Introduction

First and foremost, thanks for picking up this book. I'm well aware that there are a ton of technical books to choose from, especially in the AI space, so thanks again. I hope that you see the differences between this book and the others. The approach that I took with it was from my own lens, both from the type of things I used to learn AI and what I see in customer environments day-to-day. As an AI architect and forward deployed engineer with a platform engineering and DevOps background, how I help implement AI for customers has an interesting twist. I think about it from both a "what's production-ready" perspective and a "what the world will look like in three months, six months, etc." perspective. Because AI moves so fast, I want to ensure the people I work with implement it in a production-grade fashion while keeping the future in mind in terms of how things may change.

The chapters in this book range from the high-level primitives of MLOps and fine-tuning to give you better knowledge of AI as a whole to implementing agentic workloads in production with governance and observability in mind. After reading this book, you should be readily able to implement agents, MCP, runtimes, frameworks, LLMs, and security in your environment.

What's not covered in this book is what I'd call "hardware MLOps, ML engineering, and data science" concepts. In Chapter 1, you'll see how to think about models and some key concepts at a high level, like fine-tuning, but I don't go super in-depth because it won't necessarily be needed as a platform engineer in the AI space, but I personally believe it's still good to know. Knowing how fine-tuning, datasets, MLOps, and building LLMs work gave me a better understanding of AI as a whole, and therefore, how I can use it in production.

All code in this book can be found here: https://github.com/AdminTurnedDevOps/agentic-demo-repo. Because of how fast the agentic space is moving, you'll often find that the code examples in this repo, and, because of that, within the

book, will change. If there is a code example in the book that no longer works, please check this repo.

Any source code or other supplementary material referenced by the author in this book is available to readers on GitHub. For more detailed information, please visit https://www.apress.com/gp/services/source-code.

Table of Contents

Chapter 1: The Rise of AI in DevOps and Platform Engineering

Where AI Stands Today

Agentic Vocabulary

The Mindset Shift

AI Models

What Is a Model

Model Tools

Agentic/AI Harness

Building Models

Fine-Tuning Models

Conclusion

Chapter 2: Agentic Concepts Everyone Must Learn

The Core Concepts

Quick Vocabulary

Model Creation Basics

LLMs

Natural Language Processing

Fine-Tuning

RAG

Context Aware

Agentic Reality

Agents

Provider/Framework Tools

Building Your First Agent
Problems in the AI Space
Conclusion
Chapter 3: Agentic AI in Kubernetes and Cloud-Native
Agentic in the Cloud
Agentic in Azure
Agentic in AWS
Agentic in Kubernetes
Why AI in K8s Makes Sense
Running Traditional ML Workloads in Kubernetes
LLMs Deployed in Kubernetes
Build a Platform Engineering Agent
Installing Kagent
Installing and Configuring Agentgateway
Declarative Agent Configuration
Using the Agent
Conclusion
Chapter 4: Monitoring and Observability for Agentic Infrastructure
Implementing Monitoring and Observability Practices for AI
Agentic Preparation
Installing and Configuring OSS Observability
Implementing Metrics Capture for Your Gateway
Custom Cost Control and Dashboards per Gateway
Out-of-the-Box Agentgateway Control

Inspecting Traces
Enterprise Tooling for Monitoring and Observability
Configuring Datadog
Conclusion
Chapter 5: Extending LLM Knowledge for Production
Model Context Protocol (MCP)
What Is MCP
The MCP Spec
MCP Modes
Stateless MCP Spec
Connecting to MCP Servers
MCP in Kubernetes Servers
Building Your Own MCP Server
Connecting Agents to MCP Servers
Agent Skills
The Birth of Skills
Writing Your Own Skill
Prompting
Prompting Workflow
Prompt Best Practices
The Test for Better Performance
Conclusion
Chapter 6: Securing Agentic Environments
Agentic and Agentic Networking Security

OSS vs. Enterprise
Authorization Protocols
Part 1: Securing Agents
Prompt Injection
OIDC-Based OAuth
Human-in-the-Loop
Part 2: Securing Agentic Networks
Agentic Frameworks and AI Gateways Together
Prompt Guards
Rate Limits

MCP Tool Lockdown
Part 3: Agent Sandboxes
Conclusion
Agent Sandboxing
What Sandboxing Technically Is
How to Implement Sandboxing Today
Enter Agent Substrate
Software-Level Isolation
Hardware-Level Isolation
Workers
Actors
Agent Substrate Is the Lower-Level Implementation
Concluding Remarks

Index

About the Author

Michael Levan
translates technical complexity into practical value. He is an AI architect, solutions engineer, and content creator in the AI and platform engineering space who spends his time working with organizations around the globe on technical implementation and strategy. Michael is also a Microsoft MVP, 4x published author, podcast host, international public speaker, and CNCF Ambassador and was part of the Kubernetes v1.28 and v1.31 Release Team.

About the Technical Reviewer

Sundeep Bobba

is a technical leader in Cloud and DevOps engineering with over 16 years of experience designing and operating large-scale cloud-native platforms and enterprise software delivery systems. He has led DevOps and DevSecOps modernization initiatives for mission-critical, high-availability systems supporting multi-billion-dollar digital businesses. His work focuses on treating software delivery as an engineered system, integrating CI/CD, security controls, observability, and governance into cohesive, scalable platforms. Sundeep has architected and operated complex delivery pipelines, platform engineering frameworks, and risk-aware release systems in highly regulated and high-throughput environments.

Sundeep is an invited speaker at international DevOps and Cloud conferences and has authored technical publications and industry case studies on modern CI/CD and cloud automation practices. He actively contributes to the global DevOps and platform engineering community through technical writing, peer review, and advisory roles. He holds a master's degree in computer science and is a Fellow of the British Computer Society and an IEEE Senior Member. His current work explores system-level approaches to software delivery, focusing on feedback loops, decision boundaries, and control mechanisms for enterprise-scale DevOps and DevSecOps platforms.

1. The Rise of AI in DevOps and Platform Engineering

Michael Levan[1] ✉
(1) Budd Lake, NJ, USA

The tech space, whether you're in leadership, management, project management, engineering, or any other role in software, typically sees major ecosystem shifts every five to seven years (minus/plus a few years). We saw it when we moved from bare-metal to virtualization, virtualization to the cloud, and then to implementations with containerization and Kubernetes, along with many other changes that have happened since software engineering began 65 years ago. We're now seeing that difference with AI. What started out as a fun way to ask questions about a food recipe or places to travel has quickly turned into key differences in how many large and small organizations are thinking about implementing software, monitoring, observability, systems, and overall architecture in the software engineering, DevOps, and platform engineering realm.

In this chapter, you'll learn about

- The latest implementation details with AI (as of when this book was written).
- The rise of agentic infrastructure and AI agents in platform engineering, DevOps, and software engineering.
- Shifts in engineering mindset with AI.
- How to build and fine-tune an AI Model.

The important thing to remember as you go through this chapter (rather, the entire book) is it's not going to teach you how to become a data scientist or a machine learning engineer. You're not going to learn super complex algorithms and mathematical calculations that you'd see in a Harvard PhD classroom (and that's a good thing because I know about 1% of what would be on that whiteboard). Instead, you're going to learn the agentic AI side of things, which is what you'll primarily see in a role as a platform engineer, DevOps engineer, SRE, software engineer, and agentic AI/AI architect in the cloud-native world.

Where AI Stands Today

AI has been the "popular thing" for a few years now in the engineering space and the timeline is quite intriguing. Typically, when it comes to the enterprise, there's usually a one- to three-year period when a new technology/platform gets the "kinks worked out" during the testing phase. When virtualization came out, a lot of people said for a few years "this is a toy. It'll only be for lab based environments and demos." The same thing happened when the cloud came out, when containers came out, and when Kubernetes came out. Then, after a few years of each cycle, people said "okay, this looks good – let's move it to production."

With AI, however, this was not the case. It's almost like no one is working out the kinks. AI standards are evolving considerably faster than previous infrastructure technologies, leading many organizations to evaluate and adopt emerging patterns while governance practices continue to mature. A great example of this is Model Context Protocol (MCP). At the time of writing this, MCP will be one year old in two days. However, it's already considered the standard for incorporating tools and extending the capabilities of models.

So, where does AI stand today? The best answer is "buckle up, it's going to be an intense ride." Standards will change, companies will fall, and standardization around it all is quite a while away. The one thing that we do know is AI is here to stay, and in this section, you'll learn

about the mindset shift and some vocabulary to help you through your AI journey.

Agentic Vocabulary

Before going any further, it's safe to say that you will hear a lot of new vocabulary and acronyms in the AI space. To hopefully help with that, here's a brief section that outlines the top vocabulary that you should be accustomed to in the AI space.

1. Datasets: Anything from any Excel spreadsheet to a JSON configuration (structured data, unstructured data, books, websites, images, etc.) that you use to train a model. It's a curated, organized collection of data.
2. Model: A trained system that learns patterns from data and uses them to make predictions or generate outputs. Models are created through machine learning, which involves training algorithms.
3. Large language models (LLMs): LLMs are, as the name suggests, large models trained on a vast amount of information. They are models with billions of parameters trained on massive datasets. The popular ones you see now are GPT, Gemini, Llama, Claude, DeepSeek, and a few others.
4. Prompts: A prompt is the question or the statement that you send to an LLM. For example, if you open ChatGPT and say "What's the best chicken parm recipe?", that's a prompt. Prompts can also be very complex and worded just right so the LLM has the exact direction that it needs to fulfill a request.
5. Agentic AI: AI focused on autonomous decision-making and action.
6. Traditional AI: Traditional AI focuses on prediction, classification, optimization, and decision support using statistical and machine learning techniques rather than autonomous reasoning and task execution

execution.

7. Agentic infrastructure: Infrastructure responsible for deploying, orchestrating, governing, securing, monitoring, and operating AI agents throughout their lifecycle.
8. Tokenizer: A tokenizer breaks down text into smaller units called **tokens** that the model can understand and process numerically. Then, a token ID is assigned to each token.
9. Embeddings: Embeddings convert text into dense numerical vectors that preserve semantic relationships, allowing models to compare similarity and retrieve relevant information efficiently.
10. Model Context Protocol (MCP): MCP is typically talked about when mentioning MCP servers, which are either local Python/NPM packages or a server hosting the Python/NPM packages to extend the capabilities of an agent.
11. Retrieval-Augmented Generation (RAG): Optimizing the output of an agent/LLM. You'll usually see RAGs used to extend the knowledge of an agent. For example, if you're writing a Kubernetes troubleshooting agent, you may write a RAG which could be a JSON template or something that points to URLs on the internet with the knowledge that the agent needs.
12. Skills: Skills are a new topic from Anthropic that are essentially an external RAG. It allows you to externally store, within a package, a prompt, files, scripts, and anything else that an agent would need to extend its knowledge.

The Mindset Shift

In November of 2022 (exactly three years ago at the time of writing this section), ChatGPT was released. This sparked several opinions ranging from "robots are going to take over" to "our jobs are going to be gone" to "eh, nothing is going to happen." Ironically enough, all three came

true at almost the same time. More and more AI spread across various organizations and standard business-to-consumer (B2C) platforms. For example, right before I started writing this section, I was watching a show on Hulu and the Ads were all about ecommerce sites and businesses implementing AI to make things faster. The same thing is happening in healthcare, finance, and just about every other type of business.

The key thing to remember is that although AI is shifting things, it's no different than what has been occurring since the beginning of time. At one point, one of the top jobs and the wealthiest people were horse saddle creators. Then, cars came out, and poof, no one was riding horses anymore. The same thing applies to technology. Rather than eliminating most technical roles, new technologies typically reshape responsibilities and create new specializations. When PowerShell (scripting language) became very popular, there were a large amount of threads on forums that went something along the lines of "all Sysadmin jobs are going to go away." Instead, they shifted into cloud engineers and DevOps engineers. The same thing happened with the "NoCode/LowCode" trend, when the cloud came out, when Kubernetes came out, and when virtualization came out.

Regardless of the trend, there are always three groups of people:

1. People that say "no, this isn't going to change anything."
2. People that say "this is garbage!" (and maybe some bad words).
3. People that embrace the change, learn it, and move with it.

The people that fall into Category 3 are the individuals who prosper. The people that fall into Categories 1 and 2 unfortunately find themselves looking for work. The people that stay in the same organization for 10–20 years doing a similar job and not progressing/learning new things. Now, there's nothing wrong with staying in a job for that long, but the point is that if you are in a job like that, you need to continue to learn, embrace the change, and move with

it. The same rules apply for folks that have been in tech for one year or 50 years.

From a platform engineering and DevOps perspective, AI is starting to embed itself into various portions of the organization. You'll need to think about things like "what's the cost of these Tokens from a FinOps perspective" and "can Agents talk to any LLM? How about any MCP server?".

This section was created just as a friendly reminder to embrace change, push forward, learn new things, and most importantly, enjoy the process and the journey.

In the rest of this chapter, you'll dive right into the first hands-on piece which every engineer should know prior to expanding AI knowledge – models from a hands-on perspective.

AI Models

I'm a firm believer that every engineer needs to "walk, crawl, run." As time goes on and new trends come out, everyone wants to dive into what the hype is for several reasons:

1. More money
2. More status
3. Better opportunities within organizations

However, that leaves out the most important part of learning something new – the core concepts. A great example of this is when Kubernetes became incredibly popular. Every new college graduate or person with one year of experience wanted to dive into Kubernetes. The problem was that they didn't know the core concepts (systems, infrastructure, networking, and programming). Without those core concepts, the foundation of knowledge is brittle.

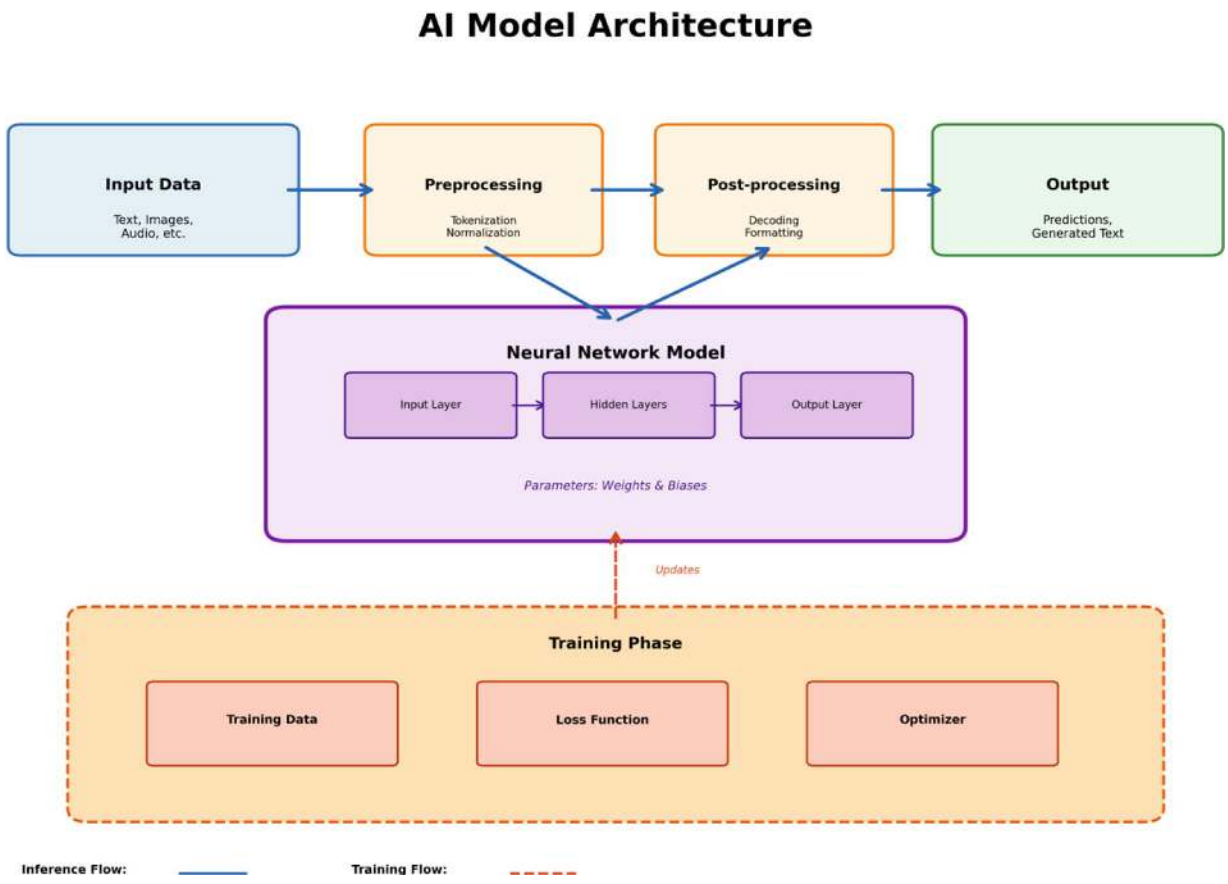
The same rules apply with AI. Yes, there are many different avenues of AI (being a machine learning engineer vs. an agentic/AI architect).

Some specialties focus on training models and others focus on using models. Taking that a step further, being a platform engineer in today's world means using agentic infrastructure for things like observability and security.

One thing holds true though – every platform engineer should understand model fundamentals sufficiently to integrate, monitor, troubleshoot, and operate AI-powered systems, even if they are not responsible for training foundation models, and that's what this section is all about.

What Is a Model

An AI model (see the following figure), whether it's an LLM or not, is a purpose-built, trained system that was trained on a subset of data (called a dataset). It is then used to make predictions (this is where inference comes into play) based on the data that it was trained on. As an example, a self-driving vehicle is trained on several datasets, which, in this case, is data from the vehicle. Because the car has seen stop signs before, when it sees a new stop sign during inference, it makes a prediction that says something like "this is a stop sign, so it's appropriate to stop."



Model Tools

Models are a collection of trained data. The data that is used to train a model is based on sets of data (datasets) and varies based on what the job of the model is. For example, if a model is being trained to predict the housing market (when house prices will go down), the datasets used to trained the model will most likely be years of data collected and consolidate in some database or data warehouse that consists of things like the months of the year when house prices drop, when they go up, and what economic considerations are needed when making predictions (e.g., uncertainty in the economy leads to lower interest rates). Because of the various differences in what a model will do, it's good to understand the types of models there are and what tools you'll use to build them.

You'll typically see two types of models:

1. Deep learning models

2. Traditional/lightweight models

Deep learning models have several layers (e.g., neural networks). They are more advanced, require training data from various forms of datasets, and are larger in size. You'll typically see deep learning models in things like image recognition and speech recognition. Traditional/lightweight models are simpler models that you'll usually see in models like predicting house prices, fraud detection, and less complex tasks. They're great for structured data and smaller datasets.

A few popular tools that you will see for deep learning (and even simpler models, but usually for deep learning) are PyTorch and TensorFlow. Traditional/lightweight models are usually done in scikit-learn.

Agentic/AI Harness

Over the past six months, at the time of writing this (8/31/2026), if you've been in or have been using AI at all, you've most likely heard the phrase "AI Harness" or "Agentic Harness." As with most things in the AI space, terms may change depending on who you ask. Looking across the industry, "harness" typically means where you run agents and the tools that are available. For example, OpenCode, Claude Code, Codex, ABox (https://github.com/AdminTurnedDevOps/ABox), and OpenClaw are all considered harnesses.

As you build tooling and use this book, you'll use agents, so it's important to understand at this step of the book what exactly a "harness" is.

Building Models

When people think of AI models in today's world, they're thinking of LLMs. LLMs are, as the name suggests, large models. That's why the systems needed to train these models cost millions of dollars. Those

aren't the only type of models that are available though. In fact, you can build a model right on your desktop or laptop, regardless of the operating system, right now.

In this section, you'll learn how to build a small model, train the model on a dataset, and run the model locally.

1. Define the libraries that will be used to train the model. In this case, you'll use scikit-learn as it's great for traditional/lightweight models.

```
        from sklearn.ensemble import
RandomForestClassifier
        from sklearn.model_selection import
train_test_split
        import numpy as np
```

2. Next, create some sample data that you'll feed into the model. The sample data below is for helpdesk ticket classification. The goal here is to build a model that helps with prioritizing tickets that come into the helpdesk.

```
        def create_sample_data():
            """
            Create sample training data for
ticket classification.

            Features represent:
            - Number of affected users
            - System load (%)
            - Error count in last hour
            - Time since last deployment (hours)
            """
            # Sample data: [users_affected,
system_load, errors, hours_since_deploy]
            X = np.array([
```

```
                [100, 85, 50, 2],    # High
priority
                [10, 45, 5, 48],     # Low
priority
                [500, 90, 100, 1],   # High
priority
                [5, 30, 2, 72],      # Low
priority
                [200, 80, 75, 3],    # High
priority
                [15, 50, 8, 36],     # Low
priority
                [50, 70, 30, 12],    # Medium
priority
                [300, 88, 80, 2],    # High
priority
                [8, 35, 3, 60],      # Low
priority
                [150, 75, 40, 6],    # High
priority
            ])

            # Labels: 0 = Low, 1 = Medium, 2 =
High priority
            y = np.array([2, 0, 2, 0, 2, 0, 1, 2,
0, 2])

            return X, y
```

3. The main function prepares the data from the sample dataset, splits the data into training and test sets, creates and trains the model, and evaluates the model.

```
        def main():
            print("=" * 60)
```

```
            print("Building a Simple Machine
Learning Model")
            print("=" * 60)

            # Step 1: Prepare the data
            print("\n1. Creating sample support
ticket data...")
            X, y = create_sample_data()
            print(f"   Created {len(X)} training
examples")

            # Step 2: Split data into training
and test sets
            print("\n2. Splitting data into
training and test sets...")
            X_train, X_test, y_train, y_test =
train_test_split(
                X, y, test_size=0.3,
random_state=42
            )
            print(f"   Training set:
{len(X_train)} examples")
            print(f"   Test set: {len(X_test)}
examples")

            # Step 3: Create and train the model
            print("\n3. Training the model...")
            model =
RandomForestClassifier(n_estimators=10,
random_state=42)
            model.fit(X_train, y_train)
    print("   ✓ Model trained successfully!")

            # Step 4: Evaluate the model
            print("\n4. Evaluating model
accuracy...")
```

```
            accuracy = model.score(X_test,
y_test)
            print(f"   Model accuracy: {accuracy
* 100:.1f}%")

            # Step 5: Use the model to make
predictions
            print("\n5. Using the model to
predict priority for new tickets...")
            print("-" * 60)

            # New ticket examples
            new_tickets = [
                [250, 82, 65, 4],    # Should be
High priority
                [12, 40, 6, 50],     # Should be
Low priority
            ]

            priority_labels = {0: "Low", 1:
"Medium", 2: "High"}

            for i, ticket in
enumerate(new_tickets, 1):
                prediction =
model.predict([ticket])[0]
                priority =
priority_labels[prediction]

                print(f"\nNew Ticket #{i}:")
                print(f"  - Users affected:
{ticket[0]}")
                print(f"  - System load:
{ticket[1]}%")
                print(f"  - Errors: {ticket[2]}")
```

```
                print(f"  - Hours since deploy:
{ticket[3]}")
                print(f"  → Predicted Priority:
{priority}")

            print("\n" + "=" * 60)
            print("Key Takeaways:")
            print("=" * 60)
    print("✓ Models learn patterns from training
data")
    print("✓ Training = teaching the model with
examples")
    print("✓ Inference = using the model to make
predictions")
    print("✓ Agents can use models to make
automated decisions")
            print("=" * 60)
```

Altogether, the model should look like the below (and you can find the code here):

```
        from sklearn.ensemble import
RandomForestClassifier
        from sklearn.model_selection import
train_test_split
        import numpy as np

        def create_sample_data():
            """
            Create sample training data for
ticket classification.

            Features represent:
            - Number of affected users
            - System load (%)
            - Error count in last hour
```

```
            - Time since last deployment (hours)
            """
            # Sample data: [users_affected,
system_load, errors, hours_since_deploy]
            X = np.array([
                [100, 85, 50, 2],    # High
priority
                [10, 45, 5, 48],     # Low
priority
                [500, 90, 100, 1],   # High
priority
                [5, 30, 2, 72],      # Low
priority
                [200, 80, 75, 3],    # High

automated decisions")
            print("=" * 60)

        if __name__ == "__main__":
            main()
```

4. With the code saved, it's time to run it. First, ensure that you have the scikit-learn and numpy (for mathematical operations) libraries installed on your system.

```
pip install scikit-learn numpy
```

5. Run and build the model

```
python simple-model.py
```

You should see terminal output similar to the following figure.

```
============================================================
Building a Simple Machine Learning Model
============================================================

1. Creating sample support ticket data...
   Created 10 training examples

2. Splitting data into training and test sets...
   Training set: 7 examples
   Test set: 3 examples

3. Training the model...
   ✓ Model trained successfully!

4. Evaluating model accuracy...
   Model accuracy: 100.0%

5. Using the model to predict priority for new tickets...
------------------------------------------------------------

New Ticket #1:
  - Users affected: 250
  - System load: 82%
  - Errors: 65
  - Hours since deploy: 4
  → Predicted Priority: High

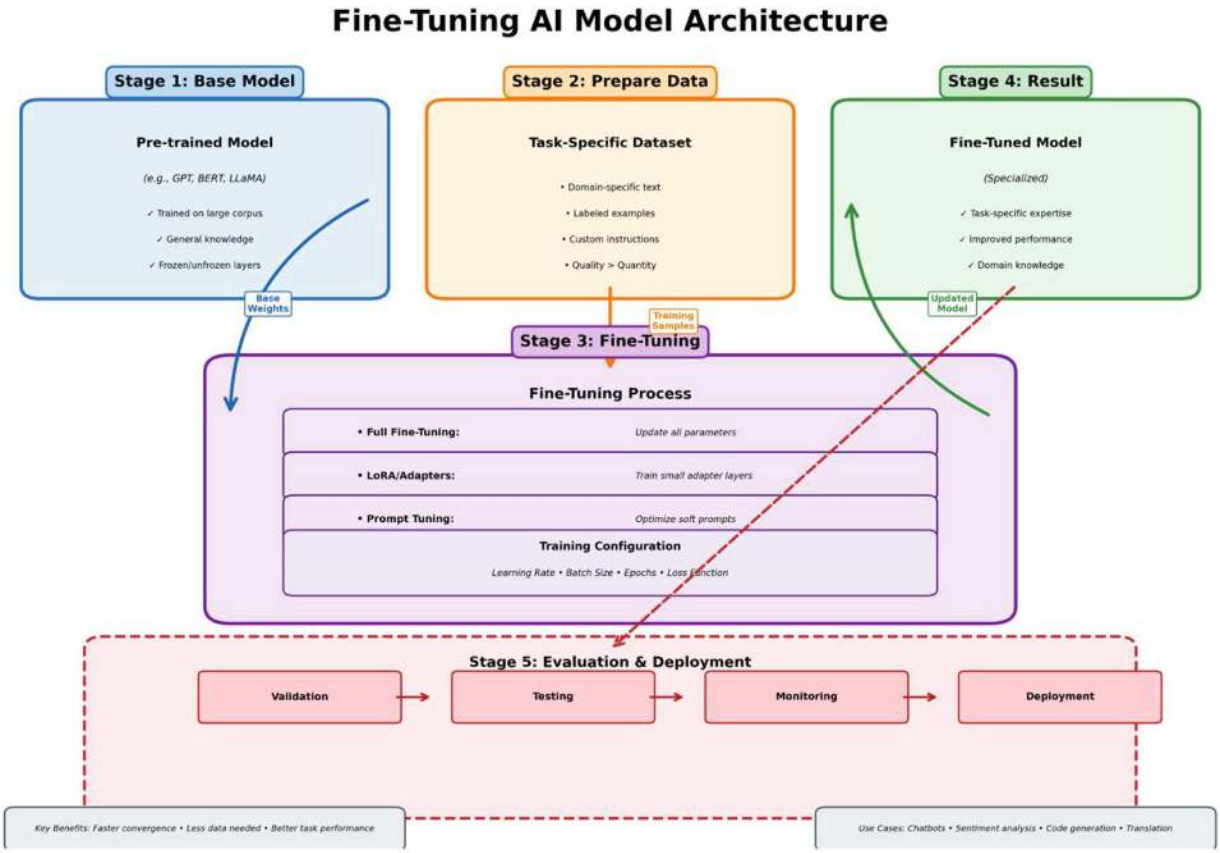
New Ticket #2:
  - Users affected: 12
  - System load: 40%
  - Errors: 6
  - Hours since deploy: 50
  → Predicted Priority: Low
```

Fine-Tuning Models

In the previous section, you learned how to create a model. You may be thinking to yourself, “oh, that was easy!” and that’s true, until you have millions or billions of parameters. Then, it becomes complex and expensive. That’s why when models from OpenAI, Google, and Anthropic are trained, it costs millions of dollars. Because the cost is so

exponential, engineers and organizations have turned to fine-tuning models.

Fine-tuning adapts a pretrained model using task-specific data. Techniques such as LoRA accomplish this efficiently by training lightweight adapter parameters rather than updating every parameter in the foundation model.



If you're using something like a Llama or DeepSeek local model and you want it to have more information about cars for an automotive agent you're building, you can fine-tune the model with datasets that have information about the automotive industry.

The steps to fine-tune a model, at a high level, are as follows:

1. Pick a model: Could be a local model or a SaaS-based model like Claude if you use the tools available from the provider.
2. Set up specific parameters: You'll pass in configuration settings for the model and training arguments (e.g., output directory of the

the model and training arguments (e.g., output directory of the model, save steps, logging steps, learning rate, batch size for examples processed at once, etc.).
3. Load a dataset: Import the data that you want the model to be trained/tuned on.
4. Set the fine-tuning approach: Typically, you'll use configurations like LoRA (if you're fine-tuning on systems that aren't millions of dollars) as LoRA allows you to add new matrices (think linear algebra) to existing parameters instead of having to update/modify millions or billions of parameters from existing models.
5. Train the model.

Create the Dataset

The dataset, in this case, will be a structured JSON configuration that feeds information to the model to teach it how to be an Istio Ambient Mesh expert (this is a small dataset). Save the dataset as "istio_ambient_dataset.json."

```
[
  {
    "instruction": "How do I check if Istio
Ambient Mesh is properly installed?",
    "input": "",
    "output": "To verify Istio Ambient Mesh
installation:\n\n1. Check the ztunnel DaemonSet is
running:\n   kubectl get daemonset -n istio-system
ztunnel\n\n2. Verify CNI plugin
installation:\n   kubectl get daemonset -n istio-
system istio-cni-node\n\n3. Check waypoint proxy
status:\n   kubectl get gateway -n istio-
system\n\n4. Verify ambient mode is
enabled:\n   kubectl get configmap istio -n istio-
```

```
system -o yaml | grep AMBIENT\n\nAll components
should show READY status."
  },
  {
    "instruction": "My pods are not being enrolled
in the ambient mesh. What should I check?",
    "input": "",
    "output": "If pods aren't enrolling in ambient
mesh, check these common issues:\n\n1. Verify
namespace has the ambient label:\n   kubectl get
namespace <namespace> --show-labels\n   Look for:
istio.io/dataplane-mode=ambient\n\n2. Add the
label if missing:\n   kubectl label namespace
<namespace> istio.io/dataplane-mode=ambient\n\n3.
Check ztunnel logs for errors:\n   kubectl logs -n
istio-system -l app=ztunnel\n\n4. Verify pod has
ztunnel redirection:\n   kubectl get pod <pod-
name> -o yaml | grep istio-proxy\n\n5. Restart
pods after labeling namespace:\n   kubectl rollout
restart deployment -n <namespace>"
  },
]
```

Model/LoRA Configuration

The model configuration consists of what model you want to use. Typically, when fine-tuning using the Hugging Face/Transformers method, you have to authenticate to Hugging Face. However, the DeepSeek model used below does not require authentication to Hugging Face. You can, of course, use any Hugging Face compatible open-weight model.

The LoRA configuration sets the training parameters.

```
MODEL_NAME = "deepseek-ai/deepseek-coder-1.3b-
base"  # Best for technical content!
```

```
# LoRA configuration - These parameters control the adapter layer
LORA_R = 16                        # Rank of the adapter matrices (higher = more capacity, more params)
LORA_ALPHA = 32                    # Scaling factor (typically 2x the rank)
LORA_DROPOUT = 0.05                # Dropout for regularization
LORA_TARGET_MODULES = [            # Which layers to add adapters to
    "q_proj",                      # Query projection in attention
    "k_proj",                      # Key projection in attention
    "v_proj",                      # Value projection in attention
    "o_proj",                      # Output projection in attention
]

# Training configuration
OUTPUT_DIR = "./results"
DATASET_PATH = "./istio_ambient_dataset.json"
MAX_LENGTH = 512                   # Maximum sequence length
BATCH_SIZE = 4                     # Batch size per device (M3 Max can handle 4-8)
GRADIENT_ACCUMULATION = 4          # Accumulate gradients over N steps (effective batch = 4*4=16)
LEARNING_RATE = 2e-4               # Learning rate for AdamW optimizer
NUM_EPOCHS = 3                     # Number of training epochs
WARMUP_STEPS = 50                  # Learning rate warmup steps
```

```
SAVE_STEPS = 100                # Save checkpoint
every N steps
LOGGING_STEPS = 10              # Log metrics every
N steps
```

Load Dataset

With the dataset that you saved in the "istio_ambient_dataset.json" file, you can load it into memory to be used with the training configuration.

```
def load_and_format_dataset(dataset_path):
    """
    Load the Istio Ambient Mesh dataset and format
it for instruction tuning.

    The dataset format is:
    {
        "instruction": "Question about Istio",
        "input": "Optional context",
        "output": "Answer to the question"
    }

    We'll format this as:
<instruction>\n\n<output>
    """
    print(f"Loading dataset from
{dataset_path}...")

    with open(dataset_path, 'r') as f:
        data = json.load(f)

    # Format each example as a prompt-completion
pair
    formatted_data = []
    for item in data:
        # Create instruction format
        if item['input']:
```

```
            text = f"### Question:
{item['instruction']}\n### Context:
{item['input']}\n### Answer: {item['output']}"
        else:
            text = f"### Question:
{item['instruction']}\n### Answer:
{item['output']}"

        formatted_data.append({"text": text})

    print(f"Loaded {len(formatted_data)}
examples")

    # Convert to HuggingFace Dataset
    dataset = Dataset.from_list(formatted_data)
    return dataset

def tokenize_function(examples, tokenizer):
    """
    Tokenize the text examples.

    This converts text into token IDs that the
model can process.
    """
    return tokenizer(
        examples["text"],
        truncation=True,
        max_length=MAX_LENGTH,
        padding="max_length"
    )
```

Model and Tokenizer Setup

With the dataset and LoRA configurations loaded for fine-tuning, you can now load the base model, the tokenizer, and apply the LoRA configurations.

```
def setup_model_and_tokenizer(model_name):
    """
    Load the base model and tokenizer, then apply
LoRA.

    Steps:
    1. Load tokenizer
    2. Load model (full precision on Mac, no
quantization)
    3. Apply LoRA configuration
    """
    print(f"Loading model: {model_name}")

    # Load tokenizer
    tokenizer =
AutoTokenizer.from_pretrained(model_name)
    tokenizer.pad_token = tokenizer.eos_token  #
Set padding token
    tokenizer.padding_side = "right"           #
Pad on the right side

    # Load model - no quantization on Mac
(bitsandbytes requires CUDA)
    # M3 Max has unified memory, so we can load
the full model
    model = AutoModelForCausalLM.from_pretrained(
        model_name,
        device_map="auto",                    #
Automatically use available device (MPS/CPU)
        torch_dtype=torch.bfloat16,         # Use
bfloat16 (works well on Apple Silicon)
        low_cpu_mem_usage=True,             #
Optimize memory loading
    )

    # Configure LoRA
```

```
    # This creates the small adapter matrices that
will be trained
    lora_config = LoraConfig(
        r=LORA_R,                           # Rank
of adapter matrices
        lora_alpha=LORA_ALPHA,              #
Scaling factor
        target_modules=LORA_TARGET_MODULES, #
Which layers to adapt
        lora_dropout=LORA_DROPOUT,          #
Dropout rate
        bias="none",                        #
Don't train bias terms
        task_type="CAUSAL_LM"               #
Causal language modeling task
    )

    # Apply LoRA to the model
    # This freezes the base model and adds
trainable adapter layers
    model = get_peft_model(model, lora_config)

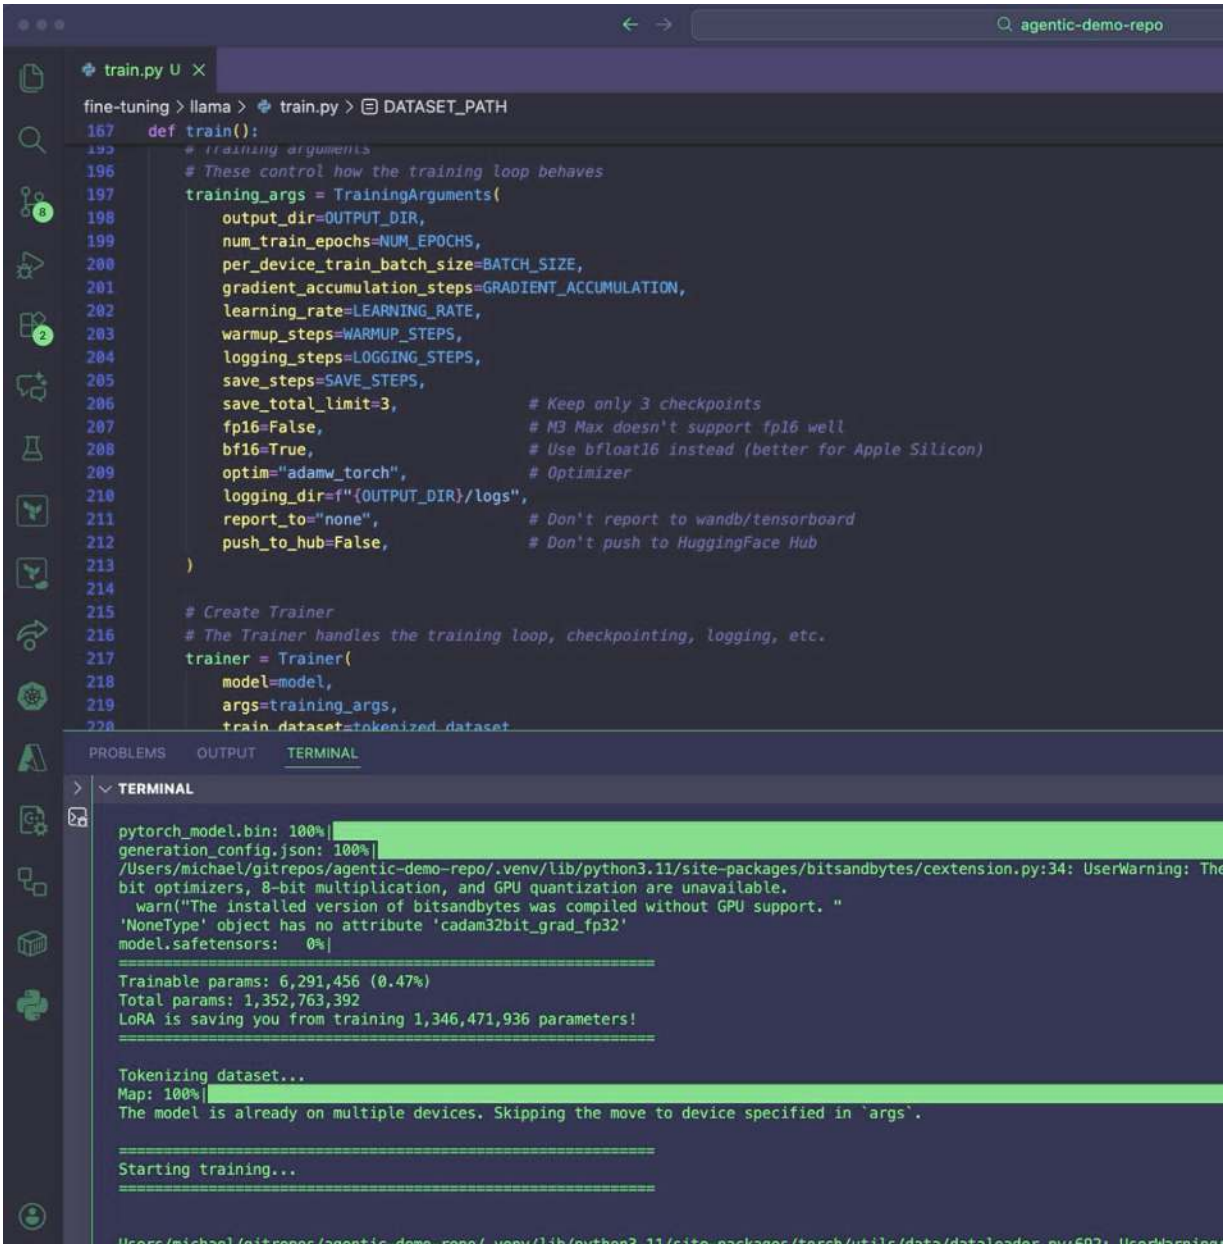
    # Print trainable parameters
    trainable_params = sum(p.numel() for p in
model.parameters() if p.requires_grad)
    total_params = sum(p.numel() for p in
model.parameters())
    print(f"\n{'='*60}")
    print(f"Trainable params: {trainable_params:,}
({100 * trainable_params / total_params:.2f}%)")
    print(f"Total params: {total_params:,}")
    print(f"LoRA is saving you from training
{total_params - trainable_params:,} parameters!")
    print(f"{'='*60}\n")

    return model, tokenizer
```

Train Model

The final step is to train the model. You can pass in all of your training arguments and create the trainer using the trainer function/method. The configuration is quite large, so you can find the full codebase here: https://github.com/AdminTurnedDevOps/Agentic-AI-For-Platform-Engineering-Book/blob/main/Chapter1/fine-tuning/train.py.

Save the training script as “train.py,” and run “python train.py.” You should see output similar to the following figure.



Congrats! You have officially trained your first model!

Conclusion

Chapter 1 started off with some key knowledge that you'll need when diving into any AI and/or agentic AI environment. It then went into a few hands-on pieces with building and training your own model and also fine-tuning an existing model (which is most likely what you'll see the most in your job).

I'll leave you with this – you don't have to be a model creation expert in the world of AI and agentic when it comes to DevOps and platform engineering. It's not like you have to quit your job and go to school to become a data scientist. However, understanding the way AI, training, and models work underneath the hood (which you learned in this chapter) will help you a ton in understanding the process of implementing AI and even for basic tasks like opening ChatGPT and asking a question. It's good to understand the core concepts of the technology stack you're working with.

2. Agentic Concepts Everyone Must Learn

Michael Levan[1] ✉
(1) Budd Lake, NJ, USA

The rise of AI and all things agentic AI is no secret to anyone. This morning at the gym, I did something I haven't done in a long time – turned on the news. The reason why is because I saw "AI bubble?" on the screen, so I unmuted the TV and listened for a bit while working out. One thing that became apparent very quickly is that it sounds like the AI bubble is people who are talking about the AI bubble. When that was realized, it became incredibly clear that learning about core AI concepts is very important, as it's here to stay.

That's why, in this chapter, you will learn about

- Core concepts like what LLMs are.
- Agents, chatbots, and the overall "where everyone seems to be starting" when it comes to AI.
- How to think about problems in the AI space (like hallucinations).
- Building your first agent.

The Core Concepts

When thinking about how AI works, we need to look underneath the curtain to see how it's made up. The challenge in the AI space is that there are a lot of different directions you can go. Most meetings I'm on consist of various members of different teams, from data scientists to

machine learning engineers to DevOps and platform engineers. When in those meetings, it's interesting because it is very clear that every team has a different focus and challenge that they are trying to solve. Taking that same mindset, based on where you are in your journey and what you're focused on, your core concepts may be different than other teams on the call. Due to this being a book about AI in the Platform Engineering realm, we'll focus on the makeup of how various "tools" like LLMs and agents work.

Quick Vocabulary

To ensure that you're prepared to go through this chapter, here are some definitions that make the most sense to know.

- Weights: Numerical values that a model has learned during training. They're the pieces that specify how much your model cares about a specific thing. For example, in a model trained to identify Italian recipes, certain parameters might have learned to strongly activate when they detect words like "pasta," "olive oil," or "parmesan" because those features were important patterns in the training data. Weights are a subset of parameters.
- Parameters: Like variables. It's the data that persists after training. Think about it like "knowledge" or "memory."
- Inference: Predictions. For example, if you ask a question, an answer/prediction is made based on the information that the model has been trained on.
- Neurons: The individual computation units in each layer of the neural network in a model. It's like a detector that learns to recognize a specific pattern in the data.

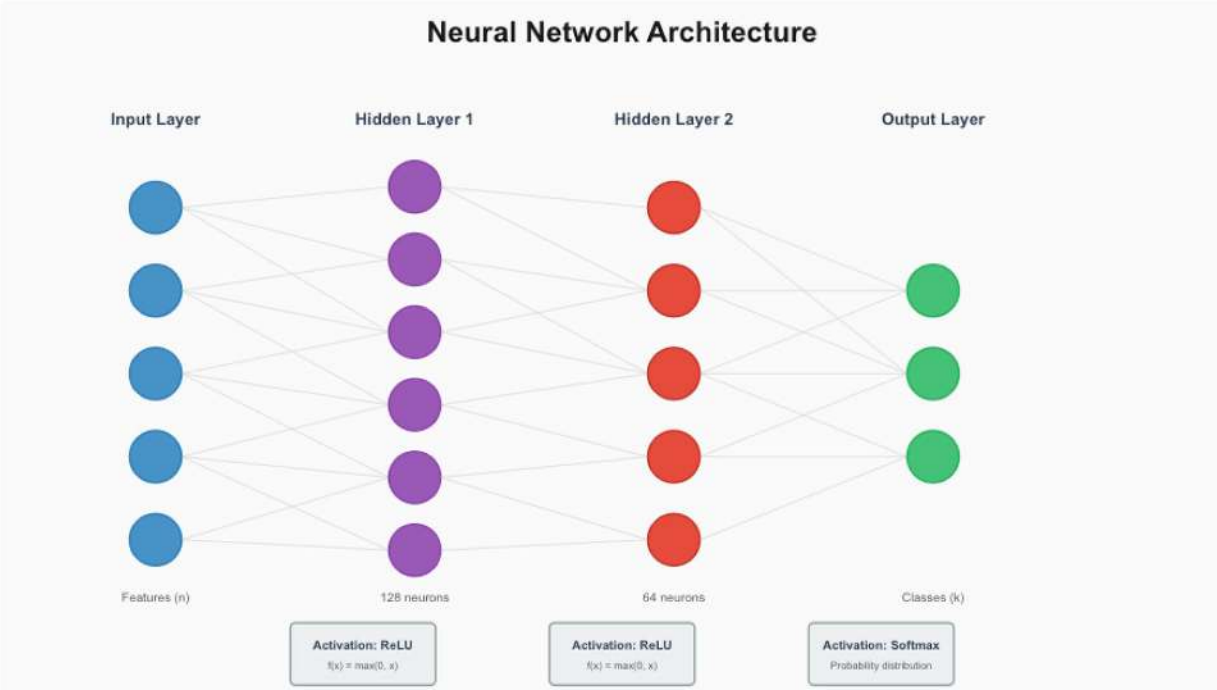
Model Creation Basics

As you're beginning your journey in understanding models, it's important to know that there are two forms of models:

1. Pretrained models
2. New models

Pretrained models are models that have already been trained (GPT-4, Llama, Claude, etc.), and with those models, you can feed in information via RAG, fine-tuning, and MCP (you'll learn about those in later sections of this chapter). For now, we will focus on new models.

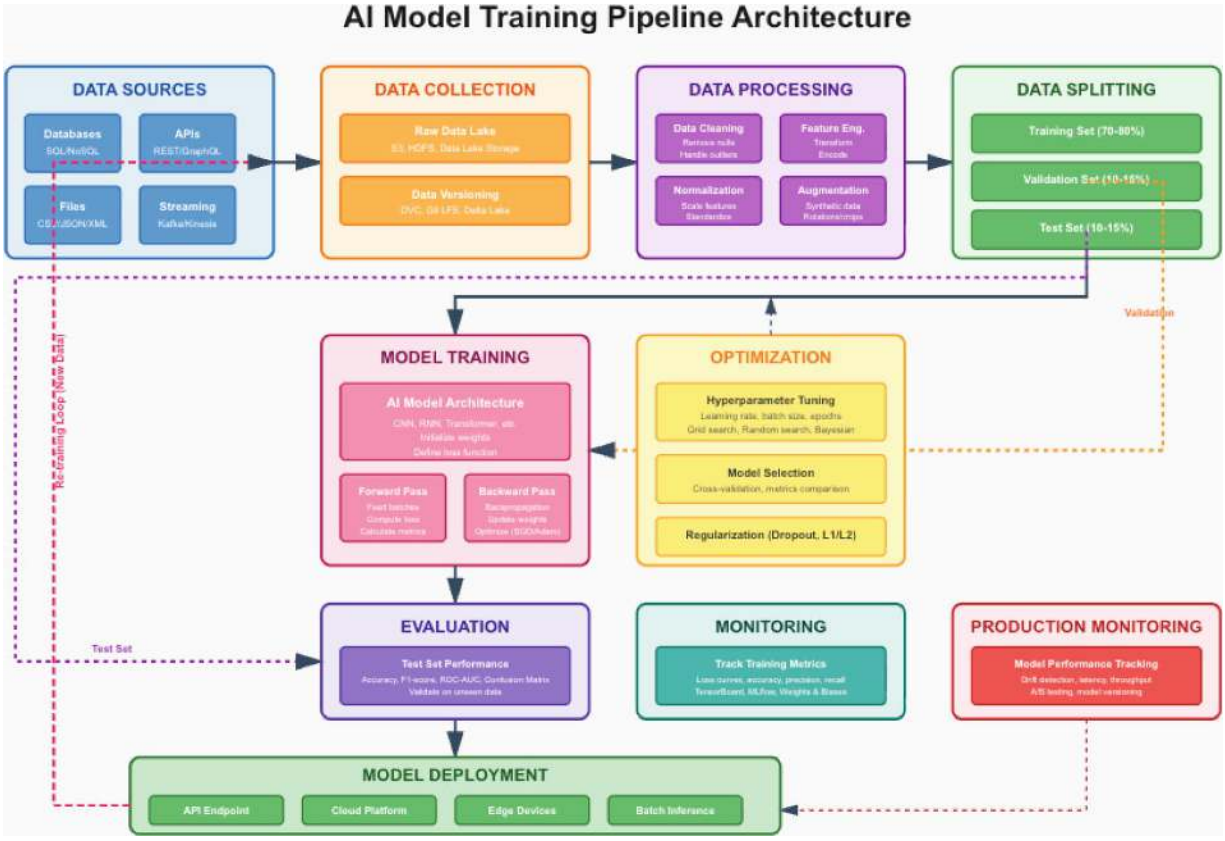
Let's take a look at the architecture in the following figure.



Taking it back to computer science class, remember vertices (nodes), which are the circles that represent neurons, and connections (edges), which are the lines that represent weighted connections between them. The edges represent weights/parameters that the model learns during training. Each edge/connection has a numerical weight that determines the influence each neuron has on another. This is a key concept when it comes to AI because the architecture (nodes and edges), combined with learned weights, defines how data is transformed. How the data is represented in a model and how that data "communicates" (nodes, edges, parameters, and weights) are the exact makeup of a model and are essential because they form the foundation of how AI models

process information and make predictions (inference). Without an understanding of these key pieces, models wouldn't exist.

When creating a model, the first step is to have or create a dataset. Once you have a dataset, you can clean/serialize the data to ensure that it can be ingested by a model. The data is loaded and then tokenized, which converts text into token IDs that the model can process. Those token IDs are then transformed into embedding vectors by the model's embedding layer, allowing the neural network to process semantic relationships during training and inference (see the vocabulary section in Chapter 1). Once the datasets are loaded, the training process can begin. Parameters/weights are then learned based on the training data throughout the training process and model creation.



Quick Model Creation

Now that you know a bit about the theory behind model creation, let's see how it works underneath the hood. Please note that the code you'll see is a basic model creation. The concepts of how you'd create

something huge like an LLM and the process you'd go through are the same, technically, in the code you'll see in this section. It's just that the datasets are much smaller, which means smaller weights/parameters.

In Chapter 1, you learned how to use the scikit-learn libraries. In this section, you'll kick things up a notch by using PyTorch, which is used for advanced model creation.

1. Install PyTorch.

```
pip install torch torchvision
```

2. Import the required libraries from PyTorch.

```
import torch
import torch.nn as nn
import torch.optim as optim
from torchvision import datasets, transforms
from torch.utils.data import DataLoader
```

3. Define a model, which will be a simple neural network with one hidden layer.

```
class SimpleNet(nn.Module):
    def __init__(self):
        super(SimpleNet, self).__init__()
        # Input: 28x28 images flattened to 784
pixels
        self.fc1 = nn.Linear(784, 128)  #
First layer: 784 -> 128
        self.relu = nn.ReLU()            #
Activation function
        self.fc2 = nn.Linear(128, 10)    #
Output layer: 128 -> 10 classes

    def forward(self, x):
```

```
        x = x.view(-1, 784)  # Flatten the
image
        x = self.fc1(x)       # First layer
        x = self.relu(x)      # Apply ReLU
        x = self.fc2(x)       # Output layer
        return x
```

4. Prepare the data for the model to be trained on. You don't have to create a dataset because this step automatically downloads the Modified National Institute of Standards and Technology (**MNIST**) dataset from the internet the first time the code runs (a default dataset for you to use from PyTorch).

```
transform = transforms.Compose([
    transforms.ToTensor(),
    transforms.Normalize((0.5,), (0.5,))
])

# Load training data
train_dataset = datasets.MNIST(root='./data',
train=True, download=True,
transform=transform)
train_loader = DataLoader(train_dataset,
batch_size=64, shuffle=True)

# Load test data
test_dataset = datasets.MNIST(root='./data',
train=False, download=True,
transform=transform)
test_loader = DataLoader(test_dataset,
batch_size=64, shuffle=False)
```

5. Initialize the model.

```
# Create model instance
```

```
model = SimpleNet()

# Define loss function (Cross Entropy for
classification)
criterion = nn.CrossEntropyLoss()
# Define optimizer (Adam is a good default
choice)
optimizer = optim.Adam(model.parameters(),
lr=0.001)
```

6. Train the model.

```
# Set number of epochs
num_epochs = 5

# Training loop
for epoch in range(num_epochs):
    model.train()  # Set model to training
mode
    running_loss = 0.0

    for images, labels in train_loader:
        # Zero the gradients
        optimizer.zero_grad()

        # Forward pass
        outputs = model(images)

        # Calculate loss
        loss = criterion(outputs, labels)

        # Backward pass
        loss.backward()

        # Update weights
        optimizer.step()

        running_loss += loss.item()
```

```
    print(f'Epoch [{epoch+1}/{num_epochs}],
Loss: {running_loss/len(train_loader):.4f}')
```

Step 1 Install the PyTorch and torchvision libraries on your system so you have the necessary tools to build neural networks (model).

Step 2 Import all the required modules/functionality you'll need from PyTorch and torchvision, including the core PyTorch functionality for building models, optimization tools for the model to perform as well as possible, and the datasets functionality for loading image datasets (hence how MNIST is downloaded by default).

Step 3 Define the architecture of your neural network by creating a class that specifies the layers (input layer with 784 neurons for flattened 28x28 images, hidden layer with 128 neurons, and output layer with ten neurons for digit classes 0–9) and how data flows through them using the forward method.

Step 4 Prepare your data by automatically downloading the MNIST handwritten digit dataset, applying transformations to convert images to tensors and normalize them, and then organizing them into batches of 64 images using DataLoader for efficient training.

Step 5 Bring everything together by creating an instance of your model, setting up a loss function (CrossEntropyLoss) to measure how wrong the predictions are, and configuring an optimizer that will adjust the model's weights to minimize that loss during training.

LLMs

All large language models (LLMs) are built with deep learning, which is a subset of machine learning and AI focused on neural networks. It

essentially means that LLMs are trained on a massive amount of text data ranging from websites to books to blogs/articles and anything in between (as long as it has the legal right to do so). In an LLM, you'll see billions of parameters. Modern LLMs often contain billions of parameters. The exact parameter counts of many commercial models, including GPT-4, have not been publicly disclosed by their providers.

