For Paris, Sarah, Jake, Jessica and Dylan

The wounded surgeon plies the steel

That questions the distempered part;

Beneath the bleeding hands we feel

The sharp compassion of the healer's art

Resolving the enigma of the fever chart.

T.S. Eliot. *Four Quartets*. East Coker. IV

# Contents

Contributors, xxvii

Editor's Preface, xxxv

## Section I: An overview of mesenchymal stem cells and mesenchymal stromal cells

**1** The mesenchymal stem cell, the mesenchymal stromal cell, and the mesenchymal stromal cell exosome, 3
*Kerry Atkinson*

1.1 Nomenclature, 3
1.2 The mesenchymal stem cell, 3
1.3 The mesenchymal stromal cell, 4
1.4 The mesenchymal stromal cell exosome and extracellular vesicles, 6
References, 7

**2** The nomenclature of mesenchymal stem cells and mesenchymal stromal cells, 8
*Armand Keating*

2.1 Introduction, 8
2.2 Historical perspective, 8
2.3 The need for common terminology and definition: the International Society for Cellular Therapy white papers of the mid-2000s, 9
2.4 Updating terminology, 9
References, 10

## Section II: The isolation and *ex vivo* expansion of mesenchymal stromal cells

**3** The isolation and expansion of mesenchymal stromal cells from bone marrow, 13
*Celena F. Heazlewood*

3.1 Introduction, 13
3.2 Stem cells, 14
3.3 Isolation and characterization of bone marrow mesenchymal stromal cells, 14
3.3.1 Cell surface markers, 15
3.3.2 Chemokine receptor display, 15
3.3.3 Mesodermal differentiation capability, 17
3.4 The immunomodulatory properties of mesenchymal stromal cells, 17
3.5 The transcriptome of mesenchymal stromal cells, 18
References, 20

**4** The biology and clinical applications of mesenchymal stromal cells derived from human gestational tissues, 24
*Celena F. Heazlewood*

4.1 Introduction, 24
4.2 Isolation of placental mesenchymal stromal cells, 25
4.3 Characteristics of fetally derived mesenchymal stromal cells isolated from gestational tissues, 26
4.3.1 Amniotic-membrane-derived mesenchymal stromal cells, 26
4.3.2 Chorionic-membrane-derived mesenchymal stromal cells, 26
4.4 Characteristics of maternally derived mesenchymal stromal cells isolated from gestational tissue (the decidua), 27
4.5 Comparison of mesenchymal stromal cells from fetal and maternal tissues isolated from gestational tissues, 27
4.6 Comparison of gene expression profiles between human term-placenta-derived mesenchymal stromal cells, human adult bone-marrow-derived mesenchymal stromal cells, and human umbilical-cord-derived unrestricted somatic stem cells, 28
4.7 Preclinical mesenchymal stromal cell studies, 28
4.8 Clinical applications of placental mesenchymal stromal cells, 29
4.9 Manufacturing clinical-grade placenta-derived mesenchymal stromal cells, 29
4.9.1 Phase 1 clinical trials using unrelated major-histocompatibility-unmatched placenta-derived mesenchymal stromal cells, 30
4.10 Conclusions, 30
References, 30

**5** Human placenta-derived mesenchymal stem/stromal cells: fetal and maternal origins and critical parameters for *ex vivo* expansion, 32
*Rebecca A. Pelekanos and Varda S. Sardesai*

5.1 Introduction, 32

5.2 Mesenchymal stem/stromal cells: a consensus definition?, 32
5.3 Prenatal and perinatal tissue sources of mesenchymal stem/stromal cells, 33
5.4 Fetal tissue-derived mesenchymal stem/stromal cells, 33
5.5 Placental and adnexal stem and progenitor cells, 33
5.6 Comparison of mesenchymal stem/stromal cells from different gestational sources, 33
5.7 Consensus classification of human placental mesenchymal stem/stromal cells, 34
5.8 Differentially isolating fetal or maternal mesenchymal stem/stromal cells from term placental villi, 34
5.9 Confounding factors for the isolation of fetal placental mesenchymal stem/stromal cells from chorionic villi, 34
5.10 Assumptions from the literature: lack of data, specific assays, and specific methodological detail, 35
5.11 Methods for determining fetal and maternal mesenchymal stem/stromal cells in a cultured cell population, 35
5.12 A novel method to isolate fetal and maternal placental mesenchymal stem/stromal cells, 36
5.13 Understanding the maternal origin of the placental mesenchymal stem/stromal cells: the septa, 36
5.14 Conclusions and future directions, 36
Acknowledgments, 37
References, 37

## Section III: The cellular and molecular biology of mesenchymal stromal cells

**6** Epigenetic regulation of mesenchymal stem/stromal cell growth and multipotentiality, 41
*Sarah Elizabeth Hemming, Dimitrios Cakouros, and Stan Gronthos*

6.1 Introduction, 41
6.2 Mesenchymal stromal/stem cells, 42
6.3 Epigenetics, 42
6.4 DNA methylation and histone modifications in mesenchymal stem/stromal cells, 45
6.5 Epigenetic regulation of osteogenic differentiation, 45
6.6 Epigenetic regulation of adipogenic differentiation, 47
6.7 Epigenetic regulation of myogenic differentiation, 48
6.8 Epigenetic regulation of chondrogenic differentiation, 48
6.9 Epigenetic regulation of mesenchymal stem/stromal cell lifespan and senescence, 52
6.10 Regulation of epigenetic modifications in mesenchymal stem/stromal cells for clinical use, 52
6.11 Conclusions, 52
References, 53

**7** Biological changes in human mesenchymal stromal cells during monolayer culture, 58
*Marietta Herrmann and Jennifer J. Bara*

7.1 Introduction, 58
7.2 Mesenchymal stromal cell isolation from bone marrow, 59
7.3 Mesenchymal stromal cell isolation from adipose tissue, 60
7.4 Biological characteristics, 60
7.4.1 Morphology and colony formation, 60
7.4.2 Growth kinetics, 61
7.4.3 *In vitro* multipotency, 62
7.4.4 Gene expression, 62
7.4.5 Cell surface marker profile, 63
7.4.6 Secretory profile, 66
7.5 Influences on tissue culture parameters, 66
7.5.1 Seeding density, 66
7.5.2 Culture medium and supplementation, 67
7.5.3 Growth factors, 67
7.5.4 Xeno-free media, 67
7.5.5 Platelet-derived supplements, 67
7.5.6 Serum-free media, 68
7.5.7 Hypoxia, 68
7.6 Implications for basic and clinical research, 68
7.6.1 Trial disparity, 68
7.6.2 Alternative culture systems, 69
7.7 Conclusions and future directions, 70
References, 70

**8** The effect of three-dimensional aggregates on the biology of mesenchymal stromal cells, 75
*Yijun Liu, Ang-Chen Tsai, Xuegang Yuan, and Teng Ma*

8.1 Three-dimensional multicellular aggregates, 75
8.2 Three-dimensional aggregates of mesenchymal stromal cells, 76
8.3 Mechanism of mesenchymal stromal cells self-assembly into three-dimensional aggregates, 77
8.3.1 Cell–cell contact, 77
8.3.2 Extracellular matrix and the cytoskeleton, 77
8.3.3 Mesenchymal stromal cells heterospheroids, 78
8.4 Mechanisms of aggregate-mediated mesenchymal stromal cell functional enhancement, 78
8.4.1 Role of cell adhesion molecules in the fate decision of mesenchymal stromal cell three-dimensional aggregates, 79
8.4.2 Effects of extracellular matrix, cytoskeleton, and morphology on mesenchymal stromal cell lineage commitment in three-dimensional aggregates, 80
8.4.3 Role of molecular milieu and hypoxia-inducible factor activation, 80
8.4.4 Metabolism changes in three-dimensional aggregates of mesenchymal stromal cells, 81

8.4.5 Enhanced anti-inflammatory properties of three-dimensional aggregates of mesenchymal stromal cells, 81
8.5 Bioreactor systems for three-dimensional aggregate production, 81
8.5.1 Scale-up and dynamics of culture, 81
8.5.2 Spinner flasks, 82
8.5.3 Rotary wall vessel, 82
8.5.4 Rotary orbital system, 83
8.5.5 Comparison of spinner flask and rotary wall vessel, 83
8.5.6 Other systems, 84
8.6 Transplantation of three-dimensional mesenchymal stromal cell aggregates in preclinical animal models of disease, 84
8.6.1 Enhanced secretory properties of mesenchymal stromal cells aggregates, 84
8.6.2 Immunomodulation by mesenchymal stromal cell aggregates, 84
8.6.3 Enhanced multilineage differentiation of three-dimensional mesenchymal stromal cells aggregates, 84
8.6.4 Recapitulation of mesenchymal condensation and osteochondral differentiation in bone and cartilage regeneration, 86
References, 87

**9** Cell–cell signaling pathways that regulate mesenchymal stromal cell differentiation, 91
*Leah Etheridge, Rebecca A. Mason, Fatima Saleh, and Paul Genever*

9.1 Introduction, 91
9.2 Mesenchymal stromal cell signaling is dependent on its type, 91
9.3 Identity of bone-marrow-derived mesenchymal stromal cells, 92
9.4 Mesenchymal stromal cell signaling in the stem cell niche, 93
9.5 Regulation of mesenchymal stromal cell differentiation by the TGF-β/BMP signaling pathway, 95
9.6 Regulation of mesenchymal stromal cell differentiation by the Wnt signaling pathway, 97
9.7 Conclusions, 99
References, 99

**10** Regulation of mitochondrial transport in mesenchymal stromal cells, 104
*Shravani Mukherjee, Naveen K. Bhatraju, Tanveer Ahmad, and Anurag Agrawal*

10.1 Introduction, 104
10.2 Intercellular organelle transport, 105
10.2.1 Intercellular communication, 105
10.2.2 Mitochondrial biology, 105
10.2.3 Intercellular mitochondrial transport/mitochondrial donation, 105
10.3 Mesenchymal stromal cells as potential mitochondrial donors, 107
10.3.1 Mechanism of intercellular mitochondrial transport regulation, 108
10.4 Strategies to improve mitochondrial delivery to target cells, 110
10.5 The road ahead, 111
References, 111

**11** The regulation of adipogenesis from adipose-derived stem/stromal cells, 114
*Lin Chen and Lei Liu*

11.1 Introduction, 114
11.2 Adipose-derived stem/stromal cells, 115
11.2.1 Preparation and molecular characterization of adipose-derived stem/stromal cells, 115
11.2.2 Differentiation capacity of adipose-derived stem/stromal cells, 116
11.3 Process of adipogenic differentiation from adipose-derived stem/stromal cells, 116
11.3.1 Adipocyte development program, 116
11.3.2 Signaling pathways associated with adipogenic differentiation, 117
11.4 Regulation of adipogenic differentiation from adipose-derived stem/stromal cells, 118
11.4.1 Transcriptional regulation, 118
11.4.2 Epigenetic regulation, 119
11.4.3 Post-transcriptional regulation, 121
11.5 The future, 125
References, 125

**12** Modulation of osteogenic differentiation in mesenchymal stromal cells, 131
*Sean Gaynard, Jessica Hayes, and Mary Murphy*

12.1 Introduction, 131
12.2 Biology, 132
12.2.1 Sources of mesenchymal stromal cells, 132
12.2.2 Cellular regulation of osteogenic differentiation from mesenchymal stromal cells, 132
12.2.3 Molecular regulation of osteogenic differentiation from mesenchymal stromal cells, 134
12.2.4 Factors regulating homing of mesenchymal stromal cells to bone, 136
12.2.5 *In vivo* detection and contribution of mesenchymal stromal cells to osteogenesis, 137
12.2.6 Regulating the immune system for bone formation, 138
12.3 Clinical applications of mesenchymal stromal cells in bone disorders, 138
12.3.1 Bone regeneration, 138

12.3.2 Osteoarthritis, 139
12.3.3 Osteogenesis imperfecta, 140
12.4 Summary, 141
References, 141

**13** The role of glycogen synthase kinase-3 inhibitors on bone remodeling, 148
*K. Jane Escott and Patrick J. O'Shea*

13.1 Overview of glycogen synthase kinase-3, 148
13.2 The response of skeletal cells to glycogen synthase kinase-3 inhibitors *in vitro*, 149
13.2.1 Lithium chloride, 149
13.2.2 SB-216763 and SB-415286, 151
13.2.3 6-bromoindirubin-3′-oxime, 152
13.2.4 LY603281-31-8, 153
13.2.5 CT99021/CHIR99021, 153
13.2.6 AR28 (AZD2858), AR79, and AZ13282107, 154
13.3 Bone anabolism through inhibition of glycogen synthase kinase-3 *in vivo*, 155
13.3.1 Functional Wnt/β-catenin responses in *Xenopus laevis* model systems, 156
13.3.2 Progenitor cell involvement in bone anabolism *in vivo*, 156
13.3.3 Alteration in bone resorption *in vivo*, 158
13.4 Impact of glycogen synthase kinase-3 inhibition in bone disease, 159
13.4.1 Osteopenia and osteoporosis, 159
13.4.2 Methotrexate-induced bone loss, 160
13.4.3 Fracture healing, 160
13.4.4 Multiple myeloma-associated bone disease, 161
13.4.5 Periodontal disease, 161
13.4.6 Clinical findings with lithium, 161
13.5 Summary, 162
References, 163

**14** Early molecular events during *in vitro* chondrogenesis, 167
*Tommy A. Karlsen, Rune B. Jakobsen, and Jan E. Brinchmann*

14.1 Introduction, 167
14.2 Adult articular cartilage, 168
14.3 Developmental chondrogenesis, 168
14.4 Molecular aspects of *in vivo* chondrogenesis, 169
14.5 Determinants of *in vitro* chondrogenesis, 171
14.6 Tissue source of mesenchymal stromal cells, 171
14.6.1 *In vitro* cell culture, 171
14.7 Three-dimensional culture systems and bioscaffolds, 172
14.8 Epigenetic changes during early *in vitro* chondrogenesis, 172
14.8.1 An introduction to epigenetics, 172
14.8.2 DNA methylation of the *COL2A1* and *COL10A1* promoters, 173
14.8.3 DNA methylation of promoters in other chondrogenesis candidate genes, 173
14.8.4 Genome-wide map of quantified epigenetic changes during *in vitro* chondrogenesis of bone marrow mesenchymal stromal cells, 174
14.8.5 Epigenetics: conclusions, 175
14.9 Role of microRNAs during early *in vitro* chondrogenesis, 176
14.9.1 An introduction to microRNAs, 176
14.9.2 Role of miRNA-140 in developmental chondrogenesis, 177
14.9.3 miR-140 targets identified *in vivo* and in vitro, 178
14.9.4 Defining the role of miR-140 during chondrogenic differentiation of mesenchymal stromal cells and dedifferentiation of articular chondrocytes, 178
14.9.5 Impact of microRNAs other than miR-140 on chondrogenic differentiation of mesenchymal stromal cells, 179
14.9.6 MicroRNAs in chondrogenesis: conclusions, 181
14.10 Early changes in gene expression during *in vitro* chondrogenesis, 182
14.10.1 Genes involved in collagen fibrillogenesis, 183
14.10.2 Genes involved in synthesis of proteoglycans and glygosaminoglycans, 183
14.10.3 Transcription factor genes, 183
14.10.4 Genes encoding other important cartilage molecules, 184
14.10.5 Genes encoding unwanted molecules, 184
14.10.6 Effect on gene expression of changes in the differentiation cocktail, 184
14.11 Conclusions, 186
References, 186

**15** The role of the extracellular matrix in the differentiation of mesenchymal stromal cells, 191
*Peishun Shou, Qing Chen, and Yufang Shi*

15.1 Summary, 191
15.2 Multipotency of mesenchymal stromal cells, 191
15.3 The extracellular matrix and mesenchymal stromal cell differentiation, 192
15.3.1 The role of osteopontin in mesenchymal stromal cell differentiation, 193
15.3.2 Geometric cues in mesenchymal stromal cell differentiation, 193
15.3.3 Crosstalk between the extracellular matrix and mesenchymal stromal cells, 193
15.4 Conclusions and future perspectives, 194
Acknowledgments, 194
References, 194

**16** Effects of hypoxic culture on bone marrow multipotent mesenchymal stromal cells: from bench to bedside, 196
*Shih-Chieh Hung*

16.1 Introduction, 196
16.2 Multipotent mesenchymal stromal cells, 196
16.3 Criteria for defining human multipotent stromal cells, 197
16.4 Problems encountered in the clinical application of multipotent mesenchymal stromal cells, 197
16.5 The hypoxic niche of multipotent mesenchymal stromal cells, 197
16.6 Involvement of hypoxia-inducible factor-1α in hypoxia-mediated effects, 198
16.7 Effects of hypoxic culture on glucose metabolism and oxidative stress of multipotent mesenchymal stromal cells, 198
16.8 Effects of hypoxic culture on the apoptosis of multipotent mesenchymal stromal cells, 199
16.9 Effects of hypoxic culture on expansion and life span of multipotent mesenchymal stromal cells, 199
16.10 Effects of hypoxic culture on maintaining self-renewal and differentiation potential of multipotent mesenchymal stromal cells, 200
16.11 Differentiation of multipotent mesenchymal stromal cells under hypoxic conditions, 200
16.12 Effects of hypoxic culture on secretion of paracrine factors by multipotent mesenchymal stromal cells, 201
16.13 Effects of hypoxic culture on engraftment of multipotent mesenchymal stromal cells, 202
16.14 Effects of hypoxic culture on allogeneic transplantation of multipotent mesenchymal stromal cells, 202
16.15 Conclusions, 203
Acknowledgments, 203
References, 203

**17** The role of cyclic tensile strain on osteogenesis and angiogenesis in human mesenchymal stem/stromal cells, 208
*Adisri Charoenpanich, Josephine Bodle, and Elizabeth Loboa*

17.1 Introduction, 208
17.2 Applications of tensile strain: an interpretation from physiological stimuli *in vivo* to bioreactors *in vitro*, 209
17.2.1 Uniaxial tensile strain, 209
17.2.2 Equi-/biaxial tensile strain, 210
17.3 Mechanical sensing of mesenchymal stem/stromal cells, 211
17.3.1 Integrins and the cytoskeleton, 211
17.3.2 The nucleoskeleton and lamins, 212
17.3.3 Primary cilia, 212
17.3.4 Stretch-activated calcium channels, 213
17.3.5 The glycocalyx, 213
17.4 The molecular response of mesenchymal stem/stromal cells to cyclic tensile strain, 214
17.4.1 Restructuring of mesenchymal stem/stromal cells and the surrounding extracellular matrix by mesenchymal stem/stromal cells in response to cyclic tensile strain, 215
17.4.2 Mesenchymal stem/stromal cell secretomes that induce further responses from other cells, 216
17.5 Summary, 217
Acknowledgments, 217
References, 217

**18** The evolving concept of mesenchymal stromal cells in regenerative medicine: from cell differentiation to secretome, 222
*F.G. Teixeira, A. Pires, S.C. Serra, N. Sousa, and A.J. Salgado*

18.1 Mesenchymal stromal cells, 222
18.2 The mesenchymal stromal cell secretome, 224
18.2.1 Concept, 224
18.2.2 Characterization techniques, 224
18.3 The mesenchymal stromal cell secretome in transplantation and regenerative medicine, 225
18.3.1 Graft-versus-host-disease, 225
18.3.2 The central nervous system, 226
18.4 The peripheral nervous system, 229
18.5 Future perspectives, 230
References, 231

**19** The secretome of mesenchymal stem/stromal cells undergoing chondrogenic differentiation and those undergoing osteogenic or adipogenic differentiation, 236
*Beatriz Rocha, Francisco J. Blanco, and Cristina Ruiz-Romero*

19.1 Introduction to protein secretion and the analysis of secretomes, 236
19.2 Analysis of mesenchymal stem/stromal cell secretomes using proteomic approaches, 237
19.2.1 Approaches to obtaining secretome samples, 237
19.2.2 Experimental strategies for *in vitro* secretome analysis of mesenchymal stem/stromal cells, 237
19.3 Analysis of the secretome of mesenchymal stem/stromal cells undergoing chondrogenesis, 242
19.4 Characterization of chondrogenesis markers by secretome analysis, 242
19.5 Characterization of osteogenesis markers by secretome analysis, 247
19.6 Characterization of adipogenesis markers by secretome analysis, 247
19.7 Conclusions and future perspectives, 247
References, 247

**20** Mesenchymal stromal cell extracellular vesicles/exosomes, 250
*Ronne Wee Yeh Yeo, Ruenn Chai Lai, and Sai Kiang Lim*

20.1 From cell to secretion to exosome, 250
20.1.1 Mesenchymal stromal cells, 250
20.1.2 Cell secretion, 251
20.1.3 Mesenchymal stromal cell extracellular vesicles as the active therapeutic factor, 251
20.2 Extracellular vesicles, 251
20.2.1 Exosome biology and general functions, 252
20.3 The therapeutic use of exosomes, 252
20.3.1 Mesenchymal stromal cell exosomes, 253
20.3.2 Characterization of mesenchymal stromal cell exosomes, 254
20.3.3 The biochemical potential of mesenchymal stromal cell exosomes, 254
20.3.4 Biochemical potency, 255
20.3.5 Glycolysis, 256
20.3.6 Proteasome activity, 256
20.3.7 Signaling: adenosine signaling, 256
20.3.8 Inhibition of complement activation, 256
20.3.9 Restoring homeostasis, 256
20.3.10 Bioenergetic homeostasis, 257
20.3.11 Immune homeostasis, 257
20.4 The clinical translation of mesenchymal stromal cell exosomes, 258
20.5 Conclusions, 258
References, 258

**21** Role of tunneling nanotube crosstalk with distressed cardiomyocytes in controlling the heart repair potential of mesenchymal stromal cells, 264
*Anne-Marie Rodriguez and Meriem Mahrouf-Yorgov*

21.1 Introduction, 264
21.2 Mesenchymal stromal cells as a promising tool to regenerate damaged heart tissue, 264
21.2.1 Degenerative cardiac diseases: a major public health problem, 264
21.2.2 Mesenchymal stromal cells: a promising tool to treat the effects of myocardial infarction, 265
21.2.3 Mechanisms underlying the regenerative effects of mesenchymal stromal cells, 266
21.3 Tunneling nanotubes: a universal route of intercellular communication between distant cells, 268
21.3.1 Structural diversity of tunneling nanotubes, 269
21.3.2 Mechanisms and factors involved in tunneling nanotube formation, 269
21.3.3 The diversity of compounds transferred by tunneling nanotubes and their physiological relevance, 271
21.4 Tunneling nanotubes: a novel cell-to cell communication pathway improving the cardiac regenerative properties of mesenchymal stromal cells, 273
21.4.1 Evidence of tunneling-nanotube-mediated communications between stromal cells and cardiomyocytes, 273
21.4.2 Tunneling nanotube cell-to-cell communication with mesenchymal stromal cells rejuvenates distressed cardiomyocytes through a progenitor-like state, 275
21.4.3 Tunneling nanotube cell-to-cell communication with distressed cardiomyocytes stimulates the paracrine repair function of mesenchymal stromal cells, 277
21.5 Conclusions, 279
References, 280

**22** The preferential homing of mesenchymal stromal cells to sites of inflammation, 286
*Catherine Sullivan*

22.1 Introduction, 286
22.2 Molecular mechanisms of migration, 287
22.2.1 Chemokines, 287
22.2.2 Integrins, 289
22.2.3 Toll-like receptors, 289
22.2.4 Matrix metalloproteinases, 290
22.2.5 Growth factors, 291
22.3 The inflammatory milieu, 291

**38** Treatment of lung disease by mesenchymal stromal cell extracellular vesicles, 553
*Antoine Monsel, Ying-gang Zhu, Varun Gudapati, and Jae-Woo Lee*

38.1 Introduction, 553
38.2 Definitions and characterization of extracellular vesicles, 554
38.3 Nomenclature defined by size and morphology, 555
38.4 Common methods of collection of extracellular vesicles, 556
38.4.1 Ultracentrifugation, 556
38.4.2 Size exclusion, 556
38.4.3 Immunoaffinity isolation, 556
38.4.4 Polymeric precipitation, 556
38.5 Quantification of extracellular vesicles, 556
38.5.1 Optical single-particle tracking: nanoparticle tracking analyses, 556
38.5.2 Flow cytometry, 557
38.5.3 Electron microscopy, 557
38.5.4 Protein concentration, 557
38.5.5 Cell count, 557
38.6 Interaction of extracellular vesicles with targeted cells, 557
38.7 Endogenous extracellular vesicles in lung disease, 558
38.7.1 Endogenous extracellular vesicles in acute respiratory distress syndrome, 558
38.7.2 Endogenous extracellular vesicles in chronic obstructive pulmonary disease, 560
38.7.3 Endogenous extracellular vesicles in asthma, 561
38.7.4 Endogenous extracellular vesicles as biomarkers in lung disease, 561
38.7.5 Endogenous extracellular vesicles as potential therapeutic targets for lung diseases, 562
38.8 Therapeutic properties of extracellular vesicles derived from mesenchymal stromal cells, 562
38.8.1 Mesenchymal stromal cell vesicles for kidney injury, 562
38.8.2 Mesenchymal stromal cell vesicles for cardiac injury, 564
38.8.3 Mesenchymal stromal cell vesicles for liver injury, 565
38.8.4 Mesenchymal stromal cell vesicles for neural injury, 565
38.8.5 Mesenchymal stromal cell vesicles for lung diseases, 565
38.9 Remaining questions on the therapeutic use of mesenchymal stromal cell extracellular vesicles, 566
38.9.1 Isolation and quantification techniques, 566
38.9.2 Extracellular vesicle characterization, 566
38.9.3 Feasibility of large-scale generation of extracellular vesicles, 566
38.10 Regulatory considerations for the clinical use of extracellular vesicles, 566
38.11 Conclusions, 566
References, 567

**39** Evaluating mesenchymal stem/stromal cells for treatment of asthma and allergic rhinitis, 573
*Tatyana Gavrilova, Saritha Kartan, Lauren S. Sherman, Oleta A. Sandiford, and Pranela Rameshwar*

39.1 Summary, 573
39.2 Introduction, 573
39.3 Early and late asthma response, 573
39.4 Airway remodeling, 574
39.5 Innate immunity of the airway, 574
39.6 Adaptive immunity of the respiratory tract, 575
39.7 Toll-like receptors, 575
39.8 Allergic rhinitis and immunology, 575
39.9 Immune modulation by mesenchymal stem/stromal cells, 577
39.10 The future of mesenchymal stem/stromal cells as therapy for allergic diseases, 578
References, 578

**40** Stem cell therapies for Huntington's disease, 581
*A.T. Crane, J. Rossignol, and G. L. Dunbar*

40.1 Introduction, 581
40.2 Huntington's disease, 581
40.2.1 Prevalence and symptomology, 582
40.2.2 Neuronal pathology, 582
40.2.3 Mechanisms of neurodegeneration, 583
40.3 Animal models, 584
40.3.1 Transgenic models, 584
40.4 *In vitro* models, 584

40.5 Experimental therapies, 585
40.6 Cell transplantation, 585
40.6.1 Mesenchymal stem/stromal cells, 585
40.6.2 Genetic engineering of mesenchymal stem/stromal cells, 587
40.6.3 Embryonic and fetal stem cells, 588
40.6.4 Neural stem cells, 589
40.6.5 Induced pluripotent stem cells, 590
40.6.6 Co-transplantation paradigm, 593
40.7 Conclusions, 593

## Section IV: The role of bioengineering in the therapeutic applications of mesenchymal stromal cells

**41** Endometrial mesenchymal stromal cell and tissue engineering for pelvic organ prolapse repair, 601
*Shanti Gurung, Jerome A. Werkmeister, and Caroline E. Gargett*

41.1 Introduction, 601
41.2 Pelvic floor disorders, 601
41.3 Pelvic organ prolapse, 602
41.3.1 Surgical treatment for pelvic organ prolapse, 602
41.3.2 New meshes for treatment of pelvic organ prolapse, 603
41.4 Tissue engineering, 603
41.4.1 Candidate cells for tissue engineering applications for pelvic organ disorders, 603
41.5 Endometrium is highly regenerative and contains stem/stromal cells, 606
41.5.1 Human endometrial mesenchymal stem/stromal cells, 606
41.6 Culture expansion of endometrial mesenchymal stem/stromal cells toward current good manufacturing practice conditions, 608
41.7 Tissue engineering for pelvic organ prolapse repair, 609
41.7.1 A large animal preclinical model for pelvic organ proplapse, 611
41.8 Conclusions, 612
Acknowledgments, 612
References, 612

**42** Closed automated large-scale bioreactors for manufacturing mesenchymal stromal cells for clinical use, 616
*Kerry Atkinson, Nicholas Timmins, G. Kiel, Celena Heazlewood, Michael Doran, and Gary Brooke*

42.1 Introduction, 616
42.2 Design of a semi-automated closed-system bioreactor capable of manufacturing mesenchymal stromal cells for clinical use, 616
42.3 A commercially available closed-system bioreactor for manufacturing mesenchymal stromal cells for clinical use, 617
References, 618

## Section V: GMP manufacturing of mesenchymal stromal cells for clinical use

**43** Current good manufacturing practice for the isolation and *ex vivo* expansion of mesenchymal stromal cells derived from term human placenta for use in clinical trials, 621
*Kerry Atkinson, Dahlia Khalil, Celena Heazlewood, and Nina Ilic*

43.1 Source of mesenchymal stromal cells for use in clinical trials, 621
43.2 Inclusion criteria for mothers wishing to donate their term placenta for isolation and expansion of mesenchymal stromal cells for use in clinical trials approved by a human research ethics committee, 622
43.3 Exclusion criteria for mothers wishing to donate their term placenta for isolation and expansion of mesenchymal stromal cells for use in clinical trials approved by a human research ethics committee, 622
43.4 Mesenchymal stromal cell manufacturing, 623
43.4.1 The good manufacturing process facility, 623
43.4.2 Quality control and quality assurance, 623
43.4.3 Isolating and expanding mesenchymal stromal cells from human term placenta, 623
43.4.4 Testing performed on mesenchymal stromal cells manufactured for clinical use, 623
43.5 Phase 1 trials using placenta-derived mesenchymal stromal cells, 625
References, 627

**44** A comparison of high-tier regulatory documents pertaining to biologic drugs including mesenchymal stromal cells in Australia, Europe, and the USA using a manual documentary analysis, 628
*Nina Ilic*

44.1 Introduction, 628
44.2 Background, 628
44.3 Definitions used by the Australian Therapeutic Goods Administration, the European Medicine Agency, and the US Food and Drug Administration for "biologicals", 629
44.4 Complexity of the area, 632
44.5 Analysis of documents, 633

44.6 Regulatory science, 639
44.7 Interpretation of the analysis of the documents, 640
44.8 Conclusions, 641
References, 641

## Section VI: The therapeutic application of mesenchymal stromal cells

**45** The use of mesenchymal stromal cells in acute and chronic heart disease, 647
*Ariel Wolf, Wayne Balkan, and Joshua Hare*

45.1 Introduction, 647
45.2 The biology of acute and chronic ischemic cardiomyopathy, 647
45.3 Characterization of mesenchymal stromal/stem cells, 648
45.3.1 Immunomodulatory properties, 649
45.3.2 Antifibrotic effects, 650
45.3.3 Cardiomyogenesis *in vitro* and *in vivo*, 650
45.3.4 Neovascularization, 651
45.3.5 Paracrine effects, 652
45.3.6 Exosomes, 652
45.3.7 Mitochondrial transfer, 652
45.3.8 Preconditioning, 652
45.3.9 Genetic modification, 653
45.4 Cell combination therapy, 653
45.5 Clinical trials utilizing bone-marrow-derived mesenchymal stromal/stem cells, 654
45.5.1 Acute myocardial infarction, 654
45.5.2 Chronic myocardial infarction, 655
45.6 Clinical trials utilizing adipose-derived mesenchymal stromal/stem cells, 656
45.7 Preconditioning in the clinical setting, 657
45.8 Conclusions, 657
References, 657

**46** The role of mesenchymal stem/stromal cells in the management of critical limb ischemia, 661
*P.K. Gupta, Chullikana Anoop, Balasubramanian Sudha, R Mathiazhagan, Raj Swathi Sundar, and Majumdar Anish Sen*

46.1 Introduction, 661
46.2 Mesenchymal stem/stromal cells and angiogenesis, 663
46.3 Potency assays for cells to be used in critical limb ischemia, 664
46.3.1 Ixmyelocel-T, 664
46.3.2 Stempeucel®, 665
46.4 Preclinical studies, 665
46.4.1 Preclinical safety studies, 665
46.4.2 Preclinical efficacy studies, 667
46.5 Clinical trials in critical limb ischemia, 667
46.5.1 Safety of mesenchymal stromal cells in clinical trials, 667
46.5.2 Efficacy of mesenchymal stromal cells in clinical trials of critical limb ischemia, 668
46.5.3 Clinical trials in India, 671
46.5.4 Stempeutics research experience in critical limb ischemia, 671
46.5.5 Phase I/II study in patients with critical limb ischemia, 671
46.5.6 Phase II study in patients with Buerger's disease, 673
46.6 Conclusions, 673
References, 674

**47** The role of mesenchymal stromal cells in the management of musculoskeletal disorders, 677
*Stefan Zwingenberger, Ishaq Ojodu, Maik Stiehler, and Stuart B. Goodman*

47.1 Summary, 677
47.2 Introduction, 677
47.3 Stem cells for bone regeneration, 679
47.3.1 Bone defects, 679
47.3.2 Osteonecrosis, 680
47.3.3 Wear-particle-related osteolysis, 681
47.3.4 Systemic bone diseases, 681
47.4 Stem cells for cartilage regeneration, 682
47.4.1 Osteoarthritis, 683
47.5 Stem cells for tendon regeneration, 683
47.6 Stem cells for skeletal muscle regeneration, 684
47.7 Stem cells for wound repair, 685
47.8 Conclusions, 685
References, 685

**48** The potential role of bone marrow mesenchymal stromal cells in the treatment of ischemic stroke, 690
*Yujun Pan and Ruohan Sun*

48.1 Introduction, 690
48.1.1 Stroke, 690
48.1.2 Stem cells, 691
48.1.3 Mesenchymal stromal cells, 691
48.2 Transplantation route and mechanisms of migration, 693
48.3 Tracking techniques for transplanted mesenchymal stromal cells, 698
48.4 Cytokines and neurotrophic factors, 699
48.5 Angiogenesis, 699
48.6 Neurogenesis, 700
48.7 Axonal sprouting and remyelination, 701
48.8 Antiapoptotic effects, 701
48.9 Immunomodulation, 702
48.10 Pretreatment of mesenchymal stromal cells prior to their administration in animal models of ischemic stroke, 702

48.10.1 Administration of genetically engineered mesenchymal stromal cells, 704
48.10.2 Administration of mesenchymal stromal cells in combination with chemical agents, 704
48.11 Clinical trials involving bone-marrow-derived mesenchymal stromal cells in the treatment of ischemic stroke, 705
48.12 Controversies and safety analysis of bone-marrow-derived mesenchymal stromal cells in the treatment of ischemic stroke, 706
48.12.1 Conflicting results in animal models, 706
48.12.2 Combined transplantation of mesenchymal stromal cells and neural stem/precursor cells, 706
48.13 Conclusions and perspectives, 707
Acknowledgments, 707
References, 707

**49** The role of mesenchymal stromal cells in spinal cord injury, 714
*P. Jendelova, L. Machova-Urdzikova, and E. Sykova*

49.1 The central nervous system, 714
49.2 Spinal cord injury, 714
49.3 Cell therapy, 715
49.3.1 Mesenchymal stromal cells, 716
49.4 Chronic spinal cord injury, 721
49.5 Cellular transplants for spinal cord injury, 722
49.5.1 Use of hematopoietic stem/progenitor cells for spinal cord injury, 722
49.5.2 Use of mesenchymal stromal cells for spinal cord injury, 723
49.6 Conclusions, 723
Acknowledgments, 725
References, 725

**50** The role of mesenchymal stromal cells in the treatment of ulcerative colitis and Crohn's disease, 730
*Céline Gregoire, Chantal Lechanteur, Alexandra Briquet, Etienne Baudoux, Olivier Giet, Olivier Delloye, Frédéric Baron, Edouard Louis, and Yves Beguin*

50.1 Inflammatory bowel diseases, 730
50.2 Pathogenesis of inflammatory bowel diseases, 731
50.3 Treatment of Crohn's disease, 734
50.3.1 Current treatment options for Crohn's disease, 734
50.3.2 Potential treatment options, 735
50.4 Treatment of ulcerative colitis, 737
50.4.1 Current treatment options for ulcerative colitis, 737
50.4.2 Potential new treatment options, 737
50.5 Properties of mesenchymal stromal cells, 737
50.5.1 Immunomodulation, 738
50.5.2 Immune tolerance, 739
50.5.3 Tissue regeneration, 740
50.5.4 Homing, 740
50.5.5 Differentiation and stimulation of tissue repair, 740
50.6 Mesenchymal stromal cell administration in inflammatory bowel diseases, 740
50.6.1 Mesenchymal stromal cell administration for fistulizing Crohn's disease, 741
50.6.2 Autologous mesenchymal stromal cell administration for fistulizing Crohn's disease, 741
50.6.3 Allogeneic mesenchymal stromal cell administration for fistulizing Crohn's disease, 742
50.6.4 Autologous mesenchymal stromal cell administration for luminal inflammatory bowel diseases, 742
50.6.5 Allogeneic mesenchymal stromal cell administration for luminal inflammatory bowel diseases, 742
50.7 The future of mesenchymal stromal cell treatment in inflammatory bowel diseases, 743
50.7.1 Ongoing protocols, 743
50.8 Issues to be resolved, 744
50.8.1 Source of mesenchymal stromal cells, 744
50.8.2 Autologous versus allogeneic mesenchymal stromal cells, 745
50.8.3 Dosage and modalities of administration, 745
50.8.4 Concomitant use of other drugs, 745
50.9 Safety, 745
50.10 Conclusions, 745
References, 746

**51** Mesenchymal stromal cells targeting kidney disease: benefits of a combined therapeutic approach, 754
*Brooke M. Huuskes and Sharon D. Ricardo*

51.1 Introduction, 754
51.2 Immune modulation and protective effects of mesenchymal stromal cells, 754
51.3 Mesenchymal stromal cell homing, recruitment, and tracking, 757
51.4 Mechanisms of kidney injury and capacity for repair, 759
51.5 Kidney injury and repair in balance with fibrosis, 759
51.6 Mesenchymal stromal cells as delivery tools for therapies, 760
51.7 Clinical trials with mesenchymal stromal cells, 761
51.8 The antifibrotic functions of relaxin, 763
51.9 Combination therapy using mesenchymal stromal cells and relaxin, 764
51.10 Conclusions, 764
References, 765

**52** The biology and potential clinical applications of mesenchymal stromal cells in diseases of the lung, 770
*Yuben P. Moodley, Jesse D. Armitage, and Dino B.A. Tan*

52.1 Introduction to lung disease, 770
52.1.1 The global burden of lung disease, 770
52.1.2 The pathogenesis of lung diseases, 770
52.1.3 The range of lung diseases, 771
52.2 What are stem cells?, 771
52.3 What are mesenchymal stromal cells?, 771
52.4 Lung-resident mesenchymal stromal cells, 772
52.5 Tracking mesenchymal stromal cells in the body, 772
52.6 The properties of mesenchymal stromal cells that favor repair, 772
52.6.1 Avoidance of immune recognition, 772
52.6.2 Mechanisms of mesenchymal stromal-cell-mediated immunomodulation, 772
52.6.3 Mesenchymal stromal-cell-mediated repair via trophic factors, 775
52.7 Mesenchymal stromal cells as delivery agents for drugs, 775
52.7.1 Viral transduction, 775
52.7.2 Genetic modulation, 776
52.7.3 Nanoparticle incorporation, 776
52.7.4 Surface modification, 776
52.7.5 Preconditioned mesenchymal stromal cells, 776
52.8 Preclinical and clinical studies of mesenchymal stromal cells in pulmonary diseases, 776
52.8.1 Idiopathic pulmonary fibrosis, 776
52.8.2 Chronic obstructive pulmonary disease, 779
52.8.3 Acute lung injury and acute respiratory distress syndrome, 780
52.9 Challenges in mesenchymal stromal cell administration in lung diseases, 781
52.9.1 Optimal dosage of mesenchymal stromal cells, 781
52.9.2 Timing of mesenchymal stromal cell administration, 782
52.10 Summary and conclusions, 782
References, 782

**53** The role of mesenchymal stromal cells in diseases of the lung, 787
*Kerry Atkinson*

53.1 Introduction, 787
53.2 Pulmonary fibrosis, 787
53.2.1 Animal models, 788
53.2.2 Clinical trials of mesenchymal stromal cells, 788
53.3 Asthma, 788
53.3.1 Preclinical models, 790
53.3.2 Clinical trials of mesenchymal stromal cells, 790
53.4 Obliterative bronchiolitis, 790
53.4.1 Preclinical animal models, 790
53.4.2 Clinical trials of mesenchymal stromal cells, 791
53.5 Chronic obstructive pulmonary disease and emphysema, 791
53.5.1 Preclinical animal models, 792
53.5.2 Clinical trials with mesenchymal stromal cells, 792
53.6 Bronchopulmonary dysplasia, 792
53.6.1 Preclinical animal models, 792
53.6.2 Clinical trials using mesenchymal stromal cells, 792
53.7 Acute respiratory distress syndrome and acute lung injury, 792
53.7.1 Preclinical animal models, 793
53.7.2 Clinical trials with mesenchymal stromal cells, 793
53.8 Conclusions, 793
References, 793

**54** Mesenchymal stromal cells for the treatment of autoimmune diseases, 794
*Christopher N. Lewis and Jacques Galipeau*

54.1 Cell biology of endogenous mesenchymal stromal cells, 794
54.1.1 Mesenchymal stromal cells coordinate hematopoietic stem cell development, 795
54.1.2 Mesenchymal stromal cells and central tolerance in the bone marrow, 795
54.2 Cell biology of mesenchymal stromal cells in culture, 796
54.2.1 Mesenchymal stromal cells and B cell immunosuppression, 797
54.2.2 Mesenchymal stromal cell and T cell co-culture assays, 797
54.3 Immunosuppression: lessons from oncology, 797
54.3.1 Programmed death ligand 1 and immunosuppression by tumors, 798
54.3.2 Programmed death ligand 1 and immunosuppression by mesenchymal stromal cells, 798
54.3.3 Indoleamine 2,3-dioxygenase and immunosuppression by tumors, 799
54.3.4 Indoleamine 2,3-dioxygenase and immunosuppression by mesenchymal stromal cells, 799
54.4 Mesenchymal stromal cell response to inflammatory signals: licensing and integration, 800
54.4.1 Mesenchymal stromal cells and complement, 800
54.4.2 Mesenchymal stromal cells and toll-like receptors, 801
54.4.3 Interferon-$\gamma$ in the immune response, 802

54.4.4 Mesenchymal stromal cells and interferon-γ, 803
54.4.5 Tumor necrosis factor-**α** in the immune response, 803
54.4.6 Synergy of interferon-**γ** and tumor necrosis factor-**α** in mesenchymal stromal cells, 804
54.5 Strength of signal and integration, 804
54.6 Clinical applications of mesenchymal stromal cells for immune-mediated diseases, 806
54.6.1 How *in vitro* data inform assessment of clinical efficacy, 806
54.6.2 Random donor, industrial scale, 806
54.6.3 Allogeneic mesenchymal stromal cells, low passage, 807
54.6.4 Autologous mesenchymal stromal cells for autoimmune diseases, 808
54.7 Conclusions and next steps, 809
References, 809

**55** The role of mesenchymal stromal cells in bacterial infection, 814
*Sailaja Ghanta, Konstantin Tsoyi, and Mark A. Perrella*

55.1 Introduction, 814
55.2 Experimental models of bacterial infection and sepsis, 815
55.3 Effects of mesenchymal stromal cells on the innate immune response, 816
55.4 Effects of mesenchymal stromal cells on the adaptive immune response, 819
55.5 Antimicrobial activity of mesenchymal stromal cells, 819
55.6 Mesenchymal stromal cells and endothelial/epithelial dysfunction, 819
55.7 Mesenchymal stromal cells and effect on organ injury in infection, 819
55.8 Mesenchymal stromal cell cytokine and growth factor production, 820
55.9 Toll-like receptors and mesenchymal stromal cells, 821
55.10 Mesenchymal stromal cell homing, 821
55.11 Mesenchymal stromal cell response to oxidative stress, 821
55.12 Paracrine effects of mesenchymal stromal cells, 821
55.13 Transcriptomic analysis of mesenchymal stromal cell therapy in sepsis, 822
55.14 Summary, 822
References, 822

**56** The use of mesenchymal stromal cells in solid organ transplantation, 825
*Céline Gregoire, Alexandra Briquet, François Jouret, Chantal Lechanteur, Etienne Baudoux, Olivier Giet, Olivier Delloye, Frédéric Baron, Olivier Detry, and Yves Beguin*

56.1 Introduction, 825
56.2 Potential effects of mesenchymal stromal cells in solid organ transplantation, 825
56.3 Immunomodulation, 826
56.4 Tissue and organ regeneration, 826
56.5 Prevention of ischemia–reperfusion injury, 826
56.6 Mesenchymal stromal cell administration in solid organ transplantation, 826
56.6.1 Kidney transplantation, 826
56.6.2 Liver transplantation, 829
56.6.3 Heart transplantation, 831
56.6.4 Lung transplantation, 831
56.6.5 Pancreas and islet transplantation, 831
56.6.6 Bowel transplantation, 832
56.7 Conclusions, 832
References, 832

**57** The role of mesenchymal stromal cells in allogeneic hematopoietic stem cell transplantation, 836
*Kerry Atkinson*

57.1 The immunobiology of allogeneic hematopoietic stem cell transplantation, 836
57.1.1 Graft rejection and late marrow failure, 836
57.1.2 Graft-versus-host disease, 836
57.1.3 The graft-versus-leukemia effect, 837
57.1.4 The recipient's response to infection, 837
57.2 The immunobiology of mesenchymal stromal cells, 837
57.3 The role of mesenchymal stromal cells in the expansion of hematopoietic stem cells, 837
57.4 The role of mesenchymal stromal cells in marrow graft rejection, 837
57.5 The role of mesenchymal stromal cells in the prevention of acute graft-versus-host disease, 838
57.6 The role of mesenchymal cells in the treatment of corticosteroid-refractory acute graft-versus-host disease, 838
57.7 The mesenchymal stromal cell exosome: a substitute for the mesenchymal stromal cell?, 839
References, 839

**58** The role of mesenchymal stromal cells in the management of skin wounds, 841
*Sung-Whan Kim*

58.1 Introduction, 841
58.2 The wound healing process, 841
58.3 The role of mesenchymal stromal cells in the wound healing process, 842
58.3.1 Immune modulation, 842
58.3.2 Antimicrobial activity, 842
58.3.3 Chemotactic and migratory activities, 842
58.3.4 Paracrine activity, 842
58.3.5 Differentiation, 842
58.4 Conclusions and the future, 842
References, 843

**59** The role of mesenchymal stromal cells in skin wound healing, 845
*Miao Teng and Hengshu Zhang*

59.1 Summary, 845
59.2 Introduction, 845
59.3 The role of bone-marrow-derived mesenchymal stromal cells in wound healing, 845
59.4 The role of adipose-tissue-derived mesenchymal stromal cells in wound healing, 849
59.5 The role of mesenchymal stromal cells from placental tissues in wound healing, 851
59.6 The role of mesenchymal stromal cells from dermal tissue in wound healing, 852
59.7 The role of mesenchymal stromal cells from blood in wound healing, 853
59.8 Questions and challenges regarding mesenchymal stromal cell administration in wound healing, 853
59.9 Conclusions, 853
References, 853

## Section VII: Mesenchymal stromal cells as delivery vehicles for therapeutic agents

**60** The role of mesenchymal stromal cells in human brain tumors, 859
*Brittany C. Parker Kerrigan, Tal Shahar, Shinji Yamashita, and Frederick F. Lang*

60.1 Introduction, 859
60.2 Mesenchymal stromal cells in the therapy of human gliomas, 860
60.3 Cellular therapy for gliomas, 860
60.4 The advantages of mesenchymal stromal cells in clinical use, 861
60.5 The rationale for using mesenchymal stromal cells in glioma therapy, 861
60.6 Mechanisms underlying mesenchymal stromal cell tropism for gliomas, 863
60.7 Strategies to enhance mesenchymal stromal cell homing to gliomas, 864
60.8 Types of therapeutic cargo, 864
60.8.1 Secreted proteins, 864
60.8.2 Prodrug enzymes, 865
60.8.3 Replication-competent oncolytic viruses, 865
60.8.4 Antibodies, 866
60.8.5 Nanoparticles, 866
60.9 Delivery routes of mesenchymal stromal cells in clinical applications, 866
60.10 Mesenchymal stem cells in the biology of gliomas, 867
60.11 Controversy over tumor-associated mesenchymal stromal cells in solid tumors and gliomas, 867
60.12 A model of mesenchymal stromal cells in glioma biology, 868
60.13 Prospects for clinical use of bone-marrow-derived mesenchymal stromal cells in glioma therapy, 868
References, 869

**61** Mesenchymal stromal cells as gene delivery vehicles to treat nonmalignant diseases, 873
*Julie R. Beegle, Jan A. Nolta, and Fernando A. Fierro*

61.1 Introduction, 873
61.2 What are mesenchymal stromal cells?, 873
61.3 Genetic modification of mesenchymal stromal cells, 874
61.3.1 Safety concerns, 874
61.3.2 Choice of vector system, 874
61.4 Preclinical models of gene-modified mesenchymal stromal cells: mesenchymal stromal cell migration and survival, 875
61.5 Gene-modified mesenchymal stromal cells as immune modulators, 877
61.6 Gene-modified mesenchymal stromal cells in skeletal disorders, 878
61.7 Gene-modified mesenchymal stromal cells in cardiovascular disease, 880
61.8 Gene-modified mesenchymal stromal cells in kidney disease, 881
61.9 Gene-modified mesenchymal stromal cells in neurological disease, 881
61.10 Gene-modified mesenchymal stromal cells in other nonmalignant diseases, 883
61.10.1 Hemophilia, 883
61.10.2 Metachromatic leukodystrophy, 883
61.10.3 Mucopolysaccharidosis type VII, 883
61.10.4 Diabetes mellitus, 883
61.11 Conclusions and future directions, 883
References, 885

**62** Gene therapy for cancer using mesenchymal stromal cells, 892
*Ryosuke Uchibori and Keiya Ozawa*

62.1 Introduction, 892
62.1.1 Biological characteristics of mesenchymal stromal cells, 892
62.1.2 Immunomodulatory effects of mesenchymal stromal cells on immune cells, 893
62.1.3 Tumor homing of mesenchymal stromal cells, 893
62.2 Applications of genetically engineered mesenchymal stromal cells for cancer therapy, 893
62.2.1 Interferons, 893
62.2.2 Interleukins, 894

62.2.3 Chemokines, 894
62.2.4 Suicide genes, 894
62.2.5 Other approaches, 894
62.3 Molecular mechanisms of mesenchymal stromal cell accumulation at tumor sites, 894
62.3.1 Migratory factors, 895
62.3.2 Interactions between mesenchymal stromal cells and endothelial cells, 895
62.4 Considerations in the use of genetically engineered mesenchymal stromal cells in cancer therapy, 895
62.5 Summary and conclusions, 896
References, 896

## Section VIII: The present and the future

**63** Breaking news, 901
*Kerry Atkinson*

63.1 *In vitro* laboratory studies, 901
63.2 Preclinical *in vivo* animal studies, 903
63.3 Clinical trials, 908
63.4 Regulatory approval for marketing mesenchymal stromal cell products, 909
References, 909

**64** Reconciling the stem cell and paracrine paradigms of mesenchymal stem cell function, 912
*Siddaraju V. Boregowda and Donald G. Phinney*

64.1 Summary, 912
64.2 Introduction, 912
64.3 The stem cell paradigm revisited, 913
64.4 The paracrine paradigm, 914
64.4.1 "Mesenchymal stem cell pharmacology": cells are not drug-like, 915
64.4.2 Priming to enhance mesenchymal stem cell paracrine action also impacts cell growth and survival, 916
64.4.3 Licensing of immunomodulatory activity biases cell differentiation, 916
64.5 Modeling mesenchymal stem cell function using lessons learned from immunology, 916
64.6 A stem-cell-centric view of mesenchymal stem cells, 919
64.7 Closing remarks, 920
References, 920

Glossary, 927

# Editor's preface

Serendipity plays a role in the lives of most, if not all, people. I was training in internal medicine at the Royal Sussex County Hospital in Brighton, UK, in 1970 when we had a number of young adults admitted with acute leukemia. We referred them to the Royal Marsden Hospital in Sutton, Surrey, which is a hospital that deals only with cancer. I got to know my opposite number there, Dr Sandy Patterson, and one day on the phone he asked me if I was interested in a job there. I said I was, had an interview, and got the job. During my rotation in the Adult Leukemia Unit run by Professor Gordon Hamilton-Fairley, Professor Tim McElwain, and Professor Ray Powles it quickly became evident to me that adults with acute leukemia, while they would often attain remission with combination chemotherapy, almost all relapsed and subsequently died. At the end of the 1960s and in the early 1970s Professor E Donnall Thomas and his team in Seattle, Washington, USA, began their pioneering work on allogeneic bone marrow transplantation for people with otherwise incurable hematologic malignancies. He received the Nobel Prize in Medicine for this work in 1990. Mac and Ray had the foresight to introduce this at the Royal Marsden, and so I got my first exposure to this therapy, which, although difficult and dangerous, miraculously cured some recipients, acting in part by the as then undescribed process known as the graft-versus-leukemia effect, mediated by T cells in the donor bone marrow. Amazing stem cell biology fact number 1: the donor's cells (usually) engraft and the reconstituted hematopoietic and immune systems in the recipient remain (usually) completely of donor origin. Thus, if a sister receives a hematopoietic stem cell (HSC) graft from her brother, her blood and immune system cells will carry an XY chromosome and not an XX chromosome. I still find this amazing. I was hooked and I did a 3 month fellowship at the Fred Hutchinson Cancer Research Center in Seattle before joining the staff working with Professor Rainer Storb in the laboratory and as an attending physician on the ward for 4 years. My wife Pauline is Australian and wanted to return there. Professor Jim Biggs had just started Australia's first bone marrow transplant program and I joined him at St Vincent's Hospital, Sydney, in 1981. In 1996 Dr Chris Juttner, who had been running an equivalent bone marrow transplant program in Adelaide, had become Vice-President of Clinical and Regulatory Affairs at Systemix Inc., a biotechnology company started by Professor Irv Weissman of Stanford University with its intellectual property wrapped around the $CD34^+$ $CD90^+$ phenotype of human HSCs. Chris asked me if I would consider running Systemix's HSC trials in the USA and Europe. This was an exciting if volatile experience. Systemix closed down 2 years later and I subsequently took a position as Vice President of Clinical and Regulatory Affairs at Osiris Therapeutics Inc., a biotechnology company in Baltimore, USA, whose intellectual property covered human mesenchymal stem cells (MSCs). Amazing stem cell biology fact number 2: I listened in astonishment as scientists at Osiris told me about the apparent lack of need for histocompatibility matching between MSC donors and MSC recipients, thus opening the door to the possibility of cryopreserved allogeneic MSC banks with an "off-the-shelf" approach to their use in clinical trials. This hooked me on MSCs and is the reason, 15 years later, for putting this book together.

It is interesting, and somewhat sobering, to compare the clinical translation of these two adult stem cell types, both discovered some 50 years ago.

After the discovery of the human leukocyte antigens (HLA) of the major histocompatibility complex (MHC), Dausset and van Rood recognized in 1958 that these antigens followed the Mendelian principles of inheritance. In 1968 Epstein and coworkers published their work on the development of antisera for typing dog leukocyte antigens (DLA). These reagents enabled Storb, Thomas, and their colleagues in Seattle to define the principles of bone marrow transplantation in large outbred animals. They used littermate beagle donor–recipient pairs that were either DLA-identical or nonidentical, as well as beagle donor–recipient pairs that were DLA nonidentical and unrelated to each other. They found that 10 Gy (1000 rads) of total body irradiation enabled donor marrow engraftment in littermate DLA-identical recipients. They examined an array of immunosuppressive agents to determine that methotrexate (at that time) was the optimal prophylaxis for graft-versus-host disease (GVHD) posttransplant. They found that antithymocyte globulin could be effective treatment for acute GVHD in some cases. With the principles established in the canine model, Thomas and the Seattle team began their clinical trials in allogeneic HSC transplantation at the end of the 1960s using sibling donor–recipient pairs who were genotypically identical for the HLA-A, -B, and -DR antigens. They found that allogeneic HLA-identical bone marrow transplantation could cure otherwise incurable hematologic malignancies. Gradually, a number of improvements resulted in allogeneic HSC transplantation becoming part of mainstream clinical medicine, where it remains. There was thus a relatively short interval between the discovery of HSCs and their translation to the clinic.

Apart from their biology, HSCs differ in two significant ways from MSCs. First, HSCs are relatively easy to procure; second, there is no intellectual property around them: they are in the public domain. In contrast, MSCs require simple but expensive *ex vivo* expansion to obtain enough numbers for clinical use – primarily of their progeny, mesenchymal stromal cells. Second, there is a swathe of intellectual property around them. These features have probably slowed their translation to the clinic, and at present, 50 years after their discovery by Friedenstein and colleagues, there is not yet a definitive role for them in mainstream clinical medicine. They have a fascinating biology, and research progress continues to expand exponentially.

There at least two potential alternatives to allogeneic MSC transplantation using unrelated MSCs from unrelated donors. One is the use of the autologous stromal vasculature fraction of fat tissue obtained by liposuction, concentrated by centrifugation and then administered directly to the patient who donated the fat. The cells present in the fraction include preadipocytes, mesenchymal stromal cells, endothelial progenitor cells, T cells, B cells, and mast cells. This approach received a boost in 2013 when the cell membrane markers of these cells were better defined (see Chapter 2). The fact that it is an autologous procedure and is minimally manipulated makes it a theoretically attractive candidate, at least when direct injection into a localized area is needed. However, like every other experimental therapeutic agent, they need to proceed through the normal channels of human research ethic committee scrutiny and, if approved, follow the phase I, II, and III clinical trial pathway.

At the other end of the scientific (and very recently clinical) spectrum is the MSC exosome (Chapters 19 and 38). These remarkable agents transport a cargo of mRNA, microRNAs, and proteins and deliver them to the appropriate target cell. Thus, acellular therapy, providing the MSCs' "goodies" without the need for the cells themselves may be possible. Will there develop a new medical specialty of exomology?

So much to do, so many avenues to explore. It will require scientists and clinicians working closely together. It will take time – witness the fact that HSC transplantation started in the clinic in the 1960s and 1970s and is still evolving. It will take the degree of erudition and hard work that the chapter authors in this book have displayed. I would like to acknowledge them for their scholarship and hard work and to thank all of them for their contribution. The book would be nothing without them. I would also like to thank Mindy Okura-Marszycki at John Wiley and Sons for championing the proposal to commission the book and Stephanie Dollan, Purvi Patel and Shikha Pahuja, Nuraiziah Johri who provided all the logistical support required to actually produce the book; in addition I would like to acknowledge the skill and hawk-like vision of Peter Lewis, the book's copy editor, who never failed to get back to me even while on holiday. I have learned an enormous amount from editing it.

## 1.1 Nomenclature

This book is front-ended by a brief description of my own view of the "MSC" – stem cell or stromal cell or both – and is a polarized view. The book is back-ended by a much more nuanced and erudite interpretation written by Siddaraju Boregowda and Don Phinney of the two populations and allows for a neat amalgam of the two. This shows that the term "mesenchymal stem/stromal cell" is not as much of an exercise in hedge-sitting as I had previously viewed it. Drs Boregowda and Phinney make the excellent point that one cannot know what mesenchymal cells at what time in their development are present in a given bulk preparation unless detailed assays of true stem cells are carried out. This is often not practical and is never easy. However, I still find the term "mesenchymal stem/stromal cell" disconcerting when it is applied to studies using *ex vivo* expanded mesenchymal cells without any attempt being made to see if there are true mesenchymal stems cells contained within the population. If mesenchymal stromal cells are the subject of a chapter I have used mesenchymal stromal cells and their abbreviation "MSC." If mesenchymal stem cells are the subject of a chapter or part of a chapter I have referred to them as such and have not used any abbreviation for them.

## 1.2 The mesenchymal stem cell

In 1970, Till and McCullagh in Canada discovered the hematopoietic stem cell (HSC) [1]. This was the first adult stem cell to be discovered. This discovery was quickly exploited clinically with the introduction in the late 1960s of allogeneic bone marrow transplantation using HLA-identical siblings as donors for people with hematologic malignancies refractory to conventional chemotherapy [2]. Other sources than bone marrow became available, such as peripheral blood stem cells mobilized out of the marrow and into the circulation by the administration of hematopoietic growth factors, several of which were discovered by Don Metcalf in Melbourne, Australia [3]. Subsequently, Eliane Gluckman in Paris demonstrated that blood taken from the umbilical cord immediately after the birth of the baby contained sufficient numbers of HSCs to allow this source to be used in HSC transplantation, at least in children [4]. HSC transplantation has been part of mainstream clinical practice for over 40 years. E. Donnall Thomas, who headed the Adult Leukemia Center at the Fred Hutchinson Cancer Research Center in Seattle, USA, where HSC transplantation was pioneered, was awarded the Nobel Prize in Medicine for this work in 1990.

Stem cells have two properties: they must be able to divide and be self-renewing and they must be able to differentiate down a specific lineage or set of lineages to produce functional cells. In the case of HSCs this was readily shown first in animal models and subsequently in humans that if the recipient's bone marrow was ablated by high-dose chemotherapy or chemoradiotherapy,

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.

donor bone marrow cells infused into the recipient after the high-dose treatment reconstituted the recipient's bone marrow both short term and long term. The HSCs infused were capable of both self-renewal and hematopoietic lineage differentiation to functional erythrocytes, white cells, and platelets. Thus, the recipient's hematopoietic and immune cells are of donor origin posttransplant. That meant that if you transplanted HSCs from a male donor into a female recipient and then karyotyped them, they would have an XY karyotype – and vice versa, a phenomenon that has amazed me ever since.

In the 1960s Alexander Friedenstein *et al.* in Russia discovered a second type of adult stem cell that he called colony-forming units fibroblastic (CFU-Fs), since single cells grew into colonies and were readily distinguishable from HSCs by their adherence to plastic and their fibroblast-like morphology [5]. Friedenstein and Owen called these cells osteoprogenitors. Subsequently, these cells were shown to differentiate to key elements of the skeleton, including bone (osteoblasts), cartilage (chondrocytes), fat (adipocytes), and periosteum (fibroblasts). Additionally, evidence of self-renewal has been shown by Sacchetti and colleagues for osteoprogenitor cells in bone marrow sinusoids that were able to organize a hematopoietic microenvironment [6]. They showed that MCAM/CD146-expressing subendothelial cells in human bone marrow stroma were capable of transferring, upon transplantation, the hematopoietic microenvironment to heterotopic sites, coincident with the establishment of identical subendothelial cells within a miniature bone organ. Establishment of subendothelial stromal cells in developing heterotopic bone marrow *in vivo* occurred via specific, dynamic interactions with developing sinusoids. Subendothelial stromal cells residing on the sinusoidal wall were found to be major producers of angiopoietin 1 – a pivotal molecule of the HSC "niche" involved in vascular remodeling. Their data revealed the functional relationships between establishment of the hematopoietic microenvironment *in vivo*, establishment of skeletal progenitors in bone marrow sinusoids and angiogenesis. Subsequently, Mendez-Ferrer *et al.* confirmed these findings by showing that mesenchymal and HSCs formed a unique bone marrow niche [7]. This area of science was well summarized by Paolo Bianco and colleagues in 2008 [8], 2011 [9], and 2013 [10]; and see Chapter 32.

In 2013, Chan *et al.* took this field several stages further when they described a lineage-restricted, self-renewing common skeletal progenitor (bone, cartilage, and stromal progenitor cell) isolated from the limb bones and bone marrow tissue of fetal, neonatal, and adult mice [11]. This cell clonally produced chondrocytes (cartilage-forming) and osteogenic (bone-forming) cells and at least three subsets of stromal cells that exhibited differential expression of cell surface markers, including CD105 (endoglin), CD90 (Thy-1) and 6C3 (ENPEP glutamyl aminopeptidase (aminopeptidase A)). These three stromal subsets exhibited differential capacities to support hematopoietic (blood-forming) stem and progenitor cells. Although the 6C3-expressing subset demonstrated functional stem cell niche activity by maintaining primitive HSC renewal *in vitro*, the other stromal populations promoted HSC differentiation to more committed lines of hematopoiesis, such as the B cell lineage. Gene expression analysis and microscopic studies revealed a microenvironment in which $CD105^{-}$, Thy-$1^{-}$, and 6C3-expressing marrow stromal cells collaborated to provide cytokine signaling to HSCs and more committed hematopoietic progenitors. As a result, within the context of bone as a blood-forming organ, this bone/cartilage/stromal progenitor cell was found to play a critical role in supporting hematopoiesis through its generation of diverse osteogenic and hematopoietic-promoting stroma, including HSC supportive $6C3^{+}$ niche cells.

Thus, the term *skeletal stem cell* for these cells is well founded scientifically and, therefore, bone or bone marrow mesenchymal cells should be the best candidate cells for repair of disorders of the skeletal system.

True mesenchymal stem cells are rare cells with a frequency in bone marrow of between 1 in $10^4$ and 1 in $10^5$. To enable both experimental and clinical trials of mesenchymal cells to be performed, it has been necessary to expand them in *in vitro* cultures. The cells obtained are not mesenchymal stem cells, but rather their progeny – often mistakenly called mesenchymal stem cells but in fact they are mesenchymal stromal cells or mesenchymal progenitor cells and their tissue of origin should be indicated, for example bone marrow mesenchymal stromal cells. They are also known as CFU-F as indicated above in Friedenstein's initial descriptions of them, in which case their organ or tissue of origin should be included – for example, bone marrow CFU-F, cardiac CFU-F, adipose tissue CFU-F, and so on.

Table 1.1 compares and contrasts allogeneic hematopoietic stem cells with allogeneic mesenchymal stem cells.

In the rest of this chapter the term mesenchymal stromal cells will be used and the abbreviation "MSCs" will be applied only to this term.

## 1.3 The mesenchymal stromal cell

While it has been shown that MSCs can differentiate *in vivo* to bone and tendon, they have also been shown to be immunomodulatory of both the innate and adaptive immune systems (see Chapters 33 and 34). Additionally, MSCs have been shown to mediate therapeutic benefit in a wide range of animal models of disease and in clinical trials in many diseases apart from musculo-skeletal disorders. It has been noted in many studies that detection of administered MSCs is difficult beyond a few days after their administration, and there is evidence that they can mediate a therapeutic benefit by secretion of proteins appropriate for repair of tissue or organ damage. Thus, they have been described by Caplan and colleagues as an injury drug store [12,13]. Additionally, they do not circulate in blood but have been found to be perivascular cells surrounding the endothelial cells [14]. Thus, they can be obtained from any vascularized tissue. Presumably this is how they "work" in damaged

**Table 1.1** Comparison of allogeneic hematopoietic stem cells with allogeneic mesenchymal stem cells.

| Parameter | Allogeneic hematopoietic stem cell | Allogeneic mesenchymal stem cell |
|---|---|---|
| Year discovered | 1961 | 1966 |
| Years to first clinical trial | 9 | 32 |
| Safe | No – can cause fatal graft-versus-host disease | Safe |
| Effective | Yes – can cure otherwise incurable diseases | Unknown. Phase III clinical trial results awaited. Likely to be useful in disorders of the musculo-skeletal system |
| Part of mainstream clinical medicine | Yes | No |
| Easy to harvest | Yes – from bone marrow, mobilized peripheral blood, or cord blood banks | No – Require careful selection (see Chapter 32) |
| Enmeshed in intellectual property rights | No | Yes |

organs or tissues – they are already present at the site of injury as long as that tissue is vascularized. While it is thought that all MSCs are pericytes, not all pericytes are MSCs; for example, smooth muscle cells form part of the vessel wall of arterioles, arteries, and larger veins. Despite their presence in almost all tissues it is of interest that they have a tropism for inflamed tissue and will home to such tissue if injected intravenously (see Chapters 22–24).

In 2006 the International Society for Cell Therapy proposed the following minimal criteria for the definition of MSCs. First, MSCs must be plastic-adherent when maintained in standard culture conditions (Figures 1.1 and 1.3). Second, MSCs must express CD105 (endoglin), CD73 (lymphocyte-vascular adhesion protein 2 (L-VAP-2), also known as 5′ nucleotidase) and CD90 (Thy-1), and must lack expression of CD45 (a pan-leukocyte marker), CD34 (a sialomucin present on hematopoietic stem cells and endothelial cells), CD14 (a co-receptor for the detection of bacterial lipopolysaccharide), CD11b (integrin alpha M, ITGAM), CD79A (which identifies the B cell antigen receptor complex-associated protein alpha chain and MB-1 membrane glycoprotein), CD19 (also a B cell antigen), and the major histocompatibility complex class II molecules. Third, MSCs

must differentiate to osteoblasts, adipocytes, and chondroblasts *in vitro* [15] (Figure 1.2 ci, cii and ciii).

This area took another significant step forward with the publication in 2013 of a joint statement from the International Federation for Adipose Therapeutics and Science and the International Society for Cellular Therapy on stromal cells from the adipose tissue-derived stromal vascular fraction and culture expanded adipose tissue-derived stromal/stem cells (ADSCs) [16].

The centrifuged but uncultured stromal vascular fraction was identified as being $CD45^-$, $CD235a^-$ (glycophorin A), $CD31^-$ (platelet endothelial cell adhesion molecule), and $CD34^+$, while cell surface positivity for CD13 (alanine aminopeptidase), CD73, CD90, and CD105 were best used in conjunction with CD45, CD235a, and CD31 [16].

*Ex vivo*-expanded ADSCs retain cell surface markers expressed by other mesenchymal stromal/stem cells, including CD44 (the hyaluronic acid receptor), CD73, CD90, and CD105, and are also negative for CD45 and CD31, but can be distinguished from bone-marrow-derived MSCs by being $CD36^+$ (fatty acid translocase, also known as glycoprotein IIIb) and $CD106^-$ (vascular cell-adhesion molecule 1) [16].

## 1.4 The mesenchymal stromal cell exosome and extracellular vesicles

Extracellular vesicles (EVs) are membrane vesicles that are released by many cell types into the extracellular space and consist of several classes, including exosomes, microvesicles, ectosomes, membrane particles, and exosome-like vesicles or apoptotic bodies (see Chapters 20 and 38 for detailed descriptions). However, the defining parameters for each of these different classes are not definitive, and the use of the terms exosomes, microvesicles, and microparticles is often ambiguous and not rigorously qualified. Generally, EVs can be formed by either inward budding of endolysosomal vesicles followed by exocytosis (e.g., exosomes), or shedding from the plasma membrane (e.g., microvesicles). They have attracted much interest

from the biomedical research community because of their potential as sources of biomarkers for diseases, therapeutic agents, or vehicles for drug delivery. Generally, EVs carry a cargo of proteins and nucleic acids that reflect their cell of origin and the pathologic or physiologic state of their cell source. In addition, these EVs with their cargoes could be internalized by other cells as a form of intercellular communication, making these vesicles potential therapeutic agents or delivery vehicles of therapeutic agents.

The exosome is the best characterized of all the EVs described to date and can be differentiated from other EVs by its biogenesis. The exosome is the only EV known to be derived from endosome, and this endosomal origin of exosomes is reflected in its membrane, which is enriched for lipids commonly found in lipid rafts such as cholesterol, sphingomyelin, and ceramide. Lipid rafts are specialized microdomains in the plasma membrane where much of the cellular endocytosis takes place to form endosomes. Subsequent invaginations of the endosomal membrane generate numerous intraluminal vesicles (ILVs) within the multivesicular body (MVB). If the MVB fuses with the plasma membrane, the ILVs are released as exosomes. The process by which cellular proteins and RNAs are selected and loaded into exosomes has not been elucidated. MSC exosomes have been among the best characterized exosomes to date (Chapters 20 and 38).

Recently, MSC exosomes were administered to a person with treatment-refractory grade IV (severe) acute graft-versus-host disease who went into remission with a dramatic alleviation of her disease symptoms and who remained stable for 5 months [17]. If confirmed in clinical trials this might represent a way to exploit the benefits of MSCs without having to administer the cells themselves.

2.1 Introduction, 8
2.2 Historical perspective, 8
2.3 The need for common terminology and definition: the International Society for Cellular Therapy white papers of the mid-2000s, 9
2.4 Updating terminology, 9
References, 10

## 2.1 Introduction

Nomenclature is important in science, not least because it sometimes channels research based on the assumptions that underlie the names we ascribe to cells or biological processes. It can be imagined that if terminology is inaccurate or misleading, advances could be delayed or misdirected. The nomenclature of mesenchymal stem cells and mesenchymal stromal cells has evolved with the field and has been influenced considerably at various times by the prevailing scientific controversies surrounding these cells.

## 2.2 Historical perspective

Friedenstein's seminal studies in the 1960s and 1970s laid the groundwork for the mesenchymal stem cell and mesenchymal stromal cell field. It was not unreasonable that early in the studies he termed the cells mechanocytes or osteogenic stem cells and then marrow stromal cells, but in subsequent work they became known as marrow fibroblasts, underscored by the terminology of his assay of the mesenchymal stromal cell progenitor, CFU-F (colony forming unit–fibroblast) [1].

Subsequent work in the 1970s by Michael Dexter and others identified an adherent cell population present in cultured bone marrow cells that could maintain hematopoiesis for many weeks [2]. Ongoing hematopoiesis *in vitro* was demonstrated with human long-term bone marrow cultures that also depended on an adherent marrow stromal cell population [3]. During the 1980s the term *marrow stromal cells* (abbreviated to MSCs) became well established and was used to distinguish the population from adherent hematopoietic cells such as macrophages and from marrow fibroblasts, which were considered phenotypically and functionally distinct from mesenchymal stem cells and mesenchymal stromal cells by the inability of the former to support long-term hematopoiesis *in vitro* [4].

At that time, research with marrow stromal cells focused on understanding the interactions taking place in this *in vitro* model of the hematopoietic microenvironment and in the processes mediating hematopoiesis. The area was challenging, and advances with the model were relatively limited. During this period, scientific productivity plateaued.

It was in this context that the proposal in 1991 by Arnold Caplan to consider marrow stromal cells as *mesenchymal stem cells* (also then abbreviated to MSCs) captured the attention of many investigators in the field [5], especially after the publication by Pittenger and colleagues in 1999 on the "multilineage potential of adult human mesenchymal stem cells" [6].

This coincided with other studies suggesting the ability of hematopoietic and other cells to undergo transdifferentiation. Although numerous reports supported the notion of the ability of mesenchymal stem or stromal cells to undergo differentiation to cells not only of mesodermal origin, but also of endodermal and even ectodermal origin, almost all lacked evidence of the acquisition of the functional characteristics of the differentiated cells [7]. Moreover, other work refuted earlier reports showing that hematopoietic cells undergo transdifferentiation to cardiac and other cell types [8].

Despite these formidable caveats and the lack of convincing mechanistic data, a consequence of the use of the term "stem" by

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.
© 2017 John Wiley & Sons, Inc. Published 2017 by John Wiley & Sons, Inc.

many investigators in the field was the promotion of the notion that mesenchymal stem or mesenchymal stromal cells could be used as cell *replacement* therapy. An explosion in research on the potential role of these cells in tissue regeneration ensued and continues to the present. However, it has been shown definitively by Méndez-Ferrer *et al.* [9] and Sachetti *et al.* [10] that non-hematopoietic cells in the bone marrow of mice could form new bone on serial transplantation into recipient mice and that this new bone was populated by the recipient's hematopoietic cells. These studies showed that there was indeed a population of rare mesenchymal cells in murine marrow that fulfilled the criteria of stem cells by being able to produce daughter stem cells and to differentiate along at least one line of mesodermal differentiation – osteogenesis. This gave rise to yet another name: skeletal stem cells.

## 2.3 The need for common terminology and definition: the International Society for Cellular Therapy white papers of the mid-2000s

A major concern among investigators in the field in the early 2000s was the lack of a common definition of mesenchymal stem cells or mesenchymal stromal cells among the many papers published in the field. This dilemma was further reflected by the absence of an accepted terminology for the cell population and the persistent notion that the cells under study were invariably *stem cells*. It became increasingly difficult, if not impossible, to compare the results of studies. In response, the Non-hematopoietic Mesenchymal Cell Committee of the International Society for Cellular Therapy (ISCT) prepared two white papers, published in *Cytotherapy*, to address these limitations. The first paper was a clarification of the terminology, emphasizing that while most mesenchymal stem or stromal cells are not stem cells, the bulk population represents a multipotent mesenchymal stromal cell (MSC) population [11]. The second white paper provided minimal criteria for the definition of MSCs [12]. These were as follows. First, MSCs must be plastic-adherent when maintained in standard culture conditions. Second, MSCs must express CD105 (endoglin), CD73 (lymphocyte-vascular adhesion protein 2 (L-VAP-2), also known as 5′ nucleotidase) and CD90 (Thy-1), and must lack expression of CD45 (a pan-leukocyte marker), CD34 (a sialomucin present on hematopoietic stem cells and endothelial cells), CD14 (a co-receptor for the detection of bacterial lipopolysaccharide), CD11b (integrin alpha M), CD79A (which identifies the B cell antigen receptor complex-associated protein alpha chain and MB-1 membrane glycoprotein), CD19 (also a B cell antigen), and the major histocompatibility complex class II molecules. Third, MSCs must differentiate to osteoblasts, adipocytes, and chondroblasts *in vitro*.

This area took another significant step forward with the publication in 2013 of a joint statement from the International Federation for Adipose Therapeutics and Science and the ISCT on stromal cells from the adipose-tissue-derived stromal vascular fraction and culture expanded adipose-tissue-derived stromal/stem cells (ADSCs) [13].

The centrifuged but uncultured stromal vascular fraction was identified as being $CD45^-$, $CD235a^-$ (glycophorin A), $CD31^-$ (platelet endothelial cell adhesion molecule) and $CD34^+$, while cell surface positivity for CD13 (alanine aminopeptidase), CD73, CD90, and CD105 were best used in conjunction with CD45, CD235a, and CD31 [13].

*Ex-vivo*-expanded ADSCs retain cell surface markers expressed by other mesenchymal stromal/stem cells, including CD44 (the hyaluronic acid receptor), CD73, CD90, and CD105, and are also negative for CD45 and CD31, but can be distinguished from bone-marrow-derived MSCs by being $CD36^+$ (fatty acid translocase, also known as glycoprotein IIIb) and $CD106^-$ (vascular cell-adhesion molecule 1) [13].

## 2.4 Updating terminology

It has become increasingly apparent that both the nomenclature and definition of mesenchymal stromal cells requires updating. The field has continued to evolve, and over the past decade more evidence has accumulated that MSCs exert effects on tissue regeneration by mechanisms independent of the regeneration of new tissue. Because of the plethora of anti-inflammatory, anti-apoptotic, pro-angiogenic, and immunosuppressive proteins secreted by MSCs, Dr Caplan later suggested the term "medicinal signaling cell" to describe them – also abbreviated to "MSC." The abbreviation "MSC" in this book, however, refers only to mesenchymal stromal cells.

MSCs can now be derived from many different tissues and exhibit differences in immunophenotype and functional characteristics. To help chart the update, a consortium of international MSC investigators held a series of workshops to address the challenges facing the field, including a reassessment of MSC nomenclature. The consensus of the Nomenclature Working Group has recommended the following terminology for mesenchymal stromal cells [13]: donor type (autologous or allogeneic), species of origin (e.g., human, mouse), tissue source (e.g., bone marrow, adipose tissue, cord blood), mesenchymal cell type (stem cell, stromal cell, or progenitor cell). An example of this would be human allogeneic cord-blood-derived mesenchymal stromal cells.

In summary, it appears that there is indeed a rare population, at least in bone marrow, that fulfills the criteria of mesenchymal stem cells. In addition, there are the undifferentiated progeny of these cells that can be expanded massively in *in vitro* culture and are termed mesenchymal stromal cells or mesenchymal progenitor cells or multipotent mesenchymal stromal cells.

This exciting field is likely to benefit further from adoption of a common nomenclature that more precisely defines the cells under study.

## 3.1 Introduction

Cell-based therapies (other than hematopoietic stem cell (HSC) transplantation, which has been part of mainstream medicine for over four decades) are a new wave in the development of biological agents to treat or cure a wide range of medical conditions, including hereditary, acquired, and degenerative human diseases [1]. Stem cells or their differentiated progeny appear to be powerful candidates for cell therapy and cell-based gene therapy since they have the capacity to undergo extensive replication in an undifferentiated state as well as to proliferate along committed lines of differentiation. They have the potential to differentiate either *in vitro* or *in vivo* into distinct tissues, making them an attractive candidate for clinical applications especially in the field of regenerative medicine.

Mesenchymal stem/stromal cells (MSCs) are a heterogeneous population of multipotent cells that can differentiate into the mesenchymal lineages of fat, bone, tendon, muscle, and cartilage [2]. They have the ability to modulate oxidative stress and secrete cytokines and growth factors that have immunomodulatory, anti-inflammatory, angiogenic, and anti-apoptotic effects [2]. Increasingly, evidence is focusing on these paracrine effects rather than transdifferentiation as a mechanism for MSC-mediated effects in both preclinical models and clinical applications.

MSCs are also of interest because they preferentially migrate to sites of inflammation and injury when injected systemically (see Chapters 22 and 23). They can also be transplanted across major histocompatibility complex (MHC) barriers into immune competent recipients without the need for immune suppression of the recipient before or after MSC administration. This enables them to be cryopreserved as an allogeneic off-the-shelf cellular therapy available for immediate use in acute or chronic medical settings. These remarkable qualities have encouraged clinical trials of MSCs in a range of differing medical conditions with some promising early results. Indeed, two MSC products have received marketing approval by national regulatory authorities: one for the repair of chronic non-union bone fractures using autologous bone-marrow-derived MSCs (in Australia) and one for treatment-refractory acute graft-versus-host disease following allogeneic HSC transplantation in children using allogeneic bone-marrow-derived MSCs (in Canada).

MSCs have been traditionally derived from bone marrow. However, as humans and animals increase in age there is a decrease in MSC production in the bone marrow. Additionally, bone marrow aspiration is a painful procedure. Crisan *et al.* reported that MSCs were a component of the endothelium and thus are present in all vascularized organs [3]. Other tissue sources, such as adipose tissue derived from liposuction aspirates [4–6] and gestational products, including the placenta [7,8] and umbilical cord [9] obtained at term delivery of the baby, have been reported as alternative sources [10]. These alternative sources are more easily accessible than bone marrow, generally less invasive, and larger amounts of MSCs can be obtained compared with bone marrow. Although MSCs from different tissue sources share many biological characteristics, functional

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.
© 2017 John Wiley & Sons, Inc. Published 2017 by John Wiley & Sons, Inc.

and gene expression differences between MSCs from different sources have been reported [11–13]. Some of these differences, such as cell surface phenotype, differentiation potential, transcriptome/proteome characteristics, and immunomodulatory activity, represent specific features of MSCs from a specific tissue source [14–17], while others reflect the heterogeneity of MSC populations from different organs [18]. Still other differences may simply be due to different isolation and culture protocols.

## 3.2 Stem cells

Stem cells are characterized by two major attributes: their unlimited capacity to self-renew and their potential to give rise to progeny that can differentiate into specialized cell types. A true stem cell must be able to self-renew while maintaining an identical and undifferentiated state. In addition, they must be able to differentiate into multiple cell types. Their degree of possession of these qualities determines how potent these cells are.

Stem cells exist at different hierarchical levels in the development of an organism (Figure 3.1). There are pluripotent or totipotent stem cells that occur at one end of the spectrum. These cells arise during fertilization and have the ability to form an entire organism (e.g., the fertilized oocyte, embryonic stem cells, or induced pluripotent stem cells). This type of stem cell can replace cells or tissues from any organ or tissue. However, owing to their unlimited self-renewal and differentiation potential, tumor (teratoma) formation can occur, which increases the risk of using progeny derived from them for clinical application if not all of the original stem cells have differentiated. Examples of such stem cells are embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs). Deriving differentiated tissues and organs from ESCs destroys the embryo, and this has generated significant ethical debate. iPSCs are generated in the laboratory and are not part of the mammalian body. They are not, however, associated with the ethical concerns surrounding ESCs.

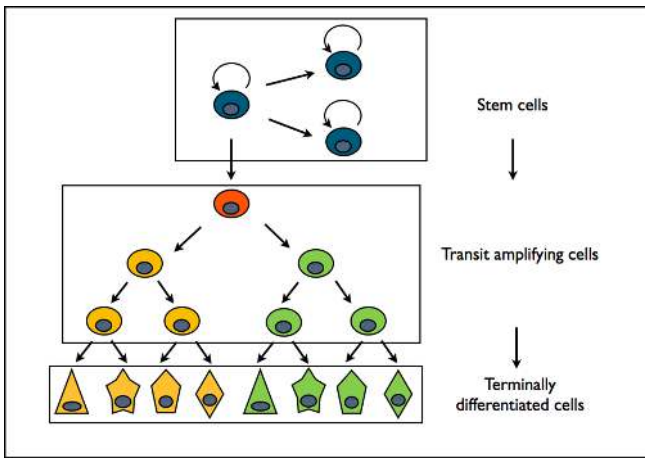

**Figure 3.1** The different hierarchical levels of stem cell potency. Image adapted from Perez-Losada and Balmain [19].

At the other end of the spectrum are adult stem cells, better considered as postnatal stem cells, whose differentiation capability is restricted to the formation of cell types within a single tissue lineage. These cells are multipotent, not pluripotent or totipotent, stem cells and do not form teratomas. Thus, these cells are at present safer for clinical use, albeit more limited in their potential application. HSCs are examples of such stem cells. They can self-renew, as demonstrated by their ability to reconstitute the hematopoietic and immune systems of animals, including humans, whose marrow has been ablated by high-dose total body irradiation and chemotherapy. They can, however, only differentiate to blood and immune system cells [20].

Mesenchymal stem cells are another type of adult multipotent stem cells and were discovered by Friedenstein and his colleagues in the 1960s. The term mesenchymal stem cell was coined by Caplan in 1991 as these cells were able to differentiate into multiple cell types of the mesenchymal lineage (including bone, cartilage, and fat) [21]. However, at this time there was a lack of convincing evidence that such cells could self-replicate into daughter stem cells. This changed when Sacchetti and colleagues demonstrated in 2007 the existence of self-renewing, plastic-adherent $CD146^+$ bone marrow stem cells using serial transplantation experiments in immunocompromised mice [22]. These mesenchymal stem cells are rare, with a frequency in bone marrow of 1 in $10^4$ cells to 1 in $10^5$ cells. In order to secure sufficient numbers of MSCs to perform experiments or for clinical transplantation it is necessary to expand them *ex vivo*, and the cells that are produced are not stem cells as defined previously here [23]. True self-renewing stem cells constitute only a fraction, if any, of such populations, with the majority of cells so produced being a heterogeneous population of progenitor cells called mesenchymal stromal cells, mesenchymal progenitor cells, or transit amplifying cells [24].

In 2005 the International Society for Cellular Therapy proposed that bone-marrow-derived plastic-adherent cells, generally described as 'mesenchymal stem cells,' should be renamed "mesenchymal stromal cells" [23]. Thus, the remainder of this chapter will discuss mesenchymal stromal cells and the abbreviation MSC will be used to denote this type of cell.

## 3.3 Isolation and characterization of bone marrow mesenchymal stromal cells

MSCs were first discovered in the bone marrow by Friedenstein more than 40 years ago [25]. These cells give rise to tissues of mesodermal lineage, including bone, cartilage, muscle, tendons, and adipose tissue [26–33]. Bone-marrow-derived MSCs are a rare cell population (~0.001%) of bone marrow mononuclear cells *in vivo*, resulting in a low yield upon initial isolation. Therefore, as already indicated, *ex vivo* expansion of these cells

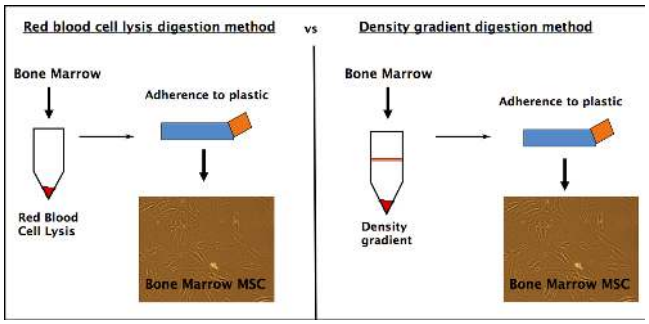

**Figure 3.2** Comparison of the red blood cell lysis and density gradient digestion methods for the isolation of bone-marrow-derived MSCs.

is required to gain sufficient numbers for laboratory experiments or clinical trials. The isolation method consists of the whole marrow being subjected to fractionation using a density gradient such as Percoll for animals or Ficoll in humans. Alternatively, red blood cell lysis can be performed and the cells are then cultured in basal medium such as Dulbecco's modified Eagle's medium and 10–20% fetal calf–bovine serum [18,34–36]. Subsequently, cells are maintained in culture for several days during which contaminating nonadherent hematopoietic cells such as macrophages are depleted (Figure 3.2).

In some instances the property of plastic adherence alone is not sufficient to allow purification of MSCs, as in the case of cells derived from murine bone/bone marrow. Phinney *et al.* [37] reported the presence of hematopoietic $CD45^+$ $CD11b^+$ granulocytic and monocytic precursors in these cultures. Owing to the lack of specific phenotypic markers, these observations led to the development of new methods involving CD34, CD45, and CD11b immunodepletion to generate purified bone marrow MSC preparations [38].

### 3.3.1 Cell surface markers

The International Society for Cell Therapy developed the following criteria for identifying human MSCs [39]. First, MSCs must be plastic-adherent when maintained in standard culture conditions using tissue culture flasks. Second, 95% or more of the MSC population must express the cell surface markers CD105, CD73, and CD90, which are characteristic but not unique markers for MSCs. Additionally, these cells must lack cell surface expression (<2% positive) of CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA class II. Third, the cells must be able to differentiate to osteoblasts, adipocytes, and chondrocytes under *in vitro* differentiating conditions. Other cell surface antigens also characteristic of, but not unique to, MSC populations obtained from various sources include nestin [40], CD29, CD44, CD49b, CD130, CD146, CD166, CD271, CD200, and αV/β5 integrin [3,41–43].

Simmons and other workers suggested that expression of Stro-1 and VCAM-1 can be used to preferentially enrich for multipotent MSCs [44–46]. In addition, it has been reported that CD271 on bone marrow MSCs selects for a subpopulation that has higher clonogenicity, increased paracrine secretion of cytokines, and enhanced engraftment properties [42,47]. However, the phenotype of MSCs can change during *ex vivo* expansion, and this may represent alterations in the biological features of the MSC population involved (see Chapter 7). For example, Stro-1 is present on freshly isolated bone marrow MSCs as well as other tissues. However, expression of Stro-1 is lost from MSCs during *ex vivo* expansion and it cannot be considered a unique MSC marker [48]. Indeed, even at the clonal level there remains diversity within these populations.

Murine MSCs derived from crushing the long bones and obtaining a cellular population from a combination of bone and bone marrow also lack specific cell surface markers, thus requiring multiple cell surface marker co-expression to assist in identification. Murine MSCs have been reported to express Sca-1, CD90, CD29, CD44, CD49e, CD51, CD81, CD24, CD105 and lack expression of CD45, CD11b, CD31, and CD117 [49]. They also display a transient cell surface phenotype related to the duration of *ex vivo* expansion in culture. The loss of CD90, CD15, and CD309 has been associated with *ex vivo* expansion [50]. The lack of a unique marker or markers for MSCs is a limitation in current MSC research.

We compared the cell surface markers present on adult human bone marrow-derived MSCs with those on term placenta-derived MSCs and with those on umbilical cord-blood-derived unrestricted somatic stem cells (USSCs) (Table 3.1). Based on a standard panel of MSC-descriptive antibodies, all the lines were virtually identical. All expressed CD29, CD44, CD49d, CD49e, CD73, CD90, CD105, CD146, CD49e, and CD166. All three cell populations were negative for Stro-1, CD45, CD34, CD50, CD106, and the pluripotency markers SSEA-4, Tra 1–60, and Tra1-81 [51].

Despite lacking a specific cell surface marker or markers, MSCs are unique among nucleated mammalian cells in that they stimulate little or no allogeneic reactivity when administered to MHC-unmatched adult immune competent recipients, perhaps due to their lack, at least in the human, of expression of co-stimulatory cell surface molecules such as CD40, CD80, or CD86 that are involved in the activation of T cells that mediate rejection of foreign tissues [52–56]. Furthermore, they are actively suppressive of T cell, NK cell, dendritic cell, and B cell function [52,53,57].

### 3.3.2 Chemokine receptor display

We also compared the cell surface and intracellular chemokine receptor display on adult human bone-marrow-derived MSCs with those on term-placenta-derived MSCs and with those on cord-blood-derived USSCs (Table 3.2). The surface and intracellular chemokine displays of bone marrow MSCs and placental MSCs were very similar. USSCs differed from bone marrow MSCs and placental MSCs by showing positive staining for the presence of intracellular CCR8, CCR10, and CCR11 [51].

**Table 3.1** Cell surface markers on adult human bone-marrow-derived MSCs (BM-MSCs), human term placenta-derived MSCs, and USSCs. Reproduced from Matigian *et al.*, *Genomics Data* 2015; **3**: 70–74 [51] under a Creative Commons License (CC BY). doi:10.1016/j.gdata.2014.11.011.

| Marker association | CD number/ name | Other name | BM-MSCs | Placental MSCs | USSCs |
|---|---|---|---|---|---|
| Mesenchymal stromal cell-associated markers | CD29 | Integrin-β1 | Positive | Positive | Positive |
| | CD44 | HCAM (homing cell adhesion molecule) | Positive | Positive | Positive |
| | CD73 | Ecto-5′-nucleotidase | Positive | Positive | Positive |
| | CD90 | Thy-1 | Positive | Positive | Positive |
| | CD105 | Endoglin | Positive | Positive | Positive |
| | CD146 | MCAM (melanoma cell adhesion molecule) | Positive | Not done | Positive |
| | GD2 | Neural ganglioside 2 | Faint staining | Faint staining | Faint staining |
| Mesenchymal stem-cell-associated marker | Stro-1 | Stromal cell molecule-1 | Negative | Negative | Negative |
| Endothelial marker | CD31 | PECAM-1 (platelet/endothelial cell adhesion molecule) | Negative | Negative | Negative |
| Hematopoietic cell-associated markers | CD34 | Mucosialin | Negative | Negative | Negative |
| | CD45 | Leukocyte common marker | Negative | Negative | Negative |
| Other adhesion molecules | CD49d | VLA-4 (very late antigen-4) | Positive | Positive | Positive |
| | CD49e | VLA-5a (very late antigen-5a) | Positive | Positive | Positive |
| | CD50 | ICAM-3 (intercellular adhesion molecule) | Negative | Faint staining | Negative |
| | CD166 | ALCAM (activated leucocyte cell adhesion molecule | Positive | Positive | Positive |
| Pluripotency markers | SSEA-4 | Stage-specific embryonic antigen-4 | Negative | Negative | Negative |
| | TRA 1–60 | | Negative | Negative | Negative |
| | TRA 1–81 | | Negative | Negative | Negative |

**Table 3.2** Chemokine receptor display by bone marrow MSCs, placental MSCs, and UCCSs. Reproduced from Matigian *et al.*, *Genomics Data* 2015; **3**: 70–74 [51] under a Creative Commons License (CC BY). doi:10.1016/j.gdata.2014.11.011.

### 3.3.3 Mesodermal differentiation capability

We also compared the *in vitro* mesodermal differentiation potential of adult human bone-marrow-derived MSCs with those on term-placenta-derived MSCs and with those on cord-blood-derived USSCs (Figure 3.3). All three populations showed marked ability to differentiate to the osteogenic lineage. Bone marrow MSCs showed stronger differentiation to the adipogenic pathway than placental MSCs and USSCs, each of which showed only a slight degree of adipogenesis [51].

## 3.4 The immunomodulatory properties of mesenchymal stromal cells

The immunomodulatory properties of adult bone marrow MSCs have been extensively studied [58]. Secretion of soluble factors – including IL-1β [59], TGF-β1 [60], hepatocyte growth factor [60], prostaglandin $E_2$ [61], indoleamine 2,3-dioxygenase [62], heme oxygenase-1 [63], leukemia inhibitory factor [64], insulin-like growth factor (IGF) [65], soluble human leukocyte antigen G5 [66], galectin [45], and Jagged-1 [67] – have all been suggested as responsible for mediating the immunomodulatory effects of MSCs.

Several studies have demonstrated that both undifferentiated and differentiated bone marrow MSCs have suppressive effects on alloantigen and mitogen-stimulated lymphocyte proliferation in vitro, with a concomitant reduction in the production of proinflammatory cytokines such as interferon-γ (IFN-γ) and tumor necrosis factor-α [54,68].

To date the interactions between adult bone marrow MSCs with T lymphocytes have been the most extensively studied. Many reports have demonstrated that adult bone marrow MSCs affect several properties of T cells, including suppression of the proliferation of activated $CD4^+$ T helper cells and $CD8^+$ cytotoxic T cells [69,70]. In addition, bone marrow MSCs can prolong the survival of unstimulated T cells by rescuing the lymphocytes from activation-induced cell death through down-regulation of Fas receptor and the Fas ligand on T cells as well as by inhibition of endogenous proteases involved in cell death [71]. Other studies have shown that bone marrow MSCs reduce IFN-γ production by $CD4^+$ Th1 cells and interleukin (IL)-17 release by $CD4^+$ Th17 lymphocytes, while IL-4 secretion by $CD4^+$ Th2 cells is increased [72,73].

Crisan *et al.* reported that MSCs migrate in response to digested extracellular matrix and other chemotactic stimuli, which recruit MSCs from both local surrounding environments to the site of injury or inflammation [3]. It is likely that increased inflammatory chemokine concentration at the site of inflammation is a major factor causing MSCs to migrate to these sites. Chemokines are released after tissue damage, and MSCs are known to express the receptors for many of these [74,75], including the chemokine receptor CXCR4, which is important in MSC migration [76–78]; and see Chapters 22 and 23. Furthermore, Ceradini *et al.* showed that the attraction of MSCs expressing CXCR4 to injured tissue is facilitated by hypoxia-inducible factor-1 (HIF-1), which causes overexpression of the CXCR4 ligand, stromal cell-derived factor-1 (SDF-1, also known as CXCL12) in a gradient proportional to tissue hypoxia [79]. A decline in HIF-1 expression has been associated with increasing age and may be responsible, at least in part, for the impaired ability of MSC migration to wound healing in the elderly [40].

As indicated earlier, it has been reported that both humans and animals demonstrate a decreased rate of production of bone marrow mesenchymal stem and progenitor cells with increasing age [80,81]. Several studies have provided evidence of a strong correlation between donor age and the proliferative potential exhibited by MSCs *in vitro* [81–84]. Thus, the MSC progenitor pool may be depleted following extensive proliferation. These findings correlate with *in vivo* studies of aging individuals [85,86]. A dramatic decrease in MSCs in bone marrow is observed from infants to the elderly, and a direct functional correlation exists between advanced age and decreased osteogenic potential [86,87]. This may contribute to diseases in the aging population, such as osteoporosis [84]. In addition, isolated MSCs with lower proliferative potential from older donors may be responsible for the reduced wound healing potential that is also associated with the aging population [88]. Such a decline in the quality of the cells is suboptimal for therapeutic applications.

For such reasons, alternative sources of MSCs are being investigated for clinical use in diseases in which the regenerative and/or immunomodulatory functions of MSCs may be useful [35,62,89,90]. A readily available and younger source that can be obtained by a noninvasive procedure, and which yields large numbers of MSCs for *ex vivo* expansion, would be an ideal alternative to adult bone marrow. One such tissue is term placenta (see Chapters 4 and 5).

Until recently the exact anatomical location of MSCs had not been well defined *in vivo*. It has now been established that MSCs

can be isolated from all vascularized tissues in the body since MSCs reside in the walls of blood vessels, forming part of the endothelium [3,41,91,92]. While MSCs are one form of pericyte, not all pericytes are MSCs: smooth muscle cells also form part of the endothelial wall in arterioles, arteries, and large veins. Several studies have indicated that MSCs also reside in specific niches in the bone marrow, where they provide essential support for HSCs – see Chapter 32. Thus, MSCs contribute to tissue, hematopoiesis, and immune system homeostasis [41,92].

Although bone marrow is the traditional source of MSCs, other sources are easily accessible, less invasive, and contain large numbers of MSCs [7,8,93–95]. MSCs have been isolated from first-trimester fetal liver, blood, and bone marrow [86], and broadly comparable cells have been isolated from a range of fetal and adnexal gestational tissues. MSCs have been isolated from amniotic fluid [96,97], umbilical cord blood [98], umbilical cord, including Wharton's jelly and perivascular tissue [99,100], first-trimester [101] and second-trimester liver, lung, bone marrow [102], and pancreas [103], term placenta [7], and amniotic and chorionic placental membranes [104]. Gestational sources can be collected at delivery or from prenatal diagnostic specimens such as amniotic fluid. The latter can be sourced by the minimally invasive technique of amniocentesis or obtained peripartum from tissue that would usually be discarded [105].

Though the minimal criteria for classifying MSCs have been established and many of these MSC populations share biological characteristics, functional differences between some of them have been reported [11–13]. These differences include cell surface phenotype, differentiation potential, and immunomodulatory activity and represent specific features of MSCs from different tissue sources [14–17], while others are reflective of differences in cell isolation and culture protocols [18]. These functional discrepancies between MSC populations have led to further characterization of these cells by a global, genomics-based approach whereby functional differences between MSC populations are reflected in their transcriptome. These findings have highlighted the need for a reproducible classification of a common gene expression profile for MSC populations regardless of their tissue source, and one that is distinct from that of differentiated cell types.

## 3.5 The transcriptome of mesenchymal stromal cells

Studies have reported the identification of the core MSC genomic profile and their functional pathways. A study by Shi *et al.* compared the gene expression profiles of human dental pulp and that of human bone marrow MSCs [106]. They reported that these MSC populations had a similar level of gene expression for approximately 4400 known human genes. Although they did not report all these genes, they mentioned genes that encoded extracellular matrix proteins (collagen types III and V, osteopontin, osteonectin, matrix-gla protein, decorin, biglycan, and alkaline phosphatase), cellular adhesion molecules (VCAM-1, CD44, integrins $\beta_1$, $\alpha_{v2}$, $\alpha_v$, and $\beta_3$), growth factors (IGF-1, PDGF, FGF-2, TGF-β1, BMP-2, BMP-4, and BMP-7), and transcription regulators (CBFA1,SX1, Msx2, c-FOS, c-JUN, and JUN-B).

These molecules are associated with the development and function of osteoblasts and/or odontoblasts and are indicative of cellular differentiation reflective of their tissue environment. Menicanin *et al.* isolated and characterized clonal populations of bone marrow, dental pulp, and periodontal-ligament-derived MSC populations to identify potential biomarkers associated with the long-term survival of multipotent MSCs [107]. They identified 24 genes, including the transcription factors E2F2, PTTG1, TWIST-1 and transcriptional cofactor LDB2 that were expressed in common between the MSC populations. These molecules could be grouped into categories based on their involvement in the cell cycle, mitosis, cell division, DNA repair and replication, and cellular differentiation.

A study by Wagner *et al.* compared MSCs from umbilical cord blood, adipose tissue, and bone marrow [17]. The primary aim of their study was to analyze the reproducibility of generating different MSCs under standardized conditions and to compare the gene expression profiles of MSCs derived from different sources. They found 25 upregulated genes that were common to all three MSC populations, and these included the genes for fibronectin, ECM2, glypican-4, ID1, NF1B, HOXA5, and HOXB6. Many of these genes are involved in extracellular matrix, morphogenesis, and development.

Al-Nbaheen *et al.* [11] performed a comparative study of adult adipose tissue, skin, and bone-marrow-derived MSC populations. They reported 6533 genes commonly expressed in each of these populations. Using a microarray-based approach they reported a common MSC molecular signature composed of 33 CD markers, including known MSC markers and several novel markers such as CD165, CD276, and CD82.

CD165 is a 37–42 kDa transmembrane glycoprotein, also known as AD2, gp37, and SN2. It is expressed on immature thymocytes, most platelets, thymic epithelial cells, fibroblasts, and acute T lymphoblastic leukemia cells. CD165 has also been found to be expressed on monocytes and circulating T cells as well as on islet cells of the pancreas, Bowman's capsule of the kidney, and on central nervous system neurons. The biological function of CD165 is still not clear, though it has been proposed that CD165 plays a role in cell adhesion between thymocytes and thymic epithelial cells during development.

CD276 (B7-H3) is a type I transmembrane protein belonging to the B7 family of co-stimulatory proteins. CD276 is mostly expressed on professional antigen-presenting cells, including dendritic cells, macrophages, and B cells. Initial studies showed that CD276 provides a stimulatory signal to T cells. However, more recent studies suggest a negative regulatory role for CD276 in T cell responses. Mouse CD276 protein inhibited T cell activation and effector cytokine production. CD276 is involved in the suppression of Th1-mediated immune responses and

played an important role in the development of pathogenic Th2 cells in a murine asthma model. Monoclonal antibody against B7-H3 enhances T cell proliferation *in vitro* and leads to exacerbated experimental autoimmune encephalitis *in vivo*.

CD82 is a 45–90 kDa type III tetraspan membrane protein. A member of the 4-span transmembrane protein superfamily (TM4SF), CD82 forms a complex with CD37, CD53, CD81, ECM, and MHC molecules. CD82 is expressed on monocytes, granulocytes, lymphocytes, epithelial cells, endothelial cells, and fibroblasts and plays a role in signal transduction and adhesion.

Significant differences in the molecular phenotype between the three different MSC populations in this study were observed, suggesting ontological and functional differences between the three populations. Al-Nbaheen *et al.* concluded that MSC populations obtained from different tissues exhibit significant differences in their molecular phenotype and suggested that this should be taken into consideration when planning their use in clinical protocols.

Tsai and colleagues also performed a comparative functional analysis from the gene expression signatures of fetal-derived MSCs (amniotic-membrane-derived MSCs, amniotic fluid MSCs, and umbilical cord blood MSCs) and adult MSCs derived from bone marrow [108]. They categorized the core genes found in common into five main groups related to plasmin-related extracellular matrix remodeling, cytoskeletal regulation, chemokine regulation and adhesion, plasmin activation, and TGF-β receptor signaling. Plasmin is an enzyme present in blood that degrades many blood plasma proteins, including fibrin clots.

Weng *et al.* also compared the transcriptomes of fetal umbilical cord blood and Wharton's jelly MSCs with that of adult bone-marrow-derived MSCs [109]. Their findings were similar to those of Tsai *et al.* and Menicanin *et al.*, in that cell adhesion molecules and Wnt signaling pathway genes were found to be significantly enriched in all the MSC populations. When they compared the gene set with gene ontology classification, the top four themed biological processes for adult bone-marrow-derived MSCs were immune system processes, biological adhesion, developmental processes, and locomotion. Fetal MSC processes included metabolic processes, cellular processes, developmental process, and signaling. Though there are differences in the molecules reported, these functional processes are consistent with previous studies of extracellular matrix remodeling, cellular and tissue development, and differentiation. In addition, a major network in fetal MSCs consisted of 547 genes that were involved in cell cycle development, RNA posttranscriptional modification, including RNA splicing, and DNA replication, recombination, and repair. They also reported that the targets of several microRNAs, including miR-124, miR-1, miR-199a1, miR-17, and miR-181b2, were enriched in fetal MSCs.

Miranda and colleagues observed that highly expressed genes in both human bone-marrow-derived MSCs and human umbilical cord vein MSCs can be modulated by microRNAs, which in turn can change protein abundance [110]. Their results showed that MSCs from both sources were similar in metabolic and functional processes relevant to their therapeutic potential, especially in immune system processes, their response to stimuli, migration and adhesion.

Similarly, Spitzer *et al.* studied the transcriptome and signaling pathways of endometrial MSCs [111]. They used fibroblasts and endothelial cells for comparison. They reported that endometrial MSCs expressed genes involved in angiogenesis/vasculogenesis, steroid hormone/hypoxia responses, inflammation, immunomodulation, cell communication, proteolysis/inhibition, and inhibition of Notch, TGF-β, IGF, Hedgehog, and G-protein-coupled receptor signaling pathways, which are involved in self-renewal and lineage specification pathways.

Studies have also compared MSC populations derived from alternative species to humans. A study by Monaco *et al.* compared porcine adipose-tissue-derived MSCs with bone-marrow-derived MSCs [112]. They reported a Pearson correlation coefficient between the complete transcriptome of adipose and bone marrow MSCs of 0.79 ($p < 0.0001$). When these MSC populations were compared with differentiated tissues, they reported that the significantly enriched functions of MSCs were related to protein synthesis with roles in extracellular matrix formation, differentiation, immune suppression, and cell cycle regulation.

Our group compared the gene expression profiles of multipotent human stromal cells isolated from cord blood, human term placenta and adult human bone marrow and showed distinct differences in gene expression patterns [51].

Pelekanos *et al.* conducted a comparative study of murine kidney, heart, and bone marrow MSCs. Some 81.1% of genes were expressed across the combined set of samples with the Pearson correlations of pairwise comparisons ranging from 0.878 to 0.924, thus indicating a high level of similarity between all MSC populations [18]. The majority of the top 100 genes encoded were housekeeping proteins. However, also included were regulatory molecules and secreted proteins involved in tissue-remodeling, repair, and inflammatory modulation, with the most highly expressed genes being zyxin, thymosin β10 and macrophage inhibitory factor. Zyxin may function as a messenger in the signal transduction pathway that mediates adhesion-stimulated changes in gene expression and may modulate the cytoskeletal organization of actin bundles. Thymosin β10 has direct inhibitive effects on endothelial migration and tube formation.

Other commonly expressed genes included biglycan, Serpinh1/HSP47, SerpinF1, also known as pigment epithelium-derived factor (PEDF), Sparc/Osteonectin, and CTGF/CCN2. Biglycan is a small leucine-rich repeat proteoglycan that is found in a variety of extracellular matrix tissues, including bone, cartilage, and tendon. Biglycan interacts with collagen both via the core protein and GAG chains. It is believed to play a role in the mineralization of bone. Knockout mice that have had the gene for biglycan suppressed have an osteoporosis-like phenotype with reduced growth rate and lower bone mass than mice that can express biglycan. Serpins are a group of

proteins that were first identified as a set of proteins able to inhibit proteases. The acronym serpin was originally coined because many serpins inhibit chymotrypsin-like serine proteases (serine protease inhibitors). The first members of the serpin superfamily to be extensively studied were the human plasma proteins antithrombin and antitrypsin, which play key roles in controlling blood coagulation and inflammation. Heat shock protein 47 (HSP47) is a member of the serpin family and is a collagen-specific molecular chaperone. Knockdown of HSP47 in murine models of fibrosis decreases the accumulation of collagen in fibrotic tissues and prevents the promotion of fibrosis. On the other hand, mutations in HSP47 cause collagen-related genetic diseases such as osteogenesis imperfecta. SerpinF1, also known as PEDF, is a multifunctional secreted protein that has antiangiogenic, antitumorigenic, and neurotrophic function. Osteonectin, also known as secreted protein acidic and rich in cysteine (SPARC), is a glycoprotein in the bone that binds calcium. It is secreted by osteoblasts during bone formation, initiating mineralization and promoting mineral crystal formation. Osteonectin also shows affinity for collagen in addition to bone mineral calcium. CTGF, also known as CCN2 or connective tissue growth factor, is a matricellular protein of the CCN family of extracellular matrix-associated heparin-binding and intercellular signaling proteins. CTGF has important roles in many biological processes, including cell adhesion, migration, proliferation, angiogenesis, skeletal development, and tissue wound repair and is critically involved in fibrotic disease. The acronym CCN is derived from the first three members of the family discovered, namely CYR61 (cysteine-rich angiogenic protein 61 or CCN1), CTGF (connective tissue growth factor or CCN2), and NOV (nephroblastoma overexpressed or CCN3). Together with three Wnt-induced secreted proteins, they comprise the CCN family of matricellular proteins. These proteins have now been renamed CCN1-6 by international consensus.

Functional pathways commonly expressed between these populations included immunity, cell adhesion, BMP signaling, chemokine signaling, homeodomain transcription factors, and metalloproteinases and their TIMP inhibitors.

Though these studies reported many similarities in gene expression and function pathways, there were discrepancies in the genes generated between the studies. Such discrepancies may be the outcome of variables such as tissue sources, isolation and culture expansion conditions, as well as array platforms and methods of analysis. To eliminate bias, a database of global gene expression profiles from published MSCs regardless of tissue source, culture conditions, array platform, or species needs to be established to then compare the commonly expressed genes within different MSC populations. The identification of genes that are commonly upregulated in all preparations of MSCs may serve as a novel parameter for the definition and characterization of MSCs. The identification of a core MSC transcriptome will be critical for improving our understanding of the mechanisms involved in the properties of these cells and is likely to influence parameters such as choice of MSC tissue source for clinical use (See Breaking News, Chapter 63). However, it is reassuring that, to date, no serious safety issues have been noted in the clinical use of MSCs [113].

## 4.1 Introduction

The gestation period for humans is approximately 40 weeks with a normal range of 37–42 weeks. Placenta at this time is known as term placenta. The word placenta comes from a Greek word meaning "cake," referring to its round flat slab-like appearance (Figure 4.1).

The mammalian placenta is composed of both fetal and maternal elements. The chorion and amnion membranes on the outside of the placenta are of fetal origin. The rest of the placenta is of maternal origin. The human term placenta averages 22 cm (9 inch) in length and 2–2.5 cm (0.8–1 inch) in thickness, with the center being the thickest and the edges being the thinnest. It typically weighs approximately 500 g (just over 1 lb). It has a dark reddish–blue or crimson color. It connects to the fetus by the umbilical cord, which is approximately 55–60 cm (22–24 inch) in length and contains two umbilical arteries and one umbilical vein. The umbilical cord inserts into the chorionic plate. Vessels branch out over the surface of the placenta and further divide to form a network covered by a thin layer of cells. This results in the formation of villous tree structures. On the maternal side, these villous tree structures are grouped into lobules called cotyledons (Figure 4.2).

The human term placenta has aroused significant interest as a source of mesenchymal stromal cells (MSCs) for use in regenerative and immunodulatory medicine. Literally billions of MSCs can be isolated from a single placenta taken through to passage 5. It is an interesting tissue for studying MSCs because their environment is unique due to the development and growth of the fetus throughout gestation. The cells derived from the fetus are hypothesized to be more primitive than those derived from the mother due to the age and external environmental factors to which the mother may have been previously exposed, including pathogens or chemicals. Thus, we postulated that the MSCs that reside here may be more advantageous than the more traditional bone-marrow-derived MSCs for use in MSC-based clinical applications.

Term placental tissue is easily accessible, is usually considered a waste product after birth, and its use for treatment purposes is free from ethical concerns. Many reports have described stem/stromal cells from different components of the placenta using many different isolation and characterization techniques.

However, the lack of universal assays to define an MSC has resulted in many discrepancies in the literature.

Stem cells have two properties: they must be able to divide and be self-renewing, and they must be able to differentiate down a specific lineage or set of lineages to produce functional cells. In the 1960s, Alexander Friedenstein and colleagues in Russia discovered a type of adult stem cell that they called colony-forming units fibroblastic (CFU-Fs), since single cells grew into colonies and were readily distinguishable from hematopoietic stem cells (HSCs) by their adherence to plastic and their fibroblast-like morphology [1]. Friedenstein and Owen called these cells osteoprogenitors. Subsequently, these cells were shown to differentiate to key elements of the skeleton, including bone (osteoblasts), cartilage (chondrocytes), fat (adipocytes), and periosteum (fibroblasts). Evidence of self-renewal has been shown by Sacchetti and colleagues for osteoprogenitor cells in bone marrow sinusoids that were able to organize a hematopoietic microenvironment [2]. They showed that MCAM/CD146-expressing subendothelial cells in human bone marrow stroma were capable of transferring, upon transplantation, the hematopoietic microenvironment to heterotopic sites, coincident with the establishment of identical subendothelial cells within a miniature bone organ. Subsequently, Méndez-Ferrer and colleagues confirmed these findings by showing that mesenchymal and HSCs formed a unique bone marrow niche [3]. This area of science has been well summarized by Paolo Bianco and coworkers in 2008 [4], 2011 [5], and 2013 [6].

Thus, the term skeletal stem cell for these cells is well founded scientifically. True mesenchymal stem cells, however, are rare cells with a frequency in bone marrow of between 1 in $10^4$ and 1 in $10^5$. To enable both experimental and clinical trials of mesenchymal cells to be performed, it has been necessary to expand them in *in vitro* cultures. The cells obtained are not mesenchymal stem cells, but rather their progeny – often mistakenly called mesenchymal stem cells but in fact they are mesenchymal stromal or mesenchymal progenitor cells. In the rest of this chapter the term mesenchymal stromal cells will be used and the abbreviation MSCs will be applied only to mesenchymal stromal cells.

MSCs isolated from placental tissue (pMSCs) display phenotypic plasticity and are involved in maintaining fetal tolerance due to their immunomodulatory properties [7].

## 4.2 Isolation of placental mesenchymal stromal cells

Many studies have used different isolation and expansion techniques as well as different approaches to characterizing MSCs derived from human gestational products. This has made it difficult to compare and contrast different studies and their cell populations. To address this issue a report from an international workshop on placenta-derived stem/stromal cells published guidelines for the identification and verification of MSCs derived from placental tissues (pMSCs) in 2008 [7]. Minimal criteria for defining pMSCs, such as human amnion-derived MSCs (AMSCs) and human chorion-derived MSCs (CMSCs), indicated that such cells must be adherent to plastic, form fibroblast-like colony-forming units, express a characteristic pattern of surface antigens, and display differentiation potential toward one or more mesodermal lineages, including osteogenic, adipogenic, and chondrogenic lineages, and/or vascular/endothelial cell types. Furthermore, for cells to be deemed fetal in origin they had to demonstrate maternal contamination of 1% or less [7].

All but the last of these characteristics were similar to the criteria proposed by Dominici *et al.* in 2006 for adult bone-marrow-derived MSCs and adopted by the International Society

for Cell Therapy [8]. However, not all studies have reported pMSCs to possess these properties. In particular, there are conflicting reports from investigators regarding the origin of MSCs from term placental tissues. It has been reported that cultured populations of MSCs derived from placental fetal membranes consisted of cells of maternal origin presumed due to overgrowth of maternal MSCs that had "contaminated" the fetal tissues. Therefore, to document the frequency and determinants of maternal cell contamination in cultured chorionic MSCs, we undertook a PRISMA-compliant systematic review of publications in PubMed, Medline, and Embase databases from January 2000 till July 2013 on placental and/or chorionic MSCs from uncomplicated pregnancies [9]. We discovered that of 147 studies only 26 (18%) investigated the question of fetal and/or maternal cell origin. After excluding studies that did not satisfy minimal MSC criteria, we found 8 of 15 informative studies that documented MSC cultures as fetal in origin (53%). The remaining seven studies reported that expanded human chorionic MSC populations were either maternal in origin ($n = 6$) or mixed ($n = 1$). Maternal cell contamination was associated with term placentas, chorionic membrane samples, and greater passage number, but was also present in 3 of 10 studies of chorionic villous MSCs. While most studies have assumed a fetal origin for MSCs sourced from chorion, this systematic review documented a high incidence of maternal-origin MSC populations in pMSC cultures. Given that fetal MSCs may be more primitive than adult MSCs, our findings have implications for clinical trials. Therefore, we recommended sensitive methods to quantitate the source and purity of pMSCs [9].

Isolation of MSCs from whole term placenta involves dissection of the placenta into small pieces using scissors and scalpels followed by enzymatic digestion, removal of red cells by lysis or density gradient separation, and finally seeding cells from the mononuclear cell monolayer on to plastic tissue cultures flasks. The culture medium is a basic one such DMEM supplemented with 20% fetal calf serum (FCS). pMSCs generally become almost confluent after approximately 1 week in culture, when they are harvested and the next set of flasks are seeded.

## 4.3 Characteristics of fetally derived mesenchymal stromal cells isolated from gestational tissues

Fetally derived MSCs are theoretically attractive because they may contain less genetic abnormalities than adult-tissue-derived MSCs, have greater proliferative capacity, and a greater retention of "stemness" memory. It is thought that they have properties intermediate between embryonic and adult stem cells [10]. Thus, they may be a superior MSC source for clinical trials and therapies compared with traditional sources such as bone marrow.

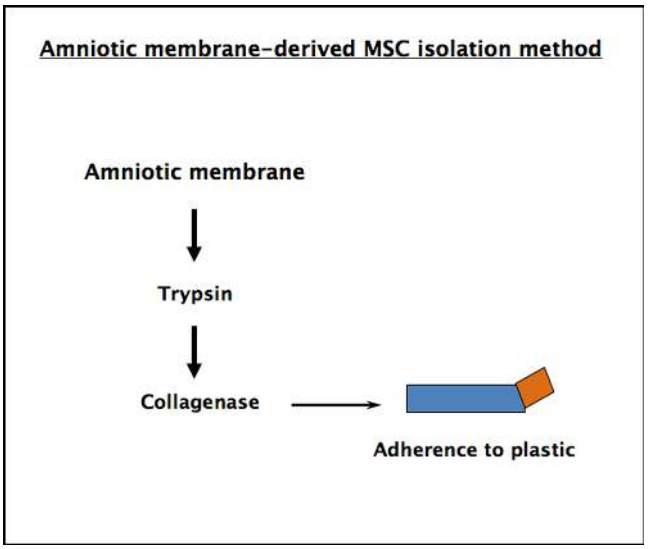

**Figure 4.3** The method used in our laboratory to isolate human AMSCs.

### 4.3.1 Amniotic-membrane-derived mesenchymal stromal cells

The amniotic membrane is a fetal tissue and contains a mesodermal layer in which MSCs reside. Many researchers have attempted to isolate fetally derived MSC-like cells from the amniotic membrane. Both mechanical and enzymatic digestions are amongst the most popular techniques.

There are many different methods used to isolate AMSCs. However, typically, AMSCs are isolated using trypsin followed by a collagenase digest [11] (Figure 4.3). AMSCs expanded in culture exhibit a fibroblast-like morphology and express CD90, CD105, and CD73 on their surface membrane but not CD45. AMSCs can differentiate *in vitro* along the mesodermal lineage, including osteocytes, chondrocytes, and in some studies adipocytes. Interestingly, AMSCs have been reported to differentiate into lineages of all three germ layers, ectoderm [12], mesoderm [13], and endoderm [14], and give rise to progeny such as lung alveolar type II cells, endothelial cells, hepatocytes, cardiomyocytes, and neuronal-like cells [15–18]. It has also been reported that AMSCs spontaneously differentiate *in vitro* into endothelial cells through secretion of vascular endothelial growth factor [15]. However, none of these studies showed any functional analysis of their findings *in vivo*, and this renders the claims to non-mesodermal lineage differentiation incomplete.

### 4.3.2 Chorionic-membrane-derived mesenchymal stromal cells

CMSCs are similar to AMSCs, in that they demonstrate mesodermal lineage differentiation potential *in vitro*, do not form teratomas *in vivo*, and have an immune privileged status [19,20]. Despite CMSCs residing in a separate niche to AMSCs, they are still fetus derived from the extra-embryonic blastocyst.

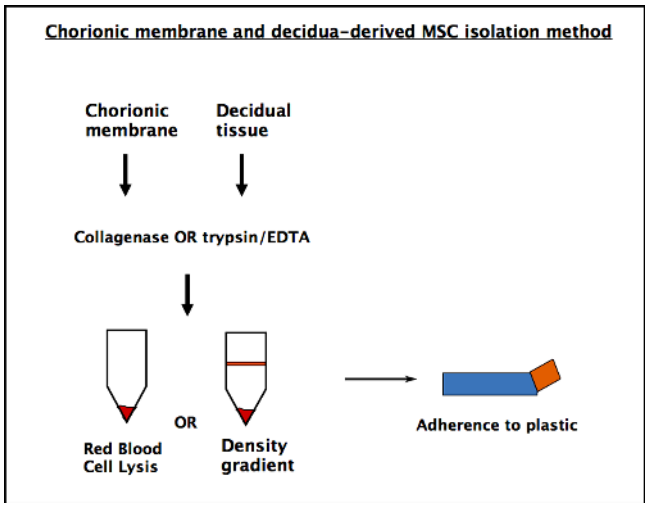

**Figure 4.4** The method used in our laboratory to isolate CMSCs and decidua MSCs.

Numerous methods have been adapted to isolate these cells, including mechanical digestion, explant cultures, and enzymatic digestion, similar to those used for AMSCs. To obtain potentially purified CMSC populations, the chorionic membrane must be physically separated from the rest of the placenta. This is usually followed by enzymatic digestion, such as collagenase or trypsin/EDTA digestion, followed further by either red blood cell lysis or a Ficoll density gradient to remove debris and red blood cells. The mononuclear layer of cells containing MSCs is then collected and plated in culture, where they usually adhere within 1 day (Figure 4.4). Contaminating nonadherent cells, such as hematopoietic cells, are washed and removed from culture 48–72 h after plating.

The chorionic villi of human term placenta are also a rich source of MSCs. Many studies have reported the isolation of CMSCs from the chorionic villi [7,19,21–26]. To remove contaminating decidua tissue of maternal origin, the villi are carefully separated from the decidua using a dissection microscope and then the villous tissue is enzymatically and mechanically digested prior to expansion in culture. It is thought that the stem cell niche within the chorionic villi regulates the way CMSCs participate in placental tissue generation, maintenance, and repair. A number of cell surface markers have been used to identify the stem cell niche within the chorionic villi of first trimester and term human placenta. These have included pericyte cell surface markers such as CD146 and other markers such as STRO-1 and microtubule-associated protein 1B (MAP1B) which have been used to identify MSCs in other tissues [27]. One study indicated that some CMSCs have a pericyte-like phenotype. Furthermore, it has now been proposed that the vascular niche harbors a pool of MSCs that can give rise to committed progenitors for tissue maintenance and repair and that these MSCs contribute to vessel maturation and stabilization [28].

## 4.4 Characteristics of maternally derived mesenchymal stromal cells isolated from gestational tissue (the decidua)

Guo *et al.* described an adult stem/stromal cell population reported to have remarkable regeneration ability [29]. This population of cells was found within the decidua tissue and was thought to be responsible for the implantation of the embryo and formation of the placenta in the uterus. There is limited knowledge regarding decidua-derived MSCs. Our laboratory found that MSCs isolated from whole placentas were of maternal origin despite the babies being of male gender [30,31]. This indicated maternal MSC contamination and subsequent overgrowth of maternal MSCs in these placental cultures [30–33]. Because of these findings we undertook a study to determine a method for isolating and characterizing fetal-derived cells from term placenta uncontaminated by maternal cells.

## 4.5 Comparison of mesenchymal stromal cells from fetal and maternal tissues isolated from gestational tissues

We established a method for isolating efficient and viable amnion, chorion, and decidua MSC populations [34] (Figures 4.3 and 4.4). Using placentas from babies of male gender we found CMSCs to be of male origin throughout their culture period, while AMSCs were initially of male origin but were subsequently overgrown in culture by MSCs of maternal origin. MSCs derived from decidua were always of female origin. We therefore focused on searching for differences between CMSCs and decidua-derived MSCs [34]. MSC cultures were characterized by cell morphology, cell surface phenotype, clonogenic ability, proliferative capacity, mesodermal differentiation ability, immune suppressive capacity, genotyping, as well as fluorescence *in situ* hybridization or sex-determining region of the Y chromosome analysis to determine the gender of the source of the cells [34]. All three cell populations (amnion, chorion, and decidua) displayed similar cell morphology and characteristic MSC cell surface marker expression. However, some differences were noted between the three populations. Cell proliferation differences were found between all three populations in early passages. Decidua MSCs had a more than twofold increase in population doublings compared with that of AMSC and CMSC populations in early cultures, and this likely explained the maternal overgrowth in MSC populations derived from the chorion [34].

Other differences were noted, such as the limited adipogenic potential of gestational product MSCs compared with that of bone marrow MSCs [34]. These findings re-enforced the concept that multipotent stroma-like cells from different tissues are similar but not identical [35]. Although amnion and decidua MSCs showed some similarities, they were found to be unique cell populations. We compared the gene expression profiles of

each population of fetal- and maternal-derived MSCs in order to further explore differences between these MSC populations [34].

The top functional pathways for AMSCs involved cell-to-cell signaling, cell death, and the development and function of the hematological system. These pathways were regulated by the transcription factors NFkB and SOX9, which are known to regulate cellular and organismal processes such as immune and inflammatory responses, developmental processes, cellular growth, and apoptosis. Several AMSC molecules were of interest, including CD46, a complement regulatory protein, and NIPA-like domain containing 3 (NIPAL3). Although CD46 is not a unique MSC marker, it could be used in conjunction with characteristic MSC markers to discriminate between fetal and maternal MSC populations. NIPAL3 was also a molecule of interest since little is known about its function. Therefore, together these molecules could be used to enrich for a fetal MSC population. NFkB and SOX9 may play a critical role in AMSC survival and immune response, and it is proposed that AMSCs are involved in the innate immune response against viruses and bacteria, representing at least part of the neonatal defense system against the earliest encountered pathogens [34]. Tsai *et al.* reported similar findings in term cord blood MSCs [36].

In contrast, the top functional pathways of decidua MSCs were cellular development and growth and proliferation [34]. These results are compatible with the finding that decidua MSCs proliferate faster and outgrow fetal MSCs in culture, indicating more robust self-renewal and differentiation potential. It was also found that numerous transcription factors, including *FOXC1*, *FOXF1*, *FOXL2*, *FOXO2*, *GATA2*, *HAND2* and *HOX* genes, were upregulated in the decidua MSC population [34]. This has also been described in endometrial stromal cell populations, as well as in embryonic stem cells and HSCs.

The progesterone receptor was also enriched in the decidua MSC population. This may indicate that decidua MSCs are regulated by progesterone. Moreover, two zinc finger proteins, zinc finger MIZ-type containing 1 and zinc finger protein 318, with no known function were also upregulated. This indicated that they are involved in MSC development, growth, and proliferation [34]. It was also found that many plasma membrane molecules were upregulated in the decidua MSC population. The G-protein receptor CD97 was upregulated and may prove to be a specific decidua MSC marker. It was also found that endothelin, bradykinin receptor B1, and thrombin receptors were expressed [34]. These genes were also reported to be upregulated in MSCs from amniotic fluid and amniotic-membrane-derived MSCs in the study by Tsai *et al.* This may indicate that they are involved in uterine contractions, and Tsai *et al.* considered that they may have a role in the homeostasis of fluids and electrolytes.

Functional network analyses in this study provided insights into the transcriptomes of MSCs derived from different sources [34]. AMSCs were involved in cell death and hematological system development and function, and, thus, as indicated earlier, may be involved in the neonatal innate immune system. Decidua MSCs were involved in cell development, growth, and proliferation, characteristic of their tissue of origin – the highly proliferative and regenerative endometrium. Molecules were identified at the transcriptomic level that may discriminate between fetal and maternal populations. However, future studies are required to confirm these findings at the protein level.

AMSCs did not proliferate as efficiently as their maternal counterpart [34]. Therefore, for pragmatic reasons, such as obtaining sufficient MSCs for clinical trials, large-scale expansion of decidual MSCs is our current preferred source for MSCs. Decidua MSCs may prove most useful in their own environment; for example, in improving the implantation rate of the blastocyst during *in vitro* fertilization treatments: a phase 1 clinical trial has been registered to investigate this (clinicaltrials.gov identifier: NCT01649752).

## 4.6 Comparison of gene expression profiles between human term-placenta-derived mesenchymal stromal cells, human adult bone-marrow-derived mesenchymal stromal cells, and human umbilical-cord-derived unrestricted somatic stem cells

We compared gene expression profiles by microarray of these three populations with cells from each source derived from four different donors. Principle component analysis was performed to demonstrate the difference between the cell sources and the reproducibility of the replicate donors. When plotting on the first two components, the samples clustered based on their tissue source, but some donor variation was apparent (Figure 4.5a). All replicates were tightly clustered except for one unrestricted somatic stem cell (USSC) sample (Chip ID: 4294077038_D; Sample ID: USSC4). However, this sample was still highly correlated to the other USSC donors (average Pearson of 0.89) compared with 0.95 for the bone marrow MSCs and the pMSCs. When plotting components 2 and 3 the samples clustered based on their tissue source (Figure 4.5b).

## 4.7 Preclinical mesenchymal stromal cell studies

Several animal studies have demonstrated prolonged survival of human AMSCs with no evidence of immunological rejection after xenogeneic transplantation into immune competent animals, including rats [38,39] and swine [38]. Additionally, human amniotic fluid MSCs appeared to be relatively resistant to rejection by the recipient, possibly due to their expression of immunosuppressive factors such as CD59 (protectin) and HLA-G [40]. Cotransplantation of umbilical cord blood HSCs together with fetal MSCs can reduce the risk of graft-versus-host disease in HSC transplant recipients, as well as enhance umbilical cord

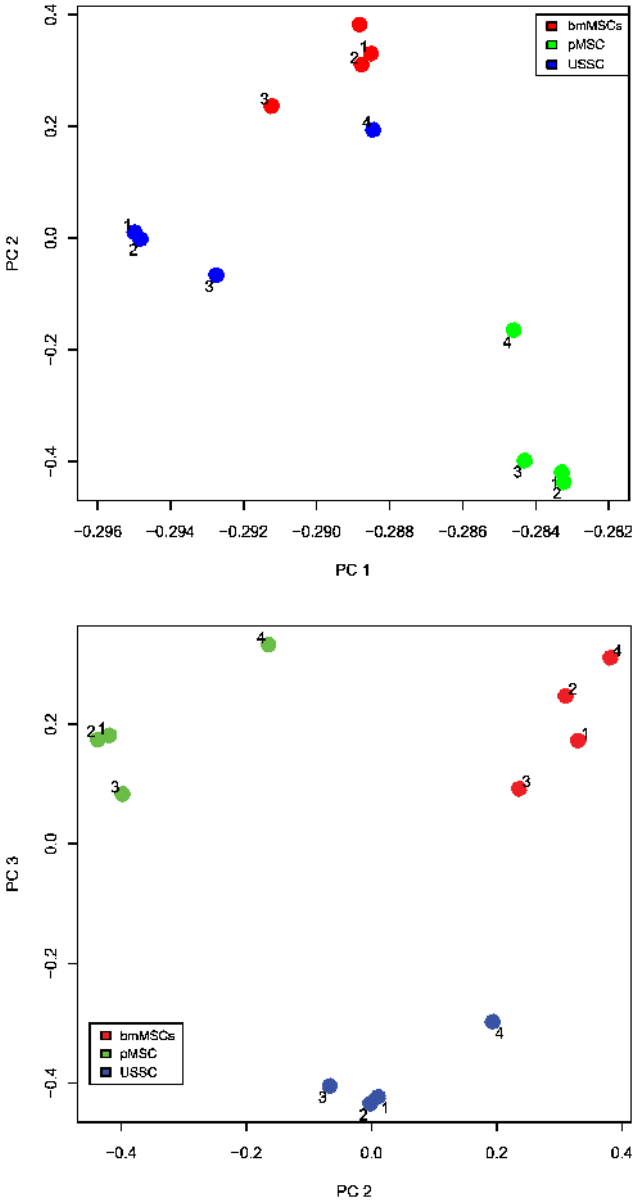

**Figure 4.5** Quality control and principal component analysis of gene expression data (detected probes only). (a) Comparing components 1 (89.1% variance) and 2 (4.1% variance); (b) Comparing components 2 (4.1% variance) and 3 (2.3% variance). *Source:* the images are reproduced from [37], Matigian *et al.*, *Genomics Data* 2015; **3**, 70–74 under a Creative Commons License (CC BY). doi:10.1016/j.gdata.2014.11.011.

blood cell engraftment and the homing of $CD34^+$ HSCs [41,42]. Amniotic membrane MSCs have been reported to promote the repair of ischemic heart damage [43]. Transplantation of AMSCs efficiently improved left ventricular function and reduced scar tissue in the myocardium after acute myocardial infarction in a rat model. AMSCs have also been reported to be neuroprotective in animal models of Parkinson's disease and stroke [39,44]. Transplantation of allogeneic and xenogeneic placenta-derived cells reduced bleomycin-induced lung fibrosis in mice [45] and proved effective in mice with critical limb ischemia [46].

Preclinical studies in mice with osteogenesis imperfecta showed that first-trimester fetal blood MSCs markedly reduced fracture rates and skeletal abnormalities [47]. Firinci *et al.* examined the efficacy of MSCs on lung histopathology in a murine model of chronic asthma. The results showed that MSCs migrated to lung tissue and ameliorated allergic asthma [48].

## 4.8 Clinical applications of placental mesenchymal stromal cells

MSCs are being tested in clinical trials, with over 450 MSC-related clinical trials listed in www.clinicaltrials.gov. There are currently 194 registered bone marrow MSC clinical trials and 28 pMSC trials registered. A meta-analysis of clinical trials in which MSCs were administered either intravenously or intra-arterially to over 1000 patients, over 300 of whom were recruited in randomized clinical trials, did not report a single serious adverse event associated with administration of the MSCs [49].

National regulatory bodies provide guidelines on the administration of cellular products for human use including requirements for current good manufacturing practice. Release criteria for the administration of MSCs in clinical trials should include cell viability, purity, sterility, negative mycoplasma testing, and minimal levels of endotoxin [50]; and see Chapters 43 and 44.

Most protocols for the manufacture of clinical-grade MSCs use FCS as a component of the *ex vivo* expansion medium. This is currently approved by the Australian regulatory authority, the Therapeutics Goods Authority as long as the FCS is sourced from a herd in a country that has never had a case of bovine spongiform encephalopathy (mad cow disease – http://www.tga.gov.au/industry/clinical-trials-handbook.htm). This is likely to change in the future when a serum-free medium will likely be required. It will be important to determine MSC genotype, phenotype, and function when culture media are modified.

Since allogeneic MSCs appear as effective as autologous MSCs, they can be manufactured in bulk and cryopreserved until needed. They are thus an off-the-shelf therapeutic agent similar to conventional therapeutic drugs. It is likely that MSC banks will be established. After several passages of *ex vivo* expansion, MSCs can be cryopreserved and stored long term, shipped to a clinical site, and thawed without loss of function. Haack-Sorensen *et al.* compared fresh and frozen *ex vivo* expanded MSCs and found that frozen MSCs still expressed the same phenotypic and cellular characteristics as fresh MSCs [51]; and see Chapter 7.

## 4.9 Manufacturing clinical-grade placenta-derived mesenchymal stromal cells

Our laboratory has provided maternal-derived placental MSCs for clinical trials [32]. Manual manufacturing of MSCs in large

quantities is laborious, time consuming, and expensive. An automated closed system would be highly beneficial. Pluristem Therapeutics Inc., an Israeli company, has developed large-scale production of placenta-derived MSCs using their proprietary PluriXTM 3D bioreactor system. Using this system, they have been able to expand adherent pMSCs (PLX-PAD cells) that retained their immunomodulatory properties [52]. A closed system also decreases the potential risk of contaminating the cell product from external environmental factors.

### 4.9.1 Phase 1 clinical trials using unrelated major-histocompatibility-unmatched placenta-derived mesenchymal stromal cells

Our laboratory generated enough maternally derived placental MSCs for three phase 1 clinical trials using two maternal donors who were unrelated to, and major histocompatibility (MHC) unmatched with, the MSC recipients. Our first trial was a phase 1 multicenter open-label dose-escalation study of unrelated MHC-unmatched placenta-derived mesenchymal stromal cells in recipients of unrelated umbilical cord blood hematopoietic stem cell transplants. No adverse events related to the MSCs were reported [50].

The second trial was a phase 1 trial of unrelated MHC-unmatched placenta-derived MSCs administered intravenously in patients with idiopathic pulmonary fibrosis. This disease affects middle-aged individuals and there is no effective treatment other than lung transplantation. It is usually fatal after 3–5 years. The primary objective of this trial was to establish the feasibility and safety of intravenous infusions of pMSCs in people with this serious lung disease. No serious adverse events related to the MSCs were noted [53].

The third trial was a phase 1 trial of pMSCs administered intratendinously in recipients with treatment-refractory Achilles tendinopathy. Two of the three planned dose escalation cohorts with MSCs injected directly into the tendon under ultrasound guidance were performed. No serious adverse events related to the MSCs were noted and a remarkable improvement in symptoms and exercise performance was noted (see Chapter 47).

## 4.10 Conclusions

At term the placenta contains both fetal and maternal MSC populations. The amniotic membrane is fetal in origin and is the preferred source for isolating human term fetal MSCs from the human term gestational product. The decidua is maternal in origin and is the preferred source for isolating maternally derived MSCs. Both of these MSC populations exhibited unique cellular and molecular characteristics and functional abilities reflective of their environment. Owing to the higher proliferation potential of maternal MSCs over fetal MSCs, they are at present the preferred gestational product MSC for large-scale production in our clinical trials program.

## 5.1 Introduction

The placenta is derived from the blastocyst and composed of fetal cells, although it is intimately linked to the maternal circulation and uterine lining throughout pregnancy [1,2]. Even after delivery the placental tissue contains both fetal and maternal cells. The human placenta and adnexa are a rich source of several stem and progenitor cells types, including mesenchymal stem/stromal cells (MSCs), endothelial progenitor cells (EPCs), and hematopoietic stem cells (HSCs) [3–6]. Research into placental-derived cells is increasing due to their tissue regeneration potential for a number of human diseases [7].

However, full understanding of the basic biology of placenta-derived cells, in particular its MSCs, is lacking. The literature reports that both fetal and maternal MSCs can be cultured *ex vivo* from the placental chorion. A recent systematic review of the literature of 147 papers that isolated chorionic MSCs found that only 15 determined if the cells were fetal or maternal in origin [8]. Of those papers examining donor origin, half reported the cells were of fetal origin and half reported the cells were of maternal or mixed origin. None of the papers indicated clearly why fetal or maternal cells were obtained, nor did the systematic review shed light on to procedural conditions that could have been responsible for the differences in MSC origin.

This chapter discusses our approach to isolating fetal or maternal MSCs from the chorionic villi (CV) of the human term placenta. We discuss the conditions required for fetal MSC proliferation, prevention of maternal MSC contamination, and determination of the optimal method to quantitate fetal/maternal MSCs in culture.

## 5.2 Mesenchymal stem/stromal cells: a consensus definition?

MSCs from both adult and perinatal sources have been isolated [9–18] and are often characterized using the guidelines proposed by the International Society for Cellular Therapy (ISCT) [19]. According to these guidelines, adult bone marrow MSCs (BM-MSCs) are defined as (1) cells that possess a

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.
© 2017 John Wiley & Sons, Inc. Published 2017 by John Wiley & Sons, Inc.

fibroblast-like morphology, (2) are adherent to plastic, (3) differentiate *in vitro* to cells of mesodermal lineages, (4) express the cell surface markers CD105, CD73, and CD90, and (5) do not express hematopoietic or endothelial markers such as CD34 and CD31. Although this definition was initially developed for adult bone-marrow-derived MSCs it has since been applied to human and non-human MSCs from different organs [9,20–22]. However, more recent literature suggests that MSCs should be characterized based on their tissue source and/or potential clinical application, as the ISCT definition did not address these issues [23,24]. One significant advance was made in 2013 in a joint statement from the International Federation for Adipose Therapeutics and Science and the International Society for Cellular Therapy on stromal cells from the adipose-tissue-derived stromal vascular fraction and culture expanded adipose-tissue-derived stromal/stem cells (ADSCs). The centrifuged but uncultured stromal vascular fraction was identified as being $CD45^-$, $CD235a^-$ (glycophorin A), $CD31^-$ (platelet endothelial cell adhesion molecule), and $CD34^+$, while cell surface positivity for CD13 (alanine aminopeptidase), CD73, CD90, and CD105 are best used in conjunction with CD45, CD235a, and CD31. *Ex-vivo*-expanded ADSCs retain cell surface markers expressed by other MSCs, including CD44 (the hyaluronic acid receptor), CD73, CD90, and CD105, and are also negative for CD45 and CD31, but can be distinguished from bone-marrow-derived MSCs by being $CD36^+$ (fatty acid translocase, also known as glycoprotein IIIb) and $CD106^-$ (vascular cell-adhesion molecule 1) (and see Chapter 1).

To date, no one cell surface marker has been identified that is specific to MSCs or is able to prospectively isolate MSCs *ex vivo* [25,26], although the antibodies Stro-1 and Stro-3 have been used to obtain a purified population of MSCs from adult bone marrow. Studies have suggested that factors including donor age, cell source, and niche are responsible for variability in basic characteristics such as differentiation propensities and cell surface markers [23]. Additionally, *in vitro* culture-expanded MSCs are a heterogeneous population and may comprise a mixture of true stem cells with fully and partially committed mesodermal progenitors such as osteoblasts, chondrocytes, and adipocytes [26]. Notably, MSCs differ in their differentiation and proliferation characteristics depending on their tissue of origin [27–29].

## 5.3 Prenatal and perinatal tissue sources of mesenchymal stem/stromal cells

MSCs derived from prenatal and perinatal tissues, including the fetus, placenta, umbilical cord, and amniotic fluid, have the basic properties of all MSCs. However, they also are reported to possess a wider differentiation potential, greater colony forming ability, faster growth kinetics, and greater long-term proliferative ability in *ex vivo* expansion cultures than adult MSCs [30–32]. It is emerging that, when directly compared, MSCs from different origins often show subtle differences. Because of their primitive characteristics and ease of isolation prenatal and perinatal MSCs offer promising alternatives as a source of MSCs for clinical trials.

## 5.4 Fetal tissue-derived mesenchymal stem/stromal cells

MSCs have been isolated and characterized from bone marrow, blood, and liver from the early trimester human fetus [30]. Fetal BM-MSCs were determined to have an increased osteogenic capacity in *vitro* and *in vivo* [31–33], greater expansion capacity and faster doubling time, a greater telomere length, higher telomerase activity, and greater telomerase reverse transcriptase gene expression than adult BM-MSCs [13,32]. Although fetal tissue MSCs may appear to be superior to adult MSCs [34], associated ethical issues and the small amount of starting material are disadvantages.

## 5.5 Placental and adnexal stem and progenitor cells

Stem and progenitor cells have been derived from amniotic fluid [35–37], umbilical cord [38], and first-, second-, and third-trimester placenta, including the amniotic membrane, chorionic membrane, chorionic plate, CV, and maternal decidua [12,17,39–41] (Figure 5.1).

The derived stem/progenitor cells include amniotic fluid stem cells [35], EPCs [42,43], chorionic trophoblastic cells, amniotic epithelial cells [41], and MSCs [41,44]. MSCs isolated from these anatomical locations have been reported to have different properties. For example, MSCs isolated from the villi/decidua proliferate faster than amniotic membrane-derived MSCs (AM-MSCs) [41], with decidual MSCs (D-MSCs) demonstrating the highest proliferation rate in some studies [44,45]. Additionally, MSCs isolated from different regions vary in their fetal or maternal origin. For example, maternal MSCs often contaminate fetal MSCs isolated from the CV [17,46–48]. Compared with adult BM-MSCs, placental MSCs have greater proliferative capacity and immunomodulatory potential and are generally reported to be equivalent in terms of their osteogenic and chondrogenic differentiation *in vitro*, but they have a lower adipogenic differentiation potential [17,46].

## 5.6 Comparison of mesenchymal stem/stromal cells from different gestational sources

Interestingly, MSCs from the same placenta have different functional properties depending on their anatomical origin. CV-MSCs had greater osteogenic potential than AM-MSCs

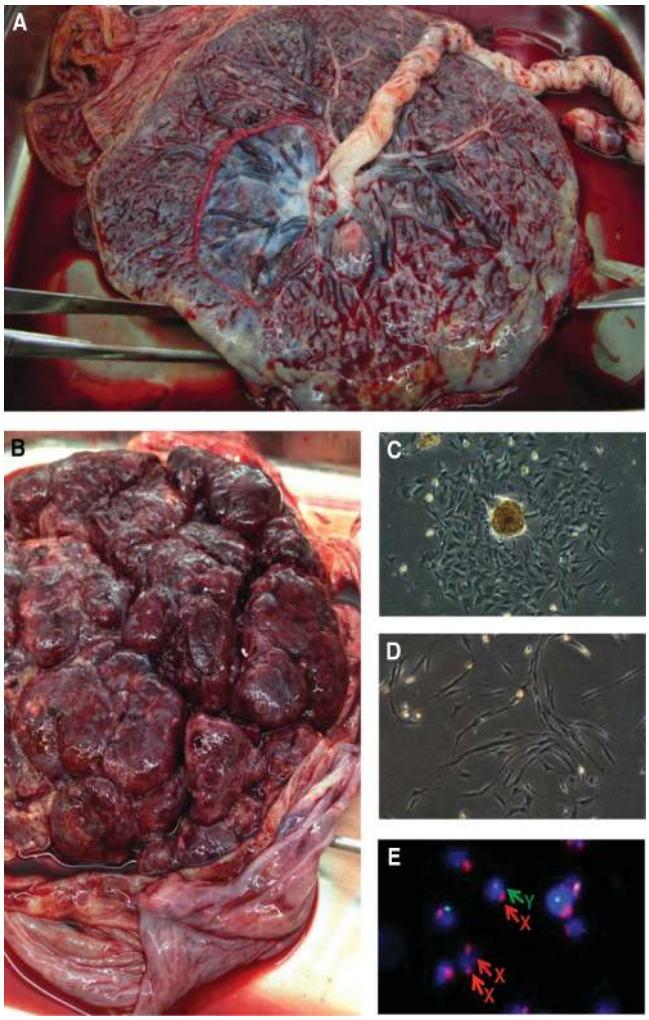

**Figure 5.1** The human term placenta and placental-derived MSCs. The fetal (A) and maternal (B) surfaces of the human term placenta. Note the umbilical cord on the fetal side and the cotyledons (lobes) on the maternal side. (C) Fetal CV-derived MSCs and (D) maternal MSCs 7 days after isolation using our novel method developed to ensure pure fetal MSCs (×10 magnification). (E) A representative image of XY chromosome fluorescence *in situ* hybridization (FISH) carried out on a sample of placental MSCs. Some cells have two red fluorescent signals, which indicate two X chromosomes; they are female and therefore maternal cells. Other cells have one green and one red fluorescent signal, which indicate one X and one Y chromosome; they are male and therefore fetal cells. (See color plate section.)

(around 50% cells versus 10%), whereas the AM-MSCs had greater adipogenic differentiation [41,49].

Samples obtained by different routes or methods have been determined to be selectively fetal or maternal in origin [44]. Amniotic fluid MSCs of fetal origin can be obtained by abdominal amniocentesis, whereas amniotic fluid sampling using the trans-cervical route obtained MSCs of mixed fetal and maternal origin [44].

In one study, the immunological effects of fetal MSCs mixed with maternal MSCs were greater than that of maternal MSCs alone [50]. Placenta-expanded stromal cells derived from pure maternal placental cell preparations increased the survival rate of irradiated mice from 27% in untreated animals to 68%. However, a mixture of maternal- and fetal-derived MSCs increased the cell survival rate by 98% [50]. This difference was attributed to the stronger inhibitory effect of fetal-derived MSCs on T cell proliferation at the feto-maternal interface compared with that of adult MSCs.

## 5.7 Consensus classification of human placental mesenchymal stem/stromal cells?

A classification of placental MSCs has been generated by the International Placenta Stem Cell Society (IPLASS) [51] and is shown in Table 5.1. The IPLASS recommendations for the characterization of human placental MSCs included the ISCT criteria for human BM-MSCs as well as niche-specific identification and characterization details. One specific criterion for placenta-derived MSCs was testing for fetal origin using methods sensitive enough to detect less than 1% maternal MSC contamination. In addition, as placenta-derived MSCs display a variable differentiation capacity, differentiation into only one or more mesodermal lineages (osteogenic, adipogenic, or chondrogenic) was suggested. These criteria were meant only to apply to amnion and chorion membrane-derived MSCs [41,47] as there are clear protocols for the isolation of fetal MSCs from these tissues. Parolini *et al.* also suggested that MSCs isolated from the CV are more likely to contain contaminating maternal MSCs and were thus excluded from this report [51].

## 5.8 Differentially isolating fetal or maternal mesenchymal stem/stromal cells from term placental villi

To date, one study has isolated and compared fetal and maternal MSCs from the same placenta. Patel *et al.* developed a method of $CD45^-$ $CD34^+$ magnetic and flow cytometric separation and culture to isolate fetal or maternal MSCs from term placenta [52]. Their primary goal was the isolation of placental EPCs from the CV [5]. Fetal MSCs were present in the $CD34^+$ $CD45^-$ fraction, while maternal MSCs were present in the $CD34^-$ $CD45^-$ fraction. In this study fetal MSCs required culture in endothelial growth medium, as was required for the placental EPCs [5,52].

## 5.9 Confounding factors for the isolation of fetal placental mesenchymal stem/stromal cells from chorionic villi

The IPLASS consensus report explicitly excluded maternal MSCs derived from placenta but did not give clear instruction

**Table 5.1** The defining characteristics of human BM-MSCs and placental stem cells.

| Source | ISCT [19] | IPLASS [51] |
|---|---|---|
| Definition | *Ex vivo* expanded human BM-MSCs for clinical use should conform to the following parameters:<br>**1.** Adherence to plastic<br>**2.** Fibroblast-like morphology<br>**3.** Differentiation *in vitro* to mesodermal lineages (adipocytes, osteoblasts, and chondrocytes)<br>**4.** >95% positive for mesenchymal cell surface markers CD105, CD73<br>**5.** <5% positive for mature hematopoietic and endothelial markers | **1.** Cells isolated from the placenta should be determined to be fetal in origin<br>**2.** Four regions of the placenta contain stem/progenitor cells: amniotic epithelial cells, AM-MSCs, chorionic mesenchymal stromal cells, and chorionic trophoblastic cells<br>**3.** Stem cell hierarchy and self-renewal may not be critical parameters of "stemness"<br>**4.** Placental membrane MSCs should conform to the ISCT criteria as described in column 1 of this table |
| Limitations | **1.** Not all of these characteristics correlate with MSCs from other organs or species<br>**2.** Does not include minimal criteria to address immune suppressive or anti-inflammatory properties of MSCs | **1.** Does not include maternally derived MSCs isolated by a number of groups from human placenta<br>**2.** Does not include MSCs from placental adnexa (e.g., umbilical cord, Wharton's jelly, and amniotic fluid)<br>**3.** Does not include placental stem/progenitor cells from other species |

on how to obtain pure fetal MSCs from the CV [51]. A systematic review also failed to determine why some groups isolated fetal and some maternal MSCs from the placenta [8]. No studies have addressed the mechanism responsible for maternal MSC contamination of *ex vivo* cultured term CV-derived MSCs, but this is likely due to the difficulty in avoiding maternal tissue even when the CV are dissected carefully using a dissecting microscope.

## 5.10 Assumptions from the literature: lack of data, specific assays, and specific methodological detail

It is sometimes assumed that MSCs isolated from the placenta will be fetal in origin since these cells grow faster than maternal cells [50]. Fukuchi *et al.* tested samples where the gender of the fetus was known and confirmed that three were male and three were female and assumed that the entire MSC population isolated was fetal in origin [12]. Jones *et al.* reported MSC-like chorionic stem cells to be fetal but provided no quantification of the fetal : maternal ratio despite utilizing both sex-determining region Y gene (*SRY*) polymerase chain reaction (PCR) and XY FISH testing [39]. Barlow *et al.* reported that in three of three informative cases in which the gender of the delivered baby was male, human placenta-derived MSCs were of maternal origin [17]. The lack of clear descriptions in the literature of the location of placental tissue isolated, different sample collection methods, and different enzymes used in the digestion of the placental tissue adds to the confusion and difficulty in the replication of results [39,41].

## 5.11 Methods for determining fetal and maternal mesenchymal stem/stromal cells in a cultured cell population

The origin of the placental MSCs has been examined by FISH [12,39,46,53–58], human leukocyte antigen (HLA) typing [44], karyotype analysis [17,46], or reverse transcription PCR for *SRY* or forensic markers [47,59,60]. The advantages and disadvantages of these methods are summarized in Table 5.2.

HLA typing and standard or quantitative PCR give an accurate representation of the dominant MSC donor in a population and can be used for placentas from both male and female babies, but they do not give information at the single cell level. Karyotype analysis is limited to only a few cells (between 6 and 20 cells in a population of millions), and is thus inadequate for high throughput characterization of a large population of *ex vivo* expanded cells.

XY FISH is the most common technique used to determine fetal : maternal cell ratio and was used in approximately 50% of studies investigating the origin of placenta-derived MSCs (reviewed in [8]). However, this method is only suitable if the placenta is from a male baby with one Y chromosome and one X chromosome, while MSCs of maternal origin will have two X chromosomes. MSCs derived from term decidua are always female and have been reported to proliferate faster than fetal MSCs derived from the amnion. Thus, even a small number of D-MSCs contaminating a fetal MSC source can outgrow the fetal MSCs in culture [44,46].

Detection of *SRY* (located on the human Y chromosome) by PCR has also been used as a method to determine the presence of maternal MSCs contaminating MSCs derived from a fetal source [59,61,62]. This technique can quickly and easily

**Table 5.2** Methods for detecting fetal MSCs and maternal MSC contamination.

| Method name | Result output | Advantages | Disadvantages |
|---|---|---|---|
| *SRY* PCR | PCR product: present = male absent = female | Determines the sex of the fetus | Determining maternal cell contamination in the placental setting is not possible |
| XY FISH | Immunofluorescence detection of red signal (X chromosome), and/or green signal (Y chromosome) | Male and female cells can be analyzed and represented as a percentage of the MSCs in the sample | Technically challenging, very expensive, time-consuming to manually count cells; however, could be automated. Can be used on fixed cells, frozen or paraffin embedded tissues |
| D1S80 PCR | 16 base pair standard tandem repeat (STR). Different band sizes that can represent different individuals | Detects the presence of various individuals in one sample confirmed by the respective controls. Can be used to detect contaminating maternal cells irrespective of the sex of the fetus. Quantitative analysis possible on digital PCR machines | Less effective because two individuals can have the same STR numbers and therefore needs to be used in combination with other techniques (e.g., full STR analysis) |
| STR PCR | Same as D1S80 but combines numerous STR sequences, including for sex chromosomes | Commercial quantitative STR analysis provides forensic quality results | Not economically feasible for a large number of experimental samples. Does not provide information on the origin of individual cells |

determine whether the sample is male. Additionally, it can be used on genomic DNA from archived samples such as fixed, frozen, or paraffin-embedded tissues.

## 5.12 A novel method to isolate fetal and maternal placental mesenchymal stem/stromal cells

In order to isolate CV MSCs we combined the dissection methods reported in the papers by Fukuchi *et al.*, Igura *et al.*, and Abumaree *et al.* [12,53,59]. This required starting from the maternal side of the placenta, removal of a whole cotyledon, followed by careful removal of the outside villous tissue to physically exclude maternal decidual cells. The 1 $cm^3$ of villous tissue from the center of the cotyledonary lobe was finely minced. We tested a variety of preparation conditions, including explant culture of CV tissue, enzymatic digestion protocols, and different culture media, including endothelial growth medium as described in [5]) in order to promote the *ex vivo* expansion and maximize purity of cultured fetal CV-MSCs. The only method that consistently supported the growth of the fetal CV-MSCs was dissection and collagenase digestion followed by explant culture in endothelial growth medium. Small pieces of tissue, similar to cell colonies or the "mushroom-like" colonies described by Nazarov *et al.* [54] remained in culture and were passaged with the cells over several passages.

We determined the gender of the cells obtained from each method using Y-chromosome-based PCR and FISH during the entire *ex vivo* culture period. We found that fetal CV-MSCs isolated by this method had superior growth and differentiation properties as well as different cell surface and genetic profiles that were not simply due to the gender difference between fetus and mother.

## 5.13 Understanding the maternal origin of the placental mesenchymal stem/stromal cells: the septa

In an intact gravid uterus the septa consist of anchoring columns between the cotyledon-composed extracellular matrix, fetal intermediate trophoblasts, and maternal decidual stromal cells [63]. Septa are formed by the folds in the decidua as a result of traction during villous development [63]. These placental septa can extend anatomically up to the chorionic plate [63]. Therefore, tissue samples taken from the fetal side and dissecting between cotyledons could contain maternal decidua cells. We found that taking CVsamples from the fetal side of the placenta, even as shallow as 1–5 mm under the chorionic plate, still resulted in collection of some decidual tissue and led to overgrowth by maternal MSCs.

## 5.14 Conclusions and future directions

We found that (1) fetal cells can be isolated and cultured from the term placenta free of maternal contamination, (2) dissection and culture methods are critical to exclude maternal cells, (3) serum plus the added growth supplements contained in EGM2 + 10 media are necessary for *ex vivo* proliferation of fetal CV-MSCs, and (4) standard MSC media such as Dulbecco's modified Eagle's medium and 10% fetal calf serum is advantageous for the *ex vivo* proliferation of maternal over fetal placental MSCs.

It is important in the future to determine the exact nutrients or growth factors required for fetal CV-MSC expansion and to provide detailed methods, including video or photographic images of the isolation procedure. Finally, thorough comparison of fetal and maternal MSCs from the same placenta has widespread implications for placental MSC banking and future regenerative medicine applications.

## 6.1 Introduction

Mesenchymal stem/stromal cells (MSCs) are considered to be a reliable source of stem cells for cellular-based regenerative medicine applications owing to their multipotent potential, proangiogenic, and immunomodulatory properties. While the use of MSCs is less controversial than embryonic-derived stem cells (ESCs), they, like all somatic stem cells, have a finite lifespan *ex vivo*. Key master regulatory genes and signaling pathways critical for MSC self-renewal and lineage determination are the subjects of intense investigations. However, the role of epigenetic modifiers in regulating the chromatin structure and accessibility of DNA on genes of various signaling pathways has only recently been investigated. With the increasing evidence implicating epigenetic modifiers in MSC differentiation, growth, and the correlation between mutations in epigenetic modifiers resulting in human disorders with musculoskeletal phenotypes, these findings suggest the importance of these proteins in skeletal tissue development.

