be assessed further.

Answer 12. C. In PDA, the shunt is at the PA level and thus, unlike ASD and VSD, the flow across the RVOT is proximal to the shunt and corresponds to Qs, whereas the flow across the LVOT is past the shunt and corresponds to Qp. Thus:
Systemic stroke volume = RVOT area × RVOT VTI = $0.785 \times (2.5)^2 \times 12$ = 59.8 ml; Qs = systemic stroke volume × heart rate = 5 L/min
Pulmonic stroke volume = LVOT area × LVOT VTI = 93.4 ml. *Qp/Qs* = 93.4/59.8 = 1.55.

Answer 13. It is generally harder to be aligned with the aortic flow in TEE vs. TTE, and thus harder to obtain a proper AS gradient. The best TEE view to assess AS gradient is the deep transgastric 5-chamber view, wherein the probe looks at the heart through the apex.

Answer 14. C. Echo generally visualizes well the inflow cannula at the LV apex: high velocity (>1.5–2 m/s) suggests inflow obstruction, while low velocity with a near-absent diastolic signal indicates pump thrombosis or complete inflow obstruction. The outflow graft is more difficult to visualize (right parasternal, or high left parasternal); high outflow velocity also suggests obstruction, but CT may be needed for better assessment.

Answer 15. *Regurgitant AI flow = ERO area × peak AI velocity. This is also equal to: 2π $PISA^2$ × aliasing velocity
→ERO = 2π $PISA^2$ × aliasing velocity/peak AI velocity
→ERO = $6.28 \times 0.8^2 \times 0.4/4$ = 0.4 cm^2. Remember to use same unit for both velocities. PISA being a hemisphere, not a circle, 2π $radius^2$ is used for its area.
**Regarding LVEDP*: (End-diastolic BP-LVEDP) = 4× end-diastolic AI $velocity^2$
→ LVEDP = $55 - (4 \times 2^2)$ = 39 mmHg

XII. Additional hemodynamics

Answer 1. A. A high baseline systemic cardiac output causes a high mixed venous O_2 saturation MV O_2 before the shunt (e.g., 80%) and makes a lesser O_2 step-up (e.g., 5%) more significant hemodynamically. An O_2 step-up of 7% is seen between the high SVC and the PA and suggests a shunt in this case. It is notable that IVC O_2 is very elevated even proximally close to the iliac veins, which suggests that the shunt is at the IVC level. RA O_2 is lower than IVC O_2 probably because the RA was sampled closer to the SVC than IVC stream. This patient has Scimitar syndrome, wherein the right inferior and superior pulmonary veins are draining in the IVC, instead of the LA. The Scimitar shunt is swirling retrogradely throughout the IVC territory, hence the elevated iliac vein O_2. *IVC O_2 is useful to identify the step-up chamber, but* ***the step-up chamber is not used in Qp/Qs calculation; rather, it is the pre-step-up O_2 and the PA O_2 that are used in Qp/Qs calculation***. High SVC is the pre-step-up O_2 here and is used as MV O_2 in the calculation:

Qp/Qs = (100-MV O_2)/(100-PA O_2) = (100 – 80)/(100 – 87)~1.5

This equation also shows that for a high baseline MV O_2 of 80, a lesser O_2 step-up translates into a Qp/Qs of 1.5. For example, if MV O_2 was 60 with the same O_2 step-up of 7, the Qp/Qs would have been: (100 – 60)/(100 – 67) = 1.2

Anatomically, one would expect Qp/Qs to be 2 here, as half of the systemic pulmonary venous circulation is draining in the RA (Qs would be half Qp). But the right lung is hypoperfused in these patients, hence Qp/Qs is only 1.5.

Answer 2. C. The aortic pulse pressure and systolic pressure decline after a PVC: this is Brockenbrough phenomenon and suggests HOCM. In HOCM, the LVOT obstruction increases on the post-PVC beat, causing a paradoxical drop in stroke volume and aortic pulse pressure, and the emergence of the characteristic spike-and-dome aortic morphology.

Answer 3. A-AS; B-AI; C-HOCM; D-severe HF. Tracing A shows a narrow pulse pressure with a low anacrotic notch on its upslope, suggestive of AS. Tracing B shows a wide pulse pressure with double peaking in systole, the so-called pulsus bisferiens, suggestive of AI: the first peak results from the large initial stroke volume percussing the peripheral artery; the second peak results from the reflected peripheral waves. Tracing C shows a spike and dome morphology, suggestive of HOCM: unlike AS, dynamic LVOT obstruction occurs in late systole and causes a late pressure gradient and a late drop in systolic pressure (the dome). Tracing D shows a pronounced dicrotic notch, the so-called dicrotic pulse, suggestive of severe peripheral vasoconstriction, as in severe HF; the narrow pulse pressure also supports severe HF.

Answer 4. D. The following features suggest severe AI: wide femoral artery pulse pressure (>½ SBP), low diastolic pressure that nearly meets LVEDP (end-diastolic aortic pressure-LV pressure ≤ 30 mmHg), and attenuated dicrotic notch.

Analyze systole as well: AS is present with a peak-to-peak LV-aortic pressure gradient of 40 mmHg and with an anacrotic notch on the aortic upslope. Yet, Gorlin equation suggests that pressure gradient is strongly dependent on the square of the flow crossing the valve:

$$AVA = flow/ (k \times \sqrt{\Delta Pressure}) \rightarrow \Delta Pressure = flow^2/(k^2 \times AVA^2)$$

Thus, for the same valve area, pressure gradient and hemodynamic severity are exaggerated by flow. In mixed AS-severe AI, total flow across the aortic valve increases and is more than double the net systemic flow (as >50% of the initial stroke volume regurgitates). This exaggerates the transaortic systolic gradient. A decent aortic orifice may become flow-limiting because of the high flow trying to cross it, hence the early anacrotic notch on the aortic upslope. The elevated gradient still correlates with the overall hemodynamic impact of mixed AS-AI.