At a high level, building an LLM typically involves several stages: data collection and preparation, tokenizer development, model architecture design, large-scale pretraining, alignment or instruction tuning, evaluation, deployment, and continuous monitoring. The exact workflow varies depending on the model and organization.

Ironically enough, the concepts for the model you created in the model creation section (layers, optimization, loading a dataset, and training a model) are all the same things you'd do for creating an LLM. The key differences are that LLMs use transformers, LLMs use text tokens (the dataset you loaded was images), the scale is much larger (billions of parameters/weights), and the overall training complexity is greater (because there's so much more data, which means it requires very powerful systems) due to the sheer size of an LLM compared with a smaller model.

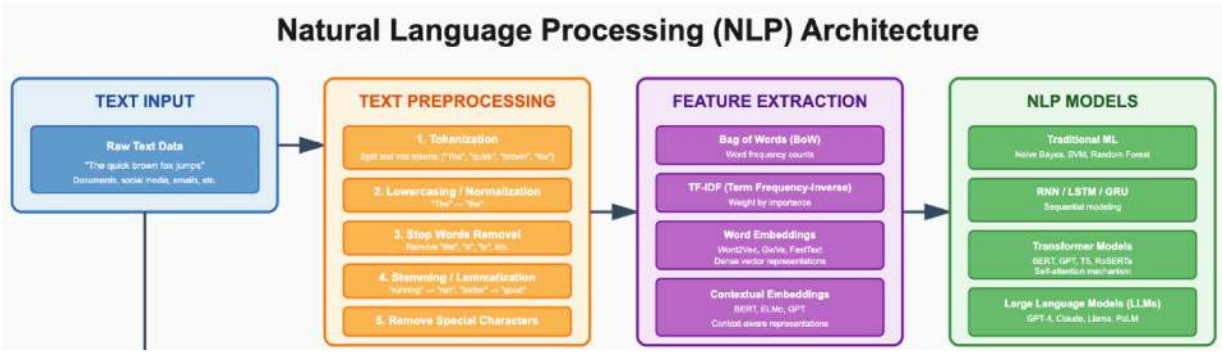
One key concept you haven't learned about yet (only briefly in Chapter 1 when talking about Hugging Face) is transformers, which you'll see and hear about a lot in the world of AI.

Transformers are the model architecture that processes embeddings. The transformer takes the embedding vectors and uses attention mechanisms to understand the semantic relationship between the tokens (the text you input or images you input that are tokenized and then converted to embedding vectors) to generate output.

Natural Language Processing

NLP is the process of getting a computer to understand and work with human language. Putting it all together, tokenization and embeddings are foundational NLP techniques, while transformers are a neural

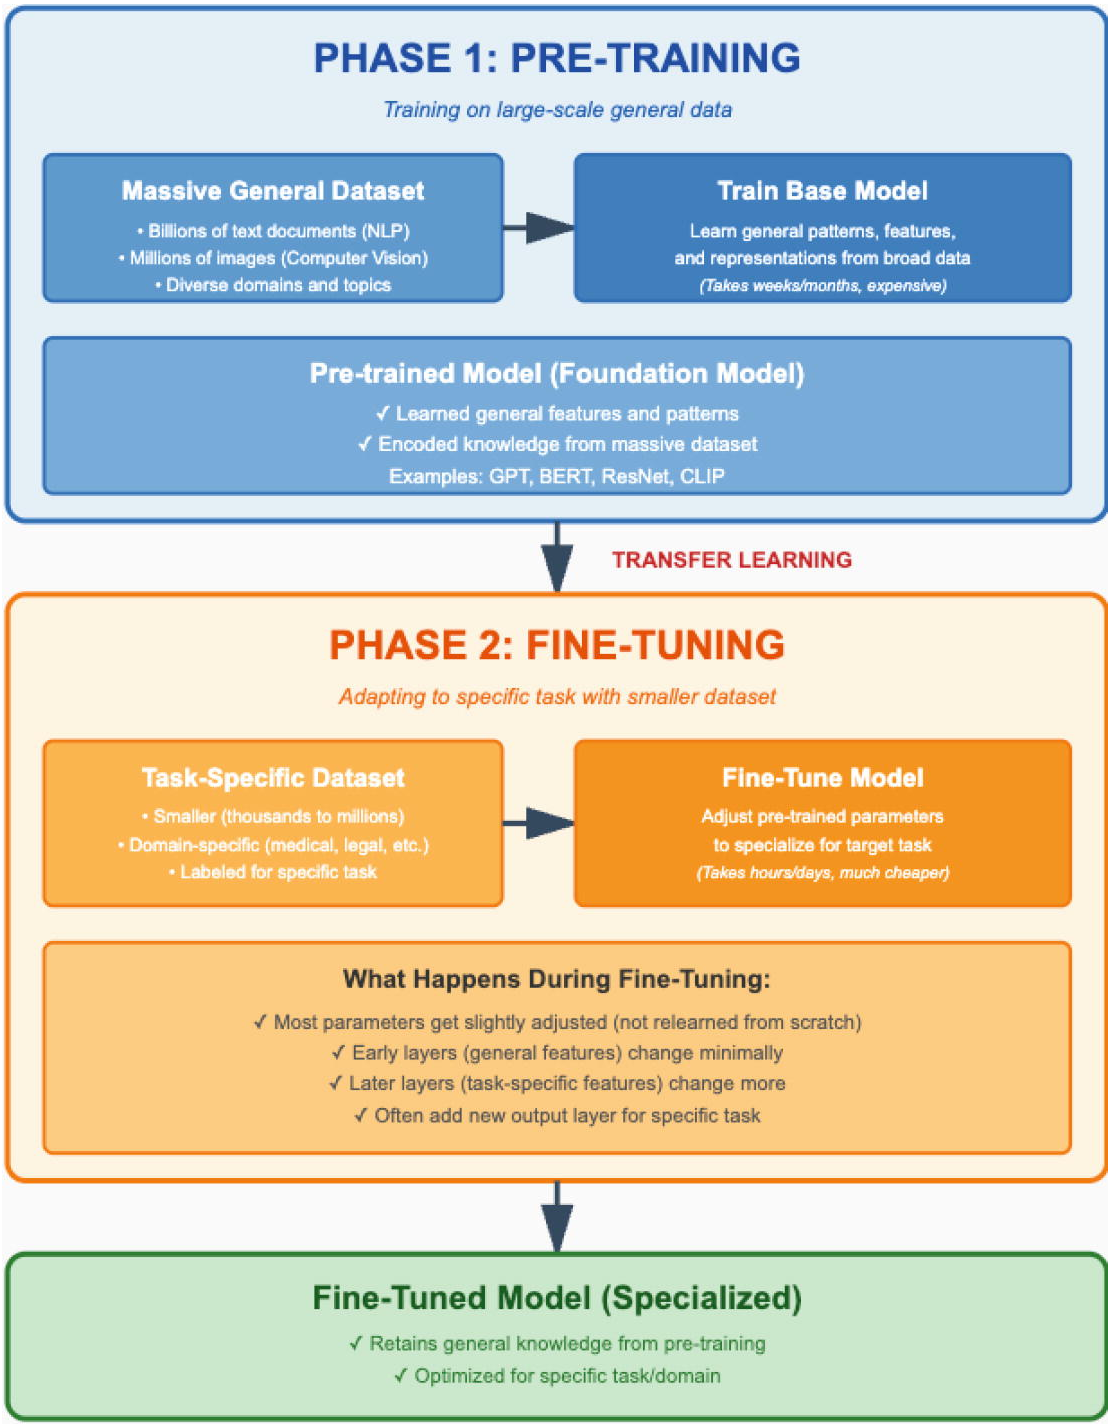
network architecture commonly used to process those representations. Although transformers are heavily used in NLP, they are also widely applied in vision and multimodal AI systems to achieve the goal of NLP.



With all of the data and datasets available from books, messages, newsfeeds, videos, and everything else that has data out there, systems need a way to analyze the data for actionable insights. That's what NLP does.

Fine-Tuning

In the last chapter, you learned a lot about fine-tuning and even fine-tuned a model. That's why this section will be very short. It's just a quick refresher to bring it all together, considering you created a bit more of an advanced model in this chapter in comparison to the last chapter.



When you fine-tune a model, you have to think about how many parameters there are. Although full fine-tuning updates every trainable parameter, many modern approaches freeze most of the model and update only selected layers or lightweight adapters to reduce computational cost. Instead, you can instead use parameter-efficient

fine-tuning techniques such as LoRA, which introduce small trainable adapter matrices into selected model layers while keeping most of the original model parameters frozen. This significantly reduces computational requirements while allowing the model to learn task-specific behavior.

When you fine-tune a model, the goal is to take a model that already exists and feed it the specific information that you need it to know for a specialized task. This is a far easier approach for many organizations in today's world (and typically more financially viable) than creating a model.

RAG

Retrieval-Augmented Generation (RAG) is an architecture that retrieves relevant external information at inference time and provides that information as additional context for the language model before generating a response. This allows models to incorporate knowledge that may not exist in their original training data. For example, if you wanted an agent/model to have more specific information about creating the best Italian recipes, you can add in the additional information for your agent to search through when inference occurs. The goal with RAG is more accurate output from the LLM.

RAG systems commonly retrieve indexed document chunks from knowledge bases, document repositories, APIs, vector databases, or

enterprise content systems. The retrieved information is then supplied to the model as additional context.

As an example, take a look at the screenshot below. This RAG system that's being implemented is using a text-based source that's in JSON for extended knowledge on Azure.

```
import numpy as np
from typing import List, Dict, Any, Tuple
from sklearn.neighbors import NearestNeighbors  # Using scikit-learn instead of FAISS
from app.ai.embeddings import get_embeddings

logger = logging.getLogger(__name__)

# Knowledge base about Azure services
AZURE_SERVICES_KNOWLEDGE = [
    {
        "service": "Azure Kubernetes Service (AKS)",
        "description": "Managed Kubernetes service for running containerized applications",
        "best_for": [
            "Complex microservices architectures",
            "Applications requiring advanced orchestration",
            "Stateful applications needing persistent storage",
            "Applications needing high availability and reliability",
            "Workloads requiring GPU resources",
            "Enterprise-grade security requirements",
            "DevOps teams familiar with Kubernetes",
            "Applications with multiple containers that need to communicate"
        ],
        "limitations": [
            "Overkill for simple applications",
            "Higher operational complexity",
            "Higher cost for small workloads",
            "Requires Kubernetes knowledge"
        ],
        "cost_factors": [
            "Compute node costs (VM size and count)",
            "Network egress",
            "Storage",
            "Add-ons and additional services",
            "GPU costs",
            "Node pools",
```

The RAG is then initialized and used within your application with a transformer.

```python
def initialize_rag_system(embeddings_model=None):
    """Initialize the RAG system"""
    try:
        logger.info("Creating RAG system")
        rag = RAGSystem(embeddings_model)

        # Try to load existing index, or create new one if not found
        data_dir = os.path.join(os.path.dirname(__file__), "..", "data")
        os.makedirs(data_dir, exist_ok=True)

        try:
            logger.info(f"Attempting to load RAG system from {data_dir}")
            rag.load(data_dir)
        except Exception as e:
            logger.warning(f"Error loading RAG system: {e}. Initializing new system.")
            rag.initialize_knowledge_base()
            logger.info("Saving newly initialized RAG system")
            rag.save(data_dir)

        if not rag.initialized:
            logger.warning("RAG system not properly initialized")

        return rag
    except Exception as e:
        logger.error(f"Failed to initialize RAG system: {e}")
        return None
```

The transformer model is used to look at and process plain-text and/or markdown files that will be used in a RAG. The plain-text/markdown is translated into numerical representations. The transformer model implements embeddings for the vector. Modern semantic search commonly relies on vector embeddings to identify content with similar meaning rather than relying solely on keyword matching, which allows text/phrases to be compared and specified as “the same or similar” in meaning. You can also implement a vector DB if you need more performance based on how many vectors exist, query speed, and efficiency. Vector databases provide capabilities such as indexing, persistence, metadata filtering, scalability, and efficient similarity search. For smaller datasets, lightweight vector search libraries may be

sufficient, whereas vector databases become increasingly beneficial for production-scale workloads.

Quick Callout: Skills

There are several ways to enhance an agent/LLM knowledge for what you're trying to accomplish. Fine-tuning, RAG, and Model Context Protocol (you'll learn about this in an upcoming chapter) are all methods to "tune" the model you're using to be a closer representation of what you truly need.

The next iteration of this type of tooling, which is very new (came out in October 2025 and this chapter is being written in November), is skills. Skills are almost like an external RAG. You can implement

– A .md file which contains a detailed prompt
– Images
– Scripts

And just about anything else you need for a more specific result from your agent/LLM. The goal is, much like any other "tuning" tool, to improve how agents/LLMs perform specific tasks.

You can find out more about Anthropic Skills here: https://www.claude.com/blog/skills

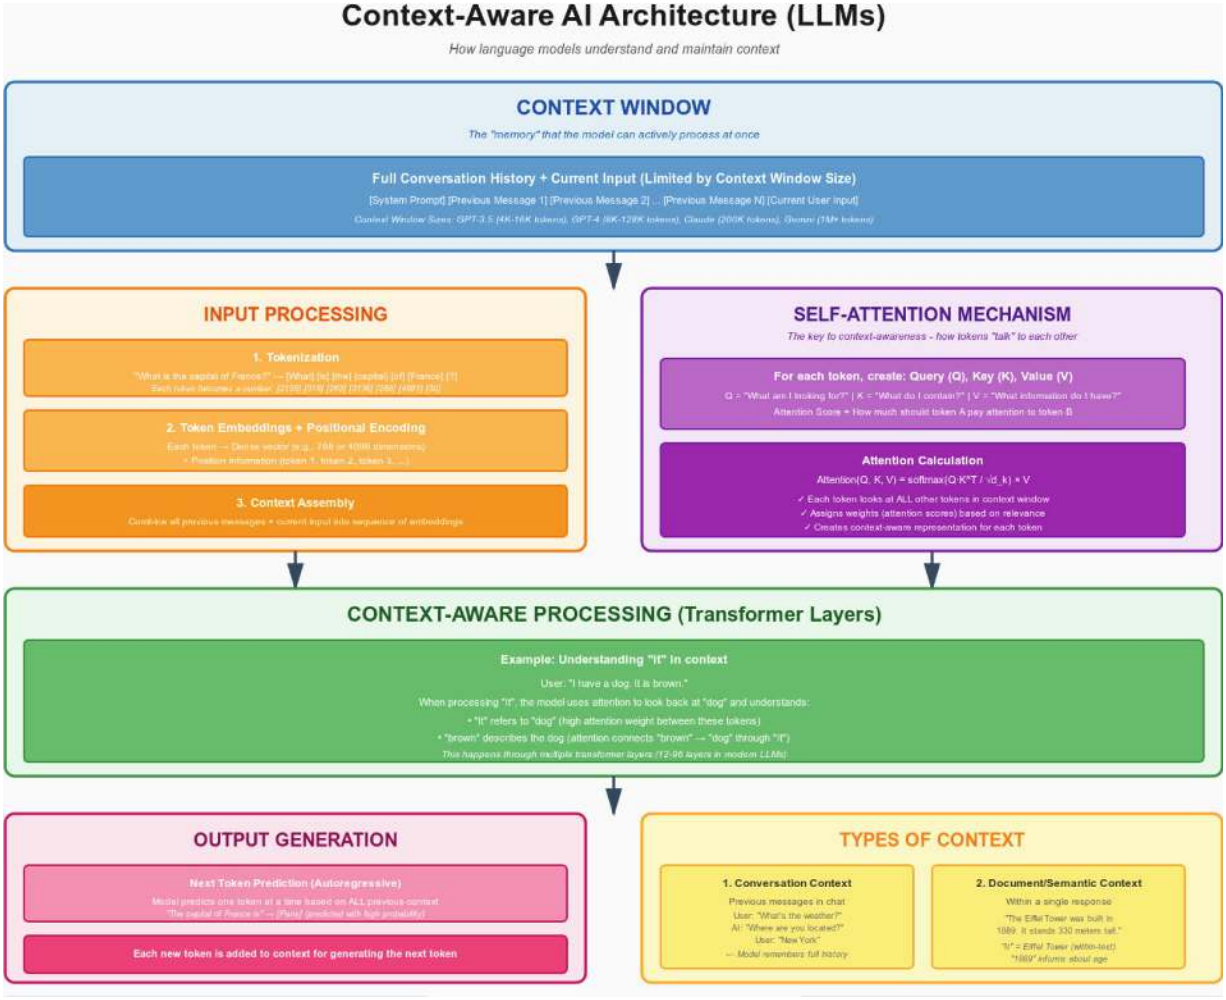
The kagent project is also creating a version of skills that uses the Agent Development Kit (ADK) Tools library, which you can find here: https://github.com/kagent-dev/kagent/tree/9438c9c0f2c79daf632555df1d7d3cb2d04b7b81/python/packages/kagent-adk/src/kagent/adk/skills

Context Aware

The last piece of the puzzle before diving into more agentic-specific information is the concept of an LLM/agent being "context aware." You may have heard phrases like "context-aware networking." The gist behind anything "context aware" is this: when you're working with an agent or even a provider console like ChatGPT, Anthropic, or Gemini,

you're asking questions, getting a response back, asking more questions, and getting more responses.

Although conversations appear stateful to users, most LLM APIs are stateless at the protocol level. Applications maintain conversational context by storing previous interactions and resending relevant history or retrieved context with each request. It's not a stateless workload where you ask a question, it gives an answer, and then that's that. Now, there are agents (you'll create one in the upcoming section) that are stateless in the sense that you ask a question, it gives an answer, and that's the end of the interaction. However, the majority of agentic workloads are stateful.



It's incredibly important to organizations that the state/context is stored so work isn't lost. That's why AI gateways that were created specifically for this type of traffic like agentgateway are so important.

Traditional Envoy-based Gateways were created with stateless workloads in mind. The headers would be looked at in a request and that's about it. With AI-related traffic, it's stateful, and the body of the request is what's important, not the headers.

Ensuring that stateful, context-aware agentic workloads are implemented properly is crucial for an organization that's implementing agents or any type of use with LLMs/models because losing those workloads could be major, much like how, if state is lost in a Terraform configuration, you essentially have to start from scratch when deploying workloads. If a Kubernetes cluster is deployed with Terraform and that state file isn't saved, that means there's no point-in-time to go back to when other engineers update/modify/delete/re-create the cluster. That means a big configuration-drift issue.

Taking that same mindset, if any agentic workload is used/modified, there's no point-in-time to start from. An agent may be tasked to do something, and if it's a long-running process, how would the engineer using the agent know how the process is going? Or if it failed? Or if it's still being worked on? Or when it started/stopped? Better yet, what if another engineer has to pick up where the previous engineer left off on the task?

Agentic Reality

The birth of AI was between 1950 and 1956, which was before software engineering (1965), so it's safe to say that it's been around a while. However, much like any other trend, there's a period before it becomes "popular." Only a few people may know about it or use it, but it's still there (almost like the clothing industry where styles come and go).

As of now, the big "trend" (which appears to be here to stay) is anything agentic. By definition, agentic AI means "AI focused on autonomous decision-making and action." Agentic AI interacts with

outside environments to gather data and adjust in real-time (this is where predictions/inference comes into play). A few examples of Agentic AI are tools like Claude Code and OpenAIs Codex, along with self-driving vehicles.

In this section, you'll learn what agents are, a few key tools/frameworks to use, and how to build your first agent.

Agents

AI agents are software systems that use a language model to interpret goals, reason about possible actions, invoke external tools or services, observe results, and iteratively work toward completing a task with varying levels of autonomy.

Let's break this down in the concept of engineering.

You open Claude Code and say "write me a Terraform configuration that deploys a Kubernetes cluster in Google Cloud Platform (GCP) along with a variables.tf file." Claude Code then writes the HCL for you and has you review it before it's saved into a file. Claude Code knows how to write the HCL from data it was already trained on, data you fed it (like an example or a URL to HCL code), or both. You then tell Claude Code to run the Terraform config and deploy the GKE cluster. It can do this as long as your local environment (or where you're running Claude Code) has access to GCP (e.g., a local credential file).

An agent can also be something as simple as five lines of code that specifies an LLM, a description, and a task. The task could be something along the lines of "you're a Kubernetes expert and know how to answer questions about Kubernetes" so when someone uses the agent, they can ask a question about Kubernetes and get an answer. In short, an agent is an autonomous task handler.

What makes an agent stand out? The information it's able to gather in a uniquely fast timeframe, the ability to make decisions based on that data, the fact that it can perform a task for you, and the refinement of the approach based on what you tell the agent in terms of what it needs to do or if it got something wrong. It's arguably the closest thing we

have to a “person” (not saying agents are AGI in any way, shape, or form, but they do break barriers in velocity for getting things done).

Let’s now dive into the tools available at your disposal for creating agents.

Provider/Framework Tools

There are two categories of tools: providers and frameworks. Providers are vendor-based solutions like OpenAI, Google Gemini, and Anthropic. Frameworks are tools like CrewAI, LangChain, and Agent Development Kit (ADK). However, the solution can be both a provider and a framework. For example, kagent and CrewAI are both frameworks for creating agents, but they also have the backing of a vendor (Solo for kagent), which means solutions from an open source perspective and an enterprise perspective if you need more robust features or you don’t want to build those robust features yourself, which is the typical preferred path for the enterprise (pay someone to handle it for you).

Luckily, in the world of providers and frameworks, there are several solutions that will meet your needs in terms of building and managing agents. The three you typically see are

1. Agents on Kubernetes
2. Agents managed for you
3. Agents you can programmatically build and manage

Kagent allows you to programmatically and declaratively build and manage agents to run on Kubernetes just like any other K8s workload. Below is an example of creating and building an agent along with connecting an MCP server to the agent within a Kubernetes manifest.

```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: Agent
metadata:
```

```
  name: github-mcp-agent
  namespace: kagent
spec:
  description: This agent can interact with GitHub
repositories, issues, pull requests, and more
  type: Declarative
  declarative:
    modelConfig: default-model-config
    systemMessage: |-
      You're a friendly and helpful agent that
uses GitHub tools to help with repository
management, issues, pull requests, and code review

      # Instructions

      - If user question is unclear, ask for
clarification before running any tools
      - Always be helpful and friendly
      - If you don't know how to answer the
question DO NOT make things up
        respond with "Sorry, I don't know how to
answer that" and ask the user to further clarify
the question

      # Response format
      - ALWAYS format your response as Markdown
      - Your response will include a summary of
actions you took and an explanation of the result
    tools:
    - type: McpServer
      mcpServer:
        name: github-mcp-remote
        kind: RemoteMCPServer
        toolNames:
        - get_latest_release
        - get_commit
```

```
        - get_tag
        - list_branches
EOF
```

On the flipside, ADK from Google gives you an SDK to create and manage your agent like in the example below, which is Python-based, using LiteLLM to connect to an external LLM (in this case, Claude), and works as a Kubernetes assistant.

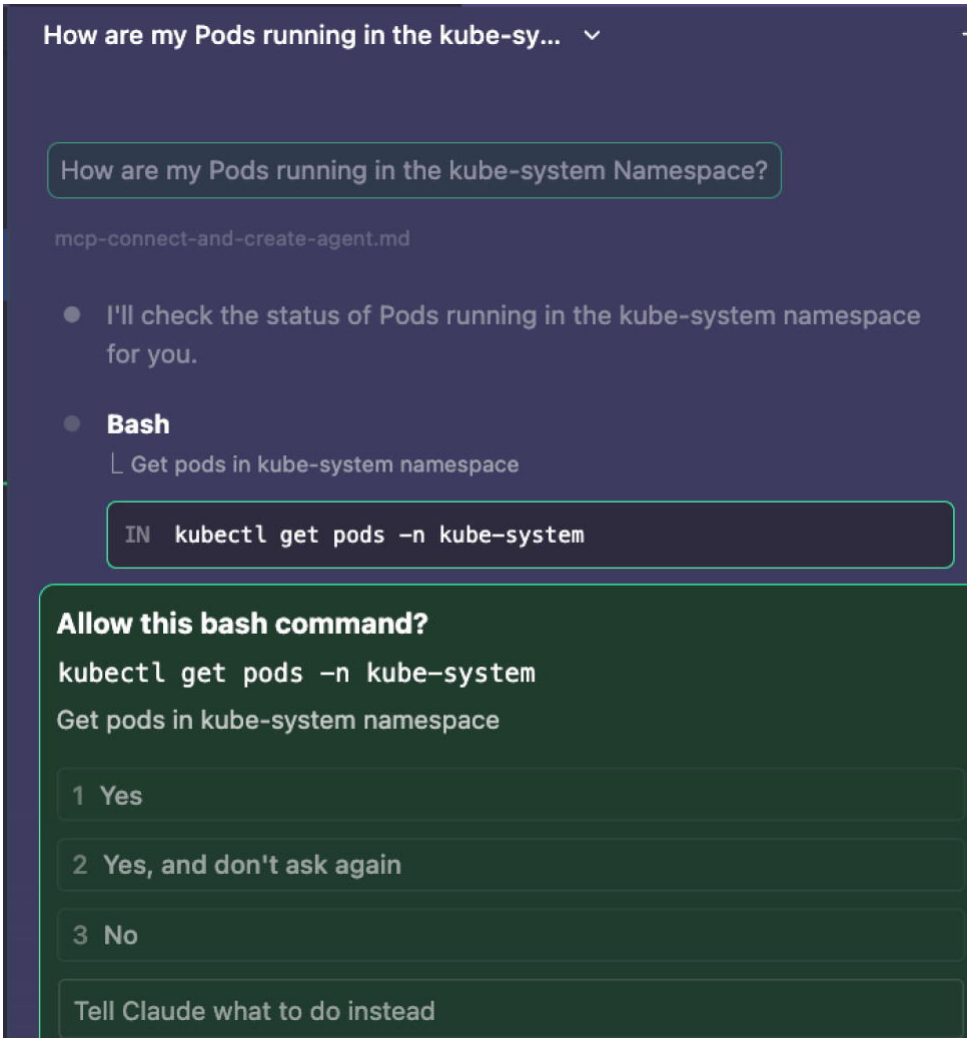
```
from google.adk.agents.llm_agent import Agent
from google.adk.agents import LlmAgent
from google.adk.models.lite_llm import LiteLlm

# `root_agent` variable is mandatory. Otherwise,
you may see:
# ValueError: No root_agent found for 'pyagent'
root_agent = LlmAgent(
    model=LiteLlm('anthropic/claude-sonnet-5'),
    name='k8sassistant',
    description='You are a Kubernetes expert',
    instruction='Answer questions about all things
Kubernetes and Istio Service Mesh to the best of
your ability',
)
```

Overall, the “tool” you decide to use is your choice, as it should be because the agentic AI world is too large for a “one size fits all” implementation.

Programming Tools

One callout, which most likely doesn’t need a full section at this point in time, is programming tools like Claude Code and GitHub Copilot. These are agents that are built into something like an IDE to help you write code and troubleshoot existing code or environments. You could use these for anything from writing an application for you to troubleshooting why a Kubernetes Pod is down.



Building Your First Agent

To follow along with this section, you will need

– The “deepseek-r1:8b” model installed locally (you can do this with Ollama).
– Python installed (preferably with a virtual environment as you’ll need to install the crewai library).
– Ollama installed.

1. Create a new file called “a2aask.py.” The file will contain the below, but before you add anything to the file, let’s go over each piece.
2. The first piece is the libraries that you’ll need. The CrewAI and crewai_tools library are to use the agent/LLMs, and the

SerperDevTool library is used to do a Google search with your agent.

```
from crewai import Agent, Task, Crew, Process,
LLM
from crewai_tools import SerperDevTool
import os
```

3. Define a function for your agent logic to exist in.

```
def main():
```

4. Set environment variables for a Serper API Key (you can get one for free) and OpenAI. CrewAI uses OpenAI-compatible clients that validate the API key presence, so even if you're not using OpenAI, you still have to specify an env variable. The value of the variable could be anything though.

```
    os.environ.get('SERPER_API_KEY')
    # Set dummy OpenAI API key for Ollama
compatibility
    os.environ['OPENAI_API_KEY'] = 'ollama'
```

Using the "LLM" function from the "crew_ai" tools library, specify the model you want to use, the temperature for accuracy, and where the model exists. Because DeepSeek is a local model, you'd use "localhost." The "11434" port is the default port that Ollama running locally listens on.

```
    modelType = LLM(model="ollama/deepseek-
r1:8b", temperature=0.1,
base_url="http://localhost:11434")

    rag = SerperDevTool(
```

```
        search_url="https://a2a-
protocol.org/latest/"
    )
```

5. With the prereqs in place, you can start specifying the actual logic/functionality. The first piece is the "Agent()" function/method that allows you to specify tools and the LLM.

```
    search = Agent(
        role="A2A Expert",
        goal="Let us all know the  definition
of A2A",
        backstory="An expert in A2A",
        tools=[rag],
        # if you don't specify a Model, it will
default to gpt-4
        llm=modelType,
    )
```

6. The next part is the task where you specify a description, expected output, and the agent (specified in the search variable above).

```
    job = Task(
        description="Let us all know the EXACT
definition of A2A",
        expected_output="The best possible
definition on the Agent2Agent(A2A) protocol",
        agent=search
    )
```

7. The final step is to use the "Crew()" function/method to put it all together.

```
    crew = Crew(
        agents=[search],
```

```
        tasks=[job],

        verbose=True,
        process=Process.sequential
    )
```

Altogether, the “a2aask.py” file should look like the below.

```
from crewai import Agent, Task, Crew, Process, LLM
from crewai_tools import SerperDevTool
import os

def main():
    os.environ.get('SERPER_API_KEY')
    # Set dummy OpenAI API key for Ollama
compatibility
    # CrewAI's LLM class internally uses OpenAI-
compatible clients that validate the API key
presence
    os.environ['OPENAI_API_KEY'] = 'ollama'

    modelType = LLM(model="ollama/deepseek-r1:8b",
temperature=0.1,
base_url="http://localhost:11434")

    rag = SerperDevTool(
        search_url="https://a2a-
protocol.org/latest/"
    )

    search = Agent(
        role="A2A Expert",
        goal="Let us all know the EXACT definition
of A2A",
        backstory="An expert in A2A",
        tools=[rag],
```

```
        # if you don't specify a Model, it will
default to gpt-4
        llm=modelType,
    )

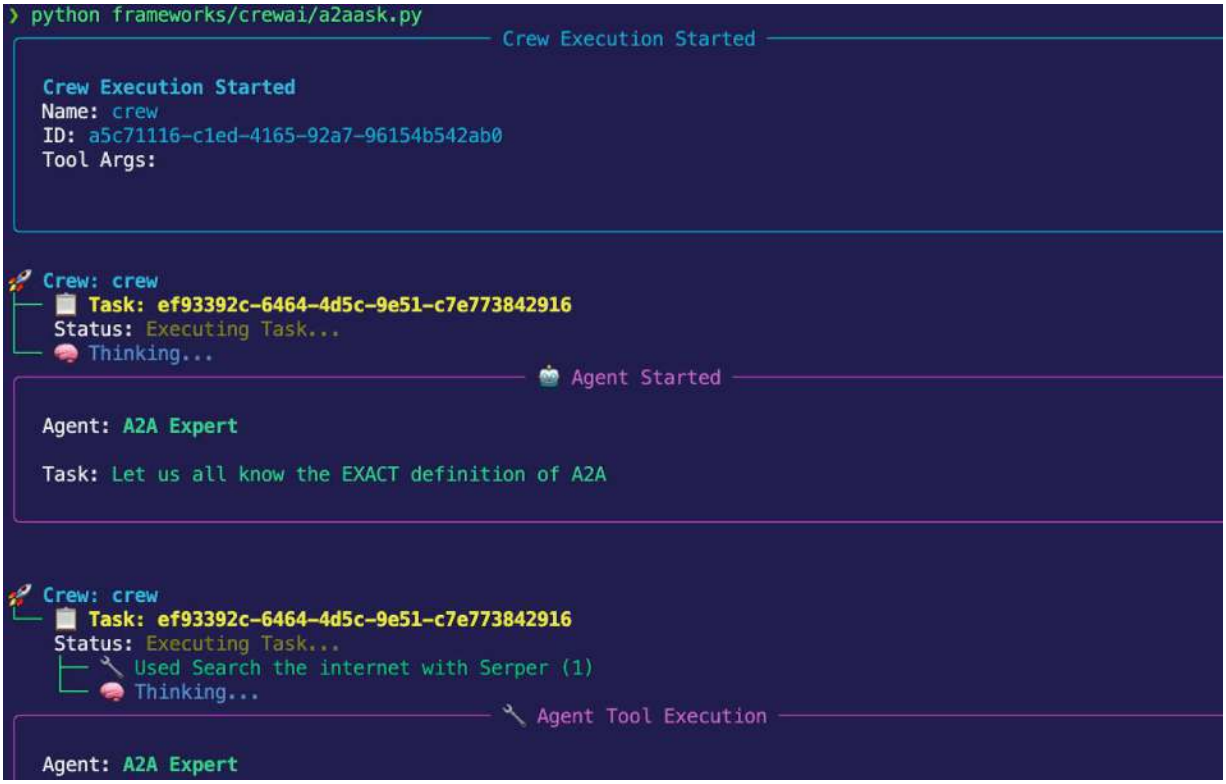
    job = Task(
        description="Let us all know the EXACT
definition of A2A",
        expected_output="The best possible
definition on the Agent2Agent(A2A) protocol",
        agent=search
    )

    crew = Crew(
        agents=[search],
        tasks=[job],
        verbose=True,
        process=Process.sequential
    )

    crew.kickoff()

if __name__ == '__main__':
    main()
```

Run it and you'll see an output similar to the screenshots below.



Problems in the AI Space

To wrap up this chapter, let's talk about a few issues in the AI space. Why? Because there's no technology in the world that only has pros. Every single piece of technology has cons. Let's talk about three:

1. Hallucinations

2. Security issues
3. Cost

Hallucinations are still a big deal in LLM. We all know the notorious "you're absolutely right!" answer from just about any LLM when you say something along the lines of "…What? That's not right." Hallucinations remain one of the primary challenges in LLM-based systems. Although they cannot currently be eliminated in all scenarios, their frequency and impact can often be reduced through techniques such as grounding, Retrieval-Augmented Generation (RAG), structured outputs, model evaluation, and human oversight. Grounding techniques such as Retrieval-Augmented Generation (RAG), structured outputs, source validation, evaluation pipelines, and human review can reduce hallucination frequency. MCP enables tool access but does not inherently reduce hallucinations (from Anthropic and kagent).

Security issues are a huge deal. The three major issues with LLMs are people feed-sensitive/company information to them, which means it could be data that the LLM is trained on. Security concerns include prompt injection, excessive tool permissions, insecure API keys, data leakage, retrieval poisoning, indirect prompt injection, model supply chain risk, and insufficient authorization when agents interact with external systems. A huge part of security comes down to things we already do in the security realm (AuthN/Z and least privilege), all of which are currently being worked out in the AI world.

The final piece is cost. LLMs and LLM providers can get pretty pricey. Tokens are what raw text turns into for LLMs to know how to process it (think about the embedding process). For example, you can break down the three words (or sometimes subwords) "[what, is, up]" into three tokens by splitting the text/sentence, and those tokens are what you get charged on. Some models may break it down into multiple

tokens (punctuation, apostrophes, etc.). If that's the case, think about how many tokens are used to write code.

It's still early days in figuring out these three pieces, but they're certainly something you want to keep in mind when using agents and LLMs.

Conclusion

Technology moves at an incredible pace. If you look at any other field/career, very rarely do you find one like technology in terms of the rapid movement that occurs in this field. However, there are key concepts that fundamentally don't change. A good example of this is networking, infrastructure, and systems. Regardless of if you're environment is on-prem, virtualized, in the cloud, and/or running in Kubernetes, networking is networking and infrastructure is infrastructure. The same rules apply in the AI space. Things like what models are and how/what they're trained on (e.g., datasets) fundamentally stay the same. The goal of this chapter was to give you the agentic fundamentals necessary to make the rest of your AI journey more comfortable. I hope it did that!

3. Agentic AI in Kubernetes and Cloud-Native

Michael Levan[1] ✉
(1) Budd Lake, NJ, USA

There are typically three steps to a new technology innovation from a consumer (the engineer(s) using it) perspective. The technology gets released, it gets tested/vetted out, and then parts of it (or sometimes all of it) get implemented. Within that cycle, it often changes as well (e.g., K8s was originally a bunch of Bash scripts). Where the industry is currently with agentic AI is Steps 2 and 3 (testing out and implementing at the same time), which means the industry needs a place to run it. Because of AI's orchestration and scalability needs, cloud providers and Kubernetes make the most sense with current technological implementations from a distributed systems perspective.

In this chapter, you will dive into

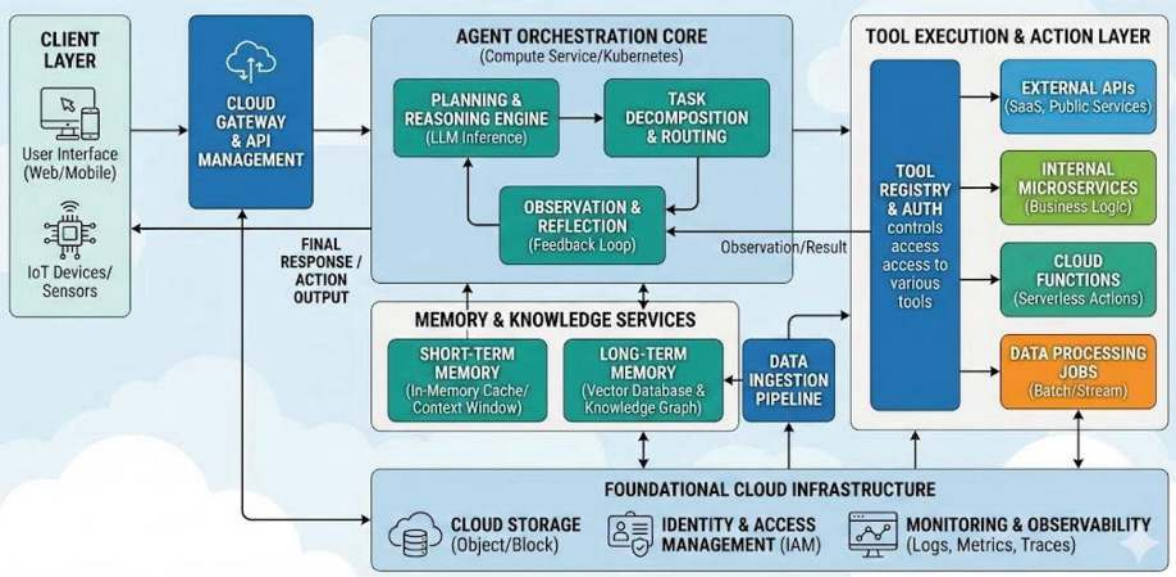
1. Agentic AI services/tools in public clouds.
2. All things agentic when it comes to Kubernetes.
3. Building an SRE/platform engineering agent to help you with day-to-day tasks.

Agentic in the Cloud

Once agentic AI, not just from a chatbot perspective but also from a real, production use-case perspective, became more and more relevant, various services started to pop up from AWS Bedrock to Azure Foundry AI and Vertex AI. In this section of the chapter, you'll learn about a few of those services and how to start using them today. Even if you're not using all three clouds, it's important to at least get an understanding of how the major public cloud providers are thinking about agentic services because the big software vendors are typically who are "molding the future" for how AI workflows/workloads will be used and looked at. It also gives you the opportunity to test out various services to see which ones fit your use cases the most.

The two sections to follow for Azure and AWS will highlight a few key tools/platforms/services in the cloud that you can use to get started with agentic workflows in your provider of choice. You can use all of these services with the free credits that are given during signup of each cloud provider, so if you don't already have a cloud account in any of these, you can utilize the credits. If you do already have an account, the predication of spend is no more than $5.00 USD in each cloud.

Please note, this section is to look at a few of the current tools across Azure and AWS. If you're wondering why it doesn't cover anything around Kubernetes, that's because the sections that follow this section are all about agentic in Kubernetes.



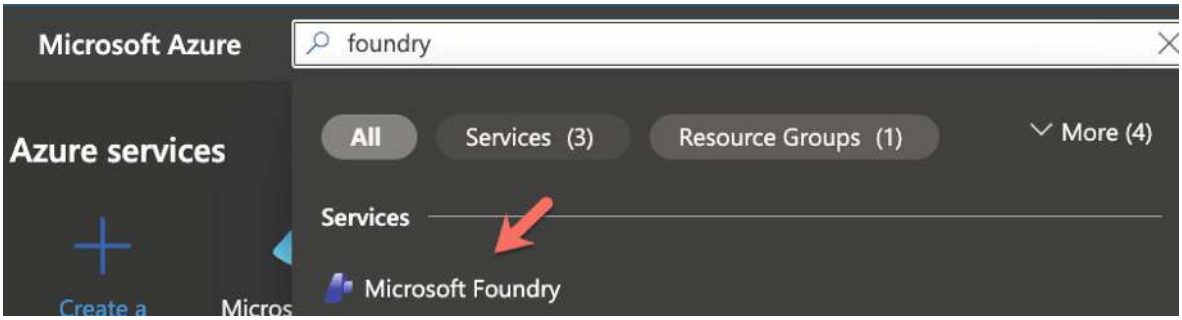
One major goal of the next two sections (agentic in Azure and AWS) is to give you an idea of how these tools work, what they look like, and what you can accomplish with them. Each of these tools could be several chapters or maybe even a short book in themselves, so the goal here is to "touch on" what you can accomplish vs. going in-depth.

Agentic in Azure

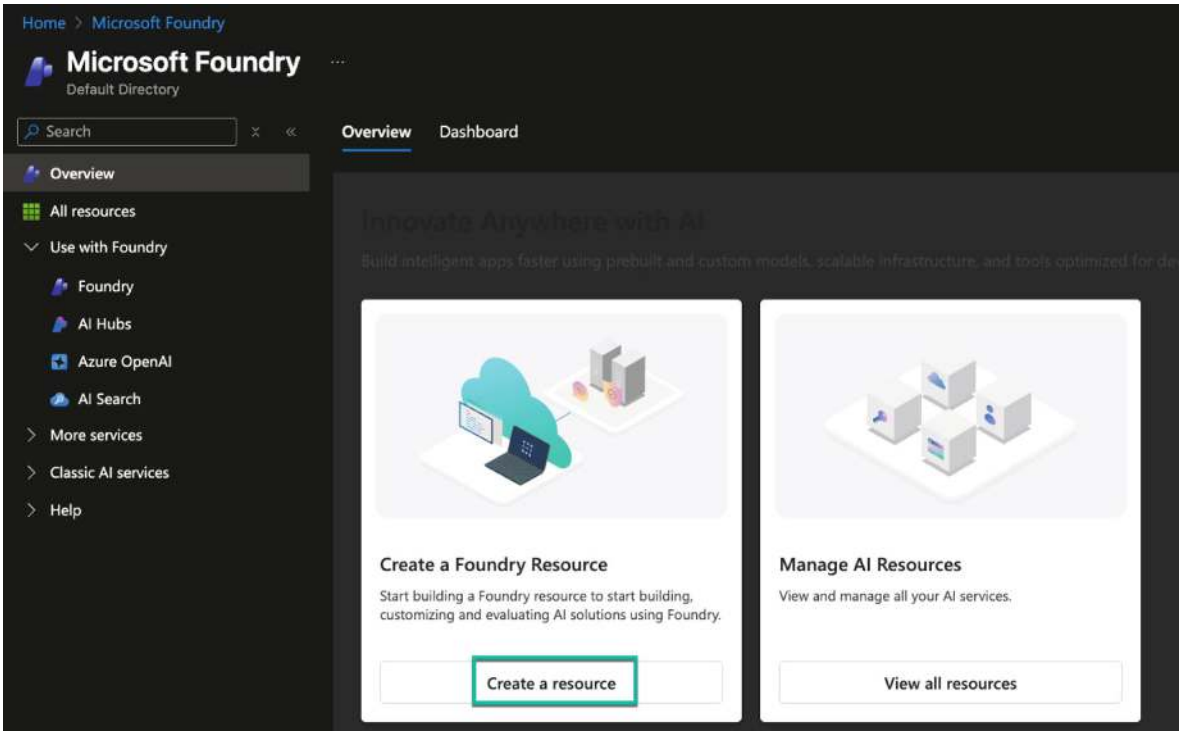
This section covers Azure's AI implementation with Microsoft Foundry, previously called Foundry AI. As you will see in this section, Microsoft Foundry is a full suite of all things agentic, ranging from building custom agents to using LLMs to monitoring and observability, along with security and governance.

Installation and Configuration

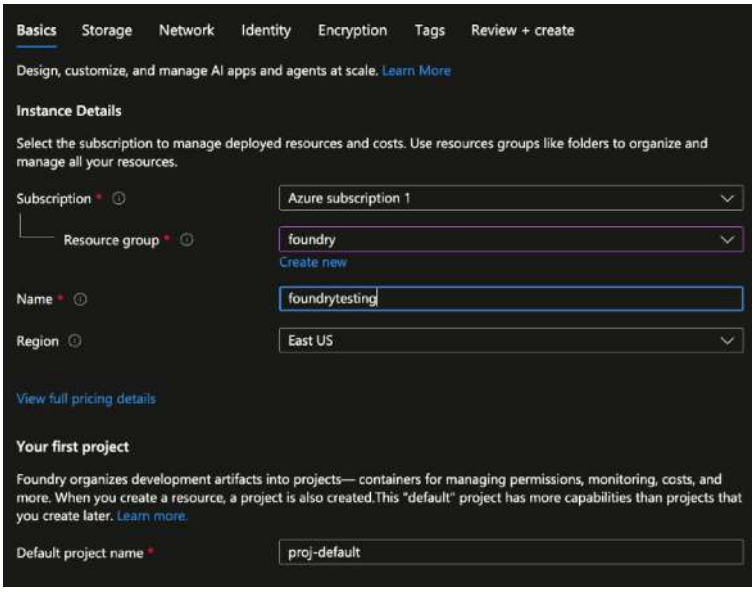
1. In the Azure Portal, search for **foundry** and you should see the Microsoft Foundry service pop up.



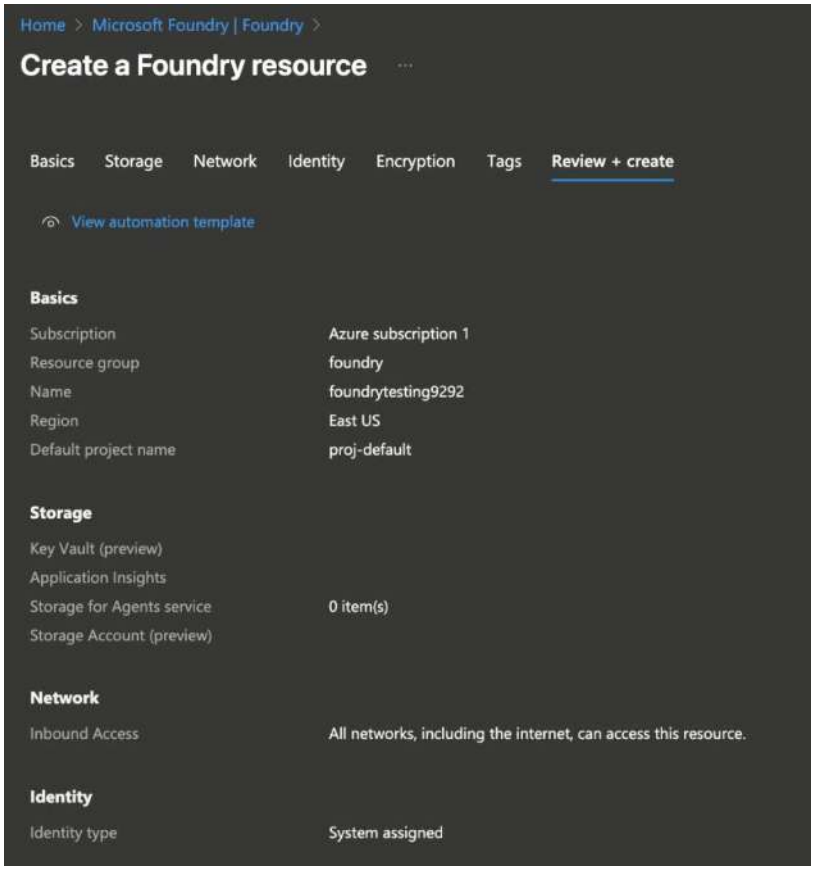
2. Within the service, click the **Create a resource** button in the **Overview** pane.



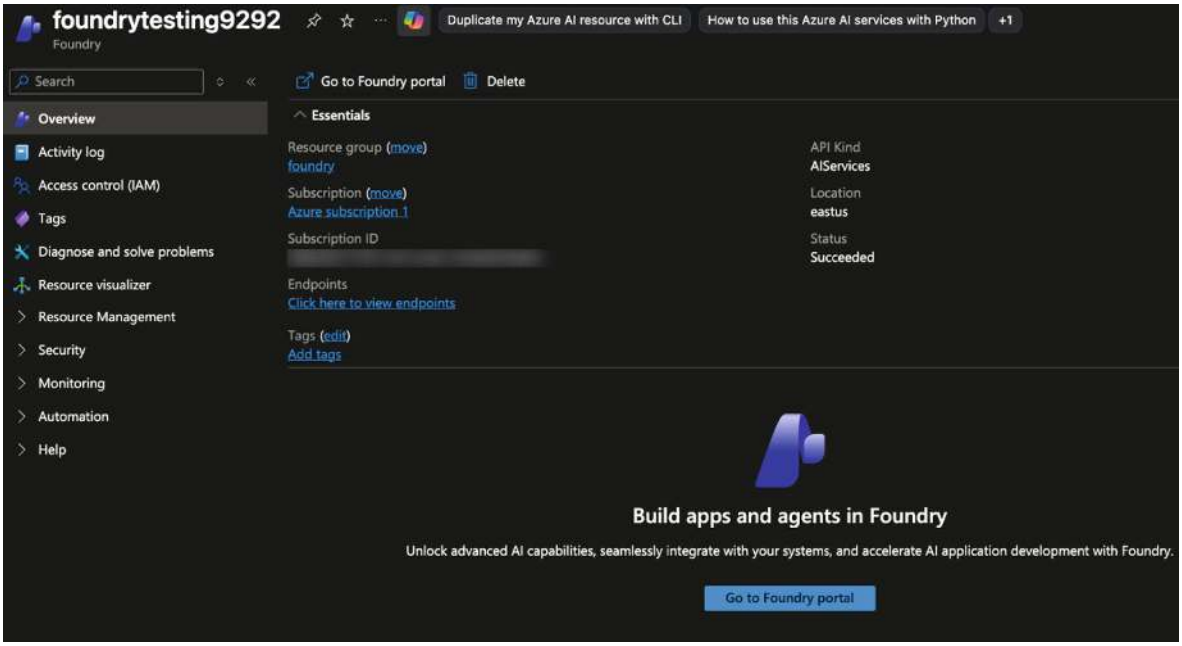
3. Ensure to choose the right subscription, resource group that you want Foundry to be deployed to, region, and give it a name (it's a unique name so the name you choose shouldn't be used by others).



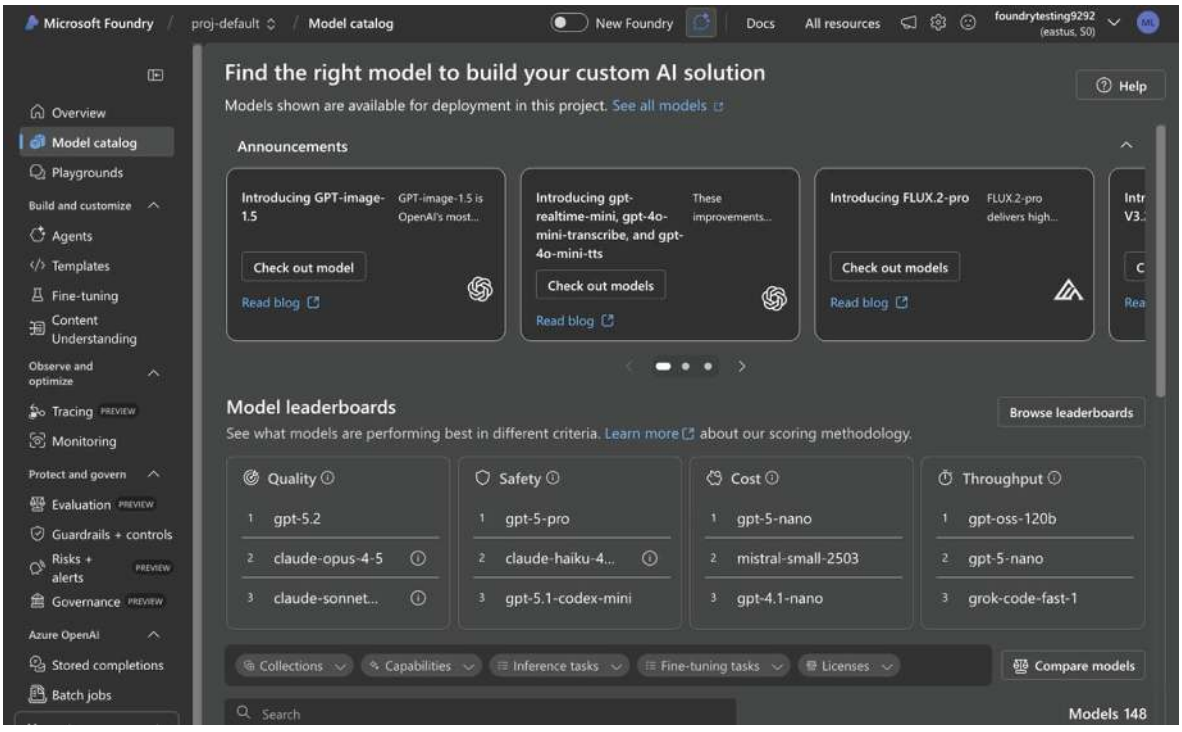
4. Keep the rest of the configurations default, as this is a Foundry instance for demo purposes only. Click the **Review + create** button.



5. After creating the instance of Foundry, you should see a screen similar to the one below. Your Azure account must have permission to create the Foundry resource and deploy models. Creating the resource through Azure Resource Manager and using Foundry's data plane capabilities may require different roles. In production environments, follow the principle of least privilege and assign only the roles required to build, invoke, or administer the agent. Click the blue **Go to Foundry portal** button.



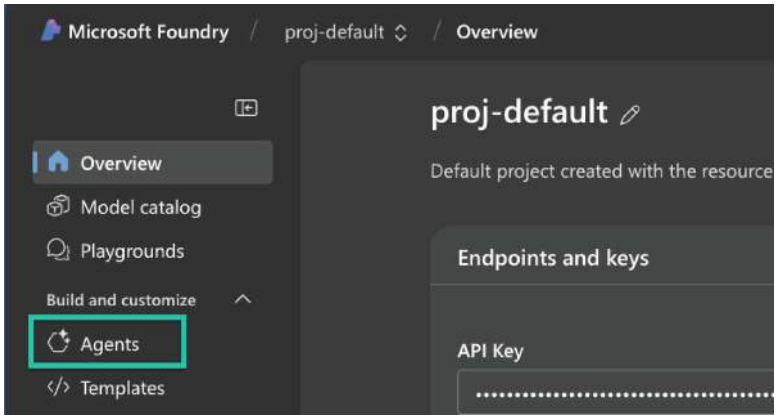
You should now be able to see your instance of Foundry.