Stem cells are characterized by their capability to self-renew and to terminally differentiate into multiple mature cell types. Somatic or adult stem cells have a finite self-renewal capacity and are lineage restricted. The use of adult stem cells for therapeutic purposes has been a topic of enormous interest given the ethical considerations associated with ESCs. Mesenchymal stem cells are adult stem cells that can differentiate into osteogenic, adipogenic, chondrogenic, or myogenic lineages. Owing to their ease of isolation and their unique characteristics, including lack of immunogenicity in their recipient, MSCs have been widely regarded as potential candidates for tissue engineering and repair. While various signaling molecules important to MSC differentiation have been identified, our complete understanding of this complex process is lacking.

Recent investigations focused on the role of epigenetic regulation in lineage-specific differentiation of MSCs have shown that unique patterns of DNA methylation and histone modifications play an important role in the induction of MSC differentiation toward specific lineages. Nevertheless, MSC epigenetic profiles reflect a more restricted differentiation potential compared with ESCs. Here, we review the effect of epigenetic modifications on MSC multipotency and differentiation, with a focus on osteogenic and adipogenic differentiation. We also highlight clinical applications of MSC epigenetics and nuclear reprogramming.

## 6.2 Mesenchymal stromal/stem cells

Bone marrow MSCs (BM-MSCs) are tissue-specific postnatal stem cells that are restricted in their differentiation potentials to form functional skeletal tissues and myelosupportive stroma. Mesenchymal stem-like cells have also been identified in other tissues, such as peripheral adipose tissue, umbilical cord blood, amniotic fluid, placenta, dental pulp, periodontal ligament, tendons, synovial membrane, and skeletal muscle [1–13]. However, these different MSC-like populations exhibit wide variations in their multidifferentiation potentials, hematopoietic supportive properties, and proliferation capacities. This variation is most likely due to the different developmental origins and tissue-specific nature of the different MSC-like populations, which may be under the direct control of epigenetic patterning.

BM-MSCs were first identified as clonogenic stromal precursor cells, termed colony-forming unit–fibroblastic (CFU-F) within bone marrow aspirates of rodents [14] and subsequently in other species, including humans [15]. A common feature of the *ex vivo* expanded progeny of CFU-Fs is their heterogeneity with respect to morphology, ability to undergo self-renewal, myelosupportive capacity, lifespan, and multidifferentiation potential [1,16–19]. These observations have led to the proposal that the stromal component within bone marrow is comprised of a hierarchy [20] of immature stem cells, committed progenitor cells, and mature functional stromal populations (Figure 6.1)

Since the vast majority of CFU-Fs demonstrate limited growth and differentiation potential, the general term describing MSCs should only refer to the *ex vivo* expanded progeny of a minor subset of long-lived multipotential CFU-Fs, with the potential to form osteoblasts, adipocytes, chondrocytes, smooth muscle cells, and myelosupportive fibroblasts *in vitro* or when transplanted *in vivo*. While attempts have been made to establish an immunophenotype specific for MSC-like populations (HLA-ABC$^+$, CD73$^+$, CD105$^+$, CD29$^+$, CD13$^+$, CD44$^+$, CD90$^+$, CD45$^-$, CD34$^-$, CD31$^-$, and CD14$^-$ [21,22], the cell surface markers used are generic to a wide range of cultured fibroblastic cells and some vascular and hematopoietic cell populations with different growth and developmental potentials. Moreover, none of the positive selection markers (HLA-ABC$^+$, CD73$^+$, CD105$^+$, CD29$^+$, CD13$^+$, CD44$^+$, and CD90$^+$) are capable of distinguishing between immature and committed stromal cell lineages or non-MSC fibroblasts. The identification of multipotential clonogenic MSCs from aspirates of human bone marrow has been achieved based on their high expression of the stromal precursor cell surface antigen STRO-1, which is downregulated in committed stromal lineages. Purification of STRO-1$^{bright}$ BM-MSCs was achieved by dual fluorescence-activated cell sorting based on their co-expression of the perivascular markers CD106 and CD146 and their lack of expression of the hematopoietic markers CD34, CD14, CD45, and glycophorin-A [4,16,23,24]. Therefore, the development of immunoselection protocols to obtain purified populations of BM-MSCs has allowed the identification of putative regulatory genes critical for maintaining the MSC population following *ex vivo* expansion [25–27].

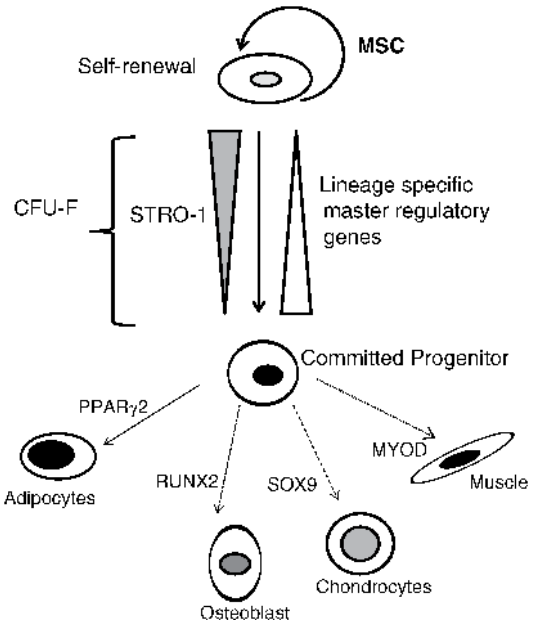

**Figure 6.1** Stromal hierarchy of MSCs. BM-MSCs contain a heterogeneous population of stem cell progenitors and committed lineage progenitors. Stem cell progenitors (MSCs) express high levels of STRO-1 and low levels of lineage-specific master regulatory genes. These cells have the capacity to self-renew and differentiate. Committed lineage progenitors express low levels of STRO-1 and higher expression of specific master regulatory genes. As the committed progenitors differentiate they express key master regulator genes such as *PPAR-γ2*, *RUNX2*, *SOX9*, and *MYOD* as MSCs differentiate into mature adipocytes, osteoblasts, chondrocytes, and muscle cells respectively.

Understanding the processes that drive BM-MSC lineage commitment may one day allow us to manipulate MSCs to differentiate down specific lineages required for cellular therapies where stromal cells are defective in their differentiation and renewal capacity. Signaling pathways such as Wnt, Notch, bone morphogenetic protein (BMP) [28] and key transcription factors RUNX2, PPAR-γ2, MOYD, and SOX9 have been implicated as critical drivers of MSC lineage commitment. The activation of these signaling pathways and expression of transcription factors are dependent on the regulation of chromatin, allowing the activation of these genes and their targets. Therefore, it is important to identify which epigenetic modifications are critical for the regulation of MSC growth and lineage specification. This chapter will identify the relationship of important epigenetic modifications involved in MSC maintenance, self-renewal, and differentiation.

## 6.3 Epigenetics

Epigenetics is the cellular modification of reversible and heritable changes in gene expression that occur without changes in the

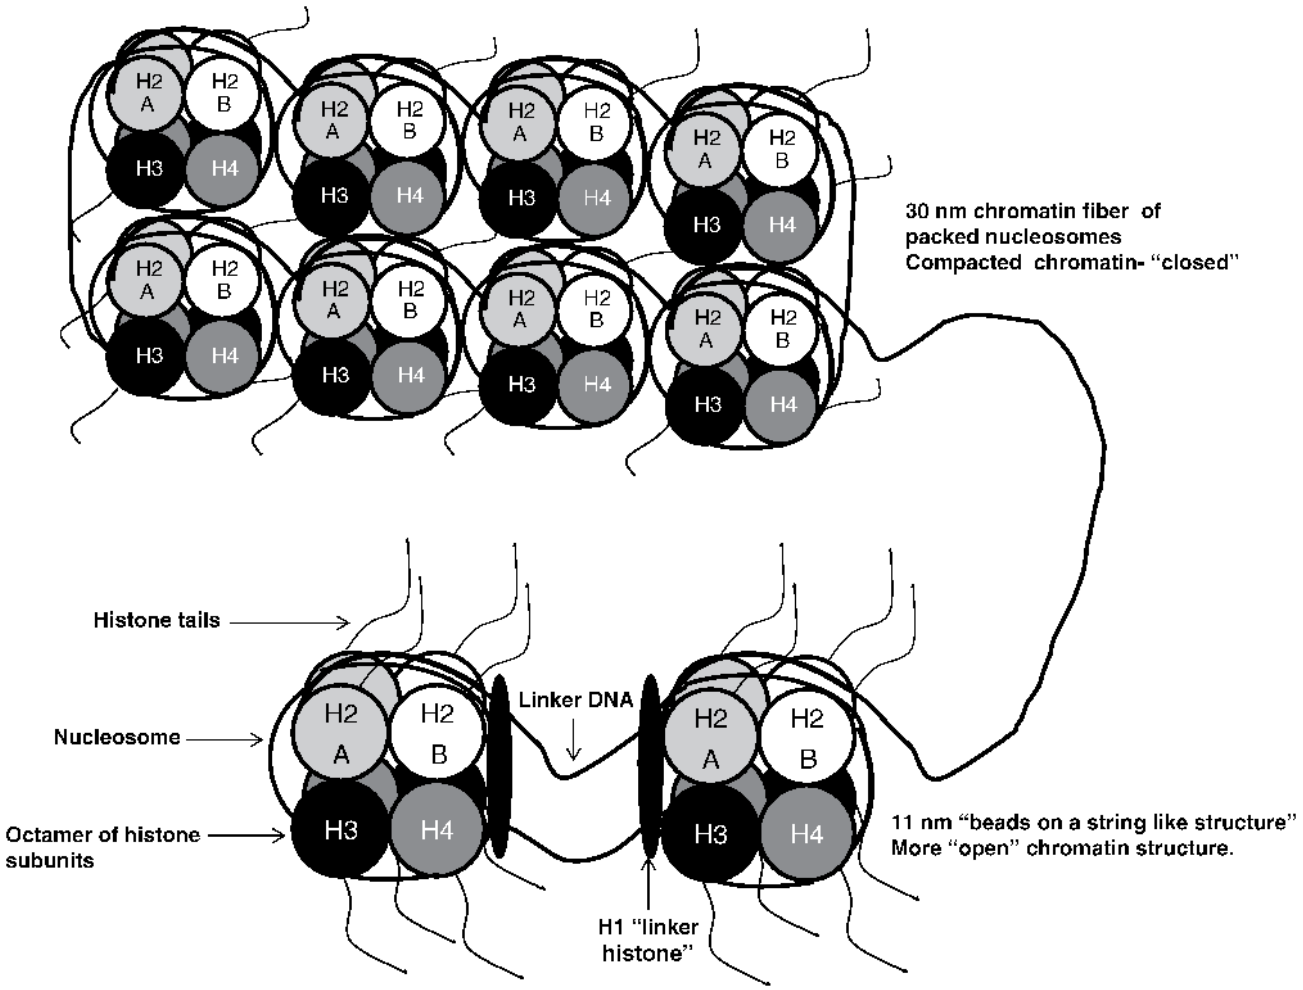

**Figure 6.2** Compaction of DNA through the formation of chromatin. DNA is compacted within a cell through chromatin. 145–146bp DNA is wrapped around a nucleosome structure consisting of an octamer of histone subunits, two copies of H2 A, H2 B, H, and H4. H1 "linker histone" anchors the DNA wrapped around the nucleosome in place. A region of DNA is present in between nucleosomes known as linker DNA. Histone tails protrude out of the histone subunits and these are regions of posttranslational modifications that dictate a more open ("beads on a string") or closed chromatin structure. Nucleosomes are further compacted to form a 30 nm closed chromatin fiber structure. The structure can be further condensed to chromosomes.

DNA code [29]. Epigenetic modifications such as DNA methylation and posttranslational modifications include histone modifications and chromatin remodeling. These molecules regulate the structure of chromatin, determining the accessibility of genes to transcription factors and other modulators involved in gene regulation. Chromatin is formed through the compaction of a large amount of DNA where 145–146 base pairs of DNA are wrapped around a nucleosome, consisting of an octamer of histone subunit [30,31] (Figure 6.2).

Nucleosomes are joined together by linker histone 1 (H1) and a small region of DNA, which form a "beads-on-a-string-like structure." Each histone subunit has a specific sequence of amino acids in a tail-like structure defined as a "histone tail" that protrudes out from the nucleosomes and can be posttranslationally modified (Figure 6.2).

The functional state of chromatin can be modified through C5 methylation of DNA at cytosines within cytosine–phosphate–guanosine (CpG) dinucleotides and the posttranslational modification of histone proteins and residues within the histone tails (Figure 6.2). DNA methylation is commonly located at the cytosine of the dinucleotide sequence CpG and is often located at genes that have tissue-restricted expression and become stably silent. The activity of DNA methyltransferases (DNMTs) is critical for genome stability, X inactivation, genomic imprinting, and regulating key developmental genes during cellular differentiation [32–42]. DNA methylation can be separated into two types: *de novo* and maintenance. In early mammalian development the mature oocyte, primordial germ cells, and blastula DNA are relatively unmethylated. During embryogenesis and the formation of the three germ layers, DNA methylation plays a pivotal role in patterning tissue-specific expression [43–45].

DNMT1, known as the "maintenance methyltransferase," is responsible for copying methylation patterns after DNA replication, imprinting, X activation, and CpG methylation [38,46].

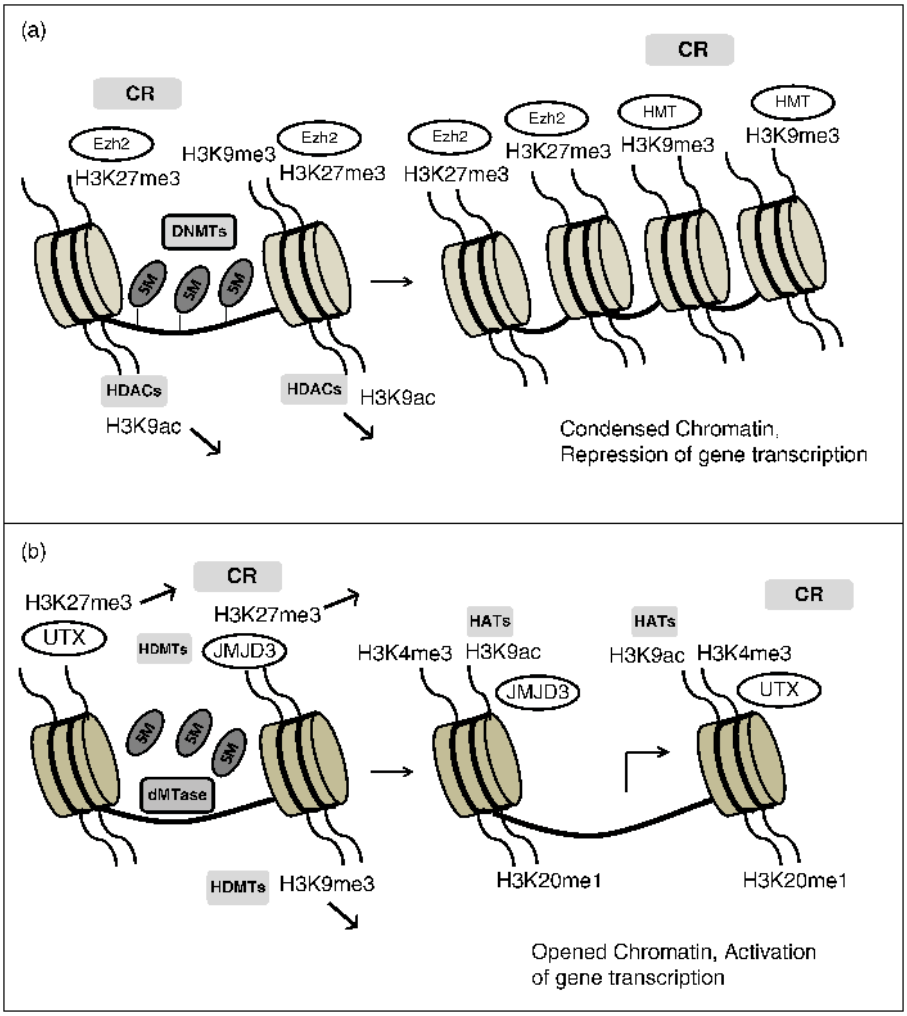

**Figure 6.3** Chromatin-modifying proteins modulate chromatin structure. DNA accessibility is dictated by chromatin structure; chromatin can be compacted or opened up, leading to repression or activation of genes through DNA and posttranslational histone modifications (PTMs). (a) 5-Methyl cytosine methylation (5M) of DNA by DNMTs. Histone 3 lysine 27 methylation by HMTs can trimethylate histone 3 lysine 9 and 27 (H3K27me3 (Ezh2)) and the removal of H3K9 acetylation (ac) by HDACs. All these epigenetic modifications facilitate the compaction of the chromatin structure and gene repression. (b) Removal of 5M from DNA by DNA demethylases (dMTase). The removal of H3K9me3 and H3K27me3 is mediated by UTX and JMJD3 histone demethylases (HDMs). The addition of H3K4me3 and H3K420me1 methylation by HMTs and H3K9ac by HATs lead to the opening up of chromatin and activation of gene transcription. Chromatin remodelers (CRs) are recruited to chromatin by a combination of DNA and PTM leading to either the unravelling or condensation of chromatin, depending on the histone code cellular signals.

Gene silencing can occur via DNA methylation of CpG islands to prevent the binding of proteins to DNA. This in turn acts as a marker for CpG-binding domain proteins (MBD), which recruit histone deacetylases (HDACs) and histone 3 lysine 9 (H3K9) methyltransferase, allowing the compaction of chromatin [47–52]. DNA methylation can then be modified by DNA demethylases, which remove the cytosine di-methylation modification allowing the recruitment of factors involved in transcriptional activation. The 10-11-translocation 1–3 (TET1–3) proteins are dioxygenases that form 5-hydroxymethylation (5hmc), 5-formylcytosine (5fC), and 5-carboxylcytosine (5caC), which are intermediates that form in the process of the removal of methylation [53,54]. With the development of methyl-DNA immunoprecipitation microarray hybridization and bisulfite sequencing [55,56], investigations examining the role and patterns of DNA methylation in different processes such as development, stem cell self-renewal, and pluripotency have yielded an enormous amount of information showing methylation of developmental genes as a cell becomes more restricted in its multipotent capacity and less stem cell-like [57,58]. Posttranslational modification of histones is another level of transcriptional regulation that can result in repression or activation of gene expression. The structure of chromatin can be regulated through methylation, acetylation, phosphorylation, sumoylation, and ubiquination of histone tails. Posttranslational modification of 28 known residues gives rise to over 100 million differentially modified nucleosomes within cells, accounting for the great diversity of signals and gene expression outcomes [59]. The regulation of DNA through epigenetic modifications allows the specification and maintenance of cellular identity in a wide range of cell types [37,60]. Acetylation of histones by histone acetyl-transferases (HATs) leads to the activation of transcription, whereas, histone methylatation by histone methyltransferases (HMTs) can regulate gene activation or repression depending on which residues are methylated. Histones can be mono- (me1), di-, (me2) or trimethylated (me3) on lysine

residues and me1 or me2 on arginine residues. Methylation of histone 3 lysine 4 (H3K4), lysine 36 (H3K36), and lysine 79 (H3K79) is associated with active transcription, and methylation of H3K9 and lysine 27 (H3K27) is associated with gene repression [61] (Figure 6.3).

With the development of chromatin immunoprecipitation (ChIP) techniques researchers can now identify histone proteins that are associated with a particular region of the genome. Recent investigations of ESCs using microarray and ChIP techniques have revealed the presence of both H3K27me3 and H3K4me3 specific modification patterns on chromatin termed "bivalent domains." The presence of both these bivalent domains within ESC genomes allows the silencing of developmental regulators whilst keeping them poised for activation. Upon ESC differentiation these bivalent domains become univalent, allowing the activation of genes that drive lineage commitment [62]. Methyltransferases and demethylases are thought to be responsible for the switch between repressive H3K27 domains and active H3K4 domains. Different combinations of histone modifications can influence the recruitment of different effector proteins and transcription factors to chromatin, and these combinations are known as the "histone code," which determines the functional state of chromatin [63,64].

Furthermore, the interplay between the different epigenetic modifying enzymes (HATs, HDACs, DNMTs, MBD, and HMTs) is critical for normal gene transcription, suggesting the importance of epigenetic gene regulation in many cellular processes.

## 6.4 DNA methylation and histone modifications in mesenchymal stem/stromal cells

The importance of key transcription factors and signaling pathways in regulating MSC differentiation, growth, and lifespan has been widely investigated. However, the role of epigenetic modifiers in regulating chromatin structure allowing the activation or repression of these key genes and signaling pathways in MSCs has only recently been explored [65].

Studies have assessed the DNA methylation profiles between different MSC-like cells derived from bone marrow, adipose tissue, and skeletal muscle using bisulfite sequencing, methyl-DNA immunoprecipitation, and promoter array hybridization (MeDIP-chip) [66]. Analysis of reference sequence promoter arrays (Re-Seq) revealed that promoter DNA methylation patterns were similar in MSC-like populations derived from adipose tissue, bone marrow, or skeletal muscle [67]. It was proposed that a core of hypermethylated genes constituted a common intrinsic epigenetic marking of different MSC-like populations, lending support to the common features of MSC-like cells identified in various tissues. It is suggested that promoter methylation patterns may dictate gene expression, where strong methylation dictates repression, while hypomethylation in some tissues determines either repressive or active gene expression when complemented with other modifying proteins. Furthermore, promoter DNA methylation is only one part of the regulation of lineage determination since low levels of DNA methylation are not a reliable predictor of differentiation capacity [66,68,69]. These studies further suggested that the overall CpG methylation status of genes is not indicative of differentiation potential [70–72], implying that processes other than DNA methylation contribute to the differentiation capacity and lifespan of MSCs. Therefore, the role of other posttranslational histone modifiers is becoming increasingly more important in the study of stem cell biology. With the use of techniques such as chromatin immune-precipitation sequencing (ChIP-Seq) it is now possible to identify the epigenetic patterns of cells during many cellular process under varying environmental conditions.

## 6.5 Epigenetic regulation of osteogenic differentiation

Osteogenic differentiation of MSCs is controlled by key signaling pathways and transcription factors that can be regulated through epigenetic modifications [73]. For example, DNA methylation and demethylation have been reported to play a role during osteogenic differentiation where highly methylated osteogenesis-associated genes *DLX5*, *RUNX2*, *BGLAP*, and *OSTERIX* in adipose-derived MSCs undergo demethylation and increased gene expression during osteogenic differentiation [7]. Similarly, alkaline phosphatase, *Trip10*, and rank ligand have also been shown to be regulated by DNA methylation during BM-MSC osteogenic differentiation [75–77], while another report observed reduced gene expression levels of the stem-cell-associated genes *BRACHYURY* and *LIN28* by hypomethylation of the promoter during BM-MSC differentiation [78]. Furthermore, the intrinsic and extrinsic signals that MSCs receive during maturation can also govern the epigenetic regulatory outcome of MSC cell fate determination [79].

Besides DNA methylation, gene repression can be mediated through H3K27 methylation. Studies have found that the H3K27 methyltransferase Enhancer of Zeste Homolog 2 (*EZH2*), a component of the polycomb repressor complex 2 (*PCR2*), can interact with DNMTs to promote gene repression [80]. EZH2 has been widely implicated as a regulator of developmental processes and differentiation-associated genes [81,82]. EZH2 activity can lead to either mono-, di-, or trimethylation of the K27 residue of H3 tails (H3K27me1/2/3) and is associated with heterochromatin, chromatin compaction, and repression of gene transcription [83–85]. EZH2 influences chromatin structure through adding an me3 modification to H3K27, where this mark is recognized by PRC1, which recruits effector proteins such as chromatin remodelers involved in compaction of chromatin [86]. EZH2 deficiencies in mice lead to perinatal mortality due to deformities in morphological movement of ESCs in the developing embryo.

More recently it was shown that overexpression of *EZH2* in human BM-MSCs inhibited osteogenic differentiation, while siRNA knockdown of *EZH2* or treatment with the methyltransferase inhibitor DZNep promoted osteogenic differentiation, identifying a direct role for EZH2 in regulating bone cell differentiation of human BM-MSCs [87]. Furthermore, EZH2 was found to bind and methylate the promoter regions of RUNX2 and osteopontin using ChIP analysis [87], suggesting that EZH2 may be a key regulator for MSC cell fate determination. During MSC differentiation, cyclin-dependent kinase 1 (CDK1) represses EZH2 methyltransferase activity through the phosphorylation of residue threonine 487, thus promoting BM-MSC osteogenic differentiation *in vitro* [88]. ChIP-on-chip analysis of adipocytes and osteoblasts revealed that the myocyte enhancer factor-2 interacting transcription factor (MITR or HDAC9c) is bound by EZH2 in adipocytes but not in osteoblasts. During osteogenesis, EZH2 binding to MITR is repressed, allowing MITR to complex with PPAR-γ2, thereby directly interrupting PPAR-γ2 activity [89]. These observations have led to the hypothesis that the known H3K27 demethylases (HDMs) KDM6A (UTX – ubiquitously transcribed tetra-tricopeptide repeat X) and Jumonji domain-containing protein 3 (JMJD3, also known as KDM6B) could also be pivotal in dictating the lineage specificity of MSCs.

Histone methylases and demethylases control the level of methylation present within a cell. An increase in H3K27 demethylation leads to the recruitment of gene-activating factors and activation of gene transcription. UTX and JMJD3 have both been identified as having potential roles in regulating MSC osteogenic differentiation [87,90–93]. *UTX* overexpression in MSCs was found to promote osteogenic differentiation, while siRNA knockdown of *UTX* resulted in decreased osteogenesis *in vitro* and *in vivo* [87]. However, the role of JMJD3 in osteogenic differentiation is thought to act by regulating RUNX2 and OSTERIX expression in osteoblasts [91–93], which is regulated by MIR146A during osteogenic differentiation [92]. Therefore, it is still unclear whether UTX and JMJD3 work synergistically or individually to regulate osteogenic differentiation. While it is well established that the BMP, Wnt, and Notch signaling pathways all play important roles in osteoblast differentiation [28], these two demethylases could play different roles in regulating osteogenic differentiation based on the cellular signals they encounter leading to specialized effects on cellular differentiation.

Methylation of another lysine residue on H3, H3K9, is associated with chromatin compaction and gene repression. H3K9me and H3K27me modifications are usually present on silenced genes, where H3K9 methylation can depend on the H3K4 methylation status of the adjacent lysine residue [94]. There are also multiple known H3K9 HMTs, including SUV39h, Set domain bifurcated 1 (SETDB1), G9a, and Set7/Setd8, which are potentially involved in the global enrichment of H3K9Me2 during MSC osteogenic differentiation [95]. Other studies have demonstrated that the activation of the noncanonical Wnt signaling pathway resulted in promotion of osteogenic differentiation due to H3K9 methylation and repression of PPAR-γ2 [96]. During osteogenic differentiation the promoter regions of *ALP*, *RUNX2* and *OP* were acetylated and underwent H2K9me2 demethylation. Therefore, it appears that the addition of acetylation and removal of H3K9me3 facilitates the expression of bone-associated genes to help drive osteogenesis. Conversely, stem-cell-associated genes such as *OCT4* and *NANOG* were downregulated with a corresponding deacetylation and increase in H3K9me3 on the promoters of these genes. Furthermore, KDM4B, a H3K9 demethylase, was found to remove H3K9me3 and H3K27me3 from osteogenesis-associated genes such as *HOX* and *DLX*, resulting in the opening up of chromatin and promotion of MSC osteogenic differentiation [90].

H3K4 methylation has been shown to positively regulate transcription by recruiting nucleosome remodeling enzymes and histone acetylases [97]. H3K4 methylation is mediated by SET domain-containing methyltransferases, such as mixed lineage leukemia 1–5 (MLL1–5), SET1A/B, and SET7/9. H3K4 is critical for gene activation, where this histone modification mark is widely expressed on genes involved in differentiation, growth, and self-renewal [98]. The balance of H3K4 methylation is controlled by H3K4 HMTs and H3K4 HDMs. MLL proteins often associate in a complex with HDM UTX/KDM6A or JMJD3/KDM6B and Pax transactivation domain-interacting protein (PTIP; nuclear protein associated with active chromatin), allowing the rapid removal of the repressive methylation and the application of the active methylation H3K4 [99].

Opening up of chromatin to allow for gene transcription is regulated by active histone modifications such as H3K4me3. Studies have identified that H3K4me3 and hyperacetylation mediated by HOXA10 induces chromatin remodeling, facilitating *RUNX2* activation and its downstream target gene, *OSTEOCALCIN* [100]. H3K4 HDMs are associated with removal of the H3K4 active methylation modification involved in transcriptional activation. Jumonji domain-containing histone demethylases such as the JARID1 family of HDMs (JARID1A–D) remove H3K4me3 and H3K4me2 modifications. JARID1A inhibits osteogenesis through the promoter demethylation of *RUNX2*, *OSTERIX*, *OSTEOCALCIN*, and *ALKALINE PHOSPHATASE* in human adipose-derived MSCs [101]. The Nucleolar protein 66 is also known to have H3K4me3/2/1 demethylase activity and has been found to demethylate the promoter region of *OSTERIX* and interact directly with *OSTERIX* preventing activation of its downstream target genes [102]. Furthermore, in human adipose-derived MSCs, osteogenic differentiation was found to be regulated by the H3K4 demethylase retinoblastoma-binding protein 2 (RBP2). Knockdown of *RBP2* increased H3K4me3 and promoted *ALKALINE PHOSPHATASE*, *OSTEOCALCIN*, and *OSTERIX* expression. Furthermore, RBP2 directly associates with the RUNX2 protein, where knockdown of *RPB2* leads to activation of *RUNX2* [101].

Other modifications, such as acetylation of the histone tails lead, to neutralization of the partial electric charge of lysine, which in turn results in opening of the chromatin structure.

HATs and HDACs are responsible for the maintenance of cellular histone acetylation. H3K9 and H4K16 acetylation (H3K9ac and H4K16ac) are commonly associated with euchromatin and transcriptional activation. During osteogenic differentiation, H3K9ac enrichment decreased on the stem-cell-associated genes *NANOG* and *OCT4* and were enriched with an increase in H3K9me2 [95].

Following long-term *ex vivo* expansion, MSCs undergo spontaneous osteogenic differentiation with an increase in *RUNX*2 and *ALKALINE PHOSPHATASE* expression. This observation has been correlated with an increase of H3K9ac and H3K14ac modifications on these osteogenic genes [103]. There are 18 known HDACs that contribute to skeletal development and bone homeostasis. Many of these HDACs regulate bone formation and development through the regulation of *RUNX*2 [104–107]. H3 and H4 hyperacetylation was identified on osterix and osteocalcin promoters, leading to decreased HDAC1 recruitment to these promoters [108]. Furthermore, the treatment of MSCs with the HDAC inhibitors vorinostat, sodium butyrate, valproic acid, and trichostatin A was found to promote osteogenic differentiation [109–114].

These studies have identified a wide range of DNA and histone posttranslational modifications directly involved in the osteogenic differentiation of MSCs, but have yet to determine the sequential and temporal activities of these epigenetic modifiers during the process of osteogenesis.

## 6.6 Epigenetic regulation of adipogenic differentiation

Adipogenic differentiation of MSCs is thought to be regulated, in part, by DNA methylation, where CpG sites have been shown to be hypomethylated in key adipogenic genes such as *PPAR-γ2*, *C/EBP-α*, *leptin*, *fatty acid-binding protein 4* and *lipoprotein lipase* in *ex vivo* expanded adipose-derived MSCs [70].

The H3K27 methyltransferase EZH2 is also known to promote adipogenesis by repressing Wnt-1, -6, -10a, and -10b, leading to disruption of Wnt/β-catenin signaling rather than directly regulating *PPAR-γ2* [115]. In human studies, overexpression of *EZH2* in BM-MSCs promoted adipogenic differentiation, while siRNA knockdown inhibited adipogenic differentiation [87]. Overexpression of the HDM UTX inhibited adipogenesis, while siRNA knockdown promoted adipogenic differentiation of BM-MSCs [87], possibly by demethylating Wnt-associated genes, therefore inhibiting adipogenesis indirectly. Other studies have shown that knockdown of H3K27me3 demethylase JMJD3/KDM6B and H3K4me3 demethylase KDM4B inhibit adipogenesis, further supporting the role of demethylases in adipogenic differentiation [90]. Additional research has shown that, during adipogenic differentiation, histones bound to adipogenesis-associated gene promoters undergo H4K20me1 methylation mediated by the methylase, PR-Set7/Setd8 [116]. During MSC adipogenic differentiation the H3K9 HMT Suv39h1 mediates activating enhancer binding protein 2-α (AP-2-α)-dependent inhibition of CCAAT-enhancer-binding protein (C/EBP-α) [117]. Furthermore, *PPAR-γ2* target gene expression is blocked by SUV39H1, suggesting that H3K9 methylation is a negative regulator of adipogenesis [118]. Similarly, Wnt5a-induced H3K9 SETDB1 methylation was found to activate the noncanonical Wnt signaling cascade, resulting in the inhibition of *PPAR-γ2* function and adipogenesis, while promoting osteogenic lineage commitment [119,120]. In another report the HMT G9a was found to be responsible for di-methylation of H3K9, which regulates gene repression [121]. Furthermore, ChIP-Seq analysis of preadipocytes revealed that H3K9me2 and H3K27me3 modifications at gene loci were largely nonoverlapping [122]. In these studies, *WNT* gene loci exhibited high levels of H3K27me3 and low levels of H3K9me2, while *PPAR-γ2* was found to have high levels of H3K9me2 and low levels of H3K27me3. Inhibition of G9a methylation activity was also found to increase *PPAR-γ2* gene expression, leading to promotion of adipogenesis. While G9a represses *PPAR-γ2* expression in an HMT activity-dependent manner, it has also been shown to facilitate *WNT10A* expression independent of its enzymatic activity [122]. Therefore, WNT10A facilitates β-catenin stabilization, leading to the inhibition of adipogenesis and promotion of osteogenic commitment.

Lysine-specific demethylase 1 (LSD1), also known as KDM1, forms a complex with androgen receptors and can act as an H3K9 di-demethylase. LSD1 can regulate C/EBP-α by decreasing H3K9me2 and maintaining H3K4me2 at its promoter, counteracting the activity of the H3K9 methyltransferase, SETDB1 [123]. Activating methylation modifications such as H3K4 play a critical role in activation of key adipogenic differentiation genes. MLL3 and MLL4 are mono- and di-methyltransferases targeting H3K4, which are required for enhancer activation, gene activation, and differentiation and are critical for *PPAR-γ* and *C/EBP-α* expression during adipogenesis [99,124–126]. Moreover, H3K4 di-methylation, a mark of poised genes, has been shown to be present on the promoters of the adipose-associated genes *APM1*, *GLUT4*, *GPD1*, and *LEPTIN* in preadipocytes [98,127].

Other studies have shown that H4K20 methylation, often associated with gene repression, can aid in gene activation via mono-methylation. H4K20 mono-methyltransferase *PR-SET7/SETD8* gene is upregulated by PPAR-γ2 during adipogenesis, and knockdown of *PR-SET7/SETD8* suppressed adipogenesis [116]. These findings suggest that combinations of lysine methylation patterns are required for promotion or repression of adipogenesis.

The histone 3 argine 8 methylase (H3R8) known as the protein arginine methyltransferase (PRMT) family of enzymes is divided into two classes. Type I PRMTs asymmetrically mono- and di-methylate arginine residues, whereas type II PRMTs symmetrically mono- and di-methylate arginine residues [128]. Both types of PRMT form complexes with SWItch/Sucrose Non-Fermentable (SWI/SNF) ATP-dependent chromatin-remodeling enzymes, adding another functional layer on to chromatin

regulation. Knockdown of *PRMT5* inhibits adipogenic differentiation and adipogenic gene expression, while overexpression accelerates adipogenic differentiation [129]. The presence of PRMT5 recruits SWI/SNF binding of *PPAR-γ2* and downstream adipose-associated target genes allowing the opening up of chromatin and activation of gene transcription. The Brg1 SWI/SNF remodeling enzyme appears to play a critical role in remodeling chromatin at the PPAR-γ2 gene locus to facilitate *PPAR-γ2* gene expression [130].

Histone acetylation has been reported to be an important modification in regulating white adipocyte differentiation. HATs promote the recruitment of factors involved in opening up of chromatin and the activation of key genes critical for adipogenesis [131,132]. HATs such as H3K27ac CBP/p300 have been shown to be involved in mediating *PPAR-γ2* gene expression and promoting adipogenesis in 3T3-L1 preadipocytes. Furthermore, genome-wide profiling of H3K9ac and H3K27ac in 3R3-L1 preadipocytes identified their presence on the *PPAR-γ2* gene locus during adipogenesis. However, little is known of the role of CBP/p300 and other HATs in the regulation of *PPAR-γ2* and other key adipogenic genes in human MSCs.

The removal of acetylated histones is important for gene repression during maturation where adipogenic differentiation can be repressed through the unphosphorylated form of retinoblastoma (Rb) protein, which recruits HDAC3 to the promoter of *PPAR-γ2* preventing its activation of its target genes [133]. Moreover, treatment of cultured MSCs with the HDAC inhibitor trichostatin A decreased adipogenic differentiation [112,134].

While it has been shown that some epigenetic modifiers act by direct activation or repression of *PPAR-γ2*, other modifiers such as EZH2 regulate adipogenesis indirectly through the inhibition of signaling pathways that promote osteo/chondrogenesis [115]. Furthermore, the recruitment of epigenetic modifiers to the chromatin by other molecules can act as another level of control to further regulate the expression of adipose-associated genes.

Collectively, these studies depict the complexity of epigenetic modifications involved in adipogenic differentiation, where various modifiers appear to be pivotal for the switch between osteogenic and adipogenic lineage commitment (Table 6.1).

## 6.7 Epigenetic regulation of myogenic differentiation

DNA methylation has been shown to be important for gene silencing during MSC differentiation. However, studies have found that the known myogenic differentiation 1 MyoD1 CpG islands are not methylated in many nonexpressing tissues, such as the brain [135]. These findings demonstrated that, in some instances, the CpG methylation status of genes did not dictate whether these genes were silenced or expressed, suggesting that other regulator mechanisms are required.

Other studies have shown that protein levels of the DNA methyl binding factors MeCP2 and MBD-2 significantly increased during myogenic differentiation and they are known to regulate chromatin reorganization and promotion of terminal differentiation [136]. While non-muscle-derived MSC-like populations do not normally form myotubes or constitutively express MYOD1 during culture, treatment with 5-azacytidine, which removes DNA methylation, was found to induce myosin heavy chain expression and myotube formation in these cells, and promoted skeletal muscle differentiation [137]. Furthermore, reports have described the localization of EZH2, YY1, and HDAC1 on silent muscle-specific genes in different MSCs-like populations, preventing gene muscle creatine kinase (MCK) and myosin heavy chain (MHC) transcription [138,139]. During muscle differentiation, EZH2, Y11, and HDAC1 are removed from muscle genes, allowing the recruitment of MYOD and serum response factor (SRF) to chromatin [138,140]. EZH2 has also been found to repress the microRNA miR-214 in MSCs, where EZH2 is removed from the chromatin during myogenic induction, allowing activation of miR-214 and activation of *MYOD* and *MYOGENIN* [141]. (MYOD is a protein with a key role in regulating muscle differentiation. Myogenin is a muscle-specific basic-helix–loop–helix (bHLH) transcription factor involved in the coordination of skeletal muscle development (myogenesis) and repair.)

The role of H3K27me HDMs in MSC differentiation was first described in muscle differentiation, where recruitment of UTX by the homeodomain transcription factor Six4 during myogenesis resulted in H3K27 demethylation of muscle-specific genes, RNA polymerase elongation, and gene expression [142]. In another study, MLL5, which lacks methyltransferase H3K4 activity like its family members MLL3 and MLL4, is critical for the regulation of LSD1 and SET7/9 and the expression of muscle regulators paired box 7 (PAX7), myogenic factor 5 (Myf5), and MYOGENIN [143]. However, the role of these factors in MSC skeletal muscle differentiation remains to be determined.

Collectively, studies suggest that epigenetic modifiers may play a role in regulating lineage-specific genes in myogenesis. However, further investigations are needed to determine which modifiers are critical for driving myogenic lineage-commitment in muscle- and non-muscle-derived MSC-like populations.

## 6.8 Epigenetic regulation of chondrogenic differentiation

Early studies showed that collagen type I is methylated in fibroblasts and chondrocytes, while the cartilage-specific collagen type II gene exhibits reduced methylation in chondrocytes compared with fibroblasts. In human chondrocytes the CpG sites within the COL10A1 promoter are normally methylated; however, during MSC chondrogenic differentiation *in vitro*, two CpG regions within the COL10A1 promoter undergo demethylation [144]. In another report, DNA hypermethylation of COL9A1 downregulated its expression in osteoarthritic chondrocytes, while treatment with 5-azadeoxycytidine increased

**Table 6.1** Histone modifiers that regulate MSC osteogenic and adipogenic differentiation.

| Epigenetic modifier | Modification | Osteogenesis | References | Adipogenesis | References |
|---|---|---|---|---|---|
| *DNA methylation* | | | | | |
| DMT1 | 5MC | Represses Runx2 and Alx5 in ADSCs.<br>Regulates ALP, Trip10, and RANKL in MSC. | [74–77] | DNA hypomethylation on PPARγ2 and Leptin in cultured adipose-derived MSC. | [118] |
| *Methylation* | | | | | |
| EZH2 | H3K27me3 | CDK1 phosphorylates EZH2, promoting osteogenesis. Overexpression repressed RUNX2 and OP expression. Ezh2 represses PPARγ2, promoting osteogenesis. | [87–89] | EZH2 regulates/represses noncanonical pathway promoting adipogenesis. Overexpression promotes adipogenesis. | [87,115] |
| Setdb1 | H3K9me3 | Suppresses PPARγ2 activation by H3K9me3. | [119,120] | Downregulated during adipogenesis. | [119,120] |

COL9A1 expression in these cells [145] and has previously been shown to induce chrondrogenesis [146]. In accord with these studies, the DNA methylation status of MSC chondrogenic differentiation was investigated, identifying eight key chondrogenic CpG-rich promoters – SOX9, RUNX2, the PAK kinase CHM1, fibroblast growth factor receptor (FGFR) 3, chondroadherin (CHAD), matrilin 4 (MATN4), SOX4, gremlin 1 (GREM1), and G-protein coupled receptor 39 (GPR39) – that were observed to be stable throughout differentiation [147]. These findings are consistent with previous reports suggesting that CpG-rich promoters remain stably hypomethylated in adult somatic cells, but not all methylation patterns are indicative of gene silencing or activation [148,149].

While studies examining the epigenetic regulation of chondrogenic differentiation of human MSCs are scant, one report showed that the chondrogenesis-specific gene collagen type II loses H3K27me3 and gains H3K4 and H3K36 active methylation during early chondrogenic induction [150]. In mice, chondrogenesis is regulated by Sox9 and its co-regulator AT-rich interactive domain 5b, which recruits the H3K9 demethylase plant homeodomain zinc finger-like 2 (Phf2) to the Sox9 promoter to reduce H3K29me2 levels and promote chondrogenesis [151].

In other studies the acetylase Tat interactive protein-60 (Tip60) can activate Sox9 and histone 4 (H4) acetylation, promoting Sox9-mediated transcription of COL2A1 [152]. Several other transcription factors and co-activators interact directly with Sox9 to modulate Sox9 activity. For example, The Sox9-dependent transcription of cartilage-associated target genes is thought to act via p300-mediated-histone acetylation on chromatin [153]. Consistent with these findings, the HDAC inhibitor trichostatin A was shown to stimulate the expression of Sox9-regulated cartilage matrix genes and induced histone acetylation around the enhancer region of the collagen alpha 1 (II) gene in chondrocytes [154,155]. Therefore, it appears that Sox9 interacts with chromatin and activates transcription via regulation of chromatin modification. Other studies have demonstrated that HDAC activity promotes type II collagen expression in chondrocytes by suppressing the transcription of *WNT-5A* [156]. Furthermore, overexpression of HDAC4 in synovium-derived MSCs was found to promote chondrogenesis in the presence of TGF-β1 [157], and is thought to also function by inhibiting RUNX2 activity [158].

With limited studies using MSC-derived chondrocytes, the impact of epigenetic modifiers on regulating chondrogenic differentiation is unclear. Collectively, these studies have shown that epigenetic modifiers play a role in articular cartilage and synovium-derived chondrocyte development.

This chapter has identified the role of epigenetic modifiers driving MSC lineage commitment. It has identified the direct regulation of key transcription factors RUNX2, SOX9, PPAR-γ2, and MYOD for MSC differentiation as targets of epigenetic modifiers (Table 6.2). These findings suggest a significant level of complexity driving MSC lineage determination.

**Table 6.2** Epigenetic modifiers regulate DNA and histone marks on master regulatory genes during MSC differentiation.

| Modification | PPARγ2 | RUNX2 | MYOD | SOX9 |
|---|---|---|---|---|
| 5-Methyl cytosine | Hypomethylation during adipogenesis [118] | Demethylation during osteogenesis [74] | Unmethylated in nonexpressing tissues [138] | — |

| H3K4me2 | Promotes adipogenesis [98,99,125,126] | Promotes osteogenesis. Methylation removed in adipocytes [100] | — | — |
| H4K20me1 | Promotes adipogenesis [116] | — | | — |
| H3R8 | Promotes adipogenesis [128] | — | | — |
| H3K9ac | Prevents PPARγ2 activation [133] | Dysregulation in MSCs lead to spontaneous osteogenic differentiation [103]<br>HDAC4 inhibits RUNX2, promoting chondrogenesis [157] | | Acetylases inhibition promotes chondrogenesis [154] |

H3K4me3: histone 3 lysine 4 trimethylation; H3K27me3: histone 3 lysine 27 trimethylation; H3K9me3: histone 3 lysine 9 trimethylation; H4K20me2: histone 4 lysine 20 monomethylation; H3K9ac: histone 3 lysine 9 acetylation; HDAC: histone deacetylase; *RUNX2*: Runt-related transcription factor 2; *PPARγ2*: peroxisome proliferator-activated receptor γ; *MYOD*: myogenic differentiation antigen; *SOX9*: SRY-related HMG-box 9.

## 6.9 Epigenetic regulation of mesenchymal stem/stromal cell lifespan and senescence

MSCs have a limited growth and differentiation potential when propagated *ex vivo*. DNA methylation plays critical roles in not only MSC differentiation but also in regulating the lifespan of MSCs. DNA methylation profiles of late-passage senescent BM-MSCs and adipose-derived MSCs revealed highly consistent modifications at specific CpG sites. These DNA methylation changes have been correlated with histone marks of previously published data sets, such as trimethylation of H3K9, H3K27, and EZH2 targets [159]. However, the reduced adipogenic differentiation capacity of late-passage senescent MSCs cannot be attributed to DNA methylation of adipogenic gene promoters alone [71]. Maharia and colleagues identified the role of 10-11-translocation 1/2 (TET1/2) DNA demethylases in regulating the DNA demethylation of insulin-like growth factor-binding protein 1. These findings suggest that TET1/2 regulates MSC self-renewal and proliferation [160].

EZH2 is important for senescence [159], where Twist-1 induces EZH2, directly or indirectly, which in turn suppresses the Ink4A/Arf locus and p16/p14, preventing senescence of human MSCs [161]. (ArF is an abbreviation for alternate reading frame; p16 Ink4A is named after its molecular weight and its role in inhibiting cyclin-dependent kinase 4A.) By analogy, EZH2 is also involved in preventing hematopoietic exhaustion and stem cell maintenance [162]. Spontaneous transformation of rat-derived MSCs has been attributed to the increase of histone H3K27me and H3K9me on the *p16 INK4a* gene and increased DNA methylation [163]. Furthermore, the replicative senescence of MSCs mediated by DNA methylation has been associated more with H3K27me histone marks rather than bivalent domains [159], meaning they have lost the activating H3K4me3 mark. (Bivalent chromatin is chromatin that contains both activating and repressing epigenetic modifications in the same area.) This is in contrast to differentiation of nonsenescent cells, which show many bivalent genes to have increased H3K4me3 levels and decreased H3K27me3 levels while being transcriptionally activated during differentiation [66,68–72,164]. During long-term culture, MSCs undergo spontaneous osteogenic differentiation associated with downregulation of telomerase reverse transcriptase and the self-renewal genes *OCT4* and *SOX2* and an upregulation of osteogenic genes.

DNA methylation and histone modification play a role in dictating MSC lifespan and senescence. It is important to understand how these modifiers can influence the lifespan of MSCs, since this may aid in prolonging the survival and expansion capacity of MSCs. Extending the *in vitro* expansion capacity of MSCs would be highly beneficial for manufacturing MSCs for cell-based therapies.

## 6.10 Regulation of epigenetic modifications in mesenchymal stem/stromal cells for clinical use

Following on from the initial human safety trials in 1995 [165], both allogenic and autologous MSC preparations have now been used to treat patients with conditions such as graft-versus-host disease, cardiovascular diseases, neurologic diseases, autoimmune diseases, organ transplantation, refractory wounds, and bone and cartilage defects [166,167]. Continued investigations into the molecular mechanisms that regulate MSC development, self-renewal, and proliferation will likely help develop optimal cell expansion protocols and quality control criteria to overcome the features currently associated with MSCs following *ex vivo* expansion. These include donor variability, diminishing functionality, and limited lifespan. Therefore, a better understanding of the epigenetic modifications, which regulate the growth and multipotential capability of MSCs, could be used in strategies to manipulate MSC populations *ex vivo*. The application of chemical and pharmaceutical agents that regulate epigenetic modifiers may be beneficial in priming MSCs for specific therapies and could potentially be incorporated into scaffold and cell delivery systems. However, potential therapeutic strategies, such as the use of inhibitor molecules, have to await the development of novel agents that target specific epigenetic modifiers in order to maximize tissue regenerative ability with minimal side-effects.

## 6.11 Conclusions

This chapter has summarized the role of epigenetic modifiers in MSC differentiation, lifespan, and senescence. The presence of repressive DNA methylation, H3K27me3, H3K9me3, and HDACs on the promoter regions of key genes and signaling pathways often prevents adipogenic, osteogenic, chrondrogenic, and myogenic differentiation of MSCs, whereas the presence of DNA demethylases H3K4me3, H3K20me1, and HATs on the promoter regions of key genes and signaling pathways can facilitate adipogenic, osteogenic, chondrogenic, and myogenic differentiation of MSCs. Ultimately, the histone/DNA modifications lead to recruitment of chromatin remodelers which results in gene activation or repression. While some chromatin remodelers have been identified during osteogenic, adipogenic, chondrogenic, and myogenic differentiation, it is still unclear how and which posttranslational modifications work together to determine the activation and repression of genes important for MSC lineage commitment and lifespan.

With the use of genome-wide sequencing techniques such as ChIP-seq, RNA-seq, ChIP-on-chip, and microarray, future studies may be able to correlate the epigenetic patterning during many cellular events, including MSC multidifferentiation ability and growth to aid in the development of more potent MSC preparations for regenerative medicine applications. It is also

hoped that increased knowledge in this field may lead to the identification of epigenetic marks associated with impaired MSC growth and function associated with different musculoskeletal diseases, such as osteoporosis and osteoarthritis, in order to develop better prognostic criteria and novel treatment regimes.

## 7.1 Introduction

In addition to hematopoietic stem cells that give rise to the cells of the hematopoietic and immune systems, bone marrow also contains a second type of adult stem cell: the mesenchymal stem cell. This cell can both self-renew and differentiate to tissues of the skeleton, including bone, cartilage, and adipose tissue. These cells were first identified in bone marrow cultures of several mammalian species in the late 1960s by Friedenstein and co-workers, who cloned them and called the colonies that single cells gave rise to as colony-forming units–fibroblastic (CFU-Fs) because of their morphological similarity to fibroblasts [1,2]. The true mesenchymal stem cell is a rare cell in the bone marrow, its frequency being assessed at 1 cell in $10^4$ to 1 cell in $10^5$ of bone marrow mononuclear cells. The mesenchymal stem cell also differentiates to mesenchymal stromal cells (MSCs), which form part of the wall of blood vessels, which are sometimes known as mesenchymal progenitor cells and can be derived from all vascularized tissues [3]. The abbreviation "MSC" will be used in this chapter to denote mesenchymal stromal cell – one of the progeny of true mesenchymal stem cells.

Multiple human prenatal, postnatal, and adult tissues contain this population of stromal progenitors. MSCs have been extensively characterized as a progenitor/stromal cell population on the basis of their ability to differentiate along mesenchymal lineages *in vivo* [3] and *in vitro*. The potential of these cells to give rise to multiple cell types, including chondrocytes, osteoblasts, adipocytes, myocytes, and tenocytes, initiated an entire field of research focused on harnessing the regenerative capacity of these cells to repair or engineer musculoskeletal tissues.

With regard to adult tissues, MSCs have been isolated from many tissues, including bone marrow (iliac crest, vertebral body, cancellous bone) [4,5], adipose tissue [6], skeletal muscle [7], dental pulp [8], periosteum [9], synovium [10], and gestational products. MSCs derived from human bone marrow or from human gestational products are described in Chapters 3–5. MSCs are typically identified and characterised in accordance with criteria proposed by the International Society of Cellular Therapy [11] as follows. Adherence to plastic; multipotent mesodermal differentiation potential *in vitro*; and the following CD (cluster of differentiation) marker profile: ≥95% $CD90^+$,

$CD73^+$, $CD105^+$ and $\leq$95% $CD45^-$, $CD34^-$, $CD14/CD11b^-$, $CD79\alpha/CD19^-$, and $HLA\text{-}DR^-$. Although stromal cells from the tissues mentioned may all be termed MSCs, differences in phenotype, response to growth factors, and the molecular regulation of their lineage commitment suggests discrete differences between these cell populations. Since the *in vivo* characterization of these stromal cells is still lacking, our knowledge and understanding of these cell populations is limited principally to cells that have been expanded as monolayer cultures on tissue culture plastic. After over 40 years of MSC research it is now very clear that this method of culture induces wide-ranging phenotypic changes in a temporal manner. Thus, certain aspects of observed MSC behavior may not only be artefactual, but may also prevent us from understanding the true nature of these cells. As we will discuss later, this has significant implications not only for *in vitro* research but also for clinical transplantation.

From the few studies that have investigated the MSC niche in bone marrow, it is evident that MSCs are not simply one cell type, but a heterogeneous population, exhibiting discrete phenotypic differences, including ability to self-renew and degree of lineage commitment. This partly accounts for the range in nomenclature used when describing this cell population (mesenchymal stem cells, MSCs, mesenchymal progenitor cells, reticular cells). Moreover, there is also uncertainty as to whether pericytes – the vascular stromal support cells – may in fact be equivalent to MSCs, a subpopulation or their developmental precursor. For the purposes of this chapter, we refer to the population of plastic-adherent stromal cells which may be isolated from the mononuclear cell fraction of bone marrow or adipose tissue as MSCs or adipose stromal cells (ASCs) respectively.

In this chapter we describe the phenotype of MSCs isolated and cultured in monolayers and compare them with what is known of the MSC phenotype *in vivo*. We pay particular attention to the influence of isolation method and culture conditions on a range of phenotypic characteristics as measured *in vitro*. Finally, we discuss the implications of phenotypic changes upon both basic and clinical research. Bone marrow represents the most commonly used and traditional tissue source of MSCs. However, in the past decade there has been a significant increase in the body of adipose-derived MSC (ASC) research, due mainly to the greater ease and less invasiveness of collecting adipose tissue (by liposuction) compared with bone marrow aspiration. Thus, in this chapter we will focus primarily on MSCs derived from human bone marrow with reference to ASCs where appropriate. MSCs can also be isolated from human gestational organs, and these are discussed in Chapters 4 and 5.

## 7.2 Mesenchymal stromal cell isolation from bone marrow

In the absence of a universal standard isolation protocol, MSCs are isolated from bone marrow by different laboratories using different methods; these include plating whole bone marrow, red blood cell lysis, density centrifugation, and magnetic activated cell sorting (MACS)/fluorescence activated cell sorting (FACS). For MSC isolation, bone marrow is most frequently processed by density centrifugation, using Ficoll™, Lymphoprep™, or Percoll™ density media. This process separates the mononuclear cell (MNC) fraction from the other cellular and noncellular constituents of the marrow aspirate (e.g., red blood cells, plasma, and lipids). The resulting MNC fraction comprises a mixed population of cells, including T cells, B cells, monocytes, hematopoietic stromal cells, endothelial progenitor cells (EPCs) and MSCs. This mixed population of cells is seeded on to tissue culture plastic and is generally cultured for 3–5 days prior to the first media change. During this period, MSCs adhere to the tissue culture plastic and begin to form colonies. Hematopoietic, nonadherent cell populations are subsequently removed by serial media changes. It is also possible to isolate EPCs from the MNC fraction. However, their selection and expansion typically requires a basement membrane substrate such as fibronectin and the presence of specific growth factors [12]. A schematic for human bone marrow processing and MSC isolation procedures used in our laboratory is shown in Figure 7.1.

The density centrifugation process itself reduces the total yield of MNCs from bone marrow [13–15]. Plating whole bone marrow directly has been reported to increase CFU-F efficiency and to also result in a population of MSCs demonstrating longer telomere length compared with isolation protocols using either Ficoll or Percoll [14]. However, another group described reduced CFU-F efficiency by plating whole marrow compared with either density centrifugation or red blood cell lysis [16]. This same group demonstrated no difference in mesodermal differentiation potential or CD marker profile between cells isolated using either of the three techniques, although differences in cellular growth kinetics were less clear. Other laboratories use magnetic bead separation techniques, which deplete the polymorphonuclear cell population on the basis of granularity or expression of CD15. MNC recovery from both rat and human bone marrow was reported to be highest after MACS separation, followed by Percoll and then Ficoll density centrifugation [15]. Conversely, other studies directly comparing the efficiency of Ficoll with Lymphoprep [13] or with Percoll showed no significant difference in MNC yield [14]. Importantly, there is an increasing body of evidence to suggest that an MSC population is present in the initial, nonadherent MNC fraction [17–20]. This initially nonadherent MSC population is capable of forming CFU-Fs by serial plating. Importantly, the survival and subsequent expansion of these cells was shown to be critically dependent upon fibroblast growth factor-2 (FGF-2) signaling [20]. These MSCs demonstrated greater proliferation and tri-lineage differentiation potential *in vitro* and improved osteogenesis *in vivo* compared with a standard monolayer culture of MSCs. Together, these studies suggest the existence of heterogeneous MSC populations in the MNC fraction, and that those in the initially nonadherent fraction may represent a more naive stromal cell population. Owing to the apparent selection of an MSC population from the

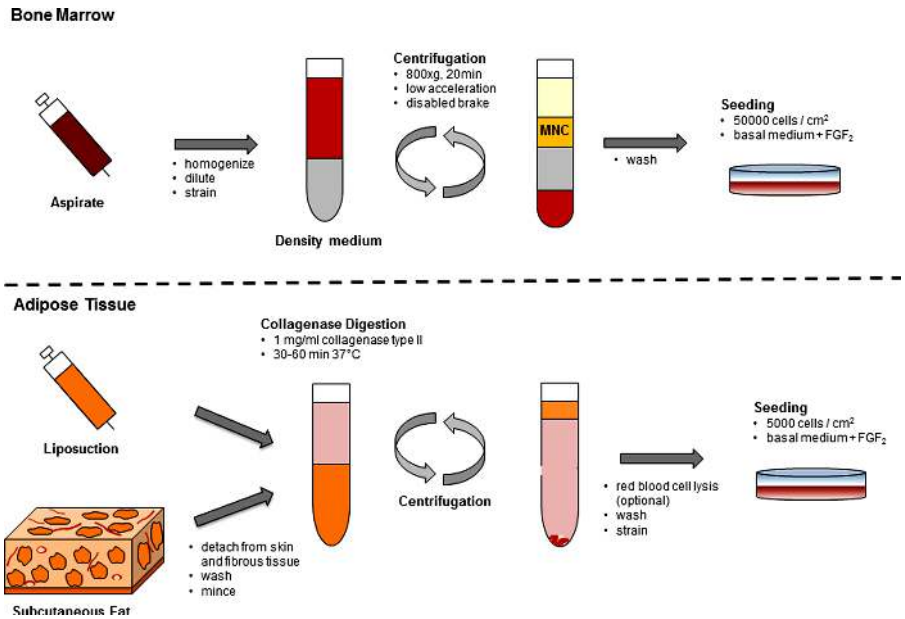

**Figure 7.1** Isolation of MSCs from bone marrow and adipose tissue. Schematic representation of standard experimental procedures for the isolation of mesenchymal stem cells isolated from bone marrow aspirate and adipose tissue (liposuction material/resection tissue). $FGF_2$: fibroblast growth factor-2.

original marrow aspirate, we propose that the term monolayer selection is adopted when discussing the isolation and culture of MSCs using the plastic adherence method [21]. MSCs are grown in basal medium such as Dulbecco's modified Eagle's medium (DMEM)/DMEM F12 or alpha minimum essential medium (MEM) with 10% fetal bovine serum (FBS) and cultured at 37 °C in 5% $CO_2$ and 20% $O_2$. One refinement of the isolation of MSCs from marrow is an initial purification step using a Stro-1 or similar antibody.

## 7.3 Mesenchymal stromal cell isolation from adipose tissue

Solid tissues such as adipose tissue, periosteum, and synovium are usually first dissected with scissors and scalpels prior to digestion with enzymes such as collagenase to break down the extracellular matrix prior to cell seeding and *ex vivo* expansion. ASCs are obtained from adipose tissue harvested by tissue resection or liposuction from thighs, flank, breast, or abdomen [22,23]. Adipose tissue is composed of two cell fractions: mature adipocytes and the stromal vascular fraction (SVF). The SVF is a heterogeneous cell mixture containing endothelial cells, hematopoietic cells, and an MSC population [24]. The frequency of stromal cells in the SVF is 1–10%, which is significantly higher than their frequency in bone marrow [23,25]. Donor age, harvest site, and isolation methods appear to affect yield and growth characteristics of the subsequently derived ASC population [22,23,26]. A schematic of the adipose tissue processing and cell isolation procedure used in our laboratory is shown in Figure 7.1. Tissue samples are first dissected to remove surrounding fibrous tissue and skin tissue, washed with phosphate-buffered saline (PBS) and then minced into small pieces. Cells are extracted from the minced tissue or liposuction sample by digestion with an equal volume of collagenase type II 1 mg/mL in cell culture medium with 3.5% bovine serum albumin (BSA) for 30–60 min at 37 °C. The fatty layer and adipocytes are removed by centrifugation and the cell pellet filtered through a 70 μm nylon mesh filter followed by additional washing with PBS. Afterwards, red blood cell lysis can be performed for samples containing large numbers of erythrocytes. Finally, a cell count is determined and cells seeded at a suitable density (approximately 3000/$cm^2$) in basal medium such as DMEM/DMEM F12 or alpha MEM with 10% FBS with or without FGF-2 and cultured at 37 °C in 5% $CO_2$ and 20% $O_2$.

As with bone marrow MSC isolation, seeding and expansion in a monolayer culture selects tissue culture plastic-adherent cells from the heterogeneous SVF, giving rise to a population of multipotent adipose-derived stromal cells (ASCs). The terminology ASC was first introduced by the International Fat Applied Technology Society (IFATS) referring to the multipotent plastic-adherent cell population. Prior to that, a variety of nomenclature has been used to describe this cell population, including "adipose-derived adult stromal cells," "adipose-derived stromal cells," "ASCs," "adipose mesenchymal stromal cells," "preadipocytes," and "processed lipoaspirate cells" [27].

## 7.4 Biological characteristics

### 7.4.1 Morphology and colony formation

When isolated on tissue culture plastic, MSCs adhere and proliferate, forming colonies. The heterogeneous nature of these cell populations is visibly evident at passage (p) 0 with morphologically distinct cell types present (Figure 7.2A and B). Small, spindle-shaped cell colonies are typically fast growing and more

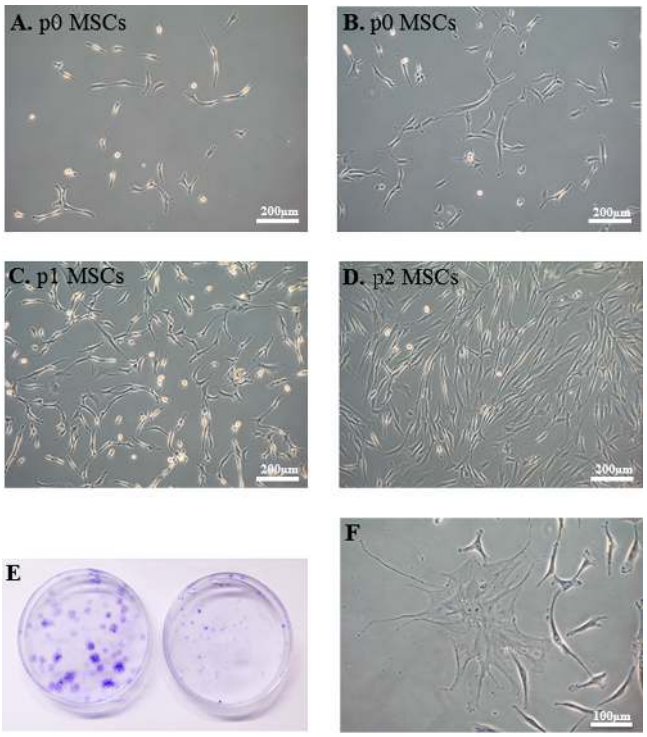

**Figure 7.2** Cellular morphology and colony-forming unit ability of MSCs cultured in monolayer. Phase-contrast images of human bone-marrow-derived mesenchymal stem cells at (A, B) p0, (C) p1, and (D) p2. (E) Crystal-violet-stained MSC colonies from a colony-forming unit (CFU) efficiency assay. (F) Visualization of stress fibers in an enlarged, senescent MSC.

abundant early on in the culture period. A population of larger cells is also present that appear to be less proliferative [28,29]. After subsequent passaging (p1) and expansion in monolayer culture, the cells become morphologically more homogeneous (Figure 7.2C and D).

The proportion of MNCs that attach and subsequently form MSC colonies may be described in terms of CFU efficiency. Colonies can be counted manually or by using automated techniques by first fixing the cells and then applying a suitable stain such as crystal violet (Figure 7.2E). CFU efficiency may be calculated using the following formula:

$$\text{CFU \% efficiency} = \frac{\text{number of colonies}}{\text{number of cells originally seeded}} \times 100$$

### 7.4.2 Growth kinetics

When calculating and describing MSC growth kinetics *in vitro*, passage number and/or population doublings may be referred to. However, since both cell size and the time taken to reach confluence varies significantly between donors, the passage number alone is not sufficient to provide accurate information as to growth rate. This may not only hinder data interpretation, but also prevents reliable comparison of MSC growth kinetics between laboratories. Population doublings may be calculated by using the following formula, which takes the initial cell number and final cell number during a single passage into consideration:

$$\log_{10}\left(\frac{\text{NF}}{\text{NO}}\right) \times 3.33$$

where NF is the final cell number and NO is the original cell number.

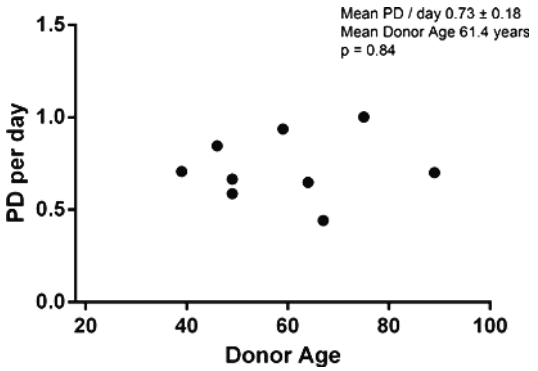

**Figure 7.3** Donor variation of MSC growth kinetics. Growth kinetics of bone-marrow-derived mesenchymal stromal cells harvested from vertebral body. Population doublings (PDs) recorded for MSCs between passage 1 and 2 show high donor variability and no correlation between growth rate and donor age. Pearson correlation coefficient was performed to test for correlation of PD and donor age.

Growth kinetics of MSCs are highly variable between different donors. Results from several studies suggest that older individuals demonstrate reduced initial CFU efficiency compared with younger cohorts [30,31]. However, donor characteristics such as age or gender cannot be used to reliably predict proliferation rate during extended culture periods. Figure 7.3 shows the population doubling time for nine human MSC donors, all from vertebral body bone marrow aspirates, indicating high variability but no correlation in terms of donor age. It is most likely that the variation in growth rate between MSC donors is attributed to sample variation in the original bone marrow aspirate. For example, when a bone marrow aspirate is taken, blood from the marrow sinusoids may also be aspirated, resulting in dilution of the bone marrow. Also, the proportion and number of more primitive and proliferative MSCs with a more "stromal-like" phenotype present in the aspirate is likely to be variable between separate aspirates and between different donors [32]. This has been clearly demonstrated by comparing the phenotype of MSC populations derived from two serial bone marrow aspirates from the same person [33].

With regard to ASCs, it has been proposed that population doubling time correlates with donor age, with a significantly lower proliferation rate of cells obtained from older donors [34]. As with bone-marrow-derived MSCs, it appears that the growth kinetics of ASCs are also dependent, in part, on the initial harvest method [22].

After an extended time in culture, MSCs will ultimately undergo replicative senescence [28,29,35]. The point at which a primary human MSC culture will undergo senescence is very variable between donors, but is typically seen between 10 and 38 population doublings [28,29,30,35]. Similarly, increased senescence has been reported after serial passaging of ASCs [34]. Stress fibers formed from actin-myosin cytoskeletal filaments are readily visualized by phase-contrast microscopy and are a good indicator of the replicative senescence of MSCs (Figure 7.2F). Senescence may be more reliably confirmed by staining cells for β-galactosidase, whereby 5-bromo-4-chloro-3-indolyl-β-D-galactoside (X-Gal) is cleaved, resulting in a blue–green substrate [36]. This lysosomal enzyme is present in most mammalian cells and detectable at pH 4. However, it is much more abundant in senescent cells, enabling it to be detected at the suboptimal pH of 6.

MSCs, as with most primary human cells, senesce during monolayer culture as a result of the Hayflick limit (after Leonard Hayflick, born 1928, an American anatomist), caused by telomere shortening [30,37]. DNA methylation and other epigenetic modifications may also contribute to the replicative senescence of MSCs [33,38]. In ASCs it has been shown that the frequency of chromosomal aberrations significantly increases after five passages [39]. With regard to long-term *in vitro* cultures, chromosomal stability should certainly be considered with respect to both the safety and efficacy of cell-based therapies.

### 7.4.3 *In vitro* multipotency

A universally accepted criterion defining *in vitro* cultured MSCs is their ability to differentiate along chondrogenic, osteogenic, and adipogenic lineages. For chondrogenesis, this is typically performed by culturing the cells as spherical pellets/micromass cultures and exposing them to a defined chondrogenic medium containing ascorbic acid, dexamethasone, insulin–transferrin–selenium, and TGF-β [40]. For osteogenic induction, MSCs can be cultured in monolayers or in three dimensions as pellets in osteogenic differentiation medium containing ascorbic acid, dexamethasone, and β-glycerophosphate. Adipogenic induction is achieved in monolayer culture by supplementation with 3-isobutyl-1-methyl xanthine, insulin, indomethacin, and dexamethasone. Although these *in vitro* assays demonstrate the quintessential multipotent MSC phenotype, there is currently no evidence to suggest that they are predictive of the ability or behavior of *in vitro* cultured MSCs to undergo lineage commitment and differentiation once implanted *in vivo*. As such, the relevance of these assays is a topic of much debate among researchers. The exception to this, however, is that the serial transplantation of MSC clones (CFU-Fs) generated from a single mesenchymal stem cell does result in both mesenchymal stem cell renewal and osteogenic differentiation in which the transplanted ossicle is populated by the recipient animal's hematopoietic system (see Chapter 32). Thus, the mesenchymal stem cell (as opposed to MSCs) is the stem cell of the skeleton.

After prolonged *in vitro* culture, MSCs appear to lose multipotency and display a propensity toward osteogenic differentiation [33,35,41]. Osteogenic lineage commitment appears to coincide with a reduction in proliferation and gene expression changes [37,41]. Other studies reported donor-dependent differential gene expression of integrins [42], extracellular matrix molecules, growth factors, and cytokines, including C–X–C motif chemokine 12 (CXCL12, also known as stromal-derived factor 1 (SDF-1)) [43] throughout the culture period.

### 7.4.4 Gene expression

Analysis of MSCs cultured in monolayers has demonstrated that gene expression changes occur directly after isolation and continue throughout culture. After extended culture, senescent MSCs downregulate genes associated with the cell cycle, DNA replication, and repair [41]. Their gene expression profile is also highly influenced by culture conditions and cell source [44,45]. The expression of specific stem cell markers, also referred to as "stemness" markers, has been studied in detail in embryonic stromal cells. Candidate markers for MSCs include the transcription factors OCT-4, NANOG, and SOX2. The expression of these transcription factors in MSCs is variable and likely dependent upon tissue source and culture conditions. MSCs that were shown to express OCT-4 and NANOG did not express SOX2 [46]. Other studies have failed to detect these markers in MSCs. This might be attributed to genotypic differences between the MSC populations isolated by different laboratories or to the detection methods used [47]. Interestingly, the latter study identified three genes – attenuated familial adenomatous polyposis (AFAP), protein tyrosine phosphatase receptor type F (PTPRF), and RAB3B, which encodes Ras-related protein Rab-3B – which were differentially regulated when MSCs were stimulated to undergo either osteogenic, adipogenic, or chondrogenic differentiation. Furthermore, the expression level of these genes was restored upon de-differentiation of the cells [47]. In order to identify MSC-specific genes, a comparative gene expression study comparing MSCs with other stromal cell populations revealed that colony-forming cells were enriched for *NOTCH3* (which encodes the neurogenic locus notch homolog protein 3), *ITGA11* (which encodes integrin α11), and *JAG1* (which encodes jagged 1 protein).

*NOTCH3*-positive cells displayed superior multipotency, while *ITGA11* expression indicated a more osteogenic progenitor phenotype [48]. Lineage commitment of MSCs is associated with gene expression changes, and differentially expressed genes have been identified during adipogenic, osteogenic, and chondrogenic differentiation. For a concise review, see reference [49] and Chapters 11–14. They will not be addressed in this chapter. However, while most of these typical genes are upregulated in the later stages of lineage commitment, recent work suggests that the ratio of the osteogenic gene runt-related transcription factor 2 (*RUNX2*) and the chondrogenic gene sex-determining region Y-box 9 (*SRY*, also known as *SOX9*) may be used to predict the fate of MSCs at much earlier stages [50].

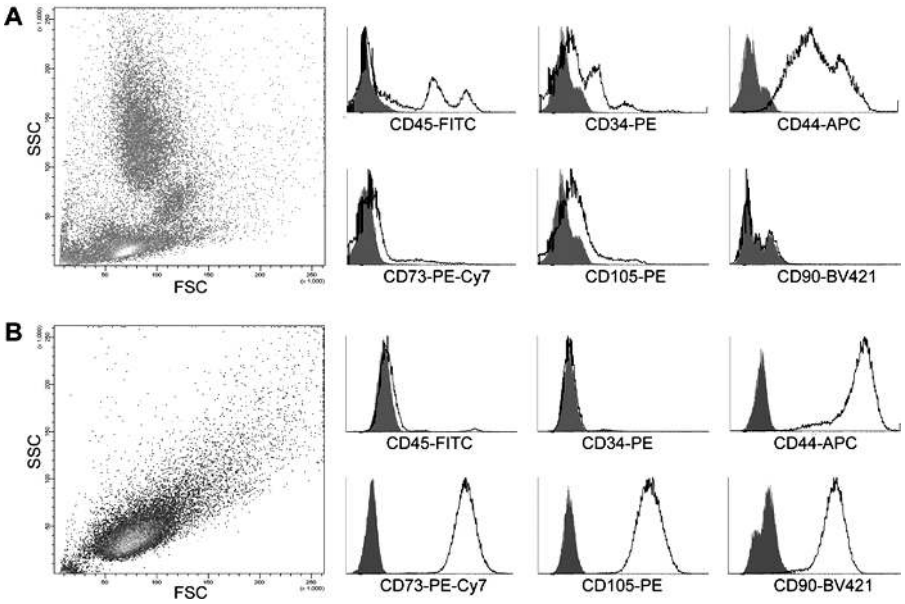

**Figure 7.4** Flow cytometry analysis of cell surface markers. (A) Flow cytometry dot plot depicting a representative profile of MNCs in respect of size (FSC: forward scatter) and granularity (SSC: site scatter) revealing that the MNC fraction consists of multiple cell populations expressing different levels of surface markers (filled dark curves indicate unstained controls). (B) Analysis of monolayer cultured MSCs upon first passage. The FSC–SSC plot reveals only one major cell population representing MSCs as selected by plastic adherence. In line with the current literature, monolayer cultured MSCs are negative for the hematopoietic markers CD45 and CD34 but express CD44, CD73, CD105, and CD90.

### 7.4.5 Cell surface marker profile

Human monolayer-expanded MSCs express various cell membrane-associated proteins that are used for identification and characterization purposes. The first of these markers to be recognized were CD73 [2,3] and CD105 [3,51]. Since there is no cell surface marker unique to MSCs, combinations of several cell surface markers are typically used to distinguish MSCs from other nucleated cell populations. In 2006 the International Society for Cellular Therapy recommended a panel of positive and negative cell surface markers to define MSC populations [11]. According to these guidelines, MSC populations were defined as being >95% positive for CD105, CD73, and CD90 and >95% negative for CD45, CD34, CD14, CD11b, CD79α or CD19, and HLA-DR. Note, however, that $CD34^+$ has been detected in tissue-resident MSCs but not on *ex vivo* expanded MSCs. A typical flow cytometry profile showing a heterogeneous population of bone-marrow-derived MNCs and the subsequently derived MSC population at passage 1 is shown in Figure 7.4.

CD105 is endoglin. CD73 is ecto-5′-nucleotidase. CD90 is Thy1. CD45 is the common leukocyte antigen. CD34 is an antigen present on hematopoietic stem and progenitor cells, EPCs, endothelial cells, pleural lymphatics vessels, mast cells, a subpopulation of dendritic cells in the interstitial tissues, around the adnexa of dermis of skin, and on tissue-resident MSCs. CD14 is a co-receptor for bacterial lipopolysaccharide. CD11b is an integrin family member that pairs with CD18 to form the complement receptor 3 heterodimer. CD11b is also a receptor for fibrinogen gamma chain, factor X, and intercellular adhesion molecule 1 (ICAM-1), also known as CD54. CD79α forms a complex with the B cell receptor (BCR) and generates a signal following recognition of antigen by the BCR. CD19 is a B cell surface marker. HLA-DR is a major histocompatibility complex class II cell surface receptor encoded by the human leukocyte antigen complex on chromosome 6 region 6p21.31.

Additional cell surface markers known to be expressed by MSC populations are CD44 [3,52], CD166 [53,54], CD106 [3,55], Stro-1 [56], CD146 [54,55], and CD271 [42]. CD44 is the receptor for hyaluronic acid and is also known as homing cell adhesion molecule. CD166 is also known as activated leukocyte cell adhesion molecule. CD106 is vascular cell adhesion molecule 1. Stro-1 (stromal precursor antigen-1) is a protein present on MSCs and on endothelium. CD146 is also known as melanoma cell adhesion molecule or cell surface glycoprotein MUC18, a mucin cell surface glycoprotein. CD271 is the low-affinity nerve growth factor receptor.

There are several important points to consider concerning the MSC markers described above, including their specificity, the transient nature of expression, and functional relevance. Other cell types of mesenchymal origin, including fibroblasts [57] and intervertebral disc cells [58], show a similar CD marker profile to that of MSCs. Moreover, we know that the cell surface marker expression profile of MSCs is affected by *in vitro* culture conditions.

Table 7.1 summarizes differences between the cell surface marker profiles of both human and murine MSCs in the bone marrow *in vivo*, freshly isolated cells, and in those that have been expanded *ex vivo* in monolayer culture on plastic. CD73 and CD105 appear to be expressed by the majority of freshly isolated MSCs with CFU-F capability, and are robustly maintained throughout culture [43,54]. Interestingly, it has been demonstrated that freshly isolated MSCs from both humans and mice do not express CD44, and that expression of this marker is acquired early on in culture [43]. Using DNA microarrays the same authors demonstrated that CD73 and the putative pericyte/

Note that cell surface antigen expression was ascertained by flow cytometry unless stated otherwise.

vascular niche MSC marker CD146 are upregulated during monolayer culture. Several studies indicate that CD271 and CD146 are expressed by subsets of freshly isolated MSCs and that cells initially negative for these markers acquire their expression during culture [42,43,54,59]. Conversely, another study reported that all CFU-F cells were present in either Lineage$^-$ CD45$^-$ CD271$^+$ CD146$^-$ or Lineage$^-$ CD45$^-$ CD271$^+$ CD146$^+$ sorted fractions [63]. Blocki *et al.* also demonstrated that initially CD146$^-$ MSCs acquire this marker during expansion in monolayer culture [64]. However, other groups have reported the loss of CD106 and CD146 expression during *in vitro* culture [59]. Discrepancies between these studies may be due to a range of factors including donor variation, different culture conditions, antibody clone and source, immunostaining protocol, FACS/magnetic bead sorting, and gating/analysis of flow cytometry data.

Significant changes in cell surface marker expression have also been observed in ASCs after monolayer selection and culture expansion. While ASCs in passage 2 or 3 expressed all the characteristic MSC markers listed by Dominici *et al.* [11], Gronthos *et al.* used flow cytometry and immunohistochemistry to also show that human adipose-tissue-derived stromal cells have a protein expression phenotype similar to that of human bone marrow stromal cells; expressed proteins included CD9, CD10, CD13, CD29, CD34, CD44, CD49d, CD49e, CD54, CD55, CD59, CD105, CD106, CD146, and CD166. Unlike human bone-marrow-derived stromal cells, they did not detect the Stro-1 antigen on human adipose-tissue-derived stromal cells [69]. CD9 is a member of the tetraspanin family of proteins, which are thought to act as scaffolding proteins, anchoring multiple proteins to one area of the cell membrane. CD10 is neprilysin, also known as membrane metallo-endopeptidase (MME), neutral endopeptidase (NEP), and common acute lymphoblastic leukemia antigen (CALLA). Neprilysin is a zinc-dependent metalloprotease that cleaves peptides at the amino side of hydrophobic residues and inactivates several peptide hormones, including glucagon, enkephalins, substance P, neurotensin, oxytocin, and bradykinin. CD13 is alanine aminopeptidase, an enzyme that is used as a biomarker to detect damage to the kidneys, and that may be used to help diagnose certain kidney disorders. CD29 is integrin β1. CD49d is an integrin alpha subunit and is also known as very late antigen-4 (VLA-4). It makes up half of the α4β1 lymphocyte homing receptor. CD49e is integrin α5 and is also known as VLA-5. CD54 is intercellular adhesion molecule 1 (ICAM-1). CD55 is complement decay-accelerating factor (DAF), a protein that regulates the complement system on the cell surface. CD59 is a glycoprotein also known as MAC-inhibitory protein (MAC-IP), membrane inhibitor of reactive lysis (MIRL), or protectin. CD59 attaches to host cells via a glycophosphatidylinositol anchor. When complement activation leads to deposition of C5b678 on host cells, CD59 can prevent C9 from polymerizing and forming the complement membrane attack complex.

Some markers are altered within the stromal cell population present in freshly isolated stromal vascular fractions. Although no specific marker profile identifying colony-forming cells has been found, most of the literature suggests that ASCs are contained in the CD34$^+$ cell fraction. Interestingly, it has been suggested that typical markers of monolayer cultured MSCs/ASCs such as CD105 and CD73 were absent or low on freshly isolated ASCs but were dramatically increased after plating on plastic [70,71].

The cell surface marker expression profiles of MSC populations within the bone marrow milieu have also been investigated immunohistochemically [60,63]. CD73 is widely expressed by morphologically heterogeneous MSC populations in stromal, endosteal and perivascular locations [60], whereas CD271 is expressed by cells within the stroma and at the endosteal surface. In accordance with previous work, CD146$^+$ cells were exclusively localized immunohistochemically in perivascular regions. Rasini *et al.* also reported expression of neural ganglioside GD2 by endosteal and perivascular MSCs, supporting a previous study identifying this neural protein as a marker of MSCs before *ex vivo* expansion [60]. Conversely, Tormin *et al.* did not observe any immunostaining of GD2 by MSCs in bone marrow. Notably,

OCT4, NANOG, and stage-specific embryonic antigen-4 (SSEA-4) were immunolocalized to MSCs at endosteal and stromal locations but not in perivascular structures, suggesting that phenotypically different MSC populations reside in anatomically distinct niches within the marrow [63] and see Chapter 32.

Taken together, it appears that the cell surface marker profile of MSCs *in vitro* is subject to change as a result of artificial culture conditions and is not necessarily representative of their expression profile *in vivo*. Importantly, differential marker expression has not been correlated to changes in cell characteristics such as growth kinetics or plasticity, which brings their functional significance into question. In practical terms, cell surface marker profiling becomes important when dealing with freshly isolated, heterogeneous cell populations and in co-culture studies with other cell types. Further investigation of the functional relevance of differentially expressed markers by specific MSC populations within the bone marrow may help further understanding of the biological significance of stromal, endosteal, and perivascular niches and their constitutive stromal cell populations (see Chapter 32).

### 7.4.6 Secretory profile

The secretory profile of tissue-specific MSCs within their *in vivo* environments is largely unknown. Conversely, extensive literature exists regarding the composition and effects of the secretome from MSCs cultured *in vitro*. Bone-marrow-derived mesenchymal stromal cells secrete a multitude of extracellular matrix molecules, growth factors, cytokines and chemokines when cultured in monolayers [72–74]; and see Chapters 18 and 19. The presence and level of such molecules have significant implications with regard to autocrine signaling when the cells are expanded in monolayer and in a paracrine context when exposed to other cell types in co-culture systems. Moreover, it is widely believed that the therapeutic effects observed following MSC transplantation may largely be attributed to the release of trophic factors [75]. MSC-secreted factors may be categorized in terms of physiological function: mitogenesis, cell survival/anti-apoptosis, chemotaxis, immunomodulation, angiogenesis, and neurogenesis. A detailed review of the MSC secretome has been published by Da Silva Meirelles *et al.* [75] and Hsiao *et al.* [74]; and see Chapters 18 and 19. Similarly, ASCs have been shown to release soluble factors modulating angiogenesis, inflammation, and apoptotic signaling [76].

MSCs produce many anti-inflammatory factors, including hepatocyte growth factor (HGF) [72,77], cyclooxygenase 1 and 2, interleukin-10 (IL-10), prostaglandin $E_2$ [78], interleukin-1 receptor antagonist (IL-1Ra) [79], and tumor necrosis factor α-induced protein 6 (TSG-6) [80]. When cultured in monolayers MSCs produce pro-angiogenic factors – including vascular endothelial growth factor (VEGF), FGF-2, placental growth factor, angiopoeitin-1, platelet-derived growth factor (PDGF), matrix metalloproteinase-9, monocyte chemoattractant protein-1 (MCP-1) [72] – and the neurotrophic factors brain-derived neurotrophic factor [81,82], nerve growth factor [81], neuroregulin-1 (NRG1-β1) [83], glial-derived neurotrophic factor (GDNF) [84], artemin, and persephin [85]. Artemin is a neurotrophin in the glial cell line-derived neurotrophic factor (GDNF) family of ligands, which are a group of ligands within the TGF-β superfamily of signaling molecules. GDNFs are unique in having neurotrophic properties and have potential use for gene therapy in neurodegenerative diseases. Persephin is also a neurotrophic factor in the glial cell line-derived neurotrophic factor family.

Neutralizing antibody experiments suggest that the mitogenic effects of the MSC secretome are not attributable to the presence of one particular growth factor, but are the result of the combinatorial effects of many factors [72].

It is important to consider that the secretory profile of MSCs may be modulated by different *in vitro* culture techniques. It is known, for example, that transition from two-dimensional to three-dimensional culture results in an increase in the production of pro-angiogenic factors [86]. Differentiation status has also been shown to affect the secretory profile of MSCs. Specifically, when differentiated osteogenically or chondrogenically, human and equine MSCs reduce production of angiogenic and neurogenic factors and demonstrate anti-angiogenic effects *in vitro* [85,87]. The secretory profile of MSCs also appears sensitive to changes in oxygen tension. When cultured under hypoxic conditions (<5% $O_2$) cells increase production of SDF-1, angiogepoietin-1, and VEGF via hypoxia-inducible factor-1 (HIF-1) [88,89]. A detailed review on the effects of hypoxic preconditioning on the secretory profile of MSCs has been published by Hsiao *et al.* [74] and is discussed later in this chapter.

Of note, the time-related characteristics of the secretome by MSCs expanded in monolayer culture have not yet been reported and represent a significant gap in our knowledge. Moreover, we do not know how the secretome of *in vitro* cultured cells compares with that of unmanipulated MSC populations *in vivo* or with that of transplanted MSCs previously cultured *in vitro*. This information will be crucial for understanding the physiological function and realizing the full therapeutic potential of these cells.

## 7.5 Influences on tissue culture parameters

### 7.5.1 Seeding density

In the absence of standardized culture protocols, researchers culture MSCs at varying seeding densities, often between 2000 and 5000 cells/$cm^2$. Several studies suggest that lower seeding densities increase the rate of cellular proliferation by reducing contact inhibition [42,52,90,91]. Reducing seeding density has been reported not to affect the expression of CD markers or trilineage mesodermal differentiation capability *in vitro* [52,91]. It is important not to allow MSC cultures to become overconfluent during monolayer expansion since, besides contact inhibition

and nutritional restrictions which induce growth arrest and ultimately lead to cell death, this may also induce irreversible phenotypic changes and prime the culture to undergo osteogenic differentiation as a default pathway [35,38,41]. Thus, it is common practice to passage MSCs when the culture reaches approximately 80% confluency.

### 7.5.2 Culture medium and supplementation

A basal medium such as DMEM/DMEM F12 or alpha MEM containing 10% FBS is typically used to culture MSCs *in vitro*. The composition of growth media may affect MSCs at the genomic, transcriptomic, and proteomic levels. For example, in a study comparing the effects of different culture media on monolayer-expanded ASCs, cell morphology, growth kinetics, immunophenotype, and expression of stemness-related transcription factors were all significantly modulated [92]. FBS is subject to batch variation, which may also greatly affect aspects of MSC behavior, such as growth rate and multipotency. Therefore, serum testing should be performed in order to maintain consistent growth conditions. Alternatively, commercially available MSC-qualified batch-tested sera are available at a considerable cost to the user.

### 7.5.3 Growth factors

Supplementation of culture media with specific growth factors and cytokines influences the genotype and phenotype of MSCs. FGF-2 is a known mitogen of MSCs, also functioning to maintain multipotency and to promote subsequent chondrogenic differentiation *in vitro* [20,93–95]. There is evidence to suggest that FGF-2 supplementation may reduce CD146 expression in primary cells and cell lines [96,97]. However, as discussed previously in this chapter, the functional significance of this and other markers has yet to be elucidated. Concentrations between 0 and 10 ng/mL of FGF-2 are reported in the literature, adding another compounding factor when attempting to compare studies.

### 7.5.4 Xeno-free media

Although FBS is the most widely used medium supplementation for the *in vitro* expansion of MSCs, concerns arise when considering the clinical application of cells. Transplantation of FBS-cultured MSCs may cause immune reactions [98] and may be contaminated with bacteria, viruses, or prions [99]. For these reasons there has been a drive to establish FBS-free MSC culture methods by using autologous serum, platelet lysate (PL), platelet-rich plasma (PRP), or serum/plasma-free growth factor supplementation. A detailed review of this area was been published by Tonti and Mannello in 2008 [100]. It has also been reported that autologous serum maintains genomic stability whilst promoting the proliferation of primary MSCs [101]. Of note, the use of fetal calf serum (FCS) for the production of MSCs to be used in clinical trials in Australia is allowed by the Australian regulatory authority, the Therapeutic Goods Agency, as long as the FCS is sourced from a herd in a country that has never had an outbreak of bovine spongiform encephalopathy (mad cow disease). This is currently the case for Australia and New Zealand.

### 7.5.5 Platelet-derived supplements

PDGFs have been employed as an alternative to serum supplementation. Platelet-derived medium supplementation can be prepared from donor-matched blood and can be thus considered as xeno-free (i.e., free from any contamination by components of nonhuman species), with the autologous medium circumventing safety concerns associated with the use of FBS.

Although platelet products have been used for several years now, no consensus with regard to preparation methods and terminology exists. PL or platelet-released growth factors (PRGFs) generally refer to a concentrate of growth factors obtained after platelet activation in either the presence or absence of platelet-poor plasma. Commonly used activation methods include repetitive freeze–thaw cycles and sonication. PRP refers to a concentrate of platelets that may or may not be activated by the addition of thrombin and/or calcium chloride ($CaCl_2$), resulting in growth factor release and fibrin clot formation. Platelet preparations contain different growth factors, including FGF-2, TGF-β, and PDGF-BB, with inhibition of these factors resulting in a significant reduction in MSC proliferation in PL-medium [102]. In chemical terms, PDGF is a dimeric glycoprotein composed of two A (−AA) or two B (−BB) chains or a combination of the two (−AB).

Besides this there is also evidence that microRNAs and exosomes represent functional components of platelet products [99]. The actual growth factor content in platelet preparations is highly dependent upon the donor as well as on the preparation and activation method, which altogether will affect the phenotype and behavior of MSC cultures. For cell culture purposes, PL is favored over PRP preparations since these are rich in potentially disturbing platelet debris and have the risk of spontaneous aggregation and fibrin clot formation, although it may be possible to prevent the latter by the addition of heparin. Furthermore, in cultures of ASCs it has been shown that certain growth factors influencing cell proliferation are expressed at greater levels in PL compared with activated PRP [103].

Both PL/PRGF and PRP supplementation have been reported to increase MSC CFU-F efficiency and proliferation compared with both FBS and autologous serum [104–110]. An increase in proliferation rate has also been reported in low-density MSC cultures supplemented with PL under good manufacturing practice-compliant conditions [102]. Similarly, enhanced proliferation of ASCs was shown with PL supplementation [106,107]. Most studies suggest that this occurs without affecting CD marker profiles.

More importantly, functional parameters including gene expression, plasticity, and the MSC secretome are influenced by PL/PRP supplementation. For example, PRP increases the expression of genes associated with osteogenic and chondrogenic lineage commitment – *RUNX2*, *SOX9*, and *AGGRECAN* [106]. On the other hand, several studies using PL showed that MSCs

preserve their multipotency [108–110,113]. These conflicting outcomes are, again, likely attributed to variability in preparation procedures as well as to donor variability. This is supported by a study comparing the effects of PL donors of different ages [114]. In this particular study, a higher proliferation rate and enhanced osteogenic differentiation with PL from younger donors (<35 years of age) compared with PL from older donors (>45 years of age) was observed. Interestingly, these effects could not be correlated to levels of growth factors, including PDGF-AB, TGF-β1, FGF, IGF-1, or hormones, including estradiol, parathormone, leptin, or vitamin D3. The secretome of MSCs is also influenced by PRP or PL supplementation [107,110]. The secretion of IL-6 and IL-8 was shown to be increased by MSCs cultured with PL compared with FBS [110]. Additionally, PL supplementation is also associated with changes in MSC gene expression [109,110].

### 7.5.6 Serum-free media

The use of serum-free culture media for MSC expansion is reported in the literature and is commercially available at considerable cost. Serum-free cultures contain a number of different recombinant growth factors and generally involve a coating of cell culture plates to facilitate cell attachment. The main advantage of serum-free media is that they have a defined composition (although this is often proprietary) compared with serum or PL/PRP-containing media. While both FBS and PL/PRP exhibit batch and donor variation, serum-free media consist of an unchanging, defined mixture of growth factors and proteins.

A combination of PDGF-BB, FGF-2, and TGF-β1 has been reported to support MSC proliferation whilst maintaining multipotency [115]. Furthermore, it has been shown that proliferation rate, multipotency, and surface marker expression of MSCs cultured in commercially available serum-free supplements were generally comparable to MSCs cultured with FBS [116,117]. Conversely, serum-free cultures of MSCs were associated with greater levels of cell senescence at early passages, changes in the surface marker profile, and differentiation capacity [118]. Interestingly, these deleterious effects of serum-free culture media were not evident on ASC cultures. Besides the uncertainty over phenotypic stability, the application of serum-free media for the initial steps of MSC isolation and expansion might impair cell adherence to tissue culture plastic and CFU-F efficiency [99].

### 7.5.7 Hypoxia

Most laboratories culture MSCs under atmospheric oxygen tension (21% $O_2$). This, however, does not reflect the *in vivo* situation, where stromal cells reside in their niche with generally much lower oxygen tensions ranging between 1 and 5%. Accordingly, studies addressing MSC culture under low oxygen tension typically use oxygen levels within such physiological ranges. It is noteworthy that different oxygen tensions, together with different culture methods and conditions (including media composition, supplementation, seeding densities, and donor variation), are likely to influence experimental outcomes and thus hinder the comparability of results between studies. Nonetheless, the culture of MSCs under hypoxic conditions has been shown to influence many aspects of cell phenotype, such as growth kinetics, migratory capacity, gene expression, and the secretome.

When comparing MSC isolation and expansion under either hypoxic or normoxic conditions, a decrease in initial CFU-F efficiency under hypoxia was observed. However cells were more proliferative and outgrew normoxic cultured MSCs at passage 2 [119]. The majority of published studies have evaluated the effect of hypoxia on MSCs already selected by plastic adhesion. During monolayer expansion, it appears that low oxygen tension leads to increased cell proliferation and clonogenic potential, whilst cell morphology and surface marker expression are not significantly influenced [120–123]. These conclusions are highly dependent upon the exact culture parameters. This was particularly evident in a study comparing the colony-forming capability of MSCs cultured in different oxygen tensions, demonstrating a significantly different outcome when cells were cultured in either 2% or 5% $O_2$ [124].

The effect of hypoxic culture conditions on the differentiation potential of MSCs is not fully understood. On the one hand, it has been reported that multipotency is maintained under hypoxia [119,120]. In line with this, upregulation of the stemness marker genes *SOX2*, *OCT4*, and *NANOG* was reported when ASCs were incubated at 2% $O_2$ [122]. On the other hand, several studies have suggested that hypoxic conditions do indeed affect the differentiation potential of MSCs and ASCs [121–127]. These studies are thus conflicting.

In addition to culturing MSCs in hypoxic conditions during the monolayer expansion phase, hypoxic preconditioning prior to transplantation has also been investigated and proven beneficial [123,128]. Specifically, the upregulation of hypoxia-inducible factor 1α and its downstream targets promotes cell survival after transplantation *in vivo*. Moreover, it has been reported that hypoxia induced the expression of CMET via AKT signaling. This in turn supported cell migration and recruitment by HGF *in vivo* [123]. (CMET, a receptor tyrosine kinase, is also called MET and hepatocyte growth factor receptor; AKT, also known as protein kinase B, is a serine/threonine-specific protein kinase that plays a key role in multiple cellular processes such as glucose metabolism, apoptosis, cell proliferation, transcription, and cell migration. The "Ak" in Akt was a temporary classification name for a mouse bred and maintained that developed spontaneous thymic lymphomas. The "t" stands for thymoma.)

## 7.6 Implications for basic and clinical research

### 7.6.1 Trial disparity

Methods of bone marrow preparation and MSC isolation and *in vitro* expansion vary significantly between laboratories. Thus, the resulting MNC population and the *in vitro* phenotype

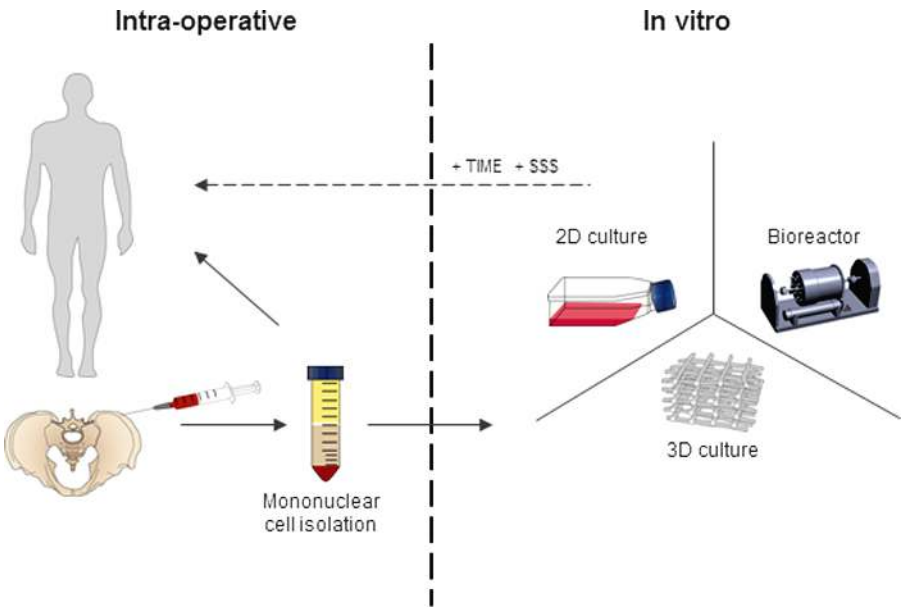

**Figure 7.5** Intraoperative versus *in vitro* approaches to mesenchymal stem cell therapy and tissue engineering.

acquired by MSCs during monolayer culture is also likely to vary between research groups. This is evident from observed discrepancies between *in vitro* and *in vivo* studies in published literature. Importantly, it also appears that seemingly minor differences in isolation and culture methodology may affect the clinical performance of both MNCs and MSCs, resulting in discrepancies in results between trials using these cell populations. Indeed, this was shown by a group who compared two very similar, randomized, placebo-based controlled trials in which MNCs were transplanted after myocardial infarction [129]. In this trial, known as the REPAIR-AMI (The Reinfusion of Enriched Progenitor cells And Infarct Remodeling in Acute Myocardial Infarction) trial, improved left ventricular ejection fraction was reported following MNC transplantation [130], whereas no significant improvement in clinical outcome compared with placebo was reported in the ASTAMI (Autologous Stem cell Transplantation in Acute Myocardial Infarction) trial [131].

By replicating the isolation methods of both trials, Seeger's group demonstrated that the protocol used by researchers of the REPAIR-AMI trial yielded greater numbers of MNCs with enhanced CFU-F efficiency, improved therapeutic effect in a mouse model of hindlimb ischemia, and that MNC-derived MSCs were more responsive to SDF-1 *in vitro*. These differences appeared to be attributable to differences in culture media, centrifugation speeds used, wash steps and cell storage protocol. Additional variables, including the degree of red blood cell contamination and abundance of apoptotic cells have also been correlated with reduced clinical efficacy of transplanted MNCs [132,133].

### 7.6.2 Alternative culture systems

It is clear that a plethora of phenotypic changes are experienced by MSCs as a result of monolayer culture. Thus, the behavior of MSCs *in vitro* may largely be artefactual and likely not representative of their behavior *in vivo*. This has significant implications for basic researchers aiming to investigate the behavior and function of resident MSCs within bone marrow and adipose and other tissues. Modulation of MSC biology caused by monolayer expansion may ultimately compromise the therapeutic value of the cells. For example, several groups have reported improved multipotency and increased trophic factor release in MSC spheroid cultures generated from MSCs initially cultured in monolayers [134].

From both clinical and economic perspectives, the expansion of MSCs *in vitro* is a lengthy and costly process. Some investigators are now focusing on developing intraoperative therapies in which the MNC cell fraction is isolated and implanted during a one-step procedure and taking advantage of the capacity of MSCs to home to damaged tissues (Figure 7.5). However, the lack of knowledge we possess on the biology of tissue-resident MSCs is impeding the development of both such intraoperative MNC therapies and targeted homing strategies. For example, processes developed for monolayer-expanded MSCs may simply not be effective on a tissue-resident unmanipulated MSC population – either in *ex vivo* or *in vivo* systems. Thus, there is a need to develop alternative culture systems that avoid the use of tissue culture plastic, thereby maintaining MSCs in a more native state.

As an alternative to tissue culture plastic, MSCs may be cultured and expanded using microcarriers within stirred bioreactors [135–138]. These systems may also be used to generate clinical-grade cultures for human transplantation [139]. Three-dimensional culture systems, although not necessarily able to meet the demands of clinical scale-up, offer the opportunity to co-culture previously unmanipulated MSCs with other niche cells, thus better mimicking their *in vivo* environment. Several groups have demonstrated that mixed populations of MNCs,

including CFU-F-forming MSCs can be maintained *in vitro* either by using hydroxyapatite scaffolds under perfusion [140–142] or by culture within type I collagen hydrogels [143]. Refinement of culture systems such as these may provide us with the means to maintain MSC phenotype *in vitro* and therefore allow us to better study and understand their function *in vivo*.

## 7.7 Conclusions and future directions

Monolayer expansion on tissue culture plastic is the most widely used method for growing MSCs in *in vitro* culture. Selection and culture of these cells on plastic results in wide-ranging phenotypic changes that prevent us from understanding the true biology of these cells in their native resident *in vivo* state. Compounding this, there is great variation between research groups with regard to isolation and culture parameters. Although a significant challenge, the standardization, isolation, and expansion in monolayer culture would bring a greater degree of uniformity within the field. This would not only allow more reliable comparisons to be made between *in vitro* studies, but could also improve the consistency in clinical outcome observed after MSC transplantation. Furthermore, improved culture systems that maintain phenotypic stability and allow us to study these cells in more physiologically relevant environments will improve our understanding of the function of these cells *in vivo* and assist in the development of clinically efficacious and more economically viable MSC therapies.

## 8.1 Three-dimensional multicellular aggregates

Spherical aggregates of mammalian cells have been widely used in biological research for many decades. A variety of names, such as aggregates, spheroids, spheres (e.g., neurospheres, cardiospheres), have been used to describe the phenomenon in which single cells in suspension spontaneously coalesce and form stable and spherical aggregates in culture composed of multiple cells. In the pioneering studies by Holtfreter on tissue morphogenesis, spherical aggregates of embryonic cells were obtained by culturing embryonic explants or single cells on nonadherent agar as a substratum or on a shaking device to reduce cell–substratum interactions [1,2]. These techniques were later used by Moscona to obtain multicellular tumor spheroids as an *in vitro* model to understand the formation and invasive potential of tumor cells [3]. The approaches employed in these studies, such as using nonadherent culture surfaces and/or a gyratory shaker to maintain individual cells in suspension in order to encourage aggregation and prevent cell attachment to surfaces, have been the major methods in the subsequent studies on multicellular aggregates in tissue morphogenesis, tumor malignancy and response to therapy, and in somatic cell reprogramming [4,5]. The persistent interest in three-dimensional (3D) cellular aggregates stems from the unique biological properties exhibited by 3D cellular aggregates compared with their two-dimensional (2D) adherent counterparts. It has been observed in neural stem cells that the *in vitro* formation of multicellular spheroids by nestin-expressing neural cells on a nonadhesive substratum (i.e., neurospheres) confers upon the cells many defining properties of

stem cells. This has led to the use of cell aggregations to define and measure neural stem cells. In these studies the presence, frequency, and dimension of neurospheres have been used as a colony-forming assay to assess the ability of the cells to yield stem cells as well as to assess their clonality and mitogenic potential. Further studies, however, suggest that the ability to form floating cell clusters on nonadherent surfaces or in suspension is not limited to neural cells but shared by virtually all dividing cells in many tissues and organs with intercellular adhesive properties, including the ear, skin, pancreas, and mammary gland [6–10]. In addition to being a defining feature of embryonic stem cells, the persistent proliferation of cells in suspension indicates the loss of anchorage dependence, which is also a hallmark of tumor cells. On the other hand, differentiated somatic cells also have the ability to coalesce and form 3D aggregates and a 3D environment that drastically changes their phenotypic properties. Because of anchorage dependence, somatic cells typically do not exhibit extensive proliferative properties in 3D aggregates and instead they form 3D aggregates based on cell–cell interactions mediated by the extracellular matrix (ECM). For example, multicellular spheroids of endothelial cells consist of a surface layer of differentiated cells and a core of unorganized cells undergoing apoptosis [11]. Depending on cell type, formation of multicellular aggregates also significantly alters cell phenotypic properties. Thus, formation of multicellular aggregates promotes fibroblast reprogramming and acquisition of stemness properties [5]. Although *in vitro* self-assembly of multicellular aggregates is a common phenomenon for many cell types, the mechanism underling the self-assembly varies, and its subsequent impact on cell property is cell-type specific and regulated by extrinsic environmental factors as well as intrinsic cell susceptibility to these environmental factors.

## 8.2 Three-dimensional aggregates of mesenchymal stromal cells

Mesenchymal *stromal* cells (MSCs), defined as having the ability for colony-forming unit–fibroblast formation, plastic adherence, trilineage mesodermal differentiation potential, and expression of characteristic surface markers, were originally derived from bone marrow but have now been isolated from multiple tissues and organs, including adipose tissue, Wharton's jelly, amniotic fluid and dental pulp. The *in vivo* mesenchymal *stem* cell identity and developmental origin is believed to be a skeletal stem cell that not only can self-renew into daughter mesenchymal stem cells but also can give rise to mesenchymal *stromal* progenitor cells for tissues of the musculo-skeletal system, and, in addition and importantly, can support hematopoiesis [12] (and see Chapters 32 and 47). Studies have demonstrated that transplantation of the nonmineralized cartilage pellets formed by human bone marrow MSCs (BM-MSCs) *ex vivo* can generate complete ossicles with normal bone marrow structures in the absence of exogenous scaffolds, demonstrating their multipotency [13]. *In vitro* MSCs are clonogenic and are able to initiate clonal growth in a density-dependent fashion to form colony-forming unit–fibroblasts (CFU-Fs), a defining property of MSCs. Another feature of MSCs is their strong plastic adhesion property, which allowed their separation from hematopoietic cells in their original discovery by Friedenstein [14]. However, MSCs in adherent plastic culture are sensitive to culture density and change their population characteristics during expansion, resulting in a remarkable population heterogeneity within a small number of population doublings. These results suggest that MSCs in *in vitro* cultures are not equivalent to the culture of "stromal cells" and that factors in their environmental milieu, such as oxygen tension, substrate stiffness, and cell–cell interactions, significantly influence MSC properties. To optimally translate MSCs into a therapeutic agent there is a need to understand the impact of environmental factors on MSC fate and properties.

*In vitro* formation of 3D aggregates has emerged as an important approach by which to study MSC biology. It may also be important for augmenting their biological properties for therapeutic applications. During development, bone, cartilage, and bone marrow stroma differentiate from, and are downstream of, mesenchymal condensation, which is a critical transitional stage in the development of mesenchymal tissues and which precedes cartilage during embryonic development. It is regulated by cell adhesion and the ECM [15]. Condensation occurs when a previously dispersed population of cells gathers together to differentiate into a single cell/tissue type such as cartilage, bone, muscle, tendon, kidney, or lung and is the earliest stage during organ formation when tissue-specific genes are upregulated [15].

The *in vitro* ability of MSCs to form 3D multicellular aggregates free of exogenous scaffolds was first studied in pellet culture of bone-marrow-derived progenitor cells during their differentiation into chondrocytes [16]. In the presence of transforming growth factor-β3 the formation of tightly packed cellular aggregates eventually developed into well-stratified cartilage and the condensed mesenchymal bodies were able to fuse and form mechanically functional cartilaginous tissue interfacing with bone [17]. These studies suggested that *in vitro* MSC aggregation mimics mesenchymal condensation and is integral to establishing the physiologic milieu for early skeletal development.

Subsequent studies have shown broad changes in MSC properties upon 3D aggregation compared with their 2D counterparts. It was reported that scaffold-free culture of MSCs as spheroids preserved multilineage potential and enhanced their differentiation into multiple lineages while downregulating the genes maintaining the self-renewal phenotypes of MSCs [18,19]. The 3D aggregation also significantly enhanced their trophic effects and therapeutic outcomes in various disease models. Thus, it is important to understand the mechanism of MSC self-assembly and its role in functional enhancement and in animal models, as well as to develop technology for the production of 3D aggregates.

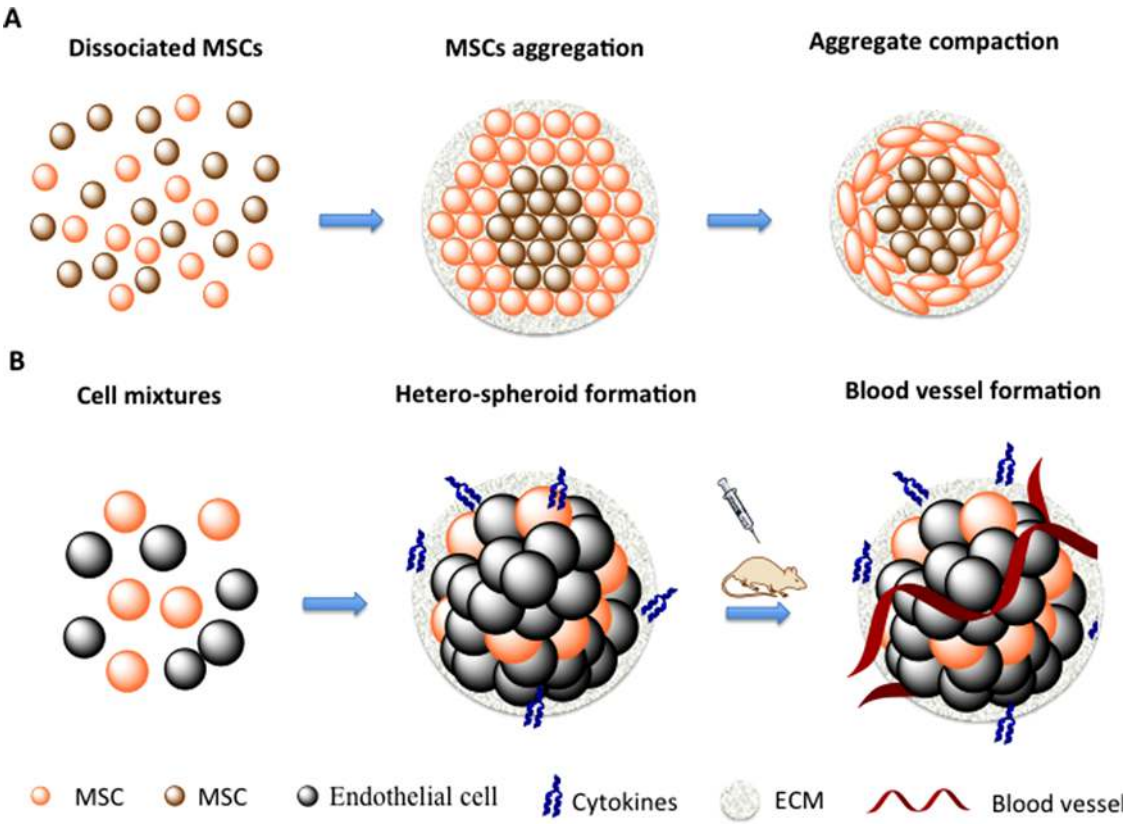

**Figure 8.1** MSCs 3D aggregate self-assembly and MSC heterospheroid formation. (A) MSC aggregation process. Dissociated MSCs first form loosely packed aggregates in which cells with more cadherin cluster in the interior of the aggregate, whereas cells with less cadherin are aligned along the exterior of the aggregate. Aggregate formation is followed by reorganization of the ECM and actomyosin-mediated compaction that leads to mechanical polarization and cell spreading at the exterior of the aggregate. (B) Formation of a heterospheroid comprised of MSCs and endothelial cells and their application in cardiac vascularization. Dissociated MSC and endothelial cell mixtures form 3D heterospheroid aggregates *in vivo* via cell–cell adhesion molecules. The heterospheroids exhibit more potent angiogenic properties *in vivo* because of increased secretion of ECM, abundant antiapoptotic and proangiogenic cytokines, and increased cell survival.

## 8.3 Mechanism of mesenchymal stromal cells self-assembly into three-dimensional aggregates

### 8.3.1 Cell–cell contact

The differential adhesion hypothesis suggested that embryonic cells have liquid-like behavior and are able to sort out from each other during the developmental stage to achieve their normal histological pattern. This cell segregation phenomenon is regulated by tissue surface tension arising from differences in intercellular adhesiveness. A cell aggregate of lower surface tension tends to envelop one of higher surface tension to which it adheres, and the surface tension is linearly correlated with cell cadherin expression level [20]. MSCs share similarity to embryonic cells in terms of liquid-like behavior and readily self-assemble into 3D aggregates in suspension culture, as depicted in Figure 8.1A.

While the role of cadherin in regulating MSC cytoskeleton tension during aggregate formation is not conclusive, E-cadherin is reported to be a key inducer mediating human umbilical cord blood-derived MSCs (UCB-MSCs) to form 3D aggregates, among several calcium-dependent adhesion molecules [21]. In addition, cadherin-mediated adhesion is intrinsically mechanosensitive and is a crucial component of the cells' tension-sensing apparatus [22]. The observations that human adipose-tissue-derived stromal cells (ADSCs) can self-assemble into 3D aggregates in serum-free media and that the switch between N-cadherin and OB-cadherin in rat ADSCs in 3D aggregates is substrate-dependent further indicate that cadherin is not only involved in MSC aggregate self-assembly but is also highly dynamic and tightly regulated during aggregate rearrangement [23,24].

### 8.3.2 Extracellular matrix and the cytoskeleton

Apart from cadherin, ECM proteins also play important roles in aggregate formation and compaction. During hepatoma spheroid formation, ECM fibers act as a long chain linker for the attachment of dispersed single cells to form loose aggregations through the binding of integrin [25]. In addition, integrin-mediated cell–ECM connections are crucial for tissue

homeostasis during embryonic development as well as for wound healing [26]. The study of an α5 integrin-transfected Chinese hamster ovary cell line showed that the interplay between α5 integrin and soluble fibronectin contributes significantly to tissue cohesion and mediates a shift from liquid to elastic behavior of 3D cellular aggregates, demonstrating the importance of integrin and ECM interaction in mediating cell aggregate mechanical properties, as well as in segregation between cells [26]. Indeed, contiguous scanning electron microscopy and transmission electron microscopy analysis of 3D aggregates of human MSCs over a 7-day period revealed that cell aggregates undergo dynamic compaction with changes in cellular architecture and mechanical properties [27]. Both cell-secreted ECM and incorporated exogenous ECM have been reported to enhance the mechanical properties (e.g., stiffness) of human MSCs in 3D aggregates [18,24]. Integrin expression is also found to be altered in cells derived from human MSC spheroids, in that cells from human MSC spheroids upregulate expression of the integrin α2 subunit but suppress that of the integrin α4 subunit. However, the expression of these integrin subunits can be restored when the cells are cultured in monolayer culture [28], indicating the important role of integrin in cytoskeleton reorganization during aggregate compaction [29].

Along with changes in cadherin and integrin expression, 3D self-assembly and subsequent compaction reduce MSC size and alter cell morphology and cytoskeleton tension in a spatially dependent manner [30,31]. The significant size and morphological changes of MSCs in 3D aggregates require effective rearrangement and adaptation of the actomyosin network. Actin filaments, known to form stress fibers in response to external biomechanical stress in 2D adherent culture, control cell morphology in 2D adherent culture and regulate the contraction and fusion of 3D embryoid bodies [32,33]. In MSC 3D aggregates, adaptive changes in actin spatial distribution lead to mechanical polarization with cells at the interior of the aggregates having lower cytoskeleton stress compared with cells at the exterior of the aggregates [31,34]. Thus, actin plays a major role in mediating the compaction of 3D MSC aggregates and their interactions with the external environment. Unpublished data from our laboratory have shown that interfering with actin-mediated contractility by cytochalasin D, nocodazole, lysophosphatidic acid, and ROCK inhibitor Y-27632 not only influenced human MSC 3D aggregation and compaction, but also fusion between the adjacent aggregates and their spreading on an adherent surface. Cytochalasin D is a cell-permeable potent inhibitor of actin polymerization. Nocodazole is an antineoplastic agent that exerts its effect on cells by interfering with the polymerization of microtubules. Microtubules are one type of fiber that constitutes the cytoskeleton. Lysophosphatidic acid is a phospholipid derivative that can act as a signaling molecule and is a potent mitogen owing to its activation of three high-affinity G-protein-coupled receptors. ROCK inhibitor Y-27632 is a cell-permeable, highly potent and selective inhibitor of Rho-associated, coiled-coil-containing protein kinase (ROCK).

### 8.3.3 Mesenchymal stromal cells heterospheroids

By taking advantage of their trophic and adhesive properties, MSCs have been used to form heterospheres with other cell types to augment their therapeutic effects (Figure 8.1B). For example, heterospheroids composed of rat islet cells and human MSCs have been successfully engrafted in the same area of liver as islet cells after transplantation via the portal vein, resulting in increased angiogenesis and decreased apoptosis of islets compared with transplantation of islets alone [35]. Similarly, the transplantation of 3D composite aggregates of co-cultured human umbilical vein endothelial cells (HUVECs) and UCB-MSCs considerably enhanced the vascular densities and the blood flow recovery in the ischemic myocardium in rats with myocardial infarction compared with their dissociated counterparts [36]. As with 3D MSC aggregates, both cadherin-mediated cellular adhesion and integrin-mediated cytoskeleton tension play important roles in regulating 3D aggregation and compaction of heterospheres. In MSC/islet cell heterospheres treated with the ROCK inhibitor Y-27632, cell segregation was observed within 3 days of aggregation in which aggregates sorted into core–shell structures with islet-derived cells occupying the exterior while MSCs occupied the core [37]. Similarly, by changing integrin signaling and cell–cell interaction by altering the biomaterial substrate, the cellular pattern of self-assembled MSC and endothelial progenitor cell (EPC) aggregates exhibited different morphologies, including randomly mixed, bumped, or concentric spheroids, in which EPCs were wrapped by MSCs with a well-aligned organization [23]. Further understanding the mechanisms underlying segregation of MSCs within heterospheroids into certain patterns will be important for the fabrication of MSCs and other cell mixtures for the production of complex tissue patterns.

## 8.4 Mechanisms of aggregate-mediated mesenchymal stromal cell functional enhancement

MSCs were initially studied as stromal cells in tissue engineering and regeneration research because of their potential for differentiating into a number of tissues of mesodermal lineage, including bone and cartilage. Additionally, MSCs have strong tropic (migratory) effects and are a significant source of ECM components. Through these mechanisms, administered MSCs can establish a niche that stimulates the propagation and differentiation of endogenous stromal cells. MSCs are also highly responsive to the macromolecular milieu and can engage in extensive crosstalk triggered by signals from injured tissues. The secretion of many proteins by MSCs plays an important role in this because some of the factors can downmodulate excessive and harmful inflammation; MSCs can also play an immunomodulatory role on both the innate immune response (see Chapter 33) and the adaptive immune response (see Chapter 34) and can

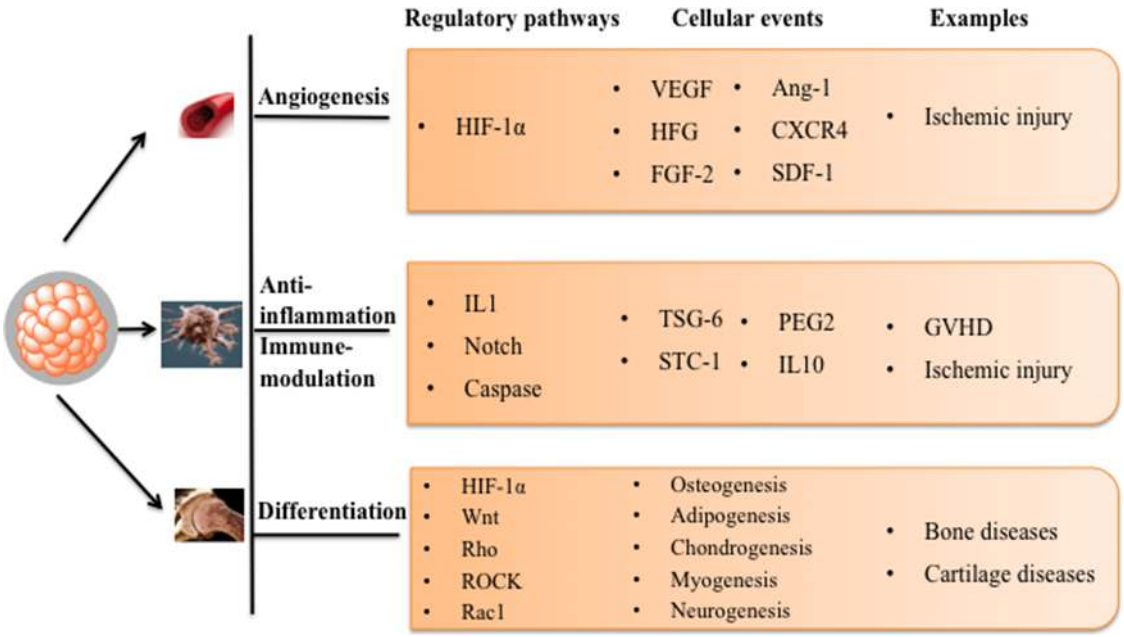

**Figure 8.2** Summary of the therapeutic properties and regulatory pathways of MSC 3D aggregates.

establish a macromolecular milieu that promotes tissue regeneration. Thus, preserving the mesodermal lineage differentiation potential, the secretory function and the migratory functions of MSCs are important. Studies have shown that MSC self-assembly into 3D aggregates significantly influences these properties by regulating the aggregation-associated changes in inter- and intra-cell interactions, cytoskeleton and cell morphology changes, and alterations in the molecular milieu of the 3D aggregates (Figure 8.2).

### 8.4.1 Role of cell adhesion molecules in the fate decision of mesenchymal stromal cell three-dimensional aggregates

Cellular adhesion molecules (CAMs) such as the cadherins and connexins are among key factors governing the transition from single cells to tissues during tissue development. The expression of adhesion molecules often undergoes change during the *in vitro* differentiation of pluripotent aggregates; for example, the high expression of E-cadherin in undifferentiated pluripotent embryonic stem cells decreases upon differentiation, concomitant with differential expression of many other cell adhesion molecules during lineage commitment [33]. MSC 3D aggregates are also sensitive to regulation by adhesion molecules. Cell–cell contact or culture surface profoundly impact MSC fate decision [38]. By controlling cell–cell contact on RGD-coated micropatterned material surfaces, osteogenic and adipogenic differentiation by MSCs were regulated by cell-cell contact. (RGD is an abbreviation for the tripeptide arginylglycylaspartic acid and is composed of L-arginine, glycine, and L-aspartic acid. The sequence is a common element in cellular recognition processes.) Paired or aggregated cells exhibited significantly enhanced differentiation capacity compared with isolated cells, and the extent of differentiation appeared to be linearly related to the extent of contact factor [39]. A dense mass of aggregated MSCs with strong cell–cell interaction promotes the immediate differentiation of MSCs into chondroblasts that can be further enhanced through the addition of cellular interaction enhancement components such as poly-L-lysine [40]. In addition to the extent of cell–cell contact, MSC differentiation *in vitro* is also correlated with a specific pattern of cadherin molecules, as selectively enhanced expression of N-cadherin, OB-cadherin, and R-cadherin were observed during differentiation of MSCs to osteogenesis, myogenesis, and adipogenesis respectively [41]. In 3D spheroids of rat adipose-tissue-derived MSCs there was differential upregulation of N-cadherin and OB-cadherin upon chondrogenic and osteogenic induction. This further suggests a differential association of CAMs by 3D MSC aggregates upon lineage commitment [42].

The regulatory effect of cell contact-mediated cadherin molecules on MSC 3D aggregate differentiation is regulated through transcriptional signaling. By manipulation of cellular adhesion patterns using different biomaterial substrates, MSC spheroids showed increased expression of Wnt and its downstream signaling, which correlated with MSC aggregate differentiation. It was shown that canonical Wnt3a-mediated signaling was more active for MSC spheroids differentiated osteogenically, while Wnt5a-mediated noncanonical Wnt signaling was more active for MSC spheroids that had undergone chondrogenic differentiation [43]. Adipose tissue-derived MSC spheroids cultured on chitosan membrane also showed increased expression of N-cadherin and Wnt-11 signaling and increased cardiomyogenic differentiation [42]. Thus, MSC 3D aggregates provide a microenvironment that has strong cell–cell contact and selectively

enriched cell adhesion molecules that can be utilized to control cell fate and recapture tissue development.

### 8.4.2 Effects of extracellular matrix, cytoskeleton, and morphology on mesenchymal stromal cell lineage commitment in three-dimensional aggregates

In addition to CAMs, 3D multicellular aggregates are also in contact with ECM. This is known to influence stromal cell fate and functions via a myriad of intercellular signaling pathways [22]. ECM and cells bind and interact through integrins that influence the intercellular actomyosin network via a ROCK-mediated pathway, which in turn controls matrix assembly, stabilization, and biomechanical properties of cells [34]. In 3D aggregates interactions between the ECM and the actomyosin network via integrins influence the biomechanical properties and cell fate decision of the aggregates. It has been reported that 3D aggregates of human ADSCs formed on chitosan films produced more extracellular molecules, such as laminin and fibronectin, compared with those in a monolayer culture. They readily differentiated into neuron and hepatocyte-like cells upon induction [44]. (Chitosan is a linear polysaccharide composed of randomly distributed β-(1–4)-linked D-glucosamine (the deacetylated unit) and *N*-acetyl-D-glucosamine (the acetylated unit). It is made by treating shrimp and other crustacean shells with the alkali sodium hydroxide).

Incorporating gelatin into 3D aggregates of human MSCs also changed aggregate stiffness and mechanical properties [18].

Approaches to modulate cell adhesion, morphology, and cell fate through manipulation of adhesive ligand properties or micropatterned substrates have also been extensively explored in monolayer cultures. Downstream signaling of the Rho-associated protein kinase (ROCK) pathway is often implicated in cytoskeletal reorganization and stiffness-mediated phenotypic changes [45]. MSCs undergo dramatic size changes within 3D aggregates. Cells derived from 3-day and 7-day aggregates showed significantly decreased cell size compared with monolayer MSCs [30]. In addition to changes of cell size, cell morphology also showed changes in spatial distribution. In 7-day aggregates, cells on the surface of the spheroids were more spread out and had less distinct boundaries between each other, whereas cells in the interior had a more irregular morphology [30]. The spatial differences in cell morphology within 3D aggregates of MSCs correlated well with differentiation ability: on induction of soluble factors permitting osteogenic and adipogenic differentiation, human MSCs at the edge of multicellular spheroids underwent osteogenic differentiation whereas those in the center of the aggregate underwent adipogenic differentiation, possibly via Ras homolog A (RhoA) signaling [31,46]. This differentiation pattern was further shown to result from different levels of cytoskeleton stress, where regions of high stress resulted in osteogenesis, whereas cells in regions of low stress differentiated to adipocytes [31]. Examination of cell morphology during BMP-2-induced cartilage formation of human MSC micromasses also demonstrated that the spatial patterns of cell distribution were closely associated with distinct cell fate and ECM-building ability [47]. As with MSCs in 2D adherent culture, MSC fate decision in 3D aggregates is thought to be regulated by RhoA and Rac1 (Ras-related C3 botulinum toxin substrate 1), which integrate signaling from cytoskeleton tension or crosstalk with adhesion molecules, thus highlighting the tight coupling between lineage commitment and changes in cell shape, cell-matrix adhesion, and cell–cell adhesion that occur during cell morphogenesis [46].

### 8.4.3 Role of molecular milieu and hypoxia-inducible factor activation

Compared with 2D adherent culture, 3D multicellular aggregates form diffusional barriers and create concentration gradients of oxygen, cell-secreted cytokines, and serum-borne macromolecules in the interior of the aggregates [48]. Of these molecules, restricted oxygen delivery and formation of a hypoxic core have been frequently cited as the primary factor for activation of hypoxia-inducible factor (HIF) and the subsequent upregulation of proangiogenic factors, proinflammatory cytokines, and increased resistance to oxidative stress [49–51]. Using ADSCs transfected with a fluorescence HIF probe, HIF activation in the ADSC aggregate was shown to be induced by controlling the size of the aggregates and that HIF-1 activity increased with increasing aggregate size and with decreasing external oxygen concentration [52]. However, modeling of the oxygen gradient in 3D human MSC aggregates indicated limited oxygen depletion and oxygen concentration far above the threshold for HIF activation in 2D adherent culture. Further study showed that HIF-1α expression is not strongly influenced by aggregate size but is correlated with the level of cell compaction after centrifugation [53]. Thus, reduced oxygen concentration may not be the sole factor for HIF activation in 3D aggregates. Although post-translational HIF regulation by hypoxia has been most frequently studied, there is growing evidence that HIF is also subject to transcriptional and posttranscriptional modification by non-hypoxic stimuli such as angiotensin II, thrombin, vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF), interleukin (IL)-6, IL-8, and glucose [54]. Since 3D aggregation of MSCs is a potent inducer of angiogenic factors and several ILs, the molecular milieu formed in the interior of the aggregates may also contribute to HIF upregulation. Thus, HIF activation in the 3D aggregates may be modulated by multiple environmental factors, including both hypoxic and nonhypoxic stimuli.

HIF activation in 3D MSC aggregates is a major mechanism for the enhanced secretion of angiogenic and antiapoptotic factors. For example, spheroid culture of human ADSCs upregulated HIF-1α expression with enhanced secretion of HGF, VEGF, and fibroblast growth factor 2 (FGF-2) [49]. Co-cultured

HUVEC/UCB-MSCs in 3D aggregates with different degrees of internal cell density also exhibited HIF-1α-mediated upregulation of VEGF, adrenomedullin, angiopoietin 1, stromal cell-derived factor 1 (SDF-1, also known as CXCL12), and chemokine motif C–X–C receptor 4 (CXCR4), suggesting enhanced angiogenesis, cell retention and homing ability [53]. (Adrenomedullin is a ubiquitously expressed peptide hormone that was initially isolated from a pheochromocytoma, a tumor of the adrenal medulla – hence its name). HGF, matrix metalloproteinase (MMP)-2 and MMP-14 are also seen to be significantly produced in human ADSCs, resulting in increased wound closure rate compared with monolayer cells in a diabetic animal model [55].

Apart from enhancing secretory functions, HIF activation also upregulates genes associated with stemness, including *OCT-4*, *SOX-2*, and *NANOG* in MSCs [50]. Of these, *OCT-4* expression is essential for maintaining an undifferentiated cell fate. Studies have shown that extended HIF-2α expression increased *OCT-4* mRNA and protein levels in embryoid bodies and is an upstream regulator of *OCT-4* expression in embryonic stem cells [56]. Similar findings on *OCT-4* upregulation via HIF-1α activation under hypoxic conditions, with a subsequent increase in neurogenic potential in response to environmental cues, have also been reported for ADSCs [57]. Thus, HIF activation resulting from a limitation of oxygen diffusion, or its interaction with the molecular milieu in the 3D aggregate, is an important factor in the multilineage potential observed in various types of MSC aggregates.

### 8.4.4 Metabolism changes in three-dimensional aggregates of mesenchymal stromal cells

Since multicellular aggregates create a heterogeneous microenvironment accompanied by size-dependent gradients of oxygen and nutrients, cells within a 3D aggregate may undergo metabolic changes that have an impact on their cellular properties. It has been demonstrated that malignant cell aggregates can adapt their metabolism to the specific environment conditions in a 3D aggregate by reducing their metabolic activity [58,59]. This contributed significantly to their viability and clonogenicity.

MSCs derived from normal gum (gingiva) tissue and cultured as multicellular spheroids were found to be arrested in a quiescent stage of the cell cycle with a significantly decreased number in S phase and more than 90% of cells in $G_0/G_1$ phases. An increased level of reactive oxygen species and antioxidants such as manganese superoxide dismutase were also observed in these aggregates [50]. Human dermal stromal cells cultured in 3D aggregates showed higher expression of dermal progenitor markers, including SOX2, Nanog, S100B, and enhanced expression of human telomerase reverse transcriptase [60]. S100 proteins are localized in the cytoplasm and nucleus of a wide range of cells and are involved in the regulation of a number of cellular processes, such as cell cycle progression and differentiation.

### 8.4.5 Enhanced anti-inflammatory properties of three-dimensional aggregates of mesenchymal stromal cells

Another interesting property of MSC 3D aggregate cultures is the self-activated release of anti-inflammatory cytokines, including tumor necrosis factor (TNF)-α-induced protein-6 (TSG-6), stanniocalcin-1 (STC-1), prostaglandin $E_2$ ($PGE_2$), and IL-10, which have been shown to suppress the activity of stimulated macrophages *in vitro* and *in vivo* [61–63]. Although human MSCs grown in a standard monolayer culture have been shown to improve cardiac function and decrease cardiac scarring in a murine model of acute myocardial infarction by secretion of the anti-inflammatory factor TSG-6, its secretion has to be activated by incubation with the inflammatory cytokine TNF-α for at least 24 h [64]. In the absence of inflammatory cytokines, 3D MSC aggregates can self-activate to secrete potent anti-inflammatory cytokines such as TSG-6 and $PGE_2$. The mechanisms by which they do this are under exploration. Culture medium appears to be one factor that turns on/off the expression and secretion of $PEG_2$ and TSG-6 [51,61,65]. Culture-medium-mediated control of the secretory function of MSC 3D aggregates is closely correlated with cell survival. It appears that culture medium that supports cell survival and reduces cell stress during 3D aggregation has a negative effect on secretory ability of the MSC aggregate. Bartosh *et al.* reported that the stress-activated signaling pathway of IL-1α/β is involved in the activation of the immune response of MSC aggregates, including the secretion of TSG-6 and STC-1, and that an independent contact-dependent Notch signaling pathway is required for secretion of $PGE_2$ production [63].

## 8.5 Bioreactor systems for three-dimensional aggregate production

### 8.5.1 Scale-up and dynamics of culture

Enhancement of the properties of human MSCs by 3D aggregate formation has motivated the development of bioreactor systems for aggregate production. This is due to their scalability and the ability to provide a physiochemical environment with tightly controlled culture parameters, such as oxygen tension, mechanical stresses, and nutrient gradients. Bioreactor systems for multicellular aggregate formation and production have already been developed and used for tumor spheroids, pluripotent stem cells, and neural stem cells [66–68]. Compared with these cell types, MSCs have a significantly lower proliferation potential in suspension, are highly adhesive, and have high sensitivity to mechanical stress. For example, MSCs form 3D aggregates primarily through cell-cell adhesion rather than by proliferation because they have limited proliferative ability in suspension.

MSC aggregates are highly adhesive to the external surface and have a strong tendency to coalesce into larger aggregates [51]. MSC aggregates also exhibit viscoelastic properties and are highly sensitive to external mechanical stresses. These properties strongly influence the initiation of MSC aggregation, aggregate

deformation, their biological properties, and consequently the design and operation of bioreactor systems to produce them in bulk.

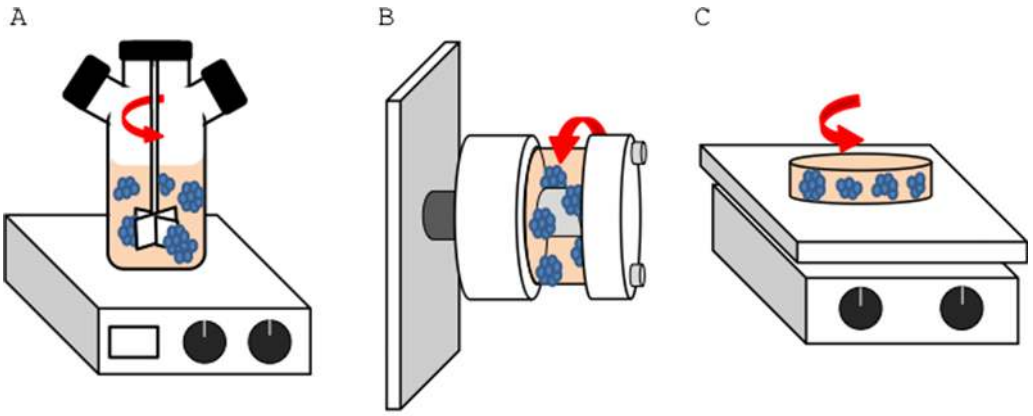
In suspension, the initial process of multicellular aggregation depends primarily on cell–cell collision followed by cell–cell contact via intercellular adhesion and coalescence [69]. Owing to the low MSC survival in suspension cultures, bioreactors used in MSC aggregate production typically require preseeding of the aggregates formed in ultralow attachment culture dishes, hanging-drop plates, or by centrifugation in AggreWell™ plates [18,27]. Following the seeding of the preformed aggregates, the magnitude and profile of shear rate and shear stress influence the size of MSC aggregates [70–72]. This is likely due to higher force input interrupting cell–cell connections, thereby reducing coalescence and limiting aggregate size. At low shear, smaller MSC aggregates easily adhere to each other and coalesce into larger aggregates. When growing embryonic stem cells in culture, Mogi *et al.* reported an inverse correlation between the average diameters of embryoid bodies and the rotation rate in rotary orbital suspension culture [73]. This phenomenon can be explained by hydrodynamic analysis of the microcarrier bioreactor in which the Kolmogorov eddies decrease with the decrease of fluid viscosity or the increase of dissipation energy per unit mass [74,75]. Kolmogorov microscales are the smallest scales in turbulent flow. Very similar to Jossen's eddy analysis in microcarrier systems with turbulent flow, the higher energy input increases the turbulent eddy number but decreases the eddy diameter, thus generating directional forces to detach cells from aggregate surfaces [74]. However, if the shear stress is too high, the possibility of cell–cell collision increases concomitant with the decrease of collision time, which inhibits cell–cell contact and the cadherin accumulation in the cell–cell contact area. This prevents the establishment of stable cell–cell connections [69]. Quantitative analysis of shear stress on aggregate structure has reported that 6.5 dyn/cm$^2$ (0.65 Pa) is sufficient to remove the outer cells of an aggregate in suspension [76,77].

MSC aggregates are viscoelastic and are highly sensitive to mechanical force [78]. They exhibit solid-like properties when the stress is not large enough or over a short duration, but behave as liquid when the stress overcomes the sustainable threshold, inducing the cells to reorganize and change aggregate shape. In bioreactors, the 3D MSC aggregate may deform and reorganize as a result of external mechanical forces such as centrifugation and shear stress. The degree of deformation is determined by the ratio of external stress to aggregate stiffness, where stiffness is defined as the stress needed to achieve a certain deformation of a structure. Baraniak *et al.* reported that the Young's modulus for human MSC aggregates measured by a parallel-plate compression configuration is from $42.28 \pm 6.14$ Pa at day 2 to $62.4 \pm 5.58$ Pa at day 7, suggesting a reduction in deformation ability as the aggregates mature [18]. (Young's modulus, also known as the tensile modulus or elastic modulus, is a mechanical property of linear elastic solid materials. It measures the force (per unit area) that is needed to stretch (or compress) a material sample.) Based on the stiffness measurement, a 1% aggregate deformation is estimated in a bioreactor with shear stress in the range of 5–6.5 dyn/cm$^2$ (0.5–0.65 Pa). While the shear stress typically used in a bioreactor system has a limited impact on aggregate deformation, very high stress (15–30 dyn/cm$^2$, or 1.5–3.0 Pa) may reduce cell viability and induce apoptosis [79,80].

Bioreactor systems used in 3D MSC aggregate cultures are shown in Figure 8.3.

### 8.5.2 Spinner flasks

Spinner flasks are one of the simplest bioreactor systems with high scalability and have been used in MSC aggregate cultures. A spinner flask is a cylindrical glass container with an internal magnetic stirrer with two side-arms controlled by a stirring platform designed to agitate and aerate the medium to provide a homogeneous culture environment. One characteristic of the spinner flask is that higher agitation to achieve a well-mixed culture may generate turbulent flows, leading to a very high shear stress on MSC aggregates.



The flow rate and fluid shear in the spinner flask have been reported to be predominantly regulated by the impeller geometric shape and spatial position as well as the agitation speed, whereas the mass transfer coefficient increases as a power function of agitation speed under normal conditions [87]. Ismadi *et al.* reported that the mean shear stress in spinner flasks is a linear function of the impeller rotation speed and that the mean shear stress changes from 3 to 4.2 dyn/cm$^2$ (0.3 to 0.42 Pa) with two different types of impellers at a rotation speed 80 rpm [81]. In general, the highest shear stress level is typically at the end of the longest impeller [88] or at the base of the spinner flask, while the highest flow rate was observed in the meridional plane at the highest impeller position [81]. The profile of shear forces and the effect of hydrodynamics on MSC aggregates need to be considered when determining the aggregate size in the spinner flask bioreactor. Sen *et al.* used a formula proposed by Moreira to estimate the average diameter of neural stem cell aggregates in a spinner flask:

$$\text{Average diameter} = C\epsilon\alpha\nu/\beta$$

where $C$, $\alpha$, and $\beta$ are constants, $\epsilon$ is the power dissipated per unit mass, and $\nu$ is the medium kinematic viscosity [89]. This method can be applied to the dynamic culture of MSC aggregates. Given that Young's modulus of an MSC aggregate is around 520 dyn/cm$^2$ (52 Pa) and the shear stress in the spinner flask is around 3 dyn/cm$^2$ (0.3 Pa) with a rotation speed 80 rpm, the structural deformation is estimated to be less than 1%, suggesting that a spinner flask is a feasible method for MSC aggregate cultures [18,81].

### 8.5.3 Rotary wall vessel

The rotary wall vessel (RWV) system developed by NASA provides a microgravity environment for cell expansion and overcomes many limitations of the spinner flask bioreactor

| Spinner flask (A) | Rotary wall vessel (B) | | Rotary orbital shaker (C) |
|---|---|---|---|
| Rotation speed (rpm) | 30–70 | 11–25 | 45–65 |
| Shear stress (dyn/cm$^2$ (Pa)) | <5 (<0.5) | <1 (<0.1) | <1.5 (<0.15) |
| Aggregate size control | Yes | No | Yes |
| Reference | [27,49,81] | [27,82–85] | [18,61,73,86] |

**Figure 8.3** Comparison of three different types of bioreactors for aggregate formation and maintenance.

[90,91]. The structure of an RWV system is a horizontal cylinder with horizontal rotation and a silicon member for gas transfer. The laminar flow is driven by the outside horizontal vessel wall, which avoids the large shear stress associated with turbulent flow, thus providing a much more homogeneous shear stress field [92] and compensating for the gravity effect [91]. However, an RWV system retards the control of the MSC aggregate size, resulting in large variation of aggregate size because its low shear stress may increase the heterogeneous environment. The reported average shear stress in an RWV bioreactor is around 0.5–1.0 dyn/cm$^2$ (0.05–0.1 Pa), depending on rotation speed [82–85]. The rotation speed of the inner wall and the outer vessel in the same direction or in the opposite direction may not result in too much variation in velocity or stress profile [93]. Thus, the RWV bioreactor system provides a culture environment that improves mass transport with reduced mechanical stress on 3D cell aggregates.

### 8.5.4 Rotary orbital system

Some groups have used bacteriological-grade Petri dishes on a rotary orbital shaker to maintain MSC 3D aggregate cultures after aggregation by centrifugation [86]. It was reported that the rotary culture system increased the efficiency of the formation of embryoid bodies during embryonic stem cell culture and the uniformity in size distribution compared with that of static culture [94]. While direct formation of MSC 3D aggregates in the rotary orbital system has not been reported, increased mass transport under rotation helps maintain 3D aggregate viability and prevents their re-aggregation. Owing to the horizontal rotation without vertical circulation and noneven distribution of the fluid flow, the system has limited scalability. Computational analysis indicates that the maximum flow rate occurs in the peripheral region of the bottom of the well at a low rotation speed below 100 rpm, and at the center region of the bottom of the well at a high rotation speed such as 120 rpm. The maximum fluid shear occurs in the bottom of the well at around 1.5 dyn/cm$^2$ (0.15 Pa) and increases with the increase of the rotation speed [73].

### 8.5.5 Comparison of spinner flask and rotary wall vessel

Frith and colleagues developed dynamic 3D techniques for *in vitro* MSC culture using spinner flasks and an RWV bioreactor. They characterized these two methods for dynamic 3D MSC culture and compared the properties of these cultures with a conventional monolayer culture of MSCs. They showed that under optimal conditions MSCs formed compact cellular spheroids and remained viable in dynamic 3D culture. They demonstrated altered cell size and surface antigen expression together with enhanced osteogenic and adipogenic differentiation potential in the MSCs from the dynamic 3D conditions. By microarray analysis of monolayer and spinner flask MSCs they identified many differences in gene expression, including those confirming widespread changes to the cellular architecture and ECM. The upregulation of IL-24 in dynamic 3D cultures was shown to selectively impair the viability of prostate cancer cells cultured in medium conditioned by dynamic 3D MSCs [30]. However, anoikis, a form of programmed cell death that is induced by anchorage-dependent cells detaching from the surrounding ECM, was not entirely overcome [30].

### 8.5.6 Other systems

Other systems have been described, including the use of microcarrier beads, which provide a much greater surface area to which MSCs can adhere. Timmins *et al.* described the development of a closed process for bulk isolation of MSCs from human placenta and their subsequent cultivation on microcarriers in scalable single-use bioreactor systems. The authors estimated that a single placenta might produce over 7000 doses of therapeutic MSCs using a large-scale process [95].

The commercial company Terumo BCT sells its Quantum™ System, which is a functionally closed, automated, and scalable expansion method to grow preselected MSCs to yield clinically relevant doses in only 5 days.

## 8.6 Transplantation of three-dimensional mesenchymal stromal cell aggregates in preclinical animal models of disease

The functional enhancement induced by 3D aggregation of MSCs and the associated changes in structural and biophysical properties have given impetus to their application in preclinical studies in a variety of disease models. To date, suspension of single cells is the most common mode of cell delivery but suffers significant loss due to anoikis on detachment from the ECM, with a reduced ability to withstand an inflammatory *in vivo* environment [96]. Although trophism (support through trophic factors) is thought to be the main mechanism by which MSCs mediate their effects, increased survival and persistence of the transplanted cells at the wound site would likely be beneficial. To this end, transplantation of MSC aggregates or aggregate-derived cells appears to offer several advantages compared with transplantation of a single cell suspension. As discussed previously, 3D aggregation enhances the secretion of anti-inflammatory, anti-apoptotic, and immune modulating factors and increases their resistance to ischemic stress. The increased ECM in 3D human MSC aggregates protects them against damage induced by inflammatory cytokines at the wound site, increases cell adhesion, and prevents cell leakage. Because of their increased size, MSC aggregates are more readily visualized by *in vivo* imaging after their transplantation. While systemic administration of MSC aggregates is not feasible in some disease settings because of the possibility of vascular embolism, their transplantation has been actively pursued in several clinical models (Table 8.1).

### 8.6.1 Enhanced secretory properties of mesenchymal stromal cells aggregates

Multiple studies have shown that 3D MSC aggregation increases the expression of HIF and HIF-mediated genes, including VEGF, HGF, FGF-2, SDF-1α and CXCR4, and significantly enhances their proangiogenic and migratory properties. One application of the enhancement of angiogenesis by altering the secretion profile in aggregates is the salvage of the ischemic limb [49]. Hindlimb ischemia is a commonly used rodent model for the study of peripheral arterial disease and is induced by ligating the femoral artery and its branches through a skin incision. One day after the surgery, human ASDC aggregates were injected intramuscularly into the gracilis muscle of the medial thigh. Immunohistochemistry showed a three- to fivefold increase of angiogenic growth factors, including HGF, VEGF, and FGF-2, compared with 2D cultured cells. Immunofluorescent staining of murine von Willebrand Factor (vWF) and the quantification of the density of capillaries and arterioles indicated that transplantation of spheroid human ADSCs significantly enhanced the formation of capillaries and arterioles. The improvements were confirmed by histology. The mechanism of this enhanced therapeutic outcome is thought to be due to the combined effects of the increased angiogenic growth factors as well as higher survival of MSC aggregates in the ischemic damage sites compared with that of 2D cultured MSCs.

Similar findings for aggregate-mediated enhancement in angiogenesis have also been reported in animal models of oral mucositis [50]. Human gingival tissue-derived MSC aggregates or 2D cultured cells were injected intravenously into the areas of injury. Expression of VEGF and angiogenin in the MSC aggregates significantly enhanced the angiogenesis in the wound sites and promoted the restoration of weight loss due to decreased food intake because of the oral mucositis. (Angiogenin is a potent stimulator of new blood vessels through the process of angiogenesis.) In addition, the gingival MSC aggregates also had higher antioxidant property and exhibited higher resistance to oxidative stress at the wound site.

### 8.6.2 Immunomodulation by mesenchymal stromal cell aggregates

Another function of MSCs is downmodulation of excessive inflammatory responses by secretion of anti-inflammatory cytokines such as the IL-1 receptor antagonist, TSG-6, and $PGE_2$, which can be significantly enhanced by 3D aggregation. The murine model of zymosan-induced peritonitis has been used to evaluate the anti-inflammatory effects of MSC aggregates *in vivo* [51]. Aggregates and monolayer culture MSCs were injected intraperitoneally and the inflammatory exudates were collected by peritoneal lavage. There was a significant decrease of proinflammatory proteins in the lavage fluid in the MSC aggregate groups, including TNF-α, IL-1β, and CXCL2 (also known as macrophage inflammatory protein-1 (MIP-2)). Activity of serum plasmin, an inflammation-associated protease inhibited by TSG-6, was reduced to noninflammatory levels, suggesting that MSC aggregates are more effective in suppressing inflammation *in vivo* than MSCs cultured as monolayers.

### 8.6.3 Enhanced multilineage differentiation of three-dimensional mesenchymal stromal cells aggregates

Transplantation of 3D MSC aggregates enhances tissue repair and regeneration by better maintaining their multipotential lineage-specific differentiation compared with dissociated cells

**Table 8.1** Transplantation of MSC 3D aggregates in preclinical animal models.

| MSC source | Methods of aggregation and dissociation | Disease model | Method of delivery | Mechanisms of action | Ref. |
|---|---|---|---|---|---|
| Human gingival MSCs | 3 days of aggregation on ultra-low attachment plates | Oral mucositis | Intravenous infusion of dissociated aggregates | Increased stemness and trans-differentiation; increased secretion and migratory properties; higher resistance to oxidative stress | [50] |
| Human ADSCs | 4 days of hanging-drop culture | Parkinson's disease model | Intranigral[a] injection of dissociated human ADSCs | Enhanced endogenous neurogenesis; increased expression of prosurvival factors; stabilization of blood vessels | [97] |
| Human ADSCs | 3 days of spinner flask culture | Peripheral arterial disease (hindlimb ischemia) | Intramuscular injection of aggregates into the gracilis muscle[b] | Three- to fivefold increase in local HGF, VEGF, and FGF-2; two- to fivefold increase in host cells expressing α-actin, ICAM-1, VCAM-1 and PECAM-1 compared with dissociated cells | [49] |
| Human umbilical cord MSCs | 1 day hanging drop, then 2 days spinner flask culture | Peripheral arterial disease (hindlimb ischemia) | Intramuscular injection of aggregates into the gracilis muscle | Increased number of microvessels and smooth muscle α-actin compared with dissociated cells | [98] |
| Human bone marrow MSCs | 4 days of hanging drop culture | Peritonitis and inflammation | Intraperitoneal infusion of aggregates and aggregate-derived MSCs | Decrease of protein content including proinflammatory molecules and serum plasmin[c] | [51] |
| Human umbilical cord MSCs | 2 days of aggregation on ultra-low attachment plates | Myocardial infarction | Injection of aggregates into peri-infarct zones | Fourfold decrease in LV end-diastolic and systolic diameters; LV fractional shortening | [21] |
| Human ADSCs | 1 day of aggregation on maltose-binding protein-FGF2-coated surface | Myocardial infarction | Injection of aggregates into infarct border zones | Infarct size reduction and cardiomyocyte protection; threefold increase of human VEGF and angiogenesis; endothelial and smooth muscle cell differentiation | [99] |
| Human ADSCs | 5 days of microgravity bioreactor culture | Liver disease (acute liver failure) | Injection of aggregates into spleen | Improvement of liver function tests; suppressed cell necrosis; enhanced antiapoptosis | [100] |
| Human placental MSCs | 1 day hanging-drop culture | Ischemic stroke | Injection of aggregates into carotid arteries | Reduced cerebral infarct volume; restoration of neurologic functions; enhanced angiogenesis; neuronal differentiation | [101] |
| Rabbit bone marrow MSCs | 2 weeks of cell sheet culture | Bone non-unions and defects | Ectopic[d] and orthotopic[e] injection aggregates | Twofold increase in bone formation and higher bone mass compared with injection of single-cell suspension | [102] |
| Rabbit bone marrow MSCs | 2 weeks of cell sheet culture | Bone non-unions | Implantation of aggregates in dorsal pocket[f] | New bone and cartilage formation; enhanced compressive strength | [103] |
| Human synovial[g] MSCs | 3 days of hanging-drop culture | Cartilage defect | Osteochondral implantation of aggregates | Cartilage regeneration; defect was fully filled with cartilage matrix; border between cartilage and bone moved up | [104] |
| Rabbit articular cartilage and synovial MSCs | 2–3 days of low attachment dish with rotary shaker | Cartilage defect | Micropipette aspiration delivery of aggregates | Effective restoration of articular cartilage; higher *in vivo* ECM production | [105] |

[a] The substantia nigra is a brain structure located in the midbrain that plays an important role in reward, addiction, and movement. Parkinson's disease is characterized by the death of dopaminergic neurons in the substantia nigra.
[b] A slender superficial muscle in the thigh.
[c] Plasmin is an important enzyme present in blood that degrades many blood plasma proteins, including fibrin clots; the latter process is known as fibrinolysis.
[d] Located in an anatomical site other than the normal one for a given tissue or organ.
[e] Located in the normal anatomical site for a given tissue or organ.
[f] A triangular deepening on the radial dorsal aspect of the limb (in the hand in humans).
[g] The synovium or synovial membrane is the soft tissue found between the articular capsule (joint capsule) and the joint cavity of synovial joints.

in suspension. In the mouse hindlimb ischemia model, aggregates of human UCB-MSCs formed by the hanging-drop method were injected into the gracilis muscle and monitored for 4 weeks [98]. In addition to elevated values of VEGF and FGF-2, the number of vWF-positive microvessels, expression of NG2, and smooth muscle-α actin-positive vessels were increased in the spheroid transplantation group, revealing direct incorporation of human UCB-MSCs into blood vessels. NG2 (neural/glial antigen 2) is believed to play a role in functions such as cell adhesion, cell–cell and cell–ECM communication, cell migration, proliferation, as well as axonal growth, guidance, and regeneration. NG2-positive cells include oligodendrocyte progenitor cells and other progenitor cell populations, such as chondroblasts, myoblasts, and pericytes. Limb salvage of the human UCB-MSC spheroid group improved compared with that of MSC monolayer culture or control groups and was accompanied by decreased fibrosis in the ischemic region.

In the rat myocardial infarction model, human UCB-MSC aggregates prepared on ultralow attachment plates were injected into three different peri-infarct zones [21]. Results showed a fourfold decrease in left ventricular end-diastolic diameter, reduced systolic diameters, left ventricular fractional shortening, a reduction in cardiac fibrosis, and an increased density of capillaries. These results were thought to be due to increased engraftment in the aggregate group compared with that of the monolayer group. DiI-labeled MSC tracking revealed the expression of isolectin B4 and α-sarcomeric actin, indicating their differentiation into endothelial cells and cardiomyocytes respectively.

Similar findings of MSC differentiation into cells of the cardiac lineage were reported in another study that used MSC aggregates generated from maltose-binding protein-FGF-2-coated surfaces [99]. Cells in suspension and 3D MSC aggregates were injected into the infarct border zone at three locations after ligation of the left coronary artery induced an acute myocardial infarction. Histology and immunofluorescence staining of anti-human CD31 antibody (PECAM) and anti-human-α-smooth muscle actin antibody (hα-SMA) were used to verify endothelial cell and smooth muscle cell differentiation respectively. Densities of the $CD31^+$ and $\alpha\text{-}SMA^+$ cell in the 3D groups were higher than in the 2D group. The significant reduction in infarct size and better protection of cardiomyocytes were attributed to the direct differentiation of 3D MSC aggregates into smooth muscle cells and endothelial cells. Most of the differentiated cells in the 3D group were integrated into recipient blood vessels and contributed to neovascularization.

The enhanced multilineage potential of MSCs in 3D aggregates has also been demonstrated in other diseases, including liver disease and stroke. In a model of acute liver failure, MSC aggregates produced by a microgravity bioreactor were injected into the spleen [100]. A number of studies have shown that MSC aggregates have higher expression of pluripotent genes, such as *OCT-4*, *NANOG*, *SOX-2*, and *REX-1*, and a greater capacity to undergo lineage-specific differentiation compared to the MSCs cultured in monolayers. Expression of hepatic markers, including albumin, cytokeratin 18 (CK-18), and cytochrome P450 3A4 (CYP3A4), in human ADSC aggregates was increased in response to hepatocyte induction by conditioned medium. After transplantation into mice, levels of the hepatic enzymes aspartate aminotransferase and alanine aminotransferase were increased in mouse blood in those that received the MSC aggregates. Liver cell necrosis was also suppressed. While further studies are needed, these studies demonstrated that MSC 3D aggregates *may* have the capability to transdifferentiate into cells of the endoderm and ectoderm lineages, but this will need to be verified by specific *functional* tests.

Enhanced neurogenesis was observed in rats receiving MSC aggregates after an ischemic stroke due to occlusion of the middle cerebral artery [101]. *In vitro* expression of nestin and microtubule-associated protein 2 (MAP-2) in MSC aggregates could have been due to an enhancing effect on residual host nerve cells, or less likely due to MSC differentiation into nerve cells. It must be emphasized that there are very few, if any, convincing reports that MSCs can differentiate into functional cells of the ectoderm lineage. Nevertheless, in this model the MSC aggregate group showed a significant reduction in infarct volume, as well as an improved neurologic severity score and adhesive removal test. These results indicate recovery of neurologic functions in the brain after stroke. When tissue sections of the stroke brain were co-stained with antibodies against MAP-2 or the astrocyte-specific protein glial fibrillary acid protein (GFAP) and the human-specific nuclear protein (antibody M1281), there was a significant increase in co-expression of $MAP\text{-}2^+$ or $GFAP^+$ and $M1281^+$ cells in the spheroid MSC group.

### 8.6.4 Recapitulation of mesenchymal condensation and osteochondral differentiation in bone and cartilage regeneration

During embryonic development, condensation of previously dispersed cells is a pivotal stage in the development of mesenchymal tissues, including cartilage and bone. The 3D aggregates of MSCs have been shown to recapitulate mesenchymal condensation *in vitro* with enhanced chondrogenic and osteogenic potentials [106,107]. *In vivo* transplantation of scaffold-free MSC aggregates also enhanced mesenchymal condensation and osteochondral differentiation.