Answer 5. B. According to Hakki's equation, AVA ~ cardiac output/ $\sqrt{\Delta Pressure}$. Keep in mind, however, that in severe AI, the total cardiac output crossing the aortic valve is more than double the net cardiac output measured by thermodilution or Fick (as <50% of the ejected cardiac output stays in the aorta, assuming a regurgitant fraction >50%). Thus, the cardiac output used in this equation should be at least double the thermodilution cardiac output (8 L/min).

Answer 6. B. This is a ventricularized RA pressure with very tall and broad CV wave, and deep Y descent, indicative of very severe TR. Simultaneous RA-RV recording shows how RA pressure mimics RV pressure and nearly equalizes with it.

Answer 7. B. PCWP V wave is massively increased to 70 mmHg, which suggests severe MR. In a patient with mechanical mitral valve replacement, the main differential diagnosis is massive paraprosthetic leak, usually in the setting of prosthetic dehiscence. The RA V wave is markedly tall and wide, i.e., ventricularized; in fact, it is wider than PCWP V wave and peaks throughout systole, which suggests torrential TR. In torrential TR, RA V wave ventricularizes; conversely, in torrential MR, PCWP V wave becomes tall but remains somewhat peaked, i.e., does not ventricularize: on the left, it is more difficult for the LA to equalize with the large LV pressure.

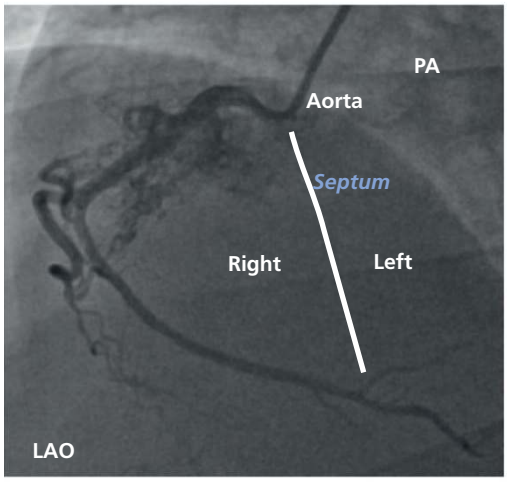
Answer 8. This second pressure waveform is upsloping in diastole; thus, it is not an arterial waveform (not PA). It peaks late in systole compared to the LV; it is rather bisected by the LV descent, which is characteristic of LA pressure's V wave. This is LA pressure with a large V wave, close to 50 mmHg. It may be secondary to severe MR, including dynamic exertional MR, but may also be due to the combination of diastolic HF and AF (AF inherently exaggerates V wave, as the loss of atrial kick reduces LA emptying, facilitating LA overdistension during ventricular systole). Remember to analyze diastolic behavior as well: is there MS? PCWP and LV equalize in end-diastole on multiple beats (e.g., beat in the center of Figure 52 and beat before last), despite a fast heart rate of ~90 bpm; this *end-diastolic diastasis* rules out significant MS.

Answer 9. B. RA pressure, while normal in mean value, has a plateaued ventricularized morphology, pathognomonic for severe TR. This morphology is usually seen in conjunction with severe RA pressure elevation and RV failure, as in Question 6. The normal mean RA pressure suggests *primary* severe TR, at a chronic stage that has not led to RV failure yet. Ventricular functional TR is, by definition, related to RV failure, and thus must be associated with elevated RA pressure: RA pressure may improve with diuresis, at which time functional TR improves as well.

XIII. Percutaneous coronary intervention and shock

Answer 1. C. The pressure ventricularizes upon RCA engagement. The most common explanation is selective conus engagement, in which case the catheter would be pointing up. In this case, however, the catheter is rather pointing down, which suggests that the true RCA is engaged, and that it is small or severely diseased ostially. Coronary injection in this situation may cause ischemia, VF, and coronary dissection. It is best to disengage, give sublingual nitroglycerin, and try to obtain non-selective images using a catheter with a shorter tip that is less likely to dive deeply, e.g., JR4; in addition, a smaller catheter (4 Fr) is preferred. At last resort, a small injection of 1 ml in a damped position, followed by quick catheter withdrawal, may be performed ("hit and run"). Side-hole catheters have no role in the brief injection of diagnostic angiography; they slightly relieve ischemia when the catheter is sitting in the coronary ostium for prolonged periods, during coronary interventions, and reduce the risk of contrast stain and VF in that case. They provide false security by attenuating pressure damping and only have some value during RCA coronary interventions (they should not be used in left coronary interventions as they conceal significant left main ischemia while providing a false reassurance).

Answer 2. B. This patient has a fistula originating from the mid-RCA (*arrows*, Figure 55). Cardiac structures are localized fluoroscopically using (Figure 65): (1) LAO straight, which looks straight into the septum and separates left heart structures from right heart structures. On the LAO view provided, the fistula seems to drain on the right side, to the right of the PDA. (2) RAO straight, which looks straight in the AV groove and separates the atria on the one side, from the ventricles on the other. On the RAO view provided, the fistula seems to drain in the high RV, i.e., RVOT. Note that the PA is on the left of the aorta (on LAO), and more anterior and superior to it (RAO), making it an unlikely termination site in this case.



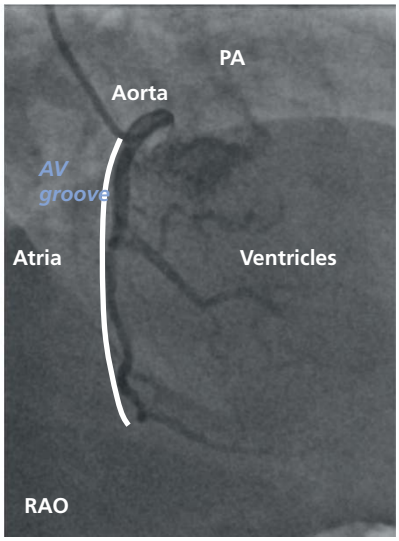


Figure 65

Answer 3. B. This fistula is complex (plexiform network) but small. A fistula is considered large and consequential if any of the following 2 features is present: (1) the artery dilates proximally to the fistula and becomes aneurysmal, with slow flow distally; this is because coronary steal occurs at the level of the fistula and forces the proximal artery to provide larger flow; (2) significant left-to-right shunt with significant O_2 step-up on right heart oximetry. In this patient, the artery is not dilated proximally, which suggests a small and benign fistula. Biventricular failure may result from a large coronary artery-to-RV fistula, but this is not the case here; right heart catheterization is performed to further confirm the fistula is small. Cardiac CTA is useful for planning surgical or percutaneous closure of a large fistula, not the case here.