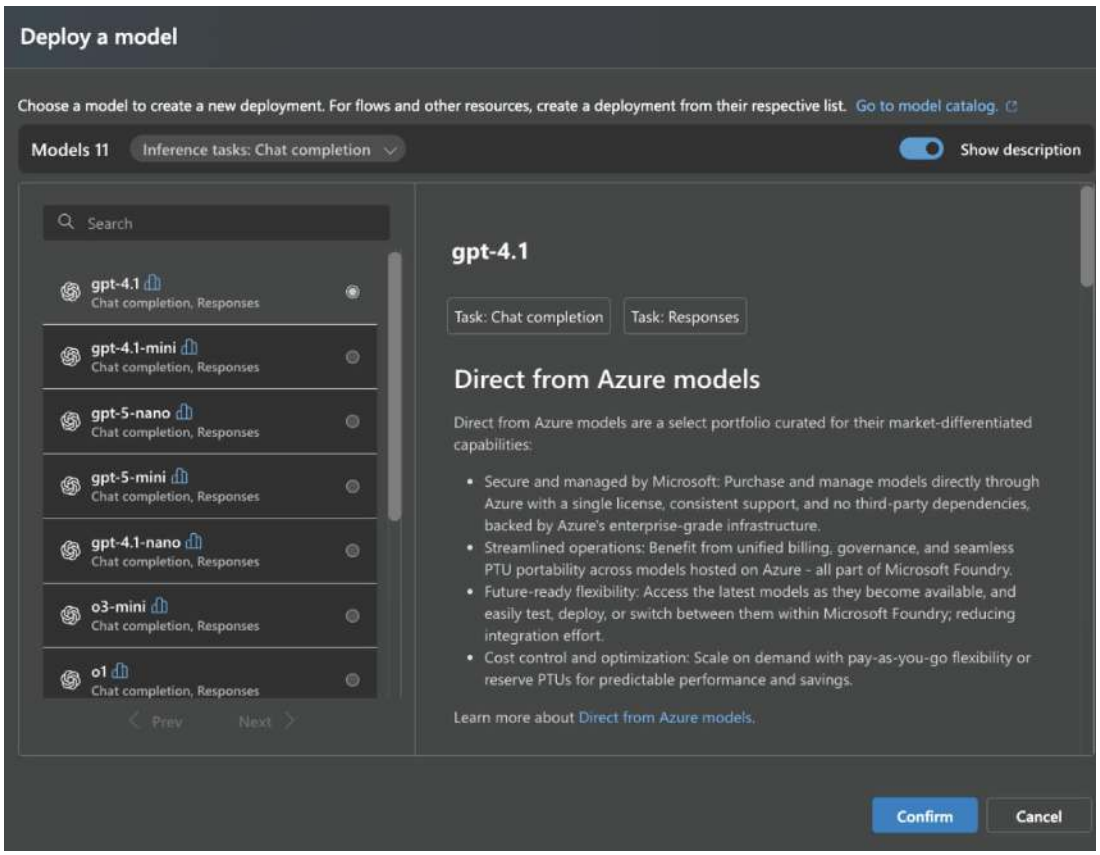
Configure an Agent

With the Foundry instance set up, let's configured our first agent.

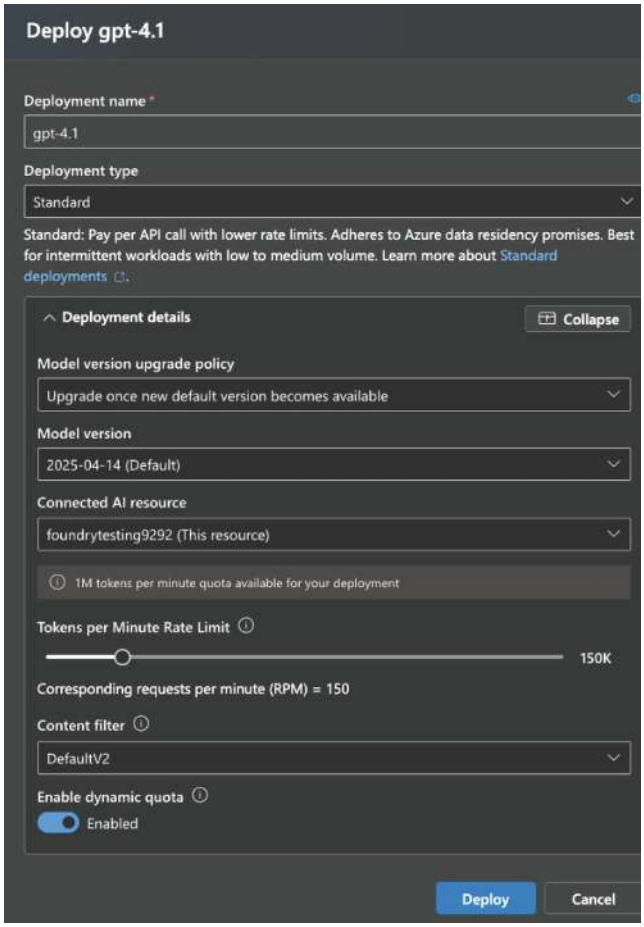
1. Within Foundry under **Build and customize**, click the **Agents** button.



2. You'll see several models available. For testing purposes, choose **gpt-4.1** (or another model you have access to based on your region, subscription, and quota) and then click the blue **Confirm** button.

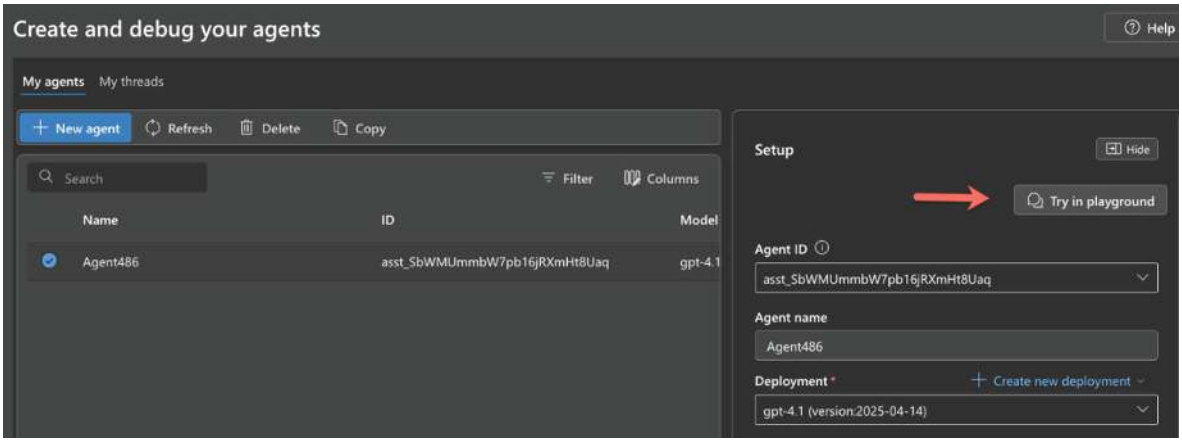


3. For the deployment type, choose **Standard** as GPT models don't work with development types. You can leave the rest of the options default and click the blue **Deploy** button.

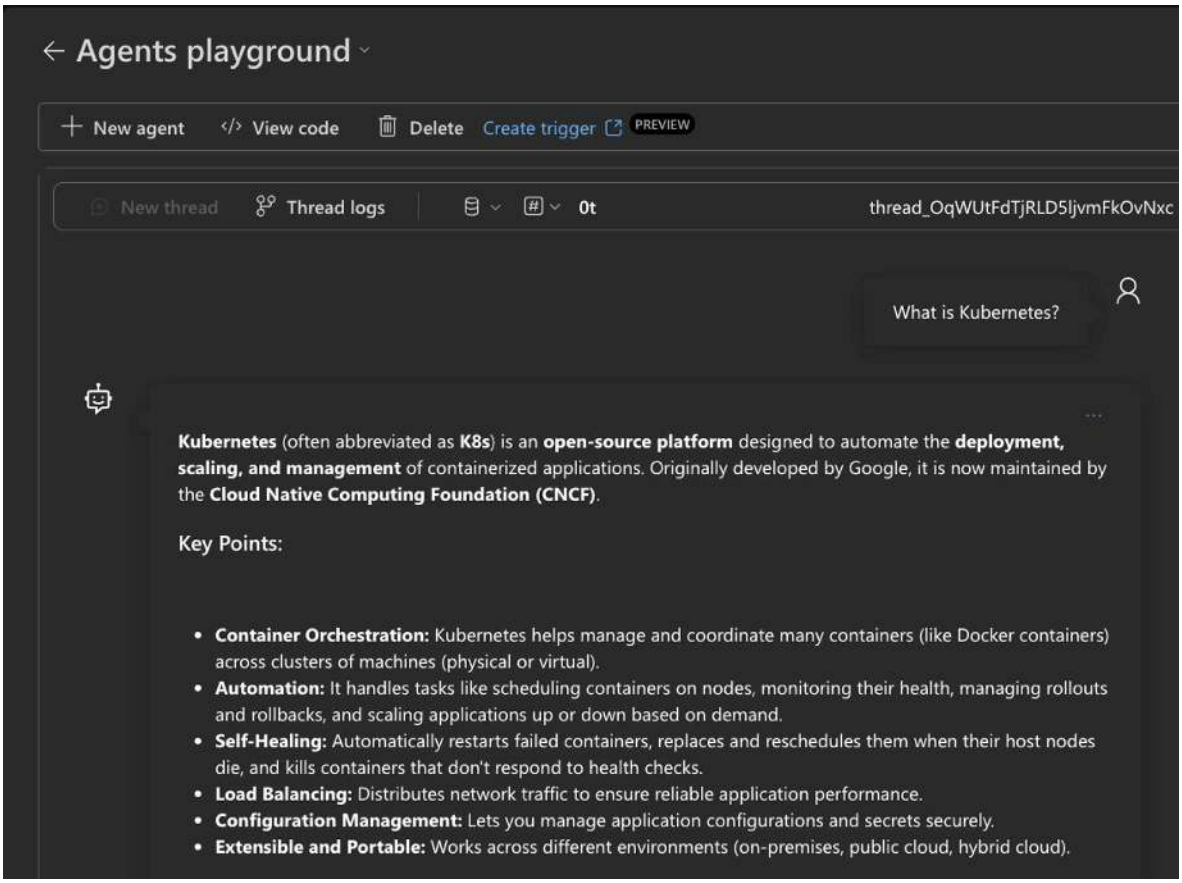


4. Click your newly created agent.

5. Click the **Try in playground** button.



6. You can now test your agent. For example, ask it “What is Kubernetes?”.



Agentic in AWS

Switching gears to AWS, one thing you may notice with other cloud providers is that there are particular agentic services that are split up. In Azure, you saw that everything was under one service. AWS provides several complementary services for generative and agentic AI. Amazon Bedrock provides managed access to foundation models and capabilities such as knowledge bases, agents, guardrails, evaluations, and model customization. Amazon Bedrock AgentCore provides services for deploying and operating agents and their tools with capabilities such as runtime execution, identity, memory,

observability, and gateway integration. The services can be used together, but they address different parts of the agent lifecycle.

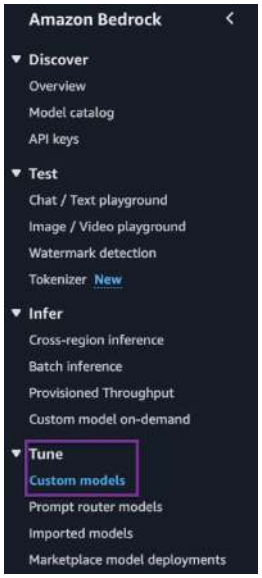
Amazon Bedrock is a suite of tools much like Foundry AI that allows you to do anything from connecting to other LLMs to creating agents. A lot of what is seen in the field is that Bedrock is used as a "bridge" to LLMs (Claude, GPT, Gemini, etc.). Amazon Bedrock AgentCore is a subset of capabilities to build, deploy, and use production-ready AI agents and tools in a secure and scalable fashion. You can think of it as a runtime of sorts for your agents. In this section, let's focus on Amazon Bedrock.

Bedrock

In this section, you'll learn how to fine-tune an LLM in Bedrock.

1. Within the AWS portal, search for **bedrock** and choose the **Amazon Bedrock** service.

2. Within Bedrock under **Tune**, click **Custom models**.

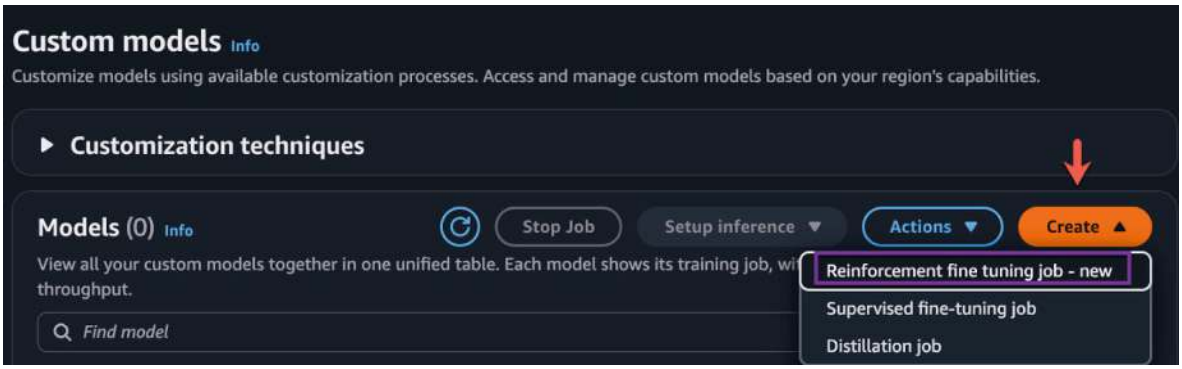


3. Save the following JSONL dataset in a file called `testing.jsonl` as you'll use it for the fine-tuning. This is meant to be a very small dataset just for testing purposes.

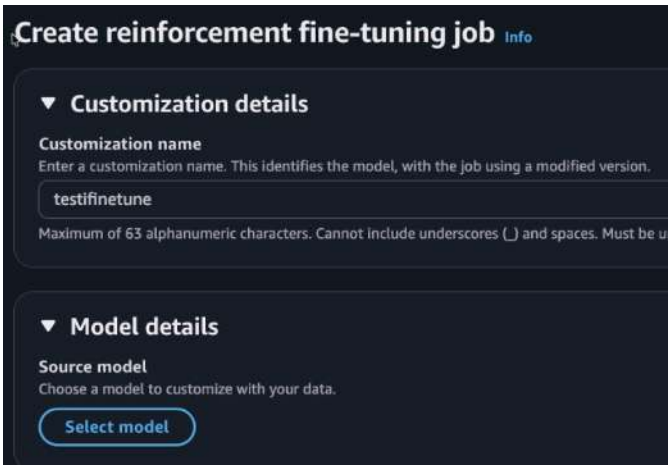
```
{"messages": [{"role": "user", "content": "How do I create a basic
deployment in Kubernetes?"}, {"role": "assistant", "content": "To
create a basic deployment in Kubernetes, use a YAML manifest with
apiVersion: apps/v1, kind: Deployment, and specify your container
image, replicas, and selectors. Apply it with `kubectl apply -f
```

```
deployment.yaml`. The deployment controller will create a ReplicaSet
that manages the desired number of pods."}]}
{"messages": [{"role": "user", "content": "What's the difference
between a Service and an Ingress?"}, {"role": "assistant", "content":
"A Service exposes pods within the cluster or via
NodePort/LoadBalancer, providing stable networking and load balancing.
An Ingress sits at the cluster edge, managing external HTTP/HTTPS
access to services, offering path-based routing, SSL termination, and
name-based virtual hosting. Think of Services as internal load
balancers and Ingress as your L7 HTTP router."}]}
```

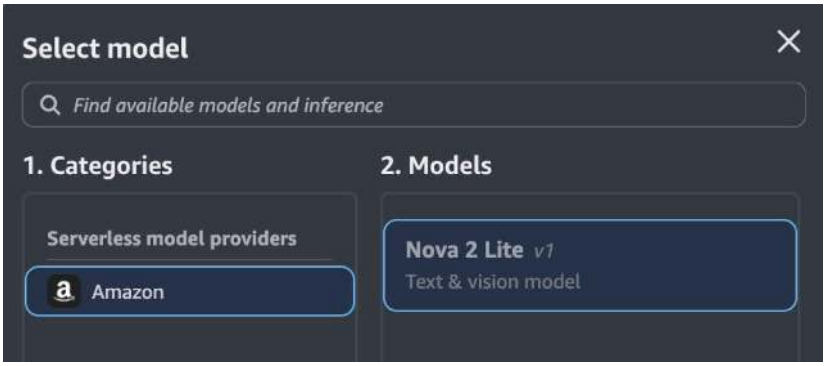
4. Click the orange **Create** button and choose the **Reinforcement fine tuning job – new** option.



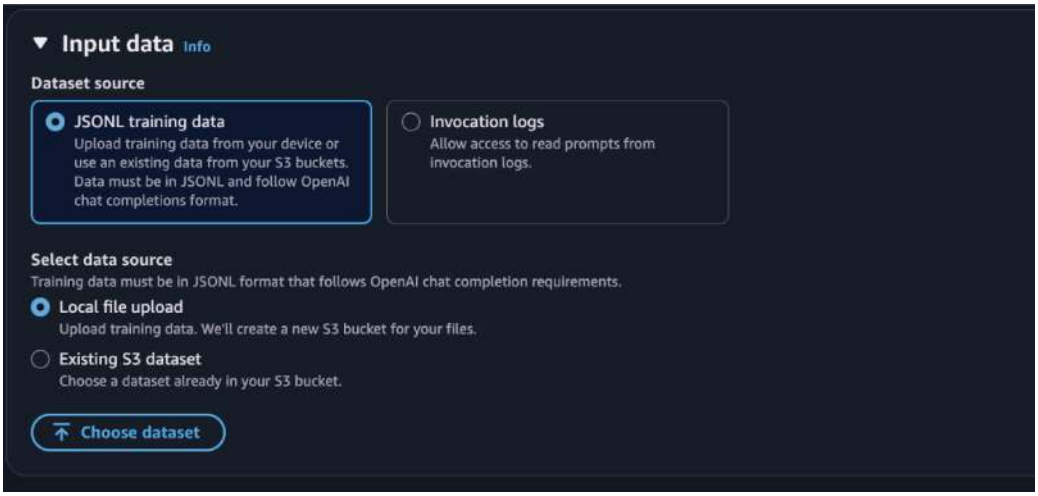
5. Click the blue **Select model** button.



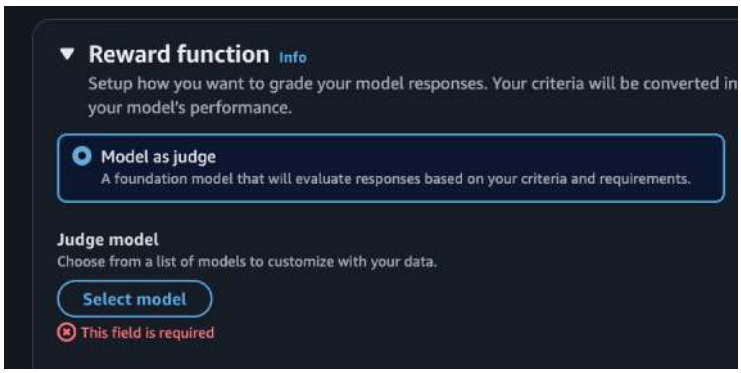
6. Under the model options, choose Nova 2 Lite as that's a smaller model and this is for testing purposes (the goal is to save money here).

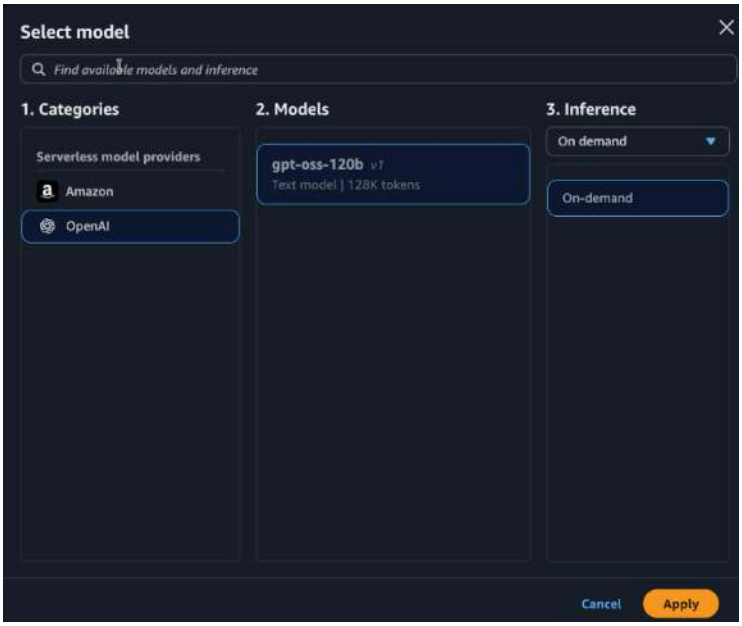


7. Upload the `testing.jsonl` file that you created in Step 2.

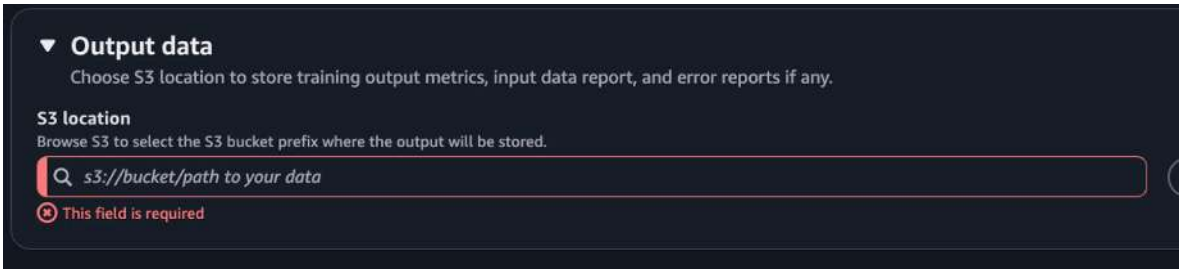


8. Add a model judge. The “Model as judge” option is for agent-to-agent evaluation. The goal is to have a second model that can evaluate the quality of the response.

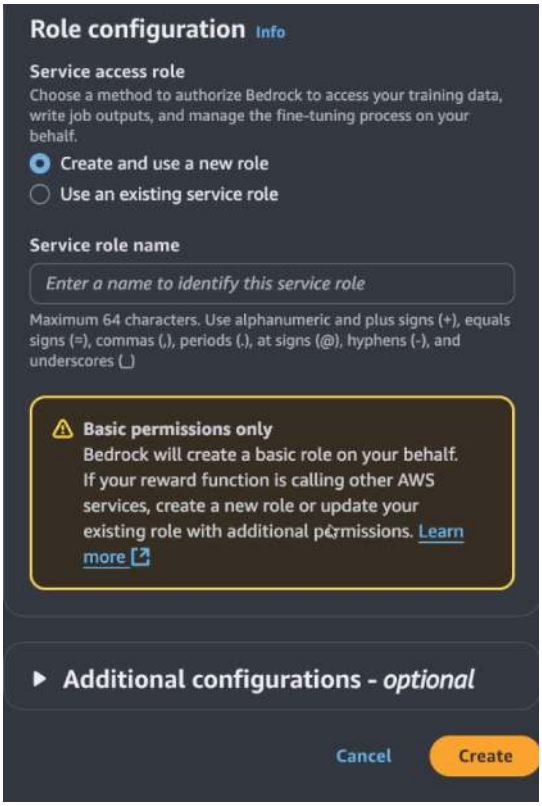




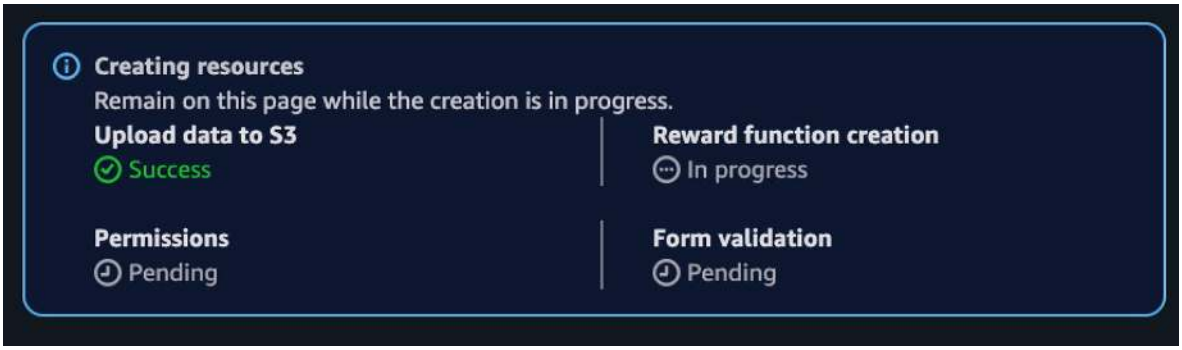
9. The last step is to choose an S3 bucket that will be used to store the training output metrics.



10. Create a new IAM service role if you don't already have one (no action needed other than giving it a name) and then click the orange **Create** button.



You'll now see the model being trained.



With two configurations done in the cloud (one in Azure and one in AWS), you should now have an understanding of a few key services in the cloud for creating, using, and fine-tuning agents. As you continue your AI journey, you'll realize something that's pretty similar to other services in each cloud provider – they're more or less "doing the same thing." Because of that, the goal is less about the service in this case and more about understanding which cloud provider you want to be locked into for your agentic AI usage.

If you don't want to be locked into a specific cloud provider and a very narrow way of doing things, you can run all things agentic AI in Kubernetes. Keep in mind that, of course, there will be needs for storage classes, load balancers, GPU offerings, etc., but the goal is to have a uniform standard that works across a platform type (in this case, K8s).

Agentic in Kubernetes

There are typically two camps of thought and sometimes it could vary on the company (e.g., one company has multiple engineering teams with many different opinions):

1. Use a PaaS/SaaS so people aren't on the hook for things going down.
2. The need for more control over systems/workflows.

And sometimes, you see both within the same team. An example is that a team may use a SaaS-based monitoring and observability tool, but use an on-prem Kubernetes implementation that's 100% managed by them.

If you're using Kubernetes, whether it's a managed service (AKS, EKS, GKE, etc.) or a raw Kubernetes cluster (kubeadm, microk8s, k3s) for your workloads, you're somewhere in the middle between a managed service and needing to ensure enough control over the systems and application stacks. Agentic AI implementations are very much in the middle as well. You may be creating your own agents, but you're connecting those agents to LLMs that already exist and are managed for you. With this level of thought, Kubernetes is the best place to orchestrate, manage, and deploy agentic AI. You have the best of both worlds (control and managed services).

Why AI in K8s Makes Sense

One of the main selling points for teams when it comes to Kubernetes, aside from it being the current standard and therefore a lot of information about it out in the world, which allows for far greater and easier adoption, is the fact that Kubernetes in itself is agnostic. It's an open source project, and despite cloud providers "sprinkling cloud goodness" on their versions of K8s (AKS, EKS, GKE, etc.), it's still the same open source project underneath the hood. Because of that, you can take the same configurations/manifests and run them on any Kubernetes cluster. There may be some differences (e.g., volume is pointing to an S3 bucket and needs to point to Azure Storage), but aside from some metadata, the configurations/manifests run the same way regardless of where your Kubernetes is running.

The second major point to using Kubernetes for today's workloads is scalability. Whether you want to add more resources to pods (vertical), add more pods (horizontal), or do the same thing for nodes, engineers have a unique flexibility for ensuring that the workloads running on a Kubernetes cluster are as performant as they should be.

The two points made above are key in understanding why DevOps and platform engineering teams are choosing to run agentic AI workloads on Kubernetes. The benefits that the industry has received by running application stacks on Kubernetes (many of which are why K8s became so popular) are the same benefits you get when running AI workloads on K8s: scalability, performance optimization, agnostic configurations, declarative by nature, and many others. Because of that, the rest of this chapter will be about running agentic on Kubernetes, and you'll see many different ways to do so.

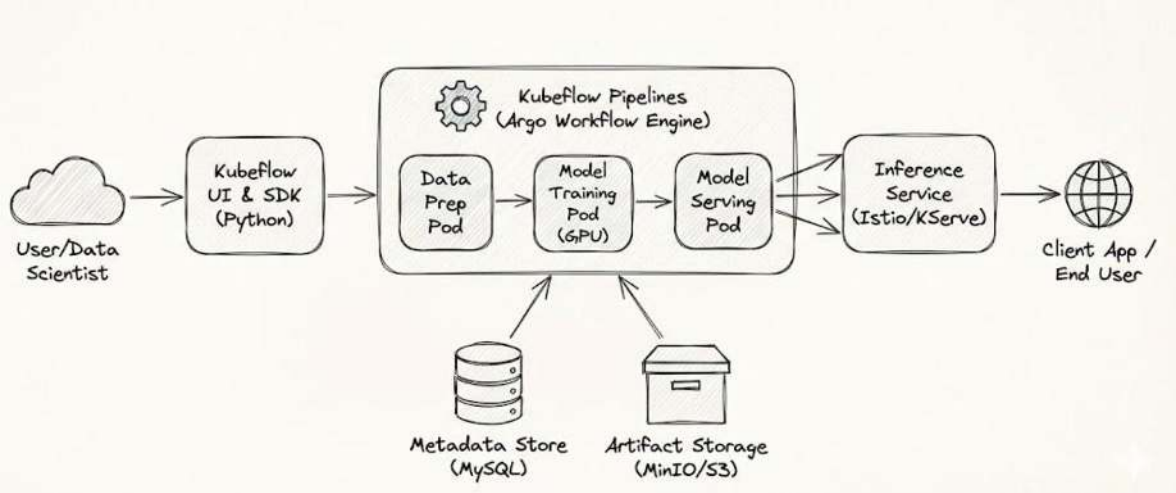
One thing to leave you with before we move on to the next section: something that engineers tend to think about often in the industry is the 360 that all of us end up doing in our careers. We start off in one area, move on to the latest and greatest, and then somehow find our way back to where we started. These are the "cycles" we go through in the industry as a whole. If you've ever thought to yourself "I remember doing this 10 years ago in another platform," that's because you probably have. When it comes to agentic AI in Kubernetes, it's no different. Now that the use of agents and AI is becoming more and more relevant in the enterprise, the conversations are beginning to shift from "this is a neat new way to run stuff" to "wait, how do we secure agents? Can we set up observability for agent usage? Do we need a new gateway? How do we configure auth?". You'll find the answers to those questions through this chapter and the rest of the book.

Running Traditional ML Workloads in Kubernetes

To start off, this brief section will discuss running traditional machine learning (ML) workloads on Kubernetes.

Training models can get expensive. That's why the major AI providers spend millions of dollars on hardware (GPUs, memory, CPU). However, many of these servers with this expensive hardware have the same problem that servers had before virtualization. At times, the servers aren't training any models, which means these servers that are ridiculously expensive are just sitting there.

With Kubernetes, these models can be pods that share GPUs (with tools like NVIDIA Operator and DRA), memory, and CPUs. The major project based on current adoption that is leading the way in this area is Kubeflow.



Kubeflow is a stack of tools ranging from model training to fine-tuning to the pipelines used to run and automate the process of creating and fine-tuning models.

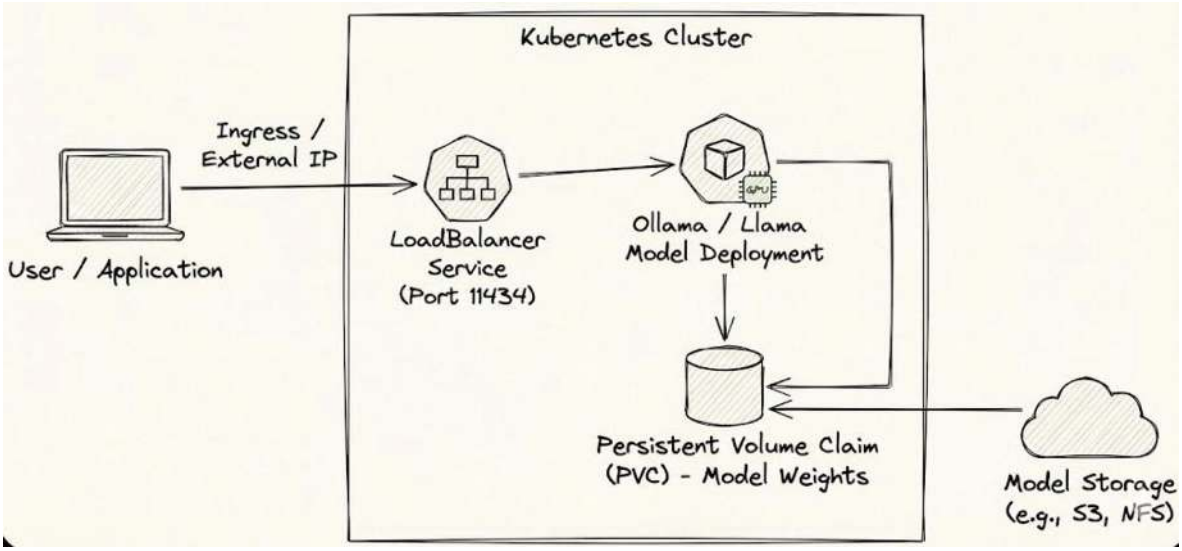
We won't dive deeper into Kubeflow, and this section certainly doesn't give it justice as it's an incredibly popular and powerful platform, but the goal is to give you an idea that platforms like this exist, even though, as a platform or DevOps engineer, you may not be using it all that much. You most likely will be the one that deploys the platform itself, but Kubeflow is used more by machine learning engineers and data scientists. It's still good to have the knowledge that it exists though, especially in a dynamic specialty like AI.

LLMs Deployed in Kubernetes

There are two schools of thought when running LLMs:

1. Use LLMs that are provided to us in a SaaS-based fashion (Claude, Gemini, GPT, etc.).
2. Run self-hosted LLMs to ensure control over the data, where the prompts are going, and fine-tuning the LLMs to be more purpose-built.

In Kubernetes, you have the option to run Number 2. Right now, the two most popular self-hosted model familyies are DeepSeek and Llama.



As mentioned, the biggest goal of running your own LLM in an environment that you manage is to control what is fed to it. A downfall of using a hosted/SaaS-based LLM like Claude, GPT, or Gemini is that it's not managed by you. When you run a prompt, that information is sent to an environment that you don't control. If a password or an API key is sent in a prompt, that's a major security risk. If you want a specialized model that is small or a model that has specific information, you can use Agent Skills, MCP Servers, and RAG, but what if you want to take it a step further and have a model that has less parameters with specialized data and, therefore, less prone to hallucinations? Those are all reasons why you'd either run your own LLM or train your own model. Luckily, both options can be run in Kubernetes.

Deploying Llama

For the purposes of this section, you should have a Kubernetes cluster up and running. If you don't want the model to be incredibly slow, you should have at least 16 GB of memory available in the cluster.

1. Within your Kubernetes cluster, create a new namespace for the Llama Model Pod to reside in.

```
kubectl create ns ollama
```

2. Deploy the Llama Model as a deployment object with a K8s service so it's accessible. The goal with the K8s service is like any other service – to ensure that the pods can be reached despite the actual pod name (if one pod goes down). That's especially important for AI workloads as the last thing you want is to be dependent on one LLM pod, and if it goes down, the agent calling out to Llama will not be usable. Pods running LLMs need to be able to be accessed in a load-balanced fashion. A Kubernetes service provides stable discovery and can distribute connections across replicas. Production LLM serving may additionally require request queuing, concurrency limits, backpressure, session handling, model-aware routing, and accelerator-aware scheduling. These concerns should be addressed by the inference runtime or serving platform rather than assumed to be solved by the service alone.

   Notice that the pod is being created like any other pod despite it being an LLM. A key difference you may not always see in a traditional application stack is the arguments. See how it's using the Pull command to pull down a specific model. That's because even though the Ollama container image is being used, that doesn't specify that an LLM in the Ollama family is being pulled down. That's where the Pull command comes into play.

```
kubectl apply -f - <<EOF
apiVersion: apps/v1
kind: Deployment
metadata:
  name: ollama
  namespace: ollama
spec:
  selector:
    matchLabels:
      app: ollama
  template:
    metadata:
      labels:
        app: ollama
    spec:
      initContainers:
      - name: model-puller
        image: ollama/ollama:latest
        command: ["/bin/sh", "-c"]
        args:
          - |
            ollama serve &
            sleep 10
            ollama pull llama3
            pkill ollama
        volumeMounts:
        - name: ollama-data
          mountPath: /root/.ollama
        resources:
          requests:
            memory: "8Gi"
          limits:
            memory: "12Gi"
      containers:
      - name: ollama
        image: ollama/ollama:latest
        ports:
        - name: http
          containerPort: 11434
          protocol: TCP
        volumeMounts:
        - name: ollama-data
          mountPath: /root/.ollama
        resources:
          requests:
            memory: "8Gi"
          limits:
            memory: "12Gi"
      volumes:
      - name: ollama-data
```

```
        emptyDir: {} # Note this is for testing purposes only as the
  emptyDir only exists for the lifetime of the Pod
  ---
  apiVersion: v1
  kind: Service
  metadata:
    name: ollama
    namespace: ollama
  spec:
    type: ClusterIP
    selector:
      name: ollama
    ports:
    - port: 80
      name: http
      targetPort: http
      protocol: TCP
  EOF
```

3. As you can imagine, even with a small model, they're still gigabytes in size, so you will need to give it a few minutes to download based on your internet connection. After a few minutes, run the following command to see the model.

```
kubectl exec -n ollama deployment/ollama -- ollama list
```

You should now be able to see an output similar to the below.

```
Defaulted container "ollama" out of: ollama, model-puller (init)
NAME             ID              SIZE      MODIFIED
llama3:latest    365c0bd3c000    4.7 GB    About a minute ago
```

4. To use the model, you'll need to exec into the pod.

```
kubectl exec -it -n ollama $(kubectl get pod -n ollama -l app=ollama -
o jsonpath='{.items[0].metadata.name}') -- bash
```

5. You can now run and prompt the model.

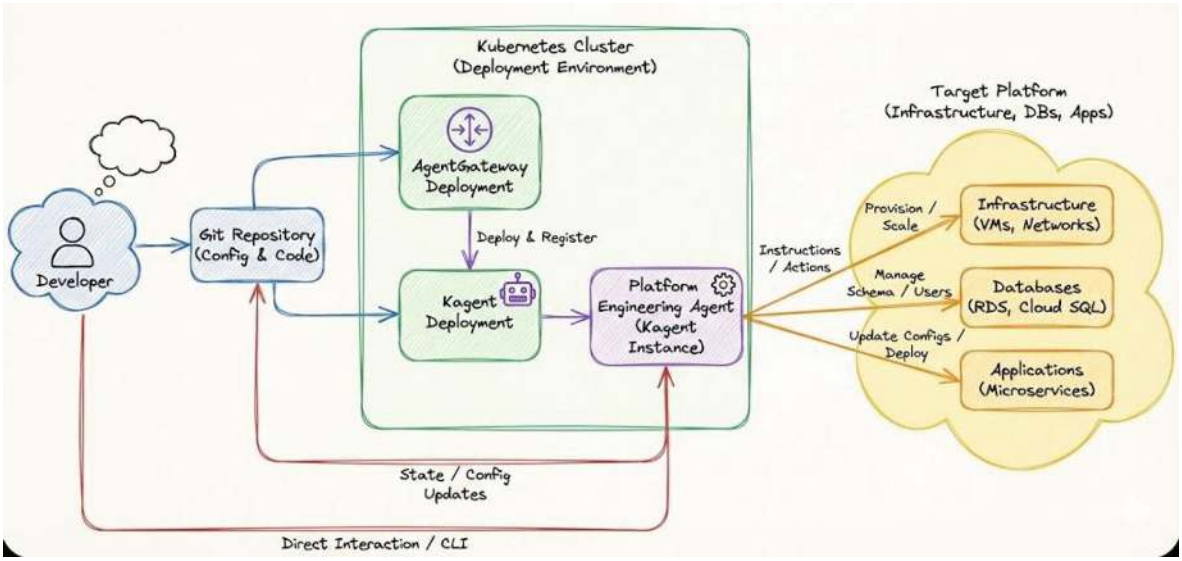
```
ollama run llama3:latest
```

Feel free to ask it a question to confirm it's working.

With this information, you now know how to run/deploy/use self-hosted LLMs or even your own models in Kubernetes, which is great for teams that need to interact with those models, but how are teams interacting with the models whether they're self-hosted or SaaS-based? You don't want to have every single engineer or person in an organization exec'ing into a Kubernetes pod every time they have a prompt. It's not scalable and it's not secure in the slightest. Understanding how to deploy a model in Kubernetes and manage it like any other workload is absolutely crucial to this journey, but now you need to learn how to actually use it.

Build a Platform Engineering Agent

In the previous sections of this chapter, you learned everything from running agentic workflows in cloud-based/PaaS services to building and training models via traditional ML workflows with Kubeflow and deploying LLMs within Kubernetes. With the knowledge you've obtained, it's time to dive in and build your first AI agent that will run on Kubernetes. You will learn how to install an agentic framework, an AI gateway (both OSS), and use them as a platform engineering agent assistant.



The goal of this AI agent will be a platform engineering helper. It should be able to help with everything from looking at observability data (logs/traces/metrics) to deploying Kubernetes pods and everything in between.

Please note that this chapter doesn't show utilizing other methods like MCP Servers, Agent Skills, and specialized prompts because that is all covered in Chapter 5's agent that you will be building. The agent you'll be building in this section is supposed to be your "entry point" into building agentic AI on Kubernetes and the lab in Chapter 5 will be far more advanced with MCP, Agent Skills, monitoring, and observability.

The following four sections will contain the two tools/platforms you need to install (kagent and agentgateway), how to declaratively configure an agent, and how to use the agent.

Installing Kagent

The first step is to install kagent, which is the agent framework that you will see within Kubernetes. Despite other frameworks that lock you into a particular vendor or a specific SDK and programming language, kagent allows you to run, deploy, manage, observe, and build agents in any Kubernetes cluster.

The one thing that you need to think about when installing kagent is the LLM provider that you'd like to start with. The configuration/installation below shows how to do it with Anthropic, but you can use any provider that is supported: https://kagent.dev/docs/kagent/supported-providers

1. First, install the kagent CRDs in your cluster.

```
helm install kagent-crds oci://ghcr.io/kagent-dev/kagent/helm/kagent-
crds \
```

```
    --namespace kagent \
    --create-namespace
```

2. Use an environment variable to specify the LLM provider API key.

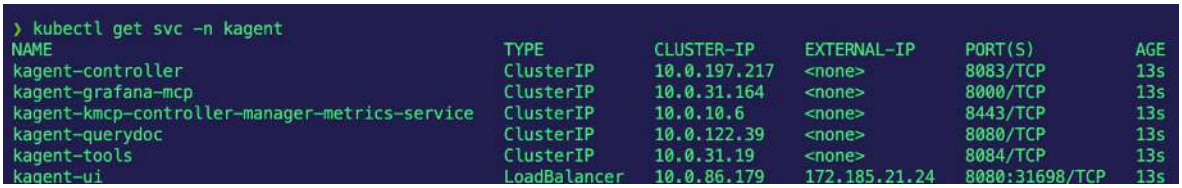
```
export ANTHROPIC_API_KEY=your_api_key
```

3. Install kagent. The installation below contains ui.service.type=LoadBalancer, which is a good option if you're on a managed K8s cluster or have access to deploy LBs with something like metallb. If you don't, you can remove that line and access kagent via port-forwading the kagent UI service.

```
helm upgrade --install kagent oci://ghcr.io/kagent-
dev/kagent/helm/kagent \
    --namespace kagent \
    --set providers.default=anthropic \
    --set providers.anthropic.apiKey=$ANTHROPIC_API_KEY \
    --set ui.service.type=LoadBalancer
```

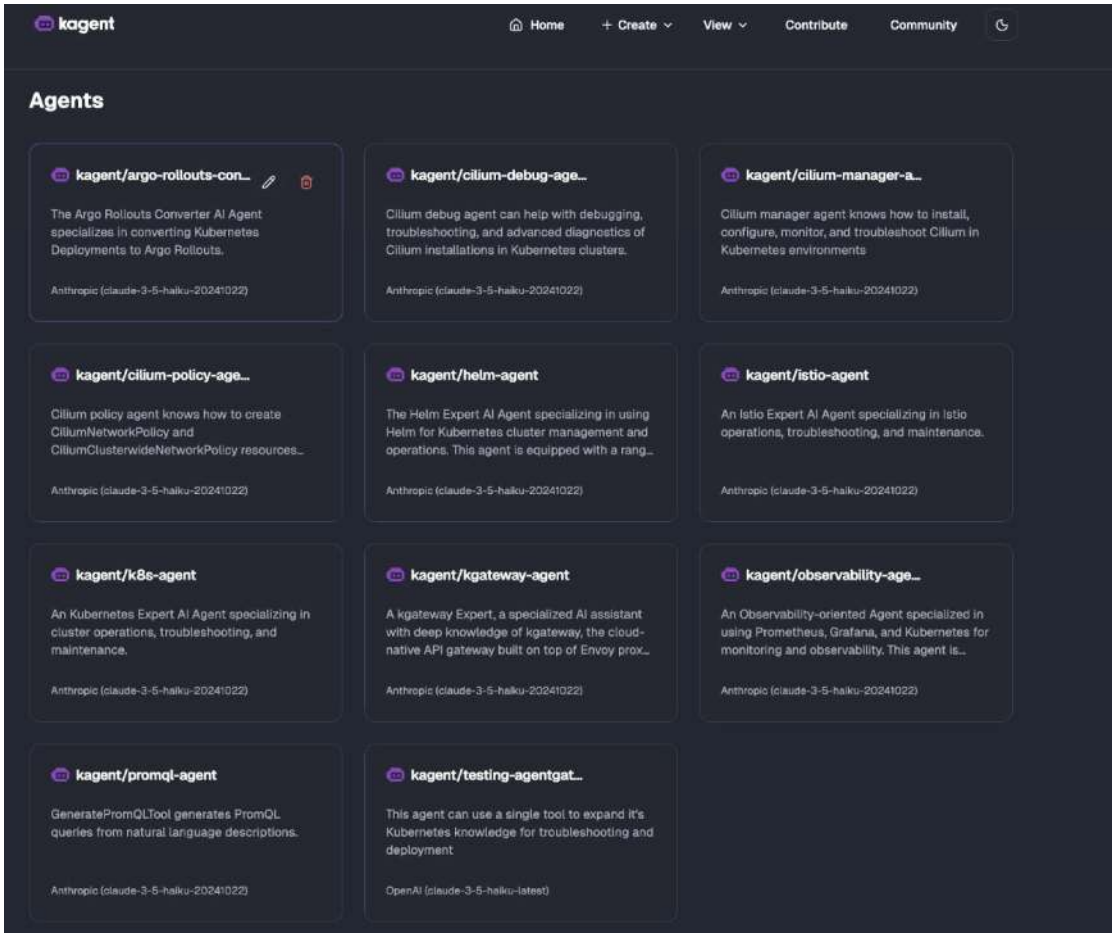
4. Ensure that kagent is running.

```
kubectl get svc -n kagent
```



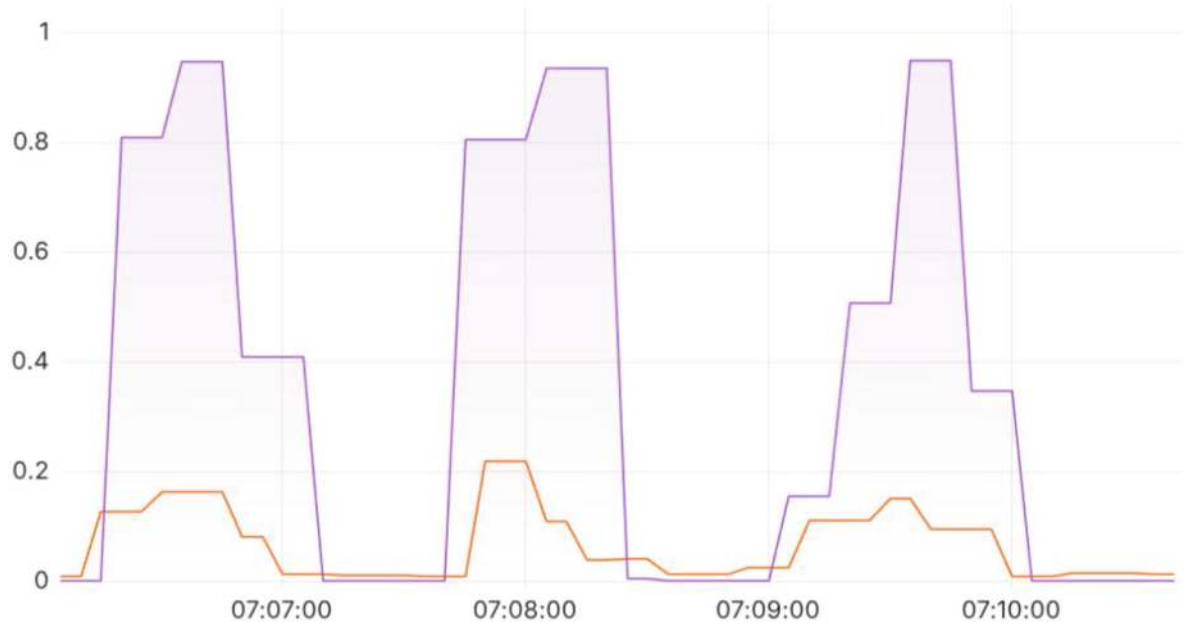
```
❯ kubectl get svc -n kagent
NAME                                          TYPE           CLUSTER-IP     EXTERNAL-IP     PORT(S)          AGE
kagent-controller                             ClusterIP      10.0.197.217   <none>          8083/TCP         13s
kagent-grafana-mcp                            ClusterIP      10.0.31.164    <none>          8000/TCP         13s
kagent-kmcp-controller-manager-metrics-service ClusterIP     10.0.10.6      <none>          8443/TCP         13s
kagent-querydoc                               ClusterIP      10.0.122.39    <none>          8080/TCP         13s
kagent-tools                                  ClusterIP      10.0.31.19     <none>          8084/TCP         13s
kagent-ui                                     LoadBalancer   10.0.86.179    172.185.21.24   8080:31698/TCP   13s
```

Now that kagent is installed, you can access the UI with the public ALB IP address in the kagent-ui service or by port-forwarding that service.



Installing and Configuring Agentgateway

After you have an agentic framework installed, you then need to think about the traffic flowing from an agent to an LLM, another agent, or an MCP Server from not only a security perspective, but an observability perspective. Just like any other packets that are flowing, you want to ensure that you have an understanding of what's going from Point A to Point B (agent to destination). A great example of this that constantly pops up is around token usage. A lot of teams want to know what agents are being used with what LLMs and what the overall token usage is, as it could cost the organization a lot of money. Agentgateway is a purpose-built AI gateway that is written in Rust for the overall speed, memory, and security benefits. After benchmarking done in the community, it's far more performant in comparison to Envoy-based Gateways for AI workloads.



1. Install the Kubernetes Gateway API CRDs, as agentgateway is built on top of the Gateway API, which is an agnostic standard for gateways.

   ```
   kubectl apply -f https://github.com/kubernetes-sigs/gateway-api/releases/download/v1.4.0/standard-install.yaml
   ```

2. Install the CRDs for agentgateway.

   ```
   helm upgrade -i --create-namespace \
     --namespace agentgateway-system \
     --version v2.2.0-main agentgateway-crds oci://ghcr.io/kgateway-dev/charts/agentgateway-crds
   ```

3. Install agentgateway.

   ```
   helm upgrade -i -n agentgateway-system agentgateway
   oci://ghcr.io/kgateway-dev/charts/agentgateway \
   --version v2.2.0-main
   ```

4. You should now see the agentgateway control plane running.

```
kubectl get pods -n agentgateway-system
```

5. With agentgateway installed, you can configure the gateway, routing, and backend (which will be an LLM). First, create a Kubernetes Secret with the LLM provider API key. It will be used in the agentgateway backend, as that's what tells the gateway what to route to.

   ```
   kubectl apply -f- <<EOF
   apiVersion: v1
   kind: Secret
   ```

```
metadata:
  name: anthropic-secret
  namespace: agentgateway-system
  labels:
    app: agentgateway-route
type: Opaque
stringData:
  Authorization: $ANTHROPIC_API_KEY
EOF
```

6. Create the gateway object which contains the agentgateway gateway class and HTTP listeners.

```
kubectl apply -f - <<EOF
apiVersion: gateway.networking.k8s.io/v1
kind: Gateway
metadata:
  name: agentgateway-route
  namespace: agentgateway-system
  labels:
    app: agentgateway
spec:
  gatewayClassName: agentgateway
  listeners:
    - name: http
      port: 8080
      protocol: HTTP
      allowedRoutes:
        namespaces:
          from: Same
EOF
```

7. Configure the agentgateway backend object which will contain the model that you want your gateway to route to and the LLM provider secret.

```
kubectl apply -f - <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayBackend
metadata:
  labels:
    app: agentgateway-route
  name: anthropic
  namespace: agentgateway-system
spec:
  ai:
    provider:
        anthropic:
          model: "claude-3-5-haiku-latest"
  policies:
    auth:
      secretRef:
        name: anthropic-secret
EOF
```

```
EOF
```

8. Apply the routing configuration so the gateway has a path to route to.

```
kubectl apply -f - <<EOF
apiVersion: gateway.networking.k8s.io/v1
kind: HTTPRoute
metadata:
  name: claude
  namespace: agentgateway-system
  labels:
    app: agentgateway-route
spec:
  parentRefs:
    - name: agentgateway-route
      namespace: agentgateway-system
  rules:
  - matches:
    - path:
        type: PathPrefix
        value: /anthropic
    filters:
    - type: URLRewrite
      urlRewrite:
        path:
          type: ReplaceFullPath
          replaceFullPath: /v1/chat/completions
    backendRefs:
    - name: anthropic
      namespace: agentgateway-system
      group: agentgateway.dev
      kind: AgentgatewayBackend
EOF
```

9. Retrieve the gateway's IP address, as it will be used in the next section when configuring the agent in kagent.

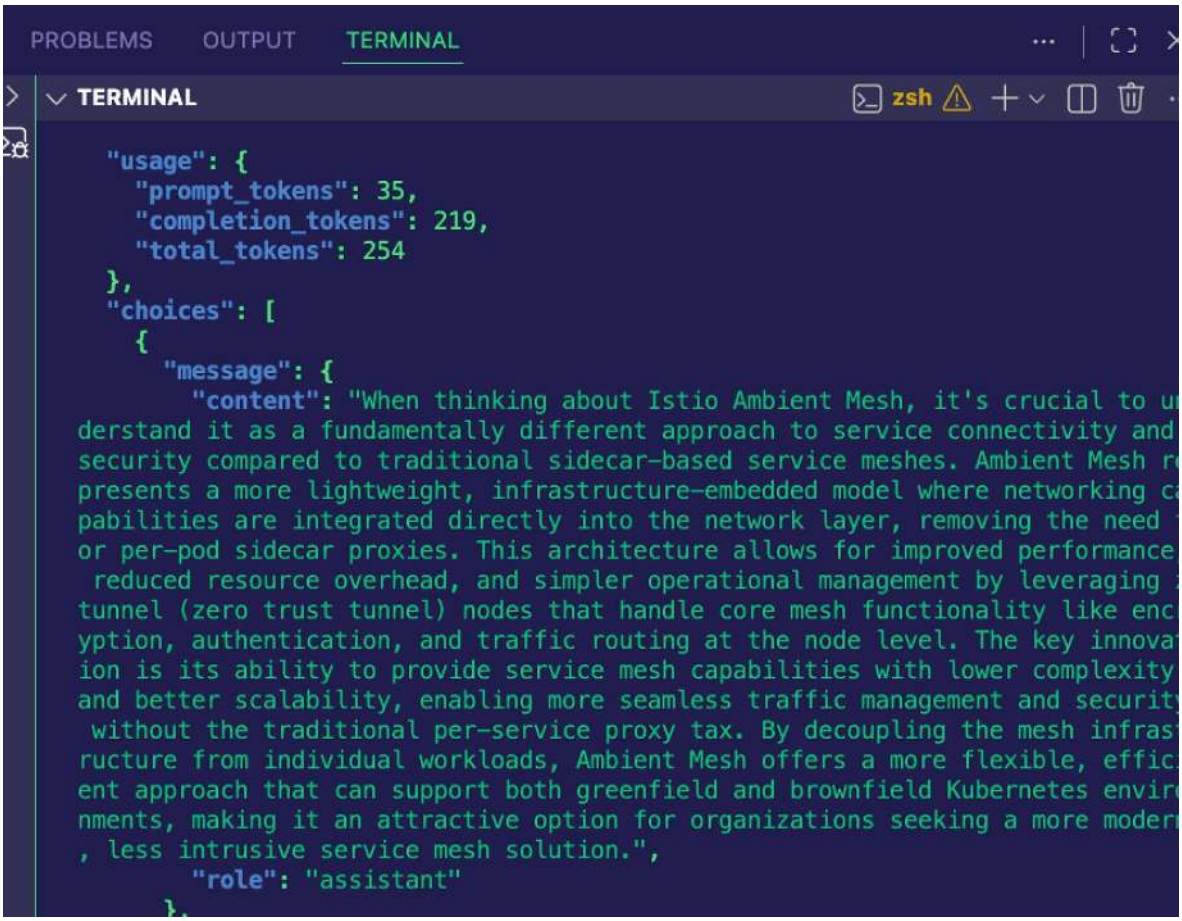
```
export INGRESS_GW_ADDRESS=$(kubectl get svc -n agentgateway-system
agentgateway-route -o jsonpath="{.status.loadBalancer.ingress[0]
['hostname','ip']}")
echo $INGRESS_GW_ADDRESS
```

10. Test the gateway and route with a curl to ask the LLM a question.

```
curl "$INGRESS_GW_ADDRESS:8080/anthropic" -H content-
type:application/json -H "anthropic-version: 2023-06-01" -d '{
  "messages": [
    {
      "role": "system",
      "content": "You are a skilled cloud-native network engineer."
    },
    {
```

```
    {
      "role": "user",
      "content": "Write me a paragraph containing the best way to
think about Istio Ambient Mesh"
    }
  ]
}' | jq
```

You should see an output similar to the screenshot below.