Rabbit bone marrow MSC aggregates have shown increased cell survival and enhanced bone healing through endochondral and intramembranous ossification compared with dissociated or 2D monolayer culture MSCs in a model of delayed bone fracture healing [102,103]. The mineralization mass was highly increased in the aggregate recipients. After 4 weeks, both bone (intramembranous ossification) and cartilage (endochondral ossification) formation were observed at the same time, with histomorphometry demonstrating approximately 33.3% bone and 17.5% cartilage of the cross-sectioned area. By 8 weeks, mineralized bone replaced some cartilage-like tissue, and bone

and cartilage occupied 56.5% and 7.1% of the total cross-sectional area respectively. Analysis of the fracture gap showed that the bone volume fraction of the aggregate group was significantly higher than that of the cell suspension or control groups. The expression of osteocalcin, collagen type I, osteopontin, and other osteogenic differentiation markers was also significantly higher in the MSC aggregate group. Moreover, when the mechanical properties of newly formed bone were measured, the compressive strength of the aggregate recipient group was greater than that of the 2D MSC group [103].

Transplantation of synovial MSC aggregates has been shown to enable their differentiation into chondrocytes and subsequently participate in the reparative process of osteochondral defects in the rabbit knee model [104]. MSC aggregates adhered promptly at the site of osteochondral defects without cell loss. Aggregation of human synovial MSCs also increased the expression of several chondrogenesis-related genes, including *BMP-2*. Transplanted aggregates of synovial MSCs directly differentiated into chondrocytes to participate in the reparative process. Four weeks after transplantation the osteochondral defect was mostly covered with a thick cartilaginous matrix. It was noted that increasing the number of MSC aggregates at the wound site did not result in improved healing. This may have been due to nutrition depletion and associated cell apoptosis or to reduced access to synovial fluid by the 3D aggregate at high density.

Undifferentiated MSCs can also aid chondrocyte differentiation in 3D aggregates of multiple cell types. In a study by Lee *et al.*, aggregate composites of chondrocytes and synovium-derived MSCs were transplanted into superficial osteochondral defects in a rabbit model [105]. Effective restoration of articular cartilage and *in vivo* ECM production were observed. The defects were covered with tissue that had a smooth surface, and the regenerated tissue was connected with adjacent normal cartilage when examined at 8 and 16 weeks after administration of the aggregates. No infiltration of inflammatory cells was found in the subchondral bone. Thus, MSCs may enhance musculoskeletal tissue repair and regeneration by supporting the host's parenchymal cells.

## 9.1 Introduction

The cell–cell signaling mechanisms controlling mesenchymal stromal cell (MSC) behavior are often examined using heterogeneous cultures that may contain clonal cells of varying potencies alongside other stromal populations. While this approach may obscure some ligand-induced effects, it may also reveal important interrelationships between different stromal cell types. In addition, MSCs will reside in a multicellular niche *in vivo*, where heterotypic cell–cell interactions will be highly influential. From this perspective, we discuss some of the key signaling pathways controlling MSC differentiation.

## 9.2 Mesenchymal stromal cell signaling is dependent on its type

The term MSC (usually referring to mesenchymal stromal cells, and rarely in the literature to true mesenchymal *stem* cells) is widely used to describe adherent stromal cells with the capacity to differentiate into the skeletal lineages of bone, fat, and cartilage. There is significant clinical interest in MSCs, but in order for these cells to fulfill their therapeutic potential it is important to gain a better understanding of the signaling mechanisms that control their proliferation and differentiation *in vivo*. However, discrepancies in reports from different research groups are not uncommon, and these inconsistencies may be a consequence of differences in the nature of the cell populations being studied. Early work in the MSC field isolated non-hematopoietic cells from bone marrow. They were characterized as a fibroblastic, plastic-adherent cell population, a fraction of which exhibited clonal expansion capacity and could generate osteoblasts, adipocytes, and chondrocytes on heterotopic implantation *in vivo* in the absence of exogenous differentiation stimuli [1,2]. Since that time, standardized methods to identify and isolate MSCs are still lacking due to the absence of a single, definitive marker for these cells. Current protocols often generate a heterogeneous population of cells that is not always consistently uniform between research groups. Furthermore, recent evidence suggests that subpopulations of MSCs exist *in vivo* and disparities in expansion protocols may promote the growth of different subtypes, which may account for the observed variability in the cells being studied. It has been demonstrated that cells isolated from bone marrow and other tissues as diverse as adipose tissue, synovium, and umbilical cord appear morphologically similar and undergo trilineage differentiation to osteogenic, adipogenic, and chondrogenic cells when exposed to differentiation stimuli *in vitro* [3–5].

The implication of this has been that MSCs isolated from anatomically varied sites are functionally equivalent. However, the *in vivo* MSC will be exposed to a tissue-specific environment and, it should be assumed, receive signaling inputs from the resident cells. It should also be noted that during embryonic development there is no single common precursor cell that can

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.

give rise to all the different skeletal tissue types, let alone a common precursor cell for the diverse range of tissues from which it is reported that multipotent MSCs can be isolated. Bone formation occurs prior to development of the marrow stroma [6], and different parts of the skeleton arise from different regions of the embryo. Facial bones are derived from the neural crest, while the axial skeleton is derived from paraxial mesoderm and the limb bones from lateral plate mesoderm [7]. The stromal compartment is then established from local progenitor cells in each tissue [6]. Identifying specific, preferably tissue-specific, developmental MSC markers is crucial to understanding the signaling mechanisms that drive their growth and differentiation. Most progress has been made with bone marrow-derived MSCs.

## 9.3 Identity of bone-marrow-derived mesenchymal stromal cells

In the absence of a unique marker, the International Society for Cellular Therapy (ISCT) in 2006 proposed minimal criteria for classifying cells as MSCs [8]. These included adherence to plastic, demonstration of multipotent differentiation potential *in vitro*, and expression of the cell surface markers CD105/endoglin, CD73/ecto-5′-nucleotidase, and CD90/Thy-1 by ≥95% of the population. It was also stated that the cells must be negative for CD45, CD34, CD14 or CD11b, CD79α or CD19, and HLA class II (≤2% of the population positive for these markers). The CD34 negativity of MSCs, however, is somewhat controversial, as several reports suggest that MSCs freshly isolated from tissues do indeed express CD34, but that expression is lost with culture *in vitro* [9]. However, since these surface proteins are also expressed by several other cell types, these criteria alone are insufficient to identify a homogeneous population of cells. Although several other cell surface proteins, such as CD13, CD29, and CD44 [10,11], are known to be characteristic of human MSCs, their expression is also not restricted to MSCs and, therefore, are of limited use in generating a pure population of cells.

Several other cell surface proteins expressed on MSCs have since been proposed to further enrich the population. The monoclonal Stro-1 antibody was one of the earliest antibodies used to enrich for MSCs in human bone marrow [12]. The subset of cells recognized by this antibody are capable of multilineage differentiation and include almost all fibroblast colony-forming unit (CFU-F) cells [12–14]. However, recent findings that Stro-1 is also expressed by the endothelium question its use as an MSC marker *in vivo* [15]. CD106/vascular cell adhesion molecule-1 is also expressed on human MSCs and has been used in combination with Stro-1 to isolate a more purified MSC population [16]. CD106 was found to be expressed by a subset of 1.4% of Stro-1-positive cells, and this population was highly enriched for CFU-Fs with multipotent mesodermal differentiation potential [16]. Other markers used to identify human MSCs have included: CD166 (activated leukocyte adhesion molecule) [17,18]; CD63, which is mainly associated with the membranes of intracellular vesicles and is also known as HOP-26 [19]; the α1 integrin subunit CD49α [20,21]; and stage-specific embryonic antigen-4 [22]. Recently, more specific MSC markers, such as CD271 (low-affinity nerve growth factor receptor) [23,24] and CD146 (melanoma cell adhesion molecule) [25] have also been shown to be expressed by bone-marrow-derived MSCs.

However, standard protocols used to isolate MSCs include expansion *in vitro*, and several reports suggest that an alteration in cell phenotype is associated with time in culture (see Chapter 7). Whereas expression of CD73, CD90, CD105, and CD166 have been shown to remain constant with increased passage [11,26], expression of CD106, CD146, Stro-1, and CD34 have all been reported to decrease with time in culture [9,12,27,28]. Furthermore, it has been suggested that MSCs directly isolated from bone marrow are in fact CD44-negative, and that expression of this antigen is an artefact of *in vitro* culture [29]. Reports demonstrating MSC marker expression *in situ*, as well as phenotypic studies of MSCs freshly isolated from bone marrow, have provided cell surface protein expression information without the problems associated with manipulation of the cells *in vitro*. CD271 was shown to be expressed in human bone marrow *in situ* by perivascular and bone-lining stromal cells [30,31]. CD146 expression was also demonstrated in MSCs in the subendothelial layer of sinusoids in human bone marrow [25]. Furthermore, it has been reported that a subset of CD271-positive MSCs are also positive for CD146 expression. At least two subpopulations of MSCs have been proposed: $CD271^+/CD146^+$ MSCs, which reside in perivascular locations; and $CD271^+/CD146^-$ MSCs, which exist endosteally [31].

A rare population of Nestin-positive ($Nestin^+$) mesenchymal cells isolated from mouse bone marrow exclusively contain CFU-F activity, are capable of self-renewal and expansion in serial transplantations, and also demonstrate multilineage differentiation, thus fulfilling the criteria of true (mesenchymal) *stem* cells [32]. Furthermore, these cells are located in close proximity to the vasculature and hematopoietic stem cells (HSCs), and have been shown to form an essential element of the HSC niche through expression of genes required for HSC maintenance, such as CXC chemokine ligand (CXCL) 12 and stem cell factor (SCF). These $Nestin^+$ MSCs appear very similar to CXCL12-abundant reticular (CAR) cells, identified surrounding sinusoidal endothelial cells in mouse bone marrow [33,34]. CAR cells reside in locations very similar to those described for $Nestin^+$ MSCs, mainly in central areas of mouse bone marrow, but also near the endosteum, and also promote HSC maintenance. $Nestin^+$ MSCs and CAR cells could potentially be two overlapping cell populations, although $Nestin^+$ MSCs appear to represent a rarer, more primitive cell type, being capable of multilineage differentiation, extensive self-renewal, and containing all CFU-F activity in the bone marrow (reviewed in [35]). Expression of the Leptin receptor (LepR) has also been used to identify cells with similar properties in mice [36,37]. $LepR^+$ perivascular cells express CXCL12 and SCF and are important components of the HSC

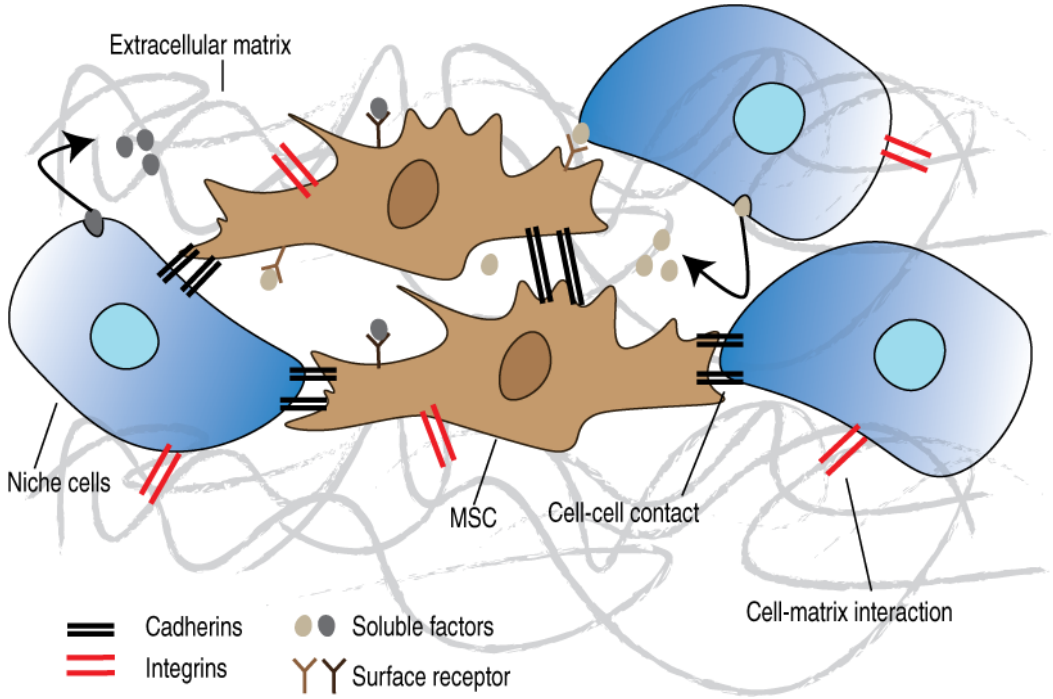

**Figure 9.1** The MSC niche.

niche. These LepR$^+$ MSCs have also been shown to account for most of the CFU-F activity in the bone marrow and are capable of multilineage differentiation [38]. A large overlap has been reported between LepR$^+$ cells and Nestin$^+$ populations in the bone marrow [39], though findings using lineage-tracing mice identified MSCs as LepR$^+$, SCF$^+$, CXCL12$^{high}$, and Nestin$^{low}$ [38].

An equivalent cell type has also recently been identified in humans. A subset of CD146$^+$ cells also express Nestin, as well as platelet-derived growth factor receptor α and CD51, and these cells were shown to be highly enriched in CFU-F activity, possess extensive self-renewal capacity, and express CXCL12 and SCF to support HSC maintenance [39].

Following the finding that MSCs are perivascular in both human [25] and in mouse [32] bone marrow, it has been proposed that MSCs are derived from pericytes [40–42]. Crisan *et al.* demonstrated that pericytes expressed a panel of MSC markers before culture, and that cultured pericytes display a phenotype similar to bone marrow MSCs, with proliferative capacity and multilineage differentiation potential. The common perivascular location *in vivo* and shared cell marker expression profiles of these two cell types has sometimes led to the suggestion that MSCs are pericytes [43].

Advances have been made in identifying authentic mesenchymal *stem* cells, most convincingly using mice models as described previously, which may not necessarily translate to human biology, and uncertainties persist. Functional markers, including cell surface receptors that can reveal more about MSC activity, are equivocal. Therefore, when examining the signaling inputs that regulate MSCs, it is often difficult to compare results across the scientific community where different antigens are used to identify MSCs or when the study relies on unsorted heterogeneous stromal cells where "average" effects will be reported. These comments are to provide context to the work reviewed here and are not intended to diminish the value of the published findings. One strategy gaining momentum has been to examine cell–cell signaling interactions in relation to the MSC niche (Figure 9.1).

## 9.4 Mesenchymal stromal cell signaling in the stem cell niche

Adult stem cells do not exist in isolation. They interact locally with their surrounding environment or niche, which is composed of a mixed community of stem cells and their differentiated progeny, niche-resident cells, and components of the extracellular matrix (ECM). The crosstalk between the stem cells and niche elements determines cell behavior and fate. Shear stress, oxygen gradient, neural input, and blood supply are also major determinants of stem cell function [44–46]. Progress has been made in defining niche composition and function for other adult stem cell types, including epithelial [47,48], intestinal [49], and neural [50] stem cells. The HSC niche [51] has received particular attention. In adult bone marrow, an endosteal HSC niche near the endosteal surface of the trabecular bone and a perivascular or

sinusoidal niche toward the center of the marrow have been described [52–54]. Further analyses indicated that HSCs preferentially occupied the perivascular niche, whereas lymphoid progenitors were endosteally located [36]. As discussed earlier, it is becoming clear that MSCs can be identified alongside HSCs in bone marrow. Mendez-Ferrer *et al.* revealed that Nestin$^+$ MSCs interact with HSCs at perivascular sites via CXCL12–CXCR4 signaling [32] and co-localize with sympathetic nerve fibers that can regulate HSC mobilization through circadian oscillations [55]. However, targeted depletion of CXCL12 in perivascular stromal cells was sufficient to deplete HSCs, whereas loss of CXCL12 from Nestin-*cre*-expressing cells had little effect on HSCs [36].

Detailed analysis of the *in vivo* MSC niche per se has been hampered by the lack of discriminating markers. Evidence that cells with MSC-like characteristics have been isolated from virtually every tissue type [56] would perhaps argue against the existence of a common MSC niche, with identical composition across all anatomical locations. However, evidence does suggest that MSCs are frequently associated with the vasculature and therefore reside in a perivascular niche [56], and several studies have determined the effects of MSC interactions with vascular endothelial cells (see Chapters 25 and 26). The intimate functional relationship between marrow angiogenesis and MSC differentiation has recently been demonstrated in the mouse [57]. Here, it was shown that Notch signaling in endothelial cells was required for appropriate blood vessel formation and osteo/chondrogenesis, with the Notch ligand Jagged 1 identified in perivascular stromal cells [57]. Using a three-dimensional co-culture model, it has been shown that endothelial cells significantly inhibited MSC proliferation, which may suggest a role in maintaining MSC quiescence or stemness. This study also demonstrated that, following exposure to differentiation stimuli, endothelial cells enhanced osteogenesis of MSCs at the expense of adipogenesis [58]. Related work has demonstrated enhanced osteogenesis in co-cultures of human MSCs and endothelial cells on polymeric microfiber scaffolds [59], whilst Xing *et al.* showed that endothelial cells enhanced *in vivo* bone formation when co-cultured with MSCs using poly(L-lactide-co-1,5-dioxepan-2-one) scaffolds [60]. Gene expression profiling has been used to help identify potential signaling mechanisms operating between MSCs and endothelial cells, using a direct-contact co-culture model [61], and identified the upregulation of genes associated with angiogenesis, such as von Willebrand factor, platelet/endothelial cell adhesion molecule-1 (PECAM1 or CD31), vascular endothelial growth factor, cadherin 5, angiopoietin-related protein 4, and CD34. Genes related to osteogenesis, such as alkaline phosphatase (ALP), FK506 binding protein 5, and bone morphogenetic proteins (BMPs), were also elevated. The authors concluded that the transforming growth factor-β (TGF-β)/BMP signaling pathway played an important role in the osteogenic induction of MSCs by endothelial cells [61], which has been noted elsewhere in studies that also highlighted the role of the Wnt signaling pathways [62]. These will be discussed in more detail later.

In addition, intercellular diffusion of signaling molecules through gap junctions appears important. It has been reported that communication through connexin 43 (CX43) contributes to osteogenic differentiation in two-dimensional co-cultures of endothelial cells and human MSCs [63,64] and the role of CX43 in osteogenesis has been demonstrated *in vitro* and *in vivo* [65,66]. Carrion *et al.* also reported that the interaction of MSCs with the laminin-rich vascular basement membrane deposited by endothelial cells via α6β1 integrin was essential for their perivascular localization [67]. Treating MSCs with an anti-α6 integrin antibody disrupted their adhesion to endotheial cell networks, preventing a perivascular association [67]. Matsubara *et al.* demonstrated that growth on a basement membrane-like ECM produced by primary endothelial cells enhanced MSC proliferative life-span and trilineage differentiation potential [68]. Other studies have focused on the regulation of niche ECM turnover by matrix metalloproteinases (MMPs). MSCs have been shown to protect their perivascular niche from high levels of endogenous MMP-2 through increased expression of tissue inhibitor of metalloproteinase (TIMP)-2 [69]. Even when exposed to pro-inflammatory cytokines and hypoxia, the matrix-protective property of MSCs was sustained by increased TIMP expression and thus augmented MMP-inhibition [69]. This highlights the importance of MSCs in regulating and being regulated by the structural organization of their local microenvironment, which includes stiffness and elasticity (see Chapters 15 and 17).

For example, varying matrix stiffness can exert a profound effect on the lineage specification and commitment of naive MSCs. MSCs grown on rigid matrices, resembling bone, promoted osteogenesis; softer matrices, resembling muscle, promoted myogenesis [70,71]. Additionally, MSCs are maintained in a quiescent state when cultured on soft polyacrylamide substrates to mimic the elasticity of the bone marrow niche [72]. There is evidence that mechanical stress may also influence MSC fate in the niche. The application of tensile mechanical strain to a collagen I substrate promoted osteogenesis of MSCs via the mitogen-acivated protein kinase signaling pathway [73]. Additionally, mechanical strain reduced the rate of MSC proliferation [74]. Likewise, bone-like ECM combined with fluid shear stress exposure synergistically enhanced the osteo-differentiation of three-dimensional cultures of MSCs even in the absence of the osteogenic supplement, dexamethasone [75], supported by findings that mechanical strain enhances osteogenesis but inhibits adipogenesis of MSCs [76].

It is clear that MSCs are influenced by a vast array of physical and biochemical factors. Two key signaling mechanisms that have interrelated regulatory effects on MSCs, either on undifferentiated cells in the niche or at different stages of differentiation and maturation, are the TGF-β/BMP and Wnt signaling pathways (Figure 9.2).

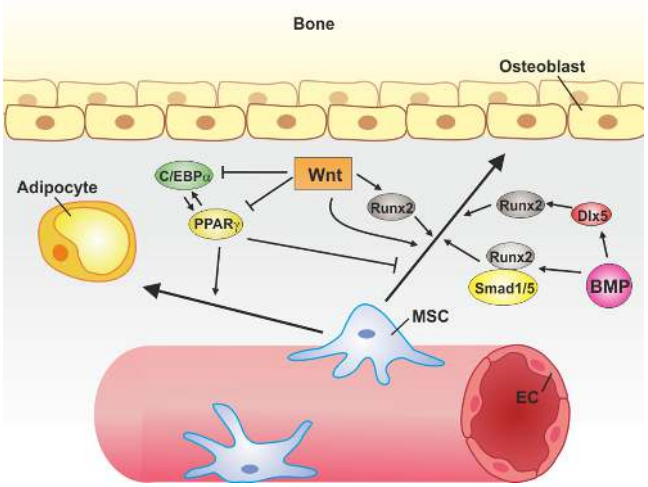

**Figure 9.2** Schematic representation of some of the signaling mechanisms that regulate MSC differentiation. MSCs are thought to occupy a perivascular niche where they can interact with endothelial cells (EC) and other vascular elements. Effects of Wnt and BMP on osteogenesis and adipogenesis through activation of key transcription factors are depicted. See Figure 9.3 for more detail of Wnt/BMP downstream signaling pathways. (See color plate section.)

## 9.5 Regulation of mesenchymal stromal cell differentiation by the TGF-β/BMP signaling pathway

The BMPs were initially identified as a group of proteins that induce endochondral bone formation [77] and are members of the TGF-β superfamily of signaling molecules. These secreted dimeric ligands bind to cell surface receptors with intracellular kinase activity. Ligand binding results in phosphorylation of specific receptor-regulated SMAD (R-SMAD) proteins. SMADs 2 and 3 are specific for TGF-β receptors, while SMADs 1, 5, and 8 are phosphorylated via BMP signaling. Following R-SMAD phosphorylation, an interaction complex is formed with Co-SMAD (SMAD4), and this complex is then able to translocate to the nucleus and regulate gene transcription [78]. Regulation of TGF-β/BMP signaling occurs via inhibitor SMAD (I-SMAD) proteins, which function in a negative feedback loop following upregulation by TGF-β ligands. I-SMADs can interfere with signal transduction by binding receptors and preventing R-SMAD phosphorylation, competing for complex formation between R-SMADs and SMAD4 and increasing receptor turnover [79] (Figure 9.3).

Signaling by TGF-β superfamily members regulates many aspects of embryonic development, including those related to specification of mesoderm and the differentiation of mesodermal progenitors into cells of skeletal lineages. During gastrulation, early mesendoderm is formed from epithelial cells during epithelial to mesenchymal transition (EMT). EMT is also a key part of the development of head structures from neuroepithelium-derived neural crest cells, which require TGF-βs and BMPs to generate craniofacial bone, cartilage, and connective tissue. TGF-$\beta3^{-/-}$ mice and those with a neural-crest-specific deletion of the BMP receptor Alk2 display cleft palate defects, demonstrating the requirement of TGF-β/BMP signaling in normal craniofacial development [79,80]. The importance of TGF-β/BMP signaling in mesoderm specification is also illustrated by work to derive

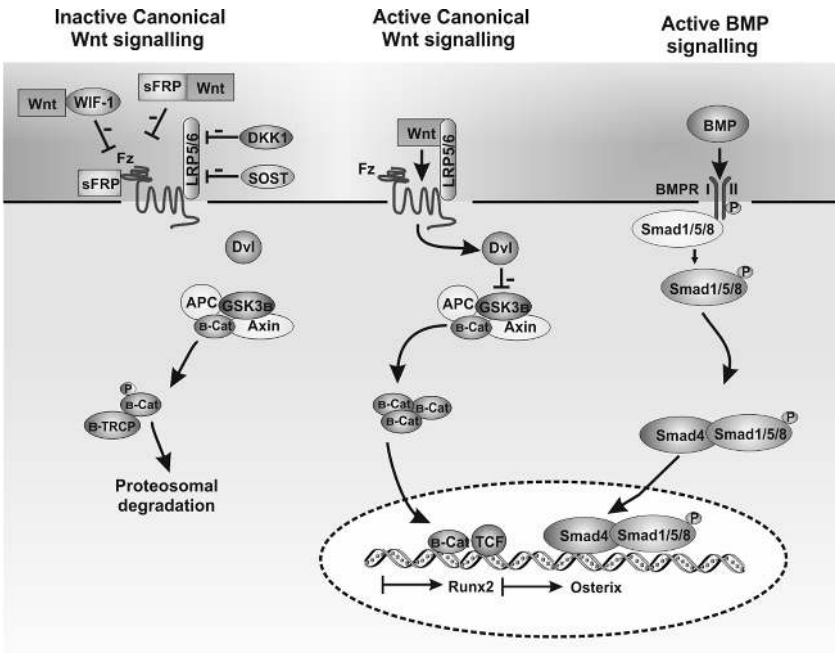

**Figure 9.3** Overview of the canonical Wnt and BMP signal transduction pathways. Wnt signaling is shown in the inactive (absence of Wnt signal) and active (following Wnt ligand binding) pathways. Crosstalk between Wnt and BMP intracellular signaling mechanisms will affect MSC responses to these regulatory cues.

induced pluripotent stem cells from fully differentiated cells by exogenous expression of pluripotent transcription factors (reprogramming). During the process of reprogramming, fully differentiated cells undergo dedifferentiation to a pluripotent state. Dedifferentiation can require mesenchymal to epithelial transition (MET), and it has been noted in a number of studies that inhibition of TGF-β signaling can improve the efficiency of this process [81,82]. It was also observed that addition of TGF-β1 or TGF-β2 acted as a barrier to reprogramming [82]. Taken together, these results demonstrate that TGF-β signaling acts to inhibit MET during reprogramming (dedifferentiation), which may be related to its role in driving the converse process of EMT during embryogenesis (differentiation).

BMP signaling also plays a role in embryonic limb and digit development. Targeted deletions of BMP2 and BMP4 in the limb mesenchyme resulted in failure to complete osteogenesis [83]. Digit defects, including polydactyly (extra digits) and syndactyly (interdigital webbing), were also observed when BMP2 and BMP4 were conditionally deleted in the apical ectodermal ridge [84] and the limb mesenchyme [83] of developing mouse embryos, demonstrating key roles for BMP signaling in limb skeletogenesis, including patterning and controlled cell death.

Along with its roles in embryonic development of the mesodermal lineage, BMP/TGF-β signaling also acts to regulate MSC differentiation *in vitro*. Recombinant BMP induces osteogenesis in preosteoblast cultures, while blocking BMP signaling inhibits osteogenesis [77]. BMPs act to induce the expression of the key osteogenic transcription factor Runx2. The induction of Runx2 by BMP signaling is mediated by another osteogenic transcription factor, Distal-less homolog (DLX5). DLX5 is specifically induced by BMP signaling, but not by other TGF-β superfamily members. It is expressed in response to BMP signaling and is upregulated prior to increased Runx2 expression. Robust BMP2 signaling cannot induce Runx2 expression in the absence of DLX5, indicating a key role for DLX5 in mediating BMP-induced Runx2 expression [85]. DLX5 also plays a vital role in the induction of ALP, which is known to be upregulated in response to BMP signaling. Runx2 has an additive effect on the DLX5-mediated expression of ALP, although DLX5 can induce ALP in the absence of Runx2, demonstrating that it acts independently of Runx2. Furthermore, the stimulation of ALP expression by BMP signaling is known to be abrogated in the absence of DLX5, demonstrating a critical role for DLX5 in BMP induction of ALP during osteogenesis [86]. The Runx2-independent induction of osteogenic markers by DLX5 is also observed for osterix (OSX), which is stimulated by BMP signaling via DLX5, even in Runx2-null cells. BMP signaling is unable to induce OSX expression in the absence of DLX5, again demonstrating the mediation of BMP signaling in osteogenesis via DLX5 [87]. Although DLX5 is clearly a critical regulator of BMP-induced osteogenesis, Runx2 also plays a vital role in transcriptional regulation of BMP-induced ostogenesis via interactions with SMAD 1 and SMAD 5. When BMP signaling is active, Runx2–SMAD complexes form and are targeted to specific nuclear matrix-associated sites where they regulate the expression of target genes [88]. The C-terminal domain of Runx2 is necessary for the induction of osteogenesis by BMP signaling, as it contains sequences for both SMAD interactions and nuclear matrix targeting required for the regulation of gene expression [89]. A triple mutation at positions 426–428 of the C-terminal domain of Runx2 is sufficient to disrupt Runx2–SMAD complex formation, prevent nuclear matrix targeting, and inhibit BMP-induced osteogenesis [90].

Unlike BMP signaling, TGF-β signaling acts to inhibit osteogenesis through the repression of pro-osteogenic BMP signals [91]. Although TGF-β1 acts to upregulate expression of the master osteogenic transcription factor Runx2, this does not result in osteogenic differentiation [85]. In fact, TGF-β acts through SMAD3 to inhibit osteogenesis by repressing the transcriptional activity of Runx2 [91]. Furthermore, specific inhibition of a TGF-β type I receptor kinase, or use of a TGF-β neutralizing antibody, is sufficient to enhance ALP and matrix mineralization in MSCs undergoing osteogenesis [92]. TGF-β also acts to inhibit adipogenic differentiation of MSCs. In contrast to its inhibitory activities in osteo- and adipogenesis, TGF-β, along with BMP signaling, induces chondrogenesis *in vivo* and *in vitro*. TGF-β stimulates the expression of chondrogenic genes in human MSCs *in vitro*, and also results in increased Alcian blue staining, indicative of glycosaminoglycan deposition. Interestingly, both its chondro-inductive and adipo-inhibitory roles are enhanced in the presence of lithium chloride (LiCl), a stimulator of Wnt signaling, suggesting TGF-β and Wnt signaling may work cooperatively to induce chondrogenesis and inhibit adipogenesis [93] (and see Chapter 14). Further crosstalk between the BMP and Sonic hedgehog/Indian hedgehog (SHH/IHH) signaling pathways is also necessary during chondrogenic differentiation. SHH signaling upregulates the expression of the NKX3.2 (also known as NK3 homeobox 2) protein, which acts as a transcriptional regulator, and BMP signaling then acts to maintain its expression [94]. NKX3.2 represses expression of factors that inhibit BMP-induced chondrogenesis. Interestingly, it also acts to repress the activity of Runx2 [95]. The combination of repression of anti-chondrogenic signals and the induction of the expression of the chondrogenic master regulator SOX9, which in turn can feedback and maintain expression of Nkx3.2 [96], allows the onset of chondrogenesis. The upregulation of SOX9 by BMP2 signaling also increases expression of the SOX9 downstream target collagen type 2, alpha 1 (Col2a1). BMP4 signaling can also induce SOX9 expression and the formation of ectopic cartilage in mouse mandibular extracts [97].

A common regulatory mechanism for BMP-induced differentiation is observed in both osteogenic and chondrogenic cultures. Despite similar upregulation of SOX9, ectopic cartilage was only observed when BMP4-soaked beads were implanted in proximal but not rostral regions of mouse mandibular extracts. The expression of the homeodomain transcription factor homeobox protein MSX-2 was also observed in mouse mandibular extracts, but at much higher levels in rostral than proximal regions. Furthermore, ectopic expression of Msx2 was sufficient

to inhibit BMP4-induced chondrogenesis, suggesting that Msx2 acts as a chondrogenic inhibitor [97]. Notably, Msx2 was also sufficient to inhibit BMP-induced osteogenic differentiation by competition with DLX5 for response element binding in the promoter of ALP. ALP was not expressed immediately after BMP signaling, when Msx2 levels were high and DLX5 expression was low. ALP induction occurred later, when Msx2 levels had dropped but DLX5 levels had risen, suggesting a threshold level regulation of osteogenic induction [86]. It was also possible that this occurred during chondrogenic induction in mouse mandibular extracts, thus providing a means of positional regulation of differentiation. It is interesting that Msx2 acts to regulate BMP-induced differentiation in both osteogenic and chondrogenic cultures. It has been demonstrated that Msx2 is involved in EMT in differentiating cultures of embryonic stem cells, and that BMP4 induces expression of Msx2 in these cultures [98]. Given that BMP signaling itself can induce Msx2 expression, this could suggest a mechanism of autoregulation in BMP-induced differentiation to osteogenic and chondrogenic lineages.

BMP signaling has clear roles in regulating MSC fate, but will operate alongside other regulatory pathways. Of fundamental importance is the cooperation of the BMP and Wnt signaling pathways in MSC regulation (Figure 9.3).

## 9.6 Regulation of mesenchymal stromal cell differentiation by the Wnt signaling pathway

Much research has focused on Wnt signaling since the discovery of mammalian Wnt1 [99], and such efforts have determined roles for this pathway in the regulation of many cellular activities, including cell proliferation, differentiation, and migration [100]. Nineteen mammalian Wnt genes have now been identified. These cysteine-rich secreted glycoproteins can signal either through the canonical β-catenin-dependent Wnt pathway or through noncanonical Wnt pathways that are independent of β-catenin activity. In the canonical pathway (Figure 9.3) the Wnt ligand binds to a Frizzled (Fz) receptor and a co-receptor, either low-density lipoprotein receptor-related protein (LRP) 5 or LRP6. This activates the intracellular protein Dishevelled (Dvl), which then inhibits a β-catenin destruction complex. This complex, involving axin, adenomatosis polyposis coli, and glycogen synthase kinase (GSK)-3β, causes β-catenin phosphorylation and its subsequent proteasomal degradation. Once stabilized by a canonical Wnt signal, β-catenin translocates to the nucleus and binds with members of the T-cell factor/lymphoid enhancer binding factor (TCF/LEF) transcription factor family to control expression of target genes. β-catenin-independent noncanonical Wnt signaling mechanisms include the Wnt/calcium pathway and the planar cell polarity (PCP) pathway. In the Wnt/calcium pathway the binding of specific Wnt ligands to Fz receptors activates calcium/calmodulin-dependent kinase II (CAMKII) and protein kinase C, whereas the PCP pathway activates Jun-N-terminal kinase to cause cytoskeletal rearrangements and regulate polarity within the tissue. Several antagonists ensure that Wnt signaling is tightly regulated. Secreted frizzled-related protein (SFRP) family members and Wnt inhibitory factor 1 inhibit the interaction between Wnt ligands and Fz receptors, whereas sclerostin and members of the Dickkopf (Dkk) family inhibit the Wnt co-receptors LRP5 and LRP6 (see Figure 9.3).

A vital role for canonical Wnt signaling in bone formation was first demonstrated when it was discovered that mutations in the Wnt co-receptor LRP5 led to skeletal defects. A gain-of-function mutation in LRP5, causing increased Wnt signaling, induced high bone mass in patients [101,102]. The same high bone mass phenotype was also seen in transgenic mice expressing a gain-of-function mutant LRP5 gene [103]. Conversely, a loss-of-function mutation in LRP5 causes osteoporosis-pseudoglioma (OPPG) syndrome in humans, resulting in reduced bone mass [104]. OPPG syndrome is a rare condition characterized by severe osteoporosis and eye abnormalities that lead to vision loss. The osteoporosis is usually recognized in early childhood. It is caused by a shortage of minerals, such as calcium, in bones (decreased bone mineral density), which makes the bones brittle and prone to fracture. Affected individuals often have multiple bone fractures, including in the vertebrae. Multiple fractures can cause collapse of the affected vertebrae, scoliosis (abnormal side-to-side curvature of the spine), short stature, and limb deformities. Most affected individuals have impaired vision at birth or by early infancy and are blind by young adulthood. Vision problems are usually caused by one of several eye conditions, grouped together as pseudoglioma, which affect the retina. Pseudogliomas are so named because, on examination, the conditions resemble a retinal glioma.

Furthermore, LRP5-deficient mice display a low bone mass phenotype reminiscent of OPPG syndrome in humans and caused by decreased proliferation and impaired function of osteoblasts [105]. Mutations in other components of the canonical Wnt signaling pathway, such as LRP6, sclerostin, SFRP4, and Dkk1, have now been similarly associated with abnormal bone mass, highlighting the importance of this pathway in bone formation [106–111].

Genetic mouse studies have revealed that one of the mechanisms through which canonical Wnt signaling increases bone mass is by stimulation of osteoblast differentiation, and evidence suggests that the canonical Wnt pathway is involved in numerous stages of the differentiation process. At early stages, conditional deletion of both LRP5 and 6 receptors, or β-catenin in mesenchymal progenitor cells, arrested differentiation into preosteoblasts, probably due to reduced expression of OSX [112–114]. At later stages, knockout of β-catenin in OSX-expressing osteoblasts inhibited their differentiation into mature osteoblasts [115], and in committed osteoblasts a lack of β-catenin caused deficiencies in maturation and mineralization [106]. Several studies using cell culture models have corroborated these results from mouse models and verified that

canonical Wnt signaling acts to stimulate osteogenic differentiation. In the mesenchymal cell line C3H10T1/2, expression of stabilized β-catenin, or the induction of β-catenin stabilization with either LiCl treatment or small molecule GSK-3β inhibitors, promoted osteoblast differentiation [116–118] (and see Chapter 13). More specifically, stimulation of canonical Wnt signaling by Wnt1, Wnt3a, and Wnt10b has been shown to stimulate osteoblastogenesis in *in vitro* and *in vivo* studies, while inhibition of Wnt signals using Dkk1 inhibits osteogenesis [117,119–121]. One mechanism through which canonical Wnt signaling may stimulate osteoblast differentiation is through upregulation of Runx2 [122]. SFRP1-null mice exhibit increased Wnt signaling levels and a high bone mass phenotype. Increased expression of TCF-1, Runx2, and the Runx2 target gene osteocalcin was also observed in these mutants [122]. Furthermore, a functional TCF regulatory element was identified in the promoter of Runx2, and elevated Runx2 expression was observed following co-expression of TCF1 and canonical Wnt proteins in osteoprogenitor cells, suggesting canonical Wnt signaling can directly activate Runx2 expression to promote osteoblast differentiation [122].

The discovery of the essential role of Wnt signaling in bone formation has provided targets for novel therapies to treat osteoporosis. Potentially, the downregulation of inhibitors of the canonical Wnt pathway may activate new bone formation to combat the low bone mass phenotype of this disease. Current targets for intervention include the Wnt antagonists Sclerostin and Dkk1 [123]. Dramatically increased bone formation, as well as bone mineral density, has been associated with downmodulation of each of these proteins. Accordingly, phase II clinical trials with an anti-Sclerostin antibody and preclinical trials with an anti-DKK1 antibody are underway [124,125].

Further evidence suggests that noncanonical Wnt signaling pathways are also involved in osteogenic differentiation. Downregulation of Wnt5a using neutralizing antibodies when culturing human MSCs inhibited their osteogenic differentiation [126]. Furthermore, $Wnt5a^{+/-}$ mice show reduced bone mass with decreased osteoblastogenesis [127], and deletion of Wnt5a specifically in osteoblast lineage cells also produces a low bone mass phenotype [128]. One study has determined that noncanonical Wnt signaling, stimulated by Wnt5a, can enhance osteoblast differentiation by upregulating LRP5 and 6 [129]. Signaling through another noncanonical Wnt family member, Wnt4, has also been reported to enhance bone regeneration by MSCs *in vivo* [130].

The canonical Wnt pathway is also involved in regulating adipogenic differentiation, with activation of canonical Wnt signaling acting to inhibit adipogenesis [131]. In preadipocytes, Wnt10b was found to inhibit the adipogenic transcription factors CCAAT-enhancer binding protein-α and peroxisome proliferator-activated receptor-γ (PPAR-γ) and arrest adipogenic differentiation, maintaining the cells in an undifferentiated state [132]. The inhibition of PPAR-γ is mediated by upregulation of the chicken ovalbumin upstream promoter transcription factor II by canonical Wnt10b, which in turn recruits the silencing mediator of retinoid and thyroid hormone receptors co-repressor complex [133]. This complex binds to the PPAR-γ gene and inhibits its expression by keeping the chromatin in a hypoacetylated state. Stimulation of Wnt signaling with Wnt1 in preadipocytes also causes inhibition of PPAR-γ expression and blocks adipogenic differentiation [134]. The inhibition of PPAR-γ by canonical Wnt signaling is reciprocal, as increases in PPAR-γ cause inhibition of β-catenin signaling [135]. Conversely, inhibition of Wnt signaling in preadipocyte cells using a dominant-negative TCF4 leads to increased adipocyte differentiation [132]. These and other studies have highlighted an important role for the canonical Wnt signaling pathway in controlling adipogenic differentiation in MSCs. An active canonical Wnt signal maintains the cells in an undifferentiated multipotent state until it is suppressed to allow adipogenesis. Canonical Wnt signaling evidently has an inverse effect on MSC differentiation along osteogenic and adipogenic lineages. Addition of LiCl to stimulate canonical Wnt signaling in MSCs causes adipogenic differentiation to be suppressed and osteogenic differentiation to be enhanced [136]. Similarly, through stimulation of canonical Wnt signaling, Wnt10b inhibits adipogenesis from preadipocytes, but promotes osteogenesis both *in vivo* and *in vitro* [132,137] and other Wnt family members, Wnt6 and Wnt10a, also show similar effects [138]. Furthermore, inhibition of Wnt signaling with DKK1 in precursor cells suppresses osteogenesis and enhances adipogenesis, demonstrating that Wnt antagonists also follow the same inverse pattern [139].

As well as the effects of canonical Wnt signaling on adipogenic differentiation, noncanonical Wnt signaling pathways also appear to be important regulators of adipogenesis. The noncanonical Wnt5a has been shown to suppress adipogenic differentiation of MSCs through suppression of PPAR-γ expression [127]. Interestingly, noncanonical Wnt signals also appear to show the same inverse effect on osteogenic and adipogenic differentiation of MSCs, as Wnt5a induces osteogenesis of MSCs, while also inhibiting adipogenesis [140–142]. Therefore, Wnt signaling mechanisms appear to promote osteogenic and suppress adipogenic MSC differentiation, through both canonical and noncanonical pathways.

Canonical Wnt signaling is also involved in the chondrogenic differentiation of MSCs. Ectopic canonical Wnt signaling in the developing limb bud of mice was found to promote ossification and inhibit chondrocyte formation [114]. Conversely, inhibition of canonical Wnt signaling led to ectopic chondrocyte differentiation and reduced osteogenesis. Overexpression of Wnt8c, 9a or β-catenin caused enhanced chondrocyte hypertrophy in chick upper sternal chondrocytes *in vitro* [143], again demonstrating a role for Wnt signaling in chondrogenesis. These effects are mediated, at least in part, through the LEF activation of Runx2, which may then increase Col10A1 expression [143]. These findings are consistent with *in vitro* studies of human MSCs in which enhanced

chondrogenesis was observed after inhibition of Wnt signaling with DKK-1 and SFRP-1 [144].

## 9.7 Conclusions

MSCs are intriguing cells that have attracted growing global research interest. The potential therapeutic value of these cells in regenerative medicine and immunomodulation applications sits somewhat awkwardly with their enigmatic identity, which has sometimes clouded full understanding of MSC biology. Here, we have focused on some of the signaling stimuli that MSCs receive to regulate their behavior, including effects on differentiation.

Of equal interest is a clearer comprehension of the MSC secretome and how MSCs are able to modify local cell activity by the release of bioactive ligands (see Chapters 15, 18, and 19). Consequently, there is likely to be significant and complex bidirectional signaling interplay within the MSC cellular microenvironment, which may be dependent on MSC subtype or tissue location.

## 10.1 Introduction

Mitochondrial donation is being envisioned as the "magic bullet" for a multitude of genetic disorders with deleterious mitochondrial DNA (mtDNA) mutations and diseases involving mitochondrial dysfunction. A number of methods have been described in the literature for detecting intercellular mitochondrial transfer. These methods include microinjection of mitochondria into recipient cells [1–4], incubation of recipient cells with mitocytoplasts (prepared from cells with microinjected mitochondria) or intact purified mitochondria [5,6], microvesicle-mediated transfer [7], and direct transfer through the formation of tunneling nanotubes (TNTs) between donor and recipient cells [8–11] and see Chapter 21. Of these, mitochondrial transfer through TNTs has been observed in many organisms and is considered to be evolutionarily conserved [12,13]. While it has been shown that a variety of cell types are capable of communicating through TNTs, mesenchymal stromal cells (MSCs) have caught the attention of the scientific and medical communities owing to their unique properties, such as their capacity to home to a site of inflammation (see Chapters 22–24), their contribution to tissue repair and regeneration (see Chapters 45–62), and their modulation of immune response (see Chapters 33 and 34). MSCs have some advantages over other cell choices, like embryonic stem cells and induced pluripotent stem cells (iPSCs): they are not the subject of ethical challenges, they have minimal or no risk of inducing tumor formation, and they are poorly immunogenic. Thus, MSCs from donors that are unrelated to and major histocompatibility complex (MHC)-unmatched with the recipient can be used without any need for immune suppression of the recipient. Although the clinical application of MSCs extends beyond being mitochondrial donors, mitochondrial transfer appears to be one of the critical mechanisms by which MSCs mediate their therapeutic effect. In this chapter we will explore this characteristic of MSCs, emphasizing the various regulatory mechanisms guiding mitochondrial transport. We will trace the evolution and shaping of the concept of intercellular mitochondrial transport, summarize the studies in which mitochondrial transfer from MSCs to recipient cells has been observed, discuss the regulatory mechanisms of mitochondrial transport, and postulate what lies ahead in the use of MSCs as therapeutic mitochondrial donors. We will demonstrate how MSCs donate mitochondria and rescue cellular bioenergetics. We will show that mitochondrial Rho GTPase 1 (Miro 1) is a critical regulator of MSC mitochondrial donor function, and we will show that enhancing the mitochondrial donor capacity of MSCs by overexpressing Miro-1 increases their therapeutic efficacy.

## 10.2 Intercellular organelle transport

### 10.2.1 Intercellular communication

Cellular synchronization by intercellular communication is critical to a number of physiological and pathological processes, such as development, cell motility, embryogenesis, and tumorigenesis [14–18]. Information transfer *in vivo* can be achieved either by soluble mediators, microvesicles, or physical contact. Cell-to-cell communication can be divided into long-range, short-range, and close-range communications. The secretions of the body's endocrine system are the best examples of long-range intercellular communication. One example is the hypothalamus–pituitary–gonadal axis, whereby hormones secreted in the brain, such as follicle-stimulating hormone, induce the secretion of sex (or gonadal) steroids such as testosterone and estradiol, from the testicles and ovaries respectively, and which in turn interact with androgen or estrogen receptors respectively. Extracellular vesicles (e.g., microvesicles and exosomes) also participate in long-range communication through transfer of macromolecules (e.g., mRNA, micro RNAs, and proteins) and organelles such as mitochondria [19]. However, only microvesicles are capable of organelle transport.

Short-range communications are also mediated by soluble chemical mediators that diffuse into the extracellular environment, but their effect is limited to the cell releasing them (autocrine signaling) and/or to neighboring cells located close by. This is termed paracrine signaling, examples of which include fibroblast growth factor and transforming growth factor-β.

Close-range communication is mediated through formation of physical connections between neighboring cells (e.g., electrical synapses in the brain) [20]. The physical connections can be either noncytoplasmic or cytoplasmic. The noncytoplasmic physical contacts involve membranous extensions without cytoplasmic continuity; for example, cytonemes and filopodial extensions. These connections are firmly attached to the substratum and support the transport of their cargo along the outer side of the membranous extensions. Cytoplasmic bridges ensure intercellular cytoplasmic continuity and allow the exchange of ions and small molecules. Gap junctions represent an example of this. TNTs are a special form of these cytoplasmic bridges that were initially reported by Rustom *et al.* [11]. These are significantly different from the noncytoplasmic membrane extensions in both structural and functional aspects, as discussed later. TNTs enable cells to exchange organelles, and this property has created widespread interest in terms of the basic understanding of intercellular communication and its clinical translation. While various subcellular organelles can be exchanged through these structures, mitochondrial transport has gained particular focus in recent years. Knowledge of mitochondrial biology will quickly substantiate its application to cell-based therapeutic agents.

### 10.2.2 Mitochondrial biology

Mitochondria are double membrane cytoplasmic organelles found in all nucleated eukaryotic cells. These are the sites for the majority of the generation of cellular energy, producing >90% of the cellular energy through oxidative phosphorylation [21]. Besides energy production, mitochondria are also known to play a pivotal role in various other cellular processes, including inter-organelle communication, calcium signaling, amino acid and fat metabolism, cell proliferation, and apoptotic signaling [22]. Mammalian mitochondria are considered remnants of an ancient proteobacterium, obtained through endosymbiosis about 1.5 billion years ago [23]. These organelles have a compact (16 569 base pairs (bp)) circular DNA (mtDNA), which is thought to have transferred most of its genetic material to the nucleus during the course of evolution. mtDNA encodes only 37 genes, of which 13 are proteins coding for oxidative phosphorylation subunits, 22 are for transfer (t)RNAs, and 2 are ribosomal (r)RNAs associated with mitochondrial protein translation [24]. Another interesting characteristic of these organelles is cellular polyploidy [25]. The number of mitochondria in each somatic cell potentially varies between 200 and 1000 and is dependent on the energy requirements of the cell. For instance, skeletal muscle cells and neuronal cells contain the highest number of mitochondria. Each mitochondrion contains ~10–35 copies of mtDNA and carries a 10-fold increased risk of mutations in comparison with nuclear DNA due to three reasons: (a) the high oxidative environment of mitochondria due to free radical generation; (b) lack of DNA binding histones; and (c) ineffective repair mechanisms associated with mitochondria. The pathogenic mutations are not expressed until the mutation is accumulated in 60–90% of the total mtDNA of a somatic cell. This is called the threshold effect. Furthermore, single mitochondrion units are highly dynamic and constantly exchange their genetic material through mitochondrial fusion and fission, diluting the mutant mtDNA. This phenomenon is known as mitochondrial complementation [26,27]. Apart from mtDNA, mitochondrial proteins and lipids are also vulnerable to mitochondrial damage, which in turn may initiate a feed-forward process that results in additional damage and thus mitochondrial dysfunction.

Mitochondrial dysfunction has long been implicated in a wide array of inherited and acquired conditions, together known as mitochondrial cytopathies [21,22,28]. The concept that mitochondrial complementation can be imposed on the cells with mitochondrial damage by transferring healthy mitochondria is the basis for mitochondrial donation-based therapeutics.

### 10.2.3 Intercellular mitochondrial transport/ mitochondrial donation

Many different techniques for successful mitochondrial delivery, both *in vitro* and *in vivo*, to cells have been developed. The techniques include spontaneous engulfment of extracellular mitochondria by cells, cytoplast fusion (the cytoplast is the inner part of a cell without the cell wall, nucleus, or plasma membrane), microinjection of isolated mitochondria into specific cells, and transport of mitochondria either through the *de novo* formation

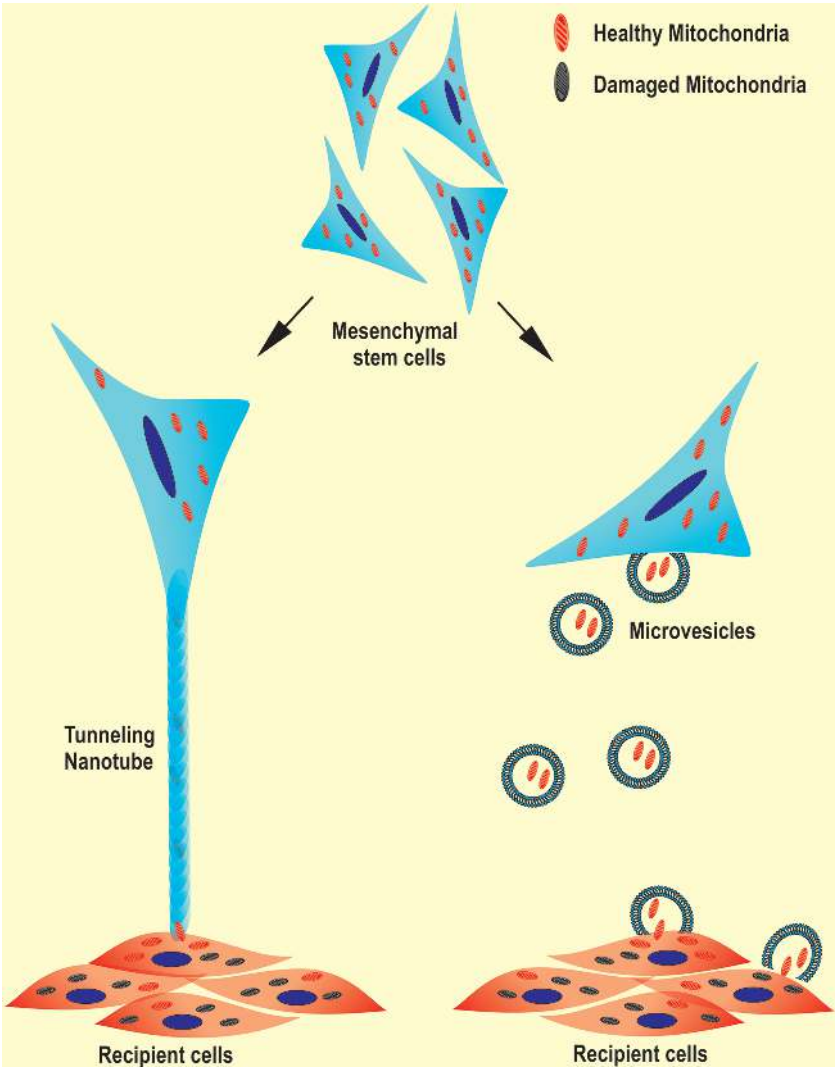

**Figure 10.1** Modes of intercellular transport of mitochondria from MSCs. Schematic diagram showing "Tunneling nanotube (TNT)" -mediated, and "Microvesicle"-packaged mitochondrial transfer.

of intercellular nanotubes (ICNs) or TNTs or through microvesicle-mediated delivery (Figure 10.1).

The mechanistic aspects and applicability of some of the important techniques are discussed in the following subsections.

#### 10.2.3.1 Microinjection of isolated mitochondria

This technique was pioneered by Tatum's group in *Neurospora crassa*, a species of fungus [1], and was later used by many other groups to generate cell lines with a host nucleus and foreign mitochondria known as transmitochondrial cell lines [2,4,26,29,30]. These cell lines have provided significant insights into mitochondrial genetics, mitochondrial complementation, and the role of nucleus–mitochondria compatibility in the survival of foreign mitochondria in recipient cells. Based on these studies, Pinkert *et al.* microinjected healthy mitochondria into fertilized murine oocytes and demonstrated the maintenance of the xenogenic (from a different species) mitochondria until the blastocyst stage of embryonic development (about 200–300 cells in humans) [3]. The results obtained from this study can be used along with assisted reproduction techniques to correct for maternal mtDNA mutations that lead to congenital mitochondrial diseases.

#### 10.2.3.2 Macropinocytosis of mitochondria

Clark and Shay demonstrated the spontaneous incorporation of isolated mitochondria stained with rhodamine$^{123}$ dye into recipient cells using fluorescence microscopy [2]. The spontaneous engulfment of isolated mitochondria was demonstrated in other studies [31–33], and Kitani and co-workers proposed that macropinocytosis is the underlying mechanism facilitating spontaneous mitochondrial uptake [5,6]. This mitochondrial transfer method has been called into question based on the negative results obtained in other studies [23,34]. Recently, cell-penetrating peptide-tagged mitochondria were engineered *in vitro* for efficient

cell penetration of mitochondria [34]. The therapeutic potential of this method was assessed in a rabbit model of myocardial infarction. The delivery of isolated autologous mitochondria through microinjection into the heart tissue was able to improve tissue adenosine triphosphate content and post-infarct cardiac function [33].

#### 10.2.3.3 Microvesicle-mediated mitochondrial delivery

Microvesicles are relatively large vesicles with a diameter of 100 nm to 1 μm and are shed from the plasma membrane of actively growing cells in a calcium- and calpain-dependent manner [19,35]. Calpain is a protein belonging to the family of calcium-dependent, nonlysosomal cysteine proteases (proteolytic enzymes) expressed ubiquitously in mammals and many other organisms. Microvesicles are capable of transferring macromolecules (mRNA, microRNA, and plasma membrane receptors). Microvesicles have recently been shown to be involved in the transfer of healthy mitochondria from MSCs to lung epithelial cells in a mouse model of acute lung injury *in vivo* [7]. This will be discussed further in subsequent sections.

#### 10.2.3.4 Tunneling nanotubes: highways for mitochondrial transport

TNTs are F-actin-based intercellular membrane channels facilitating the exchange of ions, plasma membrane components, vesicles, and organelles between remotely connected cells [9,36]. TNTs are also known to transport virus particles and pathogenic prion proteins [36]. These structures were first described by Rustom *et al.* in a rat phaeochromocytoma cell line (PC12) *in vitro* [11]. Following this pioneering observation, a number of reports demonstrated the formation of TNTs in a variety of cell types *in vitro*. TNTs connecting dendritic cells in the cornea of mice produced the first evidence of TNT formation *in vivo*, thus excluding the possibility of these structures being an *in vitro* artefact [37]. TNTs are involved in the transport of various subcellular organelles (mitochondria, lysosomes, Golgi complex, and endoplasmic reticulum), plasma membrane components, calcium ions, and electrical signals [9,36]. These functions performed by TNTs were found to be important for a wide range of physiological processes, including wound healing, cell migration, and neuronal communication [38]. Of all these functions, mitochondrial transport has gained a lot of attention in recent years owing to its application in restoring the bioenergetics of cells with mitochondrial damage. Subsequent sections explore the regulatory mechanisms in greater detail in the context of MSCs.

## 10.3 Mesenchymal stromal cells as potential mitochondrial donors

An MSC is a type of adult (or postnatal) progenitor cell found in the connective tissue of multiple organs. The therapeutic applications of these cells have evolved in line with knowledge of MSC biology [39]. Initially, these cells were evaluated for their tissue regeneration capabilities. The discovery of their role in cell proliferation, neovascularization, and immunomodulation further broadened the horizons of their therapeutic application for the treatment of inflammatory and immune-mediated diseases [40,41]. Prockop's group showed for the first time that mitochondria or mtDNA can move between cells, and thereby can rescue aerobic respiration in mammalian cells with nonfunctional mitochondria [23]. This discovery extended the potential clinical application of MSCs to a wide array of diseases associated with mitochondrial dysfunction [7,8,10,42–48].

Spees *et al.* co-cultured MSCs with mutant human lung alveolar epithelial cells (A549 cells) that are specifically depleted of mitochondrial genes and require a permissive medium additionally supplemented with pyruvate and uridine for growth. However, when co-cultured with human MSCs or fibroblasts, A549 cells showed rescue of proliferation and rate of growth even in restricted media. An analysis of the protein content in the revived population of A549 cells, derived from co-cultures of human MSCs and A549 ρ0 cells, revealed the presence of mitochondrial complex proteins such as COX-2 in the progeny A549 cells, which were absent in parental mutant A549 ρ0 cells. COX-2 is an enzyme responsible for inflammation and pain. Genetic screening of both the mitochondrial and nuclear DNA from the revived cells confirmed that the mitochondria in the revived cells were derived from either of the donor cells (human MSCs or fibroblasts). Cell fusion was excluded. The mitochondria that were received were metabolically active and capable of self-renewal. Notably, in the same study, an attempt to revive the A549 ρ0 cells with isolated mitochondria had failed, suggesting that specialized mechanisms were involved in mitochondrial donation by MSCs [23].

Further detailed evidence confirming the mitochondrial donor capacity of MSCs came in 2008 from the Zorov Laboratory exploring mitochondrial donation from MSCs to cardiomyocytes. In their co-cultures the transfer of mitochondria was via cytoplasmic bridge-like structures between MSCs and cardiomyocytes, and the movement of the mitochondria was exclusively unidirectional from MSCs to the cardiomyocytes [49]. An earlier study by Dimmeler's group had already shown that characteristic TNTs to facilitate transfer of mitochondria formed between co-cultured adult human endothelial progenitor cells and neonatal rat cardiomyocytes [50]. Based on these observations, Plotnikov and colleagues explored the possibility of transient cell-to-cell exchange of cytoplasm and organelles during co-culture of bone-marrow-derived MSCs and cultivated rat embryonic cardiac myocytes. In their study they observed the formation of TNTs in monocultures of MSCs and cardiomyocytes, which increased in number when the MSCs and cardiomyocytes were co-cultured. The study confirmed that intercellular TNT structures represented a mechanism for cytoplasmic continuity and bidirectional cytoplasmic flow. However, the mitochondrial transfer was exclusively unidirectional from the MSCs to the cardiomyocytes and could not thus be explained

by simple cytoplasm exchange. They reported vesicles with mitochondrial cristae structures traversing the TNTs, thereby concluding that "cytoskeleton filaments found within nanotubes may be an important element of directed vesicle-transporting machinery" [49]. Another important observation was the induced differentiation of MSCs after cytoplasmic transfer, leading to speculation that cytoplasmic exchange via TNTs could guide differentiation of MSCs into cardiomyocytes that would replace and repair injured myocardium. Similar findings were reestablished for co-cultivated human mesenchymal multipotent stromal cells and rat renal tubular cells [10]. Acquistapace *et al.* extended this concept further by finding transient partial cell fusion and mitochondrial transfer to differentiated mouse cardiomyocytes from human multipotent adipose-derived stromal (hMADS) cells [42]. A significant observation was that the terminally differentiated cardiomyocytes underwent somatic reprogramming to form cardiac progenitor-like cells when co-cultured with hMADS, rather than any evidence of hMADS differentiation. Thus, while mitochondrial transfer has been a consistent finding in multiple studies, its relative importance compared with cellular reprograming effects of cytoplasmic exchange was not clear.

Further confirmation of mitochondrial transfer by MSCs came from multiple laboratories around the world. Cho *et al.* confirmed that mtDNA-depleted ρ0-cells derived from human osteogenic sarcoma 143B cells could take in mitochondria from MSCs, with formation of cell–cell contacts and without cell fusion [44]. Dumler's group found that co-cultured MSCs and blood-vessel-derived vascular smooth muscle cells exchanged mitochondria bidirectionally, leading to MSC proliferation. This observation suggested that dual donor and recipient roles were also possible [51].

Together, these studies provided strong evidence for MSC-mediated mitochondrial transfer that appeared suitable for therapeutic purposes. Such therapeutic effects were further demonstrated in *in vivo* lung injury models by Bhattacharya's laboratory and our group [7,8].

Islam and colleagues provided the first *in vivo* evidence that bone marrow-derived MSCs formed connexin 43 (Cx43)-containing gap junctional channels with alveolar epithelium, releasing mitochondria-containing microvesicles that the epithelial cells engulfed [7]. In mice with septic peritonitis-induced acute lung injury, this attenuated alveolar injury and had marked survival benefits. In current work, we found that a Rho GTPase, Miro 1, which was known to regulate intracellular mitochondrial transport in neurons, also regulated intercellular mitochondrial transport from MSCs to lung epithelial cells (Figure 10.2).

Such mitochondrial transport from MSCs to airway epithelium was critical in attenuation of lung injury by rotenone or allergic inflammation. Rotenone is an odorless, colorless, crystalline ketonic chemical compound used as a broad-spectrum insecticide, piscicide, and pesticide.

An important role for directed TNT-mediated mitochondrial transport was suggested in our model since it was highly dependent on tumor necrosis factor, alpha-induced protein 2/M-Sec1, which regulates TNT formation. Together, these studies provided a mechanistic basis for MSC therapy in diseases characterized by mitochondrial dysfunction and inflammation. These include neurodegenerative diseases (amyotrophic lateral sclerosis, Alzheimer's disease) [52–54], respiratory diseases (chronic obstructive pulmonary disease, idiopathic pulmonary fibrosis) [45,46,55–58], cardiovascular diseases (myocardial ischemia, myocardial infarction) [42,48,59,60], immune diseases (graft-versus-host disease, Crohn's disease) [40,61,62], and diabetes mellitus [63,64]. A number of phase I, II, and III clinical trials are in progress for the evaluation of the safety and therapeutic efficacy of MSCs in some of the diseases mentioned [65–67]. Important factors that would likely determine success include retention of MSCs at the site of injury, the dose of MSCs administered, and mitochondrial donor efficiency. Several strategies are being developed to improve the therapeutic efficiency of MSCs. In subsequent sections we explore the regulation of mitochondrial donation in more detail and describe strategies proposed to improve the mitochondrial donation capacity of MSCs.

### 10.3.1 Mechanism of intercellular mitochondrial transport regulation

Mitochondrial transport is now a well-studied characteristic of MSCs. However, mechanistic insight into its regulation is still in a nascent state. The various evidence and theories regarding the modes of transport (Figure 10.1) and the mechanisms, as understood so far, have been discussed. Passive diffusion is unlikely based on current understanding of membrane transport, and is not discussed further in view of lack of any strong evidence in support.

#### 10.3.1.1 Microvesicular export of mitochondria

Microvesicle-mediated transport as one of the underlying mechanisms for horizantal transfer of mitochondria between donor and target cells was initially suggested by Prockop's group [23]. However, this hypothesis did not initially receive much attention owing to lack of definitive evidence. Later, Islam *et al.* provided the first experimental evidence for microvesicle-mediated mitochondrial transport as one of the mechanisms for MSC-mediated rescue [7]. In a mouse model of acute lung injury they showed that calcium-dependent microvesicle shedding was strongly associated with the restoration of lung mitochondrial bioenergetics through mitochondrial transfer from bone-marrow-derived stromal cells (BMSCs) to alveolar epithelium. They also demonstrated the formation of closed-ended TNTs containing Cx43-mediated gap junctions *in vivo*. These TNTs were found to mediate the calcium communication essential for microvesicle shedding. Loss of mitochondrial transfer, either through expression of mutant Cx43 in BMSCs or inhibition of endocytosis of microvesicles through inhibition of dynamin GTPase, confirmed the role of microvesicles in the horizontal transfer of mitochondria *in vivo*. However, *in vitro* co-culture studies demonstrated spontaneous formation of open-ended TNTs supporting the transfer of mitochondria, and thus

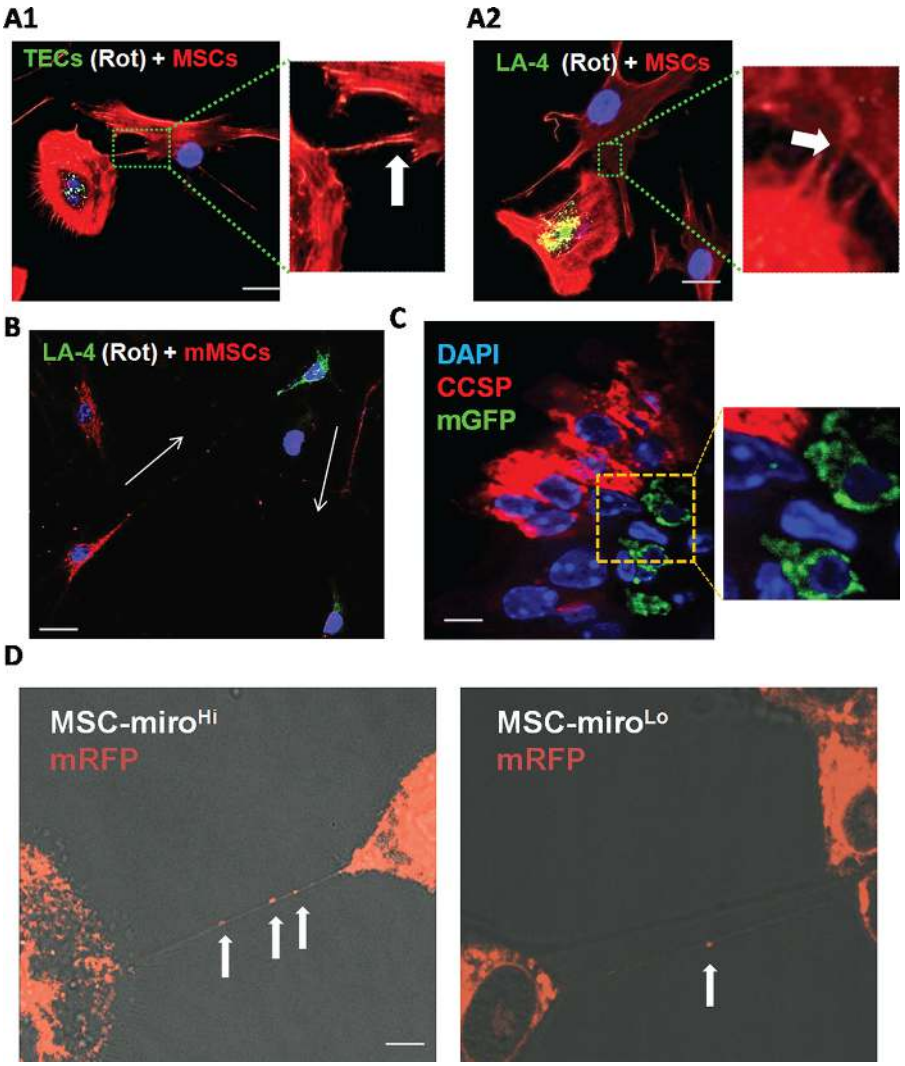

**Figure 10.2** TNT-mediated mitochondrial transfer from MSCs is regulated by Miro-1. (See color plate section.) **(A1 and A2)** Representative images showing TNTs between rotenone-treated epithelial cells (LA-4 or TECs) and MSCs. LA-4 cells or TECs were labeled with mGFP, while MSCs were unlabeled and co-cultured for 24 h, followed by fixation and staining with phalloidin to label TNTs. Insets show the zoomed-in portion of the images, while arrows indicate the TNT zoomed-in portions of the images. Scale bar: 10 μm **(B)** The image shows mitochondrial transfer from MSCs to stressed epithelial cells (LA-4 cells treated with rotenone). Prior to co-culture, MSCs were labeled with mitoRFP and the LA-4 were labeled with mitoGFP. Both cell populations were labeled with DAPI (blue), and the arrows indicate the unidirectional intercellular transfer of mitochondria from MSCs to LA-4 cells. Scale bar: 25 μm. **(C)** A representative image showing an allergically inflamed mouse lung tissue section labeled with the airway epithelial-cell-specific marker CCSP (red) and DAPI (blue) to label nuclei. This image was taken 24 h after mitoGFP-labeled MSCs were administered. Significant traces of green fluorescence can be seen in the lung. The enlarged section shows the mitoGFP-positive signals in lung epithelium. Scale bar: 30 μm. **(D)** The figure shows that mitochondrial movement is regulated by Miro-1.The left panel shows MSCs with overexpression of Miro-1 (cDNA treated), resulting in higher intercellular mitochondrial movement, in comparison with the right panel showing MSCs in which Miro-1 has been knocked down by shRNA. Arrows indicate the mitoRFP-labeled mitochondrial content moving inside the TNT as seen with phase-contrast microscopy. Further details can be found in [8]. Scale bar: 10 μm.

plausibly emphasized the co-occurrence of these two mechanisms. The following section focuses on the mechanisms underlying TNT-mediated mitochondrial transfer.

#### 10.3.1.2 Trafficking across intercellular nanotubular highways

In pioneering studies in nerve cells it was observed that mitochondria traversed the nerve cell body to energy-depleted sites all the way from the cyton (the cell body or soma of the neuron) to dendritic axons [68]. A set of proteins had been identified that constituted the intracellular mitochondrial transport machinery. This specific set of proteins were the group of mitochondrial Rho GTPases 1 and 2 (rhot1/Miro-1 and rhot2/Miro-2), which are anchored on to the outer membrane of mitochondria and are attached on to the kinesins or motor proteins via an adaptor protein termed Milton [69]. This helped the mitochondria to walk on the actin cytoskeletal flooring of cytoplasm. We hypothesized that the components

of intracellular mitochondrial transport could possibly also play a role in the intercellular mitochondrial transport across TNTs. MSCs were found to highly express the known critical components of intracellular mitochondrial transport machinery (Miro-1, Miro-2, Trak1, Trak2, KHC and Myo19). Knockdown of protein expression of Miro-1 with targeted shRNA in MSCs inhibited mitochondrial transfer from MSCs.

In naive MSCs, overexpression of approximately threefold upregulation in Miro-1 protein levels facilitated a significantly high amount of mitochondrial transport as well as efficient rescue and reversal of disease symptoms. The results were found to be similar when Miro-1 was overexpressed in human bronchial smooth muscle cells or fibroblasts used as mitochondrial donors *in vitro*. Taken together, these results confirmed that the enhancement effect on mitochondrial transfer was specific to modulation of Miro-1 expression.

The exact function of Miro-1 in MSC-mediated mitochondrial transfer is not known but is expected to be similar to its role in neurons. Kittler's group have shown that Miro-1 is involved in the calcium-dependent regulation of mitochondrial movement in neuronal cells [68]. Miro-1 protein has a transmembrane domain anchored into the mitochondrial outer membrane along with a couple of calcium sensor EF-hand domains flanked by two GTPase domains protruding into the cytoplasm. (The EF hand is a helix–loop–helix structural domain or motif found in a large family of calcium-binding proteins. The EF-hand motif contains a helix–loop–helix topology, much like the spread thumb and forefinger of the human hand, in which $Ca^{2+}$ ions are coordinated by ligands within the loop.)

The cytoplasmic domains of Miro-1 link the mitochondria to KIF5, a kinesin motor protein, which allows the movement of mitochondria on the microtubular network. Macaskill *et al.* demonstrated that the binding of Miro-1 to KIF5 is calcium-sensitive and is blocked at the intracellular sites with high calcium concentrations, leading to mitochondria mobility arrest [68]. This claim was substantiated by studies on EF-hand mutants of Miro-1 protein to prevent calcium binding, in which it was observed that these mutations had no effect on mitochondrial motility but calcium-dependent motility arrest was lost. So far they are the only known (mitochondrial) surface receptors that attach mitochondria to cytoskeletal structures via adaptors and motor proteins for their motility [70].

Recent studies probing the physiological significance of Miro-1 showed that the loss of Miro-1 which caused defects in mitochondrial motility was sufficient to potentiate neurological abnormalities in murine models [70]. Miro-1 has also been implicated as having a crucial role in the maintenance of mitochondrial turnover with PTEN-induced putative kinase 1, a mitochondrial serine/threonine-protein kinase, thought to protect cells from stress-induced mitochondrial dysfunction, as well as in PARKIN-mediated Miro degradation leading to arrested mitochondrial movement and capture autophagosomy (also known in this context as mitophagy – the selective degradation of mitochondria by autophagy; it often occurs in defective mitochondria following damage or stress) [71]. PARKIN is a protein that in humans is encoded by the *PARK2* gene. Its precise function is unknown, but the protein is a component of a multiprotein E3 ubiquitin ligase complex, which in turn is part of the ubiquitin-proteasome system that mediates the targeting of proteins for degradation.

We thus expect that the primary role of Miro-1 in MSCs is to regulate mitochondrial motility, and this can be harnessed for increased mitochondrial transfer. Effects of Miro-1 modulation on mitochondrial bioenergetics and turnover need to be better understood.

## 10.4 Strategies to improve mitochondrial delivery to target cells

Transplanted MSCs, after successful homing to the site of injury, have been demonstrated to exert their therapeutic effects in a number of ways. These include, first, promotion of tissue repair and regeneration either by engraftment in the recipient's tissue or by reprogramming the recipient's cells; second, by organelle donation through the formation of ICNs and/or microvesicle-mediated delivery of organelles and macromolecules; and, third, by paracrine signaling through the secretion of immunomodulatory cytokines and growth factors. Some lines of evidence suggest the interconnected nature of these mechanisms. As discussed previously, mitochondrial transfer through TNTs is also associated with cytoplasm exchange and reprogramming of donor or target cells. Similarly, transfer of mitochondria from vascular endothelial cells into MSCs has been shown to promote proliferation of the MSCs. Taken together, these reports suggest that the role of MSC-mediated mitochondrial transport has potential beyond the restoration of cellular bioenergetics. Therefore, it is logical to assume that potentiating mitochondrial donation capacity would enhance the therapeutic efficiency of MSCs. This is consistent with what we have seen in our study, where we enhanced mitochondrial transfer by overexpressing Miro-1 and found increased therapeutic efficacy. Miro-1-overexpressing-MSCs were more effective in restoring mitochondrial dysfunction and reversing pathological features (eosinophilic infiltration, airway hyperresponsiveness, mucin secretion, and subepithelial collagen deposition) in three independent mice models with experimentally induced allergic airway inflammation [8]. However, the enhanced therapeutic potential of Miro-1-overexpressed-MSCs may not warrant universal application since Miro-1-mediated mitochondrial mobility requires microtubules for regulation of the mitochondrial transport and is sensitive to high calcium in the local environment. To date, different types of TNTs with varied molecular compositions have been identified, and some of them did not contain microtubules. Further, Islam *et al.* showed that the movement of calcium through TNTs from damaged alveolar epithelial cells to the MSCs was a necessary event for

mitochondrial transfer [7]. Very high levels of calcium may not allow Miro-dependent intercellular mitochondrial transport through TNTs. However, microvesicle-mediated mitochondrial transport could still be active. Whether mitochondrial mobility stimulates or impedes microvesicle capture and release is not known. Strategies to stimulate TNT formation without impeding the function of Miro-1 may be suitable for increasing MSC efficacy, as may strategies to stimulate microvesicle-based transfer. These questions clearly require further exploration.

The relationship between MSC type and mitochondrial transfer also merits speculation. While little is known about the mitochondrial donation properties of various types of MSCs, there are clear differences in therapeutic efficacy. Accumulating data suggest that MSCs derived *ex vivo* from iPSCs (iPSC-MSCs) may have enhanced therapeutic potential compared with MSCs isolated from bone marrow or adipose tissue [61,72]. Taking leads from previous studies demonstrating the superior effect of iPSC-MSCs in attenuating limb ischemia and alleviating allergic airway inflammation, Li *et al.* have recently studied the role of iPSC-MSCs on cigarette-smoke-induced lung injury both *in vitro* and *in vivo* [58]. The results from their study confirmed the superior efficacy of iPSC-MSCs over normally derived MSCs in alleviating cigarette-smoke-induced lung damage. They attributed the observed enhanced potential to a high retention rate of iPSC-MSCs and high mitochondrial transport via TNTs. However, the role of paracrine effects and microvesicle-mediated transfer of macromolecules also require further investigation.

## 10.5 The road ahead

The use of MSCs as therapeutic agents for targeted mitochondrial delivery appears promising. This has particular promise in antiaging and regenerative medicine, as well as in the treatment of diseases characterized by mitochondrial dysfunction. While this is being explored in clinical trials, it is desirable that short- and intermediate-term metabolic consequences of MSC therapy be carefully studied. This is necessary to further refine the effectiveness of MSC therapy. Another area of interest is likely to be cancer, where delivery of mitochondria from MSCs may lead to cancer cell sensitization to toxins. We foresee that the incremental knowledge of MSC biology, supported by the rapidly developing tools to engineer MSCs, will lead to more MSC-based therapeutics emerging as the face of future medicine.

## 11.1 Introduction

Adipose tissue or fat is a loose connective tissue in the body composed mostly of adipocytes (fat cells). There are at least three types of adipose tissue: white adipose tissue stores energy and brown adipose tissue generates body heat. Brown adipocytes are located in dedicated depots and express constitutively high levels of thermogenic genes, whereas inducible "brown-like" adipocytes, also known as beige cells, develop in white fat in response to various activators. The activities of brown and beige fat cells reduce metabolic disease (including obesity) in mice and correlate with leanness in humans. Many genes and pathways that regulate brown and beige adipocyte biology have now been identified.

In addition to adipocytes, adipose tissue contains the stromal vascular fraction of cells, which comprises preadipocytes, fibroblasts, vascular endothelial cells, and a variety of immune cells, such as adipose tissue macrophages. Adipose tissue is derived from preadipocytes. Its main role is to store energy in the form of lipids, although it also cushions and insulates the body. Fat cells have an important physiological role in maintaining triglyceride and free fatty acid levels, as well as determining insulin resistance. Abdominal fat has a different metabolic profile, being more prone to induce insulin resistance. Adipose tissue has been recognized as a major endocrine organ, since it produces hormones and other proteins, including leptin, estrogen, estradiol, resistin, adiponectin, plasminogen activator inhibitor-1, tumor necrosis factor-α (TNF-α), interleukin-6, and monocyte chemoattractant protein 1. Adipose tissues also secrete types of cytokines called adipokines (adipocytokines), which play a role in obesity-associated complications. Perivascular adipose tissue releases adipokines, such as adiponectin, that affect the contractile function of the vessels that they surround. Moreover, adipose tissue can affect other organ systems of the body and may lead to disease. White adipose tissue is emerging as an active participant in regulating physiologic and pathologic processes, including immunity and inflammation. Macrophages are components of adipose tissue and actively participate in its activities. Furthermore, crosstalk between lymphocytes and adipocytes can lead to immune regulation.

Obesity is a condition in which a person has an abnormally high and unhealthy proportion of body fat. It is a metabolic syndrome that has become a major public health concern and which presents a formidable therapeutic challenge as well as being a major socioeconomic problem [1]. To measure obesity a scale known as the body mass index (BMI) is used. BMI is

calculated by dividing a person's weight in kilograms by their height in meters squared. BMI provides a more accurate measure of obesity or being overweight than weight alone. Results from the 2007–2008 US National Health and Nutrition Examination Survey showed that 68% of adults aged 20 years and older in the USA were overweight or obese.

It is widely accepted that obesity is associated with an increased incidence of type II diabetes mellitus, hyperlipidemia, fatty infiltration of the liver (steatosis), cardiovascular disease, and osteoarthritis as well as a number of malignancies, including cancer of the esophagus, breast (after the menopause), colon and rectum, thyroid, endometrium, kidney, and gall bladder [1].

Within adipose tissue, adipocytes are derived from adipose-derived stem/stromal cells (ASCs). ASCs have a propensity for adipogenic differentiation and play a key role in the generation and metabolism of adipose tissue [2,3]. Therefore, understanding the molecular events involved in adipogenesis may contribute to the development of preventive measures and treatments for obesity-related metabolic diseases.

Since ASCs were successfully isolated from adipose tissue by Zuk *et al.* in 2001 [3] much research has been done on their multipotency and on adipogenic differentiation mechanisms. ASCs are easy to harvest with a minor degree of invasiveness, proliferate readily, and their default differentiation pathway is adipogenesis [4–7]. In addition, ASCs can be easily genetically modified with high transfection efficiency and stable gene expression. Thus, ASCs are useful cells for the study of adipogenic differentiation mechanisms [8,9], and it is pertinent to review current knowledge of the regulatory mechanisms in adipogenesis using ASCs.

## 11.2 Adipose-derived stem/stromal cells

### 11.2.1 Preparation and molecular characterization of adipose-derived stem/stromal cells

Adipose tissue consists of many kinds of cells, including mesenchymal stromal cells, preadipocytes, mature adipocytes, fibroblasts, vascular endothelial cells, macrophages, and lymphocytes [10–12]. The stromal-vascular cell fraction of adipose tissue has become the focus of research because it is a rich source of pluripotent cells: ASCs [3,13]. Other names for these cells include adipose-derived adult stromal cells, adipose-derived adult stem cells, adipose mesenchymal stem cells, adipose stromal cells (also abbreviated ASCs), preadipocytes, and ASCs, thus creating some confusion. To minimize confusion, the term adipose-derived stromal/stem cells (ASCs) was recommended by the International Fat Applied Technology Society (IFATS) to describe the plastic-adherent, *ex vivo* expanded and serially passaged multipotent cell population derived from adipose tissue [14–16]; therefore, ASCs will be used throughout this chapter to identify this population of cells.

Adipose tissue can be obtained by surgical resection, tumescent lipoaspiration, or ultrasound-assisted lipoaspiration. The word "tumescent" means swollen and firm. This technique involves subcutaneous infiltration of large volumes of crystalloid fluid that contains low concentrations of epinephrine (adrenaline) and the local anesthetic lignocaine followed by suction-assisted aspiration of fat using small aspiration cannulae called microcannulae. The term tumescent liposuction specifically excludes the use of any additional anesthesia, either intravenous or gaseous, and by definition is a method for performing liposuction surgery with the patient using local anesthesia only. The principal protocols can be obtained from the literature [17–19], and the ASC harvest procedures are shown in Figure 11.1.

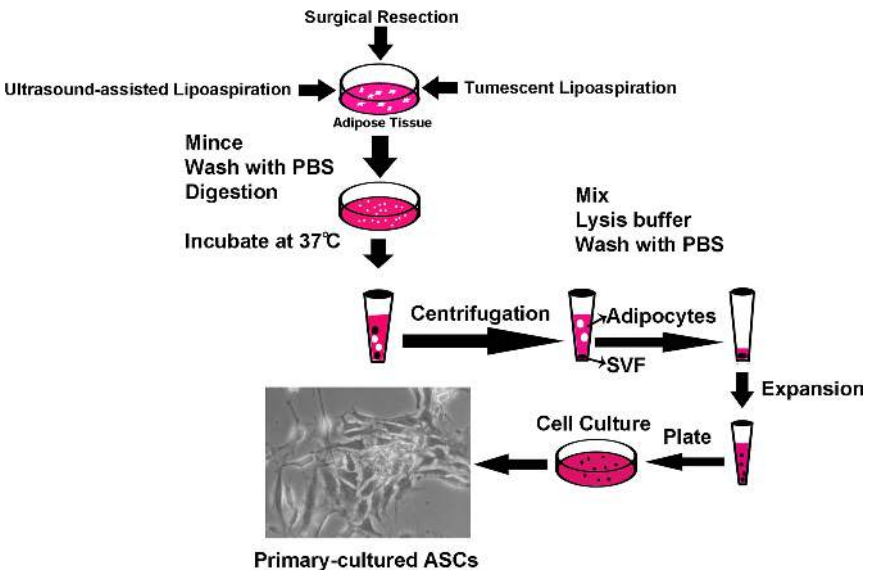

**Figure 11.1** Schematic diagram of the preparation and isolation of ASCs. Adipose tissue can be obtained by surgical resection, tumescent lipoaspiration, or ultrasound-assisted lipoaspiration. The adipose tissue is minced, incubated at 37 °C for 40 min with 0.075% type I collagenase and then centrifuged at 1000 rpm for 5 min. After washing with phosphate-buffered saline (PBS) and expanded in α-minimum essential medium with 10% fetal bovine serum, the cells are cultured in a 5% $CO_2$ humidified atmosphere. Finally, cells are identified by their multilineage differentiation potential, cell surface antigen profile, plastic adherence ability, and colony formation ability. SVF: stromal vascular fraction.

It should be noted that there are discrepancies in the results obtained from different laboratories. There are a number of potential reasons for this. First, ASCs are isolated from donors who differ in ethnicity, medical history, age, gender, and BMI. One study reported that BMI negatively correlated to the number of stromal cells per unit volume and their differentiation capacity [17]. Second, it has been reported that operative site and surgical procedure are relevant to the proliferation and differentiation capacity of ASCs. Third, the quality of ASC isolation and the culture procedure for isolating ASCs differ between laboratories [18,19]. These variables may affect the composition of the initial cell population isolated, but it is difficult to standardize these variables. In addition, other variables such as initial cell plating density and confluence, coating of culture dishes, cell culture media, cell culture environment, and cell subculture procedures may influence the ASC population obtained.

Studies have shown that ASCs in passage 2 or 3 have a distinct cell surface phenotype and express CD10, CD13, CD29, CD44, CD49e, CD73, CD90, CD105, and CD166 and do not express CD11b, CD14, CD31, and HLA-DR [20,21]. However, some surface markers, including CD29, CD90, and CD166, increase during culture [14], while other markers, such as CD34, decrease. It has been reported that CD34 is expressed in the initial cultures of ASCs, but decreases dramatically during culture [22]. Therefore, it is necessary to characterize the expression profile of ASCs at different times in culture and during different passages.

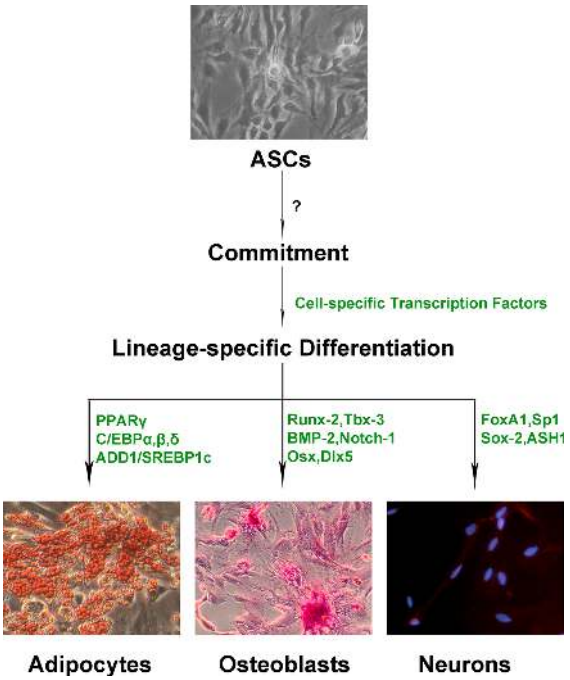

**Figure 11.2** The multilineage differentiation model of ASCs. The mechanisms by which ASCs commit to the adipogenic lineage are poorly understood, although lineage-specific terminal differentiation is regulated by cell-specific transcription factors. The adipogenic, osteogenic, and neurogenic differentiations of ASCs are shown. (See color plate section.)

### 11.2.2 Differentiation capacity of adipose-derived stem/stromal cells

ASCs have the capacity to differentiate into cells of the mesodermal lineage, including adipocytes, fibroblasts, myocytes, osteocytes, and chondrocytes [23]. Overexpression of peroxisome proliferator-activated receptor-γ (PPAR-γ) in ASCs results in adipogenic differentiation. Surprisingly, there appears to be evidence that ASCs also have the ability to differentiate into non-mesodermal cells, including hepatocytes, neurons, pancreatic cells, endothelial cells, and cardiomyocytes [24–27]. However, before initiating lineage-specific differentiation, ASCs have to be "allocated" or "committed" to a certain lineage. Although several studies have investigated the commitment process and the mechanisms by which pluripotent stem cells commit to a certain lineage, little information is available as yet [28,29]. The multilineage differentiation model of ASCs is shown in Figure 11.2.

## 11.3 Process of adipogenic differentiation from adipose-derived stem/stromal cells

### 11.3.1 Adipocyte development program

#### 11.3.1.1 Commitment

The initial stage of commitment to adipogenic differentiation is ASCs differentiating into adipocyte precursor cells and the subsequent differentiation of adipocyte precursor cells into preadipocytes. The mechanisms of this process are poorly understood [15,29]. To date, no specific adipogenic commitment factor has been found. There is some evidence that adipogenic orientation may be associated with cytokines secreted by the mature adipocytes, but no specific factors have been identified [30,31]. Tang *et al.* [32] reported that bone morphogenetic protein 4 (BMP4) induced the commitment of the pluripotent cells C3H10T1/2 to preadipocytes, suggesting that BMP4 may be involved in the commitment process of adipogenic differentiation. (The C3H10T1 cell line was established in 1973 from 14- to 17-day-old C3 H mouse embryos. These cells display fibroblastic morphology in cell culture and are functionally similar to mesenchymal stem cells.)

McBeath *et al.* [33] found that ASCs cultured in high density with cell-to-cell contact and no room to "stretch" showed a tendency to adipogenic differentiation, whereas cells plated at low density or on a large island of fibronectin, which allowed them to spread, were more likely to become osteoblasts. Those studies suggest that cell density and cell morphology may be related to lineage commitment.

#### 11.3.1.2 Growth arrest and mitotic clonal expansion

When ASCs differentiate into preadipocytes, cell confluence and contact inhibition occur, making the cell cycle stop in the $G_0/G_1$

phase [34]. Cells subsequently reenter the cell cycle by induction of lipogenic hormones and mitogenic compounds and undergo several rounds of DNA replication and mitosis, resulting in an increase in cell number. This process is called mitotic clonal expansion. In this process, DNA replication and changes in chromosome conformation first induce the expression of CCAAT (cytosine–cytosine–adenosine–adenosine–thymidine) enhancer binding proteins (C/EBP) β and δ and subsequently the core and crucial transcription factors C/EBPα and PPAR-γ are expressed. Once C/EBPα and PPAR-γ are expressed, various other adipocyte-related genes, such as adipocyte protein 2 (AP2) and glucose transporter (GLUT) 4, begin to be expressed [34,35]. With the increase of C/EBPα and PPAR-γ, cyclin dependent kinase inhibitor p21 is upregulated, cells gradually stop clonal expansion, exit from the cell cycle, and reach a terminal differentiation stage [36–38]. A number of studies have demonstrated that inhibition of clonal expansion or blockade of the cell cycle impair adipogenesis [39–42], while other studies have reported that mitotic clonal expansion is not required in adipocyte development [43,44].

#### 11.3.1.3 Terminal differentiation

Following exit from clonal expansion, cells enter an irreversible terminal differentiation stage. Lipoprotein lipase (LPL) is considered to be the marker of the terminal stage of adipogenic differentiation [34], although some studies indicate that LPL is not a fat-specific marker because of its expression in myocardial cells and macrophages [45,46]. At this stage, C/EBPα and PPAR-γ act synergistically to activate the adipocyte-specific genes that produce the adipocyte phenotype [47]. Subsequently, lipid droplets begin to form and gradually accumulate, and cell shape becomes rounded rather than its previous fibroblast-like appearance. With the enlargement of fat droplets, the cells are gradually filled with a single and large lipid droplet, and the cytoplasm and nucleus are extruded to one side. At the same time, many adipocyte-specific genes are expressed, which enhance the sensitivity of the cells to insulin. After this the adipocytes begin to secrete a variety of adipokines or cytokines, culminating in mature adipocyte differentiation [2,34,42]. This process of adipogenic differentiation from ASCs is illustrated in Figure 11.3.

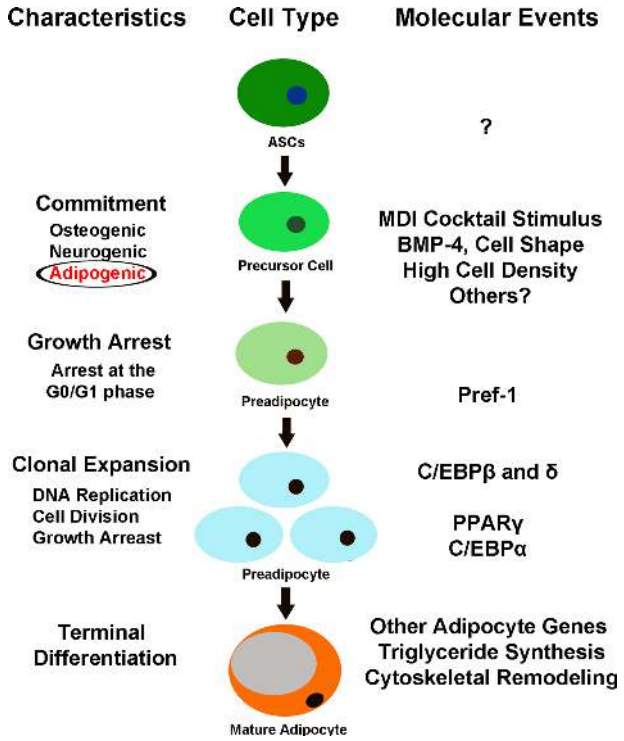

**Figure 11.3** The adipogenic differentiation process of ASCs. ASCs commit to precursor cells and subsequently differentiate to preadipocytes induced by 3-isobutyl-1-methylxanthine, dexamethasone, and insulin (MDI) cocktail, BMP-4, high cell density, and cell shape. Preadipocytes reach confluence and arrest at $G_0/G_1$ phase. These growth-arrested cells subsequently reenter the cell cycle and undergo several rounds of cell division, referred to as mitotic clonal expansion, during which cells gradually express C/EBPs and PPARs. After the clonal expansion process, cells exit the cell cycle and reenter a unique growth-arrested stage. Subsequently, they commit to their terminal differentiation stage, during which they express many other adipocyte-specific genes, increase glucose uptake, and enable fat accumulation.

### 11.3.2 Signaling pathways associated with adipogenic differentiation

#### 11.3.2.1 The PI3K/Akt signaling pathway

Insulin-like growth factor-1 (IGF-1) was the first reported cytokine able to promote adipocyte development. It activates phosphatidylinositol (−3) kinase (PI3K) through binding to the IGF-1 receptor and further activates the serine/threonine protein kinase Akt, leading to activation of the PI3 K/Akt pathway. Once the PI3 K/Akt pathway is activated, GLUT1 and −4 translocate to the cell membrane and glucose is absorbed into cells to synthesize triglyceride, which promotes the maturation of adipocytes [48,49]. A previous study showed that activating Akt can promote the differentiation of 3T3-L1 cells into mature adipocytes, while RNA interference (RNAi)-mediated inhibition of Akt1 expression can block the adipogenic process [50]. Embryonic stem cells from Akt1 knockout mice are unable to express PPAR-γ and thus cannot differentiate into adipocytes [51,52]. In contrast, exogenous upregulation of PPAR-γ in Akt1 knockout stem cells enables the adipogenesis process, suggesting that PPAR-γ may be the direct downstream gene of Akt1 [52,53].

#### 11.3.2.2 The cAMP/PKA/CREB signaling pathway

The key activation event of the cyclic AMP response element-binding protein (CREB) is phosphorylation on the Ser 133 site. G protein–cyclic adenosine monophosphate–protein kinase A (G protein–cAMP–PKA) is the classical pathway that acts on CREB. Activated PKA enters the nucleus and

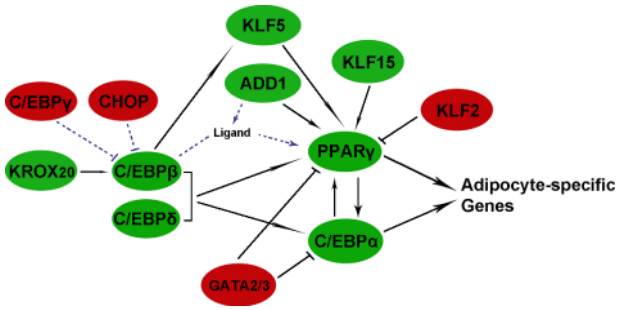

**Figure 11.4** The transcriptional cascade that regulates adipogenesis is shown. PPAR-γ and C/EBPα lie at the core of the transcriptional cascade that regulates adipogenesis. The transcription factors in light gray ovals are anti-adipogenesis and the transcription factors in dark gray ovals are pro-adipogenesis. Solid lines indicate effects on gene expression, whereas dashed lines represent effects on protein activity.

phosphorylates CREB. Homodimers of phosphorylated CREB play a role in regulating the transcription of target genes by binding to their cAMP response elements with the associated factor phosphorylated CREB binding protein [54]. Expression of constitutively active CREB strongly activates C/EBPβ promoter–reporter genes, which induce expression of endogenous C/EBPβ and results in adipogenesis. Conversely, expression of a dominant-negative CREB impairs promoter–reporter activity, expression of C/EBPβ, and adipogenesis [54,55] (Figure 11.4).

#### 11.3.2.3 The MAPK signaling pathway

Mitogen-activated protein kinase (MAPK) is another member of the serine/threonine protein kinase family. The MAPK signaling pathway is involved in cell proliferation, cell differentiation, and cell apoptosis. The MAPK signaling pathway is comprised of three sequentially activated kinases and regulated by phosphorylation. MAPK kinase kinases (MKKKs) are the first component of this phosphorelay system. MAPK kinases (MKKs) serve as the phosphorylation substrates of MKKKs. MAPKs are the downstream component activated by MKKs. The MAPK signaling pathway in mammals has three well-characterized subfamilies: the extracellular signal-regulated kinases (ERKs), the c-Jun NH2-terminal kinases, and the p38 enzymes [56,57]. The role of the MAPK signaling pathway in the process of adipocyte differentiation is complex and depends on the phase of cell differentiation. When cell differentiation is in the phase of clonal expansion, the MAPK signaling pathway is required for mitosis, whereas when cells enter their terminal differentiation stage the MAPK signaling pathway is inactivated so that MAPKs can phosphorylate PPAR-γ, forming inactivated p-PPAR-γ, an inhibitor of adipogenesis [40,58,59]. Additionally, the role of MAPKs may be different in different species and in different cellular models [60].

#### 11.3.2.4 The Wnt/β-catenin signaling pathway

The Wnt/β-catenin pathway is also involved in the regulation of adipogenic differentiation. β-catenin plays a key role as a second messenger in this process [61,62]. When the Wnt/β-catenin pathway is activated, Wnt proteins such as Wnt10B bind to its specific receptor Frizzled and its auxiliary receptor low density lipoprotein receptor-related protein, inactivating Dishevelled protein, which has an inhibitory role on glycogen synthase kinase-3β, cytoskeletal protein (Axin), and colorectal adenoma-like protein (APC). Thus, β-catenin is not phosphorylated, permitting the binding of activated β-catenin and lymphoid enhancer-binding factor (LEF) and Transcription Factor (TCF) family members, which in turn triggers the expression of downstream genes. These activated downstream genes inhibit the expression of PPAR-γ and C/EBPα, thereby inhibiting adipogenesis [63,64].

#### 11.3.2.5 The TGF-β signaling pathway

The transforming growth factor-β (TGF-β) pathway initiates signaling by binding to transforming growth factor beta type I and type II receptor kinases (TβRI and TβRII). Certain TGF-β superfamily members, including TGF-β, bone morphogenetic proteins (BMPs), and activins, may initiate signaling by binding to TβRII, which leads to the recruitment of an appropriate TβRI. Activated TβRs induce the phosphorylation of receptor-associated SMADs such as SMAD2 and SMAD3. (The SMAD proteins are homologs of both the *Drosophila* protein, mothers against decapentaplegic (MAD), and the *Caenorhabditis elegans* protein SMA – from gene SMA for small body size. The name is a portmanteau of the two.) Activated SMAD2 and SMAD3 bind to SMAD4. The compound thus formed translocates to the nucleus and binds to DNA binding assistant factors to regulate transcription [65]. TβRs can also activate other signaling pathways, such as the MAPK signaling pathway [66,67]. Previous studies have shown that TGF-β inhibited adipogenic differentiation of primary cultured preadipocyte *in vitro* and *in vivo* [68–70]. Overexpression of TβRI in adipose tissue severely blocks both white and brown adipose tissue formation [71].

## 11.4 Regulation of adipogenic differentiation from adipose-derived stem/stromal cells

### 11.4.1 Transcriptional regulation

#### 11.4.1.1 The PPAR family

The transcriptional activation role of PPARs, a subgroup of nuclear hormone receptors, on adipogenic differentiation has been widely confirmed. It has been shown that PPARs can induce adipogenic differentiation, not only of ASCs and preadipocytes [72–75] but also myoblasts [76]. PPARs have three subtypes: PPAR-α, PPAR-δ, and PPAR-γ. They are

directly regulated by steroids, thyroid hormones, vitamins, lipid metabolites, and xenobiotics [77]. (A xenobiotic is a foreign chemical substance found within an organism that is not normally naturally produced by, or expected to be present within, that organism. It can also cover substances that are present in much higher concentrations than are usual. Specifically, drugs such as antibiotics are xenobiotics in humans because the human body does not produce them itself, nor are they part of a normal food.) PPAR-α and PPAR-δ are not only expressed in adipose tissue, but also in other tissues and cell lines [78,79]. Compared with the high level of PPAR-α in brown adipose tissue, the level in white adipose tissue and adipocyte cell lines is extremely low [80,81], suggesting that the role of PPAR-α in white adipose tissue or in adipocytes from white adipose tissue is minor. PPAR-γ is expressed almost exclusively in adipose tissue and adipocyte cell lines and is hardly expressed at all in other tissues and cell lines [42,47,82]. The role of PPAR-α and PPAR-γ as the critical regulators of adipogenesis has been supported by overwhelming evidence from both *in vivo* and *in vitro* studies [2,82–84]. PPAR-α and PPAR-γ are induced in the early phase of the adipogenic differentiation process. Once expressed they ensure that terminal differentiation is maintained and can activate adipocyte-specific genes, producing the adipocyte phenotype [47,82].

#### 11.4.1.2 The C/EBP family

The C/EBP family has three isoforms: C/EBPα, C/EBPβ, and C/EBPδ. All of them possess C-terminal basic region/leucine zipper domains that confer DNA-binding ability and the ability to dimerize. Many studies have confirmed that the C/EBP family plays an important role in adipogenesis. The expression of C/EBPα occurs prior to the expression of most adipocyte-specific genes. Gain-of-function studies demonstrated that expression of C/EBPα was sufficient to induce adipogenic differentiation of preadipocytes without the addition of external hormonal inducers. Disruption of C/EBPα resulted in failure to develop white adipose tissue in mice [34,85]. Additionally, C/EBPα can maintain the terminally differentiated state through autoactivation of its own gene in the differentiation process [86,87]. An increasing body of evidence indicates that C/EBPβ and C/EBPδ function in the early stage of the adipogenic differentiation process and are expressed prior to C/EBPα as transcriptional activators in the sequence of events leading to adipogenic differentiation. Adipogenic induction on growth-arrested preadipocytes provokes an immediate and transient burst of expression of C/EBPβ and C/EBPδ [88]. Subsequently, the preadipocytes reenter the cell cycle, undergoing several rounds of mitotic clonal expansion and expressing C/EBPα, which arrests growth, and a return to terminal differentiation ensues [34,47]. Generally, C/EBPβ is regarded as the transcriptional activator of the C/EBPα gene and C/EBPδ may act synergistically with C/EBPα in the induction of PPAR-γ [89]. The transcriptional cascade that regulates adipogenesis has been reviewed by Rosen and MacDougald [35], and a schematic diagram is shown in Figure 11.4.

#### 11.4.1.3 ADD1/SREBP-1c

Adipocyte determination and differentiation-dependent factor 1 (ADD1), also called sterol regulatory element binding protein 1 (SREBP-1), is a transcription factor that regulates the synthesis of unsaturated fatty acids, glucose metabolism, and the synthesis of cholesterol [90]. SREBPs have three isoforms: SREBP-1a, SREBP-1c, and SREBP-2. SREBP-1c is highly expressed in white adipose tissue, brown adipose tissue, and liver cells, with the capacity of promoting fat synthesis in the liver and adipogenic differentiation of 3T3-L1 preadipocytes. There are two main ways by which SREBP-1c promotes the synthesis of triglyceride in the liver and adipocytes: first, by upregulating the expression of fatty acid synthetase, acetyl coenzyme A decarboxylase, stearoyl coenzyme A, and phosphoenolpyruvate carboxykinase to promote triglyceride synthesis [91]; second, by transcription of activating PPAR-γ or induction of the expression of the ligand of PPAR-γ to promote adipogenic differentiation [92]. Although details of the regulatory mechanism of ADD1/SREBP-1c in adipocyte differentiation have not been fully elucidated, many studies suggest that ADD1/SREBP-1c plays an important role in the development of adipocytes. In addition, the role of ADD1/SREBP-1c in the differentiation process of adipocytes from brown adipose tissue remains unclear.

### 11.4.2 Epigenetic regulation

#### 11.4.2.1 DNA methylation

DNA methylation was the first recognized epigenetic mechanism and the one that has been the most extensively studied. DNA methylation in mammals is the process by which methyl from *S*-adenosylmethionine is transferred to a specific nucleotide, usually at position 5 of cytosine, and catalyzed by DNA methyltransferase. Generally, DNA methylation occurs on CpG islands, but it also occasionally occurs on in a CpHpG context where H = A (adenosine), T (thymine), or C (cytosine) [93]. DNA methylation does not alter DNA sequence, but it is an important epigenetic modification in the maintenance of normal cell function, genetic imprinting, embryonic development and human oncogenesis [94]. The main role of DNA methylation is the regulation of gene expression, and it is one of the most important epigenetic mechanisms of this. It has been found that DNA methylation plays an important role in development of adipose tissue and occurrence of obesity [95].

##### *11.4.2.1.1 DNA methylation at the genomic level*

Zhu and colleagues analyzed human genomic DNA methylation in preadipocytes and mature adipocytes and found that hypomethylation occurred on 2701 genes and that hypermethylation occurred on 1070 genes [96]. This suggests that genomic DNA

methylation is involved in adipogenic differentiation. Further analysis found that the genes with methylation were mainly those of the signaling pathways of inflammatory cytokines, the Wnt signaling pathway, the MAPK signaling pathway, and insulin-induced signaling pathways. Signaling pathway network analysis showed that TNF-α and interleukin-8 played a key role in this network [97].

#### *11.4.2.1.2* C/EBP *methylation*

Li *et al.* found that hypomethylation occurred on the *C/EBPα* gene in preadipocytes, while hypermethylation occurred on the *C/EBPα* gene in mature adipocytes, suggesting that DNA methylation regulates adipocyte development [97]. Another study found that the levels of DNA methylation on the promoter region of *C/EBPα* were significantly elevated after contact inhibition of 3T3-L1 cells for 48 h. However, when cells were induced by the cocktail of isobutylmethylxanthine, dexamethasone, and insulin for 24 h the level of DNA methylation on the promoter region of *C/EBPα* was downregulated. If the cells were treated with insulin only, the methylation of *C/EBPα* was maintained at a high level. Meanwhile, the expression of C/EBPα was upregulated when induced with isobutylmethylxanthine, dexamethasone, and insulin, whereas there was almost no change when induced with insulin only [96]. These results indicate that the commitment of preadipocytes may be associated with DNA methylation and that this epigenetic modification for cell commitment promotes genetic stability.

#### *11.4.2.1.3* PPAR-γ *methylation*

In contrast to the effect of DNA methylation of *C/EBPα*, Noer *et al.* found that hypomethylation occurred on the promotor region of *PPAR-γ* in mesenchymal stem cells, whereas hypermethylation occurred on the promotor region of *PPAR-γ* in preadipocytes, and demethylation gradually occurred as adipogenic differentiation got under way [98]. Additionally, the mRNA level of PPAR-γ became elevated, which suggested that the demethylation of *PPAR-γ* can promote preadipocytes to differentiate into mature adipocytes [99]. The DNA methylation-inhibitor 5-azacytidine was capable of downregulating the level of methylation on *PPAR-γ* and increased the expression of *PPAR-γ* [100]. In addition, chromatin immunoprecipitation experiments showed that methyl CpG binding protein 2 had bound to the promoter region of *PPAR-γ* early in the adipogenic commitment process [101]. Interestingly, this study showed that there were some CpG sites 500 base pairs upstream of the transcription start site of human *PPAR-γ*2, but these were absent at the same sites for the mouse *PPAR-γ*2 gene, suggesting that DNA methylation of a given gene may differ in different species [99].

#### *11.4.2.1.4 Leptin methylation*

Leptin is a hormone secreted mainly by adiopcytes. It can inhibit appetite and regulate energy metabolism. One study found that *leptin* expression was regulated by DNA methylation on its promoter region. In mesenchymal stem cells the promoter region of *leptin* was in a hypomethylation state, but in preadipocytes it was in hypermethylation state without *leptin* expression in the cells [98]. Okada *et al.* reported that methylation inhibitor treatment of 3T3-L1 preadipocytes did increase expression of *leptin* mRNA [102]. In other studies of the process of preadipocyte differentiation to mature adipocytes, demethylation of the *leptin* promoter site gradually occurred and the mRNA level of *leptin* increased [103,104]. Milagro *et al.* [105] also found that in adipose tissue of high fat diet-induced obese rats, the methylation level in the promoter region of *leptin* slightly increased. These results suggest that methylation of *leptin* plays a regulatory role in adipogenesis.

#### *11.4.2.1.5 Methylation of* ARHGEF*19*

Ras homolog gene family member A guanine nucleotide exchange factor 19 (ARHGEF19) is a member of the RhoGEFs family. RhoGEFs play an important role in many physiological and pathological processes. RhoGEFs promote conversion of GDP to GTP and produce the active form of GTP enzyme. ARHGEF19 is mainly expressed in the intestine, liver, heart, and kidney [106]. ARHGEF19 can activate RhoA, which is capable of inhibiting adipogenesis through the RhoA-Rho kinase (ROCK) signaling pathway by regulating cytoskeletal tension [33]. Wang *et al.* found that the level of methylation on the promotor region of *ARHGEF19* in adipogenically differentiated 3T3-L1 cells was downregulated compared with that in undifferentiated cells [106]. Additionally, the mRNA level of *ARHGEF19* also decreased markedly, suggesting that methylation of *ARHGEF19* upregulates the transcription of the *ARHGEF19* gene. This seems contrary to the consensus that DNA methylation inhibits gene expression, but other studies have shown that methylation on the 5′ end or 3′ end of the gene can activate gene expression [107].

#### *11.4.2.1.6 Methylation of other adipocyte-specific genes*

GLUT4 can translocate to the cell membrane to participate in the transport of glucose as a result of insulin stimulation. In preadipocytes the promoter region of *GLUT4* is methylated, but demethylation occurs when cells start to differentiate adipogenically. In addition, methylation on specific sites of the promoter region inhibits the binding of nuclear factor and promoter, leading to downregulation of *GLUT4* expression [108]. Additionally, fatty acid binding protein 4 and LPL are highly expressed in adipose tissue. It is hypomethylated on the promotor region of the two genes and is hypomethylated in freshly isolated mesenchymal stem cells, cultured mesenchymal stem/stromal cells, and in differentiated mesenchymal stem/stromal cells [98].

### 11.4.2.2 Histone modification

Histone modifications include acetylation and deacetylation, phosphorylation and dephosphorylation, and methylation

**Figure 11.5** Histone modifications. Acetylation (ac) generally correlates with gene activation. Histone lysine (K) methylations (me) that correlate with gene activation are shown in light script (as opposed to bold script).

and demethylation. These modifications not only lead to conformational change of chromatin by affecting the affinity between histones and the DNA chain, but also affect the binding affinity between transcription factors and the response element in DNA sequences, thus indirectly influencing gene expression and resulting in phenotypic change [109,110]. The commonest histone modification pattern is shown as Figure 11.5.

Kim *et al.* reported that histone deacetylase (HDAC) led to a dramatic attenuation of adipogenic differentiation from preadipocytes [111]. In contrast, sodium butyrate treatment increased adipogenic differentiation, while apicidin treatment decreased the expression of adipogenic marker genes, indicating that the adipogenic differentiation process can be differentially regulated depending on the type of HDAC inhibitor used. Additionally, this differential effect seemed not to be due to disruption of the insulin-signaling pathway. Chatterjee *et al.* found that HDAC9 markedly downregulated adipogenic differentiation [112]. ASCs from HDAC9 gene-knockout mice exhibited accelerated adipogenic differentiation, whereas HDAC9 overexpression in 3T3-L1 preadipocytes suppressed adipogenic differentiation, demonstrating its direct role as a negative regulator of adipogenesis. Yoo *et al.* presented evidence that HDACs are downregulated during adipocyte differentiation [113]. Histone hyperacetylation was selectively induced at the promoter regions of adipocyte-specific genes during adipogenic differentiation, producing a dramatic decrease of HDAC1, −2, and −5 and a reduction of HDAC enzyme activity. Similarly, HDAC1-knockdown promoted adipogenesis, whereas HDAC1 overexpression attenuated adipogenic differentiation in 3T3-L1 cells.

PPAR-γ has two main isoforms: PPAR-γ1 and PPAR-γ2. Although they are transcribed by two different promoters, they are expressed at comparable levels in adipogenesis [114]. Mono-, di-, and trimethylations on histone H3K4 (H3K4me1, H3K4me2, and H3K4me3 respectively) generally correlated with gene activation. Studies showed that the action of H3K4me3 on promotors of PPAR-γ1 and PPAR-γ2 increased the expression levels of both PPAR-γ1 and PPAR-γ2 [115]. In addition, Wang *et al.* reported that decreases of H3K27me3 on promotors of Wnt1, Wnt6, Wnt10A and Wnt10B, which are negative regulators of adipogenesis, increased their expression levels and led to inhibition of adipogenesis [116]. Taken together, these results suggest that histone modification is crucial for the execution of adipogenesis.

## 11.4.3 Post-transcriptional regulation

### 11.4.3.1 Regulation of adipogenesis by microRNAs

#### *11.4.3.1.1 MicroRNAs*

MicroRNAs (miRNAs or miRs) are a class of endogenous noncoding single-stranded RNA of 21–25 nucleotides in length [117]. Usually, miRNAs regulate gene expression by binding to complementary target sites in the 3′ untranslated region (3′ UTR) of protein-coding genes [118], although there are a few reports that some miRNAs can activate translation as well [119,120]. miRNAs have several remarkable characteristics: first, they do not have the open reading frame or other characteristics of protein-coding genes [121]; second, most miRNAs are derived from intergenic sequences, although a few are derived from intronic sequences [122–124]; third, the sequences of mature miRNA are highly conserved among different species [125]; and fourth, miRNAs are expressed with high temporal, spatial, and tissue specificity [121].

#### *11.4.3.1.2 MicroRNAs regulate adipogenesis by targeting the PI3K/Akt signaling pathway*

He *et al.* reported that overexpression of miR-29 in diabetic rats sharply repressed insulin-stimulated glucose uptake by downregulating Akt activation, whereas inhibition of miR-29 potentiated Akt phosphorylation, thus augmenting insulin-dependent glucose uptake [126]. The results suggested that miR-29 is capable of decreasing glucose uptake and inhibiting triglyceride formation by impairing the activation of Akt. A study by Ouaamari *et al.* showed that miR-375 can repress the glucose-mediated stimulatory effect on insulin gene expression by targeting phosphoinositide-dependent protein kinase-1 (PDK1), which activates Akt in the presence of phosphatidylinositide 3-kinase (PI3K) [127]. Another study determined that the levels of miR-320 increased approximately 50-fold in insulin-resistant adipocytes. When these adipocytes were transfected with specific antisense (AS) oligonucleotides against miRNA-320, the PI3K/Akt pathway was activated by increasing the expression of PI3K, the phosphorylation of Akt, and the protein expression of GLUT-4, as well as insulin-stimulated glucose uptake. Further study showed that PI3K may be the target of miR-320 [128]. Yi *et al.* reported that miR-143 promoted adipogenesis by targeting pleiotrophin (PTN), which plays a negative role on the PI3K/Akt1 signaling pathway [129]. Jordan found that the expression level of miR-143 was higher in the liver of obese mice [130]. Further study showed that overexpression of miR-143 impairs glucose homeostasis and insulin-stimulated Akt activation via the downregulation of oxysterol-binding-protein-related protein 8. Conversely, a reduction in miR-143 can reduce obesity-associated insulin resistance. Taken together, these studies provide direct evidence that miRNA is capable of regulating adipogenesis by acting on the PI3 K/Akt signaling pathway. The miRNA regulatory PI3 K/Akt signaling pathway of adipogenic differentiation is illustrated in Figure 11.6.

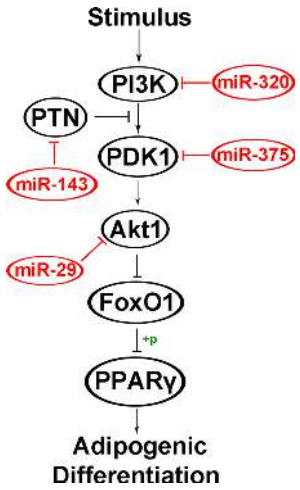

**Figure 11.6** miRNAs regulate adipogenesis by targeting the PI3 K/Akt signaling pathway. miR-320, miR-375, and miR-29 inhibit adipogenic differentiation by targeting PI3 K, PDK1, and Akt1 respectively. miR-143 promotes adipogenesis by targeting PTN, which exerts a negative role during adipogenesis via the PTN/PI3 K/AKT signaling pathway.

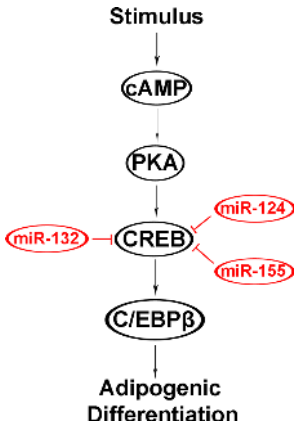

**Figure 11.7** miRNAs regulate adipogenesis by targeting the cAMP/PKA/CREB signaling pathway. cAMP induced by insulin regulates target gene transcription primarily by catalyzing the phosphorylation of CREB through PKA. In adipogenic differentiation, CREB activates C/EBPβ, which triggers adipogenic differentiation. miR-124, miR-132, and miR-155 repress adipogenic differentiation by targeting CREB.

#### *11.4.3.1.3 MicroRNAs regulate adipogenesis by targeting the cAMP/PKA/CREB signaling pathway*

Rajasethupathy *et al.* [131] and Millan [132] found that the brain-specific miRNA miR-124 was able to de-repress the expression of CREB, and a conserved miR-124 target site was found in the 3-UTR of CREB. Downregulation of miR-124 promoted adipogenesis. Liu and colleagues found that when 3T3-L1 preadipocytes were treated with TNF-α, an inhibitor of adipogenesis, miR-155 was up-regulated, while the expression of CREB was reduced [133]. Bioinformatic analysis showed a region in miR-155 complementary to the sequences in 3′ UTR of CREB, suggesting that miR-155 can directly target CREB. Another miRNA that is highly expressed in brain tissue and neuronal cell, miR-132, also plays a role in glucose homeostasis in adipocyte differentiation by regulating the expression of CREB [134]. Therefore, we conclude that miRNAs can regulate adipogenesis by targeting the cAMP/PKA/CREB signaling pathway (Figure 11.7).

#### *11.4.3.1.4 MicroRNAs regulate adipogenesis by targeting the MAPK signaling pathway*

Esau *et al.* first reported that the expression level of miR-143 varied in the adipocyte development process: treatment with AS miR-143 oligonucleotides effectively impaired adipogenic differentiation [135]. The protein level of extracellular signal-regulated kinase 5 (ERK5) that was predicted to be the target gene of miR-143 by bioinformatics analysis increased when the expression of miR-143 was inhibited, suggesting that miR-143 serves as a regulator in adipogenesis and may play a role through acting on ERK5. Similarly, Takanabe *et al.* found that the expression of miR-143 in the mesenteric adipose tissue of mice fed a high fat diet was upregulated, while the protein levels of ERK5 were not significantly downregulated [136]. Oskowitz *et al.* also observed that miR-143 was upregulated during the adipogenic differentiation of human multipotent bone marrow stromal cells and that overexpression of miR-143 promoted adipogenic differentiation [137]. However, the role of ERK5 remains unclear. Chen *et al.* first reported that the regulatory role of miR-143 may depend on the adipogenic differentiation stage [138]. When miR-143 was overexpressed during the clonal expansion stage, the adipogenic differentiation of adipose-derived stromal cells was inhibited, whereas overexpression of miR-143 during the growth arrest stage or terminal differentiation stage promoted differentiation. This study provided evidence that miR-143 plays the role of regulating adipocyte differentiation in part by promoting the transition from the clonal expansion stage to the terminal differentiation stage and validated that miR-143 regulating adipogenesis may act through direct repression of MAP2K5, a key member of the MAPKK family in the MAPK signaling pathway. In addition, Ling *et al.* reported that in 3T3-L1 preadipocytes the expression level of miR-375 was increased by adipogenic induction and that overexpression of miR-375 promoted 3T3-L1 adipogenic differentiation [139]. Further studies found that miR-375 was capable of suppressing phosphorylation levels of ERK1/2, which play an important role in the ERK1/2 signaling pathway. Other miRNAs, such as the *Drosophila* microRNA miR-14, can suppress fat metabolism by targeting the p38 MAPK signaling pathway [140]. In conclusion, miRNAs targeting the MAPK signaling pathway serve as both promoters and inhibitors for adipogenesis depending on which differentiation stage they act on.

High-mobility group AT-hook 2 (HMGA2) is an important architectural transcription factor that is involved in cell

mitosis. The protein belongs to the non-histone chromosomal high-mobility group (HMG) protein family. HMG proteins function as architectural factors and are essential components of the enhanceosome. HMGA2 contains three basic DNA-binding domains (AT-hooks) that cause the protein to bind to adenine–thymine (AT)-rich regions of nuclear DNA. HMGA2 does not directly promote or inhibit the transcription of any genes, but alters the structure of DNA and promotes the assembly of protein complexes that do regulate the transcription of genes. It can be directly repressed by the well-known miRNA, lethal-7 (let-7) [141]. Sun *et al.* reported that let-7 was downregulated during the clonal expansion stage and upregulated later in the terminal differentiation stage in the adipogenic differentiation process of 3T3-L1 proadipocytes [142]. Ectopic overexpression of let-7 markedly reduced HMGA2 and blocked adipogenesis. Conversely, miR-17-92 was significantly upregulated in the clonal expansion stage and accelerated adipocyte differentiation [143]. A target gene reporter assay demonstrated that miR-17-92 directly targets the 3′ UTR region of retinoblastoma binding protein 2 (Rb2/p130), which can form heterodimers with the E2 transcription factor 4 (E2F4) and E2F5, leading to the repression of cell cycle progression [144,145]. The miRNAs regulating the MAPK signaling pathway of adipogenesis are illustrated in Figure 11.8.

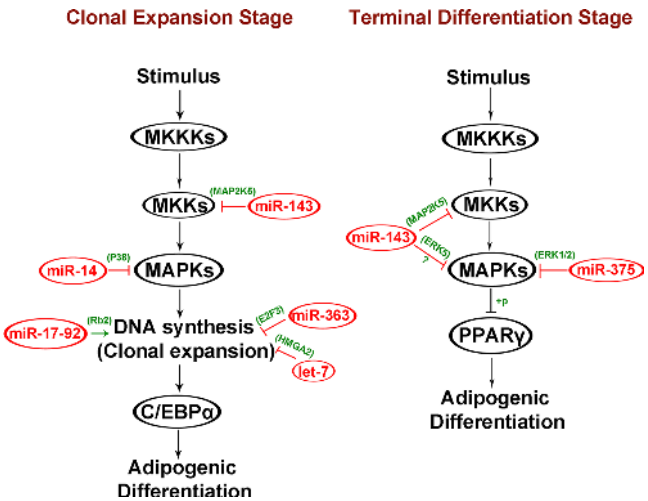

**Figure 11.8** miRNAs regulate adipogenesis by targeting the MAPK signaling pathway. The MAPK signaling pathway (MKKKs–MKKs–MAPKs) is involved in both the mitotic clonal expansion stage and the terminal differentiation stage of adipogenic differentiation. In the mitotic clonal expansion stage, DNA synthesis and cell division require the activation of the MAPK signaling pathway, whereas in the terminal differentiation stage it is the activation of MAPKs that inhibits differentiation via the phosphorylation of PPAR-γ. Thus, miRNAs targeting the MAPK signaling pathway in the mitotic clonal expansion stage may inhibit adipogenic differentiation (let-7, miR-14, miR-17-92, miR-143, and miR-363), and miRNAs targeting the MAPK signaling pathway in the terminal differentiation stage promote adipogenic differentiation (miR-375 and miR-143).

#### *11.4.3.1.5 MicroRNAs regulate adipogenesis by targeting the Wnt/β-catenin signaling pathway*

In a high-throughput microarray study, Qin *et al.* found that miR-322, miR-210, miR-194, and miR-148a might promote adipogenesis by repressing Wnt signaling, while miR-181, miR-344, and miR-27 might inhibit adipogenesis by activating Wnt signaling [146]. The targets of these miRNAs were also analyzed by bioinformatics. miR-210 was chosen as a representative miRNA to validate the predicted targets and the potential functions in adipogenesis. Mimics of miR-210 were transfected into 3T3-L1 preadipocytes and the results showed that overexpression of miR-210 stimulated lipid droplet formation, while downregulation of miR-210 strongly blocked adipogenesis, suggesting that miR-210 might play a specific role in adipogenesis. The expression of TCF 7-like 2 (T-cell specific, HMG-box) also known as TCF7L2 or TCF4, a transcription factor triggering the downstream responsive genes of Wnt signaling, was decreased. Furthermore, luciferase reporter assays showed that *TCF7L2* is the target gene of miR-210. miR-8 may be another negative regulator of Wnt signaling at multiple levels, from secretion of the ligand to the transcription of target genes. One study showed that mammalian homologues of miR-8 were capable of promoting the adipogenesis of marrow stromal cells by directly antagonizing TCF [147]. The miRNA-related Wnt/β-catenin signaling pathway in adipogenesis is illustrated in Figure 11.9.

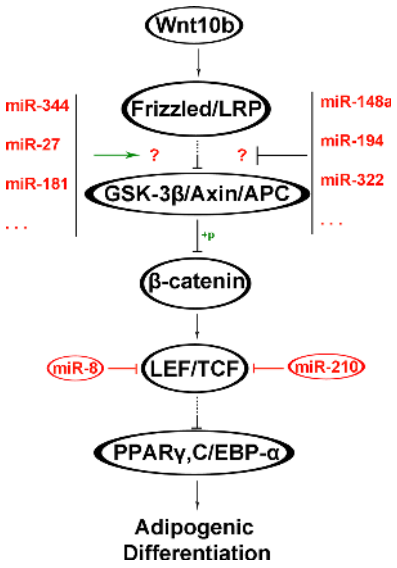

**Figure 11.9** miRNAs regulate adipogenesis by targeting the Wnt/β-catenin signaling pathway. miR-8, miR-148a, miR-194, miR-210, and miR-322 may promote adipogenesis by repressing Wnt signaling, while miR-27, miR-181, and miR-344 may inhibit adipogenesis by activating Wnt signaling. TCF, which is a transcription factor triggering the downstream genes of Wnt signaling, has been identified as the target gene of miR-210 and miR-8. The targets of the other miRNAs await identification.

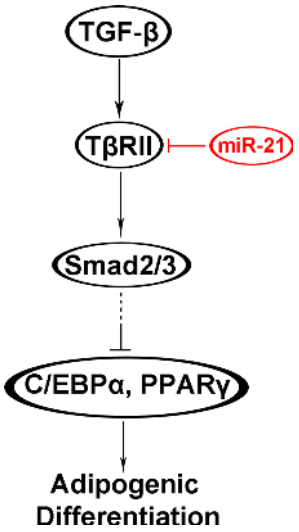

**Figure 11.10** miRNAs regulate adipogenesis by targeting the TGF-β signaling pathway. TGF-β initiates signaling by binding to TβRII in adipogenesis. Activated TβRII induces the phosphorylation of Smad2 and Smad3. Activated Smad2 and Smad3 inhibit the expression of C/EBPα and PPAR-γ. miR-21 promotes adipogenesis mainly by repressing expression of TβRII.

#### *11.4.3.1.6 MicroRNAs regulate adipogenesis by targeting the TGF-β signaling pathway*

Kim *et al.* reported that the expression level of miR-21 varied in the adipogenic differentiation process of human adipose-derived mesenchymal stromal cells. Lentiviral overexpression of miR-21 in these cells enhanced adipogenic differentiation, whereas its downregulation with AS miR-21 oligodeoxynucleotides inhibited this process. Western blot testing and the luciferase reporter assay showed that miR-21 promoted adipogenesis mainly by repressing expression of TβRII, an important member in the TGF-β signaling pathway [148]. miR-21 regulation of the TGF-β signaling pathway in adipogenesis is shown in Figure 11.10.

#### *11.4.3.1.7 MicroRNAs regulate adipogenesis by directly targeting key transcription factors*

PPARs can be targeted by miRNAs in adipogenesis. Many studies have shown that the miR-27 family is potentially an important class of negative regulators of adipogenesis. Michael *et al.* found that the expression level of miR-27b decreased during adipogenic differentiation [149]. Upregulation of miR-27b levels decreased the expression of PPAR-γ and C/EBPα. A luciferase reporter assay identified that PPAR-γ was the target gene of miR-27b. Similarly, Kim *et al.* [150] found that ectopic overexpression of another miR-27 family member, miR-27a, in 3T3-L1 preadipocytes also inhibited adipogenesis by reducing PPAR-γ expression. (Ectopic expression of a gene is the expression of a gene in an abnormal place in an organism.) Curiously, in the adipose tissue of obese mice the expression of miR-27 was upregulated and was regulated by hypoxia. Lin *et al.* found similar results during adipogenic differentiation of mouse embryonic fibroblast-derived 3T3-L1 preadipocytes and mouse bone-marrow-derived OP9 mesenchymal stem/progenitor cells [151], as did Ji *et al.* in hepatic stellate cells [152]. Martinelli *et al.* reported that miR-519d could specifically and dose dependently suppress PPAR-α protein level during adipogenic differentiation of preadipocytes [153]. The 3′ UTR of PPAR-α harbors a putative miRNA binding site that has been shown to specifically bind to miR-519d. Yang *et al.* found that miR-138 was downregulated during adipogenic differentiation of human adipose-tissue-derived stromal cells [154]. Overexpression of miR-138 effectively reduced lipid droplet accumulation. Further study identified that *EID-1*, the gene that encodes EP300-interacting inhibitor of differentiation 1, can interact with a small heterodimer partner, an endogenous enhancer of adipogenic PPAR-γ2, and is the target gene of miR-138.

C/EBPs are also targets of miRNAs in adipogenesis. Sun *et al.* reported that when the abundance of miR-31 in the murine mesenchymal stem cell line C3H10T1/2 was upregulated by induction of BMP-2, the adipogenic differentiation of BMSCs was repressed, and C/EBPα was regarded as the target gene of miR-31 [155]. Similarly, Tang *et al.* found that expression of miR-31 and miR-326 were significantly downregulated during adipogenic differentiation of adipose-derived stem cells [156]. C/EBPα was also predicted to be the target gene of the two miRNAs by bioinformatics analysis. In addition, C/EBPβ was identified as the target gene of miR-155 in the hepatic cells of C57BL/6 mice. The role of miR-155 in adipogenesis needs further study [157].

### 11.4.3.2 Regulation of adipogenesis by long noncoding RNAs

Long noncoding RNAs (lncRNAs), a significant and different class of transcripts, have been described. They were first discovered following large-scale sequencing of a full-length murine cDNA library [158]. LncRNAs are larger than 200 nucleotides and lack protein-coding function. They have been found to be transcribed throughout the eukaryotic genome. They account for the majority of the transcripts in the mammalian genome. In comparison with small noncoding RNAs, such as miRNAs, the functions of lncRNAs are as yet poorly understood [159]. However, a growing number of studies have shown that lncRNAs are involved in gene regulation at multiple levels. They play important roles in the process of embryonic development, the evolution of species, cell proliferation, cell differentiation, and diseases [160].

Sun *et al.* profiled the transcriptome of various cell models, including primary adipocytes from brown and white adipose tissue, preadipocytes, and cultured adipocytes [161]. They identified 175 lncRNAs that are specifically involved in adipogenesis. Many lncRNAs are adipose enriched, strongly induced during adipogenesis, and bound at their promoters

by crucial transcription factors such as PPAR-γ and C/EBPα. RNAi-mediated loss-of-function screens identified functional lncRNAs, and numerous lncRNAs were found to be required for functional adipogenesis. Zhao *et al.* globally profiled lncRNA gene expression during thermogenic adipocyte formation and identified brown adipose tissue lncRNA 1 (Blnc1) as a nuclear lncRNA that promoted brown and beige adipocyte differentiation and function [162]. Blnc1 formed a ribonucleoprotein complex with transcription factor early B cell factor 2 (EBF2) to stimulate the thermogenic gene program. Further, Blnc1 itself was a target of EBF2, thereby forming a feedforward regulatory loop to drive adipogenesis toward a thermogenic phenotype. (A feedforward regulatory loop involves specific circuitry in which the timely controlled expression of two genes is reciprocally regulated in order to establish correct progression of cell differentiation.)

PU.1 is an Ets family transcription factor involved in myelo-lymphoid cell differentiation but is also expressed in the adipocyte lineage. Pang *et al.* found that expression levels of PU.1 mRNA and protein in preadipocytes did not match the levels in mature adipocytes [163]. PU.1 mRNA level was higher in preadipocytes, whereas its protein was expressed in adipocytes but not in preadipocytes. They also found that miR-155 knockdown or overexpression had no effect on the levels of PU.1 mRNA and protein in preadipocytes or adipocytes. MiR-155 regulates adipogenesis not through PU.1, but via C/EBPβ, which is another target of miR-155. They also determined expression levels of PU.1 mRNA and AS (antisense) lncRNA. Compared with the level of PU.1 mRNA, the level of PU.1 AS lncRNA is much higher in preadipocytes, whereas it was the opposite in adipocytes. They further discovered that PU.1 AS lncRNA bound to its mRNA, forming an mRNA/AS lncRNA compound. The knockdown of PU.1 AS by small interfering (siRNA) inhibited adipogenesis and promoted PU.1 protein expression in both preadipocytes and adipocytes. Repression of PU.1 AS decreased the expression and secretion of adiponectin. They also found that the level of PU.1 AS lncRNA was much higher in preadipocytes than in mature adipocytes [163]. They further discovered that PU.1 AS lncRNA bound to its mRNA, forming an mRNA/AS lncRNA compound. Taken together, these findings suggest that lncRNAs play an important role in regulating adipogenesis.

## 11.5 The future

Adipogenesis is a complex physiological process that involves a large number of molecular events. The regulatory mechanisms of adipogenesis are gradually being elucidated, but many challenges remain. First, further research should be done in understanding the molecular details of the commitment of ASCs to the adipocyte lineage. Second, more signaling pathways that may be involved in adipogenesis, such as the FGF signaling pathway and the Hedgehog signaling pathway, should be studied in greater depth. Third, the epigenetic regulation of adipogenesis and the relationship between DNA/histone methylation/acetylation, miRNAs, and lncRNAs should be investigated more thoroughly. Fourth, the regulatory mechanisms of lncRNAs in adipogenesis and additional direct target genes of miRNAs need to be explored. Finally, since previous studies focused mainly on *in vitro* cell culture, more *in vivo* experiments are needed.

## 12.1 Introduction

The late 1990s were marked by the significant emergence of pluripotent stem cell lines derived from human embryos and essentially the nascence of regenerative medicine [1]. At the time it was hoped that stem cell therapy would provide an unprecedented opportunity of curing millions of patients suffering from debilitating diseases. However, unresolved ethical issues relating to the origin of the cells generated major legal, ethical, and political obstacles that remain to date. In the first decade of the 21st century, induced pluripotent stem cells were described; these did not have the ethical issues associated with human embryonic stem cells, but both shared, by definition, the ability to form teratomas, and the technology of differentiating functional end cells such as neurons or cardiomyocytes remains challenging.

Adult stem cells, such as bone- or bone marrow-derived mesenchymal stromal cells (MSCs), are considered an ethically and morally acceptable alternative to embryonic stem cells and induced pluripotent stem cells. While initially thought to be more restricted in their potential applications, the identification and characterization of MSCs in an increasing number of tissues has led to a surge of research and clinical interest in utilizing these cells for cell-based regenerative therapies [2,3]. Furthermore, clarification on the multifaceted mechanisms by which these cells exert their effects has allowed better understanding of the modulation of stem cell activity both *in vitro* and *in vivo* [4].

True mesenchymal stem cells that fulfill the criteria of both self-renewal and differentiation to functional end cells have been described. However, mesenchymal stem cells are rare cells and therefore their progeny - undifferentiated mesenchymal stromal (or progenitor) cells – are isolated by expansion in *ex vivo* culture for most laboratory investigations and for clinical trials. The abbreviation MSCs will refer to mesenchymal stromal cells in this chapter unless specifically indicated otherwise.

Bone regeneration is an area that may benefit from a cell-based approach [5]. Each year, millions of patients undergo treatment for bone fractures, with most healing satisfactorily using current orthopedic techniques. Nevertheless, fracture nonunion and bone defects remain a significant clinical challenge in a minority of such cases, especially when associated with diseases such as diabetes, osteoarthritis, and osteoporosis [6]. While several studies have shown efficacy of cell-based therapy for bone regeneration, many issues remain unresolved. For instance, a clear understanding of the molecular mechanisms governing

osteogenic differentiation of MSCs *in vivo* remains to be established. More recently, better insights into the optimal sources of MSCs that demonstrate osteogenic propensity and how these contribute to tissue repair *in vivo* are emerging. Finally, the ability to monitor implanted cells to assess where they go and what they do when they arrive there is necessary for further development of successful therapies. Here, we explore these issues and examine the success to date of MSCs in the context of a cellular therapy in bone-related orthopedic disorders.

## 12.2 Biology

### 12.2.1 Sources of mesenchymal stromal cells

Mesenchymal stem/stromal cells were first described by Friedenstien *et al.* as plastic-adherent cells capable of differentiation towards the osteogenic lineage [7]. Subsequently, the ability of MSCs to differentiate towards the chondrogenic lineage was shown, identifying a role of the cells in cartilage as well as endochondral bone formation [8,9]. Similarly, the osteogenic differentiation of MSCs facilitates direct bone formation via intramembranous ossification. This ability to form bone via multiple lineages has led to extensive research into these cells for tissue engineering applications. Since their discovery in bone marrow, MSCs have been identified in virtually every tissue within the body, including adipose tissue and placenta [10–14]. Interestingly, the location of MSCs within each tissue seems to affect their physiological function and differentiation capabilities. Nowhere is this more evident than within bone and bone marrow.

MSCs in bone and bone marrow exist within a number of anatomical locations. Two distinct niches exist in bone marrow: the perivascular niche where MSC precursors known as pericytes exist in association with blood vessels [15], and the endosteal or bone-lining niche, where MSCs are found on the surface of bone [16–18]. MSC progeny such as osteoblasts and fibroblasts are found at the endosteal niche [18]. Additionally, lining the surface of bone is a thin layer of connective tissue known as the periosteum that has also been identified as a source of MSCs [19–21]. It is unclear which endogenous cell population contributes toward tissue repair after fractures with no evidence to date definitively identifying the population of MSCs responsible for bone repair. A comprehensive review on the healing of postnatal fractures by Gerstenfeld *et al.* highlighted this issue [22]. During fracture healing, bone repair is initiated in distinct crescent-shaped cartilaginous centers. Two centers develop symmetrically to the fracture line with intramembranous bone formation occurring concurrently at separate centers proximally and distally. These two distinct bone healing responses initiated upon injury may be induced by different cells located in the surrounding tissue. The bone marrow itself and the surrounding periosteum and soft tissue may all be sources of these reparative cells [22]. The periosteum is believed to be the primary source of cells required to form the callus [23], with removal of the periosteum resulting in incomplete fracture callus formation [22]. The periosteum has also been proposed as a novel source of progenitor cells capable of contributing to bone regeneration [21]. In a direct comparison, periosteum-derived rat MSCs produced 100-fold more colonies than bone marrow-derived MSCs and had a higher proliferative rate and trilineage differentiation potential [20]. Periosteal cells also maintained chondrogenic differentiation potential *in vitro* after prolonged culture [24]. Human studies on the periosteum as a source of such cells has also identified this tissue as being superior to other sites in terms of *in vitro* differentiation and proliferation potential [25]. Skeletal muscle has also been explored as a potential source of osteoprogenitors that contribute to bone formation. Ectopic bone formation can occur within muscle [26], and a subpopulation of muscle progenitor cells, identified by expression of alkaline phosphatase (ALP) after exposure to bone morphogenetic protein (BMP)-2, was observed in the lacunae of newly formed bone matrix when injected into the hindlimbs of mice with severe congenital immune deficiency. These cells are co-localized with osteocalcin (OC)-producing cells, indicating potential differentiation to osteoblasts and osteocytes [26].

However, identification of a definitive cell source for endochondral ossification in fracture callus has not been described. A number of MSC populations within the bone marrow that may contribute to bone repair have been identified based on expression of surface markers. Sacchetti *et al.* identified a population of osteoprogenitors based on expression of CD146 (also known as melanoma cell adhesion molecule) [17]. These cells were deemed to be *bona fide* mesenchymal stem cells after subcutaneous transplantation into nude (athymic immune deficient) mice resulted in formation of bone and induced the hematopoietic stem cell niche [17]. Prior to this, CD271, also known as low-affinity nerve growth factor receptor, was shown to select for the entire fibroblastic colony-forming unit (CFU-F) population within bone marrow, thus identifying the MSC fraction [27]. $CD271^+$ cells were subsequently shown to reside in the intramedullary cavity of long bones [28]. Combining both CD146 and CD271 expression resulted in the identification of the two distinct MSC niches already described: the endosteal niche and the perivascular niche, with $CD271^+$ $CD146^+$ cells residing in the perivascular niche and $CD271^+$ $CD146^-$ residing in the endosteal niche [29]. The presence of MSCs at a bone-lining niche and their osteogenic potential suggest a role for these cells in maintaining bone homeostasis (and see Chapter 32).

### 12.2.2 Cellular regulation of osteogenic differentiation from mesenchymal stromal cells

Bone is a highly dynamic tissue composed of type I collagen deposited with hydroxyapatite, also known as calcium phosphate. This provides the framework of the highly cellularized, highly vascularized bone tissue. It has been reported that approximately 10% of bone in adult vertebrates is remodeled every year [30]. For normal bone homeostasis this process must be highly regulated, with dysregulation resulting in catabolic bone

diseases such as osteoporosis and anabolic bone diseases such as osteopetrosis [31]. The three main cellular components involved in skeletogenesis and bone homeostasis are osteocytes and osteoblasts, which differentiate from MSCs, and osteoclasts derived from a hematopoietic stem cell lineage [32,33]. There are three modes of communication between osteoblasts and osteoclasts as outlined by Matsuo and Irie [34]. The first occurs via direct contact, whereby membrane-bound ligands interact with receptors, most notably the receptor activator of nuclear factor kappa-B and its ligand (RANK/RANKL). The second is the formation of gap junctions mediated by connexin 43 between the two cells, which allows passage of water-soluble molecules [35,36]. The third method of communication is the production and recognition of paracrine factors such as sclerostin, a potent inhibitor of bone formation [37]. Immune cells have also been reported to mediate bone homeostasis, which will be discussed later [38,39].

Coupling of osteoblasts to produce new bone and osteoclasts to resorb bone is essential for maintenance of healthy bone, and this process is dependent on RANK, its ligand RANKL, and the decoy receptor osteoprotegerin (OPG) (Figure 12.1) [40].

Of the three molecules, OPG was the first to be discovered owing to its inhibitory effect on osteoclast development both *in vitro* and *in vivo* [41,42]. As a consequence, it was initially termed osteoclastogenesis inhibitory factor (OCIF) before being rebranded as OPG, meaning "protector of bone" [43]. Concurrently, members of the tumor necrosis factor (TNF) cytokine family were described; TNF-related activation-induced cytokine (TRANCE), now commonly referred to as RANK [44] and its ligand RANKL, was also identified by the same group as a highly upregulated molecule in T cells after antigen stimulation [43].

One of the key functions of osteoblasts, besides induction of mineralization of bone extracellular matrix, is induction of osteoclast differentiation [45]. This process is highly regulated, with the immune system being a key player. The existence of the relationship between the immune system and bone has been known for some time and highlights the complexity involved in maintenance of bone homeostasis. Studies carried out nearly four decades ago reported the ability of stimulated immune cells to produce soluble factors capable of inducing osteoclast-mediated bone resorption [46]. Since then, the role of the immune system in bone homeostasis has been widely reported, particularly as similar pathways are activated during development of both systems [47]. In bone, RANKL is produced by osteoblasts and is fundamental to osteoclast activation and differentiation [40]. Apart from osteoblasts, a number of immune cells also produce RANK, including B cells, T cells, monocytes, neutrophils, and dendritic cells [38,39]. This is a key mechanism of immune activation of osteoclast differentiation and results in increased bone resorption. Furthermore, these immune cells can also produce proinflammatory cytokines that can lead to bone damage, adding to the bone loss effect that occurs through the RANK/RANKL pathway [48,49]. In mouse models, disruption of either RANK or RANKL results in mice presenting with an osteopetrotic ("stony bone" or marble bone disease) phenotype and tooth defects due to a lack of osteoclasts to negatively regulate bone [50]. Conversely, mice lacking OPG present with advanced osteoporosis due to the increase in osteoclast number and activity [50]. A number of disease states have been identified in humans due to mutations in the RANK/RANKL system, including Paget's disease of bone, which occurs as a result of mutated OPG [51], familial expansile osteolysis due to mutations in RANK [52], and autosomal recessive osteopetrosis due to RANKL mutations [53].

Stimulation of RANKL in osteoblasts can be regulated by a number of factors, which include parathyroid hormone (PTH), PTH-related protein (PTHrP), 1,25-$(OH)_2$-vitamin-$D_3$, TNF-α, and interleukins (ILs) such as IL-8 and IL-17 [54–57]. Conversely, attenuation of RANKL expression can be regulated by transforming growth factor β (TGF-β) and estrogens [57]. As a result, this pathway has been a therapeutic target for drug development for bone loss diseases such as osteoporosis (Figure 12.2). Similarly, estrogen-dependent RANKL expression can account for the high prevalence of osteoporosis in postmenopausal women with reduced estrogen levels. The incidence of osteoporosis in those over the age of 50 is three to four times higher in women than men [58]. This is due primarily to the decrease in estrogen levels postmenopause [59]. Reduced estrogen levels lead to reduced OPG expression, shifting normal bone

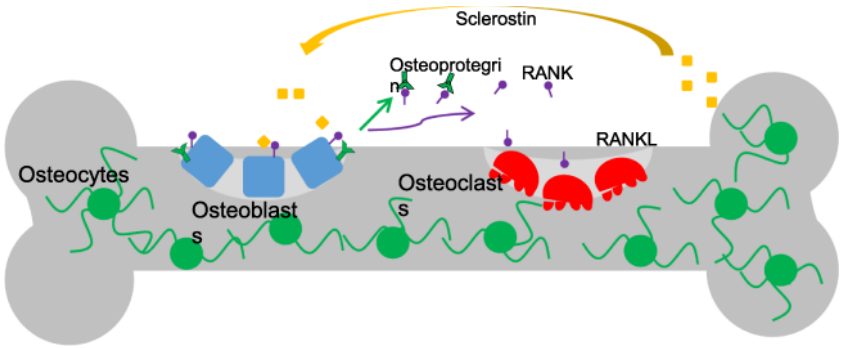

**Figure 12.1** RANK/RANKL/OPG interaction in osteoblast/osteoclast communication. Bone-lining osteoblasts produce RANK, which can bind to RANKL on osteoclasts. Osteoblasts also produce decoy receptor OPG, which can dampen the effect of RANK on osteoclasts. As osteoblasts get embedded in new bone, they terminally differentiate into osteocytes, which secrete sclerostin through their dendrites, which can inhibit the action of osteoblasts. (See color plate section.)

**Figure 12.2** Osteoporosis. Lateral spine X-ray showing wedge fractures of lumbar vertebrae 1 and 2 due to severe osteoporosis. *Source*: http://commons.wikimedia.org/wiki/File:L1_2_vertebral_fracture.jpg#mediaviewer/File:L1_2_vertebral_fracture.jpg.

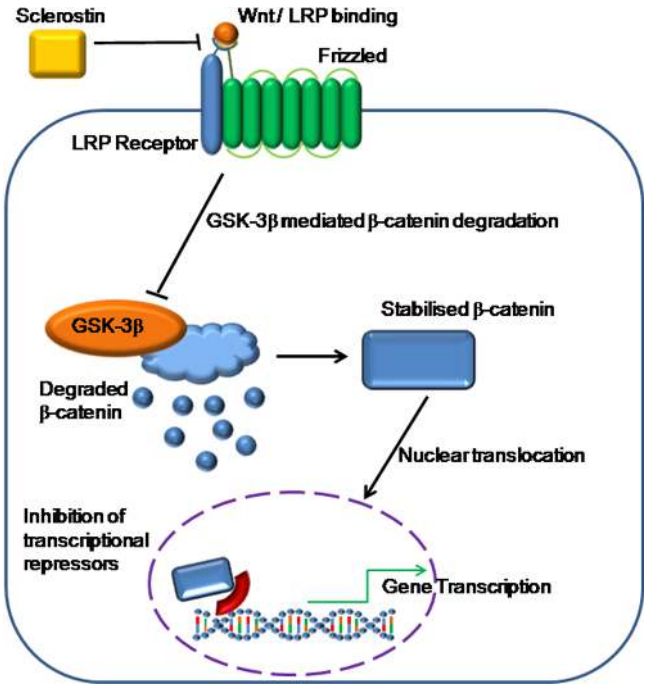

**Figure 12.3** Sclerostin inhibition of Wnt canonical pathway induction of osteogenesis. Sclerostin binding to LRP receptor prevents formation of a Wnt/FZD/LRP complex with GSK-3β resulting in degradation of β-catenin in the cytosol. Thus, transcriptional repressors of *Runx2* gene are not inhibited and *Runx2* gene transcription does not occur.

homeostasis toward bone resorption and the typical menopause-induced bone loss [60]. Equivalently in men undergoing androgen-deprivation therapy for prostate cancer, decreased testosterone levels lead to increased bone turnover and bone loss [61].

In addition to the interplay between osteoblasts and osteoclasts, osteocytes or terminally differentiated osteoblasts embedded within bone matrix are also involved in regulation of bone. Sclerostin encoded by the SOST gene and a potent inhibitor of bone formation is produced for the most part by embedded osteocytes and is secreted through the processes or dendrites of these cells [62]. It is also produced by other cells embedded in a matrix, such as cementocytes in teeth and hypertrophic chondrocytes during growth plate development and osteoarthritis [63,64]. Although expression of sclerostin mRNA has been reported in a number of other tissues post-natally, including heart, liver, and high levels in the kidneys [65], sclerostin protein has only been reported by cells within matrix-rich tissues such as bone [62]. Sclerostin inhibition of bone formation has previously been reported to function through inhibition of the Wnt canonical pathway [66].

## 12.2.3 Molecular regulation of osteogenic differentiation from mesenchymal stromal cells

The molecular cues required to direct MSCs to form osteoblasts are not fully understood. However, a number of factors necessary for the process have been identified. These include transcription factors such as Runt-related transcription factor 2 (RUNX2), growth factors such as BMPs and TGF-β, along with the Wnt pathway. Recently, the role of Wnt has received increased attention owing to the identification of novel therapeutic targets of the pathway, such as the generation of antibodies against the Wnt antagonists sclerostin and Dickkopf factor 1 (DKK1), which will be explored further later.

### 12.2.3.1 Wnt pathway

The Wnt canonical pathway is essential for lineage regulation of MSCs and osteochondral progenitors to an osteoblast phenotype (Figure 12.3) [67,68].

The pathway is evolutionarily highly conserved and plays an important role in cell-to-cell communication, cell proliferation, migration, and differentiation during development and healing [69,70]. Moreover, Wnts also prevent osteoblast and osteocyte apoptosis by both canonical-dependent and -independent mechanisms [71]. Secreted frizzled related protein 1 (SFRP-1), an antagonist of the Wnt canonical pathway, has also been suggested to play a role in the regulation of osteoblast/osteocyte apoptosis [72]. Understanding the role of inhibitors of the Wnt pathway, such as sclerostin, has been possible due to knockout models of the Wnt canonical pathway and has resulted in the development of a number of therapeutic avenues currently being explored in regenerative orthopedics [73–76].

A combination of canonical and noncanonical Wnt signaling is essential for normal cell physiology. The Wnt/β-catenin or canonical pathway is essential for bone development [77–79]. During activation of this pathway, Wnt binding to Frizzled (FZD) receptor and either of the low-density lipoprotein receptors (LRPs) 5 or 6 results in a number of intercellular events. These include stabilization and accumulation of β-catenin in the cytosol and its ultimate translocation to the nucleus [80]. Here, β-catenin displaces repressors of target genes normally involved in bone formation, including *RUNX2* and downstream genes of *RUNX2* such as *OC* [81–83].

A number of endogenous inhibitors of this pathway exist that primarily function by interfering with the formation of the Wnt/LRP/FZD complex [84]. These include sclerostin, DKK1 [85,86] and sclerostin-domain-containing protein-1 (SOST-dc1), also known as WISE [83]. The molecules act by binding to the LRP5 and LRP6 receptors, preventing Wnt binding to the LRP/FZD complex. Other inhibitors of this pathway include SFRP1 and Wnt inhibitory factor (WIF), which bind directly to Wnt [84,87–89], preventing its binding to receptors.

DKK1 and sclerostin antagonize the Wnt canonical pathway. The inhibitory function of SOST-dc1 has only been demonstrated in tooth development to date [90]. Although early invertebrates expressed DKK1 [91,92], sclerostin expression has only been reported in bony vertebrates, which has previously been suggested to be due to sclerostin function being specific to bone [93]. Interestingly, positive expression of sclerostin has also been detected from osteocytes of a *Tyrannosaurus rex* dinosaur, implying that dinosaur bone was regulated similarly to that of extant vertebrates, indicating the highly conserved nature of sclerostin [94].

Although DKK1, SOST-dc1, and sclerostin all affect the Wnt pathway in a similar way [95], the apparent specificity of sclerostin to bone seems to suggest a more targeted effect of sclerostin to bone. The role of the Wnt pathway is highlighted in studies of mesenchymal progenitor cell differentiation during vertebrate skeletogenesis. Inactivation of β-catenin results in chondrocyte differentiation instead of osteoblast differentiation in models of both endochondral and intramembranous ossification, indicating a role for β-catenin in the regulation of the switch between osteogenesis and chondrogenesis [67,96].

#### 12.2.3.2 TGF-β superfamily

The TGF-β superfamily of secreted molecules, including BMPs, has also been identified as a key factor in the induction of bone formation [97]. TGF-β/BMP signaling is involved in a wide array of cellular processes during bone formation, both prenatally and postnatally. TGF-β/BMPs act via two pathways during bone formation, which merge at the *RUNX*2 gene directing MSCs towards differentiation [97]. The first pathway is the canonical SMAD-dependent pathway in which isoforms of TGF-β and their receptors TGF-βRI (ALK5) and TGF-βRII (TGF-βR2) are essential for both intramembranous and endochondral ossification [98]. The noncanonical TGF-β pathway, which is not dependent on SMAD, is also essential for osteoblast differentiation [98]. The noncanonical pathways are activated by direct ligand-bound receptor activation to modulate downstream cellular processes [99]. *In vitro* analysis of murine osteoprogenitors deficient in TGF-βRI indicated that TGF-β is involved in proliferation, differentiation and osteoblast lineage commitment via selective MAPKs and SMADs 2/3 pathways [100]. The phenotype of animals with a TGF-βRI defect displayed skeletal abnormalities, including the presence of short and wide long bones and reduced bone collars and trabecular bone. Moreover, TGF-βRI-deficient mice possessed growth plates with unusually thin perichondral cell layers, which the authors suggested may have been associated with the short bones and ectopic cartilaginous protrusions observed [100]. This indicates the essential role of TGF-β signaling in perichondrium formation and differentiation and growth plate integrity during development [100].

BMPs belong to the TGF-β superfamily and are heavily involved in bone and cartilage formation. BMPs play a role in bone maintenance by binding to either BMP receptor type-1A or -1B (BMPR-1A or BMPR-1B) to direct osteoblast cell function [101]. BMPR-1A in mouse osteoblasts negatively regulated bone mass by upregulation of the WNT inhibitors sclerostin and DKK1 [102]. BMPs have also been shown to positively regulate expression of osteoblast proteins associated with bone formation such as ALP, OC, osterix, and RUNX2 [103,104]. Binding of BMPs to their receptors results in mobilization of receptor-regulated SMADs, namely SMADs 1, 2, 3, 5, and 8 [103]. These SMADs are phosphorylated and form a co-SMAD protein with SMAD 4 that is ultimately translocated to the nucleus, where it exerts its effect. At the nucleus, this co-SMAD protein interacts with the osteogenesis master gene *RUNX2* to facilitate gene transcription [103].

In addition to TGF-β signaling, a number of BMPs are involved in regulation of bone. Overexpression of BMP-6 and BMP-2 results in increased osteogenic differentiation *in vitro* and *in vivo*, with BMP-6 having the greatest effect [105]. BMP-2 is involved in initiating osteoblast differentiation and regulating bone mineral density [106]. Knockout studies indicate a role of BMP-2 and -4 in normal bone development and maintenance, since knockouts of these factors resulted in reduced osteogenesis and bone fracturing [98]. BMP-7, or osteogenic protein-1 (OP-1), has been used clinically for the treatment of long bone, scaphoid, and nonunion fractures. Similarly, there is supportive evidence for the use of BMP-7 as a therapy for spinal fusion and as a replacement for autografts [107]. However, BMP-7 knockdown does not result in an observable negative effect in bone development or maintenance [108]. Conversely, BMPs such as BMP-3 negatively regulate bone marrow stromal cells, with targeted deletion of BMP-3 resulting in increased trabecular bone loss and transgenic overexpression of BMP-3 leading to spontaneous fractures [109].

#### 12.2.3.3 Transcriptional regulators

The transcription factors that regulate osteoblast differentiation can be divided into two groups. The first are those that are specific to various stages of osteoblast differentiation and include RUNX2, osterix, and activating transcription factor 4. The second group of transcription factors are those that are not specific to osteoblasts but act downstream of other pathways but can nonetheless regulate the differentiation process. Examples of these include Twist-1 and Twist-2 [110,111].

*RUNX2*, also referred to as core-binding factor alpha 1, is widely considered the master gene for osteogenic differentiation, being essential for both intramembranous and endochondral bone formation [112]. *RUNX2* expression is typically observed with loss of expression of proliferator-activated receptor-γ (*PPAR-γ*), indicating a switch between differentiation of MSCs toward adipogenic or osteogenic lineages [113]. A number of downstream genes from *RUNX2*, including *OC*, *ALP*, bone sialoprotein (*BSP*), and osteopontin, are essential for various processes during bone formation, including osteoblast differentiation, production of matrix, and mineralization during bone formation. RUNX2 mediates its effect via a direct binding site called osteoblast-specific cis-acting element (OSE2) that is present in the osteoblast-specific genes mentioned earlier [114]. The essential role of RUNX2 has been evaluated in overexpression and knockdown studies. In CBAF1 null mice, neither endochondral nor intramembranous bone formation occurred due to an arrest in osteoblast differentiation [115,116]. Additionally, CBAF1-overexpressing chondrocytes underwent endochondral ossification at an accelerated rate [116]. These studies demonstrated the role of RUNX2 as a key regulator of both intramembranous and endochondral bone formation. Overexpression of RUNX2 in bone marrow-derived MSCs resulted in increased expression of ALP, OC, OP, and BSP [117]. Moreover, increased mineralization *in vitro* was also reported [117]. When MSCs overexpressing RUNX2 were used to treat a cranial defect in BALB/c mice, increased wound healing was observed [117]. These data indicate a role for RUNX2 in both *in vitro* and *in vivo* osteogenesis of MSCs.