Answer 4. C. Paclitaxel has a minimal anti-inflammatory effect.

Answer 5. C. The Mehran score for post-PCI contrast nephropathy may be used. The combination of the following 3 features predicts a high risk of contrast nephropathy: severe underlying CKD (GFR < 20), hemodynamic compromise (hypotension and/or severe HF), and age >75.

Answer 6. A. After proximal RCA stenting, one or more RV marginal side branches may occlude and induce RV injury. This manifests as anterior ST elevation and ample T waves. RV being an anterior structure, RV infarct may mimic anterior infarct on ECG (V_1-V_3). It is generally a benign occurrence and RV ischemia will improve spontaneously.

Answer 7. B. Retrograde iliac artery dissection may occur during retrograde wire advancement or even sheath angiography in a tortuous iliac artery (contrast injection through the sheath may create hydraulic iliac dissection). If non-flow limiting, it is treated conservatively because the forward blood flow tends to "tuck" the dissection. The key is to avoid rewiring the dissection plane and further expanding it. As long as the true iliac lumen can be wired, the procedure does not need to be aborted and the patient does not need to be exposed to the risk of a second access.

Answer 8. B. A catheter crossing the radial artery will create a tamponade of the bleeding site. Thus, the radial perforation is treated with pursuing the procedure. The tortuous segment is crossed using a 0.014" guidewire, and a catheter is then advanced with a 2-mm balloon inflated at its tip, serving to smooth the catheter edge. Alternatively, the radial artery may be crossed with 0.018" wire, which is later exchanged via a small 4 Fr catheter to 0.035" guidewire, over which the catheter is advanced. BP cuff inflation may be performed for a few minutes to control the bleeding before the above manipulation, and the radial artery is re-imaged at the end of the case.

Answer 9. C. This patient has hemolysis secondary to Impella. Hemolysis may be due to: (i) inlet obstruction from contact with the subvalvular apparatus or low preload; this causes slow flow through the impeller and more exposure to its shear stress; (ii) clotting of the pump; (iii) outlet obstruction if the outlet is too close to the aortic valve (i.e., Impella itself is too deep and the bend, which should be at the valve level, is too deep).

The first step is to ensure proper Impella position (especially not too deep), and to ensure proper preload. The pump may be repositioned, and fluids may be given if CVP is <10 mmHg. If hemolysis persists, the power may be reduced by 2 levels. If hemolysis persists, Impella may need to be removed.

Answer 10. A. Contrast swirling outside the LV may be consistent with any of the 3 answers. In MR, the contrast swirls toward the LA. In VSR, contrast swirls toward the RV and PA, with no persistent stain. In free wall rupture, contrast swirls out of the LV and stains the myocardium/pericardium.

Answer 11. A. TRIGGER PCI trial randomized patients with stable CAD PCI and high on-clopidogrel platelet reactivity to prasugrel vs. clopidogrel. Prasugrel dramatically decreased platelet reactivity, but ischemic events were low and similar with prasugrel vs. standard clopidogrel. GRAVITAS trial randomized patients with stable CAD or ACS PCI and high on-clopidogrel platelet reactivity to double-dose clopidogrel vs. standard-dose clopidogrel; again, while double-dose improved platelet reactivity, it did not improve clinical outcomes. Ticagrelor has not been studied in stable CAD PCI.

Suggested readings:

Price MJ, Berger PB, Teirstein PS, et al; GRAVITAS Investigators. Standard- vs high-dose clopidogrel based on platelet function testing after percutaneous coronary intervention: the GRAVITAS randomized trial. JAMA 2011;305(11):1097-105.

Trenk D, Stone GW, Gawaz M, et al. J Am Coll Cardiol 2012;59(24):2159-64.

Answer 12. E. Clopidogrel is a prodrug that needs to be metabolized into an active metabolite by the cytochrome CYP2C19. Mutation of CYP2C19 alleles translates into clopidogrel hypo-responsiveness. Clopidogrel responsiveness may be assessed via point-of-care platelet function testing or genotype testing. *Unlike the preceding question, this patient is presenting with NSTEMI, not stable CAD*. TAILOR PCI trial tested the genotype of patients who underwent PCI for ACS or stable CAD (mostly ACS); patients were randomized to a genotype-guided strategy, where those with CYP2C19 loss-of-function alleles received ticagrelor, or to a conventional strategy, wherein all patients, including those with loss-of-function alleles, received clopidogrel. The genotype-guided strategy did not significantly improve ischemic outcomes, regardless of whether the whole population, or the specific population with loss-of-function alleles receiving ticagrelor vs. clopidogrel, was analyzed. *As such, testing for poor clopidogrel response and upgrading from clopidogrel to another anti-P2Y12 regimen according to the result has not proven beneficial in neither stable CAD nor ACS undergoing PCI*. Genotype testing may better serve to safely downgrade from ticagrelor to clopidogrel in ACS PCI patients with good-function alleles (Popular Genetics trial). Prasugrel and ticagrelor are appropriate therapies in this patient, not because of genotype testing, but because of the randomized ACS clinical trials showing superior ischemic reduction with the latter drugs vs. clopidogrel in general (TRITON-TIMI 38 and PLATO trials). Clopidogrel is an appropriate therapy for ACS and compared favorably to ticagrelor in patients older than 70, with less bleeding and similar ischemic outcomes (POPular age trial).