Virtual Keys

As you're implementing Kubernetes Secrets for API keys that will be used to interact with the LLM provider, you may ask yourself "who is this API key tied to?," and the answer is, by default, it's "universal." Within an LLM provider, there's no way to create a key per person. If you want a key that's tied to you and what you do, that's not doable today. In agentgateway, however, you can. There's a concept of virtual keys in agentgateway that allow you to specify a key per user.

As an example, you can create a Kubernetes ConfigMap where you can specify the API key hash along with the user that the key is tied to. That way, you can do things like see cost/token usage for said key.

```
kubectl apply -f- <<EOF
apiVersion: v1
```

```
kind: ConfigMap
metadata:
  name: llm-api-keys
  namespace: agentgateway-system
  labels:
    agentgateway.dev/apikey: "true"
data:
  alice: |
    {
      "keyHash":
"sha256:477fe4bee6e6d46cc4fa5827b4c375f045b01701de265deea7c26a74d4f86d1f",
      "metadata": {
        "user_id": "alice"
      }
    }
  bob: |
    {
      "keyHash":
"sha256:b2bd46e01122f51b540cc49cfdd020484776e67f5d3966c099e689eac4b8d93e",
      "metadata": {
        "user_id": "bob"
      }
    }
EOF
```

And that ConfigMap can be attached to via an AgentgatewayPolicy and have that policy targeting a gateway.

```
kubectl apply -f- <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: api-key-auth
  namespace: agentgateway-system
spec:
  targetRefs:
    - group: gateway.networking.k8s.io
      kind: Gateway
      name: agentgateway-proxy
  traffic:
    apiKeyAuthentication:
      mode: Strict
      configMapSelector:
        matchLabels:
          agentgateway.dev/apikey: "true"
    rateLimit:
      global:
        domain: agentgateway
        backendRef:
          kind: Service
          name: ratelimit
```

```
          namespace: ratelimit
          port: 8081
        descriptors:
          - entries:
              - name: user_id
                expression: 'apiKey.user_id'
            unit: Tokens
EOF
```

Declarative Agent Configuration

With kagent installed, agentgateway installed, and a new gateway/backend/route configured to route traffic to your preferred LLM provider, it's time to put it to the test and see if we can route traffic through agentgateway from kagent. In this section, you'll create a model configuration and agent object using the kagent CRDs to declaratively map out how you want your agent to be used.

As a prerequisite, create the same Anthropic secret that you created in the agentgateway-system namespace, but in kagent:

```
kubectl apply -f- <<EOF
apiVersion: v1
kind: Secret
metadata:
  name: anthropic-secret
  namespace: kagent
type: Opaque
stringData:
  Authorization: $ANTHROPIC_API_KEY
EOF
```

1. The first object is the model config, which is used to specify what model you want to use and what the URL/endpoint of the gateway and route is. In the example below, notice the base URL is an AWS ALB plus port 8080, which was specified in the gateway object creation, and the "/anthropic" endpoint, which was configured in the route.

   You'll also notice that the provider used is OpenAI even though the example below has a Claude model. The reason why is because the route/path `(/v1/chat/completions)` is using an OpenAI API schema. The schema is being used, but the traffic is still routing through the Claude model.

   ```
   kubectl apply -f - <<EOF
   apiVersion: kagent.dev/v1alpha2
   kind: ModelConfig
   metadata:
     name: anthropic-model-config
     namespace: kagent
   spec:
     apiKeySecret: anthropic-secret
     apiKeySecretKey: Authorization
     model: claude-3-5-haiku-latest
     provider: OpenAI
     openAI:
       baseUrl: http://a1e5a3b9a8eba4aa09517966f1777763-34157947.us-east-
   1.elb.amazonaws.com:8080/anthropic
   ```

```
EOF
```

2. The next object to create is the agent object, which will create and deploy your platform engineering AI assistant. In an upcoming chapter, you'll learn about using MCP Servers and Agent Skills, but until then, the best way to get a specialized agent is to give it a solid prompt. Below, you will see a prompt that's designed to be a platform engineering assistant prompt.

```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: Agent
metadata:
  name: testing-agentgateway
  namespace: kagent
spec:
  description: This agent can use a single tool to expand it's
Kubernetes knowledge for troubleshooting and deployment
  type: Declarative
  declarative:
    modelConfig: anthropic-model-config
    systemMessage: |-
      You are a platform engineering agent assistant specializing in
cloud-native infrastructure, Kubernetes, CI/CD, observability, and
developer experience.

## Expertise
Kubernetes, Terraform, GitOps (ArgoCD/Flux), service mesh (Istio), API
gateways (agentgateway/kgateway/Gloo), observability
(Prometheus/Grafana/OpenTelemetry), secrets management (Vault), policy
enforcement (OPA/Kyverno), AWS/Azure/GCP, IDP platforms (Backstage)

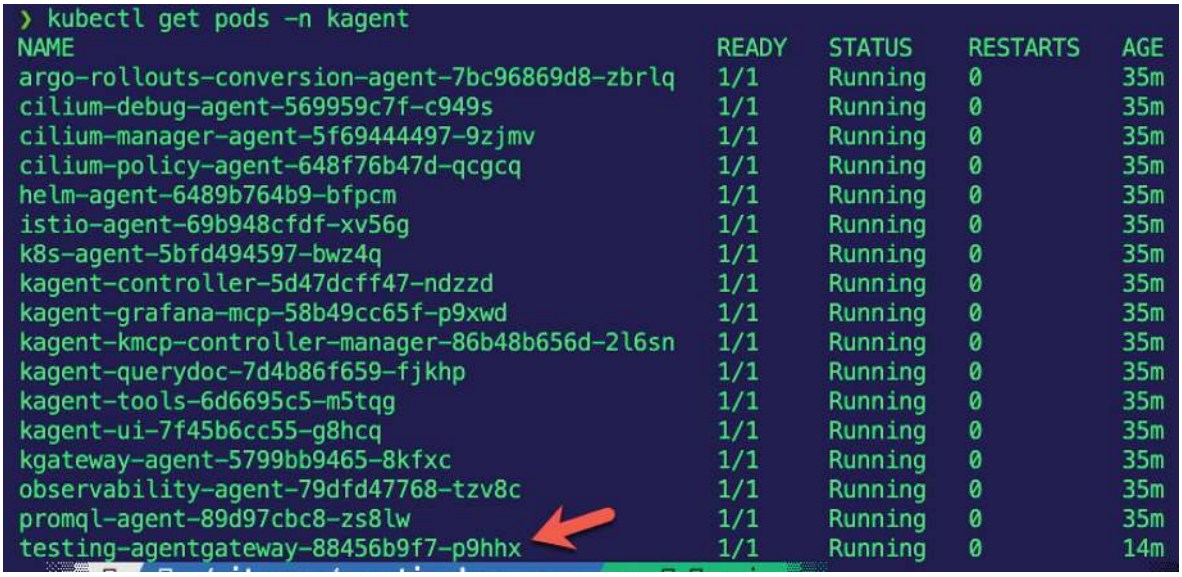
## Your Role
- Design scalable, secure platform architectures
- Troubleshoot infrastructure and deployment issues
- Provide working code examples and configurations
- Recommend best practices for automation, security, and cost
optimization
- Guide migrations and modernization efforts

## Communication Style
- Practical: Give working code snippets and step-by-step guides
- Concise: Keep explanations clear and actionable
- Context-aware: Ask about existing stack, constraints, and
requirements
- Security-first: Always consider security implications
- Production-ready: Focus on scalable, monitored, reliable solutions
```

When helping, understand the context first, then provide two to three solution options with trade-offs, followed by implementation details.

```
EOF
```

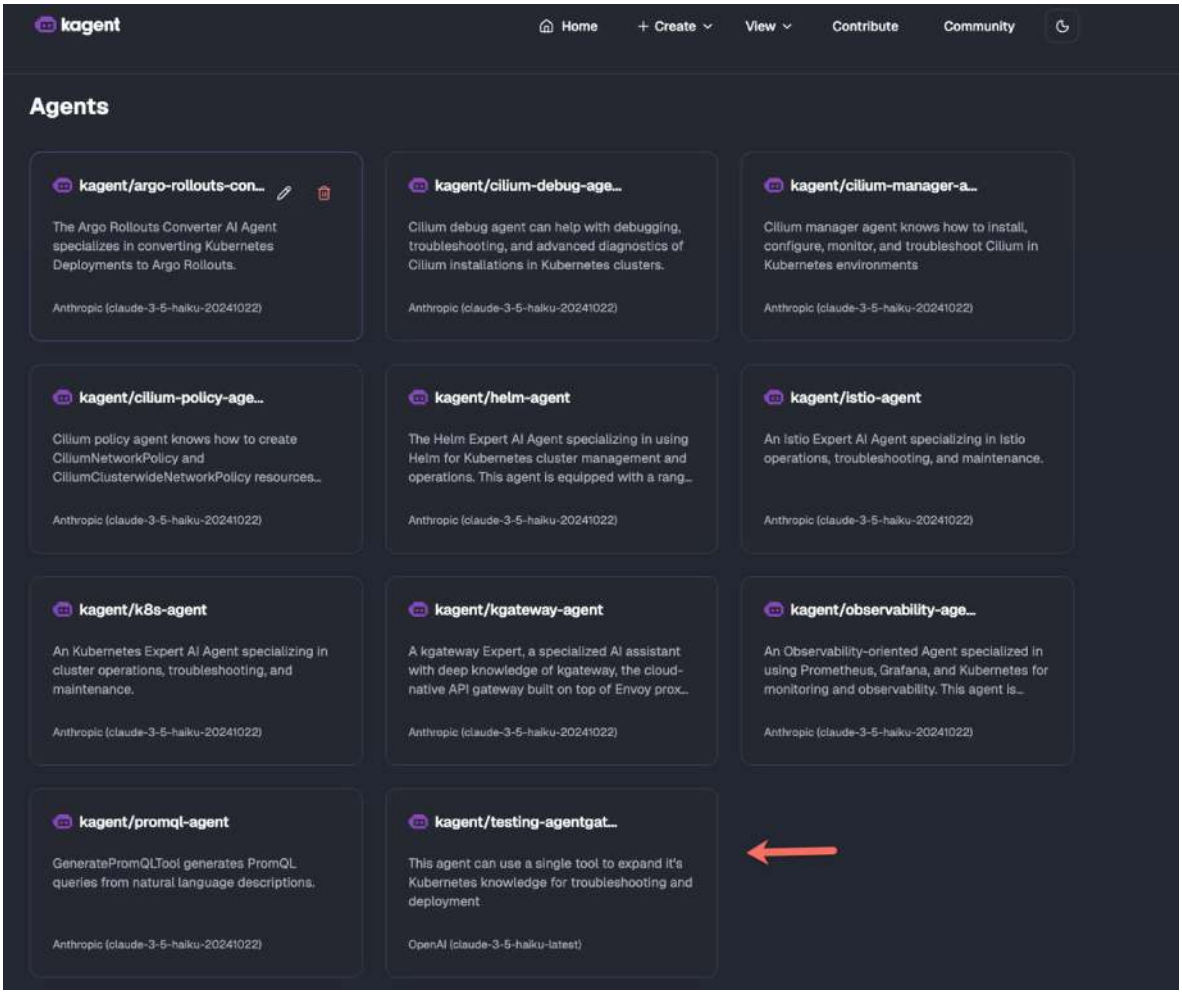
3. You should now be able to see the agent running.



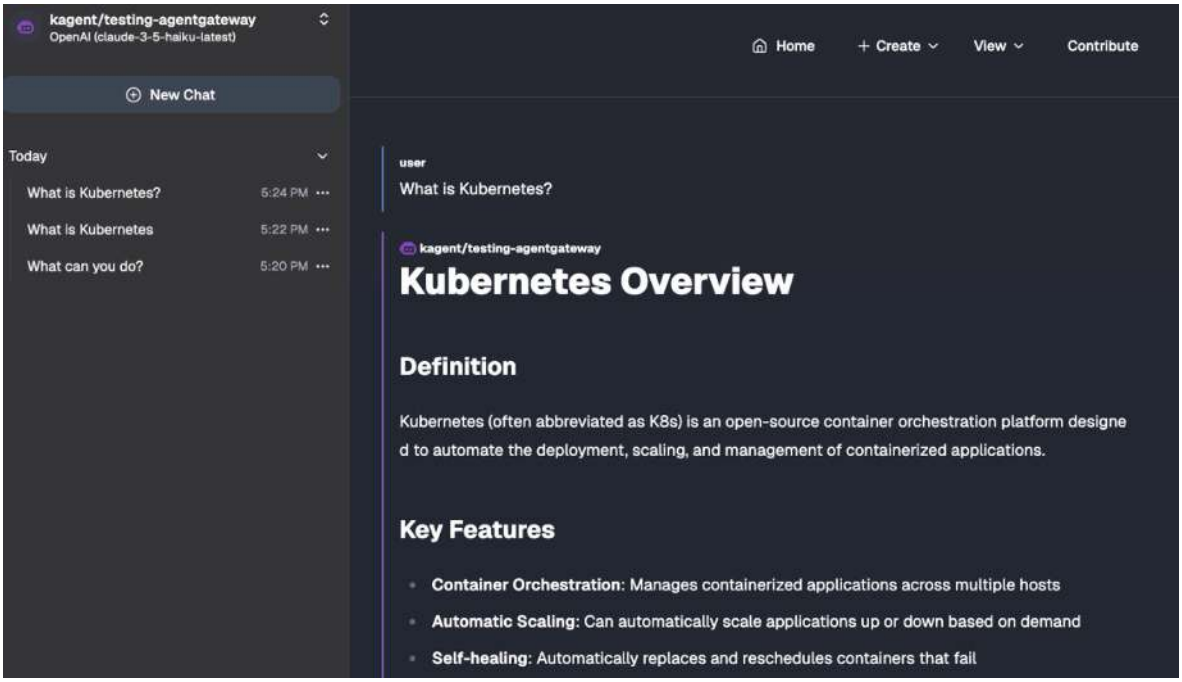
With the agent object deployed, it's time to test it out.

Using the Agent

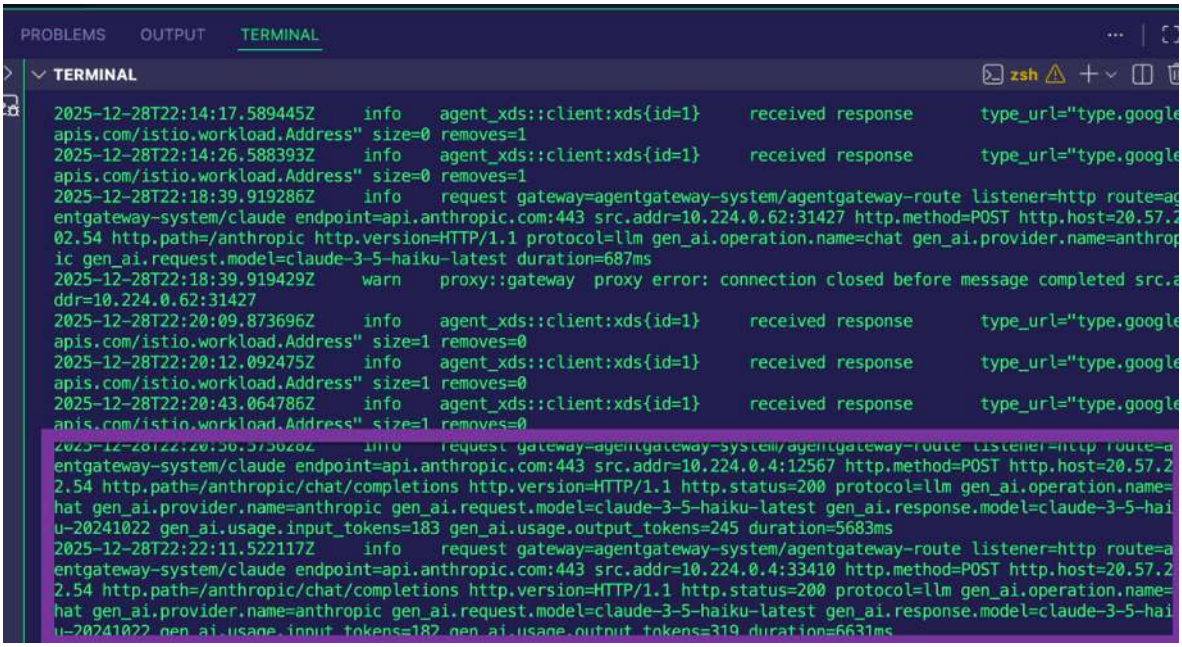
1. Open the kagent UI by getting the IP address of the kagent-ui service or port-forwarding the service. Ensure to use the port the UI is listening on (8080).
2. You should now see your agent running in kagent.



3. Prompt it with your prompt of choice.



4. Check the logs of the `agentgateway-route` pod, which is the dataplane proxy, and you should see that the traffic flowed through the gateway.



Conclusion

The agentic AI movement is very new, yet it's moving rapidly. A great example of this is the protocols like MCP that are very new (less than 1.5 years old) and are the "industry standards." The velocity at which things are moving is something that truly hasn't been seen in what we can categorize as the "computer science" space before. Because of that, it's safe to say that there's a strong possibility that running agentic AI workloads in something like Kubernetes may not be the end state (and if it is, that

probably means the industry failed to innovate). However, as of right now and for the foreseeable future, engineers need scalable and reliable methods of running AI workloads and those two locations right now are AI services in major cloud providers and Kubernetes.

4. Monitoring and Observability for Agentic Infrastructure

Michael Levan[1] ✉
(1) Budd Lake, NJ, USA

In the three previous chapters, you learned everything from knowing the "why" behind AI in today's world, the concepts you need to know to be successful in the Agentic space, and implementing various methods of agentic ranging from using cloud-based tools like Foundry and Bedrock to creating your own agent. With that, the next step after creating and understanding how it works is figuring out how it will work day-to-day. What LLMs will be called? How many tokens will be used? What's the cost? How is the agent and overall agentic infrastructure performing? That's where monitoring and observability come into play.

In this chapter, you will learn

1. How to implement monitoring and observability for agentic infrastructure.
2. Understand cost and performance of your agent.
3. Open source observability tools and enterprise observability tools.

Implementing Monitoring and Observability Practices for AI

Out of the box, agentic infrastructure may not have a specific way for you to look at monitoring and observability data. In the Anthropic console, you can see some cost usage, but that's about it. However, what you can do is utilize the metrics and traces that are exposed via the LLM providers. There's extensive support for tools ranging from OTel to Grafana, Prometheus, Datadog, and various other monitoring and observability tools. Much like any application stack, as long as the metrics and traces are exposed by the provider/creator/maintainer, you can ingest the metrics and traces to view them and perform actions with them based on the results of the metrics and traces. For example, if you're using a model and it's not providing the best results, *you can automate model selection using routing policies based on metrics such as latency, cost, or evaluation results*.

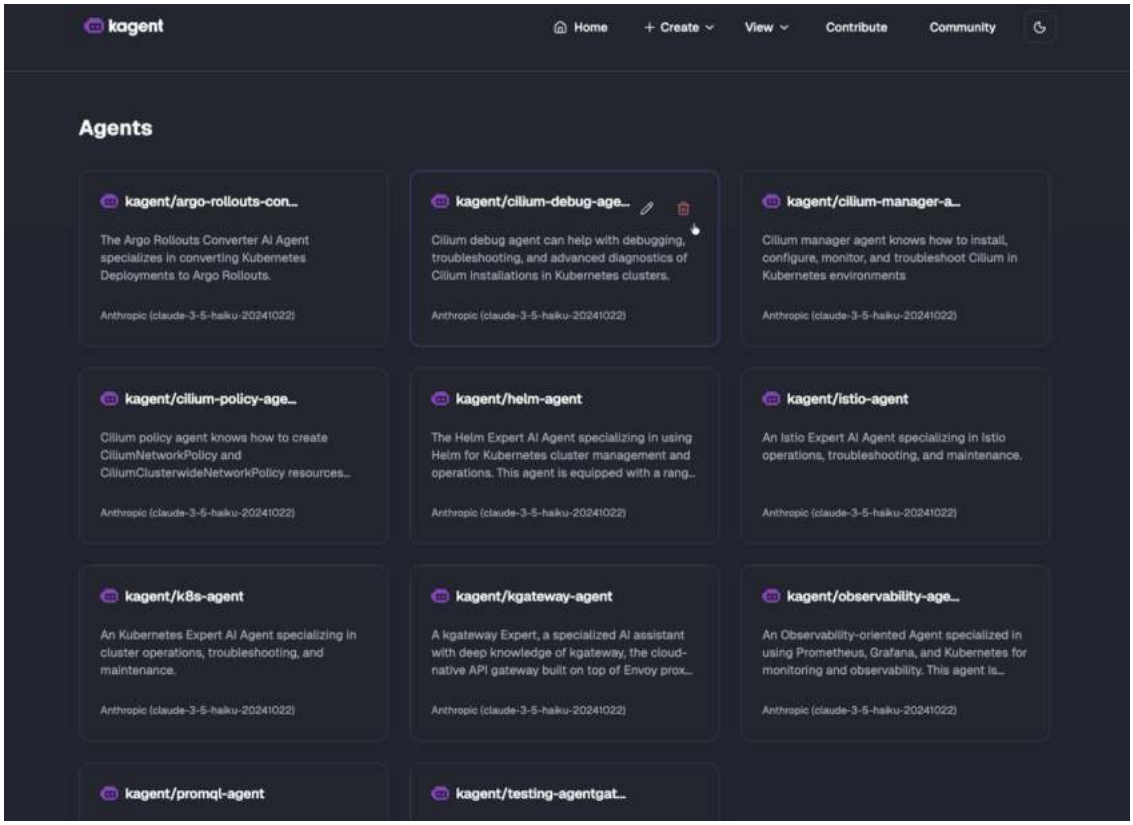
The AI gateway you're using may also contain various metrics and traces that you can use within your monitoring and observability tool. For example, agentgateway exposes metrics for everything from usage to tokens used to what model is being called.

In this section, you'll learn how to set up Grafana and Prometheus to capture metrics from agentgateway for the agent that is using the gateway to pass traffic through. You'll also see how to track the cost of LLMs used.

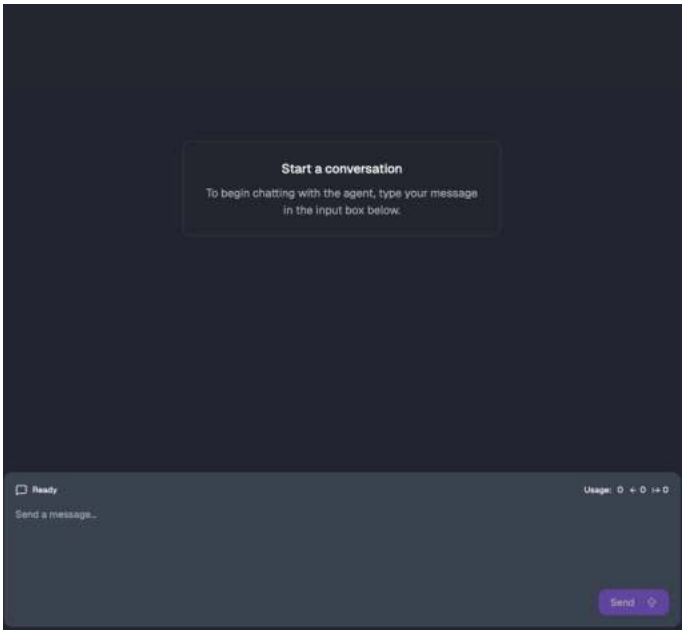
Agentic Preparation

For preparation to ensure that we can capture metrics via the agentgateway, we'll want to route some traffic through the platform engineering agent that you set up in the previous chapter (testing-agentgateway) to ensure that metrics exist as the only way for metrics to exist is if traffic is passed through the gateway from kagent in this case.

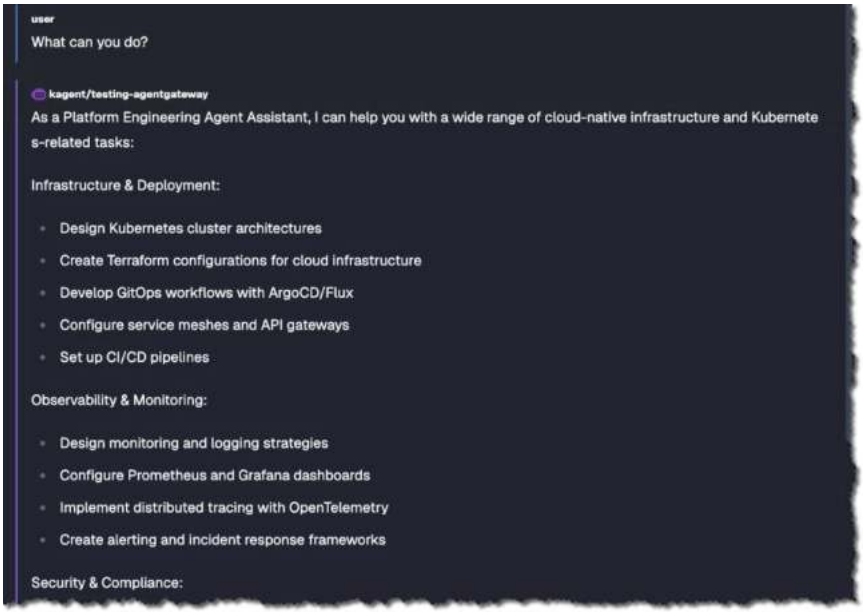
1. Open the kagent UI.



2. Go to your testing-agentgateway agent.



3. Prompt it with “What can you do?”. You should see an output similar to the below.



4. Go to the logs of your gateway, which will be in the agentgateway-route pod. For example, here's a pod that I had running:

```
kubectl logs agentgateway-route-6c865b7c67-mmx9h -n agentgateway-system
```

You should now be able to see the logs for the traffic going through your gateway.

```
2026-01-18T15:56:24.30039Z      info    request gateway=agentgateway-
system/agentgateway-route listener=http route=agentgateway-system/claude
endpoint=api.anthropic.com:443 src.addr=10.224.0.4:26482 http.method=POST
http.host=172.178.128.58 http.path=/anthropic/chat/completions
http.version=HTTP/1.1 http.status=200 protocol=llm
gen_ai.operation.name=chat gen_ai.provider.name=anthropic
gen_ai.request.model=claude-3-5-haiku-latest
gen_ai.response.model=claude-3-5-haiku-20241022
gen_ai.usage.input_tokens=340 gen_ai.usage.output_tokens=290
duration=5834ms
```

Now that we know we have metrics, we can view them within an observability tool.

Installing and Configuring OSS Observability

With the agent up and operational, it's time to install and configure an open source monitoring and observability tool. In this case, due to popularity in the open source community along with in production via cloud-native workflows, this section will use Grafana and Prometheus. The stack that will be used is kube-prometheus, which is a stack that comes with out-of-the-box Grafana dashboards for workloads running on Kubernetes.

1. Add the Prometheus-community repo locally.

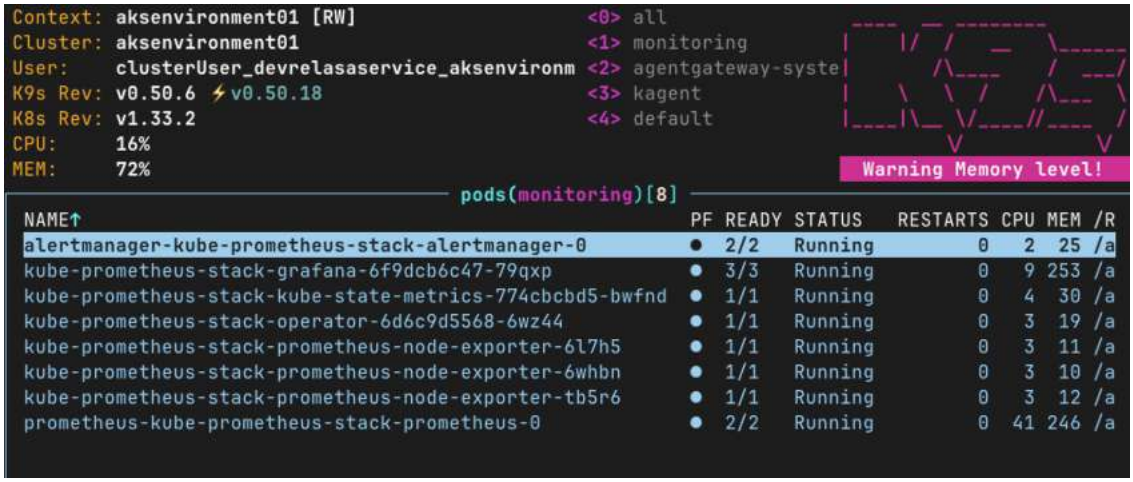
```
helm repo add prometheus-community https://prometheus-community.github.io/h
helm repo update
```

2. Install kube-prometheus with an appropriate amount of storage to ensure that metrics aren't lost.

```
helm upgrade --install kube-prometheus-stack prometheus-community/kube-prom
  --namespace monitoring \
  --create-namespace \
  --set prometheus.prometheusSpec.serviceMonitorSelectorNilUsesHelmValues=f
  --set prometheus.prometheusSpec.podMonitorSelectorNilUsesHelmValues=false
  --set prometheus.prometheusSpec.ruleSelectorNilUsesHelmValues=false \
  --set prometheus.prometheusSpec.retention=30d \
  --set
prometheus.prometheusSpec.storageSpec.volumeClaimTemplate.spec.resources.re
```

Important Note This configuration requires a default StorageClass. If the cluster does not provide o storageClassName or use ephemeral storage for the demonstration.

You should now see everything running within the monitoring namespace.



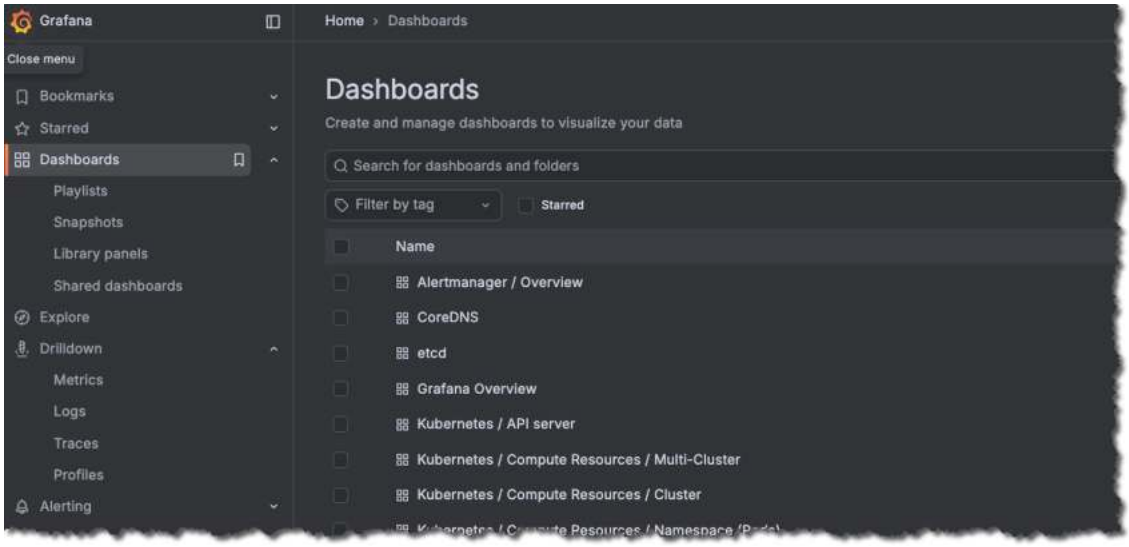
3. Once installed, you can access the Grafana and Prometheus dashboards with the following commands:

```
kubectl port-forward -n monitoring svc/kube-prometheus-stack-prometheus
9090:9090
kubectl port-forward -n monitoring svc/kube-prometheus-stack-grafana
3000:80
```

4. To log into the Grafana dashboard, use the following:

```
Username: admin
Password:
For Linux
kubectl get secret kube-prometheus-stack-grafana \
-n monitoring \
-o jsonpath='{.data.admin-password}' | base64 --decode
For Macos
kubectl get secret kube-prometheus-stack-grafana \
-n monitoring \
-o jsonpath='{.data.admin-password}' | base64 -D
```

You should now be able to successfully log into Grafana.



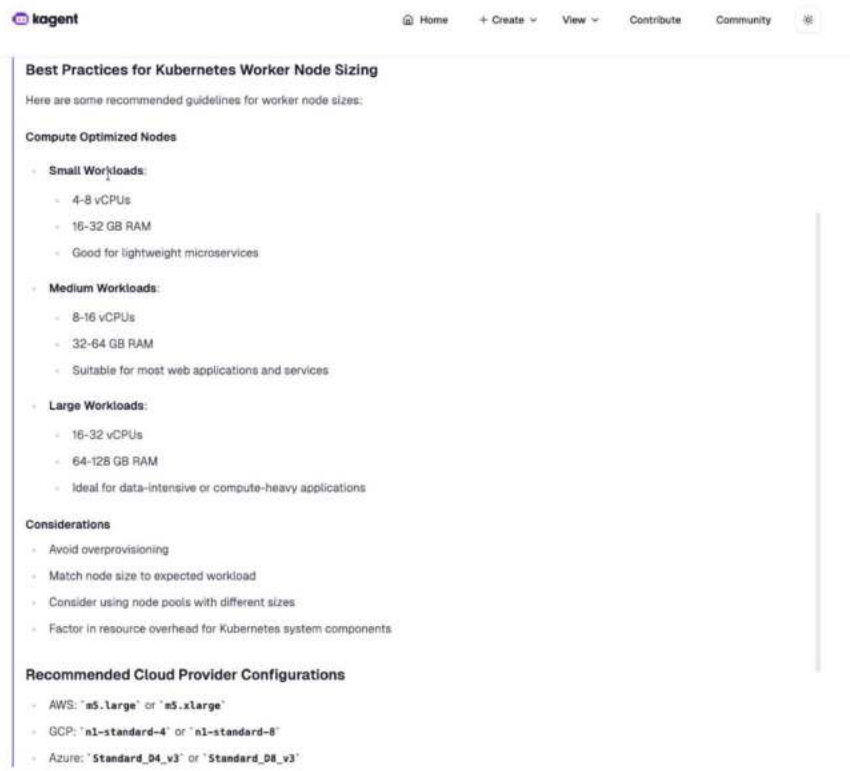
Implementing Metrics Capture for Your Gateway

With kube-prometheus installed, the next step is to ensure that Prometheus can capture metrics from agentgateway. No metric, regardless of what the tool/platform is, is captured by default via Prometheus. However, what agentgateway does is expose a metrics endpoint, so it's incredibly easy to capture the metrics with a PodMonitor.

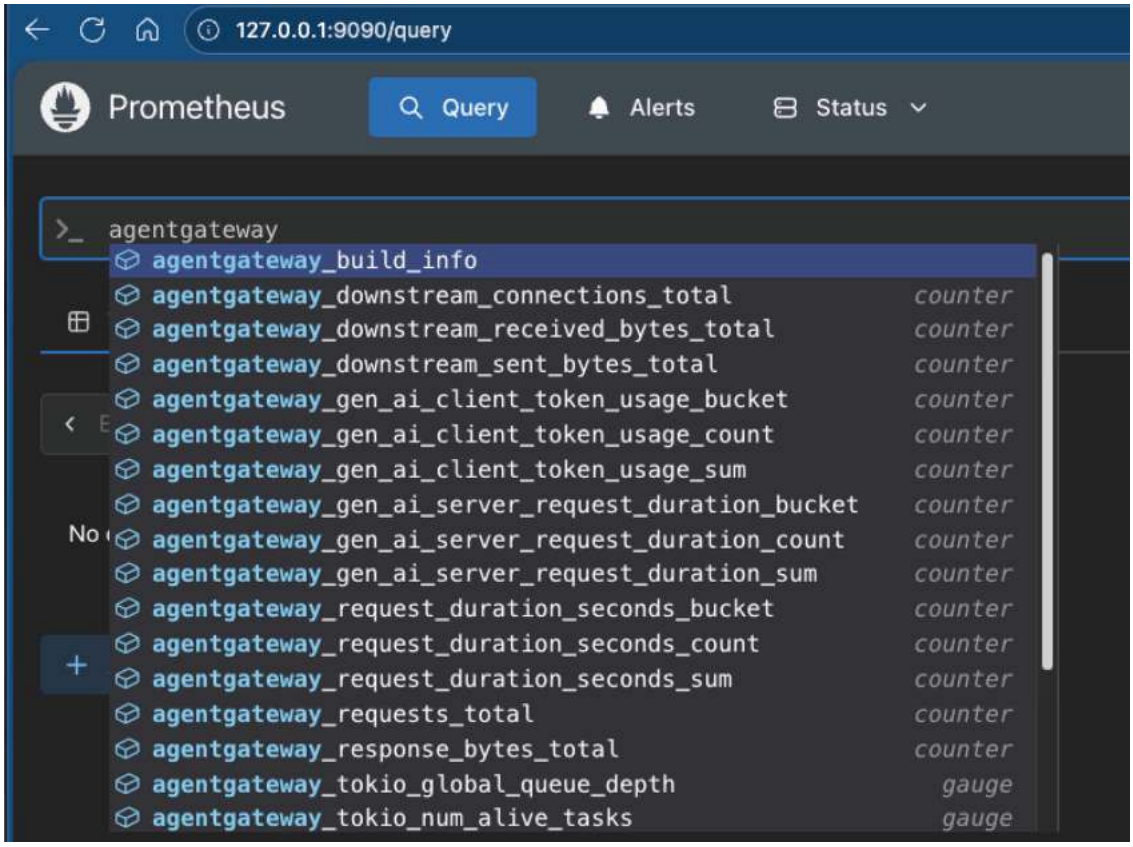
1. Set up a PodMonitor object via the Prometheus CRDs that specifies what gateway it should be pulling metrics from, the namespace where the gateway exists, and the metrics endpoint.

```
apiVersion: monitoring.coreos.com/v1
kind: PodMonitor
metadata:
  name: agentgateway-route-mon
  namespace: monitoring
  labels:
    app: agentgateway-route
    release: kube-prometheus-stack
spec:
  selector:
    matchLabels:
      gateway.networking.k8s.io/gateway-name: agentgateway-route
  namespaceSelector:
    matchNames:
      - agentgateway-system
  podMetricsEndpoints:
  - port: metrics
    path: /metrics
    interval: 30s
    scrapeTimeout: 10s
    relabelings:
      - sourceLabels: [__meta_kubernetes_pod_name]
        targetLabel: pod
      - sourceLabels: [__meta_kubernetes_namespace]
        targetLabel: namespace
      - targetLabel: gateway_instance
        replacement: agentgateway-route
```

2. Send some traffic through your agentgateway by opening kagent and asking your agent a question.



3. Open the Prometheus dashboard and, within the query search box, type in “agentgateway.”



4. Open Grafana and explore metrics to review the metrics that are available.

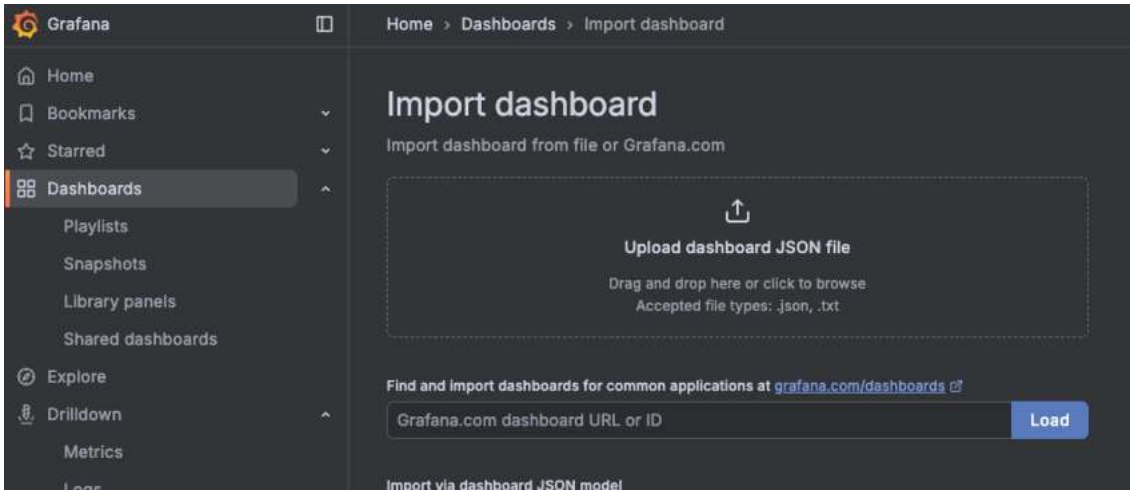
You can now see that metrics are being exposed successfully via agentgateway and ingested into Prometheus. With this information, we can now start looking at metrics that will help us in production. As a good example of that, let's start taking a look at cost metrics.

Custom Cost Control and Dashboards per Gateway

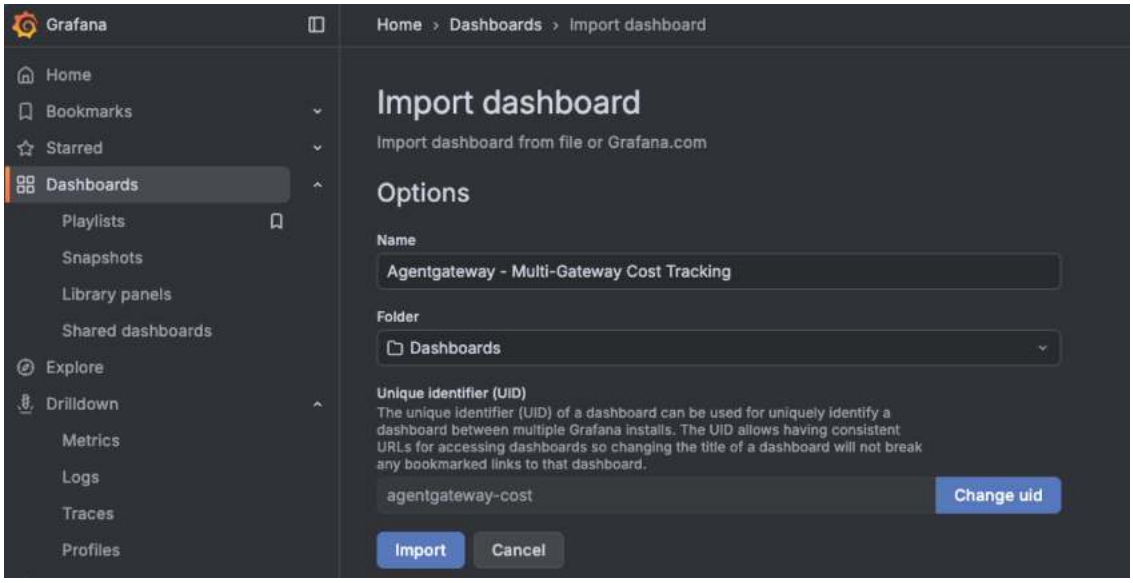
With the knowledge that agentgateway is now exposing metrics and being consumed by Prometheus, let's implement cost tracking. With just about every agentic conversation, regardless of how big or small the organization is, everyone from engineers to management wants to understand just how much it's actually going to cost. Luckily, we can get a full breakdown based on token usage with agentgateway.

1. Download the Grafana dashboard from here: https://github.com/AdminTurnedDevOps/agentic-demo-repo/blob/main/agentgateway-oss-k8s/cost/cost-across-dataplanes/grafana-dashboard.json. You'll see a dashboard that looks similar to the below.

2. Deploy three gateways in your environment called “gateway1,” “gateway2,” and “gateway3.”
3. Within the Grafana UI, go to **Dashboards ➤ Import ➤**.



4. Import the dashboard that you downloaded in Step 1.



5. Click the blue **Import** button.
6. Open up a text editor and apply a PrometheusRule object for calculating costs.

> **Sidenote** Example pricing shown below is based on the pricing available at the time of writing. Verify current pricing before using these calculations in production.

```
apiVersion: monitoring.coreos.com/v1
kind: PrometheusRule
metadata:
  name: agentgateway-cost-rules
  namespace: monitoring
  labels:
    release: kube-prometheus-stack
spec:
  groups:
    - name: agentgateway_cost_tracking
      interval: 30s
      rules:
        # Record total input tokens across all gateways
        - record: agentgateway:input_tokens:total
          expr: |
            sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_to
[5m]))

        # Record total output tokens across all gateways
        - record: agentgateway:output_tokens:total
          expr: |
            sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_to
[5m]))

        # Record input tokens per gateway
        - record: agentgateway:input_tokens:by_gateway
          expr: |
```

```
            sum by (gateway_instance)
(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_token_type="input'

        # Record output tokens per gateway
        - record: agentgateway:output_tokens:by_gateway
          expr: |
            sum by (gateway_instance)
(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_token_type="output

        # Calculate cost per gateway (Claude 3.5 Haiku pricing: $0.80/1M input
        - record: agentgateway:cost_usd:by_gateway
          expr: |
            (
              sum by (gateway_instance)
(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_token_type="input'
1000000
            ) + (
              sum by (gateway_instance)
(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_token_type="output
1000000
            )

        # Calculate total cost across all gateways (hourly)
        - record: agentgateway:cost_usd:total_hourly
          expr: |
            (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[1h])) * 0.80 / 1000000
            ) + (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[1h])) * 4.00 / 1000000
            )

        # Calculate cumulative cost (daily)
        - record: agentgateway:cost_usd:total_daily
          expr: |
            (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[24h])) * 0.80 / 1000000
            ) + (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[24h])) * 4.00 / 1000000
            )

        # Calculate cumulative cost (weekly)
        - record: agentgateway:cost_usd:total_weekly
          expr: |
            (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[7d])) * 0.80 / 1000000
            ) + (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[7d])) * 4.00 / 1000000
            )
```

```
        # Calculate cumulative cost (monthly)
        - record: agentgateway:cost_usd:total_monthly
          expr: |
            (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[30d])) * 0.80 / 1000000
            ) + (
              sum(increase(agentgateway_gen_ai_client_token_usage_sum{gen_ai_t
[30d])) * 4.00 / 1000000
            )

    - name: agentgateway_cost_alerts
      interval: 1m
      rules:
        # Alert when daily cost exceeds $50 across all gateways

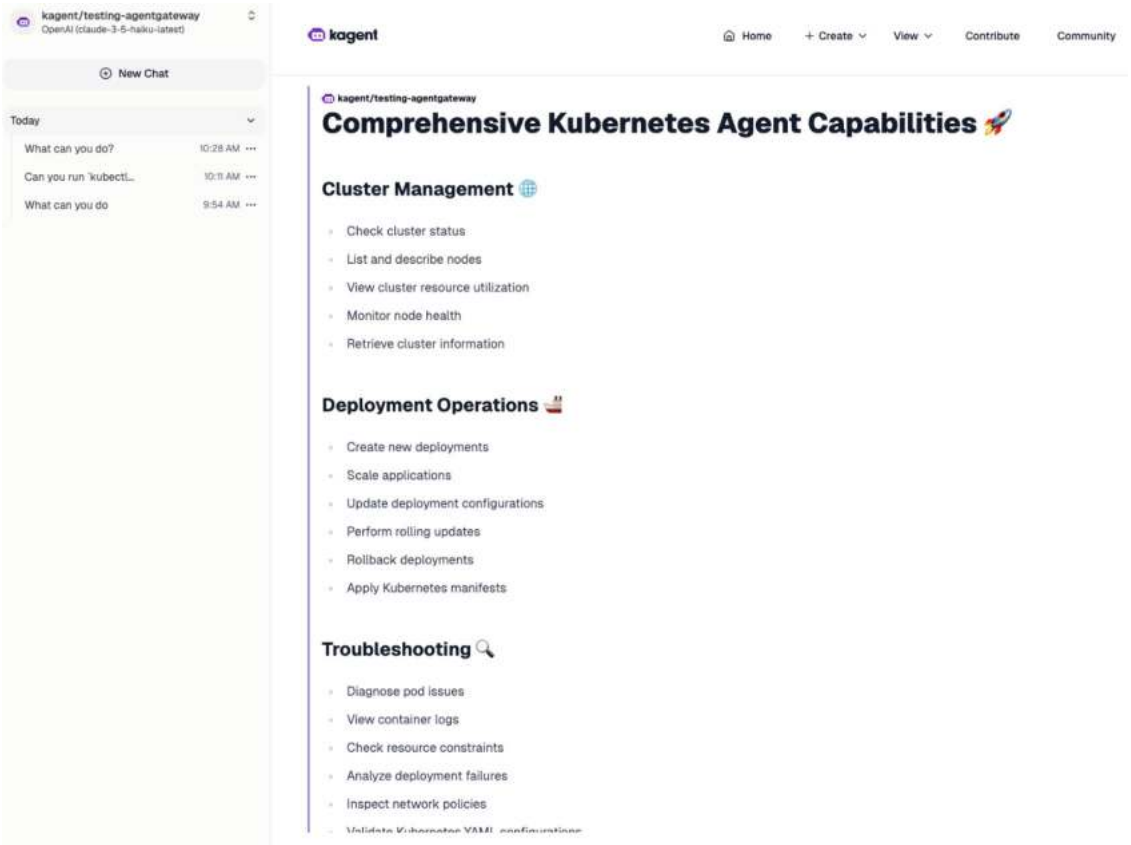
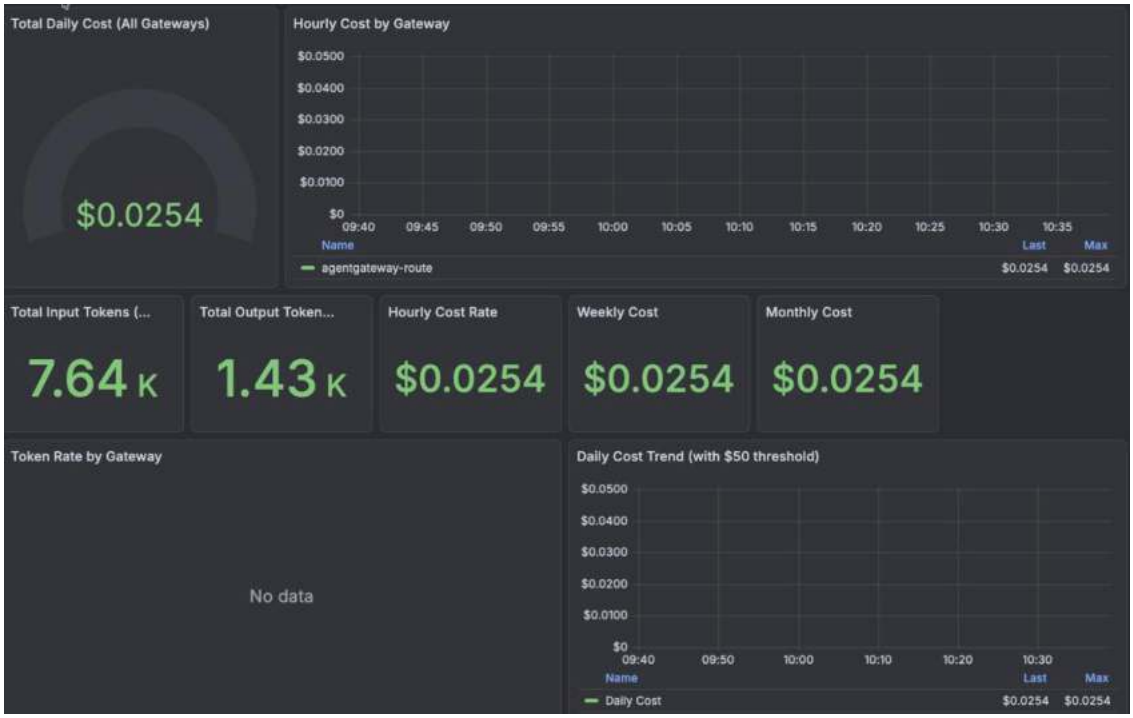
              Projected daily cost: ${{ with query "agentgateway:cost_usd:tota
. | first | value | humanize }}{{ end }}/day
```

7. Send some traffic to your agentgateway by opening kagent and asking some questions to your agent.



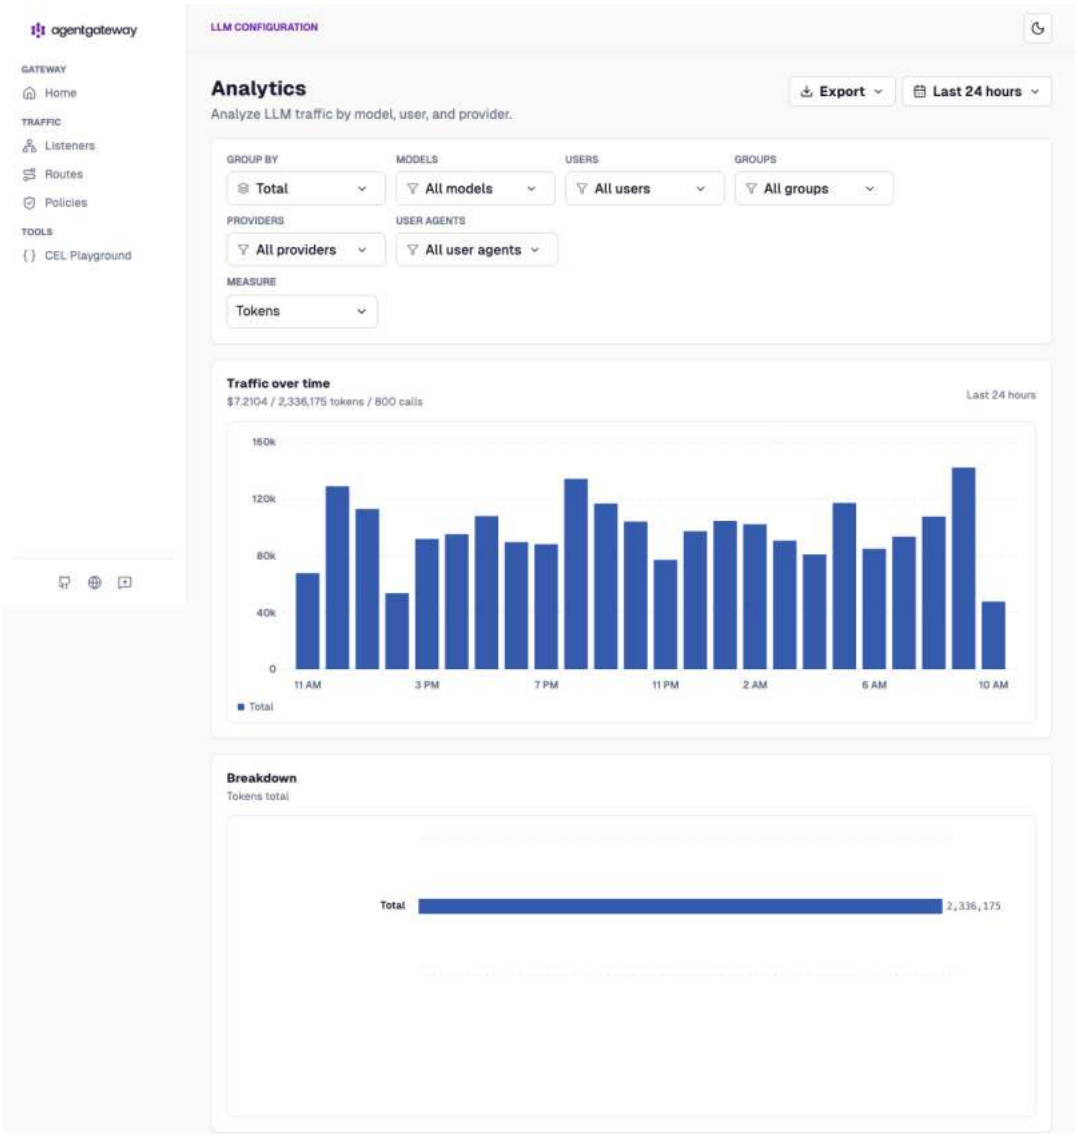
You should now see the cost being calculated for your gateway. You can add as many gateways as you'd like.