As mentioned previously, Twist proteins have also been reported to regulate osteogenesis. Twist is a basic helix–loop–helix transcription factor that reduces mRNA levels of CBAF1 by binding to OSE2 in the OC reporter [118]. In *Drosophila*, Twist acts to regulate mesoderm formation and dorsal–ventral patterning. In mammals, Twist-1 and Twist-2 are essential for normal bone formation. In both human and mouse, Twist-1 heterozygotes exhibit premature osteoblast differentiation in the skull [119]. Additionally, Twist-1 and Twist-2 heterozygotes and Twist-2 homozygote negatives died early after birth due to activation of multiple cytokine pathways [119,120]. Twist suppresses osteogenesis through either RUNX2 or histone deacetylases, with a reduction in levels prior to the onset of osteogenesis [121].

The transcription factors discussed are involved in regulation of osteogenesis. However, additional transcription factors are involved in osteochondrogenesis and so also contribute to bone formation. These include SOX9 and musculoaponeurotic fibrosarcoma oncogene homologue [121,122].

### 12.2.4 Factors regulating homing of mesenchymal stromal cells to bone

MSCs exist within all vascularized tissues and organs and have been shown to be capable of homing to injured tissues. This has been observed in a number of injury models, including migration of MSCs to bone fractures [123–125], lung injury [126], brain injury [127], and to sites of wound healing [128]. Mobilization of MSCs to other injury sites has also been reported [129]. The mechanism of this homing of MSCs is the subject of an intense research effort in the hope of identifying a means of improving tissue repair by endogenous cells. The current consensus suggests that injured tissue produces factors and ligands that can be used by MSCs to migrate, adhere, and infiltrate damaged tissue [130–132], a process similar to that by leukocytes migrating to sites of inflammation. This idea was validated in a recent paper that described the migration of MSCs in an *in vitro* model [133]. MSC migration was dependent on their ability to adhere to, and migrate through, TNF-α-activated endothelium, a process dependent on both the G-protein-coupled receptor and vascular cell adhesion molecule (VCAM-1) pathways. The process is shown in Figure 12.4.

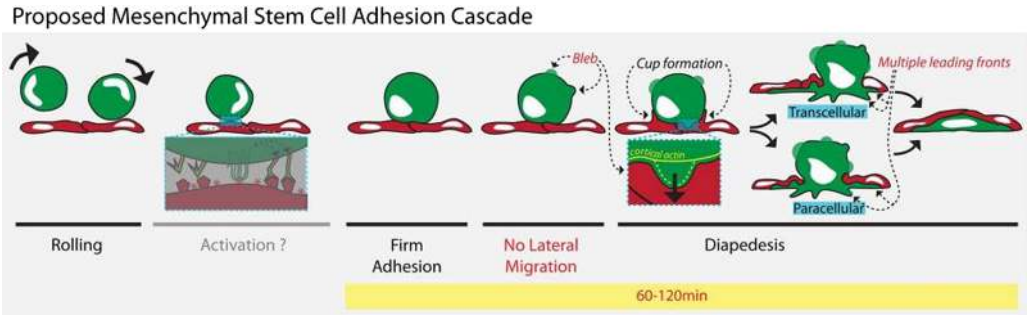

**Figure 12.4** Proposed mechanism of MSC migration to injured tissue in comparison with leukocyte migration to inflammation. (See color plate section.)
*Source*: Teo 2012 [133], pp. 2472–2486. Reproduced with permission of John Wiley and Sons.

First, rounded MSCs adhere to epithelium in an integrin-dependent manner. Next, a transmigratory cup is formed in which VCAM-1-enriched microvilli projections extend around the MSC and form a cup shape. The next step involves formation of a gap or pore by a process described as blebbing in which MSCs apply a force on the epithelium that is associated with the formation of gaps or pores. This stage is not observed in the migration of leukocytes, which migrate through intact gap junctions, a process known as diapedesis. Following this, MSCs penetrate and spread through the subendothelium layer and transmigration is complete [133].

Initiation of this migration is induced by chemokines and cytokines at the site of injury. A number of studies of the chemotactic effect of particular cytokines on the migration of MSCs have been performed. C–X–C chemokine receptor type 4 (CXCR4), the receptor for stromal-derived factor-1 (SDF-1) that is encoded by the C–X–C motif chemokine 12 (*CXCL12*) gene, has been associated with migration of murine and human MSCs from various sources, including bone marrow, adipose tissue, and umbilical cord [134–138]. In these studies, overexpression of CXCR4 enhanced the migratory ability of MSCs [139]. The migration of MSCs to sites of fracture healing is exclusively CXCR4 dependent, with migrated MSCs contributing to fracture repair by production of BMP-2 when they engraft in the fracture site [123]. Additionally, during healing of live bone grafts, increased expression of SDF-1 messenger RNA is observed in the periosteum, with the addition of anti-SDF-1 antibody inhibiting bone formation [140]. This study also reported the ability of CXCR4-expressing MSCs, which had homed to the site of bone injury, to contribute to bone repair via endochondral ossification [140]. In addition to CXCR4, a number of additional factors have been identified that can both enhance and reduce MSC migration [141]. In a study by Ozaki *et al* 26 growth factors were assessed for migration of human and rabbit MSCs. Factors that consistently enhanced MSC migration were platelet-derived growth factor (PDGF)-BB and -AB, epidermal growth factor, TGF-α, fibroblast growth factor-2, insulin-like growth factor, and hepatocyte growth factor, with PDGF-BB having the greatest effect on migration. Interestingly, combinations of growth factors that shared the same receptor did not result in an enhanced effect on migration of MSCs, while other combinations, such as FGF-2 and PDGF-BB, actually inhibited migration. This indicates a highly complex, regulated process of MSC migration (and see Chapters 22 and 23).

### 12.2.5 *In vivo* detection and contribution of mesenchymal stromal cells to osteogenesis

The potential of cell-based therapies for tissue regeneration is well accepted. Although the paradigm may have shifted from the initial belief that implanted cells fundamentally contribute to regeneration through direct incorporation into the tissue to a more complex understanding of the importance of indirect regeneration via paracrine mechanisms, the ability to monitor implanted cells in order to assess where they go and what they do when they arrive is necessary for the development of more successful therapies. A variety of modalities based on bioluminescent imaging, single-photon emission computed tomography, positron emission tomography, multiple photon microscopy, and magnetic resonance imaging are currently used for preclinical tracking of MSCs *in vivo*. Labeling of the cells is necessary for visualization and may include contrast reagents such as quantum dots [142,143], superparamagnetic iron oxide nanoparticles [144–146], or reporter genes such as luciferase and green fluorescent protein (GFP). Despite the apparent high level of choice of reagents, they are not without issues owing to the short half-life of the reagent [147], donor-to-host transfer [148–151], and virus toxicity [152].

While the clinical importance of *in vivo* tracking of MSCs is obvious, the contribution of the cells to tissue repair at their target destination requires clarification. Some common methods to address this include lineage mapping, sex-mismatched donor–recipient pairs, and detection of the human Alu sequence in human cells in the tissue of animal models [153–155]. In one study, human MSCs were transplanted subcutaneously into immune-compromised mice either undifferentiated or after *in vitro* chondrogenic preinduction for 6 weeks. Using *in situ* hybridization, the authors delineated the contribution of human cells to tissue formation via detection of human-specific Alu repeat sequences. Interestingly, the authors showed that after 8 weeks' subcutaneous implantation in mice, bone-lining cells producing new bone were of human origin while adjacent bone marrow was of murine origin [153]. Using a GFP reporter model, Kalajzic *et al.* identified a defined population of mesenchymal progenitor cells expressing α-smooth muscle actin (α-SMA) that were associated with the perivascular niche and demonstrated pro-osteogenic characteristics [156]. In a related study, Grcevic *et al.* created male α-smooth muscle actin promoter-directed Cre recombinase estrogen receptor ligand-binding domains (αSMACreERT2) transgenic mice that were crossed with female Ai9 reporter mice to allow temporal and spatial detection of the $\alpha SMA^+$ progenitor cells by tamoxifen-induced Cre recombinase activated tdTomato expression [155]. tdTomato is an exceptionally bright red fluorescent protein - 6 times brighter than EGFP. Using this approach the authors traced the $\alpha SMA^+$ progeny into mature osteoblasts and terminally differentiated osteocytes. Interestingly, in a tibial fracture repair model the majority of the callus cells, including chondrocytes and osteoblasts, were identified as $SMA9^+$-expressing cells [155]. Mizoguchi *et al.* used double-transgenic osx-creERT2/ROSA26-loxP-stop-loxP-tdTomato (iOsx/Tomato) reporter mice to trace osterix-expressing ($osx^+$) cells to delineate three distinct mesenchymal precursors in fetal, perinatal, and adult bone marrow [157]. To assess whether the iOsx/$Tomato^+$ stromal cells displayed mesenchymal stromal and progenitor cell characteristics, the authors then generated Nes-Gfp/iOsx/Tomato triple-transgenic mice. They observed that approximately 85% of iOsx/$Tomato^+$ bone marrow cells also expressed

Nes-GFP. In a previous study, the same group had identified leptin receptor positive cells ($Lepr^+$) overlapping with those cells of the bone marrow that were Nes-$GFP^+$ [158]. Interestingly, the majority of iOsx/$Tomato^+$ cells that were positive for Nes-GFP also expressed leptin receptor and previously identified mesenchymal stromal and progenitor cell markers [158]. However, Lepr expression was initially low in iOsx/$Tomato^+$ cells after 1 day of exposure to tamoxifen, which suggested a temporal increase in Lepr expression in the postnatal day 5 (P5)-iOsx/$Tomato^+$ bone marrow cells during bone maturation. The authors also investigated the contribution of $Lepr^+$ cells to bone tissues in Nes-Gfp/Lepr-cre/Tomato triple-transgenic mice and found that Lepr-cre-derived $Tomato^+$ cells (Lepr/$Tomato^+$) expressed Nes-GFP, PDGFR-α, and PDGFR-β, which have been previously identified as markers of mesenchymal stromal and progenitor cells [158]. Moreover, clonally derived Lepr/$Tomato^+$ cells were capable of trilineage differentiation, which the authors suggested implied that these populations associate with bone marrow P5-iOsx/$Tomato^+$ cells. Subsequent experiments showed that Lepr/$Tomato^+$ mature osteolineage cells were descendants of $Lepr^+$ precursors and that iOsx/$Tomato^+$ cells that co-expressed Lepr-cre appeared to be a source of osteoprogenitors that contributed to bone homeostasis. To further explore this relationship, a tibial fracture model was employed to determine the contribution of iOsx/$Tomato^+$ and $Lepr^+$ cells to bone regeneration. Both iOsx/$Tomato^+$ and lepr/$Tomato^+$ cells were identified within the periosteum, indicating a role in the fracture healing process. The iOsx/$Tomato^+$ cells were identified within the soft callus approximately 8 days after the fracture, and within this population a subset of cells also expressed SOX9. Lepr/$Tomato^+$ cells were also detected as $SOX9^+$ cells in the fracture callus in Lepr-cre/Tomato mice, thus supporting their role in bone regeneration [157] and correlating with findings of Ono *et al.* [154]. It will be of interest to assess the association between $iOsx^+$, $Lepr^+$, and $SMA9^+$ cell in a similar repair model.

### 12.2.6 Regulating the immune system for bone formation

In addition to their ability to differentiate into multiple tissue types, MSCs are also being considered as a therapeutic agent based on their immunomodulatory properties [159]. Osteoimmunology or how the immune system regulates bone formation is an emerging field in bone biology [160–163]. Numerous types of immune system cells, including B cells, T cells [164], natural killer cells [165], and dendritic cells [166], have all been reported to play a role in osteoclast function. The high level of interaction is not surprising as osteoclasts are terminally differentiated macrophages [166]. B cells have been reported to induce osteoclast apoptosis via production of TGF-β1 [165], reducing levels of bone resorption and hence increasing overall bone mass. The effect of cytokines secreted by cells of the immune system has also been reported to play a role on osteoblast function, although this has not been defined to the same extent as for osteoclasts. In addition to the inhibition of osteoblast differentiation by TNF-α [167], TNF-α, interferon-γ (IFN-γ), and IL-1 have all been reported to suppress collagen type I synthesis by osteoblasts [160,168–170]. There are conflicting data on the mechanism by which T cells activate osteoblastogenesis. However, it is logical to assume that any cell attempting to differentiate into bone in an environment at least partially governed by the immune system needs to be able to act in an immunomodulatory or suppressive manner. A growing body of *in vitro* and *in vivo* data now exists to support the idea that MSCs can act as immunosuppressive agents [159,171–174]. The low level of immunogenicity of MSCs as a consequence of their low expression of major histocompatibility complex (MHC) class I molecules and absence of MHC class II molecules and absence of CD40, CD80, and CD86 co-stimulatory molecules has been a driving force toward the clinical use of these cells [175–178]. Owing to this lack of immunogenicity, MSCs in theory should elicit little to no immune response by the recipient's immune system, which in turn suggests that allogeneic transplantation from unrelated and MHC-unmatched MSC donors should be clinically feasible. The mechanisms by which MSCs exert their immunomodulatory effects include both the production of soluble factors and direct cell-to-cell contact [179,180]; and see Chapters 33 and 34. There are a number of soluble factors produced by MSCs that play a role in MSC-mediated immunosuppression, including indoleamine 2,3-dioxygenase (IDO), TGF-β1, prostaglandin $E_2$, nitric oxide, hepatocyte growth factor, and human leukocyte antigen-G. The production of soluble immunosuppressive factors such as IDO requires initial activation of MSCs by immune-cell-mediated IFN-γ, which can work synergistically with a combination of IL-1α, IL-1β, and TNF-α [180,181]. T cells were the first cell of the immune system to be demonstrated to be suppressed by MSCs [182]. This effect has been observed with autologous, allogeneic, and xenogeneic MSCs [173,175]. Similarly, activated B cells are suppressed by MSCs in the presence of exogenous IFN-γ [181]. This effect is through release of factors that both increase B cell viability while also inhibiting proliferation and arresting the cells in the $G_0/G_1$ phase of the cell cycle [183].

## 12.3 Clinical applications of mesenchymal stromal cells in bone disorders

### 12.3.1 Bone regeneration

Clinical trials investigating the efficacy of MSCs in bone regeneration are limited to early phase I and II studies. Indications for these trials include avascular necrosis of bone (osteonecrosis) (NCT016105383), distraction osteogenesis with limb length discrepancies (NCT01210950), and fracture nonunion (NCT01206179, NCT01429012, NCT01842477). Completed trials investigating the use of autologous MSCs for the treatment of nonunion fractures have not yet been published (NCT01206179, NCT02177565). Quarto *et al.* have demonstrated healing of

nonunion fractures in a three-patient pilot study involving bone marrow-derived osteoprogenitors implanted in the defect site on a custom-fit hydroxyapatite scaffold [184]. Hernigou *et al.* treated 60 cases of tibial nonunion with a percutaneous infusion of concentrated autologous bone marrow cells [185]. Bone union was achieved in 53 patients. In those patients where bone union was not achieved, significantly fewer progenitor cells were present [185]. Similar successful outcomes using bone marrow-derived cells for the treatment of nonunion fractures have been reported with significant follow-up times [186]. Hibi *et al.* described the treatment of an alveolar cleft defect in a 9-year-old female patient with culture-expanded, osteogenically induced bone marrow-derived MSCs using platelet-rich plasma as a scaffold material [187]. Regenerated bone was evident 3 months after implantation with approximately 79% bridging observed after 6 months. Mesimäki *et al.* reported the first clinical case in which ectopic bone was produced using autologous adipose-derived stem cells (ADSCs) in a microvascular reconstruction study of the maxilla [188]. The expanded autologous ADSCs were seeded onto a β-tricalcium phosphate scaffold containing recombinant human BMP-2. This cell-seeded scaffold was implanted beneath a muscle flap of the rectus abdominus muscle, where it remained for 8 months. Integration was described as excellent at 4 months after implantation [188]. Determining the relative contribution of cells, scaffold, or growth factors to tissue regeneration in these studies is difficult. Several other small clinical studies using MSCs and ceramic scaffolds for the treatment of cranio-maxillofacial defects have been reported [189]. Generally, restorative dentistry has proved relatively successful for MSC-based bone tissue engineering approaches, most likely given the non-load-bearing nature of this anatomical site. The treatment of long bone defects, however, still remain largely centered on animal studies.

The lack of clinical activity in this specific area may arise from the challenges faced relating to treatment of bone defects in long bones, such as the size of the defect and the mechanical environment (i.e., high load). While several animal studies support the concept of a cell therapy approach for the treatment of bone defects [190,191], there are also other studies that failed to find a positive outcome of human bone marrow aspirate or MSCs in the treatment of femoral defects [192]. In recent years a more biologically tailored approach to MSC-based therapies for the treatment of long bone defects has been attempted. Specifically, chondrogenic predifferentiation of MSCs in an attempt to favor endochondral ossification within the defect site has been reported [153,191,193,194]. Van der Stok *et al.* implanted undifferentiated and *ex vivo* chondrogenically predifferentiated MSCs into a 6 mm rat femoral defect. In all cases chondrogenically differentiated pellets induced significantly more bone formation than undifferentiated MSCs over an 8-week period. The extent of bone formation, however, was observed to be donor dependent [193]. In a similar study, Harada *et al.* chondrogenically predifferentiated MSCs and then them seeded on to a polylactic-glycolic acid scaffold and implanted it into a 5 mm critical size defect and a 15 mm full-thickness defect in rats. At 4 weeks after implantation, immunohistological staining for collagen type II appeared to decline, with an associated increase in type I collagen staining. At 8 weeks after implantation the biomechanical strength of the 15 mm defect samples reached 75% that of the contralateral untreated femora and did not differ significantly from the 5 mm defect samples [194]. Janicki *et al.* found in a study which assessed heterotopic bone formation of chondrogenically predifferentiated human MSCs implanted subcutaneously in mice that the human MSCs contributed to bone formation observed, while the host cells contributed primarily to supporting tissues such as the marrow niche [153]. Tortelli *et al.* [191] described how commitment of implanted cells can influence the role of host versus implanted cells in bone formation as well as the type of ossification observed. Syngeneic (genetically identical) MSCs induced bone formation by endochondral ossification, while implanted osteoblasts led to intramembranous ossification. Notably, the bone formed in MSC-implanted mice appeared to be derived from host cells and was associated with increased recruitment of $CD31^+$ endothelial cells. In contrast, bone formed in the osteoblast-implanted group primarily displayed direct bone formation from the implanted donor cells without a noteworthy contribution of host cells [191].

### 12.3.2 Osteoarthritis

Osteoarthritis is a common but currently incurable disease. Treatment normally involves palliative measures to reduce pain and swelling, surgical intervention to increase longevity of the joint, and, finally, total joint replacement once joint destruction has occurred. Several clinical trials assessing the safety and efficacy of MSCs in the treatment of osteoarthritis have been completed or are under way. A major unexpected obstacle that emerged from some of the studies was failure to meet primary endpoints. Furthermore, the eventual fate and tissue destination of the injected cells has yet to be fully defined both in preclinical and clinical models [195,196]. There has more recently been a shift in focus to the immunomodulatory function of MSCs in tissue repair and how this may be best exploited therapeutically. This refocusing was brought about by increasing reports of reductions in inflammation, apoptosis, and fibrosis in the apparent absence of engraftment of MSCs in the target tissue. The trophic effects of MSCs, therefore, have become increasingly important for progressing the clinical application of MSCs. A recent paper describing injection of human MSCs in a hemimeniscectomy rat model demonstrated a cascade of gene expression associated with cartilage formation and repair [197]. It is likely that both the differentiation of MSCs into the desired cell type and their trophic effect on endogenous cells contribute to their therapeutic action, and it has been shown that these events are closely linked. For instance, recent studies have shown that trophic factors released by MSCs regulate the chondrocyte phenotype [198,199]. Moreover, the co-culture of human MSCs with osteoarthritis chondrocytes resulted in differentiation of MSCs toward chondrocytes. This occurred in the absence

of growth factors, and the co-culture condition prevented hypertrophic differentiation of the chondrocytes [200]. Another study also implied that this trophic effect extends to ADSCs in that the ADSCs decreased expression of hypertrophic and fibroblastic markers on osteoarthritis chondrocytes and the authors identified hepatocyte growth factor as a key mediator of this process [201].

### 12.3.3 Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is a genetic disorder characterized by production of defective type I collagen, the principal structural protein of bone. OI patients are faced with frequent bone fractures, often without appreciable trauma, retarded bone growth, and progressive bone deformity. A characteristic clinical feature is blue, instead of white, sclerae of the eyes. The sclerae are thin and allow the color of the choroid membrane behind to be seen. No other disease has this feature (Figure 12.5).

Bisphosphonates have been found to be somewhat effective in the treatment of OI by strengthening the bones, reducing pain, and reducing the frequency of fracture. However, this disease remains incurable. Several early studies assessing the potential of stem cell therapy in OI focused on murine models [202]. Pereira *et al.* transplanted culture-expanded bone marrow-derived MSCs harvested from transgenic mice that expressed a type I collagen mini-gene into normal mouse recipients [203]. Up to 12% of donor cells were located in the connective tissues of recipient animals, suggesting that these cells can act as long-term precursors for connective tissues [203]. In another study, a significant, albeit small, increase in collagen and mineral content was reported 1 month after the MSCs were transplanted [204]. These findings formed the basis of a small clinical trial in three infants with severe OI [205]. At 3 months after allogenic hematopoietic stem cell transplantation, using bone marrow as the source, an increase in mineral density in all three patients was observed. In two of the three patients the growth velocity posttransplant was significantly increased and ultimately was found to be comparable to the normal median growth velocity of age- and sex-matched children. Furthermore, the frequency of fractures was significantly reduced in all three patients [205]. Interestingly, these substantial clinical outcomes were achieved with approximately 2% cell engraftment. In a follow-up study the authors assessed growth rate and mineral density in three severe OI infant patients (two from the original study) compared with two untreated age- and sex-matched patients at 18–36 months posttransplant of unmanipulated bone marrow. Similar to the pilot study, the authors observed increased rates of growth compared with controls and increased bone mineral density that reached the lower limit of the normal range. Again, similar to the pilot study, a decrease in fracture frequency in bone marrow-treated patients was observed [206]. Combined, these studies are indicative of a therapeutic effect of bone marrow-derived cells in reducing the severity of OI with increases in mineral content and growth and a reduced fracture frequency. The mechanism whereby this small population of engrafted cells contributed to the clinical effect observed remains to be elucidated.

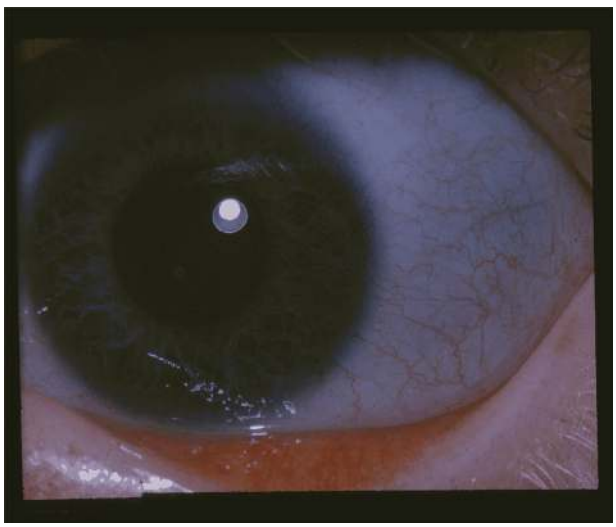

**Figure 12.5** The blue sclerae seen in OI. The patient was a 15-year-old male with OI who had been followed for some years because of fractures. The patient was first seen at age 30 months. He had a fracture of the right tibia at age 18 months without trauma. At 30 months he had a new fracture of the right tibia and a fracture of the left finger from a fall from a bicycle. The sclerae were noted to be blue. The blue coloration is caused by scleral thinness allowing the pigmented coat of the choroid to become visible. (See color plate section.) *Source*: "Osteogenesis sclerae" by National Eye Institute.

Le Blanc *et al.* successfully implanted *ex vivo* culture-expanded MSCs isolated from the liver of a 10-week-old aborted male fetus into a 32-week-old female fetus *in utero* that was diagnosed during gestation as having severe OI with multiple intrauterine fractures [207]. Nine months after birth a centromeric XY-specific probe on a bone biopsy sample revealed positive staining in approximately 0.3% of cells. The infant showed an increase in growth rate. The contribution of the engrafted cells, if any, was not defined [207].

The main question that arises from these studies is how so few engrafted cells achieved positive clinical outcomes. In all studies cited, analysis of cell engraftment took place at the earliest at 3 months after treatment. Initial cell engraftment may have been higher immediately postimplantation and may have declined with time [207,208]. A more recent line of thinking relates to the immunosuppressive function of MSCs and their ability to provoke an endogenous cell response [3,209]. The lack of categorical answers from clinical trial data has led researchers to reexamine animal models [208]. In a mouse model of OI, Niyibizi *et al.* tagged MSCs from normal mice with GFP which were then injected via the superficial temporal vein into immune-compromised mice. The vast majority of implanted cells reached the lungs and persisted there for up to 150 days [210]. However, 25 days after injection the donor cells were detected within the bone of several recipient mice. Donor cells were retrieved from these

mice, culture-expanded, and reinjected into new recipient mice. Interestingly, 35 days after reinjection the majority of donor cells were found in bone and were also found to migrate into cartilage, where they underwent chondrocyte differentiation [210]. Li *et al.* further identified subpopulations of MSCs that had a higher efficiency for migrating to bone and when injected colonized long bones of the mice where they differentiated into osteoblasts and deposited collagen type I, thus contributing to bone formation [211]. The authors noted that this subpopulation expressed RUNX2 and, therefore, may have represented an osteoprogenitor population rather than an undifferentiated MSC population. Otsuru *et al.* attempted to elucidate the mechanism by which whole bone marrow and *ex vivo* expanded MSCs exerted their clinical benefit [212]. They demonstrated in a mouse model of $CD3^+$ T cell-depleted nonadherent bone marrow cell transplantation that cells in the injected population were more potent osteoprogenitors than MSCs. They also observed that T cell-depleted bone marrow infusion in children with OI caused an increase in their rate of growth. Interestingly, in a murine model they suggested that the nonadherent bone marrow cells differentiated into osteoblasts and produced collagen type I, whereas MSCs secreted soluble factor(s) to indirectly stimulate growth [212].

## 12.4 Summary

The field of regenerative medicine has evolved exponentially over the last 20 years. Basic science has been accompanied by a multimillion-dollar business model that has led to ever-evolving stringent regulations. The commercialization of cell-based therapies has also been accompanied by a more sophisticated understanding of the cellular therapy paradigm. Where once it was thought that simple engraftment of these cells into an injury site would provide a reparative boost by direct transdifferentiation, more and more we are learning to understand the complexity of the bone marrow niche (see Chapter 32) and the importance of their trophic (see Chapters 18–21) and immunomodulatory effects (see Chapters 33 and 34). Nevertheless, in the context of bone regeneration, clinical application has been relatively slow. Interestingly, a severe genetic bone disease such as OI appears to be very responsive to cell-based therapies with minimal cell engraftment reported [206,207]. Recent studies assessing MSC populations in bone-related disease models have highlighted the importance of the MSC secretome (see Chapters 18 and 19) [213]. Moreover, lineage tracing studies have demonstrated the complexity of osteogenic differentiation of MSCs and the varying populations contributing to this [157,158]. Advances of cell-based therapies in bone regeneration have emerged with the realization that cell priming may provide a more robust endochondral bone formation response and that support of adequate angiogenesis is a key determinant in maintaining bone vitality [153,193]. Identification of pericytes and appreciation of the perivascular niche has been a significant development. Our once simple paradigm of cell engraftment for regeneration has been replaced by the need to understand and support a complex three-dimensional cell niche. Furthermore, the field has expanded to include the emergence of new and more sophisticated materials to help support osteogenic differentiation of MSCs. Given these developments, the onus on understanding where these cells go upon implantation and the biological role they play at their destination becomes fundamental to successful clinical application. This has led to the need for significant development in imaging and cell-tracking technologies. Regardless of the unresolved issues and need for constant adaptation and development to remain in sync with our increasing understanding of MSC biology, the studies that do demonstrate clinical efficacy suggest that it is just a matter of time before cell-based therapies for bone regeneration become a reality.

## 13.1 Overview of glycogen synthase kinase-3

The human skeleton is constantly renewing itself through a process called remodeling. Remodeling is achieved by the tightly coupled activities of bone-resorbing osteoclasts and bone-building osteoblasts, with the process regulated by osteocytes. Some bones, for example those of the craniofacial skeleton, are formed by intramembranous ossification, whilst most of the skeleton is formed through endochondral bone formation on to a cartilage scaffold [1]. In this chapter we describe the impact of the inhibition of glycogen synthase kinase-3 (GSK-3) on normal bone remodeling and within the context of bone disease. GSK-3 is a negative regulator of bone formation, with inhibition of GSK-3 activity resulting in the stimulation of bone formation. Preclinical data from *in vitro* and *in vivo* studies will be used to describe the impact of GSK-3 inhibition on bone loss in osteoporosis, multiple myeloma, and periodontal disease as well as in bone healing such as in fracture models. Key published data will be highlighted which suggest that this anabolic response can be attributed to alterations in mesenchymal stromal cell (MSC) functions, including proliferation, commitment, and differentiation of MSCs.

GSK-3 is a ubiquitously expressed serine/threonine kinase that inactivates glycogen synthase and was originally identified as an enzyme involved in the synthesis of glycogen [2,3]. More recently this multifunctional kinase has been shown to regulate additional cellular processes, including Tau protein and the canonical Wnt/β-catenin signaling cascade [4,5]. There are two isoforms of GSK-3 encoded by two genes, GSK-3α and GSK-3β, which in humans are located on chromosomes 19 and 3 respectively. At approximately 98%, the homology between GSK-3α (51 kDa) and GSK-3β (47 kDa) is particularly high in the catalytic domain, although overall homology is reduced to approximately 85% due to variability at the N- and C-termini [6]. GSK-3 is somewhat unusual in that its activity is generally high in resting cells and is inhibited upon cell stimulation through phosphorylation of $Ser^{21}$ in GSK-3α and $Ser^{9}$ in GSK-3β [3] either by insulin/phosphatidylinositide 3-kinase (PI3K)/AKT signaling [7] or through the disruption of the protein complex involved in canonical Wnt/

β-catenin signaling [8]. There is also an alternatively spliced variant of GSK-3β encoding GSK-3β2, which contains a 13-amino-acid insert in the kinase domain and is reported to be neuron specific and to possess reduced phosphorylation activity toward Tau protein relative to GSK-3β [9,10]. In addition to glycogen metabolism, GSK-3 is involved in a variety of biological processes, including embryonic development, cell proliferation and apoptosis, insulin signaling, neuronal function, and oncogenesis. GSK-3 has been reported to have a number of putative targets, including Tau [11], microtubule-associated protein 1B [12], insulin receptor substrate 1 [13], β-catenin [14], cyclic AMP response element-binding protein [15], nuclear factor of activated T cells (NFAT) [16], CCAAT-enhancer binding protein (C/EBPα) [17], eukaryotic initiation factor 2B [18], and c-jun [19]. In addition to roles in insulin and Wnt/β-catenin signaling, GSK-3 also plays regulatory roles in the Hedgehog signaling pathway [20]. GSK-3 has been implicated in the pathogenesis of a range of diseases, including diabetes mellitus, cancer, neurodegenerative diseases, and bipolar affective disorders [20,21]. Consequently, GSK-3 has been considered an attractive drug target, and a range of GSK-3 inhibitors have been developed as potential treatment options for these diseases. The role of GSK-3 in these diseases has been reviewed extensively and falls outside the scope of this chapter [22–25].

## 13.2 The response of skeletal cells to glycogen synthase kinase-3 inhibitors *in vitro*

The effects of GSK-3 inhibition on osteoblastogenesis and osteoclastogenesis have been investigated using a range of GSK-3 inhibitors with variable potencies and selectivity profiles (Table 13.1).

GSK-3 inhibitors have been assigned as activators of the canonical Wnt/β-catenin signaling cascade and GSK-3 inhibition results in an induction of β-catenin transcriptional activities [33,34]. To confirm Wnt/β-catenin activity, investigators have used a number of *in vitro* methods. The three most commonly used methods are first, the stabilization of β-catenin within cell nuclei; second, an increase in dephosphorylated β-catenin levels; and third, the expression of a β-catenin/Transcription Factor (TCF)/lymphoid enhancer-binding factor (LEF)-responsive reporter construct; for example, TOP-flash [35] or one of its variants. The following section summarizes the role of GSK-3 in bone remodeling from studies that have utilized these GSK-3 inhibitors in *in vitro* assays in progenitor stem cell lines, preosteoblastic and osteoblast cell lines, and in primary skeletal cells or tissues. It is important to note that although GSK-3 inhibitors are often reported as GSK-3β inhibitors, the inhibitors included in this chapter demonstrate similar potency by both GSK-3α and GSK-3β. They should therefore be thought of as dual GSK-α/β inhibitors, and elucidating the precise roles of the individual isoforms in bone remodeling would be an interesting focus of future studies.

**Table 13.1** GSK3 inhibitors reported to affect bone remodeling *in vitro*.

| GSK-3 inhibitor | Parameter | GSK-3β potency (nM) | Reference |
|---|---|---|---|
| LiCl | $IC_{50}$ | 2000 | [26] |

[a] Represents measurements of GSK-3α potency for SB-216763 and SB-415286. Potency is reported as equivalent at GSK-3β [27].

### 13.2.1 Lithium chloride

Lithium ions ($Li^+$) and lithium chloride (LiCl) have been reported to inhibit GSK-3 family members and produce effects in cellular systems consistent with GSK-3 inhibition [36,37]. These include, for example, the activation of glycogen synthase and subsequent insulin-mediated glycogen deposition demonstrated in rat adipocytes [38], and Wingless signaling reported in *Drosophila* [36]. GSK-3β was reported to be inhibited by $Li^+$ ($IC_{50}$, 2000 nM; Table 13.1) at three- to sevenfold lower concentrations than a range of other protein kinases, including MAPK-activated protein kinase 2 (MAPKAP-K2), p38-regulated/activated kinase (PRAK), and checkpoint kinase 2 [26]. In addition, glucocorticosteroids, including dexamethasone, have been shown to inhibit osteoblastic commitment and differentiation, resulting in the downregulation of the GSK-3 target gene *c-MYC*, increased GSK-3β kinase activity, and attenuation of GSK-3β $Ser^9$ inhibitory phosphorylation. However, the reduction in *c-MYC* expression has been reported to return to control levels by GSK-3 inhibition using LiCl [39].

Murine C3H10T1/2 cells are multipotent MSCs that have the ability to differentiate into osteoblasts, adipocytes, chondrocytes, and myoblasts. Nuclear translocation of β-catenin has been shown to be induced by 10 mM LiCl in a manner similar to Wnt3a in C3H10T1/2 cells [40]. Moreover, LiCl has been reported to increase TOP-flash activity in a time- and concentration-dependent manner, indicating that LiCl has the ability to stimulate TCF-dependent transcriptional activity [40,41]. For example, over a 24 h treatment period, 20 mM LiCl caused a 10-fold increase in TCF/LEF reporter activity relative to sodium chloride (NaCl) controls [41].

Similar results were obtained using human SaOS-2 osteoblastic cells in which exposure to LiCl led to a marked increase in nuclear β-catenin levels compared with controls [42]. In these studies the investigators demonstrated similar nuclear

accumulation of β-catenin in Wnt3a-treated murine MC3T3 preosteoblasts. The similarities observed between the distribution of β-catenin in the murine and human Wnt3a- and LiCL-treated osteoblastic cells led to the suggestion of a central role for GSK-3 inhibition and canonical Wnt/β-catenin signaling in osteoblasts [42].

The activation of endogenous Wnt/β-catenin signaling in C3H10T1/2 cells with LiCl led to an increase in the mRNA expression of the osteoblast marker alkaline phosphatase (ALP), which was of similar magnitude to that observed following bone morphogenetic protein 2 (BMP-2) stimulation, as well as an increase in alkaline phosphastase activity [40,43]. Runt-related transcription factor 2 (RUNX2) plays an essential role in osteoblastic differentiation and *RUNX2* knockout mice demonstrate a complete absence of bone due to the arrest of osteoblast maturation [44,45]. *RUNX2* has also been reported to be a Wnt/β-catenin/TCF target gene product [46]. RUNX2 protein expression was significantly increased in a time- and concentration-dependent manner following treatment with LiCl. Unlike BMP-2, however, these results indicated that LiCl has the ability to activate canonical Wnt/β-catenin signaling and accelerate early commitment to osteogenesis [40,43].

In addition, the canonical Wnt/β-catenin signaling may play an integral role in osteoblast differentiation and function. Using microarray technology, Vaes *et al.* investigated the expression of components of the Wnt signaling cascade during osteoblast differentiation induced by BMP-2 in murine C2C12 mesenchymal progenitor cells (MPCs) and MC3T3-E1 preosteoblasts [47]. Interestingly, the Wnt antagonists secreted frizzled related protein 2 and Wnt inhibitory factor 1, which were reported to be strongly upregulated during the late phase of osteoblast differentiation. Using human mesenchymal stromal cells the group further analyzed the effects of continuous activation of Wnt signaling by LiCl and observed that dexamethasone-induced osteoblast differentiation was reduced, as measured by expression of the osteoblast marker genes encoding ALP, osteocalcin, and osterix, as well as by the amount of calcium released. Taken together, the data indicated that endogenous expression of Wnt antagonists by osteoblasts provides a negative Wnt feedback loop that may be essential in regulating the final stages of osteoblast maturation [48].

The literature on the effects of glucocorticosteroids, and particularly dexamethasone, on osteoblast differentiation and maturation is conflicting. In MC3T3-E1 preosteoblast cells dexamethasone has been reported to cause a reduction in β-catenin levels and an inhibition in TCF/LEF-mediated transcriptional activity [49]. Abrogation of Wnt/β-catenin signaling is suggested to be a mechanism by which glucocorticosteroids inhibit the commitment-associated cell cycle during osteoblast differentiation. Dexamethasone-mediated reduction in β-catenin expression levels was attenuated by both GSK-3 inhibition with LiCl and PI3K/Akt inhibition with Wortmannin, leading the investigators to suggest that glucocorticosteroids may inhibit the osteoblast differentiation-related cell cycle through both Wnt/β-catenin-dependent and -independent mechanisms, and that PI3K/Akt/GSK-3/β-catenin/LEF axis inhibition and histone deacetylase stimulation may together mediate the effects of glucocorticosteroids on osteoblast differentiation [49]. (Wortmannin, a steroid metabolite of the fungus *Penicillium funiculo*sum, is a specific, covalent inhibitor of phosphoinositide 3-kinases.)

The effects of dexamethasone on canonical Wnt signaling were further investigated in primary human osteoblasts prepared from bone fragments from the femoral neck. Treatment with LiCl caused a 3.5-fold induction in TOP-flash reporter activity, comparable to effects observed following the use of Wnt3a-conditioned media [50]. Interestingly, the LiCl-mediated increase in Wnt/β-catenin signaling was not attenuated by dexamethasone, which led to the suggestion that dexamethasone affects canonical Wnt/β-catenin signaling either directly through GSK-3 or through regulation of an upstream component of the canonical Wnt cascade; for example, Dickkopf-1 [51].

As demonstrated so far, and throughout this chapter, the involvement of the canonical Wnt/β-catenin signaling cascade, including GSK-3 as a key regulator, has been generally accepted among the research community with regard to osteoblast differentiation. In contrast, however, the role of Wnt/β-catenin signaling in osteoclastogenesis remains controversial [52–54]. Osteoclast precursor cells, derived from the monocyte–macrophage lineage, fuse to form multinucleated cells that express tartrate-resistant acid phosphatase (TRAP). These cells function to resorb bone, and osteoclast differentiation is regulated by two cytokines: macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor-κB ligand (RANKL) [55].

To understand how osteoclast formation might be regulated by canonical Wnt/β-catenin signaling, Spencer *et al.* set up co-culture assays consisting of murine primary osteoblasts and spleen mononuclear cells. Treatment of these co-cultures with up to 20 mM LiCl over 12 days caused a significant, concentration-dependent reduction in the formation of multinucleated TRAP-positive cells relative to control cultured cells treated with NaCl. To provide evidence that the effects observed with LiCl treatment were mediated through Wnt/β-catenin signaling, similar experiments were performed to measure the effects of Wnt3a-conditioned medium on osteoclast formation *in vitro*. Over 12 days, treatment with Wnt3a-conditioned medium inhibited osteoclast differentiation to levels comparable to that observed with LiCl [42]. The investigators also demonstrated that RANKL mRNA and protein expression were completely inhibited in MC3T3-E1 and MG-63 osteoblastic cells following exposure to LiCl. While similar results were obtained in MC3T3 cells treated with Wnt3a, RANKL expression was not affected by exposure to the noncanonical Wnt ligand Wnt5a. These data appear to indicate that canonical Wnt/β-catenin signaling may inhibit osteoclastogenesis through the regulation of RANKL expressed by osteoblasts and suggest that changes in bone remodeling following modulation of the canonical Wnt pathway

may be due to effects on both bone formation and bone resorption [42].

Arioka *et al.* have investigated the effect of GSK-3 inhibitors on osteoclastogenesis using the murine osteoclast precursor RAW-D cells, isolated from RAW 264 cells [40]. RAW-D cells are responsive to RANKL and tumor necrosis factor-α and have been shown to differentiate to osteoclasts [56,57]. To determine the role of GSK-3 in osteoclastogenesis, RAW-D cells were incubated with RANKL for 4 days with or without GSK-3 inhibitors. Treatment with LiCl significantly reduced TRAP activity and the number of TRAP-positive multinucleated cells (MNCs) with >10 nuclei in a concentration-dependent manner, although treatment with Wnt3a produced contrasting effects, notably an increase in both TRAP activity and TRAP-positive MNC accumulation. The group then examined the effect of GSK-3 inhibitors on the expression of NFAT cytoplasmic 1 (NFATc1), which has been reported to be an essential transcription factor for osteoclast differentiation [58]. LiCl significantly inhibited NFATc1 mRNA and protein expression, whereas, once again, Wnt3a conversely increased their expression [40]. Thus, GSK-3 is thought to be involved not only in osteoblastogenesis but also in osteoclastogenesis [52–54] and the results reported by Arioka *et al.* [40] are consistent with previous reports [53,54]. However, the involvement of the canonical Wnt/β-catenin signaling pathway in osteoclastogenesis is still somewhat controversial, and the effects of GSK-3 inhibitors on osteoclastogenesis may be independent of Wnt/β-catenin signaling since Wnt3a was reported to stimulate osteoclast differentiation from precursor RAW-D cells.

The cellular responses to LiCl in both osteoblast and osteoclast differentiation are dependent on the cell culture conditions, serum concentration, the inducing factors used, and the timing of their administration [43].

### 13.2.2 SB-216763 and SB-415286

SB-216763 and SB-415286 are structurally distinct maleimide compounds that have been reported to inhibit GSK-3α *in vitro* with $IC_{50}$ values of 34.3 nM and 77.5 nM respectively in an ATP competitive manner. (Maleimides are chemical compounds with the formula $H_2C_2(CO)_2NH$. The name is a contraction of maleic acid and imide, the —C(O)NHC(O)— functional group.) These compounds were reported to inhibit GSK-3β with similar potency and were selective for GSK-3 over a panel of other protein kinases [27]. These compounds thus represent potent pharmacological tools with which the role of GSK-3 in cellular signaling can be further elucidated.

As with LiCl, SB-216763 treatment led to a significant reduction in phosphorylated β-catenin levels, increased nuclear stabilization of β-catenin and stimulated TCF/LEF transcriptional activity in C3H10T1/2 cells. SB-216763 also induced osteoblast differentiation, causing an increase in ALP expression, elevated R2 expression, and increased osteogenic mineralization relative to controls [40].

To further understand the role that GSK-3 plays in endochondral bone growth, Gillespie *et al.* investigated the effects of SB-415296 in e15.5 (15.5 days of gestation) mouse tibial organ cultures cultured for 6 days. Treatment with 10 μM SB-415286 led to a 31% increase in total tibial length. A similar trend was also observed using 10 μM SB-216763 [59]. This increase in tibial length did not affect the overall length of the epiphyseal growth plate of the treated tibia. However, treatment with SB-416286 did affect the organization and relative lengths of the component chondrocyte zones within the growth plate. The division between resting zone and proliferating zone chondrocytes was less distinct in SB-415286-treated tibias relative to controls, and the combined length of resting and proliferating zones was 13% longer in SB-415286-treated tibias relative to controls. In addition, SB-415286 treatment led to a 57% reduction in the length of hypertrophic zone of chondrocytes and a concomitant increase in the relative area of the tibia that had undergone mineralization. Together, these results suggest that inhibition of GSK-3 promotes long bone longitudinal growth by promoting bone formation [59].

The expansion of a capillary network and the provision of a functional microvasculature within the skeleton is essential for bone remodeling and fracture healing [60]. Vascular endothelial growth factor (VEGF) released from osteoblasts plays a significant physiological role as an intercellular mediator between osteoblasts and vascular endothelial cells. Furthermore, VEGF has been reported to be involved in trabecular bone formation and hypertrophic chondrocyte zone expansion in murine growth plates [61]. Using MC3T3-E1 preosteoblasts, Natsume *et al.* demonstrated that Wnt3a potentiated the release of VEGF stimulated by transforming growth factor-β (TGF-β) [62]. In addition, these investigators went on to show that TGF-β-stimulated VEGF release was markedly enhanced by treatment with SB-216763. Similar results were also observed following LiCl treatment and led to the suggestion that upregulation of TGF-β-stimulated VEGF synthesis following Wnt3a treatment is mediated through canonical Wnt/β-catenin signaling in osteoblasts. Kondo *et al.* demonstrated that Wnt3a significantly increased prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)-stimulated VEGF synthesis in MC3T3-E1 cells and also showed that SB-216763 markedly enhanced VEGF synthesis in response to $PGF_{2\alpha}$ stimulation to a similar degree [63]. Furthermore, and again in similar fashion to Wnt3a, SB-216763 had little effect on $PGF_{2\alpha}$-stimulated interleukin (IL)-6 synthesis, a potent bone resorptive agent [64]. Taken together, these studies led to speculation that the effects of canonical Wnt/β-catenin in bone metabolism is mediated, at least in part, by VEGF release from osteoblasts through fine modulation of signaling molecules, including TGF-β and $PGF_{2\alpha}$ [62,63].

Studies utilizing SB-415286 in the context of mechanical loading have provided interesting insights into the complex interactions of canonical Wnt/β-catenin signaling and additional signaling mechanisms in mesenchymal stromal cells. Mechanical strain has previously been reported to inactivate GSK-3 through $Ser^9$ phosphorylation within 30 min of the strain being

applied [65]. In C3H10T1/2 cells, mechanical loading has been reported to inhibit adipogenesis and, using 20 μM SB-415286 added to C3H10T1/2 cells cultured with the adipogenic supplements dexamethasone, insulin, and indomethacin, Sen *et al.* demonstrated that GSK-3 inhibitor treatment was able to prevent increases in peroxisome proliferator-activated receptor-γ (PPAR-γ) and adiponectin mRNA and protein expression in a manner similar to that induced by the application of strain. Similar results were obtained using LiCl [65]. In follow-up studies by the same group, small interfering RNA (siRNA) targeting GSK-3β prevented both strain-induced induction of β-catenin and an increase in cyclooxygenase-2 (COX2), a factor associated with increased osteoprogenitor phenotype [66]. siRNA knockdown of β-catenin blocked the mechanical strain-induced reduction of PPAR-γ and adiponectin expression, implicating Wnt/β-catenin signaling in strain-mediated inhibition of adipogenesis. In contrast, the effect of both mechanical strain-induced inhibition of GSK-3 and pharmacological inhibition using SB-415286 on the putative β-catenin target, COX2, remained unaffected by knockdown of β-catenin. SB-415286 treatment and mechanical strain caused nuclear accumulation of NFATc1, independent of β-catenin, and subsequent NFATc1 knockdown prevented the mechanical stimulation of COX2 expression, implying a role for NFATc1 signaling. Furthermore, GSK-3 inhibition led to the association of RNA polymerase II with the COX2 gene, suggesting the initiation of transcription [66]. In summary, these studies suggest that mechanical inhibition of GSK-3 induces activation of both canonical Wnt/β-catenin and NFATc1 signaling, limiting adipogenesis via Wnt signaling and promoting osteoblastic differentiation, in part, through NFATc1/COX2 [65,66]. Importantly, the inhibition of GSK-3 may affect MSC differentiation through the regulation of multiple downstream targets.

Similar to the results reported earlier with LiCl, treatment of RAW-D cells with SB-216763 significantly decreased both TRAP activity and the number of TRAP-positive MNCs in a concentration-dependent manner, indicating a potential role for canonical Wnt/β-catenin signaling in the regulation of osteoclastogenesis [40]. Interestingly, use of the other maleimide GSK-3 inhibitor SB415286 provided additional evidence of a potential effect of GSK-3 inhibition on osteoclastogenesis. Giant cell tumor of bone is a benign yet destructive neoplasm, with tumors consisting of mesenchymal fibroblast-like stromal cells, monocyte-like mononuclear cells of myeloid lineage, and characteristic osteoclast-like multinucleated giant cells. Notably, SB-415286 reversed the RANKL/osteoprotegerin (OPG) expression ratio and led to a significant reduction in the numbers of TRAP-positive MNCs, indicating a reduction in osteoclastogenic capacity. In contrast, recombinant human BMP-2 had the opposite effect, resulting in enhanced osteoclastogenesis. These data provide early evidence to suggest that targeting the giant cell tumor stromal cell may be worth investigating as a potential adjunct to existing antiresorptive strategies [67].

### 13.2.3 6-bromoindirubin-3′-oxime

The indirubin 6-bromoindirubin-3′-oxime (BIO) is a synthetic cell-permeable derivative of the natural product 6-bromoindirubin, a constituent of Tyrian purple, an indigo dye obtained from gastropod molluscs. Indirubins were discovered to be potent protein kinase inhibitors initially on cyclin-dependent kinases (CDKs) [68] and later on GSK-3 [69]. BIO retains enhanced selectivity for GSK-3 over CDKs [28].

COS-1 cells, fibroblast-like cells derived from African green monkey kidney, were exposed for 24 h to BIO, which caused a significant increase in the levels of unphosphorylated β-catenin accompanied by a modest increase in total β-catenin protein expression [28]. Wang *et al.* investigated MC3T3-E1 preosteoblasts maintained in an osteogenic medium containing β-glycerophosphate and ascorbic acid and used dexamethasone at high concentrations to model the effects of glucocorticosteroid administration on bone deterioration [70]. As with MC3T3-E1 cells, BIO treatment at 1 μM led to the stabilization of β-catenin protein in cell nuclei [71]. Treatment with 10 μM BIO was reported to attenuate dexamethasone-mediated inhibition of phosphorylated GSK-3$\beta^{Ser9}$ and nuclear β-catenin. BIO thus acted as a selective GSK-3 inhibitor in this cell line [70]. In addition, BIO induced a 100-fold increase relative to controls in TOP-flash TCF/LEF transcriptional activity in C3H10T1/2 cells following a 40 h treatment [41]. Krause *et al.* incubated human bone marrow-derived MSCs (BM-MSCs) prepared from iliac crest marrow aspirates under osteogenic conditions; BIO treatment resulted in elevated levels of β-catenin in cell nuclei and a reduction in cytoplasmic GSK-3β, consistent with an upregulation of Wnt/β-catenin signaling [72]. Indirubins have been described to interact with the aryl hydrocarbon receptor (AhR) [73]. To determine whether the observed BIO-induced β-catenin dephosphorylation and stabilization was mediated through an AhR-dependent effect, cell lines deficient either in AhR or AhR nuclear translocator (a co-transcriptional factor of AhR) were evaluated. BIO-induced β-catenin stabilization was maintained in both cell lines, demonstrating that its effects are mediated directly through GSK-3 rather than through an indirect, AhR-dependent pathway [28].

BIO treatment was also shown to increase Runx2 expression and the formation of mineralized nodules in MC3T3-E1 cells, assessed through von Kossa staining following dexamethasone-induced suppression, demonstrating that GSK-3 inhibition can protect osteoblasts against glucocorticosteroid-induced suppression of osteogenic differentiation [70]. Watanabe *et al.* showed that 1 μM BIO treatment stimulated osterix nuclear translocation and caused an upregulation of the mRNA transcription of Runx2, osterix, collagen type I, alpha 1 (Col1a1), and bone-specific ALP. In contrast, mRNA expression of osteocalcin, osteopontin, and dentin matrix protein 1, markers associated with osteoblast maturation and extracellular matrix mineralization, were reduced, suggesting that BIO treatment leads to increased numbers of cells with a relatively immature osteoblastic phenotype [71].

Human BM-MSCs were also incubated in osteogenic medium without dexamethasone; treatment with BIO at doses up to 200 nM led to increased ALP activity. However, doses of 400 nM and above caused ALP activity to return to control levels. OPG expression was increased in a concentration-dependent manner [72]. In extended cell culture experiments, BIO was reported to be unable to induce osteogenic mineralization in the presence of β-glycerophosphate and ascorbic acid but in the absence of dexamethasone. When osteogenic media was supplemented with dexamethasone, however, BIO increased mineralization in a concentration-dependent manner, as assessed through Alizarin red S staining. BIO was demonstrated to enhance dexamethasone-dependent mineralization when used either as an 8 day pretreatment or when present throughout a 17 day culture period, indicating that Wnt/β-catenin stimulation is required to induce an osteoprogenitor phenotype in human BM-MSCs [72].

### 13.2.4 LY603281-31-8

LY603281-31-8 is an orally bioavailable GSK-3 inhibitor that exhibits selectivity for GSK-3β over a panel of other kinases [29] (Table 13.1). The effects of LY603281-31-8 on MSCs have been investigated in two main studies [74,75]. Treatment of murine C3H10T1/2 cells for 24 h led to increased β-catenin protein expression in whole-cell lysates and a two- to sevenfold increase in TCF/LEF transcriptional activity following transient transfection with the TOP-flash reporter [74]. LY603281-31-8 was therefore reported to be a potent activator of canonical Wnt/β-catenin signaling.

Although being reported to exert biphasic effects on a number of bone-specific marker genes, LY603281-31-8 treatment caused increased mRNA expression of collagen-α1 (I) and -α1 (V), bone sialoprotein, Runx2, and osteocalcin after 24 h of treatment relative to controls. In addition, ALP mRNA expression and enzyme activity were increased significantly in C3H10T1/2 cells after 24 h, and the investigators reported a reduction in cell proliferation [74].

In addition to evaluating markers of osteoblast differentiation, Kulkarni *et al.* also investigated the effects of LY603281-31-8 on markers of adipogenic differentiation. LY603281-31-8 treatment led to significant reductions in the expression of CEBP-α (which encodes CCAAT-enhancer-binding protein-α), GPD1 (which encodes glycerol-3-phosphate dehydrogenase), lipoprotein lipase (LPL), fatty acid binding protein 4, and PPAR. These results are consistent with LY603281-31-8 causing enhanced osteogenic commitment and osteoblastic differentiation and suppression of adipogenic differentiation [74].

Kulkarni *et al.* also investigated the effects of LY603281-31-8 on MPCs isolated from rat bone marrow stromal cells (BMSCs). In *ex vivo* studies, osteoprogenitor cells were identified by colony-forming unit–fibroblast (CFU-F) assays followed by ALP staining [75]. Rats were subjected to oophorectomy (removal of the ovaries) and treatment with parathyroid hormone (PTH) or LY603281-31-8. Oophorectomy led to a significant 18% reduction in CFU-F colony numbers. While this was further decreased following treatment with PTH, treatment with LY603281-31-8 increased the number of CFU-F colonies to 125% of oophorectomized control levels. In addition, while oophorectomy led to a significant reduction in the ratio of ALP-positive CFU-F colonies, treatment with PTH or LY603281-31-8 significantly increased the production of putative osteoblasts [75]. In summary, LY603281-31-8 acts as a selective GSK-3 inhibitor to induce osteoblast differentiation, leading to an increase in bone formation, further supporting a role for canonical Wnt/β-catenin signaling in osteoblastogenesis.

### 13.2.5 CT99021/CHIR99021

The aminopyrimidine GSK-3 inhibitor CT99021/CHIR99021 is a potent GSK-3 inhibitor that has demonstrated 500- to >10 000-fold selectivity over a panel of other kinases [30] (Table 13.1). This compound is extremely interesting, in that, in addition to its reported effects on osteoblastogenesis, CT99021/CHIR99021 is routinely used in combination with a mitogen-activated protein kinase inhibitor, PD0325901, to maintain mouse embryonic stem cells (mESCs) in a ground state of pluripotency [76]. A ground state of pluripotency is a basal proliferative state that is free of epigenetic restriction and has minimal requirements for extrinsic stimuli.

CT99021/CHIR99021 has been recommended for use as a potent and selective GSK-3 inhibitor and is reported to completely prevent the phosphorylation of a number of GSK-3 substrates, including *N-Myc* downstream-regulated gene 1 [77].

Canonical Wnt signaling cues have also been reported to specify the differentiation of germ layers and multipotent stem cells into mesodermal cells [78]. Kanke *et al.* have reported a strategy to efficiently differentiate both mESCs and mouse induced pluripotent stem cells toward the osteoblast lineage by sequentially treating the cells with four small molecules, CT99021/CHIR99021, cyclopamine, SAG (a small-molecule agonist of the Sonic hedgehog-Smoothened (Shh-Smo) signaling pathway), and a helioxanthin-derivative -(4 methoxyphenyl)pyrido[4′,3′:4,5]thieno[2,3-*b*] pyridine-2-carboxamide [79].

Using CT99021/CHIR99021 Bennett *et al.* reported that Wnt/β-catenin signaling was able to stimulate osteoblastic differentiation and inhibit adipogenic differentiation of bipotential mouse ST2 BMSCs. Following incubation in a medium containing β-glycerophosphate and L-ascorbic acid, CT99021/CHIR99021 treatment led to elevated ALP activity and increased osteogenic mineralization as assessed by Alizarin red staining. CT99021/CHIR99021 also inhibited adipogenesis as visualized by Oil red O staining [80]. Although the effects of CT99021/CHIR99021 were consistent with canonical Wnt/β-catenin signaling inducing osteoblast differentiation directly, Bennett *et al.* identified that, with GSK-3 playing a regulatory role in a number of signaling pathways, there is the potential that CT99021/CHIR99021 stimulates osteoblastogenesis through alternate signaling mechanisms. To address this, activation of canonical Wnt/β-catenin signaling was achieved through retroviral

infection of Wnt1, Wnt10b, or dominant-stable β-catenin in ST2 cells. These cell lines demonstrated increased ALP activity, accelerated osteoblast differentiation, and increased mineralization when cultured in osteogenic media. Control ST2 cells demonstrated relatively low levels of ALP activity and mineralization under these conditions, and background levels of osteoblastic differentiation were not increased either by the presence of a dominant negative transcription factor 7-like 2 (TCF7L2) construct or through the activation of noncanonical Wnt signaling using Wnt5a. Wnt5a also demonstrated no appreciable effect on adipogenesis in ST2 cells, whereas activation of the canonical pathway with Wnt10b or Wnt1 completely inhibited adipocyte differentiation. Similar results were also observed in C3H10T1/2 cells [80].

However, contrasting data have been reported by Frith *et al.* [81]. Using stromal precursor antigen-1-positive human bone-marrow-derived MPCs in a continuous perfusion microbioreactor array (MBA) platform, enzyme-labelled fluorescence 97 (ELF97) was used to assess ALP activity as a marker of early osteogenic differentiation. Treatment with CT99021/CHIR99021 led to a significant reduction in ELF97 expression that correlated with an increase in DNA content. In additional studies this group investigated whether similar results would be obtained with MPCs grown in standard culture formats. Similar to the results obtained with the MBA platform, ELF97 expression was increased when MPCs were cultured in the presence of osteogenic supplements. However, ELF97 expression was strongly inhibited by treatment with CT99021/CHIR99021. CT99021/CHIR99021 was profoundly inhibitory of ALP activity at all concentrations above 1 μM. In additional studies the group investigated the effects on the later stages of osteoblast differentiation using Alizarin red S staining to determine the extent of mineral deposition after 21 days. Osteogenic medium induced the formation of Alizarin red deposits across the majority of the culture surface, and this was almost completely abolished with CT99021/CHIR99021 treatment. In contrast, however, determination of gene expression at 7 days showed that expression of the osteoblastic markers Runx2, Msh homeobox protein 2 and distal-less homeobox 5 was significantly upregulated in MPCs treated with CHIR99021 relative to controls. However, ALP expression remained significantly inhibited by CT99021/CHIR99021 [81].

### 13.2.6 AR28 (AZD2858), AR79, and AZ13282107

AZD2858, AR79, and AZ13282107 are potent GSK-3 inhibitors derived from three chemical series (Table 13.1). The compounds exhibit similar potency on GSK-3β and GSK-3α and cause the stabilization of β-catenin in cell nuclei [32].

In studies by Gambardella *et al.*, AR28, hereafter referred to as AZD2858, was shown to increase functional β-catenin protein expression in a concentration-dependent manner following 24 h of treatment of C3H10T1/2 cells [31]. In further studies designed to understand whether AZD2858 could promote an increase in MPC number, murine bone marrow cells were exposed to AZD2858 and the numbers of CFU-Fs, colony-forming unit–adipocytes (CFU-As), and colony forming unit–osteoblasts (CFU-Os) were determined. Relative to controls, treatment of bone marrow cells with AZD2858 led to significant increases in the number of CFU-Fs and in the numbers of MPCs with adipogenic (CFU-A) and osteogenic (CFU-O) potential. To determine whether AZD2858 was able to stimulate differentiation of MPCs towards the osteogenic lineage, bone marrow cells were cultured for 14 days in a medium supplemented with β-glycerophosphate, L-ascorbic acid, and dexamethasone. Significant increases in ALP and osteocalcin gene expression were observed following exposure to AZD2858, suggesting that GSK-3 inhibition promoted differentiation towards the osteogenic lineage. The numbers of CFU-As were determined using a 4 week assay comprising a 2 week expansion phase in basal medium followed by a 2 week differentiation phase using adipogenic medium supplements. AZD2858 was added either during the expansion phase or the differentiation phase and it was reported that a significant increase in CFU-As was only observed when the GSK-3 inhibitor was added during the expansion phase. There was no increase in CFU-A number when AZD2858 was added during the differentiation phase. Exposure to AZD2858 also caused no change in the expression of the adipogenic marker genes LPL and PPAR-γ. Thus, these data suggested that GSK-3 inhibition using AZD2858 increased the number of MPCs with both osteogenic and adipogenic potential, but drove differentiation only toward the osteogenic lineage [31]. The data are consistent with observations from rat BM-MSCs, indicating a relative increase in the numbers of putative osteoblast cells generated following treatment with the GSK-3 inhibitor LY603281-31-8 [75].

The ability of AZD2858, AR79, and AZ13282107 to drive the commitment of human adipose-derived stem cells toward osteoblastogenesis was investigated by assessment of the osteoblast-specific markers osterix and the protein transcriptional co-activator with PDZ-binding motif (TAZ). Similar to Runx2, osterix is a master regulator of skeletal development and has been reported to be essential for osteoblast differentiation and bone formation, exemplified by the absence of osteoblast differentiation and maturation in osterix-null mice [82]. TAZ has been reported to modulate the activity of Runx2 and PPAR-γ during MSC lineage commitment [83], and has recently been reported as an integral component of the canonical Wnt/β-catenin pathway [84,85]. Protein expression of both osterix and TAZ was increased following treatment with AZD2858, AR79, and AZ13282107 relative to vehicle controls [32]. In follow-up studies the three GSK-3 inhibitors were evaluated for their ability to drive osteogenic mineralization in human adipose-derived stromal cells (ADSCs) as assessed by Alizarin red S staining. Over 25 days of cell culture, incubation with AZD2858, AR79, or AZ13282107 led to a marked enhancement in osteogenic mineralization relative to controls. Importantly, it should also be noted that the human ADSCs exposed to GSK-3 inhibitors were maintained in a basal medium without the

addition of osteogenic supplements. Taken together, these findings indicate that AZD2858, AR79, and AZ13282107 stimulate osteoblastogenesis and enhance osteogenic differentiation of human ADSCs [32].

In C3H10T1/2 MPCs, human BMSCs isolated from the bone marrow from the femoral head, and primary human osteoblast-like cells isolated from hip arthroplasty patients, AZD2858 was demonstrated to increase nuclear β-catenin translocation and to increase stable dephosphorylated β-catenin levels [41,86]. AZD2858 treatment led to a dose-dependent increase in TCF/LEF transcriptional activity with 2.5 μM AZD2858 causing an approximate 1000-fold increase relative to controls, an effect comparable to the magnitude of effect induced by Wnt3a (100 ng/mL), 100-fold greater than that of LiCl, and 10-fold greater than that induced by BIO [41]. Following the removal of the AZD2858 stimulus the Wnt/β-catenin response remained elevated for several hours before declining, leading to the suggestion that canonical Wnt/β-catenin activation may be reversible.

The effect of AZD2858 on adipogenesis of BMSCs was evaluated. When BMSCs were cultured in adipogenic medium, a large increase in Oil Red O staining was observed. However, AZD2858 treatment abrogated Oil Red O staining in a concentration-dependent manner, indicating that AZD2858 inhibits adipogenic differentiation in BMSCs. After 14 days in adipogenic medium, human ADSCs were stained for the adipocyte markers fatty acid binding protein 5 (FABP5) and BODIPY (borondipyrromethene, a lipid probe) and the Hoechst nuclear stain. Approximately 50–60% of human ADSC controls demonstrated positive staining for both FABP5 and BODIPY. Consistent with the results obtained with BMSCs, AZD2858 significantly inhibited adipogenesis in human ADSCs [41].

BMSCs were initially cultured for up to 3 weeks in the presence of β-glycerophosphate, L-ascorbic acid, and dexamethasone. AZD2858 caused a significant reduction in ALP expression in a concentration-dependent manner. Osteogenic mineralization, assessed by von Kossa staining, was also reduced in response to administration of AZD2858. Under standard dexamethasone-induced osteogenic conditions, these data indicated that Wnt/β-catenin activation with AZD2858 significantly inhibits ALP activity and does not stimulate significant osteogenic mineralization *in vitro* [41]. Work by other groups [72,87] has demonstrated that canonical Wnt/β-catenin signaling may increase early osteogenic differentiation of BMSCs. Therefore, Cook *et al.* cultured BMSCs in media containing β-glycerophosphate and L-ascorbic acid but without dexamethasone. Under these conditions, small but significant increases in ALP activity were observed following treatment with low doses of AZD2858. However, ALP activity was reduced when AZD2858 concentrations were increased to 0.5 μM. In addition, although AZD2858 had no effect on von Kossa staining, osteogenic mineralization was increased in a concentration-dependent manner as assessed by Alizarin red S staining when dexamethasone was removed from osteogenic medium. This suggests that, when dexamethasone is absent, AZD2858-stimulated Wnt/β-catenin signaling can elevate osteoblastic differentiation in a manner that is dependent on BMSC number [41].

Taken together, work from a variety of *in vitro* studies utilizing a range of GSK-3 inhibitors has indicated that pharmacological GSK-3 inhibition results in commitment of MSCs to osteoblastic differentiation and mineralization. The canonical Wnt/β-catenin signaling pathway is complex, being regulated by multiple Wnt ligands, Wnt receptors, and numerous soluble inhibitors [88]. In addition, the variety of MSCs and osteoblastic cells studied, combined with differences in species, study protocols, and the timing and duration of GSK-3 inhibitor treatment have led to some variability in the results obtained from different research groups. However, as detailed below, the indications of a pro-bone formation phenotype derived from *in vitro* assays translates *in vivo* to serum bone turnover biomarker changes consistent with increased bone formation and reduced resorption.

## 13.3 Bone anabolism through inhibition of glycogen synthase kinase-3 *in vivo*

The development of GSK-3β knockout mice and treatment with small molecule inhibitors of GSK-3 have consistently shown changes in bone remodeling resulting in an overall increase in bone mass in rodents *in vivo*. Heterozygous GSK-3β-deficient (GSK-$3\beta^{+/-}$) mice grow normally without disorders in major organs and without gross skeletal abnormalities. However, radiographs and three-dimensional computed tomography (CT) imaging identified an increase in bone mass and cortical and trabecular bone volumes in femurs taken from GSK-$3\beta^{+/-}$ mice compared with wild-type littermates [89,90]. These changes in bone mass were accompanied by increases in trabecular bone volume and cortical thickness, as well as enhanced bone formation rates, in GSK-$3\beta^{+/-}$ mice compared with wild-type mice. In a partial bone defect model using femoral burr holes, accelerated bone healing was measured in GSK-$3\beta^{+/-}$ compared with wild-type mice [90]. In GSK-$3\beta^{+/-}$ mice, accelerated bone formation was associated with increased protein expression of β-catenin and the Wnt target genes cyclin D1, *C-MYC* and *RUNX2* [90]. Runx2 is known to be a critical transcription factor in the differentiation of osteoblasts. Thus, enhanced expression of Runx2 in GSK-$3\beta^{+/-}$ mice is thought to stimulate bone anabolism by regulating osteoblastogenesis *in vivo*. In fact, heterozygous deficient $Runx2^{+/-}$ mice showed delayed closure of the skull fontanelles and hypoplasia of the clavicles due to impaired bone formation. The fontanelles are an anatomical feature of the infant human skull comprising any of the soft membranous gaps between the cranial bones that make up the calvaria of a fetus or an infant. (The calvarium is the portion of the skull bones forming the roof of the cranial cavity.) Fontanelles allow for rapid stretching and deformation of the neurocranium, as the brain expands faster than the surrounding bone can grow. $Runx2^{+/-}$ mice have a similar phenotype to that of the human disease cleidocranial dysplasia [89]. Cleidocranial dysplasia is a

generalized skeletal disease so named from the collarbone (cleido-) and cranium deformities that people with it often have. These abnormalities in the fontanelles and clavicles were less in dual GSK-3$\beta^{+/-}$ Runx2$^{+/-}$ mice. Additionally, LiCl administration restored both the fontanelle and clavicle abnormalities in the Runx2$^{+/-}$ mice. These studies inducing a genetic deficiency in GSK-3β have clearly shown GSK-3β to be a negative regulator of bone formation. Inhibition of GSK-3β not only stimulates bone formation in mice but also rescues bone abnormalities induced by defects in the pathways involved in osteoblastogenesis.

Several rodent studies using small molecule inhibitors of GSK-3 have corroborated these findings by demonstrating increased bone mass/volume assessed by peripheral quantitative CT/micro-CT and bone formation assessed by dynamic or static histomorphometry analysis following compound treatment in mature animals. Bone anabolism was seen after only 2–6 weeks of repeat dosing in mice or rats with LiCl, BIO, AZD2858, AR79, and AZ13282107 (Table 13.2).

Repeat dosing with LiCl, BIO, or AZD2858 increased trabecular number and thickness and bone volume/trabecular volume (BV/TV) ratio in normal healthy mice. In rats, increases in bone mass following chronic AZD2858 treatment also resulted in stronger bones as measured by biomechanical bending tests [86].

Bone anabolism observed following inhibition of GSK-3 could be attributed to the regulation of multiple pathways involved in osteoblastogenesis and mature osteoblast function, such as:

- commitment of undifferentiated cells to the osteoblast lineage with a reduction in adipogenesis through canonical Wnt signaling, as demonstrated by genetic modification of Wnt signaling *in vivo* [80,91];
- proliferation of preosteoblasts, as suggested by the increased number of osteoblasts per total bone area with GSK-3 inhibitor treatment *in vivo* [31,91];
- reduced osteoblast apoptosis, as observed following GSK-3 inhibitor treatment of calvarial cultures *in vitro* [91].

Alterations in the control of bone resorption may also play a role in the overall increase in bone mass observed with GSK-3 inhibition. The regulation of bone anabolism versus resorption will be expanded upon in subsequent sections of this chapter.

### 13.3.1 Functional Wnt/β-catenin responses in *Xenopus laevis* model systems

*Xenopus laevis* is the scientific (Latin) name of the African clawed frog, which is commonly used as an organism for studying developmental biology, cell biology, toxicology, and neuroscience. Maternal Wnt activity is required for dorsal axis formation in *X. laevis* embryos [28]. Axis duplication has been assessed using *in vivo* model systems of *X. laevis* to determine whether compounds have the ability to selectively activate a functional canonical Wnt/β-catenin response [99]. Cook *et al.* demonstrated that injection of AZD2858 into *X. laevis* embryos caused an axis duplication event, visible as Y-shaped dorsal axes and secondary neural tube formation. The severity of axis duplication increased with increasing concentration of AZD2858, visualized by a higher rate of occurrence of duplicated eyes [41]. Similar effects can be generated via the manipulation of alternative signaling pathways such as BMPs [100]. Therefore, chordin expression was assessed in order to confirm that the effects were due to the specific activation of Wnt/β-catenin. Chordin is a marker of the Spemann organizer [101,102] and is specific for canonical Wnt/β-catenin activation. The Spemann organizer is the organizer for gastrulation in vertebrates. Gastrulation is a phase early in the embryonic development of most animals during which the single-layered blastula is reorganized into a trilaminar ("three-layered") structure known as the gastrula. These three germ layers are known as the ectoderm, mesoderm, and endoderm. Injection of AZD2858 led to the development of distinct secondary regions of chordin expression on the ventral side in 95% of the embryos injected. No second regions were identified in control embryos. AZD2858 induces specific canonical Wnt/β-catenin responses *in vitro* and *in vivo* [41]. In addition to chordin, the canonical Wnt/β-catenin pathway can induce dorsal genes such as the direct Wnt target siamois [103]. *Siamois*, a *Xenopus* zygotic homeobox gene with strong dorsalizing activity, is expressed in the dorsal–vegetal organizer known as the Nieuwkoop center. RT-PCR analysis of animal cap explants treated with either BIO or LiCl resulted in induction of both chordin and siamois [28].

### 13.3.2 Progenitor cell involvement in bone anabolism *in vivo*

Although GSK-3 inhibitors have demonstrated an ability to stimulate preosteoblast differentiation to osteoblasts *in vitro*, there is limited information on the role of GSK-3 and stromal progenitor cells in the bone anabolic response *in vivo*. This section summarizes data in healthy rodents.

#### 13.3.2.1 Alteration in osteoblast progenitor cell lineage *in vivo*

In 8-week-old rats, repeat dosing with AZD2858 daily for 14 days produced an increase in bone mass that was characterized by an increase in both total and cortical bone mineral content, trabecular bone mineral density (BMD), and a dramatic increase in bone formation rate of 480% (Figure 13.1).

In addition, AZD2858 produced a significant increase in force at failure in bone bending tests, denoting increased bone strength. Enhanced bone mass with increased trabecular thickness and number was also seen after 14 days of treatment with AZD2858 in mice [31]. In this study, colony-forming units taken from the bone marrow were counted after 3 and 14 days of dosing with AZD2858; a rise in both CFU-Os and CFU-As was noted after 3 days but not 14 days, compared with vehicle control mice. At day 14, only an increase in CFU-Fs was seen. Thus, a transient early rise in progenitors with potential to differentiate to osteoblasts or adipocytes was observed prior to the increase in bone mass. In tibias, mature osteoblast numbers were increased after 14 days of treatment with AZD2858 with a reduction in the bone

**Table 13.2** Summary of bone changes with GSK3 inhibitors in animal models.

| Animal model | GSK3 inhibitor | Duration of dosing with GSK3 inhibitor | Bone findings with GSK3 inhibitor compared with vehicle group | Reference |
|---|---|---|---|---|
| *Healthy rodents* | | | | |
| Naive mice | LiCl | Daily for 1 month | Increase in trabecular number and thickness, 35% increase in BV/TV and osteoblast number | [91] |
| Naive mice | BIO | Every 48 h for 6 weeks | Increased trabecular number, 18% increase in BV/TV and 30% serum ALP | [92] |
| Naive mice | AZD2858 | Daily for 14 days | Increase in trabecular number and thickness and 50% increase in BV/TV | [31] |
| Naive rats | AZD2858 | Daily for 14 days | Increase in bone mass, rate of bone formation and bone strength, and plasma osteocalcin | [86] |
| Naive rats | AZD2858, AR79, AZ13282107 | Daily for 14–28 days | Increase in bone mass and changes in bone turnover biomarkers (increased P1 NP and decreased TRACP-5b) | [32] |
| *Models of bone loss* | | | | |
| Ovariectomy-induced osteopenia in 6-month-old rats | 603281-31-8 | Daily for 2 months post-ovariectomy | Increased BMD, restored bone volume, normalized marrow adiposity, and increased vertebral biomechanical strength. Increased mRNA expression levels of osteoblast differentiation/function | [74,75] |
| Glucocorticoid-induced bone loss in rats | BIO | Weekly for 6 weeks with methylprednisolone | Prevented the loss in BMD and biomechanical strength and the reduction in bone formation induced by glucocorticoid | [70] |
| Osteopenia in SAMP6 mice | LiCl | Daily for 4 weeks | Increased BV/TV, osteoblast number, and mineral surface | [91] |
| Methotrexate (Mtx)-induced bone loss in rats | BIO | Daily for 5 days with Mtx | Prevented the reduction in BV/TV and trabecular number induced by Mtx. Reduced $TRAP^+$ cells in bone | [93] |
| Osteolysis in 5TGM1 myeloma mice | LiCl | Daily from tumor inoculation | Increased BMD, trabecular volume, and osteoblasts. Reduced $TRAP^+$ cells in bone | [94] |
| Osteolytic lesions induced by xenograft myeloma in SCID mice | BIO | Peri-tumoral injection every 2 days after onset of plasmacytomas | Improved bone area, trabecular thickness, and bone fraction and quality at the bone–tumor interface | [92] |
| Alveolar bone loss in *P. gingivalis*-infected mice | SB-216763 | 1 day prior to infection and then every other day | Prevented alveolar bone loss and reduced systemic inflammation | [95] |
| Periapical bone lesions in rat apical periodontitis | LiCl | Daily after lesion: | | [96] |
| | | from day 7 to 21 | Decreased bone lesions and $TRAP^+$ osteoclasts with increased BV/TV and osteoblast number/surface | |
| | | from day 0 to 28 | No change in bone lesions | |
| *Fracture healing* | | | | |
| Fracture (mouse tibia with intramedullary fixation) | LiCl | Dosed 2 weeks before fracture | Reduced bone density and volume at the fracture site | [97] |
| | | Dosed from 4 days after fracture | Increased bone density and volume at the fracture site | |
| Fracture (rat femur with intramedullary fixation) | AZD2858 (AR28) | Dosed for 3 weeks after fracture | Increased callus area, BMD, BMC, and strength in the fractured limb | [98] |

BV/TV: bone volume/trabecular volume ratio; BMC: bone mineral content.

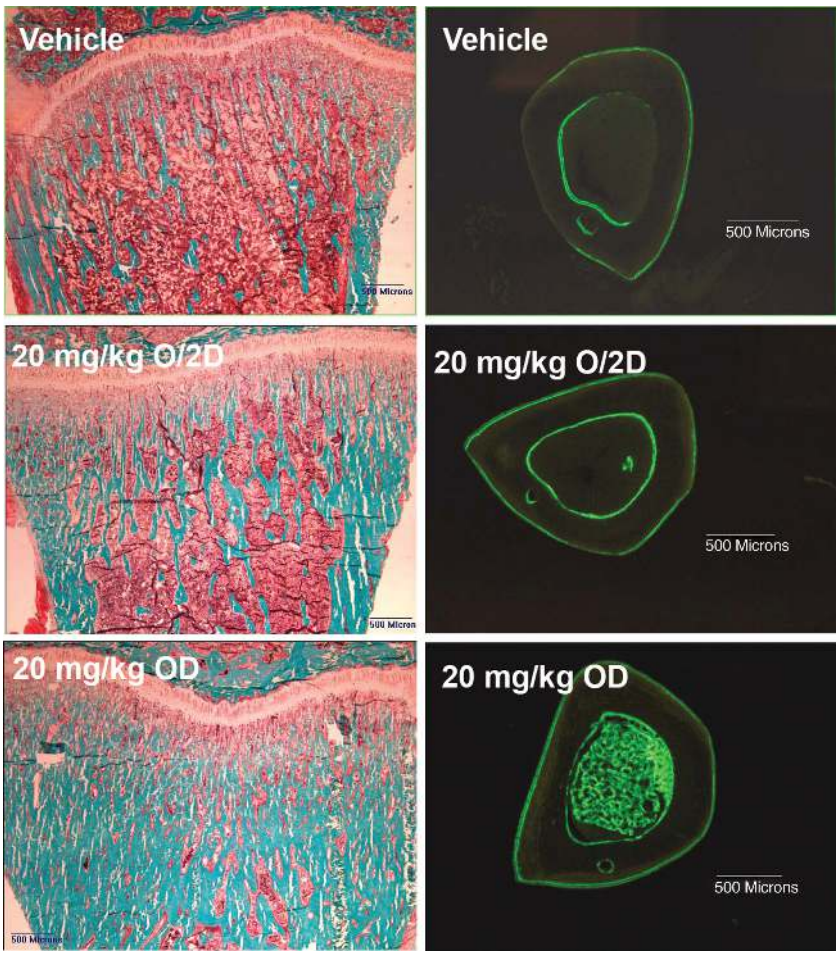

**Figure 13.1** Images showing increased bone formation with AZD2858 treatment in rats. Histology of the proximal tibia metaphysis and mid-diaphysis is shown. Left panels show Masson-Trichrome stained longitudinal sections from the proximal tibia (bright-field microscope pictures). Blue staining indicates bone tissue and red staining indicates soft tissues, including the growth plate and marrow cavity. Right panels show transverse sections of mid-diaphysis double labeled with calcein, a green fluorescent bone-staining dye. (OD; once daily, O/2D; once every 2 days). (See color plate section.) *Source*: Marsell 2012 [86], pp. 619–627. Reproduced with permission from Elsevier.

marrow area occupied by the lipid content of adipocytes at 3 and 14 days. These data suggested that treatment with AZD2858 results in an early wave of MPCs that commit to the osteogenic but not the adipocyte lineage *in vivo* [31]. This provides *in vivo* evidence that stromal progenitor cells commit to the osteoblast lineage and likely contribute to bone anabolism following chronic treatment of GSK-3 inhibitor in rodents. We are not aware of any other *in vivo* studies that have investigated progenitor cell changes after GSK-3 inhibitor treatment in normal healthy rodents.

Biomarkers of osteoblast activity/bone formation, including ALP, osteocalcin, and the N-terminal propeptide of type 1 procollagen (P1NP), are released from mature osteoblasts during bone formation. GSK-3 inhibitors (BIO, AZD2858, AR79, and AZ13282107) increase the levels of these biomarkers in the systemic circulation in rodents [32,86,92], thus providing further evidence that there is increased osteoblast activation and/or number when GSK-3 enzyme activity is reduced *in vivo*.

### 13.3.3 Alteration in bone resorption *in vivo*

The relative impact of GSK-3 inhibition on bone resorption in normal or diseased bone is not well understood *in vivo*. A change in the balance between the rate of bone formation and resorption can alter serum biomarkers, and three different GSK-3 inhibitors have shown an increase in the serum bone formation biomarker P1NP with a concomitant reduction in the bone resorption marker tartrate-resistant acid phosphatase 5b (TRACP5b) *in vivo* [32], thus suggesting an uncoupling of bone formation and bone resorption following inhibition of GSK-3 in rats. However, enhanced bone turnover was demonstrated in a separate study in which the collagen breakdown product C-telopeptide (CTX) was increased with AZD2858 administration in rats [86]. These contrasting findings on biomarkers of bone resorption may be attributed to differences in the magnitude and duration of GSK-3 inhibition achieved *in vivo*. For example, daily dosing with AZD2858 20 mg/kg per day significantly increased serum CTX, whereas intermittent dosing once every other day with 20 mg/kg did not alter CTX levels, even though both dosing regimens produced a significant increase in bone mass at 14 days [86].

Murine colony-forming units of granulocytes and macrophages, which are precursors to osteoclasts, either rose at 3 days or were the same as those in vehicle-treated mice at 14 days of AZD2858 treatment, although a significant increase in

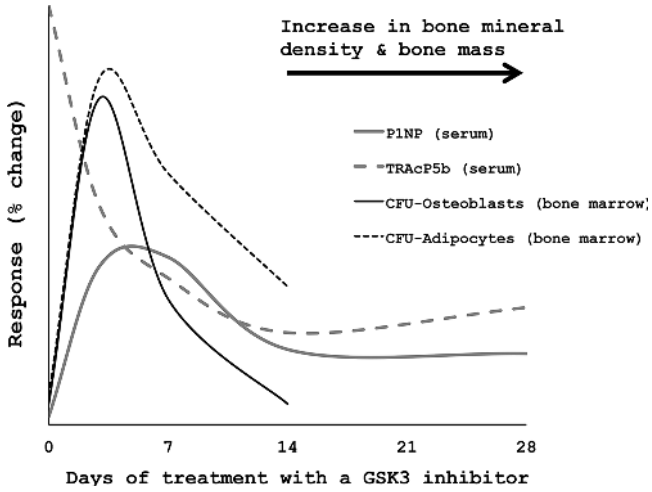

**Figure 13.2** Schematic illustrating the temporal changes in bone marrow progenitor cells, serum bone turnover biomarkers, and bone mass in rodents following daily treatment with GSK-3 inhibitors.

osteoclasts on the endocortical surface was measured in the AZD2858-treated mice compared with vehicle-treated mice [31]. To date, GSK-3 inhibition *in vivo* has shown an overall rise in bone mass, probably as a result of enhanced osteoblast numbers/function that outweighed any increase in bone resorption. The conflicting literature on the role of GSK-3 in osteoclastogenesis and mature osteoclast function and the limited *in vivo* data in this area make it difficult to determine whether GSK-3 inhibition directly or indirectly affects bone resorption. Thus, this area of biology warrants further investigation.

In summary, it is interesting to note that in adult rodents there is a rapid mobilization of bone marrow stromal progenitor cells and systemic biomarkers of bone turnover within a few days of dosing with GSK-3 inhibitors, which then leads to discernable mineralized bone within weeks in otherwise healthy, uninjured bone (see schematic in Figure 13.2).

This bone anabolic response is rapid even in adult rodent bones where bone turnover has slowed due to the natural reduction in bone growth with age. Bone mass is increased globally within the body and particularly within trabecular bone in long bones such as the tibia and femur. The mechanisms behind this change in bone turnover with GSK-3 inhibitors are not localized to a specific type of bone, and this is not unexpected due to the ubiquitous distribution of GSK-3 within osteoblasts and progenitors.

## 13.4 Impact of glycogen synthase kinase-3 inhibition in bone disease

Inhibition of GSK-3 may be beneficial in treating osteoporosis and osteolytic diseases by driving the maturation of osteoblasts, and thus osteogenesis. Several animal models of bone loss have been used to explore the biology of GSK-3 in bone anabolism and resorption, with some evidence of alterations in progenitor cell lineage toward osteoblastogenesis over adipogenesis and chondrogenesis (summarized in Table 13.2).

### 13.4.1 Osteopenia and osteoporosis

Osteopenia can be induced by estrogen depletion following oophorectomy or chronic dosing with glucocorticosteroids *in vivo*. Oophorectomy in rats leads to significant bone loss and increased marrow adiposity, which is associated with changes in the expression of multiple genes, including a decrease in markers of osteogenesis and chrondrogenesis and an increase in markers of adipogenesis and lipid metabolism [74,75]. Long-term administration of LY603281-31-8 in oophorectomized rats restored bone loss and reversed bone marrow adiposity. Analysis of marrow stromal cells measured by the number of CFU-Fs from rats treated with LY603281-31-8 showed an increase in total CFU-Fs and CFU-F/ALP$^+$ cells compared with oophorectomized control rats. These results suggest that the reversal in bone loss with GSK-3 inhibition is caused by progenitor cell commitment to the osteoblast lineage with a concomitant reduction in adipogenesis in osteopenic rats [75].

It is well known that long-term treatment with glucocorticosteroids suppresses the formation of bone which can lead to osteoporosis and an increased risk of fractures. Animal models have therefore been developed to recapitulate some of these bone changes. Male rats treated with methylprednisolone for 6 weeks demonstrated reductions in bone weight, global mineral content, and femoral mineral density [70]. In addition, bone strength and bone formation rate were reduced in methylprednisolone-treated rats. BIO, administered for six consecutive weeks, attenuated the loss of bone density and biomechanical strength and prevented the reduction in bone formation rate induced by chronic glucocorticosteroid treatment. The precise mechanisms by which BIO altered bone turnover in this model are not known, but *in vitro* studies using BIO suggest that increases in osteoblast differentiation, maturation, and viability may be involved. GSK-3 inhibitors such as BIO can also protect against glucocorticosteroid-induced apoptosis in osteoblastic cell lines *in vitro* [70]. In addition, increases in marrow adipocytes and osteoclasts were observed with glucocorticosteroid treatment, and these responses were reversed with BIO, thus suggesting that inhibition of GSK-3 may be regulating adipogenesis and/or osteoclastogenesis induced by glucocorticosteroids.

LiCl was found to alter the balance of adipocytes and osteoblasts in bone marrow progenitor cells obtained from femurs in a murine dexamethasone-induced bone loss model. Daily injection of dexamethasone for 5 weeks caused a reduction in trabecular bone volume, bone thickness, and BMD in mice [104]. A rise in adipocyte numbers in the trabecular bone marrow space of these dexamethasone-treated mice was also seen. Studies using BMSCs from the femurs of dexamethasone-treated mice demonstrated a reduced ability to differentiate into osteoblasts and an upregulation of adipocyte markers

compared with BMSCs from normal mice. LiCl treatment of the BMSCs from dexamethasone-treated mice produced an increase in the osteoblastogenic markers osterix and osteocalcin with a dramatic reduction in the adipocyte markers C/EBP, adipocyte protein 2, and Glut4 in the presence of BMP-2. Thus, LiCl, through the activation of Wnt signaling, regulated progenitor cell differentiation pathways of dexamethasone-treated BMSCs to favor differentiation to osteoblasts over adipocytes. Additional studies with GSK-3 inhibitor treatment *in vivo* are required to determine the translatability of these *in vitro* BMSC findings of preference for osteoblastogenesis and bone formation over adipogenesis in glucocorticosteroid-induced osteoporosis models.

GSK-3 inhibition has also been investigated in a murine model of senescence-induced osteopenia. The senescence-accelerated mouse (SAMP6) has many features of senile osteoporosis, showing an accelerated osteoporosis phenotype due to reduced osteoblastogenesis [105]. Treatment of SAMP6 mice for 4 weeks with LiCl increased bone volume and osteoblast number and reduced marrow adiposity [91]. No changes in osteoclast numbers were observed. In this model, GSK-3 inhibition could again be diverting stromal bone marrow cells from the adipocyte lineage toward the osteoblast lineage, thus favoring bone formation.

Osteoporosis is also observed in low-density lipoprotein receptor-related protein 5 (LRP5)-deficient mice. LRP5 transduces the Wnt signal via the canonical pathway, leading to β-catenin accumulation in the nucleus and stimulation of gene transcription, resulting in bone production. One month of treatment of $LRP5^{-/-}$ mice with LiCl increased bone volume and bone formation rates *in vivo* and was associated with a concomitant increase in Wnt-response genes in bone marrow cells. LiCl was shown to activate intracellular Wnt signaling, independently of LRP5, which caused osteoblastogenesis in $LRP5^{-/-}$-deficient cells *in vitro* and increased bone formation in $LRP5^{-/-}$ mice *in vivo* [91].

### 13.4.2 Methotrexate-induced bone loss

Long-term chemotherapy with agents such as methotrexate is associated with an increase in the prevalence of bone-related complications, such as reduced BMD, osteoporosis, marrow adiposity, and an increased fracture risk. In rodent models, methotrexate decreases trabecular bone volume and increases marrow fat accumulation. As well as myelosuppression, methotrexate alters the balance of osteogenesis and adipogenesis in the bone marrow with short-term (5 days) and longer term (intermittent over 6 weeks) dosing regimens in rats [93]. This was demonstrated in *in vitro* differentiation assays with BMSCs by a decreased potential for osteogenic differentiation manifested by decreased expression of Runx2 and osterix and an increased commitment to adipogenesis manifested as increased PPAR-γ levels [93]. Methotrexate was shown to reduce Wnt and β-catenin signaling in bone and bone marrow cells (BMSCs) after 5 days of dosing in rats [106]. Administration of BIO concomitantly with methotrexate over 5 days attenuated the decrease in bone volume and trabecular number and abrogated the increase in adipocyte number, but not fat volume, induced by methotrexate treatment. In addition, the reduction in Wnt/β-catenin gene expression in metaphyseal bone induced by methotrexate was prevented by concurrent BIO treatment. Analysis of BMSC populations *in vitro* following methotrexate treatment demonstrated a reduction in mineralization potential that was reversed by BIO. However, BIO did not have an effect on the methotrexate-induced adipogenesis at day 6. Thus, in this model of methotrexate-induced bone loss, BIO treatment preserved bone loss through activation of Wnt signaling, which led to osteogenesis but only partially abrogated adipogenesis. This suggests that other non-Wnt pathways could be involved in the regulation of adipocyte differentiation and fat deposition following methotrexate treatment.

Long-term treatment with drugs such as glucocorticosteroids and methotrexate can cause bone loss in patients. Preclinical models, which reproduce some of these bone findings, demonstrate changes in stromal progenitor cell differentiation with a preference for adipogenesis over osteogenesis *in vivo*. GSK-3 inhibitors were able to prevent drug-induced bone loss and stimulate bone formation via activation of the Wnt/β-catenin signaling pathway.

### 13.4.3 Fracture healing

Fracture healing is a complex process involving many different cell types, including stromal progenitor cells. Initially, during fracture repair, MSCs accumulate at the site of bone injury, proliferate, and differentiate during two healing processes: intramembranous ossification and endochondral ossification. Intramembranous ossification involves bone formation directly from committed osteoprogenitor cells and undifferentiated MSCs in the periosteum, leading to hard callus formation. In endochondral ossification, MSCs differentiate to chondrocytes, producing a cartilaginous matrix that then becomes calcified and replaced by bone. Since GSK-3 inhibitors can upregulate β-catenin and stimulate progenitor cell commitment to the osteoblastic lineage they are likely to impact on fracture healing. LiCl or AZD2858, administered after induction of a fracture, enhanced fracture healing, as demonstrated by increases in bone volume, mass, and strength as well as by the rate of healing of fractures in rodents [97,98]. Improved fracture healing by LiCl acts in part via β-catenin signaling, as demonstrated using conditional β-catenin null mutations in a mouse fracture model. LiCl increased β-catenin levels in tissues at fracture sites, which was thought to stimulate osteoblast differentiation and new bone formation [97]. AZD2858 administration produced an increase in BMD and content in bone fracture calluses after only 2–3 weeks of treatment in a rat fracture model [98]. Histological analysis of the time course of bone healing showed a more rapidly healing process without the preformation of cartilage tissue, suggesting GSK-3 inhibition may prevent differentiation of chondrocytes and enable preferential differentiation of MSCs to osteoblasts [98].

The timing of intervention with GSK-3 inhibitors during the different stages of fracture repair may be critical for successful healing [107]. In contrast to the enhancement in healing observed with LiCl treatment that started 4 days after the fracture, pretreatment of mice with LiCl for 2 weeks prior to induction of fractures prevented healing of the fractures. At the fracture site, even though an increase in β-catenin expression was seen, there was evidence of undifferentiated MSCs with this "prophylactic" LiCl treatment. This finding suggests an inability of GSK-3 inhibitors to stimulate chondrogenesis and/or osteoblastogenesis during the early stages of fracture healing [97]. Although β-catenin stabilization is thought to be an important signaling process in fracture repair, it has been shown that changes in β-catenin levels in both gain-of-function and loss-of-function mutations in mice can prevent fracture healing *in vivo*. The cellular localization of β-catenin is critical as stabilization of β-catenin in specific osteoblast cells in conditional gain-of-function mice led to enhanced bone healing [97]. Thus, controlled stimulation of β-catenin during the initial stages of fracture healing with respect to timing and cellular locations is important in ensuring successful fracture healing through differentiation of MSCs from osteoblastic precursors to mature osteoblasts without altering chondrogenesis.

### 13.4.4 Multiple myeloma-associated bone disease

Multiple myeloma is a malignant neoplasm of mature plasma cells in the bone marrow, one result of which is the occurrence of osteolytic (bone loss) lesions throughout the skeleton. These osteolytic lesions develop in the bone as a consequence of complex changes in cytokines in the bone marrow, including increased RANKL and decreased OPG, osteoclastogenesis, and a reduction in MSC differentiation to osteoblasts. The malignant plasma cells impair osteogenic differentiation of MSCs through cell contact or release of soluble factors, including IL-7, hepatocyte growth factor, IL-3, and Wnt inhibitors. These changes in the skeletal microenvironment result in an overall increase in bone loss with impairment of bone formation, bone pain, and an increased risk of fractures. A variety of DNA polymorphisms, including the *GSK-3β* gene, have been linked to bone disease in people with myeloma [108]. GSK-3 is thought to be a prosurvival kinase in myeloma primary cells or cell lines. The GSK-3β inhibitors thiadiazolidinone, BIO, SB-216763, and SB-415286 are effective at inducing apoptosis of these malignant cells [92,109,110].

In addition to reducing myeloma cell survival, GSK-3 inhibitors may also reduce the osteolytic lesions in multiple myeloma. Blockade of GSK-3 could bypass the inhibition of the Wnt cascade in multiple myeloma induced by soluble Wnt inhibitors such as Dickkopf factor (DKK1) and thereby improve osteoblast maturation and osteogenesis. LiCl administration in the 5TGM1 murine myeloma model prevented osteolysis as measured by an increase in BMD, trabecular volume, and osteoblast numbers. A reduction in $TRAP^+$ cells and tumor burden within the bone was also seen [94]. Peritumoral administration of BIO after induction of plasmacytomas (malignant plasma cell tumors) in mice increased bone area, trabecular thickness, bone perimeter, bone fraction, and quality at the bone–tumor interface [92]. The improvement in bone quality could be due to a direct effect on osteogenesis rather than a reduction in tumor survival as the rate of growth of the tumor was similar in control versus BIO-treated groups. However, as BIO caused an increase in necrotic tumor tissue and LiCl reduced tumor burden in the bone, a direct effect of GSK-3 inhibition on tumor cell burden cannot be excluded [92,94]. As bone resorption is a prominent feature in myeloma, further studies are warranted to understand the ability of GSK-3 inhibitors to modulate osteoclastogenesis as well as osteoblastogenesis in these preclinical models of the disease.

### 13.4.5 Periodontal disease

Bone loss in the jaw from oral diseases such as periodontitis and periapical infections is common in adult humans. The bacterium *Porphyromonas gingivalis* initiates an innate immune system response mainly through activation of the toll-related receptors TLR-2 and TLR-4 (see Chapter 33). This produces an inflammatory response and periodontal bone loss. The exact mechanisms involved in this bone loss are unknown. *In vitro P. gingivalis* lipopolysaccharide (also known as endotoxin) reduces GSK-3β phosphorylation, β-catenin nuclear localization, and ALP activity in BM-MSCs, resulting in a reduction of osteogenic potential [96]. Osteogenesis can be restored by the addition of Wnt3a to the BM-MSC cultures, inhibition of GSK-3β, and activation of Wnt signaling.

Periapical lesions were formed by occlusal exposure of the pulp in both mandibular first molars for 4 weeks in rats. Rats treated with LiCl from days 7 to 21 after induction of the lesion had reduced periapical lesions and improved BV/TV ratios compared with control groups [96]. In addition, an increase in osteoblast numbers and expression of the osteoblast differentiation markers Runx2, osterix, osteocalcin, and bone sialoprotein in the periapical region were observed, as well as a reduction in $TRAP^+$ osteoclasts adjacent to periapical bone [96]. In contrast, continuous dosing for 28 days did not alter apical lesion and significantly prevented bone formation. In a mouse model of *P. gingivalis* infection, systemic pretreatment with SB-216763 prevented pathogen-induced bone loss on the buccal surface of the maxillary molar teeth [95]. In addition, this GSK-3 inhibitor reduced neutrophil infiltration and IL-17 levels in gingival tissues and decreased the level of circulating inflammatory cytokines, thus suggesting that GSK-3 inhibition may restore osteoblastogenesis via Wnt pathway activation and reduce osteoclastogenesis via a reduction in IL-17 in periodontal *P. gingivalis* infection.

### 13.4.6 Clinical findings with lithium

The only clinical trials that have investigated the effect of GSK-3 inhibition on bone turnover have been with lithium. Conflicting reports from these clinical studies have shown either no effect or

a decreased or an increased bone turnover. An example of a positive effect on BMD was evaluated in people on lithium carbonate therapy for psychiatric disorders for more than 1 year. These individuals had a 4.5–7.5% increase in BMD in the spine, femoral neck, and trochanter of the hip compared with control individuals [111]. Reduced levels of serum ALP, C-telopeptide, and osteocalcin in the lithium recipients also suggested an overall lowering of bone turnover.

The increased risk of fractures in osteoporotic patients has led to the development of new therapies for bone loss. The relationship between the long-term use of lithium and fracture risk has been investigated in a number of clinical studies. An observational study investigating the impact of chronic lithium treatment on the risk of any fracture demonstrated a reduced risk of fracture (odds ratio 0.75) in individuals treated with lithium over age- and gender-matched controls [112]. In a case–control study, the use of lithium was associated with a decreased risk of fractures that was not altered by the cumulative duration of lithium use [113]. However, robust clinical data are limited owing to the lack of randomized controlled trials in this field and the lack of GSK-3 inhibitors with suitable properties for use in humans.

## 13.5 Summary

It is widely recognized that key developmental signaling pathways, including those involving bone morphogenetic proteins, fibroblast growth factor, and wingless (Wnt), have a critical role to play in MSC biology, with a complex interplay of signaling through these pathways coordinating both proliferation and lineage specification [114]. However, although much has been elucidated about the roles of different signaling mechanisms on MSC fate, many conclusions have been confounded by the fact that the cellular response is critically dependent on microenvironmental parameters such as cell density at the onset of differentiation [115], the timing of exposure to inductive signals, and the impact of autocrine and paracrine signaling [116–118].

Clearly, GSK-3 inhibitors stimulate bone formation in both healthy bones and in a variety of disease models of bone loss, such as myeloma, and in fracture healing in rodents. Bone anabolism is observed with GSK-3 inhibition in the healthy bones and fractured bone within the same animal, demonstrating the ubiquitous role that GSK-3 plays in regulating bone turnover [98]. GSK-3 inhibitors have been shown to alter progenitor cell commitment in bone to an osteoblastic/ALP$^+$ phenotype, suggesting that bone anabolism induced by GSK-3 inhibitors is likely to be caused by increased osteoblastogenesis. The main signaling pathway for this anabolic effect is likely to be activation of Wnt signaling and upregulation of nuclear β-catenin. In addition, it is possible that GSK-3 inhibitors may have a dual role in stimulating bone formation and altering bone resorption. Uncoupling of bone anabolism and resorption has been demonstrated in healthy rodents [32], and a reduction in osteoclast number has been observed in several models using GSK-3 inhibitors, including oophorectomized rodents, a rodent model of myeloma, and a rodent model of periodontal disease. However, there is conflicting literature on the role of GSK-3 in bone resorption, osteoclastogenesis, and osteoclast function, particularly from *in vitro* studies that unfortunately cannot recapitulate the complex microenvironment of intact bone.

Depending on the complexity of the microenvironment of the bone during disease, GSK-3 can alter commitment of stromal progenitor cells to different lineages: osteoblasts, adipocytes, or chondrocytes. In models of osteopenia, such as that seen in oophorectomized animals or in recipients of glucocorticosteroids, the reversal in bone loss following GSK-3 inhibition was caused by progenitor cell commitment to the osteoblast lineage with a concomitant reduction in commitment to adipogenesis. For healing of bone fractures, increased osteoblastogenesis with GSK-3 inhibitors occurred but was associated with a reduction in chondrogenesis in some circumstances. In periodontal infection due to *P. gingivalis*, GSK-3 inhibition restored osteoblastogenesis as well as reduced osteoclastogenesis. The commitment of progenitor cells to different lineages was probably due to the ability of GSK-3 inhibitors to modulate many different intracellular pathways, including those of Wnt, AKT, and SMAD, but was also likely affected by the specific bone microenvironment altered by the disease. Further studies are required to understand the interplay between GSK-3 inhibition and these pathways in stromal progenitor cell commitment *in vivo*.

The timing of intervention with GSK-3 inhibitors may be critical in achieving a successful therapeutic intervention, as illustrated in the healing process of fractures and periodontal bone lesions. Prophylactic or early intervention with lithium during the healing process delayed bone healing. In contrast, enhanced bone healing was observed when dosing started at 4 days and 7 days after the lesion was induced in the fracture and periodontal models respectively. The mechanisms behind these differences – for example, Wnt- or non-Wnt-mediated mechanisms – is currently unclear, but inhibition of chondrogenesis during the early phase of fracture healing is known to cause delayed healing.

Translating these preclinical findings with GSK-3 inhibitors to the clinic is key to understanding the role of GSK-3 in human bone disease and could potentially provide new treatments for bone diseases. However, the impact of GSK-3 inhibitors on other cell types and tissues has potential to limit utility in the clinic owing to possible side effects with continuous dosing [119]. Intermittent dosing may allow stimulation of bone anabolism while allowing other tissues to recover from the potential adverse effects of GSK-3 inhibition. Intermittent dosing was effective in models of bone loss due to myeloma or to glucocorticosteroid administration and in healthy rats *in vivo*.

Small molecules may be an attractive alternative to cell replacement approaches to amplify progenitor cell pools or to direct their differentiation by targeting specific signaling pathways. Moreover, they can be used to understand basic mechanisms regulating progenitor cell self-renewal and differentiation.

Elucidating how Wnts act as instructive cues for the recruitment, maintenance, and maturation of MSCs and their differentiated progenies is of significant interest given the potential use of these cells in regenerative medicine [31].

In conclusion, our data are compatible with inhibition of GSK-3 acting on proliferation and commitment of MSCs with osteo- and adipogenic potential and which is driven to osteogenic differentiation at the expense of adipogenic differentiation. Our data also highlight the complex network of responses taking place with time and occurring in different cell types at specific stages of commitment. The work draws attention to the powerful effect that amplifying progenitor cells *in vivo* may have on bone mass. Further work is required to exclude the possibility of a reduction in progenitor cell numbers following prolonged treatment. It will also be important to determine the optimal dose and schedule of administration and to dissect the molecular events mediating the feedback mechanism to guarantee a prolonged and sustained effect of GSK-3 inhibitors as a bone anabolic treatment.

CHAPTER 14

# Early molecular events during *in vitro* chondrogenesis

**Tommy A. Karlsen, Rune B. Jakobsen, and Jan E. Brinchmann***

Norwegian Center for Stem Cell Research, Department of Immunology, Oslo University Hospital and University of Oslo, Oslo, Norway

**Chapter menu**

14.1 Introduction, 167
14.2 Adult articular cartilage, 168
14.3 Developmental chondrogenesis, 168
14.4 Molecular aspects of *in vivo* chondrogenesis, 169
14.5 Determinants of *in vitro* chondrogenesis, 171
14.6 Tissue source of mesenchymal stromal cells, 171
14.6.1 *In vitro* cell culture, 171
14.7 Three-dimensional culture systems and bioscaffolds, 172
14.8 Epigenetic changes during early *in vitro* chondrogenesis, 172
14.8.1 An introduction to epigenetics, 172
14.8.2 DNA methylation of the *COL2A1* and *COL10A1* promoters, 173
14.8.3 DNA methylation of promoters in other chondrogenesis candidate genes, 173
14.8.4 Genome-wide map of quantified epigenetic changes during *in vitro* chondrogenesis of bone marrow mesenchymal stromal cells, 174
14.8.5 Epigenetics: conclusions, 175
14.9 Role of microRNAs during early *in vitro* chondrogenesis, 176
14.9.1 An introduction to microRNAs, 176
14.9.2 Role of miRNA-140 in developmental chondrogenesis, 177
14.9.3 miR-140 targets identified *in vivo* and in vitro, 178
14.9.4 Defining the role of miR-140 during chondrogenic differentiation of mesenchymal stromal cells and dedifferentiation of articular chondrocytes, 178
14.9.5 Impact of microRNAs other than miR-140 on chondrogenic differentiation of mesenchymal stromal cells, 179
14.9.6 MicroRNAs in chondrogenesis: conclusions, 181
14.10 Early changes in gene expression during *in vitro* chondrogenesis, 182
14.10.1 Genes involved in collagen fibrillogenesis, 183
14.10.2 Genes involved in synthesis of proteoglycans and glygosaminoglycans, 183
14.10.3 Transcription factor genes, 183

## 14.1 Introduction

Cartilaginous tissues are found in many parts of the body, and as three different types: elastic, hyaline, and fibrocartilage. Elastic cartilage is found in the external ear, the auditory tube, and the epiglottis; fibrocartilage is found mainly in the intervertebral discs and in the menisci; and hyaline cartilage is found covering the articular surfaces of synovial joints. The functional difference between these tissues is determined by the composition of their extracellular matrix (ECM).

The ECM is a collection of extracellular molecules secreted by cells that provides structural and biochemical support to the surrounding cells. The composition of the ECM varies between multicellular structures. However, cell adhesion, cell-to-cell communication, and differentiation are common functions of the ECM. The ECM includes the interstitial matrix and the basement membrane. Gels of polysaccharides and fibrous proteins fill the interstitial space and act as a compression buffer against the stress placed on the ECM. Basement membranes are sheet-like depositions of ECM on which various epithelial cells rest.

As the vast majority of *in vitro* cartilage research is focused on hyaline cartilage, this will be the tissue of interest for this chapter.

Research on *in vitro* hyaline cartilage formation may be performed in order to establish a model system for cartilage diseases, or as a model to study the *in vitro* differentiation of mesenchymal stromal cells (MSCs) to the end-differentiated

articular chondrocytes (ACs), but mostly this research is motivated by the desire to create tissue-engineered cartilage for repair of lesions of articular cartilage. This is a highly desirable endpoint because lesions of articular cartilage do not usually heal spontaneously. A persisting lesion with increasing pain and reduced functionality of the joint usually leads to surgical intervention. Today, the most frequently used surgical technique is microfracture of the bone plate between the cartilage lesion and the bone marrow. This leads to the release of bone marrow and blood into the lesion cavity with the subsequent formation of a clot. Over time the clot will be replaced by fibrocartilage [1]. This will provide symptomatic relief initially, but the long-term result is uncertain, with osteoarthritis (OA) a relatively common outcome. The modern alternative to microfracture surgery is to implant cells in order to regenerate the lost cartilage. This strategy was initiated by Brittberg *et al.* in 1994 when they removed a small piece of cartilage from a damaged knee through an arthroscope, isolated single chondrocytes from the biopsy, expanded the cells *in vitro*, and implanted them back into the lesion covered by a flap [2]. This procedure, autologous chondrocyte implantation (ACI), has been followed by second-generation procedures in which synthetic membranes, able to act as cell carriers, have replaced the flap. In third-generation procedures the ACs are established in a biomaterial before implantation. However, a 2010 Cochrane review concluded that there was no evidence that ACI of any generation performed better than microfracture surgery [3]. This may be because ACs, when they are expanded in monolayer cultures *in vitro*, lose their ability to produce ECM molecules typical of hyaline cartilage, such as type II collagen (COL2) and aggrecan, and begin instead to produce COL1 and versican in a process called dedifferentiation [4].

When the cartilage biopsy is taken in order to get tissue for isolation of ACs, a small injury to the healthy cartilage is created. Although this lesion is frequently situated in the periphery of the articular cartilage, outside that part of the cartilage which functionally interacts with the cartilage covering the end of the opposing bone, there is still a risk of morbidity to this procedure [5]. To avoid this problem, MSCs may be used instead. MSCs can be obtained from several sites, particularly from the bone marrow, with minimal pain and no morbidity. Human adult MSCs may resemble the mesenchymal cells from which cartilage and bone are formed during embryogenesis [6]. If so, it should be possible to mimic the developmental stages involved in embryological chondrogenesis when MSCs are differentiated to chondrocytes *in vitro*. Developmental chondrogenesis has been carefully studied and well reviewed, based mostly on studies in rodents [7–9] and humans with developmental disorders of cartilage and bone [6]. Recently, data were published based on studies of human fetal tissues [10]. The purpose of this chapter is to review current knowledge about the early molecular changes observed during *in vitro* chondrogenesis and then, where possible, to compare this with *in vivo* chondrogenesis. To do so we need to first review the composition of adult articular cartilage and its developmental history.

## 14.2 Adult articular cartilage

Where mobile bones meet, the areas of contact are covered by a highly specialized tissue called hyaline cartilage. Because this hyaline cartilage is part of the joint, it is also frequently called articular cartilage. Articular cartilage has no blood supply and no nerve supply, which are probably the main reasons why lesions of this tissue heal poorly or not at all. The cells make up only 2–3% of the volume of the cartilage, the rest being ECM and water. All the cells are end-differentiated chondrocytes, but their ECM synthesis profile varies a little depending on their anatomical situation within the cartilage.

The most abundant ECM protein is COL2. These are homotrimeric molecules, synthesized as procollagens with propeptides at both ends that need to be cleaved off after secretion from the chondrocytes in order for fibrillation to occur. COL2 fibrils also contain small amounts of COL9, localized at the fibril surfaces, and COL11, which is important for regulation of fibril diameter. The collagen fibrils provide tensile strength to the cartilage. Other collagens in articular cartilage include COL6 (found predominantly in the pericellular region), COL1 (synthesized by some of the chondrocytes near the cartilage surface), and COL10 (synthesized sparsely in the calcified zone of articular cartilage near the subchondral bone).

The major proteoglycan in articular cartilage is aggrecan. Aggrecan is modified by side chains of glycosaminoglycans (GAGs), such as chondroitin and keratan sulfate and other oligosaccharides, and forms large aggregates with the long molecules of hyaluronic acid linked together by the link protein. These aggregates bind water and give cartilage its compressive strength. Proteoglycan 4, also called lubricin, is found on the surface of articular cartilage. It serves to reduce friction between the two articular surfaces [11].

Other molecules of importance are cartilage oligomeric protein (COMP) of the thrombospondin family, fibronectin, matrilins, fibrilins, and chondroadherins. The functional roles played by these molecules are incompletely understood.

## 14.3 Developmental chondrogenesis

The limb skeleton is formed from lateral plate mesoderm cells that migrate to the sites where the skeletal elements will develop. Here, they form mesenchymal condensations of high cell density [12]. These cells proliferate and begin to differentiate into chondroprogenitor cells. Further differentiation leads to the formation of chondrocytes. These cells continue to proliferate, but they also start to produce ECM, which, with the chondrocytes, makes up cylindrical structures called cartilage anlagen, produced in sequence from proximal to distal ends [6]. Beginning in the center of the anlagen, the chondrocytes subsequently exit the cell cycle and increase their cell volume to become hypertrophic chondrocytes. Through secretion of angiogenic factors, these cells induce sprouting angiogenesis from the

surrounding perichondrium. The vessels allow invasion of osteoblasts, osteoclasts, and hematopoietic cells; the hypertrophic chondrocytes undergo apoptosis, and cartilage is replaced by bone in what is called the primary ossification center [6,7,9]. At the same time, osteoblasts in the perichondrium around the middle portion of the cartilage anlagen, called the diaphysis, form a bony collar around the anlagen [6]. The rounded ends of the anlagen are called the epiphysis. Between the diaphysis and the epiphysis, in a region called the metaphysis, secondary ossification centers are formed at both ends of the anlagen. Here, a plate of cartilage called the growth plate becomes the site for bone elongation through a coordinated sequence of chondrocyte proliferation, hypertrophy, apoptosis, and replacement by osteoblasts and osteoclasts and subsequent bone formation [13].

Starting from the prechondrogenic condensations, there is now evidence for the development of two different types of chondrocytes. One is the type just described, which gives rise to the cartilage anlagen and becomes replaced by bone in the process called endochondral ossification. The other type of chondrocyte is formed from mesenchymal cells developing in a region called the interzone that forms at the sites of prospective joints. Some of the cells in the interzone die by apoptosis, and the space left behind becomes the synovial cavity. Cells in the interzone layer closest to the epiphyseal part of the anlagen differentiate to become ACs which produce the hyaline ECM of articular cartilage [14,15].

## 14.4 Molecular aspects of *in vivo* chondrogenesis

The molecular events associated with the developmental features described above are complex and still incompletely understood. In this Chapter only those aspects of gene expression and protein synthesis that are most relevant for *in vitro* chondrogenesis will be described. It should be noted, however, that most of what is known today about molecular aspects of *in vivo* chondrogenesis stems from chondrogenesis occurring within the cartilage anlagen. Scientists attempting to make cartilage from MSCs *in vitro* may perhaps be better served by trying to imitate the process by which cells of the mesenchymal condensations differentiate through interzone cells to become ACs. Unfortunately, this process is less well described.

In the mesenchymal condensations, important cell adhesion molecules are neural cadherin (N-cadherin) and neural cell adhesion molecule. The ECM is composed mainly of fibronectin, COL1, the IIA splice variant of COL2, and COMP (Figure 14.1) [7].

The transcription factor (TF) most closely associated with *in vivo* chondrogenesis is Sry-like homeobox TF (SOX) 9. *SOX9* transcripts are detected in prechondrogenic mesenchymal condensations as early as 8.5–9.5 days of mouse embryonic development. However, the stage of mesenchymal condensation is thought to last until day 11.5 to 12.5, at which time *SOX6* and some other *SOX* genes are also expressed [8]. At early stages of mesenchymal condensation patterning, systems such as fibroblast growth factors (FGFs), hedgehog, bone morphogenetic proteins (BMPs), and wingless-type mouse mammary tumor virus integration site family (WNTs) coordinate signaling along the three axes of the limb [7]. However, perhaps the most important signaling axis at this stage occurs between growth differentiation factor 5 (GDF5) and its receptor BMP receptor 1B (BMPR1B) [10,16]. Expression of *GDF5* was found to differentiate cells within the mesenchymal condensations toward interzone cells. These cells, in turn, gave rise to articular cartilage, the synovial lining, and other joint tissues, but

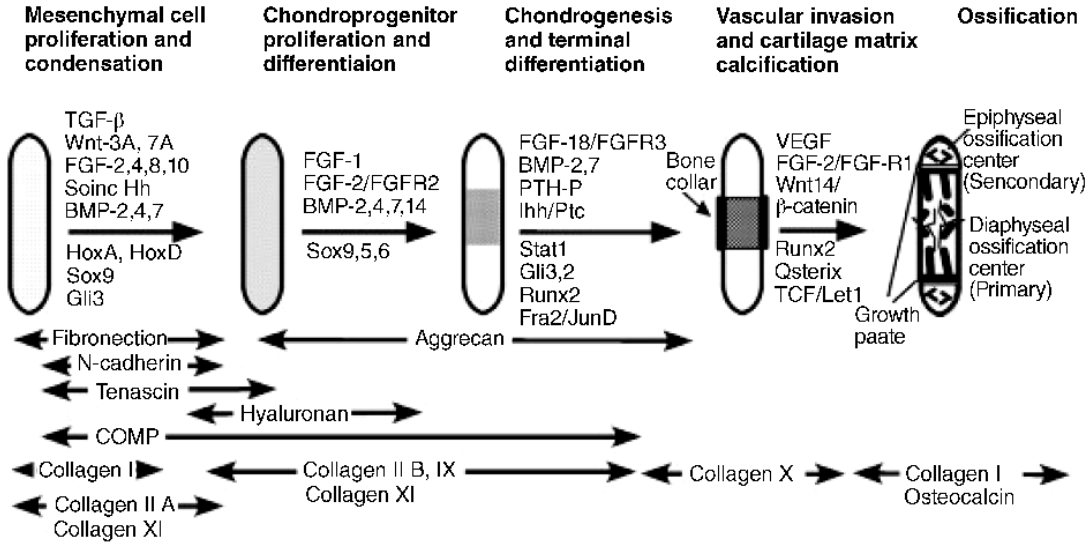

**Figure 14.1** Sequence of events of chondrogenesis during the development of long bones. The different stages are represented schematically, showing the temporal patterns of growth and differentiation factors above the arrows and the TFs involved below the arrows. The ECM proteins that distinguish the different stages are indicated below. *Source*: [7] Goldring, M.B. *et al.*, *J Cell Biochem* 2006; **97**, 33–44.

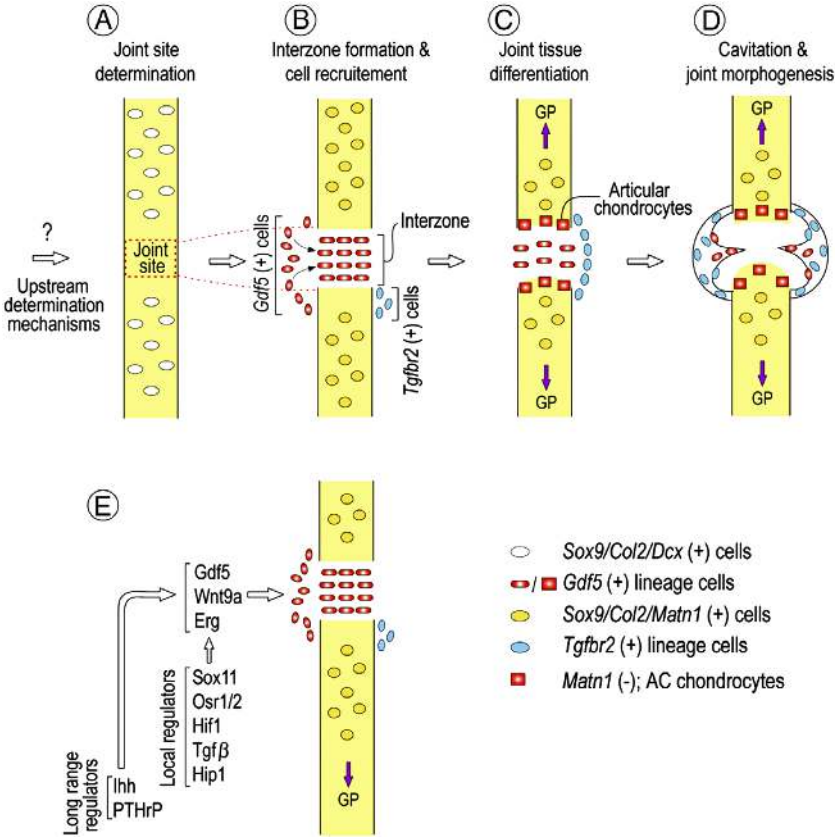

**Figure 14.2** Generalized model of limb joint formation and morphogenesis. (A) At early developmental stages, an as-yet unknown upstream determination mechanism would identify and prescribe the location of the joints along *SOX9*/*COL2*/*DCX*-expressing anlagen. (B) Soon after, *GDF5* expression would be activated along with other interzone-specific genes (see (E)) that would define the initial interzone mesenchymal population within the *SOX9*/*COL2*/*MATN1*-positive cartilaginous anlagen. This would be accompanied by cell immigration from the flank, and cells located dorsally and ventrally would activate *TGFBR2* expression. (C) *GDF5*-positive cells adjacent to their respective cartilaginous anlagen, with a *SOX9*/*COL2* history but negative for *matrilin-1* expression, would differentiate into ACs. (D) Additional differentiation processes and mechanisms, such as muscle movement, would bring about cavitation and genesis of other joint tissues, such as ligaments and other meniscus tissue, involving *GDF5*- and *TGFBR2*-positive and -negative cell progenies. (E) Schematic summarizing local and long-range regulators that converge to regulate interzone gene expression at the early stages of joint formation. *Source*: [16] Decker 2014, pp. 5–10. Reproduced with permission of Elsevier.

contributed little to the development of the cartilage anlagen. *GDF5* null mutants formed functionally defective joints [15]. The development of articular cartilage from interzone cells requires the hypoxia regulator HIF-1α to function, and SOX11, TGF-β, WNT9a, and odd-skipped related 1/2 (OSR1/2) were also found to be involved in this process (Figure 14.2) [16]. Additionally, during human fetal development, *GDF5* and its *BMPR1B* receptor were found to be highly expressed in prechondrocytes, with much higher expression in prechondrocytes than in the cartilage anlagen [10].

Through the stage of chondroprogenitor proliferation and the formation of cartilage anlagen, *SOX9* and *SOX6* remain highly expressed; *SOX5*, the last member of the so-called Sox trio, is barely expressed, while *SOX8* is considerably upregulated. Several forkhead/winged helix box (*FOX*) and *BMP* genes are upregulated, while TFs of the T-box (*TBX*) and homeobox (*HOX*) families are downregulated [8]. Col2 now switches to the IIB splice variant, and transcripts for other ECM molecules, such as aggrecan (*Acan*), *Comp*, and the link protein hyaluronan and proteoglycan link protein 1 (*Hapln1*), are greatly upregulated. This is also the case for matrilin 1, which has been shown not to be expressed in the interzone, but rather in the anlagen chondrocytes [8,17].

As the cells change from terminally differentiated to hypertrophic chondrocytes, a series of fundamental changes occurs in the repertoire of molecules produced by the cells. The SOX trio TFs cease to be produced and, as a consequence, Col2, Col9, Col11, and aggrecan are also no longer secreted by the cells. Instead, runt related TF 2 (*Runx2*), the TF most essentially involved in bone formation, is produced; vascular endothelial growth factor production leads to ingrowth of blood vessels, and the new blood supply brings with it osteoblasts, osteoclasts, and matrix metalloproteinases (MMPs), produced by the hypertrophic chondrocytes. At this stage, *COL10* is greatly upregulated and serves as a marker for chondrocyte hypertrophy. As hypertrophic chondrocytes die by apoptosis they are replaced by osteoblasts, which lay down new ECM typical of bone, and this ECM is subsequently calcified under the influence of alkaline phosphatase [6,7]. These changes begin to occur at the primary ossification center and then spread along the shaft (diaphysis) of the anlagen, which gradually becomes a bony tube. The process of proliferating chondrocytes changing to become hypertrophic chondrocytes that die and become replaced by osteoblasts continues to lead to elongation of the bone shaft in the secondary ossification center until the skeleton is fully developed. At this stage the remaining cartilage is replaced by bone, and the only cartilage left is the hyaline cartilage covering the articular surface at the end of the bone.

## 14.5 Determinants of *in vitro* chondrogenesis

The molecular events occurring during *in vitro* chondrogenesis may vary depending on the cells used, the culture medium, the differentiation cocktail, and the three-dimensional (3D) culture used for the chondrogenic differentiation of the MSCs. These determinants of *in vitro* chondrogenesis also need to be discussed before the early molecular events during *in vitro* chondrogenesis are described.

## 14.6 Tissue source of mesenchymal stromal cells

MSCs are found in almost all tissues in the body, but the tissues used most to provide MSCs for *in vitro* chondrogenesis are the bone marrow MSCs (BM-MSCs), adipose tissue MSCs (AT-MSCs), and synovial membrane MSCs (SY-MSCs). Most comparative studies have been performed between BM-MSCs and AT-MSCs [18]. Of relevance, adipose tissue yields a much higher number of MSCs per weight of tissue, and the proliferative capacity of AT-MSCs is higher. However, most studies conclude that BM-MSCs have a better chondrogenic differentiation capability than AT-MSCs [19–22]. SY-MSCs are relatively easily accessible, and have been compared with other sources of MSCs [23]: SY-MSCs were found to have a higher proliferative capacity and showed better *in vitro* chondrogenic differentiation capability than MSCs from any other source. Thus, although MSCs from all tissues by definition should differentiate to become chondrocyte-like cells, the best choices for *in vitro* chondrogenesis seem to be BM-MSCs and SY-MSCs.

Recently, the use of co-cultures of MSCs and ACs has been investigated [24]. This is predominantly done to reduce dedifferentiation and enhance redifferentiation of the chondrocytes, but the addition of chondrocytes to enhance chondrogenic differentiation and prevent hypertrophy of the differentiated MSCs has also been investigated. Although the results vary somewhat, the general impression from these studies is that co-culture with chondrocytes improves the expression of chondrogenic genes, enhances the synthesis of cartilaginous ECM, and reduces the expression of marker genes for hypertrophy. The mechanism for the latter effect may be through the secretion of parathyroid hormone related protein by chondrocytes [24].

### 14.6.1 *In vitro* cell culture

In order to obtain the best results from assays of *in vitro* chondrogenesis, the materials and reagents used for the expansion cell cultures are important. From the early days of MSC research it has been known that MSCs require fetal bovine serum (FBS) for rapid proliferation to occur, and that there are considerable differences between different batches of FBS in their ability to support MSC proliferation [25]. Additionally, the type of culture flask used has been shown to impact on MSC proliferative capacity [26]. There may also be differences between culture media in their ability to support cell proliferation versus chondrogenic differentiation [27].

If *in vitro* chondrogenic differentiation of MSCs is performed with the aim of providing tissue for repair of lesions of human articular cartilage, the use of FBS may be unfortunate because it carries the risk of inducing xenogeneic immune responses and it may contain zoonotic agents or prions [28–30]. Regulatory agencies in several countries will not accept the use of MSCs cultured in FBS as human medicinal products [31]. One alternative may be the use of autologous serum, which is easily available, free of charge, and acceptable to all regulatory authorities. Using BM-MSCs and serum from healthy donors we showed that MSCs cultured in autologous serum proliferated faster and showed better *in vitro* chondrogenic differentiation capability than if FBS was used [32]. However, MSCs from patients with advanced OA have reduced *in vitro* proliferation capacity, and it is our unpublished impression that serum from these patients occasionally may also be less supportive of *in vitro* proliferation than serum from healthy donors (Brinchmann JE, unpublished observations) [33]. The mechanisms behind these observations have not yet been determined. However, the reduced proliferation rate may be counterbalanced by the addition of FGF2 [34,35]. Using allogeneic human serum alone is not a good alternative: in most cases MSCs will not expand adequately *in vitro* under such circumstances [32,36]. However, if allogeneic human AB plasma is spiked with human platelet lysate, the proliferation rate will usually be found to supersede that observed with FBS, and *in vitro* chondrogenesis is as good or better [37,38]. This serum supplement is likely to be acceptable to regulatory authorities, but it should be kept in mind that platelet lysate contains a large number of growth and differentiation factors, the impact of each of which has not yet been fully determined.

In addition to the right choice of plastic, medium, serum, and growth factors, the chondrogenic differentiation of MSCs may also be affected by the concentration of oxygen in the incubator atmosphere. Normally, the concentration of oxygen in the incubator atmosphere is around 20%. With the cells in monolayer culture covered by only a thin layer of medium, oxygen consumed by the cells is rapidly replaced by oxygen from the incubator air. This supports aerobic respiration in the proliferating MSCs. This makes the milieu surrounding the proliferating MSCs very different from that of the mesenchymal condensations and their chondrogenically differentiating offspring. This tissue is avascular and hypoxic and entirely dependent on hypoxia-inducible factor-1 (HIF-1) [39]. Following conditional knock-out of *HIF-1α*, Provot *et al.* observed malformation of the limbs and joints [40]. However, the impact observed by culturing MSCs in oxygen-depleted atmosphere *in vitro* varies between species and also varies between different studies [41]. Most impressive, perhaps, is the effect observed by differentiating micromasses of human MSCs in either room air or hypoxia (2.5%). Here, differentiation into articular, permanent-type chondrocytes, and

inhibition of genes associated with hypertrophy was observed under hypoxic conditions [42]. However, for these experiments the MSCs were first expanded *in vitro* in monolayer with room air in the incubator atmosphere.

## 14.7 Three-dimensional culture systems and bioscaffolds

Optimal chondrogenic differentiation of MSCs *in vitro* requires some sort of 3D culture system. In part this has to do with the organization of the cytoskeleton and focal adhesions: *in vitro* chondrogenesis could be shown to be encouraged by the cells having a rounded shape without focal adhesion attachments [43]. Classically, this has been achieved by gently centrifuging the cells to form a pelleted micromass, perhaps resembling the mesenchymal condensations of embryological chondrogenesis [44].

Micromass culture systems have been extensively used to characterize aspects of *in vitro* chondrogenesis, but until recently this model system has not been applied to strategies of *in vitro* chondrogenesis for clinical use. Using a model system where *in vitro* expanded human MSCs were cultured for a specified period in aggregates called condensed mesenchymal bodies in medium supplemented with TGF-β3 and dexamethasone, Bhumiratana *et al.* tried to mimic embryological chondrogenesis [45]. They then pressed a layer of the condensed mesenchymal bodies on to porous decellularized bone matrix. After 5 weeks of cultivation, hyaline cartilage with clinically relevant thickness, width, and compression capability was formed. This model is perhaps too cumbersome for routine production of autologous cartilage or osteochondral implants, but may arguably be the best and most physiologically appropriate model system for *in vitro* chondrogenesis published to date.

Most groups working toward clinically applicable systems for cartilage tissue engineering use biomaterial scaffolds in their efforts [41]. The scaffolds may be made from naturally occurring proteins, polysaccharides, or polyesters, or from various types of synthetic biomaterials. The biomaterials may have different formats, such as gels, foams, sponges, or membranes. The best biomaterial has not yet been identified, but the winner should be biocompatible and most likely biodegradable. It may also turn out to be an advantage if the biomaterial is able to contain growth or differentiation factors. Data on early molecular events during *in vitro* chondrogenesis derive from many of these model systems and may help to distinguish useful combinations of cells, biomaterials, and growth or differentiation factors.

## 14.8 Epigenetic changes during early *in vitro* chondrogenesis

### 14.8.1 An introduction to epigenetics

Epigenetics (see Chapter 6) is the name used to describe a heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence. Briefly, the basic unit of chromatin is the nucleosome. The nucleosome consists of homodimers of each of the four histones H2A, H2B, H3, and H4, forming a histone octamer (Figure 14.3A). DNA encircles the

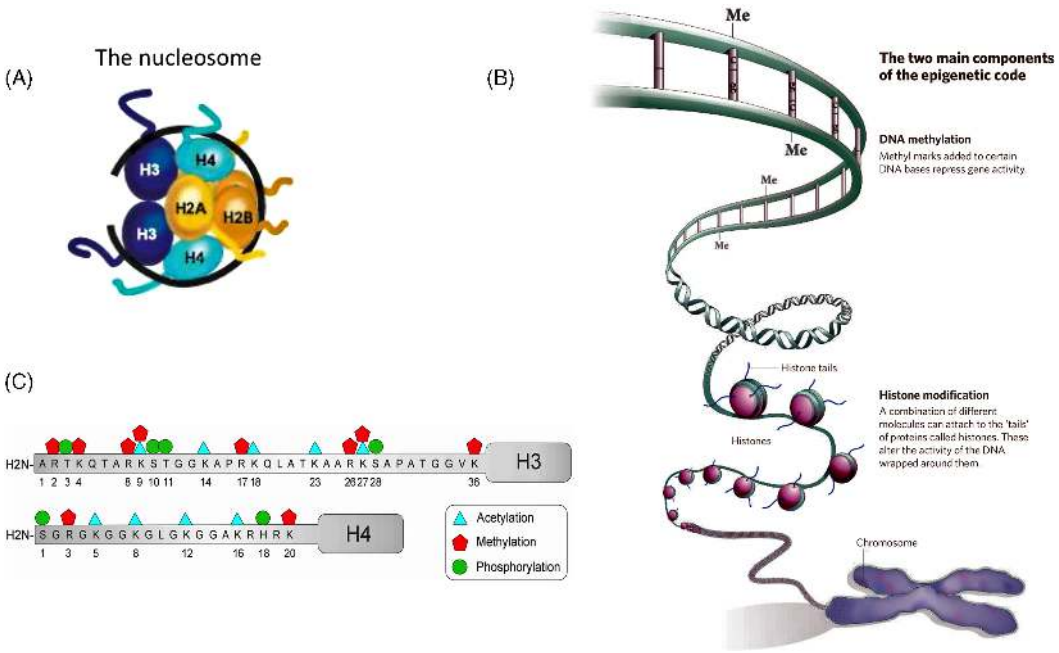

**Figure 14.3** Schematic presentation of components of the epigenetic code. (A) Cross-section of the nucleosome. (B) Diagram describing both components: methylation at CpG dinucleotides and histone modifications. (C) Some of the most common modifications of the tails of histones H3 and H4. *Sources*: Philippe Collas (A and C) and [46] Qiu J, *Nature* 2006; **441**: 143.

histone octamer nearly twice, before moving on to encircle the next histone octamer. The DNA that is not involved in the nucleosome is associated with the linker histone H1. The nucleosomal histones all have tails that protrude from the nucleosome. Chromatin is organized into higher order structures, including loops and folds; there is variation in the density of chromatin packing, and the position of chromatin relative to the nuclear membrane is also considered an epigenetic parameter.

All the aspects of chromatin modification and organization described may impact on the level of gene expression. First, DNA nucleotides may be modified, most commonly by methylation of cytosine–phosphate–guanosine (CpG) dinucleotides (Figure 14.3B). CpG islands is the name given to short sequences of DNA with a higher than average proportion of CpG dinucleotides. These are commonly found in or near gene promoters. The degree of methylation of these CpG islands may impact strongly on gene expression.

Second, the protruding histone tails may be modified, most commonly the tails of histones H3 and H4. These tails may undergo any of a number of modifications involving many of the amino acids making up the tails (Figure 14.3C). The histone modifications have different types of impact on gene expression depending on the nature of the modification and the amino acid involved. The histone modifications that will be described here are all located in the tail of H3. Trimethylation of lysine at amino acid position number 4 (H3K4me3) is a promoter mark associated with transcriptional activation. The same goes for acetylation of lysine at position 9 (H3K9ac), also most commonly a promoter mark associated with gene expression. Another promoter mark, H3K27me3, is associated with silencing of genes. The mark H3K36me3, when it occurs, is commonly found throughout the gene body, and is closely associated with gene transcription.

Third, we will discuss two histone modifications that have been found to define active enhancers: H3K4me1 and H3K27ac. Higher order organization of the chromatin, such as loops and folds, may bring distally placed regulatory sequences into contact with promoter sequences or other regulatory factors near the transcription start site. When chromatin is packed loosely it is called euchromatin, while densely packed chromatin is called heterochromatin. Euchromatin allows access of the transcriptional machinery to DNA, and is associated with gene expression. Heterochromatin is more often found close to the nuclear membrane and is associated with gene silencing [47].

### 14.8.2 DNA methylation of the *COL2A1* and *COL10A1* promoters

Little has been published on epigenetic changes during *in vitro* chondrogenesis. In 2008, Richter's group investigated the methylation status of CpG islands in the *COL2A1* and *COL10A1* promoters in MSCs before and after chondrogenic differentiation of MSCs and in ACs in the uncultured, *in vitro* expanded and dedifferentiated state and after redifferentiation [48]. They found that CpG islands were unmethylated around the *COL2A1* transcription start site of all cell groups, independent of *COL2A1* expression. The situation was different for the *COL10A1* promoter: all nine CpG sites in the sparse *COL10A1* promoter in uncultured ACs were consistently methylated, although a low level of *COL10A1* mRNA was expressed. The same observation was made after chondrogenic redifferentiation of dedifferentiated ACs. Undifferentiated MSCs showed a state of partial methylation, with no expression of *COL10A1* mRNA. Upon differentiation, two of the partially methylated CpG sites became less methylated, and *COL10A1* mRNA increased dramatically. These observations are consistent with later observations made by our own group [49]. We found that, after chondrogenic differentiation of both cell types, differentiated MSCs expressed *COL10A1* mRNA at levels almost 100-fold higher than in redifferentiated ACs. When the cells in an alginate biomaterial differentiation scaffold were stained for COL10 protein, this was found in or around practically every differentiated MSC, but only in about 1% of the redifferentiated chondrocytes. We interpret this to mean that every MSC, when exposed to chondrogenic differentiation medium, will express *COL10A1* mRNA and protein, suggesting that the state of partial methylation of CpG islands in the undifferentiated MSCs does not represent an epigenetic block for *COL10A1* expression. For ACs, *COL10A1* expression is epigenetically blocked in practically all the cells, even after redifferentiation with a differentiation cocktail. The exception is approximately 1% of the cells, too few to impact on assays of CpG methylation of the whole population of chondrocytes and perhaps representing the cells in the calcified zone of articular cartilage known to express COL10 *in vivo*. For *COL2A1*, the lack of expression of mRNA in the undifferentiated MSCs must be independent of CpG methylation, as the islands near the promoter were all unmethylated.

### 14.8.3 DNA methylation of promoters in other chondrogenesis candidate genes

In terminally differentiated mammalian cells, approximately 60–80% of all CpGs are methylated [50]. Most CpGs in mammalian genomes remain methylated during development, but CpG islands found at promoters of many housekeeping and developmentally regulated genes are constitutively hypomethylated. As pluripotent stem cells differentiate toward specific lineages, genes associated with other lineages tend to become silenced, and this is associated with increased DNA methylation of their promoters. However, the exact relationship between differentiated phenotypes and DNA methylation status remains complex [50]. It was interesting, therefore, when Ezura *et al.* found that the promoters of 10 genes relevant to *in vitro* chondrogenesis were hypomethylated in human MSCs collected from joint synovium, both during *in vitro* expansion and after chondrogenic differentiation, and regardless of expression level of the genes [51]. One possible interpretation of these observations is that the synovium-derived MSCs were sufficiently close to the chondrocyte progenitors in developmental terms for genes of

importance to *in vivo* chondrogenesis to still be epigenetically accessible. Some of these genes were not expressed in the undifferentiated MSCs, like *COL2A1* in the study from Richter's group, suggesting that DNA methylation is not an essential aspect of gene regulation in these cells.

### 14.8.4 Genome-wide map of quantified epigenetic changes during *in vitro* chondrogenesis of bone marrow mesenchymal stromal cells

To the best of our knowledge, the only other study of epigenetic changes during *in vitro* chondrogenic differentiation of MSCs is our own work on genome-wide quantified changes in histone modifications and DNA methylation during *in vitro* chondrogenic differentiation of BM-MSCs [52]. Using cells from four donors, we performed assays on MSCs in monolayer culture on day 0 and after 7 days of chondrogenic differentiation in an alginate scaffold. At this time, all the changes in gene expression that will occur during *in vitro* chondrogenesis have begun. We identified a set of 10 genes that were important for chondrocyte functionality, and another set of 10 genes described to be important for MSC functionality, and showed how the expression of all the chondrocyte signature genes were upregulated and all the MSC signature genes were downregulated after 7 days of differentiation. Genes that were not described to have a role in chondrogenesis showed unchanged expression. We found that all the chondrogenesis signature genes had increased levels of H3K4me3, H3K9ac, and H3K36me3 and reduced levels of H3K27me3, while all the MSC signature genes had reduced levels of H3K4me3, H3K9ac, and H3K36me3 and increased levels of H3K27me3, showing an absolute correlation between changes in gene expression and changes in histone modifications for these signature clusters. In fact, there was a significant correlation between the magnitude of upregulation of H3K4me3 and the magnitude of increase in gene expression. No changes in histone modifications were observed for the control genes. Examples of ChIP-seq signal tracks for these histone modifications in MSCs and chondrogenically differentiated MSCs (Chondro) for the MSC gene *CXCL12* (also known as *SDF-1*) and for the chondrocyte gene *COL2A1* are shown in Figure 14.4. Note in the figure that, although *COL2A1* mRNA is expressed at relatively high level by day 7, H3K27me3 is reduced but still present in chondrogenically differentiated cells. Although not formally tested, we have taken this to suggest that the MSCs have not been differentiated in synchrony, so that the expression of *COL2A2* mRNA is still inhibited by H3K27me3 in some cells, while being expressed, presumably in the absence of H3K27me3 and the presence of H3K4me3, H3K9ac, and H3K36me3 in other cells.

Interestingly, we also found moderate upregulation of H3K4me3 and H3K9ac in a large number of genes with no significant increase in gene expression. Ontogenetically, these genes were linked to the ECM and the skeletal system. However, increased H3K36me3 was usually not found to be increased along the sequence of these genes. A similar phenomenon has also been observed in other model systems and has been called prepatterning of the genes [53]. We interpret this to mean that our differentiation cocktail, combined with placing the cells in the alginate scaffold, opened up an epigenetic landscape that could potentially allow differentiation into bone and other skeletal components. Then, under the influence of TFs and other elements, the actual transcription is restricted predominantly to those genes required for chondrogenesis. Upregulation of H3K36me3 was the single epigenetic mark most closely correlated with an increase in transcriptional activity.

The data obtained in this study also provide more information about the epigenetic regulation of *COL10A1* expression. Within the limitations given by the number of histone modifications examined, no histone marks at all were detected near the *COL10A1* transcription start site. After the onset of differentiation, the usual combination of histone marks were observed, including marks for local enhancer regions. Combined with the data described earlier, this suggests that epigenetic restriction to *COL10A1* transcription may indeed be provided by methylation of CpG islands in the promoter region, as the histone silencing mark H3K27me3 was not present near this gene in undifferentiated MSCs.

A genome-wide approach like the one used here can also be used to identify distant regulatory sequences. The two histone modifications used to identify enhancer regions in our study were H3K4me1 and H3K27ac. Upregulation of these marks co-occurred with high frequency. When we examined regions around *COL2A1*, we found six regions where these marks were increased (Figure 14.5A). Two of these had already been validated as *COL2A1* enhancers; the other four were new enhancer regions. However, to be functionally active enhancer regions one would expect them to contain binding sites for TFs known to be relevant for chondrogenesis. In many cases the sequences most likely to bind TFs are known. Using known binding motifs to scan the enhancer regions found near *COL2A1*, we found possible binding motifs for a number of TFs relevant for chondrogenesis in all the enhancer regions, including SOX9 and SP1/SP3 (Figure 14.5B) [41].

In this study, we also performed a genome-wide analysis of DNA methylation using a reduced representation bisulfite sequencing strategy. We found a highly significant correlation between the undifferentiated and chondrogenically differentiated MSCs ($r^2 = 0.78$), with the methylation states of the vast majority of promoters remaining unchanged. For the MSC and chondrocyte signature genes, promoters were hypomethylated both before and after differentiation, consistent with the observations made by Ezura *et al.*, although only *SOX9* and *CXCL12* were overlapping between their 10 candidate genes and our 20 signature genes [51]. This confirms the impression that DNA methylation is unlikely to play a major role in the regulation of

key chondrogenesis genes. Of note, *COL10A1* was not included in any of these series of genes, and the resolution of our method used for detecting DNA methylation was not sufficient to pick up the changes in DNA methylation reported in the study from Richter's group [48].

### 14.8.5 Epigenetics: conclusions

For the vast majority of genes of relevance to *in vitro* chondrogenesis of human MSCs the promoters are hypomethylated both before and after differentiation. This suggests that DNA methylation does not regulate the differentiation process in

these genes. One important exception is *COL10A1*. Here, most CpG sites are methylated, while two sites are partially methylated in the promoter region of undifferentiated MSCs. These sites were less methylated after differentiation. As no restrictive histone modifications are present in the *COL10A1* promoter in undifferentiated MSCs, the DNA methylation is likely to contribute to the lack of *COL10A1* transcription in the undifferentiated state, while the reduced DNA methylation in the two CpG sites may facilitate *COL10A1* transcription in the course of differentiation. Changes in histone marks can reproducibly be used to predict changes in gene transcription, with H3K36me3 the mark most closely associated with active transcription. Increases in promoter marks H3K4me3 and H3K9ac may identify genes that are prepatterned for transcription before active transcription occurs. Histone marks H3K4me1 and H3K27ac may be used to identify active enhancer regions.

## 14.9 Role of microRNAs during early *in vitro* chondrogenesis

### 14.9.1 An introduction to microRNAs

MicroRNAs (miRNAs) are small double-stranded RNA molecules that regulate gene expression by targeting complementary nucleic acid sequences (Figure 14.6). miRNAs are transcribed as large transcripts called primary miRNA (pri-miRNA). In the nucleus, pri-miRNAs are recognized and processed by the nuclease Drosha [55]. The resulting product is called precursor miRNA (pre-miRNA) and contains a two-nucleotide overhang at its 3′ end. The Exportin complex then transports the pre-miRNA into the cytoplasm, where another nuclease, Dicer, cleaves the pre-miRNA into mature double-stranded miRNA molecules approximately 21–23 nucleotides in length [56]. One or both of the miRNA strands are incorporated into the RNA-induced silencing complex where they can bind to complementary mRNA

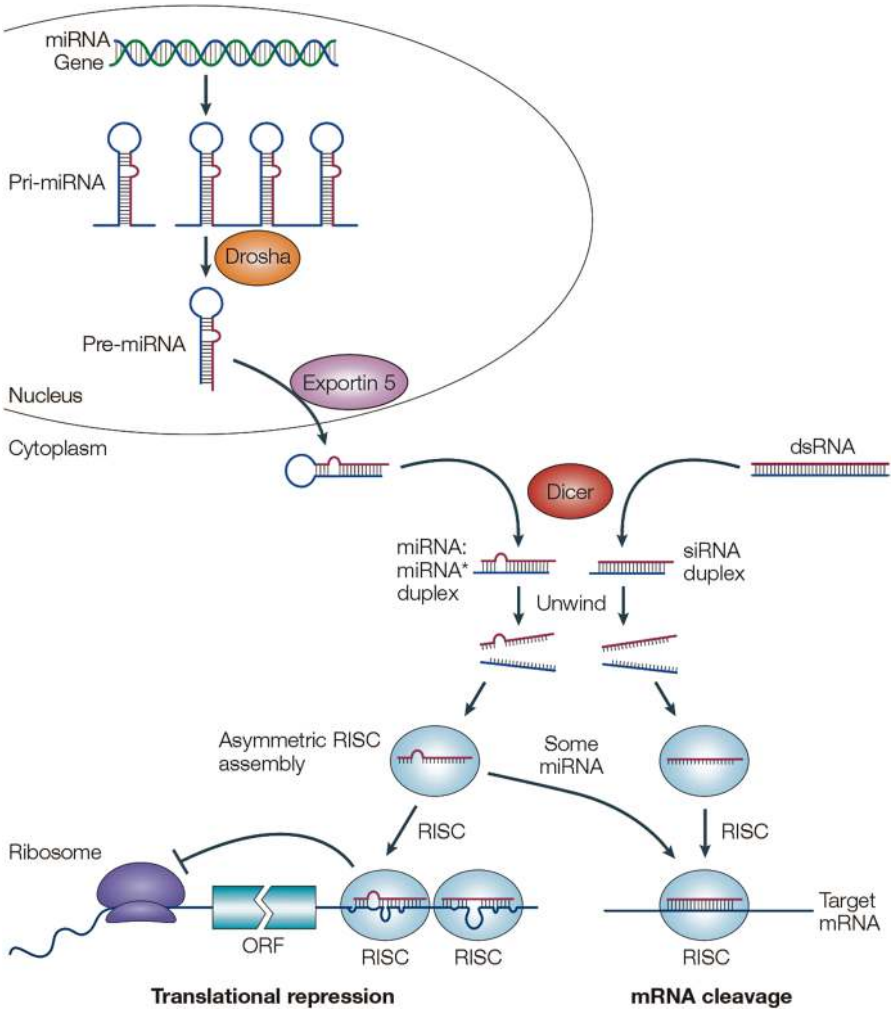

**Figure 14.6** MicroRNA biogenesis. The nascent pri-microRNA (pri-miRNA) transcripts are first processed into 70-nucleotide pre-miRNAs by Drosha inside the nucleus. Pre-miRNAs are transported to the cytoplasm by Exportin 5 and are processed into miRNA duplexes by Dicer. One strand (usually) of the miRNA duplex is assembled into the RNA-induced silencing complex (RISC), which subsequently acts on its target by translational repression or mRNA cleavage, depending, at least in part, on the level of complementarity between the small RNA and its target. ORF: open reading frame. *Source*: [54] He L and Hannon GJ 2004, p. 522. Reproduced with permission of Nature Publishing Group.

molecules by base-pairing, resulting in either degradation of the mRNA or translational repression [57,58]. The two miRNA strands are sometimes given the suffix 5p and 3p, which indicates whether the strand is derived from the 5′ or the 3′ arm of the pri-miRNA. The nucleotides at positions 2 to 8 at the 5′ end of the mature miRNA strand are called the seed sequence and have been demonstrated to be crucial for recognizing mRNA target sequences. It is believed that most target sequences are found in the 3′ untranslated region (UTR) of the mRNA, but miRNAs can also target sequences in the 5′ UTR coding regions and in promotor regions [59–61].

Most studies have demonstrated that miRNAs predominantly downregulate gene expression, but miRNAs have also been shown to stimulate gene expression. This may occur through activation of translation [62,63] or by targeting complementary sequences in promotor regions to induce transcription [60,64]. Because the seed sequence is short, one miRNA has the potential to regulate many genes. Several studies have shown that a single miRNA can affect the expression of hundreds of genes, directly or indirectly [65–67]. More than 2500 miRNAs have been discovered in humans so far (www.miRbase.org), and it has been estimated that 60% of human genes are regulated by miRNAs [68]. This indicates that most biological processes are regulated by miRNAs.

### 14.9.2 Role of miRNA-140 in developmental chondrogenesis

Deletion of the miRNA processing enzyme Dicer will greatly reduce or abolish production of most mature miRNAs. Cartilage-specific knockout of Dicer in mice leads to reduced chondrocyte proliferation and accelerated hypertrophic differentiation, resulting in severe skeletal defects and premature death [69]. These results show that miRNAs are important regulators of cartilage biology. Several miRNAs have been investigated during chondrogenesis. Perhaps the best understood and most studied miRNA in cartilage biology is miRNA-140 (miR-140). miR-140

is considered to be a cartilage-specific miRNA as its expression is restricted to cartilaginous tissues during embryonic development in mouse and zebrafish [70,71]. Whole mount *in situ* hybridization demonstrates overlapping expression of miR-140 with *SOX9* and *COL2a1* in mouse limb buds during development [72,73]. Miyaki *et al.* showed that miR-140 was expressed in proliferating chondrocytes in the growth plate but not in hypertrophic chondrocytes. In addition, miR-140-deficient mice had fewer proliferating chondrocytes, indicating that the skeletal phenotype was due to reduced chondrocyte proliferation in the growth plate [74]. In fact, miR-140 knockout mice show similarities with cartilage-specific Dicer knockout mice, indicating that miR-140 is one of the most important miRNAs for normal cartilage and skeletal development.

### 14.9.3 miR-140 targets identified *in vivo* and in vitro

Reduced chondrocyte proliferation may be a result of miR-140 targeting the TF SP1, as SP1 inhibits cell cycle progression and has been shown to be a target of miR-140 in micromass cultures [72,75]. In another *in vivo* study, Nakamura *et al.* showed impaired endochondral bone formation and enhanced hypertrophic differentiation in miR-140 knockout mice. It was demonstrated that miR-140 targeted DNPEP (aspartyl aminopeptidase), which modulates BMP signaling [76]. A study in zebrafish embryos showed that inhibiting miR-140 led to craniofacial defects such as clefting of the cartilage structures in the mouth of the zebrafish larvae. Platelet-derived growth factor-α (*PDGF-α*) was validated as a target of miR-140, and reduced PDGF-α was identified as the cause of the defect [77]. In a mouse model of antigen-induced arthritis, Miyaki *et al.* demonstrated that overexpression of miR-140 in cartilage ameliorated the arthritis phenotype by reducing the loss of PGs and COL2, while miR-140 knockout mice were predisposed to OA. The aggrecan-degrading enzyme ADAMTS5 (a disintegrin and metalloproteinase with thrombospondin motif 5) was identified as a direct target of miR-140, partially explaining the protective role of miR-140 against OA progression [74].

SMAD3 is a key TF in transforming growth factor (TGF)-β signaling and has been shown to be a target of miR-140 in C3H10T1/2 cells (a multipotential mesenchymal cell line derived from C3H mice) [78]. Other validated targets of miR-140 are *BMP2*, *CXCL12*, and *HDAC4* [71,79,80]. BMP2 is a member of the TGF superfamily and is important for chondrogenesis and bone formation [81]. Overexpression of *BMP2* in developing chick limbs led to increased number of chondrocytes and increased deposition of ECM [82,83]. miR-140 may therefore regulate proliferation and ECM production via BMP2. CXCL12 is a ligand for the CXCR4 receptor and regulates several physiological functions, such as angiogenesis and migration of several cell types, including MSCs [84]. During murine embryogenesis CXCL12 is synthesized by prehypertrophic and hypertrophic chondrocytes and stimulates bone growth by modulating the actin cytoskeleton [85]. CXCL12 is also elevated in the synovial fluid of OA patients and enhances proliferation and COL1 synthesis in osteoblasts from OA patients [86,87]. During *in vitro* chondrogenesis of human MSCs the expression of *CXCL12* shows an inverted relationship with miR-140 [67,88]. Thus, miR-140 induced downregulation of CXCL12 may in several ways be beneficial for chondrogenesis. Finally, the miR-140 target *HDAC4* encodes a histone deacetylase that modulates the TF RUNX2, an important regulator of hypertrophic differentiation [89].

### 14.9.4 Defining the role of miR-140 during chondrogenic differentiation of mesenchymal stromal cells and dedifferentiation of articular chondrocytes

In 2011 our group published the first study investigating global miRNA changes during dedifferentiation of human ACs. Several miRNAs decreased during dedifferentiation, including miR-140 [90]. We later compared these results with those obtained during *in vitro* chondrogenic differentiation of MSCs [67]. miR-140 was the most highly expressed miRNA in chondrogenically differentiated MSCs and in uncultured ACs. Comparing expression changes of all miRNAs, miR-140 was both the most upregulated miRNA during chondrogenesis of MSCs and the most downregulated miRNA during dedifferentiation of ACs (Figure 14.7 and Table 14.1). Thus, both *SOX9* and miR-140 increase during chondrogenic differentiation of MSCs. This may reflect the regulatory role played by SOX9 on miR-140 transcription. miR-140 is an intronic miRNA located in the *WWP2* (WW domain containing E3 ubiquitin protein ligase 2) gene and it is activated by SOX9 [72,91]. SOX5 and SOX6 also enhance expression of miR-140 by facilitating dimerization and DNA binding of SOX9 to the miR-140 promoter region [73].

In order to be able to describe the miR-140 interactome during *in vitro* chondrogenesis we inhibited miR-140 by introducing an anti-miR-140 into MSCs by lentiviral transduction [67]. (An interactome is the whole set of molecular interactions in a particular cell.) Gene ontology analysis of differentially expressed genes between miR-140 inhibited cells and control cells subsequently exposed to chondrogenic differentiation showed that inhibition of miR-140 during chondrogenesis led to decreased expression of genes that were mainly related to ECM, while the upregulated genes were mainly involved in the cell cycle and the cytoskeleton. These results were mirrored in dedifferentiating chondrocytes overexpressing miR-140 [67]. *ACAN* and *SOX9* mRNAs were not differently expressed in miR-140 inhibited cells, but the proteins were strongly reduced, suggesting a translational effect of miR-140 on these molecules. miR-140 inhibition also resulted in reduced synthesis of GAGs. In the same study we identified *RALA* (v-ral simian leukemia viral oncogene homolog A), a small GTPase, as a direct target of miR-140. Small interfering (siRNA)-mediated knockdown of *RALA* reduced SOX9 protein, suggesting that miR-140 works by inhibiting *RALA*, which is an inhibitor of *SOX9* translation. The net

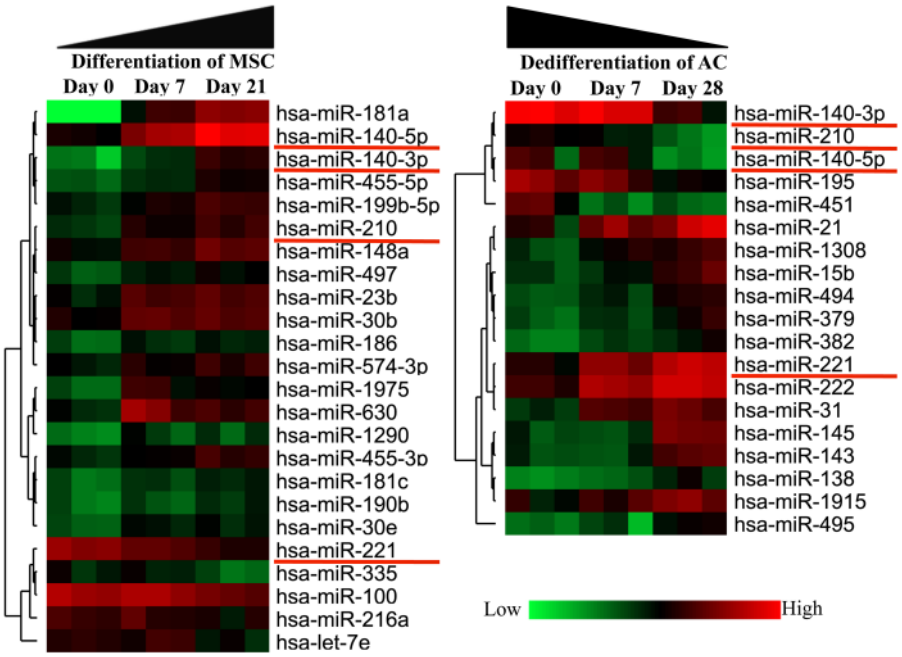

**Figure 14.7** miRNA profile relationship between differentiating MSCs and dedifferentiating ACs. Heat maps of differentially expressed miRNAs in differentiating MSCs and dedifferentiating ACs ($n = 3$ for each time point, false discovery rate <0.05). Reciprocally regulated miRNAs are underlined. (See color plate section.) *Source*: [67] Karlsen TA *et al.*, *Stem Cell Dev.* 2014; **23**: p. 293.

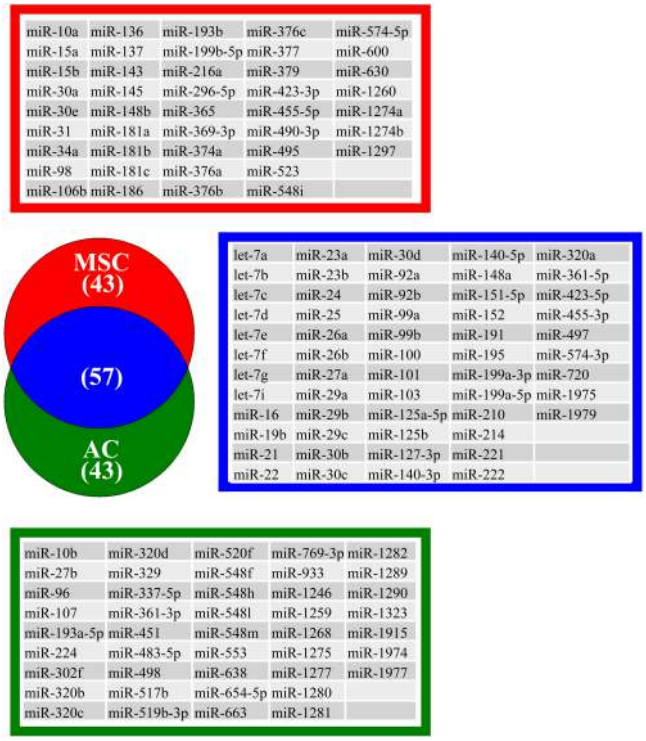
effect is that upregulation of miR-140 leads to upregulation of SOX9, which stimulates chondrogenesis and maintains cartilage homeostasis. We also found potential binding sites for miR-140 in the 5′ UTR of *SOX9* and *ACAN*, suggesting a potential binding of miR-140 to these mRNAs. As explained earlier, 5′ binding of miRNAs to their target mRNAs has been shown to enhance translation, and this could be another as yet unknown function of miR-140.