Suggested readings:

Answer 13. C. According to CULPRIT-SHOCK trial, multivessel PCI in the setting of MI with cardiogenic shock worsens survival and is not indicated. Biventricular support with Impella and Impella RP may be considered for patients with biventricular failure, such as patients with a combined high PCWP and low PA pulsatility index (PA pulse pressure/RA <1), particularly if the latter persists after LV support. However, the main diagnosis here is ventricular septal rupture, as evidenced by the large O_2 step-up between SVC and PA. The diagnosis needs to be immediately made by echo and left ventriculography, followed by IABP and emergent surgical consult.

Answer 14. D. *LAO view* shows that the RCA has an anomalous origin from the left cusp, not the anterior right cusp. *RAO view is the view used to delineate the path of the anomalous RCA*. On RAO view, the PA is anterior to the aorta (i.e., anterior to the catheter):

- A posterior course will go behind the aorta and the catheter (not the case here).
- A course anterior to the PA will create a long anterior curve, like an "upper eyebrow." A subpulmonic septal course would dive below the PA and give a "lower eyebrow" appearance, not the case here.
- An interarterial course would be anterior to the aorta and directly pointing at us, which is the case here.

A left coronary artery arising from the right cusp with a malignant course qualifies for surgical correction even with no symptoms, as it is more clearly associated with a risk of sudden death (class IIa). For a malignant RCA course, surgery is not immediately indicated, particularly at an age >35, as sudden death is mainly reported in the very young with this anomaly. In order to qualify for surgical correction, there must be clear-cut evidence of ischemia clinically (typical exertional angina) or by exercise stress testing. Also, the RCA must have malignant features, such as interarterial course, slit-like origin, or intramural course on CT.

Answer 15. C. On the pressure-volume loop, stroke volume corresponds to the width of the loop, while stroke work (SW) corresponds to the area of the loop. Besides stroke work, the area contained to the left of the loop also affects myocardial oxygen consumption and is called potential energy (PtEn): it represents the residual tension of the myocardium after ejection. Imagine pushing an object and keeping your arms up at the end of the push: residual energy is required to keep the arms up, and this corresponds to PtEn. The *summation of the potential energy area and the stroke work area is called pressure-volume area (PVA)* and is the best indicator of myocardial O_2 consumption per beat. The top dashed line is the *intrinsic contractility line (Ees)*: it moves up with increased contractility (→larger stroke volume) and down with reduced contractility. For a given contractility line, the end-systolic point depends on *afterload*. The following effects are noted:

- ***IABP*** reduces afterload on the top contractility line, reduces preload on the bottom line, and increases stroke volume; but the myocardium itself is increasing its stroke work, hence the reduction in O_2 consumption is limited.
- ***Impella*** dramatically reduces preload but also afterload, as the LV systolic pressure becomes uncoupled and lower than aortic pressure (work is carried by Impella); this dramatically shrinks SW and PtEn.
- ***Norepinephrine*** increases myocardial contractility (raises the top line) but also raises the afterload point and overall increases stroke work area while only mildly increasing the stroke volume.
- ***TandemHeart*** is not represented here. It reduces preload but increases afterload. It shrinks the loop and reduces stroke work but not potential energy (see Chapter 39, Figure 39.22).
- ***ECMO*** increases LV preload and afterload, while supporting the systemic circulation independently. It moves the curve rightward and is not favorable for PVA.

Answer 16. D. iFR assesses the summation of diastolic pressure drop throughout the whole left main-LAD segment and is significant when ≤0.89. LM is anatomically significant (<6 mm^2), yet iFR is not significant. It is possible that left main is falsely measured by IVUS, or is hemodynamically insignificant despite being <6 mm^2, but considering the extent of angiographic diffuse disease, and the fact that LAD supplies a large territory encompassing the RCA, it is likely that iFR is lower than 0.93. The top reason for a falsely high iFR or FFR in a patient with ostial LM disease is deep guide catheter engagement during iFR measurement. The deep guide creates further ostial LM obstruction, reducing the hyperemic flow across the LAD and the drop in pressure across it; also, the distal pressure Pd is referenced to a proximal pressure Pa that is past the LM disease, not a true aortic pressure.

Answer 17. A. This patient has *coronary artery aneurysm*, which is defined as a focal dilatation that is at least 1.5 times larger than a normal adjacent coronary segment in the same artery. The term *coronary artery ectasia* is used for diffuse dilation that is at least 1.5 times the adjacent normal segment. The term *giant coronary aneurysm* is used for aneurysms exceeding 20 mm. All the listed answers may cause coronary aneurysms, but the most common process is atherosclerosis (>50–75%). Atherosclerosis may cause stenoses but may also weaken the arterial wall and cause aneurysms. In the CASS registry of patients undergoing coronary angiography for suspected CAD (mean age 52), the prevalence of coronary artery aneurysms was 4.9%. Kawasaki is the most common cause of coronary aneurysm in childhood; the infection occurs mainly in children <5 years old, and coronary aneurysms develop in 15–25% of children who do not receive immunoglobulin therapy; the latter reduces their prevalence to 5–10%. Regardless, 75% of Kawasaki's coronary aneurysms regress by 2 years.

Answer 18. C. The patient's symptoms are best served by revascularization, considering the severity of his angina despite 2 antianginal drugs (refractory angina is defined as angina that remains severe despite 2 antianginal drugs). LAD is mildly significant by FFR; it is made more hemodynamically significant by supplying collaterals to the RCA, i.e., supplying a larger territory. If the RCA is revascularized, the LAD will be supplying a smaller territory, the extent of microvascular hyperemia will decline, and FFR will rise. While A and B are acceptable options, it is best to revascularize the RCA and reassess LAD FFR. The RCA CTO has clinical features favorable for antegrade crossing with dissection-reentry (the length >2 cm reduces the success of antegrade wire escalation, but it has good proximal cap and distal reconstitution to allow dissection-reentry).