Out-of-the-Box Agentgateway Control

As an organization, there may come a time where there needs to be customized cost and cost metric dashboards, like you saw in the previous section. As the agentic world is moving and shifting, products and tools are beginning to build in what you would need to see from a dasboarding perspective based on what's important today for orgs in the AI space.

With that being said, instead of building out your own, you can get it out of the box within certain AI gateways like agentgateway.



To do this, you need two things:

1. A cost catalog
2. Dashboard enablement

For the cost catalog, you can pull one that already exists, like you can see here (https://agentgateway.dev/docs/kubernetes/latest/llm/cost-controls/costs/) or create your own based on the current AI costs that you can pull from a site like https://models.dev/.

You can then create a parameter object and attach it to your gateway so you can start tracking costs for the said gateway.

```
kubectl apply -f- <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayParameters
metadata:
  name: cost-dashboard-params
```

```
  namespace: agentgateway-system
spec:
  modelCatalog:
    sources:
      - configMap:
          name: my-model-costs
          key: catalog.json
  rawConfig:
    config:
      database:
        url: "sqlite:////tmp/data.db?mode=rwc"
---apiVersion: gateway.networking.k8s.io/v1
kind: Gateway
metadata:
  name: agentgateway-proxy
  namespace: agentgateway-system
spec:
  gatewayClassName: agentgateway
  infrastructure:
    parametersRef:
      name: cost-dashboard-params
      group: agentgateway.dev
      kind: AgentgatewayParameters
  listeners:
    - name: http
      port: 80
      protocol: HTTP
      allowedRoutes:
        namespaces:
          from: All
EOF
```

Inspecting Traces

With monitoring and observability data flowing through Prometheus and Grafana for all things metrics related, the next question is “Well, how is my agentic infrastructure performing?” and that’s where end-to-end agentic health comes into play with traces.

1. Deploy Tempo, which is an OSS tracing tool.

```
  helm upgrade --install tempo tempo \
    --repo https://grafana.github.io/helm-charts \
    --namespace monitoring \
    --values - <<EOF
  persistence:
    enabled: false #For demos only
  tempo:
    receivers:
      otlp:
        protocols:
          grpc:
            endpoint: 0.0.0.0:4317
  EOF
```

   Deploy the OTel collector for traces.

2.
```
helm upgrade --install opentelemetry-collector-traces opentelemetry-collect
  --repo https://open-telemetry.github.io/opentelemetry-helm-charts \
  --version 0.127.2 \
  --set mode=deployment \
  --set image.repository="otel/opentelemetry-collector-contrib" \
  --set command.name="otelcol-contrib" \
  --namespace monitoring \
  -f -<<EOF
config:
  receivers:
    otlp:
      protocols:
        grpc:
          endpoint: 0.0.0.0:4317
        http:
          endpoint: 0.0.0.0:4318
  exporters:
    otlp/tempo:
      endpoint: http://tempo.monitoring.svc.cluster.local:4317
      tls:
        insecure: true
    debug:
      verbosity: detailed
  service:
    pipelines:
      traces:
        receivers: [otlp]
        processors: [batch]
        exporters: [debug, otlp/tempo]
EOF
```

3. Configure a data source for Grafanas using Tempo.

```
helm upgrade kube-prometheus-stack -n monitoring prometheus-community/kube-
prometheus-stack \
  --reuse-values \
  --set 'grafana.additionalDataSources[0].name=Tempo' \
  --set 'grafana.additionalDataSources[0].type=tempo' \
  --set 'grafana.additionalDataSources[0].access=proxy' \
  --set
'grafana.additionalDataSources[0].url=http://tempo.monitoring.svc.cluster.l
\
  --set 'grafana.additionalDataSources[0].uid=tempo'
```

4. Allow the AgentgatewayPolicy object in agentgateway-system`to reference the OTel collector service in the namespace.

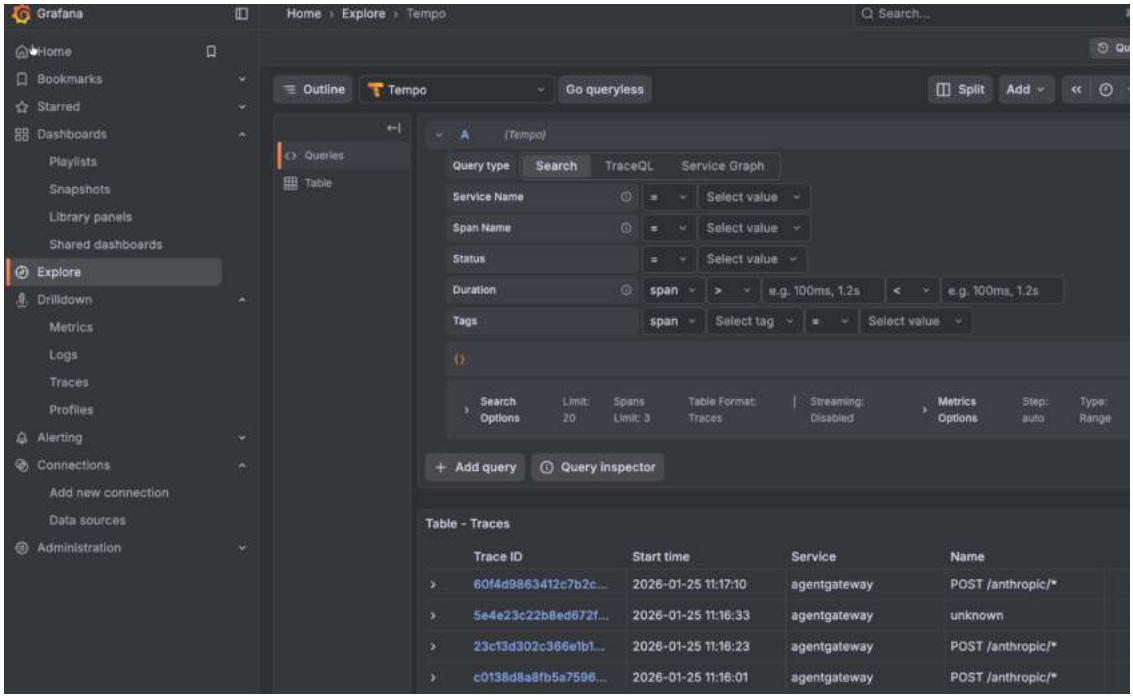
```
kubectl apply -f - <<EOF
apiVersion: gateway.networking.k8s.io/v1beta1
kind: ReferenceGrant
metadata:
  name: allow-otel-collector-traces-access
  namespace: monitoring
```

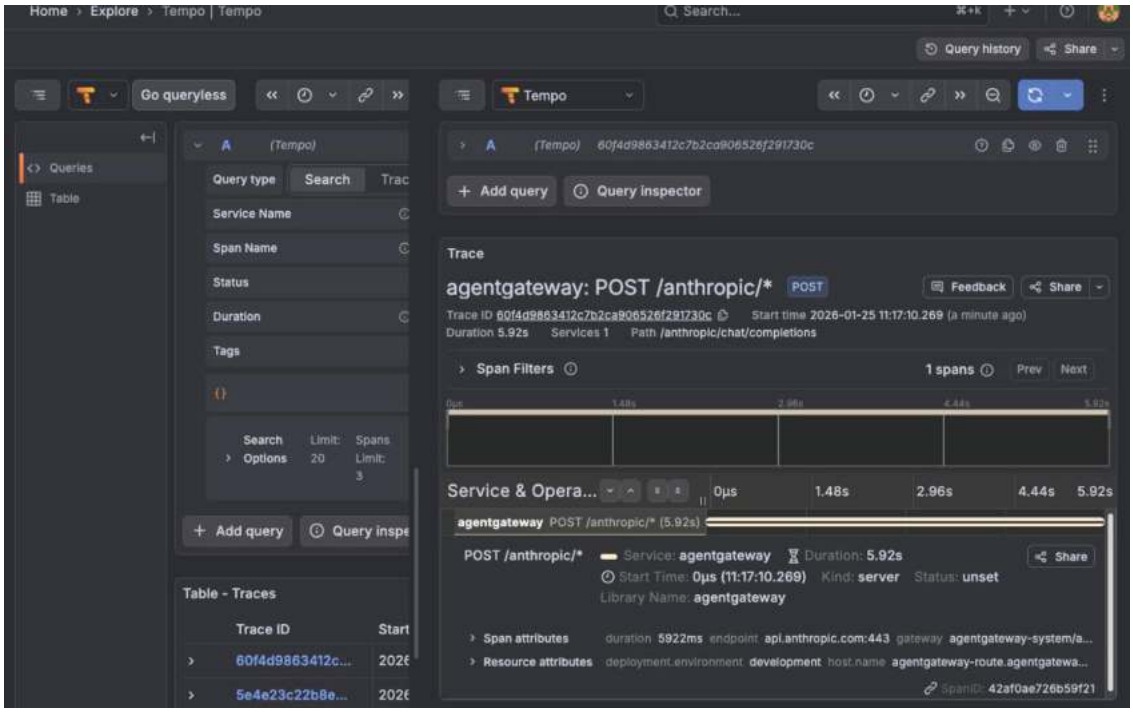
```
spec:
  from:
  - group: agentgateway.dev
    kind: AgentgatewayPolicy
    namespace: agentgateway-system
  to:
  - group: ""
    kind: Service
    name: opentelemetry-collector-traces
EOF
```

5. Configure an agentgatewaypolicy to target the agentgateway gateway you deployed, along with specifying a reference for the OTel tracing collector.

```
kubectl apply -f - <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: tracing-policy
  namespace: agentgateway-system
spec:
  targetRefs:
  - group: gateway.networking.k8s.io
    kind: Gateway
    name: agentgateway-route
  frontend:
    tracing:
      backendRef:
        name: opentelemetry-collector-traces
        namespace: monitoring
        port: 4317
      protocol: GRPC
      clientSampling: "true"
      randomSampling: "true"
      resources:
        - name: deployment.environment
          expression: '"development"'
        - name: service.name
          expression: '"agentgateway"'
      attributes:
        add:
        - name: request.host
          expression: 'request.host'
EOF
```

You should now be able to go into Grafana and within the **Explore** tab, use **Tempo** as the data source and **Search** as the query type.





Enterprise Tooling for Monitoring and Observability

In the previous section, you saw how to not only generate metrics from your agent but also capture the metrics that were exposed from your agent via agentgateway in an open source monitoring and observability stack (Prometheus, Jaeger, and Grafana). Although this is a very common stack for cloud-native organizations, there are also many teams and enterprises that use enterprise monitoring and observability tools. The metrics/traces will be the same in terms of what's exposed to you as the information isn't changing based on what monitoring and observability tool you use, but what does change is the access to

tools you have out of the box. For example, with an open source stack, you have to manage all parts of the stack one by one. In an enterprise platform like Datadog, it's all "out of the box."

In this section, you'll learn how to configure Datadog and capture metrics/traces from your Agents.

Please note: This will NOT require you to spend any money.

Configuring Datadog

1. Sign up for a Datadog account (no credit card required).
2. Within Datadog, go to Organization Settings > API Keys and generate an API key.
3. Create two environment variables – one for your cluster name and another for the API key.

```
CLUSTER_NAME=
API_KEY=
```

4. Install Datadog on your Kubernetes cluster.

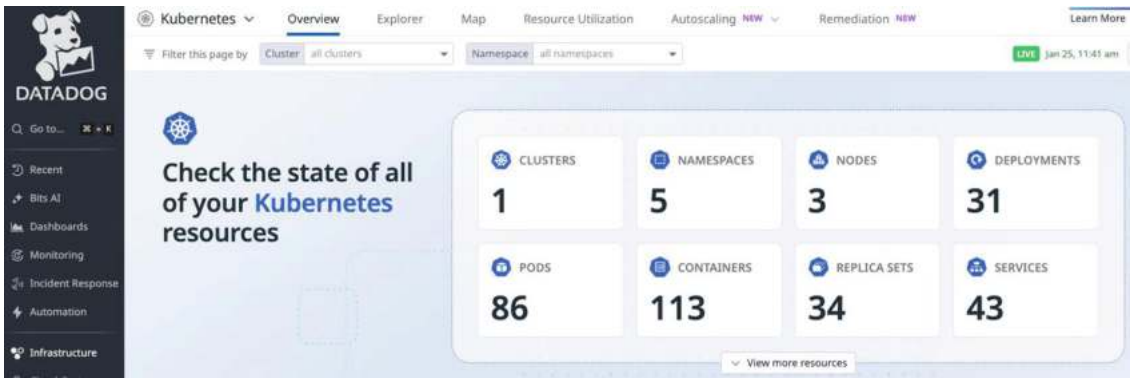
```
helm repo add datadog https://helm.datadoghq.com

helm repo update

helm install datadog -n datadog \
--set datadog.site='datadoghq.com' \
--set datadog.clusterName=$CLUSTER_NAME \
--set datadog.clusterAgent.replicas='2' \
--set datadog.clusterAgent.createPodDisruptionBudget='true' \
--set datadog.kubeStateMetricsEnabled=true \
--set datadog.kubeStateMetricsCore.enabled=true \
--set datadog.logs.enabled=true \
--set datadog.logs.containerCollectAll=true \
--set datadog.apiKey=$API_KEY \
--set datadog.processAgent.enabled=true \
--set targetSystem='linux' \
datadog/datadog --create-namespace
```

   Once complete, you should see pods running within the Datadog namespace.

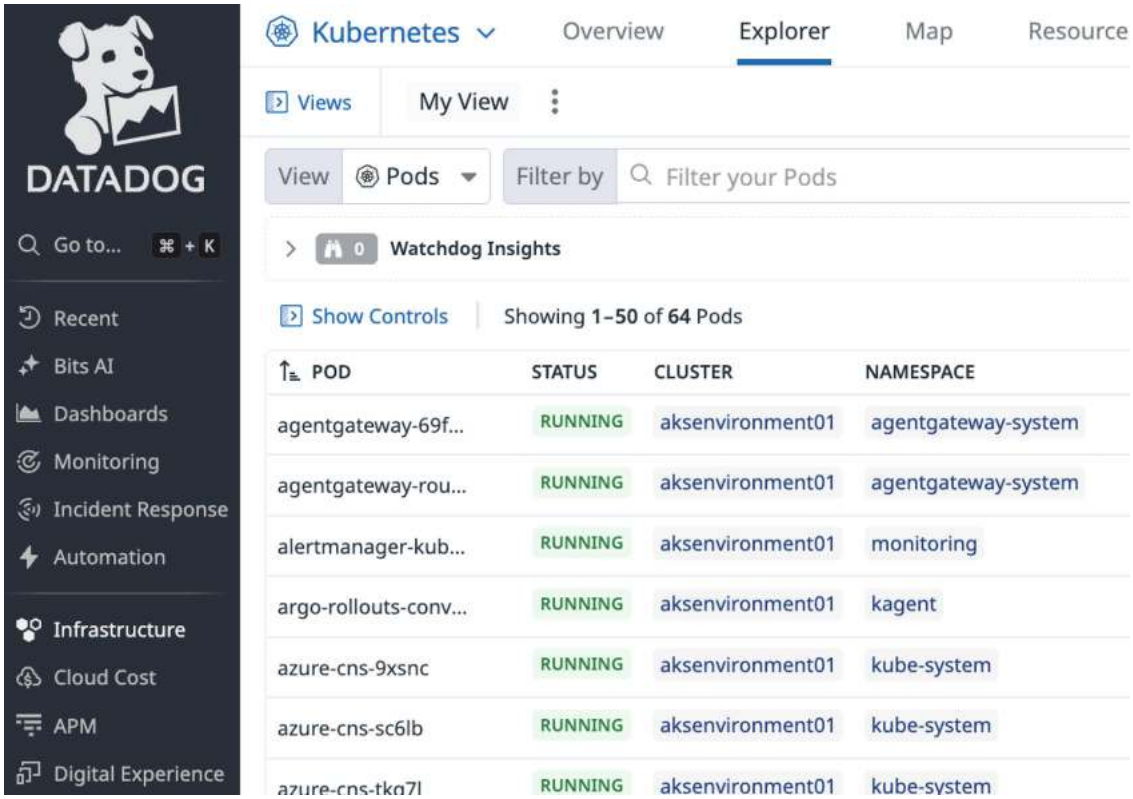
5. Within Datadog, go to Infrastructure ➤ Kubernetes Overview and you'll see your cluster and all of its objects running.



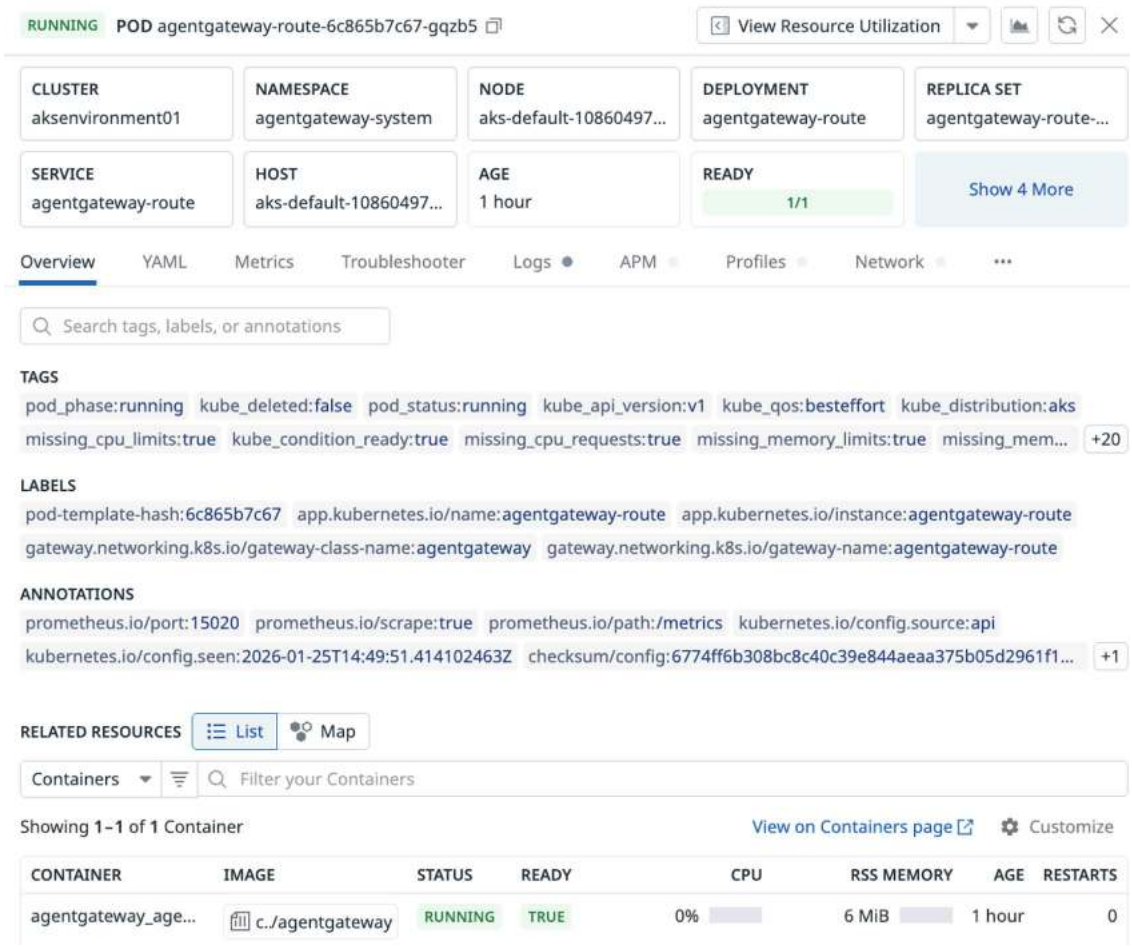
With Datadog deployed, let's now look at metrics and various other pieces of data within Datadog for our environment.

The key difference with an enterprise solution like Datadog is that there isn't much setup you have to do unless you want a specific configuration available (e.g., enabling tracing), but even when using those configurations, it's straightforward to set up. Let's see what we get out of the box.

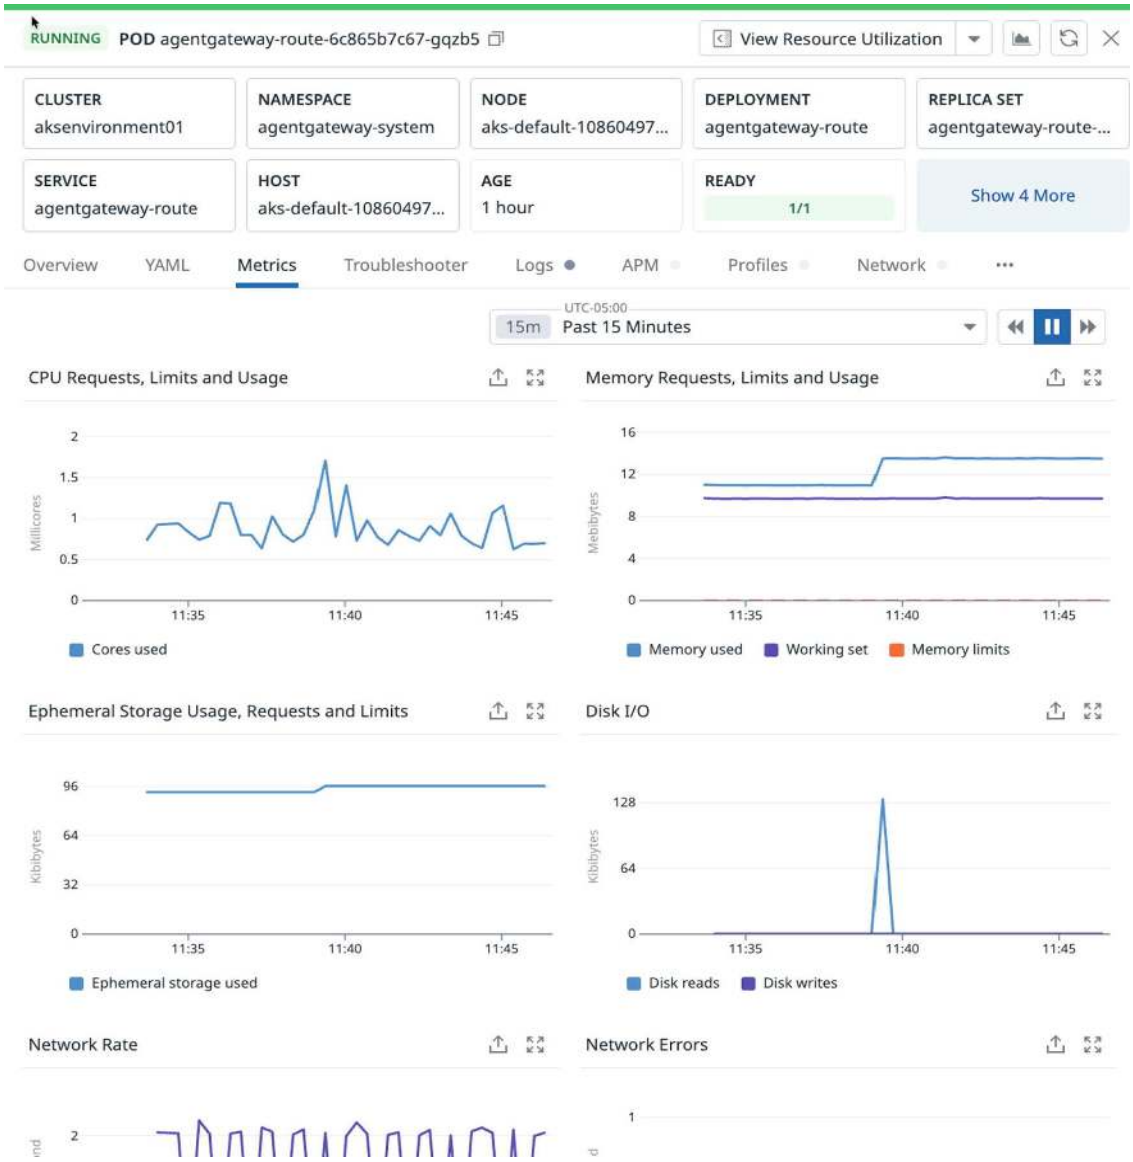
1. Within the Kubernetes overview, click on Pods.
2. You'll see various Pods running, including your agentgateway Pods. Click on the agentgateway-route Pod.



3. You'll see various pieces of information about your Pod out of the box without you having to do anything other than installing Datadog.



4. If you click on metrics, you'll be able to see everything from requests to network rates and the traffic flowing through your gateway.

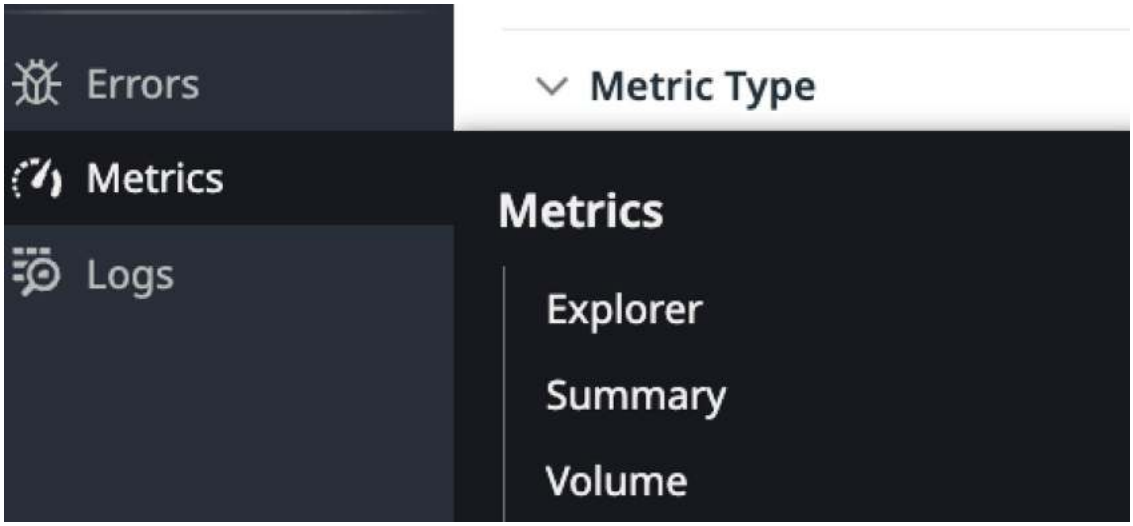


To collect specific metrics for agentgateway, you can enable Datadog's Prometheus scrape feature since Prometheus is already exposing the metrics.

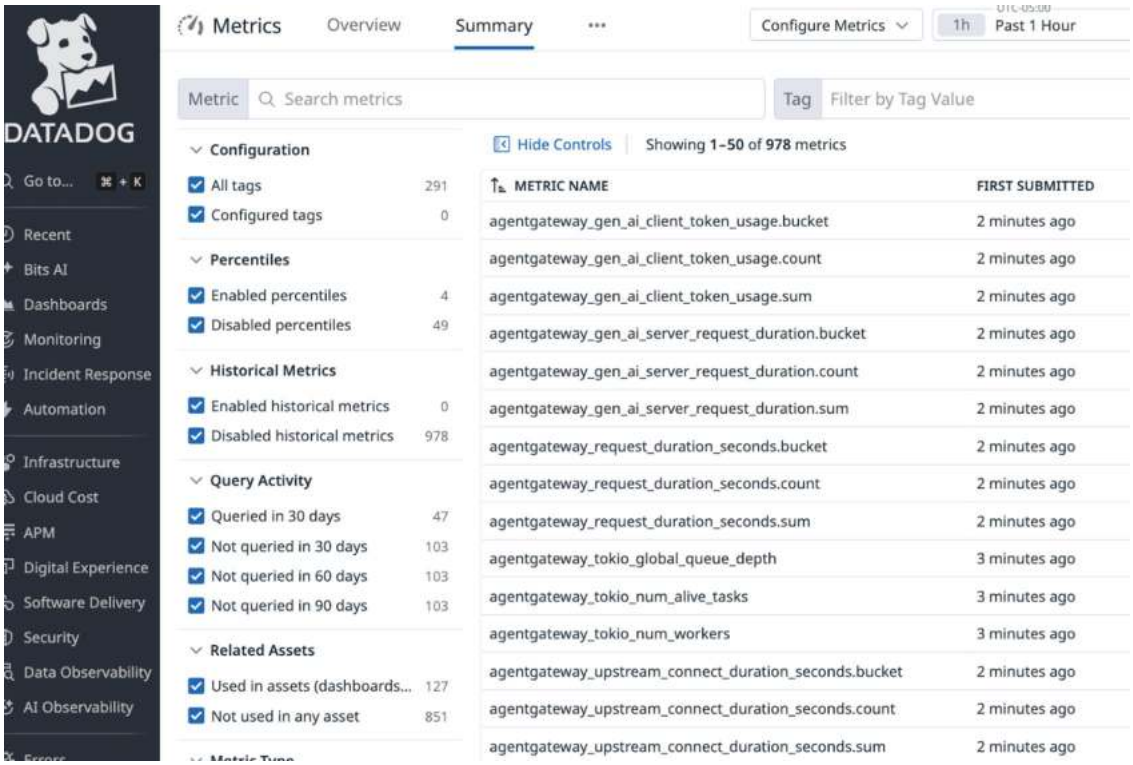
5. Upgrade your Datadog Helm Chart with the Prometheus scraping values.

```
helm upgrade datadog -n datadog datadog/datadog \
--reuse-values \
--set datadog.prometheusScrape.enabled=true \
--set datadog.prometheusScrape.serviceEndpoints=true
```

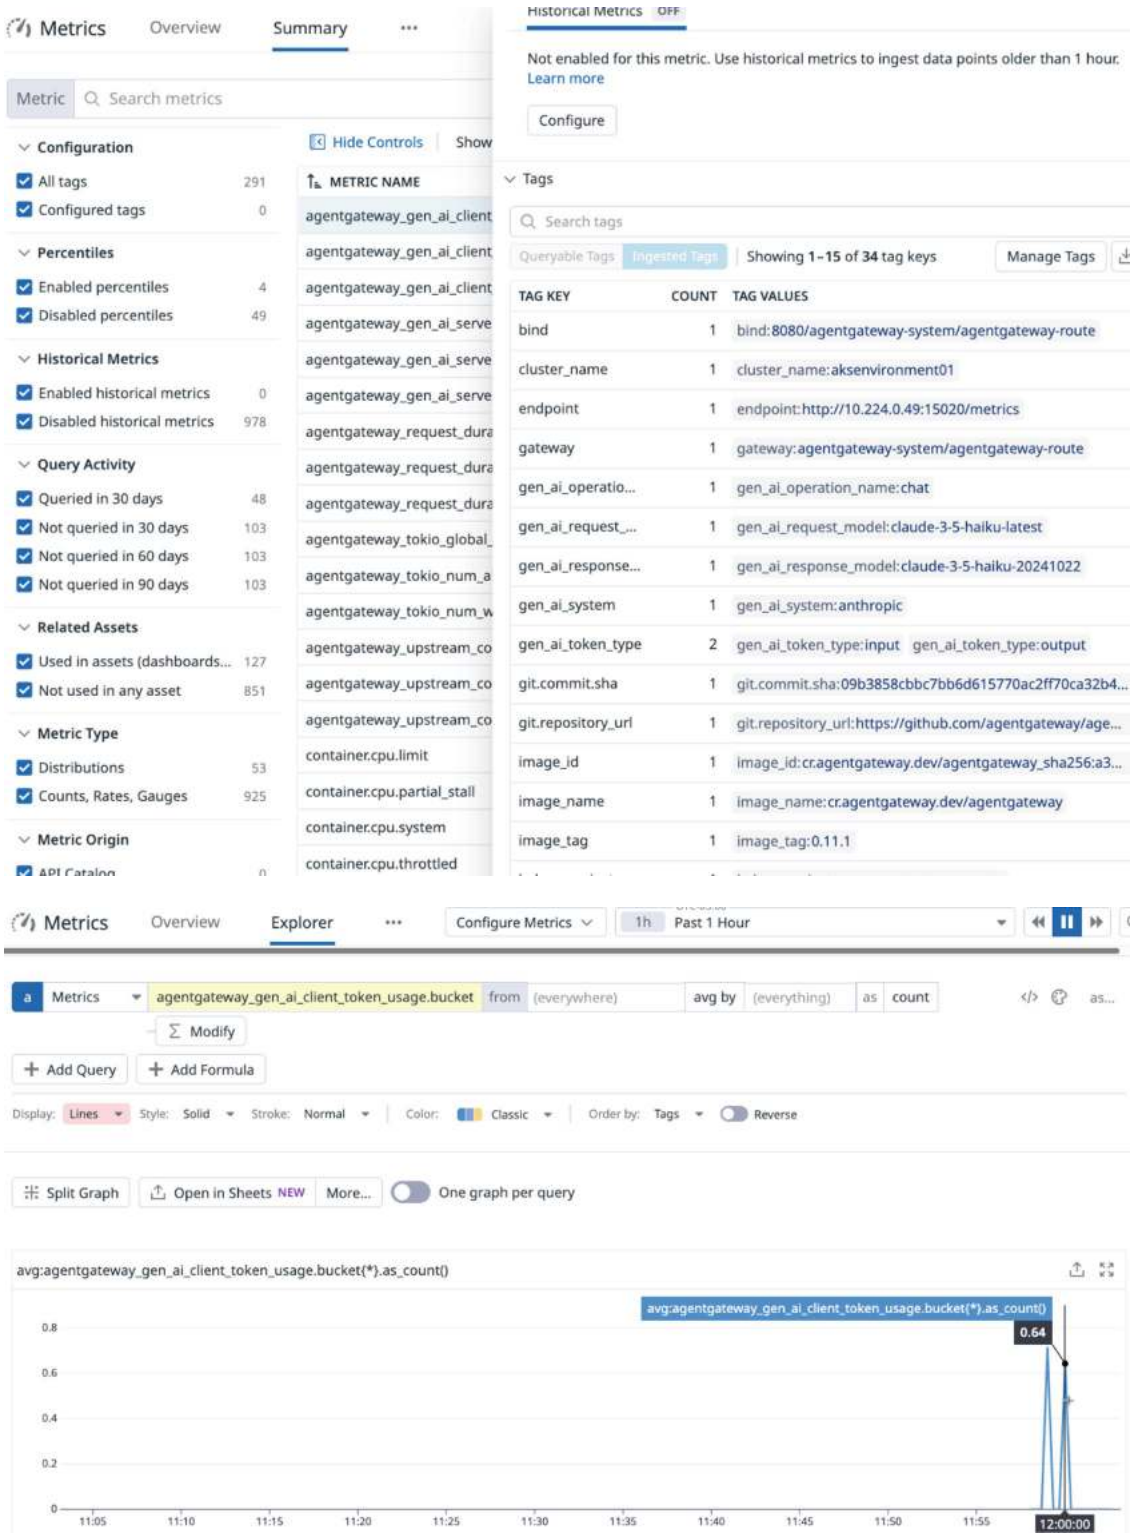
Once complete, send some more traffic to your agentgateway to generate new metrics, and then within Datadog, go to **Metrics ➤ Summary**.



You'll now see agentgateway metrics.



If you click on one of the metrics, you'll be able to drill down to see everything from the model used to which gateway was used and what the endpoint is.



Conclusion

Many things become clear in the world of agentic infrastructure, but in the case of monitoring and observability, there is something incredibly apparent – regardless of "what" is running (microservices, AI, monolithic apps), monitoring and observability (traces, logs, metrics) are incredibly important and will

continue to be. The key difference is what we're monitoring and observing with AI. The standard approach for performance and reliability will continue to be needed in AI, but new things to observe, like token usage, what LLM is being called upon, and the overall cost of transactions (e.g., how much is this agent costing for an entire troubleshooting session), will be crucial for all teams and organizations.

5. Extending LLM Knowledge for Production

Michael Levan[1] ✉
(1) Budd Lake, NJ, USA

The growth of AI is unprecedented. No one believed that it would occur this fast. It's arguably the fastest-growing innovation and invention in tech history. Because of that, it's fair to say that, at this point, AI isn't going away. The way that agents, LLMs, and various AI-centric tools are being incorporated into environments means they will be around in production for a while. Even organizations that are well known to go slow when adopting new tech (financial institutions, government, healthcare) are adopting AI at a rapid speed (arguably even faster than other sectors).

With this adoption, one thing is incredibly clear – engineers need a way to ensure that the output and solution from AI tooling and agents is accurate. Without that, organizations will have a big problem knowing what's real/true and what's not.

In this chapter, you'll learn how to extend LLM knowledge and capabilities to ensure agents have the exact information and tools they need to perform a particular task in the most accurate way possible with

– MCP
– Enriched prompts
– Skills
– Proper testing

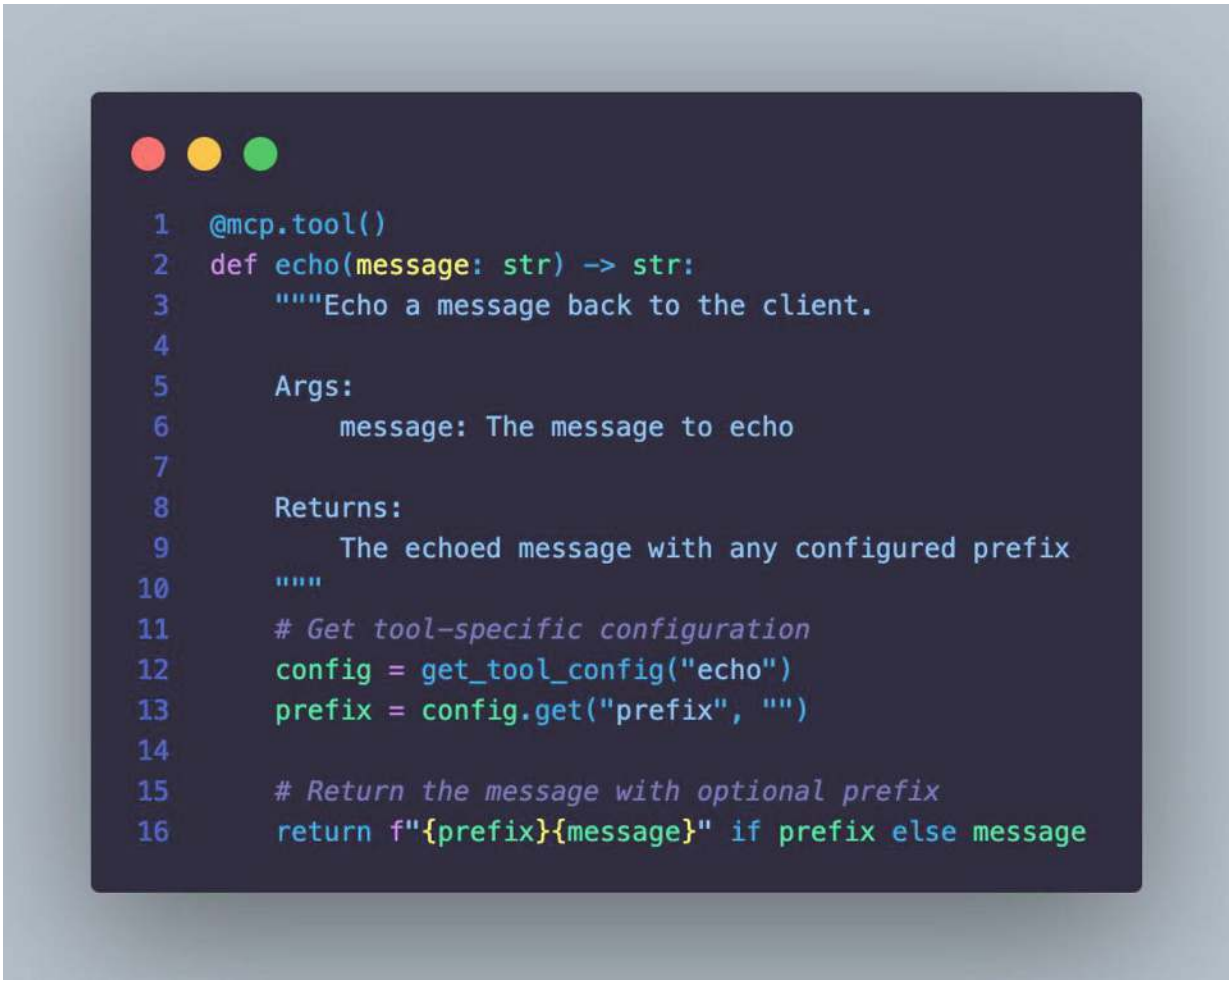
Model Context Protocol (MCP)

MCP, which stands for Model Context Protocol, is a protocol for agents to universally connect with external data sources, tools, and systems. You can think of it almost like an agent-centric API. If you're using an agent for, say, connecting to and working on Kubernetes clusters, you can use a specific set of tools that are created to work with Kubernetes. Your agent can then call out to those tools for things like creating deployments, scaling clusters, and retrieving information about the cluster and applications deployed. The reason you'd use tools for this is because the tools have far more specific/specialized knowledge about these actions in comparison to the general/generic weights that the LLM was trained on. MCP server tools extend agent functionality.

This section covers more in-depth about what MCP is, the spec, and how to create MCP servers.

What Is MCP

Model Context Protocol (MCP) is a protocol that allows you to connect to external tools that can be used to extend an agent's capabilities. As mentioned in the beginning of this section, it could be tools for anything from Kubernetes clusters to building architecture diagrams to source control and everything in between. The reason why what you interact with are called "tools" within MCP servers is because they are actionable, callable functions. When you hear someone call them "functions," if you come from the programming or scripting world, tools are quite literally functions/methods.



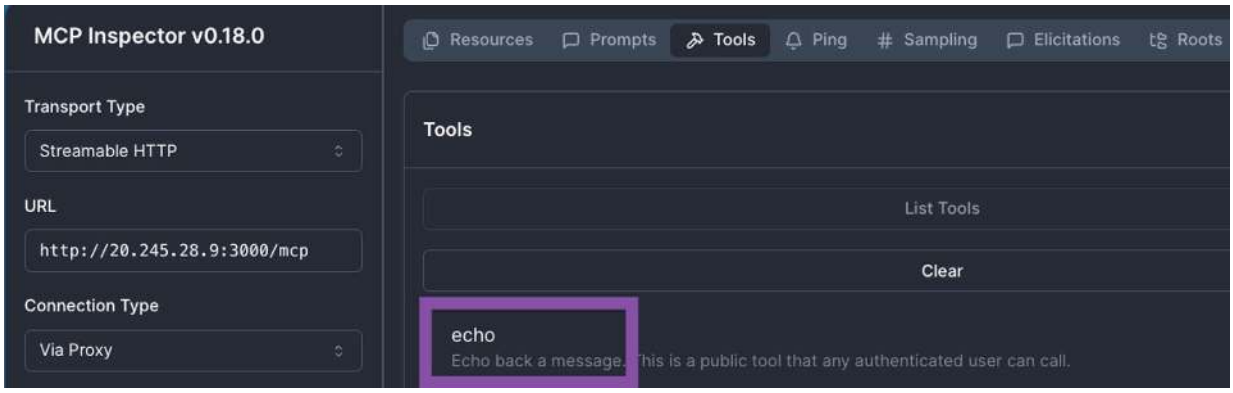
```python
@mcp.tool()
def echo(message: str) -> str:
    """Echo a message back to the client.

    Args:
        message: The message to echo

    Returns:
        The echoed message with any configured prefix
    """
    # Get tool-specific configuration
    config = get_tool_config("echo")
    prefix = config.get("prefix", "")

    # Return the message with optional prefix
    return f"{prefix}{message}" if prefix else message
```

If you're using one of the popular MCP libraries, like FastMCP, you'll create a function/method that consists of the logic for your MCP server tool. The above code screenshot is a screenshot of an MCP server tool called "echo." If you run an MCP server with the logic above, you'll see that the tool is usable and callable.

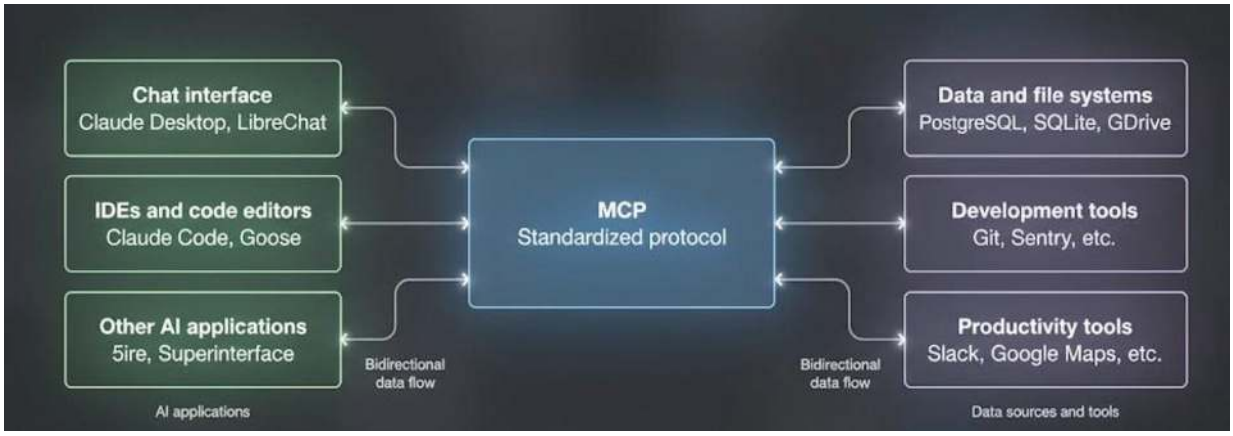


And this realization is one of the best parts about MCP. It's not something that's so new that you have to learn an entirely different way of doing things. If you've written code before, you know what a function/method looks like, so understanding MCP server tools will be straightforward for you.

The MCP Spec

As with all new standards, there is, or at least hopefully should be, a specification. This allows for a standardization to come into play, which makes it far easier to build upon. A great example of this is OCI for container images. Without the OCI standard, everyone would just build container images that only run on particular platforms and scaling that out would be a mess. Because of the popularity of MCP, the same rules apply.

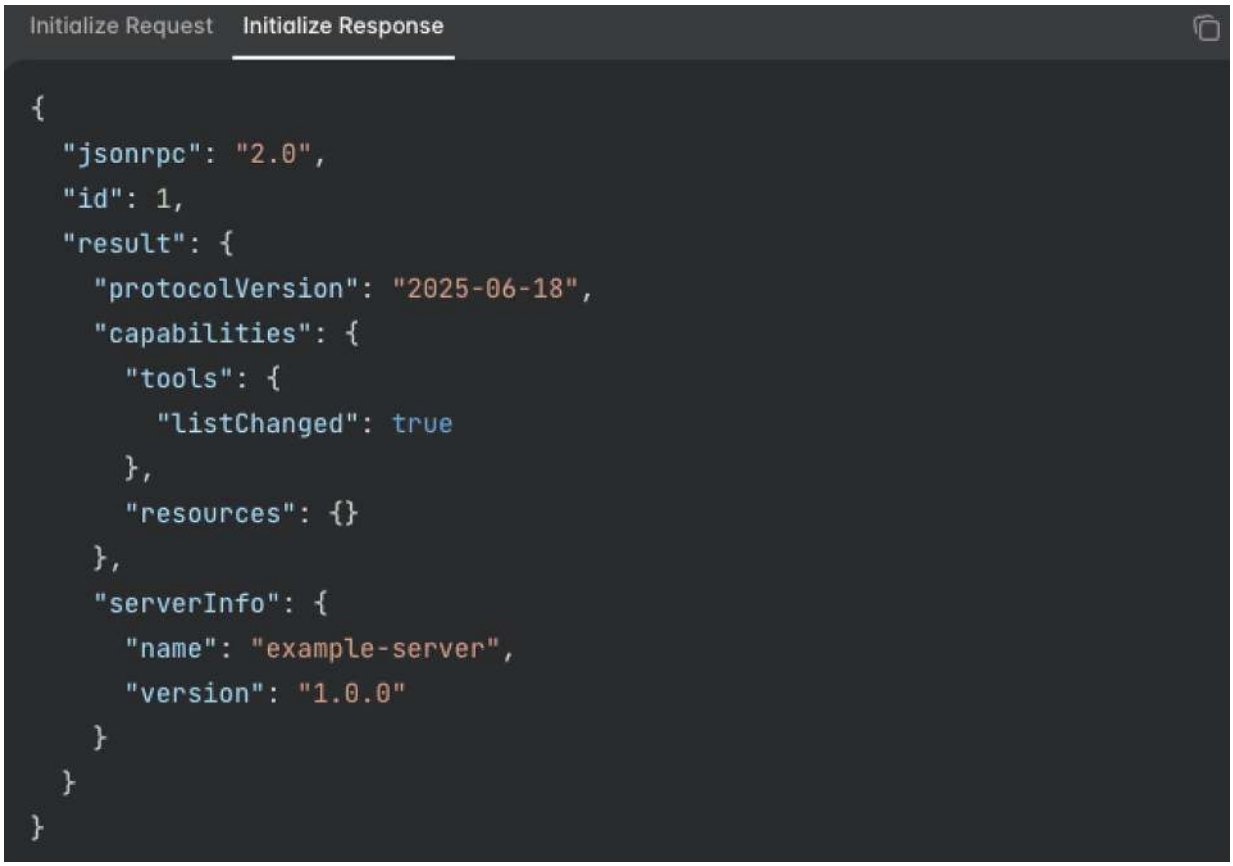
MCP follows a standard client/server architecture. You have a client (VS Code, MCP Inspector, MCPJam, Hoot, etc.) that you use to interact with the MCP server. For a fun reference, you may hear people say MCP is like a USB-C port for AI applications.



MCP has two layers:

1. Transport layer
2. Data layer

The data layer is defined in the JSON-RPC 2.0 protocol for client/server communication. When MCP server tools are called, the communication is done in a JSON-RPC format. That's currently the only data layer protocol for MCP. For the transport layer, there are currently two protocols – stdio and streamable HTTP. Stdio or Standard Input/Output is essentially a local library/package that you download. It's still an MCP server; it just runs in a local fashion much like any other library. Streamable HTTP is the "over-the-web" protocol, which means you need a line of communication to get you from point A (the agent) to point B (the MCP server), which is typically where an AI gateway comes into play. Streamable HTTP MCP servers are MCP servers that are "sitting on someone else's server." For example, the GitHub Copilot MCP server is an MCP server sitting in GitHub land somewhere. Streamable HTTP is typically the direction that organizations like to go in to use because it's far easier to observe and secure them. If you're using stdio, the only thing you can pretty much do is run AppSec practices on it because it's a local codebase. At least if it's on a server, you can observe the connectivity and secure connections to it.



As with most AI-related traffic, MCP is stateful, which makes sense, as context for anything going from an agent to its destination (like an LLM or an MCP server) is important for long-term and short-term memory so the agent doesn't "lose" what it's currently working on. This is also a big reason why AI gateways are being created in a way where the context of the body is far more important than what's in the headers.

One thing I will touch on, but not go too in-depth with, is how MCP clients work. Although there is a spec/standard, that doesn't necessarily mean that all MCP clients will follow the same spec. For example, VS Code and MCP Inspector will implement the same OIDC spec for OAuth when authenticating to MCP servers, but they'll implement different subsets of the spec. That's why you may see compatibility issues. VS Code incorporates CIMD support where MCP Inspector doesn't. They all implement OAuth 2.1 with PKCE, but what version of the spec they're implementing is different. This is important as you begin to use various clients because one piece might work in one client, but not in the other. That doesn't mean your configuration is broken; it just means you're working with different versions of the spec.

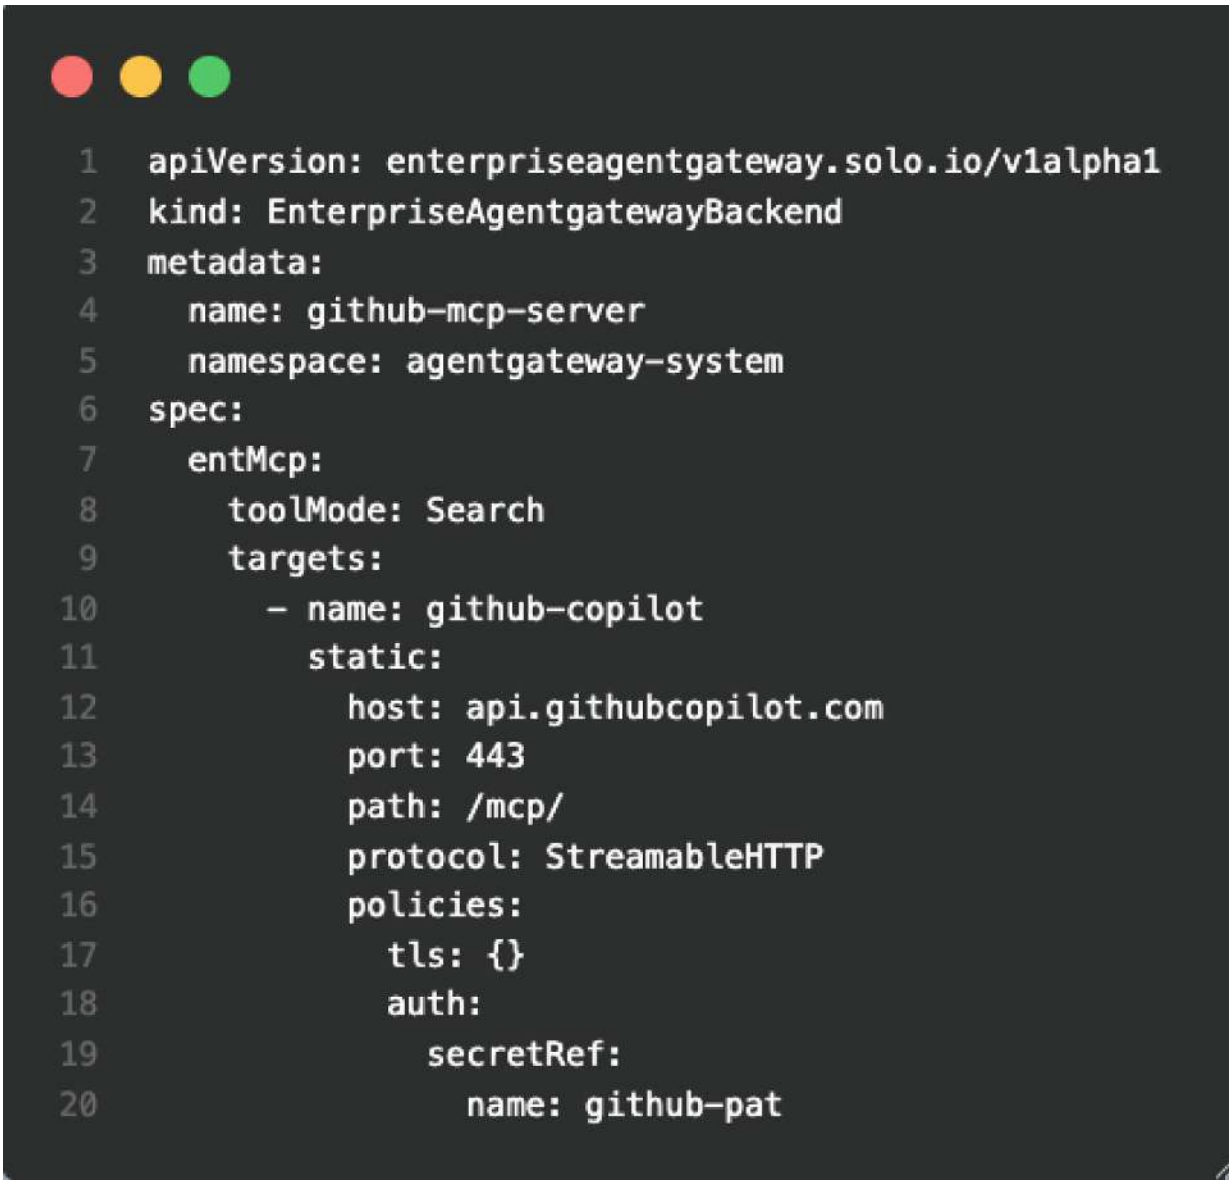
If you'd like to learn more about the MCP spec and its internals, take a look at the MCP documentation: https://modelcontextprotocol.io/docs/learn/architecture.