### 14.9.5 Impact of microRNAs other than miR-140 on chondrogenic differentiation of mesenchymal stromal cells

In addition to miR-140, other miRNAs were differently expressed at days 1, 3, 7, and 21 during chondrogenesis of MSCs [67]. Several of these miRNAs have already been associated with cartilage biology, including the upregulated miRNAs miR-16, 21, 23b, 26a, 30a, 30b, 148a, 181a, 199b, 210, 222, 455-3p, 630, and 1290 and the downregulated miR-100, 221, and 335 (Figure 14.8 and Table 14.1). Elevated levels of miR-16 have been associated with OA [92]. The upregulation of miR-16 may therefore be unwanted, as this could potentially promote OA progression. miR-21 is associated with fibrosis in several tissues, and inhibition of miR-21 leads to reduced COL1 production [93]. Upregulation of miR-21 is common for both differentiating MSCs (day 7) and dedifferentiating ACs (Figure 14.8 and Table 14.1). Both cell types produce COL1, consistent with a role for miR-21 in fibrocartilage formation during *in vitro* and *in vivo* chondrogenesis [88,94]. In addition, miR-21 is upregulated in OA cartilage, where it targets *GDF5*, the gene encoding the factor involved in the differentiation of the hyaline cartilage precursor interzone cells [95]. Thus, the upregulation of miR-21 may be involved in COL1 synthesis during chondrogenesis of MSCs and, therefore, may be one of the factors leading to fibrocartilage formation after ACI. Downregulation of *GDF5* may reduce the likelihood of producing hyaline cartilage as repair tissue in OA. Overexpression of miR-23b facilitates chondrogenic differentiation of synovial-fluid-derived MSCs by inhibiting protein kinase A. miR-23b also decreased the expression of *MMP2* and *MMP9* [96]. miR-26a is differently expressed at different developmental stages in rat cartilage [97] and is one of the miRNAs shown to be upregulated in OA cartilage [92]. miR-199b and miR-30a are upregulated during chondrogenic differentiation of murine MSCs [98,99]. miR-30a has been found to be essential for normal tracheal hyaline chondrocyte differentiation. Inhibition of miR-30a in tracheal chondrocytes reduced both ACAN and COL2 deposition [100]. miR-30b is upregulated in OA cartilage [92]. Upregulation of miR-148a may be beneficial since overexpression of miR-148a promotes cartilage formation and inhibits hypertrophic differentiation and degradation in OA chondrocytes [101]. miR-181a has been shown to inhibit *ACAN* and *CCN1*. The net effect is inhibition of chondrogenesis and promotion of osteoblast differentiation [102,103]. miR-210 is a so-called "hypoxic miRNA" because it is induced under hypoxic conditions [104]. miR-210 is also upregulated during chondrogenesis of adipose tissue-derived MSCs and has recently been shown to prevent cartilage degradation and to stimulate *COL2A1* in rat meniscus [105,106]. miR-210 is also downregulated in OA cartilage and in dedifferentiated chondrocytes compared to uncultured ACs (Figure 14.8) [92], indicating a positive effect of miR-210 on chondrogenesis. miR-222 expression is higher in weight-bearing cartilage compared with non-weight-bearing cartilage, suggesting miR-222 to have a role in

**Table 14.1** Significantly up- and downregulated miRNAs in MSCs undergoing chondrogenic differentiation [67].

mechanotransduction [107]. miR-455-3p is upregulated during chondrogenesis of AT-MSCs and has been shown to be upregulated in human OA cartilage [106,108]. On day 3 and day 7 of *in vitro* chondrogenesis miR-630 was the most upregulated miRNA (Table 14.1). This is consistent with recent findings linking miR-630 to chondrogenesis [109]. In the same study, miR-1290 was also upregulated during chondrogenesis while miR-100 was downregulated. No known function of miR-1290 and miR-100 in cartilage biology has been identified so far. Downregulation of miR-221 during chondrogenesis is consistent with a publication demonstrating upregulation of *COL2A1* and *SOX9* after inhibition of miR-221 during MSC chondrogenesis [110]. miR-221 has also been shown to regulate chondrogenesis in chick limb MSCs [111]. We also observed downregulation of miR-335 during chondrogenesis. This is in line with earlier findings that downregulation of miR-335 is critical in MSC differentiation [112].

Some of the miRNAs discussed here are associated with OA or have other unwanted functions. This should be kept in mind when using MSCs for chondrogenesis and tissue engineering purposes. MSCs differentiated to chondrocytes should be as similar to native cartilage as possible. This includes miRNA expression profiles. In our study we compared the 100 most highly expressed miRNAs in uncultured ACs and differentiated MSCs and found a 57% overlap of shared miRNAs (Figure 14.8). We found that the nonoverlapping miRNAs highly expressed in differentiated MSCs were either not expressed or barely detectable in uncultured ACs, and the nonoverlapping miRNAs highly expressed in uncultured ACs were either not expressed or barely detectable in differentiated MSCs [67]. This shows that differentiated MSCs may express several unwanted miRNAs and lack expression of many wanted miRNAs in order to be regarded as true chondrocytes. For example, miR-181a is highly expressed in chondrogenically differentiated MSCs but has a very low expression in uncultured ACs. This miRNA was described earlier to be inhibitory of chondrogenesis by downregulating *ACAN* and *CCN1*.

Several miRNAs previously associated with cartilage and chondrogenesis were not differently expressed in our experiments using MSCs. However, some of the nondifferently expressed miRNAs had a very high or very low expression in MSCs, and several changed during dedifferentiation of ACs. miR-145 is highly upregulated during dedifferentiation of ACs and highly expressed by MSCs (Figures 14.8 and 14.9). *SOX9* has been verified as a target of miR-145 in two studies demonstrating an inhibiting effect of miR-145 in chondrogenesis and cartilage formation [107,113]. miR-145 is also increased in IL-1β-treated chondrocytes and in OA chondrocytes, where it modulates *SMAD3* [114]. Thus, suppressing miR-145 expression may be beneficial for tissue engineering of cartilage. Overexpression of miR-675 positively regulates COL2 synthesis, possibly via a SOX9-dependent mechanism [115]. miR-199a inhibits early BMP2-induced chondrogenesis in C3H10T1/2 cells by targeting *SMAD1* [116]. In another study, miR-1 was found to be repressed during hypertrophic differentiation and to inhibit the expression of *ACAN* [117]. miR-365 has been shown to be highly expressed in hypertrophic chondrocytes and to stimulate COL10 synthesis [118]. miR-365 is also highly expressed in MSCs but not expressed in uncultured ACs (Figure 14.9) [67]. miR-138 and miR-495 both increase during AC dedifferentiation (Figure 14.8 and Table 14.1). In one study, miR-138 was found to be overexpressed in differentiated and hypertrophic chondrocytes compared with precursor cells [119]. In other studies, miR-138 inhibited osteogenic and adipogenic differentiation [120,121], while miR-495 targeted *SOX9* and inhibited chondrogenesis in human MSCs [122].

### 14.9.6 MicroRNAs in chondrogenesis: conclusions

A wide range of miRNAs have been shown to be involved in chondrogenesis in different model systems. miR-140 seems to be the single miRNA most prominently promoting chondrogenesis, both *in vitro* and *in vivo*. In addition, miR-140 may have a protective role in arthritis. A number of mRNAs have been shown to be targets for miR-140, but none of them seem, on their own, to be able to explain the important role played by miR-140. We have recently demonstrated that miR-140 may induce translational upregulation of SOX9. The mechanism is not fully identified, but the prominent role played by SOX9 both for

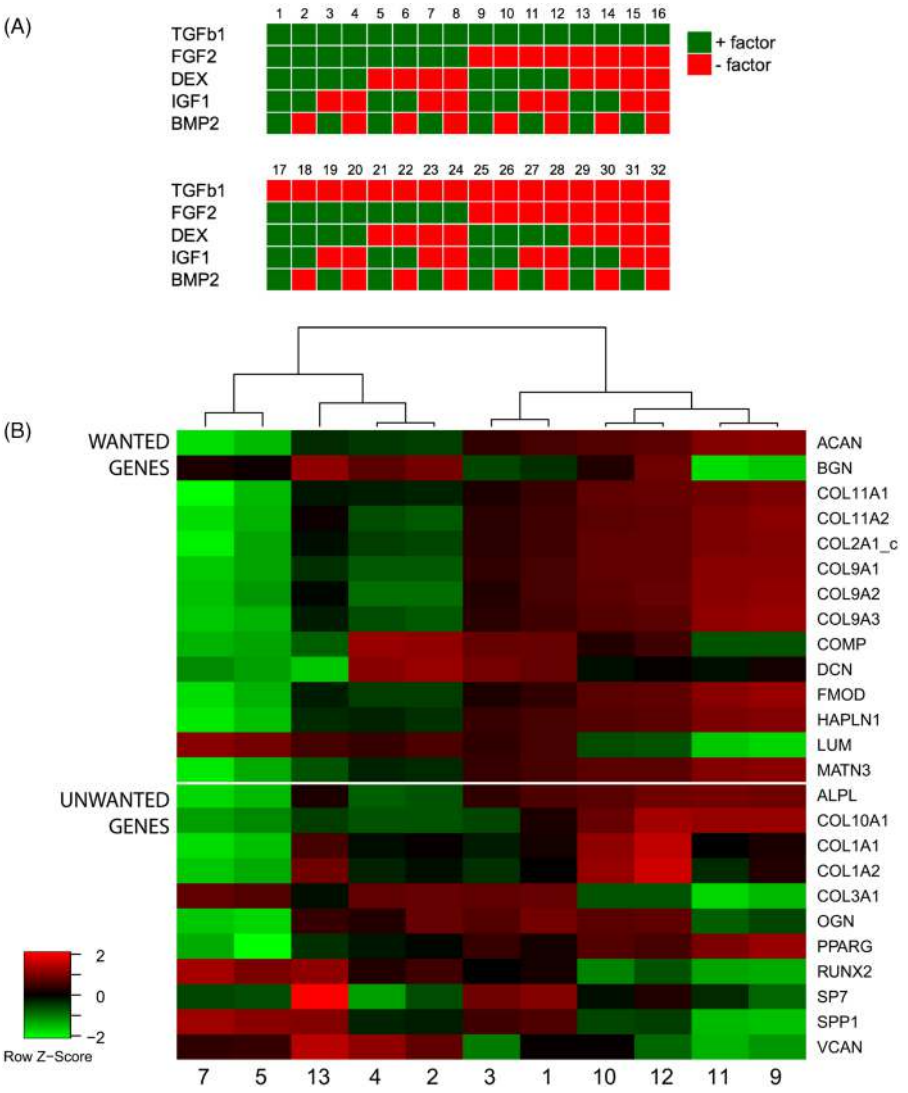

**Figure 14.9** (A) Experimental setup with numbering of the different conditions in a factorial analysis of five factors relevant to chondrogenesis. (B) Gene set enrichment analysis. Heat map of the expression of wanted and unwanted genes in the top ranking conditions significantly enriched for wanted genes (false discovery rate <0.05) but not enriched for unwanted genes. Color coded by the Studentized score. (See color plate section.) *Source*: [37] Jakobsen, *PLoS ONE* 2014, **9**: e96615.

chondrogenesis and OA suggests that it must be mechanistically important. A number of other miRNAs are differentially regulated during *in vitro* chondrogenic differentiation of MSCs. Some of these have been shown to be highly expressed in uncultured ACs and to be reduced during dedifferentiation. These are probably miRNAs with beneficial effects. Other miRNAs are not found in ACs, suggesting that they are not required in functional ACs. As miRNAs have regulatory effects on a wide range of genes, the role played by these potentially unwanted miRNAs requires further investigation.

## 14.10 Early changes in gene expression during *in vitro* chondrogenesis

The expression of key chondrogenesis genes has been reported in hundreds of papers. For biological relevance one needs to look at all or most of the genes that are essential for the formation of hyaline cartilage: genes involved in COL2 fibrillogenesis, in the synthesis if the major PGs and GAGs, some of the other major components of the cartilage ECM, and some of the unwanted genes expressed in fibrocartilage, in hypertrophic cartilage, and in bone formation. We studied changes in gene expression when MSCs were placed in alginate discs and exposed to a differentiation cocktail of TGF-β1 10 ng/mL, BMP2 500 ng/mL, and 0.1 μM dexamethasone for 3 weeks. The data were collected by microarray analysis at 0, 7, 14 and 21 days for cells from three donors, in some cases confirmed by real-time quantitative polymerase chain reaction and immunohistochemical stainings [88]. We also have unpublished data in gene expression analysis at earlier time points on days 0, 1, 3, and 7 using the NanoString nCounter system where 350 custom selected genes were analyzed at each time point in cells from three donors using a similar chondrogenic differentiation system. For both these datasets we have control results from the same time points of cells in alginate discs without differentiation factors. We will shortly discuss below

changes in gene expression that are influenced by the composition of the differentiation cocktail.

### 14.10.1 Genes involved in collagen fibrillogenesis

The signature gene of hyaline cartilage, *COL2A1*, is not expressed in MSCs. This makes results describing fold change increases in gene expression relative to day 0 difficult to interpret. *COL2A1* mRNA begins to increase between day 3 and day 7, is almost at peak expression by day 14, and by day 21 is one of the most highly expressed genes. The IIB splice variant is expressed at a very much higher level than the embryological IIA variant, but both are expressed. *COL9A2* and *COL9A3* are expressed from day 3, with maximal expression from day 14. However, *COL9A1*, which is essential for COL9 heterotrimer formation and thus for functionality, only increases between days 7 and 14 and is expressed at lower levels than the *A2* and *A3* isoforms. *COL11A1* is expressed at low levels in MSCs, increases from day 3, and is expressed at moderate levels on day 21. In contrast, *COL11A2* is not expressed in MSCs, is expressed on day 7, but is expressed at lower levels than its isoform counterpart on day 21. Other molecules of importance for the formation of COL2 fibrils are the small leucine-rich PGs decorin (*DCN*), biglycan (*BGN*), fibromodulin (*FMOD*), and lumican (*LUM*). *DCN* is expressed in MSCs, increases by day 1, and is highly expressed from day 3. *BGN* follows a similar pattern but at lower levels of expression. *FMOD* is expressed at very low levels in MSCs, but increases throughout differentiation to reach high levels on day 21. *LUM* is expressed at moderately high levels in MSCs and does not change much during differentiation. Finally, for fibrillation to occur, procollagen propeptides at either end need to be cleaved off. C-proteinase activity is possessed by BMP1, while N-proteinase activity is provided by ADAMTS2, -3, and -14 [123]. *ADAMTS2* and *BMP1* are expressed at low to moderate levels in MSCs and do not change much during differentiation [124]. Thus, all the genes associated with COL2 fibrillogenesis are expressed in this model, albeit at different levels and with different kinetics. The slow onset of expression of COL9A1 may be the limiting factor for the onset of fibrillogenesis. One previous study of microarray analysis of gene expression in pellet differentiation cultures has been described. Where results from expression of the same genes were presented, they largely corroborated our findings [25].

### 14.10.2 Genes involved in synthesis of proteoglycans and glygosaminoglycans

The other major group of cartilage ECM molecules are the PGs and GAGs. Of these, aggrecan (*ACAN*) is expressed at low levels in MSCs and increases gradually from day 3 to reach moderately high expression levels on day 21. Hyaluronic acid is a high molecular weight polysaccharide synthesized by members of the hyaluronic acid synthase (HAS) family. *HAS1*, *HAS2*, and *HAS3* are all expressed in MSCs, *HAS3* at very low levels, and none of them change during *in vitro* chondrogenesis. Link protein links aggrecan to hyaluronic acid. Genes encoding link protein are hyaluronan and PG link protein (*HAPLN*) family members 1–4. Of these, *HAPLN1* and *HAPLN3* are expressed in MSCs. *HAPLN1* decreases after establishment in 3D culture, then increases to moderately high levels on day 21. *HAPLN3* remains at relatively low expression levels. An enzyme family of importance for the synthesis of the small GAGs that branch off from aggrecan is the xylosyltransferases. *XYLT1* and *XYLT2* are both expressed in MSCs at low levels. While *XYLT2* retains its expression level throughout chondrogenic differentiation, *XYLT1* increases a little. Finally, the surface lubricant lubricin, a PG encoded by the PG 4 gene (*PRG4)*, is marginally expressed in MSCs, increases somewhat by day 3, and then remains expressed at low levels. Together, these results show that gene expression changes during *in vitro* chondrogenesis. For optimal cell-based treatment it will be important to ensure that synthesis of all the major PGs and GAGs is present in the cells used.

### 14.10.3 Transcription factor genes

The TFs of greatest importance for transcription of many of the ECM molecules belong to the SOX group. *SOX9* is expressed throughout developmental chondrogenesis in mice and is found at high levels also in human prechondrocytes [7,8,10]. In our *in vitro* chondrogenesis assay *SOX9* mRNA is found in MSCs, increases about 10-fold by day 7 and then remains at moderately high expression levels throughout the assay. For complete generation of hyaline cartilage, SOX9 must interact with SOX5 and SOX6 [125]. In our differentiation assay *SOX5* and *SOX6* transcripts are either extremely low or absent in MSCs, are expressed at low levels on day 3, and remain at low levels throughout the assay. However, another member of the SOX family, SOX8 was found to rise from no expression in MSCs to low expression on day 7 and to moderate expression from day 14 onwards.

This TF is interesting, because it is one of the most highly upregulated TFs during murine developmental chondrogenesis and it is also found to be upregulated during human embryological chondrogenesis [8,10]. We studied the role of SOX8 in *in vitro* chondrogenesis [126]. Using siRNA inhibition assays we found that the expression of *SOX8* mRNA was regulated by SOX9 but not vice versa. Transfection with either siRNA greatly reduced the expression of a long list of mRNAs essential for chondrogenesis. such as *COL2A1*, *COL9A2* and *A3*, *COL11A1* and *A2*, *HAPLN1*, *ACAN*, and many others, suggesting that SOX8 and SOX9 cooperate in ensuring transcription of these molecules and that neither of them is redundant. Interestingly, for molecules involved in chondrocyte hypertrophy the situation was entirely different. *SOX8* inhibition did not seem to affect these at all. Inhibition of *SOX9* led to increased expression levels of *MMP13* and *ALPL* (alkaline phosphatase), with no change seen in *COL10A1* mRNA levels. These observations were confirmed by experiments with synthetic mRNAs [126]. This shows that SOX9 inhibits hypertrophy by inhibiting MMP13 and ALPL, while SOX8 does not seem to impact on the process of hypertrophy.

### 14.10.4 Genes encoding other important cartilage molecules

Other molecules are also important for the *in vitro* formation of hyaline cartilage. *COMP* was expressed at low levels in MSCs, increased considerably by day 7, and then remained expressed at slightly lower levels for the duration of the assay. COL6 is found in the immediate vicinity of the ACs. *COL6A1*, *-A2*, and *-A3* were all found to be expressed at moderately high levels in MSCs, and expression remained at approximately the same level throughout the assay. Fibronectin (*FN*) is a molecule thought to be of importance for collagen assembly [127]. *FN* is expressed at high levels in MSCs and with transcription it is one of the most abundant mRNAs in the cells by day 7. In order to exert its effect on collagen assembly, FN must bind to its cell receptor integrin α5β1. The mRNAs encoding these molecules – integrin α5 *(ITGA5*, also known as the fibronectin receptor, CD49e, and very late activation protein 5), and integrin β1 (*ITGB1*, also known as CD29, glycophorin IIa, and very late activation protein, β subunit) – are both expressed in MSCs at relatively high levels. During *in vitro* chondrogenesis *ITGA5* increases slightly and *ITGB1* is slightly reduced, but both are persistently expressed. It is thought that the COL2 integrin receptor α2β1 also needs to be expressed [127].

*ITGA2* (integrin α2, also known as CD49B, α2 subunit of the very late activation antigen-2 receptor, and platelet membrane glycoprotein Ia) is marginally expressed in MSCs, and expression is increased a little during the differentiation assay. It is not known if this low expression of the COL2 integrin receptor may be a hindrance for COL2 fibril formation. Apart from this, the vast majority of the molecules required for hyaline cartilage formation are expressed at the mRNA level.

### 14.10.5 Genes encoding unwanted molecules

Unfortunately, several unwanted molecules are also expressed. First, however, it is worth appreciating that a number of mRNAs that encode chemokines, cytokines, and ECM degradation molecules important for the role played by MSCs in inflammation are all downregulated as early events in chondrogenesis [52]. *COL1A1* and *-A2*, which ensure the synthesis of COL1, the most abundant collagen in fibrocartilage, are both expressed at high levels in MSCs. The expression is reduced considerably just by placing the MSCs in the alginate scaffold, but addition of the differentiation cocktail induces expression that is maintained at approximately the same level as in MSCs. Versican (*VCAN*) is the most important PG in fibrocartilage. *VCAN* is expressed at moderate levels in MSCs and is reduced, but not eliminated, in differentiating cells. Thus, the molecular basis for the formation of fibrocartilage is present side by side with the genes necessary for the formation of hyaline cartilage, although *COL2A1* and *ACAN* are expressed at 5–10 times higher levels than their fibrocartilage counterparts *COL1A1* and *VCAN* on day 21. Genes involved in chondrocyte hypertrophy are also expressed. *COL10A1*, which appears to be under different transcriptional control than *COL2A1*, is marginally expressed in MSCs, but already on day 1 significant mRNA levels are found, and levels similar to those observed for *COL2A1* are found on day 21. The MMPs most involved in COL2 breakdown are MMP13, MMP1, and MMP8. Of these, *MMP1* and *MMP13* are expressed at extremely low levels throughout differentiation, while *MMP8* is not expressed. Cleavage of aggrecan is mediated by the aggrecanases ADAMTS4 and ADAMTS5. Of these, *ADAMTS5* is expressed at very low levels in MSCs and then falls to near undetectable levels during differentiation, while *ADAMTS4* is not expressed at any time. Thus, the major chondrocyte hypertrophy catabolic enzymes are absent or only barely expressed during *in vitro* chondrogenesis. Another molecule involved in chondrocyte hypertrophy is *RUNX2*. This mRNA is present at low levels in MSCs and remains at unchanged levels throughout differentiation. Alkaline phosphatase (*ALPL)*, the gene product of which is responsible for deposition of calcium during bone formation, is expressed in MSCs, and increases between days 7 and 14 to moderately high levels. However, although genes involved in endochondral ossification are expressed at variable levels in our model of *in vitro* chondrogenesis, we have never seen evidence of bone formation in this model system.

### 14.10.6 Effect on gene expression of changes in the differentiation cocktail

The results presented here from our laboratory were all created using a differentiation cocktail containing TGF-β1, BMP2, and dexamethasone [128]. However, as our chondrogenic differentiation assay in alginate discs is different from the micromass cultures previously used to determine the optimal differentiation cocktail, we wanted to perform an optimalization study using our own chondrogenic differentiation assay. For this, we established a checkerboard factorial analysis involving TGF-β1, BMP2, dexamethasone, FGF2, and insulin-like growth factor 1 (IGF1). As a read-out system we used the custom-made NanoString nCounter assay, which allowed us to quantify 350 genes of our own selection for every condition established. Primary MSCs from three donors were used and data were collected from day 1 and day 7 [37]. First, however, we analyzed experiments to determine if any of the TGF-β isoforms TGF-β1, TGF-β2, or TGF-β3 performed better than the others in the presence or absence of dexamethasone or in the presence or absence of BMP2. Our conclusion was that there was no significant difference between these different isoforms, so we chose TGF-β1 for the remaining experiments. We also tested for differences between the use of BMP2, BMP4, or BMP6 in the presence or absence of TGF-β1, and since we did not discover important differences between these, we used BMP2 for the remaining experiments.

This discussion will be based predominantly on data from day 7. We had observed a trend toward the same results on day 1, suggesting that many of the important molecular events during *in vitro* chondrogenesis occur early, but robust distinguishing features between the differentiation cocktails tested were most obvious on day 7. It was clear that the factor with the greatest

influence on our gene set was TGF-β1. No other factor, regardless of the presence or absence of other factors, had the same effect on the upregulation of wanted chondrogenic genes. Unfortunately, addition of TGF-β1 also led to the upregulation of unwanted genes, but to a lesser extent. We concluded that TGF-β1 was indispensable in an *in vitro* chondrogenesis assay. As IGF1 has been described to have an influential role in developmental chondrogenesis we expected this factor to also have a positive influence in our *in vitro* chondrogenesis assay, but this was not the case. Analyzing lengthy lists of wanted and unwanted genes, we found that IGF was entirely neutral relative to the expression of these genes. FGF2 is a known stimulator of MSC proliferation, and the addition of FGF2 to the medium during the *in vitro* expansion stage has been shown to enhance subsequent chondrogenic differentiation [129,130]. In the present study, however, we only examined the effect of adding FGF2 to the differentiation cocktail. We found that FGF2 induced downregulation of both wanted and unwanted genes, both at relatively low magnitudes, but with a trend toward greater downregulation of wanted genes. The data can be visualized in Figure 14.10: compare conditions 1–4 (with FGF2) with conditions 9–12 (without FGF2). Of note, genes such as *COL2A1*, *COL9A1*, *-A2*, and *-A3*, and *COL11A1* and *-A2* were all downregulated in the presence of FGF2. On the other hand *COL10A1*, *PPAR-γ*, and to some extent *COL1A1* were also downregulated in the presence of FGF2. We concluded that FGF2 should not be part of our differentiation cocktail.

Corticosteroids have not been described as playing a role in embryological chondrogenesis, but dexamethasone has been included in protocols for *in vitro* chondrogenesis since the early studies of this process were performed [131]. In our own *in vitro* chondrogenesis assay it was obvious that addition of dexamethasone to TGF-β1 in the differentiation cocktail led to upregulation of all the wanted genes except for two of the small leucine-rich PGs (*BGN* and *LUM* – compare conditions 1 with dexamathasone and 5 without – but also to upregulation of some of the genes within our selection of unwanted genes, such as *COL10A1*, *COL1A1* and *-A2*, *ALPL*, *PPARG*, and *OGN* (osteoglycin). A more detailed inspection of the 20 most highly upregulated and downregulated genes following addition of dexamethasone revealed that the vast majority of the most highly

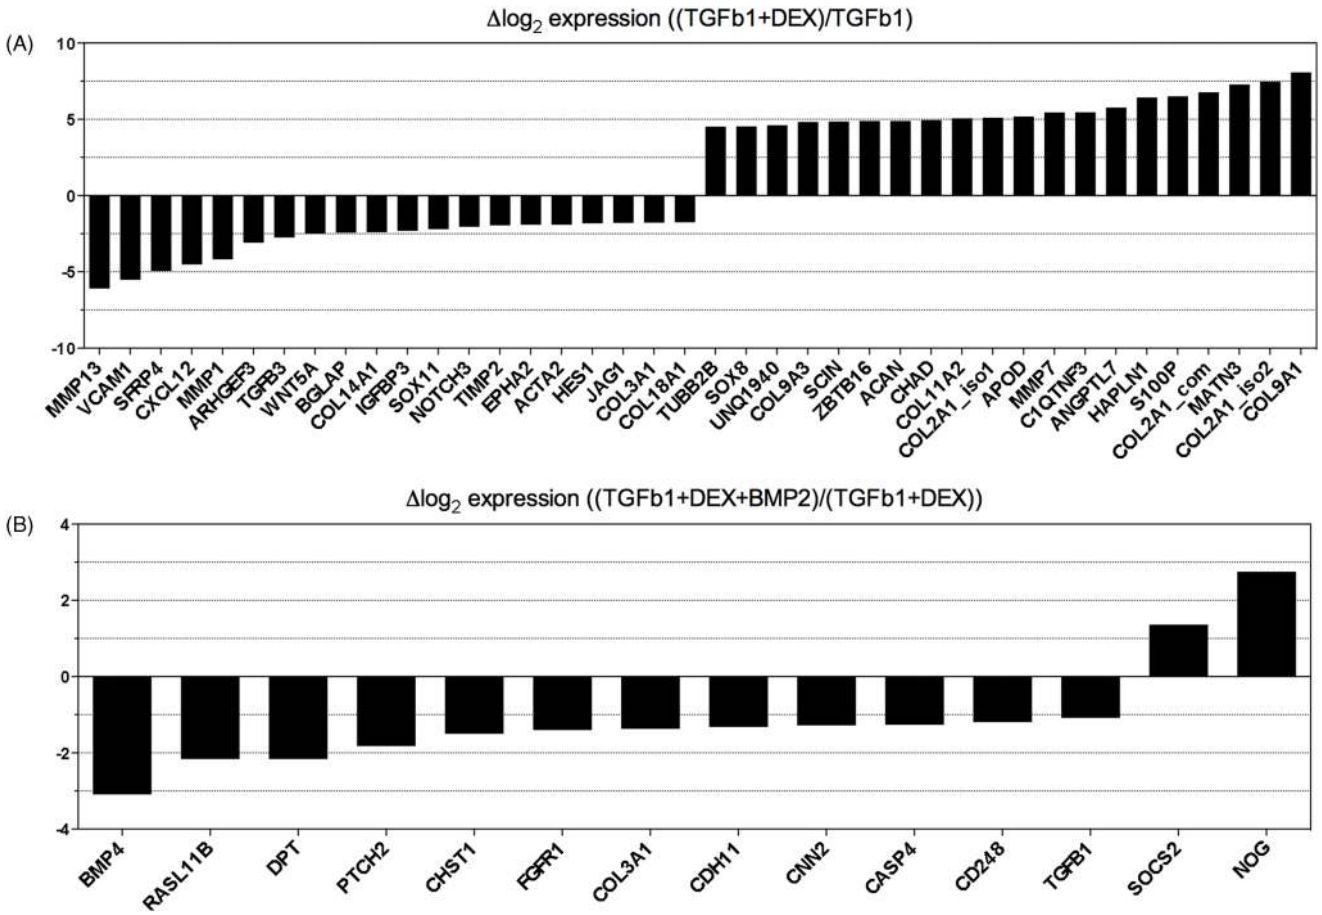

**Figure 14.10** Genes significantly regulated between key conditions (day 7). (A) Top 20 upregulated and top 20 downregulated genes when dexamethasone is added to TGF-β1. (B) Changes in gene expression when BMP2 is added to TGF-β and dexamethasone. Values represent log 2 to the fold change between the gene expression in the condition without and the condition with the specified factor added. *Source*: [37] Jakobsen, *PLoS ONE* 2014, **9**: e96615.

upregulated genes were likely to have a positive effect on *in vitro* chondrogenesis, while the majority of the downregulated genes were genes with gene products most likely to exert an unfavorable effect in our assay. Thus, dexamethasone was included in our differentiation assay.

With TGF-β1 and dexamathasone in place in the differentiation cocktail, we needed to determine whether to add BMP2 also. There were significantly upregulated or downregulated genes when BMP2 was added on a background of TGF-β1 and dexamethasone. The most highly upregulated gene, *NOG*, encodes the polypeptide NOGGIN, which binds and inactivates BMPs belonging to the TGF-β superfamily, particularly BMP4 [132]. This may be the reason why *BMP4* was the most downregulated gene, an effect that is presumably unwanted in this assay. Another downregulated gene was *NOTCH1*. The protein encoded by this gene has been shown to be required in early chondrogenesis, but must be turned off for complete chondrogenesis to occur [133]. In addition, several other downregulated genes, such as *DPT* (dermatopontin), *FGFR1* (FGF receptor 1), and TGF-β1, are likely to have prochondrogenic effects. We concluded that the addition of BMP2 to a chondrogenic cocktail already consisting of TGF-β1 and dexamethasone is not likely to improve cartilage formation.

## 14.11 Conclusions

The factors involved in developmental chondrogenesis in rodents are well described, and corresponding data from investigations in humans are accumulating [6,7,9,10]. These results have established a benchmark for scientists trying to make cartilage *in vitro*. The best approach so far is perhaps an assay that uses condensed masses from MSCs, potentially similar to the mesenchymal condensations observed during development. These condensations were press fitted into a porous decellularized bone matrix [45]. Although this model created cartilage of the right thickness and acceptable compressive capabilities, the system is probably too cumbersome for routine tissue engineering of cartilage for clinical use. For this, the use of MSCs in a biomaterial may still be the best choice. In this chapter we have discussed some of the molecular events occurring when MSCs are exposed to a chondrogenic differentiation cocktail in such a model system. We have shown that the vast majority of genes encoding proteins required for the synthesis of hyaline cartilage are expressed in this model. However, a number of unwanted genes are also expressed. Research is ongoing to find differentiation protocols that allow expression of all the wanted genes while avoiding the unwanted genes.

However, there are a number of other problems that need to be solved before the perfect implant can be developed. One issue is whether COL2 proteins are present as fibrils throughout the intercellular space. In hydrogel biomaterials this may not be the case [124]. Another issue is how important it is to achieve an overall architectural structure similar to that seen *in vivo*. This issue may perhaps not be solved before experimental therapies have been followed up for a number of years. Development of a perfect synthetic cartilage graft has the potential to help millions of people with OA and in so doing would also save a great deal of money currently spent on analgesics, joint surgery, or joint replacement. The book on this type of research is certainly not closed yet.

## 15.1 Summary

Mesenchymal stromal cells (MSCs) are a heterogeneous population of stromal cells that exist in almost all tissues. Owing to their relatively easy acquisition, large-scale expansion capability, and their ability to differentiate into cells of mesenchymal lineages, MSCs are a promising candidate for cell-based tissue regeneration. The regulation of their lineage commitment, especially that of adipogenic and osteogenic differentiation, has been widely studied. The microenvironment of the MSC niche, including the geometric extracellular matrix (ECM), adjacent cells, and a number of cytokines and growth factors, are critical for their lineage commitment. ECM, as a major component of the MSC niche microenvironment, is essential for cell fate determination by providing specific geometric cues and direct interactions with cell surface receptors. This chapter reviews advances in elucidating the role of the ECM in regulating MSC differentiation.

## 15.2 Multipotency of mesenchymal stromal cells

Friedenstein *et al.*, who discovered MSCs, implanted them under the renal capsule or in diffusion chambers and then harvested the implants for histological examination 30–90 days later. They observed bone formation and hematopoiesis in the MSC implants [1]. In 1999, Pittenger *et al.* induced MSCs to differentiate *in vitro* into osteoblasts, adipocytes, and chondrocytes by using various combinations of chemicals [2]. These pioneering studies clearly demonstrated the multipotency of MSCs in the mesenchymal lineage. This ability of MSCs to differentiate into cells of the mesenchymal lineage has been recognized as one of the criteria by which MSCs are defined [3]. The differentiation ability of MSCs has been extensively studied, mainly using well-established *in vitro* assays with clonally expanded MSCs. Typically, MSCs cultured in medium with 1-methyl-3-isobutylxanthine (IBMX), dexamethasone, insulin, and indomethacin differentiate into adipocytes [4]. IBMX and dexamethasone are important for the initiation of adipogenic differentiation. IBMX is believed to inhibit phosphodiesterases, which cause an elevation of intracellular cyclic adenosine monophosphate [5]. Elevation of cyclic adenosine monophosphate leads to alteration of transcription factors through the protein kinase A pathway. IBMX has also been shown to directly induce

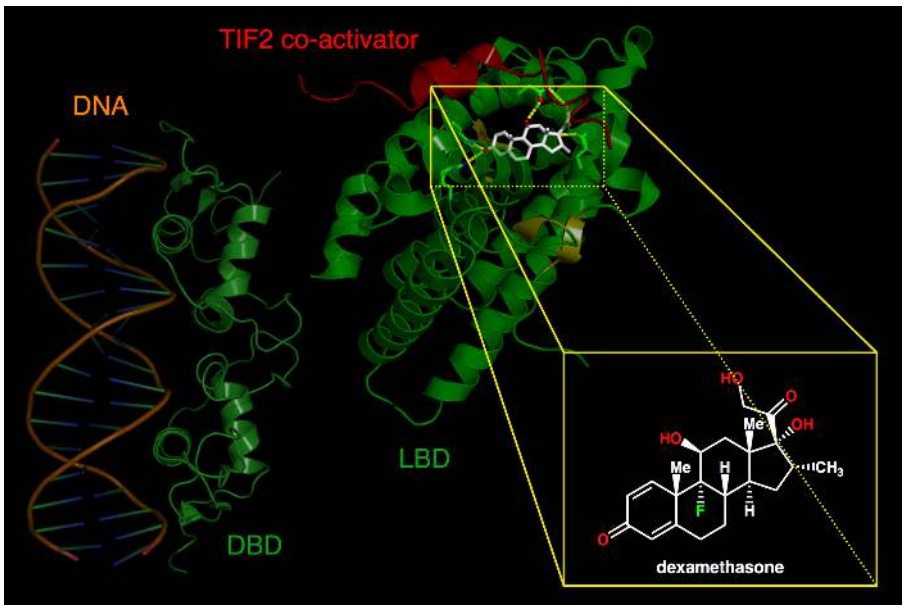

**Figure 15.1** Crystallographic structures of the glucocorticoid receptor DNA binding domain (DBD, left, PDB: 1R4O bound to DNA) and ligand binding domain (LBD, right, 1M2Z bound to dexamethasone and the TIF2 co-activator protein). Dashed lines represent hydrogen bonding interactions between the receptor and ligand. The two-dimensional (2D) structure of dexamethasone is also depicted in the lower right-hand side of the picture for reference. *Source*: https://commons.wikimedia.org/wiki/File:Glucocorticoid_receptor.png#/media/File:Glucocorticoid_receptor.png.

CCAAT-enhancer-binding protein (C/EBP)-β expression [6]. Dexamethasone activates C/EBPδ expression through binding to the glucocorticoid receptor [6] (Figure 15.1).

Indomethacin is a well-known inhibitor of cyclooxygenase 1/2 (Cox1/2) activities. However, the adipogenic activity of indomethacin is not related to the inhibition of Cox1/2 but rather by activation of peroxisome proliferator-activated receptor-γ (PPAR-γ) [7]. Insulin functions as a promoter of glucose uptake, which is stored as triglycerides in adipocytes.

For *in vitro* osteogenic differentiation MSCs are normally cultured with β-glycerophosphate sodium (β-GP), L-ascorbic acid (vitamin C), and dexamethasone [8]. To analyze the effects of these chemicals on the differentiation of MSCs, Coelho and Fernandes cultured MSCs in standard medium supplemented with vitamin C, β-GP, or dexamethasone alone or in the combinations vitamin C + β-GP or vitamin C + β-GP + dexamethasone [9]. Vitamin C was found to initiate the formation of a collagenous extracellular matrix that led to upregulation of alkaline phosphatase (ALP) and osteocalcin [10]. Dexamethasone promoted cell proliferation, resulting in an increase in ALP activity and mineral deposition. β-GP could be hydrolyzed by ALP, which provided a high level of phosphate ions for mineral deposition of ECM [9].

However, *in vivo*, MSC fate decision is much more complex and plastic [11]. In healthy individuals under normal conditions there is a reciprocal relationship between adipocyte and osteoblast differentiation of MSCs. Alteration in this balance of MSC differentiation is believed to occur in a number of diseases, most notably osteoporosis [12]. Conversely, various diseases, particularly obesity, alter the differentiation potential of MSCs [13,14]. Interestingly, it has been shown that adipogenic differentiation was favored in MSCs derived from people with osteoporosis or aging people. Corroborating these findings, numerous *in vitro* studies have demonstrated that fat-induction factors can inhibit osteogenesis [15,16] and that bone-induction factors can inhibit adipogenesis [17]. Thus, there is evidence of a reciprocal relationship between adipogenic and osteogenic differentiation in MSCs.

## 15.3 The extracellular matrix and mesenchymal stromal cell differentiation

Stromal cell differentiation is also mediated in part by signals from the extracellular environment. Although many reports have shown that cytokines and growth factors are the primary determinants of stromal cell lineage differentiation, much attention has also focused on molecules within the ECM, as well as those from neighboring cells during MSC fate determination [18]. The ECM is an acellular component secreted by cells present in all tissues and organs. It provides not only critical physical scaffolding for tissue remodeling, but also initiates important biological cues that control cell differentiation, adhesion, and interaction with other cells [19]. ECM components, such as osteopontin (OPN), cadherins, ephrins, and Notch family members, have been reported to regulate cell differentiation [20–22].

Cell fate regulation by the ECM can be exerted via two main mechanisms: (1) the harboring of growth factors or growth-factor-binding proteins and (2) direct regulation of cell behavior either through receptor-mediated signaling or by modulating the cellular response to growth factors. Interestingly, ECM components have also been found to play an active role in regulating the mobilization of growth factors and cytokines rather than passively impeding their binding to their corresponding receptors. Mutation of the ECM remodeling enzyme matrix

metalloproteinase (MMP) 9 resulted in delayed bone development as well as altered vascular differentiation and tissue repair ability [23]. Ligation of cell surface integrins by ECM components can directly induce downstream signaling pathways, the so-called outside–in signaling. There are 24 distinct integrins assembled from 8 β and 18 α subunits [24]. The diversity of ECM receptors and their ligands allows MSCs to monitor their own microenvironment and respond to various kinds of stimulation. Thus, the complex signaling network downstream of these receptors provides a source of diversity for cell–matrix interactions. These two types of regulatory mechanisms do not act in isolation from each other; rather, they crosstalk to each other. In the following we discuss several key regulators, including cytokines and geometric cues, to demonstrate the critical roles of the ECM in directing MSC differentiation.

### 15.3.1 The role of osteopontin in mesenchymal stromal cell differentiation

OPN, also known as secreted phosphoprotein 1, is a major component of noncollagenous ECM. Extracellular OPN exerts its effects through interactions with multiple ubiquitously expressed cell surface receptors, including integrins ($\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_v\beta_1$, $\alpha_4\beta_1$, $\alpha_8\beta_1$, and $\alpha_9\beta_1$) [25–27] and the non-integrin receptor CD44, which is the receptor for hyaluronic acid [28,29]. Upon ligation of OPN receptors different cell signals are generated and various tasks are performed, including cell adhesion [30], cell survival [31], and cell migration [32]. OPN is expressed by a variety of cell types, including fibroblasts, osteoblasts, and a range of immune cells [33]. It is deposited in the ECM and is present in circulating fluids. Moreover, OPN is also expressed during numerous physiological and pathological processes. Because of its widespread expression it has been implicated in cancer metastasis, progression of autoimmune disease, bone remodeling, wound repair, and responses to stress [33–35].

Bone has been implicated as an endocrine organ in energy metabolism by exerting effects through molecules secreted by osteoblasts and osteoclasts [36]. OPN is an osteoblast biomarker and is abundantly secreted by MSCs. It is upregulated during osteogenesis. However, its role in MSC differentiation has not been elucidated. Compared with wild-type MSCs, our group found that adipogenic differentiation of $OPN^{-/-}$ MSCs was dramatically accelerated while osteogenic differentiation was inhibited. Consistent with these findings, specific knockdown of OPN by shRNA promoted robust adipogenic differentiation and inhibited osteogenic differentiation. Re-expression of OPN restored a normal balance between adipogenesis and osteogenesis in $OPN^{-/-}$ MSCs. Retardation of bone formation by $OPN^{-/-}$ MSCs was verified by *in vivo* implantation of MSCs with hydroxyapatite–tricalcium phosphate, a bone-forming matrix. The role of extracellular OPN in MSC differentiation was also demonstrated by supplementation and neutralization of OPN. Blocking the highly expressed OPN receptors integrin $\alpha_v/\beta_1$, but not CD44, also affected the balance of MSC differentiation between adipocytes and osteoblasts. Further studies revealed that OPN inhibits the signaling pathway of C/EBPs through integrin $\alpha_v/\beta_1$ receptors. Consistent with these *in vitro* results, $OPN^{-/-}$ mice had a higher fat to total body weight ratio than wild-type mice. Thus, the interaction of OPN and integrin $\alpha_v/\beta_1$ plays a key role in regulating MSC differentiation.

### 15.3.2 Geometric cues in mesenchymal stromal cell differentiation

Nanoscale symmetry and disorder have been shown to play important roles in dictating various types of cell behavior and stromal cell differentiation [37,38]. Geometric cues, such as the stiffness and topology (biophysical forces) of the cell microenvironment, which are dictated by the ECM *in vivo*, have dramatic effects on MSC lineage commitment [39]. By culturing geometrically patterned MSCs in medium containing either adipogenic or osteogenic chemical inducers, Kilian *et al.* showed that geometric cues suitable for the contractile cytoskeleton were osteogenic, while those disrupting contractility were adipogenic [40].

Micropatterning technology, which is able to precisely control cell attachment by depositing specific proteins on a substrate, has been widely used to geometrically define the substrate surface in order to study the interaction between MSCs and patterned substrates [41]. Nanoscale cues have been reported to induce a change in cell shape by altering the organization and assembly of the cytoskeleton. It has been shown that the balance between adipogenic and osteogenic differentiation of MSCs was disrupted by micropatterned protein-induced cell shape change [42]. Although the Rho/ROCK (Ras homolog/Rho-associated protein kinase) pathway has been implicated during this process, details of the mechanisms involved in geometric cue-induced MSC differentiation are still largely elusive.

To better mimic the microenvironment of stromal cell differentiation *in vivo*, powerful three-dimensional (3D) culture systems have been developed (see Chapter 8). The 3D culture system allows us to artificially control cell shape more precisely compared with the use of cell monolayers [43]. The 3D systems most commonly used involve poly(ethylene glycol)-based hydrogels. In such systems, cells are more rounded and under spatial orientation similar to that found with the ECM *in vivo*, unlike cells cultured in standard 2D systems. It has been reported that the shape of MSCs can be modulated dynamically by creating photodegradable poly(ethylene glycol)-based hydrogels [44]. This system makes it possible to study complex physical interactions between MSCs and the ECM. Thus, the 3D culture system provides a much improved opportunity by which to study the detailed mechanism of lineage commitment of MSCs *in vivo*.

### 15.3.3 Crosstalk between the extracellular matrix and mesenchymal stromal cells

In addition to their passive response to ECMs, MSCs also possess the ability to actively remodel their ECM microenvironment. A study by Tang *et al.* showed that MSCs remodeled the ECM by secreting a membrane-anchored metalloproteinase MT1-MMP

(MMP 14) [45]. Since deletion of MT1-MMP is embryonic lethal, the authors generated a conditional knockout mouse in which MT1-MMP was specifically deleted in mesenchymal progenitors and skeletal stromal cells. These mice showed a decrease in bone formation and an increase in bone marrow adipose cells and articular cartilage generation. Interestingly, MSCs isolated from these MT1-MMP conditional knockout mice were able to differentiate normally into osteoblasts in a traditional 2D culture system. However, when cultured in 3D collagen gel, these MSCs tended to differentiate into adipocytes rather than osteoblasts. Further study showed that MT1-MMP exerted its effect on MSC lineage commitment through remodeling the ECM. This, in turn, altered the cell shape and ultimately activated the downstream cell signaling cascade involved during MSC differentiation.

## 15.4 Conclusions and future perspectives

In today's society obesity, diabetes mellitus, and osteoporosis are major public health concerns. Investigation of the relationship between bone and fat in energy metabolism are being explored, aiming at improving human health and reducing the burden on society. Osteoblasts and adipocytes are both derived from MSCs and constitute the major cellular components of bone and fat respectively. Ever since Meunier *et al.* reported the replacement of the cell populations in the marrow by adipose tissue in people with osteoporosis [46], the intimately competitive balance between adipocytes and osteoblasts in bone marrow has attracted significant attention.

A series of important factors have been implicated in the fate decision of MSCs. Among these, the cues and signals originating from the ECM play a critical role in regulating MSC lineage commitment *in vivo*. In addition, previous studies on the role of the ECM in MSC differentiation provide critical insight into the superiority of 3D system in modeling the *in vivo* situation *in vitro*. The widely used 2D culture systems are inadequate for addressing questions about the microenvironment *in vivo*, where stromal cells undergo lineage commitment. In conclusion, this chapter has discussed how ECM and the cytokines and growth factors in the microenvironment exert critical roles during the lineage commitment of MSCs.

## 16.1 Introduction

Human multipotent mesenchymal stromal cells (MSCs) isolated from human tissues such as bone marrow have become a promising tool for clinical applications. However, successful application of MSCs for therapeutic uses requires the development of techniques and protocols for the preparation of cell products. New techniques for expanding MSCs need to overcome cell senescence, loss of pluripotent gene expression, decreased self-renewal and differentiation potential, low engraftment after transplantation *in vivo*, and rejection by allogeneic recipients. Moreover, expanded MSCs should have a normal karyotype and genome integrity to prevent tumorigenic transformation. MSCs cultured under hypoxic conditions, the normal physiological state of the bone marrow, represent a new source of expanded MSCs for clinical applications. This chapter will address the effects of hypoxia on MSCs especially for the purpose of translation from bench to bedside and will emphasize that hypoxia is a key aspect of the biological profiles of MSCs.

## 16.2 Multipotent mesenchymal stromal cells

Multipotent MSCs are the best-studied subpopulations of stem/progenitor cells in the bone marrow, which are capable of differentiating into several nonhematopoietic cells after isolation from bone marrow by adherence to tissue culture surface [1–4].

They are easily isolated, can be expanded in culture without the loss of differentiation potential and immune modulating properties, and have limited, if any, tendency to form tumors. Thus, MSCs have emerged as a promising tool for clinical applications such as tissue engineering and cell-based therapy. This first drug of stem/progenitor cells in the world was approved in Canada in May 2012 for the treatment of children with severe treatment-refractory acute graft-versus-host disease occurring after allogeneic hematopoietic stem transplantation.

## 16.3 Criteria for defining human multipotent stromal cells

Because the therapeutic potential of MSCs has generated significant increase in a wide variety of biomedical disciplines and because of difficulty in comparing the results of *ex vivo* expanded MSCs from one laboratory to another, the International Society for Cellular Therapy proposed minimum criteria to define human MSCs. The expanded MSCs for clinical applications must meet all the criteria [5]. First, the MSCs should be plastic adherent when maintained in standard culture conditions. Second, the MSCs must express CD105, CD73, and CD90 and lack expression of CD45, CD34, CD14 or CD11b, CD19 or CD79α, and HLA-DR surface molecules. Third, the MSCs must possess the ability to differentiate into osteoblasts, adipocytes, and chondroblasts *in vitro*.

## 16.4 Problems encountered in the clinical application of multipotent mesenchymal stromal cells

There are several problems associated with the clinical application of MSCs (Table 16.1). For clinical applications these cells must be expanded in large scale using a gold-standard protocol without undergoing senescence or loss of proliferative capacity. Moreover, expanded cells must meet the criteria for MSCs, maintain mesodermal lineage differentiation potential, and graft into, or regenerate, tissues after their autologous or allogeneic transplantation. Since it has been proposed that MSC-derived microvesicles may protect against injuries or inflammation in injured tissues such as the kidney of the mouse remnant kidney model [6] or the cornea following chemical or mechanical injury [7], the actual functions of MSCs or their secreted factors – such as tumor necrosis factor-inducible protein 6 [8] in mediating therapeutic effects – should be clarified before clinical application. More importantly, processing procedures, instruments, or installation used for cell manipulation or expansion should be regulated and approved to provide products that pass the tests regarding the identity, strength, purity, and product safety of cell product (see United States Pharmacopeia 32 ⟨1046⟩ and Chapters 43 and 44).

## 16.5 The hypoxic niche of multipotent mesenchymal stromal cells

The bone marrow niche facilitates the maintenance of hematopoietic stem cells (HSCs) as undifferentiated stem cells while supporting lineage commitment of the cells of the hematopoietic and immune systems [9]. MSCs residing in the bone marrow are associated with, and maintain, HSC functions and produce mesenchymal cells such as osteoblasts and adipocytes for maintaining the structure of bone. Bone marrow is hypoxic, with oxygen tension about 1 to 7% [10,11]. Because the general culture condition of 21% $O_2$ in the air of the incubator is hyperoxic compared with that of the normal bone marrow niche of MSCs, one strategy to solve the problems encountered in the clinical application of MSCs is expansion of these cells under hypoxic conditions. Therefore, the roles of the bone marrow niche in maintaining MSC properties and functions should be well investigated (see Chapter 32). For investigation of the effects of the marrow niche on MSC properties and functions we and other groups cultured MSCs under hypoxic conditions and compared the results with those obtained under normoxic conditions. Consistently, these studies have shown that MSCs cultured under hypoxia or absolute hypoxia meet the criteria for defining MSCs [5] without undergoing apoptosis or changes in immunophenotype [12,13]. Most of these studies also found that culture under hypoxic conditions had beneficial effects on the properties and functions of MSCs. This chapter aims to discuss the effects of hypoxic culture on MSC properties and functions, especially for their translation from bench to bedside.

## 16.6 Involvement of hypoxia-inducible factor-1α in hypoxia-mediated effects

Hypoxia is known to regulate various cellular processes, including signal transduction. Under hypoxic conditions, regulatory α subunits of hypoxia-inducible factors (HIFs) 1α and 2α are constitutively stabilized by escaping from oxygen-dependent and von Hippel–Lindau tumor suppressor-mediated ubiquitylation and proteasomal degradation [14–17], leading to increased levels of HIF-1 and HIF-2 and a wide range of hypoxia-inducible mRNAs, including those involved in energy metabolism, angiogenesis, and apoptosis, such as glucose transporter and vascular endothelial growth factor (VEGF). Most of the effects of HIF-1α have been investigated for cancer cells. Hypoxia or the hypoxic state, mimicked by the use of cobalt chloride ($CoCl_2$) and the iron chelator desferrioxamine, induced the accumulation of wild-type p53 by HIF-1α-dependent association with, and stabilization of, p53 protein [18]. (Tumor protein 53, or p53, is crucial in multicellular organisms, where it prevents cancer formation and thus functions as a tumor suppressor. p53 has been described as "the guardian of the genome" because of its role in conserving stability by preventing genome mutation. The International Cancer Genome Consortium established that the *TP53* gene is the most frequently mutated gene (>50%) in human cancers, indicating that the *TP53* gene plays a crucial role in preventing cancer formation. The *TP53* gene encodes proteins that bind to DNA and regulate gene expression to prevent mutations of the genome.)

HIF-1α blocks neuronal and myogenic differentiation via recruitment to Notch-responsive promoters after Notch activation under hypoxic conditions in neural stem cells and myogenic cells respectively [19]. Recently, HIF-1α was shown to regulate the proliferation of MSCs through enhanced TWIST expression, which downregulates the E2A–p21 pathway, and thus inhibits replicative senescence and stimulates proliferation [20]. It should be noted that HIF-1α upregulates the surface expression of chemokine (C–X–C motif) receptor 4 (CXCR4) and chemokine (C–X3–C motif) receptor 1 (CX3CR1) in MSCs, thereby enhancing their migration and engraftment after transplantation [21]. HIF-1α also plays an important role in the mobilization into the peripheral blood of hypoxia-induced MSCs, possibly acting via its downstream genes VEGF and stromal-cell-derived factor-1α (SDF-1α, also known as CXCL12) [22]. Recent studies have also suggested that HIF-1α and hypoxia-mimicking agents trigger the initiation of the angiogenic–osteogenic cascade and promote bone repair and regeneration [23]. Furthermore, networks of transcription factors related to HIF-1α and miR-124a in part control extensive changes of their global gene expression profile during the conversion of MSCs into neural stem cell-like cells [24]. Although HIF-2α is known to upregulate the expression of pluripotent genes such as *OCT4* [25], thereby maintaining embryo development, few studies have mentioned the involvement of HIF-2α in regulating the properties of MSCs. We have previously compared the protein levels of HIF-2α between MSCs cultured under normoxic and hypoxic conditions and found no difference in the level of HIF-2α between these two conditions [20].

## 16.7 Effects of hypoxic culture on glucose metabolism and oxidative stress of multipotent mesenchymal stromal cells

It has been shown that exposure to hypoxia or hypoxia-mimetic agents, such as $CoCl_2$, induces expression of HIF-1α and glucose-6-phosphate transporter (G6PT) in MSCs. Moreover, knockdown of HIF-1α inhibited the expression of G6PT in hypoxic MSCs, whereas constitutive expression of HIF-1α with a mutant oxygen-dependent degradation domain resulted in increased G6PT expression in normoxic MSCs, suggesting the involvement of the HIF pathway in G6PT expression [26]. Additionally, a potent G6PT inhibitor, AD4-015, specifically causes cell death in MSCs constitutively expressing the HIF-1α mutant. Collectively, these data suggest that G6PT may account for metabolic flexibility allowing MSCs to survive under conditions characterized by hypoxia [26]. MSCs cultured under hypoxic conditions also have a higher specific consumption of nutrients, especially at the beginning of culture, but exhibit a lower specific production of inhibitory metabolites. However, the hypoxic culture of MSCs has been shown to increase cell division and expansion for the progeny of colony-forming units–fibroblasts, while maintaining the characteristics of MSC-like immunophenotype and differentiation [27]. These data suggest that MSCs expanded under hypoxia favor increased cellular metabolism efficiency, leading to maximization of the yield of cells for application in clinical settings [27]. MSCs were also resistant to exposure to absolute hypoxia (0.5% $O_2$) and inhibition of mitochondrial respiration with 2,4-dinitrophenol [28], indicating that, in the absence of oxygen, MSCs may survive using anaerobic adenosine-5′-triphosphate production. Other studies have demonstrated that MSCs are able to survive hypoxia owing to their ability to rely on glycolysis instead of mitochondrial respiration [28]. Hypoxic preconditioning of MSCs also induces glycogen synthesis to provide additional sources of glycogen for glycolysis, thereby improving MSC survival and therapeutic effects in ischemic tissues [29]. Taken together, these studies suggest that MSCs are characterized by metabolic flexibility, allowing them to survive in conditions of hypoxia and ischemic stress, and enabling them to function in a restorative or regenerative capacity in the treatment of ischemic diseases.

## 16.8 Effects of hypoxic culture on the apoptosis of multipotent mesenchymal stromal cells

Significant apoptosis in MSCs has been demonstrated in conditions associated with the depletion of serum, especially during an extended period [30]. Most studies, however, have demonstrated that MSCs cultured under hypoxia or absolute hypoxia do not undergo apoptosis or changes in immunophenotype [12,13]. Moreover, the combination of exposure to hypoxia partly inhibited apoptosis induced by serum depletion [30,31]. The mechanisms that MSCs use to survive under hypoxic or ischemic conditions include the use of the glycolytic pathway [28] and the production of glucose-6-phosphatase for using glucose [26]. These results suggest that MSCs are characterized by metabolic flexibility, allowing them to survive from hypoxic and ischemic stress and retain their stem/progenitor cell phenotype. These results indicate the potential usefulness of MSCs in treating ischemic diseases.

The survival rate of MSCs at 4 days of transplantation into an ischemic heart was 0.44% [32]. Hypoxic preconditioning enhances the ability of MSCs to survive after transplantation into the ischemic heart [33–35] and limb tissues [29]. Similarly, hypoxic preconditioning of neural stem cells and MSCs also increased their survival and decreased the activation of caspase-3 after their transplantation into ischemic brain [36]. One proposed mechanism is that hypoxia-induced glycogen-synthesis-associated metabolic adaptation promotes the survival of MSCs in long-term ischemia [29]. These data suggest that short-term exposure of MSCs to hypoxia prior to transplantation improves survival rates following transplantation. Although hypoxic preconditioning increases survival, MSCs still cannot stay long in ischemic tissues, conditions associated with hypoxia and lack of nutrition [30]. To overcome these obstacles, several measures have been shown to help MSCs survive under these conditions, including transfection of MSCs with plasmids carrying the integrin-linked kinase [37], heme oxygenase-1 (HO-1) [38], angiogenin [39], angiopoietin-1, Akt [40], and the 70 kDa heat-shock protein [41], or pretreatment of MSCs with cyclosporine [42] or lysophosphatidic acid [43]. Most of these measures increased the survival of MSCs through downregulating pathways associated with apoptosis. In addition, HO-1 significantly affected the potential of cell differentiation through suppression of the microRNAs miR-1, miR-133a, miR-133b, and miR-206 [44].

## 16.9 Effects of hypoxic culture on expansion and life span of multipotent mesenchymal stromal cells

The effects of hypoxia on the proliferation and expansion efficiency of MSCs depend on the sources from which the MSCs are derived, the oxygen concentration, the seeding density, and the duration of time used for culture (Table 16.2).

Some studies found that hypoxia significantly inhibited proliferation [21,45,46,49,51], while others found that hypoxia increased proliferation or increased the culture duration for approaching senescence [12,45,48,50,53–56]. We have shown that hypoxia inhibited proliferation at the earliest passages of culture either at low density (10–200 cells/cm$^2$) or at high density (1000–4000 cells/cm$^2$) [21], while hypoxia significantly increased the efficiency of expansion in long-term culture (up to 60 days) of MSCs at low density (Table 16.3) [20].

Moreover, hypoxia also inhibited senescence, increased proliferation, and enhanced differentiation potential *in vivo* and *in vitro* [20]. Together, these results show that the effects of

hypoxia on the short-term proliferation of MSCs varied and depended on the oxygen tension, seeding densities, and sources from which the MSCs were isolated. The beneficial effects of hypoxia on long-term expansion of MSCs are consistent even with different sources of MSCs in a variety of concentrations of oxygen [12,20,50].

## 16.10 Effects of hypoxic culture on maintaining self-renewal and differentiation potential of multipotent mesenchymal stromal cells

Proliferation and differentiation potential are important hallmarks of viable multipotent MSCs. Low-density culture under normoxic conditions provides a method for the rapid expansion of MSCs [57] at the expense of a loss in proliferation ability and differentiation potential [20,58]. Furthermore, long-term expansion of MSCs under normoxia adversely affects cell function when MSCs were applied for protecting the myocardium [59]. In contrast, the combination of low-density culture with hypoxic culture maintains proliferation and differentiation potential, increases the expression of pluripotency genes, such as *OCT4*, *NANOG*, and *SOX2* [60], and inhibits senescence [20]. Similarly, MSCs with hypoxic preconditioning have been shown to exhibit increased differentiation into bone [61], fat, and cartilage lineages [62] both *in vitro* and *in vivo* [20]. Hypoxic MSCs have also been observed to increase telomere length and telomerase activity, and have normal karyotyping and chromosomal integration [20]. Moreover, MSCs with long-term hypoxic preconditioning do not form tumors when transplanted into immunodeficient mice. These results suggest that the hypoxic culture provides a method for expanding MSCs efficiently without losing stemness [60,63] or increasing tumorigenicity. Notably, the effects of hypoxic culture on the maintenance of self-renewal and differentiation potential and inhibition of senescence of expanded stem cells have also been observed in MSCs derived from amniotic fluid [64], adipose tissue [48], umbilical cord [65,66], and endothelial progenitor cells [67]. Of note, however, is the fact that multipotent MSCs have not shown any proclivity to form tumors, regardless of culture conditions and regardless of their tissue source. In this respect they behave quite differently to embryonic stem cells and to induced pluripotent stem cells, in which teratoma formation is one criterion that indicates multipotency or totipotency.

## 16.11 Differentiation of multipotent mesenchymal stromal cells under hypoxic conditions

It is well documented that hypoxic culture inhibits osteogenic and adipogenic differentiation of bone-marrow-derived MSCs [12,46,68]. The same effects have also been shown for adipose-tissue-derived MSCs [68]. Compared with normoxic cultures, hypoxic cultures with induction of MSCs to osteogenic differentiation show decreased expression of osteogenic genes, such as *RUNX2* and osteocalcin, and reduced alkaline phosphatase activity and mineralization capacity [12,13,46,68,69]. The mechanism is mediated through downregulation of the transcription factor RUNX2 by the activation of the HIF–TWIST pathway (Figure 16.1) [70].

In particular, hypoxia or activation of HIF-1α also improved *in vivo* osteoclastogenesis [71,72]. Similarly, MSCs induced in adipogenic medium under hypoxic conditions show decreased expression of adipogenic genes, such as *PPAR* and *LPL*, and a reduced ability to accumulate lipid droplets [12,46]. However, MSCs that were induced for chondrogenesis under hypoxic conditions show increased expression of chondrogenic genes, such as *SOX5*, *-6*, and *-9*, aggrecan, and type II collagen [73–77], decreased expression of genes associated with endochondral bone formation, such as *COL-1a1* and *COL-10a1*, as well as suppression of interleukin (IL)-1β-induced loss of extracellular matrix proteins [74]. One of the mechanisms by which hypoxia mediates enhanced chondrogenesis and inhibits endochondral ossification of MSCs is through the activation of PI3K/AKT/FOXO-dependent anti-apoptotic effect [78]. Similarly, hypoxic culture has also been applied for inducing MSCs to differentiate into nucleus pulposus-like cells both *in vitro* [79] and *in vivo* [65].

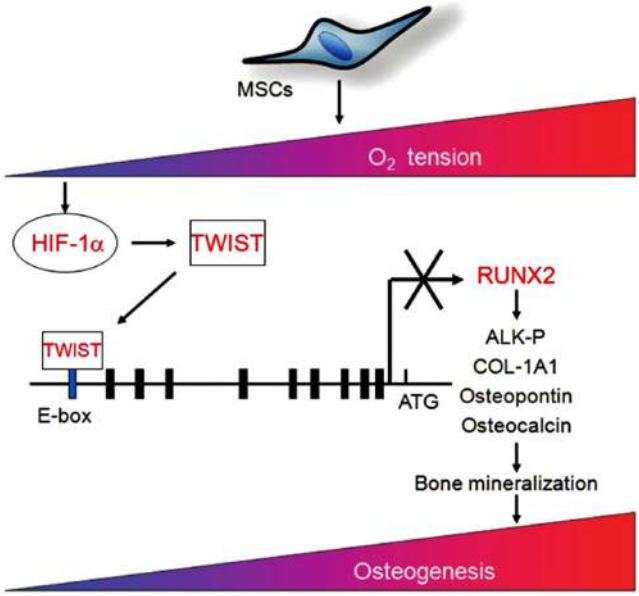

**Figure 16.1** A schematic representation showing the underlying mechanism that hypoxia mediates to downregulate RUNX2 expression and inhibit osteogenesis in bone marrow MSCs [70]. *Source:* adapted from *Am J Blood Res* 2012, **2**, pp. 148–159 [52].

Furthermore, hypoxic culture and agents that mimic hypoxia have been shown to increase the ectodermal differentiation of neuron-like cells [80] and the regenerative potential of the skin [81]. A prolyl hydroxylase inhibitor, FG-0041, in combination with an inhibitor of ROCK, Y-27632, showed initiation of differentiation of MSCs into neuron-like cells [82].

## 16.12 Effects of hypoxic culture on secretion of paracrine factors by multipotent mesenchymal stromal cells

It has been proposed that the properties of endogenous MSCs in the bone marrow of mice with recent myocardial infarction (MI) changed along with the exposure to hypoxia and inflammation. Wang *et al.* demonstrated that the therapeutic efficacy of bone marrow cells was impaired by a recent MI. MI led to inflammation of the myocardium and an increased inflammatory state in the bone marrow, thereby changing the composition of bone marrow cells and reducing its effectiveness. Injection of a general anti-inflammatory drug or a specific IL-1 inhibitor to mice after MI prevented this deterioration [83]. In contrast, *in vitro* hypoxic preconditioning enhanced the ability of MSCs to repair infarcted myocardium or diabetic cardiomyopathy. This is attributable to reduced apoptosis and cell death of the implanted cells, increased angiogenesis/vascularity, and enhanced paracrine effects [33–35]. It has been demonstrated that conditioned medium (CM) of MSCs from mice overexpressing the antiapoptotic proto-oncogene *AKT* markedly inhibited apoptosis induced by hypoxia and triggered vigorous spontaneous contraction of adult rat cardiomyocytes *in vitro* [84]. Similarly, MSC CM has also been observed to reduce apoptosis or enhance tube formation in human endothelial cells [31]. Moreover, the effects were more evident in the CM of MSCs cultured in hypoxic conditions compared with those of MSCs cultured in normoxic conditions. This is due in part to their higher content of antiapoptotic and angiogenic factors, including IL-6, VEGF [33,64,85], transforming growth factor-β1 [64], fibroblast growth factor 2, insulin-like growth factor 1, brain-derived growth factor, glial-cell-derived neurotrophic factor, and hepatocyte growth [86]. Analysis of gene expression profiles using microarrays also showed that MSCs cultured in hypoxic conditions increased expression of various growth factors involved in cell proliferation, apoptosis, and angiogenesis [87]. In addition, the CM of MSCs grown in hypoxic conditions activated the PI3K–AKT pathway in endothelial cells and thus inhibited hypoxia-induced apoptosis and increased angiogenesis of endothelial cells [32]. The *in vivo* cardioprotection effect of the CM of hypoxic MSCs was tested in a model of MI induced in Wistar male rats by permanent occlusion of the left coronary artery. Intramyocardial injection of 25× concentrated CM 3 h after coronary occlusion was able to promote a significant reduction (35%) in the left ventricular end-diastolic pressure and improve cardiac contractility (15%) and relaxation (12%) compared with unconditioned medium 19–21 days after the medium was injected [88]. These results suggest that soluble factors released by MSCs *in vitro* are able to promote cardioprotection and improve cardiac function *in vivo*. Additionally, CM of human hypoxic MSCs also enhanced wound healing in the skin [89] and small bowel lesions induced by radiation in mice [90] and promoted fracture healing in diabetic rats [91]. Together, these results suggest that administration of hypoxic MSCs or their secreted factors provides a therapeutic method for enhancing angiogenesis, epithelialization, wound healing, and fracture repair (Figure 16.2).

Furthermore, hypoxic MSCs, but not normoxic MSCs, restored conduction velocities, suppressed focal activity, and prevented sudden arrhythmic deaths when delivered to the border zone of infarcted myocardium in rats [92]. Hypoxic MSCs have also been demonstrated to ameliorate atherosclerotic lesions both *in vitro* and *in vivo* by secreting IL-8/MIP2 [93]. (MIP2, macrophage inflammatory protein, is the murine homolog of IL-8.)

In addition to the increase in the secretion of paracrine factors, hypoxic MSCs have also been shown to increase levels of total protein and different patterns of fibronectin expression throughout the culture period, suggesting that oxygen levels can significantly affect tissue development patterns [94]. The mechanism that hypoxic MSCs use to increase the release of angiogenic factors such as VEGF is partly through the HIF-1α pathway [95]. Moreover, the advantages of using CM instead of cells are twofold: (1) CM-based therapy avoids some of the problems

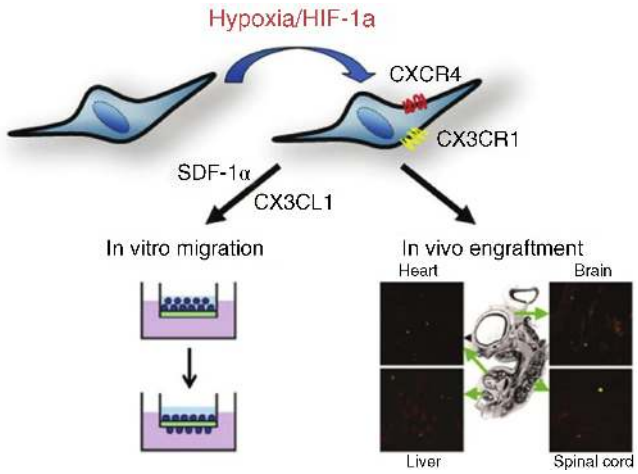

**Figure 16.2** A schematic representation summarizing the effects of hypoxic exposure on enhancing the expression of chemokine receptors and increasing *in vitro* migration and *in vivo* engraftment in bone marrow MSCs [21]. *Source:* adapted from *Am J Blood Res* 2012, **2**, pp. 148–159 [52].

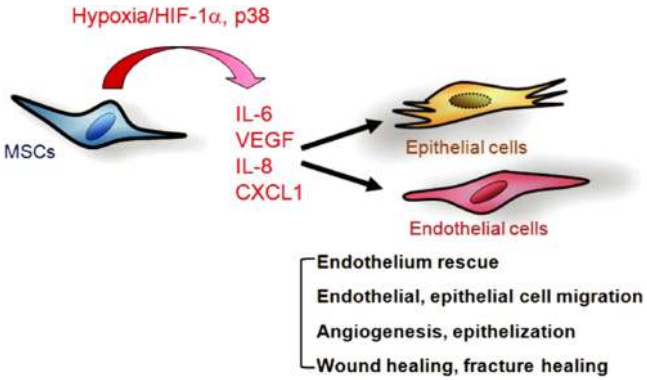

**Figure 16.3** A schematic representation summarizing the effects of hypoxic culture on enhancing secretion of paracrine factors and promoting therapeutic effects in bone marrow MSC [31,89,91]. *Source:* adapted from *Am J Blood Res* 2012, **2**, pp. 148–159 [52].

and limitations associated with viable and nonreplicating cells and does not compromise all of the advantages associated with the use of cells; (2) CM-based therapy is an ideal therapeutic approach because the complex load of proteins and genetic material has the diversity and biochemical potential to participate in multiple biochemical and cellular processes, an important attribute in the treatment of complex diseases [96].

## 16.13 Effects of hypoxic culture on engraftment of multipotent mesenchymal stromal cells

The capacity of MSCs for homing to, and engraftment in, target tissues after transplantation is the key to success in their clinical application. The degree of homing and engraftment of MSCs in adult recipients is very low [97–99]. Interestingly, it has been shown that short-term (more than 1 day) exposure of MSCs to hypoxia, such as 1% $O_2$ or hypoxic preconditioning of MSCs, increases *in vitro* migration, *in vivo* engraftment, and therapeutic effects in stroke or other ischemic tissues by an increase in CX3CR1–Fractalkine and CXCR4–SDF-1α interactions (Figure 16.3) [21,100], CXCR7 expression [101] or the upregulation of matrix metalloproteinase (MMP) 2, MMP-9 [100], $K^+$ channel, $K_v2.1$ [102] or Wnt4 [103], and FAK activation [102].

MSCs cultured under hypoxic conditions also increased the expression of VEGF and VEGFR1 or placental growth-factor-dependent migration [104]. Moreover, hypoxia-dependent MSC migration relies on a biphasic scenario involving an early phase, requiring generation of reactive oxygen species, and a delayed phase sustained by HIF-dependent expression of VEGF [105]. Hypoxia preconditioning when combined with glucose depletion also increased the survival of Sca-$1^+$ cells via PI3K/AKT-dependent connexin-43 upregulation and caspase-3 downregulation, and thereby increased the engraftment rate [106]. In addition to increased migration and survival, MSCs incubated in hypoxic conditions or in a hypoxic microenvironment such as cell aggregates have also been shown to enhance revascularization after transplantation for hind limb ischemia [107,108]. These results suggest that short-term hypoxic preconditioning of MSCs may provide a method of improving their survival, migration, angiogenesis, and engraftment *in vivo* into a variety of tissues.

## 16.14 Effects of hypoxic culture on allogeneic transplantation of multipotent mesenchymal stromal cells

The use of MSCs from healthy donors unrelated to, and major histocompatibility complex (MHC)-unmatched with, the MSC recipient as an "off-the-shelf" cellular product has been shown to be safe in multiple clinical trials (http://www.clinicaltrails.gov/). Additionally, it has been reported that such allogeneic MSCs improved the ejection fraction in patients after acute myocardial infarction [109]. The immunosuppressive properties of human, murine, and baboon MSCs have been demonstrated both *in vitro* [110–113] and *in vivo* [113], and human MSCs have been shown to ameliorate severe acute graft-versus-host disease in recipients of HSC transplants [114].

Two studies using murine MSCs and one using human MSCs, however, showed that allogeneic MSCs were rejected in MHC-mismatched recipients [115–117]; and see Chapter 29. Therefore, the use of MHC-unmatched MSCs for allogeneic transplantation to immune-competent recipients remains controversial, although the widespread use of autologous MSC production is not commercially feasible at the present time. The identification of methods to increase the immune privilege

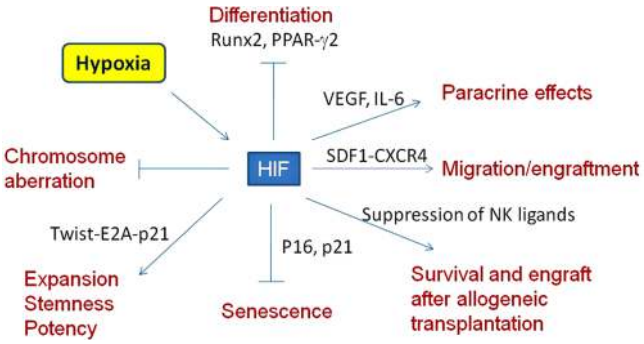

**Figure 16.4** A schematic representation summarizing the effects of hypoxic culture on proliferation, expansion, differentiation, engraftment, stem cell properties, and resistance for immune rejection by allogeneic recipients in bone marrow MSCs [20,21,31,60,70,89,91,117,118,119]. The mechanism that hypoxia mediates to suppress NK ligands is still unknown. *Source:* adapted from *Am J Blood Res* 2012, **2**, pp. 148–159 [52].

of MSCs so that they do indeed become a "true universal donor cell" is important. One study showed that allogeneic hypoxic MSCs increased the therapeutic effects in a bone-defect repair model compared with allogeneic normoxic MSCs [118]. The superiority of hypoxic MSCs to normoxic MSCs for allogeneic transplantation was also demonstrated when applied to animal models of tendon injury [119] and ischemic limb injury [120], as well as for xenograft transplantation in a swine model of chronic MI [121]. Hypoxic MSCs escape immune rejection by allogeneic recipients through suppression of NK ligand expression during hypoxic preconditioning [119]. These results suggest that hypoxic MSCs are intrinsically immunoprivileged and may be a more clinically effective "universal donor cell" than MSCs grown in normoxic conditions.

## 16.15 Conclusions

Currently available studies suggest that hypoxic cultures have multiple effects on MSCs, affecting short-term proliferation, long-term expansion efficiency, differentiation potential, stemness or maintenance of stem cell properties, the expression of chemokine receptors, migration, and engraftment ability. Moreover, MSCs are able to survive and engraft in allogeneic recipients. Notably, most of the effects are mediated through the HIF-1α-related pathways (Figure 16.4).

A manufacturing platform based on hypoxic cultures of MSCs help develop more effective strategies for their clinical application.

## 17.1 Introduction

Mesenchymal stem/stromal cells (MSCs) are a mechanosensitive, promising cell source for cell and tissue engineering therapies. The cells can be isolated from multiple tissues, including bone marrow, adipose tissue, gingiva, skin, uterus, oviduct, and from physiological waste such as urine and menstrual blood [1–6]. As a reservoir cell source residing within fully differentiated tissues, MSCs experience and respond to both chemical and mechanical stimuli in the *in situ* environment. MSCs are highly sensitive to mechanical stimuli in their undifferentiated state. We and others have shown that appropriate mechanical loads can regulate MSC differentiation response *in vitro* [7–13]. A variety of cellular structures and proteins have been implicated as mechanosensors and mechanotransducers in MSCs and will be discussed in subsequent sections of this chapter.

Day-to-day activities and normal physiological processes exert a variety of mechanical loading environments on the human body, with the musculoskeletal tissue bearing some of the highest loads. The crucial role of mechanical loading for healthy bone has long been recognized, particularly in the context of bone loss observed in patients requiring prolonged bed rest and in astronauts exposed to a microgravity environment. Generally, a certain level of mechanical loading is understood to maintain bone homeostasis, as evidenced by increased bone formation in response to regular load-bearing exercise. The cells of the cardiovascular system also undergo extensive mechanical loading. In the aortic blood vessels, smooth muscle and endothelial cells are exposed to cyclic stretch as a result of pulsatile blood flow.

Changes in the mechanical environment have also been found to contribute to the process of skin tissue regeneration during wound healing [14,15]. Multiaxial tension generated during the process of wound healing alters the wound morphology from a circular incision into an elliptical shape, elongated toward the

direction of greater tensile strain [16]. Tension produced during the wound healing process is also known to induce cell proliferation in skin tissue, with migration of keratinocytes and epidermal cells toward the wound void [17]. Successful generation of engineered tissues that can withstand physiological mechanical environments is critical to the success of tissue replacement therapies in the clinic.

Mechanical loading alone can shape cell and tissue phenotypes. It is therefore critical to understand and elucidate the specific loading modality and magnitude of the forces applied. Specific loading parameters can alter MSC response via alterations in gene expression, type of extracellular matrix (ECM) production, and differentiation into various lineages. Typically, application of mechanical stimulation to cells or tissues *in vitro* is based on attempts to mimic the *in vivo* mechanical environment.

Physical stimuli that affect musculoskeletal tissues include shear stress (often applied as fluid flow), tensile strain, compression, hydrostatic pressure, electrical stimulation, and substrate stiffness. In this chapter we specifically focus on tensile strain, a mechanical loading modality that is relevant to many tissues, including blood vessels, muscle, bone, tendon, and ligament. While tensile forces in the bone may not be as intuitive as in elastic tissues in tendon or muscle, our mechanobiology studies demonstrated that certain magnitudes of tensile strain significantly enhance formation of new bone [10,18–25]. In fully differentiated bone tissue, distraction osteogenesis is a surgical method by which bone is osteotomized and placed under tensile strain to encourage new bone tissue growth, resulting in expanded bone tissue. (An osteotomy is a surgical operation in which a bone is cut to shorten, lengthen, or change its alignment.) Both empirical and computational studies have identified optimal bone formation at tensile strains at a magnitude of approximately 10–12% [24,26]. These distraction osteogenesis analyses formed the basis for culturing human stem/stromal cells under tensile strain for many *in vitro* approaches to osteogenic differentiation. (Distraction osteogenesis is a surgical process used to reconstruct skeletal deformities and lengthen the long bones of the body. A corticotomy is used to fracture the bone into two segments and the two bone ends of the bone are gradually moved apart during the distraction phase, allowing new bone to form in the gap. When the desired or possible length is reached, a consolidation phase follows in which the bone is allowed to keep healing. Distraction osteogenesis has the benefit of simultaneously increasing bone length and the volume of surrounding soft tissues.)

Our group has worked with both adipose-derived and bone-marrow-derived MSCs in both two- (2D) and three-dimensional (3D) cultures. In all cases, application of 10% cyclic tensile strain increased osteogenesis of these cells compared with static culture [10,18–25].

Further, recent microarray studies from our group have shown that 10% cyclic tensile strain increases not only genes indicative of osteogenesis but also those for angiogenic factors. In this chapter the response of MSCs to cyclic tensile strain will be discussed in the context of both osteogenesis and angiogenesis.

## 17.2 Applications of tensile strain: an interpretation from physiological stimuli *in vivo* to bioreactors *in vitro*

As already described, tensile strain is a mechanical stimulus that occurs in multiple types of tissue, including muscle, tendon, ligament, cardiovascular tissues, and during bone formation in distraction osteogenesis. A multitude of bioreactors have been designed for *in vitro* application of tensile strain to tissues or cells. Dense elastic tissue (such as vascular tissue) can be excised and then exposed to tensile strain using an appropriate bioreactor to maintain or enhance its vascular phenotype through emulation of the native mechanical environment [27,28]. Select cells can be seeded onto elastomeric materials such as silicone membranes or embedded in materials such as collagen gels and/or electrospun polymers [29–33]. Biomaterials can be used to modulate the architecture and dimensionality of the culture environment for cells in 2D or 3D culture systems. The material architecture used for 2D culture systems can vary from fibrous to spongy, or even to a rubber structure. The 3D culture material properties can vary even more. However, there are many challenges associated with their use, such as cell-seeding, dispersion, and nutrient perfusion throughout the 3D construct. As a result, 3D culture is frequently performed with gel-like materials (e.g., collagen) in which cells can be thoroughly mixed with the gel in its liquid form. Once the gel polymerizes and solidifies the cells are fully embedded and distributed throughout the construct. Whether cells are seeded on 2D substrates or embedded within 3D materials, tensile strain can be applied in the form of uniaxial or equi-/biaxial strain, dependent upon the bioreactor design.

### 17.2.1 Uniaxial tensile strain

The cells in musculoskeletal tissues are predominantly exposed to uniaxial cyclic tensile strain as a result of normal daily physiological activities. A common bioreactor design for application of uniaxial tensile strain is often composed of a string-shaped elastomeric material as a substrate for cell-adherent (2D) or cell-ingrowth (3D) culture, placed within a chamber containing culture medium, and strained via an actuator (Figure 17.1).

Tissue-mimetic 3D constructs comprised of elastomeric materials can be pulled and retracted from one end, or both ends, during the application of cyclic tensile strain. Actuation can be generated from an actuator grip, a vacuum suction pump, or by bending approaches (e.g., three-point or four-point) [34–36]. (An actuator is a type of motor that is responsible for moving or controlling a mechanism or system; the three- and four-four point bending tests provide values for the modulus of elasticity in bending, flexural stress, flexural strain, and the flexural stress–strain response of the material.)

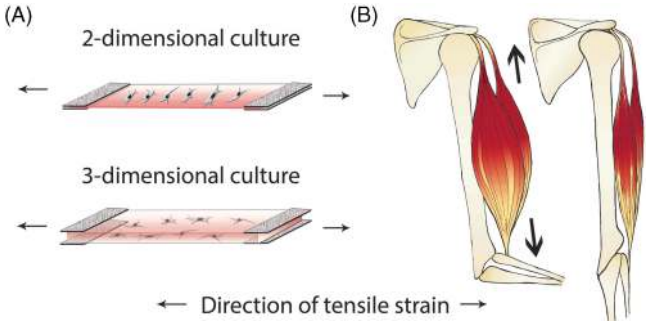

**Figure 17.1** Interpretation of uniaxial tensile strain from physiological forces in musculoskeletal tissue translated to an *in vitro* culture system. (A) Elastomeric material with cell-adherent (2D) and cell ingrowth (3D) systems for *in vitro* uniaxial tensile strain application. (B) Simplified idealized representation of *in vivo* uniaxial tensile strain in musculoskeletal tissue during arm flexure. Arrows show the direction of tensile strain. (See color plate section.)

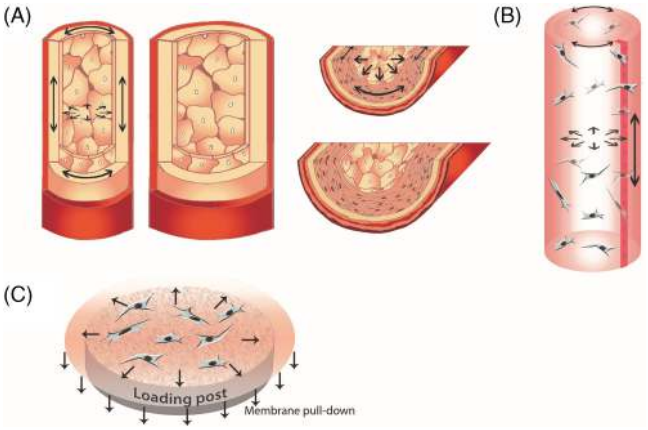

**Figure 17.2** Interpretation of equi-/biaxial tensile strain from physiological forces of an idealized blood vessel translated to an *in vitro* culture system. (A) Expansion of blood vessel and shear stresses from pulsatile blood flow. For a simplified, idealized analysis, smooth muscle cells and endothelial cells in the blood vessel are sometimes modeled as experiencing equi-/biaxial tensile forces during the expansion of blood vessel. (B) A simple 3D *in vitro* culture system to mimic physiological forces in blood vessels. (C) A simplified 2D *in vitro* culture system for the application of equi-/biaxial tensile strain. (See color plate section.)

Such models have been used to understand, apply, and elucidate tensile stimuli in the context of bone, muscle, and tendon tissue as comparable forces, stresses, and strains experienced by the cells *in vivo* (Figure 17.1B).

### 17.2.2 Equi-/biaxial tensile strain

While a uniaxial tensile strain approach simplifies multidirectional tensile stimuli to the cells, it also provides a straightforward mechanical model system to mimic the mechanical environments in skeletal muscle, bone, ligament, and tendon. Equi-/biaxial tensile strain is another loading modality and can be used to better represent mechanical environments during the process of wound healing, expansion and contraction of internal organs by smooth muscle, and in some cases changes in aortic blood vessel diameter during pulsatile blood flow (Figure 17.2A)

In the case of multiaxial tensile strain, an *in vitro* model system commonly used to mimic tensile strain in vascular tissue is a pulsatile flow stretch bioreactor. In such a system the elastomeric biomimetic tissue constructs are formed in a cylindrical shape and then expanded multiaxially by application of pulsatile flow of culture medium through the cylinder [37–39] (Figure 17.2B).

Another simplified system that is widely used employs the use of a soft elastic membrane on a flat surface that is stretched by a vacuum force. While this model does not exactly match the *in vivo* architecture and mechanical environment of a blood vessel (which is exposed to both fluid shear and hoop stresses/strains), it complies to some extent with the localized forces experienced by the cells (Figure 17.2C).

Localized cellular forces often differ from tissue-level forces and must also be considered in the creation and utilization of *in vitro* culture systems. It has been shown that application of 2D equi-/biaxial strain in some systems results in consistent equi-/biaxial strain only in the center area of the circular well, while the edges of the well are predominantly subjected just to uniaxial forces [40,41]. Not unexpectedly, differences in these patterns of localized force affect cell morphology. An investigation of human dermal fibroblasts by Xie *et al.* showed that the application of 7% equiaxial tensile strain at low frequency (1 cycle/min) for 2 days resulted in fibroblastic-shaped cells in the central area and round/polygonal cell shapes at the edge area [41]. In another study with porcine chondrocytes, application of 10% equiaxial tensile strain at 0.5 Hz for 24 h resulted in different cell morphologies: cells in the center area were polygonal in shape (remained a chondrocytic shape) while cells on the edge were spindle shaped and were aligned perpendicular to the radial direction. Similarly, in adipose tissue-derived MSCs (ADSCs) cultured two-dimensionally under 10% cyclic tensile strain on Bioflex (Flexcell, Inc.) plates, we observed reorientation of the cells perpendicular to the axis of uniaxial strain and independent of chemical induction media (i.e., regardless of whether ADSCs were cultured in expansion medium, osteogenic differentiation medium, or adipogenic differentiation medium). Additionally, the application of tensile strain altered the morphology of the ADSCs, causing them to become more elongated and tightly packed, particularly in osteogenically differentiated ADSCs (Figure 17.3).

These changes in cell morphology and alignment occur simultaneously with the alteration of cytoskeletal alignment within the cells. The orientation of microfilaments composed of actin–myosin inside skeletal muscle cells and smooth muscle cells are naturally occurring physiological examples of functional cytoskeletal alignment in response to tensile strain. These mechanical subunits are found to arrange parallel to the direction of tissue tension (Figure 17.4).

In the next section we discuss methods by which cells detect changes in their mechanical environment.

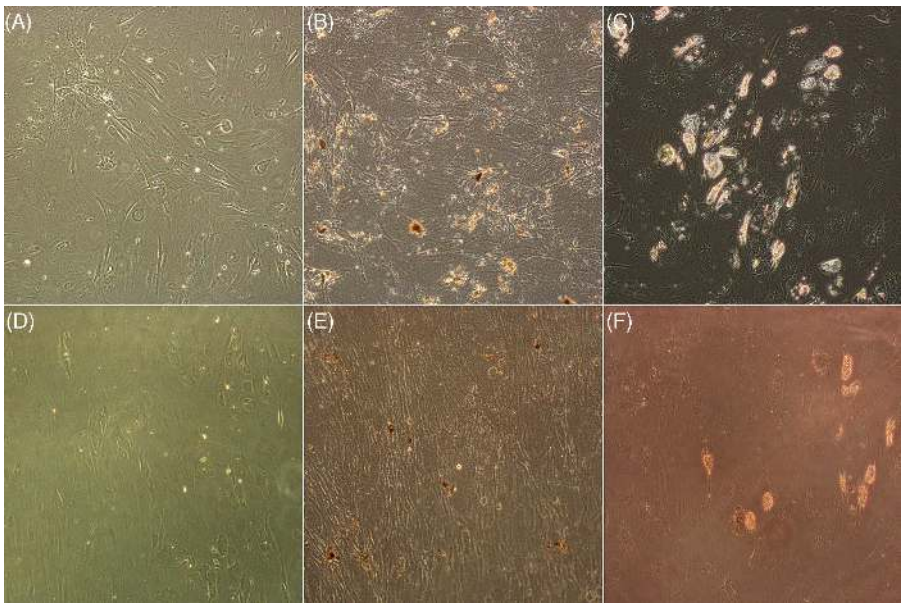

**Figure 17.3** ADSCs cultured for 14 days in expansion medium (a, d), osteogenic induction medium (b, e), or adipogenic induction medium (c, f) under static culture conditions (a–c) or under 10% cyclic tensile strain (d–f) for 4 h/day at a frequency of 1 Hz. The axis of uniaxial strain runs from left to right. (See color plate section.)

## 17.3 Mechanical sensing of mesenchymal stem/stromal cells

MSs express mechanosensitivity to a wide range of mechanical environments, most notably cyclic tensile strain, fluid shear, and substrate stiffness. Typically, integrin binding and cytoskeletal reorganization are thought to be the primary players in MSC mechanosensation, although in recent years the nucleoskeleton, the primary cilium, the glycocalyx and stretch-activated ion channels have been recognized as other important mediators of mechanosensation and mechanotransduction processes.

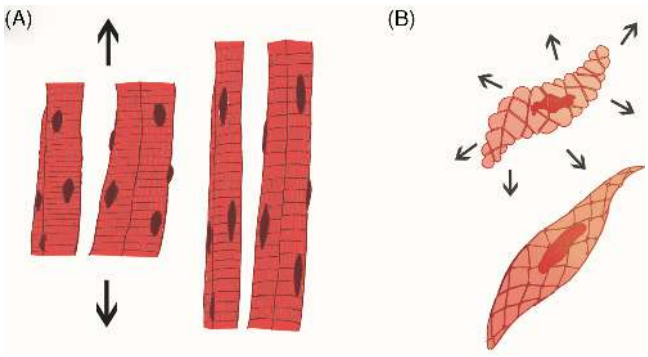

**Figure 17.4** Differences in cell morphology and cytoskeletal alignment between skeletal muscle and smooth muscle. (A) Skeletal muscle cells are elongated with a cylindrical morphology and with actin–myosin microfilament alignment parallel to the uniaxial direction of tissue tension and cell expansion/contraction. (B) Smooth muscle cells are spindle shaped and the actin–myosin microfilaments are aligned in a multidirectional network consistent with multiaxial cell expansion/contraction.

### 17.3.1 Integrins and the cytoskeleton

Integrin and cytoskeletal activity is one of the more thoroughly studied areas of cellular mechanosensation, and their activity is in part responsible for the MSC response to mechanical stimulation. Together, the integrins and cytoskeletal proteins form the foundation of the cellular tensegrity model. The theory of cellular tensegrity proposes a process through which cytoskeletal proteins integrate their function through a balance of global tension coupled with localized compressive forces within the cytoskeleton [42]. More specifically, the actin filaments provide the primary tensional component to the tensegrity model, while the microtubules provide a compression-resistant structural brace in the system. Lastly, intermediate filaments are hypothesized to stabilize the nucleus [42]. In addition to the cytoskeletal pieces of the tensegrity model, the cells must be anchored to the surrounding ECM in order to generate intracellular tension, which is where integrins come in. Integrins provide the protein anchors connecting the cells to the surrounding matrix. Since the initial introduction of the concept of cellular tensegrity, empirical and computational research has confirmed and expanded this model of cellular mechanics [43].

Integrins are heterodimeric transmembrane proteins that bind to specific active-site peptides (such as arginine, glycine, and aspartic acid sites) on the surrounding ECM environment [44]. They provide a platform by which MSCs can transmit and receive mechanical signals through contracting the ECM. The signals transmitted by the integrins are thought to be integrated by focal adhesion kinase (FAK), frequently in the form of focal adhesions comprised of actin bundles that anchor to the intracellular portion of integrin proteins via adaptor proteins such as vinculin [44]. The maturation of focal adhesions allows cells to generate traction forces that in turn allow cells to contract and pull on their surrounding matrix environment. FAK has

been implicated not only as a mechanosensory protein facilitating focal adhesion formation, but also as a regulator of mechanically directed lineage commitment in MSCs. FAK signaling controls cyclic tensile-strain-enhanced collagen-I-induced osteogenic differentiation of human mesenchymal stem/stromal cells [45].

Blocking specific integrins on MSCs has been shown to alter their ability to detect and respond to a given mode of mechanical stimulation or culture environment [46]. Substrate stiffness is one of the most prevalent and direct ways to modulate the mechanics of the culture environment, and this is frequently used to direct MSC differentiation [47]. A study of MSCs and osteogenic differentiation showed that MSCs upregulated FAK during substrate-enhanced osteogenic differentiation and that the $\alpha_2$-integrin in part mediated the enhanced osteogenic response of MSCs on rigid culture substrates [46]. Another study with MSCs cultured on laminin, collagen I, fibronectin, or adult rat cardiac ECM-coated polyacrylamide gels demonstrated that the integrin β1 subunit plays a specific role in substrate-mediated traction forces within the cell [48]. In general, this study reported an increase of MSC β1 integrin expression with increasing substrate rigidity and thus increasing intracellular traction force on all ECM coatings with the exception of adult rat cardiac ECM, which yielded MSCs with unchanged traction forces with increasing substrate stiffness. However, inhibition of β1 integrin binding restored MSC stiffness-mediated behavior with an increase in traction forces, suggesting that β1 integrin may have a specific signaling role in modulating the effect of substrate stiffness, specifically in the mature cardiac ECM [48].

In addition to integrin-mediated mechanosensing mechanisms, the cytoskeletal proteins play an important role in this process. In MSCs cultured in agarose gels, vimentin, an intermediate filament protein, was identified as a mechanosensitive protein in MSCs exposed to cyclic hydrostatic pressure in chondrogenic differentiation medium [49]. Furthermore, this study noted the importance of pericellular matrix formation and its mechanical properties, which in turn regulate MSC mechanosensation in a 3D gel environment.

Studies in MSCs that disrupt cytoskeletal reorganization in response to mechanical stimulation and/or disrupt focal adhesion formation provide strong evidence of this mechanosensation mechanism. This has been shown directly in MSCs by Müller *et al.* following treatment with drugs that depolymerize or stabilize actin filaments [50]. Using magnetic beads, a force was applied directly to MSCs via β1-integrin to MSCs with depolymerized or stabilized actin cytoskeletons. MSCs with disrupted cytoskeletal organization exhibited suppressed extracellular signal-regulated kinase (ERK) activation in response to mechanical stimulation compared with MSCs with intact cytoskeletal structures. Moreover, characteristic mechanically enhanced osteogenic differentiation was abrogated in MSCs with cytoskeletal inhibition, suggesting that cytoskeletal disruption also plays a role in the differentiation capabilities of MSCs [50]. Cytoskeletal organization plays a critical role in cell morphology, which is directly linked to the physiological function of a particular cell lineage. When the actin cytoskeleton is disrupted, MSCs change or lose their proclivity to commitment to specific cell phenotypes. Modulating cytoskeletal tension induced by the surrounding mechanical environment has also been shown to influence mechanically induced MSC lineage specification processes [51].

Interestingly, when exposed to cyclic tensile strain in 2D culture, MSCs typically undergo actin cytoskeletal reorganization and the cells align perpendicularly to the direction of strain to minimize stress and disruption of focal adhesions [52].

We have observed that, in 3D culture, MSCs present a differential response with their actin cytoskeleton aligning along the direction of strain, suggesting that uniaxial tensile strain applied to MSCs cultured three-dimensionally yields a different physiological effect to that of MSCs cultured two-dimensionally.

### 17.3.2 The nucleoskeleton and lamins

Nuclear lamins, also known as Class V intermediate filaments and not to be confused with the laminins of the ECM, are fibrous proteins providing structural function and transcriptional regulation in the cell nucleus. Nuclear lamins interact with membrane-associated proteins to form the nuclear lamina on the interior of the nuclear envelope. They are involved in the breakdown and reformation of the nuclear envelope during mitosis as well as the positioning of nuclear pores.

Recent studies on nuclear membrane proteins such as lamins have revealed a critical mechanosensing function of the nucleoskeleton. A study by Swift *et al.* showed that lamin A expression scales with stiffness in MSCs [53]. On a stiff substrate (40 kPa) their nuclei appeared flattened, spread and with a smooth surface, corresponding to increased lamin A expression. Conversely, MSCs cultured on a soft substrate (0.3 kPa) expressed wrinkled, rounded nuclei and decreased nuclear lamin A expression. Additionally, knockdown of lamin A expression lowered the effective nuclear stiffness and enhanced the effects of soft substrate-directed adipogenesis, whereas overexpression of lamin A enhanced substrate-directed osteogenesis on a stiff substrate. When lamin A is knocked down, MSCs have a limited capacity to generate cytoskeletal tension and reorganization, suggesting that the nuclear skeletal proteins are required for MSC mechanosensation. Further, another study from the same group reported that lamin-A and -C knockdown in MSCs conferred downregulation in expression of actomyosin genes, implicating an interplay between the nucleoskeleton and the cytoskeleton [54]. Recent reports on lamins and the nucleoskeleton are beginning to elucidate a new component of MSC mechanosensation as well as providing empirical support for the tensegrity model.

### 17.3.3 Primary cilia

In humans, primary cilia are found on nearly every cell in the body. In comparison with motile cilia, nonmotile (or primary)

cilia usually occur at a frequency of one per cell. Nearly all mammalian cells have a single nonmotile primary cilium. Recent findings regarding its physiological roles in chemical sensation, signal transduction, and control of cell growth have led to an acknowledgement of its importance in cell function. The primary cilium is now known to play an important role in the function of many human organs. The current scientific understanding of primary cilia views them as sensory cellular antennae that coordinate a large number of cellular signaling pathways, sometimes coupling the signaling to ciliary motility or alternatively to cell division and differentiation. A scanning electron microscopic image of primary cilia in the lungs is shown in Figure 17.5.

Primary cilia have also been identified as an additional mechanosensing structure in a variety of cell types, including MSCs [55]. In bone cells the primary cilium is thought to deflect under fluid shear and promote a prototypical osteogenic cell response to this mechanical stimulation. However, in the absence of a prominent primary cilium structure, osteogenic cells lose their sensitivity to fluid shear stimulation [56]. Additionally, in tenocytes, primary cilia modify their length in response to a cyclic tensile strain loading environment [57].

Primary cilia on MSCs exhibit a similar response to osteoblasts under oscillatory fluid flow, acting as mechanotransducers of fluid shear. More specifically, when primary cilia expression was disrupted through small interfering RNA (siRNA) knockdown of Polaris, a cilia-associated structural protein, MSCs exhibited a loss of their characteristic osteogenic gene upregulation in response to oscillatory fluid flow [55]. The MSC primary cilia not only mediated mechanically induced osteogenic differentiation but also regulated mechanically enhanced proliferation. Fluid shear increased the proliferation activity of MSCs, and this was more pronounced in MSCs devoid of Polaris siRNA [55].

In addition to cilia mechanosensitivity to active sources of mechanical stimulation, topographical architecture has also been shown to dictate primary cilia orientation and structure expression, suggesting that the cilium structure has some sort of intrinsic mechanosensitivity to the culture substrate [58]. MSCs cultured on grooved substrates exhibited cellular and ciliary alignment along the direction of the grooved surface. Further, the primary cilium structure was on average longer on MSCs on the grooved surface than that of MSCs cultured on a flat surface. Topography-directed changes in cilia expression were Rock/Rho dependent, suggesting that actin organization is involved in cilia expression and extension. Additionally, this study highlighted an important relationship between Wnt signaling and changes in cilia structure, which may have a mechanosensitive component.

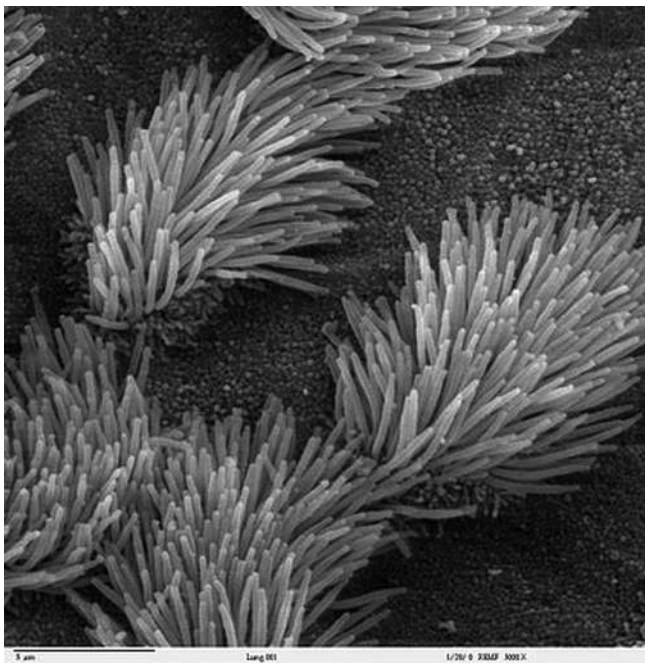

**Figure 17.5** Scanning electron microscope image of lung trachea epithelium showing primary cilia on tracheal epithelial cells. There are both ciliated and non-ciliated cells in this epithelium. Note the difference in size between the cilia and the microvilli (on the non-ciliated cell surface). *Source:* http://commons.wikimedia.org/wiki/File:Bronchiolar_epithelium_3_-_SEM.jpg#/media/File:Bronchiolar_epithelium_3_-_SEM.jpg.

### 17.3.4 Stretch-activated calcium channels

Stretch-activated ion channels are another mechanism by which MSCs can sense the surrounding environment. The physical application of strain to the membrane of a cell can open or activate particular ion channels, altering the flow of ions between the intracellular and extracellular spaces. MSCs seeded onto 3D scaffolds exposed to 10% cyclic tensile strain and cultured in chondrogenic culture medium displayed an increase in glycosaminoglycan (GAG) synthesis, characteristic of chondrogenic differentiation. This GAG synthesis was higher than GAG synthesis in MSCs cultured in chondrogenic medium under static culture. However, when stretch-activated ion channels were blocked with gadolinium chloride, GAG synthesis in strained MSCs was significantly reduced, suggesting that stretch-activated ion channels likely regulate mechanically induced chondrogenic differentiation of MSCs [59]. The reduction in GAG synthesis with blocked ion channels was significantly lower than that in untreated MSCs cultured under tensile strain. However, they were still higher than GAG levels on chondrogenically differentiated MSCs, thus suggesting that stretch-activated ion channels are not the only mechanosensors in this process.

### 17.3.5 The glycocalyx

The glycocalyx is a glycoprotein polysaccharide covering that surrounds the cell membranes of some bacteria, epithelia, and other cells. Most animal epithelial cells have a fuzz-like coat on the external surface of their plasma membranes. This coating consists of several carbohydrate moieties of membrane glycolipids and glycoproteins, which serve as backbone molecules for

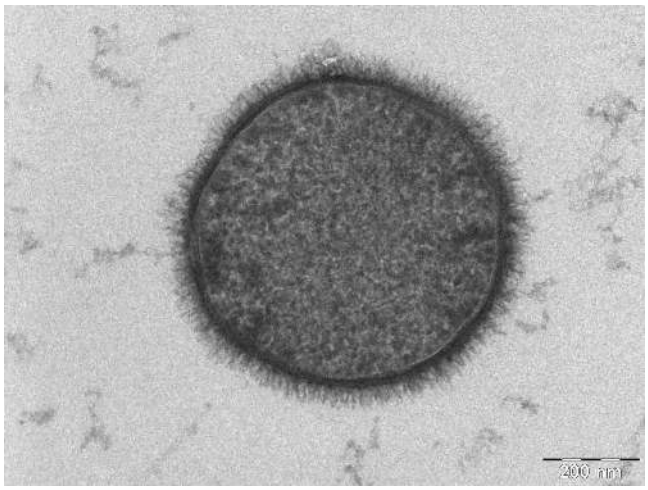

**Figure 17.6** Transmission electromicrograph of a *Bacillus subtilis* bacterium with the hair-like glycocalyx visible surrounding the cell membrane (scale bar: 200 nm). *Source:* http://commons.wikimedia.org/wiki/File:Bacillus_subtilis.jpg#/media/File:Bacillus_subtilis.jpg.

support. Generally, the carbohydrate portion of the glycolipids found on the surface of plasma membranes helps these molecules contribute to cell–cell recognition, communication, and intracellular adhesion. The glycocalyx is a type of identifier that the body uses to distinguish between its own healthy cells and transplanted tissues, diseased cells, or invading organisms. Included in the glycocalyx are cell-adhesion molecules that enable cells to adhere to each other and guide the movement of cells during embryonic development. The glycocalyx plays a major role in regulation of endothelial vascular tissue, including the modulation of red blood cell volume in capillaries (Figure 17.6).

The glycocalyx frequently forms on the apical cell membrane surface of many cell types in 2D culture, and some hypothesize that this structure is present in MSCs. Perturbations in the glycocalyx as a result of mechanical stimulation are generally thought to transduce mechanical signals to the cell, and this structure has been frequently implicated in endothelial cell mechanotransduction [60]. There is some evidence that a glycocalyx is present in MSCs derived from the umbilical cord, and the glycocalyx is potentially another mechanosensory structure of MSCs [61]. However, mechanisms downstream of the glycocalyx remain unclear.

## 17.4 The molecular response of mesenchymal stem/stromal cells to cyclic tensile strain

The fundamental responses of MSCs to changes in the mechanical environment often minimize cellular injury and/or promote physiological functions in the body. The MSC response to mechanical stimuli integrates with tissue function. However, the mechanisms underlying the MSC response are complex and somewhat elusive. For the purposes of this chapter the MSC response to mechanical loading will be divided into two major categories (Figure 17.7).

The first one encompasses MSC response with respect to changes within the cells themselves or via modification of their surrounding ECM. Such adaptations to the mechanical environment include reorganization of the cytoskeleton, changes in cell morphology, cell differentiation, rearrangement of the overall tissue structure by increases in cell number, and production of specific types of ECM and/or release of proteases to degrade or remodel the existing ECM.

The second category involves the MSC secretome and the autocrine and paracrine effects of MSCs on other cells or tissues. The active proteins and molecules secreted by MSCs induce responses from other tissues throughout the body, including cell proliferation, cell migration to the site, and vascular ingrowth.

In the context of bone, homeostasis requires dynamic tissue remodeling with continuous changes of bone structure via bone formation and bone resorption. This remodeling process is performed by osteoblasts and osteoclasts. While osteoblasts are bone-forming cells derived from the mesenchymal stem cell lineage, osteoclasts are derived from scavenger macrophages in the hematopoietic stem cell lineage. It has been shown that osteoblasts can be induced to produce the receptor activator of nuclear factor kappa B ligand (RANKL), a factor that stimulates the process of bone resorption by osteoclasts [62–64]. In *in vitro* co-culture experiments it was shown that tensile-strain-induced secretion of RANKL by osteoblasts further stimulated the

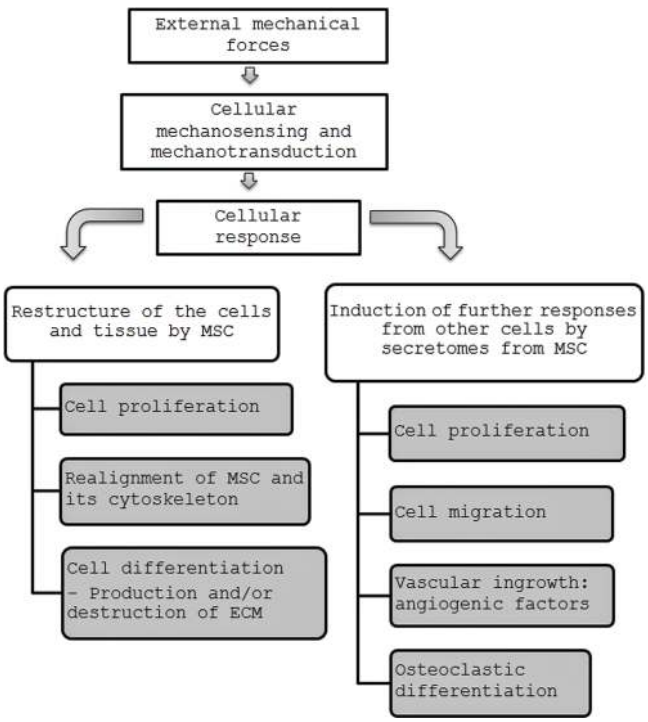

**Figure 17.7** Categorized responses of MSCs to cyclic tensile strain reviewed in this chapter.

production of tartrate-resistant acid phosphatase by murine macrophages [65].

The ability of MSCs to differentiate down an osteogenic pathway both *in vivo* and *in vitro* has been extensively reported [66–70]. *In vivo*, the mesenchymal *stem* cell niche is most commonly thought to reside in the bone marrow. However, the progeny of mesenchymal *stem* cells, known usually as mesenchymal *stromal* cells, can be found in all vascularized tissues, since mesenchymal stromal cells form part of blood vessel endothelium and are pericytes. Mesenchymal *stromal* cells have been isolated from bone, olfactory mucosa, endometrium, adipose tissue, dermal tissue, and many other tissues and can also differentiate down the osteogenic pathway [71–74]. Our previous work showed that uniaxial cyclic tensile strain at a magnitude of 10% induced osteogenesis of human bone-marrow-derived MSCs with calcium deposition, the expression of the bone marker genes bone morphogenetic protein-2 (BMP-2) and osteopontin, as well as the secretion of the inflammatory cytokines interleukin (IL)-6 and IL-8 [23,25,75,76]. Further, microarray analyses showed that signaling pathways regulated by 10% uniaxial cyclic tensile strain in human MSCs and human ADSCs were associated not only with osteogenesis but also with cell proliferation, migration, proinflammatory cytokines, and angiogenesis [19,20]. In the following section, further details of the cellular and molecular responses of MSCs to cyclic tensile strain will be discussed. Tensile-strain-induced cell proliferation, osteogenic differentiation to promote bone formation, and MSC signals that initiate vascular ingrowth or osteoclastogenesis for bone remodeling are evaluated while also considering MSCs as a candidate for therapeutic applications in bone regeneration and bone tissue engineering.

### 17.4.1 Restructuring of mesenchymal stem/stromal cells and the surrounding extracellular matrix by mesenchymal stem/stromal cells in response to cyclic tensile strain

As discussed previously, MSCs change their morphology and surrounding ECM in response to chemical and mechanical environments. In this section, the changes by MSCs in response to cyclic tensile strain will be specifically explored in the context of bone tissue regeneration, including increases in MSC proliferation, changes in cell fates with rearrangement of the cytoskeleton, changes in cell morphology, osteogenic lineage specification, and the secretion of new ECM or enzymes to remodel the existing ECM.

#### 17.4.1.1 Increases in cell proliferation by cyclic tensile strain

An important characteristic of MSCs as a cell reservoir in vascularized tissues is their proliferative ability, which is critical to their role in replacing worn-out or injured tissues. Mesenchymal *stromal* cells can be extensively expanded *in vitro* and maintain their characteristics during long-term cryopreservation, especially if handled by reducing the use of enzymatic digestion [76–78].

Multiple pathways have been shown to be involved in the self-renewal and proliferation of stem cells and their progeny. Most are cell cycle regulatory proteins/antiapoptotic proteins, transcription factors, microRNA regulators, and signal transducers [79–83]. A knockdown and overexpression study of the transcription factors OCT4 and NANOG demonstrated their role in maintaining self-renewal in MSCs [84]. The known regulatory signaling pathways in self-renewal and proliferation of MSCs include transforming growth factor beta (TGF-β), Wnt/BMP, intracellular PI3K-AKT, and MAPK signaling [85–96]. An androgen receptor knockout study of MSCs showed an increased self-renewal ability with the activation of ERK/Akt signaling through epidermal growth factor [94]. Enhanced cell survival and self-renewal of pluripotent stem cells by doxycycline was found to be mediated by direct activation of a PI3K–AKT intracellular signal [95].

Increases in cell proliferation induced by certain magnitudes and duration of cyclic tensile strain have been demonstrated in multiple systems [34,96,97]. A study of rat MSCs found that 4% and 8% equiaxial tensile strain significantly increased rat MSC proliferation [98]. Uniaxial tensile strains at different magnitudes at 0%, 5%, or 10% and different durations ranging from 1 h, 2 h, or 4 h also resulted in increased proliferation of human MSCs in response to uniaxial tensile strain, with maximum proliferation occurring with the application of 10% tensile strain for 4 h [99]. Microarray analysis on the effect of 10% cyclic tensile strain applied for 4 h/day for 14 days on human MSCs isolated from osteoporotic donors showed a higher total RNA yield and modulation of 32 genes involved in cell proliferation. These included upregulation of T-box 3, phosphoinositide-3-kinase, phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit delta (PIK3CD), insulin-like growth factor 1 receptor, plasminogen activator, urokinase-type plasminogen activator receptor (PLAUR), vascular endothelial growth factor (VEGF) A, PDZ and LIM domain 4 (PDLIM4), and melanoma cell adhesion molecule. There was downregulation of six genes, including paired related homeobox 1, frizzled class receptor 8, and latent transforming growth factor beta binding protein 2 [19].

#### 17.4.1.2 Restructuring of mesenchymal stem/stromal cells by cyclic tensile strain

During the process of cell differentiation and maturation, progenitor cells go through major changes in cell structure with rearrangement of the cytoskeleton and restructuring of cell shape. Cytoskeletal tension has been shown to determine the lineage commitment of human MSCs. Active expression of RhoA allows cells to generate tension, which is required for osteogenesis by differentiated MSCs, while inhibition of RhoA function has been found to decrease myosin-generated cytoskeletal tension, resulting in adipogenesis of MSCs [100]. When cells are exposed to tensile strain, they adapt to this mechanical stimulus with changes in cytoskeletal arrangement and cell shape. Short-term

2D studies of application of tensile strain on endothelial cells showed increases in stress fibers as assessed by parallel arrays of actin filaments with reorientation perpendicular to the direction of strain [101]. Exposure of MSCs to 15% strain for 2 h induced F-actin reorganization perpendicular to the axis of mechanical strain [99]. However, opposite results were found when MSCs were cultured in a 3D scaffold, in which MSCs aligned parallel to the direction of tensile strain [102,103]. These opposite cell-alignment behaviors in 2D and 3D culture systems are likely a result of substrate realignment having a greater influence than the application of uniaxial tensile strain, since cells in 3D culture are highly influenced by contact guidance by the ECM fibers, as is also found in native ligament and muscle tissues [104–107]. Our studies on MSCs cultured in 3D collagen gels also showed that application of uniaxial cyclic tensile strain influenced cells to reorientate parallel to the direction of tensile strain [75,108].

#### 17.4.1.3 Induced osteogenic differentiation of mesenchymal stem/stromal cells in response to cyclic tensile strain: cellular signaling responses and extracellular matrix production/remodeling

Specific magnitudes of tensile strain have been established as mechanical stimuli that can induce osteogenesis from *in vivo* analyses during the process of new tissue formation in distraction osteogenesis to the *in vitro* application of cyclic tensile strain directly to the cells [24,26,109–111]. Many bone markers have been detected as osteogenesis was promoted and increased in response to cyclic tensile strain applied to MSCs, including RUNX2, also known as core-binding factor alpha 1, alkaline phosphatase, collagen type I, osteocalcin, and BMP-2 [25,109]. Cyclic tensile strain alone, however, has not been reported as a factor that induces MSCs to attain the final stage of osteogenic differentiation and deposit calcium phosphate without additional chemical induction *in vitro*. A combination of mechanical loading with chemically induced osteogenic media, however, significantly increased calcium deposition by MSCs both in 2D and 3D cultures relative to unloaded MSCs maintained in osteogenic induction medium alone [20,76,112].

As many genes are used as bone marker genes when determining the effects of cyclic tensile strain on MSCs, it has been assumed that increased osteogenesis by MSCs through mechanical loading includes those genes involved in the signaling pathways that induce osteogenesis by chemical stimuli. Three major signaling pathways that have been identified as associated with osteogenesis of human MSCs by chemical induction and by 10% cyclic tensile strain are Wnt, BMP, and phosphatidylinositide 3-kinases (PIK signaling) [19,20]. Increased production of ECM proteins by MSCs in response to cyclic tensile strain includes collagen I, elastin, and tenascin C [36,113–115].

Using microarray analyses we have also identified other genes that may play a role in enhanced osteogenesis of MSCs in response to cyclic tensile strain, including jun D proto-oncogene, PLAUR, PIK3CD, wingless-type mouse mammary tumor virus integration site family member 5B, and PDLIM4 [19,20]. Further studies are required to fully understand the mechanistic role of these genes.

### 17.4.2 Mesenchymal stem/stromal cell secretomes that induce further responses from other cells

MSCs have shown their ability to generate various secretomes in response to changes in the mechanical environment or during a chemically induced differentiation process [116–118]. Proteomic analysis of secretomes from MSCs isolated from adipose tissue showed 51 proteins that were differentially expressed during the course of a 4-week osteogenic differentiation protocol [119]. Work by Ando *et al.* reported that the secretomes released by cultured human MSCs into the culture medium accelerated the process of distraction osteogenesis in an *in vivo* mouse model [120]. Secretions of MSCs into the culture medium have also been hypothesized as a potential intravesical therapy for interstitial cystitis since it contains antiapoptotic, anti-inflammatory, angiogenic, and immunosuppressive properties [121]. Lovoie and Rosu-Myles have categorized MSC secretomes by their functional roles in immune and inflammatory modulation and paracrine effects on tissue repair [122].

The process of bone healing has been known to involve multiple angiogenic factors, resulting in the formation of new blood vessels in the fracture callus. Angiogenic factors found at the fracture site during regeneration of bone tissue include VEGF, placental growth factor, fibroblast growth factor (FGF), and matrix metalloproteinases (MMPs) [123]. Interestingly, implantation of MSCs or application of factors released by MSCs to bone defect sites resulted in recruitment of macrophages and endothelial cells to the injured sites and enhanced the process of recovery [124,125]. Similarly, an investigation of skin wound healing using the scratch assay showed that the secretomes produced by *in vitro* culture of human MSCs accelerated the wound healing process by accelerating cell migration to, but not cell proliferation at, the wound site [126]. Chemokines and cytokines released from human MSCs include TGF-β1, IL-6, IL-8, chemokine (C–C motif) ligand 2, chemokine (C–C motif) ligand 5, collagen type I, fibronectin, osteonectin (also known as secreted protein, acidic, cysteine-rich), and insulin-like growth factor binding protein [126] (and see Chapters 18, 19, 22, and 23). Further, a study of menstrual-blood-derived MSCs that were co-cultured with monocytes showed that MSCs suppressed maturation of monocyte-derived dendritic cells through secretion of IL-6 and IL-10 [127].

As described earlier, in a co-culture study of osteoblasts and macrophages exposed to tensile strain, it was shown that osteoclastic differentiation of macrophages occurred [65]. In an *in vitro* study of MSCs we showed that the expression of the proinflammatory cytokines IL-6 and IL-8 increased in response to 10% and 12% uniaxial cyclic tensile strain [75]. We then performed a microarray analysis of human ADSCs exposed to 10% cyclic tensile strain for 4 h/day for 14 days and found upregulation of the proinflammatory cytokine regulators IL-1

receptor antagonist, suppressor of cytokine signaling (SOSC) 3, and the angiogenic factors FGF-2, MMP-2, and VEGFA. SOCS3 is a protein that in humans is encoded by the *SOCS3* gene. This gene encodes a member of the signal transducer and activator of transcription (STAT)-induced STAT inhibitor (SSI) (also known as SOCS) family. SSI family members are cytokine-inducible negative regulators of cytokine signaling.

## 17.5 Summary

In summary, MSCs hold considerable potential for use in regenerative medicine applications as indicated by their ability to respond to both chemical and mechanical induction. The MSC response to cyclic tensile strain is of particular interest as this mechanical stimulus appears to induce an MSC response that results in maintenance of physiological function in musculoskeletal and cardiovascular tissue. When appropriate mechanical loading is applied, such as the specific cyclic tensile strains discussed in this chapter, various mechanotransduction mechanisms lead to an MSC response that includes adaptation of the MSCs themselves and adaptations to both the ECM and other types of cells. MSCs proliferate, differentiate, and secrete signaling molecules that further induce migration of other cells for vascular ingrowth and macrophage differentiation to the osteoclastic lineage. While many studies have reported some similarities in increased MSC osteogenesis by chemical and mechanical induction, many genes that have been found to respond during increased osteogenesis of MSCs by cyclic tensile strain are unique and should be explored further.

## Acknowledgments

We thank T. Diteepeng and K. Thanomwong, students from The Biological Illustration Class at Silpakorn University, for the art work in the figures. The studies in this chapter were supported in part by the Intramural Research Program of the NIH, National Institute of Environmental Health Sciences, by the National Center for Research Resources grant 10KR51023 (EGL), NIH/NIBIB grant R03EB008790-01A2 (EGL), and by NSF/CBET grant 1133427 (EGL).

## 18.1 Mesenchymal stromal cells

Mesenchymal stromal cells (MSCs), derived from mesenchymal stem cells, have been suggested as possible therapeutic tools for regenerative medicine [1–3]. Indeed, when compared with other sources, they do not have the ethical and moral questions raised by embryonic stem cells or the technical issues regarding the isolation and further *in vitro* expansion of, for instance, other sources, such as neural stem cells [2,4]. This great potential has been associated with their widespread availability throughout the human body, along with the fact that, when isolated, they display great proliferative potential with minimal senescence through multiple passages [5,6]. In 2006, the International Society for Cell Therapy introduced the minimal criteria for the identification of MSCs, defining them as a plastic-adherent multipotent population, with the ability to differentiate *in vitro* down the osteogenic, chondrogenic, and adipogenic lineages, displaying CD105, CD90, and CD73 surface markers, while being negative for typical hematopoietic markers such as CD45 and CD34 [7]. Following the pioneering work of Friedenstein *et al.* [8], several reports have confirmed that MSCs are not only present within the bone marrow, but also in other sources in the body, including adipose tissue [9,10], dental pulp [11,12], placenta [13,14], umbilical cord blood [15] and Wharton's jelly [16,17], and brain [18]. Wharton's jelly is a gelatinous substance within the umbilical cord largely composed of the mucopolysaccharides hyaluronic acid, and chondroitin sulfate. It also contains some fibroblasts and macrophages. Thomas Wharton was an English physician and anatomist (1614–1673) who first described it in his publication *Adenographia*, or "The Description of the Glands of the Entire Body," first published in 1656.

Thus, there has been an increasing interest in MSCs as candidates for new therapeutic strategies [19–22]. In fact, over the last decade, there has been a substantial effort to assess the impact of MSCs into different types of disease [23–28]. Studies have demonstrated that these cells are able to induce a significant recovery in some diseases, such as graft-versus-host-disease (GVHD) following allogeneic hematopoietic stem cell transplantation (HSCT) [27], acute lung injury [26], peripheral nerve injury [29] and neurodegenerative disorders such as stroke [30,31], demyelination [32,33], Parkinson's disease [34,35] and spinal cord injury (SCI) [36,37]. Despite these observations, the main mechanisms mediating these effects of MSCs are still a matter of intense debate [38]. Parkinson's disease is named after the English doctor James Parkinson, who published the first

detailed description of the disease in *An Essay on the Shaking Palsy* in 1817.

Initially it was believed that the therapeutic potential of these cells relied on their multilineage differentiation ability [39]. Indeed, most of the literature of the 1990s and early 21st century focused on the differentiation of these cells down mesodermal lineages, often within three-dimensional (3D) matrices as scaffolds. Around the same time it was also suggested that MSCs had an even greater differentiation potential than was originally predicted, as several reports indicated that these cells could be differentiated beyond the mesodermal lineages [7]. However, the real nature of the differentiated cells in the observed regenerative processes was never fully revealed [40,41]. In 2005, Gnechhi *et al.* [42] put forward a new concept that would change the paradigm of how MSCs could be used in regenerative medicine, by showing that their therapeutic potential was mostly related to the growth factors that they secreted into the extracellular milieu, rather than to their differentiation potential [42]. Since then different reports have revealed the role of the MSC secretome in controlling key processes such as cell proliferation, survival, differentiation, and extracellular matrix deposition, among others [38,43–46]. Recently, it has even been proposed that the secretome alone, with no need for cell transplantation, could be used for therapeutic purposes [47]. In fact, Teixeira *et al.* [47] have recently shown that animals injected with the secretome of MSCs isolated from the Wharton's jelly component of the umbilical cord perivascular cells into the hippocampal dentate girus displayed similar levels of proliferation, neuronal/glial survival, and differentiation, when compared with those transplanted with MSCs.

With this in mind, we will discuss in this chapter the current understanding of the MSC secretome and its possible applications to regenerative medicine. We will focus particularly on the secretome composition and characterization, as well as its application in GVHD and disorders of the nervous system (Figure 18.1).

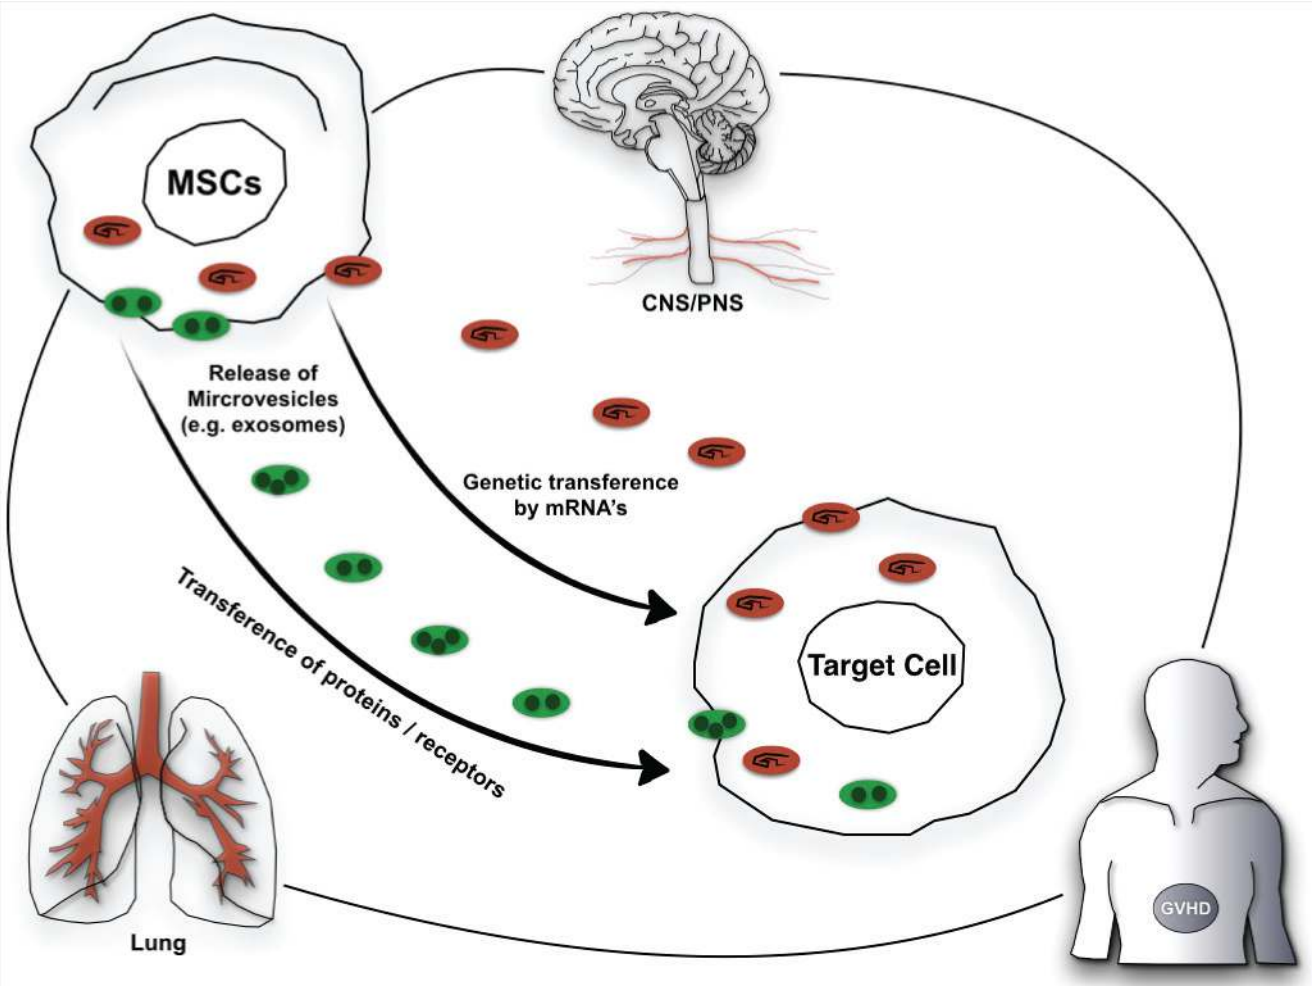

**Figure 18.1** The interactions between MSCs and their target tissues.

## 18.2 The mesenchymal stromal cell secretome

### 18.2.1 Concept

Over the last several years it has become evident that some therapeutic effects mediated by MSCs are mainly associated with the secretion of bioactive molecules and vesicles, which constitute their secretome [48]. The definition of secretome has not yet been completely defined; however, one definition is that it comprises the proteins or vesicles (microvesicles or exosomes) that are released by a cell, tissue, or organism that are subsequently crucial for the regulation of different cell processes. In this sense, studies have suggested that, in response to injury, MSCs have the capacity to migrate to the site of damage, leading to the promotion of regenerative processes through the secretion of trophic molecules such as growth factors, cytokines, and antioxidants [49,50]. Indeed, despite the capacity of cell–cell interaction of MSCs with their surrounding microenvironment, their secretome seems to be the main effector of their immunomodulatory and regenerative capacity at the site of the lesion [51,52]. As a consequence of this, Caplan and Dennis [53] have designated MSCs as trophic mediators of regenerative processes. In addition to this, it has also been demonstrated that MSCs from different sources can secrete important trophic molecules such as brain-derived neurotrophic factor (BDNF), β-nerve growth factor (β-NGF), insulin-like growth factor-1 (IGF-1), hepatocyte growth factor (HGF), vascular endothelial growth factor (VEGF), transforming growth factor-β, glial cell line-derived neurotrophic factor (GDNF), fibroblast growth factor-2 (FGF-2), stem cell factor (SCF), granulocyte colony-stimulating factor, and stroma-derived factor-1 (SDF-1) (also known as CXCL12) both *in vitro* and *in vivo* in different disease contexts [3,48,49,53–55]. In fact, the latter have been considered important mediators of MSC action in a variety of cell processes, including immunomodulatory capacity, inhibition of apoptosis, promotion of angiogenesis, and stimulation of adjacent cells [53]. In addition to these soluble paracrine factors, recent findings have shown that an important component of their secretome is constituted in vesicular bodies, known as microvesicles or exosomes [56,57]. Indeed, robust data from the literature indicate that MSCs are able to secrete large amounts of these vesicles either constitutively or after signal activation [56]. These vesicles secreted by MSCs have been considered as a vehicle of paracrine or endocrine signaling, able to transport defined signaling molecules to distant target cells or tissues [58–60].

The biochemical composition and the complex biogenesis of these vesicles, as well as their physiological roles, have not been fully elucidated [57,61]. Their potential as mediators of cell-to-cell communication has been demonstrated. They have demonstrated features such as the ability to transfer proteins and functional genetic material such as microRNAs to other cells [62,63]. The release of exosomes has received much attention. The secretion of these nanovesicles was first described by Harding *et al.* during the maturation of sheep reticulocytes, who considered them necessary to remove unneeded proteins from the cells [64]. Typically, exosomes are formed by inward budding of late endosomes, having a diameter of 40–10 nm, with a density of 1.13–1.19 g/mL in a sucrose solution [65]. A unique function associated with exosomes is their capacity to interact with targeted cells, which putatively enable cell-to-cell communications in physiological processes such as antigen presentation, genetic exchange, immune responses, and angiogenesis [65]. MSCs have recently been considered an efficient mass producer of exosomes [66]. Indeed, it has been suggested that MSCs can produce higher amounts of exosomes than other types of cell or cell lines, including myoblasts, the human acute monocytic leukemia cell line THP-1, and the human embryonic kidney cell line [66]. Characteristically, MSC-derived exosomes express their common cell surface markers such as CD9, CD63, and CD81 as well as adhesion molecules such as CD29, CD44, and CD73, which are also expressed on the cell surface membrane of MSCs [65].

The amount of these vesicles in the secretome of MSCs seems to be highly variable from batch to batch. Lai *et al.* [63] demonstrated by liquid chromatography–tandem mass spectrometry that MSC-derived exosomes obtained from three different MSC batches contained different proteins, with only a few common to each batches. The inclusion of all these proteins suggests that MSC-derived exosomes have the potential to drive a number of different cellular processes [65,67–70].

MSC-derived exosomes have demonstrated promising results in a wide range of diseases [26,27,67,71–77]. Thus, despite knowledge gaps regarding the exosomal/vesicular fraction of the MSC secretome, studies have already demonstrated that MSC-derived exosomes, when compared with whole cells, are more stable and present a lower risk of aneuploidy and immune rejection after *in vivo* allogenic administration, thus themselves representing a potential therapeutic tool for the treatment of a number of different diseases [65].

### 18.2.2 Characterization techniques

Although important progress has been made on the characterization of the MSC secretome in the last 10 years, only the "tip of the iceberg" has been uncovered. It is therefore important to further characterize it, using state-of-the-art techniques to provide a broad overview of its composition. By doing this, it may possible to understand fully the mechanisms by which the MSC secretome mediates its effects.

Proteomic-based techniques have been the most widely used methodology for this purpose [78,79]. Proteomics has been defined as a discipline focused on the large-scale analysis of proteins and their physiological functions [79]. Typically, such analysis is performed on the conditioned medium (CM) of cultured MSCs. To date, different proteomic techniques such as protein separation techniques (two-dimensional gel electrophoresis (2-DE) or liquid chromatography), mass spectrometry (MS), and antibody-based methods (enzyme-linked immunosorbent assay (ELISA) or multiplex assay) have been used to

obtain a broad characterization of the MSC secretome. Two-dimensional gel electrophoresis or liquid chromatography is necessary for proteome analysis of most mammalian cell secretomes (including that of MSCs) since mammalian cell secretomes comprise a large number of different proteins with broad dynamic ranges [80].

#### 18.2.2.1 Two-dimensional gel electrophoresis, sodium dodecyl sulfate polyacrylamide gel electrophoresis, and mass spectrometry

Using 2-DE, the proteins in the MSC secretome are separated according to their isoelectric points, followed by use of sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), which allows separation of different proteins based on their molecular weight [81,82]. In addition to this first step, the use of Coomassie blue, silver nitrate, or fluorescent dyes are subsequently used to identify protein spots in the gels [79]. After this, spots of interest are removed, alkylated, and enzymatically digested into peptides for subsequent protein identification by MS [83]. This methodology is considered the most powerful methodology in the separation of translational modifications and isoforms of specific proteins [84]. An example of this is the recent report by Fraga *et al.* [46], in which 2-DE and MS were used to characterize the secretome of MSCs isolated from the Wharton's jelly of the umbilical cord. Its limitations are mainly related to the solubilization and analysis of highly hydrophobic proteins or proteins with high molecular weights.

#### 18.2.2.2 Liquid chromatography

Proteins or peptides can also be isolated by liquid chromatography [79]. This technique may overcome some of the limitations of 2-DE [85,86]. Liquid chromatography is the most common technique used in the analysis of the MSC secretome, by chromatographically separating proteins digested into peptides [85]. Reversed-phase liquid chromatography (RPLC) is often used, providing a reliable peptide separation of CM samples [87,88]. To increase the accuracy of the separation of the peptides, a combination of two RPLC runs using different pH values during the mobile phases is performed [85,87,88]. The final product of this process is the achievement of a dissected panel of peptides, which can be directly analyzed in a mass spectrometer allowing the identification of proteins within the CM samples [86].

#### 18.2.2.3 Mass spectrometry

MS is a powerful technique for the identification of proteins in serum-free CM samples through the exact determination of molecular mass of the peptides [89,90]. Protein identity is assigned using a protein database, comparing the CM samples being analyzed with the mass data obtained [91,92]. There have been recent improvements in MS, including stable isotope labeling by amino acids in cell culture, isotope-coded affinity tagging, isobaric tagging for relative and absolute quantitation, selected reaction monitoring, and spectral counting or ion intensity measurement, allowing the relative quantification of proteins in the CM samples [90,93–97]. The performance of these different techniques allows a direct comparison of proteins among samples (e.g., CM from different MSC sources), thus providing more reliable and comprehensive information about protein expression of MSCs [79].

#### 18.2.2.4 Enzyme-linked immunosorbent assay

Finally, in addition to all the techniques described so far, the use of immunological assays such as ELISA and multiplex assays have also been described as promising tools in the proteomic field [79]. The advantages of these techniques is based on the use of specific antibodies, allowing higher sensitivity levels in the detection of antigens, and thus enabling the identification of proteins present in low concentrations, such as cytokines [79].

ELISA (or Western blot) can easily be used for the detection of a single analyte (i.e., in this case a protein of interest), and can provide accurate quantification of proteins when compared with calibration standards.

#### 18.2.2.5 Multiplex assay

A multiplex assay is a type of assay that simultaneously measures multiple analytes (dozens or more) in a single run/cycle of the assay. It is distinguished from procedures that measure one analyte at a time. Multiplex assays within a given application area or class of technology can be further stratified based on how many analytes can be measured per assay, where "multiplex" refers to those with the highest number of analyte measurements per assay (up to millions), and "low-plex" or "mid-plex" refers to procedures that process fewer (tens to thousands), though there are no formal guidelines for calling a procedure multi-, mid-, or low-plex based on number of analytes measured. The use of multiplex techniques in proteomics has been developed and the technique is a powerful tool capable of detecting and quantifying a wide panel of analytes across multiple and different samples [79,98]. This is based on the comparison of the fluorescence intensity of the samples with that of the calibration standards, allowing a broad and reliable dynamic range of detection [79].

## 18.3 The mesenchymal stromal cell secretome in transplantation and regenerative medicine

### 18.3.1 Graft-versus-host-disease

Allogeneic HSCT is most commonly used to treat hematological malignancy for which no other potentially curative procedure is available. GVHD remains a major cause of morbidity and mortality in allogeneic HSCT recipients, even when the donor and recipient have a high level of human leukocyte antigen compatibility. It commonly affects the skin, gastrointestinal tract and liver, and the acute form of the disease, by definition, presents within 100 days of the transplant. The pathophysiology of acute GVHD is characterized by three well-established stages. The first stage, commonly known as "the cytokine storm," is a

result of the high-dose chemotherapy or chemoradiation conditioning regimen given to the recipient before the transplant in order to eradicate the underlying disease, as well as eradication of the recipient's immune system, so that the recipient will not reject the donor transplant. The second stage involves cellular activation and is characterized by activation of donor T cells by recipient cytokines and antigen-presenting cells not completely eradicated by the pretransplant conditioning regimen. In the third stage, known as the "effector" stage, T cells start to damage the recipient's tissues [99,100]. As the etiology of GVHD involves an allogeneic cytotoxic reaction by donor T lymphocytes, the cornerstone treatment is immunosuppression, with the purpose of inducing donor/recipient tolerance without eliminating the therapeutically valuable graft-versus-malignancy effect [101]. Prophylactic immune suppression is routinely used to minimize the severity of GVHD and usually involves the use of methotrexate and a calcineurin inhibitor such as cyclosporine or tacrolimus. If GVHD develops in spite of prophylactic immune suppression, corticosteroids are the first-line therapy of choice [102]. A recent study confirmed that early response to corticosteroids is associated with increased survival [100]. However, only 60–70% of patients with GVHD respond to standard corticosteroid therapy. Moreover, patients with severe or steroid-refractory GVHD have few therapeutic alternatives, no established treatment protocol, and a 2-year survival as low as 10% [103].

It is in this context that MSCs have been used as treatment for corticosteroid-refractory GVHD. The rationale behind this is the known immunomodulatory repertoire of their secretome. For instance, Ringden and co-workers [104,105] reported that approximately half of patients with life-threatening acute GVHD, who were not responding to conventional immunosuppressive therapy, responded to treatment with MSCs. Additionally, it was also observed that family member MSCs or MSCs from unrelated donors were equally effective, and that children tended to have a better response than adults [104]. Furthermore, tissue toxicity, such as hemorrhagic cystitis, pneumomediastinum, and colon perforation with peritonitis, could also be reversed by their administration [104]. Similarly, Le Blanc and colleagues reported that the administration of haploidentical MSC infusions in a 9-year-old boy with severe (grade IV) acute GVHD of the gastrointestinal tract and liver also resulted in a successful outcome [106]. Kurtzberg *et al.* also reported a successful approach in children with GVHD: a 64% response rate was obtained in 59 children 28 days after infusion of MSCs from unrelated donors [107].

### 18.3.2 The central nervous system

Several studies have demonstrated, that, beyond being able to survive in the tissues of the central nervous system (CNS), MSCs are also able to secrete a wide panel of neuroregulatory molecules that leads to the enhancement of neuronal cell survival and neuritogenesis both *in vitro* and *in vivo* [45,108–110]. In addition to this, the modulation of inflammatory brain reactions and potentiation of axonal regeneration/remyelination have been associated with the use of MSCs in preclinical models of disease [33,111]. In models of Parkinson's disease and SCI, studies have demonstrated that MSCs can secrete important trophic factors, including BDNF, FGF-2, GDNF, and IGF-1. This may have been the reason for the increase in neuronal survival and regeneration noted as well as the improvement of animal performance after the administration of MSCs [111–118].

#### 18.3.2.1 Spinal cord injury

SCI is characterized by long-term functional deficits in ascending and descending motor and sensory neuronal pathways as a result of injury. In most cases it leads to a complex cascade of events that result in loss of neurons and glial cells, inflammation, demyelination, and pain.

MSC treatment has shown potential promise for SCI [36,119]. Despite the complexity of SCI lesions, transplantation with MSCs derived from bone marrow has shown that these cells were able to promote remyelination, axonal sparing, and functional recovery at different stages of SCI [120–122]. Besides the fact that MSCs are immunosuppressive, studies have shown that they can modify the SCI milieu directly through the release of trophic factors such as BDNF, NGF, and VEGF, thus promoting axonal regeneration, neurite outgrowth, and glial scar reduction [110,123]. Lu *et al.* [124] showed that bone marrow-derived MSCs secreted NGF, neurotrophin-3 (NT-3), and high levels of BDNF, contributing to host axonal growth and enhancing the growth of the host's serotonergic, coerulospinal, and dorsal column sensory axons after SCI. Similar findings were also reported by Neuhuber *et al.* [125], who demonstrated that the CM of bone marrow-derived MSCs was able to promote axon growth and functional recovery due to the presence of BDNF, VEGF, interleukin (IL)-6, monocyte chemoattractant protein-1, SCF, and SDF-1α. Recently, Gu *et al.* [111] and Park *et al.* [126] showed that these MSCs were able to secrete neurotrophic factors such as HGF, VEGF, BDNF, and GDNF, suggesting that this secretory activity was possibly the mechanism of the promotion of axonal regeneration of spinal neurons both *in vitro* and *in vivo*.

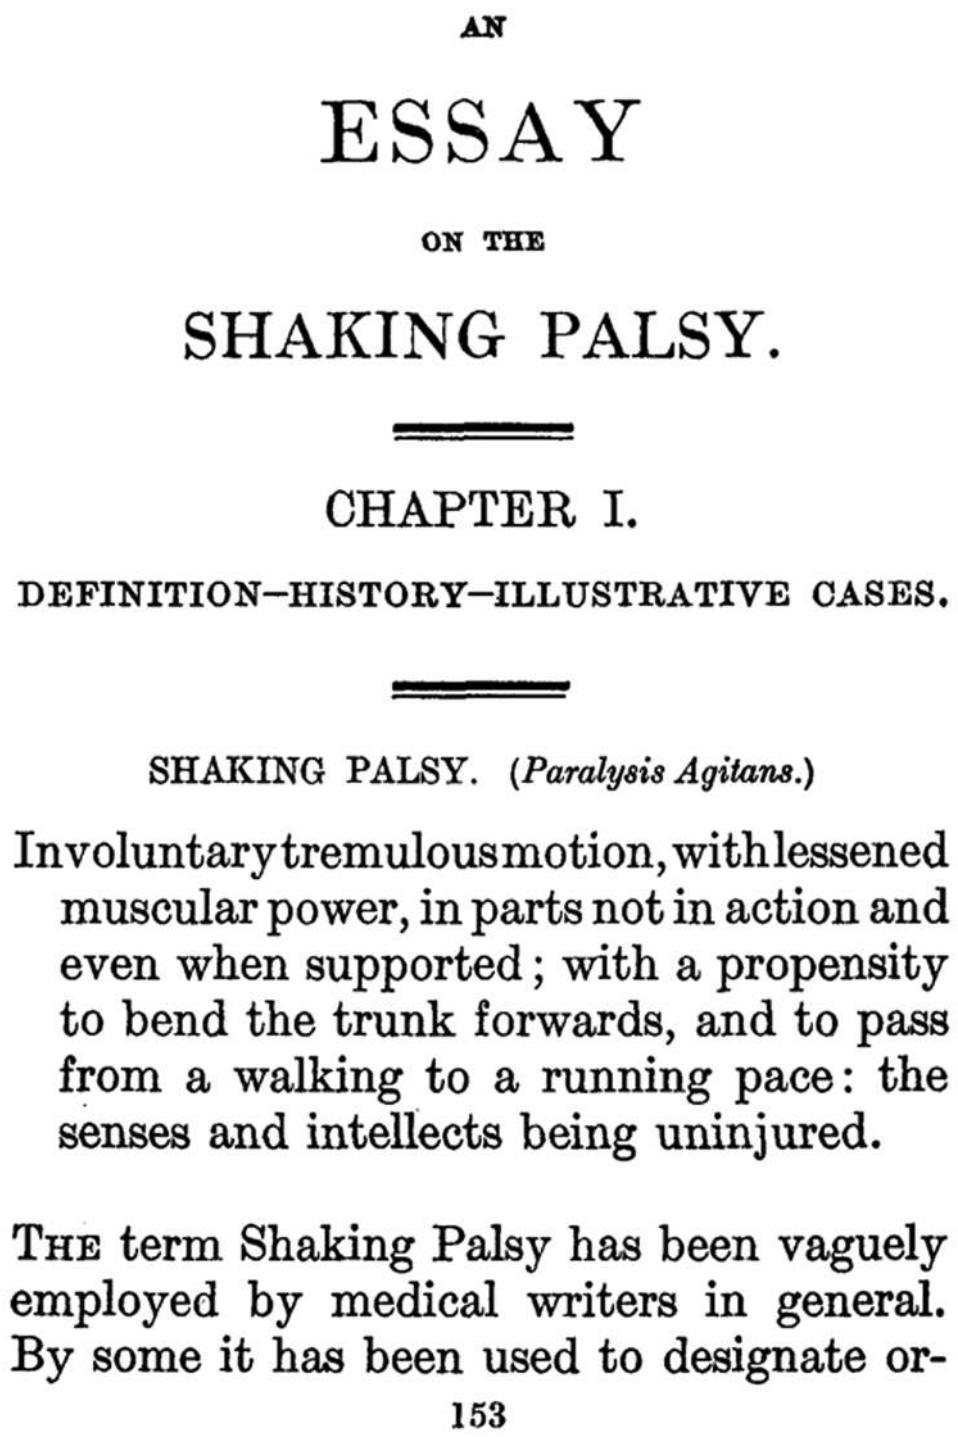
Adipose-tissue-derived stem cells (which contain MSCs) were shown to be similar to Schwann cells, secreting neurotrophic factors such as BDNF and improving remyelination [115]. Moreover, undifferentiated adipose-tissue-derived stem cells may be another promising cellular candidate for axonal regeneration that has been associated with their paracrine action [36]. Two studies have examined the use of Wharton's jelly MSCs in SCI: their transplantation into the site of SCI was able to potentiate repair and recovery due to the release of trophic factors such as NT-3, VEGF, basic FGF (bFGF), and BDNF [116,127].

More recently, Cantinieaux *et al.* [128] used an original approach: instead of transplanting MSCs, he and his colleagues administered only their secretome, in the form of CM, to animals with SCI. This CM improved motor recovery, thus indicating that the use of MSC secretome as a cell-free therapeutic agent is a possibility [128].

Owing to these results, some early clinical studies have already been reported. Saito *et al.* [129] demonstrated that the transplantation of autologous bone marrow-derived MSCs by lumbar puncture into the spinal fluid appeared to be safe and with some improvement in motor function. Similar results were also obtained by Karamouzian *et al.* [130] in subacute SCI: after the MSC transplantation the authors observed that 45.5% of patients showed improvements in neurological function [130].

#### 18.3.2.2 Parkinson's disease

Parkinson's disease is the most common motor-related disorder of the CNS in middle or late life and affects millions of people worldwide [131]. The disease is named after the English doctor James Parkinson, who published the first detailed description of the disease in *An Essay on the Shaking Palsy* in 1817 (Figure 18.2).



Parkinson's disease results in loss of dopaminergic innervation to the striatum (and other basal ganglia) and a cascade of subsequent consequences. The striatum, also known as the neostriatum or striate nucleus, is a subcortical part of the forebrain. It receives input from the cerebral cortex and is the primary input to the basal ganglia system. In all primates, the striatum is divided by a white matter tract called the internal capsule into two sectors called the caudate nucleus and the putamen. The term corpus striatum is occasionally used to refer to the striatum combined with the pallidum, which is a collective term for the dorsal pallidum (globus pallidus) and the ventral pallidum. The lenticular nucleus refers to the putamen together with the globus pallidus. Functionally, the striatum helps coordinate body movements with motivation. Coordinating motivation and body movement can be as simple as controlling fine-motor functions or as complex as inhibiting behavior depending upon social interactions.

Parkinson's disease is a slowly progressive neurodegenerative disease that is characterized by the loss of dopaminergic neurons in several dopaminergic networks, most intensively in the ventral tier of the substantia nigra pars compacta within the mesostriatal/nigrostriatal pathway [38,131–133]. The depletion of substantia nigra neurons leads to the loss of dopaminergic innervations and consequently to striatal dopamine deficiency, which is responsible for the major sensory and motor system symptoms [134]. The motor symptoms of Parkinson's disease result from death of the dopamine-generating cells in the substantia nigra, a region of the midbrain; the cause of this cell death is unknown. Early in the course of the disease, the most obvious symptoms are movement related; these include shaking, rigidity, slowness of movement, and difficulty with walking and gait. Later, thinking and behavioral problems may arise, with dementia commonly occurring in the advanced stages of the disease, whereas depression is the most common psychiatric symptom. Other symptoms include sensory, sleep, and emotional problems. Parkinson's disease is more common in older people, with most cases occurring after the age of 50 (Figure 18.3).

A considerable body of evidence has revealed the potential of MSCs to promote protection and/or recovery of dopaminergic neurons against neurotoxin-induced nigrostriatal degeneration. Several studies in animal models of Parkinson's disease have demonstrated that bone marrow-derived MSC secretome protects and/or helps dopaminergic neurons regenerate *in vitro* and *in vivo* models through the secretion of growth factors and cytokines [34,113,135–142]. For instance, Shintani *et al.* demonstrated that CM from bone marrow-derived MSCs was able to promote survival of tyrosine hydroxylase-positive dopaminergic neurons in rat primary cultures of ventral mesencephalic cells [136]. Moreover, intrastriatal transplantation of fetal mesencephalic cells, treated with CM from human bone marrow-derived MSCs during donor cell preparation and implantation, induced survival of dopaminergic transplanted cells and promoted functional recovery in a 6-hydroxydopamine (6-OHDA) neurotoxin rat model of Parkinson's disease [136]. The observed protection of dopaminergic neurons was attributed to the secretion of BDNF, GDNF, and bFGF by the MSCs, all of which had previously been shown to stimulate survival of dopaminergic neurons [136,143–147]. Similarly, Sadan *et al.* showed that human bone marrow-derived MSCs cultured in the presence of growth factors not only significantly increased the viability of the human-derived SH-SY5Y neuroblastoma cell line exposed to 6-OHDA, but also that MSCs transplanted into the striatum of a 6-OHDA rat model of Parkinson's disease migrated to the lesion site, increased the numbers of tyrosine hydroxylase-positive cells, and increased dopamine levels [137]. These neuroprotective and neuroregenerative effects were accompanied by an improvement in animals' behavioral impairments and were correlated with MSC secretion of BDNF and GDNF. Similar findings were published by Blandini *et al.* using the same animal model [139].

In contrast, Wang *et al.* associated SDF-1α expression by rat bone marrow-derived MSCs with protection of dopaminergic neurons against the 6-OHDA neurotoxin, both *in vitro* and *in vivo*, through antiapoptotic-based mechanisms [140]. Cova *et al.* demonstrated that human bone marrow-derived MSCs transplanted in the striatum of a 6-OHDA rodent model of Parkinson's disease were able to survive and interact with tissue surrounding the lesion site, thus enhancing the survival of dopaminergic terminals and neurogenesis in the subventricular zone (SVZ) in a sustained manner [34]. The SVZ is a paired brain structure situated throughout the lateral walls of the lateral ventricles. It is composed of four distinct layers of variable thickness and cell density, as well as cellular composition. Along with the dentate gyrus of the hippocampus, the SVZ is one of two places where neurogenesis has been found to occur in the adult mammalian brain.

Finally, the secretion of BDNF *in vivo* by bone marrow-derived MSCs was correlated with the activation of endogenous stromal cells, as described by Cova *et al.* [34]. In addition to the capability of MSCs to induce survival of dopaminergic

AN

ESSAY

ON THE

SHAKING PALSY.

CHAPTER I.

DEFINITION—HISTORY—ILLUSTRATIVE CASES.

SHAKING PALSY. (*Paralysis Agitans.*)

Involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forwards, and to pass from a walking to a running pace: the senses and intellects being uninjured.

THE term Shaking Palsy has been vaguely employed by medical writers in general. By some it has been used to designate or-

153

**Figure 18.2** First page of the landmark work by James Parkinson (1755–1824) *An Essay on the Shaking Palsy*, providing in 1817 the first description of the disease that would bear his name. *Source:* typeset and printed in 1817 by Whittingham & Rowland of London. neurons, its effects have also been related with their immunomodulatory properties. In this context, Danielyan *et al.* [141] showed that rat bone marrow-derived MSCs delivered intranasally into 6-OHDA-induced hemi-Parkinsonian rats migrated towards the substantia nigra and the striatum and reduced the overall expression of pro-inflammatory cytokines, such as IL-1β, IL-2, IL-12, tumor necrosis factor-α, and interferon-8. Moreover, their presence also reversed the loss of nigral dopaminergic neurons and striatal fibers [141].

**Figure 18.3** Front and side views of a man portrayed to be suffering from Parkinson's disease. These are woodcut reproductions (of two collotypes from Paul de Saint-Leger's 1879 doctoral thesis, "Paralysie agitante (maladie de Parkinson); étude clinique") published in Gowers, William Richard (1886). "Fig 145 – Paralysis agitans. (After St. Leger.)." This image, reproduced here from en.Wikimedia.org, is in the public domain. The two sketches (one from the front and one from the right side) are of a man, with an expressionless face. He is stooped forward and is presumably having difficulty walking.

## 18.4 The peripheral nervous system

Following injury the axons of the peripheral nervous system (PNS) and the CNS respond differently. While CNS regeneration is limited, severed PNS axons are able to re-extend and re-innervate their targets. However, a complete recovery of nerve function is unusual and clinical outcomes remain unsatisfactory, especially for large lesions. Injuries to the PNS are one of the major sources of disability in the USA [148], impairing the ability to move muscle and/or resulting in painful neuropathies. The standard clinical procedure after a nerve trauma is the simple suture, without generating tension, of the nerve ends. However, the absence of tension is impossible when suturing large gaps. In these cases, a nerve autograft is typically performed [149]. Although the use of autografts is currently the best clinical treatment available, this procedure has many drawbacks, including the need of a second surgery, the loss of donor site function, and limited availability. The presence of inhibitory molecules in autografts may reduce their efficacy [149,150]. Therefore, the pursuit for alternative therapies that can successfully repair peripheral nerves is important.

The trophic action and application of MSCs for PNS injuries has been demonstrated [115,151–156]. For instance, Pan *et al.* [157] demonstrated that, after administration at the site of nerve injury, MSCs were able to secrete higher levels of BDNF, GDNF, ciliary neurotrophic factor, NGF, and NT-3, leading to the reduction of fibrosis in the lesion site and to the promotion of nerve regeneration. Similar observations were also observed by Lopatina *et al.* [115], who demonstrated with MSCs derived from adipose tissue that their transplantation was able to accelerate nerve regeneration through the active secretion of BDNF, enabling a better nerve sprout growth *in vivo*. Similar findings were also reported by Duan *et al.* [151], after transplanting MSCs into an acute peripheral nerve traction model in rabbits.

Taking a different approach, Hu *et al.* [152] used chemically extracted acellular allogenic nerve segments implanted with autologous MSCs to repair a 40 mm defect in a rhesus monkey ulnar nerve injury model. Results revealed that severely damaged ulnar nerves were structurally and functionally repaired within 6 months following placement of the MSC-seeded allografts in all animals studied (six of six) [152].

Recently, mesenchymal-like stromal cells isolated from adipose tissue were used to target PNS injury [158,159]. It was found that implantation of these cells improved recovery of exercise behavior and increased wet weight ratio of the anterior tibial

muscle [158]. Moreover, electrophysiological recording found that the percentage of activated fibers was higher in animals given the cells. Histologically, the number of nerve fibers, axonal diameter, and myelin thickness were significantly higher in the groups receiving cells [158]. Additionally, they demonstrated that the progression of the regenerative process after cell implantation was accompanied by elevated expression of neurotrophic factors during both early and later phases [158].

Finally, Wrobel *et al.* [160] proposed the use of MSCs in a co-culture with Schwann cells for peripheral nerve repair. Higher neurite outgrowth from dissociated sensory neurons was noted.

## 18.5 Future perspectives

The use of MSCs has been suggested as a possible therapeutic tool for regenerative medicine, representing a promising cell source for the creation of new cell-based therapies [3,21,161,162] (Figure 18.4). Promising results have been described in this chapter for disorders of the CNS, the PNS, and in GVHD. Trophic activity of MSCs has also been described in kidney injury, bone disease, heart disease, diabetes mellitus, and cancer [19,163,164]. It is proposed that the effects of bioactive molecules secreted by MSCs can have a direct effect by intracellular signaling or an indirect effect through the activation of adjacent cells, stimulating the secretion of functionally active agents by them [165]. Studies have suggested that the use of the MSC secretome may have an application in a number of diseases, including neurodegenerative diseases [130,166]. Efforts should be targeted to fully characterizing the MSC secretome, analyzing their two fractions (protein and vesicular) in order to determine which fraction will be more useful as a therapeutic strategy in the future.