Answers 19. C and D. From tracing (1) to (2), the augmented pressure significantly declines, while the systolic pressure rises (with a rising pulse pressure). The systolic pressure exceeds the augmented pressure. This poor augmentation may be related to technical issues, such as late inflation, but it is more significant than seen with subtle timing changes. In (1), the LV function is poor, hence the narrower systolic pulse pressure; also, the concomitant systemic vasoconstriction allows the pressure to significantly overshoot during balloon inflation, i.e., to augment. In (2), the LV recovers, and as such, systolic pressure widens and vasoconstriction attenuates; balloon inflation cannot augment the pressure of the dilated circulation (large compartment) as much as it augments the pressure of the constricted circulation in LV failure (small compartment). Hence the augmented pressure declines, while the systolic pressure rises and potentially exceeds the augmented pressure. The same waveform (2) may be seen in septic shock, wherein the systolic pulse pressure rises, while the dilated circulation/large compartment prevents an overshoot during balloon inflation. Balloon kink and balloon rupture may attenuate augmentation, but the helium gas waveform will be particularly abnormal (more than the inflation waveform) and will provide a hint to the diagnosis.

Answer 20. A. TRILOGY ACS trial randomized NSTE-ACS patients who were managed medically to clopidogrel vs. prasugrel. Prasugrel did not improve ischemic outcomes. Even in the subgroup of patients with clopidogrel resistance according to platelet reactivity testing, prasugrel did not improve outcomes at 30 months of follow-up, and platelet reactivity did not correlate with long-term ischemic outcomes. Ticagrelor may be an option, as it was superior to clopidogrel in ACS patients managed conservatively or invasively in the PLATO trial (regardless of platelet reactivity).

Reference:

Gurbel PA, Erlinge D, Ohman EM, et al; TRILOGY ACS Platelet Function Substudy Investigators. Platelet function during extended prasugrel and clopidogrel therapy for patients with ACS treated without revascularization: the TRILOGY ACS platelet function substudy. JAMA 2012;308(17):1785-94.

Answer 21. C. This patient has a clinical picture of TTP (thrombotic thrombocytopenic purpura), a very rare complication of clopidogrel therapy. It used to be more common in the era of ticlopidine therapy. Clopidogrel may cause a simple rash in ~2% of treated patients, which usually responds to corticosteroids and does not require clopidogrel interruption. The presentation here is more complex and suggestive of TTP.

Answer 22. B. Ticagrelor is a reversible inhibitor of P2Y12 receptor, but unlike cangrelor, has a long half-life of 10–15 hours, hence the long duration of action of ~4 days.

Answers 23. B, D. Cangrelor and ticagrelor act directly on the P2Y12 receptor, while clopidogrel and prasugrel are both prodrugs that need to be metabolized by CYP2C19 to the same active metabolite; prasugrel is more consistently and efficiently metabolized, hence the stronger inhibition of platelet aggregation. ***Always distinguish plasma half-life from the duration of pharmacodynamic effect: the prasugrel and clopidogrel metabolite has a short half-life (~3–4 hours), but a long duration of action as it binds irreversibly to the receptor***. Ticagrelor binds reversibly to the receptor but has a long half-life (10–15 hours). It is because of the short half-life that clopidogrel and prasugrel cannot be administered during cangrelor infusion: cangrelor would prevent the short-lived metabolite from binding to the ADP receptor, and the metabolite would be eliminated by the end of the infusion.

Answers 24. A, C, D, E, G. Unfractionated heparin enhances AT III and predominantly inactivates factor II (thrombin), but also Xa, and to a lesser degree, IXa, XIa, and XIIa. Unfractionated heparin is eliminated by the reticuloendothelial system, not renally.
Note:
- Intrinsic pathway: XIIa → XIa → IXa + VIIIa.
- Extrinsic pathway: VIIa (tissue wall damage → tissue factor release → VII activation).
- Common pathway: Xa → IIa

Answers 25. A, C, G, H. Radial access reduces bleeding compared to femoral access in all settings (stable CAD, NSTEMI, STEMI). There is no evidence of mortality reduction in the stable CAD setting. Regarding mortality reduction in ACS, various studies have divergent findings. In the RIVAL trial of all ACS patients, mortality was only reduced in STEMI. In the MATRIX trial of all ACS patients, there was a marginal mortality reduction with radial access at 30 days of only 0.6% (1.6% vs. 2.2%, p = 0.045) in all ACS subsets, with no interaction between STEMI or NSTEMI, but mortality as well as the MACE reduction became non-significant at 1 year.

Two dedicated STEMI trials have been conducted: mortality was reduced in the RIFLE-STEACS but not in the STEMI-RADIAL trial. The totality of the data and their meta-analysis support mortality reduction in ACS, mainly STEMI.

Sub-analyses of the MATRIX trial show a higher radiation dose to the operator and to the patient with radial access (RAD-MATRIX) and less acute kidney injury (AKI-MATRIX trial).

Answer 26. B. RCA that arises from the left cusp with a superior configuration (a) is often best engaged with a short JL (e.g., JL3 or EBU 3) that is looped upward. The inferior configuration is often best engaged with a short JL or EBU catheter, like (a), but looking straight down rather than looped upward. The anterior configuration is often best reached with an AL catheter. Those are general rules; reaching the superior configuration (a) may require looping of a larger JL (e.g., JL5) in some cases.

Answer 27. A. It is difficult to wire a side branch after fresh stenting of the main branch. The top reason for that is that the guidewire tends to go behind the stent struts, between the stent and the vessel wall, rather than through the true lumen. This is likely to happen as the proximal portion of the stent, which is properly sized for the smaller LAD, is undersized and malapposed at the left main level. Proximal optimization technique (POT) consists of dilating the proximal stent with a properly sized balloon, 4.5 or 5 mm, then reattempting to wire the side branch. The other techniques, B–D, may prove necessary if wiring the LCx continues to be difficult. Note, however, that polymer-jacket wires are more prone to slipping behind the stent struts and a non-polymer wire may be preferred.