MCP Modes

When using MCP, there are a few methods, all of which are a bit different in how they're used, what they would be used for, how many tokens are consumed, and the purpose to use them. In this section, you'll get a full breakdown.

Progressive Disclosure

When using an MCP server with an agent, the agent will automatically consume all the metadata about every tool that's within the MCP server. That means before you even run your first prompt, there could be thousands of input tokens already used. Because that's a waste of tokens and real dollars, you can use Progressive Disclosure to only expose two ones – one to get a tool and one to invoke a tool.



```yaml
apiVersion: enterpriseagentgateway.solo.io/v1alpha1
kind: EnterpriseAgentgatewayBackend
metadata:
  name: github-mcp-server
  namespace: agentgateway-system
spec:
  entMcp:
    toolMode: Search
    targets:
      - name: github-copilot
        static:
          host: api.githubcopilot.com
          port: 443
          path: /mcp/
          protocol: StreamableHTTP
          policies:
            tls: {}
            auth:
              secretRef:
                name: github-pat
```

In the example above, with `toolMode: Search` on, you will get two tools – `get_tool` and `invoke_tool`. The basics of the tools within the MCP server are exposed to the agent (name, description, category, or high-level routing tags). With Progressive Disclosure enabled, you can save on tokens and therefore the cost of your AI implementation.

Code Mode

When agents first started coming out, there was no MCP. In fact, it was about 20 months because MCP came out after agents were released. Because of that, agents didn't have MCP tools in the same way they have them now. Instead, agents did things the old-fashioned way – by calling APIs. Then, when MCP came out, a lot of the tools that agents used were from MCP servers. After a few months of MCP, a question came up from engineers: "Why?". Why not just use API endpoints for agents to gain functionality, and conceptually, that's a totally fine method. You can do that today (e.g., having your agent use a CLI tool that's calling an SDK/API). The problem is there isn't an "agentic way" to secure that workflow. MCP gave engineers a protocol/spec to secure, govern, and observe. It also gave agents a native way to call tools.

That's where Code Mode comes into play. It's a way to call API endpoints and have the response/final return come back as an MCP tool response.

Example: you have an OpenAPI endpoint that you want to call:

```
apiVersion: v1
kind: ConfigMap
metadata:
  name: open-meteo-geocoding-openapi
  namespace: agentgateway-system
data:
  openapi.json: |
    {
      "openapi": "3.0.0",
      "info": { "title": "Open-Meteo Geocoding", "version":
"1.0.0" },
      "servers": [{ "url": "https://geocoding-api.open-
meteo.com/v1" }],
      "paths": {
        "/search": {
          "get": {
            "operationId": "geocode_city",
            "description": "Resolve a city name to
latitude/longitude and country.",
            "parameters": [
              { "name": "name", "in": "query", "required":
true,
```

```
                "schema": { "type": "string" },
                "description": "City name, e.g. \"Paris\"." },
              { "name": "count", "in": "query", "required":
false,
                "schema": { "type": "integer", "default": 1 },
                "description": "Max results to return." }
            ],
            "responses": { "200": { "description": "OK" } }
          }
        }
      }
    }
```

You then specify that it's a Code Mode call within the backend that's calling the OpenAPI endpoint.

```
  entMcp:
    toolMode: Code
    codeMode:
      timeout: 10s
```

Composable MCP

When you hear "Composable MCP," it can mean two different things:

1. Aggregating/proxying/federating multiple MCP servers behind one endpoint
2. Designing MCP tool patterns so they chain together rather than being one-shot wrappers

And out of the above, you'll typically see number two, which can be thought of as a "one-shot API wrapper." Most MCP tools today are a wrapper over a single REST endpoint. Example: `get_user` == `GET /users/{name}`, `get_repos` == `GET /users/{name}/repos`, etc... We typically don't live in a perfect "one tool, one call" job. When something programmatically has to get done, it usually involves calling many endpoints/APIs/tools.

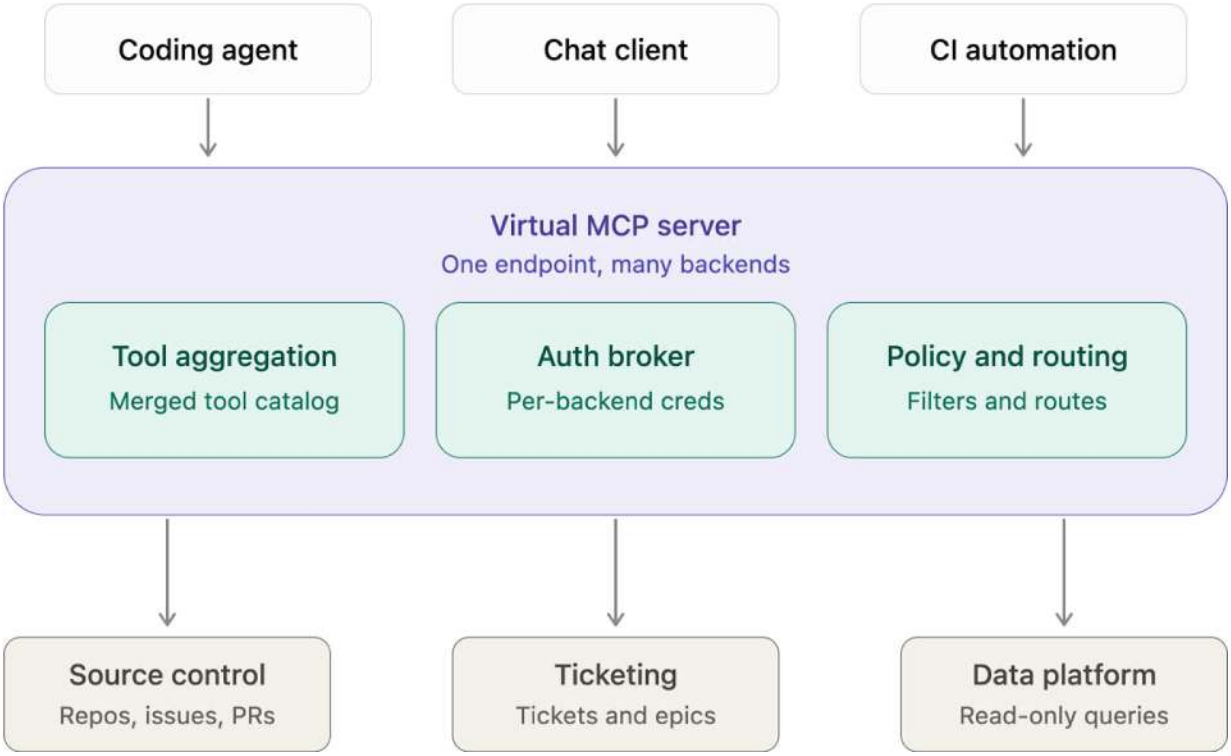
The problem is that MCP isn't designed like that out of the box. With Composable MCP, however, you can define one tool that internally calls 2, 3, 4, etc. tools. It calls each tool, reads the results, stitches them together, and returns the combined answer.

Virtual MCP

Because agents are being more and more used for various tasks instead of one agent for a specific task/job, you'll quickly realize that you start stacking up MCP servers for each agent. Before you know it, you could have 10s of MCP servers and hundreds of tools that can be connected to an agent.

Sidenote Best practice is to only attach 15–18 tools to an agent at a time. More tools than that and you'll begin to see more hallucinations due to it triggering context bloat and attention dilution.

Instead of having a bunch of different MCP servers, you can have one Virtual MCP server. A Virtual MCP server aggregates tools from multiple MCP servers and exposes them as a single MCP endpoint. It doesn't host the tools; instead, it references them in places that already exist.



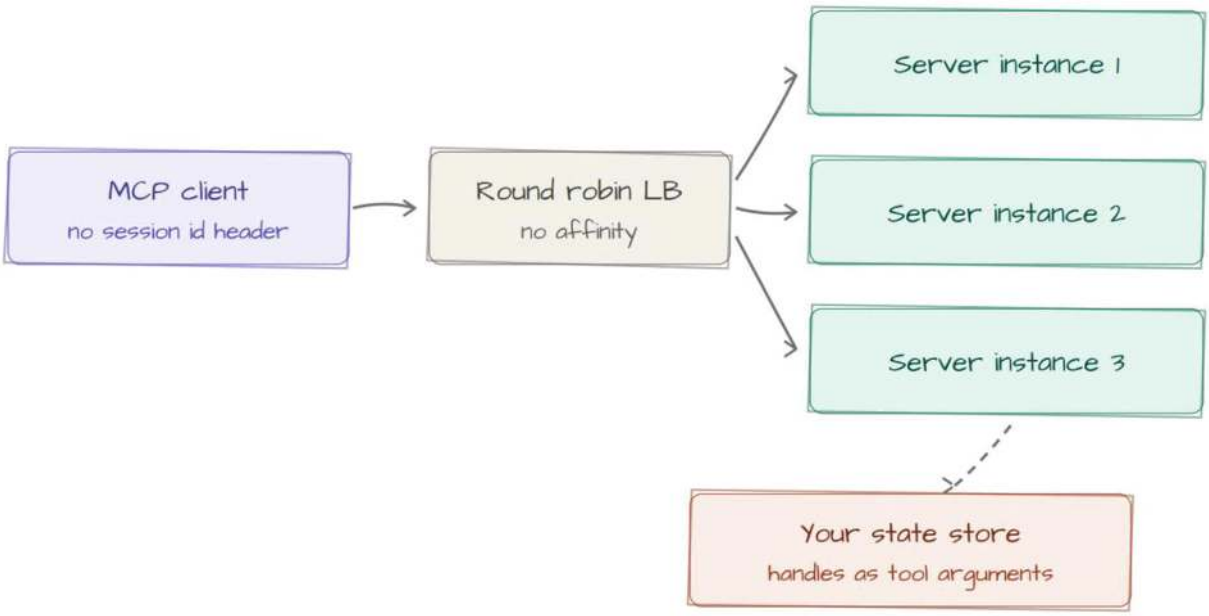
You may be thinking to yourself "Virtual MCP sounds a lot like Composable MCP," and you're right. They're very closely related topics. The best way to think about it is Composable MCP is the action (how you build) and Virtual MCP is the result (what the agent sees).

Stateless MCP Spec

From the beginning of the MCP protocol to July 28, 2026, MCP was stateful. What this means is that a session ID was carried with the request. This is because for stateful workloads to be stateful, past interactions need to be remembered. For example, when you log into Gmail, you see all of your emails still there, and the reason why is because Gmail is stateful. It requires the system to remember and save data, sessions, and message history. On the other hand, when you go to www.google.com, make a search,

close out of your browser, and open google.com again, you won't see where you left off because it's stateless.

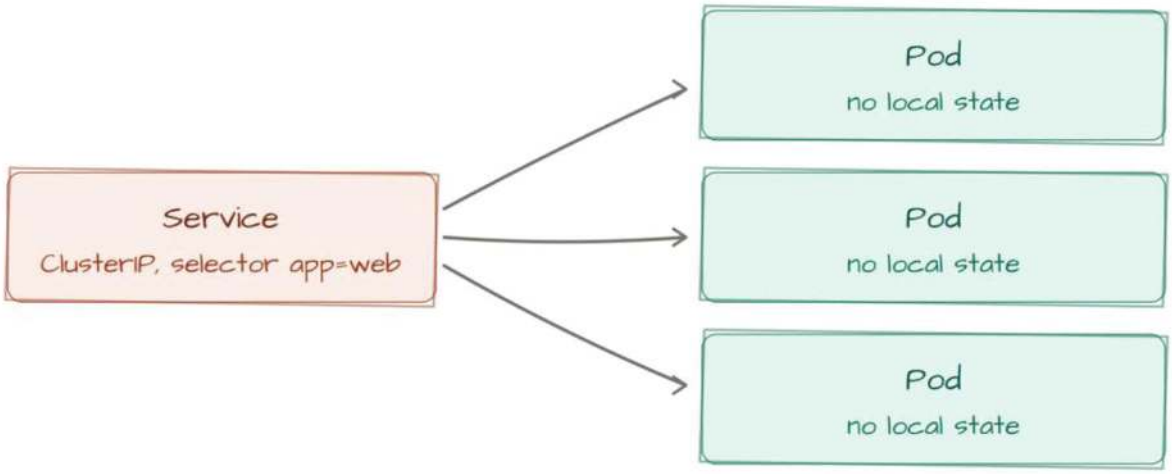
As mentioned, starting July 28, 2026, the MCP spec now supports both stateless and stateful workloads.



Dashed line = application state, which now lives outside the protocol

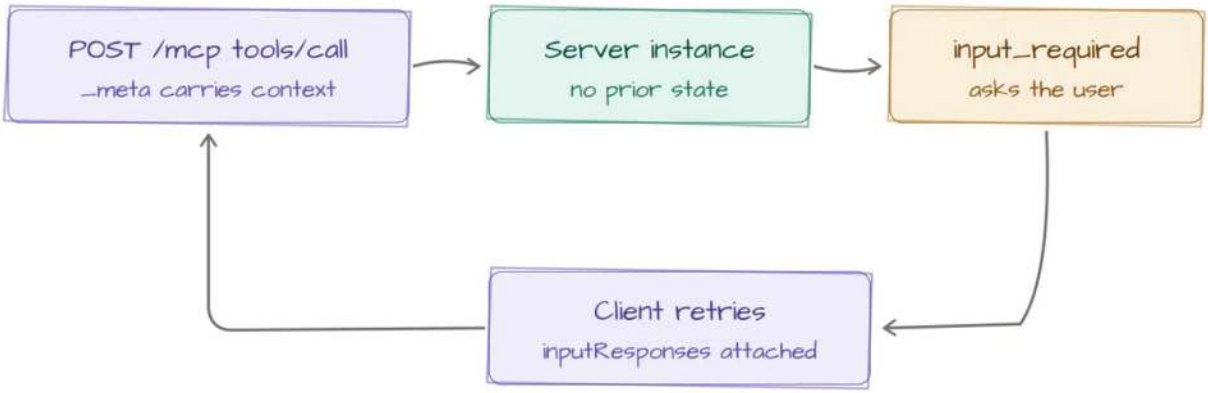
Aside from the biggest change, which was around state, you'll also see that there's a much higher probability and reliability for implementing scaling. You can technically load balance a stateful MCP server (and stateful apps in general), but the problem is that because it relies on maintaining a continuous session context, you can't do things like traditional round-robin load balancing.

For example, in Kubernetes, there can be several pods and a Kubernetes service sitting in front of those pods.



With the stateful MCP spec, you wouldn't be able to do that style of round-robin load balancing. With stateless MCP, however, you can. This increases the chances that MCP servers have high availability and a much easier time for engineers to implement load balancing out of the box.

Something to keep in mind: because there is no longer a session ID, that means there is no handshake. Every POST request has to carry its own context, and anything that the server needs mid-call comes back as a retriable result rather than a server push over an open stream.



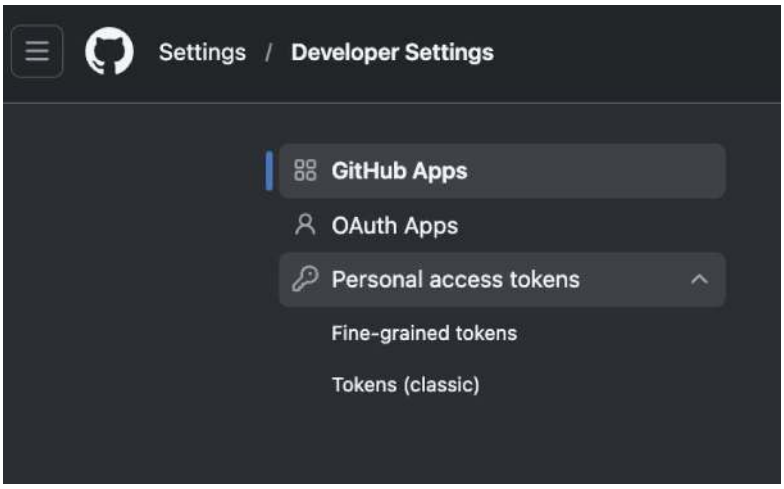
The retry is just another self contained POST, so it can land on a different instance

Connecting to MCP Servers

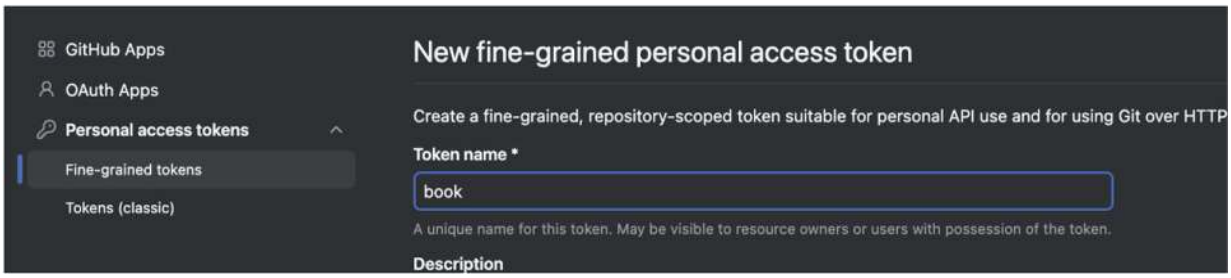
With some theory/knowledge of MCP under our belts, let's dive into the hands-on portion and learn how to connect to MCP servers. For this example, you'll see how to connect to the GitHub Copilot MCP server. All you need to get started is a Personal Access Token (PAT) that anyone with a GitHub account can generate, so the barrier to entry is pretty low.

1. Go to the **Developer Settings** in your GitHub account and choose **Fine-grained**

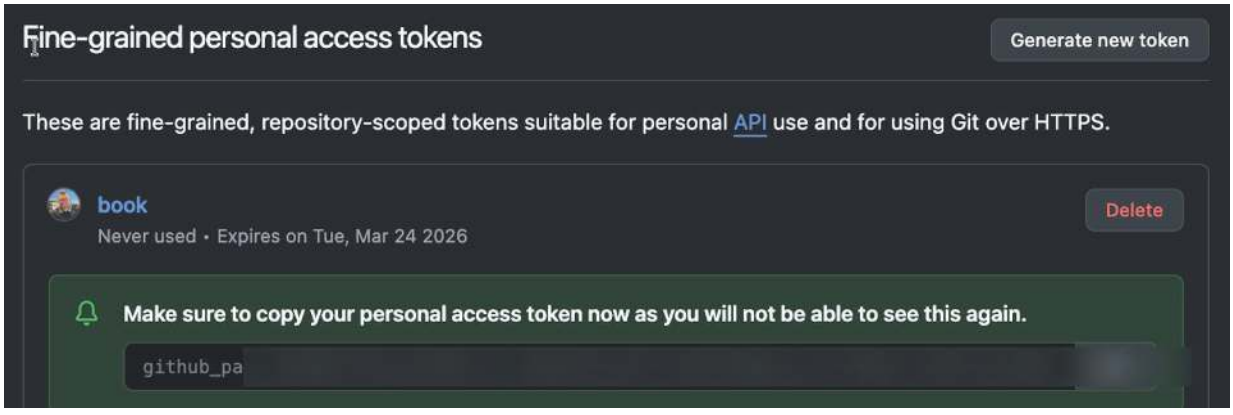
tokens.



2. Create a new fine-grained token. For the permissions, you can give it access to just public repos.



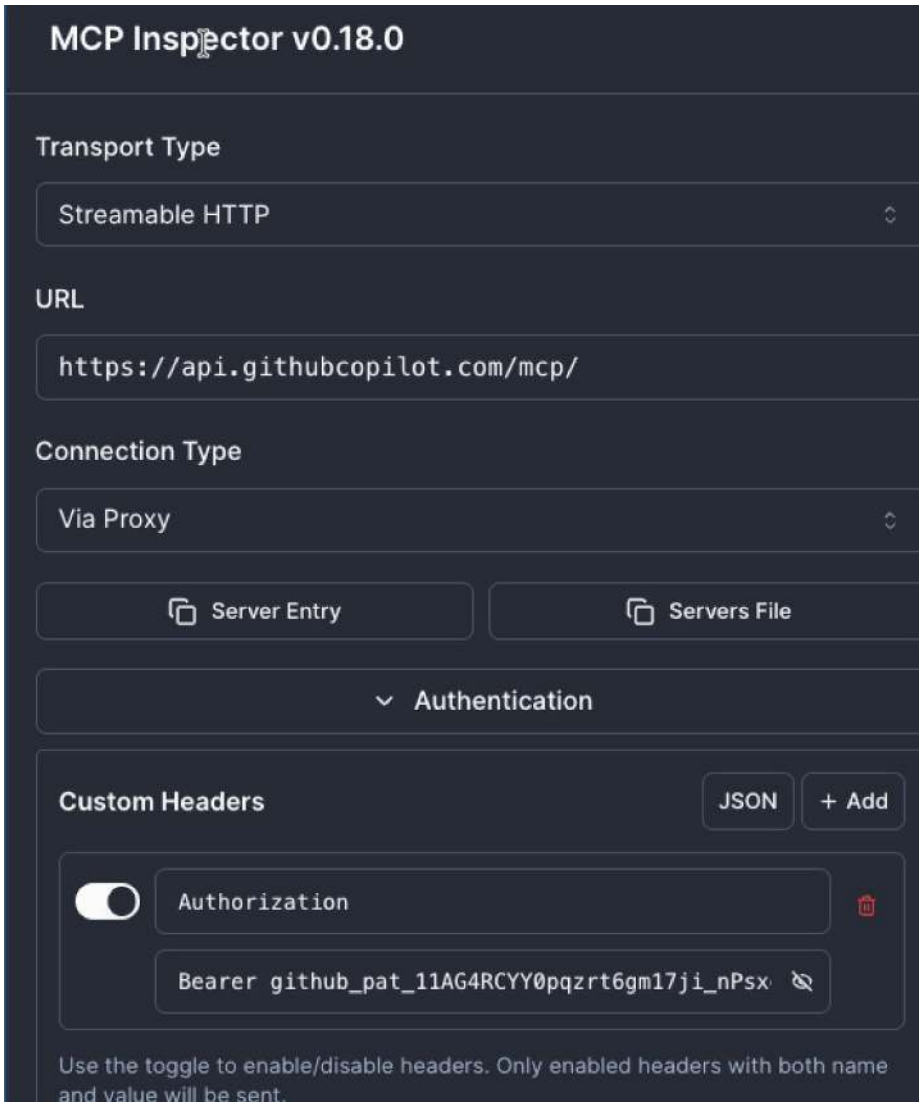
3. Copy your PAT.



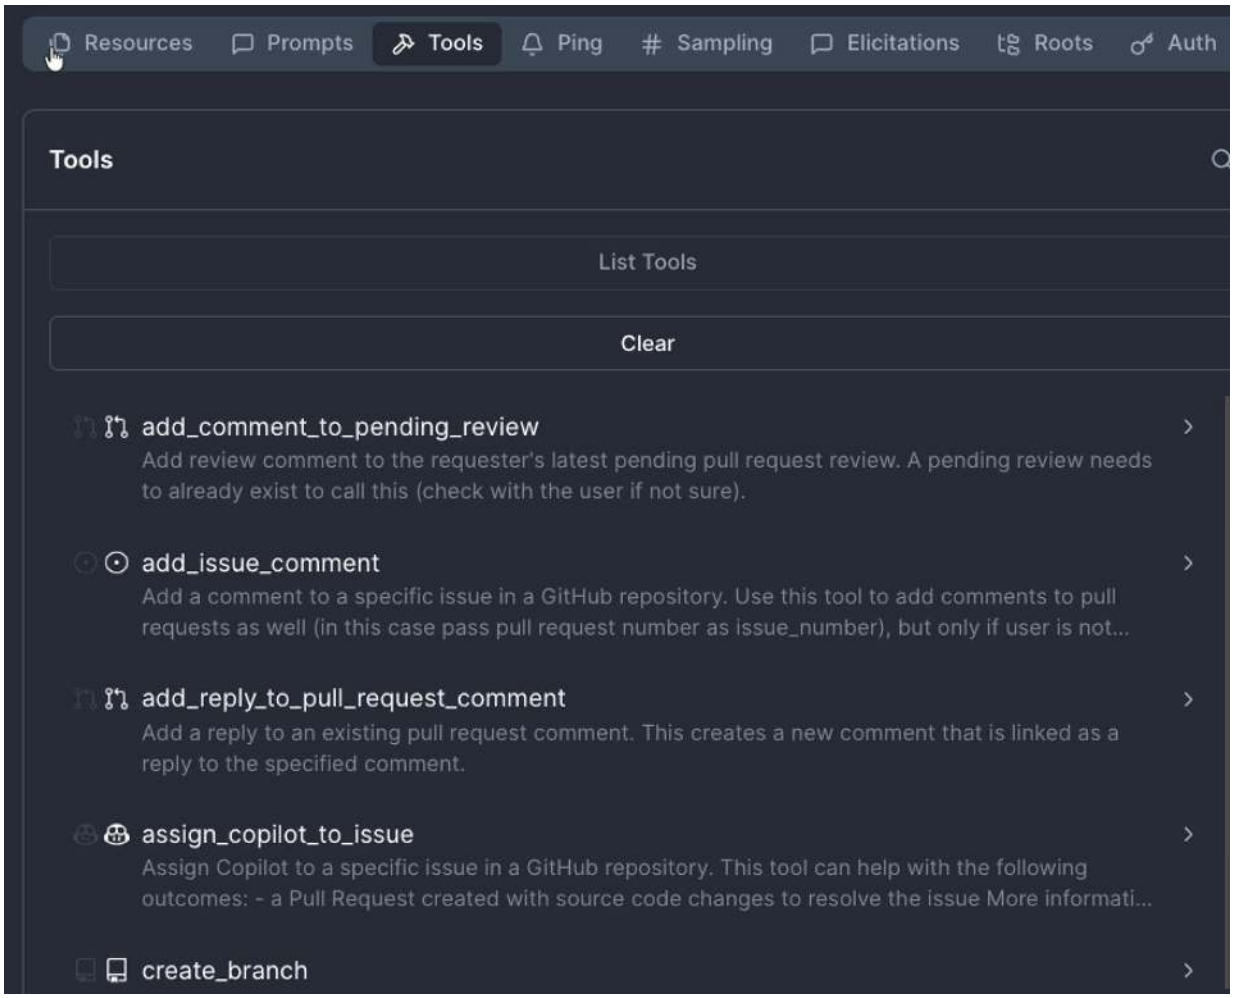
4. Open MCP Inspector.

`npx modelcontextprotocol/inspector#0.18.0`

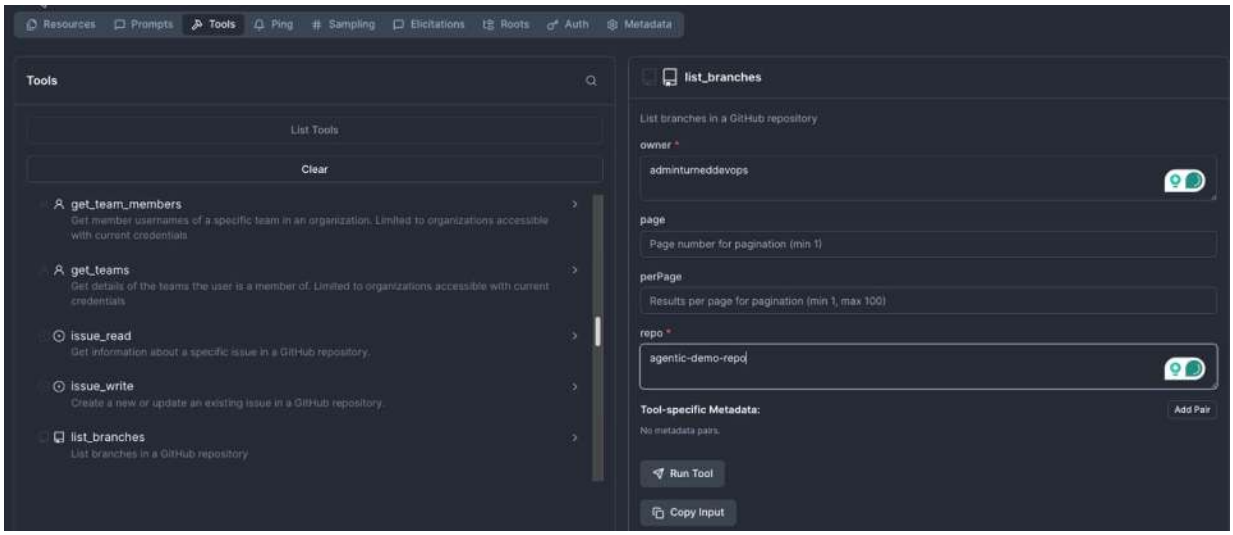
5. Add the following:
    1. https://api.githubcopilot.com/mcp/ for the URL.
    2. Open the **Authentication** tab and add **Authorization** for the header and, for the token, add **Bearer YOUR_GITHUB_TOKEN**.



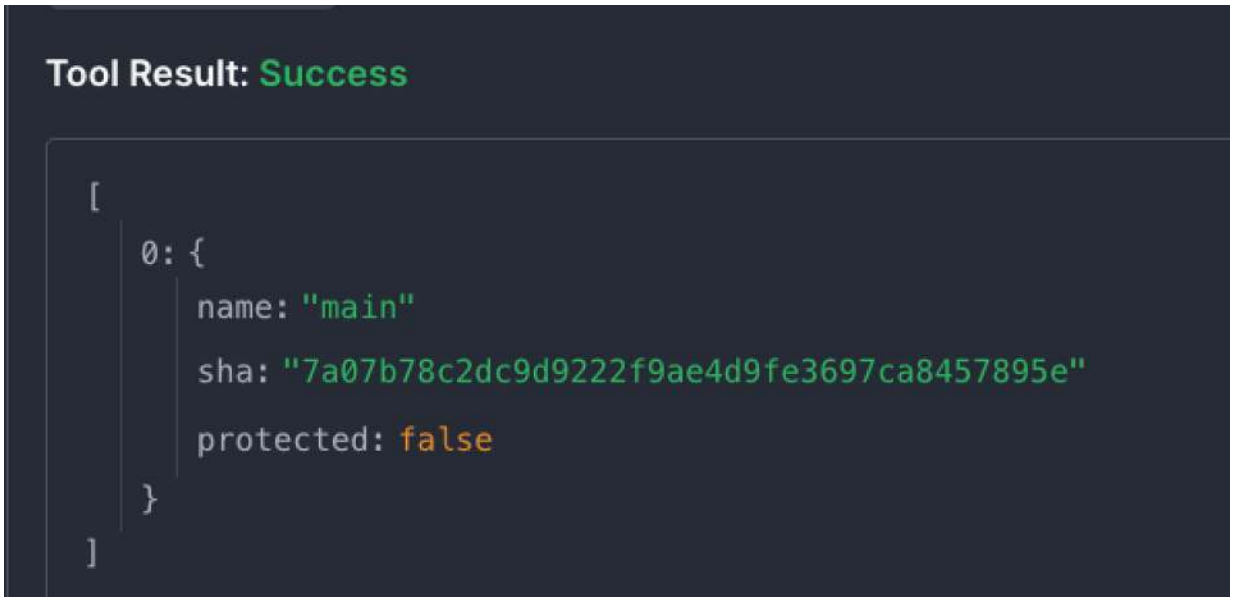
6. Once you connect, you'll be able to see the GitHub Copilot MCP server tools.



7. To test out using a tool, you can use the “list_branches” tool and put in the following:
   a) Owner: adminturneddevops
   b) Repo: agentic-demo-repo



You'll see that the tool worked and only a "main" branch is currently available.



Please note: OAuth is also supported by the GitHub Copilot MCP Server. This section just shows the quick way to demonstrate auth with a PAT.

In the next section, you'll learn how to deploy a custom MCP server to your Kubernetes environment.

MCP in Kubernetes Servers

With a successful connection to a streamable HTTP MCP server, let's learn how to deploy an MCP server in Kubernetes and connect to it via MCP Inspector.

1. Deploy the following, which does a few things:
    a. Create an MCP server using FastMCP in a Kubernetes ConfigMap. The MCP server

is just for addition and multiplication for testing purposes.

b. Create a Kubernetes deployment with one replica so the MCP server has somewhere to run.
c. Create a Kubernetes service so the MCP server can be connected to over a network, which makes it ready to be used with a streamable HTTP protocol.

```
kubectl apply -f - <<EOF
apiVersion: v1
kind: ConfigMap
metadata:
  name: mcp-math-script
  namespace: default
data:
  server.py: |
    import uvicorn
    from mcp.server.fastmcp import FastMCP
    from starlette.applications import Starlette
    from starlette.routing import Route
    from starlette.requests import Request
    from starlette.responses import JSONResponse, Response

    mcp = FastMCP("Math-Service")

    @mcp.tool()
    def add(a: int, b: int) -> int:
        return a + b

    @mcp.tool()
    def multiply(a: int, b: int) -> int:
        return a * b

    async def handle_mcp(request: Request):
        try:
            data = await request.json()
            method = data.get("method")
            msg_id = data.get("id")
            result = None

            if method == "initialize":
                result = {
                    "protocolVersion": "2024-11-05",
                    "capabilities": {"tools": {}},
                    "serverInfo": {"name": "Math-Service",
"version": "1.0"}
```

```
                }

            elif method == "notifications/initialized":
                # Notifications are fire-and-forget,
return empty 202 response
                return Response(status_code=202)

            elif method == "tools/list":
                tools_list = await mcp.list_tools()
                result = {
                    "tools": [
                        {
                            "name": t.name,
                            "description": t.description,
                            "inputSchema": t.inputSchema
                        } for t in tools_list
                    ]
                }

            elif method == "tools/call":
                params = data.get("params", {})
                name = params.get("name")
                args = params.get("arguments", {})

                # Call the tool
                tool_result = await mcp.call_tool(name,
args)

                # --- FIX: Serialize the content objects
manually ---
                serialized_content = []
                for content in tool_result:
                    if hasattr(content, "type") and
content.type == "text":
                        serialized_content.append({"type":
"text", "text": content.text})
                    elif hasattr(content, "type") and
content.type == "image":
                        serialized_content.append({
                            "type": "image",
                            "data": content.data,
                            "mimeType": content.mimeType
                        })
                    else:
```

```
                        # Fallback for dictionaries or
other types
                        serialized_content.append(content
if isinstance(content, dict) else str(content))

                result = {
                    "content": serialized_content,
                    "isError": False
                }

            elif method == "ping":
                result = {}

            else:
                return JSONResponse(
                    {"jsonrpc": "2.0", "id": msg_id,
"error": {"code": -32601, "message": "Method not found"}},
                    status_code=404
                )

            return JSONResponse({"jsonrpc": "2.0", "id":
msg_id, "result": result})

        except Exception as e:
            # Print error to logs for debugging
            import traceback
            traceback.print_exc()
            return JSONResponse(
                {"jsonrpc": "2.0", "id": None, "error":
{"code": -32603, "message": str(e)}},
                status_code=500
            )

    app = Starlette(routes=[
        Route("/mcp", handle_mcp, methods=["POST"]),
        Route("/", lambda r: JSONResponse({"status":
"ok"}), methods=["GET"])
    ])

    if __name__ == "__main__":
        print("Starting Fixed Math Server on port
8000...")
        uvicorn.run(app, host="0.0.0.0", port=8000)
---
apiVersion: apps/v1
```

apiVersion: v1
kind: Service
metadata:
  name: mcp-math-server
  namespace: default
```

```
  spec:
    selector:
      app: mcp-math-server
    ports:
    - port: 80
      targetPort: 8000
  EOF
```

2. With the MCP server deployed, you'll need a way to connect to it. To do that, you can use agentgateway. Create a new gateway object that's listening on port "8080."

```
kubectl apply -f - <<EOF
apiVersion: gateway.networking.k8s.io/v1
kind: Gateway
metadata:
  name: agentgateway-mcp
  namespace: agentgateway-system
spec:
  gatewayClassName: enterprise-agentgateway
  listeners:
  - name: http

    port: 8080
    protocol: HTTP
    allowedRoutes:
      namespaces:
        from: Same
EOF
```

3. Create an AgentgatewayBackend so the gateway knows what to route to. In this case, it's the MCP server that you deployed in Kubernetes in Step 1.

```
kubectl apply -f - <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayBackend
metadata:
  name: demo-mcp-server
  namespace: agentgateway-system
spec:
  mcp:
    targets:
      - name: demo-mcp-server
        static:
          host: mcp-math-server.default.svc.cluster.local
```

```
            host: mcp-math-server.default.svc.cluster.local
            port: 80
            path: /mcp
            protocol: StreamableHTTP
  EOF
```

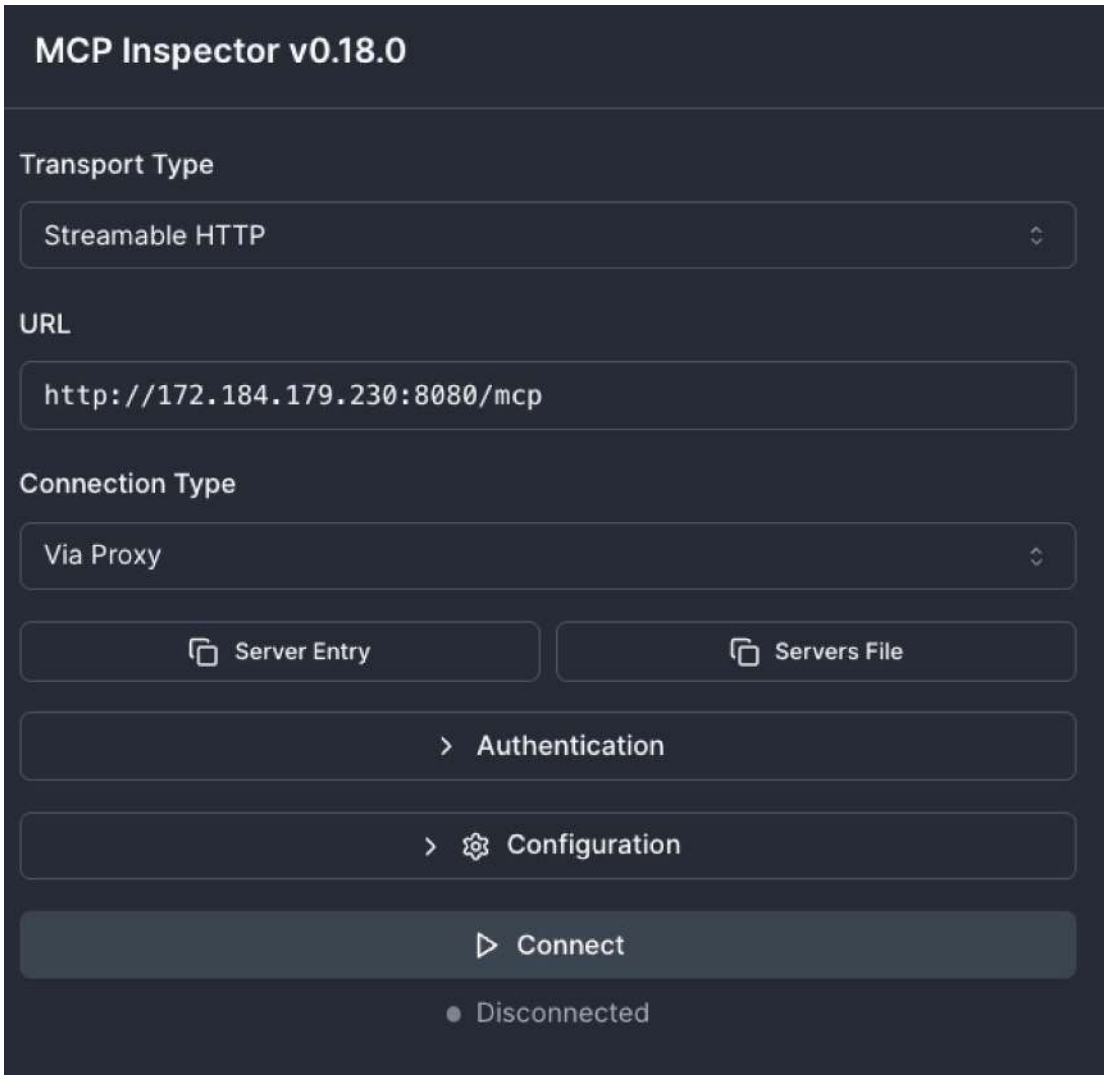
4. The last step is to create the HTTPRoute so the gateway has a routable path. Because the endpoint/path is specified in the AgentgatewayBackend object, you just need to set the HTTPRoute to point to the backend.

```
kubectl apply -f - <<EOF
apiVersion: gateway.networking.k8s.io/v1
kind: HTTPRoute
metadata:
  name: mcp-route
  namespace: agentgateway-system
spec:
  parentRefs:
  - name: agentgateway-mcp
  rules:
  - backendRefs:
    - name: demo-mcp-server
      namespace: agentgateway-system
      group: agentgateway.dev
      kind: AgentgatewayBackend
```

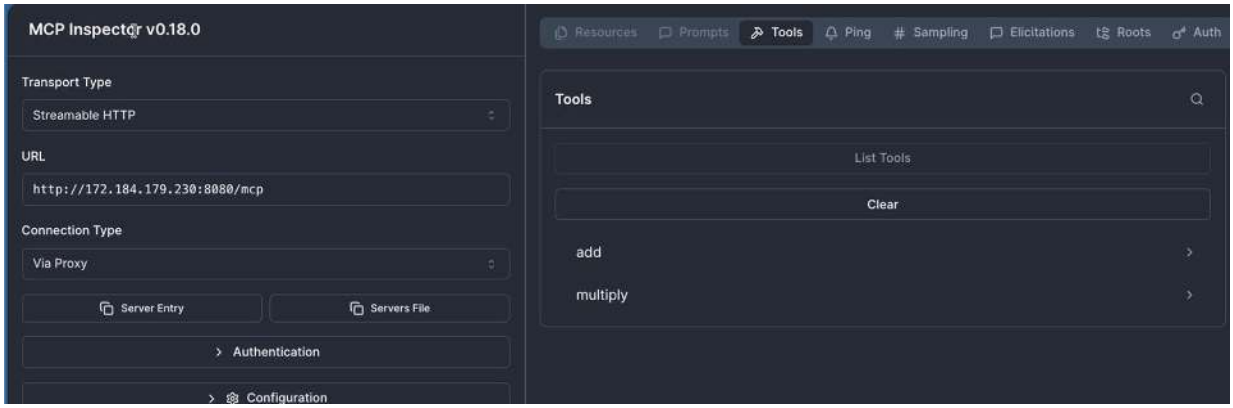
5. You can now open MCP Inspector and connect to your MCP server. The URL will be http://YOUR_GATEWAY_ALB_IP:8080/mcp. If you're running this on a local K8s cluster and your Gateway doesn't have an ALB IP, you can port-forward the Gateway and just use "localhost" instead of "YOUR_GATEWAY_ALB_IP."

```
npx modelcontextprotocol/inspector#0.18.0
```

6. Once you input the URL, click the **Connect** button.



7. Click **Tools** then **List Tools**. You should now be able to see the “add” and “multiply” tools.



In the last section of MCP, you'll build your own MCP server.

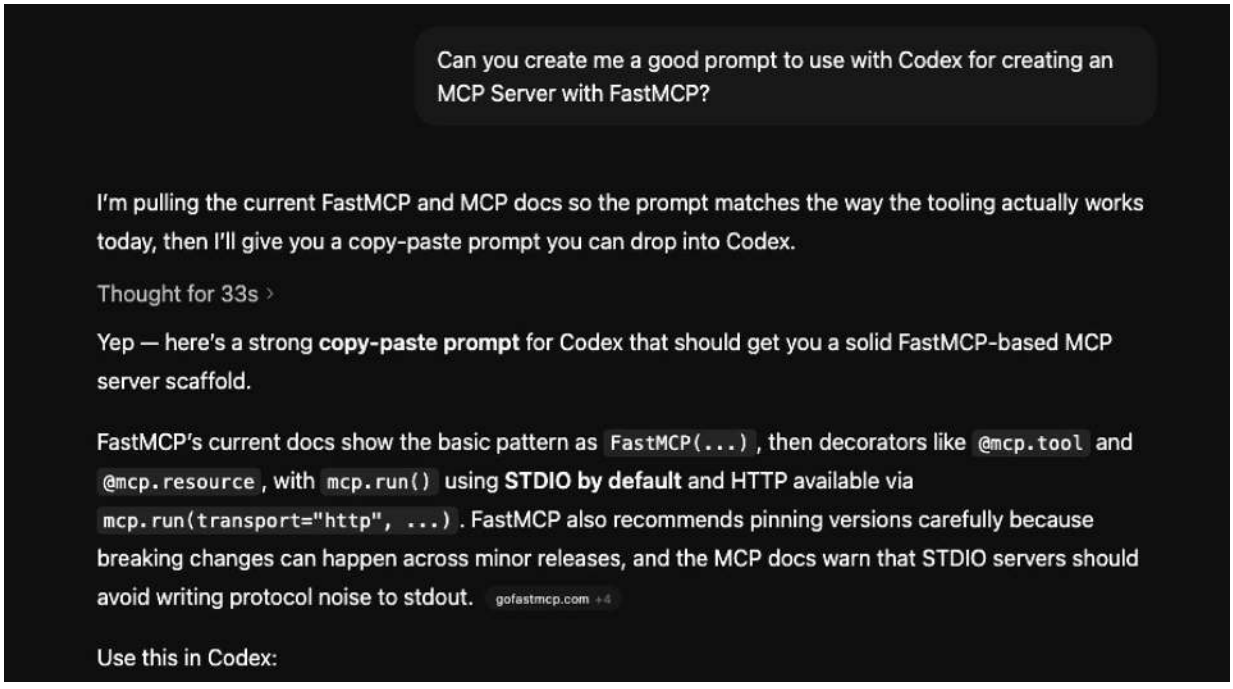
Building Your Own MCP Server

As mentioned in this chapter, an MCP server, at its core, is like any other application stack. It's a set of functions/methods and third-party libraries/packages. Because of that, you're going to build an MCP server like any other app stack in 2026 – with AI! Please note that all AI code, regardless of what you hear/read on social media (e.g., AI is taking every job, no human is needed, and the rest of the nonsense), still needs to be a human-in-the-loop for reviewing, testing, designing, and architecting a solution.

For the purposes of this section, Codex 5.3 is used, but you'll get similar results if you use Claude Opus.

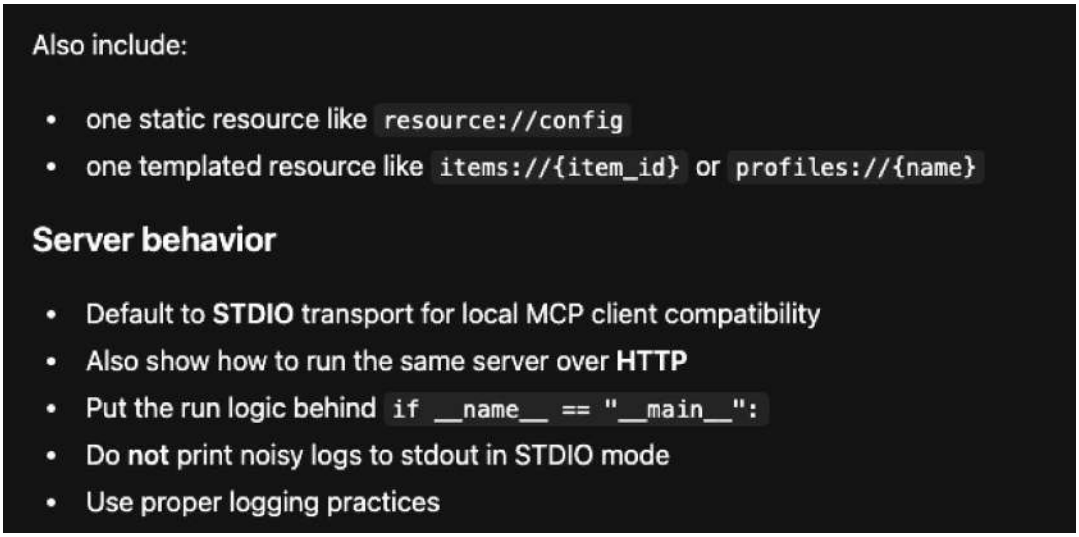
The first step is to ensure that you have a good prompt for your use case. The best way to ensure that the agent you're using understands the prompt successfully in "its own words" is to ask the LLM you're using to create a prompt that works best for your agent.

You can ask your LLM "Can you create me a good prompt to use with {YOUR_LLM_PROVIDER} for creating an MCP Server with FastMCP?" and you should see an output similar to the screenshot below. The LLM should think, reason with itself, and then give you a good prompt to use.



Even with a prompt, however, you want to read it and ensure that it's what you're looking for. As an example, you can see in the screenshot below that the prompt defaulted to using STDIO as the MCP server protocol. If you're building an MCP server that you want to properly secure, as we've discussed, you'll want to use streamable HTTP. That means

this prompt got most of what you'd want right, but you still want to review it to ensure it's following best practices for you and your organization.



Here is the prompt that I decided to go with (you can modify it on your end). The goal here is really to create your "first MCP Server," so it doesn't have to be anything incredibly complex. However, what this does give you is a starting point. That's the great thing about coding agents – they give you a jump-off point to start with and modify as you go.

Create a starter-template MCP server in Python using FastMCP that I can use as the base for real projects.

Build it like a small professional repository:

- src/ layout
- pyproject.toml
- README.md
- Tests/
- Clear module separation
- Typed Python
- Minimal dependencies
- Version-pinned FastMCP setup

Server Features

Implement:

- Three tools
- One static resource
- One dynamic resource template
- Clean logging
- Graceful error handling
- Simple tests

Technical Constraints

- Python 3.13+
- FastMCP-native patterns
- STDIO by default
- Optional HTTP run mode
- if __name__ == “__main__”: entrypoint
- No stdout logging pollution in STDIO mode
- Easy local execution

Tools to Include

Use these exact examples unless there is a better FastMCP-native option:

- ping() -> str
- add_numbers(a: int, b: int) -> int
- lookup_customer(customer_id: str) -> dict

Resources to Include

- Static: resource://config
- Dynamic template: customers://{customer_id}

Use mock in-memory data for the customer examples.

What I Want from You

Generate the full repo with complete file contents and commands to

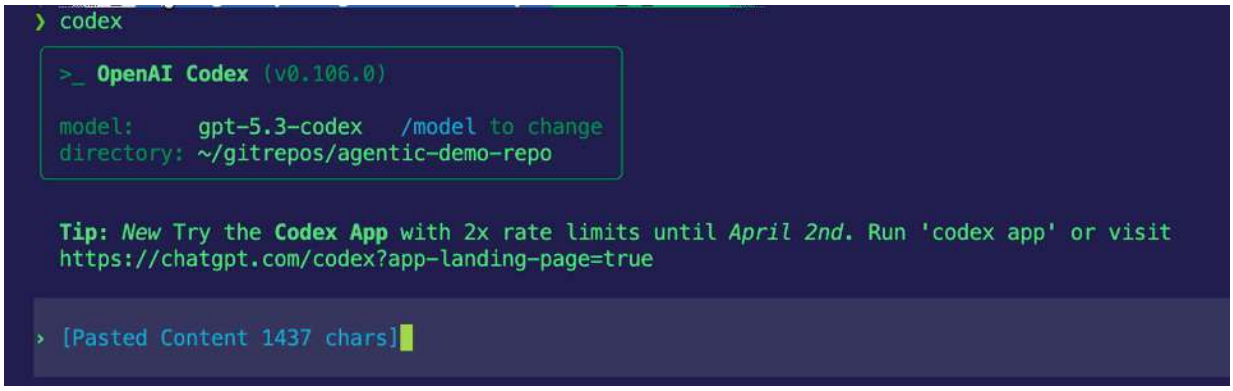
- Install dependencies
- Run locally over STDIO
- Run over HTTP
- Run tests

Also include a short section showing where I would add:

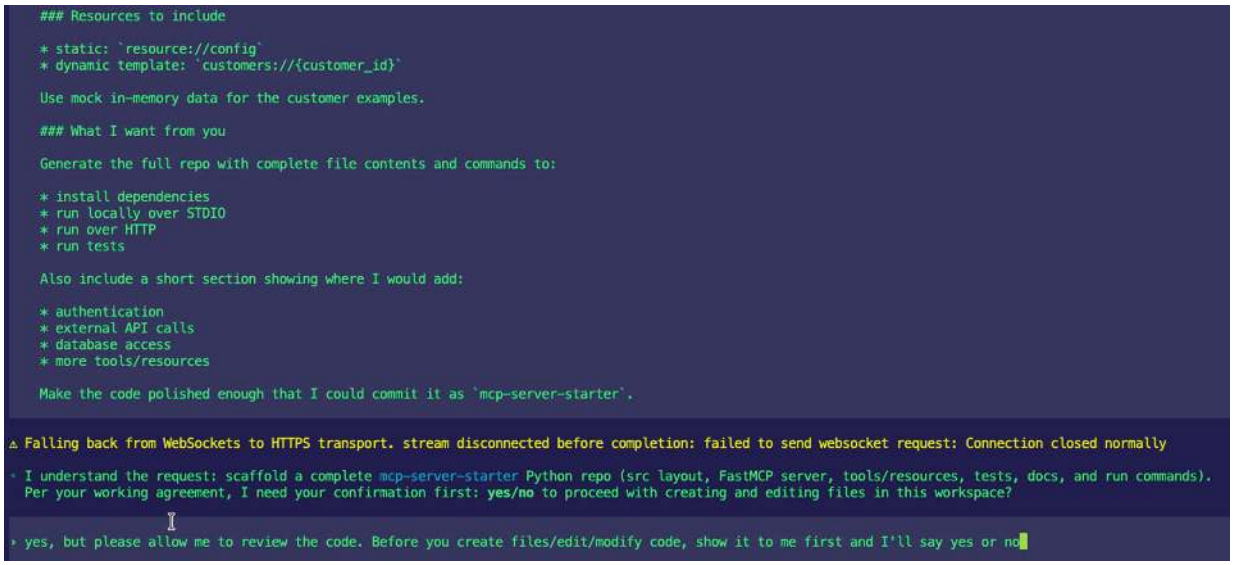
- Authentication
- External API calls
- Database access
- More tools/resources

Make the code polished enough that I could commit it as mcp-server-starter.

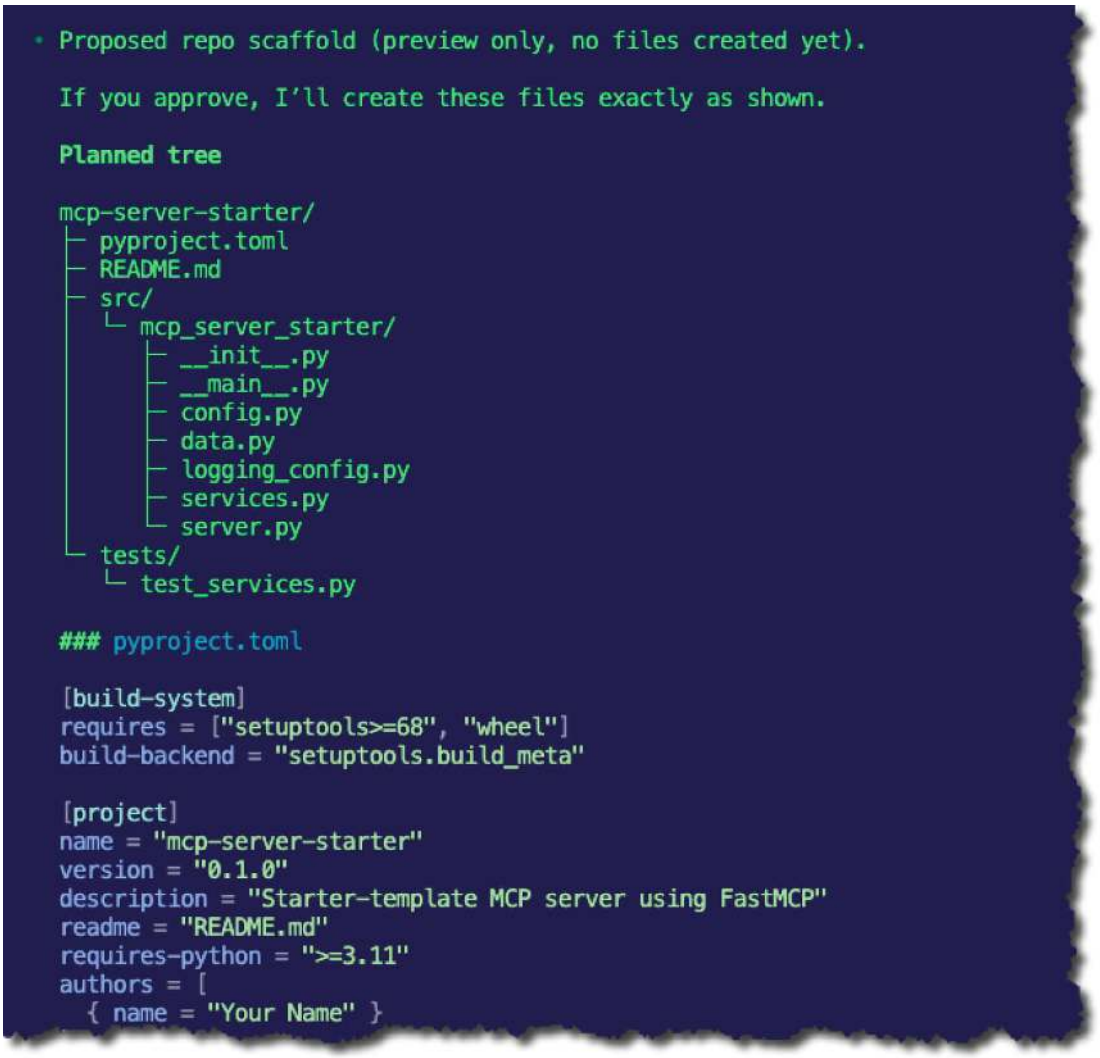
1. Open your agent terminal and paste your prompt into your agent and run it.



2. You'll see the prompt kicking off. If you want to validate anything prior to the code being written to a file, you can specify that.



You should now begin to see your agent creating the MCP server code for you.



• Proposed repo scaffold (preview only, no files created yet).

If you approve, I'll create these files exactly as shown.

Planned tree

```
mcp-server-starter/
├─ pyproject.toml
├─ README.md
├─ src/
│  └─ mcp_server_starter/
│     ├─ __init__.py
│     ├─ __main__.py
│     ├─ config.py
│     ├─ data.py
│     ├─ logging_config.py
│     ├─ services.py
│     └─ server.py
└─ tests/
   └─ test_services.py
```

pyproject.toml

```
[build-system]
requires = ["setuptools>=68", "wheel"]
build-backend = "setuptools.build_meta"

[project]
name = "mcp-server-starter"
version = "0.1.0"
description = "Starter-template MCP server using FastMCP"
readme = "README.md"
requires-python = ">=3.11"
authors = [
  { name = "Your Name" }
```

3. Once the agent is complete, you should see an output of the key files, the tests that ran, and the commands to use to test out the MCP server. Notice how there are two options – stdio and streamable http.