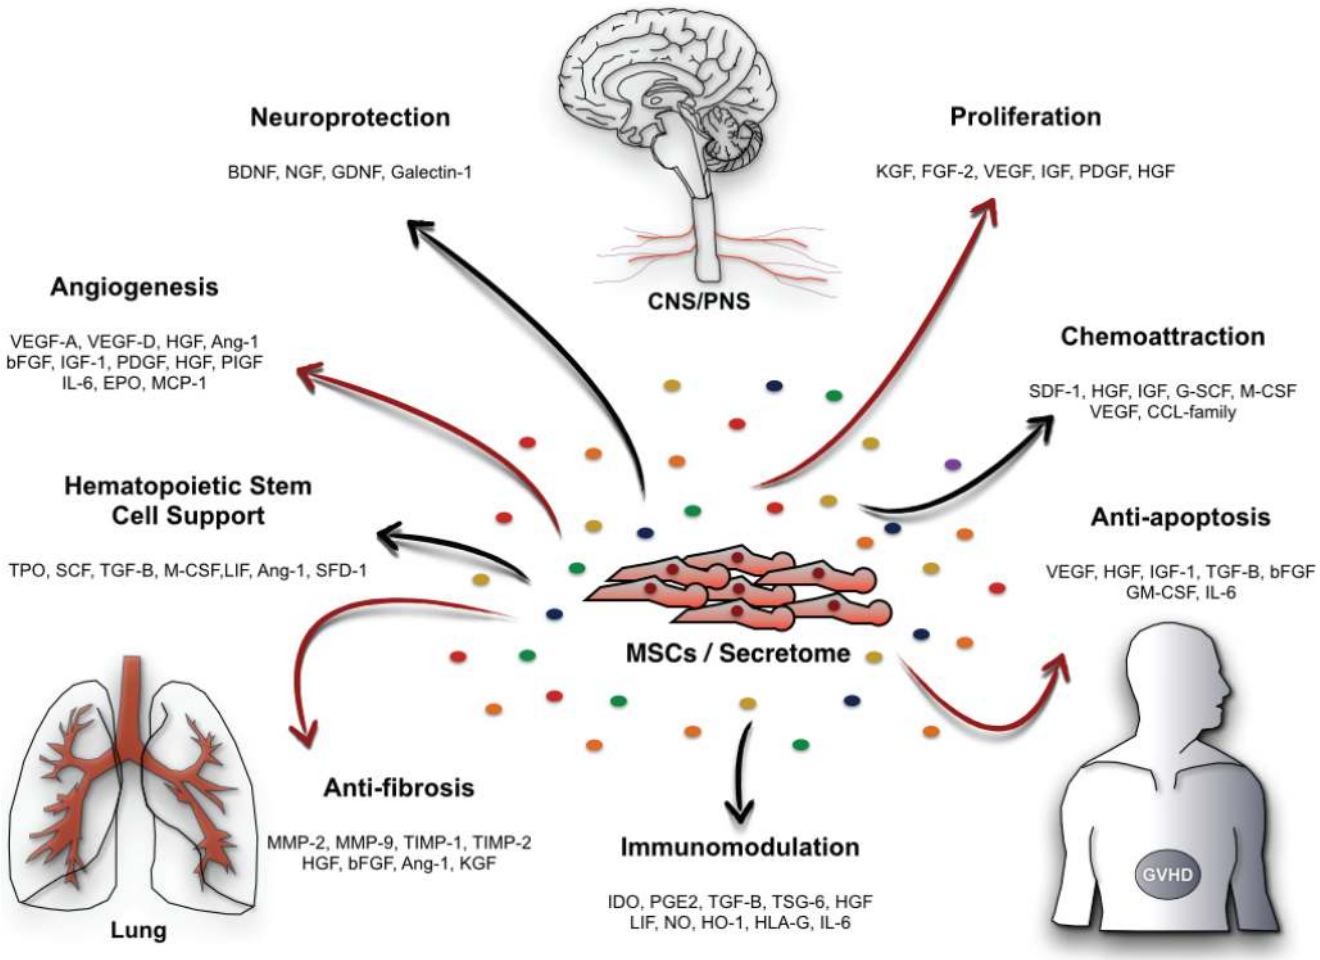

**Figure 18.4** MSCs exert most of their therapeutic actions through their secretome. This is carried out by a number of proteins involved in the regulation of phenomena such as neuroprotection, proliferation, chemoattraction, inhibition of apoptosis, immunomodulation, stromal cells support, and angiogenesis.

## 19.1 Introduction to protein secretion and the analysis of secretomes

Secretomics is a recent proteomic approach that seeks to describe the secretome, considering it as the set of proteins secreted by a cell, tissue, or organism at any given time or under certain conditions. The term *secretome* was introduced for the first time by Tjalsma *et al.* in a study of those proteins secreted by *Bacillus subtillis* [1]. It is considered to be encoded by approximately 10% of the human genome [2,3]. The secretome constitutes an important class of proteins including components of the extracellular matrix (ECM) and regulatory molecules. These play essential roles in several physiological and pathophysiological processes, including cell signaling, differentiation, cell adhesion, angiogenesis, and apoptosis [4]. To date, the secretomes of mesenchymal stem/stromal cells (MSCs) and other types of stem cells have been explored [5], leading to the identification of several different molecules, including growth factors and the proteins binding to them, proinflammatory and anti-inflammatory cytokines, chemokines, ECM structural proteins, and remodeling enzymes.

Protein secretion is a common, complex, and well-controlled process. Normally, cells react to different stimuli and signals that they receive from their environment and consequently activate or inactivate the secretion of a number of bioactive molecules. A protein secretion balance is essential for normal cell function. Thus, imbalance or alterations in the protein secretion pattern/profile (the secretome) can be indicative of a pathologic condition [6]. Furthermore, the secretome also reflects the functional status of a cell in a given environment. Hence, secretomics is a very attractive approach for discovering novel diagnostic or prognostic biomarkers and also for putative therapeutic targets.

The proteins are secreted from the cells through two main secretory pathways: conventional and unconventional [7]. In the conventional secretory pathway, proteins with a signal peptide sequence are translocated from the ribosomes into the lumen of the endoplasmic reticulum, where they undergo post-translational modifications. Once these proteins have been correctly folded and glycosylated, they travel to the Golgi apparatus before they reach their destination – the extracellular space, the plasma membrane, or other target organelles.

The conventional pathways are further divided into constitutive secretion and regulated exocytosis. In the constitutive secretion pathway, proteins are carried continuously by vesicular carriers from the Golgi apparatus to the plasma membrane or endosomes. In regulated exocytosis, proteins are sorted and stored in granules, which can reach the plasma membrane in three ways: direct fusion with the membrane, transport in small vesicles to the membrane, or fusion with each other on the cell surface [8].

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.

Unconventional secretory pathways are used by proteins with or without signal peptide sequences. Most of the cytoplasmic and nuclear proteins avoid the endoplasmic reticulum–Golgi system and are secreted by an unconventional transport pathway [9]. Unconventional secretion takes place using specialized membrane vesicles or by employing direct protein translocation across the membrane. Interleukin (ILIL)-1β, fibroblast growth factor (FGF), and galectins are exported through the unconventional transport pathways.

## 19.2 Analysis of mesenchymal stem/stromal cell secretomes using proteomic approaches

Proteomic studies on MSC secretomes have greatly increased in recent years owing to the improvements in proteomic platforms and mass spectrometry instrumentation. Although the secretome is quite complex because of the difficulties in its collection and preparation for protein analysis, more than 35 studies have focused on the characterization of the MSC secretome in the past few years. Table 19.1 summarizes the objective and technological strategy followed of each of these studies. All these publications denote the growing interest in the MSCs' secretome, which is largely due to the potential applications of these cells in regenerative medicine.

### 19.2.1 Approaches to obtaining secretome samples

Currently, secretome studies can be performed in three different ways: *in vitro*, using cell culture systems, *ex vivo*, *by* analyzing the secretome of tissue explants without isolating the cells, or *in vivo*, using animal models [48].

#### 19.2.1.1 *In vitro* secretome studies

These involve first the expansion of the cells in a serum (fetal bovine serum (FBS))-supplemented medium. Then the cells are extensively washed with sterile phosphate-buffered saline to remove FBS-derived proteins before incubating them in a serum-free medium. In these type of preparations FBS proteins are abundant and can mask the proteins secreted by the cells, affecting the separation and detection of proteins that are secreted in low amounts. The elimination of serum from the cell culture reduces sample complexity and also increases reproducibility. However, many cell lines are sensitive to serum-free media, and serum starvation can lead to an increase in cell death and the subsequent release of intracellular proteins. Additionally, the length of incubation in this type of experiment can vary from 12–24 h to 4–7 days and depends on the cell type involved.

#### 19.2.1.2 *Ex vivo* secretome studies

When the experiments are carried out under *ex vivo* conditions fresh tissue explants are incubated in serum-free medium for 12–24 h followed by the collection of the conditioned medium (CM) for protein identification. This approach has been successfully employed to study the secretome of human cartilage explants [49,50] and human adipose tissue [46]. However, *ex vivo* approaches demand careful sample handling and culturing to avoid false-positive results due to serum protein contaminants, which can remain inside or adhere to the surface of the tissue explants.

#### 19.2.1.3 *In vivo* secretome studies

These involve the analysis of body fluids, including serum, synovial fluid, urine, or interstitial fluid, that contain those proteins secreted by the tissues and cells in their native microenvironment. In this approach the body fluids are collected using microdialysis devices and capillary ultrafiltration probes [48]. The proteins are then concentrated and analyzed directly by mass spectrometry. In this way sample handling is reduced. However, *in vivo* secretome analysis has a number of issues that should be taken into account, including the high dynamic range of this type of sampling (which hampers the detection of low-abundance proteins), the possibility of contamination with blood-derived proteins, or difficulty knowing the relative contribution of a particular cell or tissue to the specific body fluid proteome [48].

### 19.2.2 Experimental strategies for *in vitro* secretome analysis of mesenchymal stem/stromal cells

Secretome analysis of MSCs is most commonly performed under *in vitro* conditions because of the low levels of secreted proteins in tissue explants or body fluids. It involves several steps, including MSC isolation, MSC expansion in a serum-containing culture medium, collection of CM, protein extraction, and proteomic analysis (Figure 19.1).

#### 19.2.2.1 Isolation of mesenchymal stem/stromal cells for proteomic analysis

MSCs can be isolated from a variety of human tissues, including, among others, bone marrow [14], adipose tissue [15], muscle [16], trabecular bone [17], and synovial membrane [18]. After harvesting the tissue, MSCs are usually extracted from the tissue by enzymatic digestion and expanded in monolayer cultures in order to obtain a sufficient number for the analyses. Classical expansion protocols involve a basic medium such as Dulbeccco's modified Eagle medium (DMEM) containing 10% FBS and cultured at 37 °C in a controlled atmosphere with 5% $CO_2$. After the initial culture phase the cells can be stimulated with different factors or differentiated to other cell types, such as chondrocytes, adipocytes, or osteoblasts. For example, to induce chondrogenic differentiation *in vitro*, cells are cultured in a three-dimensional culture system as pellets in the presence of specific growth factors that include transforming growth factor-β (TGF-β) and dexamethasone [19,20].

**Table 19.1** Studies of the secretomes of MSCs using proteomic techniques.

| Origin | MSC source | Cell treatment | Conditioning (incubation) time[a] | Sample type | Proteomic technique | Reference |
|---|---|---|---|---|---|---|
| Human | BM-MSCs/ MIAMI cells | Comparative analysis of BM-MSCs (expanded in 21% $O_2$) vs MIAMI cells (expanded in 3% $O_2$) | Not mentioned | Complete CM | Bio-Plex™ cytokine assay | [10] |
| Rat | ADSCs | None | 24 h | Complete CM (10% serum) | cDNA microarray/ELISA | [11] |
| Rat | BM-MSCs | None | 24 h | Complete CM | ELISA | [11] |

#### 19.2.2.2 Preparation of secretome samples

Prior to obtaining the CM the cells are extensively washed up to six times in serum-free medium or phosphate-buffered saline to remove the amount of FBS-derived proteins contaminating the medium. The cells are then cultured in a serum-free medium. The incubation time depends on the cell type, but it usually ranges between 12 and 48 h. At the end of this time the CM is collected and centrifuged in order to remove dead cells and remaining particles. These CMs can be concentrated by centrifugal filtration using specific membranes with a cut-off of 3–10 kDa, or precipitated with trichloroacetic acid, in order to obtain the proteins. The proteins are then quantified. This is particularly important if the samples are being used for a comparative analysis when it is essential to load equal amounts of total protein from each sample to be compared. Finally, the samples can be stored at −80 °C prior to further analysis.

#### 19.2.2.3 Proteomic approaches for the analysis of mesenchymal stem/stromal cell secretomes

Once secretome samples have been obtained, the next step is their analysis by proteomic techniques. Different proteomic approaches have been employed for the large-scale analysis of proteins secreted by MSCs. These include protein separation by 2-DE followed by MS, protein separation by LC followed by MS, and antibody-based assays.

##### *19.2.2.3.1 Protein separation by two-dimensional gel electrophoresis*

The 2-DE approach involves the separation of the proteins in two dimensions on a gel. In the first dimension the proteins are separated by their isoelectric point, while in the second dimension they are separated according to their molecular weight by SDS-PAGE. Following their separation by 2-DE, protein spots

can be picked from the gels and identified using MS or LC–MS after in-gel digestion. Although 2-DE provides valuable information about intact protein content in the secretome samples, several protein classes can be overlooked due to their low abundance, extreme isoelectric points, or molecular weights.

The 2-DE approach has been applied by many researchers to study proteins secreted by MSCs. Zvonic *et al.* applied this strategy followed by MS/MS to analyze the secretome of primary cultures of adipose-derived stromal cells (ADSCs) [42], identifying a number of established adipokines, such as adiponectin and plasminogen activator inhibitor 1, as well as multiple serine protease inhibitors (serpins). Moreover 2-DE has also been employed to identify and compare the secretome from rat ADSCs with or without insulin stimulation [40].

#### *19.2.2.3.2 Protein separation by liquid chromatography followed by mass spectrometry (shotgun approach)*

Shotgun approaches are currently the techniques most commonly employed for the study of MSC secretomes. This strategy starts with the digestion of proteins present in the samples and the separation of the resulting peptides by LC. Then MS/MS involving multiple steps of MS selection is used to identify the peptides. Before protein digestion samples can be fractionated by electrophoretic techniques such as 2-DE or 1D SDS-PAGE in order to reduce their complexity. Peptide separation is usually performed by multidimensional chromatographic techniques that combine strong cation exchange chromatography with reversed-phase LC.

*19.2.2.3.2.1 Proteomic studies of mesenchymal stem/stromal cells undergoing osteogenesis* LC–MS/MS technologies were applied by Choi *et al.* to study the secretome of BM-MSCs during osteogenic differentiation. They found a member of the SPARC (secreted protein acidic and rich in cysteine – also known as osteonectin) family, SPARC-related modular calcium-binding protein 1 (SMOC1), to be highly expressed in BM-MSCs undergoing osteogenesis [31]. In another study, Kim *et al.* analyzed the extracellular protein expression profile of undifferentiated human BM-MSCs as well as osteogenically induced BM-MSCs using LC–MS/MS [33]. This analysis resulted in the identification of 315 secreted proteins, of which more than 200 were differentially expressed during osteogenesis. Interestingly, calcium homeostasis-related proteins were increased in osteoblasts, while proteins related to stem cell proliferation were decreased. Furthermore, Lee *et al.* also used LC–MS/MS to study the human ADSC secretome after treatment with TNF-α [34]. Several cytokines and chemokines (such as IL-6, IL-8, C-X-C motif chemokine ligand (CXCL) 6, and monocyte chemoattractant protein 1 (MCP-1)) and several proteases (including cathepsin L, matrix metalloproteinases, protease inhibitors, and pentraxin 3 (PTX3)) were found to be more abundant.

LC–MS/MS-based quantitative strategies have also been employed in the analysis of secreted proteins. These can be performed using isotopic labeling or label-free approaches. The SILAC method is one of the most commonly employed labeling strategies for characterization of the MSC secretome. It is believed that SILAC has higher quantitative accuracy than other labeling methods because the samples to be compared can be mixed at the cellular or protein level prior to any further sample preparation, thus minimizing handling errors. In a typical SILAC experiment two populations of cells are differentially labeled by growing them in light medium, which contains normal arginine (Arg 0) and lysine (Lys 0), or in heavy medium with different isotope variants of these two amino acids (e.g., Arg 10/Lys6). A minimum of five cell doublings is needed to ensure complete incorporation of the heavy amino acids into the proteins synthesized by the cell. Proteins in the CM from the two cell populations are usually combined and separated by 1D SDS-PAGE. After in-gel digestion of the gel bands, the resulting peptide mixtures are analyzed by LC–MS/MS. Taking into account that trypsin digests the proteins at arginine and lysine residues, every tryptic peptide obtained from the heavy condition will contain at least one labeled amino acid and can therefore be discriminated by MS.

One of the major benefits of the SILAC strategy in secretome studies is that contaminating proteins from the FBS can be easily discriminated from the MSCs-derived proteins by their absence of stable isotope incorporation [46]. SILAC labeling coupled with LC–MS/MS was applied by Kristensen *et al.* to quantitatively assess the proteins secreted during osteoblast differentiation of human BM-MSCs at days 0, 1, 4, 7, and 14, covering the transition from undifferentiated to fully differentiated osteogenic cells [44]. These authors quantified 466 potentially secreted proteins, 41 of which were directly involved in osteoblast differentiation. Eight of them were increased in the early stages of osteogenic differentiation and were validated by quantitative real-time polymerase chain reaction (qRT-PCR). They were follistatin-like 1, cathepsin D, legumain, stanniocalcin 2, selectin-like osteoblast-derived protein, protein KIAA1199, plasminogen activator inhibitor 1, and PTX3, and they clearly play an important role in the formation of osteoprogenitor cells.

Molina *et al.* [47] focused on secreted proteins that were differentially expressed during the differentiation of 3T3-L1 preadipocytes to adipocytes, a model system for studying adipogenesis. They identified 882 nuclear/secreted proteins using 5-plex SILAC labeling followed by LC–MS/MS. Interestingly, THO complex 4, a context-dependent transcriptional activator in the T cell receptor alpha enhancer complex, showed its highest expression at the middle stage of adipogenesis. This protein is a heat-stable nuclear protein and functions as a molecular chaperone. It is thought to regulate dimerization, DNA binding, and transcriptional activity of basic region-leucine zipper proteins. On the other hand, SNF2-α, a chromatin remodeling protein, was downregulated in the early stages of adipogenesis and remained so at the other time points analyzed.

#### *19.2.2.3.3 Antibody-based assays*

Antibody-based assays have been also used to examine the MSC secretome in a targeted way. These approaches offer the opportunity of carrying out multiplexed, rapid, and sensitive profiling

of samples without any need to remove serum contaminants. Among the different types of immunological assays, ELISA has been the most commonly employed method for characterizing the MSC secretome as it allows a very accurate and sensitive detection of a single antigen of interest. Several studies have examined proteins secreted from MSCs employing ELISA. Kilroy *et al.* characterized the cytokine profile of primary cultures of undifferentiated and adipocyte-differentiated human ADSCs [14] and observed hepatocyte growth factor (HGF), a cytokine implicated in hematopoiesis and vasculogenesis, to be upregulated in the ADSC secretome after basic FGF treatment. In another study, Wang *et al.* evaluated the secretome of human BM-MSCs and ADSCs after preincubation with TNF-α. They found an increased secretion of vascular endothelial growth factor (VEGF), HGF, and insulin-like growth factor 1 (IGF-1) from both cell populations [15].

Recently, multiplex assays have been developed to quantify multiple antigens across samples. Multiplex techniques have several advantages over ELISAs, including reduced time and sample requirement, the ability to evaluate one antigen in the context of many others, and the capacity to detect different proteins across a broad dynamic range. Several different multiplex formats are currently available. Bead-based assays are probably the most commonly used (e.g., the Luminex technique). In this method each bead is coated with a specific capture antibody and streptavidin-labeled antibodies bind to the specific capture antibody complex, which can be then detected by chemiluminescence or fluorescence in a flow cytometer. Antibody microarrays are also commonly used. An example is the RayBio antibody array system, which involves the immobilization of the capture antibodies on the surface of membranes or glass slides. Roche *et al.* investigated the proteomic and secretory profile of adult multilineage inducible (MIAMI) cells and human MSCs isolated from bone marrow using a multiplex assay [10]. MIAMI cells secrete higher levels of VEGF, fractalkine, IL-6, IL-8, and growth-related oncogene proteins than human MSCs do. Finally, cytokine protein arrays have been employed to analyze the secretory profile of human umbilical cord-derived mesenchymal stem/stromal cells (UCMSCs) [28] and also to study the angiogenic factors produced during BM-MSC osteogenic differentiation [20].

## 19.3 Analysis of the secretome of mesenchymal stem/stromal cells undergoing chondrogenesis

MSCs can differentiate into different cell types, including adipocytes, osteoblasts, and chondrocytes. The process by which MSCs differentiate towards chondrocytes and start secreting the molecules that form the ECM of cartilage is called chondrogenesis [58]. The chondrogenic potential of MSCs, as well as their immunomodulatory function, renders them an interesting candidate for a cell-based therapy of cartilage defects [59].

Proteomic strategies have recently been applied in order to increase knowledge of the molecular mechanisms that participate in the differentiation processes of MSCs [60]. As indicated earlier, several proteomic studies have been performed to explore the secretome of MSCs undergoing osteogenesis and adipogenesis [33,47,61]. However, extracellular protein profiles of MSCs during chondrogenesis have been less often reported, and only a few studies have been carried out to characterize the secretome from human MSCs undergoing chondrogenic differentiation. Table 19.2 lists those proteins related to the ECM of articular cartilage that have been identified so far by immunological assays and LC–MS/MS techniques in the secretome of MSCs undergoing chondrogenesis.

Among these studies Lee *et al.* focused on proteins that were differentially expressed during chondrogenesis [62]. Undifferentiated MSCs and chondrocytes were analyzed using 2-DE andMS/MS analysis. Only nine proteins could be identified among the spots that were differentially expressed between the two groups. The expression of two extracellular proteins, collagen type II, a biomarker of chondrocytes, and matrilin-1, a noncollagenous fibrillar cartilage matrix protein, was increased during chondrogenesis. Arufe *et al.* [38] used LC coupled to matrix-assisted laser desorption ionization (MALDI) with MS/MS to characterize the secretome of MSCs obtained from umbilical cord at different time points during chondrogenesis. In MALDI imaging MS, the sample, often a thin tissue section, is moved in two dimensions while the mass spectrum is recorded. Advantages such as measuring the distribution of a large amount of analytes at one time without destroying the sample make it a useful method in tissue-based studies.

Using this strategy, Arufe *et al.* identified 209 proteins that were directly linked to extracellular processes during chondrogenesis. These included ECM-related proteins such as basement-membrane-specific heparan sulfate proteoglycan core protein and several collagens, several cartilage proteases, such as 72 kDa type IV collagenase (MMP2) and interstitial collagenase (MMP1) and their tissue inhibitors metalloproteinase inhibitor (TIMP) 1 and TIMP2. Other proteins involved in cell adhesion, such as fibronectin or dermatopontin, were also identified. These findings and those referenced in Section 19.4 have increased the knowledge on the molecular mechanisms occurring during chondrogenesis. The identification of several proteins related to cell growth and differentiation in the secretomes of MSCs during induction of chondrogenesis (Table 19.3) is valuable for the monitoring of this process *in vitro*.

## 19.4 Characterization of chondrogenesis markers by secretome analysis

One of the applications for which the study of MSC secretomes has major advantages is the identification of differentiation markers that could be applied in cell therapy-based approaches.

**Table 19.2** Known cartilage ECM-related proteins identified in the secretome of MSCs undergoing chondrogenesis by immunological and LC–MS/MS techniques.

Quantitative proteomic analyses have been performed to characterize the protein modulations in the secretome of BM-MSCs during the first steps of their differentiation towards chondrocyte-like cells. One of these studies was carried out by our group using a double-SILAC strategy coupled to LC–MS/MS. The workflow of this procedure is shown in Figure 19.2.

The double-SILAC method avoids quantification artifacts from the FBS employed in the cell culture. Two populations of human BM-MSCs are grown with isotope variants of lysine (Lys) and arginine (Arg) (Arg6, Lys4 for the "medium" labeling and Arg10, Lys8 for the "heavy" labeling) for 4–6 weeks until full labeling had been achieved. The labeled populations are then

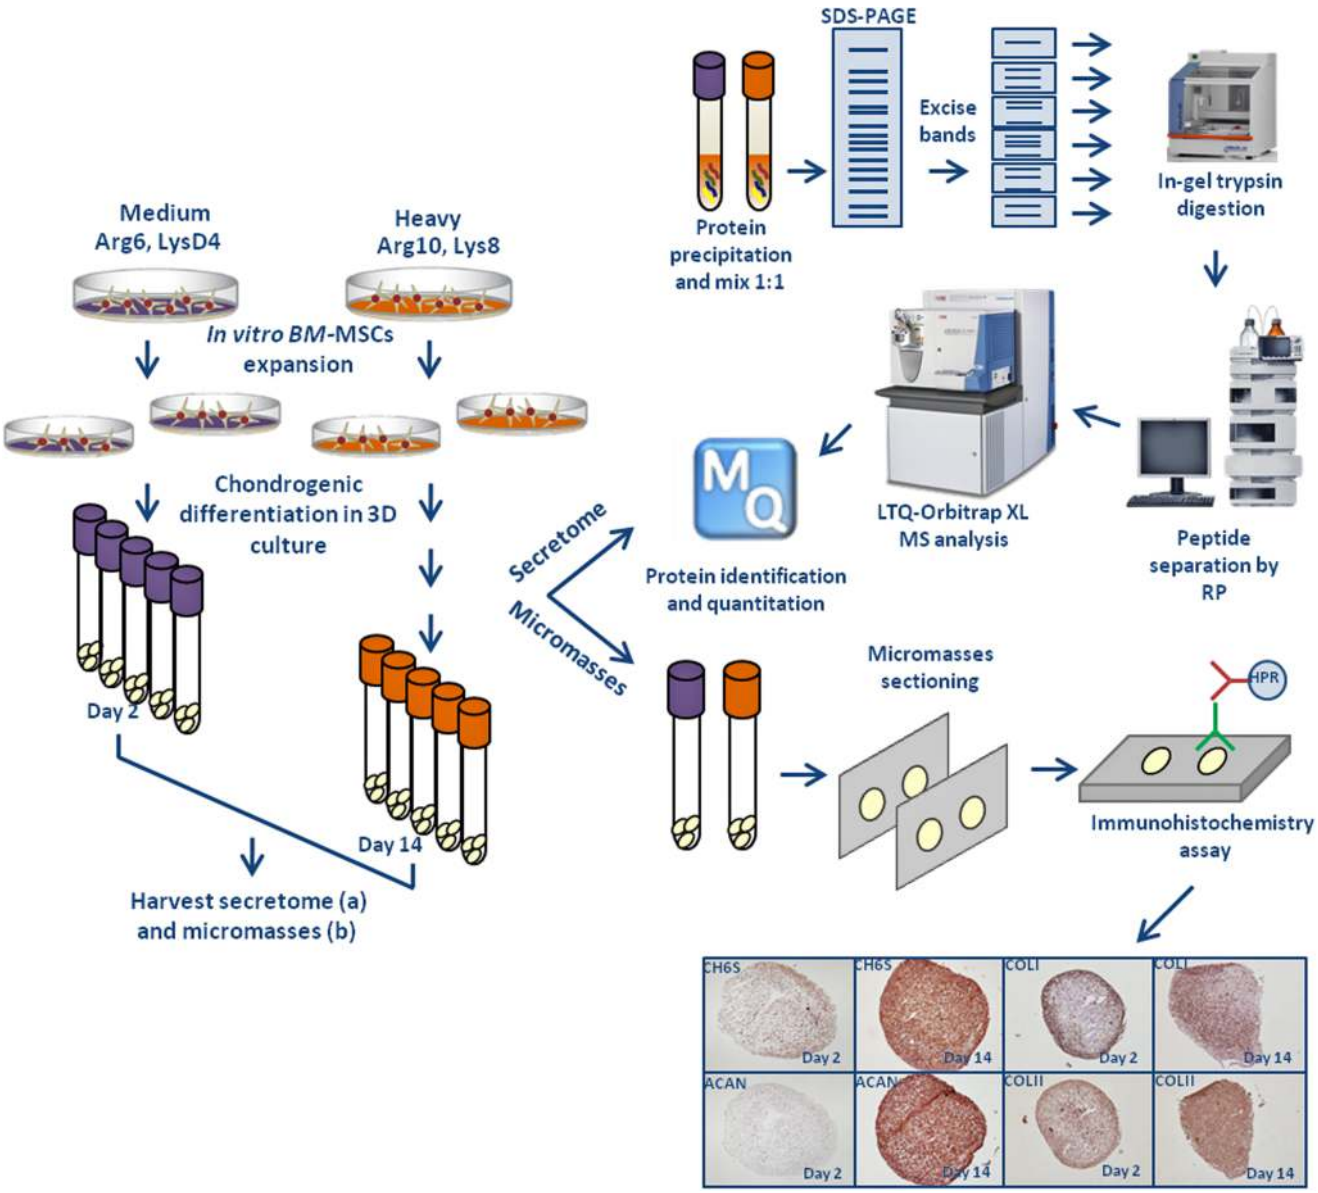

**Figure 19.2** Experimental workflow for the secretome analysis of BM-MSCs undergoing chondrogenesis. BM-MSCs, bone marrow mesenchymal stem/stromal cells; RP, reversed phase; HPR, horseradish peroxidase; COL2, type II collagen; COL1, type I collagen; ACAN, aggrecan; CH6S, chondroitin-6-sulfate. (See color plate section.)

subjected to differentiation in three-dimensional cultures (micromasses) according to standard procedures [63]. For stimulation of chondrogenesis a medium with TGF-β3 among other chondrogenic inducers [64] can be employed. At different days of differentiation (in our case 2 and 14 days) the micromasses are washed in serum-free media and incubated overnight with serum-free labeling medium supplemented with chondrogenic inducers. CM is then collected after 24 h, and the micromass pellets are also collected to perform verification studies of chondrogenesis, including immunohistochemical analysis of collagens (types I and II) and proteoglycans (aggrecan and chondroitin 6 sulfate). For the proteomic analysis, proteins in the CM are precipitated and protein samples from the two different time points to be compared are mixed 1 : 1 and separated into eight fractions by SDS-PAGE. After in-gel digestion of each fraction, the resulting peptide mixtures can be analyzed by LC coupled to MS. In our case we used an LC-linear trap quadripole Orbitrap XL instrument and quantified the proteins using MaxQuant software. Validation of the putative biomarker candidates of chondrogenesis can be carried out using orthogonal techniques such as Western blot or immunohistochemistry assays.

This study led to the identification of 221 proteins with a reported extracellular localization, many of which are

summarized in Tables 19.2 and 19.3. Most of them were characteristic of the ECM of articular cartilage, and 34 showed statistically significant quantitative modulations during chondrogenesis when comparing the secretome protein profiles between days 2 and 14 of differentiation. These proteins are listed in Table 19.4 and include typical cartilage markers, such as proteoglycan 4 (PRG4/lubricin) or cartilage oligomeric matrix protein (COMP), anticatabolic markers such as TIMP1, reported markers of cartilage development (versican), and a suggested marker of chondrogenesis, cartilage acidic protein 1 (CRAC1). All of them were increased at day 14 of chondrogenesis. Conversely, the only four proteins detected with a significant reduction in their amounts at day 14 compared with day 2 were PTX3, tenascin (TENA), Thy-1 membrane glycoprotein (THY1, CD90), and chondroitin sulfate proteoglycan 4 (CSPG4).

Apart from this work, Bara *et al.* have used an LC–MS/MS approach to profile the CM obtained from equine BM-MSCs [36]: multiple fibronectin peptides as well as peptides

of cartilage-associated matrix proteins, including biglycan and decorin, were identified in the chondrogenic CM. Type II collagen and lumican were also detected in two of the three samples analyzed. In addition, angiogenesis- and neurogenesis-related factors were screened using protein arrays against 55 proteins, leading to the detection of five angiogenic factors (VEGF, FGF-4, FGF-7, MCP-1, and activin A) at high levels during the early stages of chondrogenesis. Other work has focused specifically on the subset of glycosylated proteins in the secretome of MSCs [65]. Glycosylation is one of the most important posttranslational modifications of cell surface proteins and extracellular proteins. For this reason, glycoprotein enrichment techniques can be applied to increase the concentration of glycoproteins and eliminate cytoplasmic proteins. Ishihara *et al.* employed a

proteomics platform based on glycoprotein enrichment coupled to LC–MS to discover novel chondrogenic differentiation markers. From the total of 246 *N*-glycoproteins identified, 53 were either localized on the ECM or secreted. Among them, two well-known cartilage collagens, collagen alpha-1 (III) chain and collagen alpha-1(XI) chain, were upregulated during chondrogenic differentiation. In addition, increased expression of fibronectin and granulins was also found after 18 days of differentiation.

## 19.5 Characterization of osteogenesis markers by secretome analysis

As mentioned earlier in this chapter, Choi *et al.* studied the secretome of BM-MSCs during osteogenic differentiation and found a member of the SPARC family, SMOC1, to be highly expressed in BM-MSCs undergoing osteogenesis [31]. In another study, Kim *et al.* analyzed the extracellular protein expression profile of undifferentiated human BM-MSCs as well as osteogenically induced BM-MSCs using LC–MS/MS [33]. This analysis resulted in the identification of 315 secreted proteins, of which more than 200 were differentially expressed during osteogenesis. Interestingly, calcium homeostasis-related proteins were increased in osteoblasts, while proteins related to stem cell proliferation were decreased.

SILAC labeling coupled with LC–MS/MS was applied by Kristensen *et al.* to quantitatively assess the proteins secreted during osteoblast differentiation of human BM-MSCs at days 0, 1, 4, 7, and 14, covering the transition from undifferentiated to fully differentiated osteogenic cells [44]. They quantified 466 potentially secreted proteins, 41 of which were directly involved in osteoblast differentiation. Eight of them were increased in the early stages of osteogenic differentiation and were validated by qRT-PCR. They were follistatin-like 1, cathepsin D, legumain, stanniocalcin 2, selectin-like osteoblast-derived protein, protein KIAA1199, plasminogen activator inhibitor 1, and PTX3, and they clearly play an important role in the formation of osteoprogenitor cells.

## 19.6 Characterization of adipogenesis markers by secretome analysis

Again as mentioned earlier, Zvonic *et al.* analyzed the secretome of primary cultures of adipose-derived stromal cells (ADSCs) [42] and identified a number of established adipokines, such as adiponectin and plasminogen activator inhibitor 1, as well as multiple serine protease inhibitors (serpins). Lee *et al.* also used LC–MS/MS to study the human ADSC secretome after treatment with TNF-α [34]. Several cytokines and chemokines (such as IL-6, IL-8, CXCL6, and MCP-1) and several proteases (including cathepsin L, matrix metalloproteinases, protease inhibitors, and PTX3) were found to be more abundant in the ADSCs preincubated with TNF-α.

Molina *et al.* [47] focused on secreted proteins that were differentially expressed during the differentiation of 3T3-L1 preadipocytes to adipocytes, a model system for studying adipogenesis. They identified 882 nuclear/secreted proteins using five-plex SILAC labeling followed by LC–MS/MS. Interestingly, THO complex 4, a context-dependent transcriptional activator in the T cell receptor alpha enhancer complex, showed its highest expression at the middle stage of adipogenesis.

Kilroy *et al.* characterized the cytokine profile of primary cultures of undifferentiated and adipocyte-differentiated human ADSCs [14] and observed HGF, a cytokine implicated in hematopoiesis and vasculogenesis, to be upregulated in the ADSC secretome after basic FGF treatment. In another study, Wang *et al.* evaluated the secretome of human BM-MSCs and ADSCs after preincubation with TNF-α. They found an increased secretion of VEGF, HGF, and IGF-I from both cell populations [15].

## 19.7 Conclusions and future perspectives

This chapter summarizes studies performed to increase knowledge on the molecular mechanisms that drive chondrogenic differentiation of MSCs, and to a lesser extent on those that drive MSC differentiation to osteogenesis and those that drive MSC differentiation to adipogenesis.

The referenced studies demonstrate the usefulness of secretome analysis for understanding the mechanisms responsible for cartilage matrix formation and have described panels of extracellular/secreted markers potentially useful for the evaluation of tissue development in cell therapy- or tissue-engineering-based approaches for cartilage repair. Further efforts should be made to improve the applicability of these strategies to clinical practice. In osteoarthritis, compounds with chondrogenic capacity have recently emerged as a good option for the development of new disease-modifying drugs [66]. The existence of validated chondrogenesis markers will be useful for all such initiatives.

## 20.1 From cell to secretion to exosome

### 20.1.1 Mesenchymal stromal cells

Mesenchymal stromal cells (MSCs) are presently the most prominent stromal cell candidate in the field of regenerative medicine. They are being tested against an increasingly wide spectrum of disease indications, as reflected in the threefold increase in MSC-based product investigational new drug (IND) submissions to the USA Food and Drug Administration (FDA) between 2006 and 2012 [1]. Four hundred trials using MSCs were listed in the ClinicalTrials.gov database hosted by the USA National Institutes of Health (http://www.clinicaltrials.gov/, as of September 2014) [2]. MSCs are multipotent stromal cells. While it is generally reported that their differentiation potential is limited to osteocytes, chondrocytes, adipocytes, and myoblasts [3], they have also been reported to differentiate into other cell types outside the mesenchymal lineage, although very few, if any, of such cells have been shown to have functional activity [4]. This potential to differentiate and replace cells in injured tissues together with the relative ease of isolating and expanding these cells *ex vivo* from ethically acceptable adult tissues has provided a compelling rationale for the use of MSCs in clinical trials [2,5–7].

With the intense clinical evaluation of MSCs as potential therapeutic agents, the initial differentiation-based rationale for their use came under heavy scrutiny and stringent evaluation. Many studies reporting functional improvement after MSC transplantation observed that MSCs' engraftment and their subsequent differentiation into appropriate cell types were rare [8–10]. Although migration, engraftment, and differentiation of MSCs at sites of injury to restore tissue function after transplantation in animal models have been widely reported, the number of cells actually reaching the target tissue is <1% of those transplanted, with most of the cells being trapped in the liver, spleen, and lung [11]. Furthermore, reported evidence for differentiation of transplanted MSCs at the site of injury was often limited to the presence of new phenotypic traits in the transplanted cells, which could be acquired through fusion with endogenous host cells [8–10]. The therapeutic efficacy of transplanted MSCs was noted to be independent of their physical

proximity to the tissue [12–15]. Together, these observations contradict the cell differentiation and replacement hypothesis and led to the proposal that MSCs mediate their effects through their secretions [16].

### 20.1.2 Cell secretion

Haynesworth *et al.* first described the paracrine effect of MSCs two decades ago when they reported that MSCs synthesize and secrete a broad spectrum of growth factors, chemokines, and cytokines that could exert significant effects on cells in their vicinity [17]. This report was followed by numerous other reports that these secreted factors enhance arteriogenesis [18], protect against ischemic renal and limb tissue injury [19], promote neovascularization [20], and increase angiogenesis [21,22]. Gnecchi *et al.* demonstrated that intramyocardial injection of culture medium conditioned by MSCs overexpressing the *Akt* gene reduced infarct size in a rodent model of acute myocardial infarction to the same extent as the cells themselves [23]. Our group subsequently demonstrated that human MSCs derived from embryonic stem cells secrete more than 200 unique gene products [24] into their culture medium and this conditioned culture medium could reduce myocardial ischemia/reperfusion injury in a pig model [25]. Together, these studies provided pivotal support for the paracrine hypothesis such that MSC therapy is increasingly rationalized on MSC secretions rather than their differentiation potential [23,26–34].

Many of the initial efforts to identify the active therapeutic agent in MSC secretion centered on small molecules such as growth factors, chemokines,and cytokines [16]. Despite many promising candidate molecules, none could sufficiently account for the efficacy of MSCs (reviewed in [35]). For example, the immunotherapeutic efficacy of MSCs [36] was reported to be mediated by small molecules such as interferon-γ (IFN-γ) [37–39], a downstream IFNγ-inducible gene indoleamine 2,3-dioxygenase (IDO) [40], and inducible nitric oxide synthase (iNOS) [41]. However, none of these factors survived subsequent scientific scrutiny. IFN-γ and IDO were eliminated as candidates when the lack of IDO production caused by either defective IFN-γ receptor 1 or IDO inhibitors failed to ameliorate the immunomodulatory activity of MSCs [42]. Additionally, murine MSCs, which do not have IDO activity, exert immunomodulatory effects similar to those of human MSCs, which do have IDO activity [43,44]. iNOS was similarly eliminated as a candidate as it was expressed in mouse but not human MSCs [36]. MSCs are also known to secrete many generic immunomodulating factors, such as transforming growth factor-β1, hepatocyte growth factor, heme oxygenase 1, interleukin (IL)-6, prostaglandin $E_2$, and human leukocyte antigen-G5 [43,45–55], and it is unlikely that any one of these factors could sufficiently mediate the immunotherapeutic efficacy of MSCs.

### 20.1.3 Mesenchymal stromal cell extracellular vesicles as the active therapeutic factor

The failure to identify the efficacious molecule in MSC secretion in the complex diseases being evaluated in MSC clinical trials is compelling evidence that the secreted agent is likely to be equally complex. As early as 2008 we observed that 0.2 μm filtered culture medium conditioned by MSCs was cardioprotective [25,33]. However, when this medium was filtered through 1000 kDa filter, the >1000 kDa retentate, but not the <1000 kDa filtrate, was cardioprotective [25], placing the protective agent as a large 100–200 nm complex. In 2009 Bruno *et al.* described the efficacy of a population of MSC extracellular vesicles (EVs), which they termed microvesicles and which ameliorated glycerol-induced acute kidney injury [56]. These microvesicles had an estimated diameter of 180 nm. The authors attributed the renal protection of these EVs to their cargo of MSC RNAs, since RNase pretreatment of the EVs abrogated the protective effect. In contrast, our group, using size-exclusion high-performance liquid chromatography, reported that the therapeutic agent had a hydrodynamic radius of 55–65 nm [29]. This agent reduced the infarct size in a mouse model of myocardial ischemia/reperfusion injury to the same extent as that of unfractionated conditioned medium [29]. Using electron microscopy, ultracentrifugation studies, mass spectrometry, and biochemical assays we subsequently established that this complex was an exosome as it carried exosome-associated markers [29] and had an endosomal origin [57]. Furthermore, the RNA cargo was relatively resistant to RNAse degradation unless the EVs were pretreated with phospholipase or detergent to solubilize the lipid membrane [58]. Thus, the renal protective EVs reported by Bruno *et al.* [56] were different from the cardioprotective EVs [29].

In the last 2 years MSC EVs have been reported to be efficacious in an increasing number of animal models of human diseases, including acute kidney injury [56], cutaneous wound healing [59], cerebral ischemia [60], liver fibrosis and injury [61,62], and hypoxic pulmonary hypertension [63]. Recently, MSC exosomes were administered to a person with treatment-refractory grade IV (severe) acute graft-versus-host disease who went into remission with a dramatic alleviation of her disease symptoms and who remained stable for 5 months [64].

## 20.2 Extracellular vesicles

EVs are membrane vesicles that are released by many cell types into the extracellular space and consist of several classes, including exosomes, microvesicles, ectosomes, membrane particles, exosome-like vesicles, or apoptotic bodies [65]. However, the defining parameters for each of these different classes are not definitive, and the use of the terms exosomes, microvesicles, and microparticles are often ambiguous and not rigorously qualified. Generally, EVs can be formed by either inward budding of endolysosomal vesicles followed by exocytosis (e.g., exosomes), or shedding from the plasma membrane (e.g., microvesicles). They have attracted much interest from the biomedical research community because of their potential as sources of biomarkers for diseases, therapeutic agents, or vehicles for drug delivery. Generally, EVs carry a cargo of proteins and nucleic acids that

reflects their cell of origin and the pathophysiological state of the cell sources. Thus, these proteins or nucleic acids could be used as biomarkers to diagnose, prognosticate, or predict disease and its progression. In addition, these EVs with their cargoes could be internalized by other cells as a form of intercellular communication, making these vesicles potential therapeutic agents or delivery vehicles of therapeutic agents [6,7,66,67].

### 20.2.1 Exosome biology and general functions

The exosome is the best characterized of all the EVs described to date and can be differentiated from other EVs by its biogenesis. The exosome is the only EV known to be derived from endosome, and this endosomal origin of exosomes is reflected in its membrane, which is enriched for lipids commonly found in lipid rafts such as cholesterol, sphingomyelin, and ceramide. Lipid rafts are specialized microdomains in the plasma membrane where much of the cellular endocytosis takes place to form endosomes. Subsequent invaginations of the endosomal membrane generate the numerous intraluminal vesicles (ILVs) within the multivesicular body (MVB). If the MVB fuses with the plasma membrane, the ILVs are released as exosomes [68]. The process by which cellular proteins and RNAs are selected and loaded into exosomes has not been elucidated. While ESCRT (endosomal sorting complex required for transport) has been implicated [69], some proteins are loaded into exosomes in ESCRT-independent higher order oligomerization or a ceramide-dependent process [70,71]. This highly regulated and energy-intensive biogenesis of exosomes indicates their biological importance.

Although the distinguishing feature of the exosome is its endosomal biogenesis, this feature is seldom used as a defining parameter for exosomes, since this is technically challenging. In practice, exosomes are usually defined by technically more amenable parameters, such as a diameter of 40–100 nm, a flotation density of 1.10–1.18 g/mL in a sucrose gradient, and exosome-associated markers such as programmed cell death 6-interacting protein (PDCD6IP, also known as Alix), TSG101, and the tetraspanins, CD9, CD63, or CD81 [72,73]. Recently, we demonstrated using pulse-chase experiments that endocytosed cholera toxin-B chains (CTBs) are released with EVs carrying exosome-associated markers. This is significant as CTB is a pentamer with a high binding affinity for GM1 gangliosides, and GM1 gangliosides are enriched in lipid rafts, which are microdomains of active endocytosis. Thus, CTB-binding activity is a robust marker for the endosomal origin of MSC exosomes, and possibly exosomes from other cell sources as well [57]. As assaying for CTB affinity is technically simple, the endosomal origin of exosomes can be easily validated.

Besides MSCs [29], many other cell types are also known to secrete exosomes. The earliest cell types reported to secrete exosomes were generally, but not exclusively, hematopoietic cells such as B cells [74], dendritic cells [75], mast cells [76], T cells [77], and platelets [78]. Additional cell types included Schwann cells [79], tumor cells [80], skeletal muscle cells [81], human embryonic kidney cells [82], various cancer cell lines [83], and sperm [84]. As a reflection of the diversity in exosome-secreting cell types, exosomes are reportedly found in nearly all extracellular fluids in the body, including bronchial lavage fluid [85], urine [86,87], saliva [88], breast milk [89], and blood [87]. However, it should be noted that the term "exosome" as used in many of these reports could be a mixture of different EV classes that may or may not include bona fide exosomes. Hence, it is possible that exosomes are in fact secreted by a limited number of cell types. To test this possibility we previously evaluated the production of $CD81^+$ CTB-binding vesicles in culture medium conditioned by several cell lines, including the murine ESC-derived insulin-producing cell line ERoSHK6 [90], the human acute monocytic leukemia cell line THP-1, the human embryonic kidney cell line HEK, primary human small airway epithelial cells, and primary human myoblasts, and myotubes differentiated from them. All the lines tested produced exosomes, but in different quantities [66]. The diversity in exosome-secreting cell types indicates that exosome secretion is a conserved cellular function; therefore, exosomes must have important biological functions. When first discovered, exosomes were thought to facilitate disposal of redundant proteins [91], but they are now generally recognized as conserved vehicles for intercellular communication in many biological systems. For example, dendritic cells when pulsed with tumor peptides secrete exosomes to mediate tumor suppression [92], neurons secrete exosome for neurotransmission [93,94], oligodendrocytes secrete exosomes to inhibit myelin membrane biogenesis [95], and exosomes from cardiomyocyte progenitor cells induce migration of endothelial cells and provide cardioprotection against ischemia/reperfusion injury [96–98].

As a conserved mode of intercellular communication to transfer materials from one cell to another, exosomes are inevitably prone to being hijacked by pathogens or diseased cells as vehicles to disseminate disease. Examples to date of exosomes being implicated as carriers of pathogenic materials from diseased or infected cells to disseminate disease include cancer (reviewed in [99]), neurodegenerative diseases such as Parkinson's and Alzheimer's diseases (reviewed in [100]), transmissible spongiform encephalopathies (reviewed in [100]), viral infections (reviewed in [101]), and bacterial infections (reviewed in [102]).

## 20.3 The therapeutic use of exosomes

The conventional forms of cell signaling are autocrine (signaling to a receptor on the same cell that secreted the signal), juxtacrine (cell contact-dependent signaling), paracrine (signaling to a nearby cell), endocrine (signaling by a hormone secreted by an endocrine gland into the bloodstream which carries the hormone to its target cells/tissues elsewhere in the body) and exocrine (secretion of a substance through a duct such as the salivary glands and sweat glands). Exosome-mediated intercellular communication differs from these types of intercellular

communications in that an exosome carries a multimolecular cargo of proteins, RNAs. and lipids that can simultaneously target multiple molecular targets in diverse processes and cell types. For example, the presence of both cytosolic and membrane proteins confers on exosomes the potential to modulate both extracellular and intracellular activities. This modulation is facilitated by the bilipid membrane of exosomes, which not only stabilizes the structural configuration, and thus bioactivity of membrane proteins, but also facilitates the cellular uptake of luminal proteins or RNA through membrane fusion or endocytosis. Exosomes also have many of the desirable attributes of a liposomal drug delivery vehicle [66,67]. Unlike liposomes, the cell-derived lipid membrane is more biocompatible with the body and thus better tolerated or internalized by the body's cells. For example, exosomes derived from dendritic cells can modulate immune responses by transferring peptide-loaded major histocompatibility complex (MHC) class I and II complexes to dendritic cells [103,104]. Exosomes have also been shown to mediate intercellular transfer of mRNAs and microRNAs that resulted in the translation of the transferred mRNA in the recipient cells [105]. We have demonstrated that MSC exosomes are internalized by H9C2 cardiomyocytes [58]. Exosomes also possess the ability to home to specific cell types. For example, melanoma exosomes have been reported to home preferentially to sentinel lymph nodes to promote tumor metastasis [106]. Their membranes could also be modified to enhance cell-type-specific targeting. For example, overexpression of a fusion gene consisting of a neuron-specific rotavirus G (RVG) encoding sequence and a lysosomal-associated membrane protein (LAMP2B) sequence encoding an exosomal membrane protein in dendritic cells resulted in the secretion of exosomes with RVG peptide on their membranes. These exosomes, after loading with small interfering RNA (siRNA), could cross the blood–brain barrier to knock down more than 60% of the siRNA-targeted gene in neurons, microglia, oligodendrocytes, and their precursors [107]. Together, these attributes of exosomes have positioned them as a promising "first-in-class" therapeutic that could potentially manipulate the activities of any cell type in the body through the introduction of exogenous cargo.

### 20.3.1 Mesenchymal stromal cell exosomes

Of all EVs known to be secreted by specific cell types, exosomes secreted by MSCs are currently the best characterized in terms of their therapeutic potential. A large part of this can be attributed to the fact that MSCs are already being used to treat an increasingly wide spectrum of diseases in animal models. More importantly, they are also one of the most clinically evaluated cell types, as evidenced by the increasing number of FDA IND submissions for them, as discussed earlier. This increased scrutiny has led to the redundancy of the differentiation-based rationale for therapeutic efficacy of MSC therapy and the emergence of a secretion-based rationale, again as discussed earlier. This rationale has evolved to an even more specific secreted entity: EVs (reviewed in [7]).

The distillation of the therapeutic potential of MSC EVs represents a logical strategy to efficiently functionalize the role of MSCs as a generic stromal support cell for the maintenance of tissue homeostasis. Such a role of MSCs is consistent with their ubiquitous presence in almost all tissues [108]. Their role as a stromal support cell is best exemplified by their maintenance of homeostasis in the hematopoietic stem cell niche in the bone marrow, such that the quiescence of hematopoietic stem cells, their self-renewal, and differentiation are in equilibrium with the needs of the body [109] (see Chapter 32), as well as in the tumor microenvironment to maintain tumor growth and dissemination (reviewed in [110]).

Tissue homeostasis is an exact state that is very susceptible to the highly dynamic and rapidly evolving fluctuations of the local tissue microenvironment. Its maintenance thus requires timely and appropriate tissue responses. In this regard, MSCs – through the secretion of exosomes with a huge cargo of diverse and biologically active molecules that includes both common exosome proteins and MSC-specific proteins [7] – are well equipped to mediate a stromal support function that induces a timely and appropriate response in the target cells as well as to directly modulate the microenvironment through proteins localized on the exosome membrane or through the release of luminal proteins. Tissue homeostasis is critical to proper and efficient tissue function and is often disrupted in disease or injury. The survival of the tissue, recovery of normal tissue function, and initiation of repair are contingent on the timely restoration of tissue homeostasis. Prolonged delay can lead to irreversible tissue damage. In this regard, EVs/exosomes carrying a complex cargo of biologically active materials encapsulated within a receptor-studded lipid membrane represent the most efficient means to effect a timely restoration of tissue homeostasis. Hence, we postulate that MSCs exert their stromal support function through their exosomes to restore tissue homeostasis to diseased and injured tissues and to facilitate tissue repair and regeneration. This generic mechanism of action could rationalize the efficacy of MSCs in a wide spectrum of diseases and tissue injuries. It could also rationalize the contradicting observations that MSC exosomes both support [111–113] and suppress [114–116] tumor growth, tumor survival, and metastasis. Depending on the stage of tumor growth and the host's response to it, restoration of homeostasis to a tumor microenvironment by MSC exosomes may alleviate host-mediated disruption of the tumor microenvironment and support tumor growth, or abrogate tumor-mediated disruption to restore normal tissue homeostasis and enhance the host's antitumor response.

Evaluation of this hypothesis requires elucidation of the mechanism of action in MSC exosome-mediated therapy. The first premise for such a hypothesis must be the presence of a biochemical potential that could restore homeostasis in fundamental biological processes, and this would in turn require the characterization of the MSC exosome, its cargo, and its biochemical potency.

### 20.3.2 Characterization of mesenchymal stromal cell exosomes

Biochemically, the MSC exosome is a bilipid membrane vesicle with a receptor-studded membrane and luminal cargo of proteins and RNA. While the composition of the MSC exosome determines its biological potency, the MSC exosome should be viewed as a single biological entity and its function is more than a sum of its parts. When this entity is compromised, as in physically disrupted MSC exosomes, they are no longer cardioprotective [117].

As a first-principle approach to elucidate the biological activity of MSC exosomes, we interrogated the biochemistry of the MSC exosome. We had previously demonstrated that the MSC exosome has a cholesterol-rich phospholipid membrane [118] and that this membrane is derived from lipid rafts, which are relatively rigid cholesterol-rich microdomains in the plasma membrane [57]. Lipid rafts are microdomains in the plasma membrane, where most of the cellular endocytic activity is localized, and are enriched in rare phospholipids (such as GM1 gangliosides) and receptors (such as transferrin receptors). By pulse–chase experiments, we have demonstrated that MSC exosomes are derived from GM1-ganglioside-rich and transferrin-receptor-rich lipid rafts in the plasma membranes. Labeled ligands such as CTB (which binds GM1 gangliosides) or transferrin (which binds transferrin receptors) can be chased into exosomes after a short pulse [57].

We have also characterized the protein and RNA cargo of MSC exosomes. The proteins and RNAs are protected by a phospholipid membrane and are relatively resistant to enzymatic degradation by protease or RNAse [58,118]. This resistance is abrogated by pretreatment with phospholipase or detergent. Proteomic analysis of MSC exosomes by mass spectrometry and antibody arrays revealed a large diverse protein cargo of more than 800 unique proteins (www.exocarta.org) [7,119]. To ensure a better coverage of the exosome proteome, mass spectrometry, which has a limited dynamic range of detection, had to be complemented with antibody arrays to detect known proteins or peptides that are too small to be efficiently detected by mass spectrometry.

The RNA cargo of MSC EVs has been analyzed using microarray hybridization [58], polymerase chain reaction [120], and sequencing [121]. The coverage by the former two methods is limited to known RNAs, and both studies focused primarily on microRNAs. The first study reported the enrichment of pre-microRNAs in MSC exosomes and the absence of RNA-induced silencing complex (RISC)-associated proteins [58]. The second study using MSC microvesicles showed that, in addition to microRNAs, MSC microvesicles also contain proteins that are involved in the stability, transport, and processing of both mRNAs and microRNAs. Of the three methods, sequencing, which provides the best coverage, revealed the presence of mRNA and microRNAs in MSC exosomes.

### 20.3.3 The biochemical potential of mesenchymal stromal cell exosomes

The MSC exosome was found to contain at least 800 proteins (www.exocarta.org) [119] and >150 microRNAs [58]. The elucidated proteome of MSC exosomes was diverse and had a vast functional distribution. Collectively, the exosomal proteins were computationally predicted to be active in a wide array of biochemical and cellular processes, including communication, structure and mechanics, inflammation, exosome biogenesis, tissue repair and regeneration, and metabolism. Many of the proteins were biochemically active enzymes or enzyme complexes. The diversity of protein functions could potentially underpin the widely ranging therapeutic efficacy of MSCs, while their distribution across broad ranging cellular functions could provide the biochemical bandwidth to act against diverse and complex diseases or tissue injuries. At this time, the RNA composition of MSC exosomes has not been sufficiently characterized for meaningful analysis. Nevertheless, we note here that, unlike other exosomes reported to date, MSC exosomes are significantly enriched for precursor microRNAs and do not contain any of the RISC components, such as Dicer and Ago2 [58]. (Dicer, also known as endoribonuclease Dicer or helicase with RNase motif, is an enzyme that is part of the RNase III family. Dicer cleaves double-stranded RNA and pre-microRNA into short double-stranded RNA fragments called siRNAs and microRNAs respectively. Ago2 is a member of the Argonaute protein family, which are key players in gene-silencing pathways guided by small RNAs. Small RNAs, such as siRNAs, microRNAs, or Piwi-interacting RNAs, are anchored into specific binding pockets and guide Argonaute proteins to target mRNA molecules for silencing or destruction.)

This preferential sequestering of pre-microRNAs in exosomes demonstrated that the loading of microRNAs into MSC exosomes involved a high degree of regulation. In the absence of RISC elements, the enrichment of pre-microRNA ensures that, upon uptake by recipient cells, exosomes have the potential to exert microRNA-mediated biological activity through the uploading of pre-microRNAs on to the RISC.

Exosome-associated proteins (defined as those proteins found in at least 50% of exosomes) that have been characterized to date include glyceraldehyde 3-phosphate dehydrogenase (GAPDH), pyruvate kinase (PK), eukaryotic translation elongation factor 1A1, milk fat globule epidermal growth factor factor 8 protein, tetraspanins, 14-3-3 proteins, Gα proteins, clathrin, PDCD6IP (also known as Alix), MHC class I, annexins, Rab proteins, the ERM family of proteins (ezrin, radixin, and moesin), actin, tubulin, and heat shock proteins 70 and 90 [7,122].

When analyzed by PANTHER (protein analysis through evolutionary relationships) [123,124], the proteins in the MSC exosome could be functionally clustered into 32 overrepresented and 3 underrepresented biological processes [7,119]. A significant number of the processes, such as the trans-Golgi network, intracellular protein trafficking, general vesicle transport, endocytosis, receptor-mediated endocytosis, other protein targeting

and localization, and exocytosis, are associated with the biogenesis and release of exosomes.

Exosomes are formed through the invagination of the endosomal membranes to form ILVs in the MVBs. The fusion of MVBs with the plasma membrane results in the release of ILVs as exosomes. The mechanism of sorting of proteins, membranes, and possibly RNAs into endosomes and then laterally into ILVs has not yet been well defined. Both ESCRT and ESCRT-independent processes, such as higher order oligomerization or a ceramide-dependent process [70,125], have been implicated in the sorting of exosomal proteins (reviewed in [68]). The presence of ESCRT-associated proteins in MSC exosomes [7,119] and the dependence of MSC exosome production on sphingomyelinase [57] suggest that the loading of the MSC exosome is ESCRT- and ceramide-dependent.

There were also many processes revealed in the analysis of the MSC exosome that are relevant to intercellular communication, cellular motility, inflammation, development and differentiation of mesodermal and ectodermal tissues, including skeletal development and angiogenesis, and fundamental catabolic and anabolic metabolic processes, such as glycolysis. These processes are highly relevant to the maintenance of the tissue microenvironment and cellular homeostasis since they are usually activated or compromised during tissue injury from disease or trauma. These processes need to be restored to baseline homeostasis for the return to normalcy. An interesting feature of the MSC exosome is the underrepresentation of biological processes involved in regulating gene expression at the transcriptional level, suggesting that the MSC exosome probably does not exert its effect through gene expression.

### 20.3.4 Biochemical potency

The computationally predicted processes based on the proteome of exosomes provide an insight into the biochemical potential of MSC exosomes and generate useful testable hypotheses. Given our initial perception of the exosome as a means for disposal of redundant proteins, there is a possibility that the biochemical potential of exosomes has already been expended prior to their loading into the exosomes. Therefore, the computationally predicted processes had to be biochemically validated for potency in modulating cellular processes. Two of these processes will be discussed later (Figure 20.1).

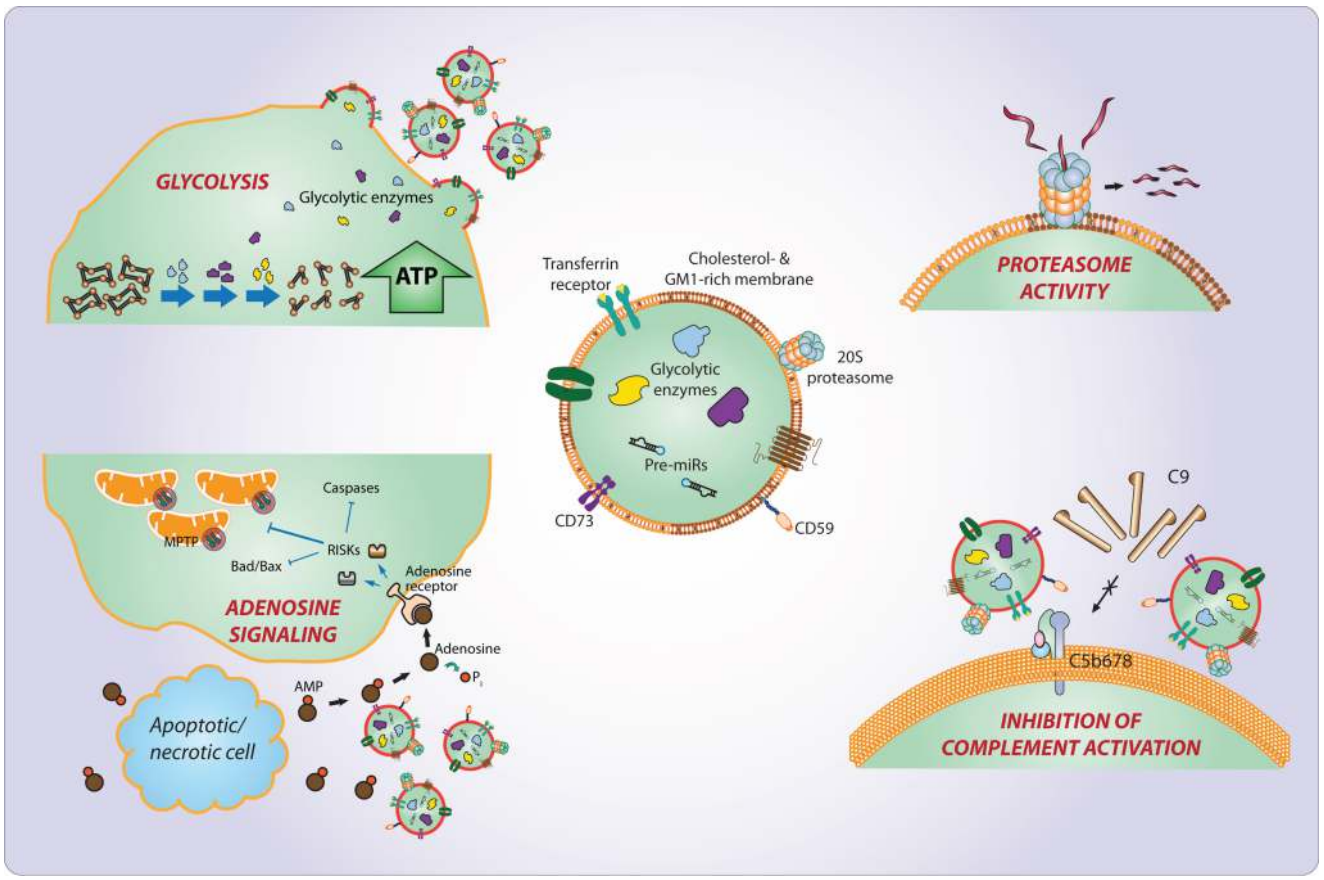

**Figure 20.1** Biochemical potential of MSC exosomes. MSC exosomes contain characteristic features, including a cholesterol- and GM1-rich membrane, transferrin receptors and microRNAs (miRNAs) predominantly in the precursor forms. In addition, they also contain glycolytic enzymes, 20S proteasome, CD73, and CD59, which play key roles in mediating bioenergetics homeostasis, immunoproteasome activity, adenosine-mediated survival signaling, and complement inhibition respectively. RISKs: reperfusion injury salvage kinases. (See color plate section.)

### 20.3.5 Glycolysis

One computational prediction is the capacity of MSC exosomes to drive glycolysis, a fundamental cellular process that is critical in the production of adenosine-5′-triphosphate (ATP) and intermediate metabolites for growth, proliferation, and repair. In MSC exosomes all five enzymes that drive ATP production in glycolysis, namely GAPDH, phosphoglycerate kinase (PGK), phosphoglycerate mutase, enolase, and PK isozyme M2 (PKm2) were present. Importantly, the three enzymes that generate either ATP or the reduced form of nicotinamide adenine dinucleotide (NADH) (GAPDH, PGK, and PKm2) were also enzymatically active [7]. When MSC exosomes were incubated with H9C2 cells that had been treated with oligomycin to inhibit mitochondrial ATPase and oxidative phosphorylation [126], an increased intracellular ATP level was observed within minutes, possibly through glycolysis. This capacity to increase glycolysis has an additional implication as glycolytic intermediates are essential in anabolic reactions to generate biomass for growth and repair (reviewed in [127]) and are critical in anabolic activities to rebuild damaged tissues.

### 20.3.6 Proteasome activity

Proteasomes are protein complexes inside all eukaryotes and archaea (single-cell microorganisms) and in some bacteria. In eukaryotes they are located in the nucleus and the cytoplasm. The main function of the proteasome is to degrade unneeded or damaged proteins by proteolysis, a chemical reaction that breaks peptide bonds. Enzymes that help such reactions are called proteases. Proteasomes are part of a major mechanism by which cells regulate the concentration of particular proteins and degrade misfolded proteins. The proteasome subcomponents are often referred to by their Svedberg sedimentation coefficient (denoted *S*). The proteasome most exclusively used in mammals is the cytosolic 26S proteasome, which is about 200 kDa in molecular mass containing one 20S protein subunit and two 19S regulatory cap subunits. Immunoproteasomes contain replacements for the three catalytic subunits of standard proteasomes. In most cells, oxidative stress and proinflammatory cytokines are stimuli that lead to elevated production of immunoproteasomes. Immune system cells, especially antigen-presenting cells, express a higher basal level of immunoproteasomes.

The MSC exosome carries all seven α and seven β chains of the 20S proteasome, and the three β subunits of "immunoproteasome," but not the components of the 26S proteasome [119], suggesting that it carries functional 20S proteasome and immunoproteasome, which is the catalytic core of the 26S proteasome. Consistent with this, MSC exosomes exhibited proteolytic activity that was sensitive to lactacystin, a proteasome-specific inhibitor [119].

### 20.3.7 Signaling: adenosine signaling

One of the characteristic surface markers of MSCs is CD73, which is also found on its exosomes as well as exosomes secreted by other cell types. CD73 is an ecto-5′-nucleotidase and is the only enzyme known to hydrolyze extracellular adenosine monophosphate (AMP) to adenosine [128]. Adenosine is a key activator of extracellular signal-regulated kinase (ERK) and AKT (protein kinase B) phosphorylation and plays a nonredundant role in attenuating inflammation and tissue damage (reviewed in [129]). In mammals, adenosine is produced by the degradation of extracellular ATP and adenosine diphosphate (ADP) that are released during tissue trauma (reviewed in [130]) and has a half-life of <10 s [131]. CD73 in the MSC exosome is enzymatically active, and, in the presence of AMP, MSC exosomes induced phosphorylation of AKT and ERK through a theophylline-sensitive receptor [7].

### 20.3.8 Inhibition of complement activation

CD59 is a small glycosylphosphatidylinositol (GPI)-anchored glycoprotein that plays a crucial role in preventing autologous complement-mediated lysis [132]. It is not only widely expressed in most tissues and in all circulating cells, but is also expressed on exosomes produced by many cell types [133]. The complement system, which consists of at least 30 serum proteins, is a first line of innate immune defense that clears invading microorganisms and cellular debris and activates proinflammatory responses (reviewed in [134], and see Chapter 33). Upon activation the complement system initiates a proteolytic cascade that generates several key defense products, such as C3b, C5a and C5b. This cascade culminates in the formation of the membrane attack complex (MAC) consisting of C5b, C6, C7, C8, and polymeric C9. MAC deposition on target cells results in the formation of a transmembrane channel to cause cell lysis. This lysis is inhibited in cis by CD59 present on the cell membrane [135]. The MSC exosome can inhibit MAC-mediated cell lysis, and this inhibition is abrogated by neutralizing CD59 antibody, suggesting that the MSC exosome can exert a CD59-mediated inhibition of MAC in a trans-acting manner. This possibility is supported by observations that soluble recombinant CD59 could also inhibit MAC formation, albeit less efficiently than GPI-linked CD59 [136,137].

### 20.3.9 Restoring homeostasis

Although MSC exosomes have the biochemical potential to modulate many processes, their efficacy in effecting the stromal support functions of MSCs and maintaining a dynamic homeostatic tissue microenvironment also depends on their versatility and capacity to interact with multiple cell types, both within their immediate vicinity and in remote areas, to elicit appropriate cellular responses.

It is unknown if the MSC exosome cargo resides in one exosome type or is distributed across several exosome or EV types. Additionally, a key requisite of the MSC exosome in mediating the role of MSCs as stromal support cells in order to maintain tissue homeostasis and to respond to the external environment is the capacity to calibrate their biological activity. Based on the enzyme-rich proteome of MCS exosomes, we have previously proposed that much of the therapeutic activity of the MSC exosome is enzymatic [7]. This has critical implications in

maintaining homeostasis, as enzymatic activity can be calibrated (i.e., amplified or inhibited) according to the microenvironment. When a tissue is in homeostasis most biological processes, such as substrates and products, would be in equilibrium, such that additional enzymes would not affect the rate of processes. During injury, when there are changes in substrate/product concentration, pH, or temperature, such that equilibrium is lost and homeostasis is disrupted, the rate of process through modulation of enzyme activity will be altered until equilibrium is restored. The degree of modulation would be calibrated to the degree of change, which in turn would be proportional to the severity of the injury. Thus, enzyme-based activity could potentially elicit a scalable biological response to restore homeostatic equilibrium and as such, mitigate the risk of overdosing or underdosing.

In addition to their biochemical potency, MSC exosomes have the capacity to protect and deliver molecules to the appropriate targets. By encapsulating enzymes within the exosomal membrane, exosomes not only protect their protein and RNA cargo against degradation, but also facilitate the intracellular uptake of enzymes through endocytosis of exosomes by the target cells [58]. We have previously reported that exosome proteins and RNAs are protected against proteinase activity and that this protection is abrogated by pretreatment with phospholipase, a cholesterol chelator or detergent [58,118]. The membrane functions beyond its physical role as a protective barrier since physical disruption of the exosomes without compromising the enzymatic activity of its cargo led to the loss of its cardioprotective function [117].

As with MSCs themselves, MSC exosomes are immune privileged. Administration or exposure of MSC exosomes to animals or immune cells did not elicit an inflammatory response [138]. As exosome uptake has been shown to be dependent on intracellular and microenvironmental acidity [139], and as tissue injury is often characterized by tissue acidosis [140–146], exosomes could be preferentially endocytosed by cells in an injured tissue. Thus, exosomes could home to injured tissues. Indeed, we have observed that uptake by MSC exosomes by H9C2 cardiomyocytes is accelerated in acidic culture medium (unpublished data). Furthermore, the small size of exosomes facilitates their transportation through the blood and other biological fluids to interact with cells in a paracrine and endocrine manner. Thus, exosomes have the biophysical capacity to mediate MSC interactions with multiple cell types both intracellularly and extracellularly in both local and remote areas. Next, we illustrate the biochemical and biophysical capability of MSC exosomes in modulating bioenergetic homeostasis and immune homeostasis.

### 20.3.10 Bioenergetic homeostasis

The first reported therapeutic efficacy of MSC exosomes was their amelioration of myocardial ischemia/reperfusion injury [118]. This injury is characterized by significant temporal quantitative changes in the cardiac proteome after 30 min of ischemia and persists for up to 120 min after reperfusion [147]. The most marked changes were associated with ATP production and apoptosis. In the case of ATP production, the ischemic and reperfused cardiac tissues were severely depleted of the rate-limiting enzymes in fatty acid oxidation, glycolysis, and the tricarboxylic acid (Krebs) cycle. As such, ATP production was curtailed during both ischemia and reperfusion, leading to an ATP deficit that was refractory to the restoration of oxygen during reperfusion. We have previously proposed that part of the therapeutic efficacy of MSC exosomes is mediated by restoring bioenergetic homeostasis. This is achieved by proteomic complementation to compensate for the loss of ATP-generating enzymes with ATP-generating glycolytic enzymes [148]. The RNA component of the MSC exosome is not likely to be the active therapeutic agent in ATP-deficient cardiac tissues since RNA generally exerts its biological activity through ATP-dependent RNA translation or degradation. In contrast, glycolytic enzymes are often driven by the relative ratio of substrate to product such that enzymatic activity is often calibrated directly to substrate concentration and inversely to product concentration. Hence, the presence of all enzymes in the ATP-generating phase of glycolysis would enable MSC exosomes to increase glycolytic flux and ATP production until bioenergetics homeostasis is restored. Thus, the concentration of substrates and products reaches equilibrium and the flux moderates to a steady state.

An important caveat in this hypothesis is that proteins in the MSC exosome can be internalized by cardiomyocytes. In general, our hypothesis that MSC exosomes reduced reperfusion injury in ischemic heart tissues by restoring bioenergetics homeostasis is consistent with our experimental observations. Indeed, MSC exosomes are internalized by H9C2 cardiomyocytes [104]. In a mouse model of myocardial ischemia/reperfusion injury, exosome-treated animals exhibited an increased ATP/ADP ratio that was concomitant with improved cardiac function [117].

### 20.3.11 Immune homeostasis

Immune homeostasis refers to physiological equilibrium between attack and defense mechanisms against pathogens, foreign or diseased tissues, and tolerance for self. This equilibrium is maintained by checks and balances involving many immune cell types and soluble mediators. Dysregulation of immune homeostasis compromises the body's defense and self–nonself recognition, leading to disease or autoimmunity.

We have previously demonstrated *in vitro* that MSC exosomes induce polarization of regulatory T cells (Tregs) through the activation of monocytes [138]. BALB/cJ mice ($H2^d$ genotype) were grafted with tail skin from C57BL/6J mice ($H2^b$ genotype, and thus mismatched for all the antigens of the MHC with BALB/cJ mice). The BALB/cJ recipients were then given subcutaneous injections of 0.3 μg exosomes in 50 μl phosphate-buffered saline (PBS) or of 50 μl PBS as control. The exosome-treated and PBS-treated mice took 13 days and 11 days respectively to reject the skin grafts. The level of Tregs was significantly higher in the spleens of exosome-treated recipient animals than in the PBS-treated animals. However, Treg induction was not observed in the spleens of non-grafted mice that were given the same

exosome regimen. Intrasplenic injection of either exosomes or PBS did not induce a higher Treg level in exosome-treated animals. The MSC exosomes induce Tregs only when the immune system is activated. Since Tregs are immunosuppressive, the induction of Tregs by MSC exosomes in an activated immune system demonstrated that MSC exosomes can attenuate immune activity and enhance the restoration of immune homeostasis. Conversely, as MSC exosomes did not elicit Treg induction in mice that had not been immunologically challenged, MSC exosomes do not induce immune suppression and disrupt immune homeostasis in normal animals.

In summary, MSC exosomes induced expansion of Tregs in animals whose immune system was stimulated. In animals without immune stimulation, MSC exosomes had no effect on Treg expansion. Thus, MSC exosomes are not immunosuppressive but are immune modulatory.

## 20.4 The clinical translation of mesenchymal stromal cell exosomes

The discovery that MSC therapeutic activity is mediated by exosomes could potentially transform MSC therapy from a cell-based approach to a biologic-agent-based approach. This change has wide-ranging ramifications. Cell-based therapies pose significant risks and challenges in manufacture, storage, delivery, safety, and regulation. Eliminating these requirements would reduce the complexity of the manufacturing, processing, and storage processes, resulting in increased reproducibility, lower costs, and better quality control and assurance. The risks inherent in the use of stromal cells include the risk of occlusion in the microvasculature after intravenous or intra-arterial administration, which can cause embolism and death [149]. Theoretically, differentiation of MSCs into inappropriate cell types could cause complications such as tumor development, immune rejection, proarrhythmic side effects [150–152], or ectopic calcifications [153]. In practice, however, these complications have not occurred in human recipients of MSCs administered either intravenously or intra-arterially.

MSC exosomes being part of MSC biology cannot pose greater risks than MSCs themselves. Their small size mitigates some of the theoretical risks of MSC administration. It is possible that their use would be safer and cheaper than MSCs.

An important factor in the translation of MSC exosome into the clinic is the manufacturing process and the most important requisite is the cell source. Ideally, the cell source would be a high exosome-yielding clonal cell line with a very large expansion potential to ensure reproducible cost-effective production of exosomes. Exosome production by MSCs is inversely correlated with the age of the MSC donor, such that MSCs derived from human embryonic stem cells produce the most exosomes per cell, followed by those derived from fetal tissues, umbilical cord, and adult bone marrow [154]. Human MSCs derived from embryonic stem cells or induced pluripotent stem cells (see Chapter 31) may the best candidate cell source for exosome production. Additionally, human embryonic stem-cell-derived MSCs can be immortalized with a *MYC* transgene and cloned without compromising the yield or quality of the exosomes [155], although the use of a potential oncogene for this purpose would be unacceptable to both clinicians and regulatory authorities. Notably, however, MSC exosomes do not have detectable MYC protein or RNA, which is consistent with the general lack of transcription factors in the proteome of exosomes [24].

## 20.5 Conclusions

Through the iterative process of scientific enquiry in animal models and clinical studies, the use of MSCs for potential treatment purposes has been evolving to a cell secretion-based approach. Among the many candidates proposed as the therapeutic agent in MSC secretions, the MSC exosome has emerged as a promising candidate. Based on the biochemical potency of its diverse cargo of proteins and RNA, MSC exosomes could underpin the potential efficacy of MSCs against diverse and complex diseases by functionalizing the stromal support role of MSCs in restoring and maintaining tissue homeostasis. The use of MSC exosomes as therapeutic agents instead of cells may simplify MSC-based therapy across the entire value chain of manufacturing, storage, delivery, and regulatory oversight. This could lead to a more affordable drug. The use of exosomes also mitigates the risks associated with the transplantation of cells. Nevertheless, the clinical development of the MSC exosome as a drug faces challenges in manufacturing and regulatory oversight that are unique to a potential first-in-class drug.

## 21.1 Introduction

Cardiovascular diseases are the main cause of death in Western countries. Fundamentally, this is due to the poor ability of dead myocardium to self-regenerate. Cell therapies represent one of the most promising approaches to rebuild the damaged heart, particularly those based on mesenchymal stromal cells (MSCs) owing to their unique properties and clinical safety. Nevertheless, despite a flurry of studies reporting the cardiac functional benefits of MSC delivery in various experimental small and large animal models of myocardial infarction, clinical trials in humans have revealed mixed results, emphasizing the need to maximize the therapeutic effectiveness of MSCs. Gaining new insights into the mechanisms underlying the regenerative effects of MSCs appears to be of critical importance. According to recent studies, these mechanisms seem to be governed by the recipient microenvironment in which MSCs support the cell-to-cell communication between the transplanted MSCs and resident neighboring cardiac cells to play a critical role in the wound healing processes.

In this chapter, after a brief introduction on the potential of MSCs in cardiac cell therapy, we will present an overview on whether cell-to-cell communication of MSCs with distressed cardiomyocytes alters MSC behavior by specially focusing on the role of tunneling nanotube (TNT)-mediated intercellular connections.

## 21.2 Mesenchymal stromal cells as a promising tool to regenerate damaged heart tissue

### 21.2.1 Degenerative cardiac diseases: a major public health problem

Heart disorders are a major health concern worldwide and responsible for millions of death every year. In particular,

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.

myocardial infarction is the cardiac disease with the most severe social and economic consequences as it affects more than 6.5 million people in Europe and more than 5 million in the USA [1].

High mortality associated with acute myocardial infarction (AMI) is due to the inability of the heart to replenish the pool of cardiomyocytes massively depleted after the ischemic insult. As a consequence, dead myocardium is replaced by a fibrotic scar, which is the cause of the development of heart failure and cardiac arrhythmias [2,3].

Until now, rebuilding damaged heart has remained a major challenge in regenerative medicine. Although pharmacological and surgical interventions, including coronary revascularization (coronary artery bypass grafting or coronary angioplasty with or without stenting) and multisite pacemakers (in which the left and right ventricles are stimulated at the same time by a pacemaker implanted in the right ventricle and another implanted in the left ventricle), have been successful in reducing the progression of myocardial fibrosis [4,5], these approaches are inefficient in promoting regeneration of the damaged heart. Consequently, they are only able to prolong survival of many patients for the short term. When patients become refractory to optimal current standard therapies, heart transplantation is considered as a last therapeutic option. Nevertheless, only a restricted number of subjects can benefit from such treatment due to the lack of sufficient heart donors, the transplant complications, and the excessive economic costs. In order to face up to these current therapeutic limits, it appears of critical importance to develop novel alternative therapies to achieve widespread regeneration of dead myocardium. In this regard, cell-based therapies, and in particular those based on the use of MSCs, have appeared as one of the most promising approaches to heal heart damage.

### 21.2.2 Mesenchymal stromal cells: a promising tool to treat the effects of myocardial infarction

Recently, cell-based treatment strategies have been introduced as an alternative to rebuild damaged heart tissue and prevent adverse cardiac remodeling and heart failure by allowing the recolonization of the infarcted area with new viable and contractile cardiomyocytes. During the last few years, many stem or progenitor cell populations from a variety of tissue sources have been tested in experimental or clinical settings for their cardiac regenerative ability (Figure 21.1).

Among cell populations tested are skeletal myoblasts, fetal and neonatal cardiac stromal cells, endothelial progenitor cells, embryonic stem cells (ESCs), and induced pluripotent stem cells (iPSCs), the latter two after their differentiation into cardiomyocytes [6–8]. Although, studies have shown that all these cell populations ameliorated heart function when delivered into animals in which an AMI had been induced, translation toward the clinic was seriously hampered by several hurdles inherent to the type of cells used. For instance, the most serious complication of using skeletal myoblasts in humans with AMI was the risk of inducing cardiac arrhythmias due to the lack of electrophysiologic coupling between transplanted skeletal myoblasts following their differentiation into skeletal myofibers with resident cardiomyocytes. As a consequence, a high incidence of sudden death in recipients of skeletal myoblasts has been reported in clinical trials [9–11].

In contrast to skeletal myoblasts, ESCs as well as fetal or neonatal cardiac stromal cells have been shown to differentiate into functional cardiomyocytes *in vivo* and thus were expected to efficiently replenish the dead myocardium. Nevertheless, the use of these cells in the clinic is compromised by limited tissue supply, ethical concerns, the risk of immune rejection, and the risk of teratoma formation should any undifferentiated ESCs remain in the transplantation of the cardiac-differentiated progeny [12–15]. A teratoma is a tumor with tissue or organ components resembling normal derivatives of more than one germ layer. Teratomas have been reported to contain hair, teeth, bone, and, very rarely, more complex organs or processes such as eyes, torso, hands, or feet. Because they are encapsulated, teratomas are usually benign, although malignant teratomas can occur. The risk of teratoma formation due to transplantation of stem cells is thought restricted to the use of ESCs or iPSCs. Teratomas have not been reported to date as a consequence of the transplantation of MSCs.

In an attempt to overcome the ethical and immunological issues encountered with the use of ESCs, rodent and human fibroblasts have been successfully reprogrammed to a pluripotent state through the introduction of several pluripotency-regulating genes. However, the discovery of such ESC-like cells called iPSCs did not unfortunately resolve the aforementioned risk of teratoma formation with the use of ESCs [16–19]. In fact, teratoma formation is one of the routine tests performed on putative ESCs or iPSCs to demonstrate their pluripotent ability.

In order to avoid the complications inherent in the use of ESCs and iPSCs, scientists have paid particular attention to MSCs, as they seem to fulfill the ethical and clinical criteria required for their administration to humans. MSCs are able to differentiate into a broad range of specialized cell types *in vitro*, including adipocytes, osteoblasts, chondrocytes, and also muscle cells, such as cardiomyocytes [20–24], although the latter finding remains controversial. MSCs have been successfully isolated from many different tissues, including skeletal muscle [25], dental pulp [26], synovial membrane [27], lung [28], umbilical cord blood [29], amniotic fluid [30], placenta, and skin [31], although the most studied remain those derived from bone marrow [32] or adipose tissue [33–35]. Interestingly, these cells can be obtained in clinically relevant numbers, can be expanded in large scale *in vitro*, and can be cultured in simple growth medium conditions [36–38]. Furthermore, MSCs exhibit immune privileged behavior, raising the possibility of using them as universal regenerative cells for allogeneic transplantation, without any need for histocompatibility between the MSC recipient and the MSC donor [39].

Studies performed during the last decade strongly indicate that intramyocardial delivery of MSCs ameliorates heart function

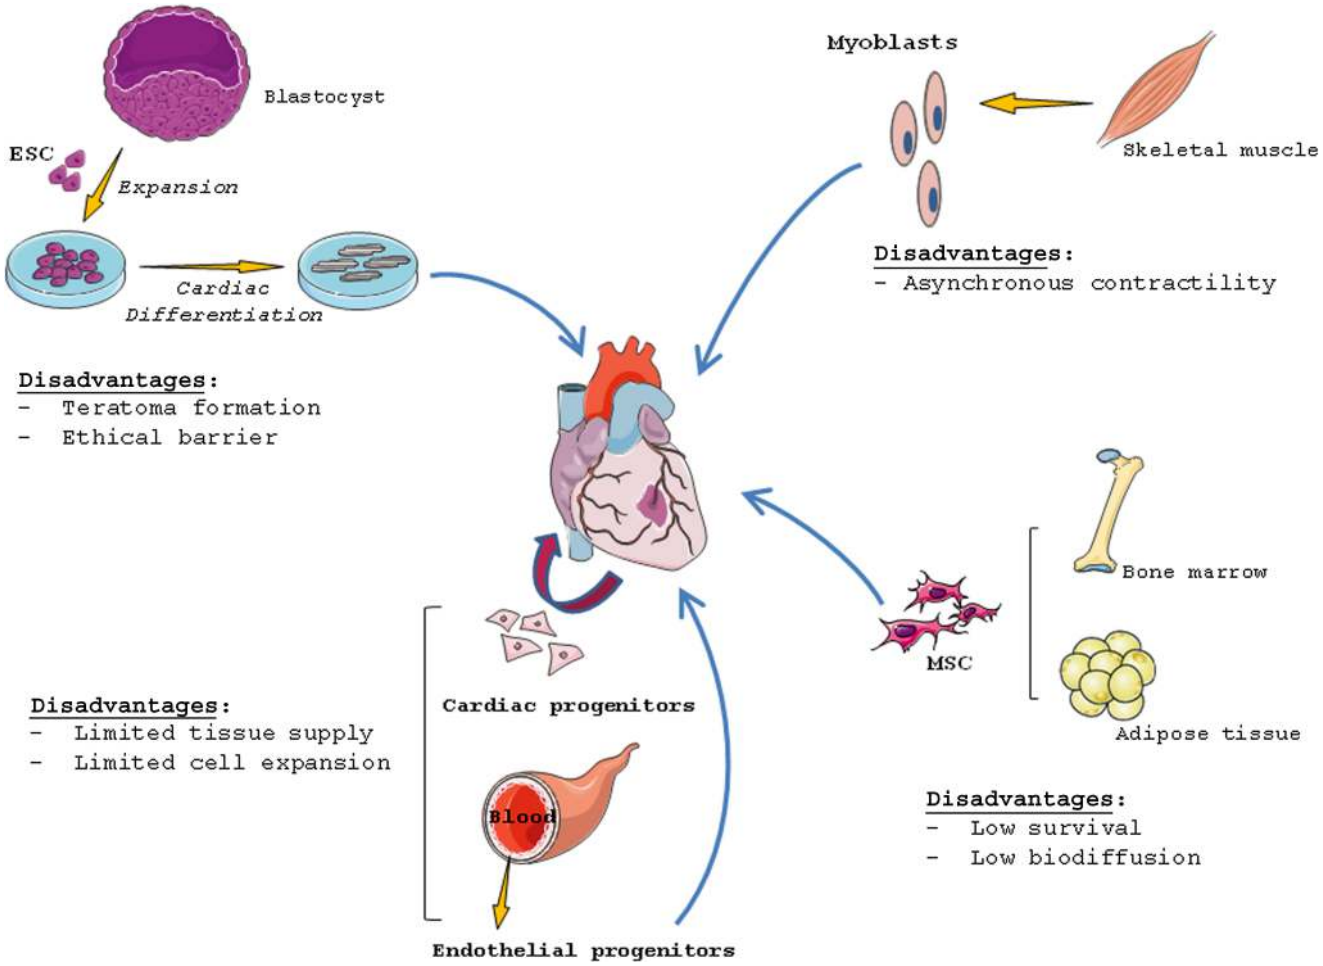

**Figure 21.1** The different kinds of cells used or potentially usable for treatment of cardiac disease. Embryonic stem cells (ESC) must be differentiated into cardiomyocyte-like cells before they can be injected into diseased heart tissue. Skeletal myocytes differentiated into multinucleated myofibers when engrafted into diseased heart. Cardiac progenitors and endothelial progenitors ameliorate heart function primarily by differentiating into cardiomyocytes or endothelial cells respectively. MSCs promote heart repair without significant cardiomyocyte transdifferentiation, but rather by indirect cytoprotective effects. Clinical limitations of the use of each cell type are mentioned in the figure. This figure was produced using Servier Medical Art.

after experimental infarction in different animal models [40–42]. However, such positive findings are less evident in clinical trials, as delivery of MSCs to diseased human hearts did always achieve robust and long-term functional cardiac recovery [43], although, again, this is controversial (see Chapter 45). The disappointing outcomes of some trials underscore the need to develop a greater understanding of the mechanisms underlying the therapeutic benefits of MSCs in the attempt to maximize their effectiveness as a therapy for repair of damaged cardiac tissues.

### 21.2.3 Mechanisms underlying the regenerative effects of mesenchymal stromal cells

Various mechanisms have been proposed for the therapeutic effect of MSC treatment on impaired cardiac function (Figure 21.2).

Transdifferentiation of MSCs into cardiomyocytes or vascular cells [44–46] and permanent cell fusion with resident cardiomyocytes leading to formation of binucleated heterokaryons or hyperploid synkarions [47,48] were initially reported as regenerative modalities employed by MSCs to improve heart function. Nevertheless, the rare occurrence of these processes has cast doubts on their functional impact [47–49].

Another body of published works indicated that MSCs ameliorated cardiac dysfunction by the release of soluble factors. According to these studies, the cardioprotective paracrine action of MSCs is manifested in different ways, including the promotion of new vessel formation, protection of cardiomyocytes against apoptosis, induction of a beneficial extracellular matrix remodeling, and modulation of postinfarction-associated inflammation [50–55]. In addition, some of these studies indicated that MSCs also stimulated myocardial regeneration through the recruitment of bone-marrow-derived stromal cells to the injury site and the activation/differentiation of resident cardiac progenitor cells [50–53].

Recently, a new concept has emerged proposing that the regenerative capacities of infused MSCs might be stimulated

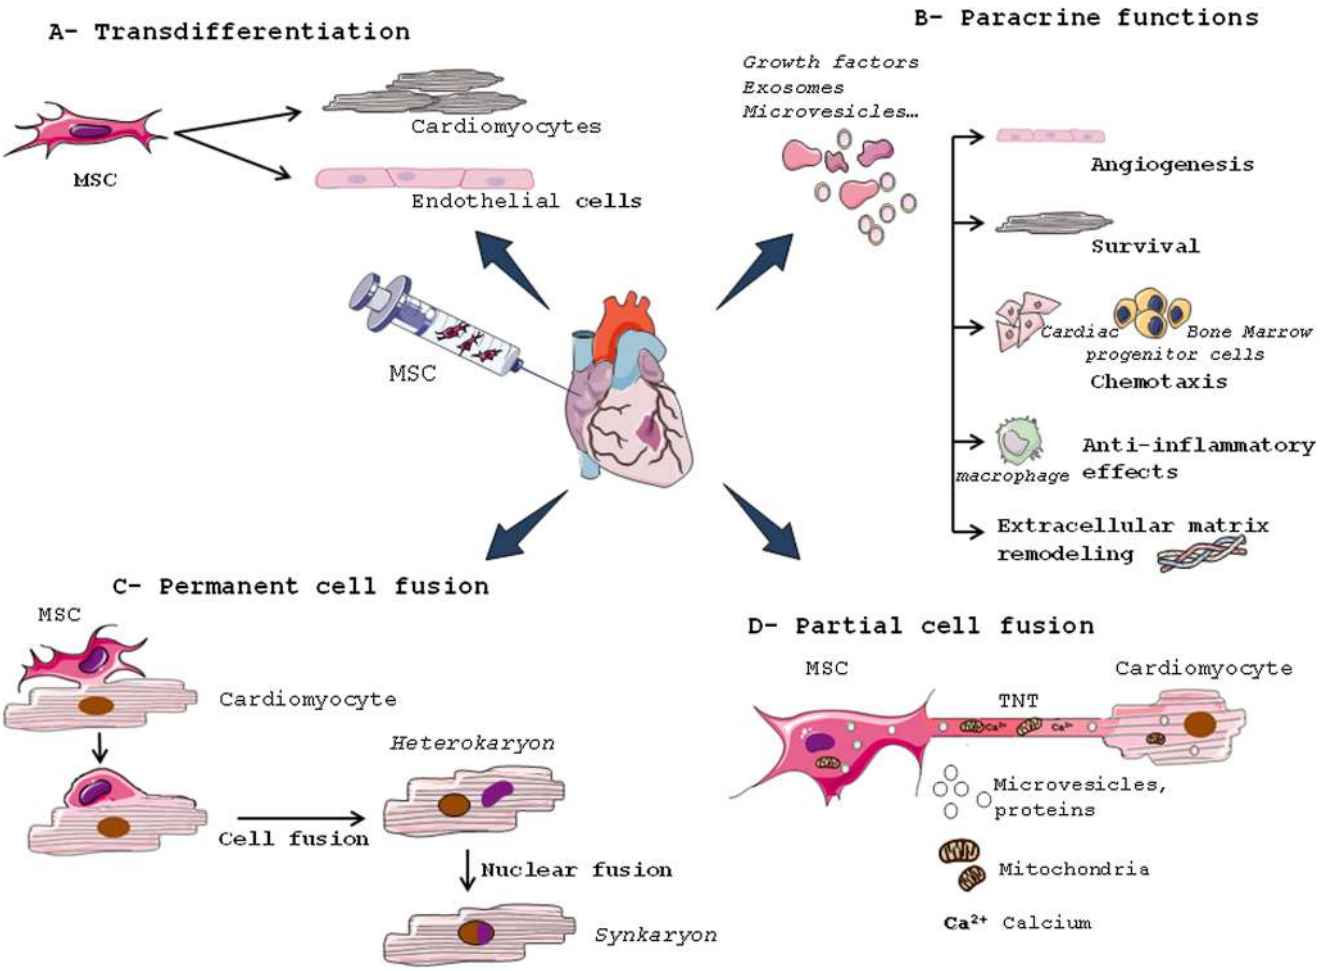

**Figure 21.2** Regenerative mechanisms employed by MSCs to repair damaged myocardium. MSCs can: (A) possibly differentiate into cardiomyocytes and endothelial cells to replace cardiomyocytes lost due to cardiac injury; (B) secrete soluble mediators, including growth factors, cytokines, exosomes, and large microvesicles that exert cytoprotective effects; (C) possibly fuse with cardiomyocytes, leading to the formation of a reprogrammed hybrid heterokaryon or synkaryon; (D) communicate through tunneling nanotube structures (TNTs), allowing intercellular exchanges of a broad range of compounds. This figure was produced using Servier Medical Art.

by the microenvironment in which they engrafted through the release of physiological cues from injured cells in that microenvironment [56]. However, the role of the microenvironment as a key regulator of MSC function is currently poorly understood. Nevertheless, this intriguing issue was retrospectively supported by a series of *in vitro* studies showing that stress cues emitted by damaged cells could be transmitted to MSCs or other progenitor cells by several pathways, including, first, gap junctions, which allow the direct passage of inorganic ions, small cytoplasmic molecules, and genetic material such as microRNAs (miRNAs). The latter have been shown recently to be involved in the differentiation of cardiac stromal cells [57]. A second pathway proposed that soluble factors underwent receptor-mediated transduction into target cells, as illustrated by the release of prostaglandin $E_2$ following activation of caspases 3 and 7 in apoptotic cells, which triggered stromal cell proliferation and tissue regeneration [58]. A third method proposed that integrins mediate interactions of cells with the extracellular matrix, allowing them to sense any stress-induced matrix changes [59–61]. Additionally, stressed cells can communicate with MSCs through the release of extracellular membrane vesicles such as apoptotic bodies, microvesicles, and exosomes [62–64]. These vesicles, which had been initially considered as cell debris, can contain protein, peptides, fragmented DNA, and several classes of mRNA molecules, including miRNAs. These miRNAs represent small noncoding RNAs of approximately 20–22 nucleotides that, upon sequence-specific binding to appropriate mRNAs, repress the translation of the corresponding proteins or induce a subsequent degradation of the miRNA/mRNA [63–65]. Fusion of these vesicles with MSCs can alter their behavior by regulating their proliferation, differentiation [62,64,66], migration [67], and paracrine function [68]. In turn, MSCs can also secrete microvesicles and exosomes to rescue distressed cells or to promote angiogenesis or to regulate inflammation [69,70].

More recently, a novel way of cell-to-cell communication between cells remote from each other has been proposed by which membrane thin channels allow intercellular exchanges of a broad range of cellular components. These latter structures, commonly referred to as tunneling nanotubes (TNTs), as well as their physiological roles will be described in more detail in the following section. Particular attention will be paid as to whether crosstalk mediated by these structures affects MSC fate and the phenotype of the interconnected somatic cells.

## 21.3 Tunneling nanotubes: a universal route of intercellular communication between distant cells

TNTs were initially described by Rustom *et al.* in rat pheochromocytoma PC12 cells as long actin-rich bridges connecting cultured cells [71]. Other cellular projections, such as filopodia and cytonemes, have been previously described. Filopodia (also known as microspikes) are slender cytoplasmic projections that extend beyond the leading edge of lamellipodia in migrating cells. They contain actin filaments cross-linked into bundles by actin-binding proteins, such as fascin and fimbrin. Filopodia form focal adhesions with the substratum, linking it to the cell surface. Many types of migrating cells display filopodia, which are thought to be involved in both sensation of chemotropic cues and resulting changes in directed locomotion.

Cytonemes are thin, cellular projections that are specialized for exchange of signaling proteins between cells. Cytonemes emanate from cells that make signaling proteins, extending directly to cells that receive signaling proteins. Cytonemes also extend directly from cells that receive signaling proteins to cells that make them. A cytoneme is a type of filopodium – a thin, tubular extension of a cell's plasma membrane that has a core composed of tightly bundled, parallel actin filaments. Filopodia can extend more than 100 μm and have been measured as thin as 0.1 μm and as thick as 0.5 μm.

TNTs are novel structures able to ensure membrane continuity between two remote cells allowing intercellular exchanges of a broad range of cellular compounds and without attachment to the substratum [71]. Interestingly, these structures appeared to be highly dynamic as they formed *de novo* within a few minutes and persisted *in vitro* from minutes to several hours [71,72]. They are transient, highly fragile, and sensitive to light exposure, shearing force, and chemical fixation. Since their discovery in 2004, TNTs have been detected in various cells types *in vitro*, including nervous system cells [71,73,74], myeloid cells [75–78], human and murine T cells [79], normal rat kidney cells [80], myogenic skeletal muscle satellite cells [81], retinal pigment epithelial cells [82], osteoclast precursors [83], and several types of malignant cells [84,85]. TNT structures have also been found to connect MSCs with several kinds of somatic cells, including cardiomyocytes [86–89], endothelial cells [90,91], renal tubular cells [92], and vascular smooth muscle cells [93]. They can also connect cancer cells to various types of stromal cells, such as fibroblasts, MSCs, as well as to endothelial cells [94,95] (Figure 21.3).

In contrast to the easy detection of TNT structures in *in vitro* systems, their assessment *in vivo* is extremely difficult because of their fragility, their transient formation, and the lack of known specific markers. Nevertheless, several *in vivo* studies have reported the presence of TNT-like connections in mouse and chick embryos during *blastocyst* formation (the structure formed in the early development of mammals and possessing an inner cell mass that subsequently forms the embryo), *neurulation* (the folding process in vertebrate embryos that includes the transformation of the neural plate into the neural tube) [96–98], *dorsal closure* (the last major morphogenetic process whereby a gaping dorsal epithelial hole – the result of germ band retraction – is sealed closed to cover an otherwise naked extraembryonic amnioserosal sheet [99], and *gastrulation* (a phase early in the embryonic development of most animals, during which the single-layered blastula is reorganized into a trilaminar (three-layered) structure known as the gastrula with the three germ layers known as the ectoderm, mesoderm, and endoderm) [100].

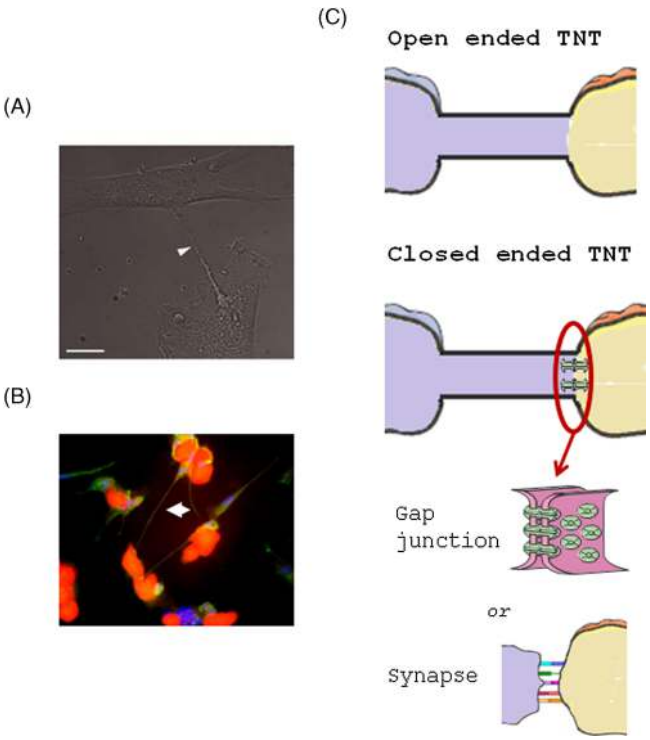

**Figure 21.3** The structural diversity of TNTs. (A) TNT morphology. Live-cell imaging microscopy showing a TNT connection between two MSCs. Scale bar: 20 μm. (B) Cytoskeletal composition of a TNT. Immunocytochemistry showing TNT connections between MSCs and cardiomyocytes (arrowhead) composed of F-actin and microtubules. (C) The two different types of TNT tips. TNT tips can be open-ended or closed-ended. In this latter situation, tips contain additional structures serving cell-to-cell communication such as gap junctions of immunological synapses. This figure was produced using Servier Medical Art.

Although more difficult to observe in adult tissues, TNT-like structures have been detected in mouse cornea [101,102], in rat lung [103], and rabbit kidney nephrons [104]. Furthermore, TNTs have also been found in malignant tissues such as human mesothelioma and lung adenocarcinoma [84].

### 21.3.1 Structural diversity of tunneling nanotubes

Several studies based on live cell imaging microscopy as well as transmission- and scanning-electron microscopy have revealed the structural diversity of TNT bridges with regard to their length, diameter, and cytosketal components. This structural diversity is dependent of the type of cells that are interconnected. Indeed, the average length of TNTs varies from 6–7 μm in adrenal pheochromocytoma PC12 cells [71] or primary neurons and astrocytes [105] to 22 μm in the Jurkat T cell line (originally called JM) established in the late 1970s from the peripheral blood of a 14-year-old boy with T cell leukemia) [79] and cervical-cancer-derived Hela cells [76]. They reach more than 40 μm in human retinal pigment epithelial ARPE-19 cells [82]. The length of TNTs is dynamically regulated, as it increases when connected cells migrate and the distances between them change, in this case exceeding 100 μm. However, TNTs break when the intercellular gap becomes too large [106]. The diameter of TNTs has been shown to vary according to the types of cells connected, ranging from 50–200 nm in PC12 cells [71], 180–380 nm in T cells [79], and exceeding 700 nm in human monocyte-derived macrophages [77], human lung carcinoma A549 cells [107], and rat cardiac H9C2 cardiomyoblasts [108]. Interestingly, these variations in TNT thickness have led to a classification of thick and thin nanotubes [77].

An additional criterion of variation in TNT structures is related to their cytoskeletal composition. All TNTs are composed of an F-actin backbone. Actin is a globular multifunctional protein that forms microfilaments. Actin participates in many important cellular processes, including muscle contraction, cell motility, cell division and cytokinesis, vesicle and organelle movement, cell signaling, and the establishment and maintenance of cell junctions and cell shape. Actin can be present as either a free monomer called G-actin (globular) or as part of a linear polymer microfilament called F-actin (filamentous), both of which are essential for such important cellular functions as the mobility and contraction of cells during cell division.

In some cases, and in particular when TNTs are thick (>0.7 μm), they can also contain microtubules [77]. Finally, another parameter contributing to TNT structural variability is the morphology of the tip that establishes contact with the remote cell (Figure 21.3C). Although TNTs are often considered as open-ended bridges that ensure membrane continuity between the two connected cells through a partial cell-fusion-like process, experiments have revealed the existence of a second kind of TNT that exhibits a closed-ended tip. Interestingly, closed-ended TNTs have been shown to be able to accumulate connexin 43 at one of their ends to form functional gap junctions. Such structures have been found to connect neurons with astrocytes [105] or normal kidney cells themselves [80]. Closed-ended TNTs have also been shown at one of their tips to exhibit protein complexes suggesting the formation of immune-like synapses. For instance, such structures were found to link natural killer (NK) cells to mastocytoma cells. In this study, NK protrusions were found to contain clusters of proteins that are involved in the biogenesis of immune synapses such as the activating receptor NKG2D (an activating receptor found on NK cells and both αβ and γδ $CD8^+$ T cells), its signaling receptor DNAX-activation protein 10, and its ligand major histocompatibility complex (MHC) class I chain-related A. Although the function of TNTs sharing immune synapses remains to be formally determined, we can speculate that such structures ensure the NK cells exert their cytotoxicity on distant target cells [109].

Thus, the series of studies cited in this section reveals the extreme diversity of TNT structures with regard to their cytoskeletal composition, length, and thickness. These variations may reflect an adaptation of these structures to the function that they exert and the kinds of cells with which they connect.

### 21.3.2 Mechanisms and factors involved in tunneling nanotube formation

The mechanisms of TNT formation are not yet fully understood. However, time-lapse imaging has suggested that TNTs can be formed within a few minutes by two modalities. These are the outgrowth of actin-driven protrusions and the dislodgement of connected cells [110] (Figure 21.4). Although these two mechanisms of TNT biogenesis are not mutually exclusive, since they could occur in the same cell type, they seem to be dependent on the mobility of the connected cells. Indeed, mobile cells such as T cells, which can easily physically interact with other cells, are thought to be more adept at forming TNTs mainly by cell dislodgement [79,80], whereas more immobile cell types, such as those of the PC12 cell line, are prone to form TNTs by *de novo* outgrowth and extensions of actin-driven protrusions toward distant cells [72].

#### 21.3.2.1 Formation of tunneling nanotubes by actin-driven protrusions

This process which was initially proposed by Rustom and colleagues in 2004 [71], consists of the ability of either one or both the cells destined to come into contact to induce the outgrowth of tubes containing F-actin (Figure 21.4A). The molecular mechanisms involved in the emergence of TNT protrusions are still unclear. However, these mechanisms probably require the activation of cell division control protein 42 (CDC42), a member of the Rho family of GTPases, to initiate the actin nucleation complex [111], which in turn enables the extension of the protrusion through actin polymerization toward the target cell. After elongation, the tip of the protrusion enters into contact with the targeted cell and fuses with its membrane. This step, which requires energy, has several implications. First, it could involve fusion proteins such as soluble *N*-ethylmaleimide-sensitive factor activating protein receptor proteins [112].

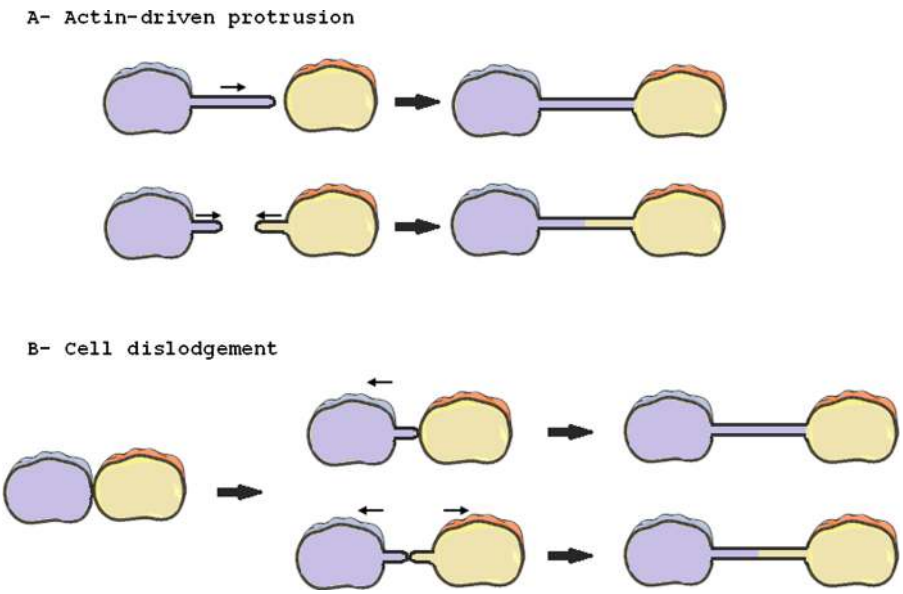

**Figure 21.4** The two modalities of TNT biogenesis. TNTs can be created through the process of (A) actin-driven protrusion or (B) cell dislodgment. This figure was produced using Servier Medical Art.

Second, it could require an appropriate lipid bilayer membrane that could confer a high degree of membrane curvature and lead to the spontaneous membrane fusion of the TNT tip with the target cell [113]. Such a process is often involved in the generation of TNT structures connecting neuronal cells [72,73], kidney cells [71], and probably MSCs with various other cell types, including cardiomyocytes [88,89], endothelial cells [90], vascular smooth muscle cells [93], and renal tubular cells [92]. Further studies are required to identify the molecular protagonists triggering TNT emergence, elongation, and fusion.

#### 21.3.2.2 Formation of tunneling nanotubes by cell dislodgement

According to the second mechanism postulated, TNTs arise from cells initially in close contact with their target cell type and with whose membranes they have fused. Subsequently, when these cells migrate in opposite directions, thin thread membrane tethers are drawn out, leading to the formation of TNTs that could belong entirely to one cell or to both cells [71,110] (Figure 21.4B). The mechanism of cell dislodgement leads to the creation of closed-ended TNTs that can exhibit at one of their tips either gap junctions [80,105], synapses [109], or receptors [79]. TNTs derived from a cell dislodgement mechanism have been shown to connect with a broad range of cells, including immune cells [77–79], normal kidney cells, neural crest cells, and primary human umbilical vein endothelial cells (HUVECs) [80]. Whether MSCs communicate through TNT bridges arising from a cell dislodgement process is still unknown. Furthermore, the cell dislodgement mechanism remains poorly characterized. In particular, it remains to be determined whether this process requires adhesion molecules or fusogenic proteins and to identify the signaling cues triggering the migration between the two cells involved in the TNT process.

#### 21.3.2.3 Factors involved in tunneling nanotube formation and regulation

Characterizing the signals and the molecular protagonists that induce TNT formation will be useful for understanding the physiological roles of TNT connections. There is emerging evidence indicating that stress signals and inflammatory cues are important regulatory factors of TNT biogenesis.

Indeed, cellular stresses induced by hydrogen peroxide or serum starvation have been shown to increase the number of TNTs in different cell types, including astrocytes and neurons [74]. In addition, data from our own laboratory have shown that priming of MSCs with inflammatory cytokines such as interferon (IFN)-γ and tumor necrosis factor (TNF)-α heighten the number of TNT connections between human MSCs and distressed cardiomyocytes [89]. Consistent with our *in vitro* studies, cues from inflammatory tissue have been reported as stimulating the formation of TNTs *in vivo* between dendritic cells located in the mouse cornea [101]. Since acute inflammation is commonly associated with tissue injury, we can speculate that pro-inflammatory signals are received by MSCs as harmful signals. As a consequence, these cells might create TNT extensions either to rescue neighboring stressed somatic cells or to counteract side effects from excessive inflammatory processes through direct interaction with immune cells such as macrophages or T lymphocytes. Further studies are required to determine whether inflammation regulates TNT-mediated cell-to-cell communications.

Another important question is related to the type of cells involved, specifically whether it is stressed or unstressed cells that initiate TNT elongation. Although there is emerging evidence that stressed cells release the upstream signals triggering TNT biogenesis, it remains to be determined if these signals attract filopodia-like protrusions from unstressed cells to stressed ones or if stresssed cells are the initiators of TNT protrusions. The

limited experimental data currently available are quite discrepant. It has been shown in co-cultures containing neurons or astrocytes damaged by treatment with hydrogen peroxide or by serum starvation that stressed cells develop TNT towards safe cells as their targets [74]. Conversely, another study was performed with endothelial progenitor cells and endothelial HUVECs previously exposed to glycated collagen I in order to induce lysosomal dysfunction and premature senescence. In this situation, progenitor cells initiated outgrowth of TNT bridges toward damaged cells [91].

These apparent discrepancies could be explained by differences in the type of initiator and receptor cells used to carry out the experiments. In addition, the kind of injury applied to initiator cells, which quantitatively and qualitatively influences the release of harmful cues, might also be an important factor involved in the decision of the cell source from which TNT protrusions must be initiated.

In addition to stress signals and inflammation, several proteins and signaling pathways have been reported to be involved in TNT formation. Wang *et al.* [74] reported that activation of p53 protein, which can induce apoptosis, or the EGF receptor through the stimulation of the Akt/PI3K/mammalian target of rapamycin pathway, was responsible for open-ended TNT formation in cultured neurons and astrocytes following stress induced by treatment with hydrogen peroxide.

Further, mSec and the Ral/exocyst complex, which is a filopodium-dependent mechanism, have been shown to be involved in the formation of TNTs in macrophages and cervical cancer Hela cells [76] as well as neurons and astrocytes. (The exocyst is an octameric protein complex involved in vesicle trafficking, specifically the tethering and spatial targeting of post-Golgi vesicles to the plasma membrane prior to vesicle fusion. It is implicated in a number of cell processes, including exocytosis and also cell migration and growth.)

Interestingly, Wang *et al.* have suggested that mSec effects are probably under the control of activated p53 [74]. More recently, Schiller and colleagues have provided evidence of the critical role of the leukocyte-specific transcript 1 protein in promoting the assembly of the multimolecular complex (mSec, the small GTPase RalA, and the exocyst complex) that together orchestrate the formation of functional TNTs [114].

Finally, activation of FAS signaling in immune cells has also been shown to increase the number of TNTs by activating Rho GTPases and CDC42 (a member of Rho small GTPase family) [115]. Fas forms the death-inducing signaling complex upon ligand binding.

Overall, the studies carried out to date have revealed the diversity of TNT structures and formations. This diversity likely results from several parameters: first, the nature of the stress signals emitted by the damaged cells, which in turn may govern activation of the appropriate signaling pathways for the initiation of TNT formation; second, the physiological role that TNTs mediate; and third, the type of cells involved.

## 21.3.3 The diversity of compounds transferred by tunneling nanotubes and their physiological relevance

### 21.3.3.1 The characteristic features of tunneling nanotube transfers

The multifaceted functions of TNT channels are illustrated by the broad range of compounds that TNTs transfer between connected cells. These compounds include organelles, proteins and vesicles containing genetic material, ions and pathogens, as well as electrical signals. Besides the heterogeneity of the cargoes transported by TNTs, it is interesting to note that such a transfer is not a single diffusion process but rather is highly regulated, since it can be either unidirectional or bidirectional according to the compounds that are conveyed. Although the specific signals and mechanisms responsible for directing traffic remain largely unknown, this process seems to be dependent on the structural composition of TNTs: bidirectional transfers have been reported as being associated with TNTs containing both actin and microtubules [77,88,115,116], while unidirectional ones have been associated with TNTs containing actin only [71,75,117]. Furthermore, several studies have shown that the direction of these exchanges is also influenced by the physiological states of the two connected cells. As an example, lysosomal exchanges from endothelial progenitor cells to HUVECs have been shown to be selectively augmented when HUVECs exhibited lysosomal dysfunction and premature senescence following glycated (nonenzymic glycosylation) collagen treatment [91]. Such a phenomenon appears to be devoted to restoring the pool of functional lysosomes in defective cells. Likewise, unpublished data from our laboratory indicate that transfer of mitochondria from stromal cells to somatic cells, such as fibroblasts, cardiomyocytes, and endothelial cells, is much more important when somatic cells have been exposed to $H_2O_2$-mediated oxidative stress prior to the co-culture, which leads to mitochondrial dysfunction. In addition, Plotnikov *et al.* described that intercellular exchanges between human multipotent stromal cells and rat renal tubular cells were more prominent toward stromal cells, thus favoring their differentiation into kidney tubular cells [92]. According to these studies, movement of cargoes along TNT bridges appears to be finely regulated, in agreement with expectations such as the rescue of injured cells, progenitor fate changes, or the immunological lysis of infected cells.

Another important point is that transfer mediated by TNTs appears to be an active process dependent on cytoskeletal actin and requiring ATP consumption. The importance of cytoskeletal components and ATP supply has been shown for the transfer of organelles and vesicles [72,73,77,118].

### 21.3.3.2 Signal transfer

#### *21.3.3.2.1 Transfer of calcium ions and electrical currents*

TNTs have been shown to propagate calcium signals between remote cells and thus constitute an alternative to gap junctions, which only allow transfer of calcium fluxes between cells in close proximity to each other. This kind of transfer has been

found in many cells types able to make connections between each other.

Initially, propagation of calcium fluxes through TNTs was observed between myeloid cells following stimulation with *Escherichia coli* supernatants or mechanical stress [78]. This study indicated for the first time that calcium transported along TNTs might be involved in initiating and amplifying pathogen signals in connected sentinel cells responsible for triggering immune responses, such as dendritic cells [78]. TNT-mediated calcium fluxes have also been observed between neurons and astrocytes [105], human retinal pigment epithelial cells [82], normal rat kidney cells [80], as well as the HEK293 and neuroblastoma SH-SY5Y cell lines [119].

Propagation of intercellular calcium signaling through TNT channels is probably important in contributing to several physiological processes, including the regulation of the antibacterial immune response [78] as mentioned earlier, the coordination of the migration and differentiation of neural progenitor cells during embryonic development [120], and the stimulation of wound healing processes triggered by membrane depolarization at the leading edge of the wound. Such depolarization leads to the activation of several downstream signaling pathways involving protein kinase A and PI3kinase, which in turn lead to synchronization of actin remodeling and repair [121–124].

According to the type of cells involved, TNT-mediated transfer of calcium can be conferred either by passive diffusion [78] or, in contrast, through an active process requiring ATP and specialized protein complexes such as IP3 receptors, which may actively propagate calcium ion $Ca^{2+}$ through a $Ca^{2+}$-induced calcium release mechanism [119], or through gap junctions that contribute to the spread of electrical currents [80,82,105].

#### *21.3.3.2.2 Transfer of death signaling*

Besides ensuring $Ca^{2+}$ signaling and electrical coupling, TNTs can also serve as conduits for the dissemination of death signals. This was illustrated by the study of Arkwright *et al.*, who reported that stimulation of FAS signaling, which is important for rapid cell death, significantly increased the number of TNT connections in T lymphocytes [115]. This process may significantly contribute to the peripheral deletion of autoreactive lymphocytes by ensuring the rapid propagation of apoptosis signals within themselves. The involvement of TNT structures in controlling autoimmunity has been strengthened by *in vivo* observations in patients with the autoimmune lympho-proliferative syndrome (ALPS). This is a form of lymphoproliferative disorder that affects lymphocyte apoptosis. It is a disorder of Ras signaling – a RASopathy. Normally, after an infection, the immune system downregulates by increasing Fas expression on activated B and T lymphocytes and Fas ligand (CD95L) on activated T lymphocytes. Fas and Fas ligand interact to trigger the caspase cascade, leading to cell apoptosis. Patients with ALPS have a defective apoptotic pathway of T lymphocytes [125] and mutations of the Fas receptor [126,127]; T lymphocytes are unable to form TNT connections [115]. This syndrome leads to chronic nonmalignant lymphoproliferation, autoimmune disease, and secondary cancers.

A second example of the transfer of death signals was provided by the work of Chaveau *et al.* showing that closed-ended TNT structures with an immune synapse at one of their tips enabled NK cells (lymphocytes involved in the elimination of infected or malignant cells) to eradicate target cells [109]. The regulatory role that TNTs exert on NK-mediated cytotoxicity is strengthened by the fact that inflammatory cytokines such as interleukin (IL)-2, -12, -15, and -18 increase the number of TNT protrusions generated by NK cells [109].

### 21.3.3.3 Transfer of organelles, proteins, and genetic material

#### *21.3.3.3.1 Transfer of organelles*

Several *in vitro* studies have reported that TNT channels promote the conveyance of various organelles, such as mitochondria and lysosomes. Interestingly, organelle transfer along TNTs is the best example in which the direction of this phenomenon is clearly dependent of the physiological state of connected cells. Transfer of these organelles is bidirectional between healthy cells, while it is usually unidirectional when injured cells are connected to normal stem or progenitor cells. Organelle transfer occurs predominantly from the healthy to the abnormal cells. Several studies in the literature indicate that transfer of organelles and particularly mitochondria are aimed at rescuing dying cells. Mitochondria exert critical functions in maintaining the life, or regulating the death, of cells. Mitochondria are commonly considered as the powerhouse of living cells as they produce more than 90% of energy, in the form of ATP through the oxidation of pyruvate in the Krebs cycle, and oxidative phosphorylation. In addition, mitochondria are key sensors of cellular stress and trigger programmed cell death by rupture of electron transport and energy metabolism, by releasing cytochrome c, by activating caspase proteins, and by producing reactive oxygen species [128]. Following exposure to injury, damaged cells try to eliminate their abnormal mitochondria through sequestration, followed by their digestion into autophagolysosomes in the process known as autophagy. Consequently, uptake of functional mitochondria from safe (stem) cells might be a valuable alternative for diseased cells to replenish their pool of organelles and thus preserve their energy metabolism. Occurrence of mitochondrial transfer by TNT structures has been described *in vitro* between stromal cells and various damaged cells, including cardiomyocytes, endothelial cells, and bronchial epithelial cells [88–90,103]. Transfer of mitochondria to stressed cardiomyocytes will be discussed in Section 21.4. Whether TNTs confer protection against apoptosis through mitochondria conveyance has been well illustrated by the recent study of Liu *et al.*, which showed that TNT-mediated mitochondria transferred from MSCs to endothelial cells, previously injured by oxygen or glucose deprivation, improved their survival by preserving their aerobic respiration and ATP production [90]. Strikingly, no protection against apoptosis occurred when injured endothelial cells were co-cultured with

MSCs that had been depleted of functional mitochondria, thus confirming the pro-survival role of stromal-cell-delivered mitochondria [90]. The benefit of stromal-cell-derived mitochondria delivery through TNTs has been confirmed *in vitro* as well as *in vivo* in cigarette-smoke-exposed epithelial airways [103].

However, although transfer of mitochondria is usually beneficial for healing damaged cells, this process may sometimes be deleterious, by, for instance, favoring tumor development. Indeed, increasing mitochondrial activity in cancer cells by the means of TNT channels has been recently reported to increase resistance to cytotoxic drugs and to increase survival of malignant cells [95]. Finally, and in combination with uptake of exogenous mitochondria, TNT-mediated supply of lysosomes can contribute to prolonged survival of diseased cells by helping eliminate dying mitochondria causing deleterious effects by fusing with autophagosomes to form autophagolysosomes [91,129].

#### *21.3.3.3.2 Transfer of protein complexes and genetic material*

TNT channels ensure exchange of proteins and genetic material that allow activation of the recipient cells over long distances. Several kinds of proteins have been shown to travel along TNT bridges. These include the multidrug resistance p-glycoprotein found in breast cancer cells, which increases their chemoresistance [85], and MHC class I complex bound to antigen between dendritic cells, which optimizes antigen presentation to, and the cytotoxic response of, alloreactive T cells [130]. Additionally, genetic material such as miRNA and DNA can be transferred by TNTs from one cell to another in order to reprogram the recipient cell. Transfer of miRNA has been well documented in *in vitro* cancer models, especially from ovarian carcinoma or osteogenic sarcoma tumor cells to stromal cells. Occurrence of this phenomenon could modify gene expression of stromal cells and favor malignant progression [94]. TNT structures have been shown to increase chemoresistance of cancer cells through genetic exchanges between themselves [131].

#### 21.3.3.4 The role of tunneling nanotubes in the spread of pathogens

It has been shown that different pathogens actively hijack TNTs like Trojan horses to be transported along their membranes or inside them, leading to the spread of infections. This transfer is often preceded by the activation of TNT formation, thus optimizing pathogen dissemination. This has been observed for exchanges of HIV particles between macrophages [75]. TNT structures also serve as conduits to allow bacteria to pass from one cell to another without contacting the extracellular environment. For instance, several species of bacteria – including *Mycobacterium bovis*, which causes tuberculosis in cattle and from which the antituberculosis vaccine BCG was derived – have been reported to "surf" TNTs between macrophages prior to being internalized by endocytosis [77].

Apart from viruses and bacteria, Gousset and colleagues provided evidence that TNT channels enable prion spreading between neurons themselves or between bone marrow-derived dendritic cells and primary neurons [73,132]. These findings strongly suggest that TNTs play an important role *in vivo* in the spreading of prions within both the central and peripheral nervous systems [133]. Interestingly, the same authors showed that prion particles travel in early endosomes and lysosomes but are preferentially enriched in the endosomal recycling compartment, thus revealing the efficiency of TNTs in permitting the passage of prions to one infected cell to an uninfected one [73].

## 21.4 Tunneling nanotubes: a novel cell-to cell communication pathway improving the cardiac regenerative properties of mesenchymal stromal cells

### 21.4.1 Evidence of tunneling-nanotube-mediated communications between stromal cells and cardiomyocytes

MSCs have been found to communicate with several types of specialized cells through TNTs, including cardiomyocytes and endothelial cells (Figure 21.5).

The structure of these channels in this setting has not been characterized in depth. No data are currently available on the signals and mechanisms involved in their formations. However,

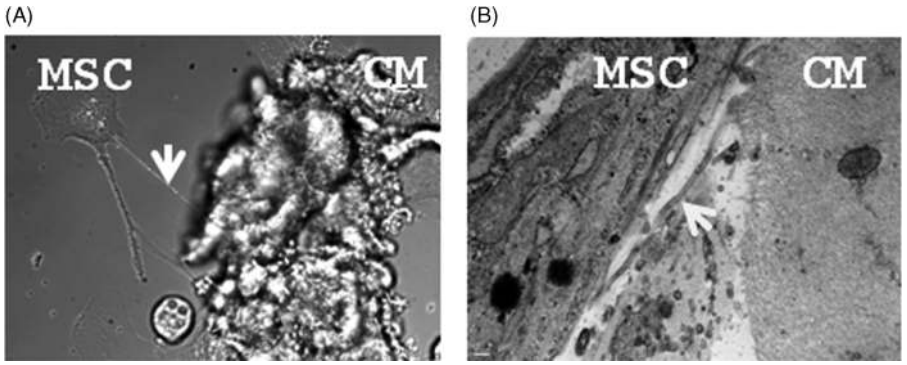

**Figure 21.5** Morphology of TNT structures connecting stromal cells to cardiac cells: (A) live cell microscopy; (B) transmission electron microscopy. Arrow designates TNT. MSC: mesenchymal stromal cell; CM: cardiomyocyte.

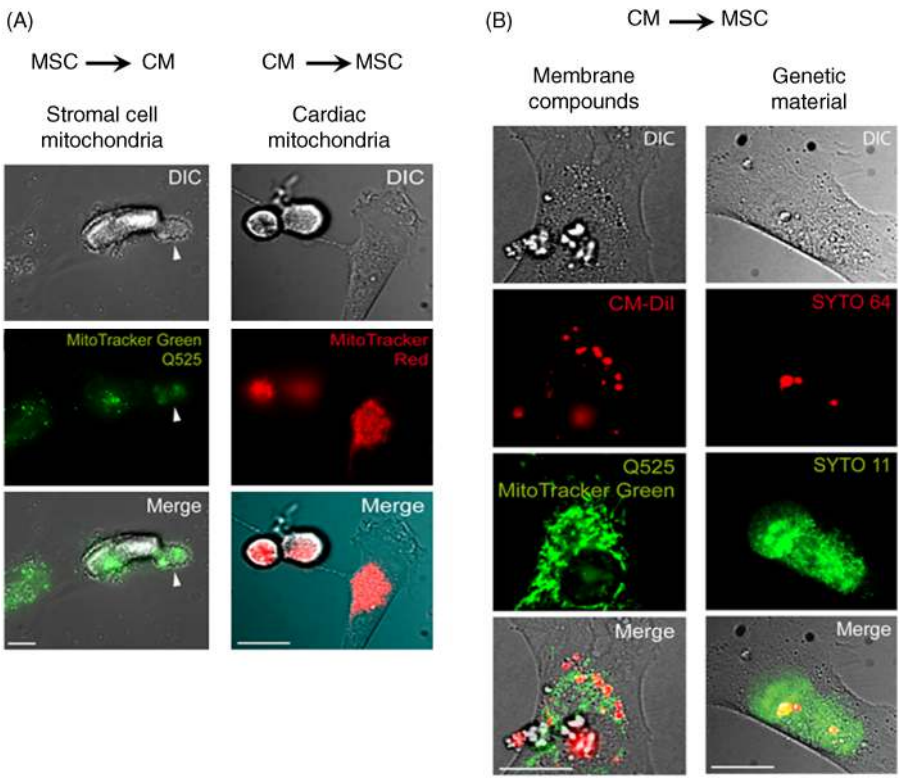

**Figure 21.6** Diversity of intercellular exchanges between MSCs and cardiomyocytes (CMs). (A) Bidirectional exchanges of mitochondria between MSCs and CMs. Left panel: detection of stromal cell mitochondria (green staining using MitoTracker Green FM in cardiomyocytes (white arrowhead). Right panel: detection of cardiac mitochondria (red staining, using Mitotracker red FM in MSCs (white arrowhead). Scale bars: 20 µm. (B) Selective unidirectional exchanges from CMs to MSCs. Left panel: live cell imaging showing that MSCs stained with quantum dot Q525 and MitoTracker Green FM dyes (green signal) contain cardiomyocyte cytoplasmic macromolecules stained previously with CM-DiI dye (red signal). (See color plate section.)

we have found that these connections are mainly composed of F-actin and microtubules and are open-ended structures, leading to the exchange of several cellular compounds, including cell membranes, DNA material, and organelles, including mitochondria and lysosomes. We have shown that transfer of cytoplasmic and genetic material was unidirectional from stressed cardiomyocytes to MSCs, while transfer of mitochondria appeared to occur in both directions (Figure 21.6).

Interestingly, we also observed that cellular components of cardiomyocytes can be exchanged between MSCs themselves to seemingly accelerate the propagation of signaling cues coming from the cardiomyocytes to the MSC population (Figure 21.7).

Although the exact role of the traffic of most of the compounds between stromal cells and cardiac cells remains elusive, great attention is currently being paid to the physiological impact of cell-to-cell transfer of mitochondria. Several questions must be addressed to clearly understand the mechanisms involved in the formation of TNTs and to fully determine their structures and functions. In particular, it remains to be determined whether MSCs and cardiac cells can communicate through closed-ended bridges containing connexins in one of their tips, whether spreading of $Ca^{2+}$ fluxes and electrical wiring occur along these connections, and, finally, from which cell population (MSCs versus cardiomyocytes) do the TNTs originate. Despite the need to improve knowledge of TNT crosstalk between stromal cells and cardiac cells, current data in this field already indicate that this way of cell-to-cell communication might be critical to the activation of regenerative functions of MSCs, the main goal of which is the rescue of damaged cells after tissue injury. The following subsections provide an overview of recent data obtained in our laboratory describing whether TNT-mediated crosstalk between MSCs and distressed cardiomyocytes affects the phenotype of these two connected cells and thus contributes to cardiac regeneration.

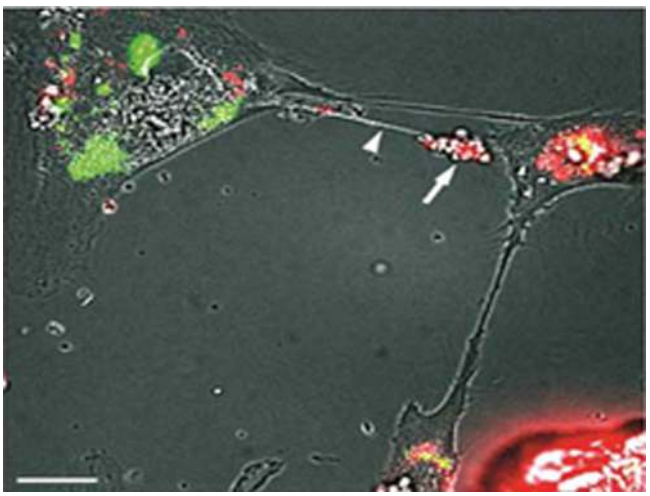

**Figure 21.7** TNT-mediated intercellular exchanges of cardiac compounds between MSCs themselves. Live cell imaging microscopy showing transfer of cardiac cytoplasm (labeled in red with CM-DiI dye, arrow) through a nanotube (arrowhead) connecting two MSC cells (stained with Q525, green signal). Scale bars: 20 µm. (See color plate section.)

### 21.4.2 Tunneling nanotube cell-to-cell communication with mesenchymal stromal cells rejuvenates distressed cardiomyocytes through a progenitor-like state

The question of whether TNT cell-to-cell communication with MSCs might affect the phenotype of adult mammalian cardiomyocytes in a distressed state was addressed in depth in the study of Acquistapace *et al.* [88]. We will summarize here the major findings of this work, which to our knowledge remain unique in this field. This study was conducted in a species-mismatch co-culture system in which human MSCs from adipose tissue or bone marrow were mixed with mouse adult cardiomyocytes, more than 90% of which were dying as assessed by flow cytometry analysis of annexin V/7ADD staining. First, characterization of the xenogeneic (heterologous) cell fusion processes, which had been reported earlier to occur *in vivo* between engrafted stromal cells and resident cardiomyocytes, was explored [48,134–137]. For this, the classical Cre/lox P strategy was used, which allows LacZ gene expression only in fused cells by co-cultivation with Cre-expressing human MSCs and cardiomyocytes from transgenic Rosa26R reporter mice.

Cre–Lox recombination is known as a site-specific recombinase technology, and is widely used to carry out deletions, insertions, translocations, and inversions at specific sites in the DNA of cells. It allows the DNA modification to be targeted to a specific cell type or be triggered by a specific external stimulus. The system consists of a single enzyme, Cre recombinase, that recombines a pair of short target sequences called the Lox sequences. This system can be implemented without inserting any extra supporting proteins or sequences. The Cre enzyme and the original Lox site called the Lox P sequence are derived from bacteriophage P1. Placing Lox sequences appropriately allows genes to be activated, repressed, or exchanged for other genes. The activity of the Cre enzyme can be controlled so that it is expressed in a particular cell type or triggered by an external stimulus like a chemical signal or a heat shock. X-gal is an analog of lactose, and therefore may be hydrolyzed by the β-galactosidase enzyme, which cleaves the β-glycosidic bond in D-lactose. X-gal, when cleaved by β-galactosidase, yields galactose and 5-bromo-4-chloro-3-hydroxyindole. The latter then spontaneously dimerizes and is oxidized into 5,5′-dibromo-4,4′-dichloro-indigo, an intensely blue product that is insoluble. Since X-gal itself is colorless, the presence of blue-colored product can therefore be used as a test for the presence of active β-galactosidase. This easy identification of an active enzyme allows the gene for β-galactosidase (the *lacZ* gene) to be used as a reporter gene in various applications.

After 2 days of co-culture, LACZ-positive hybrid cells were observed. These hybrid cells were organized into colonies and exhibited a small rounded morphology that differed from that of both MSCs and cardiomyocytes (Figure 21.8).

Interestingly, analysis of cell fusion mechanisms leading to the generation of these hybrid cells ruled out a prominent role for permanent cell/nuclear fusion processes since binucleated heterokaryons or synkaryons containing hybrid nuclei were never

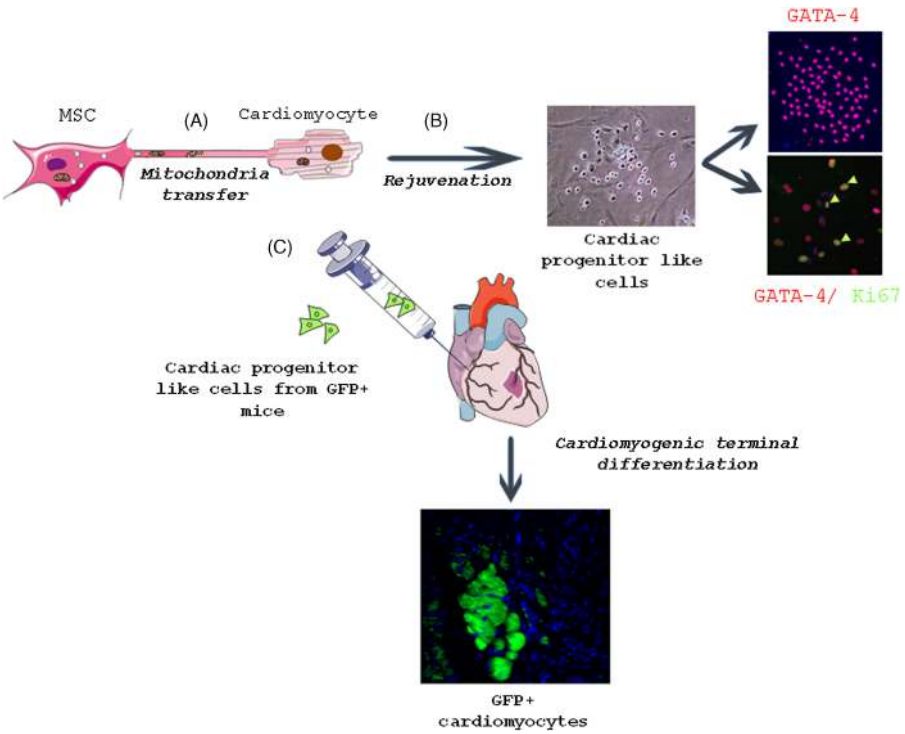

**Figure 21.8** TNT cell-to-cell communication allows MSCs to reprogram dying cardiomyocytes back to a progenitor-like state. (A) MSCs transfer mitochondria along TNTs to a dying cardiomyocyte to (B) prolong its survival and its rejuvenation into progenitor-like cells. These cardiac progenitors organized in colonies express the early cardiac marker GATA-4 and the proliferative marker Ki67. (C) Engraftment of these progenitors (GFP-positive) into mouse infarcted heart muscle leads to their differentiation into functional cardiomyocytes (green fluorescence). This figure was produced using Servier Medical Art. (See color plate section.)

detected by fluorescence *in situ* hybridization experiments. (A heterokaryon is a multinucleate cell that contains genetically different nuclei. Synkaryons are cells where the nuclei from two different parent cells have fused.)

Rather, the authors demonstrated that hybrid cells originated from partial cell fusion involving TNT structures, their generation being impeded in the presence of inhibitors of TNT formation such as nocodazole or latrunculin A. Strikingly, the molecular characterization of these hybrid cells by various methods, including real-time polymerase chain reaction assays using species-specific primers and immunocytochemistry, revealed that these cells displayed a cardiac progenitor-like phenotype. Similar to cardiac progenitors residing in the heart, hybrid cells were able to enter the cell cycle and proliferate, re-expressing early cardiac markers such as GATA-4, Nkx2.5, and MEF-2C. In addition, they had repressed expression of late cardiomyocyte differentiation markers such as desmin, cardiac troponin, and α-sarcomeric actinin, which led to the disappearance of their striated sarcomeric structures and thus the loss of contractile activity. Cytogenetic analysis demonstrated that nuclei of hybrid cardiac progenitor-like cells contained only mouse DNA material, supporting the view that these cells did not derive from transdifferentiation of MSCs into cells of cardiac lineage, but rather from fate changes of adult fully differentiated cardiomyocytes. Taken in concert, these findings indicate that MSCs can mediate the reprogramming of mouse cardiomyocytes back to a progenitor-like state through TNT bridging.

Importantly, additional findings from this study strongly suggest that the capacity to rejuvenate post-mitotic cardiomyocytes toward a more primitive state is restricted to stromal cells, since occurrence of this phenomenon was observed with multipotent stromal cells from adipose tissue and bone marrow as well as pluripotent embryonic cells (unpublished data), but not with human fibroblasts despite the fact that these cells established xenogeneic TNT connections with cardiomyocytes.

The fact that MSCs have the capacity to rejuvenate distressed cells through TNT structures raises the important questions on whether this phenomenon occurs *in vivo* and whether it contributes to healing of cardiac damage. Despite the rare frequency of reprogramming events detected in our *in vitro* experimental setting (due probably to the fact that primary myocytes were also damaged and died prior to being reprogrammed), several *in vivo* observations supported the fact that dedifferentiation and reprogramming of adult cardiomyocytes takes place in mammalian hearts under pathological conditions. Such events have been observed in infarcted myocardium as well as in hibernating myocardium and cardiomyopathy [138,139]. Hibernating myocardium is a state in which some segments of the myocardium exhibit abnormalities of contractile function and usually occurs in the setting of chronic myocardial ischemia.

Such a phenomenon might enable cardiomyocytes to survive adverse conditions such as hypoxia and ischemia [140,141]. More immature progenitor cells are able to adapt their metabolism to reduced oxygen supply by producing ATP by glycolysis (rather than by oxidative phosphorylation, as is the case in fully differentiated cardiomyocytes) and by reducing their energy consumption by the loss of their contractile apparatus. In addition, the dedifferentiation/reprogramming process might also facilitate tissue regeneration by providing a pool of progenitor cells able to proliferate and then to differentiate in order to compensate for the loss of contractile cardiomyocytes destroyed during the injury to the heart. The phenomenon of dedifferentiation/reprogramming, which remains poorly characterized in mammals, has been observed in the regeneration of several organs, including the heart in zebrafish and amphibians [142,143]. A similar phenomenon occurs frequently in plants, which allows fully differentiated, nondividing mesophyll cells to generate pluripotent protoplast cells that are able to form entire plants [144]. Likewise, unpublished data from our laboratory suggest that cardiac progenitor cells generated through TNT cell-to-cell communications between human MSCs and dying murine cardiomyocytes can contribute to healing of cardiac damage as they were shown to generate functional contractile cardiomyocytes when engrafted into the site of myocardial infarction in the mouse (unpublished data).

It is important to note that the cardiomyocyte reprogramming/rejuvenation process mediated by MSCs is finely regulated by stress cues from the microenvironment. This phenomenon occurred *in vitro* when MSCs were co-cultured with damaged cardiomyocytes but not with healthy nenonatal cardiomyocytes [86,87]. However, despite data suggesting that the occurrence of cardiomyocyte reprogramming/dedifferentiation in diseased heart tissue may be beneficial for tissue repair, it remains to be determined *in vivo* whether engrafted MSCs or resident progenitors participate in these events, and whether TNT structures contribute to these effects.

Other important issues concern the mechanisms by which MSCs mediate the rejuvenation of cardiomyocytes and, in particular, to determine the nature of the compounds transported along TNTs that are required for cardiomyocyte reprogramming. Although there may be multiple such compounds, we have focused primarily on the role of mitochondria transferred from stromal cells to cardiac cells because, astonishingly, we detected stromal-cell-derived mitochondria in the reprogrammed cardiomyocytes. To determine the importance of stromal-cell-derived mitochondria in the cardiomyocyte reprogramming process, stromal cells were depleted of mitochondrial DNA by long-term exposure to low doses of bromide ethidium in the presence of uridine and pyruvate, to allow a metabolic switch from oxidative phosphorylation to glycolysis. In these conditions, cardiomyocyte reprogramming did not occur, demonstrating the critical role of these organelles in this process. Whether transferred stromal-cell-derived mitochondria participate in cardiomyocyte reprogramming remains unclear. Such a transfer may enable

prolongation of cardiomyocytes survival since it has been reported in co-culture systems performed with endothelial or epithelial cells [90,103]. This hypothesis is supported by *in vitro* and *in vivo* observations showing that transfer of stromal-cell-derived mitochondria protect cardiomyocytes against apoptosis and is beneficial for functional cardiac recovery. A beneficial role of mitochondria in ischemic heart muscle was also recently confirmed by Masuzawa *et al.*, who showed that injection of exogenous mitochondria into ischemic mouse heart tissue conferred protection against the deleterious effects of ischemia–reperfusion injury [145].

It is important to determine if such mitochondrial transfer have only a pro-survival function or if they also play a direct role in the somatic reprogramming of cardiomyocytes by contributing to the remodeling of their transcriptional machinery through mitochondria-to-nucleus retrograde signaling [146].

Another important question concerns the molecular mechanisms that regulate the fluxes of mitochondria from stromal cells to diseased cells. These mechanisms have been partially elucidated by Ahmad *et al.* by using both an *in vitro* model of co-culture of MSCs with epithelial cells and an *in vivo* mouse model of acute lung injury treated with MSCs administered via the trachea [147]. They demonstrated for the first time that mitochondrial transfer was a well-directed process regulated by the mitochondrial Rho-GTPase 1 Miro1 [147]. Consistent with this, previous studies have shown that Miro1 is a calcium-sensitive protein and that it acts as a surface receptor that drives the movement of mitochondria along microtubules by ensuring their attachment to adaptor trafficking kinesin proteins and motor proteins such as kinesin heavy chain and dynein in the cytoskeleton [148,149]. Interestingly, MSCs, which are considered potent donors of mitochondria, were found to express high levels of Miro1 compared with other cell types, such as lung epithelial cells or fibroblasts, both of which are considered poorer donors of mitochondria. Silencing Miro1 expression in stromal cells did not inhibit TNT formation, but it did seriously hamper mitochondria motility and rescue of injured somatic cells. In contrast, overexpression of Miro1 in MSCs increased their mitochondria donor capacity and, as a consequence, their rescue ability [148–150]. The discovery of the role of Miro1 in the transfer of mitochondria from stromal cells renders this protein a promising target for improving future MSC therapies.

Although one of the critical downstream players of mitochondrial transfer has been identified, signaling pathways initiating mitochondrial transfer in the recipient and donor cells remain to be elucidated. Further insights in this field may also contribute to maximizing mitochondrial transfer and mesenchymal-mediated cytoprotective functions.

In addition to mitochondria, other organelles, such as lysosomes or ribosomes, may also be transferred along TNT structures from MSCs to damaged cardiomyocytes. Indeed, uptake of exogenous lysosomes might increase the autophagic activity of stressed cardiomyocytes and thus increase their ability to eliminate their own damaged mitochondria in a similar fashion to that previously reported in mixed cultures between progenitors and endothelial cells [91]. Transfer of ribosomes together with mRNA could trigger protein synthesis in cardiac cells to confer resistance to future injury. A similar phenomenon has been recently described in a co-culture setting between Schwann cells and injured neurons [151,152]. Although it is clearly evident that transfer of organelles contributes to survival and/or rejuvenation of injured cells and that, because of the large size of these compounds, only TNTs might be able to mediate their traffic, we can speculate that other ways of cell-to-cell communication might be involved in the reprogramming process of dying cardiomyocytes. In particular, we can speculate that paracrine factors might be produced by MSCs that favor dedifferentiation/rejuvenation of cardiomyocytes. Among these factors, the anti-inflammatory cytokine of the IL-6 family, oncostatin M, has recently been reported to be involved in the rejuvenation both *in vitro* and *in vivo* of mammalian cardiomyocytes that highly expressed oncostatin M receptors [141]. However, whether this cytokine is produced by MSCs following cell-to-cell communication with injured cardiomyocytes remains to be determined. Additionally, genetic material of MSC origin, such as miRNAs, could contribute to the somatic reprogramming of cardiac cells. In such circumstances, genetic material may be enclosed in exosomes and microvesicles, which might be secreted in the extracellular space by donor cells or transported along TNT structures [94] or gap junctions [57]. Further studies are required to identify the different modalities and mediators of cell-to-cell communication between stromal cells and cardiac cells and their respective roles in the cardiomyocyte reprogramming process. Finally, in the attempt to extrapolate observations made in the heart, it would be interesting to determine whether MSCs might be able to rejuvenate other post-mitotic cells with poor self-renewal capability, such as neurons. New insights on the cytoprotective role of stromal cell mitochondria, the mechanisms of TNT formation, and the factors governing the reprogramming will be useful in the field of regenerative medicine for improving treatments against such illnesses as myocardial infarction and brain ischemia.

### 21.4.3 Tunneling nanotube cell-to-cell communication with distressed cardiomyocytes stimulates the paracrine repair function of mesenchymal stromal cells

Although the consequences of TNT-mediated cell-to-cell communication between MSCs and damaged cells is beginning to be better characterized in both *in vitro* and *in vivo* experimental settings, little is known as to whether this process affects the behavior of MSCs.

Initial *in vitro* studies indicated that xenogeneic TNT connections between MSCs and cardiomyocytes enabled MSCs to acquire expression of some cardiac-specific markers, and thus

to adopt a cardiomyogenic-like fate [86,87]. However, these early studies were conducted with healthy neonatal cardiomyocytes and were unsuitable for determining the impact of TNT bridging on MSC functions when adult damaged cardiomyocytes were used. This issue was recently addressed by Figeac *et al.* [89] through the use of an *in vitro* system of co-culture between human multipotent adipose-tissue-derived stromal cells in a murine MSC model involving dying adult murine cardiomyocytes. In the experimental setting developed by Figeac *et al.*, no differentiation of MSCs into cardiomyocytes was observed, confirming that occurrence of this phenomenon relies on the developmental (neonatal versus adult) and/or the physiological state (healthy versus damaged) of somatic cells. The authors observed that xenogeneic (heterologous) TNT connections altered the secretome of MSCs. Specifically, Luminex quantification of the release of 20 cytoprotective soluble factors by MSCs indicated that vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF), stromal cell-derived factor-1 (SDF-1, also known as CXCL12), and monocyte chemoattractant protein (MCP)-3 were overexpressed in MSCs following co-culture with distressed cardiomyocytes through a mechanism dependent on TNT crosstalk. (Luminex's multiplex bead-based immunoassay testing platform simultaneously measures multiple analytes by exciting a sample with a laser and subsequently analyzing the wavelength of emitted light.) Additional *in vitro* experiments addressed the biological significance of these paracrine changes and clearly revealed that TNT-mediated cell-to-cell communications significantly increased the paracrine capacity of MSCs to promote angiogenesis and chemotaxis of bone-marrow-derived progenitor cells. Furthermore, Figeac *et al.* [89] used neutralizing antibodies to perform angiogenesis and chemotaxis assays and found that increased secretion of VEGF and HGF was responsible for the improved angiogenesis activity of co-cultivated MSCs, while the upregulated secretion of VEGF, HGF, SDF-1, and MCP-3 participated in recruitment of bone-marrow-derived progenitor cells. This study provided the first demonstration in a cardiac model that the secretion of MSCs is regulated by the local microenvironment (i.e., in this case, injured cardiomyocytes) and that TNT structures play a critical role by improving the angiogenesic and chemotactic capacities of MSCs. These two processes are of key importance in wound healing by providing oxygen and nutrient supply to the site of injury and by attracting bone marrow stem/progenitor cells with similar regenerative effects to the site of injury [50–53]. Thus, it is noteworthy that, in Figeac *et al.*'s study, TNT-mediated cell-to-cell communications with damaged cardiomyocytes did not apparently modify the paracrine action of MSCs exerted on the proliferation of human primary cardiac progenitor cells, the protection of cardiomyocytes against serum withdrawal-induced apoptosis, or the inhibition of fibroblast proliferation and collagen synthesis in the heart. Nevertheless, these findings do not preclude direct intercellular communication processes that include paracrine signaling or exchanges of cellular components of MSCs with cardiac fibroblasts or resident progenitor cells that could ameliorate their regenerative capacities related to inhibition of fibrosis and stimulation of progenitor proliferation. Indeed, we have already discussed direct cell-to-cell communications of MSCs with damaged cardiomyocytes that could improve their survival.

Whether TNT-mediated cell-to-cell communication improves the paracrine repair function of MSCs was confirmed by *in vivo* studies carried out in a mouse model of myocardial infarction using naive versus co-cultivated MSCs. Consistent with *in vitro* findings, MSCs previously co-cultured with dying cardiomyocytes were found to exhibit greater regenerative capacity than naive MSCs. Mice treated with co-cultivated cells displayed better cardiac contractile function associated with enhanced angiogenesis and homing of bone-marrow-derived progenitor cells to the myocardial injury site, compared with mice treated with naive MSCs. Strikingly, the increased therapeutic effectiveness of co-cultured MSCs was found not to be due to higher production of cardioprotective factors than naive ones at the time of intramyocardial delivery of the cells after 4 days of co-culture. These surprising results indicated that alteration of the MSC secretome mediated by xenogeneic TNTs was transient. Although it remains to be determined why this phenomenon is ephemeral, we can speculate that, at this later stage of co-culturing, co-cultured cardiomyocytes were mainly dead, rendering TNT bridging with MSCs impossible.

In contrast to the relative lack of secretome differences between naive and co-cultivated MSCs at later stages of co-culture, it is interesting to note that a second exposure of co-cultured MSCs to cardiomyocytes, after injection into the heart, increased *de novo* their release of TNT-dependent cytokines. The activation of the MSC secretome was shown to be more efficient after the second cardiomyocyte priming than after the first one and was dependent on the cardiomyocyte to MSC ratio. These observations suggest that activation of the MSC secretome following MSCs injection into the heart might be expected to be greater than its activation *in vitro,* since MSCs should encounter a broader range of cardiomyocytes *in vivo*.

Despite the lack of formal demonstration that TNT interactions with dying cardiomyocytes increase the regenerative properties of co-cultured MSCs *in vivo*, TNT-mediated communication between stromal cells and cardiac cells probably occurs *in vivo* since mitochondrial exchanges from stromal cells to myocardial cells were found in areas of murine myocardial infarcts that had been injected with MSCs.

Beyond the importance of TNT connections with cardiomyocytes in improving MSC paracrine function, we cannot exclude the possibility that the increased therapeutic efficacy of co-cultured MSCs *in vivo* could also result from cell-to-cell communications of injected MSCs with other cells resident in the heart, such as fibroblasts, endothelial cells, or cardiac progenitors. MSCs could communicate with these cells through TNT

structures or by other mechanisms, including gap junctions and paracrine factors. Such phenomena might maximize the healing of cardiac damage. Additionally, it is also possible that injected MSCs could directly interact with immune cells to minimize the deleterious side effects triggered by acute inflammation, which is a key component of infarcted myocardium. Whether TNT-mediated cell-to-cell communications could be involved in the modulation of inflammatory processes mediated by MSCs is unknown, but we can speculate that TNTs might activate the secretion of anti-inflammatory cytokines and decrease the secretion of pro-inflammatory cytokines by MSCs, following their interaction with damaged cardiomyocytes and other injured cells resident in the heart. Consistent with this hypothesis, TNT formation between stromal and cardiac cells has been shown to be sensitive to inflammatory stimuli, since treatment with TNF-α or IFN-γ increased the number of xenogeneic connections and the transcription of TNT-dependent cytokines such as VEGF, HGF, MCP-3, and SDF-1 by MSCs. Modulation of the inflammatory response to injury combined with potential direct interactions of MSCs with immune cells, such as macrophages, dendritic cells, or lymphocytes, might favor a phenotypic switch of these cells of the immune system from a pro-inflammatory phenotype to an anti-inflammatory phenotype.

Direct implication of TNT effects is difficult to assess *in vivo,* since these structures are transient and very fragile. Future studies could address this issue indirectly by comparing the efficacy of MSC administration as a function of increasing doses of cells administered, and/or by using different routes of MSC delivery. For example, MSCs injected intravenously may be unable to interact with cardiomyocytes because they may be retained in the lungs, thus minimizing the potential involvement of TNTs in the heart.

Finally, an important but so far unsolved question concerns the nature of the stress cues sent by cardiomyocytes along TNTs that trigger the paracrine activation of MSCs. We can speculate that miRNA, proteins, or organelles, such as lysosomes or mitochondria, likely contribute to different extents to TNT-mediated cell signaling. In addition, upstream signals initiating TNT formation during the co-culture between stromal cells and cardiac cells must be elucidated. In order to complete the work conducted by Figeac *et al.* [89], it is clearly evident that cell-to-cell communication pathways, other than TNT crosstalk, include soluble mediators, exosomes, large microvesicles, and apoptotic bodies secreted by cardiomyocytes and engulfed by MSCs. These factors also contribute to the modification of MSC paracrine activity. Diversity of the mechanisms by which MSCs and cardiomyocytes communicate during co-culture was illustrated by the decreased release of MCP-1 and MCP-3 in co-cultured MSCs, even when physical contact between the two cell types was impeded or when there was increased stromal cell release of IL-6 and growth-related protein (GRO)-1α. These observations strongly suggested that uptake by MSCs of large microparticles (>0.4 μm) [153] or apoptotic bodies of cardiac origin [62,154] might stimulate the release of IL-6 and GRO-1α, while soluble factors or exosomes/small microvesicles [155] might decrease the production of matrix metalloproteinase (MMP)-3 and MCP-1. However, despite their occurrence, these communication pathways do not appear to be responsible of the increased angiogenic and chemotactic properties of MSCs following after co-culture. We can speculate that release of IL-6 and GRO-1α by co-cultured MSCs indirectly enhances their pro-angiogenic effects by activating the secretion of VEGF and/or the myocardial homing of bone-marrow-derived endothelial progenitors [156,157].

Concomitant with the increased production of soluble factors, the enhanced effects of co-cultured MSCs may also be due to downregulation of harmful diffusible molecules that contribute to pathological left ventricular remodelling after AMI. These include MCP-1, previously reported to exacerbate myocardial inflammation [158], and MMP-3, incriminated in extracellular matrix degradation [159].

In conclusion, further studies are required to formally determine the extent of modification of the MSC secretome following intercellular communication with distressed cardiomyocytes and, in particular, the identification of additional soluble factors involved in healing processes. The principal findings of this section of the chapter are summarized in Figure 21.9.

## 21.5 Conclusions

Cell therapies based on the use of MSCs constitute a promising tool to ameliorate damaged cardiac muscle. Various clinical trials have revealed that delivery of MSCs was feasible and safe. Nevertheless, the clinical benefit of MSC treatment in some trials has been reported to be insufficient to provide long-term patient survival. Thus, intensive efforts are currently being devoted to optimizing the therapeutic efficacy of MSCs. Reaching this goal probably resides in a deeper understanding of the cell-to-cell communication processes between engrafted stromal cells and resident cardiac cells since MSCs activate their regenerative functions in contact with stressed cells in the microenvironment.

Among the diversity and complexity of intercellular crosstalk, TNT structures are particularly fascinating. Emerging data indicate that these structures are important for the rescue by stromal cells of dying somatic cells through the transfer of organelles (and probably other compounds) or for activating the paracrine pro-angiogenic and chemoattractant functions of MSCs. Further investigations are clearly needed to elucidate all facets of TNTs in controlling regenerative processes. With current insights it is likely that TNTs control inflammatory processes and maximize tissue damage by allowing stromal cells to interact with a broad ranges of cell types over long distances.

Future studies on this field may enable investigators to stimulate TNT formation and thereby further improve intercellular exchanges involved in the therapeutic effectiveness of MSCs.