XIV. Radiation in the cardiac catheterization laboratory

Answer 1. E. There are 2 doses of radiation exposure that correlate with 2 types of radiation effects:
- Skin dose (or *absorbed dose*), in mGy (milligray) or rad, which is the direct dose at each point of the skin entry site. Direct cellular death can occur when this dose exceeds a certain threshold and increases in severity with higher doses: this is the *deterministic risk*.
- Whole body scatter dose (or *effective dose*), in mSv (millisievert), refers to the radiation distributed throughout the body and originating from the localized skin entry dose, delivered to the patient (internal scatter) or to the operator (external scatter). *This dose is derived from the skin and local tissue dose and is a small fraction of it*. This dose can cause DNA damage without cell death, and slightly and incrementally increases the risk of cancer (the risk of the event increases with the dose, but not its severity, and there is no safe threshold): this is the *stochastic risk*.

Rem (radiation equivalent in man) may be used for either absorbed or effective dose. 1 REM = 1/100 Sv =1/100 Gy = 10 mGy.

Air Kerma, reported on the display monitor, is an estimate of the *skin dose*. It measures the X-ray dose delivered to a chamber in the X-ray tube, then calculates the skin dose based on the assumed standard distance between the X-ray tube and the skin.

Dose-area product is air Kerma multiplied by the total exposed area (mGy.cm^2). It correlates with both deterministic and stochastic effects.

The operator exposure results from scatter of X-rays that hit the patient at the entry point (Compton scatter); thus, the operator is directly radiated from the patient, not the X-ray tube.

Answer 2. D. As the X-ray hits the patient at a certain angle (e.g., LAO), the scatter occurs at 90° from that angle (e.g., LAO scatters to the right obliquely). Thus, LAO causes more scatter to the operator than RAO, and LAO cranial causes the most scatter to the operator. This also explains why the acrylic shield should be placed between the point where the X-ray beam first hits the patient (e.g., chest) and the operator's face. Scatter is the main source of exposure to the operator but also to the patient's body organs outside the X-ray beam.

The *inverse square law* is an important law that determines radiation exposure: the X-ray dose diminishes with the square of distance from the X-ray source. As such, raising the catheterization table high above the X-ray tube reduces the patient's exposure; similarly, moving the operator away from the patient, the primary radiation/scatter source, reduces the operator exposure. Moving 1–2 steps back from the patient reduces the operator's exposure 4-fold! Leaning over the patient dramatically increases the operator's exposure.

When performing a cardiac procedure on a pregnant woman, the fetus exposure results from scatter from the mother's chest, not the primary X-ray beam. Thus, external shields do not protect the fetus. The scatter from the chest is mostly absorbed by the abdomen, and the fetal exposure is generally limited and not enough to cause deterministic effects but may cause stochastic effects, particularly at 8–15 weeks of pregnancy.

Answer 3. B. Doubling the magnification quadruples the skin dose (see full explanation with the next answer).

Answer 4. F. The X-ray tube delivers a skin dose of ~10–100 mGy/min during fluoroscopy mode, and this is displayed on the monitor as air Kerma rate. X-ray dose increases dramatically with the amount of fat, bone (spine), and visceral tissues that must be traversed. Hence obesity dramatically increases radiation. Also, steep angles require a lot more radiation than AP, as steep angles traverse more fat and tissues, and the X-ray tube must be moved closer to the skin; the steeper the angle in any direction, the worst the skin dose, and this is synergistic with obesity. LAO caudal tends to be the worst angulation to the patient, as it traverses abdominal fat the most. LAO cranial may be the worst to the operator, as the scatter directly hits him at a 90° angle from the entry point.

Magnification increases radiation by the square of the magnification (2× magnification, such as going from a 44-cm to a 22-cm field of view→ 4× local skin dose). As the radiated area is stretched out, there is less radiation per pixel and the image becomes too dark; as such, more X-rays need to be produced to compensate for the higher pixels and preserve the brightness.

Raising the detector panel away from the patient increases scatter and reduces the intensity of the beam that reaches the detector (inverse of square distance), forcing the X-ray tube to increase its output.

Collimation reduces the skin area exposed and the total X-rays produced, i.e., the dose-area product (mGy.cm^2), but not the skin dose within the irradiated area: air Kerma (mGy) remains the same, but the dose in mGy.cm^2 decreases in half with collimating half the field. As such, the effective dose to the operator and to the patient's other organs (in mSv) is reduced in half. Also, collimation improves image quality, as it decreases scatter from undesirable areas of the image.

Reducing the frame rate in half cuts the skin dose exactly in half.

According to the inverse square law, lowering the table increases the skin dose and this is not detected by the air Kerma estimate, which assumes a certain table height.

A lower skin dose is generally required for lower extremity procedures (at similar fluoroscopic duration) because less tissue is traversed than in the trunk. The operator exposure may not be reduced as he is closer to the scatter source than during coronary procedures, particularly that these procedures tend to be longer than coronary procedures.

Collimation and lesser angulations are the 2 methods that improve image quality while reducing radiation. The biggest 3 predictors of skin dose (and consequently, scatter dose) are: obesity, angulation, and magnification.

Answer 5. A. All interventions A–F are excellent ways of reducing the patient's *skin dose* (*absorbed dose*, in mGy), but also the whole-body scatter dose (*effective dose*, in mSv) to the patient and to the operator. ***Reducing the magnification*** reduces skin dose in a squared fashion: reducing magnification 1.5 times reduces skin dose $1.5^2 = 2.25$ times (with less of an effect on the total dose-area product and whole-body dose, as the exposed area is increased). ***Reducing frame rate*** from 15 to 7.5 reduces all radiation doses exactly in half. ***Collimation in half*** reduces the dose-area product and whole-body dose in half, but the dose of each irradiated point, i.e., skin dose, remains the same. ***Raising the table*** to double its height reduces the skin dose in 4, but the table cannot be raised so dramatically throughout a long case or with angulation. ***Compared to double angulation (30°,30°), the X-ray dose delivered in AP view*** is 3- to 6-fold lower, even more so in obese patients, wherein steep angles exponentially increase the amount of fat traversed. ***Cine-fluoroscopy*** delivers over 10-fold higher radiation and is the driver of radiation exposure in diagnostic cases. Cine runs should certainly be minimized by using the "fluoroscopy-save" option, but those are brief runs (seconds) and in a long case (>10–20 minutes), most of the radiation eventually results from fluoroscopy.