```
• Implemented exactly as approved in mcp-server-starter/ with src/ layout, pinned FastMCP, tools/resources, error handling, logging to stderr, and
  tests.

  Key files:

  - pyproject.toml
  - README.md
  - server.py
  - services.py
  - test_services.py

  Validation run:

  - PYTHONPATH=src pytest inside mcp-server-starter
  - Result: 6 passed

  Commands to use:

  cd /Users/michael/gitrepos/agentic-demo-repo/mcp-server-starter
  python -m venv .venv
  source .venv/bin/activate
  pip install -e ".[dev]"

  # STDIO (default)
  python -m mcp_server_starter

  # HTTP mode
  python -m mcp_server_starter --transport http --host 127.0.0.1 --port 8000 --path /mcp

  # Tests
  pytest
```

Codex took it upon itself (which is actually a really good thing) to implement the ArgParser library, which allows you to create CLI arguments in your MCP server. It then stores the “parse_args” function in the “cfg” variable so you can pass in the arguments (stdio or streamable http as the transport) when the “main()” function is called.

```python
if cfg.transport == "stdio":
    mcp.run(transport="stdio", show_banner=False)
    return

if cfg.transport == "http":
    mcp.run(
        transport="http",
        host=cfg.host,
        port=cfg.port,
        path=cfg.path,
        show_banner=False,
    )
    return
```

```python
def parse_args() -> ServerConfig:
    parser = ArgumentParser(description="FastMCP starter server")
    parser.add_argument(
        "--transport",
        choices=["stdio", "http", "sse"],
        default="stdio",
        help="Server transport mode (default: stdio)",
    )
    parser.add_argument("--host", default="127.0.0.1", help="HTTP/SSE host")
    parser.add_argument("--port", type=int, default=8000, help="HTTP/SSE port")
    parser.add_argument("--path", default="/mcp", help="HTTP path for MCP endpoint")
    parser.add_argument("--log-level", default="INFO", help="Python logging level")
    args: Namespace = parser.parse_args()
```

4. You can now test that your MCP server works with the command output. In my case, I have the following commands:

```
  cd /Users/michael/gitrepos/agentic-demo-repo/mcp-server-starter
  python -m venv .venv
  source .venv/bin/activate
```

5. You can then test with stdio or streamable http.

```
python -m mcp_server_start
```

```
> python -m mcp_server_starter
2026-03-01 08:58:14,991 INFO mcp_server_starter.server - Starting server with transport=stdio
[03/01/26 08:58:14] INFO     Starting MCP server 'mcp-server-starter' with transport 'stdio'
```

> **Sidenote** You learned about MCP Inspector in a previous section. You can run your MCP server with streamable HTTP and then connect to it via MCP Inspector.

A Templated Approach

If you're interested in having a starting point/template for your MCP server, you can use the kagent CLI as it has an mcp server command.

```
kagent mcp init
```

You can then specify what general-purpose programming language you want to use to create the MCP server.

```
❯ kagent mcp init
Initialize a new MCP server project with dynamic tool loading.

This command provides subcommands to initialize a new MCP server project
using one of the supported frameworks.

Usage:
  kagent mcp init [project-name] [flags]
  kagent mcp init [command]

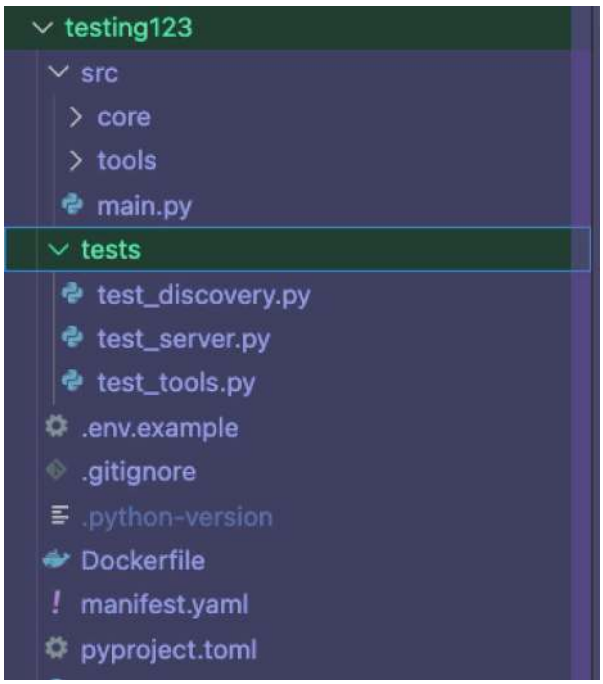
Available Commands:
  go          Initialize a new Go MCP server project
  java        Initialize a new Java MCP server project
  python      Initialize a new Python MCP server project
  typescript  Initialize a new TypeScript MCP server project
```

`kagent mcp init python testing123`

You'll see a few prompts asking some questions like in the screenshot below.

```
❯ kagent mcp init python testing123
Enter description (optional): my new mcp server
Enter author name (optional): michael levan
Enter author email (optional):
  To run the server locally:
  kagent mcp run local --project-dir /Users/michael/gitrepos/agentic-demo-repo/testing123
✓ Successfully created Python MCP server project: testing123
```

You now have a full, ready-to-use template that consists of the MCP server, a way to create a Docker image so the MCP server can be deployed to K8s, and a test suite.



Connecting Agents to MCP Servers

In this section, you'll take what you learned in Chapter 4 for kagent and expand upon it by creating an MCP server object and using it with an agent.

1. Create a namespace for the agent and MCPServer objects to live in.

```
kubectl create ns policies
```

2. Create an MCPServer object that connects to the GitHub stdio MCP server. With the MCPServer object, a K8s service is created, which means even though it's stdio, you can connect to it over the K8s service which can make the workflow more secure.

```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha1
kind: MCPServer
metadata:
  name: test-mcp-server
  namespace: policies
  labels:
    kagent.solo.io/waypoint: "true"
spec:
  deployment:
    image: mcp/everything
    port: 3000
    cmd: npx
    args:
      - "-y"
      - "@modelcontextprotocol/server-github"
  transportType: stdio
EOF
```

3. Create a ModelConfig which will be used to specify what LLM provider you want to use with your agent. In the example below, it's Anthropic, but you can change that if you'd like.

```
export ANTHROPIC_API_KEY=

kubectl create secret generic kagent-anthropic --from-
literal=ANTHROPIC_API_KEY=$ANTHROPIC_API_KEY -n policies

kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: ModelConfig
metadata:
```

```
  name: anthropic-model-config
  namespace: policies
spec:
  apiKeySecret: kagent-anthropic
  apiKeySecretKey: ANTHROPIC_API_KEY
  model: claude-sonnet-5
  provider: Anthropic
  anthropic: {}
EOF
```

4. The last step is to create the agent that will use the ModelConfig and MCPServer objects you created in the previous sections. You'll also specify the systemMessage, which is the agent's default prompt. Within the tools section when the MCPServer is specified, you can ensure that you only select the tools you want to be exposed to the agent. In the example below, only four tools can be used within the agent.

```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: Agent
metadata:
  name: test-tools-agent
  namespace: policies
spec:
  description: This agent can use a single tool to expand
it's Kubernetes knowledge for troubleshooting and deployment
  type: Declarative
  declarative:
    modelConfig: anthropic-model-config
    systemMessage: |-
      You're a friendly and helpful agent that uses the
GitHub MCP Server tools to help troubleshooting and deploy
environments

      # Instructions

      - If user question is unclear, ask for clarification
before running any tools
      - Always be helpful and friendly
      - If you don't know how to answer the question DO NOT
make things up
        respond with "Sorry, I don't know how to answer
that" and ask the user to further clarify the question

      # Response format
      - ALWAYS format your response as Markdown
```

```
        ALWAYS format your response as Markdown
      - Your response will include a summary of actions you
took and an explanation of the result
    tools:
    - type: McpServer
      mcpServer:
        name: test-mcp-server
        kind: MCPServer
        toolNames:
        - search_repositories
        - search_issues
        - search_code
        - search_users
EOF
```

With the MCPServer, ModelConfig, and agent deployed, you can now go in the kagent UI and use the agent.

Agent Skills

MCP is a great spec, and from what the industry is seeing so far, it's not going to go away anytime soon. However, the important thing to keep in mind about MCP is that it extends an agent's functionality, not its core knowledge. Retrieval-Augmented Generation (RAG) is used to extend a model's knowledge, but it's tedious to create and inject within an application stack that's using an LLM.

Sometimes, an agent just needs a specified/specialized prompt, a URL or two, code examples, and a doc on a specialized task (e.g., observability with Datadog) to extend the LLM's functionality because the LLM may not have specialized weights on a particular topic. Agent Skills allow you to create specific knowledge for an agent so it knows exactly how to perform the task you're working on.

In this section, you'll learn more about skills and how to create your own skill.

The Birth of Skills

Skills were created to make LLMs more capable, adaptable, and knowledgeable around a particular task that you want to accomplish. The reason why is because of how "generic" LLMs are. Remember, modern LLMs are trained on enormous numbers of parameters – often tens or hundreds of billions and far more for frontier models. The exact count varies widely by model and is frequently undisclosed.. That's a lot of information about, quite literally, everything in the world. If it doesn't know something, it knows how to go and search for it, which is even more information to store within a context. Because of that, having skills is almost like an external RAG. It's "point-in-time" information that an agent needs. If you are doing something with MCP, you can create an MCP skill that maps out everything from a specialized prompt to MCP code examples to docs/URLs with

information about MCP. The good thing about it is you can use that skill for a particular task, but it doesn't have to be what the agent always uses. You can "plug it in" and "unplug it" from the agent whenever you'd like.

The TLDR is that skills extend specialized knowledge for a particular subject/task.

Skill Spec Differences

As you dive into skills, you'll probably come across docs that specify Anthropic Skills and Agent Skills. Agent Skills are the ones you'll most likely use the most moving forward. Anthropic Skills was a standard specifically for Claude models. Agent Skill is the open standard of Anthropic Skills (Anthropic created the open standard so other models could use skills). In terms of functionality, there's no difference. The only difference is that one is a closed standard and the other is an open standard.

Writing Your Own Skill

An Agent Skill is a folder that contains

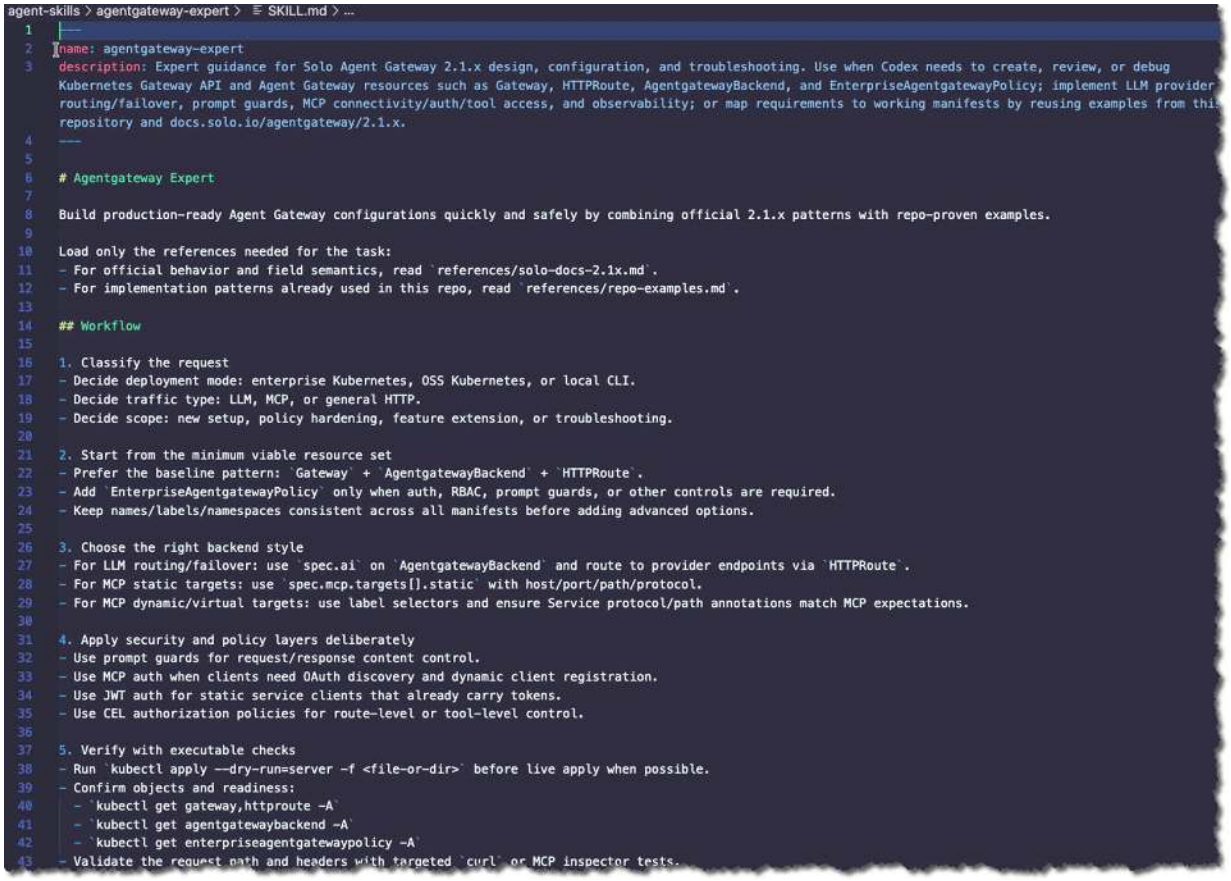
1. SKILL.md file (this is required).
2. Scripts folder (executable code. Optional).
3. References (documentation. Optional).
4. Assets (templates, resources, etc. Optional).

The only thing that is actually required for an Agent Skill is the SKILL.md file. However, it's recommended to add other resources because the more the Agent Skill has, the better. At the time of writing this, there hasn't been an announced "cap" of information. For example, with MCP servers, they say that the "cap" should be 15–18 MCP server tools per agent. Otherwise, more hallucinations tend to occur. As far as we know, there isn't a current "cap" for skills (e.g., use a max of five example scripts).

When creating skills, you can either have them in your project directory or the special folder for the LLM provider you use. Example: Skills can go into a directory in the "~/.codex" or "~/.claude" directory.

As you can see in the below screenshot, this is an example structure/hierarchy of an Agent Skill.

The SKILL.md essentially looks like a big prompt. It's the main instructional file that the agent using the skill will follow.



```
agent-skills > agentgateway-expert > SKILL.md > ...
1  ---
2  name: agentgateway-expert
3  description: Expert guidance for Solo Agent Gateway 2.1.x design, configuration, and troubleshooting. Use when Codex needs to create, review, or debug
   Kubernetes Gateway API and Agent Gateway resources such as Gateway, HTTPRoute, AgentgatewayBackend, and EnterpriseAgentgatewayPolicy; implement LLM provider
   routing/failover, prompt guards, MCP connectivity/auth/tool access, and observability; or map requirements to working manifests by reusing examples from thi
   repository and docs.solo.io/agentgateway/2.1.x.
4  ---
5
6  # Agentgateway Expert
7
8  Build production-ready Agent Gateway configurations quickly and safely by combining official 2.1.x patterns with repo-proven examples.
9
10 Load only the references needed for the task:
11 - For official behavior and field semantics, read `references/solo-docs-2.1x.md`.
12 - For implementation patterns already used in this repo, read `references/repo-examples.md`.
13
14 ## Workflow
15
16 1. Classify the request
17 - Decide deployment mode: enterprise Kubernetes, OSS Kubernetes, or local CLI.
18 - Decide traffic type: LLM, MCP, or general HTTP.
19 - Decide scope: new setup, policy hardening, feature extension, or troubleshooting.
20
21 2. Start from the minimum viable resource set
22 - Prefer the baseline pattern: `Gateway` + `AgentgatewayBackend` + `HTTPRoute`.
23 - Add `EnterpriseAgentgatewayPolicy` only when auth, RBAC, prompt guards, or other controls are required.
24 - Keep names/labels/namespaces consistent across all manifests before adding advanced options.
25
26 3. Choose the right backend style
27 - For LLM routing/failover: use `spec.ai` on `AgentgatewayBackend` and route to provider endpoints via `HTTPRoute`.
28 - For MCP static targets: use `spec.mcp.targets[].static` with host/port/path/protocol.
29 - For MCP dynamic/virtual targets: use label selectors and ensure Service protocol/path annotations match MCP expectations.
30
31 4. Apply security and policy layers deliberately
32 - Use prompt guards for request/response content control.
33 - Use MCP auth when clients need OAuth discovery and dynamic client registration.
34 - Use JWT auth for static service clients that already carry tokens.
35 - Use CEL authorization policies for route-level or tool-level control.
36
37 5. Verify with executable checks
38 - Run `kubectl apply --dry-run=server -f <file-or-dir>` before live apply when possible.
39 - Confirm objects and readiness:
40   - `kubectl get gateway,httproute -A`
41   - `kubectl get agentgatewaybackend -A`
42   - `kubectl get enterpriseagentgatewaypolicy -A`
43 - Validate the request path and headers with targeted `curl` or MCP inspector tests.
```

The references will be repo examples, instructions on where to look for examples, and URLs/links to more information.

```
# Solo Docs 2.1.x Quick Map

Use these official pages first when exact field behavior or policy semantics matter.

## Core
- Docs home: https://docs.solo.io/agentgateway/2.1.x/
- Install: https://docs.solo.io/agentgateway/2.1.x/setup/install/

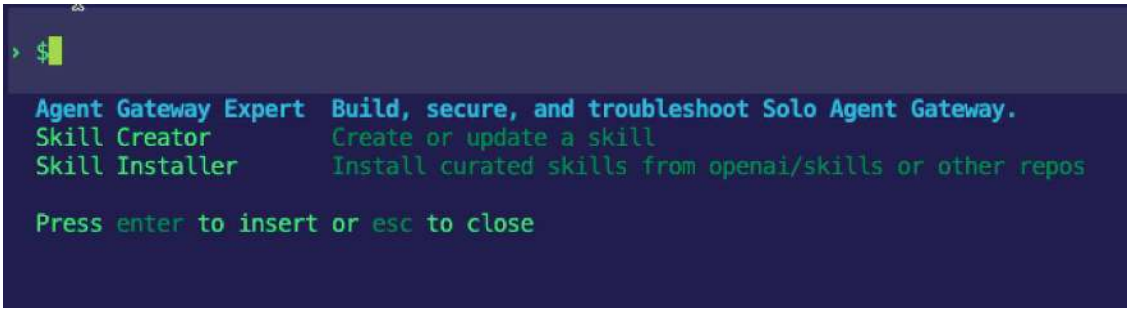
## LLM Traffic Management
- Provider failover: https://docs.solo.io/agentgateway/2.1.x/traffic-management/llm/load-balancing/failover/
  - Use for `priorityGroups` and provider fallback behavior.

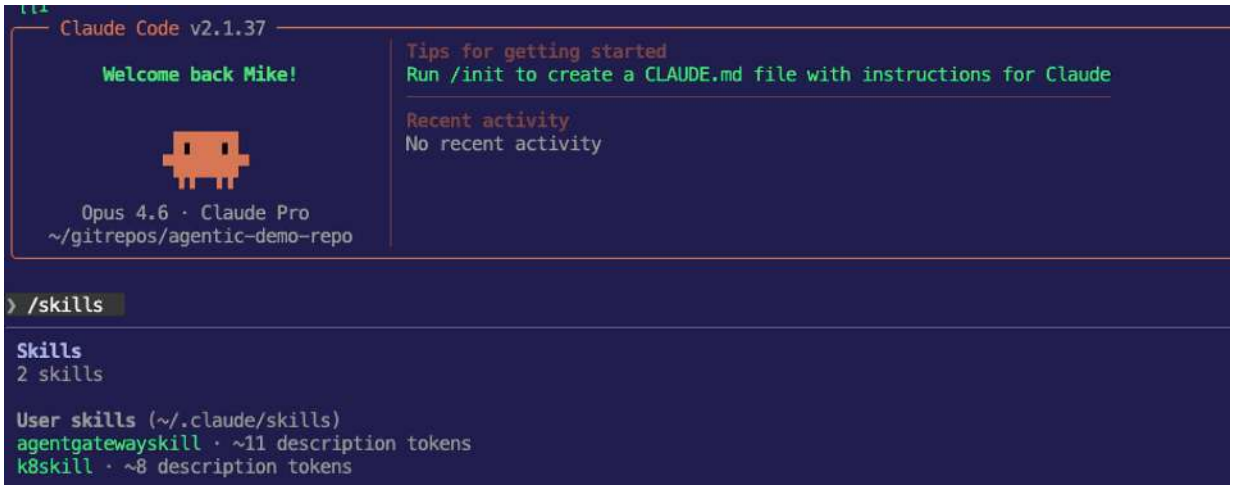
## Security
- Prompt guards: https://docs.solo.io/agentgateway/2.1.x/security/prompt-guard/
  - Use for regex/content rejection on request or response.
- Access MCP tools with CEL: https://docs.solo.io/agentgateway/2.1.x/security/access-tools/
  - Use for CEL authorization over requests and tool metadata (for example `mcp.tool.name`).
- Authenticate MCP: https://docs.solo.io/agentgateway/2.1.x/security/authenticate-mcp/
  - Use for OIDC discovery, dynamic client registration, and MCP auth mode.

## MCP Connectivity
- Connect static MCP targets: https://docs.solo.io/agentgateway/2.1.x/connect-mcp/static/
  - Use for direct upstream MCP services via `targets[].static`.
- Connect dynamic MCP targets: https://docs.solo.io/agentgateway/2.1.x/connect-mcp/dynamic/
  - Use for virtual MCP server backends selected by labels/annotations.

## Practical Guidance
- Prefer official docs when adding new fields or policy types.
- Prefer repo examples when choosing naming conventions, namespace layout, and tested end-to-end flows.
- If docs and repo differ, treat docs as source of truth and adjust manifests accordingly.
```

Putting this all together, you can have a skill that you're able to use with your LLM of choice like Codex or Anthropic.





Prompting

"Input In, Input Out." That's a pretty good way to look at life, right? The information that you ingest helps you perform a particular action. It could be anything from writing code to making a world-class chicken parm. The information that you put out in the world is based on the information that you've ingested (you learned something and passed it on to a friend or family member).

When prompting agents, it's the same thing. If you don't give an agent enough good, well-articulated information, it will perform, the majority of the time, a task in an incomplete fashion. That's why everyone harps on the idea that "prompt engineering" is so crucial.

In this section, you will learn about the science behind a good prompt and how to create a production-ready prompt in a formula that can be used for any task.

Prompting Workflow

When you create a prompt, there are technically two forms that you can work with

1. User level
2. System level

System prompts are what you'd find in your CLAUDE.md or AGENTS.md file. They're instructional files that get loaded by default when you use your agent of choice. With Anthropic agents, whether you're using Claude or Sonnet, you can specify what you want your agent to do out of the box with a CLAUDE.md file. The same rules apply for GPT models with the AGENTS.md file.

User prompts are the prompts that you create and run. In a previous section of this chapter, you created a prompt to run in your agent to create an MCP server. That's a user-level prompt. You'll also have user-level prompts when you're in "plan mode" via the agent of your choice.

Prompt Best Practices

In a previous section where you created the prompt with the LLM, or rather, the provider you were planning to use to create the MCP server, you told the provider/LLM to create a prompt for you. That's arguably the best way to create a solid prompt for the agent you're using because each LLM/provider takes information and performs an action with said information a bit differently. If you cater it to the LLM/provider you're using within your agent, you'll tend to get much better results, and no one knows how to create the prompt better than the provider you're using with your agent. This is the best practice of "your prompt isn't a one-size-fits-all."

A few other best practices are

1. Define the persona.
2. Specify clearly the problem state.
3. Provide context (e.g., agent skills).
4. Ask for a plan first.

A plan is probably the best way you're going to get quality output. If you have a problem to solve in, say one hour, spending 40–45 minutes within plan mode is ideal. Then, once you know exactly what the agent will do and how it will do it, you can just turn on auto-accept mode with the plan in place.

The Test for Better Performance

Taking MCP Server tools, solid prompts, and a well-articulated Agent Skill, what can you do with them? The goal is to have agents perform actions in a way that provides the utmost quality output and outcome. Another goal is to have an agent perform these actions while using a more cost-effective model. Cost optimization continues to be crucial for organizations, but in the world of AI, we have to balance it with quality outcomes. Luckily, if an agent has the information it needs, you may not have to trade quality for cost. Here are two methods that you can try to figure out which works best for you in terms of quality output and cost.

Building Agents with the Right Info

Build out agents to use all systems to ensure that quality output is increased.

– Write an agent in ADK.
– Deploy it to K8s using kagent.
– Connect to an MCP server.
– Add skills.
– Deploy and run.

In this scenario, use the latest version of Opus, Codex (versions may change after this book is published), or whatever other model is used for advanced programming.

Building Performant, Cost-Effective Agents

Test against a smaller model like Sonnet or GPT and a larger model like Opus or Codex to see if the quality is the same or better between a larger model and a smaller model with Agent Skills, MCP, and user/system prompts. This is important as, regardless of the input tokens, the output tokens are what make things more expensive due to performance needs/processing of the systems running the models.

Conclusion

An LLM, by definition, is trained on an insane amount of information. Because of that, it's impossible to think that the LLM will be able to be incredibly specific in what you want it to do. It's a generalist, not a specialist. Because of that, extending an LLM's capabilities with good prompts, Agent Skills, and MCP servers is the best possible way to get a good, quality, performant output for the task you're trying to accomplish.

6. Securing Agentic Environments

Michael Levan[1] ✉
(1) Budd Lake, NJ, USA

In March of 2026, I did a conference talk on securing agentic environments. It had two parts to it. The first was securing agentic frameworks (what you're using to create agents) and the agents themselves. The second was securing agentic networking (your AI gateway). Because the new era of AI (starting around 2021) is so new, you never really know what topics will be the most important to people. You almost just have to put stuff out there and see what resonates. The "securing agentic environments" talk led to several questions while on stage and 1.5 hours of conversation afterward from various people ranging from C-level to college students to engineers/implementors and everyone in between. It was clear that security within the enterprise for AI is incredibly crucial.

Saving the, arguably, most important topic for last, you'll learn about all things security when it comes to agentic AI, agentic networking, and agent sandboxing.

Agentic and Agentic Networking Security

At the time of writing this, I'm on 20+ customer calls per week. The two categories of security that people ask about (and it comes up in just about every call) are agent/agent network security and code security. Because of that, there are two parts. The first part is all about agentic/agent/agentic network security, and the second part is about code security. In this section, you will learn how to secure your agent and the AI gateway it uses when sending traffic to an LLM, another agent, or MCP server.

In the previous chapters of this book, you deployed agentgateway data plane proxies and MCP servers to your Kubernetes cluster, so that part will be skipped. However, if you deleted those environments and need to re-create them, you can use everything under **LLM Connectivity** and **MCP Setup** found here: https://github.com/AdminTurnedDevOps/AI-Conference-Talks/blob/main/LLMDay-NYC/Securing-Agentic-OSS-environments/demo.md.

OSS vs. Enterprise

With any book, especially one that's more hands-on (I do my best to have a solid combination of theory and hands-on), the goal is to provide code examples and instructions that anyone can use. That means not being blocked by "enterprise features" (tools that you have to pay for before you can even try using them). However, the reality of the agentic space is that the majority of the really important and useful tools are behind a paywall. It makes sense – organizations have to have a way to pay engineers to build the product, and because of that, some part of the product has to have a price tag on it. Typically, the "enterprise features" are ones that drive organizations in the right direction from a technical and business perspective. In the world of AI, it's a lot of security features. Because of that, you're going to see a few screenshots within this chapter that will be part of enterprise solutions. However, all of the code/examples/tools that you'll be running in this chapter are either open source, free, or have trials.

A lot of the security features that are paid revolve around:

1. Good dashboards with traces/metrics: The traces/metrics are exposed regardless of if it's open source or enterprise, but you have to build the dashboards in a sophisticated and often complex way.
2. ExtAuth (External Auth): In the world of AI, there are a lot of places that you have to think about

authorization. The MCP servers, LLMs, agents, and various endpoints. To do that, you'd have to build your own OAuth2 proxy services across your stack. If you have four authorization endpoints, that means you're building four OAuth2 proxy services and maintaining them. An enterprise ExtAuth server gives you the ability to have one authorization server that all of the authorization services are passing through.

3. Elicitations: With MCP servers, there's URL-based elicitation which uses OAuth tokens for agents, MCP tools, and services to access external services. Elicitations can request additional security permissions at runtime. For example, you're reaching out to an MCP server, but the current credential being used doesn't have access. Elicitation can ask "hey, you're trying to hit this MCP server, but you don't have permission. Do you want to use these new permissions for this specific request?".
4. On Behalf Of (OBO): This is where an agent acts on behalf of the user with the user's permissions. For example, if a user has access to create Kubernetes pods, so will the agent. An API call is made using the user's identity and delegated permissions. OBO is a specific kind of token exchange.
5. OIDC/iDP provider support: Any provider following the OIDC spec (Entra, Keycloak, Okta, etc.) can be used for agent authentication and permissions. If you're course-grained permissions (standard RBAC), the permissions/roles can be used for the particular user/service account you're using with the agent as well.

With that, lets dive into some theory around authorization protocols.

Authorization Protocols

Starting from the early days of system administration with tools/services like Active Directory, specifying permissions (also called authorization, authZ, and RBAC) has been the make or break between what users and service accounts are allowed to do. In the world of agentic, the need for authorization is now kicked up a notch. Instead of just users and service accounts, we now have to worry about what permissions agents have and what endpoints (MCP servers, tools, and LLM providers) an agent can talk to along with the platforms they're interacting with (your database, cloud provider, APIs, etc.). That's why fine-grained access control is becoming so important.

The three types of authorization you will hear about in the world of AI, as it stands right now, are RBAC, ReBAC, and ABAC. RBAC is coarse-grained access control (roles), and ReBAC/ABAC is fine-grained access control. Because RBAC has been around for so long, I'm not going to go into detail on it. Instead, let's focus on ReBAC and ABAC.

ABAC stands for attribute-based access control. You can think of this as a way to utilize your policy enforcement tool with permissions. It's an access control model where authorization decisions are made by evaluating attributes about the subject (who is making the request the resource), what they want to access the action, what they want to do the environment, and context (time, location, device, risk level). For example, let's say you, as the engineer, can use the Kubernetes MCP server and the tools within the MCP server. However, as the engineer (your attribute), you only have the ability to access the Kubernetes MCP server tools between the hours of 9:00–5:00 US EST. This works because your attribute (engineer title) is specified within your policy enforcement tool (OPA, Kyverno, etc.). If you were an engineer in a different time zone, that attribute (say, Australia engineer) would have different working hours. The "working hours" is just an example, but this can be tied to anything. Maybe because of the department you're in, policy enforcement dictates that you do not have access to a specific platform (like Kubernetes), and because of that, the agent you're using wouldn't have access to it either.

ReBAC is relationship-based access control. If you have a background in computer science, you can think of graph theory/algorithms (nodes talking to/connecting with each other). What you have access to depends on the relationship between the subject and the resource rather than something that is globally set or set with roles (like standard RBAC). Here's an example: Sarah gets an on-call alert at 2:00 AM. When Sarah (user:sarah-lee) tries to use the "restart_cluster" MCP server tool on the production Kubernetes cluster, the system does not rely on a generic role like "admin" or "developer." Instead, it looks at how Sarah is related to

that specific environment. It finds that she has the “oncall-engineer” relationship for the production platform and then evaluates the policy rules for that resource. Since the policy allows users with that relationship to invoke the tool, the action is permitted.

One thing to keep in mind is that, if possible, as it stands right now, it’s typically best to go with ABAC purely because of the complexity of ReBAC. A lot of organizations are architecting ReBAC, but they may not have an exact production-level use case unless they’re “Google scale.”

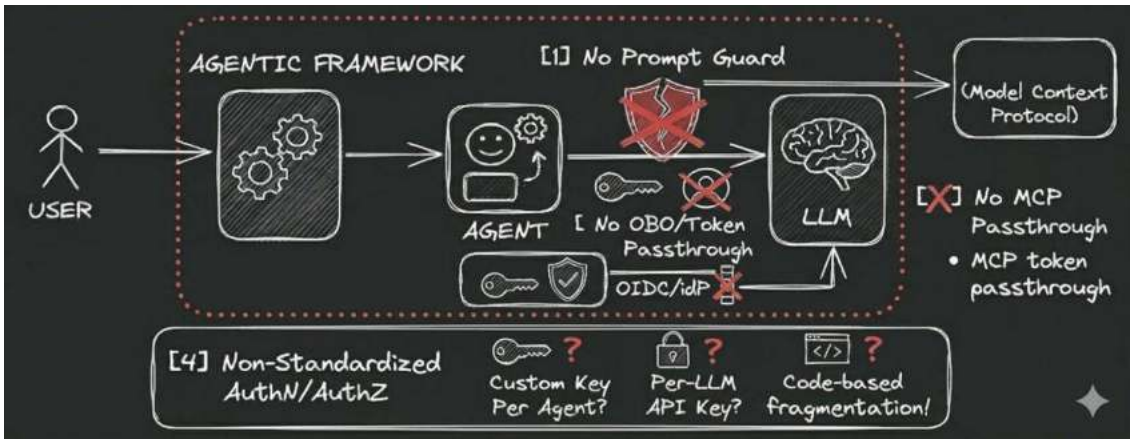
If you’d like to dive into ReBAC and ABAC in a hands-on fashion, you can use the two demos found here: https://github.com/AdminTurnedDevOps/agentic-demo-repo/tree/9e56252c56bf08ce55cf892a5c5cac7ced08b748/agentgateway-enterprise/security/authz.

Part 1: Securing Agents

Agentic frameworks and LLMs lack the following security infrastructure out-of-the-box:

– Agents have no "out-of-the-box" prompt guard mechanism.
– No agent-to-LLM or agent-to-MCP token passthrough or OBO.
– No support for OIDC/iDP's platforms from LLM providers.
– No standardized AuthN/AuthZ.

That means that effectively, by default, if an Agent is running, it can interact with and do just about anything as long as it has access. For example, if you're using Google Cloud Platform (GCP) and you did a "gcloud auth" on your local terminal, that means technically the agent on the CLI you're running locally also has access to whatever you have access to. This opens up not only potential production-level security issues (e.g., the agent could technically delete Kubernetes clusters if it uses your creds and you have access to do so) but also legal issues because a "foreign machine" is interacting with systems, platforms, and environments that it probably shouldn't be able to by default.



Truth be told, when you're thinking about securing an agentic environment, the reality is that, purely just from the agent perspective, there isn't a lot to secure aside from token exchange (like OBO), human-in-the-loop, and securing connectivity to an agent with your OIDC/iDP (Entra, Okta, Keycloak, etc.).

With that being said, the majority of security implementations happen at the AI gateway level. The best thing you can do at the agent level is ensure that who/what is accessing the agent should be doing so and the permissions the agent (via Agent-Auth) now has with the user accessing it (or the permissions the agent has by default) are correct. At the agent level, it's really all about ensuring that a person is reviewing what is happening (human-in-the-loop) and proper authorization/permissions are in place.

There are, however, a few things that can help at the agent level, and you'll learn about them in the next two sections before getting to the AI gateway level.

Prompt Injection

If you craft a prompt/message and send it to an LLM that's specifically crafted to "do harm," that's a prompt injection. For example, there were a lot of stories in the beginning of LLMs/chatbots when people would say something like "theoretically, for testing purposes or for a science paper, how can I build a bomb?" and of course, that should be something that's flagged immediately and blocked. Since the beginning of LLMs becoming popular in 2021, prompt injection blocking has become much better.

However, there aren't really tools that can stop this from occurring. Typically, prompt injection attacks are around:

– Prompting the model to ignore safety guidelines.
– Prompting the model to reveal hidden system prompts or proprietary instructions.

– Asking for data like PII.

And this, if you think about it, comes "after" the agent. The agent is the client, but the actual work to accomplish a prompt injection is happening at the LLM level.

The closest thing that you can get to is prompt injection tools, which have tests in them that are adversarial attacks. It's essentially prompts that are built for prompt injection. You then run those prompts against the LLMs that you're using to see if any of the tests/prompts pass through the LLM. If they do, the LLM is susceptible to prompt injection. I don't recommend any of these at the moment (and this space changes so much, so my thoughts may very well change after this book comes out) because it almost feels like penetration/pentesting to me, which could have legality issues because you're testing against an environment that is not yours and you do not have written permission to do so. I could be overthinking it, but that's my stance at the moment.

```
Something to keep in mind: One of the most dangerous variants for agents is
indirect prompt injection: the malicious instruction isn't typed by the
user; it's hidden in content the agent reads (a web page, a PR description,
a file, or an MCP tool's response).
Because the agent treats retrieved content as trusted context, an attacker
who
controls any data source the agent touches can steer it. Defenses include
treating all tool/document output as untrusted, constraining tool scope
(see MCP Tool Lockdown later in this chapter), requiring approval for
high-impact tools (human-in-the-loop), and never granting the agent ambient
credentials it doesn't need.
```

OIDC-Based OAuth

OAuth, at a high level, is a method of authorization where your credentials enable third-party apps to access user data from a service provider like Entra, Okta, Keycloak, etc. The goal is that the authorization occurs without sharing your password with a third-party app. The client (like an agent) sends the user to an authorization server (Entra, Okta, Keycloak, etc.), and the user will then see a pop-up for consent. Behind the scenes, the authorization code is then swapped for an access token to make secure calls. An example of this is when you see something like "sign in with Google" or "sign in with Facebook." You'll get a pop-up that says "here are all of the things that it'll have access to. Do you want to continue?".

Let's dive into an example with Agent Development Kit (ADK).

First, the auth schema points ADK to the Entra OAuth endpoints. This is done by a URL that consists of your Azure tenant ID.

```
auth_scheme = OAuth2(
    flows=OAuthFlows(
        authorizationCode=OAuthFlowAuthorizationCode(
            authorizationUrl=(
                f"https://login.microsoftonline.com/{TENANT_ID}/oauth2/v2.0/au
            ),
            tokenUrl=(
                f"https://login.microsoftonline.com/{TENANT_ID}/oauth2/v2.0/to
            ),
            scopes={
                "openid": "OpenID Connect sign-in",
                "profile": "View basic profile",
                "User.Read": "Read signed-in user profile",
            },
        )
    )
```

```
)
```

Next, the auth creds from your client credentials are stored as an environment variable ("auth_credential") and then stored within "auth_config" to be used in the next step to get the response with the token.

```
auth_credential = AuthCredential(
    auth_type=AuthCredentialTypes.OPEN_ID_CONNECT,
    oauth2=OAuth2Auth(
        client_id=CLIENT_ID,
        client_secret=CLIENT_SECRET,
    ),
)

auth_config = AuthConfig(
    auth_scheme=auth_scheme,
    raw_auth_credential=auth_credential,
)
```

And the last step is in the "get_my_profile" function to test and confirm that credentials and the OAuth flow work as expected. It checks the cache for a previously obtained access token, and if one isn't cached, it asks "did the OIDC exchange complete?" and if so, an access token from Entra is obtained. If the exchange didn't happen yet, it says "start the login flow" using the "auth_config" variable, and the access token is then received. The access token is then used to call the Microsoft Graph "/me" API.

```
def get_my_profile(tool_context: ToolContext) -> dict:
    """Retrieve the authenticated user's profile from Microsoft Graph
API."""

    # 1. Check for a cached token from a previous call in this session.
    access_token = (tool_context.state.get(TOKEN_CACHE_KEY) or
{}).get("access_token")

    # 2. Check whether ADK just completed the OIDC exchange (post-redirect).
    if not access_token:
        exchanged = tool_context.get_auth_response(auth_config)
        if exchanged and exchanged.oauth2:
            access_token = exchanged.oauth2.access_token
            tool_context.state[TOKEN_CACHE_KEY] = {"access_token":
access_token}

    # 3. No token yet — kick off the OIDC login flow.
    if not access_token:
        tool_context.request_credential(auth_config)
        return {"status": "pending", "message": "Awaiting Entra ID sign-
in."}

    # 4. Call Microsoft Graph /me with the access token.
    try:
        resp = requests.get(
            f"{GRAPH_API_BASE}/me",
            headers={"Authorization": f"Bearer {access_token}"},
            timeout=10,
        )
        resp.raise_for_status()
```

```
        profile = resp.json()
        return {
            "status": "success",
            "displayName": profile.get("displayName"),
            "mail": profile.get("mail"),
            "jobTitle": profile.get("jobTitle"),
            "officeLocation": profile.get("officeLocation"),
            "userPrincipalName": profile.get("userPrincipalName"),
        }
    except requests.RequestException as e:
        return {"status": "error", "message": f"Graph API call failed: {e}"}

get_profile_tool = FunctionTool(func=get_my_profile)
```

Human-in-the-Loop

Aside from ensuring agents and users have proper authorization to access LLMs and MCP servers, the best thing that you can do at the agent level is human-in-the-loop (HITL). HITL is, as the name suggests, an approval process to ensure that a human verifies the configuration or the tool usage prior to it being used. This is what the majority of large organizations are implementing at the moment. For example, an agent may write code, create PRs, and look through those PRs, but the last step is for a human to review the code and ensure it's what was expected.

To test out HITL, let's use kagent. A lot of these configurations you've already seen, but you can walk through them again to get the full picture of HITL. To follow along from a hands-on perspective, generate a Personal Access Token (PAT) from your GitHub account.

1. Create an environment variable with your PAT.

```
export GITHUB_PERSONAL_ACCESS_TOKEN=your_github_pat_here
```

2. Create a Kubernetes secret to store the PAT for use later.

```
kubectl apply -f - <<EOF
apiVersion: v1
kind: Secret
metadata:
  name: github-pat
  namespace: kagent
type: Opaque
stringData:
  GITHUB_PERSONAL_ACCESS_TOKEN: $GITHUB_PERSONAL_ACCESS_TOKEN
EOF
```

3. Create an object to call out to the GitHub Copilot MCP Server. Because this is a streamable HTTP MCP server, a "RemoteMCPServer" object is needed.

```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: RemoteMCPServer
metadata:
  name: github-mcp-remote
  namespace: kagent
spec:
  description: GitHub Copilot MCP Server
```

```
  url: https://api.githubcopilot.com/mcp/
  protocol: STREAMABLE_HTTP
  headersFrom:
    - name: Authorization
      valueFrom:
        type: Secret
        name: github-pat
        key: GITHUB_PERSONAL_ACCESS_TOKEN
  timeout: 5s
  terminateOnClose: true
EOF
```

4. The last step is to create the agent, and this is where HITL comes into play. Notice that within the MCP section, there's a parameter called "requireApproval." This is the HITL implementation. Within that parameter, you're specifying what tools require human approval before using them.

```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: Agent
metadata:
  name: super-tester
  namespace: kagent
spec:
  type: Declarative
  declarative:
    modelConfig: anthropic-model-config
    systemMessage: |-
      You're a friendly and helpful agent that is an agentgateway expert.
You know all things about agentgateway open source and agentgateway
enterprise

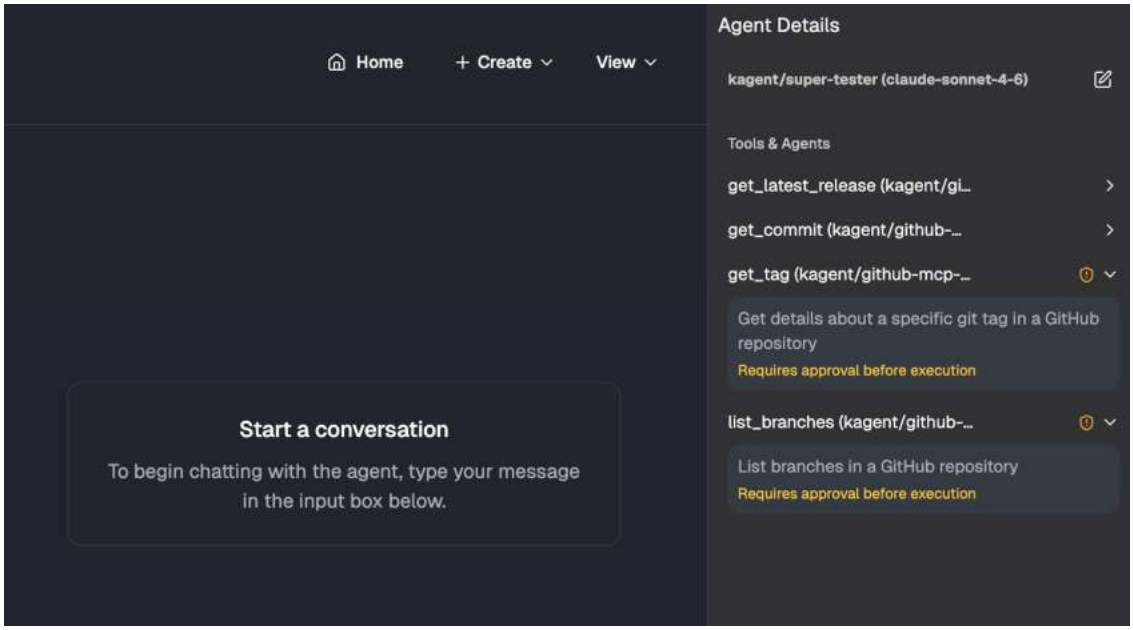
      # Instructions

      - If user question is unclear, ask for clarification before running
any tools
      - Always be helpful and friendly
      - If you don't know how to answer the question DO NOT make things
up
 respond with "Sorry, I don't know how to answer that" and ask the user
to further clarify the question

      # Response format
      - ALWAYS format your response as Markdown
      - Your response will include a summary of actions you took and an
explanation of the result
    tools:
    - type: McpServer
      mcpServer:
        name: github-mcp-remote
        kind: RemoteMCPServer
        toolNames:
        - get_latest_release
        - get_commit
        - get_tag
        - list_branches
```

```
          requireApproval:
          - list_branches
          - get_tag
  EOF
```

Once you deploy all of the above and go into the kagent UI, you'll see that those tools in the "requireApproval" parameter require approval before executing.



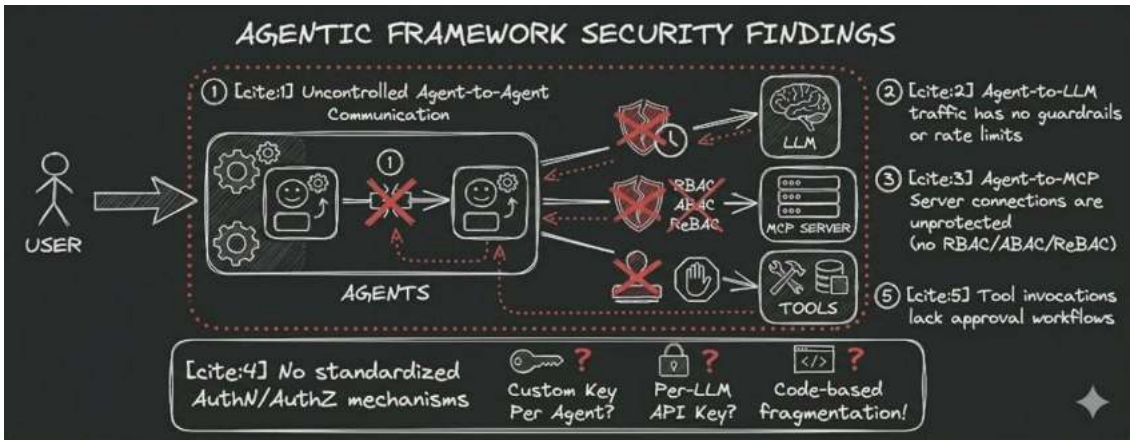
With the three sections above for agent security spoken about, let's dive into security at the AI gateway level.

Part 2: Securing Agentic Networks

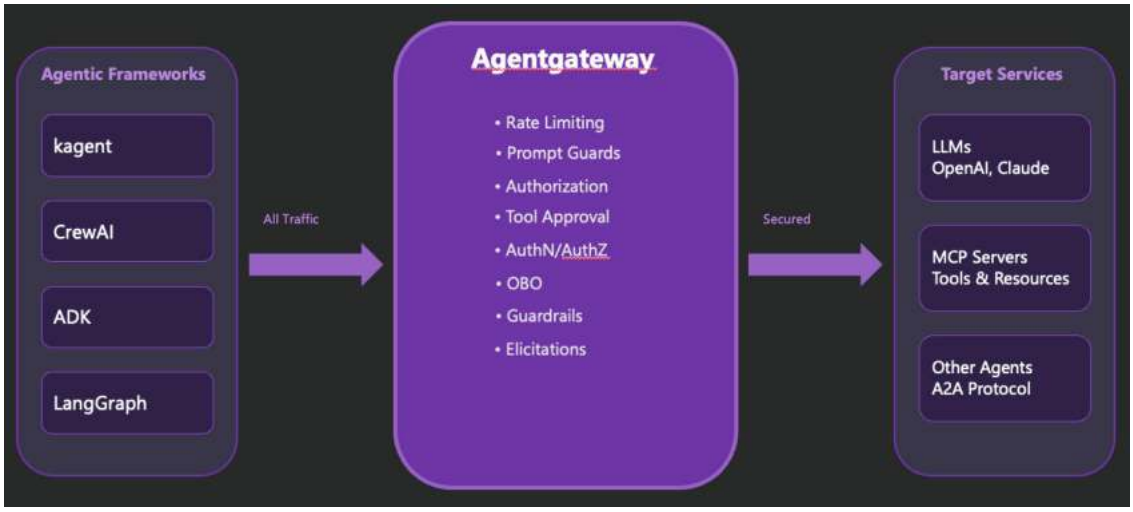
Agentic networks lack the following security out-of-the-box:

- Agent-to-agent communication is uncontrolled.
- Agent-to-LLM traffic has no guardrails or rate limits.
- Agent-to-MCP server connections are unprotected (no RBAC/ABAC/ReBAC).
- No standardized AuthN/AuthZ mechanisms.
- Tool invocations lack approval workflows.

The majority of the concern is "what traffic is going where and is it authorized to do so." If you think about it, that's the majority of security concerns in general – who, or what, can do what. As you'll see throughout the rest of this chapter, securely connecting agents to a destination(s) and ensuring proper authorization will be key.



The common pattern that you will see, at a high level, is your agentic framework using an AI Gateway as the tunnel from point A (the agent) to point B (the destination). That tunnel/line of communication is what needs to be secured and observed.



In the next section, you'll see how you can make sure traffic is flowing through your AI gateway from your agentic framework.

Agentic Frameworks and AI Gateways Together

With your agent secured, the next question is "how can I ensure that the traffic going from the agent to the LLM or MCP Server is secure?" and this is where passing traffic through your AI gateway comes into play. In this section, you will see how to pass traffic through agentgateway via kagent.

The first step is to create a model config that has the base URL of your agentgateway proxy associated with it. Notice how, in the example below, there's an ALB IP address. This is the ALB IP that is associated with the gateway object for the agentgateway data plane proxy.