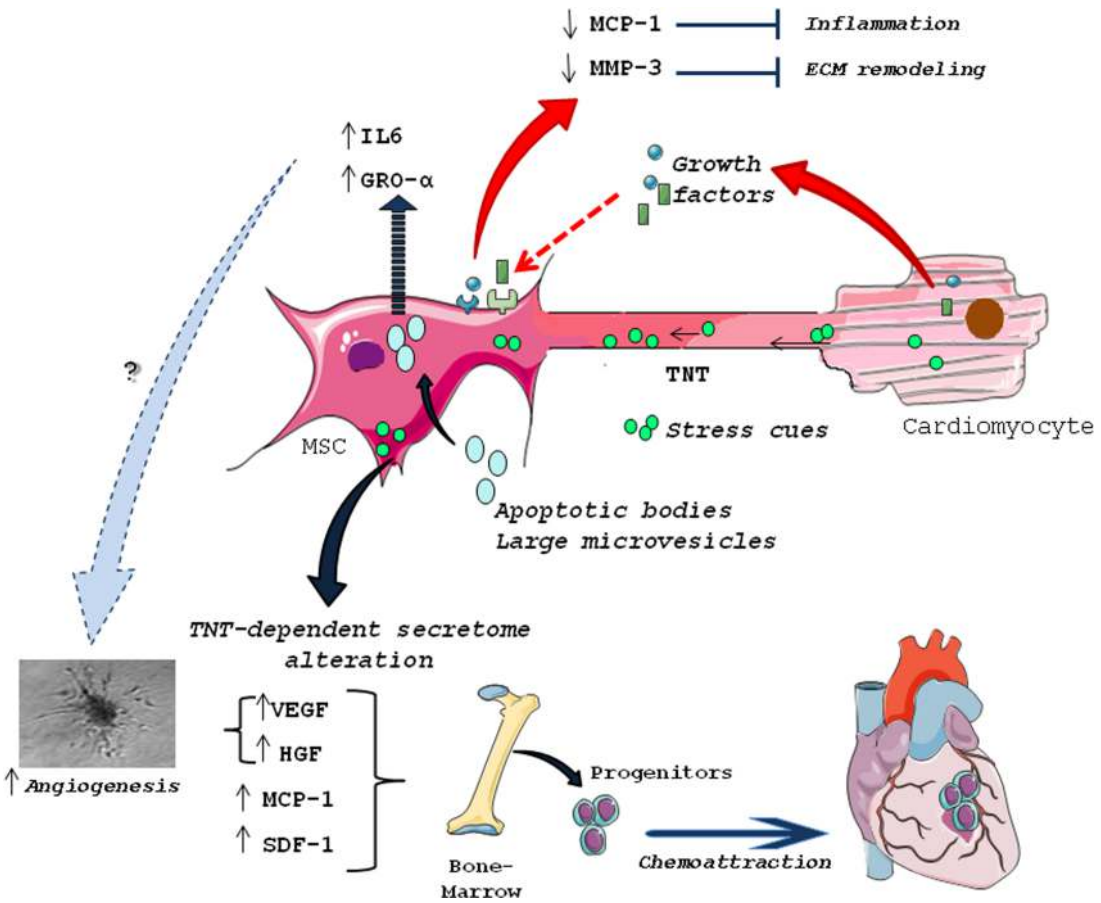

**Figure 21.9** TNT cell-to-cell communication with dying cardiomyocytes alters the secretome of MSCs. Schema summarizing TNT structures improving the paracrine, angiogenic, and chemoattractant functions of MSCs. Other pathways of cell-to-cell communications are also represented as affecting the MSC secretome. This figure was produced using Servier Medical Art.

## 22.1 Introduction

In recent years there has been a dramatic increase in the potential use of mesenchymal stromal cell (MSC)-based therapy for the treatment of degenerative, inflammatory, autoimmune, and ischemic diseases. MSCs are present in numerous tissues throughout the body and can be isolated and expanded *in vitro* with ease. They are capable of multipotent differentiation and immune modulation [1]. Initial excitement in the MSC field centered on the potential of these cells to regenerate injured tissue; for example, to grow new cartilage or repair injured cerebral tissue. However, as research progressed it has become clear that it is through paracrine signaling rather than tissue regeneration that these cells exert their influence [2,3]. This has not dulled enthusiasm for the study of MSCs, as they have numerous advantageous characteristics. MSCs are easily and frequently isolated from bone marrow and adipose tissue, large banks of allogeneic MSCs can be stored, and autologous MSCs can be isolated in a relatively time-efficient manner. MSCs interact with a wide array of other cell populations to contribute to repair and have the ability to migrate under appropriate stimuli to sites of inflammation.

An important initial consideration is whether or not native MSCs migrate to sites of injury or if they are generated and act locally. Several studies have failed to detect MSCs in the systemic circulation [4,5], supporting the local tissue location hypothesis. In solid organ transplants, MSCs present in the donor tissue are consistently of donor origin with no evidence that host MSCs are recruited. One would expect that a transplanted organ would provide enough inflammatory stimuli for host MSC migration, although of course this may be confounded by the use of immunosuppressive medication posttransplant [6]. MSCs have, however, been reported in the peripheral circulation of a minority of hip fracture patients and in just under 50% of young traumatic fracture patients, suggesting that bone fracture might be sufficient stimulus to initiate *in vivo* migration of endogenous MSCs. Alternatively, it may simply reflect mechanical disruption of bone tissue, as occurs in fat embolization following trauma [7,8]. Circulating MSCs have also been reported in rats exposed to chronic hypoxia and in liver-injured mice [9,10].

What remains unclear is why systemic recruitment of MSCs is necessary when they can be found locally in many tissues and if the immunophenotype of endogenous MSCs is the same as culture-expanded plastic adherent cells. Furthermore, if MSCs are recruited systemically they may not necessarily move through the systemic circulation as there has been a report suggesting that adipose-tissue-derived MSCs (AMSCs) migrate via lymphatics [11]. There are benefits to developing therapeutic agents to enhance homing of endogenous MSCs since neither extensive *ex vivo* manipulation nor a vehicle for delivery is needed, and this may be more acceptable in terms of safety.

Endogenous reservoirs may be depleted by age, physical illness, degenerative disease, physiological aberrations, or medications, which are the very groups of patients who would potentially benefit from the actions of MSCs. Thus, the primary focus will remain on the role of exogenously delivered MSCs in disease models. There have been studies of MSC administration in a variety of disease models, including arthritis [12], osteogenesis imperfecta [13], pancreatic islet repair [14], cardiac ischemia [15], inflammatory bowel disease [16], and ischemic stroke [17].

To maximize the potential benefit of MSCs, the mechanism of their ability to migrate to sites of injury needs to be more fully understood. There have been significant developments in identifying the chemokine receptors on MSCs and the role that they play in homing; in particular, the interaction between C–X–C motif chemokine receptor (CXCR)4 and stromal derived factor-1 (SDF-1) has been studied extensively, but other chemokines, such as monocyte chemoattractant protein (MCP)-1 and macrophage inflammatory protein-1α (MIP-1α), as well as growth factors, have been studied and will be reviewed in this chapter. The contribution of the inflammatory environment itself needs to be considered, with particular focus on the proliferation of cytokines, influx of inflammatory cells, and activation of the complement system.

Initial *in vitro* work has led to a large range of *in vivo* homing studies with mixed results. Accurate comparisons between these studies are fraught with difficulty since the phenotype and immunophenotype of MSCs is known to vary with culture conditions, passage number, and source tissue. Indeed, the criteria for identifying MSCs as proposed by the Mesenchymal and Tissue Stromal Cell Committee of the International Society for Cellular Therapy was only published in 2006, and many studies predate this. These criteria are (1) plastic adherence of isolated cells in tissue culture; (2) >95% of the cultured cells positively expressing the cell surface markers CD105, CD73, and CD90, while being negative for CD34, CD45, CD14, CD11b, CD79a, CD19, and human leukocyte antigen-DR; and (3) *in vitro* differentiation into three mesodermal cell types, namely osteoblasts, adipocytes and chondroblasts [18]. In addition to inherent differences between MSC phenotypes, consideration needs to be given to the number of cells administered, the timing of this administration, the route used, and the detection method employed. This latter element poses significant challenges, and current procedures are getting away from *ex vivo* histological analysis and moving toward *in vivo* imaging, as will be discussed further.

Despite these difficulties great strides have been made in understanding cell migration and applying this knowledge to augment migration and improve disease outcomes through alterations in culture conditions, cell engineering strategies, and host modifications.

This chapter will review the major advances in the field of MSC migration *in vitro* and *in vivo*, focusing on the potential of exogenously delivered MSCs in the treatment of inflammatory and ischemic disease models.

## 22.2 Molecular mechanisms of migration

### 22.2.1 Chemokines

Chemokines have an important role to play in the migration of both endogenous and exogenous MSCs to sites of injury. Chemokines are small polypeptides and play a central role in the trafficking and localization of hematopoietic cells, as well as cell differentiation, survival, and activation [19–21]. It has been demonstrated that ligand binding to chemokine receptors can induce phosphorylation of mitogen activated protein kinases (MAPKs) such as extracellular signal-related kinase (ERK-1 and ERK-2) and activate focal adhesion kinase (FAK) pathways [22]. It is well known that chemokines act through MAPK pathways and that FAK activation has a central role in cell migration, adhesion, and survival [23,24]. Furthermore, C–X–C motif chemokine ligand (CXCL)12, the ligand for CXCR4, and chemokine (C–C motif) ligand (CCL)5, the ligand for chemokine receptor (CCR)1, activate STAT5 and STAT1 (signal transducer and activator of transcription) respectively. Stat pathways have important roles in cell differentiation and survival [22,25].

The role of chemokines in the migration of MSCs is important as it may provide insight into MSC function and provide targets for therapies designed to improve MSC migration to sites of injury. In one report, human bone-marrow-derived MSCs (BMSCs) were shown to express CCR1, CCR7, CCR9, CXCR4, CXCR5, and CXCR6 with no expression of CCR2–6, CCR8, and CXCR1–3 demonstrated [22,26]. However, CCR2, the receptor for monocyte chemoattractant protein 1 (MCP1 or CCL2) and CCR8, the receptor for interleukin (IL)-8, have been identified by other groups on murine MSCs, human periosteal progenitor cells, and human MSCs [27–29]. Rat MSCs have also been shown to express CXCXR4, CX3CR1, CCR2, and CCR5 [27,30].

Whether or not these chemokine receptors are functionally active on MSCs and are targeted by ligands produced by inflammation has been studied by various groups both *in vitro* and *in vivo*. In 2006, Honczarenko *et al.* reported that all identified chemokines, tested with the appropriate receptor, induced migration of bone marrow MSCs (BMSCs) *in vitro* with a bell-shaped dose-response relationship [22]. CCR2 and CCR8 may be activated to stimulate MSC migration both *in vitro* and to

breast cancer tissue *in vivo* [27–29]. IL-8 is known to play a role in the aggregation of neutrophils in inflamed tissue, and a chemotactic response to an IL-8 gradient has been demonstrated *in vitro*, suggesting it plays a role in MSC migration to inflamed tissue. However, robust *in vivo* data to corroborate this are lacking [31,32]. CCL2, also known as MCP-1, is another key chemokine that regulates migration and infiltration of monocytes and is upregulated in the inflammatory environment [33,34]. However, there are conflicting reports on the role of this chemokine in MSC migration studies, with one such study failing to demonstrate an *in vitro* MSC migratory response after MCP-1 stimulation [32]. MCP-3, or CCL7, has also emerged as a potentially important MSC homing factor, with improvement in cardiac function noted after serial infusions of MSCs in MCP-3-expressing hearts and associated overrecruitment of CCL7-recruited MSCs at the site of myocardial infarction [35].

MIP-1α, also known as CCL3, is a ligand for CCR1 and CCR5 and is known to regulate migration of proinflammatory cells to sites of inflammation. It can be upregulated by inflammatory stimuli from macrophages, dendritic cells, and lymphocytes, as is seen in the synovial fluid of patients with rheumatoid arthritis [36,37]. *In vitro* studies have demonstrated an increase in murine and human MSC migration in response to MIP-1α [38–40]. There is currently no information looking at the effect of MIP-1α or CCR1 inhibition or *in vivo* evidence to support MIP-1α as a chemoattractant to systemically delivered MSCs.

The role of SDF-1, also known at CXCL12, has been extensively studied in the recruitment of MSCs expressing the corresponding receptor CXCR4. CXCR4 is a G coupled transmembrane glycoprotein that is expressed on endothelial cells and which has been shown to mediate transcytosis of circulating SDF-1 into bone marrow with a resultant increase in the migration of human $CD34^+$ progenitor cells [41–43]. (Transcytosis is the process by which various macromolecules are transported across the interior of a cell. Macromolecules are captured in vesicles on one side of the cell, drawn across the cell, and ejected on the other side.)

Bone marrow endothelial cells, immature osteoblasts, and other bone marrow stromal cells constitutively express and secrete SDF-1 [44–46]. SDF-1 is found in particular in myelosupportive stromal cells near the endosteal surfaces of bone marrow [46–48]. In addition to endothelial and hematopoietic cell migration, SDF-1 regulates the hematopoietic cell cycle and also influences the survival and migration of neuronal, muscle, and liver cells [45,49–51].

In terms of injury models, SDF-1 expression is increased and peaks within 1 day at sites of myocardial infarction, is augmented in the kidney after ischemia–reperfusion-induced acute renal failure, and has been demonstrated at the site of hypoglossal nerve injury and in rat stroke models [30,52–54]. Further *in vitro* studies have attempted to confirm the role of CXCR4 activation in specific disease models. Healing live bone grafts *in vitro* showed high expression of SDF-1 in the periosteum with new bone formation inhibited by anti-SDF1 antibodies [55]. In an acute kidney injury (AKI) model, ischemia and reperfusion of renal tubular cells was used to mimic AKI *in vitro*: migration of BMSCs toward these injured cells was CXCR4 dependent, was increased by overexpression of CXCR4, and inhibited by a CXCR4-specific antagonist. Furthermore, phosphorylated AKT and MAPK was found to be increased in this AKI model and inhibition of these pathways partially blocked migration, suggesting that the SDF1-1/CXCR4 pathway acts through the P13K/AKT and MAPK pathways [56]. Therefore, it is hypothesized that the interaction between locally produced SDF-1 and CXCR4 expression on MSCs may facilitate migration of MSCs to the site of injury.

The SDF-1/CXCR4 interaction has been a particular focus of *in vitro* MSC migration studies to date. In one such study, BMSCs were harvested from healthy individuals, CXCR4 was identified with antibody staining, and CXCR4 mRNA confirmed by reverse transcriptase polymerase chain reaction (PCR). Only small percentages (1–3.9%) of cells were shown to express CXCR4 at the cell surface membrane. However, intracellular expression was confirmed in over 80% of cells. Cells were stimulated in transwell chambers with SDF-1, resulting in a dose-dependent increase in migration that was abrogated with the addition of anti-CXCR4 antibody [57]. Induced migration by activation of this pathway *in vitro* has also been demonstrated in human umbilical-cord-derived MSCs (UMSCs), which could be inhibited by antagonists of CXCR4 and inhibitors of P13K, MAPK, and p38 MAPK [58]. An abundance of SDF-1 transcripts has been demonstrated in human BMSCs with a preferential expression in immature stromal cell populations *in vitro* [59]. The expression of SDF-1 by this population of cells was shown to decrease as cells underwent osteogenesis. The high SDF-1 expression in immature stromal cells was shown to be protective against IL-4-induced apoptosis. Again, MSCs were shown to express low levels of functionally active cell surface CXCR4. It is likely that *in vivo* the SDF-1/CXCR4 interaction may function to localize immature stromal cells in a perivascular bone marrow niche and promote their survival until recruited elsewhere [59].

In addition to *in vitro* migration studies, stromal cells challenged with SDF-1 have been shown to undergo changes in F-actin polymerization [22]. By utilizing confocal microscopy, SDF-1 stimulation was shown to lead to an increase in intensity, orientation, and organization of intracellular filamentous networks. This is an early prolonged response that is thought to influence stromal cell migration [22].

Investigation into the role of the SDF-1/CXCR4 pathway has not been limited to *in vitro* migration but has been studied *in vivo* in several models, including neural tissue damage, cardiac ischemia, AKI, and bone repair [30,52,55,56,60,61]. Rat MSCs delivered intravenously were shown to migrate preferentially to areas in the cerebral cortex where recombinant human SDF-1 had been administered, while MSCs transplanted into the lateral ventricle of rats migrated to a unilateral avulsed (forcibly detached) hypoglossal nerve. This latter migratory effect was

associated temporally with increased levels of SDF-1 at the site of injury [30]. In the spinal cord, SDF-1 is expressed in the dorsal corticospinal tract and meninges, and both SDF-1 and CXCR4 are upregulated after traumatic spinal cord injury. Additionally, there are data suggesting that this pathway is implicated in the migration of MSCs to spinal cord injury after intrathecal or intravenous delivery [62–65]. In models of cardiac ischemia SDF-1 is secreted by injured cardiac cells, which may act as a chemoattractant for MSCs expressing CXCR4 [61]. This expression peaked within 24 h of injury, during which time intravenously delivered MSCs were recruited to the injured myocardium where they enhanced angiogenesis with resulting improvements in cardiac function [52]. *In vitro* models of AKI show migration of MSCs mediated by the SDF-1/CXCR4 pathway. In addition to this, the systemic transplantation of MSCs overexpressing CXCR4 was shown to accumulate at sites of AKI *in vivo* with associated improvement in renal function. This was correlated with an increase in SDF-1 expression in the injured tissue and was greater than the effect seen with unmodified MSCs [56]. In skeletal tissue, intravenously delivered MSCs are recruited by SDF-1 and participate in endochondral bone repair, supporting *in vitro* findings [55]. In addition, MSCs engineered to overexpress SDF-1 resulted in significantly augmented new bone formation at fracture sites in rat models [66].

As always, when considering the SDF-1/CXCR4 interaction in terms of MSC migration, it is important to consider the microenvironment in which MSCs function. Many of the *in vivo* models used are sites of hypoxic damage, while hypoxia is also a feature in inflammatory and neoplastic disorders [67–69]. It has previously been demonstrated that G-protein-coupled receptors, such as CXCR4, are regulated by hypoxia in the local environment [70]. Hypoxia has been shown to regulate CXCR4 expression in association with hypoxia inducible factor 1 (HIF-1) activation; hypoxia increases CXCR4 expression in mononuclear phagocytes, endothelial cells, and malignant cells, and levels remain high for a period after reoxygenation [71]. In malignancy, hypoxia upregulates CXCR4 expression and the likelihood of metastases in gastric cancer in an HIF-1-dependent manner [72], while CXCR4 is upregulated by several factors, including a deprivation of growth factors and hypoxia, in Ewing's sarcoma cells [73]. Other local factors that may influence SDF-1/CXCR4-mediated migration are local cytokines. Transforming growth factor (TGF)-β1, a cytokine with multiple functions, including regulation of cell proliferation and migration, downregulated expression of chemokine SDF-1 expression in the murine stromal cell line MS-5 [74]. In other studies, the migration of MSCs toward SDF-1 was increased after pretreatment of the cells with IL-1β and tumor necrosis factor-α (TNF-α), both potent proinflammatory cytokines found in conditions such as rheumatoid arthritis [75]. Interestingly, this did not appear to occur via an increase in CXCR4 expression or increased SDF-1 binding, and it has been hypothesized that proinflammatory cytokines may augment signal transduction without affecting receptor expression [75,76].

The SDF-1/CXCR4 pathway is well established as playing a central role in coordinating cell survival and migration in multiple cell types. It has now been established that this interaction also plays an important role in the migration of MSCs toward injured tissue both *in vitro* and *in vivo*. Understanding the role of cell culture and the local microenvironment will aid in increasing our ability to deliver site- and time-accurate MSCs and will also provide opportunities for cell modification to optimize targeted cell delivery.

While chemokines, and in particular the SDF1/CXCR4 interaction, have been implicated in the migration of MSCs to inflamed and hypoxic tissue, there remain unanswered questions; in particular, the reported expression rate of these chemokine receptors varies between published studies. This most likely reflects variations in *in vitro* culture conditions, isolation techniques, and time in culture [77–80]. In fact, long-term culture of MSCs results in a marked reduction in the expression of chemokine receptors and the loss of chemotactic responses to chemokines [22]. It is unlikely that activation of a single pathway is responsible for MSC migration, but rather that several chemokine axes play synergistic roles in the initiation and propagation of stromal cell migration. In addition to this there is evidence that integrins, toll-like receptors, matrix metalloproteinases (MMPs), and growth factors may also all play a part in this process.

Table 22.1 summarizes molecules influencing the migration of MSCs.

### 22.2.2 Integrins

Integrins are transmembrane receptors that mediate interactions between cells and between cells and the extracellular matrix. Integrin expression on MSCs has been implicated in the trafficking of MSCs to areas of cardiac ischemia [82]. Microarray technology and real-time (RT)-PCR were used to identify ligand–receptor pairs expressed in infarcted myocardium and BMSCs respectively. Receptors upregulated on MSCs that were thought may play a role in their recruitment included CXCR4, integrin α, and integrin β. These were then blocked by culture with the appropriate antibody. Receptor inhibition reduced adherence to fibronectin *in vitro*. However, only blockade of integrin 1β inhibited integration of locally delivered MSCs to infarcted myocardium [82].

### 22.2.3 Toll-like receptors

Another important player in MSC migration is the group of toll-like receptors (TLRs) which play a significant role in the pathology of a number of chronic inflammatory conditions, including rheumatoid arthritis and inflammatory bowel disease. It has been demonstrated that MSCs express TLRs at both the protein and RNA level with confirmation of TLR 1–6 expression on both human and murine MSCs isolated from either bone marrow or adipose tissue [89–92]. Additionally, as with chemokine receptors, their expression can be modulated by hypoxia with reported increases in TLR 1, 2, 5, and 9 under conditions of reduced

**Table 22.1** Factors influencing MSC migration.

| First author, year, ref | Molecules of interest | Findings |
|---|---|---|
| Honczarenko, 2006, [22] | CCR1, CCR7, CCR9, CXCR4, CXCR5, CXCR6 | All induced MSC migration with bell-shaped dose–response relationship |
| Xu, 2010, [27] | CCR2, CCR8 | May be activated to induce migration *in vitro* |
| Ringe, 2007, [32] | IL-8 | Increased MSC migration *in vitro* in dose-dependent manner |
| | MCP-1 | No *in vitro* migratory response |
| Boomsma, 2012, [39] | MCP-1 | Increased MSC migratory response |
| Belema-Bedada, 2008, [81] | MCP-1 | MCP-1 transgenic mice recruited MSCs *in vivo* |
| Schenk, 2007, [35] | MCP-3 (CCL7) | Increased migration to infarcted heart *in vivo* |
| Sordi, 2005, [38] | MIP-1α (CCL3) | Increased MSC migratory response |
| Wynn, 2004, [57] | SDF-1 (CXCL12) | Dose-dependent increase in MSC migration |
| Ryu, 2010, [58] | SDF-1 | Increased MSC migration *in vitro* |
| Ji, 2014, [30] | SDF-1 | *In vivo* migration to neural injury associated with increased SDF-1 expression |
| Liu, 2013, [56] | SDF-1 | MSCs overexpressing CXCR4 (receptor for SDF-1) accumulated at site of AKI |
| Ip, 2007, [82] | Integrin α, integrin β, SDF-1 | Receptor inhibition reduced adherence to fibronectin *in vitro*. Blockage of integrin 1β inhibited integration of MSCs to ischemic myocardium |
| Tomchuck, 2008, [83] | TLR3 | Stimulation increased MSC migration *in vitro* |
| Annabi 2001, [84] | MT1-MMP | Inhibition decreased MSC migration independently of MMP2 |
| De Becker, 2007, [85] | MMP2 | Inhibition of MMP2 reduced MSC migration *in vitro*. |
| | TIMP3 | Addition of TIMP3 reduced cell migration. |
| Ries, 2009, [86] | MMP2, MT1-MMP, TIMP2 | Gene knockdown impaired MSC migration. Silencing of TIMP1 increased migration |
| | TIMP1 | |
| Park, 2014, [87] | PLGF | Inhibition of PLGF receptor decreased MSC migration |
| Cipriani, 2013, [88] | PDGF | Augmented MSC migration *in vitro* |

CCR: C–C chemokine receptor type; CXCR: C–X–C chemokine receptor type; IL: interleukin; MCP: monocyte chemoattractant protein; MIP: macrophage inflammatory protein; SDF: stromal-cell-derived factor; TLR: toll-like receptor; MT: membrane type; MMP: matrix metalloproteinase; TIMP: tissue inhibitor of metalloproteinase; PLGF: placental growth factor, PDGF: platelet-derived growth factor.

oxygen concentration [93]. Stimulation of TLRs has been shown to activate numerous pathways, including signaling pathways involved in cell migration such as MAPK and PI3K [83,94]. In terms of migration, the role of TLRs remains unclear. The activation of TLR3 with several ligands was shown to increase human MSC migration in transwell chamber assays [83]. However, in wound healing models it was found that TLR 2 stimulation actually attenuated mouse MSC migration [95]. The roll of TLRs in stromal cell migration in inflammation warrants further study.

### 22.2.4 Matrix metalloproteinases

MMPs have also been implicated in MSC migration and in particular with the ability of MSCs to invade basement membrane and endothelial barriers. MMPs are proteolytic enzymes that are secreted as inactive proenzymes [96]. They are subdivided into groups based on their structure and ligand specificity. These groups are collagenases, stromelysins, matrilysins, gelatinases, and membranous-type MMPs. The gelatinases MMP2 and MMP9 are known to play a role in the migration and homing of leukocytes and hematopoietic progenitor cells [97–100]. Both human and murine marrow-derived MSCs have been shown to express MMP2 and MT1-MMP [84–86]. Both MMP2 mRNA expression and protein secretion have been confirmed [78,84]. In addition, murine MSCs and, human BMSCs and cord-blood-derived MSCs express MT1-MMP, while human BMSCs express tissue inhibitors of metalloproteinase (TIMPs) 1 and 2 [78,84,86].

These MMPs have been implicated in the migration of MSCs *in vitro*. Functional inhibition of MT1-MMP in murine MSCs decreases cell migration independently of MMP2 activation [84]. In human MSCs, inhibition of MMP2 with a neutralizing antibody inhibits, although does not completely block, MSC migration through basement membrane epithelium. A similar effect is seen when MSCs are transfected with MMP2 small interfering RNA (siRNA) [85]. The addition of recombinant TIMP3, a natural MMP inhibitor, to culture models led to a reduction in cell migration. Interestingly, TIMP3 is upregulated as MSCs

become more confluent and may be the mechanism behind the observed reduction in MSC migration as confluence increases [85]. In a similar study, the ability of MSCs to invade through reconstituted human basement membrane was blocked by a synthetic inhibitor of MMP. Gene knockdown of MMP2, MT1-MMP, and TIMP2 by RNA interference impaired migration, whereas the silencing of TIMP1 actually increased migration, suggesting that the TIMPs may have varying roles in MSC migration [86]. The relationship between MMPs, hypoxia, and cell confluence suggests that MMPs may play an important role in MSC migration, particularly the ability of MSCs not just to migrate to the site of injury but to cross endothelial basement membranes and reach damaged tissue [78,86].

### 22.2.5 Growth factors

It is also worth considering the role that growth factors may play in cell migration, with particular reference to placenta growth factor (PLGF) and platelet derived growth factor (PDGF). PLGF plays a role in endothelial cell proliferation and is upregulated in inflamed tissues, where it may play a role in the production of TNF-α, IL-1, IL-8, and MCP-1 [101–104]. Expression of the PLGF receptor Flt-1 has been found on MSCs and demonstrated to play a role in MSC migration *in vitro*. This was confirmed by reduction in migration after MSC preincubation with an anti-Flt-1 antibody [87].

PDGF has also been shown to be highly expressed at sites of inflammation and malignancy, and overexpression may enhance MSC migration to lung metastases *in vivo* [88,105]. PDGF-mediated augmentation of MSC migration *in vitro* can be abrogated by PDGF receptor inhibition [88]. PDGF receptors are expressed on MSCs and may represent a more potent MSC chemoattractant than SDF-1, but not after pretreatment with TNF-α [75,106].

## 22.3 The inflammatory milieu

As indicated above there are numerous mechanisms by which MSC migration may be initiated, with most of the work to date focusing on chemokines interacting with receptors on MSCs. There is much interest in how these data fit into the migration of MSCs under inflammatory conditions. There are several features of the inflammatory milieu that will be reviewed. Hypoxia, as outlined later, has been extensively studied and is important in terms not just of acute ischemic events but also as a feature of inflamed tissue. Other characteristic features to be considered include the presence of proinflammatory cytokines, the activation of the complement cascade, and the recruitment of macrophages.

### 22.3.1 Passive migration

Before reviewing these features it is worth considering that increased migration may simply be a passive process secondary to inherent features of inflammation, such as vasodilation and new vessel formation. However, given the increasing evidence of possible migration mechanisms, it is unlikely that this is the case, although it may facilitate homing *in vivo*.

### 22.3.2 Hypoxia

It is likely that the chemotactic function of MSCs is regulated by oxygen availability within the tissues. It is known that G-protein-coupled receptors, such as CXCR4, may be controlled by environmental signals, including tissue hypoxia, which plays a pathological role in inflammatory and neoplastic conditions [67–69,71]. HIF-1 is a central player in the hypoxia–CXCR4 pathway, increasing the expression of CXCR4 on monocytes, macrophages, and endothelial cells. HIF-1 activates gene transcription, resulting in adaptive responses to reduced oxygen availability. HIF-1-regulated genes include those that play a role in angiogenesis, vascular remodeling, and glucose metabolism [71]. In models of chronic obstructive pulmonary disease hypoxia led to an HIF-1-mediated increase in SDF-1, a factor implicated in MSC recruitment [107], while hypoxia in gastric cancer cells also upregulated CXCR4 [72]. In MSCs, temporary exposure to hypoxia induces a rapid increase in the nuclear translocation of HIF-1. However, the role of this in HIF-dependent kinase pathways in MSCs is not fully understood [108,109]. In MSCs, hypoxia-induced phosphorylation of MAPK has been reported as being both increased and downregulated [109–113]. Similar contradictions have been reported in terms of hypoxia-induced stress-activated protein kinase/c-Jun NH2 terminal kinase (SAPK/JNK) [110,112–114].

Specific studies in MSCs show that ischemic cerebral rat tissue induces a modest increase in human MSC migration *in vitro* compared with nonischemic tissue [115]. However, there are likely to be multiple factors involved in this, and what is perhaps more interesting is the effect of hypoxic culture conditions on MSC migration. Studies focusing on the effects of hypoxia on migration of MSCs generally suggest that short-term exposure to hypoxic culture conditions increases migration and may promote angiogenic activity.

One group has shown that 4 h of hypoxic culture conditions increased both the migration of MSCs *in vitro* and their ability to form three dimensional capillary-like structures. This effect appears to be mediated through increases in VEGF and MT1-MMP, the latter being an MMP implicated in MSC migration [84]. Another group showed that short-term (24 h) exposure to hypoxia increased the expression of CX3R1 (the receptor for fractalkine) and CXCR4 (the receptor for SDF-1) on human MSCs and was further increased with the addition of the iron chelator desferrioxamine, which stabilizes HIF-1α. Soluble fractalkine, also known as CX3CL1, potently chemoattracts T cells and monocytes, while the cell-bound chemokine promotes strong adhesion of leukocytes to activated endothelial cells, where it is primarily expressed.

Hypoxia also induced increased migration of these MSCs *in vitro* toward media both in the absence of chemokines and toward SDF-1α and fractalkine, ligands for CXCR4 and CX3R1

respectively [116]. More recent studies of cardiac progenitor cells also demonstrated CXCR4-mediated increases in migration secondary to hypoxic culture conditions [117]. *In vitro* scratch assays demonstrated that up to 10 h of hypoxia increased the migration of human UMSCs and that this effect was lost in the presence of siRNA for FAK. FAK plays a role in MAPK and HIF-1α pathways [110]. The *in vitro* scratch assay is an easy, low-cost, and well-developed method to measure cell migration *in vitro*. The basic steps involve creating a "scratch" in a cell monolayer, capturing the images at the beginning and at regular intervals during cell migration to close the scratch, and comparing the images to quantify the migration rate of the cells.

In addition, a hypoxia-induced increase in MSC migration in both wound healing and Boyden chamber assays was inhibited by blockers of ERK1/2 of c-Jun N-terminal kinase (JNK)1/2. An increase in these kinases was associated with an early increase in reactive oxygen species and a later HIF-1-dependent increase in VEGF. The migration of MSCs was decreased in the wound healing assay but not in the 6 h Boyden chamber assay after silencing of HIF-1α [112]. The Boyden chamber is a useful tool for studying cell migration. It consists of a cylindrical cell culture insert nested inside the well of a cell culture plate. The insert contains a polycarbonate membrane at the bottom with a defined pore size. Cells are seeded in the top of the insert in serum-free media, while serum or similar chemoattractants are placed in the well below. Migratory cells move through the pores toward the chemoattractant below and can be stained or quantified in a plate reader.

It is likely that the cellular responses of MSCs to hypoxia reflect a dynamic balance between pro- and antiapoptotic pathways [109]. However, there is clear evidence that short-term exposure to hypoxia may play a role in MSC migration in inflammation and could potentially be used as a tool to augment the migration of MSCs in a therapeutic setting.

### 22.3.3 Cytokines

When evaluating the migration of cells in an inflammatory environment it is important to consider the effect of proinflammatory cytokines on those cells (Table 22.2). Both TNF-α and IL-1β are proinflammatory cytokines that play an essential role in inflammation and may exert significant effects on cells exposed to them. It is known that MSCs are affected by the inflammatory milieu. There is a negative relationship between the degree of synovial inflammation and the chondrogenic and clonal capacities of human MSCs isolated from rheumatoid synovium [125]. Furthermore, *in vitro* studies have demonstrated an effect of proinflammatory cytokines on MSC differentiation and proliferation. TNF-α transgenic mice have decreased expression of osteoblast marker genes and osteogenesis and the proliferation of MSCs from C57BL/6 mice is suppressed by treatment with TNF-α or IL-1β [126,127]. However, it is important to be aware that not all MSCs behave in the same way: a direct comparison between MSCs from Balb/c mice (MHC $H2^d$) and FVB mice (MHC $H2^q$) isolated and cultured under identical conditions showed that the suppression of osteogenesis and adipogenesis by TNF-α or IL-1β was more pronounced in MSCs from Balb/c mice [124]. In addition to affecting differentiation there is evidence to suggest that proinflammatory cytokines can alter MSC proliferation *in vitro* and promote MSC-mediated tumor growth. The mechanism underlying this is not well understood but may involve upregulation of ubiquitin ligases or β-catenin-mediated upregulation of Wnt signaling [126,128,129].

It has been hypothesized that proinflammatory cytokines play a role in the migration of either endogenous MSCs or those delivered systemically to sites of inflammation. There is some suggestion that human MSCs migrate preferentially toward TNF-α [119], and most studies demonstrate a significant augmentation of *in vitro* migration after MSCs are pretreated with either TNF-α or IL-1β for 24 h. Adult MSCs were shown to migrate significantly more towards various chemokines, in particular MCP-1, RANTES, SDF-1, and macrophage-derived chemokines, after preincubation with TNF-α but not with IL-1β [75,119]. However, subsequent studies demonstrated that human BMSCs treated for 24 h with recombinant IL-1β had increased secretion of multiple chemokines involved in cell migration, including CCL5, CCL20, CXCL1, CXCL3, CXCL5, CXCL6, CXCL10, and CXCL11. This study also showed a strong pro-migratory role for IL-1β in *in vitro* transwell migration assays. With regard to nonhuman MSCs, TNF-α was shown to upregulate vascular cell adhesion molecule (VCAM)-1 expression on rat MSCs, and pretreatment of these MSCs with TNF-α increased the *in vitro* adhesion of MSCs to endothelial cells as measured with fluorescence microscopy. Furthermore, after intravenous delivery of fluorescently labeled MSCs in an ischemic muscle rat model, pretreated MSCs accumulated in greater numbers in the ischemic muscle after 24 h compared with MSCs not exposed to TNF-α [120].

MSCs isolated from both FVB and Balb/c mice also showed a marked increase in migration toward medium supplemented with serum *in vitro* [124]. *In vitro* and *in vivo* data by Zhang *et al.* exemplified the potential role of the inflammatory milieu on MSC recruitment in models of vascular damage. In a model of rat carotid artery injury, the overexpression of the signaling molecule SMAD3 led to an increase in MCP-1 production, a known chemoattractant for BMSCs. The phosphorylation of SMAD3 and the resultant increase in MCP-1 was thought to be mediated by TGF-β production in the smooth muscle of the injured vasculature [28].

While the upregulation of chemokines has been demonstrated, the exact mechanisms behind the increased migratory capacity of MSCs prestimulated with inflammatory cytokines remains unclear. Both TNF-α and IL-1β have known effects on the MAPK and PI3K pathways, both of which have been shown to mediate migration of chondrocytes and fibroblasts [130,131]. The role of the nuclear factor (NF)-κB has also come under scrutiny. NF-κB plays a central role in the coordination of immune responses in inflammatory conditions such as rheumatoid arthritis through transcription of cytokine genes, including

**Table 22.2** Summary of cytokine effects on MSC migration.

| First author, year, ref. | Cell type | Migration assay | Results |
|---|---|---|---|
| Ponte, 2007, [75] | Human BMSCs | Transwell assay, 8 μm pores, overnight | Pre-stimulation at 1 ng/mL for 24 h with TNF-α increased migration to SFM, SDF-1, MDC, RANTES. No increase in migration to GFs. Pre-stimulation at 1 ng/mL of IL-1β had no effect |
| | | | Pre-stimulation at 1 ng/mL of TNF-α increased MSC expression of CCR2, CCR3, CCR4, and membrane binding of RANTES |
| Böcker, 2008, [118] | Human BMSCs | Transwell polycarbonate membrane coated with ECM, 8 μm pores | Pre-stimulation at 30 ng/mL of TNF-α for 30 min increased expression of VCAM1, CD44, and MMP9 on MSCs, which was blocked by inhibition of NF-κB |
| | | | Increased migration towards 50 mg/mL TNF-α was reduced by blocking NF-κB |
| Baek, 2011, [119] | Human AMSCs | Transwell assay, polycarbonate membrane, 8 μm pores, 24 h | Prestimulation with 100 ng/mL of TNF-α increased migration toward SFM, PDGF-AB, TGF-β1, TNF-α, CXCL16, BCA-1, and RANTES |
| Xiao, 2012, [120] | Rat BMSC | 24-well culture plate coated with aortic rat endothelial cells | Pre-stimulation at 1–20 ng/mL of TNF-α for 24 h increased VCAM-1 expression by MSCs |
| | | | Pre-stimulation at 10 ng/mL of TNF-α increased adhesion to endothelial cells |
| | | *In vivo* rat hind limb ischemia | Pre-stimulation at 10 ng/mL TNF-α increased *in vivo* migration to ischemic muscle after intravenous delivery |
| Carrero, 2012, [121] | Human BMSCs | Transwell assay, 8 μm pores, 4 h | Pre-stimulation at 25 ng/mL of IL-1β increased expression of CCL5, CCL20, CXCL1 ICAMs, VCAM,and IL-8 on MSCs. Increased migration toward 25 ng/mL IL-1β, which was blocked by NF-κB |
| Fan, 2012, [122] | Human UCMSCs | Transwell assay, 8 μm pores, 12 h | Increased migration toward 10 ng/ml IL-1β, which was silenced by IL-1β RNA |
| | | Acute colitis *in vivo* | Pre-stimulation at 10 ng/mL of IL-1β increased migration to spleen, mesenteric lymph nodes, and colon *in vivo* after intravenous delivery |
| Xinaris, 2013, [123] | Mouse BMSCs | Scrape healing assay | Pre-stimulation at 20 ng/mL of IGF-1, 100 ng/mL of GDNF, and 100 ng/mL of TNF-α increased migration in scrape assay and toward cisplatin-injured cells and induced cytoskeletal changes in MSCs |
| | | Transwell assay, polycarbonate membrane, 8 μm pores, 24 h | Pre-stimulation with IGF-1 increased CXCR4 expression on MSCs |
| Sullivan 2014 [124] | Mouse BMSCs | Transwell assay, 8 μm pores, 18 h | Pre-stimulation at 50 ng/mL of TNF-α or IL-1β increased migration to 10% serum. Not affected by NF-κB inhibition |

BMSC: bone-marrow-derived mesenchymal stromal cell; AMSC: adipose-tissue-derived MSC; UMSC: umbilical-cord-derived MSC; TNF-α: tumor necrosis factor-α; SFM: serum-free media; SDF-1: stroma-derived factor 1; MDC: macrophage-derived chemokine; GF: growth factor; IL: interleukin; CCR: C–C chemokine receptor type; ECM: extracellular matrix; VCAM: vascular cell adhesion molecule; CD44: cluster of differentiation 44; MMP: matrix metalloproteinase; NF-κB: nuclear factor kappa B; PDGF: platelet-derived growth factor; CXCL: C–X–C motif chemokine; BCA: B cell attracting chemokine; ICAM: intercellular adhesion molecule; IGF: insulin-like growth factor; GDNF: glial-derived neurotrophic factor; CXCR: C–X–C chemokine receptor type; RANTES: regulation on activation, normal T cell expressed and secreted (also known as CCL5).

TNF-α and IL-1β. This pathway also plays a role in the regulation of genes involved in cell proliferation, migration, and differentiation and may induce the expression of adhesion molecules, enhance vascular permeability, and recruit inflammatory cells [132]. Inhibition of the NF-κB pathway has been shown to reverse the pro-migratory effects of TNF-α on human MSCs [118,121]. Another study using UMSCs demonstrated an increase in migration in response to *Staphylococcus aureus*-infected epithelial cells, which expressed high levels of TNF-α. This effect was abrogated by using siRNA to knock down the p65 subunit of NF-κB [133]. However, this was not the case for MSCs derived from mouse bone marrow. The inhibition of NF-κB, either by transduction of MSCs with an adenoviral vector expressing a super-repressor of NF-κB or by addition of the anti-inflammatory agent curcumin to the culture medium, had no effect on the augmentation of murine Balb/c MSC migration after stimulation with TNF-α *in vitro* [124].

Table 22.2 summarizes the effects of cytokines on MSC migration.

### 22.3.4 Complement

The complement system is a complex cascade that can be activated either by the classical pathway, which is dependent on an antigen–antibody reaction, or by an alternative pathway,

which is usually mediated by bacterial endotoxins or through the binding of lectin to mannose on the surface of pathogens. All three pathways culminate in a final common pathway with production of bioactive peptides such as C3a and C5a [134]. Components of the complement system, including C1, which initiates the classical pathway, have been shown to play a role in the chemoattraction of several inflammatory cell types, including dendritic cells, mast cells, eosinophils, and neutrophils [135–139]. Therefore, it is possible that components of the complement system play a role in the chemoattraction of MSCs to sites of inflammation. It was shown in one study that both C3a and C5a are chemoattractants for human BMSCs that express C3a and C5a receptors and that this may be mediated by prolonged phosphorylation of the ERK1/2 pathway [140]. More recent studies looked at the role of C1q, a subcomponent of the C1 complex, in MSC recruitment. C1q was shown to chemoattract MSCs in a dose-dependent manner through gelatin and, to a lesser extent, through Matrigel *in vitro*. MSCs were found to express C1q receptors. However, the effects of C1q appear to be multifactorial, and findings included an increase in MSC CXCR4 expression with increased chemotaxis to SDF-1, an increase in proMMP2 secretion, and prolonged ERK1/2 phosphorylation in C1q-stimulated MSCs [141].

The effect of complement on other MSC functions has also been investigated. Studies have suggested that C3a and C5a may protect MSCs from oxidative damage since pretreatment of MSCs with these complement components decreased cell death in MSCs exposed to $H_2O_2$ *in vitro* [140]. Additionally, MSCs express CD46, CD55, and CD59, which confer protection from complement-mediated lysis [142]. However, Li and Lin suggested that these intrinsic cell surface regulators are insufficient protection against complement-mediated cytotoxicity and that the membrane attack complex, the common endpoint of complement activation, directly injures MSCs. This effect was found to be more pronounced after *in vivo* delivery of allogeneic murine MSCs compared with delivery of autologous murine MSCs [143]. Whether complement activation in the complicated setting of inflammation *in vivo* is harmful to MSCs or stimulates their recruitment is currently unknown.

### 22.3.5 Macrophages

Macrophages play a central role in the microenvironment of tumors and wound healing. They likely sense tumors as a type of wound, given the increased angiogenesis and the leukocyte infiltration characteristic of many tumors. In tumors they can further stimulate angiogenesis and promote metastatic spread of the disease [144–147]. Macrophages may play an important role in the attraction of MSCs to sites of injury. In a study by Anton *et al.* MSCs were cultured with macrophage-conditioned medium. This resulted in a change in MSC gene expression into a proinflammatory phenotype with increased gene expression of several factors involved in MSC migration, including CCL2, CXCL12, and IL-8. Interestingly, however, CXCL12 and IL-8 protein secretion did not increase [145]. Macrophage-conditioned medium increased MSC migration *in vitro*. This was mediated by CCL5, CCL2, and IL-8 (chemotactic factors secreted by macrophages) and was dependent on activation of a JNK pathway. There was some reduction in MSC migration by blocking CCL5 and IL-8, but not CCL2. This suggests that these factors alone may not be essential pathways for MSC migration but may play role in combination with other mechanisms.

## 22.4 Mesenchymal stromal cell extravasation

There have been numerous studies looking at the factors present in the inflammatory environment that may influence and augment MSC migration. Less is known about the physical behavior of MSCs that allows them to migrate through endothelial cells, a process known as extravasation. This is critical in permitting MSCs to leave the circulation and access injured tissue. The process of leukocyte extravasation is well understood and involves an active process of rolling, endothelial activation, lateral migration over endothelium, and the use of dynamic cytoskeletal protrusions such as pseudopods and lamellipodia to cross through discrete gaps in the endothelium [148,149]. MSCs have been shown previously to roll and adhere. However, the process of MSC integration in endothelium appears to differ from that of leukocytes [150–153]. High-resolution confocal microscopy and dynamic live-cell imaging was used by Teo *et al.* to characterize the extravasation of human BMSCs through endothelial cells activated with TNF-α [154]. MSCs were seen to adhere to the endothelial monolayer before becoming incorporated into a transmigratory cup formed by microvilli-like endothelial projections. MSCs did not spread like leukocytes but formed bulbous protrusions that facilitated either paracellular or transcellular endothelial integration and then subendothelial spreading. This occurred over a much longer timespan than leukocytes, taking up to 2 h compared with several minutes [154]. These data indicated that MSC migration shares some features with that of leukocytes. However, the nonapoptotic blebbing seen is similar to that seen on embryonic germ cells and metastatic tumor cells [155–157]. The role of MSCs in inflammation was also suggested when MSC endothelial transmigration was observed across endothelial barriers activated by the potent proinflammatory cytokine TNF-α. *In vitro* static models can never fully predict *in vivo* behavior and shear flow, which, along with the condition of the vascular bed in actively inflamed tissues, will almost certainly impact on MSC behavior in the setting of inflammation.

## 22.5 *In vivo* migration

### 22.5.1 *In vivo* migration studies

While there are numerous studies exploring the capacity of MSCs to migrate *in vitro*, the ultimate goal in terms of therapeutics is

the homing of systemically delivered MSCs to sites of injury *in vivo*. Over the last decade there have been a large number of reports of MSC homing in numerous disease models, including malignancy, ischemia, brain injury, pulmonary fibrosis, arthritis, and AKI. Various methodologies have been used to track MSCs, including immunohistochemistry, PCR, *in situ* hybridization, and live imaging.

Some early MSC homing studies were carried out in primates after total body irradiation [158]. Intravenously delivered autologous and allogeneic MSCs were shown to distribute widely to the gastrointestinal tract, lung, liver, and skin [158]. Later studies in NOD/SCID mice given total body irradiation demonstrated increased engraftment of human BMSCs to multiple organs compared with nonirradiated mice. Migration was further increased in areas of local tissue irradiation [159].

The development of novel therapies for use in the treatment of malignancy remains a high priority; not surprisingly, numerous studies have been carried out in an attempt to confirm the homing of systemically delivered MSCs in *in vivo* tumor models. Human BMSCs were delivered systemically to SCID mice after injection of cells from a melanoma tumor cell line. Immunohistochemistry was used to identify the X-Gal-labeled cells and after three intravenous doses cell colonies were demonstrated in the tumor stroma. When modified to express IFN-β, a reduction in tumor size after MSC administration was noted [160]. Several studies have examined the migration of MSCs in murine glioma models. Fluorescently labeled human BMSCs were delivered intra-arterially using either the carotid or intracerebral artery 10 days after glioma tumor implantation. In one study tissue was examined 1 and 7 days after the infusion of the MSCs. Fluorescent imaging identified MSCs only at the tumor sites [161]. Further glioma studies in mice examined the migration of human BMSCs modified with adenovirus for luciferase expression to high and low PDGF-expressing human glioma xenografts. After intra-arterial injection, MSCs were shown to migrate to the malignant tissue with increased engraftment in PDGF high-secreting tumors, and this correlated with *in vitro* data [105]. MSC homing has also been studied in mice with human breast cancer xenografts and intravenously delivered breast cancer cell lines to mimic metastatic disease [29]. Fluorescently labeled cells were delivered either subcutaneously or intravenously. After subcutaneous delivery, MSCs were identified at the tumor border, while intravenous delivery of cells in models of metastatic disease resulted in migration to tumor sites and lining blood vessels. By correlation with *in vitro* studies, MCP-1 has been implicated as a potential mechanism driving migratory events [29]. More recently, both human BMSCs and human umbilical cord perivascular cells (HUCPVCs) were shown to migrate to subcutaneous hepatocellular carcinoma implants in mouse models using histology and fluorescent microscopy. Cells were also found in the lung, liver, and spleen after intravenous delivery. A higher number of HUCPVCs engrafted in the tumor compared with BMSCs [162]. Other recent studies in malignancy include the demonstration of both human MSCs and murine MSCs homing to the site of mesothelioma, a malignancy of the lung pleura, after systemic delivery [163] and the successful treatment of gastric cancer xenografts in nude BALB/c mice after systemically delivered human BMSCs expressing NK4, in which $GFP^+$ MSCs were detected at the tumor site by immunohistochemistry 28 days post-systemic injection [164]. (NK4 is an inhibitor of angiogenesis as well as an HGF antagonist.)

Many studies have demonstrated MSC homing in models of ischemic diseases, particularly cerebral and cardiac ischemia. Lac-Z-transfected human BMSCs were delivered intravenously to rats after occlusion of the middle cerebral artery (MCA). The MCA is one of the three major paired arteries that supply blood to the cerebrum. The MCA arises from the internal carotid and continues into the lateral sulcus, where it then branches and projects to many parts of the lateral cerebral cortex. It also supplies blood to the anterior temporal lobes and the insular cortices (Figures 22.1 and 22.2).

Immunohistochemistry in this study demonstrated Lac-Z-positive cells in the cerebral infarct area after both single and multiple injections of MSCs and which were associated with neovascularization and improved outcomes [165]. Another study described the delivery of fluorescently labeled human MSCs to neonatal mice with hypoxic ischemic brain injury [166]. After intranasal delivery the cells were found in the sensorimotor and epithalamic region around pathological cysts, with no cells found in the contralateral (opposite) normal hemisphere. Treated mice had improved motor behavior and a decrease in the size of the hypoxia-induced lesions [166]; and see Chapter 16.

The role of MSCs in the treatment of acute cardiac ischemia and their potential to home to infarcted myocardium has also been extensively investigated. $^{99m}$Tc- or BrdU-labeled rat MSCs were delivered either intravenously or directly into the left ventricle of the heart 2, 10, or 14 days after ligation of the left anterior descending (LAD) coronary artery, which supplies the left ventricle and which is most commonly obstructed in people with an acute myocardial infarct (Figure 22.3).

Cells delivered intravenously were found predominantly in the lungs, with only a small number reaching the infarct zone. The MSCs injected directly into the myocardium integrated into the infarct zone [167]. Further studies in a similar model confirmed the migration of MSCs to infarcted myocardium after intravenous delivery using immunohistochemical staining. This was associated with a reduction in infarct size compared with mice that received vehicle control [168]. Subsequently, both fluorescent *in situ* hybridization (FISH) and confocal microscopy have been used to confirm the migration of intravenously delivered rat BMSCs to infarcted areas within 24 h of, and up to 8 weeks after, ligation of the LAD coronary artery [35,169].

*In vivo* imaging has also been carried out in canine models of myocardial ischemia [170]. Allogeneic MSCs were co-labeled with a radiotracer and a magnetic resonance contrast agent and delivered intravenously to dogs after occlusion of the LAD coronary artery. High-sensitivity single-photon emission computed tomography (SPECT) and magnetic resonance imaging

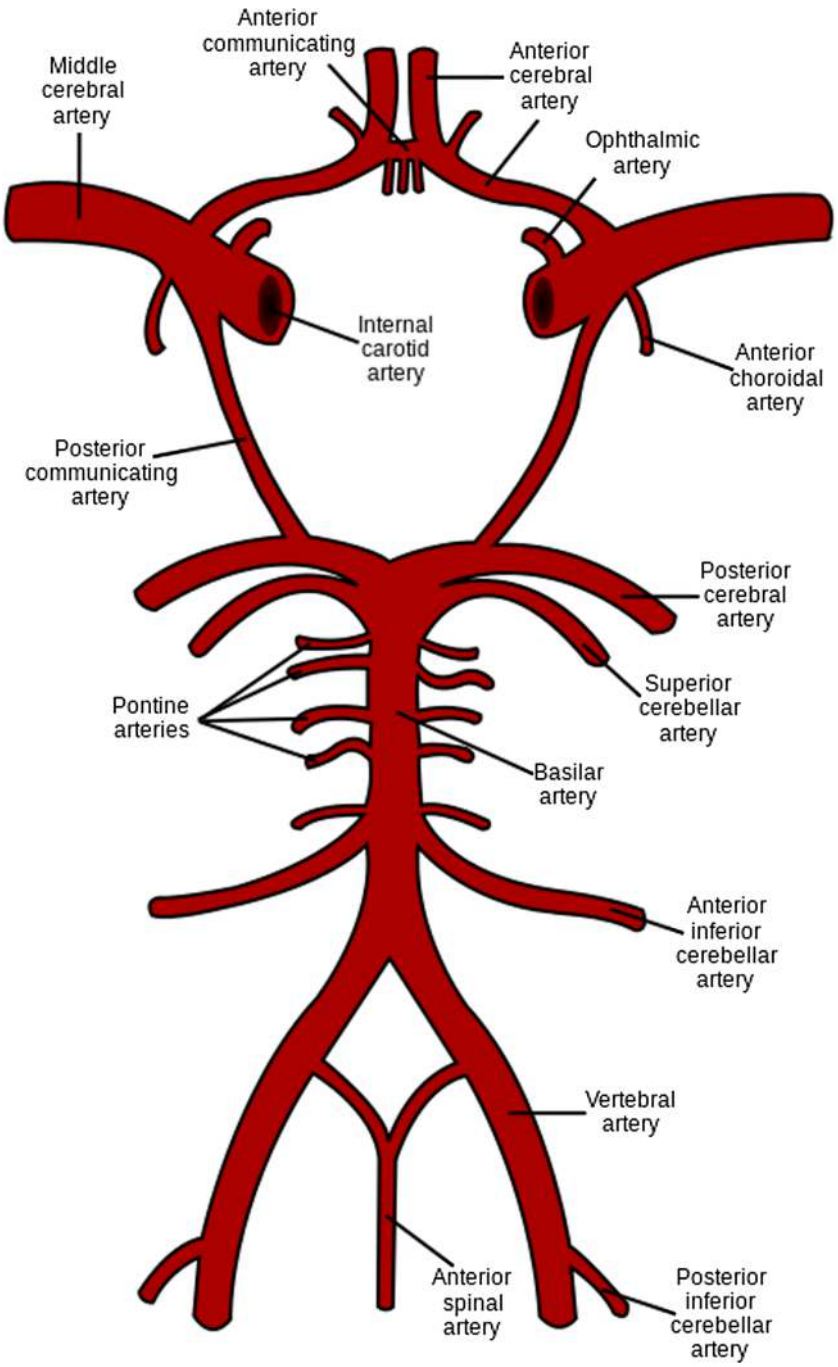

**Figure 22.1** The arterial supply to the brain, including that of the MCA. *Source:* http://commons.wikimedia.org/wiki/File:Circle_of_Willis_en.svg#/media/File:Circle_of_Willis_en.svg.

(MRI) were used to track the fate of these cells *in vivo*. After initial infusion the cells migrated to the lungs and then to other nontarget organs. However, within 24 h, focal and diffuse uptake of MSCs was seen in the infarcted myocardium using SPECT but not MRI [170].

As well as cerebral and myocardial ischemia, there have been studies of MSC delivery in hepatic ischemic–reperfusion injury models [171]. Murine MSCs were delivered intravenously and tracked either with immunohistochemistry using Lac-Z or by use of a radioactive label. While MSCs were initially found in the lung and subsequently in the liver at 24 h after injection, there was no increase in migration to the injured liver compared with controls [171]. Therefore, while there is evidence to support the migration of exogenously delivered MSCs to ischemic tissues, it is important to remember the limitations inherent in the techniques used to identify them, as well as possible differences in the degree or type of chemoattraction occurring in ischemic injury in different organs.

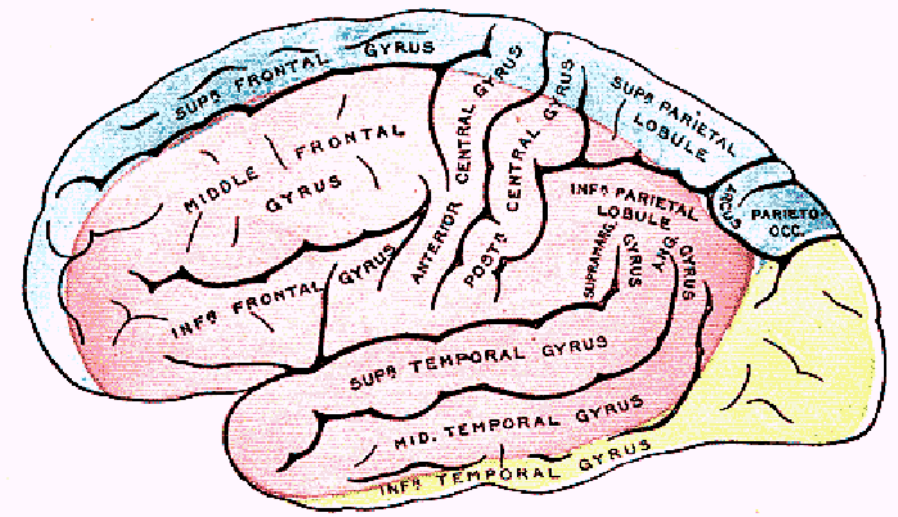

**Figure 22.2** Outer surface of a human cerebral hemisphere showing areas supplied by the cerebral arteries (see text). *Source: Gray's Anatomy*, bartleby.com.

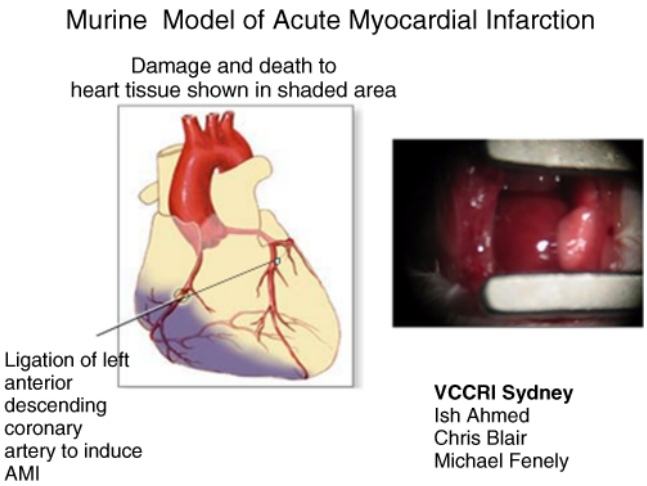

**Figure 22.3** Occlusion of the LAD coronary artery in a mouse at open thoracotomy under general anesthesia by ligation of the artery to induce an acute myocardial infarction (AMI) in the wall of the left ventricle.

Another commonly used model for studying the homing of MSCs is that of AKI. Various toxins have been used, including administration of glycerol or cisplatin [172–174]. Both murine and human MSCs have been shown to migrate to the renal cortex, peritubular cells, and tubular epithelial lining after intravenous delivery of MSCs, with associated amelioration of disease and improved survival [172–174].

In inflammatory arthritis studies there have been conflicting results. The intraperitoneal delivery of allogeneic MSCs to mice with collagen-induced arthritis (CIA) was not shown to result in homing to the joints, but rather initial localization in the peritoneum with subsequent migration to the spleen [12]. However, in a subsequent study using the intravenous route of delivery, PCR for green fluorescent protein (GFP) was used to distinguish $GFP^-$ MSCs from $GFP^+$ transgenic murine MSCs in the paws and knees of mice with CIA. In this study, GFP was also identified, as expected, in the lungs and liver of both arthritic and control mice [175].

Nonischemic cerebral injury has been another target of MSC administration, including experimental autoimmune encephalitis (EAE), hypoglossal (12th cranial) nerve injury, and models of traumatic brain injury [30,176–178]. In EAE and brain injury models, MSCs were found to penetrate the cord and the subarachnoid space (in the EAE model) as well as the boundary zone of traumatic brain lesions. In addition, the migration of MSCs reduced inflammation and demyelination and improved functional outcome [176–178]. In the model of hypoglossal nerve injury, rat MSCs labeled with carboxyfluorescein *N*-hydroxysuccinimidyl ester dye were delivered to the lateral ventricle of rats at the time of injury [30]; significantly more MSCs were found at the injured nerve site compared with the contralateral control at 1 week, which appeared to be related to fractalkine and SDF-1 expression at the site of nerve damage.

### 22.5.2 Controversies surrounding *in vivo* migration

Studies of *in vivo* models using exogenously delivered MSCs are shown in Table 22.3.

Preclinical models have included muscle injury, pulmonary fibrosis, and wound healing. What is immediately obvious is the large variety of cell types, injury models, delivery routes, and tracking methods used. This makes it difficult to compare studies. MSCs have been derived from bone marrow, adipose tissue, and umbilical cord in numerous species, including rat, mouse, dog, and human. There is variation with regard to the site of isolation and the media and incubation methods used. These variables have profound effects on the migratory potential of cells, as has been seen with hypoxia studies outlined earlier.

For initial consideration is the term MSC itself. The Mesenchymal and Tissue Stromal Cell Committee of the International Society for Cellular Therapy published criteria for defining MSCs in 2006. These required that cells be plastic-adherent, positive for

**Table 22.3** Summary of *in vivo* migration studies.

| First author, year, ref. | MSC type | Disease model | Route | Tracking method | Migration |
|---|---|---|---|---|---|
| Barbash, 2003, [167] | Rat BMSCs | Rat LAD ligation To induce AMI | IV or intraventricular | Gamma camera, immunohistochemistry | IV cells mostly lodged in lungs Intraventricular cells detected in infarct zone. |
| De Bari, 2003, [179] | Human synovial fluid MSCs | Nude mouse muscle injury | Local | ISH, immunohistochemistry | 1 week: detected in mononuclear cells 2 weeks: detected in myofibers |
| Devine, 2003, [158] | Primate BMSCs | Total body irradiation | IV | RT-PCR | Wide tissue distribution – gastrointestinal tract, kidney, lung, liver, skin |
| Ortiz, 2003, [180] | Mouse BMSCs | Lung injury | IV | RT-PCR, FISH | >20% increase in male DNA in injured lungs Engrafted cells localized to injury |
| Rombouts, 2003, [181] | Mouse BMSCs | Irradiation | IV | CFU-F assay | Uncultured cells >50% in marrow, 7% spleen After 24 h culture: 10% in marrow After 48 h culture: not detected in marrow |
| Morigi, 2004, [174] | Human BMSCs | Acute kidney injury | IV | ISH, immunohistochemistry | MSCs localized to tubular epithelial lining |
| Nagaya, 2004, [168] | Rat BMSCs | Coronary artery ligation to induce AMI | IV | Immunohistochemistry | Cells detected in infarcted myocardium |
| Studeny, 2004, [160] | Human BMSCs | SCID mouse with lung cancer | IV | Histochemistry | Cells detected in lung tumor stroma |
| Ji, 2004, [30] | Rat BMSCs | Hypoglossal nerve injury | IV | Confocal microscopy | Significantly more rat MSCs at left HN compared with right. Greatest difference after 1 week |
| Kraitchman, 2005, [170] | Canine BMSCs | LAD occlusion to induce AMI | IV | MRI, SPECT | Initial uptake in lungs. Redistributed to liver, kidney, spleen after 24 h. Engraftment in infarcted heart at 1–7 days |
| Mahmood, 2005, [178] | Human BMSCs | Brain injury | IV | Immunohistochemistry | MSCs present in lesion boundary zone |
| Nakamizo, 2005, [161] | Human BMSCs | Mouse with glioma | IA | Fluorescent microscopy | Detection of cell marker at tumor sites only |
| Zappia, 2005, [177] | Mouse BMSCs | Mouse EAE | IV | Immunohistochemistry | Detection in spleen and nodes after 24 h, in subarachnoid space after 40 days |
| François, 2006, [159] | Human BMSCs | NOD/SCID TBI | IV | PCR and immunohistology | Increased engraftment to organs after TBI and locally to irradiated tissue |
| Horita, 2006, [182] | Human BMSCs | Rat MCAO | IV | Immunohistochemistry | Detected at ischemic penumbra |
| Jiang, 2006, [169] | Rat BMSCs | Rat LAD ligation to induce AMI | IV | FISH | Detected in infarct or border zone |
| Schenk, 2007, [35] | Rat BMSCs | Rat LAD ligation | IV | Confocal microscopy | Transient migration to infarct zone within 24 h. MSCs in infarct zone with overrepression of MCP-3 and after serial infusions |
| Dwyer, 2007, [29] | Human BMSCs | Mouse: breast cancer | SC, IV | Florescent microscopy | SC: cells at tumor border. IV: detected in patches throughout tumor |
| Augello, 2007, [12] | Mouse BMSCs | CIA | IP | Immunohistochemistry | Localized to peritoneum and spleen only |
| Kanehira, 2007, [183] | Mouse BMSCs | Mice: metastatic tumor | IV | Immunohistochemistry | Detected in tumor tissue in lung |
| Herrera, 2007, [172] | Mouse BMSCs | Acute kidney injury | IV | Immunohistochemistry | In renal cortex after 24 h. A few CD44-negative cells migrated |

**Table 22.3** (*Continued*)

| First author, year, ref. | MSC type | Disease model | Route | Tracking method | Migration |
|---|---|---|---|---|---|
| Sasaki, 2008, [184] | Mouse BMSCs | Mouse punch biopsy wound | IV | Flow cytometry | MSCs in skin wound 3 days after injection. Improved wound healing |
| Omori, 2008, [165] | Human BMSCs | Rat MCAO | IV | Immunohistochemistry | Cells detected in cerebral infarct area |
| Morigi, 2008, [173] | Human BMSCs | NOD/SCID mouse AKI | IV | Immunohistochemistry | Cells located in tubular epithelium and peritubular cells |
| Loebinger, 2009, [185] | Human BMSCs | NOD/SCID mouse: IV xenograft – lung metastases | IV | MRI | MSCs integrated in pulmonary metastases |
| Constantin, 2009, [176] | Mouse AMSCs | Mouse EAE | IV | Flow cytometry and BLI | Control mice: cells in nodes and spleen EAE mice: intralesional MSCs |
| Hata, 2010, [105] | Human BMSCs | Mouse: high and low PDGF-expressing human glioma xenograft | IA | Immunohistochemistry and BLI | MSCs migrated to glioma. Increased in PDGF high secreting tumors |
| Eggenhofer, 2012, [171] | Mouse BMSCs | Mouse ischemia reperfusion liver injury | IV | Immunohistochemistry | MSc in lung after 1 h and in liver within 24 h. No increased migration in injury model |
| Donega, 2013, [166] | Human BMSCs | Mouse: hypoxic ischemic brain injury | Intranasal | Immunohistochemistry | MSCs detected in sensorimotor and epithalamic region of affected hemisphere |
| Sullivan, 2013, [175] | Mouse BMSCs | CIA | IV | RT-PCR | Detected in lung and liver control group Detected in joints of CIA mice at 5 and 14 days |
| Bayo, 2014, [162] | Human BMSCs and UC perivascular cells | Mouse hepatocellular carcinoma | IV | Histology | Both cell types detected in lung, liver, spleen, and tumor |
| Zhu, 2014, [164] | Human BMSCs | Nude mouse: gastric cancer xenograft | IV | Immunohistochemistry | GFP detected in tumor xenografts |
| Lathrop, 2014, [163] | Mouse and human BMSCs | Mouse: mesothelioma xenograft | IV or IP | Immunofluorescent staining | Cells delivered by either route localized to tumor |

AMI: acute myocardial infarction; BMSC: bone-marrow-derived mesenchymal stromal cell; AMSC: adipose-tissue-derived MSC; UC: umbilical cord; IV: intravenous; IA: intra-arterial; ISH: *in situ* hybridization; IP: intraperitoneal; SC: subcutaneous; FISH: fluorescent *in situ* hybridization; RT-PCR: real-time polymerase chain reaction; MRI: magnetic resonance imaging; SPECT: single photon emission computed tomography; LAD: left anterior coronary artery; AKI: acute kidney injury; MCAO: middle cerebral artery occlusion; EAE: experimental autoimmune encephalitis; CIA: collagen-induced arthritis; HCC: hepatocellular carcinoma; SCID: severe combined immunodeficiency; NOD: nonobese diabetic; PDGF: platelet-derived growth factor; BLI: bioluminescence imaging; MCP: monocyte chemoattractant protein; TBI: total body irradiation; HN: hypoglossal nerve (12th cranial nerve).

CD105, CD73, and CD90 cell surface markers, and negative for CD45, CD34, CD14, CD11b, CD79a, CD19, and HLA-DR cell surface markers. Cells had to be capable of trilineage mesodermal differentiation, specifically chondrogenesis, osteogenesis, and adipogenesis [18]. It is likely that prior to the introduction of these criteria that the term MSC was applied loosely to bone marrow cells.

After initial isolation the time in culture at which cells are used for studies may play a significant role in their migratory capacity. Rombouts and Ploemacher published a study looking at syngeneic MSCs delivered to C57BL/6 mice after sublethal irradiation [181]. Delivery of uncultured cells resulted in recovery of 55–65% of injected colony-forming units–fibroblast from the bone marrow. After culture for 24 h only 10% were recovered, while this decreased to 0% after 48 h of culture. There are several reasons why time in culture may influence homing potential. It may partly be due to the variability of cell surface receptor expression, with published studies demonstrating changes in SDF-1 expression over time on culture-expanded MSCs. In one report, culture-expanded BMSCs were studied to passage 16: at higher passages there was a loss of cell surface expression of all chemokine receptors studied (CCR1, CCR7, CCR9, CXCR4, CXCR5, CXCR6) and an associated lack of chemotactic response to chemokines [22]. There was also a

loss in MSC expression of adhesion molecules, an increase in apoptosis, and slowing of cell growth. Of interest is the fact that not all cells lost their receptor expression at the same rate: a major subpopulation was completely negative while some retained high levels of expression [22]. In addition, it has been shown that expression of CD105, CD146, and CD271 are upregulated in culture. In addition to this, MSC morphology changes with subsequent passages, becoming larger and more spindle shaped with diameters larger that of pulmonary microcapillaries [186–190]. Clearly, this may impact on *in vivo* studies in which passage number has not always been reported. For those reported there is a large variation in passage (P) number, ranging from P2 to P23 [35,159,162,173,176].

In addition to passage number, the degree of confluency of MSCs before harvesting has been shown to influence migration. This is harder to report accurately. In high-confluence cell cultures there may be an increase in the production of the natural MMP inhibitor TIMP3; this results in a decrease in transendothelial migration and subsequent migration to target organs [85].

Finally, the age of the animal from which the cells were harvested may also play a role in MSC migration. It has been suggested that the age of MSC donors may affect differentiation potential and proliferative capacity, although this is controversial [190–195]. Reports have suggested that older mouse donors may provide MSCs with lower expression of cytokine and chemokine receptors, thus compromising their ability to migrate to sites of injury [196].

The route of administration may also play an important role in the migration of cells to injured tissue. In some clinical settings systemic delivery by the intravenous, and less so the intra-arterial, route is preferred to local injection. Particularly problematic after intravenous cell delivery is the trapping of MSCs in the lung, with only very small percentages subsequently managing to reach target organs (Figure 22.4).

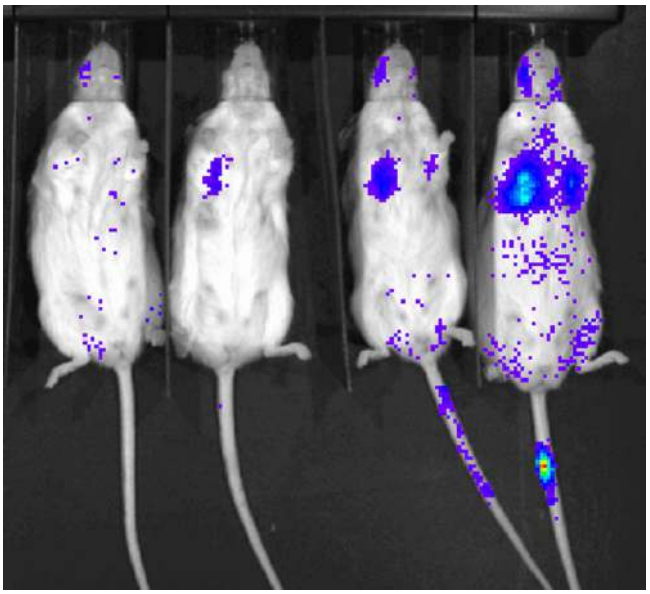

**Figure 22.4** Luciferase-positive murine MSCs injected intravenously lodge in the lungs for at least 3 days, presumably because their size prevents them from flowing freely through the pulmonary capillary bed, which is the first network of capillaries that they encounter after intravenous injection.

Migration to liver, spleen, kidney, marrow, or injured tissues is slow, and this may affect the timing of cell delivery [197,198]. However, when a small subcutaneous skin wound was made on the right side of the abdomen prior to the intravenous injection of luciferase-positive MSCs, a significant number of the injected cells passed through the lungs and homed preferentially to the wound site (Figure 22.5).

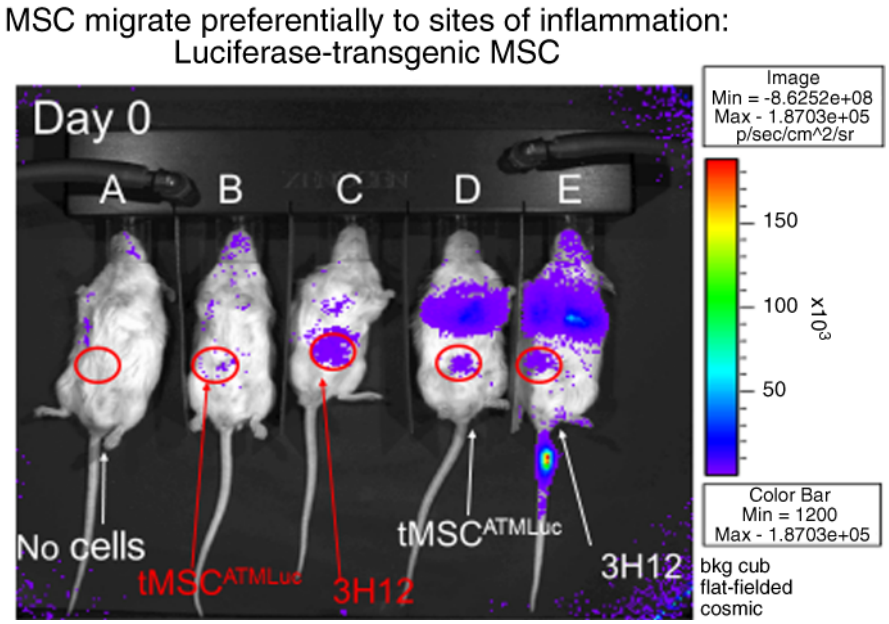

**Figure 22.5** Luciferase-positive MSCs injected intravenously in a mouse in which a subcutaneous incision had been made on the right side of the mouse's abdomen prior to injection of the MSCs. No wound was made on the left side of the mouse's abdomen. While the majority of MSCs were retained in the lungs, some MSCs flowed through the lungs and homed preferentially to the site of the skin wound on the right side of the mouse's abdomen. (See color plate section.)

Compounding the problem, however, is the short half-life of MSCs, with many cells reported to be apoptotic 12 h after injection [199,200]. Potential strategies that have been used to augment MSC migration out of the lung include co-infusion with heparin or with sodium nitroprusside treatment [190,198,200].

There are also specific challenges associated with MSC migration after intra-arterial delivery, most notably that of plugging in the microvasculature leading to obstruction of flow at a precapillary level with ensuing ischemia and loss of the injected cells [201]. This is a mechanical obstruction due to the relative size of MSCs compared with the lumen of the microvasculature, with a few surviving cells spread out on the luminal surface of small arteries and then localizing in the perivascular niche within 72 h [201]. Intravital fluorescent microscopy of the cremaster muscle (the muscle that covers the testis and the spermatic cord in males) of SCID mice after injection of human AMSCs into the abdominal aorta showed similar results. Decreased blood velocity was noted in a cell-density-dependent manner until the stoppage of blood flow in the cremaster microcirculation [202]. An interesting consideration in this regard are published results that the size of MSCs may actually increase with time in culture, further decreasing the migratory potential of high-passage cells [203,204].

Along with the route of administration, the number and frequency of MSCs infused may be critical in facilitating the desired migratory response. The idea that higher numbers of infused cells will result in higher numbers of engrafted cells does not necessarily hold true. In general, in rat and mouse models of disease, MSC doses between $1 \times 10^5$ and $1 \times 10^6$ seem to be optimal and are commonly used doses in most models outlined [162,164,165,175]. In models of brain injury, no additional engraftment was seen when the number of infused cells was increased from $1 \times 10^6$ to $3 \times 10^6$ in a rat model of brain ischemia [205]. It is possible that a plateau may be reached after a certain number of cells are infused, though there are multiple factors that may affect this further, as outlined earlier.

The MSC recipient animal should also be considered. The disease models studied represent a large array of diverse pathologies, including ischemia, malignancy, inflammation, drug-induced injury, and trauma. The degree to which inflammation is localized to a specific tissue, such as in a tumor xenograft, compared with the systemic inflammation associated with CIA is likely to impact on the behavior of the administered MSCs, though it is unclear to what extent this affects migration. Additionally, it is worth noting that many of the injury models use severely immunocompromised host animals, and the effect of this on migration and homing is not understood [158,159,173,206].

One of the final but most important considerations in terms of *in vivo* homing studies is the methods used to detect the administered MSCs. Methods published in the literature include fluorescent protein labeling, transduction of MSCs with reporter genes, detection of human genes in animal recipients, sex-linked gene detection, histology, immunohistochemistry, RT-PCR, and FISH [158,161,165,168,173,174,178,180,182,197]. The main limitation of these techniques is that they provide a static measurement without any real-time information on the fate of infused cells. Additionally, the detection of a label does not necessarily indicate live cell engraftment but may represent a macrophage that has phagocytosed a labeled MSC [171]. The role of dynamic *in vivo* imaging will be discussed later in this chapter. It is worth remembering that the methods generally employed to assess homing efficiency are often compared with controls or with nondiseased tissue.

### 22.5.3 Real-time *in vivo* imaging

The majority of studies investigating *in vivo* migration of MSCs to sites of inflammation, ischemia, and malignancy rely on *ex vivo* immunohistochemistry, histology, and PCR techniques. While these methods can provide valuable data they lack sufficient spatial and temporal information. Additionally, disruption of the target organ is necessary, and sequential time points are difficult to assess. Work is ongoing to harness modern imaging techniques to more fully understand the dynamics of *in vivo* cell biology, allowing multiple tissues to be examined at multiple time points. These include MRI, SPECT, positron emission tomography (PET), and bioluminescence imaging (BLI). In view of the increasing use of these modalities and their implications for ongoing studies in this field, they will be briefly reviewed.

MRI is a tool utilized with increasing frequency in clinical medicine and may be useful as a method of tracking exogenously delivered stromal cells to determine if they migrate preferentially to sites of inflammation. Various contrast agents can be used to enable MSC detection by MRI. These include positive contrast agents such as lanthanide chelates or manganese-containing compounds [207–209], negative contrast agents such as superparamagnetic iron oxide (SPIO) [210–213], ultra-small superparamagnetic iron oxide (USPIO) particles [213,214], or micrometer-sized iron oxide particles [215,216]. As is always the case when modifying cells, it is important to determine that MSCs retain their characteristic properties after cell labeling. Crabbe *et al.* labeled mouse embryonic stromal cells, rat multipotent adult progenitor cells, and mouse MSCs with different USPIO particles. With murine MSCs there was no difference in population doubling time at 7 days, nor was osteogenesis or adipogenesis affected [217]. In addition, the labeling of MSCs with SPIO was shown not to affect changes in surface marker expression or differentiation *in vitro* [218].

MRI has been used to study the behavior of neural progenitor cells *in vivo*, tracking migration of these cells to the olfactory bulb [216]. Similarly, MRI has been successfully used to track MSCs *in vivo*. The detection of magnetically labeled rat MSCs has been demonstrated in stroke models [219]. MSCs labeled with SPIO were infused into the ipsilateral internal carotid artery (ICA) of rats with an MCA occlusion. MRI was used before and 2–24 h after infusion and engraftment of labeled cells within the ICA vascular territory was detected by MRI and confirmed by high-resolution *ex vivo* MRI. Cells engrafted in the first pass

without entering the systemic circulation [219]. In another study, AMSCs delivered locally to a canine keratoconjunctivitis sicca (dry eye) model could be tracked locally with MRI initially. After 2 weeks the MRI signal was identified in the thymus and gastrointestinal tract [220].

Despite this, the role for MRI in this field remains uncertain. In the MCA stroke model, cerebral engraftment of MSCs was undetectable using MRI after intravenous administration [219]. Similarly, in a canine acute myocardial infarction (AMI) model in which ferumoxide-labeled canine MSCs were delivered intravenously they could not be subsequently detected by MRI, either *in vivo* or at postmortem [170]. Another study looked at the detection of SPIO-labeled stromal cells in a photothrombotic stroke model [210]. This model consists of an intravenous injection of a light-sensitive dye followed by focal illumination of the brain. The resulting dye activation causes oxidative damage, endothelial cell injury, and microvascular thrombosis. MRI detected hypointense lesions that correlated histologically with the formation of microglial scars. After initiation of an inflammatory cascade in the central nervous system the resident microglial cells become activated macrophages and infiltrate the injured tissue. These cells can incorporate ferric iron from the environment around the ischemic lesion. In this study, despite MRI lesions being identified, histological analysis was necessary to distinguish between labeled transplanted cells and immune cells in migroglial scars. Thus, caution is required when interpreting the *in vivo* monitoring of MSCs in models in which a strong inflammatory response is present [210]. Because iron oxide particles are retained in a tissue even if the grafted cell has died, false-positive signals remain a confounding factor [221]. In a nude rat model of antibody-induced arthritis, viable and nonviable human MSCs injected directly into the joint could not be distinguished with MRI [222].

SPECT and PET can also be used to determine the migration of MSCs to sites of inflammation. Previous studies in AMI models have demonstrated the potential usefulness of SPECT. In one study MSCs were labeled with $^{111}$In oxine. After confirmation that this did not alter their proliferation or differentiation *in vitro*, cells were delivered intravenously in a canine LAD occlusion model of AMI [170]. While MRI could not detect MSC migration in this model, SPECT was successfully used to demonstrate early uptake in the lungs and subsequent migration to the liver associated with migration to the infarcted heart [170]. SPECT has also been used to demonstrate human MSC homing to tumor sites after intraperitoneal delivery of $^{111}$In-oxine-labeled cells to mice with human xenografts of neuroblastoma [223].

PET imaging requires either activation of a tracer dye [224] or labeling with a radioactive tracer such as $^{18}$F-fludeoxyglucose [225]. While emissions from tracer dyes can be toxic and inhibit cellular function, labeling of murine MSCs with $^{18}$F-fludeoxyglucose does not affect cell viability, proliferation, or differentiation [221,225]. PET has been used to track MSC migration in models of malignancy and Parkinson's disease [226,227].

Finally, BLI may be used. This method of cell tracking requires the expression of a bioluminescence protein such as those from the luciferase family [221]. BLI has been shown to be useful in studying migration and engraftment of MSCs in neural tissue [228,229]; see Figures 22.4 and 22.5.

## 22.6 Optimizing homing

While work is ongoing to fully understand the mechanisms behind MSC homing to sites of inflammation, optimization of MSC homing is being developed (Figure 22.6). These include attempts to modulate the physiological barrier of blood vessels and the lung, manipulation of the inflammatory microenvironment of the body, and the augmentation of chemotactic signals from the site of inflammation [230].

### 22.6.1 Culture conditions

An initial approach augmenting MSC homing and engraftment is optimization of the culture conditions of MSCs. Two important factors in this regard include the passage and plating density of MSCs prior to systemic delivery. As previously discussed, freshly isolated MSCs have superior migratory potential that decreases rapidly as they are culture-expanded [181]. Low passage number and low-density MSC cultures express podocalyxin-like protein, 6-integrin (CD49f), 4-integrin (CD49d), c-Met, CXCR, and CX3CR1. They were previously shown to be involved in cell trafficking or tumor progression. These abilities are reduced as MSCs approach 100% confluence and with subsequent passages [231]. Increased confluence in culture

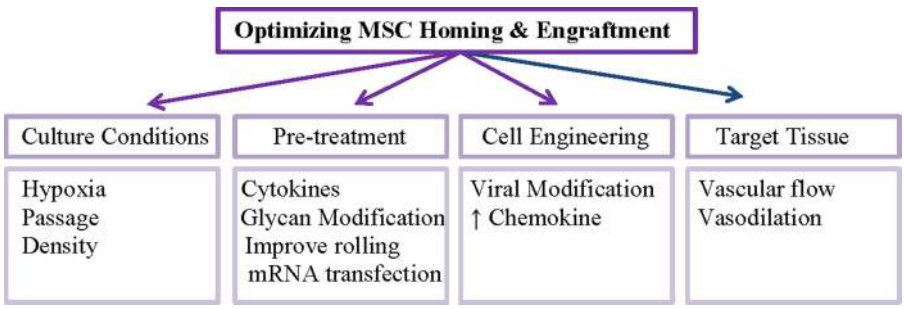

**Figure 22.6** Strategies for enhancing the homing of MSCs to sites of inflammation.

results in an upregulation of TIMP3, a natural inhibitor of MMP. The result of this is decreased transendothelial migration of MSCs *in vitro* – a process that is partly regulated by MMP-2 [85].

The downregulation of CXCR4 on cultured MSCs has been hypothesied as the mechanism the transformation of cultured MSCs into more differentiated cells [22]. However, it has been shown that culturing human MSCs as three-dimensional aggregates restores CXCR4 expression [232]. This effect was reversed when cells were re-plated in a monolayer, suggesting that cell functions are reversible and may adapt to cell culture conditions [232]; and see Chapters 7 and 8.

A novel method is the co-culture of MSCs with Sertoli cells. Sertoli cells support the development of sperm cells *in vivo* and have been shown to improve proliferation and survival of endothelial and neural cells *in vitro*. The co-culture of human UMSCs with Sertoli cells was associated with upregulation of *CXCR4*, *MMP2*, phospho-*p44MAPK*, and phospho-*p38MAPK* as well as other genes involved in cell proliferation and migration. There was also a small increase in transwell migration *in vitro* [233].

Finally, the role of short-term hypoxia in the culture of MSCs has been investigated. Hypoxic preconditioning of cardiac progenitor cells increased CXCR4 expression and augmented migration to infarcted myocardium *in vivo* [115]. Additionally, short term exposure of human MSCs to 1% oxygen was shown to result in an increased expression of CX3CR1 and CXCR4 at both mRNA and protein levels. After 24 h of hypoxia, *in vitro* migration to fractalkine and SDF-1 was increased [226].

While the ability to improve migration to inflamed tissues may be augmented by some of these modifications in culture conditions, the reality is that the low abundance of MSCs in bone marrow isolates and the likelihood that culture-expanded MSCs will be used in clinical settings represent a substantial challenge [232]. Therefore, work has focused on the engineering or pretreatment of MSCs, as well as on overcoming physiological host barriers.

### 22.6.2 Pretreatment of mesenchymal stromal cells

Pretreating MSCs during incubation has had promising and mixed results. Several studies have demonstrated an increase in MSC migration, both *in vitro* and *in vivo*, after preincubation with cytokines. A variety of MSCs have been used, including human adult BMSCs, human fetal BMSCs, human AMSCs, UCB MSCs and murine MSCs [80,119,122–124,234]. In studies with human BMSCs, cells were found to migrate in increased numbers toward chemokines *in vitro* after preincubation with TNF-α [80]. Naive MSCs migrated preferentially to growth factors PDGF-AB and insulin-like growth factor 1 (IGF-1), compared with their migration to chemokines RANTES, MDC, and SDF-1. An increase in migration towards growth factors was not seen after preincubation. An increase in migration toward chemokines was associated with an increase in MSC expression of CCR2, CCR3, and CCR4 as well as the membrane binding of RANTES. However, it was not associated with an increase in CXCR4 expression, leading the authors to suggest that TNF-α might modify the sensitivity to SDF-1 or modulate CXCR4 signal transduction [80]. However, in other studies, the expression of CXCR4 has been modified by pretreatment strategies [122,123,234]. In the first of these, both intracellular and surface expression of CXCR4 was increased after exposure of fetal BMSCs to a cytokine of cocktails in culture, which included Flt-3 ligand, SCF, IL-6, HGF, and IL-3, and resulted in an associated increase in migration toward SDF-1 *in vitro* [234]. An increase in CXCR4 mRNA and protein expression was demonstrated in UMSCs after preincubation with IL-1β [122]. This was associated with enhanced migration to an area of inflamed colon *in vivo* that could be abrogated by IL-1R1 siRNA [122]. Another strategy shown to improve MSC homing via upregulation of CXCR4 is the pretreatment of murine MSCs with IGF-1 resulting in a twofold increase in CXCR4 expression [123]. In this work, GDNF and TNF-α were also studied. While these did not increase CXCR4 expression, all three factors affected changes in the cytoskeleton of the MSCs with a more parallel orientation of filaments possibly indicative of an architectural remodeling necessary for the mechanical needs of migration [123]. Additionally, while only IGF-1 increased CXCR4 expression, pretreatment with any one of the three factors amplified the migration response to cisplatin-injured proximal tubular epithelial cells *in vitro* [123].

### 22.6.3 Cell engineering

As knowledge of factors involved in cell homing to injured tissue increases, so do attempts to modify MSCs to augment this migration process. Early studies looked at the ability of MSCs to migrate to bone marrow, including the use of α4 integrin and CD44 [235,236]. In the first of these studies murine MSCs were transduced with a recombinant adeno-associated virus (AAV2) expressing α4 integrin, which is known to play an important role in cell migration and invasion. *In vivo* studies in immunocompetent mice confirmed that, after intravenous delivery, significant enhancement of bone homing was seen after transduction. While this was not a disease or inflammation model, it confirmed the potential of this type of strategy to modify MSC behavior [235]. Subsequently, another group focused on CD44. This is expressed on MSCs but not the sialofucosylated glycoform of CD44 known as hematopoietic cell E-selectin/L-selectin ligand (HCELL), which is an E-selectin ligand expressed on hematopoietic cells. The HCELL glycoform was originally discovered on human hematopoietic stem cells and leukemic blast cells and was subsequently identified on cancer cells. HCELL functions as a bone marrow homing receptor, directing migration of human hematopoietic stem cells and mesenchymal stem/stromal cells to bone marrow. The authors converted the CD44 glycoform on MSCs into HCELL using a 1,3-fucosyltransferase preparation and specialized enzymatic conditions. Real-time intravital microscopy using NOD/SCID mice showed infiltration of the marrow with these cells within hours of transfusion. Again,

this was not a disease model but is an example of a method in which bone marrow tropism can be achieved by chemical engineering of glycans [236].

Owing to the important role of the CXCR4/SDF-1 axis in MSC migration, this pathway has been targeted by several groups to improve MSC homing. In one study, male rat MSCs were transduced with an adenoviral vector expressing CXCR4 and delivered intramyocardially in an LAD coronary artery ligation AMI model. Enhanced migration of the transduced cells toward SDF-1 was confirmed *in vitro* in cell migration assays. It was subsequently shown using FISH that, after intramyocardial delivery, cells expressing CXCR4 migrated significantly more than untransduced MSCs to the peri-infarct and infarct areas. Immunohistochemistry was used to suggest that infused MSCs contributed to the formation of new myocytes. In addition, cardiac function was significantly improved in rats receiving MSCs overexpressing CXCR4 [61]. Other groups have focused on viral vectors with more long-term gene expression, such as lentiviral and retroviral vectors. In early studies in an AMI model, MSCs transduced with a retrovirus expressing CXCR4 were delivered intravenously to a rat occlusion/reperfusion model of AMI. In comparison with untransduced MSCs, they homed in greater numbers toward the infarcted myocardium [237]. A model of acute liver injury was carried out using human bone-marrow-derived UE7T-13 cells immortalized by a retrovirus carrying human telomerase reverse transcriptase. A lentiviral vector was used to transduce MSCs to express CXCR4. These cells were shown to have a superior *in vitro* migration capacity toward SDF-1 and were subsequently delivered intravenously 24 h after an acute live injury in a nude mouse. Modified MSCs migrated to the liver in larger numbers than nonmodified MSCs. This was associated with reduced mortality and improved liver function [238]. Subsequently, a rat model of acute lung injury was used in which rat MSCs transduced to express CXCR4 with a lentiviral vector were delivered intravenously 1 h after injury induction. Expression of SDF-1 is known to be high in alveoli during acute lung injury and pulmonary fibrosis. Modified cells migrated at a higher rate to the lung, as demonstrated by immunohistochemistry and which correlated with *in vitro* migration assays [239].

Alternative methods for promoting CXCR4 expression by MSCs have been explored. Human UMSCs have been engineered to overexpress CXCR4 using a cationic liposomal reagent. In chemoinvasion assays there was a significant increase in the number of cells migrating toward an SDF-1 gradient compared with nontransfected cells [240]. Separately, a lipid–polyethylene glycol was used to apply recombinant CXCR4 to the surface of culture-expanded MSCs. This provided an ultrathin coating on the cell surface without covalent bonds or electrostatic interaction. Using these methods it was reported that recombinant CXCR4 could be incorporated into the cell surface membrane in approximately 10 min. Binding of SDF-1 was confirmed, and an *in vitro* assay demonstrated that modified MSCs migrated toward SDF-1 in a concentration-dependent manner. The authors hypothesized that this could be used for early administration of allogeneic MSCs, as SDF-1 expression is at its highest 48 h after infarction and a rapid method of cell engineering is needed [241].

Others studies have looked at the role of adhesion molecules in promoting homing, and attempts have been made to augment rolling mechanisms. It was hypothesized that coating MSCs with anti-addressin antibodies would promote more efficient delivery of MSCs to sites of inflammation in a murine model of inflammatory bowel disease. *In vivo* BLI and fluorescent imaging were used to determine that MSCs coated with VCAM showed a modest increase in migration to mesenteric lymph nodes and the colon. However, it is worth noting that in this case amelioration of disease was seen after delivery of MSCs coated with mucosal addressin cell adhesion molecule and not VCAM, suggesting that increased homing alone is not sufficient to modify disease outcomes [242].

Imparting a cell rolling characteristic to MSCs has been investigated by Sarkar *et al.* [243]. In this study, adult MSCs were generated to express functional rolling machinery, specifically P-selectin glycoprotein ligand-1 (PSGL-1) and sialyl Lewis X (SLeX) using mRNA. PSGL-1 facilitates the posttranslational modification of SLeX, creating a functional ligand for P-selectin and E-selectin and resulting in cell tethering and rolling on inflamed vascular endothelium. *In vitro* studies indicated that transfected MSCs showed a strong cell rolling response under physiological shear stress. *In vivo* using real-time confocal microscopy, transfected MSCs were seen to roll on inflamed endothelium. Furthermore, when injected intra-orbitally these cells migrated toward lipopolysaccharide-induced ear inflammation 30% more than unmanipulated MSCs after 2 h. When MSCs were triple transfected with PSGL-1, SLeX, and IL-10 a superior anti-inflammatory effect was observed. In this study, PSGL-1/SLeX MSCs demonstrated a 48.5% increase in homing to normal bone marrow compared with unmanipulated MSCs and an 88.3% increase in homing to irradiated bone marrow. These data strongly suggested that equipping MSCs with the homing ligands PSGL-1/SLeX by mRNA transfection significantly improved their homing to the marrow, especially under inflammatory conditions.

Overall, significant strides have been made in the field of cell engineering that are likely to play a role in the future of MSC therapies for inflammatory and ischemic pathologies [244]. The practical application of these strategies in terms of timing, scale and safety will need to be carefully addressed before they can be translated for clinical applications.

### 22.6.4 The host environment

Modifications of the host tissue may also be used to augment the migration of exogenously delivered MSCs. This may be by the use of medications designed to improve flow or through the overexpression of chemokines in target tissue.

In one study it was determined that MCP-3 acted via CCR1 and CCR2 on MSCs and could enhance migration *in vitro* in a

concentration-dependent manner. To test this *in vivo*, a rat LAD ligation AMI model was used. The potential role of MCP-3 was assessed by transplanting MCP-3-expressing cardiac fibroblasts into the infarct border zone 1 month after LAD ligation and induction of the infarct. In initial studies of a single infusion, MSCs were shown to migrate to the infarct. This was followed by a trial of serial infusions in an attempt to overcome lung trapping and the short half-life of MSCs. After six infusions over 12 days there were significantly more MSCs engrafted in the myocardium of animals that received MCP-3-expressing cardiac fibroblasts compared with control cardiac fibroblasts. This enhanced migration was associated with improved cardiac function in MCP-3-expressing hearts thought to be due to recruitment of myofibroblasts and remodeling of the collagen matrix. This suggests possible benefits from reestablishing MSC homing and engraftment remote from the acute injury [35]. Similar results were shown using a transgenic model in which MCP-1 was specifically expressed on myocardium. Adult BMSCs were delivered intravenously to these mice, and after 7 days engraftment of cells was visible only in the hearts of transgenic mice but not in the liver or spleen nor in control hearts [81].

The potential role of heparin and sodium nitroprusside has also been investigated. As blood vessels are the primary route of systemically delivered cells, the use of medications to ensure that vessels are free from debris and clot and to ensure adequate vasodilation to optimize passage of MSCs through capillary beds seems reasonable. As discussed earlier in this chapter, the trapping of MSCs in lung capillary beds after intravenous delivery is a significant barrier to mediating their effects in tissues other than the lungs. Using adipose cells capable of differentiation into mesenchymal and hematopoietic cells, the addition of heparin at the time of intravenously transplanted cells successfully aided homing in a model of acute liver injury and appeared to decrease lung trapping [198,245]. This was observed using *in vivo* fluorescence imaging.

Finally, in murine MSCs transfected with firefly luciferase, *in vivo* monitoring was used to assess cell distribution after intravenous injection. Cell trapping in the lungs was significantly reduced after pretreatment with sodium nitroprusside, potentially facilitating cell access to injured organs beyond the lungs [190].

## 22.7 Conclusions

MSCs are the ongoing focus of a major international effort to develop novel therapies for degenerative, inflammatory, and ischemic conditions. These cells hold the potential promise of regeneration, the modulation of damaging immune responses, and are readily isolated and cultured. There is ample evidence that the inflammatory environment augments migration both *in vitro* and *in vivo*. Whether present in endogenous reservoirs or introduced from exogenous or distant sources, MSCs are consistently exposed to tissue signals and interact with numerous immune cells and mediators that can influence their migratory behavior. *In vitro* there are multiple elements of the inflammatory milieu are at play, and they have important downstream effects. For example, the proinflammatory cytokines TNF-α and IL-1β have clear effects on MSC migration. Other effects, including the activation of the complement cascade and macrophage recruitment, appear to optimize the homing ability of MSCs.

There has been extensive *in vitro* work aimed at identifying the important factors that influence migration. This has resulted in a large number of potentially useful chemokine receptors on MSCs being detected. While these are often present in only small numbers, they appear to exert a significant effect on MSC behavior when stimulated by the appropriate ligand. Many of these ligands are endogenously upregulated in both ischemic and inflammatory tissues to create a positive cascade effect. A particular focus has been the interaction between SDF-1 and CXCR4. This has been shown to have a potent effect on cell behavior and has been adopted in cell engineering strategies designed to improve MSC homing. While an important pathway, it is likely that this effect works synergistically not only with other cytokine pathways, but also with the activation of TLRs, integrin receptors, and MMPs.

There has been a proliferation of *in vivo* MSC migration studies. Numerous models of inflammation have been studied, including cerebral and myocardial ischemia, AKI, and acute liver injury, as well as inflammatory arthritis. In almost all reported studies, *ex vivo* imaging techniques have demonstrated migration of cells to injured tissue. What has become apparent is the difficulty of determining the exact numbers of cells that do in fact migrate and indeed if the tracked cells are viable when they reach their target location. After intravenous injection the majority of MSCs are trapped in the capillary bed of the lung for up to 3 days and the number of MSCs reaching the target site and having a therapeutic effect is hard to gauge.

There are large variations between studies in terms of cell source, passage number, incubation protocols, the use of immunocompromised hosts, route and timing of delivery, and cell numbers infused. These may all act as confounding factors in the analysis of results. Real-time live imaging modalities will further improve our understanding of how these cells behave once administered to a new recipient. While MRI seems promising there have been some mixed results, as outlined earlier. In addition, the incorporation of ferric iron into macrophages and the retention of iron oxide particles in the tissue even after cell death remain important confounders. SPECT, PET, and BLI will likely prove to be more useful methods of tracking cell behavior *in vivo*.

While MSCs certainly have the potential and ability to migrate to sites of inflammation, the current challenge is the augmentation of this process by manipulation of either the MSC itself, the host environments through which they pass, or the tissues they are aiming to reach. While using very early passage MSCs is likely to optimize homing, it raises technical challenges around cell numbers and negates the benefits of using culture-expanded

MSCs. Modification of culture conditions is likely to prove useful and in particular the benefits of short-term hypoxia or cytokine pre-stimulation, as discussed earlier. The engineering of MSCs (see Chapters 23, 59, 60, and 61) to attenuate expression of chemokine receptors has been successful in improving migration, and while the laboratory methods of viral transduction are highly efficient, they will pose significant manufacturing and regulatory challenges for their translation to the clinic.

One of the most important issues to be addressed is that of accurate tracking of live cells in real time *in vivo* (see Chapter 24) and determination of the proximity to the target tissue needed for MSCs to exert their desired paracrine influence on host progenitor cells.

## 23.1 Summary

A growing body of preclinical evidence suggests that mesenchymal stromal cells (MSCs) are effective for the structural and functional recovery of damaged organs, and numerous clinical trials have been, and are, underway using MSCs in a wide range of diseases. Systemic administration of MSCs has been used extensively in clinical studies, but the efficiency of culture-expanded MSCs homing and engraftment to the target organ is questionable. The therapeutic effect of MSCs in tissue repair and regeneration appears to correlate with the number of MSCs engrafted into the damaged tissue. Considerable progress has been made in the past decade in understanding the molecular mechanisms of the homing process of MSCs to a site of injury, particularly with regard to the involvement of chemokine receptors. This will ultimately help improve the homing ability of cultured-expanded MSCs and enhance their therapeutic effects.

## 23.2 Introduction

Cell homing is a phenomenon that was initially discovered with hematopoietic stem cells (HSCs). HSCs are able to migrate through the bloodstream to various organs and return to their niche in the bone marrow under the guidance of chemical signals [1]. Bone-marrow-derived MSCs represent approximately 0.001–0.01% of all nucleated bone marrow cells and are approximately 10-fold less abundant than HSCs. It has been assumed that MSCs may exhibit a similar homing property. Clinical trials are underway in which bone marrow MSCs are administered into the blood, thereby eliminating the potential damage that could otherwise result from the use of intraorgan delivery routes [2,3]. However, studies have indicated that expansion of bone marrow MSCs *ex vivo* can severely impair their homing capacity [4], resulting in low levels of engraftment in target tissues [5–7]. Accordingly, there are concerns over the influence of poor engraftment affecting the outcome of MSC-based therapies.

In this chapter we provide an overview of the biology of MSC homing, focusing on the role of chemokine receptors and their ligands in MSC trafficking, migration, and engraftment at the site

of tissue injury. We will also discuss the influence of culture expansion on the homing capacity and potentially the therapeutic effect of MSCs in tissue repair and regeneration.

## 23.3 Homing capacity of mesenchymal stromal cells

Several lines of evidence suggest that bone marrow MSCs have the ability to home to sites of tissue inflammation or damage. For an example, 24 h after transplantation of uncultured MSCs isolated from the bone marrow of transgenic mice that expressed enhanced green fluorescence protein (EGFP) into sublethally irradiated mice, as many as 55–65% of the $EGFP^+$ cells were recovered from the bone marrow and 4–7% were recovered from the spleen [4]. This high degree of homing to the marrow compares favorably with that of HSCs, of which approximately 25% returned to the bone marrow [8]. These results suggest that bone marrow MSCs exhibit a remarkable capacity for homing. A number of studies have indicated that bone marrow MSCs are capable of migrating from the blood into damaged tissues, crossing through endothelial cells to do so. When bone marrow MSCs were administered systemically after a stroke injury, the cells migrated toward the brain and were shown to acquire expression of the neural markers neuronal nuclear antigen, microtubule-associated protein 2, and glial fibrillary acid protein. The rats showed an improved functional outcome [9]. In another study using the ischemic stroke model, human MSCs were found in the damaged brain following ipsilateral injection (injected on same side as the stroke injury) or contralateral injection (injected on opposite side of the stroke injury) [10], indicating a capacity to home across the brain to the site of the stroke damage. Systemic infusion of bone marrow MSCs in baboons after lethal total body irradiation resulted in long-term engraftment of the cells in multiple organs, including the skin, intestines, liver, lungs, thymus, and kidney [11]. These results suggest that the homing and engraftment of bone-marrow-derived MSCs to injured tissues are independent of the cause of injury and/or the type of tissue.

Increasing evidence indicates that the homing capacity of bone marrow MSCs is severely impaired after *ex vivo* culture expansion [12]. When bone marrow MSCs were subjected to 24 h of *ex vivo* culture, the fraction of bone marrow MSCs detected in the bone marrow decreased to 10% compared with noncultured bone marrow MSCs. Likewise, after 48 h of culture, $EGFP^+$ bone marrow MSCs were not detected in lymphohematopoietic organs following systemic infusion [4]. We found that direct intramyocardial injection of allogeneic MSCs that had undergone five passages of monolayer culture into the ischemic area resulted in active migration of the cells through the ischemic region of the left ventricular wall and substantial engraftment (Figure 23.1), while only approximately 1–2% of systemically infused MSCs were detected in the acutely infarcted myocardium 72 h after intravenous infusion in mice (Figure 23.2). These

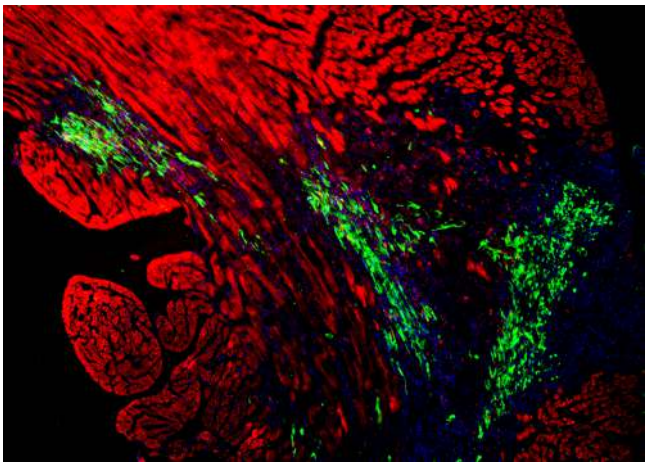

**Figure 23.1** MSC engraftment in the ischemic myocardium after intramyocardial injection in mice. A total of $0.5 \times 10^6$ bone-marrow-derived MSCs expressing green fluorescence protein were injected into the peri-infarct border zone at one site. After 72 h, MSCs (green) were found to have migrated through the ischemic areas from the injection site. Myocytes (red) were detected by antisarcomeric actin, and nuclei (blue) were stained with Hoechst. (See color plate section.)

results are consistent with other studies that also show low rates of engraftment of culture-expanded bone marrow MSCs into the ischemic myocardium following systemic infusion [13].

Studies have also indicated that culture-expanded MSCs injected intravenously lodge in the lungs and can cause vascular obstruction if sufficiently large numbers are administered. In

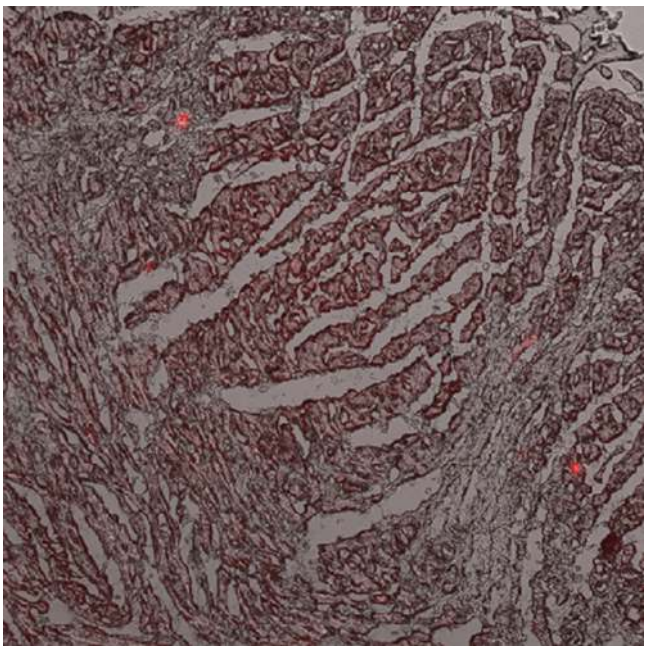

**Figure 23.2** Low engraftment of MSCs into the ischemic myocardium after systemic administration in mice. A microscopic image of a tissue section across the peri-infarct area of the acutely infarcted myocardium shows a few DiI-labeled MSCs (red) in the myocardum 72 h following intravenous infusion of $1 \times 10^6$ DiI-labeled MSCs. (See color plate section.)

several studies in mice over 80% of MSCs were trapped in the lungs following intravenous injection (Figure 23.3). These are likely stuck in the pulmonary capillary bed and appear to die of local ischemia [14–16].

Intra-arterial injection facilitates higher levels of cell engraftment in the target organ and may represent a more effective route for MSC administration [16–19]. However, intracoronary delivery of MSCs caused acute myocardial infarction (AMI) in dogs and reduction of coronary blood flow in pigs [13,20]. Similarly, intracarotid arterial infusion of MSCs caused a marked reduction in blood flow and the development of microstrokes in rats [21,22]. Thus, there is some concern over the safety of intravascular administration of MSCs. However, a meta-analysis and review of the literature by Lalu *et al.* that included over 1000 patients given human MSCs either intravenously or intra-arterially, of whom more than 300 were included in clinical trials, showed no adverse events related to the administration of the MSCs other than transient fever [23].

Bone marrow MSCs undergo dynamic changes in their molecular phenotype during culture expansion, although they may maintain stable expression of representative cell surface markers such as CD73, CD90, and CD105. Previous studies showed that human bone marrow MSCs in late passages lost surface expression of the chemokine receptors CCR1, CCR2, CCR7, CCR9, CXCR4, CXCR5, and CXCR6 together with chemotactic responses to their corresponding ligands [24,25]. Thus, it is necessary to optimize the culture condition for MSCs in order to maintain their properties, including the expression of homing receptors.

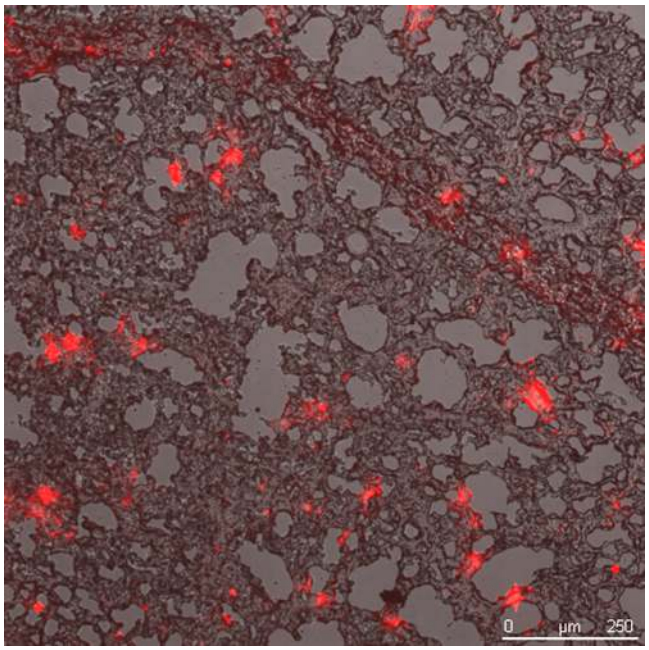

**Figure 23.3** Entrapment of MSCs in the lungs of mice. A microscopic image of a section of mouse lung tissue shows clusters of DiI-labeled MSCs (red) in the lungs 24 h after an intravenous injection of $0.5 \times 10^6$ DiI-labeled MSCs. (See color plate section.)

## 23.4 Homing ability of mesenchymal stromal cells and their therapeutic effects

Numerous animal studies have shown that direct delivery of MSCs into injured tissues can significantly enhance tissue repair [26–28]. Catheter delivery of allogeneic bone marrow MSCs to infarcted myocardium resulted in a profound reduction in scar formation and improvement in cardiac function in pigs [26]. Endocardial injection of bone marrow MSCs in pigs also showed cardioprotective effects in a model of chronic ischemic cardiomyopathy with significantly decreased fibrosis and improved left ventricular function [29]. Direct application of a monolayer sheet of MSCs on to the scarred myocardium resulted in reversed wall thinning in the scar area and improved cardiac function in rats [30].

However, comparative studies to evaluate the impact of different cell delivery routes on MSC engraftment rates and therapeutic effects are limited [3]. Three routes of bone marrow MSC administration have been used in preclinical models of cardiac disease: intramyocardial, intracoronary, and intravenous. Direct intramyocardial injection of bone marrow MSCs resulted in the highest rates of MSC engraftment and functional improvement of the left ventricle in animal AMI models [31,32]. In contrast, intracoronary infusion of bone marrow MSCs caused a reduction in coronary blood flow and microinfarction. Intravenous infusion of bone marrow MSCs resulted in a much lower rate of engraftment in the ischemic myocardium than either of the other two approaches [13]. Similarly, intracarotid administration of human MSCs led to significantly higher engraftment of MSCs in the injured brain of rats compared with intravenous transplantation [22,33]. However, whether low engraftment of intravenously infused MSCs to the target organ(s) ultimately compromises their therapeutic benefit needs to be clarified in parallel studies.

## 23.5 Mechanisms of leukocyte trafficking to sites of inflammation

Homing and engraftment is a prerequisite for cells to play their roles in the target tissue, particularly when cells are infused systemically [34]. The molecular mechanisms of homing of bone marrow MSCs have not been fully elucidated, but a preliminary study suggests that bone marrow MSCs exhibit some properties, such as rolling, similar to that adopted by leukocytes homing to inflammatory sites [35]. Thus, knowledge gained about leukocyte trafficking, adhesion, and migration may help in understanding the mechanisms mediating MSC homing. During inflammation, the recruitment of leukocytes to the inflammatory site requires a coordinated sequence of molecular and cellular events. The initial activity of leukocytes homing involves the rolling of the cells on the endothelium mediated by selectins, which are expressed in inflamed venules [36–39]. This process allows

leukocytes to become activated by cytokines and express high-affinity integrins on their surface, including CD18 and CD49d, which leads to the subsequent step of leukocyte arrest/firm adhesion on endothelial cells [40]. The transendothelial migration of leukocytes involves signals derived from clustering of apically disposed intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1), disassociation of endothelial junctions, and targeted recycling of platelet/endothelial cell adhesion molecules from the lateral border recycling compartment of endothelial cells [41]. Finally, the migration and invasion of leukocytes into the extracellular matrix (ECM) are mediated by integrin–ECM molecule interactions and matrix degradation [42].

## 23.6 Potential ligands/receptors for mesenchymal stromal cell homing

The molecular mediators involved with bone marrow MSC homing and engraftment into the site of tissue injury are not yet fully understood. Based on the hypothesis that specific chemoattractant molecules and adhesion molecules are upregulated in damaged tissue and that these induce the migration and engraftment of bone marrow MSCs, we developed a functional genomics strategy to identify candidate mediators for MSC homing. Genes that were significantly upregulated following AMI included CC chemokine ligands 2, 6, 7, and 9, chemokine CXC ligands 1, 2, and 12, interleukin (IL)-1 and IL-6, transforming growth factor (TGF)-β1 and -β2, tumor necrosis factor receptor II, and molecules involved in cell adhesion, including fibronectin 1, laminin 1, ICAM-1, VCAM-1, E-selectin, thrombospondin 1, and tenascin C [43,44]. These findings are in agreement with previous findings [45]. The expression of nine corresponding receptors of the upregulated ligands – namely, CCR2, CXCR4, IL-6RA, E-selectin ligand, CD29, CD49d, CD49f, CD49h, and CD49i – were detected in early passage murine bone marrow MSCs [43,44]. The functional involvement of some of these ligand–receptor pairs has been demonstrated.

Several additional ligand–receptor pairs have been reported that are possibly involved in MSC homing to sites of tissue injury. These include hyaluronic acid–CD44 [46], *N*-formylated peptides–*N*-formyl peptide receptor and the formyl peptide receptor-like-1 [47], platelet-derived growth factor (PDGF)-AB–PDGF-receptor alpha and beta, and insulin-like growth factor (IGF)-1–IGF receptor [48]. Further studies are required to establish their functional roles in MSC homing.

It still remains unclear whether MSCs utilize the same molecules for transendothelial migration as leukocytes do. Several molecules, such as CD18 and CD49d, which are critical for the trafficking and migration of leukocytes, are either not expressed or are expressed on the surface of a fraction of MSCs [44,49]. For leukocyte rolling along endothelial cells, the interactions of selectins with their corresponding ligands are considered essential [39]. Correspondingly, MSCs derived from bone marrow and placenta were observed to roll and adhere to postcapillary venules of a mouse model in a P-selectin-dependent manner [35]. However, it is controversial whether MSCs express functional selectin ligands, particularly after culture [50]. Nevertheless, culture-expanded bone marrow MSCs have been shown to exhibit rolling activity on activated endothelia and migrate to inflamed tissue after surface modification with a nanometer-scale polymer construct containing sialyl Lewis x [51]. Similarly, overexpression of CD49d in MSCs was shown to increase their homing to the bone marrow [52]. These studies suggest that adhesion molecules affect the homing capacity of MSCs.

## 23.7 Chemokine involvement in mesenchymal stromal cell homing

Currently, over 50 chemokines and 20 chemokine receptors have been discovered [53]. While most chemokines are secreted and are 67–127 amino acids in length, some chemokines are membrane bound (e.g., CXCL16 and CX3CL1). Chemokines are divided into four groups depending on the spacing of their first two cysteine residues near the NH2-terminus: CXC chemokines, CC chemokines, C chemokines, and CX3C chemokine [54].

Chemokine induction is a prominent feature in ischemic myocardium. Diverse chemokine/chemokine receptor axes participate in the regulation of chemotactic activities for various cell types. Following acute myocardial ischemia, several chemokines are upregulated immediately [43–45,55]. However, the upregulation is transient for many, and expression levels usually decline markedly within the first 72 h of acute AMI [43,44]. This chemokine expression pattern is consistent with the time course of homing of bone marrow MSCs. Freshly infarcted myocardium is more chemoattractive to bone marrow MSCs [56]. The expression of chemokine receptors in bone marrow MSCs and their corresponding ligands are summarized in Table 23.1. Notably, in a comparative analysis, similar expression levels of chemokine receptor proteins were found on the surface of bone marrow MSCs and MSCs derived from placenta, though differential display in mRNA expression level was found [50].

### 23.7.1 CCR1 and CCR2 involvement in mesenchymal stromal cell homing

A functional role for chemokines in the recruitment of bone marrow MSCs into infarcted myocardium has been implicated in several studies. CCL7, also known as monocyte chemoattractant protein (MCP), has previously been shown to attract monocytes and to regulate macrophage functions [62]. It has been found to be critically involved in bone marrow MSC homing to ischemic myocardium and in their intramyocardial migration and survival. Overexpression of CCL7 at the site of previous myocardial infarction recruited systemically administered bone marrow MSCs and improved cardiac structure and function in rats [56]. Consistently, increased expression of CCR1 (a receptor of CCL7) by murine bone marrow MSCs has been shown to

dramatically increase MSC chemotactic migration and to increase bone marrow MSC survival following intramyocardial delivery in mice [57]. Engraftment of bone marrow MSCs into the ischemic myocardium increased and was associated with an improved therapeutic effect.

CCR2 also appears to be a significant factor in the homing of bone marrow MSCs. MCP-1 (also known as CCL2, a ligand of CCR2) in the myocardium recruited murine bone-marrow-derived multipotent adult mesenchymal stromal cells (MASCs) administered systemically into the cardiac tissue [59]. MASCs used in the study represented a $CD34^{-}/Sca\text{-}1^{high}$ subpopulation of murine bone marrow cells that showed a high potential for differentiation and proliferation [59,63]. Following myocardial ischemia, expression of MCP-1 was upregulated immediately [43–45]. MASCs homed to regions of murine myocardium damaged by ischemia–reperfusion injury [59]. The cytoplasmic protein FROUNT has a pivotal function in CCR2-mediated monocyte chemotaxis. FROUNT, which interacts with CCR2 in the cytoplasm, appeared to be required for the effect observed with MASCs [59]. Together, these results indicate that myocardial overexpression of MCP-1 is associated with the recruitment of bone marrow MSCs to the myocardium in the absence of ischemic injury, suggesting a central role for MCPs in bone marrow MSC homing to the ischemic myocardium.

### 23.7.2 The CXCR4–SDF-1 axis in mesenchymal stromal cell homing

CXCL12 (SDF-1) has been shown to enhance the migration of uncultured bone marrow-derived hematopoietic stem cells (HSCs) to ischemic myocardium [64,65]. Because of these observations, it has been proposed that the CXCR4–SDF-1 axis also plays a role in bone marrow MSC homing. However, unlike HSCs, bone marrow MSCs express low levels of CXCR4 in a small subpopulation in early passages, and the expression levels decline progressively with successive passages [66,67]. The intracellular expression of CXCR4 appears to be sustained in bone

marrow MSCs in culture. Short-term exposure of human Flk1$^+$ bone marrow MSCs to a cocktail of cytokines consisting of Flt-3 ligand, stem cell factor (SCF), IL-6, hepatocyte growth factor (HGF), and IL-3 significantly upregulated both cell surface and intracellular levels of CXCR4, and this population of bone marrow MSCs was associated with an increase in migration capacity in response to SDF-1, as well as an increase in homing efficiency to the bone marrow of irradiated mice [68]. It is thus likely that the expression levels and distribution patterns of CXCR4 are regulated by cytokines. Similarly, exposing bone marrow MSCs to hypoxia increased their expression of CXCR4 and their migration to ischemic kidneys in mice [69]. In addition, forced expression of CXCR4 in cultured bone marrow MSCs resulted in an increase in their recruitment to acutely infarcted myocardium in rats [70] and to the site of traumatic brain injury in mice [71]. However, other studies have not confirmed these findings. In an acute kidney injury mouse model, separate and simultaneous overexpression of CXCR4 and CXCR7 (another receptor of SDF-1) in bone marrow MSCs did not increase their presence in the injured kidney [72]. Moreover, blockade of CXCR4 did not affect the intramyocardial migration of murine bone marrow MSCs to ischemic areas in mice [43]. These results suggest that the SDF-1–CXCR4 axis may be involved in the step of MSC extravasation but that the homing process requires the presence of other mediators. Preliminary data suggest that there is no correlation between serum SDF-1 levels and the number of circulating putative MSCs in patients with ischemic heart disease. For example, in patients with AMI an increase in blood SDF-1 levels was found to coincide with elevated levels of CD34$^+$ cells (normally present on human HSCs and endothelial cells) [73], but not of MSCs [71]. Thus, although the role of the CXCR4–SDF-1 axis in HSCs has been well recognized, the role of this signaling axis in the homing of bone marrow MSCs requires further study.

### 23.7.3 Other chemokines

Several other chemokines, including fractalkine (CX3CL1) and CCL25 (also known as thymus-expressed chemokine,), have been shown to influence MSC chemotaxis. Human bone marrow MSCs migrated in response to CCL25 in a dose-dependent manner [74]. CX3CR1 has been found to mediate both leukocyte migration and adhesion. Fractalkine expression is upregulated in the brain following ischemia in rats [75]. Hypoxic treatment of bone marrow MSCs increased their levels of CX3CR1 and their migration to fractalkine [76]. Knockdown of CX3CR1 expression in human bone marrow MSCs significantly reduced their recruitment to ischemic brain tissue after intravenous injection in rats [75]. These results suggest that fractalkine and CX3CR1 interactions are likely to play a role in the homing of bone marrow MSCs to sites of injured tissue. One study suggested that tissue-specific ligand–receptor pairs may be employed in the recruitment of bone marrow MSCs. As an example, the CCL27–CCR10 chemotactic axis showed the most potent effect in the recruitment of bone marrow MSCs to the skin. Increases in CCR10 expression in bone marrow MSCs or the level of CCL27 in the skin enhanced extravasation of MSCs from the circulation [25].

## 23.8 Pretreatment of mesenchymal stromal cells with cytokines and growth factors

Studies have suggested that the expression of certain chemokine receptors in MSCs can be upregulated after a brief exposure to cytokines and growth factors. PDGF-AB, TGF-β1, and tumor necrosis factor (TNF)-α showed potent chemoattractant activity *in vitro* to MSCs derived from human adipose, and these were more effective than SDF-1 or MCP-1. Pretreatment of MSCs with TNF-α significantly increased their chemotactic migration to several chemokines, such as RANTES, MCP-1, macrophage inflammatory protein 3β, and SDF-1 [77], suggesting an increase in the expression or function of the corresponding chemokine receptors. In an earlier study, exposure of human Flk1$^+$ bone marrow MSCs to a cocktail of cytokines consisting of Flt-3 ligand, SCF, IL-6, HGF, and IL-3 significantly upregulated both cell surface and intracellular levels of CXCR4 and increased their homing to the bone marrow [68]. In another study, the proinflammatory cytokines TNF-α, interferon-γ, IL-1α, and IL-6 significantly upregulated the mRNA and surface protein expressions of many chemokine receptors in murine bone marrow MSCs, including CCR2, CCR3, CCR5, and CXCR4. Moreover, MSCs pretreated with TNF-α exhibited significantly increased homing to inflamed skin or ischemic myocardium after intravenous injection into the retro-orbital sinus in mice [78]. These data suggest that priming of MSCs with proinflammatory cytokines before their administration may constitute an effective approach to enhance the homing of MSCs to sites of tissue injury.

## 23.9 Summary and future prospects

MSCs hold promise for improving the repair and regeneration of injured or diseased organs. However, the efficacy of this treatment appears to relate to the number of MSCs recruited to the target tissue. Therefore, the identification of homing mediators and the development of improved culture systems to maintain the homing capacity of MSCs are important. Chemokine receptors play a critical role in the homing of bone marrow MSCs to ischemic tissues, but many other mediators are likely involved in the complex homing process.

## 24.1 Introduction

Cells are highly dynamic biological systems that are comprised of a vast number of molecular processes that interact both spatially and temporally [1–3]. Researchers have access to many methods for studying cellular populations, though often these methods are not able to capture single cell behavior as well as rare or transient events [4,5]. Additionally, standard assays for studying cellular systems rely on snapshots of cell populations that do not reveal the true complexity and dynamics of single cell behavior [6]. Thus, continuous observations of single cells are necessary to accurately study how the fate of an individual cell is adopted in culture and how that fate is related to the cell's molecular state (Figure 24.1). For mesenchymal stromal cell (MSC) cultures, which are heterogeneous and may only contain a small population of stem cells, single cell analyses are even more critical [7,8]. This is because MSC populations are comprised of various cell types that exhibit differential growth potential and potency [9]. Population averages do not reveal the underlying detail of complex systems and often lead to incorrect conclusions [6,10] (Figure 24.1a and c). Thus, to accurately study MSC cell growth dynamics (division, apoptosis, self-renewal, and lineage commitment) it is critical to continuously observe each cell throughout its life cycle and record lifetime events [10] (Figure 24.1b).

Interestingly, the importance of continual observations of biological processes was first recognized in the 17th century by Leeunwenhoek when observing capillaries in the ears of living rabbits using the first microscopes [11]. In the 19th and 20th centuries the development of time-lapse photography, fluorescent microscopy, and improvements in cell culture techniques enabled continuous observation of molecules within living cells over long periods of time [4]. The field of live cell imaging has grown exponentially since this time, driven by the need to continuously observe cell fate outcomes in lineage-tracing and fate-mapping experiments in developmental biology research. In the 21st century, live cell time-lapse imaging has been successfully applied to understanding questions in

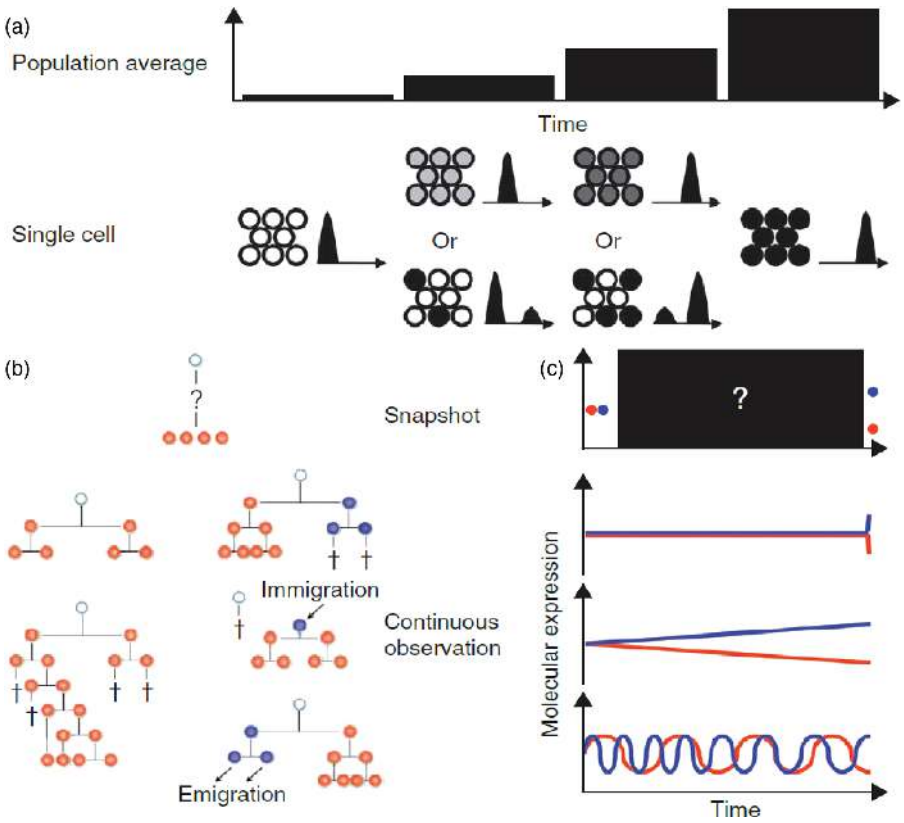

**Figure 24.1** Continuous observation of single cells versus population averages. (a) Population averages obscure population heterogeneity as determined by flow cytometry or single cell analyses. (b) Continuous observation of single cells is required to understand cell fate in detail. There are many different possibilities for how heterogeneous populations arise. For example, the only way to know how one white cell can give rise to four cells is to continuously observe each cell's fate. (c) Extrapolating from average population-based measurements of molecular expression to single cells can lead to erroneous conclusions. (See color plate section.) *Source:* [6] Schroeder 2011, pp. S30–S35. Reproduced with permission of Nature Publishing Group.

MSC biology that would otherwise have been impossible. These include, but are not limited to, characterizing the onset of heterogeneity in expanded MSCs [12], identifying a new population of MSCs in the endometrium [13], studying MSC spreading, proliferation and migration in response to chemically defined substrates [14], soluble and fixed gradients, direct current electric fields [15], and bioengineered scaffolds [16]. Indeed, there have been a greater number of studies applying live cell imaging to addressing hematopoietic, neural, and immune cell populations compared with those studying MSC populations. The most likely explanation for this is that these cellular systems have well-developed markers to track developmental stages and lineage progression. Researchers wishing to apply live cell imaging to answer questions in MSC biology will learn from other cellular systems. Examples include demonstrating blood cell generation from hemogenic endothelium [17] (hemogenic endothelium is a special subset of endothelial cells (ECs) scattered within blood vessels that can differentiate into hematopoietic cells), studying neural stromal cell progression [18], identifying new features of self-renewal in hematopoietic stromal cells [19], proving that hematopoietic cytokines are instructive and not selective [20], modeling intracellular competition for cell fate in B lymphocytes [21], and developing new models that describe lymphocyte cell cycle kinetics [22].

Live cell imaging is a multidisciplinary area of research that has evolved through input from engineers, physicists, chemists, biologists, computer scientists, and mathematicians. This level of technical sophistication can be a barrier to entry for some laboratories where there is no access to expertise from these different disciplines. Furthermore, there is not a standard protocol for live cell imaging because imaging parameters depend on the type of tracked cells and the hypothesis to be tested [4]. Thus, the great challenge is to make this technology more accessible to the biology community. This chapter will provide an in-depth understanding of the technical considerations for optimal time-lapse imaging and analysis of MSC fate.

A typical workflow involves (i) image acquisition, (ii) image processing, (iii) cell tracking, annotation of pedigrees, and (iv) quantification and visualization (Figure 24.2). Implementation of this workflow requires careful choice of imaging modalities, cell culture environments, imaging acquisition parameters (time-lapse interval, image illumination time, and experiment duration), experimental design, data storage, image processing, and software for cell tracking and annotation. Imaging parameters must be based upon the cell type and biological hypothesis that is being tested [4]. This chapter first describes technical considerations for image acquisition, process and storage (Section 24.2), methods for single cell tracking and analysis (Section 24.3) and a case study examining differentiation of ECs from cardiac-derived MSCs (Section 24.4) [23].

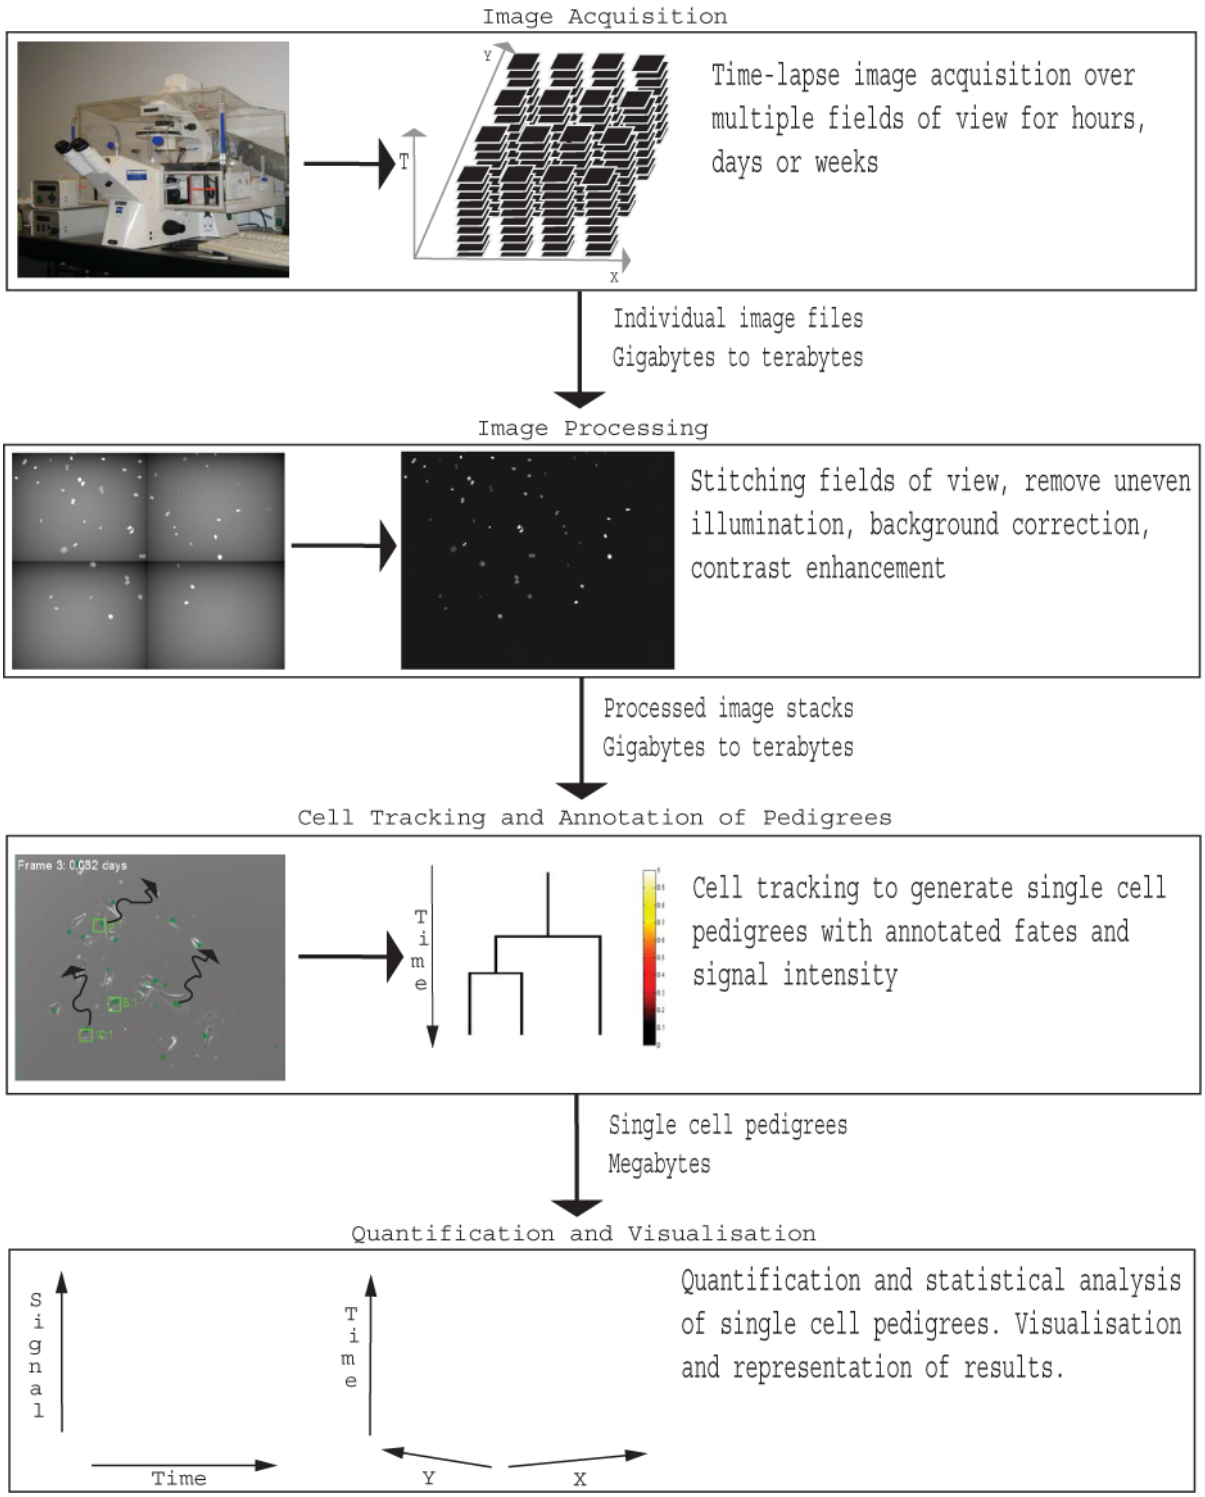

**Figure 24.2** Generic workflow for live cell imaging and cell tracking. Image acquisition is used to generate time-lapse images over multiple fields of view. Image processing is required to enhance image quality for cell tracking and quantification. Processed image stacks are then analyzed by specialized software that identifies cell trajectories from which single cell pedigrees are built. These trajectories can be annotated with discrete cell fate outcomes or continuous measurements, such as fluorescence or cell size. Finally, cell fate outcomes are visualized using specialized software with appropriate statistics to test hypotheses.

## 24.2 Technical considerations

### 24.2.1 Equipment, software, and hardware requirements

Specially designed equipment, hardware, and software are required to maintain cell viability and allow continuous observations of cells in more than one field of view (FOV) over the long term (several days or more). The hardware components of a live cell imaging system include (a) an automated inverted fluorescent microscope with a motorized *X–Y–Z* stage controller, transmitted and fluorescent light sources, and appropriate fluorochrome excitation and emission optics, (b) an environmental chamber with temperature regulation and respiratory gas controller ($CO_2$ with optional $O_2$ control), (c) a scientific complementary metal-oxide-semiconductor or charge-coupled device high-sensitivity digital camera, and (d) a computer for time-lapse image storage and programmatic control of all hardware elements [6]. Custom-written or commercially available software is required to define image acquisition parameters, control the microscope, and review data. The primary objective of a live cell imaging experiment is to maintain cell viability on the microscope stage and prevent abnormal cell growth that can arise from overexposure to light (phototoxicity) that would result in experimental artefacts [24].

Controlled temperatures are achieved by coupling of an environmental chamber to a heating unit and temperature controller that together are able to maintain the specimen at a specific temperature, typically 37 °C. In most arrangements a small temperature probe is used to continuously measure temperature as close to the sample as possible. Real-time temperature measurements are fed into a heating controller that adjusts the power of the incubator heater to maintain the sample environment at the temperature set-point. Environmental chambers either enclose the entire microscope or just the culture plates that sit on top of the microscope stage. There is often a few degrees of temperature variation within large environmental chambers; hence, there is a need for the temperature sensor to be as close to the sample as possible.

Environmental chambers are typically "leaky," so control of respiratory gases is potentially problematic. To achieve a stable pH for bicarbonate/$CO_2$-buffered culture systems, dedicated $CO_2$ controllers mix a $CO_2$ supply with air and pump the mixture through a humidification bottle and into the environmental chamber. For incubators that enclose the microscope, a secondary cover encloses the culture vessel through which respiratory gases are flowed. Humidification of the supplied gas mixture is necessary to reduce evaporation from the culture vessel, a particularly important consideration when using small-volume cell culture systems (e.g., microfluidics). While 5% $CO_2$ is commonly used for the buffering pH in standard tissue culture incubators, there are several suitable alternatives that do not require $CO_2$ control, such as HEPES (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) buffer.

Open chambers that surround the entire microscope stage are suitable for experiments using large petri dishes or multiwell plates as they provide more accessibility to the sample; for example, for microinjection, single-cell capture, addition of factors, or exchange of medium. Closed small-volume chambers that sit upon the microscope stage are a cheaper option, providing a more isolated and regulated environment surrounding the specimen but without any space to access the specimen.

Maintaining image focus is crucial for cell tracking, particularly for experiments over several days or weeks, where microscope components inevitably drift with time. Autofocus algorithms are required to maintain image focus. Software algorithms that are based on multiple captured images are slow and unreliable in comparison with hardware autofocus, which uses reflection of a light beam off the glass bottom of the culture vessel to maintain a constant optical path length between the sample and microscope lens. Hardware autofocus only works with high magnification objectives (10× or higher) and requires a focal plane to be set manually, which can increase set-up time if acquiring a large number of FOVs. However, even though software autofocus does not require additional set-up time, one must consider that acquisition of multiple images for each focus position will increase stage scanning time and potentially contribute to phototoxicity and fluorochrome photobleaching.

The quality of commercial systems for live cell imaging has improved dramatically over the last 5 years. These are available from suppliers such as Leica, Nikon, Olympus, Molecular Devices, and Zeiss. The Incucyte™ live cell imaging system (Essen Biosciences) departs from the standard configuration by microscopically scanning culture plates within an incubator. The major difference between these platforms relates to their programmatic and optical imaging flexibility.

Transmission light microscopy using phase contrast or differential interference contrast (DIC) is preferably used for cell tracking as it does not require much light to obtain an image [25]. Phase-contrast microscopy is able to convert optical path differences generated as light passes through a specimen into contrast differences in the object image. DIC is similar to phase contrast: the major difference is that DIC microscopy converts gradients in the optical path length as light passes over the specimen into regions of contrast in the object image. DIC microscopy produces images that appear almost three-dimensional and does not result in phase halos as with phase contrast.

Transmitted-light microscopy does not require significant levels of illumination, enabling more frequent visualization of cell ultrastructure without phototoxicity. Therefore, dynamic cellular process, such as division, death, and changes in cell ultrastructure, can be tracked in more detail. Additionally, this information is obtained without the use of fluorescent probes or dyes, which require phototoxicity studies to ensure that cell growth dynamics are not perturbed [26].

Fluorescent imaging modalities are required to obtain molecular information. Individual fluorescent molecules fluoresce when excited at a particular wavelength of light. The location

and dynamic movement of fluorescently labeled molecules can be used to mark specific subcellular compartments, cytoskeletal structures, or individual proteins themselves. Common fluorescent probes for directly labeling subcellular compartments include Hoeschst dye that stains DNA, and fluorescently labeled phalloidin that marks cytoplasmic actin filaments. Fluorescent proteins can also be used as reporters of gene expression within living cells. Section 24.3.3 examines the use of fluorescent biomarkers for live cell imaging of MSCs in more detail.

Some of the modalities for live cell fluorescent imaging are briefly described as follows:

- **Fluorescence recovery after photobleaching (FRAP):** FRAP can be used to estimate diffusion coefficients and dynamics of protein binding processes. FRAP provides an optical record of dynamic cellular interactions with high spatiotemporal resolution. For example, FRAP has been used to study the process of cellular coupling in a co-culture of quantum dot (QD)-labeled MSCs and cardiomyocytes [27].
- **Fluorescence energy transfer (FRET):** excitation of a shorter wavelength fluorochrome results in fluorescence of a longer wavelength fluorochrome if the two fluorochromes are within a particular molecular distance of each other. FRET can be used to study the interaction between neighboring proteins or interaction sites. For example, FRET has been used to visualize the activity of FAK and Src signaling pathways at the plasma membrane in human MSCs during stimulation of osteogenic, myogenic, and neurogenic differentiation pathways [28].
- **Total internal reflection (TIRF) microscopy:** induction of an evanescent wave in a limited area surrounding a region of interest in a specimen that is immediately adjacent to two mediums with different refractive indices. Typically, the two mediums used to generate the evanescent wave are the specimen and a glass coverslip. For example, TIRF has been used to visualize enrichment of guanine nucleotide exchange factor H1 in MSC focal adhesions after osteogenic induction [29]. Interestingly, inhibition of focal adhesion formation in MSCs resulted in suppression of osteogenic commitment, suggesting a role for focal adhesion signaling in the regulation of MSC fate decisions.

There are many detailed reviews on fluorescent imaging methods, including those already listed and others [25,30–32]. When these methods are applied to tracking single cell molecular processes one will need to optimize the trade-off between the amount of image information achieved, which usually correlates with the quantity of illumination, and phototoxicity or photobleaching.

### 24.2.2 Image acquisition parameters

Image acquisition parameters must be defined for each live cell imaging experiment. Parameters will be adjusted depending on the cell type being studied, cell culture density, use of fluorescent reporters, and the type of dynamic responses being observed. These parameters include image acquisition frequency, the length of observation period, exposure time, and the number of FOVs per time lapse. Image acquisition frequencies of the order of seconds to minutes are suitable for capturing fast processes, such as the detailed observation of phases of mitosis or intracellular vesicle trafficking. Dynamic interactions of MSCs with other cell types, such as their transmigration between and directly through ECs, requires image acquisition every 5–90 s to gain insight into the critical ability of MSCs to extravasate at sites of inflammation [33]. Furthermore, the mechanisms that MSCs use to interact with ECs and cancer cells require image acquisition every 1 min so that they can be visualized [34]. A temporal resolution of the order of several minutes to half an hour is necessary to resolve movement of individual cells in consecutive frames when tracking cells that are highly motile, or are a part of a dense culture, where cells frequently make contact. MSC cultures are highly proliferative and migratory and they can form dense colonies where cells frequently touch and move over the top of each other. Therefore, in most instances an image acquisition interval of 5–20 min is most suitable for accurately tracking individual cells in an MSC culture. At the other end of the temporal scale, an image acquisition frequency of 60 min or more would be useful for tracking cells that are not motile and do not divide rapidly. Alternatively, if studying the migration of a population of MSCs, such as in a wound healing assay where the time to wound closure is measured, a temporal resolution of 1–2 h can be sufficient [35]. Acquisition of fluorescent images at high temporal frequency can result in phototoxic effects, and therefore exposure to excitation light should be minimized. This can be achieved by reducing exposure times or setting fluorescent image acquisition to the lowest possible temporal resolution that still captures the process of interest. Image acquisition frequency determines the number of sites that can be imaged for each time lapse. If images are acquired every 15 min, then the maximum number of sites is determined by how quickly the microscope travels to and acquires images at each site. The speed of image acquisition is also dependent on the use of software or hardware autofocus and the number of image modality channels.

The duration of an experiment in some cases can be difficult to define without analysis of pilot experiments. When recapitulating a standard *in vitro* assay (for example, a colony-forming assay or differentiation assay) the duration of the assay is well known. However, it is not possible to estimate generation times or differentiation dynamics directly from bulk culture experiments or clonogenic assays [20]. A trial time-lapse imaging experiment will provide an indication of phototoxicity, division times, and photobleaching effects before large-scale experiments are planned.

### 24.2.3 Image processing

Image restoration and enhancement methods are required to improve the accuracy of cellular tracking and fluorescent quantification. Uneven illumination, though not obvious to the human eye, will add spatial bias to fluorescent measurements. An image restoration algorithm is required to return the image to even illumination so that cellular fluorescent measurements do not

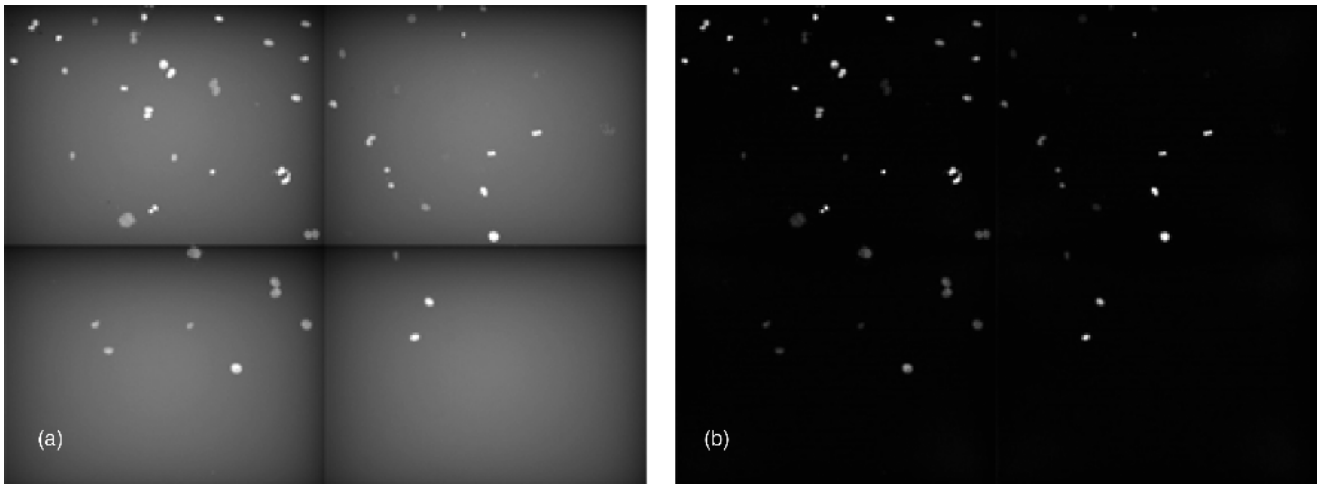

**Figure 24.3** Fluorescent images showing nuclear expression of platelet-derived growth factor receptor alpha (PDGFR-α) in cardiac MSCs before and after image processing. Four FOVs are stitched together to form one larger FOV for cell tracking. (A) Fluorescent image shows raw images after stitching and (B) the final result after correction of uneven illumination and contrast. (350 ms exposure time.)

depend on their position in the microscopic FOV. Another image restoration method that is commonly applied for wide-field imaging using multiple contiguous FOVs is image stitching. The edges of overlapping images must be registered so that the composite image appears as one image. Image registration applied to consecutive images is sometimes required to eliminate sample jitter caused by backlash in translational stage movements.

Image enhancement methods aim to accurately segment cells from their background. The toolbox of image enhancement methods includes algorithms to enhance image contrast and segmentation methods such as image thresholding, morphological operations (opening and closing), and edge detection. Figure 24.3A shows an unprocessed fluorescent image of four adjacent fields of view stitched together. Four fields of view were stitched together so that cells could be tracked in a large FOV. The fluorescent images are of a population of cardiac MSCs expressing a nuclear GFP reporter for PDGFR-α. Uneven illumination over the FOV results in a higher background reading at the center of the image. Figure 24.3B shows the same image after correction of uneven illumination, subtraction of background, and enhancement of contrast with custom-written scripts using the Matlab™ image processing toolbox.

Commercial packages such as MetaMorph (Molecular Devices), Imaris (Bitplane), PhotoShop (Adobe), and Amira (VSG) also meet these requirements and typically offer different algorithms so that image processing can be optimized. Alternatively, there are free and open-source image processing software packages available such as ImageJ and Fiji. Open-source software offers several advantages, including the addition of plug-ins developed and validated by the imaging research community. With open-source packages researchers are able to write their own plug-ins, suitable for optimization or specialized requirements. Engineering programming platforms such as Matlab can also be used to implement an image processing pipeline. Matlab has comprehensive functionality packaged into image processing and computer vision toolboxes.

Image segmentation is a commonly used image processing tool to measure morphological features such as cell size and shape. Automated cell tracking algorithms such as CellProfiler only work with segmented images. The complex morphological characteristics of MSCs should be considered when applying image segmentation algorithms to ensure individual cells are accurately segmented. MSCs can appear morphologically as small and spindle shaped, stellate, or large and flat. MSCs can also have many cellular projections, such as philopodia and lamellapodia. An example of image segmentation of MSCs using CellProfiler is shown in Figure 24.4. Figure 24.4A shows MSC image segmentation at low density and Figure 24.4B shows image segmentation of subconfluent MSCs after 5.75 days in culture, with cells color coded by their generation number.

### 24.2.4 Data storage

Live cell imaging experiments, particularly long-term imaging experiments, have the potential to generate a large volume of image data. For example, consider an experiment in which 300 positions were imaged with phase contrast every 10 min and with two fluorescent channels every 60 min for a total of 9 days. Assuming images were acquired as high-resolution TIFF files, each occupying 2.5MB, the volume of data generated would exceed 500GB. Without access to dedicated data storage architecture, long-term storage of large amounts of data can be challenging. At present, internal hard disk drives (HDDs) for desktop computers are available up to 2TB and so can only hold a few large experimental data sets. Researchers at universities and research institutions can have access to large servers to store and backup terabytes of data although such services do not always have network speeds suitable for fast data recovery. While data are being analyzed it should be accessible and retrievable at a

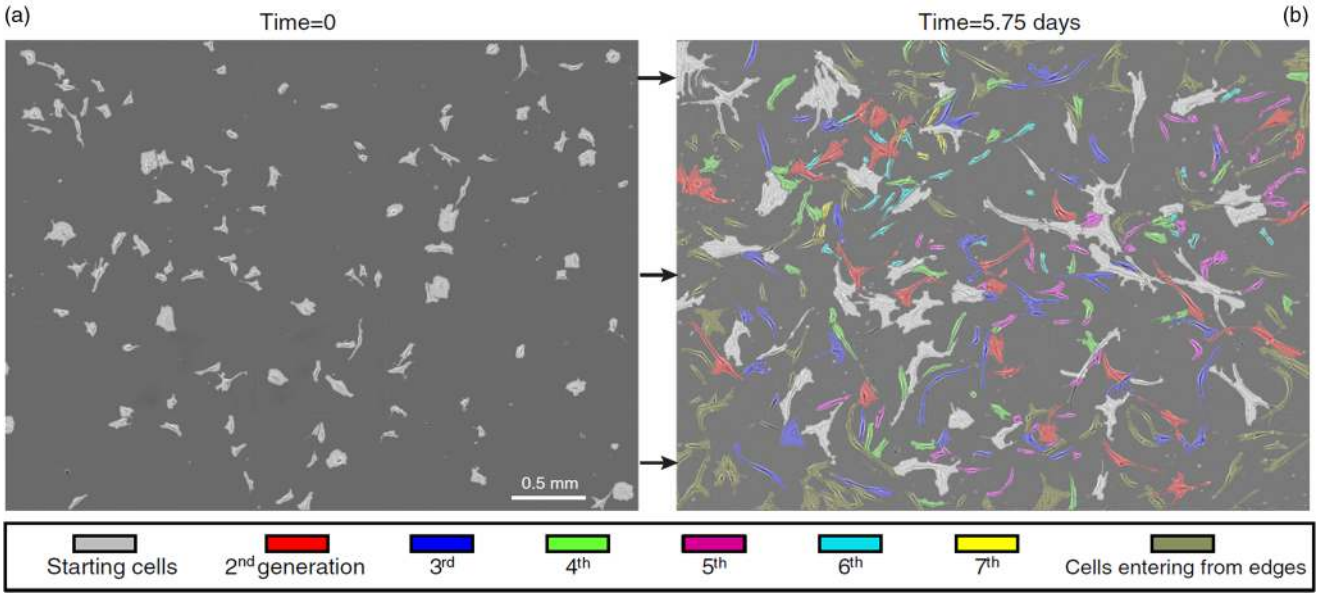

**Figure 24.4** Image segmentation of MSCs at the beginning and end of a single passage (p5). Phase-contrast image of entire FOV at (A) the beginning and (B) the end (5.75 days) of the experiment with cells false colored to represent their generation as indicated. All cells at time zero were classified as starting cells that produce two second-generation daughter cells upon division. reasonable speed. In the absence of large institutional servers, by far the simplest and cheapest option is to store data on external HDDs. Current external HDDs have a capacity to store 4TB, although external HDDs eventually fail, so a data backup system will be required. Therefore, it is recommended that researchers use a combination of technologies to maintain the fidelity of their data over the long term [36].

## 24.3 Single cell tracking and analysis

### 24.3.1 Cell tracking platforms

Time-lapse imaging experiments generate image stacks for individual FOVs over a period of hours, days, or weeks. A single cell tracking platform and an analysis pipeline are required to record the characteristics of each cell as seen in consecutive images within a time-lapse movie. The fate of each cell, be it division, death, or right censoring (lost or not observed), provides the genealogical information to construct single cell pedigrees (Figure 24.5). Pedigrees are annotated with multiple single cell measurements, such as morphological features, fate outcomes, and fluorescent intensity. An early application for single cell tracking was to prove the existence of specific cell fate transitions such as the existence of hemogenic endothelium *in vitro* [17]. Single cell pedigree information also yields important dynamic and genealogical data, which is complementary to bulk culture and clonogenic observations.

Presently, researchers use a combination of propriety software, open-source software, or custom-written algorithms for cell tracking and pedigree analysis. The most significant analysis bottleneck is cell tracking. A massive effort is underway to develop universal solutions that will improve upon "point-and-click" tracking. The following section reviews a range of cell tracking platforms and discusses their specific advantages and disadvantages.

Commercially available cell tracking software has been developed by companies such as Cellomics, Evotec, and Molecular Devices. These platforms were developed for high-throughput screening of cellular responses to pharmacological and toxicological agents. The systems were designed for detecting only relatively specific cellular responses, and not continuous cell trajectory tracking. Protein translocation, microvesicle formation, neurite growth, cell count, and viability have been screened with such systems [37]. More flexible and cost-effective tracking platforms have been implemented in a number of different image analysis packages, such as MetaMorph, ImagePro, ImageJ, and Fiji (Box 24.1). Such platforms offer automation and are suitable for researchers with basic requirements, including cell identification, cell trajectory measurements, and track creation. For example, MetaMorph's TrackObject has been used to study the migration of MSCs on polydimethylsiloxane (PDMS) substrates with 350 nm grating topographies. In this study, MSCs cultured on PDMS with such nanotopographies had faster and more directed migration [38]. The change in migration rate was related to a downregulation in zyxin protein that resulted in more dynamic and smaller focal adhesions. Zyxin may function as a messenger in the signal transduction pathway that mediates adhesion-stimulated changes in gene expression and may modulate the cytoskeletal organization of actin bundles. The ImageJ plug-in MTrackJ was used to study the effect of co-culture with dendritic cells on MSC motility [39]. Co-culture reduced both

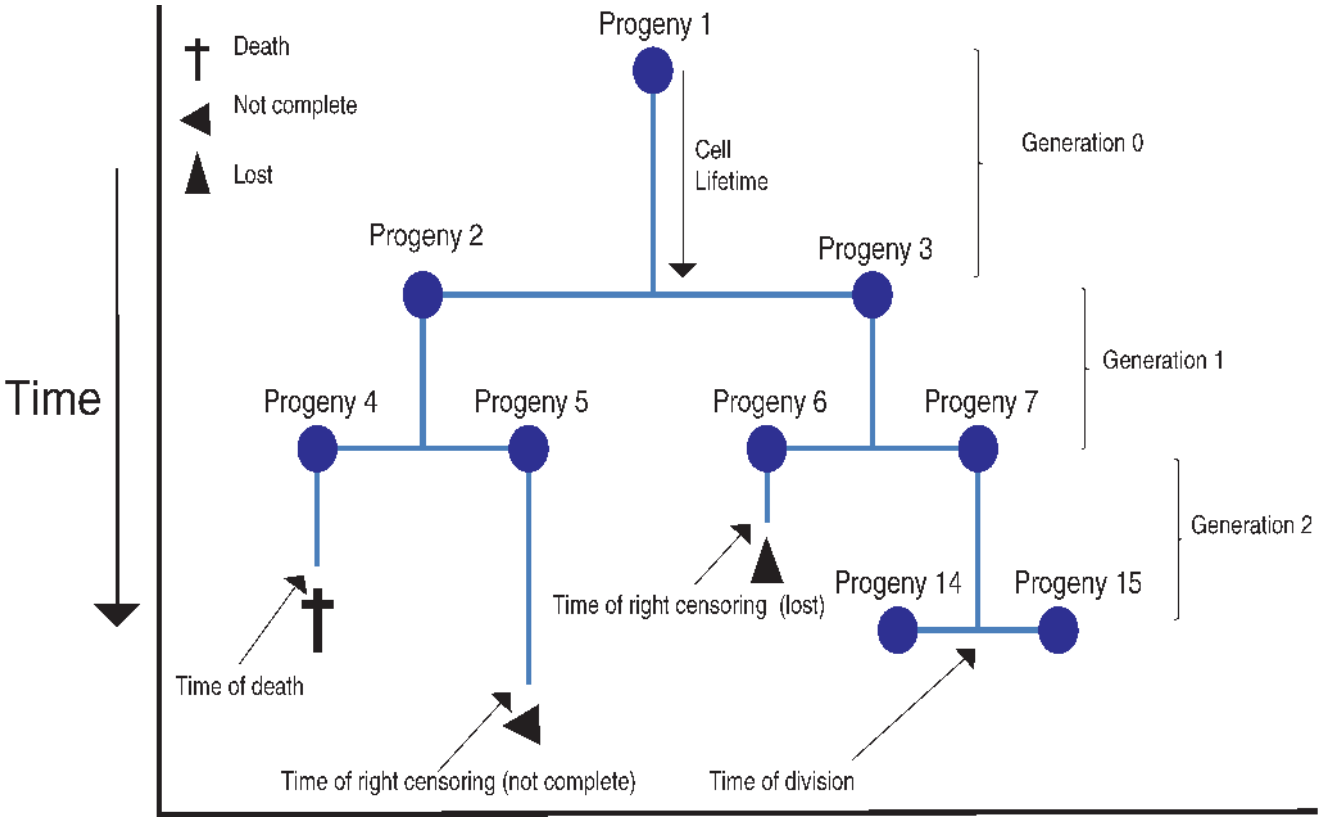

**Figure 24.5** An example of single cell pedigree annotation. Times of cell fate outcomes (death, division, lost, not complete) are recorded for all tracked cells. Cells within a pedigree are referred to as progeny and are numbered according to their position within the pedigree. Any single cell measurement, such as size or reporter expression, can be annotated.

dendritic cell and MSC motility, an effect that was strengthened by the addition of TNF-α and reversed by the anti-inflammatory factor resveratrol. Disadvantages of these platforms are that they do not necessarily include tools for quantifying reporter signals, annotating fate outcomes and morphological features, or extracting kinship relationships.