Answer 6. C. The X-ray dose is determined by the energy of the photons (KVp) and their numbers (intensity, in mA). Automatic brightness control increases both mA and KVp if the image is dark and poorly penetrated, as in obese patients. An increase in mA improves image contrast and reduces noise (e.g., think of the difference between imaging in cine vs. standard fluoroscopy). An increase in KVp increases tissue penetration and brightness in obese patients, and improves the "grainy" image appearance, but lowers the image's contrast. This is because iodine binds best to X-ray photons when their energy is 33 KeV; a higher energy makes those X-rays pass through the contrast without attenuation, creating a washed-out image. To improve image quality in the obese patient: avoid steep angles that penetrate a lot of tissue and create a lot of scatter into the image and outside it, use unmagnified views to reduce KVp, use collimation, and reduce panning to reduce motion blur.

Answer 7. E. Note that the operator's eye injury leading to cataract is deterministic, and directly dose-dependent and cumulative, not stochastic (unlike cancers). Note that the background environmental radiation exposure is ~3 mSv per year. The occupational limit for physicians is 50 mSv per year and 500 mSv per lifetime.

The lifetime risk of cancer in the US is ~20%. Note that the increase in cancer risk starts to be seen with 100 mSv of exposure: 0.4% additional lifetime risk. The risk becomes more dramatic with 1000 mSv (100 rem): 4% additional lifetime risk.

  atrial fibrillation, 348
Ventricular parasystole, 323–324
Ventricular pressure tracings, 929–930*f*, 933*f*, 934*f*, 939*f*, 940*f*, 946*f*, 948*f*
Ventricular refractory period, pacemaker, 423
Ventricular repolarization, 327, 327*f*, 467, 696–697, 715–724, 747
Ventricular safety pacing, 431–432, 431*f*
Ventricular septal defect (VSD), 502–505
  anatomy and echo views, 502–503, 503*f*
  Gerbode defect, 502–503, 503*f*
  localization, 502–504, 503*f*
  murmur, 258, 260–262, 260*t*
  natural history and treatment, 502, 504
  pregnancy, 674
  pulmonary hypertension, 506
  shunt fraction, 504
  types, 502–505, 503*f*
Ventricular septal rupture, 62*t*, 65–66, 68
  STEMI, 66–68
Ventricular systolic discordance, 481, 481*f*
Ventricular tachycardia (VT), 322–344
  ablation, 454–459
  accelerated idioventricular rhythm, 326, 326*f*
  acute treatment, 324–325, 328
  adenosine, 336
  arrhythmogenic right ventricular dysplasia or cardiomyopathy, 332–333, 333*f*, 338
  athlete's ECG screening, 336–338
  Brugada syndrome, 334–335, 334*f*, 337, 679, 731–732, 732*f*, 1054*f*
  bundle branch block reentrant VT 336
  capture complex, 312
  cardiac syncope, 632
  causes, 324
  channelopathies, 326, 333–334, 338
  chronic management, 325–326
  diagnosis, 308–314
  direct-current cardioversion, 324–325
  ECG, 308–313*f*, 743–745*f*, 1031*f*, 1067*f*
  electrophysiologic testing, 447, 449, 454–459, 463
  fascicular, 336
  fusion complex, 311–312
  ICD, 331–333, 333*f*
  idiopathic catecholaminergic polymorphic, 335
  idiopathic outflow tract PVC, 336
  inducible, EP study 454–455
  long QT syndrome, 329–331, 339
  malignant early repolarization, 335, 336*f*
  mitral valve prolapse VT, 334
  non-sustained, 324
  monomorphic vs polymorphic, 69, 324, 331
  polymorphic, 326–329, 327*f*, 328*f*, 335
  premature ventricular complexes, 322–324
  RVOT/LVOT VT 336
  sarcoidosis, 188, 334
  short QT syndrome, 335
  STEMI, 68–69, 74*f*, 76*f*
  storm, 325
  sustained, 324–326
  SVT with aberrancy vs., 308–312*f*, 1067*f*
  syncope, 632, 634
  torsades de pointes, 327–329, 327–328*f*
  types, 324, 324*f*, 327
  work-up, 325–327
Ventriculography, 66, 861
Ventriculophasic sinus arrhythmia, 402–403, 403*f*, 409–410, 409*f*, 745*f*
Verapamil, 99
  ACS, 15
  angina, 99
  atrial fibrillation, 347, 349, 349*t*
  cocaine associated myocardial ischemia, 679
  hypertension, 594, 600
  hypertrophic cardiomyopathy, 290–291, 293
  pregnancy, 676
  verapamil-sensitive PVC and VT, 336
  wide complex tachycardias, 313
Vericiguat, 148, 150
Vernakalant, 349, 357
Vertebrobasilar disease, 632
Vertical heart angiography, 845, 847*f*, 848–852, 849–851*f*, 857–858
Vertical hearts, ECG, 701
Vessel overlap, coronary views, 857–858
Viability testing, 57, 138, 830–831, 832*f*
Viral/idiopathic pericarditis *see* acute pericarditis
Viral myocarditis, 130, 184, 186–187, 471
Volume calculations, blood flow, 781, 790–791, 790*f*, 1102–1103
Volume responsiveness, 65, 579–581, 788
Volume status and volume overload
  congestive signs and symptoms, 126–127
  echocardiography, 789–790
  heart failure, 128*f*, 152, 154–156
  hemodynamics, 931–934*f*
  shock management, 569
  volume overload in valvular disease, 221, 234, 236, 264
Volumetric method, MR and AI Assessment, 781, 790–791, 790*f*, 1102–1103
VOO mode, 426, 431–432
Vorapaxar, 13, 13*f*
V pacing, 419, 421, 421*f*, 425, 425*f*, 430–433, 437–439, 437*f*
Vp (velocity of propagation on echo-Doppler), 788
VT storm, 325
V/Q scan, 555, 623
VSD *see* Ventricular septal defect
VT *see* Ventricular tachycardia
VTI *see* Velocity-time integral
VVI *see* Ventricular demand pacing
VVI pacemakers, 418–419, 423, 426, 433