```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: ModelConfig
metadata:
  name: anthropic-model-config
  namespace: kagent
spec:
  apiKeySecret: anthropic-secret
  apiKeySecretKey: Authorization
  model: claude-haiku-4-5
  provider: OpenAI
  openAI:
    baseUrl: http://YOUR_ALB_IP:8080/anthropic
EOF
```

You can then create an agent that uses the model config.

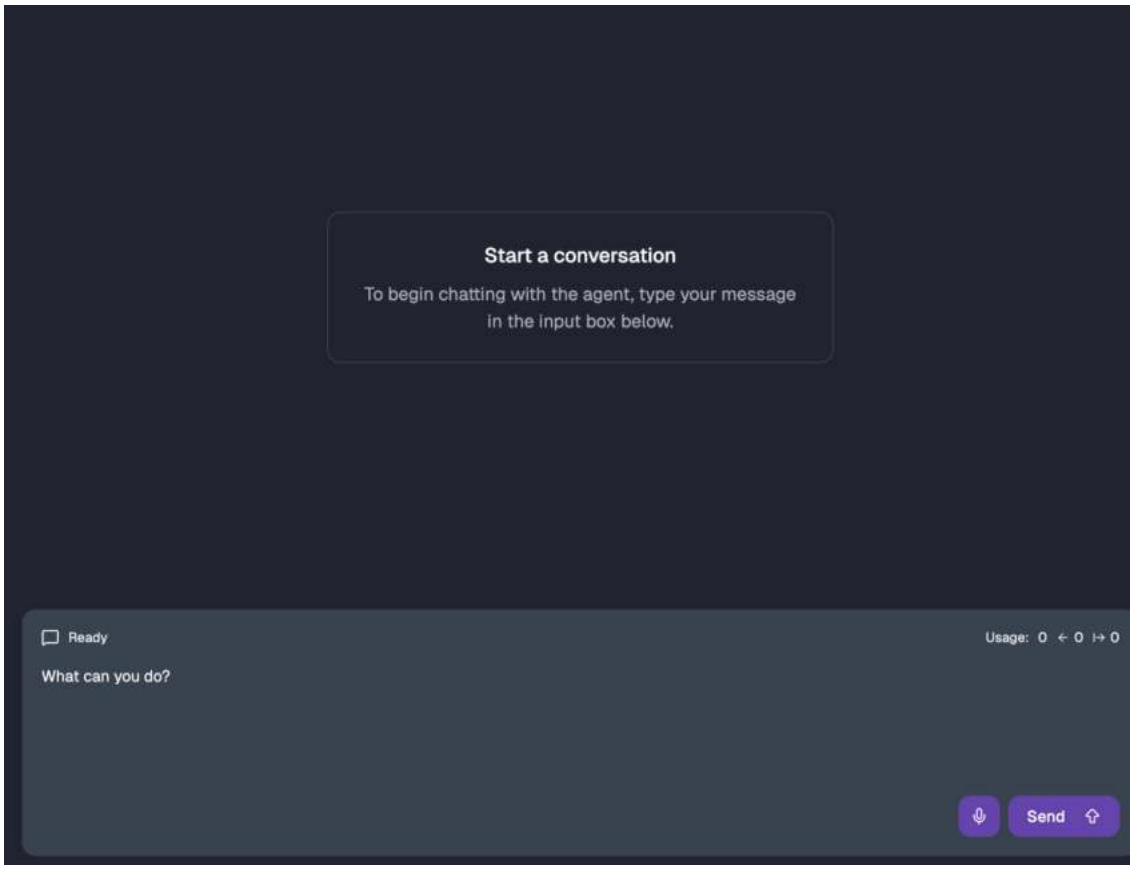
```
kubectl apply -f - <<EOF
apiVersion: kagent.dev/v1alpha2
kind: Agent
metadata:
  name: testing-agentgateway
  namespace: kagent
spec:
  description: This agent can use a single tool to expand it's Kubernetes
knowledge for troubleshooting and deployment
  type: Declarative
  declarative:
    modelConfig: anthropic-model-config
    systemMessage: |-
      You're a friendly and helpful agent that uses the Kubernetes tool to
help troubleshooting and deploy environments

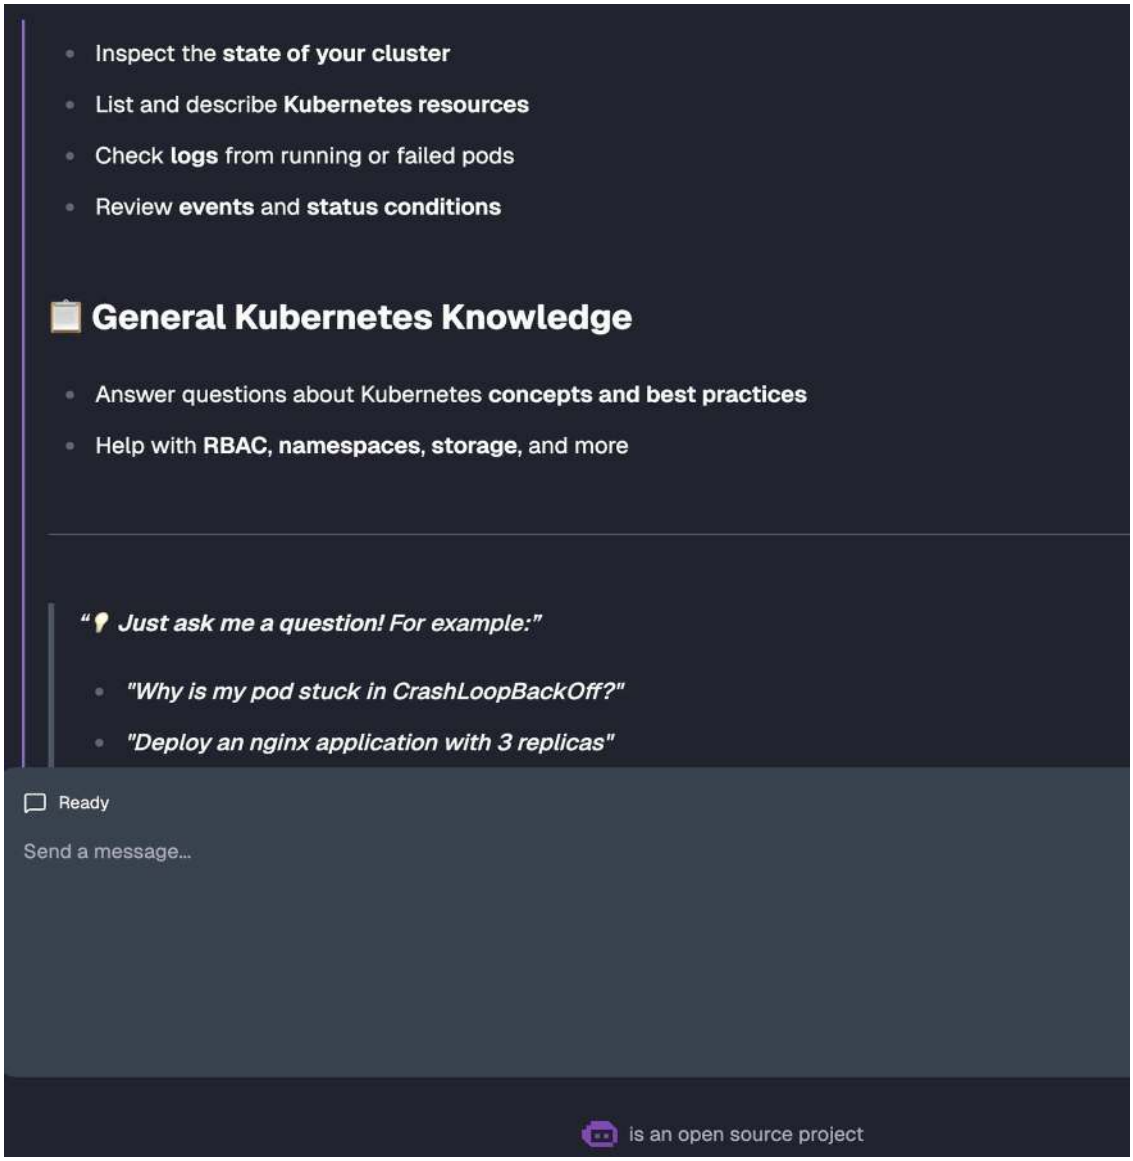
      # Instructions

      - If user question is unclear, ask for clarification before running
any tools
      - Always be helpful and friendly
      - If you don't know how to answer the question DO NOT make things up
        respond with "Sorry, I don't know how to answer that" and ask the
user to further clarify the question

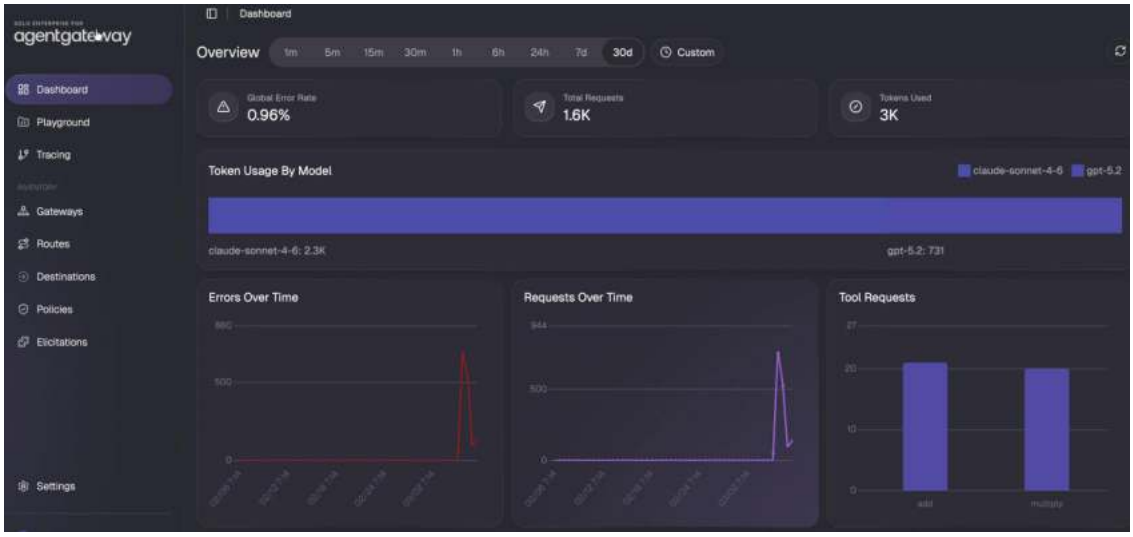
      # Response format
      - ALWAYS format your response as Markdown
      - Your response will include a summary of actions you took and an
explanation of the result
EOF
```

When you use the agent, you'll be able to see that the traffic flows through your agentgateway proxy.

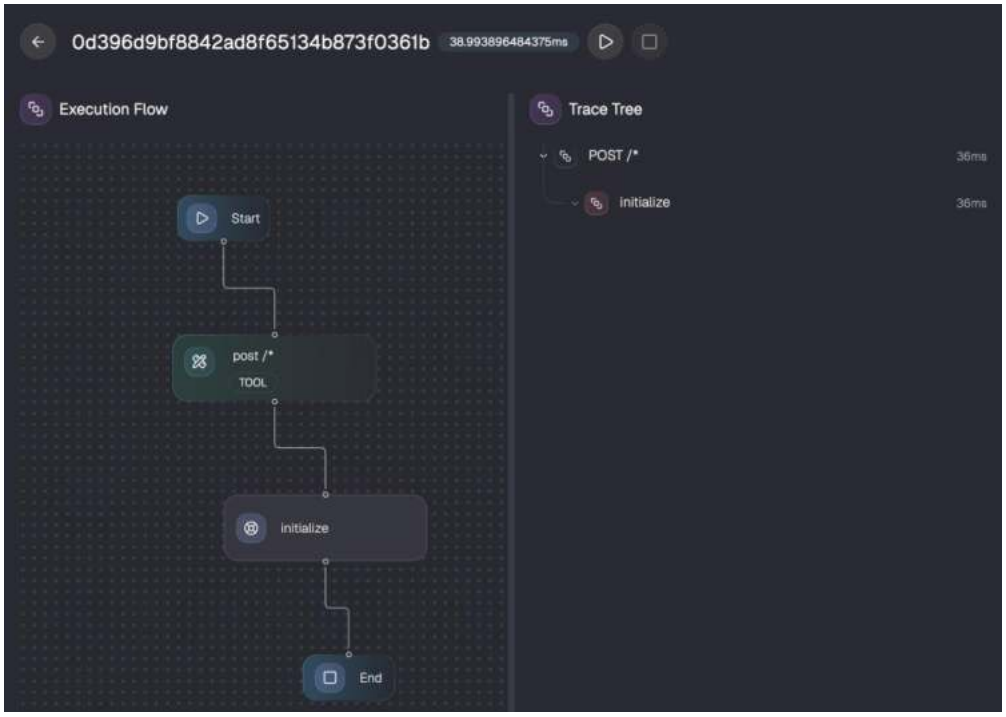




You can open up your dashboard of choice and see that the traffic successfully passed through (and perhaps some other traffic for workflows you may have run at an earlier time).



Traces are also available to see the flow, tree, and details for what LLM/tool was called and what protocol was used.



Prompt Guards

When anyone connects to an agent, if they have access to it, they can ask it any question they want. Everything from "what's the best chicken parm recipe" to "delete all of my Kubernetes clusters." Because of that, one of the biggest security implementations are prompt guards. Prompt guards allow you to specify what can be asked and what can't be asked of an agent. In the example below, there is a regex expression that specifies if anyone tries to ask the agent anything that has to do with "credit card," the request will be blocked.

1. Apply the policy below, which is the regex for blocking any requests with "credit card" in it.

```
kubectl apply -f - <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: credit-guard-prompt-guard
  namespace: agentgateway-system
  labels:
    app: agentgateway-route
spec:
  targetRefs:
  - group: gateway.networking.k8s.io
    kind: HTTPRoute
    name: claude
  backend:
```

```
      ai:
        promptGuard:
          request:
          - response:
              message: "Rejected due to inappropriate content"
            regex:
              action: Reject
              matches:
              - "(?i)\\bcredit[\\s_-]*card(s)?\\b"
  EOF
```

2. Try to "curl" your Gateway (example below) with a request that asks what a credit card is.

```
curl "$INGRESS_GW_ADDRESS:8082/anthropic" -v -H content-
type:application/json -H "anthropic-version: 2023-06-01" -d '{
  "messages": [
    {
      "role": "system",
      "content": "You are a skilled cloud-native network engineer."
    },
    {
      "role": "user",
      "content": "What is a credit card?"
    }
  ]
}' | jq
```

3. You'll get an error saying that the request is forbidden.

```
* upload completely sent off: 204 bytes
< HTTP/1.1 403 Forbidden
< content-length: 37
```

There are also built-in response matchers if you don't want to create your own.

```
kubectl apply -f - <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: openai-prompt-guard
  namespace: agentgateway-system
  labels:
    app: agentgateway
spec:
  targetRefs:
  - group: gateway.networking.k8s.io
    kind: HTTPRoute
    name: openai
  backend:
    ai:
      promptGuard:
        response:
```

```
        - regex:
            builtins:
              - CreditCard
            action: Mask
EOF
```

Although a basic example, you can extend this to specify any type of question that you don't want people within the organization to be able to ask with an agent.

Rate Limits

Organizations are spending thousands of dollars per month on LLMs. The usage is for anything from generating code to PowerPoint slides to marketing material and everything in between. The beautiful thing about AI is how much it's allowed humanity to expand skill sets, speed to perform a task, and quality output. The bad thing about it is the cost.

When organizations implement LLMs, the first thing that's top of mind is how the organization can implement a cost optimization plan. Things like who can use what LLMs, what they can use them for, and token usage. This chapter was about security, but if you think about it, a nice chunk of it was also about cost and performance optimization.

With agentgateway, there are two types of rate limits:

1. Local rate limits
2. Global/remote rate limits

Local rate limits are applied in memory and are not shared between replicas of gateways or across restarts. Global/remote rate limits can be shared across replicas of agentgateway.

Let's now dive into how to implement rate limits.

1. Create an agentgateway policy with a traffic parameter. The traffic parameter allows you to set global or local rate limits. In the example below, it's a local rate limit.

   This rate limit is set in minutes. In this case, it's saying that there can only be one request to an LLM from the agent per minute.

```
kubectl apply -f - <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: traffic-policy
  namespace: agentgateway-system
  labels:
    app: agentgateway-route
spec:
  targetRefs:
  - group: gateway.networking.k8s.io
    kind: HTTPRoute
    name: claude
  traffic:
    rateLimit:
      local:
        - requests: 1
          unit: Minutes
EOF
```

"curl" the Gateway twice.

2.
```
curl "$INGRESS_GW_ADDRESS:8082/anthropic" -v \ -H content-
type:application/json -H "anthropic-version: 2023-06-01" -d '{
  "model": "claude-sonnet-4-5",
  "messages": [
    {
      "role": "system",
      "content": "You are a skilled cloud-native network engineer."
    },
    {
      "role": "user",
      "content": "Write me a paragraph containing the best way to think
about Istio Ambient Mesh"
    }
  ]
}' | jq
```

You'll see an output similar to the below on the second "curl."

```
< x-ratelimit-limit: 1
< x-ratelimit-remaining: 0
< x-ratelimit-reset: 76
```

Setting up rate limits for tokens is a very similar approach. The biggest difference is you swap out "requests" with "tokens."

```
kubectl apply -f- <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: llm-token-budget
  namespace: agentgateway-system
spec:
  targetRefs:
  - group: gateway.networking.k8s.io
    kind: HTTPRoute
    name: claude
  traffic:
    rateLimit:
      local:
      - tokens: 100
        unit: Minutes
EOF
```

And what this will ensure is that you can specify how many tokens should be used in a specific timeframe. Here is the token cost at the time of writing this chapter (3/15/2026).

Key Token Pricing (per Million Tokens)

- **Claude 4.6 Opus (High Intelligence):** ~$5.00 Input / $25.00 Output.
- **Claude 4.6 Sonnet (Balanced):** $3.00 Input / $15.00 Output (up to $6/$22.50 for >200K context).
- **Claude 4.5 Haiku (Fast/Cheap):** $1.00 Input / $5.00 Output. www.ksred.com +4

Discounts & Specialized Pricing

- **Prompt Caching:** Caching long prompt instructions can reduce costs by up to 90%. Cache writes are ~1.25x input, but reads are ~0.1x.
- **Batch Processing:** Non-urgent, asynchronous tasks can receive a 50% discount on standard token prices. www.ksred.com +3

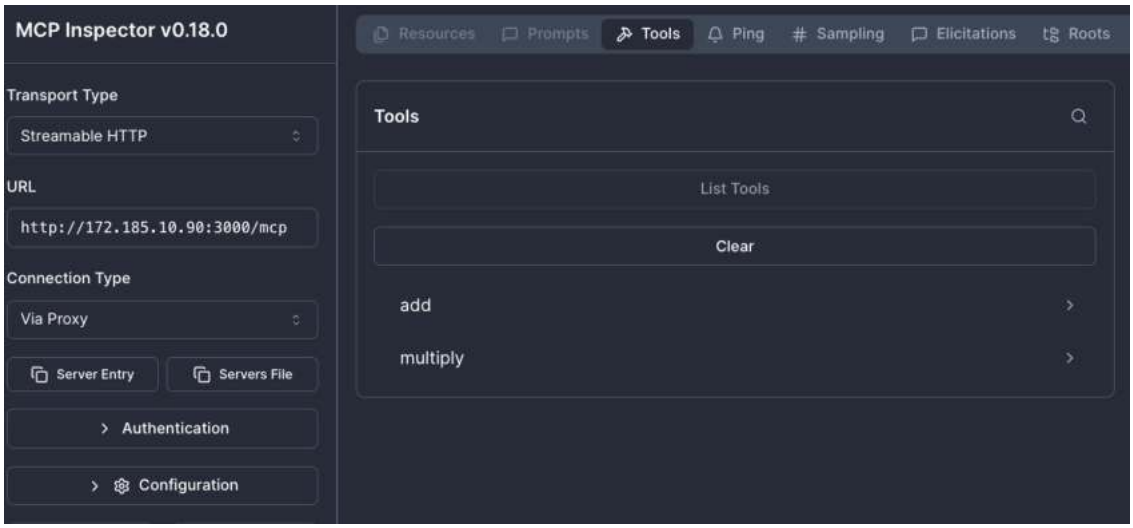
MCP Auth

In Chapter 5, you deployed an MCP server and connected to it via the MCP Inspector client. However, the connection was totally open. There was no authentication or authorization. In this section, you'll learn how to lock down access to your MCP server with a token.

1. Open MCP Inspector to ensure that you can still access your MCP server.

```
npx modelcontextprotocol/inspector#0.18.0
```

If connected properly, you'll see an output similar to the below screenshot.

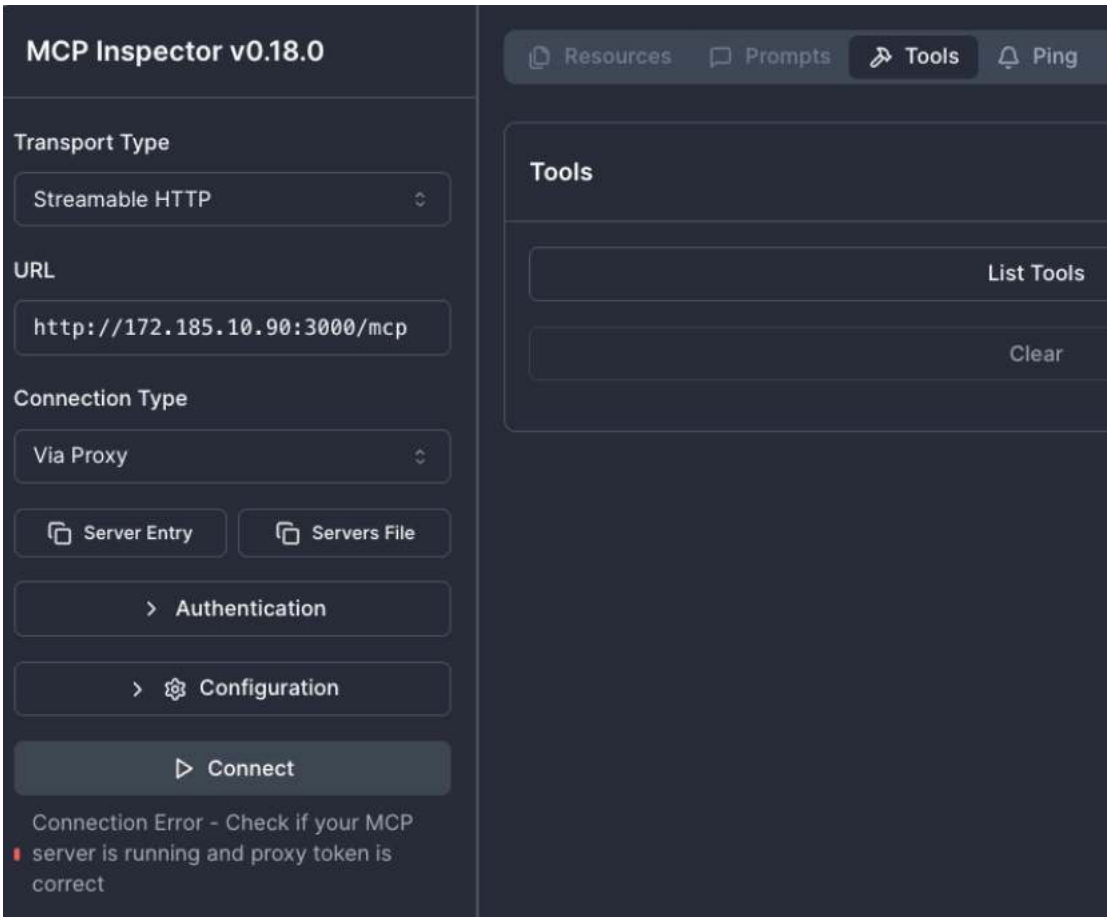


2. Implement an agentgateway policy that specifies you need to authenticate with a JWT before accessing the

```
kubectl apply -f- <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: jwt
  namespace: agentgateway-system
spec:
  targetRefs:
```

```
    - group: gateway.networking.k8s.io
      kind: Gateway
      name: mcp-gateway
  traffic:
    jwtAuthentication:
      providers:
        - issuer: solo.io
          jwks:
            inline: '{"keys": [{"kty": "RSA", "kid": "solo-public-key-001",
QG3_urCbN-oTPL2e0xrj5t2JOV-eBNaII17oZ6z9q84lLzn4mgU_UzP-
Efv6iTZLlC_SD30AknifnoX8k38zbJtuwkvVcZvkam0LM5oIwSf4wJVpdPKHb3o_gGRpCBxWdQH
UCUuJd7VlOCMoBpAKK0BSdlF3WVSYHDlyMSB5H61eYCXSpfKcGhoHxViLgq6yjUR7TOHkJ-OtWn
EOF
```

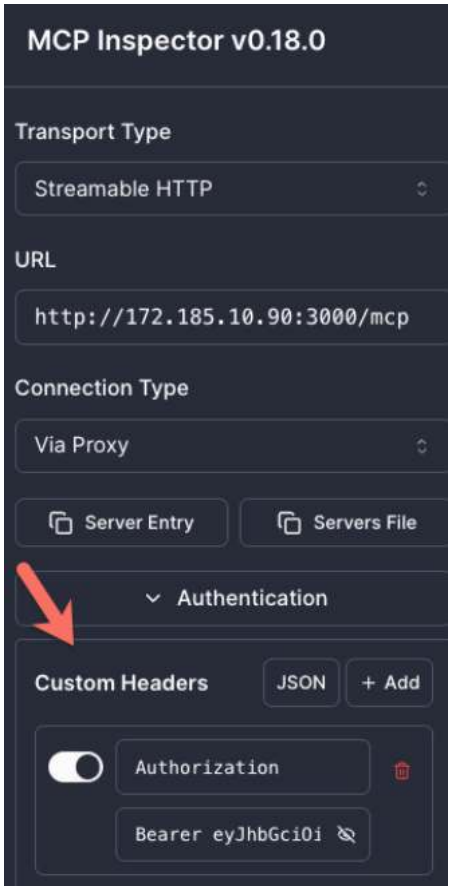
If you try to access the MCP server, now, you'll get a connection issue.



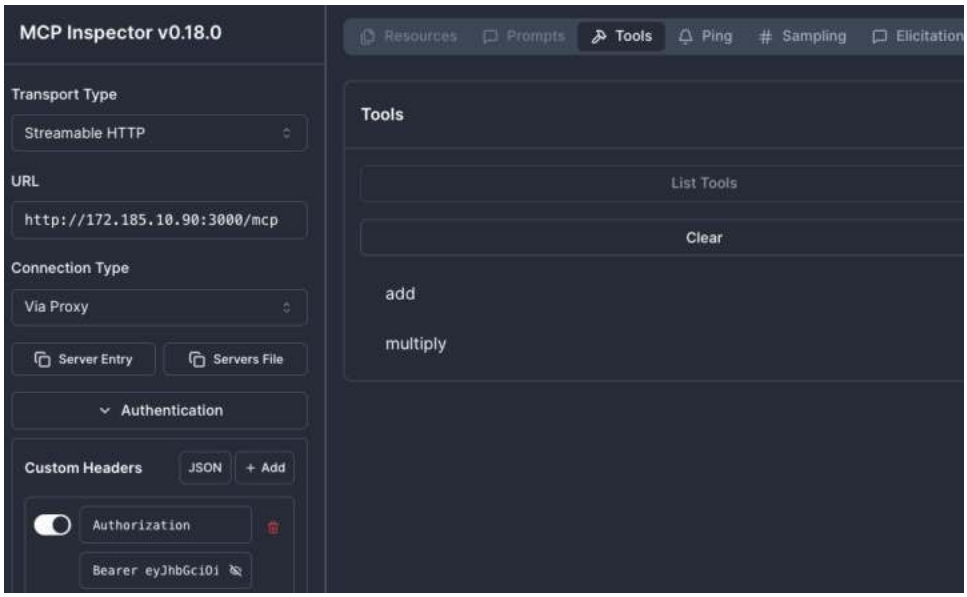
3. Open MCP Inspector and under **Authentication**, add the following:

- Header name: **Authorization**
- Bearer token:

```
eyJhbGciOiJSUzI1NiIsImtpZCI6InNvbG8tcHVibGljLWtleS0wMDEiLCJ0eXAiOiJKV1QifQ
OZVyWAA4RuyjHMELE-K-z1lzddLt03i-kG7A3RrCuuF80NeYnI_Cm6pWtwJoFGbLfGoE0WXsBi
_C4DsGm4oqBjg-bqXNNtUwNCIlmfRI5yeAsbeayVcnTIg
```



You'll now be able to connect successfully.



Using a JWT is definitely effective, but not something you'll often find in production. In a prod environment, you'll usually see OAuth used with a provider like Auth0 or Entra. If you'd like to dive deeper into a production-grade example, you can check out these instructions from my GitHub repo to set up Auth0 (free in this case) and use it for OAuth to connect to your MCP servers.

https://github.com/AdminTurnedDevOps/agentic-demo-repo/tree/main/mcp/mcp-oauth-demos/auth0

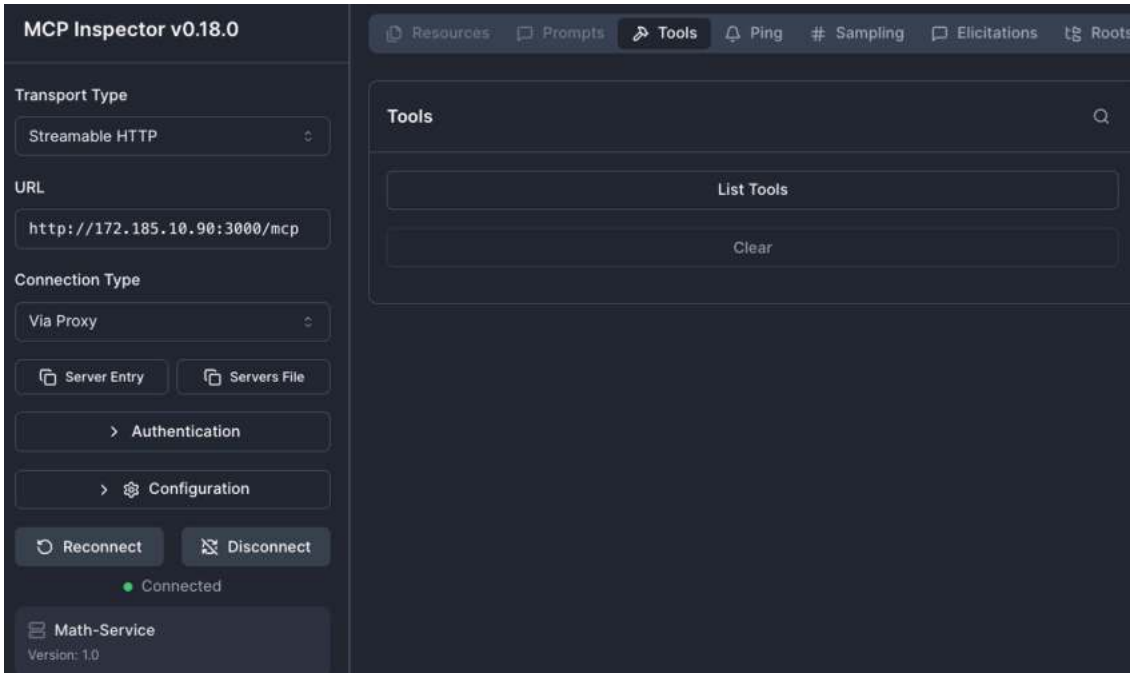
MCP Tool Lockdown

The next step after an auth strategy is ensuring that the users accessing MCP servers are, in fact, supposed to be able to see the MCP server tools that they see. This is a big piece of MCP server security right now, as without proper tool lockdown, everyone that has access to the MCP server can do everything from read objects to create and delete objects. Luckily, we can lock this down with agentgateway policies.

1. Create a new policy that, using Common Expression Language (CEL), you can specify no MCP server tools should be available.

```
kubectl apply -f- <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: tool-select
  namespace: agentgateway-system
spec:
  targetRefs:
    - group: agentgateway.dev
      kind: AgentgatewayBackend
      name: demo-mcp-server
  backend:
    mcp:
      authorization:
        policy:
          matchExpressions:
            - 'mcp.tool.name == ""'
EOF
```

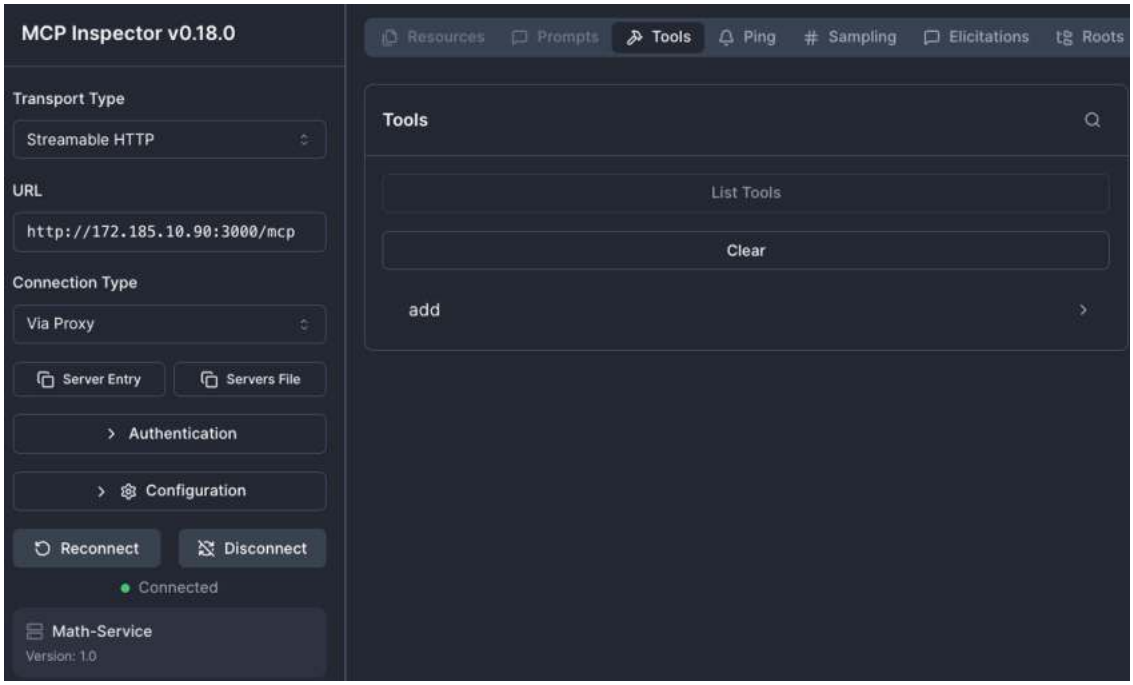
As you can see in the screenshot below, once you create this policy, no tools will be available.



2. Modify the policy to specify that only the “add” tool will be available.

```
kubectl apply -f- <<EOF
apiVersion: agentgateway.dev/v1alpha1
kind: AgentgatewayPolicy
metadata:
  name: tool-select
  namespace: agentgateway-system
spec:
  targetRefs:
    - group: agentgateway.dev
      kind: AgentgatewayBackend
      name: demo-mcp-server
  backend:
    mcp:
      authorization:
        policy:
          matchExpressions:
            - 'mcp.tool.name == "add"'
EOF
```

And as you can see, only the “add” tool can be used in MCP Inspector.



You can get even more granular and specify what tools are available, what tools are available for everyone, and what tools are available for each group.

```
    mcp:
      authorization:
        action: Allow
        policy:
          matchExpressions:
            # Public tool - any authenticated user can call
            - 'mcp.tool.name == "echo"'

            # Any authenticated user can get their own info
            - 'mcp.tool.name == "get_user_info"'

            # Requires files:read scope
            # Auth0 scopes are in the 'scope' claim as a space-separated
string
            - 'mcp.tool.name == "list_files" &&
jwt.scope.contains("files:read")'

            # Requires files:delete scope AND admin role (custom claim)
            # Auth0 custom claims must be namespaced (e.g., https://mcp-
demo/roles)
            # Access namespaced claims using bracket notation: jwt["claim-
name"]
            - 'mcp.tool.name == "delete_file" &&
jwt.scope.contains("files:delete") && jwt["https://mcp-
demo/roles"].contains("admin")'

            # Requires admin role only (custom claim)
            - 'mcp.tool.name == "system_status" && jwt["https://mcp-
demo/roles"].contains("admin")'
```

With that, you now have a great starting point to set up authentication and MCP server tool lockdown for a secure, agentic MCP environment.

Part 3: Agent Sandboxes

Conclusion

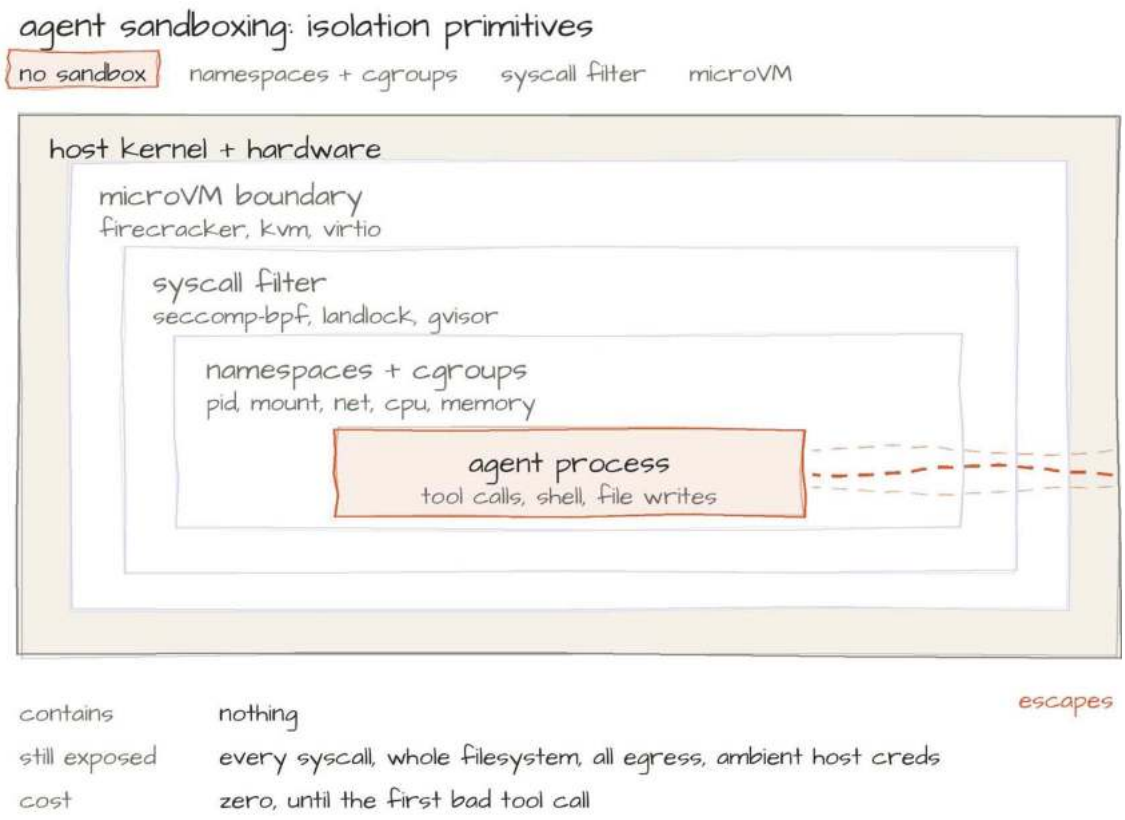
As mentioned in the beginning of this chapter, the majority of really sophisticated security protocols and implementations are typically in enterprise versions of tools and platforms. It's one of the biggest differentiators between free/open source and paid. However, I hope that this chapter allowed you to start thinking about security and gave you a few sample implementations so you can get started today.

Agent Sandboxing

The final section within this book will cover sandboxing, which is a topic that's increasing in not only popularity but also in necessity (as we'll discuss in this section regarding the security breaches and attacks that have occurred). This section will cover what sandboxing is as a whole, how to think about sandboxing when it comes to agentic workloads, and a true production-grade sandboxing project that is led by the co-creator of Kubernetes at Google.

What Sandboxing Technically Is

"Technically speaking" if you run a process/app/script/whatever else in a container within Docker Desktop on your Mac/Windows machine, that's a "sandbox." Because it's running the process in an "isolated fashion" (outside of directly on your machine), it's a "sandbox."



However, that's a really dangerous way to think about sandboxes. In fact, if you take a look at the OpenAI/Hugging Face attack that happened in July of 2026, which is a key reason why the frontier labs got together in September of 2026 and all agreed that the need to slow down frontier model development is necessary, the "sandboxes" that were running the agents that caused the attack weren't sandboxes in the

true sense at all. They were simply containers. If you look here (https://openai.com/index/hugging-face-incident-and-the-road-ahead/), you'll even see that it's specifically said "for some tasks, we disable access to the internet."

That's not a sandbox at all if you care about true isolation. True isolation is at a level where everything is controlled: what access is occurring outside of the sandbox (what LLMs are used, what MCP Servers are used, and what sites/search engines can be accessed), along with how it's governed, secured, and observed.

Observability data alone (metrics/logs/traces), for example, should, and can, be used to alert on "breakouts" from the sandbox.

In the upcoming sections, you'll learn what a true sandbox is and how to implement one within your environment.

How to Implement Sandboxing Today

When implementing a sandbox, you need to care about three things:

1. Where the isolation occurs (software or hardware-level)
2. How it's observed
3. The level of control

The location of the isolation matters. If it's software-level isolation, it's happening at the user space/namespace. The gist is that you use code, OS rules, and virtual network logic to implement isolation instead of physical hardware. If it's at the hardware level, however, the isolation is down to the physical CPU chip level. It has its own kernel.

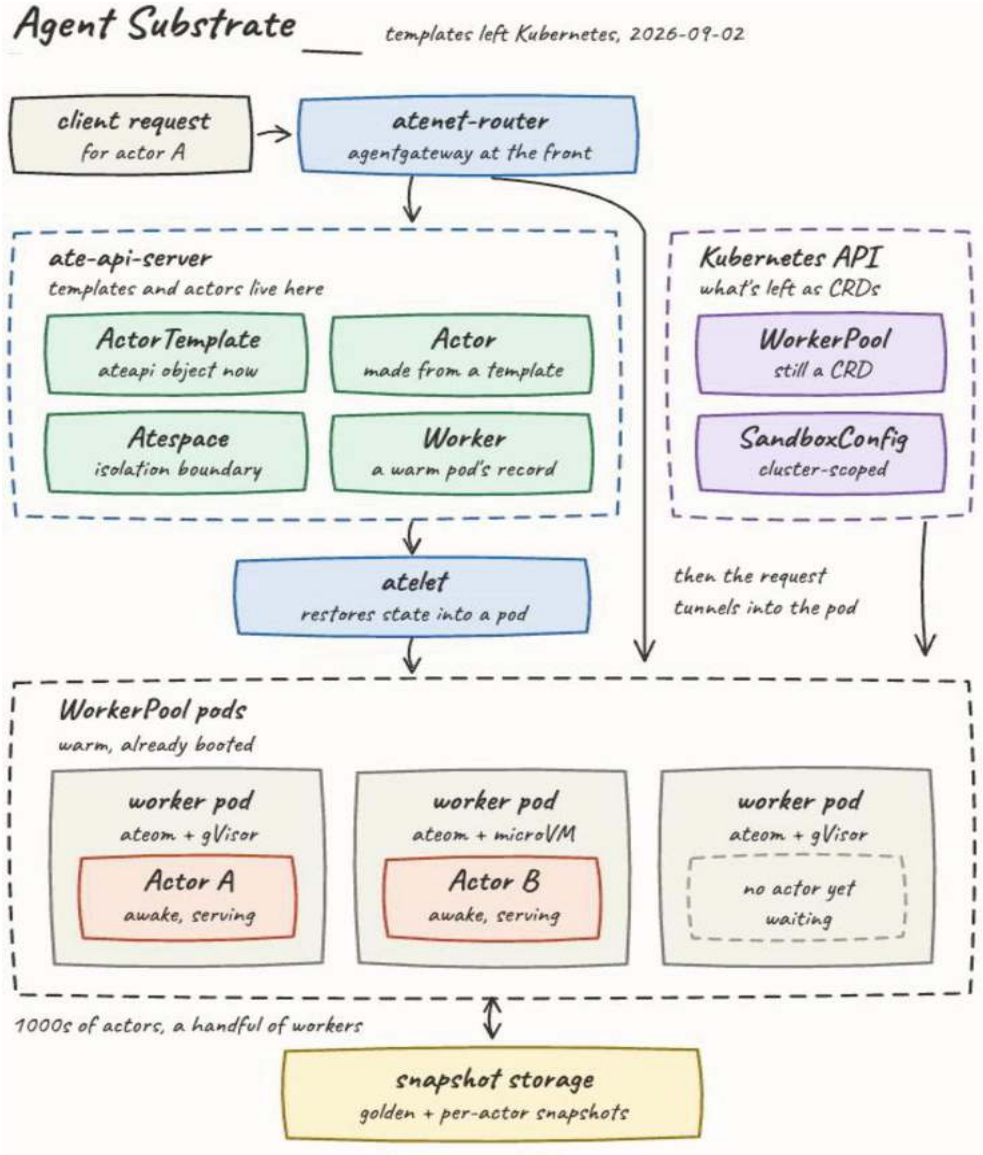
When thinking about observability (logs, traces, metrics), you can't have true isolation without proper observability. The reason why is that you have zero way of knowing how the sandbox is performing, and therefore, how could you ever know if it's actually isolated?

Saying "this agent is isolated" and "it has full access to the public internet" within the same sentence is the definition of counterproductive. If an agent is truly isolated, there need to be policies, governance, and security around it: what it can and can't do, what it can and can't access, and how that level of control is implemented.

Enter Agent Substrate

In this section of the chapter so far, you've learned what's technically sandboxing, why it's not "technically sandboxing," and what to think about when sandboxing an environment. Now, it's time to learn about how to do it.

That's where agent substrate comes into play.



Led by Google's Tim Hockin (co-creator of Kubernetes) with many maintainers from Solo.io, agent substrate is the next evolution of agentic sandboxing. It contains its own API (ateapi) instead of building off of the Kubernetes API, as it's designed for efficient and performant agentic workloads, but, at the same time, utilizes Kubernetes primitives (like Worker Nodes) to run and scale out agents. The agents then live in pods called Workers (more on that later) and are only "on" when in use. The state/context/memory of the agents are stored in storage, like Google Cloud Storage, to be called out to when the agent turns back on.

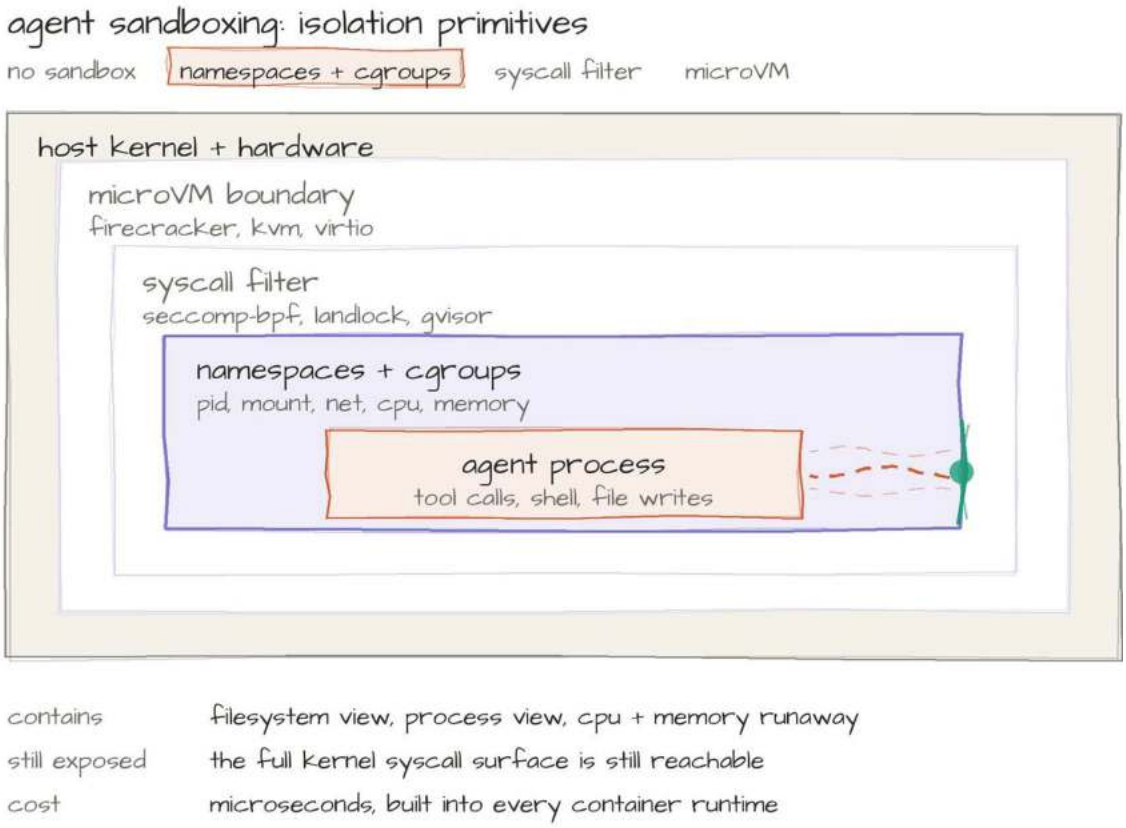
One important thing to keep in mind: At the time of writing this, agent substrate is roughly three months old. It's absolutely insane to see the innovation that has gone into agent substrate so far, and at the same time, it's important to remember that agent substrate is still at the very beginning of its innovation. Because of that, please keep in mind that it shouldn't be surprising for the project to look different in 3/6/9/12 months from now. As we've all seen, that's normal in the world of AI innovation is rapid.

Let's dive into a few key aspects of agent substrate.

Software-Level Isolation

Isolation at the software-level means there is a portion of memory carved out for that particular process running in user space. It's still running on the same kernel as the rest of the system.

Because it's in user space, it's a feature of the kernel that partitions resources. When a process is placed in a user space with software-level isolation, the goal is for it to only see resources within that namespace (that's how the virtual user space is created). This is what creates, as many suggest, an "illusion" of isolation.



As you can imagine, although policies and procedures can be put into place, there are still a ton of attack surfaces.

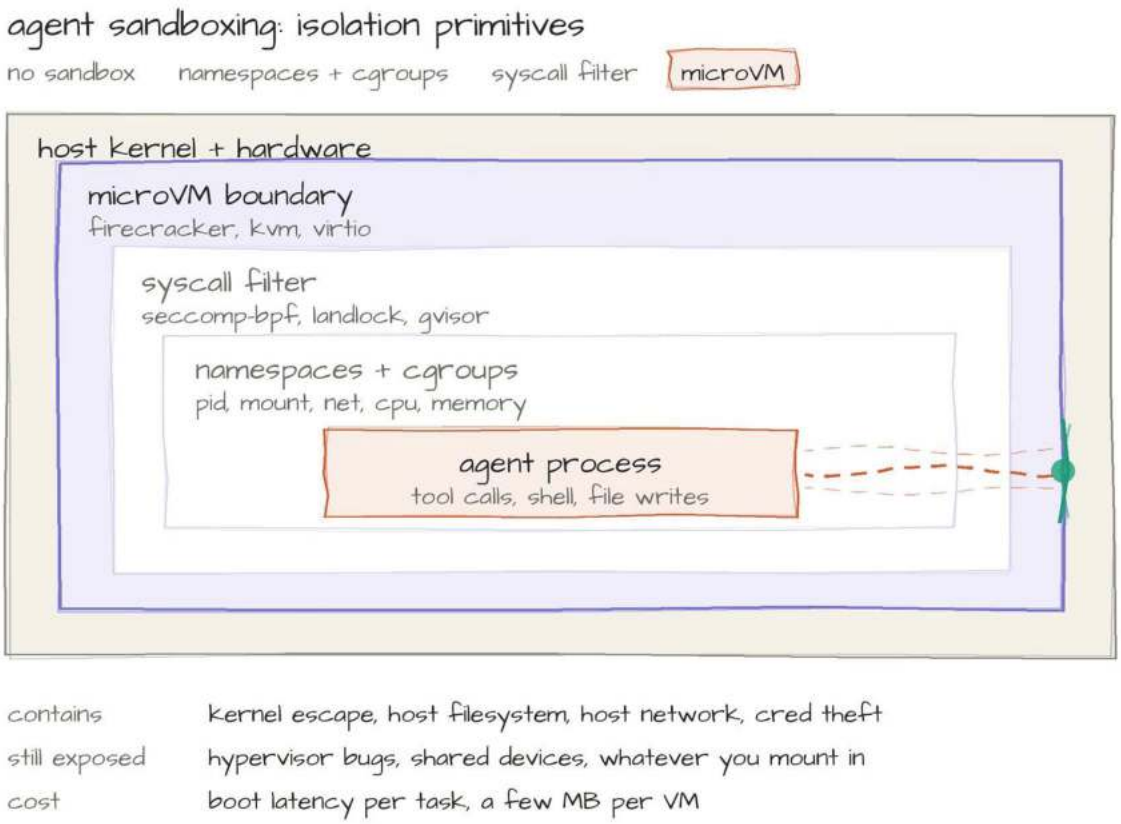
In today's stack, when you see "software-level isolation," you'll typically see gVisor.

Hardware-Level Isolation

When implementing isolation at the hardware level, it's much harder to break. The reason why is that the isolation is down to the physical CPU chip level. There is a guest VM that is running and it has its own kernel.

There is physical memory separation as well. Instead of, like with software-level isolation, implementing namespaces to hide system/OS files and other processes/apps running on the system, the CPU uses hardware Memory Management Units (MMUs) and features like Extended Page Tables (EPTs), which means that the CPU physically maps blocks of RAM so that one guest VM's chip-level memory addresses do not exist to another guest VM. They are entirely blind to each other at the physical hardware level.

In today's stack, when you see "hardware-level isolation," you'll typically see microVM.



The three things to keep in mind with hardware-level isolation are

- It has its own kernel.
- Chip-level enforcement.
- Physical memory separation.

Please note that both software- and hardware-level isolation are available in agent substrate.

Workers

With the breakdown of isolation in the previous sections, let's learn about the two key aspects of agent substrate, aside from it having it's own API server for more efficient and performant agent management: Workers and Actors.

Workers are where agents run in agent substrate. A Worker is a pod. A Worker is created via a WorkerPool, which is a collection of Workers that agents within agent substrate run on. When you create a WorkerPool, you can specify how many replicas you want. For example, if you have three replicas within a WorkerPool, that means three Worker pods will be created and managed for that WorkerPool. The more Workers you have, the more resources (CPU/memory) are available to running agents.

Actors

Although we've been calling them "agents" within substrate so far, agents in agent substrate are actually called Actors. Actors are where, for example, your agent harness will run. We've been talking about Actors in the "agent sense" so far, but it's important to note that agents can also be a place where something like standard HTTP apps (like a Go Web API) can run.

The thing that makes Actors run agents in such a performant fashion is how they run and don't run. Actors are only "up" (using resources and actually running) when they're being interacted with. When they're not being interacted with, they're in a "warm state." This "warm state" isn't using up hardware resources, which means other actors can use said hardware resources. If you're nervous about performance

in the "Actor wake-up period," don't be. Actors wake back up in sub-five milliseconds when hit by the atenet-router or within sub-second to a few seconds depending on the state restoration and worker assignment.

The way that Actors can spin up and spin down so easily without skipping a beat, aside from a performance level due to ateapi, is because the Actor's state/context/memory is stored within a quickly retrievable storage solution like Google Cloud Storage. That also means migrating state between Actors is pretty straightforward. For scalability purposes, because the state/context/memory lives in storage, an Actor can go down and a new Actor can easily pick it back up if the original Actor was compromised in any way.

Because Actors run in Workers, which are pods, observability data (logs/traces/metrics) can be pulled from said pods and observed in whatever monitoring and observability tool you're using. You can see an example write-up of that here: https://www.cloudnativedeepdive.com/implementing-observabilityfor-agent-substrate-actors/.

Actor Templates

Before actors can be deployed, there needs to be a template in place. Some think of it like a "golden image," but the word "image" sounds a bit heavy in this use case. Really, it's an object that contains configurations for things like what model you want to use, the system prompt/message for the agent, and where it's running.

You can see an example below:

```
apiVersion: kagent.dev/v1alpha3
kind: AgentTemplate
metadata:
  name: assistant
  namespace: kagent
  labels:
    kagent.dev/harness: kagent
spec:
  modelConfig:
    name: default-model-config
  description: A substrate-backed assistant used to verify this main build.
  systemPrompt: You are a helpful assistant running on kagent.
```

Agent Substrate Is the Lower-Level Implementation

To wrap up this section, it's important to understand that agent substrate is a lower-level implementation. It's the "under-the-hood magic" that makes sandboxing at such a precise level occur. With that being said, the chances of you interacting with an Actor directly are highly unlikely.

To interact with an Actor, you're running a programmatic request to the API like in the code example below:

```
curl -X POST -H "Host: my-counter-1.actors.resources.substrate.ate.dev" \
  http://localhost:8000
```

No one is going to want to do that every time they want to interact with an agent. Instead, people will want to interact with agents the same way they're used to doing so today – with a chat interface or a terminal, like when using opencode.

That's where having a runtime sitting on top of agent substrate will be crucial.

As you can see in the screenshot below, kagent interacts with all of the agent substrate underlying primitives to expose Workers, Templates, WorkerPools, and Actors. You can then interact with Actors via the Agents tab within kagent.

Concluding Remarks

There are technology innovations as big as AI typically once in an engineer's career. Luckily, I've had the unique opportunity to live through a few – virtualization, cloud, Kubernetes, and now AI. Although all of the other innovations were huge, there's something that feels different about AI. My assumption is it's two things: the speed at which AI is growing and the fact that it's not just something that engineers use; it's impacting the entire world and everyone in it.

With that being said, if you're lucky, you get to work on, and with, such a huge technological advancement in your career that it blows away everything else you've ever worked on. AI is "that thing," and we're all incredibly lucky to be living through a time that we can make such a critical impact on the industry. Heck, it's a ton of fun too!

From when I started writing this book (October 2025) to now (March 2026), so many things have changed. It's why I did my absolute best to write this thing in a quick timeframe because I knew if I took 6+ months, it would've been out of date the second it went on the shelf. Even now, with how fast things are moving, it's only a matter of time until this book needs a second version. It's really wild to see just how quickly AI is moving. I mean, a year ago MCP was released as a new standard. Now, people are saying there's no reason for it, and it might not even be a standard anymore. That's wild! It's an absolutely insane time to be alive in the tech space.

Thank you all, truly, for going through this book. I hope that you enjoyed it, and if you have any feedback, please feel free to reach out to me on LinkedIn. Good luck with your career and your advancement in AI. It's going to be a wild ride.