VVI pacing, 419, 421, 421*f*, 433
V waves, 931–933*f*, 1038*f*
cut-off sign on mitral Doppler, 774*f*, 782*t*
hemodynamics, 929*f*, 931–933*f*, 954*f*, 955*f*, 962*f*
large V wave, 221*f*, 229–230*f*, 932–933*f*, 954*f*, 955*f*, 962*f*

Wandering atrial pacemaker, 380, 701
Warfarin (Coumadin)
acute coronary syndrome, 18, 18*f*, 23
atrial fibrillation, 350–352, 351*t*, 356–362, 359*f*, 360*t*
bleeding risk, 350–352, 351*t*, 359–362, 359*f*, 360*t*
bridging anticoagulation, 257, 361
in combination with aspirin and clopidogrel, 18–19, 18*f*, 350–352, 351*t*, 356–357, 359*f*, 360*t*
cryptogenic stroke, 502
elevated INR values or bleeding, management, 256–257, 361–362
in HIT, 561
left ventricular thrombus, 73
mitral stenosis, 359
vs NOACs, 351*t*, 359–360, 360*t*
Pregnancy management, 675
prosthetic valves, 256–257, 675
pulmonary embolism and DVT, 491, 557–561
thrombophilias, 559
Warm-up
angina, 93
arrhythmias, 306, 306*f*, 461
Warranty period, stress tests, 95–96, 95*t*, 817, 819, 821
Watchman device, 362
Weaning
Impella, 578, 578*t*, 998–999
intra-aortic balloon pump, 578, 578*t*, 994
Wearable defibrillator (Lifevest), 331–332
Weight gain, in heart failure, 126–127, 140, 152, 152*f*, 161
limitations, 161
Weight loss
atrial fibrillation, 348, 355
in HFpEF, 150
Wellens syndrome, 713*f*, 716-719, 717–719*f*, 723*t*
Wells criteria, 554, 646
Wenckebach AV block, 401, 401*f*, 410, 410*f*, 743–744
AVNRT, 387
EP study/His recording, 449, 449*f*
pacemaker pseudo-Wenckebach, 423–424
Wenckebach cycle length, 400, 401*f*, 449
Wet picture, heart failure, 152
Wheezing, 648–649
White-coat hypertension, 587–588, 590, 597, 605
Wide QRS complex tachyarrhythmias, 305, 307–321, 306*f*, 308–313*f*, 313*t*, 388–396, 740–743*f*
adenosine role, 313–314
differential diagnosis VT vs. SVT with aberrancy, 305–307, 306*f*, 306*f*, 308–313*f*, 314*t*, 315–321*f*, 1067*f*
ECG, 308–313*f*, 315–321*f*, 699–700, 711–712, 712*f*, 740–743, 742*f*
physical examination, 314
practice ECGs, 315–321*f*
regular, 306*f*, 308, 308*f*, 311–314, 311*f*, 312*f*, 313*f*, 313*t*, 316–317, 316*f*, 317*f*, 321*f*
SVT with pre-excitation, 312, 312*f*, 392*f*
ventricular tachycardia features, 307–312
Wild-type (senile) transthyretin amyloidosis, 190–191, 191*f*
Wilkins score, 227, 230, 232
Williams catheter, 882
Wolff–Chaikoff effect, 468
Wolff–Parkinson–White (WPW) syndrome, 312*f*, 334–335, 337, 387–396, 388*f*, 389*f*, 390*t*, 391–394*f*, 709*f*
accessory pathways, concealed and manifest, 390–391, 390*t*, 391*f*, 451
acute and chronic therapies, 394–395
atrial fibrillation and flutter, 307*f*, 312*f*, 391*f*, 392*f*, 392
ECG, 312*f*, 388*f*, 389*f*, 390*t*, 392*f*, 393*f*, 394*f*, 396–397*f*
electrophysiology, 392–394, 393*f*
orthodromic and antidromic tachyarrhythmias, 388–395, 391*f*, 392*f*, 393*f*
PAC initiation, 391, 391*f*
refractory period of the accessory pathway, 388
Women
acute coronary syndrome in, 1, 5–6, 8–11, 10*f*, 22, 25, 25*t*, 27–28, 30
angina with normal coronary arteries, 104, 104*t*, 108–110
BNP in, 128–131, 134–135
chest pain in, 91–94, 94*t*, 104, 104*t*, 108–110
peripartum cardiomyopathy, 130
pregnancy, 674–677
prosthetic valves, 250, 256–257, 263
stress testing, 817–818
vasospasm, 2, 5–7, 10, 91–92, 107–111
WPW *see* Wolff–Parkinson–White
W shape, notched RVOT waveform in PH, 622, 793
W shape, right atrial waveform, 481, 481*f*, 481*f*, 931*f*, 956*f*

Xa, 14*f*
X descent, 474*f*, 481–482, 481*f*, 482*f*, 486*f*, 928–931, 929–931*f*, 949, 956*f*
echo correlation, 788, 793*f*

Yacoub *see* Aortic valve remodeling
Y descent, 474*f*, 481–482, 481*f*, 482*f*, 486*f*, 928–931, 929–931*f*, 949, 956*f*
echo correlation, 788, 793*f*
flat Y tamponade (FYT), 474*f*, 928, 949*f*
Y grafts, to coronary, 107, 861*f*