Establishment of kinship relationships is uniquely achievable by single cell tracking and is an important feature of pedigree data. Kinship relationships can only be established by following every cell continuously from birth until division and annotating mothers and their progeny (Figure 24.5). However, this functionality could be added to open-source cell tracking platforms through modification to existing code. Alternatively, there are academic cell tracking platforms that include both basic and advanced cell tracking features. Examples with proven utility include Timm's Tracking Tool (TTT) [20], developed by the Stromal Cell Dynamics group at the Swiss Federal Institute of Technology; TrackAssist, developed between Australia's National Information and Communications Technology Association and researchers at the Walter and Eliza Hall Institute [21]; Nordon's Tracking Tool (NTT), developed at the Graduate School of Biomedical Engineering, University of New South Wales (R.M. Hallett *et al.*, University of New South Wales,

unpublished results); and CellProfiler, developed at The Whitehead Institute for Biomedical Research and The Massachusetts Institute of Technology (Box 24.1).

Cell tracking platforms are classified as automated or manual tracking platforms. CellProfiler is an example of an open-source automated image analysis and cell tracking platform implemented in Matlab and Python [40]. Initially, it was developed as a tool for biologists to identify and quantify cell phenotypes [40,41]. Automated cell tracking platforms such as CellProfiler require image segmentation to define cells as objects in each frame and algorithms to identify each object's trajectory in consecutive frames in order to build tracks. Once tracks are built for a particular object then measurements related to that object can be annotated to its track. Automated cell tracking platforms have the capacity to dramatically increase throughput, although their utility is often restricted. This is because image segmentation and tracking algorithms are not suitable for cell cultures that are highly proliferative or confluent, since individual cells are difficult to recognize even by eye. In addition, tracking algorithms reliant on accurate segmentation rely on images that are easily segmented (e.g., fluorescently labeled nuclei and phase-contrast images of round cells). Thus, automated tracking is not suitable for all cell types and can produce errors that require manual correction, a process that is as time consuming as manually tracking cells [6]. Automated tracking software packages have implemented algorithms to detect events of interest, such as cell division, death, and differentiation [42,43]. On the other hand, manual cell tracking platforms, such as TTT and NTT, require analysts to identify the cell in each frame and annotate its fate outcomes manually while tracking. This requires continuous observation from the user and thus is more labor intensive than automated cell tracking platforms. Importantly, manual tracking allows for errors to be corrected in real time. NTT is a custom-written cell tracking platform implemented in Matlab. It was developed as a flexible tracking platform for tracking cells from a range of different cellular systems in either transmitted light or fluorescent microscopy images (see Section 24.4.2.5. for a more detailed description of NTT).

Basic features, such as cell identification labels, positional information, morphological parameters, and reporter signals, are recorded by most cell tracking platforms. The default cell tracking parameters provided by CellProfiler are shown in Table 24.1. The default cell tracking results from NTT are provided in Table 24.2 for comparison. These platforms are both open source, so functionality can be added by any user with Matlab programming skills. Therefore, single cell tracking platforms such as these can be adapted to overlay any cellular measurement onto single cell pedigrees.

**Table 24.1** Cell features recorded by default by CellProfiler cell tracking platform.

| Measurement or feature | Description |
|---|---|
| TrajectoryX | Distance traveled in *X* direction between consecutive frames |
| TrajectoryY | Distance traveled in *Y* direction between consecutive frames |
| Label | A unique identifier for the tracked object. When objects merge or split new labels are created. |
| ParentImageNumber, ParentObjectNumber | The ImageNumber and ObjectNumber of the parent object in the prior frame. For a split, each child object will have the label of the object it split from. For a merge, the child will have the label of the closest parent. |
| DistanceTraveled | Euclidean distance traveled by the object from the previous frame to the current frame. |
| Displacement | Distance traveled by the object from its initial position in the first frame to the position in the current frame. |
| IntegratedDistance | Total distance traveled by the object between the first and last frame. |
| Linearity | A measure of how linear the object trajectory is during the object lifetime. Calculated from the ratio of the displacement and integrated distance. |
| LifeTime | The number of frames an object has been tracked through. Lifetime starts at 1 in the frame when an object appears, and is incremented with each frame that the object persists. |
| FinalAge | Similar to LifeTime but is only output at the final frame of the object's life (or the movie ends, whichever comes first). At this point, the final age of the object is output; no values are stored for earlier frames. Useful for generating histograms of object lifetimes. |

### 24.3.2 Recording live cell characteristics

Live cell imaging experiments utilizing transmitted light microscopy provide enough information to generate cell trajectories, though fluorescent reporter labeling of the nucleus will significantly shorten tracking times. Cell migration is quantified from cellular (*X*, *Y*, *T*) coordinates, which are used to calculate displacement, total distance, directionality, and instantaneous and average velocities under different conditions. Such analyses have been applied to studying how physiologically relevant direct current electric fields of the order of 10–200 mV/mm, such as those established at sites of bone fracture, are able to stimulate MSC-directed migration [15]. In addition, the position of MSCs relative to each other and their microenvironment can be recorded and related to their growth dynamics; for example, a cell's location with respect to the center or edge of a colony, or whether a cell's duration of contact with neighboring cells alters cell fate [12]. The shape of the cell at each time point can be measured to provide morphological parameters such as area, length, eccentricity, and nuclear to cytoplasm ratio. Importantly,

**Table 24.2** Cell features recorded by default by NTT cell tracking platform.

| Measurement or feature | Description |
|---|---|
| Clone ID | A unique identifier for each clone. Starts at 1 and when a new clone is tracked. |
| Progeny ID | A unique identifier for cells within a clone. Founding cell starts at 1 and cells are numbered depending on their position within the pedigree structure. |
| TrackNumber | A unique identifier that corresponds to the order in which cells are tracked. Starts at 1 for the first track. |
| X and Y coordinates | The *X* and *Y* pixel coordinates for the position of the cell. 0, 0 is the top left corner. |
| Timestamp | A time vector containing the timestamps from the consecutive images in which cells are tracked. |
| BirthTime | A date vector containing the time the track started. For example, birth or left censoring. |
| DeathTime | A date vector containing the time the cell track finished. For example, death, division, lost cell, experiment finished. |
| LifeTime | A date vector containing the time elapsed between the BirthTime and DeathTime. |
| StopReason | A code for the reason a cell track was stopped:<br>0 – Fate not observed before final frame<br>1 – Division<br>2 – Death<br>3 – Lost cell<br>The time the track is stopped corresponds to the DeathTime. |
| CellMask | A matrix containing indices for each pixel in the tracking ellipse. Tracking ellipse is an adjustable ellipse placed over the nucleus of the cell for tracking. |
| Endomitosis | A binary variable and timestamp indicating if a cell has endoreduplicated and the time it occurred. 0 is default and 1 indicates endomitosis. |
| Reporter signal quantification (Max, Mean, Interpolated) | A vector with measurements from fluorescent channels. For example, for fluorescent reporters. |

the change in shape of a cell can be monitored over time and observed in response to external stimuli such as pharmacological and toxicological agents or to perturbations of signaling pathways [44]. While such observations are insightful, fundamental information, such as the age of a cell when it dies or divides, allows one to characterize and model cellular proliferation and cell fate choices at a level of detail that well exceeds standard methods, such as flow cytometry and clonogenic assays.

MSC division is easily identified from transmitted light images as MSCs become semi-adherent at the beginning of mitosis. Cells then split into two semi-adherent cells and completely separate at the end of cytokinesis before re-adhering as two separate cells. MSC death is identified when cells stop moving before membrane degradation. One is unable to distinguish apoptosis (programmed cell death) from necrosis without fluorescent markers identifying apoptosis (e.g., conjugated fluorescent monoclonal antibodies to Annexin V).

Morphological and behavioral characteristics of MSCs can also be related to their fate outcomes to identify how proliferation and differentiation generates heterogeneity [12]. Figure 24.6A shows a single cell pedigree where both twins divide in the first generation, yet in the second generation there are unequal generation times and cell age at division appears to correlate with cell area. Further quantification of extrinsic factors (cell–cell contact) and intrinsic factors (cell division history and cell area) showed that extrinsic and not intrinsic factors influenced division heterogeneity (Figure 24.6B and C). Furthermore, β-galactosidase staining revealed that the majority of large cells were senescent (Figure 24.6D).

Another feature that can be extracted from time-lapse imaging and cell tracking experiments is the inherited relationships between MSCs derived in culture. A single cell pedigree depicts the kinship relationships between members of the same clone, namely siblings, mothers and daughters, cousins, and so on. Therefore, kinship relationships can be used to study how MSC growth dynamics varies between nonrelated and related cells and how cell traits are transmitted through successive generations [45]. Such analyses have been used to study how latent heritable factors can influence cell growth dynamics as well as studying MSC heterogeneity [46,47]. There is a wealth of information that can be obtained from recording the dynamics of MSC migration, morphology, kinship relationships, and life history. However, cell fate biomarkers are required to dissect the molecular control of cell fate.

### 24.3.3 Vital biomarkers for mesenchymal stromal cells

Morphological and behavioral properties of MSCs are easily recorded using conventional phase-contrast, bright-field, or DIC microscopy in conjunction with appropriate cell tracking and image analysis software. To supplement this information and to answer more specific questions, vital biomarkers are required to relate molecular processes to cell development. Vital biomarkers can include fluorescent stains that mark specific cellular compartments or functional processes, genetic labeling with fluorescent protein probes, as well as novel fluorescent particles such as QDs [48] or nanoparticles (NPs) [13].

Differential labeling by vital stains provides additional information to help distinguish distinct cell types within a heterogeneous population (i.e., stem cells, progenitor cells, or differentiated cells) [13]. Importantly, labeling information can be overlaid on to single cell pedigrees, allowing one to correlate gene expression, cell ultrastructure, or metabolic processes with cell age, cell fates, or phenotype (e.g., morphology or

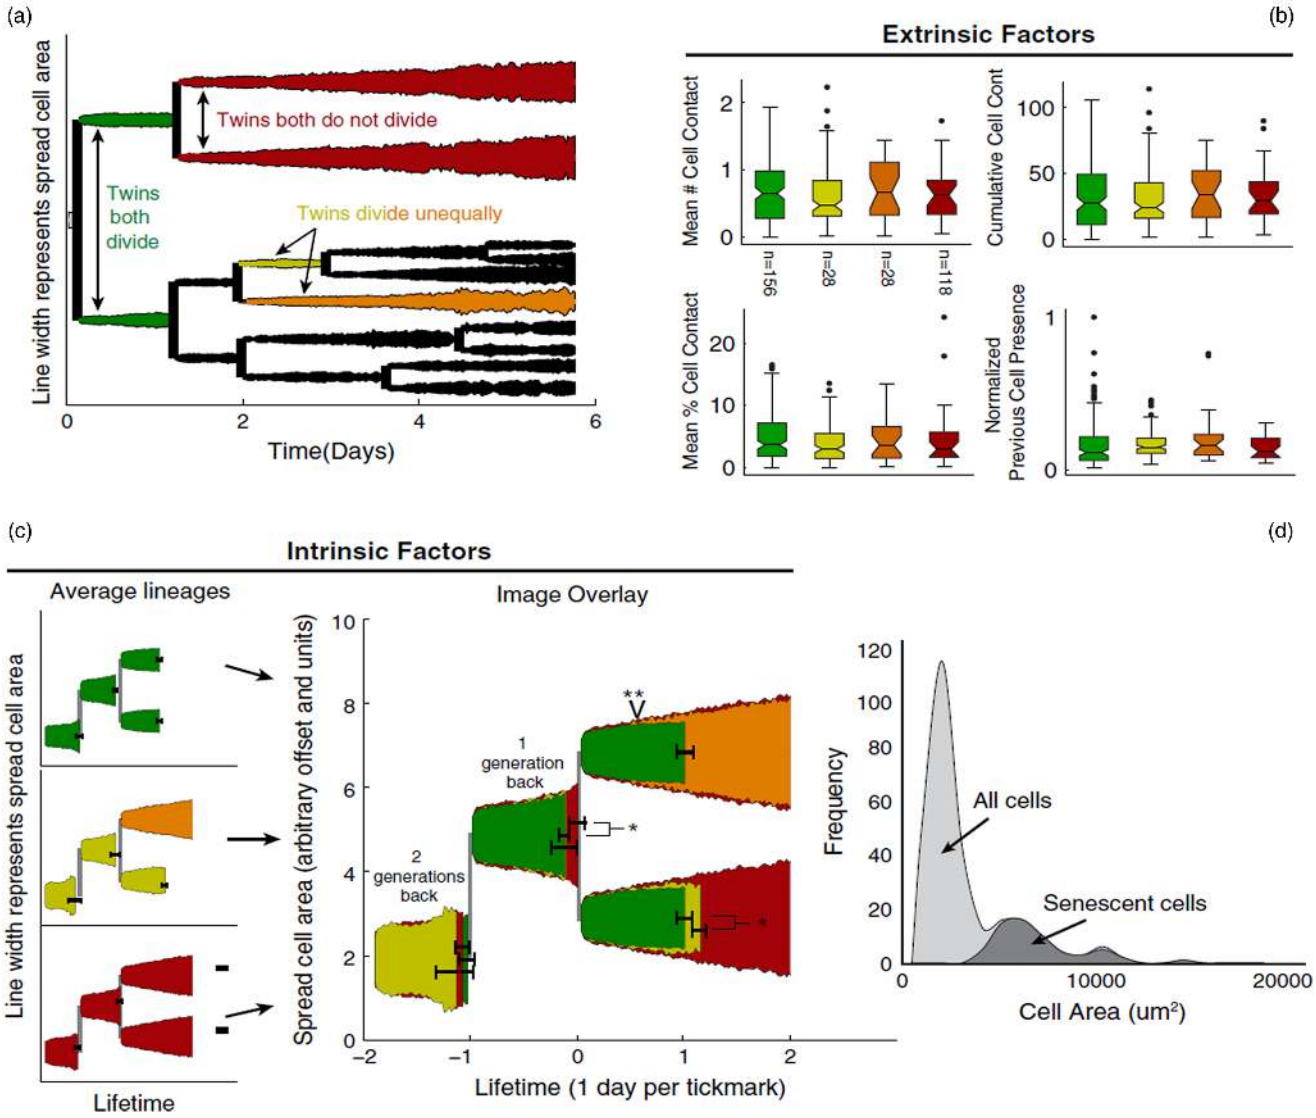

**Figure 24.6** Potential sources of size heterogeneity among MSCs. (A) A cell pedigree with heterogeneous divisions. Pedigree contains siblings that both divide, one divides and one does not, or both do not divide. (B) Extrinsic factors that could potentially influence time to cell division. Contact was defined as another cell within 12.9 μm proximity. No significant differences were observed for extrinsic factors. (C) The average lineage history of the cells (intrinsic factors) for each of the three groups overlaid and individually (inset). Line width represents spread cell area; 95% confidence intervals for lifetime are represented by error bars. ∗ denotes significance at the $p < 0.05$ level; ∗∗ marks the time that the cell area for dividing and nondividing cells becomes significantly different ($p < 0.05$). (D) Histogram showing distribution of cell sizes, including those stained positive for the cell senescence marker β-galactosidase after 7 days' culture. *Source:* [12] Whitfield *et al.*, 2013, pp. 1365–1377. Reproduced with permission of Elsevier.

motility). Thus, fluorescent labeling is crucial to gaining a molecular understanding of cellular dynamics.

The most commonly applied methods for labeling MSCs are fluorescent dyes and genetically encoded fluorescent proteins. When selecting a fluorescent label the spectral properties of the fluorophore must first be considered. These properties include emission and excitation wavelength, extinction coefficient, quantum efficiency, brightness, and photobleaching. Excitation wavelength is the wavelength of a photon that is required to excite the fluorophore. When a fluorophore is excited by an incident photon it will emit a photon with a longer wavelength than the photon it had absorbed. The wavelengths of the incident and emitted photons are referred to as the excitation and emission wavelengths respectively. Light sources, filters, and cameras capable of producing and detecting light at the excitation and emission wavelengths are necessary. Brightness is another important property of any fluorophore being used in a labeling strategy. Brightness of a fluorophore is determined by its extinction coefficient, its quantum efficiency, and its susceptibility to photobleaching [49]. The extinction coefficient is a measure of

how much of the excitation light is absorbed in relation to the concentration of the fluorophore in solution; that is, it is the efficiency of a fluorophore at absorbing photons at the excitation wavelength. Quantum efficiency is a ratio of the number of photons emitted to the number of photons absorbed. Photobleaching refers to a fluorophore that has been rendered into a nonfluorescent state due to the absorption of photons.

In addition to the properties of the fluorophore itself one must consider that detection of the fluorophore is dependent on the signal-to-noise ratio. The signal-to-noise ratio is not only dependent on the fluorophore's brightness but also on the level of background noise and autofluorescence from cells, medium, and tissue culture vessels. In order to improve signal-to-noise ratio one should attempt to reduce the degree of background noise and autofluorescence. This can be achieved by selecting appropriate medium; for example, a medium without phenol red and a tissue culture substrate that has low autofluorescence. Tissue culture vessels manufactured with a thin-film substrate are ideal since the reduced thickness significantly reduces background fluorescence. Multiwell plate designs with black walls are also suitable as they prevent internal reflections that introduce additional light into the FOV.

Cell tracking dyes such as carboxyfluorescein diacetate succinimidyl ester (CFDA-SE) can be used to track cell division because with physically symmetric divisions the fluorescence intensity halves with each successive mitosis [50]. When CFDA-SE-stained hematopoietic cells are initially sorted and then analyzed by flow cytometry, successive cell generations are identified on CFDA-SE histograms as peaks whose mode decreases geometrically by a factor of 2 [51]. Differentiation is tracked with respect to generation number using multicolor flow cytometry [52]. Cell division tracking dyes are diluted to an undetectable level after several rounds of cell division [53]. Proliferation, survival, and renewal can be calculated by counting the number of cells belonging to successive generations [50,54,55]. However, CFDA-SE division tracking has not been applied to MSCs because cell division is not always physically symmetrical.

Fluorescent labeling of cell nuclei greatly assists with MSC tracking because the nucleus of the cell is easily identified by threshold segmentation (Figure 24.3B). DNA-staining agents such as Hoechst 33342 and DAPI intercalate with DNA and are genotoxic. A better approach is to label nuclei genetically with a fluorescent protein.

There are also fluorochromes that quantify various aspects of cellular metabolism. For example, CFDA-SE and calcein acetoxymethyl ester become fluorescent upon hydrolysis by intracellular esterases [48]. Acetylated (Ac)-low-density lipoprotein (LDL) conjugated to a fluorophore can be used as a functional assay to identify ECs and macrophages [56].

The cloning of the GFP from *Aequorea victoria* revolutionized the field of live cell imaging by providing a palate of fluorescent proteins for reporting gene expression in transgenic mouse models and transduced or transfected primary cells and cell lines. Colored variants of GFP, such as red fluorescent protein (RFP), yellow fluorescent protein (YFP), and cyan fluorescent protein (CFP), can be detected independently with the potential to quantify several genes simultaneously. Fluorescent proteins that have been expressed in MSCs without any toxic or adverse effects on cell function include enhanced GFP (eGFP) [23], DsRED [57], enhanced CFP [58,59], YFP [58], Venus [60], and RFP [59].

A fundamental limitation of using fluorescent proteins for labeling cells is that an overlap in excitation and/or emission spectra is inevitable as more labels are introduced. Even though excitation and emission channels can be imaged in sequence, it may not be possible to compensate for spectral overlap. Spectral mixture analysis can deconvolve emission spectra using multiple images [30], though increased sample illumination, photobleaching, and phototoxicity is the trade-off.

Fluorescent proteins modified with amino acid sequences or fused to larger ligands can localize fluorescence to various subcellular sites. For example, a fluorescent protein fused to histone H2B will label the nucleus. The cytoskeleton is labeled using α-tubulin as a fusion partner. The inner leaf of cell membranes is labeled using a basic membrane localizing sequence isolated from the Ras oncoprotein [61]. Nuclear localizing sequences can be used to transport fluorescent proteins into the nucleus. The spatial distribution of these reporters is distinct, so spectral unmixing is not required [4].

QDs and NPs have specific advantages for labeling and tracking MSCs. QDs are NPs made from semiconductor nanocrystals. QDs are bright with a high extinction coefficient and similar quantum yield to fluorescent proteins and are photostable with less photobleaching than fluorescent proteins [62,63]. QDs have been shown to have no significant adverse effects on functional characteristics of MSCs, such as proliferation and differentiation capacity *in vitro* [63], though there have been issues regarding inconsistent retention within MSCs [64,65] and increased apoptosis due to toxicity at high concentrations [48,62]. QDs have even been used for labeling MSCs based upon specific integrin expression; for example, the immobilization of the peptide CGGGRGD on CdSe–ZnS QDs [63], as well as for identification of labeled MSCs in cardiomyocyte co-culture assays [64].

Fluorescent NPs are fabricated using organic matrices or polymers that can be formed into a variety of shapes, enabling intracellular measurements in living cells [66]. Nanoflares are an example of NPs that are used to visualize and quantify relative levels of mRNA transcripts within living cells. Nanoflares are comprised of spherical nucleic acids conjugated to gold nanoparticles. The gold nanoparticles are densely packed with oligonucleotide sequences that correspond to their mRNA target. The oligonucleotide sequences are hybridized to fluorophore labels that fluoresce when the oligonucleotide is exposed to its mRNA target. Multiplexed nanoflares have also been developed that allow

for the simultaneous detection of two distinct mRNA targets within a living cell [67].

Viable biomarkers are crucial tools for live cell imaging as they allow dynamic molecular processes to be visualized and measured. Single cell biomarker signal measurements can be overlaid onto single cell pedigrees to enable a cell's molecular or functional state to be related to its life history.

### 24.3.4 Mimicking *in vivo* microenvironments in vitro

A major drawback and a frequent criticism of studying stromal cells *in vitro* is that when they are removed from their *in vivo* niches their properties are immediately altered. Thus, cellular responses observed *in vitro*, particularly those related to differentiation potential, may be tissue culture artefacts that are not physiologically relevant [68–70]. However, the clinical potency of MSCs is currently defined in part by *in vitro* assays and immunophenotype. The International Society for Cell Therapy (ISCT) stipulates that a functional property of MSCs is the ability to adhere to tissue culture plastic and to proliferate long term *in vitro*.

While *in vitro* microenvironments do not simultaneously provide all physiological biomechanical and biochemical stimuli, their utility is related to a more precise analysis of the effect of specific stimuli. Various features of the *in vivo* niche can be recapitulated by engineering well-controlled artificial *in vitro* microenvironments [71].

The *in vivo* MSC niche is defined as the immediate microenvironment surrounding an MSC and has a nanometer to a micrometer length scale. Its microenvironment is comprised of biomechanical and biochemical cues that vary temporally and spatially to regulate cell survival, activation, self-renewal, and differentiation [71]. These cues include, but are not limited to, autocrine and paracrine growth factor stimulation, cell–cell contacts, and cell–matrix interactions (Figure 24.7).

Examples of bioengineered niches for MSCs include functionalized surfaces [72], modular biomaterials [73], three-dimensional scaffolds [74], and microfluidic devices that can generate physiologically relevant soluble and fixed gradients [75,76]. More sophisticated microfluidic systems have been designed to simulate the cardiac cycle by generating pulsatile shear flow [77]. Such *in vitro* microenvironments are suitable for dissecting the role of biomechanical and biochemical stimuli on MSC fate. For example, the effect of substrate stiffness on osteogenic differentiation of MSCs was studied by culturing cells in polyethylene glycol (PEG) hydrogel microwells with variable stiffness (shear moduli of 1–50 kPa) [78]. Using this system in conjunction with live cell imaging, an increase in substrate stiffness resulted in a significant increase in osteogenic differentiation. Substrate stiffness is well known to be a biomechanical stimulus that affects both MSC lineage specification and self-renewal ability [73,79,80].

In order to probe for effects of ECM interactions on stromal cell fate one is able to culture cells on substrates functionalized with micropatterned ECM proteins by microstamping [81] or robotic spotting [78]. Cell–cell interactions can also be mimicked *in vitro* by solid-phase immobilization of biomolecules such as cadherin. These solid-phase systems have been successfully employed to study the effect of N-cadherin and cell-adhesive fibronectin fragment 9–10 (FN9–10) on the adipogenic differentiation potential of MSCs (Figure 24.8). FN9–10 and

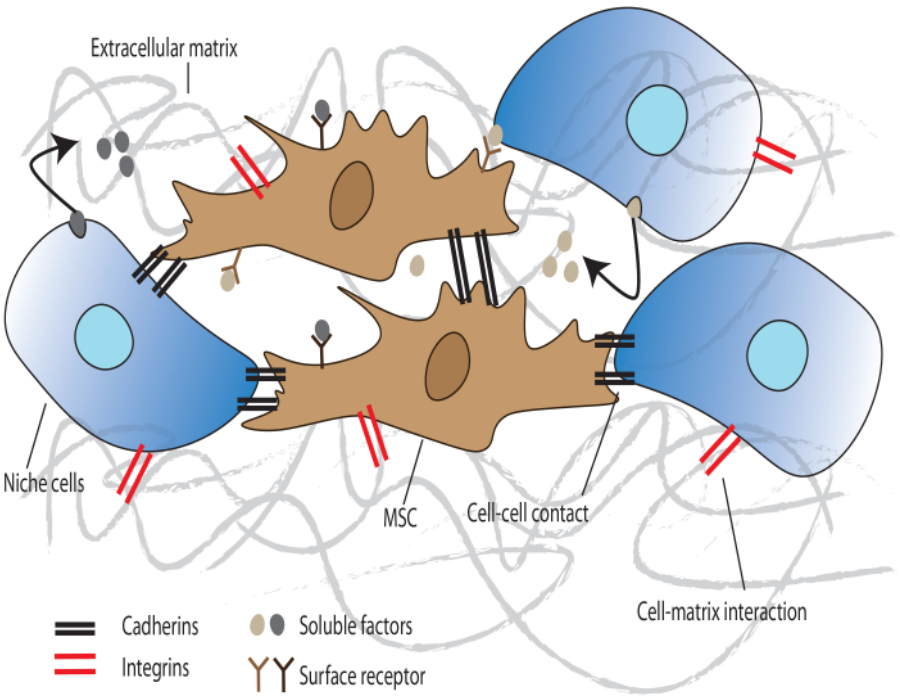

**Figure 24.7** Stylized cartoon of the *in vivo* MSC niche showing cell–cell interactions, cell–matrix interactions, soluble factor production, and stimulation of MSCs by supportive niche cells. The extracellular matrix (ECM) provides biochemical stimulation of MSCs through integrin interactions and tethered factors as well as mechanical stimulation of MSCs by its viscoelastic properties.

Error bars, standard error of the mean as computed after a multivariate analysis (generalized linear model) on $n = 5167$ (gain of function experiments) and $n = 5860$ (loss of function experiments) observations. $***p < 0.001$, $**p < 0.01$, and $*p < 0.05$; a.u.: arbitrary units. (See color plate section.) *Source:* [78] Gobaa 2011, pp. 949–957. Reproduced with permission of Nature Publishing Group.

N-cadherin were functionalized on microwells at different densities (Figure 24.8a and b). After 11 days in culture, actin network and intracellular lipid accumulation were visualized by phase contrast, fluorescently labeled phalloidin, and lipid staining with Nile red (Figure 24.8c). N-cadherin exposure significantly increased adipogenic differentiation and decreased the surface area of MSCs in a concentration-dependent manner (Figure 24.8d–g). Furthermore, a blocking antibody to N-cadherin significantly reduced adipogenic differentiation potential (Figure 24.8h and i). It is interesting to note that the average cell surface area was also significantly reduced with increasing N-cadherin concentration, revealing how cytoskeletal architecture is influenced by cell–cell interactions. In more elaborate systems, different protein solutions can be printed onto microwells for factorial analysis of the effect of these proteins on stromal cell fate outcomes. Such a system has been applied to studying neural stromal cell fate outcomes in the presence of the NOTCH ligands JAGGED and Delta like ligand 4 [78].

Mimicking of various signals that comprise the *in vivo* microenvironment of MSCs will provide researchers with greater power to understand their *in vivo* roles. The advantage of *in vitro* systems is that cell fate is more accurately quantified by live cell imaging. Indeed, if meaningful microenvironments

are created, then live cell imaging and single cell tracking experiments can provide more relevant insights into MSC biology [71].

## 24.4 Case study: tracking differentiation of endothelial cells from cardiac-derived mesenchymal stromal cells

### 24.4.1 Background and experimental aims

The aforementioned general principles of live cell imaging will now be applied to an analysis of MSC differentiation. Most of the art in this field relates to software analysis of time-lapse movies. Here, we present a detailed case study illustrating the tracking of cardiac-derived MSC-to-EC transition. ECs are cells that line the luminal surface of all blood vessels and are essential to the homeostasis and repair of organ compartments [82]. There is great interest in generating various EC populations, including progenitors for regenerative medicine applications; for example, in cardiovascular regeneration, as new tissue requires a blood supply and a vascular network to define its growth and architecture [83]. The limited expansion capacity and lack of autologous sources for ECs has hampered their use in therapy [84]. There is increasing interest in the potential of MSCs to be differentiated into ECs for clinical applications. Several important factors required to induce endothelial differentiation for MSCs have been identified. These factors include endothelial growth supplements, shear force, and ECM components. Several reports detail EC marker expression and maturation derived from adipose-tissue-derived MSCs [85,86] or bone-marrow-derived-MSCs [83,87–89].

Cardiac colony-forming units–fibroblast (cCFU-Fs) are a multipotent, cardiac-resident MSC-like population. cCFU-Fs are hypothesized to be involved in tissue remodeling of the heart during homeostasis and in response to injury, for example, in response to myocardial infarction. Relevant to their hypothesized role in cardiac tissue remodeling, cCFU-Fs have the potential to differentiate into an EC phenotype *in vitro* when stimulated with vascular endothelial growth factor (VEGF) for 12–14 days [23]. Uptake of fluorescently labeled Ac-LDL, a functional assay for the identification of ECs, was used to track endothelial differentiation of cCFU-Fs. After differentiation, cells were exposed to 10 μg/mL of fluorescently labeled Ac-LDL for 24 h, with 60–80% of cells showing significant accumulation of Ac-LDL [23].

Ac-LDL is a major carrier of cholesterol in the blood, and uptake of LDL occurs in a number of cell types, including macrophages and ECs [90]. Ac-LDL uptake occurs through LDL-receptor-mediated endocytosis during which LDL is internalized and degraded [91]. The Ac-LDL uptake assay has been widely used as a functional assay for the identification of ECs [90]. From a live cell imaging perspective, Ac-LDL is a useful vital biomarker that can be used to identify phenotype transitions, such as from hemogeneic endothelium to a hematopoietic phenotype [17].

Immunocytochemical staining and flow cytometry analyses are also routinely used to identify cells that express markers of the endothelial lineage, such as von Willebrand factor and VE-cadherin [23]. These assays quantify efficiency of differentiation by simply providing counts of marker-positive cells before and after differentiation [92]. The potency of an MSC population can be easily established by this method. However, these methods do not provide insight into the dynamics of lineage commitment. In fact, such assays only reveal that a proportion of the initial cell population has survived and differentiated into ECs.

The time course of immunocytochemical, fluorescence-activated cell sorting (FACS), and gene expression analyses will reveal differentiation dynamics of MSC populations. However, lineage commitment occurs at the single cell level, so it is more appropriate to study differentiation by continuously tracking single cells. For example, one can evaluate instructive versus permissive hypotheses for lineage development in the MSC system. The instructive hypothesis implies that cCFU-Fs will be directed to change their phenotype in response to endothelial growth conditions, whereas the permissive hypothesis states that these conditions promote survival and selection of MSCs that are EC progenitor cells. Furthermore, continuous observations of single cells allow one to determine how cCFU-F lineage commitment can influence the probability of other cell fate outcomes, such as division and death.

This case study will demonstrate the application of live cell imaging and single cell tracking to MSC differentiation. Endothelial differentiation was tracked using uptake of Ac-LDL. We addressed the following:

1 Tracking of cCFU-Fs in serum-free medium (SFM) or with endothelial growth medium (EGM).
2 Recording the dynamics of fluoroscein isothiocyanate (FITC)–Ac-LDL uptake to identify phenotype transitions.
3 Analysis of the following fate outcomes:
   **(a)** phenotype transition
   **(b)** division
   **(c)** death.

### 24.4.2 Methods

#### 24.4.2.1 Cardiac colony-forming unit isolation and culture

cCFUs were isolated from 8- to 12-week old wild-type C57BL/6 mice. Mice were sacrificed by cervical dislocation, hearts removed, and the interstitial cell fraction isolated by mechanical and enzymatic digestion with collagenase type II (Worthington) at 37 °C for a total of 30 min. Every 10 min the sample was triturated mechanically with a transfer pipette to ensure complete digestion. Supernatant was collected and filtered through a 40 μm strainer (to remove cardiomyocyte debris) into 1% fetal calf serum to stop digestion. Red blood cells were lysed with a red cell lysis buffer followed by dead cell removal using MACS Dead Cell Removal Kit (Milteny Biotec). Cells were then incubated for 30 min at 4 °C with

fluorophore-conjugated antibodies against stem cell antigen (Sca-1), platelet-derived growth factor receptor-α (PDGFR-α), and platelet EC adhesion molecule (PECAM, CD31). Using either FACS Aria or FACS Canto (Becton, Dickinson) cytometers, cCFU-Fs were enriched as Sca-1$^+$/PDGFR-α$^+$/PECAM$^-$. Cells were collected in a 15 mL Falcon tube with 2 mL serum-free medium containing 2 ng/mL of basic fibroblast growth factor (bFGF) and 1 ng/mL of transforming growth factor receptor-β1. After isolation, the enriched fraction of cCFU-Fs was centrifuged at 300*g* for 5 min, the supernatant removed, cells resuspended in 200 μL and then counted manually using a hemocytometer. Twenty-four hours after initial isolation the medium was removed and cells were washed twice with phosphate-buffered saline to remove nonadherent cells. For *in vitro* expansion, cells were plated at 150 cells/cm$^2$ in 10 cm petri dishes (BD Falcon) and cultured in SFM for 12 days with medium changes every 3–4 days. All tissue culture vessels were coated with attachment factor (Invitrogen) for a minimum of 0.5 h at 37 °C before plating cells. Attachment factors are structural proteins or protein-like substances that have adherent capabilities and increase cell–substrate interactions in a culture-dependent attachment milieu. A number of glycoproteins have been identified that promote and/or influence *in vitro* cell attachment to the surface or substratum of the culture vessel, and these include gelatin, ECM, fibronectin, and collagen type-1.

#### 24.4.2.2 Endothelial differentiation and fluorescein isothiocyanate–acetylated low-density lipoprotein uptake

For EC differentiation, cCFU-Fs expanded in SFM to passage 4 were used. cCFU-F cultures were plated at 250 cells/cm$^2$ in 24-well special-optics live cell imaging plates (Ibidi, Germany) in either SFM or EGM. EGM consisted of 1% fetal calf serum (Gibco, Australia) in Iscove's modified Dulbecco's medium (IMDM) (Invitrogen, Australia) containing 10 ng/mL bFGF (R&D, USA) and 10 ng/mL VEGF (R&D, USA). To induce differentiation into an endothelial phenotype, cells were cultured for 12 days. Medium was replaced every 3–4 days. In order to visualize cCFU-F to endothelial transitions in real time, 10 ng/mL FITC-conjugated Ac-LDL (Invitrogen) was added directly to both control (Dulbecco's modified Eagle medium (DMEM)) and differentiation conditions at 10 ng/mL. Fresh Ac-LDL was added each time medium was replaced.

#### 24.4.2.3 Live cell imaging

Once cells had attached, the plate was placed on a Leica inverted live cell imaging microscope (DMI6000B, Leica, Australia) equipped with a fully-automated *X*–*Y*–*Z* controller and hardware autofocus control. The microscope was housed in a large closed-chamber incubator box (PeCon, Germany). The sample environment was maintained at 37 °C using a heating unit and temperature controller (PeCon, Germany). A $CO_2$ controller (PeCon, Germany) was used to deliver a 5% $CO_2$ and air mixture through a small-volume cover placed over the live cell imaging plate. Default functions contained within the MetaMorph Premiere Software package (MM, MolecularDevices, USA) were used to define image acquisition parameters and control the microscope. Nine positions in the center of each well (forming a 3 × 3 contiguous grid with an overlap of 0.5 μm) of the 24-well plate were selected for imaging. Two wells for each condition were imaged. Phase-contrast images at 20× were acquired every 20 min with an exposure time of 1 ms. Phase-contrast images were acquired for cell tracking and to visualize morphological changes of cCFU-F cultures from a mesenchymal (spindle shaped) to an endothelial morphology (cobblestone appearance). To minimize phototoxicity and photobleaching effects, Ac-LDL fluorescent images were acquired every 2 h with a 750 ms exposure time. An acquisition frequency of 2 h was sufficient to capture Ac-LDL accumulation within individual cells yet did not cause phototoxicity. Every 3–4 days dishes were removed from the microscope and the medium was changed, including addition of FITC–Ac-LDL. Medium changes were performed in less than 20 min (less than the acquisition frequency). When returning the imaging plate back to the microscope stage, the last acquired imaged was used as a reference to ensure that the same FOVs were imaged.

#### 24.4.2.4 Data storage and image processing

All images were saved as .TIF files (1392 × 1040 resolution, 2.5 MB file size) on the local disk of the same computer running MetaMorph and controlling the microscope. At the end of the experiment, copies of all raw images were transferred to an external hard disk (4 TB, Western Digital) for long-term storage. Custom-written scripts implemented in Matlab were used for stitching contiguous FOVs, background removal, flattening of uneven illumination, and contrast enhancement. Flattening of uneven illumination in fluorescent images was most important as the FITC–Ac-LDL intensity was quantified by measuring pixel intensities after background subtraction.

#### 24.4.2.5 Cell tracking

All cell tracking was performed using NTT implemented on a graphics workstation equipped with a graphical processing unit (HPZ420, 16 GB RAM, Intel® Xeon® CPU E5-1607 @ 3.00 GHz). NTT reduces the labor of cell tracking using a template-matching algorithm that recognizes the cell in the current frame using past images of the cell as a learning set. The program automatically tracks the cell's position, but will revert to manual tracking if the cell image recognized by the algorithm is outside statistical confidence limits. It is best to track a cellular structure that is invariant during tracking, such as the cell nucleus. The graphical interface consists of a software controller and movie viewer (Figures 24.9 and 24.10). Cells were tracked in phase-contrast images by placing an ROI over the cell nucleus and double-clicking. The ROI is an adjustable ellipse (default 35-pixel diameter) used to record the position of the nucleus as well as all pixels contained within. The pattern of pixels recorded within the ROI

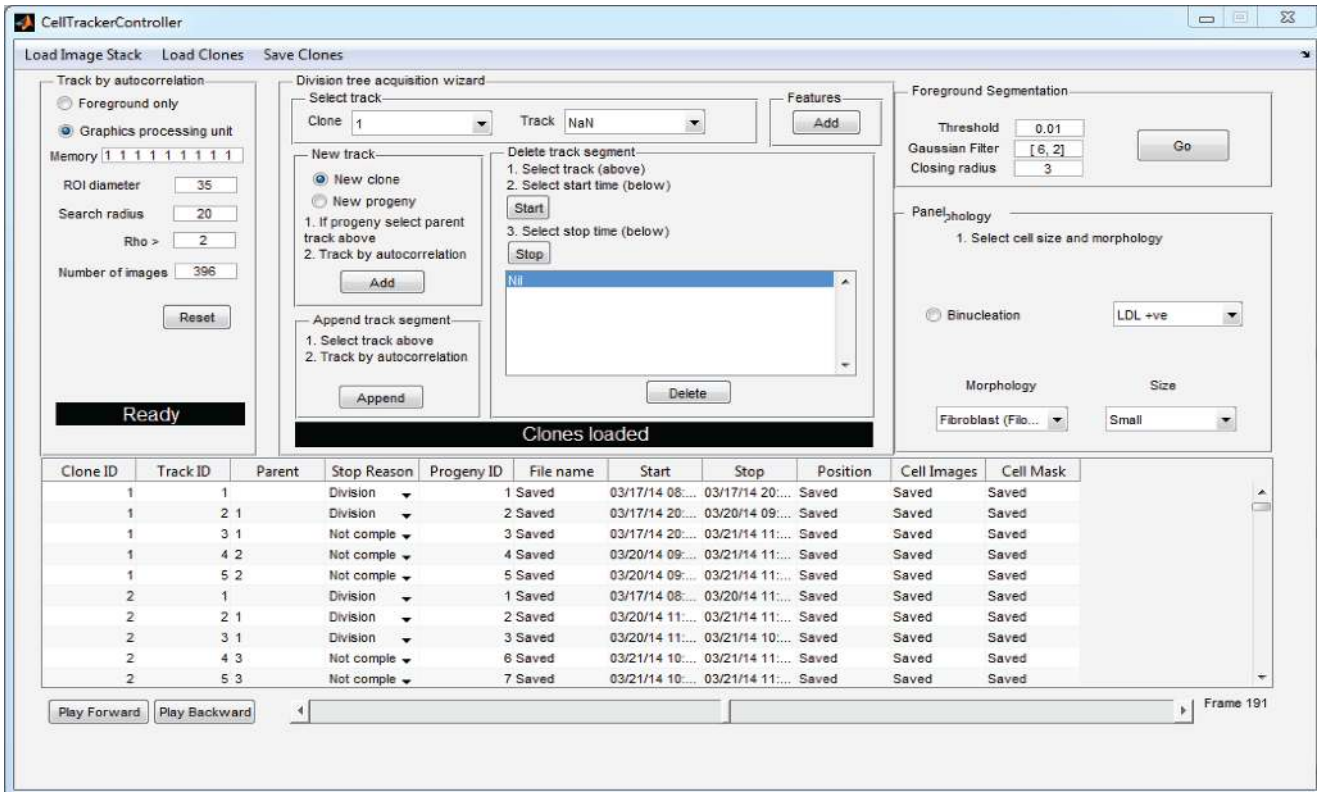

**Figure 24.9** Screenshot of NTT graphical user interface (GUI). The GUI allows control of cell tracking parameters such as region-of-interest (ROI) diameter, search radius, and correlation coefficient Rho. The GUI contains features for deleting and appending track segments as well as entering fate outcomes in a drop-down menu.

for each frame was referred to as a cell mask. To find the same cell in the subsequent frame, NTT searched all pixels within a user-defined search radius in the subsequent frame. A cross-correlation algorithm was then used to find the position of the cell mask within the search region that gave the highest correlated pixel intensity pattern. The search radius is the maximum radial distance in which to search for a cell mask in each frame. The default value of the search radius is 20 pixels, though this could be adjusted depending on cell velocity, density of the culture, and proximity to the edge of the FOV. Increasing and decreasing the search radius also respectively increased or decreased the time taken to find a cell mask in the subsequent frame. The correlation coefficient (Rho) was a commonly adjusted parameter in the cell tracking platform. Rho, a number between 0 and 1, defined the correlation between pixel patterns in consecutive frames that was required to find a match. If a correlation above the set threshold was found for two cell masks within consecutive frames the software automatically moved to the next frame and repeated. If correlation between pixel patterns in consecutive frames was below the threshold the software stopped and prompted the user to manually reposition the ROI over the cell nucleus. Rho was increased or decreased to optimize the accuracy and speed of tracking. If Rho was increased, the criteria for finding matching cells in consecutive frames was more stringent and, therefore, allowed for more accurate tracking. This is suitable for situations where cells are cultured at high density and do not have unique or distinctive features. If Rho was set >1, NTT operated in a manual tracking mode, where the user was required to reposition the ROI and double-click on each frame. If Rho was decreased, then the criteria for finding matching cells in consecutive frames was less stringent and cell tracking speed was increased. This was suitable when tracking cells at lower density and where cells had distinct features that did not change transiently.

This semiautomated method of tracking was almost error free, since all cell tracks were continuously observed as they were built and all cell event outcomes were visually identified and annotated. Division and death events were detected visually and recorded in a single cell pedigree structure along with the time of the observed event. If an error was encountered while tracking, the user stopped the software and deleted erroneous segments of a cell's track. The user entered all relevant and measureable data into a hierarchical database structure or single cell pedigree using a drop-down menu. $X$ and $Y$ positions of the center of the ROI (i.e., the center of a nucleus) were recorded for each frame, along with the time the image was acquired.

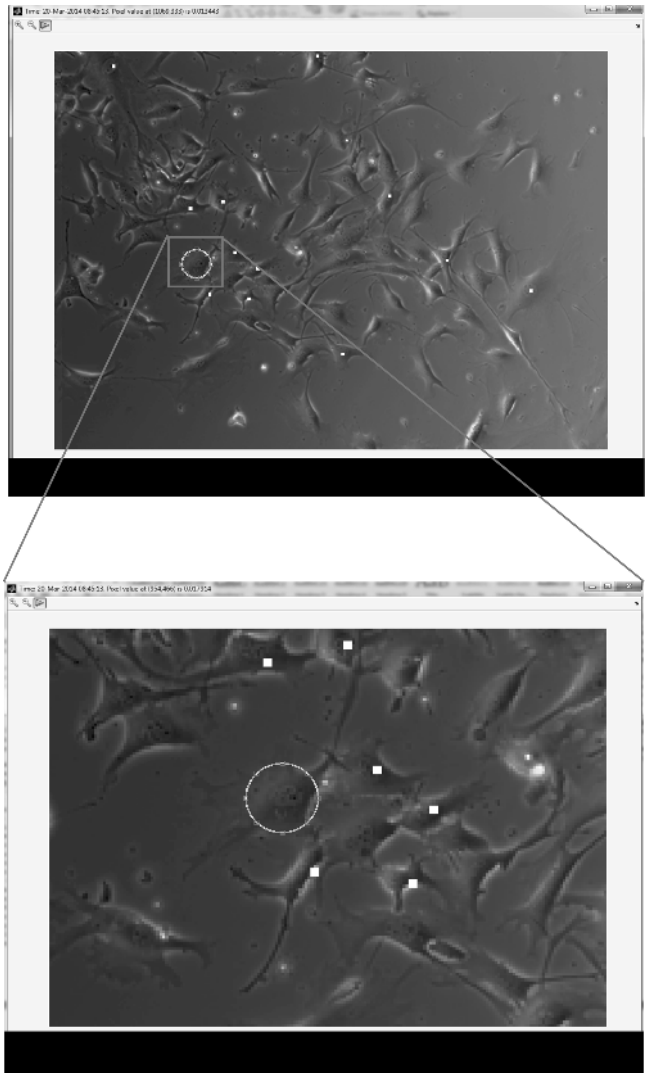

**Figure 24.10** Screenshots of NTT CellMovieViewer showing full FOV (top) and magnified region (bottom). The CellMovieViewer allows cells to be visualized while tracking. An adjustable ellipse is placed over the nucleus of the cell of interest as it is tracked through consecutive frames. White dots indicate tracked cells.

#### 24.4.2.6 Measuring fluoroscein isothiocyanate–acetylated low-density lipoprotein intensity

FITC–Ac-LDL intensity was measured for every cell at each time point using an extension of NTT developed for measuring reporter signals after cell tracking. Cell tracking produced a cell mask for every tracked cell in each frame. This mask contained pixel indices that formed a reference for the position of the cell's nucleus within each FOV. These pixel indices were used to determine the intensity of accumulated FITC–Ac-LDL by measuring the pixel intensities within the FITC channel. The cell mask provided a mapping reference to the cell nucleus. However, the FITC–Ac-LDL was accumulated in the perinuclear region and cytosol. Therefore, the cell mask was enlarged to record pixel intensities within a region surrounding the nucleus in the FITC channel. All measurements were manually validated after tracking by ensuring that the ROI was placed correctly over the cell nucleus at each time point. Once pixel intensities had been measured, the maximum and mean pixel intensities were calculated. The mean pixel intensity measurement was used for downstream analysis because intracellular staining was heterogeneous.

### 24.4.3 Results and discussion

#### 24.4.3.1 Defining cardiac colony-forming unit–fibroblast to endothelial cell fate transitions using acetylated low-density lipoprotein

Ac-LDL is known to be nonspecifically endocytosed by several cell types, including vascular smooth muscle cells, although at a slower rate than by ECs [90]. ECs can then only be identified by increased uptake of Ac-LDL compared with cell types in which endocytosis of the protein is nonspecific [90]. Therefore, to distinguish cells that had increased uptake (endothelial phenotype) from those that had nonspecific uptake (non-endothelial phenotype), a threshold of FITC–Ac-LDL intensity was established. The mean intensity of FITC–Ac-LDL accumulated within undifferentiated control cells, not exposed to differentiation conditions, was used for setting the threshold intensity. This threshold level of FITC–Ac-LDL was subtracted from FITC–Ac-LDL measurements for cCFUs exposed to EGM. Cells that had a mean FITC–Ac-LDL signal above the background level after thresholding were considered to have adopted an endothelial-like phenotype. Notably, the degree of FITC–Ac-LDL uptake in cells exposed to differentiation medium was higher than that observed for native murine aortic ECs.

However, there were differences in background fluorescence between control (DMEM) and EGM (IMDM) media because basal media were fluorescent, although at much lower levels compared with FITC–Ac-LDL. DMEM was observed to have a higher autofluorescence than IMDM, presumably due to a higher concentration of phenol red. Therefore, the mean FITC–Ac-LDL measurements were normalized to the intensity values at the beginning of the experiment for control and experimental groups.

Figure 24.11 shows the normalized mean Ac-LDL intensity measurements for control and differentiation conditions averaged over all cells. Clearly, the FITC–Ac-LDL signal in cells cultured in control conditions remained constant for the duration of the experiment. In contrast, in the first 4 days after exposure to EGM the mean FITC–Ac-LDL significantly increased to a peak level 6–10 times greater than that observed in control cells. This peak signal plateaued for some time before declining in intensity toward the end of the experiment. The reduction in mean intensity can be partly attributed to photobleaching of FITC–Ac-LDL. The time at which cells reached maximum uptake of Ac-LDL corresponded to the time at which cCFU-Fs changed from a spindle shaped to a cobblestone morphology (Figure 24.12, white arrows).

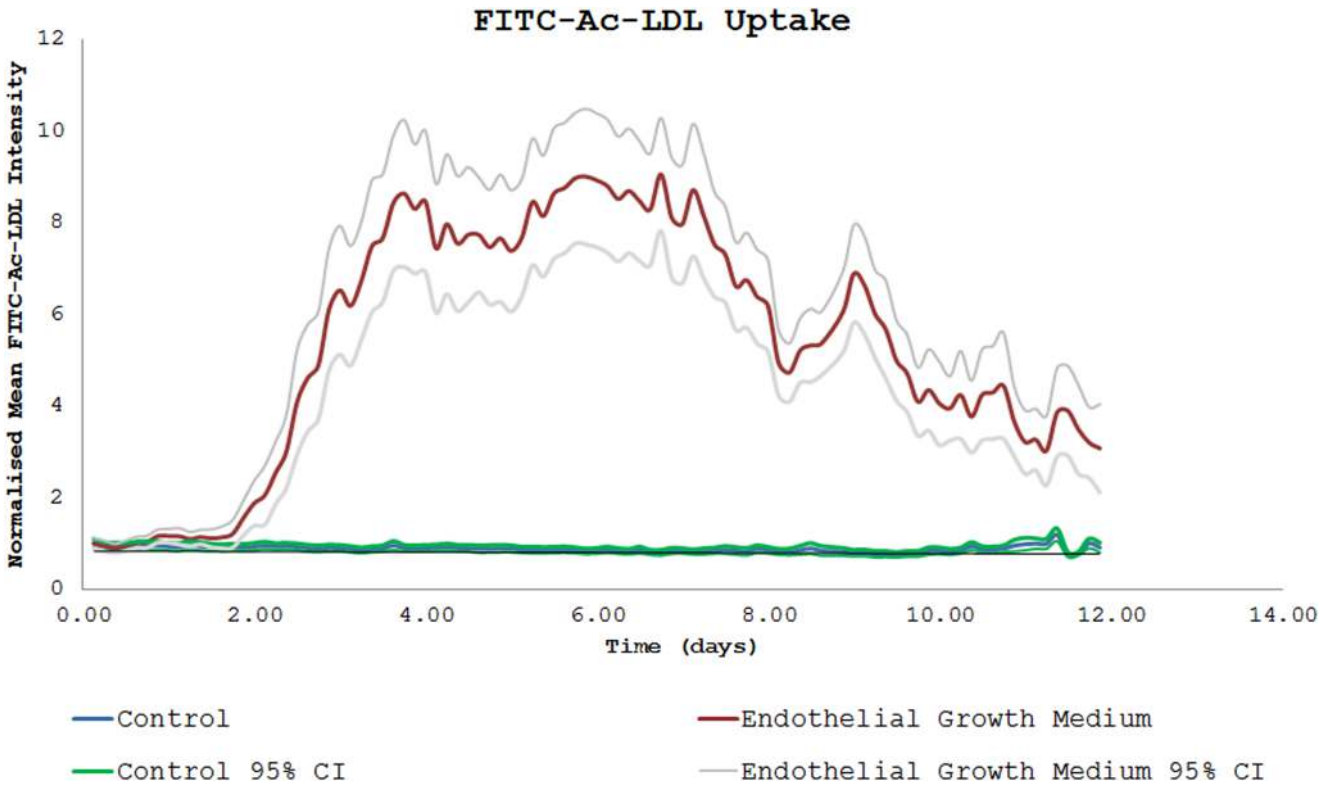

**Figure 24.11** Mean intensity of accumulated FITC-Ac-LDL (normalized to start of experiment) for cardiac CFU-F in control media and endothelial differentiation medium over 12 days in culture. Significant differences in mean intensity between control media and endothelial differentiation medium were observed. Bold black line and grey lines either side of bold black line, indicating peaking and plateauing of intensity of FITC-Ac-LDL accumulation at day 4 of culture, represent mean and 95% CI for cells grown in endothelial growth medium. The dashed line and the dotted lines either side of the dashed line running along the bottom of the figure represent mean and 95% CI for cells grown in control media.

#### 24.4.3.2 Quantifying cardiac colony-forming unit–fibroblast fate during endothelial differentiation

To analyze the effect of endothelial growth conditions on cCFU growth dynamics, the proportion of fate outcomes for Ac-LDL$^+$ and Ac-LDL$^-$ cells in both control and differentiation conditions were quantified (Figure 24.13). The fate outcomes recorded were division, death, lost, and incomplete. Incomplete fates occurred if the experiment ended before the final fate of the cell was observed. Lost cells and incomplete fates both resulted in right censoring; that is, no final fate was observed. In control conditions, all cells remained FITC–Ac-LDL$^-$ and therefore remained undifferentiated. In control cultures, approximately 38.7% divided, 9.9% died, 21.6% were lost, and 29.7% were incomplete. Figure 24.13b shows the quantification of fates for cells exposed to EGM. Approximately 53.5% of cells exposed to EGM became FITC–Ac-LDL$^+$, of which only 0.7% divided, 16.4% died, 5.7% were lost, and 30.7% were incomplete. In contrast, for the 46.5% of cells that remained FITC–Ac-LDL$^-$, 31.4% divided, 3.5% died, 10.7% were lost, and 0.7% were incomplete. Thus, distinct differences in the frequency of fate outcomes for control and differentiation cultures were observed. Furthermore, differential fate outcomes were observed for Ac-LDL$^+$ and Ac-LDL$^-$, suggesting that lineage commitment influenced the frequency of division and death. Interestingly, Ac-LDL$^+$ cells had a significantly lower frequency of division and a higher frequency of death compared with Ac-LDL$^-$ cells. It is important to note that in both control and differentiation conditions a significant number of cells were lost while tracking. Overlapping of cell trajectories was the main cause of lost cells, as it was impossible to distinguish one cell from another. This could be attributed to the high density of the culture, which was selected to achieve optimal conditions for endothelial differentiation.

As previously mentioned, analyses of cell fate outcomes revealed significant differences in the frequency of division and death for Ac-LDL$^-$ and Ac-LDL$^+$ cells. To further investigate these differences, survival analysis was employed to estimate rates of division and death in each group. Competing risks statistics, a type of survival analysis, were used to estimate cumulative incidence functions (CIFs) for division and death in each group [93]. The cumulative incidence of division can be defined as the probability that a cell has divided before a given time. To test for statistically significant differences between CIFs for each group, a *K*-sample test was applied. Figure 24.14 shows division and death CIFs for Ac-LDL$^-$ and Ac-LDL$^+$ cells. cCFUs that had become Ac-LDL$^+$ exhibited significantly reduced probability of division and a significantly increased probability of death compared with Ac-LDL$^-$ cells.

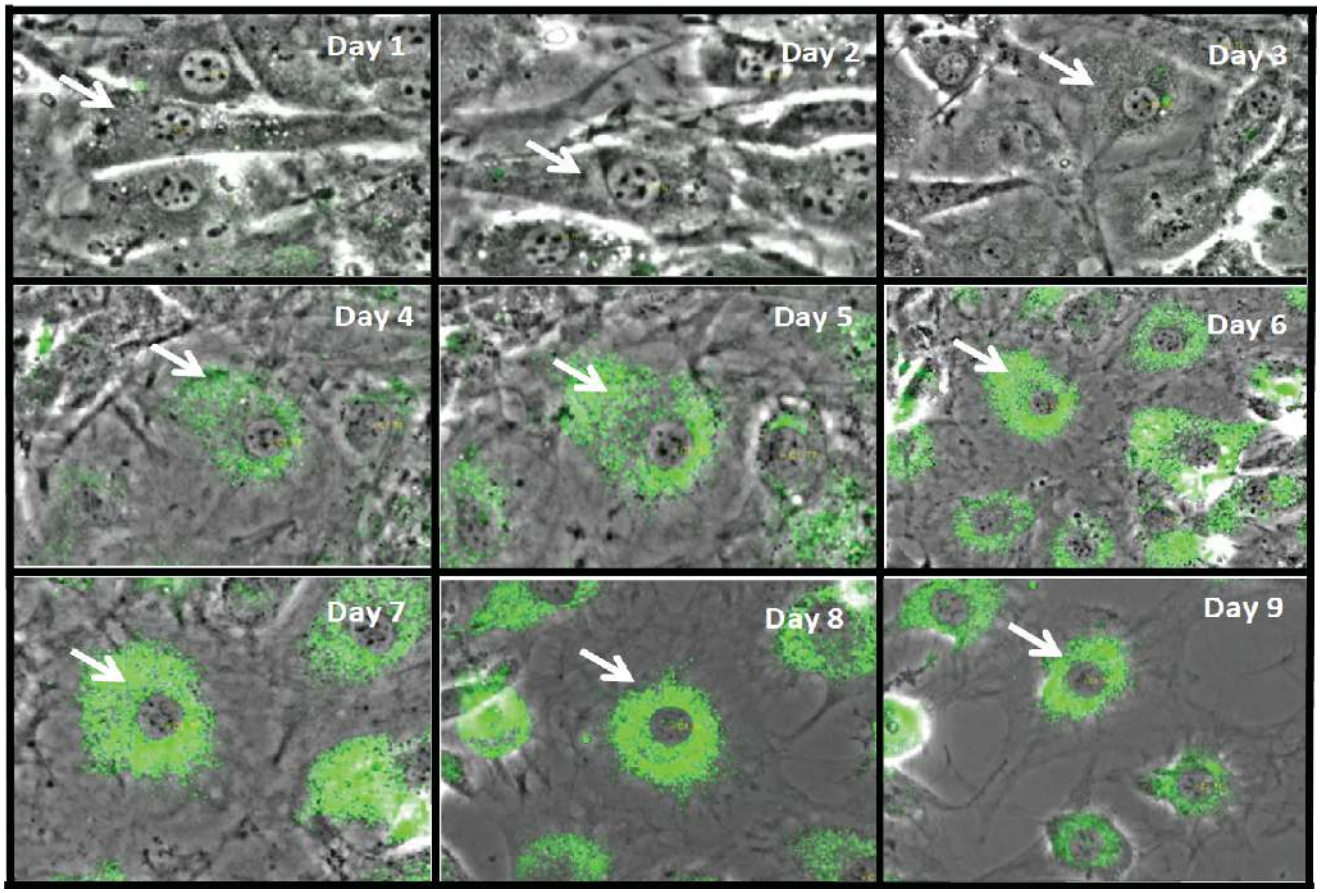

**Figure 24.12** Phase-contrast images (20×) showing transition of a cardiac CFU-F from an LDL$^-$ cell with a mesenchymal morphology to an LDL$^+$ cell with cobblestone morphology after treatment with EGM for 9 days (white arrows). Day 1 shows a typical cCFU-F with canonical MSC morphology (spindle shaped). After 4 days of exposure to EGM the cCFU-F changes to a round, flattened cell that begins to show signs of contact inhibition and intracellular accumulation of LDL. (See color plate section.)

### 24.4.4 Conclusion and future work

The dynamics of cCFU-F to EC fate transitions was studied at the single cell level by live cell imaging and single cell tracking. These experiments confirmed previous reports suggesting that cCFU-Fs differentiate into the EC lineage using fluorescently labeled Ac-LDL as a differentiation marker [23]. This example shows how endothelial fate is coupled to marked changes in cell cycle dynamics and death. A significant proportion of Ac-LDL$^-$ cells differentiated into Ac-LDL$^+$ cells without an increased rate of apoptosis of Ac-LDL$^-$ cells. Thus, VEGF directs differentiation rather than acting as a permissive survival factor that prevents apoptosis of cells not destined to become ECs (i.e., restricted endothelial progenitor cells). EGM also directs cell cycle arrest with an increased rate of cell death once cells become Ac-LDL$^+$.

Uptake of Ac-LDL alone is clearly not sufficient to prove that these are ECs. This would need to be confirmed by *in vitro* vascular network formation. While Ac-LDL uptake is an established assay for identification of ECs, additional markers such as PECAM (CD31) and VE-cadherin would need to be included to extend this study, though there are inconsistent reports on the expression of these mature EC markers by MSC-derived ECs [83,87–89]. Furthermore, we have not studied the autocrine effect of MSCs in this culture system. Future studies should examine the effect of seeding density on EC differentiation since MSCs themselves are probably secreting cytokines that modulate EC production. Future work should also include improvements to technical aspects of the study, such as continuous replacement of media and FITC–Ac-LDL to eliminate batch-to-batch variations in cell growth and Ac-LDL uptake measurements.

This study shows how MSC cultures can be directed to form ECs, which could provide a new strategy for revascularization therapy. A fascinating extension of this study would be to combine live cell imaging and single cell tracking with single cell gene expression analyses to study gene expression signatures associated with cCFU to EC transitions.

## 24.5 Future perspective on live cell imaging and single cell tracking

Current software packages for image acquisition, image management, cell tracking, and analysis and visualization tools fall

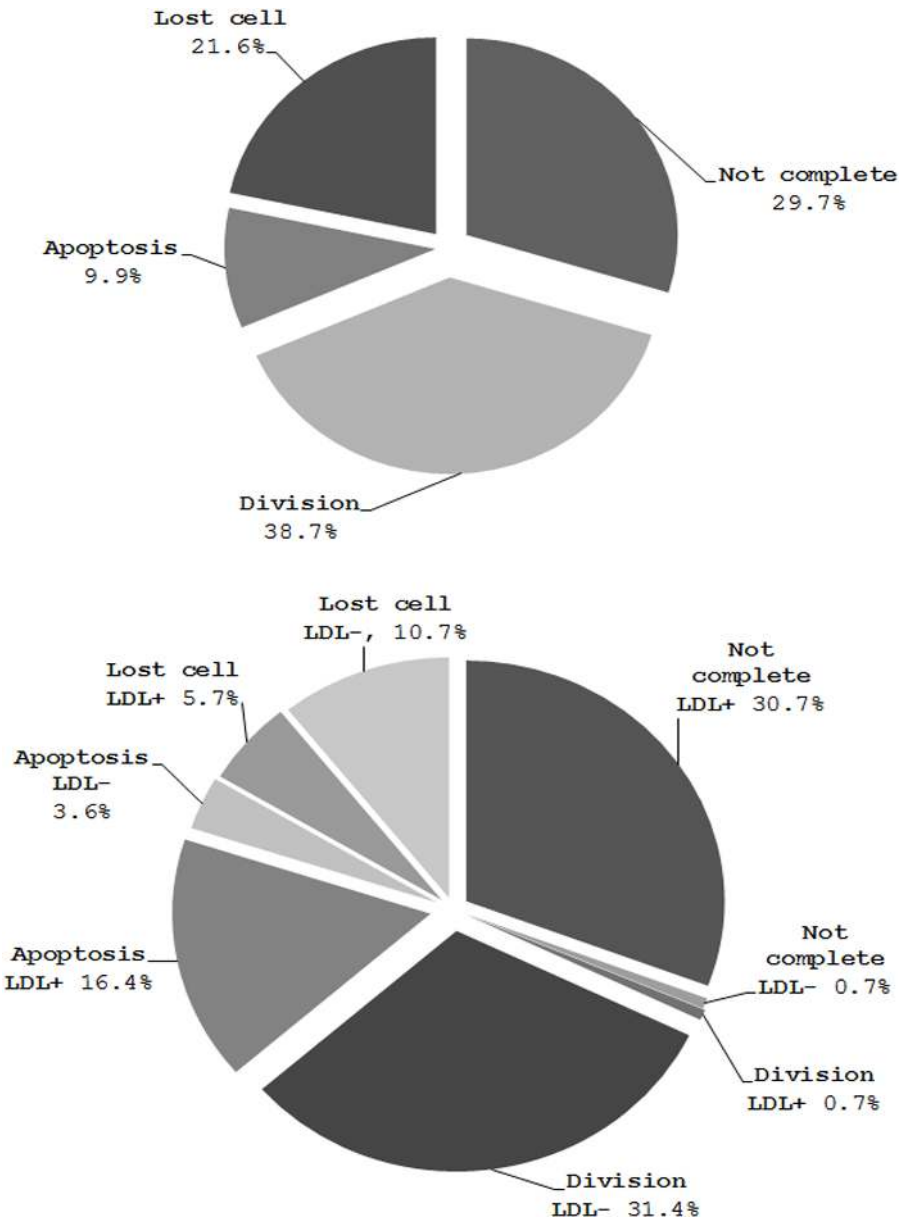

**Figure 24.13** Pie charts showing proportion of fate outcomes for cCFU-Fs cultured in control medium (a) and cCFU-Fs cultured in EGM (b). Significantly different proportions of fate outcomes were observed for control and differentiation conditions, as well as for $LDL^-$ and $LDL^+$ cells.

short of providing a user-friendly environment for most biologists to utilize live cell imaging and single cell tracking. Open-source software packages will enable software designers, statisticians, and biologists to interact and continually improve the analytical power of software. Increasing automation will remove the cell trajectory mapping bottleneck, reducing the time required to accurately track cells and annotate pedigrees. These platforms should aim to be user friendly, developer friendly, modular, validated to ensure accuracy and consistency of results, and compatible with different operating systems [94]. Appropriate and tractable statistical methodology is absolutely necessary for unbiased interpretation of cell lifetime analysis. Therefore, to maintain scientific rigor, appropriate statistical methodology should be enforced by peer review [95].

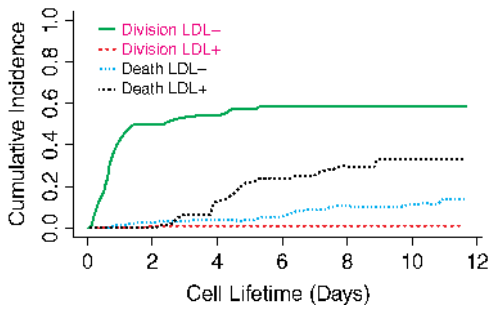

**Figure 24.14** Division and death cumulative incidence functions (CIFs) for $LDL^-$ and $LDL^+$ cells. Cumulative incidence of division was significantly higher for $LDL^-$ cells (top line) relative to $LDL^+$ cells (bottom line) ($p$ = 1:78E−15). Cumulative incidence of death was significantly lower for $LDL^-$ cells (second line from bottom) compared with $LDL^+$ cells (third line from bottom) ($p$ = 9:85E−04).

Application of live cell imaging and single cell analysis to the study of MSC biology will help address many of the methodological problems facing this research field. In contrast to phenotypically well-defined hierarchical differentiation systems such as hematopoiesis, MSC differentiation hierarchy and plasticity is poorly defined at the molecular level. Even though sets of markers to define the human MSC system have been adopted for verification of clinical MSC products [96], the lack of surface markers to identify different cell states within the MSC hierarchy is impeding progress. These should identify long-term self-renewing MSCs, transit amplifying or multipotent populations, and lineage-committed cell types.

Navigating the MSC lineage map by directing extrinsic and intrinsic signals will be made possible by discovery and development of surface markers or reporter fluorescent proteins that identify MSC fate transitions. These developments, when combined with the growing fields of single cell gene expression analysis and microfluidic technologies for single cell analysis, will usher in a new age of biological inquiry, where one is able to dissect the functional role of single molecules in single cells in real time.

## 25.1 Introduction

Blood vessels are indispensable as they deliver oxygen and essential nutrients to nearly every organ of the body. Therefore, it is not surprising that inadequate blood vessel growth and function contribute to a wide variety of diseases, such as myocardial infarction, stroke, chronic wounds, and neurodegeneration [1]. Over the past decades our understanding of the molecular mechanisms of angiogenesis (blood vessel formation) has increased exponentially and has resulted in a number of new therapeutic strategies. So far, however, these new approaches to improve blood vessel growth have had only limited success as they have mainly focused on gene therapy or the administration of recombinant proangiogenic proteins and small molecules [2]. New cell-based treatments, and especially mesenchymal stem/stromal cell (MSC) therapies, are currently being investigated as an option to enhance neovascularization. There is increasing interest in understanding and enhancing the angiogenic capability of MSCs. This chapter summarizes the current knowledge on the process of angiogenesis and provides an overview of the angiogenic actions of MSCs *in vitro* and *in vivo*. Additionally, we will discuss ongoing preclinical and clinical trials with MSCs in pathologies caused by limited blood vessel formation, such as stroke and myocardial infarction.

## 25.2 The current concept of angiogenesis

Blood vessels form extensive networks that supply oxygen and nutrients to every part of the body, dispose of waste metabolites, and allow the patrolling of immune cells. The importance of the blood vessel network is illustrated by its emergence in the early phases of the embryonic development. In vertebrates the circulatory system is the first functional organ to arise and is indispensable for nourishing the rapidly developing tissues. The vasculature is mainly formed through three cellular processes: vasculogenesis, angiogenesis, and arteriogenesis (Figure 25.1).

First, vasculogenesis occurs. This is the *de novo* formation of a basic vascular system from the mesoderm-derived endothelial

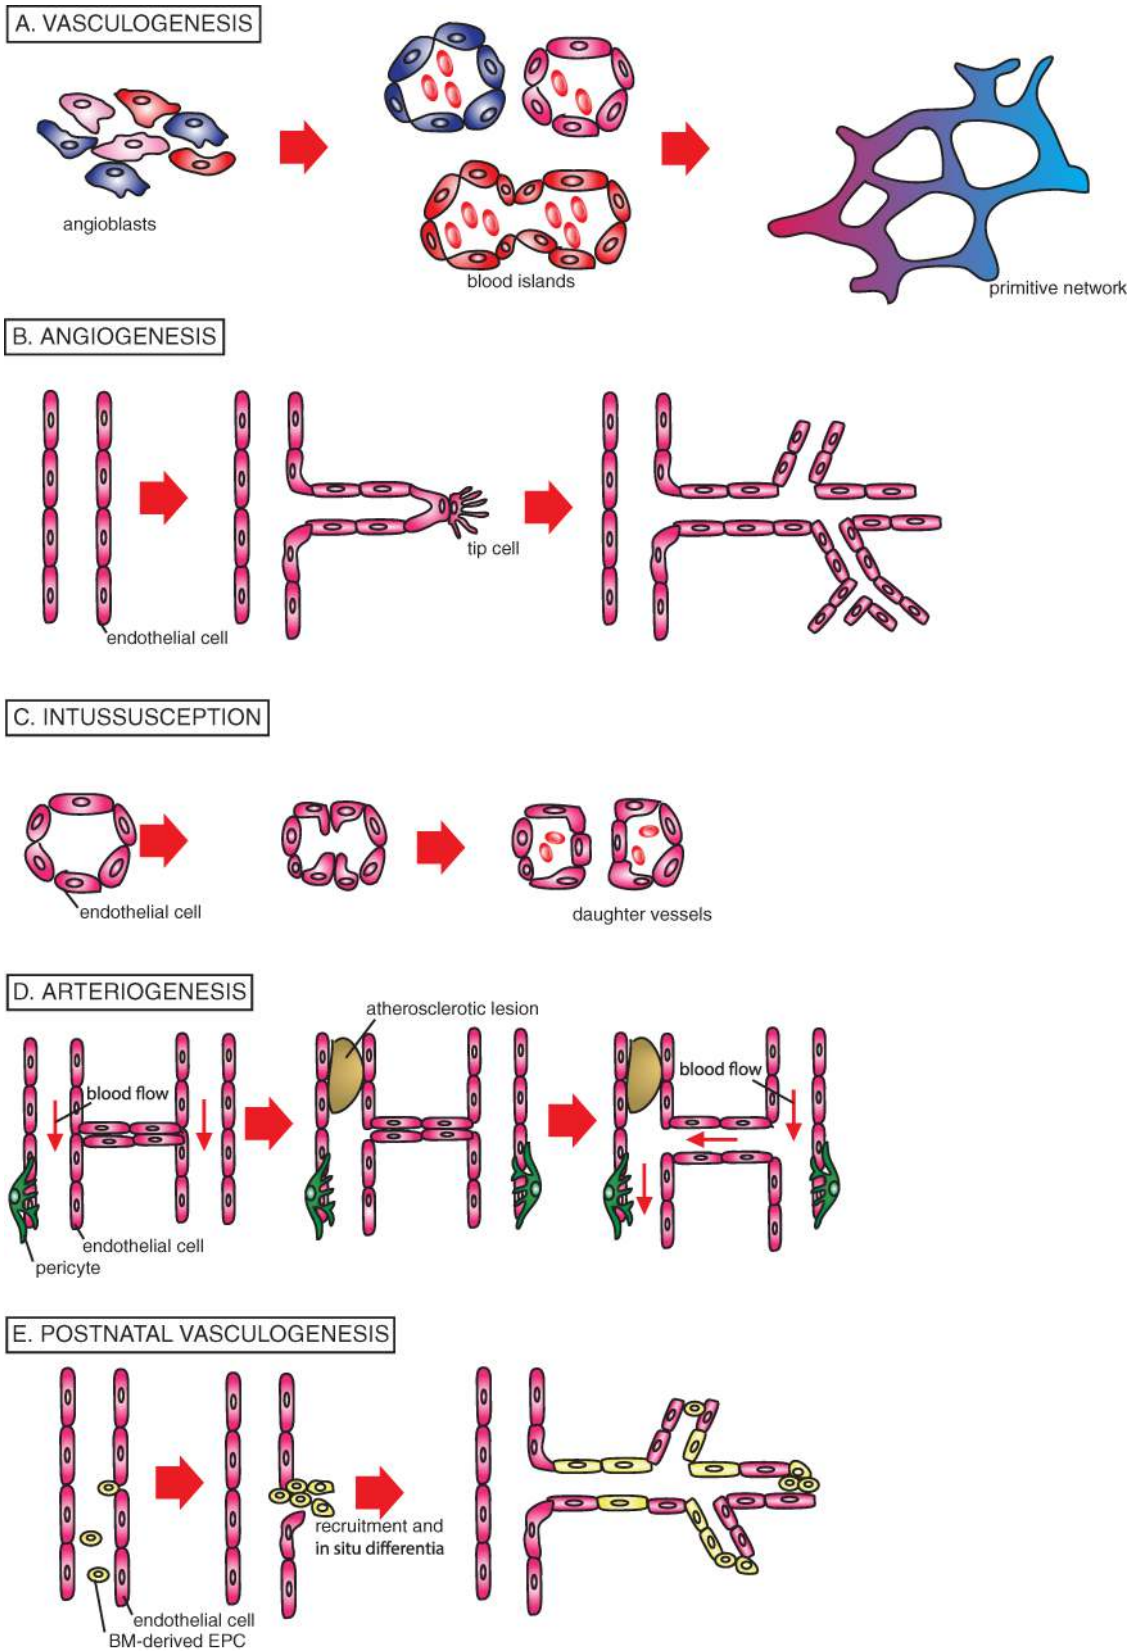

**Figure 25.1** Different types of blood vessel growth. (A) Vasculogenesis is defined as the growth of a primitive vascular network out of precursory cells, the angioblasts. (B) Angiogenesis is the growth of new blood capillaries sprouting from preexisting blood vessels. In intussusceptive angiogenesis (C) the capillary wall extends toward the lumen, splitting the blood vessel in two, resulting in two new daughter capillaries. (D) Arteriogenesis occurs mostly in adult organisms as a reaction to atherosclerotic plaques: preexisting collateral arterioles expand and form large blood vessels that are able to compensate for the loss of function of occluded arteries. (E) In adult vasculogenesis, endothelial precursory cells (EPCs) are recruited from the bone marrow (BM) followed by *in situ* differentiation, migration, and incorporation into the blood vessels.

precursor, the angioblast (Figure 25.1A) [3,4]. Second, this vascular plexus is dramatically expanded during angiogenesis, which is defined as the growth of new blood capillaries sprouting from preexisting blood vessels (Figure 25.1B) [5–7]. Finally, blood vessel maturation takes place when the endothelial cells (ECs) are covered by pericytes or smooth muscle cells, or both, to provide stability and regulate perfusion [4,8]. In the adult organism, blood vessels mostly develop through angiogenesis; but there are other mechanisms, such as the splitting of preexisting vessels, known as intussusception (Figure 25.1C), growth or increase of functional collateral arteries from preexisting anastomoses known as arteriogenesis (Figure 25.1D), or by the incorporation of circulating precursor cells into vessel structures, for example postnatal vasculogenesis (Figure 25.1E) [9–11].

Histologically, the inner wall of a blood vessel consists of a monolayer of ECs, which are surrounded by a basement membrane, extracellular matrix (ECM) and mural cells such as pericytes. This coat of mural cells and basement membrane prevent resident ECs from leaving their positions. In adults, blood vessels and ECs remain in a quiescent state and are rarely activated to form new branches. It is only in response to specific stimulation, such as hypoxia or inflammation, that the angiogenic process is initiated [1].

The first step of angiogenesis is local destruction of the basement membrane and dissociation of the mural cells to liberate the ECs (Figure 25.2A). Matrix metalloproteinases play an important role in this step. They degrade the basement membrane and ECM, thereby not only liberating the ECs but also releasing proangiogenic factors that are stored in the ECM. Next, the ECs proliferate, migrate toward the angiogenic stimuli, and form a primitive tube (Figure 25.2). For more than a decade now it has been clear that not all activated ECs play the same role in these phases of angiogenesis. A specialized endothelial tip cell, which protrudes filopodia upon activation, guides and coordinates the direction of the branch formation. It is followed by highly proliferative endothelial stalk cells [12,13]. These stalk cells form the lumen of the primitive blood vessel, either by the fusion of intracellular pinocytic vesicles or by rearrangement of their shape and junctions [4,14]. Next, the tip cell anastomoses with tip cells from adjacent sprouts and a primitive vessel loop is built that allows blood to flow through it. Finally, blood vessel maturation is established: ECs resume their quiescent state and again become covered with pericytes and new basement membrane. EC junctions are established to ensure optimal blood perfusion [15]. This maturation step is vital for the survival of the blood vessel as immature blood

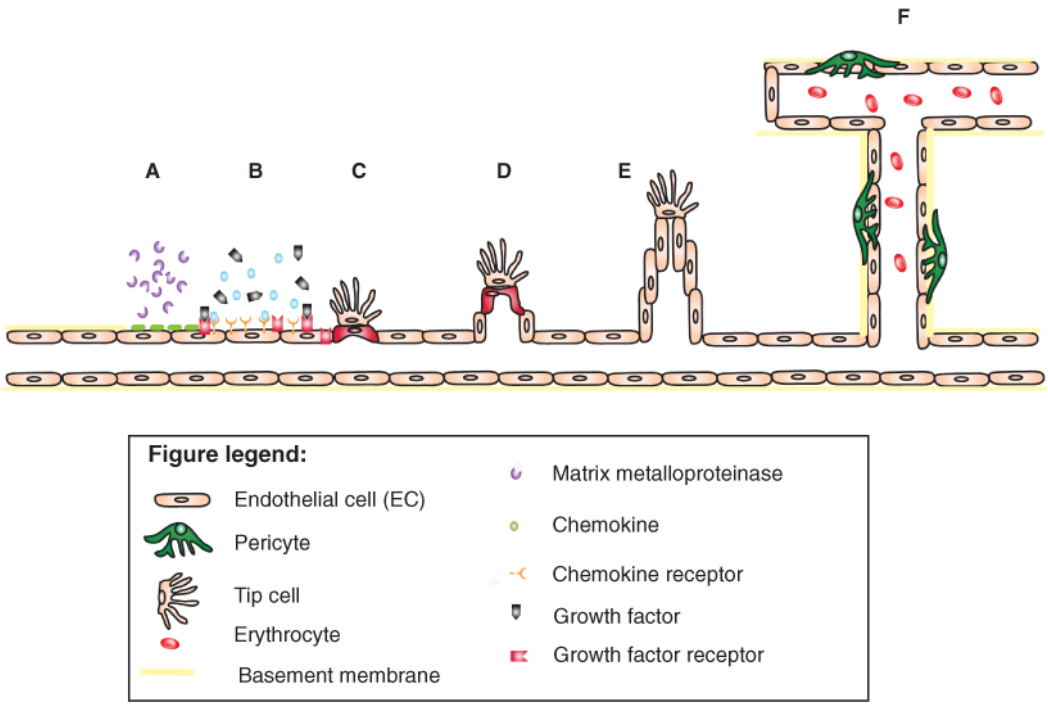

**Figure 25.2** Key steps of angiogenesis. Small blood vessels consist of hollow tubes aligned with ECs surrounded by pericytes, a basement membrane, and ECM. Angiogenesis is a multistep process involving the following steps: (A) breakdown of the ECM and basement membrane by, for example, matrix metalloproteinases. (B) EC activation by angiogenic factors, such as growth factors and cytokines. (C–E) Formation of a tip cell that guides the migration and a stack cell that proliferates and forms a primitive tube that matures into a fully functional blood vessel by pericyte attachment and deposition of ECM and basement membrane (F).

vessels are unstable and rapidly regress [4]. Observations of Carmeliet and colleagues revealed that the metabolism of the ECs is altered during angiogenesis. After stimulation with vascular endothelial growth factor (VEGF), glycolysis is induced in the ECs and is higher in tip cells than in stalk cells. The glycolytic activator phosphofructokinase-2/fructose-2,6-bisphosphatase 3 has been identified as playing a key role in EC proliferation and motility *in vitro* as well as in blood vessel growth *in vivo* in zebrafish embryos and the postnatal mouse retina [16–18].

For over 40 years now scientists have been trying to fully understand the process of normal and pathological angiogenesis. It is now clear that it is a dynamic biological process that is tightly regulated in time and space. Numerous growth factors, cytokines, enzymes, cellular receptors, ECM components, and signal molecules have been identified as modulators of the angiogenic process and each have their own specific function. Under normal physiological circumstances there is a balance between endogenous angiogenesis inhibitors and stimulators. Disturbance of this equilibrium leads to numerous pathological conditions. Exorbitant and uncontrolled blood vessel growth is implicated in rheumatoid arthritis, psoriasis, and age-related macular degeneration, and it is a hallmark of cancer growth and metastasis. Theoretically, these diseases could be treated by inhibiting angiogenesis. On the other hand, insufficient vessel growth and abnormal vessel regression not only cause heart and brain ischemia, but can also lead to neurodegeneration, atherosclerosis, and chronic wounds [9,19]. The discovery of numerous proangiogenic factors and their promising preclinical use in the 1990s–2000s led to numerous agents that entered clinical trials. These novel angiogenic therapeutic approaches attempted to stimulate vascular growth by protein or gene therapy. In protein therapy, recombinant proteins such as VEGF and fibroblast growth factor-2 (FGF-2) were used to enhance angiogenesis. Gene therapy in this setting involves the delivery of a gene construct of a proangiogenic gene using viral or nonviral vectors to MSCs. Unfortunately, most of these clinical trials to stimulate blood vessel growth had disappointing results and did not meet their goals [2,20]. Potential reasons for these failures include the short half-life of recombinant proteins and, in the case of gene therapy, poor transgene expression [20–22]. Therefore, current scientific focus has shifted from protein and gene therapy to the use of stem cells, and particularly MSCs. The concept of the application of MSCs is that the transplanted cells function as protein factories, continuously producing a cocktail of various endogenous proangiogenic factors and thus inducing angiogenesis via a paracrine mechanism. The proangiogenic properties of MSCs also make these cells an attractive cell source for tissue engineering. Rapid vascularization of newly implanted tissue constructs is an essential prerequisite for the long-term survival and function of these tissues [23].

## 25.3 Proangiogenic properties of mesenchymal stem/stromal cells

### 25.3.1 The mesenchymal stem/stromal cell secretome: a kaleidoscope of angiogenic molecules

Initially, MSCs gained attention in regenerative medicine because of their potential to differentiate into a variety of mesodermal cell types. Despite their long-lasting therapeutic efficacy in numerous *in vivo* preclinical models and clinical trials, the incidence of MSC engraftment in the injured tissue has been found to be surprisingly low. Therefore, a paradigm shift occurred, indicating that paracrine effects rather than transdifferentiation, at least in non-mesodermal tissues, are responsible for the beneficial effects of MSCs [24]. As a consequence, efforts were made to determine whether the conditioned medium (CM) of MSCs rather than MSCs themselves could be used as a therapeutic agent.

Thus, the rationale for using MSCs in diseases in which inadequate angiogenesis plays a key role is based on the fact that MSCs can secrete a number of proangiogenic proteins. With enzyme-linked immunosorbent assay, antibody arrays, and immunohistochemistry a broad repertoire of growth factors, cytokines, and other proangiogenic mediators has been detected in the CM from MSC cultures (as an indicator of the MSC secretome) from a number of MSC tissue sources. Table 25.1 summarizes the most important proangiogenic factors, their exact role in angiogenesis and the MSC type in which they were discovered.

In MSCs isolated from bone marrow (BM-MSCs) various angiogenic molecules were found, including VEGF, FGF-2, Ang-1, MCP-1, MMP-2, MIP-1β, IL-6, and PLGF [25,26,28,34,38–41]. Advanced mass spectrometry has demonstrated the presence of the protein Cyr61 (cysteine-rich angiogenic inducer 61) in the secretome of murine BM-MSCs. An anti-Cyr61 antibody inhibited BM-MSC-induced EC tube formation *in vitro* and blood vessel formation *in vivo*, indicating an important role for Cyr61 in BM-MSC-mediated angiogenesis [27]. Adipose-derived MSCs (AD-MSCs) were shown to produce VEGF, HGF, and TGF-β [30], while high levels of VEGF, MCP-1, and IL-8 were detected in the secretome of human dental pulp stem cells (DPSCs) [36,42]. The production of angiogenic molecules has been shown to be age-dependent and decreases with age in AD-MSCs [43].

Carmeliet and colleagues discovered that not only growth factors and cytokines but also metabolic enzymes and sugars play a key role in blood vessel growth [16–18]. The effect of MSCs on EC metabolism is currently unknown but needs to be explored in order to obtain a detailed insight of the effect of MSCs on angiogenesis.

Communication between MSCs and the cells they interact with, such as ECs, can also be modulated via the production of cell membrane vesicles, which can carry proteins as well as

**Table 25.1** Pro-angiogenic and anti-angiogenic factors.

| Angiogenic factor | Full name | Function | MSC type[a] | Ref. |
|---|---|---|---|---|
| *Pro-angiogenic factor* | | | | |
| Angiogenin | Angiogenin | EC migration, invasion, proliferation, and tube formation | hBM-MSC | [25] |
| Ang-1 | Angiopoietin-1 | Vessel stabilization, EC survival, recruitment of pericytes | mBM-MSC | [26] |
| Ang-2 | Angiopoietin-2 | EC migration and sprouting | mBM-MSC | [26] |
| Cyr61 | Cysteine-rich 61 | EC cell adhesion and EC migration | mBM-MSC | [27] |
| FGF-2 | Fibroblast growth factor-2 | EC proliferation, migration, remodeling of the ECM | mBM-MSC | [28] |
| HGF | Hepatocyte growth factor | EC and smooth muscle cell proliferation, migration | rBM-MSC | [29] |
| | | | hAD-MSC | [30] |
| IGF-1 | Insulin-like-growth factor-1 | EC proliferation, survival, induction VEGF and plasminogen activators | rBM-MSC | [29] |
| IL-6 | Interleukin-6 | EC proliferation and migration | hBM-MSC | [25] |
| | | | hPl-MSC | [31] |
| IL-8 | Interleukin-8 | EC proliferation, survival, migration, and tube formation | hBM-MSC | [32,33] |
| MCP-1 | Monocyte chemoattractant protein-1 | EC migration | mBM-MSC | [28,34] |
| | | | hBM-MSC | [25] |
| MIP-1α | Macrophage inflammatory protein-1α | Proinflammation, chemoattractants of immune cells | mBM-MSC | [34] |
| MIP-1β | Macrophage inflammatory protein-1β | Proinflammation, chemoattractants of immune cells | mBM-MSC | [34] |
| MMP-2 | Matrix metalloprotease 2 | ECM degradation, cell migration | hBM-MSC | [35] |
| NAP-2 (CXCL7) | Neutrophil-activating protein 2 | Neutrophil recruitment, EC migration, release of VEGF and MMP | hBM-MSC | [25] |
| PLGF | Placental growth factor | Induction of vessel formation | mBM-MSC | [28] |
| TGF-β | Tumor growth factor-β | Tube formation, vessel stabilization, ECM synthesis | hAD-MSC | [30] |
| VEGF | Vascular endothelial growth factor | Increased vessel permeability, ECM degradation, EC proliferation, migration, tube formation and survival | mBM-MSC | [26,28] |
| | | | hBM-MSC | [25] |
| | | | hDPSC | [36,37] |
| | | | hAD-MSC | [30] |
| *Anti-angiogenic factor* | | | | |
| TIMP-1 | Tissue inhibitor of metalloproteinase-1 | Inhibitor of metalloproteinases | hBM-MSC | [25] |
| TIMP-2 | Tissue inhibitor of metalloproteinase-2, | Inhibitor of metalloproteinases | hBM-MSC | [25] |
| MIG | Monokine induced by interferon-γ | Chemoattractant of T-cells, inhibition of angiogenesis | mBM-MSC | [34] |

[a] h: human; m: mouse; r: rat.

genetic information via microRNAs (miRNAs) (see Chapters 20 and 37). The miRNAs are able to target paracrine factors and molecular pathways primarily through posttranscriptional repression or mRNA degradation in a sequence-specific manner. Growing evidence indicates that various miRNAs are involved in various steps of the angiogenic process, including proliferation and migration of ECs [44]. For example, miR-210 is able to promote angiogenesis in ECs by downregulating ephrin-A3 [45], while miR-126 has been shown to upregulate VEGF and to participate in EC sprouting in response to blood flow [46]. The miRNA profile of normal and hypoxia-treated rat BM-MSCs were compared and 13 miRNAs were significantly upregulated (including miR-210), whereas 20 miRNAs (such as miR-377) were downregulated. miR-377 was shown to negatively regulate the expression of VEGF; as a consequence, MSCs in which miR-377 was knocked down promoted angiogenesis in a preclinical model of myocardial infarction [47]. The miRNA network involved in the angiogenic actions of MSCs remains to be fully

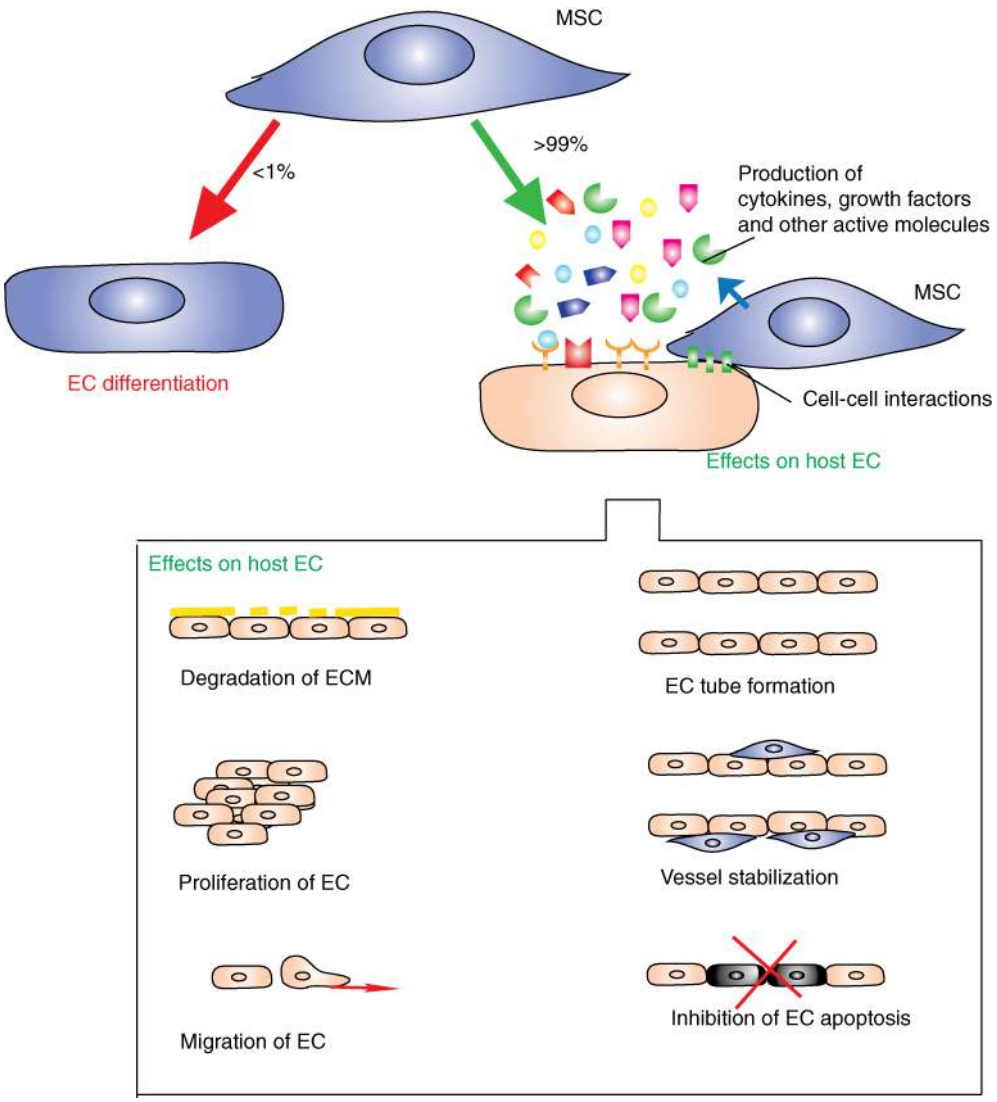

**Figure 25.3** Angiogenic actions of MSCs. Incorporation of MSCs into the host vasculature is rarely observed, the current paradigm being that MSCs induce angiogenesis mostly by activating host ECs by cell–cell contact or by secreting various angiogenic molecules. MSCs are involved in various steps of the angiogenic process, such as breakdown of the ECM, EC proliferation, migration, tube formation, and vessel stabilization. They can also protect ECs from apoptosis.

elucidated. Insight of the miRNA network responsible for the regulation of MSC-induced angiogenesis may lead to new therapeutic approaches [44].

### 25.3.2 The effect of mesenchymal stem/stromal cells on the behavior of endodothelial cells *in vitro*

In order to assess whether a particular cell population possesses angiogenic activity, it is not only necessary to identify the angiogenic mediators present in their secretome, but also to explore the effect of these cells on the behavior of ECs, the most important factors in neovascularization. EC proliferation, migration, and tube formation are key steps of angiogenesis and there are various *in vitro* models available that mimic each of these phases. Figure 25.3 summarizes the possible contribution of MSCs to each of these processes.

#### 25.3.2.1 Stimulation of endothelial cell proliferation

There is disparity in the literature with regard to the effect of MSCs on EC proliferation. On the one hand, the CM of BM-MSCs has been repeatedly reported to induce EC proliferation [28,40]. In addition, Lin *et al.* demonstrated that CM derived from $CD45^{-}/PDGFR^{+}$ murine MSCs isolated from four different tissue types (bone marrow, adipose tissue, skeletal muscle, and myocardium) stimulated proliferation of human umbilical-vein-derived ECs (HUVECs) [48] (PDFGR is platelet-derived growth factor receptor). Also, the CM of Wharton's jelly and AD-MSCs significantly increased EC growth [30,49].

On the other hand, it been demonstrated using a radioactive-labeled thymidine incorporation assay, that the CM of BM-MSCs did not induce EC growth [50]. This was confirmed by Barlacu *et al.*, who demonstrated no effect of CM from murine BM-MSCs on the proliferation of HUVECs [51]. No effect on EC proliferation was found when the CM from dental MSCs was added to the human EC line HMEC-1 [52].

Some investigators have determined that MSCs inhibit EC proliferation. For example, co-culture of ECs with MSCs on poly (L-lactide-co-1,5-dioxepan-2-one) scaffolds in a dynamic culture environment resulted in lower values of the cell proliferation markers proliferating cell nuclear antigen and Ki67, and thus proliferating ECs [53]. Menge *et al.* reported that 24 h of co-culture of MSCs with ECs resulted in reduced proliferation and a decreasing number of ECs in the S phase of the cell cycle. A transwell culture of MSCs with ECs, which does not permit direct cell–cell contact between MSCs and ECs, had no effect on the amount of ECs in S phase, leading to the conclusion that EC–MSC cell-to-cell contact is required [54]. BM-MSC-derived exosomes also inhibited proliferation of the murine EC line SVEC *in vitro* [55]. These inconsistent findings in the literature may be due to the heterogeneity of the MSCs, different sources of ECs, differences in assays to monitor EC proliferation, variations in preparation of the CM used (e.g., serum concentrations, basal medium used), and the use of CM versus co-culture with cells.

#### 25.3.2.2 Induction of endothelial cell migration

Numerous reports have shown that MSCs induce *in vitro* transwell migration of ECs [36,48–51,56]. In 2005 it was demonstrated that CM from BM-MSC cultures was chemotactic for both human umbilical vascular and uterine microvascular ECs [50]: Gruber *et al.* reported that addition of anti-VEGF antibodies had no effect in this assay, while Kwon *et al.* [40] described significant inhibition with a single neutralizing antibody against VEGF, MCP-1, or IL-6 but not by antibodies against TGF-β1 and HGF. MSCs derived from pulp were able to induce EC migration in a transwell assay. The migration-inducing capacities of these DPSCs was inhibited by an antibody against VEGF or by the PI3K-inhibitor LY294002 (10 and 1 μM) and the mitogen/extracellular signal-regulated kinase (MEK) inhibitor U0126 (10 and 1 μM). In addition, CM from MSCs derived from adipose tissue, skeletal muscle, and myocardium induced motility of ECs in the *in vitro* scratch assay [48]. The *in vitro* scratch assay is an easy and well-developed method to measure cell migration *in vitro*. The basic steps involve creating a "scratch" in a cell monolayer, capturing the images at the beginning and at regular intervals during cell migration to close the scratch, and comparing the images to quantify the migration rate of the cells.

#### 25.3.2.3 Stimulation of tube formation

The ability of MSCs to induce tube formation of ECs plated on an ECM component such as Matrigel is one of the best described measurements of *in vitro* angiogenesis. The CM of BM-MSCs is able to stimulate network formation of various ECs *in vitro* on collagen or Matrigel [27,34,40,50,56]. Depletion of Cyr61, VEGF, MCP-1, and IL-6 but not HGF and TGF-β1 significantly attenuated this MSC-mediated tube formation [27,40]. Ghajar *et al.* observed that co-culture of human BM-MSCs with HUVECs induced formation of a denser network in a three-dimensional fibrin gel [57]. Human MSCs derived from Wharton's jelly, dental pulp, adipose tissue, skeletal muscle, and myocardium stimulate EC tube formation [48,49,52].

#### 25.3.2.4 Enhancment of matrix degradation

The ability of ECs to degrade the surrounding ECM *in vitro* in the cell invasion assay is stimulated by MSCs. The cell invasion assay monitors cell movement through ECMs. AD-MSCs as well as BM-MSCs have been shown to induce EC invasion, through upregulation of distinct proteases [28,58]. In a three-dimensional model of network formation in fibrin gel, addition of human MSCs resulted in a denser network formation of HUVECs. Induction of early production of MMPs, including the soluble forms of MMP-2 and MMP-9 as well as membrane-bound MT1-MMP was shown to be the underlying mechanism, suggesting that MSCs contribute to angiogenesis by controlling extracellular proteolytic mechanisms [57]. Annabi *et al.* demonstrated that murine BM-MSCs were able to produce active MMP-2, which was able to degrade the ECM [32].

#### 25.3.2.5 Blood vessel stabilization and maturation

The origin of MSCs has been the subject of considerable discussion, but currently it is assumed that at least a significant population of MSCs in most tissues are derived from perivascular cells [24,59]. Therefore, it is not surprising that data indicate that both *in vitro* and *in vivo* MSCs play a role in tube stabilization. It was demonstrated that human BM-MSCs in direct co-culture with ECs on Matrigel increased the persistence of tubular structures compared with culture of ECs alone. This effect was considered to be caused by direct cell-to-cell contact between the BM-MSCs and ECs [60]. In a three-dimensional Matrigel co-culture system BM-MSCs co-aligned with tubular EC structures in a pericyte-like manner and some BM-MSC populations enhanced the complexity and extent of these tubes [61]. A recent study demonstrated that co-culture of MSCs with ECs on poly(L-lactide-co-1,5-dioxepan-2-one) scaffolds in a dynamic culture environment resulted in a quiescence of the ECs, as described earlier. The ECs displayed lower proliferation and increased secretion of markers of vascular maturation such as angiopoietin-1 [53]. In another study, human BM-MSCs efficiently stabilized nascent blood vessels by functioning as perivascular precursor cells in an *in vivo* tissue-engineered blood vessel construct [62]. In the light of these findings, it is worth mentioning that *in vitro* BM-MSCs have the ability to adhere to human ECs from arteries, veins, and microvasculature under static conditions. When injected into the chick embryo chorioallantoic membrane (CAM), human MSCs adhered to arterioles. Inhibition of α4 integrin and/or sialyl Lewis X with blocking antibodies reduced adhesion in arterioles [63]. Ball *et al.* demonstrated that

the receptor neuropilin-1 (NRP1) co-localizes with PDGFR and is also involved in the EC adherence and blood-vessel-stabilizing function of MSCs [64]. NRP1 is a membrane-bound co-receptor to a tyrosine kinase receptor for both VEGF and semaphorin family members.

Otsu *et al.* reported that addition of MSCs to EC-derived tubes in a two-dimensional *in vitro* Matrigel assay led to degeneration of the network. MSCs were shown to intercalate between the ECs, formed gap junctions with the ECs, and caused production of reactive oxygen species that resulted in EC apoptosis and destruction of the tubes. It should be noted that these cytotoxic effects of MSCs were only evident when the MSCs were added to the Matrigel in very high numbers with an EC : MSC ratio of 1 : 1 or 1 : 3. The toxic effects were dramatically reduced when the number of MSCs was decreased [65]. This dose dependency might also explain the difference between the findings of Otsu *et al.* and the overwhelming evidence of the proangiogenic effects of MSCs. Menge *et al.* showed that ECs which have been co-cultured with MSCs form a smaller network on Matrigel in comparison with control ECs. Interestingly, these effects appear to require EC–MSC contact and result in enhanced co-localization of VE-cadherin and β-catenin on the EC membrane. ECs cultured in contact with Wnt3a-overexpressing MSCs regained the capability of forming EC networks in Matrigel [54].

#### 25.3.2.6 Protection of endothelial cells against apoptosis

MSCs also have the capacity to protect ECs from apoptosis *in vitro*. CM of hypoxic AD-MSCs inhibited EC death induced by cycloheximide and TNF-α [30]. In addition CM of BM-MSCs reduced hypoxia-induced apoptosis of ECs through activation of the PI3K/Akt pathway but not the ERK pathway [25]. (ERKs are extracellular-signal-regulated kinases and are now known as mitogen-activated protein kinases (MAPKs); they are widely expressed protein kinase intracellular signaling molecules that are involved in functions including the regulation of meiosis, mitosis, and postmitotic functions in differentiated cells.) Many different stimuli including growth factors, cytokines, virus infection, ligands for heterotrimeric G protein-coupled receptors, transforming agents, and carcinogens activate the ERK pathway. The term "extracellular-signal-regulated kinases" is sometimes used as a synonym for MAPK, but has more recently been adopted for a specific subset of the mammalian MAPK family. Placental MSCs abrogated oxidative stress-provoked apoptosis induced by *tert*-butyl hydroperoxide via the signal transducer and activator of transcription 3 (STAT3) signal transduction cascade [31]. (*tert*-Butyl hydroperoxide is an organic peroxide widely used in a variety of oxidation processes.)

### 25.3.3 Mesenchymal stem/stromal cells induce angiogenesis *in vivo*

There is little doubt that the angiogenic effect of molecules or cells is best evaluated *in vivo*. In the field of embryology the two most commonly used animal models to study blood vessel formation in absence of any pathology are the chicken CAM assay and the mouse Matrigel plug assay. In this section we discuss the effect of MSCs on angiogenesis in each of these *in vivo* models.

#### 25.3.3.1 The chicken chorioallantoic membrane assay

Since the adaptation of this animal model by Judah Folkman in the early 1970s the CAM assay has been widely used to investigate pro- and anti-angiogenic agents. The CAM is an extraembryonic highly vascularized membrane that serves as a gas exchange surface for the embryonic chick until hatching. One of the advantages of this model is that at this developmental stage the immune system is not fully developed and the mechanisms for rejection of applied agents have not been established. As this model represents a simple and cost-effective procedure with limited ethical concerns, it has become a practical and intensively used research tool [66]. Traditionally, it has been applied to study both angiogenesis and anti-angiogenesis in response to chemical molecules, proteins, cancer cells, and tumor biopsy specimens. Recently, the model has gained attention in the field of tissue engineering to assess neoangiogenesis induced by cells or engineered cellular scaffolds [23].

The CM of murine BM-MSCs and especially that of murine BM-MSCs pretreated with TNF-α- and/or interferon-γ-induced blood vessel formation in the CAM [50,67]. Additionally, human BM-MSCs stimulated blood vessel formation in this model. This angiogenic effect was even more profound with BM-MSCs that had been cultured in serum-deprived conditions for 30 days [68]. DPSCs and placenta-derived MSCs also induced capillary formation in this model [52,69,70]. CAMs transplanted with endothelially differentiated placental MSCs stimulated a greater number of blood vessels compared with CAMs transplanted with undifferentiated human placenta-derived MSCs. Function-blocking antibodies to integrins $\alpha_5$ and $\beta_1$ prevented this human placenta-derived MSC-mediated blood vessel induction [69].

#### 25.3.3.2 The murine Matrigel plug assay

The mouse Matrigel plug assay is a relatively easy *in vivo* technique with which to validate angiogenesis. Matrigel is the trade name for a gelatinous protein mixture secreted by Engelbreth–Holm–Swarm (EHS) mouse sarcoma cells and is used as a basement membrane preparation in laboratory research. The exact composition of Matrigel is unknown, but it contains ECM proteins such as laminin, collagen IV, and entactin. Usually, a growth factor, anti-angiogenic agent, or cells are mixed with liquid Matrigel and injected subcutaneously in immunocompromised mice. At the body temperature of the mouse the Matrigel mixture solidifies and forms a plug. This plug can be recovered 7–21 days later to examine the number of blood vessels that have entered it. Quantification of blood vessels is usually performed on histological sections, which is tedious but accurate. Additionally, the hemoglobin content of the plug can be measured as a measure of angiogenesis, but this can be misleading as blood content can also be affected by blood vessel size or by stagnant pools of blood [1].

Most studies indicate that Matrigel plugs seeded with BM-MSCs have an increased blood vessel content compared with control Matrigel inserts [27,71]. Verfaillie's group found that BM-MSCs are able to attract host blood vessels to subcutaneous Matrigel transplants measured 3 weeks after injection, but that these tubes are leaky, as evidenced by the presence of red blood cell pools in the Matrigel [72]. A study by Janebodin *et al.* indicated that DPSC-containing Matrigels had more blood vessels then BM-MSCs plugs, and this neovascularization was reduced by adding soluble VEGF-receptor 1 [73]. In contrast, Menge *et al.* reported that when MSCs were injected via the tail vein they inhibited blood vessel growth in Matrigel plugs seeded with FGF-2 or MSCs. It was hypothesized that this anti-angiogenic effect of the MSCs was caused by increased IL-10 production of MSCs residing in the lung tissue after intravenous administration, but further investigation is needed [54].

## 25.4 Mesenchymal stem/stromal cells as a therapeutic tool for diseases caused by insufficient angiogenesis

In this section we discuss the effects of MSC administration in animal models of a wide variety of disorders caused by limited angiogenesis. Key observations that exemplify the pro-angiogenic impact of MSC administration will be highlighted. We will also discuss human clinical trials with MSCs in these disorders.

### 25.4.1 Peripheral ischemic arterial disease

Peripheral ischemic arterial disease is a narrowing or obstruction of the arteries of the limbs resulting from pathological changes in the arteries, such as atherosclerosis or inflammation. This results in a wide variety of symptoms and signs, ranging from weakness and cramping in the muscles to chronic wounds, ulcers, and in later stages muscle atrophy and gangrene. Since there are currently no pharmacological treatments for this, amputation of the affected limb is required in one-third of cases if the arterial blockage cannot be reversed [74]. Because of their angiogenic potential, MSCs may help to restore the blood flow to tissues distal to the obstruction. Peripheral ischemic arterial disease is mimicked in animal models by blocking the blood flow by temporary ligation or resection of important hind limb arteries such as the femoral artery, resulting in ischemia of the leg [75].

In 2004, Kinnaird *et al.* showed in a mouse model of hindlimb ischemia that the local intramuscular injection of BM-MSCs increased blood vessel density and limb perfusion, reduced the incidence of autoamputation, attenuated muscle atrophy, and significantly improved limb function. No MSC incorporation into the blood vessel walls was observed, but both VEGF and FGF-2 levels were elevated in the BM-MSC-treated muscles, suggesting that paracrine actions of MSCs were responsible for the amelioration of the BM-MSC-treated group [28]. In contrast, Iwase *et al.* and Al-Khaldi *et al.* found evidence in rat models of hindlimb ischemia of transplanted BM-MSCs in recipient blood vessel walls expressing EC markers such as von Willebrand factor (vWF) and CD34 at 3 or 4 weeks after administration. However, neither study quantitated the number of engrafted MSCs [75,76]. In both studies the BM-MSC-treated rats displayed increased limb perfusion. Intravenous injection of human AD-MSCs improved blood perfusion in a mouse hindlimb ischemia model [30,77]. Implanted DiI-labeled human AD-MSCs also seemed to differentiate into ECs as vWF/DiI double-positive cells were detected within the muscle tissue. The actual incorporation rate of these cells into the recipient's vascular structures was less than 1%, again suggesting that paracrine effects of AD-MSCs accounted for the beneficial effect on hindlimb ischemia [77]. In addition, the intramuscular injection of a side population of $CD31^-$ $CD146^-$ porcine DPSCs increased blood flow and capillary density in a murine hindlimb ischemia model. Transplanted cells were located in close vicinity to the blood capillaries. *In situ* hybridization revealed the expression of VEGF and MMP-3 by these engrafted porcine DPSC side population cells [78].

A phase II clinical trial demonstrated that the intra-arterial infusion of autologous bone marrow significantly increased both peripheral blood perfusion and the percentage of amputation-free patients with critical limb ischemia 1 year after the infusion [79].

### 25.4.2 Stroke

Stroke, also known as acute cerebral ischemia, is a sudden neurologic deficit caused by a disturbance in the blood supply to the brain. The most frequent cause of stroke (80–85%) is thromboembolism or an *in situ* thrombosis, blocking the blood circulation and leading to a decrease in oxygen and nutrient delivery to the brain. Cerebral hemorrhage resulting from hypertension or arterial wall pathology can also lead to stroke [80]. Depending on the affected area of the brain, ischemic stroke is associated with temporary or permanent loss of brain tissue and function, resulting in severe motor, sensory, and cognitive dysfunction. Cerebral ischemia or stroke is the most common cause of adult-acquired disability and the second leading cause of death worldwide [81]. Currently, the only pharmacological treatment available is tissue plasminogen activator for lysis of the blood clot in thrombotic stroke and its use is limited to a small minority of patients because of the narrow therapeutic window of 4.5 h after disruption of blood flow. It is contra-indicated in hemorrhagic stroke.

The hypothesis that MSCs could transdifferentiate into neural cells was the first rationale for their use in stroke. MSC-derived "neuronal" cells may look like neurons with long dendritic processes and may even stain positively for antigens normally restricted to neural cells such as β3-tubulin. However, functionally, they do not fire action potentials [82,83] and this transdifferentiation to neural cells has not been reproduced *in vivo* [84]. Moreover, it has been observed that MSCs only transiently engraft in the ischemic brain. A study in which human MSCs were injected intracranially after stroke induction in mice found no administered cells detectable on histological

sections 28 days later [85]. Despite this low rate of engraftement in the recipient, numerous reports have shown that BM-MSCs improve neurological function in several animal models of stroke. This is most likely mediated through a combination of protection against apoptosis, immunomodulation, stimulation of neural plasticity, and induction of angiogenesis [63,86]. These favorable effects of MSCs on functional recovery have been found to be robust across rodent and primate species, route of delivery, and type and source of MSCs [87]. Numerous studies have indicated that the improved recovery after MSC administration is associated with an increase in blood vessel density and production of angiogenic factors. For example, increased VEGF and VEGF-receptor (VEGFR)2 expression was observed after intravenous injection of human BM-MSCs in a rat model of ischemic stroke [88].

Another research group reported a significant upregulation of Ang-1 and Ang-2 mRNA levels in BM-MSC-treated rats [89]. The intraperitoneal injection of a cell-free extract derived from MSCs was shown to dramatically decrease the ischemic volume and improve motor function after stroke injury [90].

This extensive work on MSC administration in animal models of stroke injury has encouraged the study of these cells in phase I/II clinical trials [86]. Bang *et al.* were the first to describe a trial using autologous BM-MSCs: five patients received autologous BM-MSCs intravenously. Although the BM-MSC-treated group had a tendency toward a better functional outcome, this difference was not statistically significant [91]. Subsequently, the same research group published the results of a long-term follow-up study of the intravenous administration of autologous BM-MSC transplantation in patients with stroke injury that showed BM-MSC treatment improved functional outcome and survival for up to 5 years after MSC administration [92]. A nonblinded trial of 12 patients given autologous BM-MSCs expanded *ex vivo* using autologous serum indicated that the intravenous administration of these cells 36–133 days after the stroke was not only safe and feasible but could also reduce infarct size by 20% at 1 week after infusion [92]. All these clinical trials had a small sample size and the study by Honmou *et al.* [93] was nonblinded; therefore, a placebo effect could not be excluded. However, the results were encouraging enough to warrant randomized placebo-controlled double-blinded trials (see Chapter 48).

### 25.4.3 Myocardial infarction

Cardiovascular disease is responsible for >45% of all deaths in western countries and is reaching pandemic proportions worldwide. Acute myocardial infarction (AMI) resulting from ischemic coronary artery disease represents a major economic burden on the health-care system of many countries since many survivors of the acute ischemic episode subsequently develop chronic myocardial ischemia and complications such as congestive heart failure, which is often refractory to current conventional treatment [94]. The administration of MSCs is currently being explored as a potential therapeutic agent for both and chronic ischemic myocardial disease (see Chapter 45). Initial preclinical animal studies and early clinical trials have shown encouraging results. Initially, it was assumed that MSCs might improve cardiac function after AMI due to their transdifferentiation into cardiomyocytes. However, significant *in vivo* MSC engraftment and cardiomyocyte differentiation was found to be nonexistent or very rare [94–98] and this gave rise to the hypothesis that MSCs repair the damaged heart by supplying growth factors that induce angiogenesis or by stimulating resident cardiac stem cell migration and differentiation [94,99]. Numerous preclinical studies have demonstrated the functional effectiveness of MSCs from a number of different tissue sources, including bone marrow, adipose tissue, dental pulp, and amnion [96,97,100,101]. Administration of these cells resulted in more normal myocardial remodeling rather than the pathological remodeling with extensive myocardial fibrosis that is often a result of AMI, reduced infarct size, reduced myocardial fibrosis, improved cardiac contractile function, and stimulation of angiogenesis. Secretion of both VEGF and HGF was found to contribute to improved cardiac function after transplantation with AD-MSCs [100]. The critical role of VEGF in MSC-induced blood vessel growth after myocardial infarction was also demonstrated by Markel *et al.*, who described that small interfering RNA (siRNA) directed against VEGF inhibited the recovery of myocardial function in a rat model of AMI [102]. In addition, the intramyocardial injection of amniotic MSCs not only increased the levels of VEGF but also of Ang-1 in the affected heart tissue [101]. In a hamster model of cardiomyopathy, injection of porcine BM-MSCs into the hamstring skeletal muscles improved cardiac repair due to their production of multiple IL-6-like cytokines [103].

The safety, dose, and impact associated with cell administration for myocardial infarction in humans have been extensively studied and published [94,99,104]. Several trials, such as the BOOST trial (BOne marrOw transfer to enhance ST-elevation infarct regeneration) have shown an increase in left ventricular ejection fraction in recipients of autologous bone marrow cells compared with control groups at 4, 12, and 18 months after cell administration [105–107]. However, the exact type of bone marrow cells infused in the BOOST trial is unclear since the cells were infused after only an average of 5 days of culture.

Measurement of left ventricular ejection fraction is the commonest parameter for evaluating function of the left ventricle. AMIs may be ST segment elevation myocardial infarctions (STEMI) or non-STEMI myocardial infarctions with regard to the presence or absence of elevation of the ST waves on the electrocardiogram: STEMI is a more serious type of AMI than non-STEMI.

Three other clinical trials demonstrated no significant improvement in cardiac function after injection of bone marrow mononuclear or progenitor cells [108–110]. Again, it should be emphasized that the injected cells were not MSCs that had been expanded in long-term *ex vivo* culture. At 5 years after treatment there are discrepant reports in the literature: a 5-year follow-up of the patients enrolled in the BOOST trial showed that the beneficial effects observed at 18 months in terms of cardiac

contractility were not sustained, while another 5-year follow-up study did demonstrate a significant improvement in left ventricular ejection fraction in the bone-marrow-cell-treated AMI patients [111,112].

It is now generally agreed that bone marrow mononuclear cells and hematopoietic progenitor or hematopoietic stem cells are of limited use for the treatment of acute and chronic myocardial ischemia.

The focus on cellular treatment for ischemic heart disease has now turned to the use of MSCs (see Chapter 45). Two small trials demonstrated the safety and potential efficacy of autologous adipose tissue-derived MSC administration [113,114]. There have been, and are, a number of clinical trials using MSCs, including the REVITALIZE trial (NCT00874354) in which autologous BM-MSCs were injected directly into the myocardium via a catheter inserted in the recipient's femoral artery under local anesthesia. Two phase II clinical trials have been initiated using AD-MSCs [94,115]. Full details of the use of MSCs for both acute and chronic ischemic heart disease are given in Chapter 45.

### 25.4.4 Failure of surface wound healing

Surface wound healing is a complex multifactorial process involving the interaction of inflammation, re-epithelialization, angiogenesis, and remodeling of the ECM. In pathological settings such as severe burns or diabetes mellitus [116,117] normal wound repair mechanisms fail to restore skin function, leading to treatment-refractory skin ulceration. Current biological techniques used for the healing of severe wounds include the use of antimicrobial support combined with a matrix scaffold that in most cases is collagen-based and seeded with growth factors.

However, outcomes in this field remain marginal and therefore MSC-based applications are being explored [116,117]. Both allogeneic and autologous MSCs administered either locally or systemically accelerate wound closure in a wide variety of animal models [118]. In a study by Wu *et al.* BM-MSC treatment of wounds in diabetic mice resulted in accelerated wound healing, increased re-epithelialization and wound vascularity probably through the release of Ang-1 and VEGF [26]. In this study, the rate of MSC engraftment 28 days after injection was extremely low at less than 1% of the MSCs administered. No integration of the transplanted $GFP^+$ BM-MSCs into the recipients' vasculature was observed [26]. Application of AD-MSCs in cell sheets consisting of poly-*N*-isopropylacrylamide accelerated wound closure and angiogenesis in nude mice [119]. Also, concentrated CM of BM-MSCs and CM of hypoxia-pretreated AD-MSCs were both reported to enhance wound healing in a murine model of excisional wounds [120,121]. Addition of neutralizing antibodies against VEGF and FGF-2 to the wounds treated with the AD-MSC CM reduced the wound repair, indicating that VEGF and FGF-2 are key molecules in wound healing [121]. Another study considered the beneficial effect of the BM-MSC CM to be due to the recruitment of macrophages and endothelial progenitor cells to the site of injury [120]. Another study claimed that besides induction of angiogenesis, MSCs could contribute to wound repair by differentiation into keratinocytes [122], although evidence for such transdifferentiation has not been provided in all studies [118].

Initial clinical studies indicate a possible therapeutic role for MSCs in wound healing. A small pilot study in patients with acute or severe chronic wounds showed that the topical administration of autologous BM-MSCs in a fibrin spray significantly reduced wound size [123]. Another trial in which autologous BM-MSCs were administered to people with chronic nonhealing ulcers of the lower extremities showed that the MSC-treated group had significant reduction in ulcer size and improvement in pain-free walking distance compared with the control group [124]. Another study found both bone marrow mononuclear cells and tissue culture-expanded $CD90^+$ cells useful for the treatment of chronic foot ulcers in diabetic patients: wound healing and improved microvascularization were detected in some but not in all patients in this study [125]. Thus, while the results of preclinical studies and early clinical use of MSCs in the wound healing setting have given rise to optimism, further phase I and II studies are needed to determine the value of MSCs in this pathological setting in humans [116] (see Chapters 58 and 59).

### 25.4.5 The dual role of mesenchymal stem/stromal cells in cancer biology

As MSCs are able to induce blood vessel formation and since tumor growth and metastases are angiogenesis dependent, the contribution of MSCs to cancer development has been the subject of intense investigation. During tumor growth endogenous MSCs are recruited from the bone marrow to the tumor where they become a component of the tumor stroma, differentiating into tumor-associated fibroblasts and pericytes. These tumor-associated MSCs have been found in both animal models and clinical settings, and most data indicate that MSCs enhance tumor growth and metastasis [126,127]. However, in other animal studies in which MSCs were added exogenously by local or systemic injection the impact of MSCs on tumor progression was unclear.

The majority of the studies that demonstrated promotion of tumor growth by MSCs were in various cancer models, including lung adenocarcinoma [128], melanoma [129], and breast cancer [130] and are reviewed in References [126] and [127]. Although the molecular mechanisms behind the tumor-promoting capacities of MSCs are still not fully understood, several papers indicate that stimulation of angiogenesis is a crucial element [31,50,52,55,131]. In a mouse xenograft model of colorectal carcinoma it was demonstrated that BM-MSCs increased tumor growth by secreting IL-6, thereby inducing endothelin-1 expression by the cancer cells and activating ECs and thus blood vessel development. siRNA against IL-6 inhibited the MSC-induced tumor development [132]. Liu *et al.* demonstrated that inhibition of VEGF or HIF-1α with siRNA effectively reduced MSC promotion of colon tumor growth *in vivo* [67].

It has been reported that pretreatment of the gastric tumor cell line SGC-7901 with a single dose of human BM-MSC-derived CM *in vitro* was sufficient to augment tumor growth. This human MSC CM induced expression of VEGF by the tumor cells as well as the activation of RhoA-GTPase and ERK1/2 pathways [133]. Besides augmentation of angiogenesis, other suggested mechanisms of tumor growth stimulation include immunomodulation, induction of vasculogenesis, and reduction of tumor cell apoptosis [127].

In contrast to these studies, Khakoo *et al.* showed in a mouse model of Kaposi's sarcoma that human MSCs injected intravenously potently inhibited tumor growth, probably due to inhibition of Akt activity [134]. Otsu *et al.* reported that rat BM-MSCs inhibited the growth of mouse melanoma cells by inhibiting angiogenesis. It is likely that the high number of added cells ($10^6$) and the direct injection of the cells into the tumor caused the development of reactive oxygen species with consequent cytotoxicity [65]. Co-injections of other MSC types such as AD-MSCs, umbilical-cord-blood-derived MSCs, and fetal skin MSCs were shown to reduce tumor size in animal models of glioma, hepatoma, and pancreatic carcinoma [135–137]. Exosomes derived from murine BM-MSCs decreased tumor volume and suppressed angiogenesis by downregulating VEGF expression in a mouse model of breast cancer [55]. The tumor-suppressing capacities of MSCs have been attributed to the induction of apoptosis and inflammation, inhibition of angiogenesis, and alteration of the cell cycle progression [127].

The paradoxical literature findings may be due to variations in MSC source, the heterogenic nature of MSCs, the protocols used in their isolation and culture, patient variability, tumor cell types, contamination of the MSCs with tumor cells, and differences in timing, dose, and mode of MSC administration. Most investigators that reported tumor-promoting effects of MSCs mixed MSCs with tumor cells and injected them simultaneously. The presence of MSCs during the early phases of tumor development may rapidly induce angiogenesis, which in turn could result in substantial tumor growth [127] (and see Chapter 28).

Despite the lack of clarity on the exact involvement of MSCs in tumor pathogenesis, MSCs are becoming increasingly used as delivery vehicles of anticancer gene therapy and chemotherapy (see Chapters 60 and 62). MSCs have the intriguing property of homing to tumors just as they do to sites of nonmalignant inflammation. This preferential migration has been convincingly demonstrated in a number of xenograft models, including those involving hepatocellular carcinoma, breast cancer, and ovarian carcinoma [138–140]. MSCs do not only selectively home to the primary site of solid tumors, but also to metastases far removed from the primary site [141,142]. Their use as cellular vehicles for delivery of genes to tumors includes BM-MSCs overexpressing the suicide gene, herpes simplex virus thymidine kinase (HSV-TK), which successfully reduced tumor volume in a rat glioma model [11]. Should such cells cause side effects in normal tissues, they can be readily eliminated by administration of ganciclovir, which will kill all cells expressing the viral HSV-TK gene but not those cells without it. Another study demonstrated that administration of BM-MSCs overexpressing anti-angiogenic repeats of thrombospondin significantly decreased tumor vessel density and consequently tumor progression in mice with human glioma xenografts [143].

MSC administration used without gene manipulation appears to be safe in humans. A systematic review and meta-analysis of clinical trials showed no serious adverse events associated with the intravenous or intra-arterial administration of MSCs in over 1000 patients, over 300 of whom had received the MSCs in randomized clinical trials. Specifically, there were no *de novo* malignancies reported [144]. The use of MSCs as gene delivery vehicles is an exciting concept but one that will add a significant extra layer of complexity and thus increased regulatory control of their manufacturing for clinical trial purposes.

## 25.5 Enhancing the angiogenic efficacy of mesenchymal stem/stromal cells

Although MSCs display substantial endogenous angiogenic potential, large efforts have been made to further enhance their angiogenic actions [145]. The release of angiogenic factors by MSCs can be significantly augmented by the addition of various chemokines in a process referred to as priming or pharmacological preconditioning or by subjecting MSCs to hypoxia or to serum-free conditions. It has been demonstrated that TGF-α induces the secretion of VEGF, granulocyte colony-stimulating factor, HGF, IL-6, IL-8, the PDGF-BB form of PDGF, and Ang-2 in BM-MSCs. CM from TGF-α-treated MSCs induced more blood vessel growth than CM of untreated BM-MSCs in the *in vivo* CAM assay [33]. Exposure of BM-MSCs to hypoxia, TNF-α, or lipopolysaccharide (LPS) enhanced the release of VEGF, FGF-2, HGF, and insulin-like growth factor 1 (IGF-1) by induction of the transcription factor nuclear factor kappa light chain-enhancer of activated B [146]. Annabi *et al.* demonstrated in murine BM-MSCs that hypoxic conditions downregulated the mRNA and protein levels of MMP2 while those of MT1-MMP were strongly induced [41]. LPS was also able to boost the release of several chemokines, including IL-6 and TNF-α in AD-MSCs. Hypoxia has been shown to elevate the secretion of VEGF, IGF-1, SDF-1, MIP-1α, MIP-1β, and erythropoietin in BM-MSCs, and VEGF, but not FGF-2, secretion by human DPSCs [30,120]. In AD-MSCs, hypoxia selectively increased VEGF, but not FGF, HGF, or TGF-β, mRNA and protein levels in AD-MSCs [30].

Oskowitz *et al.* showed that serum deprivation for 30 days induced the release of VEGF, HGF, IGF-1, and angiogenin by human BM-MSCs. CM of these serum-deprived cells generated longer neovascular sprouts in the *ex vivo* aortic ring assay compared with CM of control BM-MSCs [68].

## 25.6 Transdifferentiation of mesenchymal stem/stromal cells towards endothelial cells

The rate of *in vivo* engraftment of MSCs within the blood vessels remains very low in most settings. This is the basis of the assumption that the angiogenic effect of MSCs is predominantly caused by their paracrine actions rather than their EC transdifferentiation potential (Figure 25.3). In 2003, Al-Khaldi *et al.* demonstrated with LacZ transgenic BM-MSCs in the mouse Matrigel plug assay that over 99% of the generated blood vessels originated from host-derived ECs and that transdifferentiation of BM-MSCs toward ECs in that setting was very rare. In addition, only 10% of injected BM-MSCs were found in close proximity to, or in, blood vessels [70]. Another study using $GFP^+$ BM-MSCs in the treatment of wounds in diabetic $GFP^-$ mice showed that the rate of MSC engraftment 28 days after injection was less than 1%, and again no participation of the transplanted $GFP^+$ BM-MSCs into the recipients' vasculature was observed [26]. Although the low engraftment of MSCs in most settings and the lack of incorporation into recipient blood vessels is widely described, it cannot excluded that in particular settings or time frames the EC differentiation of MSCs may exist. A study by Yue *et al.* in which rat BM-MSCs were injected in a rat vein grafting model showed that the injected 4′,6-diamidino-2-phenylindole-labeled BM-MSCs differentiated into ECs 2 weeks after transplantation were capable of adhering to the injured vascular wall and showed immunopositivity for CD31 and endothelial nitric oxide synthase [147].

Despite the fact that differentiation of MSCs toward ECs especially *in vivo* remains a controversial subject, numerous attempts have been made to skew MSCs towards EC transdifferentiation (summarized in Table 25.2). MSC commitment to EC is usually demonstrated by the upregulation of typical EC surface molecules such as CD31, CD34, VEGFR1, VEGFR2, and vWF. Functional tests performed include *in vitro* tube formation in Matrigel and uptake of acetylated low-density lipoproteins (Ac-LDLs), although macrophages are also able to internalize these molecules [168]. Based only on these commonly used *in vitro* assays, it may be inaccurate to designate such differentiated MSCs as fully mature and functional ECs. It is more correct to describe these cells as EC-like cells. Although the *in vitro* differentiation approaches listed in Table 25.2 demonstrate indications for EC-like characteristics, such as EC marker expression, Matrigel tube formation, and Ac-LDL uptake, there is very little evidence that shows morphological and ultrastructural evidence of EC transdifferentiation. For example, the presence of typical EC characteristics such as Weibel–Palade bodies and tight junctions, which can be demonstrated by transmission electron microscopy, have never been reported for EC-directed MSCs except in the study by Jazayeri *et al.* [153]. Additionally, there is also no evidence that links the use of these EC-like MSCs in an *in vivo* setting with functional nonleaking blood vessels.

Attempts to differentiate MSCs to ECs using VEGF have been widely described (see Table 25.2) Several reports claimed EC differentiation of MSCs with increased expression of EC markers such as VEGFR1, VEGFR2, VE-cadherin, vascular cell adhesion molecule 1, and vWF and increased formation of capillary-like tubes in an *in vitro* Matrigel assay [69,153,155,156,166]. In contrast, Roobrouck *et al.* demonstrated that incubation of human BM-MSCs in basal medium containing VEGF significantly increased mRNA expression of CD34, VEGFR1, and VEGFR2, but not of TIE-2 or vWF, and the mRNA level of CD31 was even decreased. These BM-MSCs did not form a tubular network when plated onto Matrigel *in vitro*, thereby failing the functional test of full EC differentiation [72].

In addition to molecular mediators such as VEGF and Notch, physical cues have also been investigated for their ability to transdifferentiate MSCs to ECs. Such tools include mechanical stimuli [169], shear stress [149,160], and seeding the cells on elastic nanofiber hydrogels [170] or on to three-dimensional matrices [171,172]; and see Chapter 8. For example, placenta-derived MSCs subjected to shear stress for 24 h showed a significant increase in vWF and PECAM-1 expression, LDL uptake, and Matrigel tube formation [173].

Although the evidence for full differentiation of MSCs to ECs *in vitro* and *in vivo* is debatable, preconditioning MSCs in the so-called EC differentiation medium may still be valuable as this pretreatment might transform the MSCs toward a more angiogenic cell type. For example, placental MSCs preincubated with 50 ng/mL of VEGF displayed higher angiogenic activity than normal placental MSCs in the CAM assay [69]. AD-MSCs treated with an EC growth medium EGM-2 secreted higher amounts of Ang-1, promoted HUVEC migration, and significantly suppressed neointimal formation in a wire injury model of the rat femoral artery compared with control AD-MSCs [148]. Neointimal hyperplasia refers to the proliferation and migration of vascular smooth muscle cells primarily in the tunica intima, resulting in the thickening of arterial walls and decreased arterial lumen space. Neointimal hyperplasia is the major cause of restenosis after percutaneous coronary interventions such as stenting or angioplasty. The term neointima is used because the cells in the hyperplastic regions of the vascular wall have histological characteristics of both intima and normal artery cells.

## 25.7 Conclusions, therapeutic expectations, and challenges

During the last few years intensive research has led to the identification of a multitude of bioactive angiogenic molecules, such as VEGF, FGF-2, and MCP-1 in the CM of MSCs. In addition, the role of MSCs in several key events of angiogenesis, such as EC proliferation, tube formation, and stabilization, has been unraveled. MSCs from an ever-growing list of tissue sources have been shown to induce angiogenesis in various *in vitro* and

**Table 25.2** Different protocols of *in vitro* MSC differentiation toward cells with EC-like features.

| MSC type | Reference | Incubation time (days) | Differentiation medium |
|---|---|---|---|
| AD-MSC | [148] | 7 | EGM-2 + 5% FCS |
| | [149] | 18 | ECGS (14 days) + shear stress (4 days) |
| | [77] | 2 | On Matrigel, EGM-2 + 50 ng/mL VEGF + 10 ng/mL FGF-2 |
| | [150] | 12 | EGM-2 BulletKit (without the FGF-2) + ITS + 10 ng/mL FGF-2 |
| AM-MSC | [151] | 7 | 2%FCS and 50 ng/mL VEGF |
| BM-MSC | [152] | 12 | 5% FCS + 100 ng/mL VEGF + 50 ng/mL EGF + 1 μg/mL hydrocortisone |
| | [153] | 5 | 5% FCS, 50 ng/mL VEGF, and 20 ng/mL IGF-1 |
| | [154] | 21 | EGF + VEGF + hydrocortisone |
| | [155] | 21 | EGM-2 + 2% FCS |
| | [156] | 7 | 2% FCS + 50 ng/mL VEGF |
| | [157] | 11 | EGM-2 + shear stress (10 days) + 1 day on Matrigel |
| | [72] | 14 | Basal medium + 100 ng/mL VEGF |
| | [158] | 14 or 28 | Basal medium |
| | [159] | 21 | 5% FCS + 50 ng/mL VEGF |
| | [70] | 14 | 10% FCS, 50 ng/mL VEGF |
| | [160] | 7 | VEGF alone |
| | [160] | 8 | Shear stress (24 h) + VEGF (7 days) |
| | [161] | 5 | Co-culture with rabbit EC |
| | [162] | 7 | 2% FCS + 0.5 μM simvastatin |
| | [163] | 10 | EGM-2 + 50 ng/mL VEGF |
| DPSC | [78] | 10 | On Matrigel, EGM-2 |
| | [78] | 3 | EBM-2 + 2% serum + 10 ng/mL VEGF + 10 ng/mL FGF-2 |
| | [164] | 10 | 10% FCS + 1% ITS + 20 ng/mL VEGF |
| | [165] | 7 | 2% FCS and 50 ng/mL VEGF |
| DPSC-SHED | [166] | 28 | EGM-2 + 50 ng/mL VEGF |
| Placental MSC | [69] | 21 | EGM-2 + 2% FCS + 50 ng/mL VEGF |
| UM-MSC | [167] | 21 | EGF + VEGF + hydrocortisone |
| WJ-MSC | [152] | 12 | 5% FCS + 100 ng/mL VEGF + 50 ng/mL EGF + 1 μg/mL hydrocortisone |

*in vivo* models, and their promising preclinical potential has already been translated into successful phase I and II trials.

Some major hurdles remain, especially with regard to the heterogeneity of MSCs and the variability of their isolation and expansion protocols. The discovery of a unique and unambiguous MSC marker would be useful. Advances in cell labeling and imaging techniques should help resolve questions concerning homing and engrafting of administered MSCs. Large-scale production of MSCs in serum-free conditions in closed-system bioreactors is an important goal.

For angiogenesis-related diseases the paracrine actions of MSCs account for most of their observed therapeutic effect. The CM of MSCs may theoretically be able to substitute for the cells themselves, but it is likely that the interactions between MSCs and the injured target tissue are extremely complex with multiple cell-to-cell interactions and a number of mechanisms by which therapeutic benefit occurs taking place, making it unlikely that a soup of proteins will be an adequate substitute.

The occurrence and role of MSC-derived miRNAs involved in angiogenesis is currently relatively unexplored territory and warrants further examination.

In conclusion, in recent years significant advances have been made in unravelling the angiogenic capacities of MSCs. This is illustrated by successful application of MSCs and neovascularization in a wide variety of *in vivo* preclinical models of AMI, stroke, critical limb ischemia, and wound healing, resulting in an increasing optimism of both basic scientists and clinicians [29,32,37,151,166].

## 26.1 Introduction

Mesenchymal stromal cells (MSCs) are considered important adult stem/stromal cells with a potential therapeutic role in a variety of diseases. In this context, bilateral interactions between MSCs and endothelial cells (ECs) are deemed to be of strategic relevance for the regulation of MSC function under physiologic and pathologic circumstances. Indeed, different and sometimes opposite roles are observed when MSCs are used for apparently similar purposes, in which MSC–EC interactions determine the kind of MSC behavior. For example, both stimulatory and inhibitory effects have been noted when MSCs were used for angiogenesis purposes. Understanding the molecular mechanisms that are involved in the relationship between MSCs and ECs will help to optimize therapeutic applications of these cells in regenerative medicine. In this chapter we attempt to shed further light on mechanisms of MSC–EC interactions in different physiological and pathological conditions and under specific spatiotemporal situations.

## 26.2 Transendothelial migration of mesenchymal stromal cells

### 26.2.1 Mesenchymal stromal cell adhesion to endothelial cells

An important issue is to how best to deliver MSCs to their target tissues. A number of different routes have been used, including direct administration into injured tissue and systemic administration in both preclinical animal studies and in clinical trials [1,2]. However, the precise molecular mechanisms by which MSCs migrate into their target tissues have not yet been fully elucidated.

A number of experimental studies have been conducted in an effort to illuminate the essential features of MSC trafficking and biodistribution into intact and injured tissues. It has been demonstrated that MSCs can adhere to the endothelium and extravasate at the site of inflammation by a leukocyte-like

mechanism directed by an interaction between MSCs and ECs through selectin-mediated rolling, chemokine-derived retention, and integrin-dependent arrest on the endothelium [3,4]. There is a complex interplay between MSCs and ECs in different conditions [5]. It has been well established *in vivo* and *in vitro* that MSCs and ECs are able to influence the behavior of each other via ligand–receptor interactions [6].

A vast array of cell surface transmembrane molecules, such as integrins, is involved in MSC–EC adhesion during migration and homing of MSCs to the site of injury [7]. Integrins, as eukaryotic cell surface receptors, consist of heterodimers of α and β subunits, in which eight different α chains ($\alpha_1$ to $\alpha_8$) interact with at least 16 different β subunits ($\beta_1$ to $\beta_{16}$) to constitute approximately 22 different α–β heterodimers with different functions [8]. Each subunit contains a large extracellular and a small cytoplasmic domain [8]. The α–β heterodimer complexes with cell-membrane-spanning domains mediate dynamic cell–matrix and cell–cell linkages capable of transmitting inside-out and outside-in signals, which ultimately regulate numerous cellular responses and downstream signaling events such as cell growth, differentiation, and survival [9,10].

It has been shown that MSCs express several β ($\beta_1$ to $\beta_3$) and α ($\alpha_1$ to $\alpha_6$, and $\alpha_V$) subunits of integrins (see Figure 26.1A). On reaching confluency in cell culture, MSC expression of $\beta_3$, $\alpha_1$, $\alpha_3$, $\alpha_5$, and $\alpha_V$ integrins is increased, whereas the expression of $\alpha_6$ is decreased [7] (Figure 26.1A).

Specific integrins play a role in the adhesion of MSCs to a variety of human vascular ECs, including pulmonary arteries ($\beta_1$, $\alpha_V$, and $\alpha_X$), cardiac-derived microvasculature ($\beta_2$, $\alpha_X$, $\alpha_7$, and $\alpha_D$), and umbilical veins ($\beta_1$, $\beta_2$, and $\beta_3$) (Figure 26.1B). Neutralizing antibodies against the integrins of the β subclass can reduce MSC adherence to all the types of ECs mentioned here [7]. Moreover, selective blockade of integrin $\beta_1$ by specific neutralizing antibodies resulted in a significant reduction in the total number of MSCs in a preclinical model of myocardial infarction [11]. It has also been demonstrated that osteopontin-induced rat MSCs specifically required integrin $\beta_1$ for migration to different tissues in response to injury and inflammation [12]. The authors showed that osteopontin promoted integrin $\beta_1$ expression by MSCs in a concentration-dependent manner. Another study by Veevers-Lowe *et al.* showed that crosstalk between extracellular matrix (ECM)-associated receptors and distinct integrins on MSCs participated in the oriented migration of MSCs [13]. $\alpha_5\beta_1$ integrin adhesion to ECM components, especially fibronectin, triggered MSC migration via activating platelet-derived growth factor receptor (PDGFR)-β signaling with simultaneous focal adhesion kinase (FAK)-dependent phosphatidylinositide 3-kinase (PI3K) activation, actin reorganization, and membrane ruffling in MSCs, which occurred even in the absence of growth factor stimulation [13]. In this context, phosphorylated PDGFR-β accumulated in the leading edge of MSCs and temporarily co-localized with $\alpha_5\beta_1$-integrin at the apex of focal adhesion. The authors concluded that fibronectin-rich matrices might prepare PDGFR-β to recruit MSCs to sites of vascular remodeling [13]. Integrin-dependent intracellular signaling was also thought to be induced in leukemic cells in an MSC–leukemic cell co-culture system, which was mediated by integrin-linked kinase that phosphorylated Akt in a PI3K-dependent manner [14].

Among cell-adhesion-related molecules the Notch signaling axis has been shown to be critically important in direct cell–cell communication, which is essential for the regulated proliferation, apoptosis and fate decision of stem/progenitor cells during development [15]. Notch receptors Notch-1 to -4 are type I transmembrane proteins, with five structurally similar ligands: Delta-like-1, -3, -4 (DLL-1, DLL-3, DLL-4) and Jagged-1 and Jagged-2. Jagged-1 and Jagged-2 are other types of ligand/receptors that provoke MSC–EC interaction [16] (Figure 26.1B). The Notch-1, -2, and -3 receptors and the Jagged-1 ligand were shown to be expressed at significant levels in MSCs [16]. Notch-1 was found to increase the proliferation (documented by more Ki-$67^+$ cells and less cleaved Caspase$3^+$ apoptotic cells). In addition, it recruited MSCs to infarcted murine myocardium [17]. Xie *et al.* found that blocking Notch signaling by knockout of the transcription factor recombination signal binding protein-J (RBP-J) contributed to the upregulation of CXCR4 expression in MSCs and increased MSC migration in response to stromal cell-derived factor (SDF)-1α both *in vitro* and *in vivo* [18]. RBP-J is a DNA-binding protein that is a signal mediator from the Notch receptors after association with the Notch intracellular domain, or inhibition of y-secretase, an enzyme that releases RBP-J by a proteolytic mechanism upon triggering of the receptor. Notch signaling played a critical role in the recruitment of bone marrow MSCs to ischemic myocardium, which was essential for cardiac repair [19]. Bone marrow transplantation from mice with a hemizygous deletion of Notch-1 into normal mice resulted in a larger infarct size with reduction of recruitment, proliferation, and survival of MSCs [19].

The activation of MSCs by tumor necrosis factor (TNF)-α and interleukin (IL)-1 treatment before their injection significantly enhanced adhesion to the cardiac endothelium and promoted the homing of MSCs via intercellular cell adhesion molecule (ICAM)-1/lymphocyte function-associated antigen 1 (LFA-1) and G protein-coupled receptor signaling [4,20,21] (Figure 26.1B). Pretreatment of murine MSCs with interferon-γ (INF-γ) prior to intraperitoneal administration enhanced cell recruitment, possibly through upregulation of constitutively expressed chemokines and chemokine receptors, and alleviated the complications of experimentally induced colitis in mice [22,23]. It was demonstrated that MSCs underwent coordinated rolling on ECs and then adhered to ECs under shear flow by the mediation of selectins [24]. The authors reported that preincubation of human umbilical vein ECs (HUVECs) with a blocking antibody against P-selectin strongly decreased MSC binding to ECs, indicating that MSCs might bind to P-selectin using a fucose and sialic-acid-containing ligand [24]. As human MSCs do not express detectable levels of P-selectin glycoprotein ligand 1 (PSGL-1) and preincubation of MSCs with the antibody against

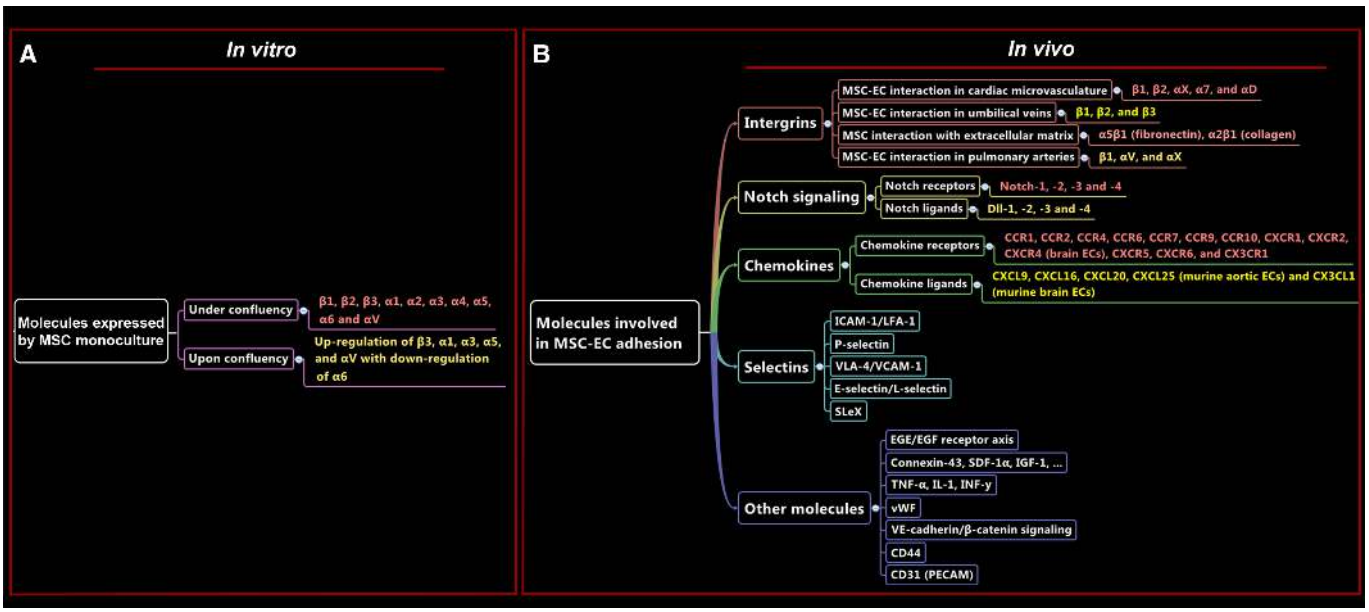

**Figure 26.1** (A) Molecules involved in MSC–EC interactions. A series of integrins are expressed by MSCs in *in vitro* culture conditions. (B) Within the body a large number of ligands and cognate receptors, including selectins, integrins, chemokines, and various signaling pathways, are involved in MSC–EC interactions in different physiological and pathological conditions. (See color plate section.)

PSGL-1 did not block the binding of MSCs to the surface of ECs, P-selectin-mediated MSC–EC binding appears to be independent of PSGL-1 [25]. Preincubation of ECs with anti-VCAM-1 (VCAM-1: vascular cell adhesion molecule 1) or of MSCs with anti-VLA-4 (VLA-4: very late activation antigen-4) prevented the adhesion of MSCs to ECs [24]. The authors concluded that MSCs bound to ECs in a P-selectin-dependent manner both *in vitro* and *in vivo*, and that CD44 along with VLA-4/VCAM-1 was engaged in the rolling of MSCs on ECs [25,26]. In support of these findings, coating the surface of MSCs with selectin-associated ligands such as sialyl Lewis X reduced the rolling velocity of these cells on an inflamed endothelial surface and enhanced the homing capacity of MSCs to the inflamed tissue [27].

Additionally, an increase in the level of expression of the cell surface molecule CD44, which is the receptor for hyaluronic acid, by platelet-derived growth factor (PDGF) stimulation of MSCs facilitated the migration of these cells through interaction with extracellular hyaluronic acid [28]. In addition, MSCs engineered with P- or L-selectin-binding nucleic acid aptamers efficiently adhered to the respective selectin surfaces of ECs and leukocytes [24]. (Aptamers are oligonucleotide or peptide molecules that bind to a specific target molecule.)

Sackstein *et al.* reported that a CD44 glycoform bearing α-2, 3-sialyl modifications was expressed on human MSCs but that these cells lacked E-selectin ligands and CXCR4, which limited tropism to bone tissue [29]. Modification of native CD44 to convert this molecule into an E-selectin/L-selectin ligand conferred potent binding capacity and tropism to bone via E-selectin-expressing marrow blood vessels [29].

Potapova *et al.* [30] demonstrated that treatment of ECs with von Willebrand factor (vWF) resulted in activation of intracellular downstream extracellular signal-regulated kinase (ERK)-1, −2, and p38 mitogen-activated protein kinase (MAPK) pathways with no effect on the gene or cell surface expression of E-selectin, P-selectin, VCAM-1, or ICAM-1. They showed that the activation of p38 MAPK in ECs by vWF could instigate MSC–EC adhesion [30]. VCAM-1/VLA-4 as well as $\beta_1$ integrins and matrix metalloproteinase (MMP)-2 play key roles in the trans-endothelial migration of MSCs [30] (Figure 26.1B). Moreover, lumican, a 37 kDa core protein proteoglycan belonging to the small leucine-rich proteoglycans family, was shown to inhibit MSC migration by a concomitant decrease of MMP-14 expression and activity, whereas the overexpression of MMP-14 improved the migratory potential of human MSCs *in vitro* [31]. Adding MSCs to EC tubes on Matrigel resulted in MSC–EC intercalation via development of connexin-43-based intercellular gap junctions [32]. Some MSC-derived secretory soluble factors, such as SDF-1α and insulin-like growth factor (IGF)-1, upregulated connexin-43 and facilitated the functional mobilization of MSCs into target tissues [33].

### 26.2.2 Trans-endothelial migration

A critical step for the successful recruitment and engraftment of systemically infused MSCs into damaged tissues is trans-endothelial migration. The exit of MSCs from the circulation requires their crossing the endothelial barrier posed by the vessel wall [4]. Moreover, the recruitment of tissue-specific MSCs (e.g., MSCs residing within the bone marrow) requires early entry into the circulation (intravasation) and subsequent transmigration across the endothelial barrier into inflamed or ischemic tissues (extravasation) [34]. Understanding bidirectional signaling cascades that regulate intravasation and extravasation during the trans-endothelial migration of MSCs will be helpful for optimization of the therapeutic use of MSCs.

The firm adhesion of MSCs to ECs is followed by endothelial transmigration via platelet-EC adhesion molecule-1 (PECAM-1/CD31), junctional adhesion molecules, and cadherins [4,35,36]. PECAM-1, a member of the immunoglobulin gene superfamily, is expressed on the surface of ECs, platelets, and hematopoietic cells and plays a pivotal role in leukocyte extravasation, modulation of integrin activity on leukocytes and T cells, and in angiogenesis [37]. Vascular endothelial cadherin (VE-cadherin)–β-catenin interaction with concurrent localization of PECAM-1 at the site of the cell–cell junction is essential for normal functioning of PECAM-1-derived signaling [38] (see Figure 26.1B). VE-cadherin is a key molecule responsible for the formation of strong intercellular junctions between ECs and connects to the underlying actin cytoskeleton through cytoplasmic interactions with the armadillo family proteins β-catenin, γ-catenin, and α-catenin [39].

As with leukocytes, MSCs transmigrate by a para-cellular route (between ECs) and by a trans-cellular route (directly through individual ECs). This diapedesis occurs through discrete pores and gaps in the endothelial monolayer mediated by VCAM-1-enriched trans-migratory cups [4]. Both lamellipodia (which are flattened cellular extensions on the cell surface) and invadosomes (which constitute a dot-like accumulation of filamentous actin at the site of cell–matrix contact) are involved in the trans-migratory process of MSCs [40]. However, unlike leukocytes, nonapoptotic membrane blebbing was also evident, as has been described in metastatic tumors [4]. Schmidt *et al.* observed that MSCs have a unique potency for abolishing, limbering, and splitting tight junctions between ECs during extravasation [41]. Using the MSC–EC co-culture system these authors showed that MSCs, after seeding on to an endothelial monolayer, became round and displayed cytoplasmic offshoots into the EC monolayer within 30 min, leading to the obliteration of tight junctions between ECs and the subsequent development of tight cell–cell contacts between MSCs and ECs with eventual trans-endothelial migration of MSCs. They also showed that connexin-43 had a key role in EC–MSC communication [41].

Chemokines are other adhesion-related molecules that are also involved in the trans-endothelial migration of MSCs (Figure 26.1B). These molecules are secreted in response to a number of signals, including proinflammatory cytokines, and are thought to bind glycosaminoglycans on ECs [42]. It is believed that sulfation of tyrosine residues in N-terminal regions of chemokine receptors occurs after interaction with their

corresponding ligands [43]. Chemokine receptors are G-protein-coupled receptors for CXC, CC, C, or CX3C chemokines. MSCs were found to express CCR1, CCR2, CCR4, CCR6, CCR7, CCR9, CCR10, CXCR1, CXCR2, CXCR4, CXCR5, CXCR6, and CX3CR1 receptors and to secrete a variety of chemokines [44–46]. It has been demonstrated that chemokine receptors and their ligands have an indispensable role in the migration of murine (m) MSCs across murine aortic ECs (MAECs) and that both chemokine stimulation and shear stress enhanced the trans-endothelial migration of mMSCs across MAECs [26]. At first, murine MSCs extended fine microvillous processes called filopodia and then extended pseudopodia in multiple directions. Subsequently, CXCL9, CXCL16, CCL20, and CCL25 ligands improved trans-endothelial migration across MAECs and shear forces markedly stimulated the crawling and spreading of the MSCs [26]. Fractalkine (CX3CL1) and its receptor CX3CR1, concomitant with the SDF-1/CXCR4 axis, governed the trafficking of transplanted MSCs into brain injuries [44] (Figure 26.1B). Flow cytometry analysis of brain biopsy samples from rats that had received an intracerebral injection of SDF-1α indicated an enhanced accumulation of 5(6)-carboxyfluorescein diacetate succinimidyl ester (CFDA-SE)-labeled MSCs in the cerebral cortex [44]. Simultaneously, a significant increase in CXCR4 expression was evident by reverse transcription polymerase chain reaction analysis [44].

The ECM is a highly dynamic structure with an intricate network of proteins and serves a multitude of functions of biological significance, including the reciprocal interactions of cells with individual molecules during cell attachment, growth, migration, and apoptosis, as well as providing structural support of cells [47,48]. It has been documented that each ECM component imposes a battery of specific biological effects on MSCs. For example, fibronectin facilitates migration, adhesion, and proliferation, whereas fibrinogen augments adhesion and proliferation, but not migration [49] (Figure 26.1B). Xiao *et al.* showed that interaction between $\alpha_2\beta_1$ on MSCs and the collagen component of ECM instigated osteoblastic differentiation of MSCs via the MAPK pathway [50]. Interestingly, the integrin expression pattern of MSCs is related to specific cell behavior on specific ECM components [49]. In addition to direct MSC–EC crosstalk via receptor–ligand interactions, ECM also directs MSC migration during vascular remodeling [13].

In an *in vitro* model the epidermal growth factor (EGF)/EGF receptor axis and relevant downstream signaling pathways such as ERK, Akt, and FAK phosphoproteins also increased MSC migration [51]. MSCs also participate in an electrotaxis process and respond to endogenous electric fields, which occur naturally in healing wounds, especially bone injuries [52].

In addition to the role of ECs in the extravasation of MSCs, MSCs in turn contribute to the growth of ECs by developing EC–MSC islets via the secretion of proteases [53]. During myocardial infarction and in other inflammatory conditions, endothelial nitric oxide synthase (eNOS)-derived nitric oxide (NO) production, and subsequent PI3K/protein kinase B (Akt)/eNOS downstream signaling and MMP-9 activation triggered MSC as well as endothelial progenitor cell (EPC) migration to target tissues [54].

## 26.3 Mesenchymal stromal cell–endothelial cell crosstalk in angiogenesis

Various types of MSC–EC three-dimensional (3D) co-culture systems and *in vivo* models have revealed extensive cellular crosstalk during endothelial angiogenesis through a variety of mechanisms. This process is exquisitely controlled by cell–cell connections, paracrine and juxtacrine interactions, or microvesicle trafficking between the MSC and EC lineages, leading to modulation of the angiogenic response [2,55–58] (Figure 26.2).

### 26.3.1 Juxtacrine interactions of mesenchymal stromal cells and endothelial cells

In an *in vitro* Matrigel assay using rat and human MSC–EC co-culture systems, self-assembled and elongated tube-like structures were developed by intimate MSC–EC contact soon after seeding on Matrigel. Subsequently, an endothelial phenotype was induced in co-aligned MSCs via VEGF-dependent signaling and then activation of the Rho/ROCK pathway [57,59] (Figure 26.2). In this context, Rho, as a molecular switch, transmits signals from cell surface receptors to its effector protein ROCK, a Rho-associated kinase enzyme, which in turn contributes to the phosphorylation of LIM-kinase and the actin-regulatory protein Cofilin, eventually leading to the rearrangement of the actin cytoskeleton [60,61]. Blocking the RhoA/ROCK pathway by its relevant inhibitor, Y-27632, abrogated VEGF-mediated activation of ECs, disrupted tube formation on Matrigel, and reduced CD31 expression in ECs [62]. Intriguingly, the key modulatory effect of the RhoA/ROCK pathway in MSC orientation, elongation, alignment, and contact guidance was also determined on a patterned nanometric surface [63]. A number of studies have shown a significant upregulation in Rho activity during the development of a new cell adhesion, whereas its activity is downregulated in stably adhered cells [64]. Additionally, ROCK activity was shown to play a role during transmigration of MSCs from the brain endothelial barrier [65].

A pericyte-like function has been reported for MSCs *in vitro* and *in vivo* conditions during vascular network formation and stabilization through direct contact with ECs [66–68]. The SLIT3/ROBO4 (roundabout homolog 4, also known as magic roundabout) signaling pathway, as also described in pericytes, was activated when MSCs were juxtaposed and co-aligned with ECs in a co-culture system [69] (Figure 26.2). It has been reported that downregulation of VEGF receptor (VEGFR) occurred immediately after activation of ROBO4 [70]. Seeding of human ECs and MSCs on to poly(L-lactide-co-1,5-dioxepan-2-one) scaffold in a 5 : 1 ratio increased Ang-1 and perivascular gene

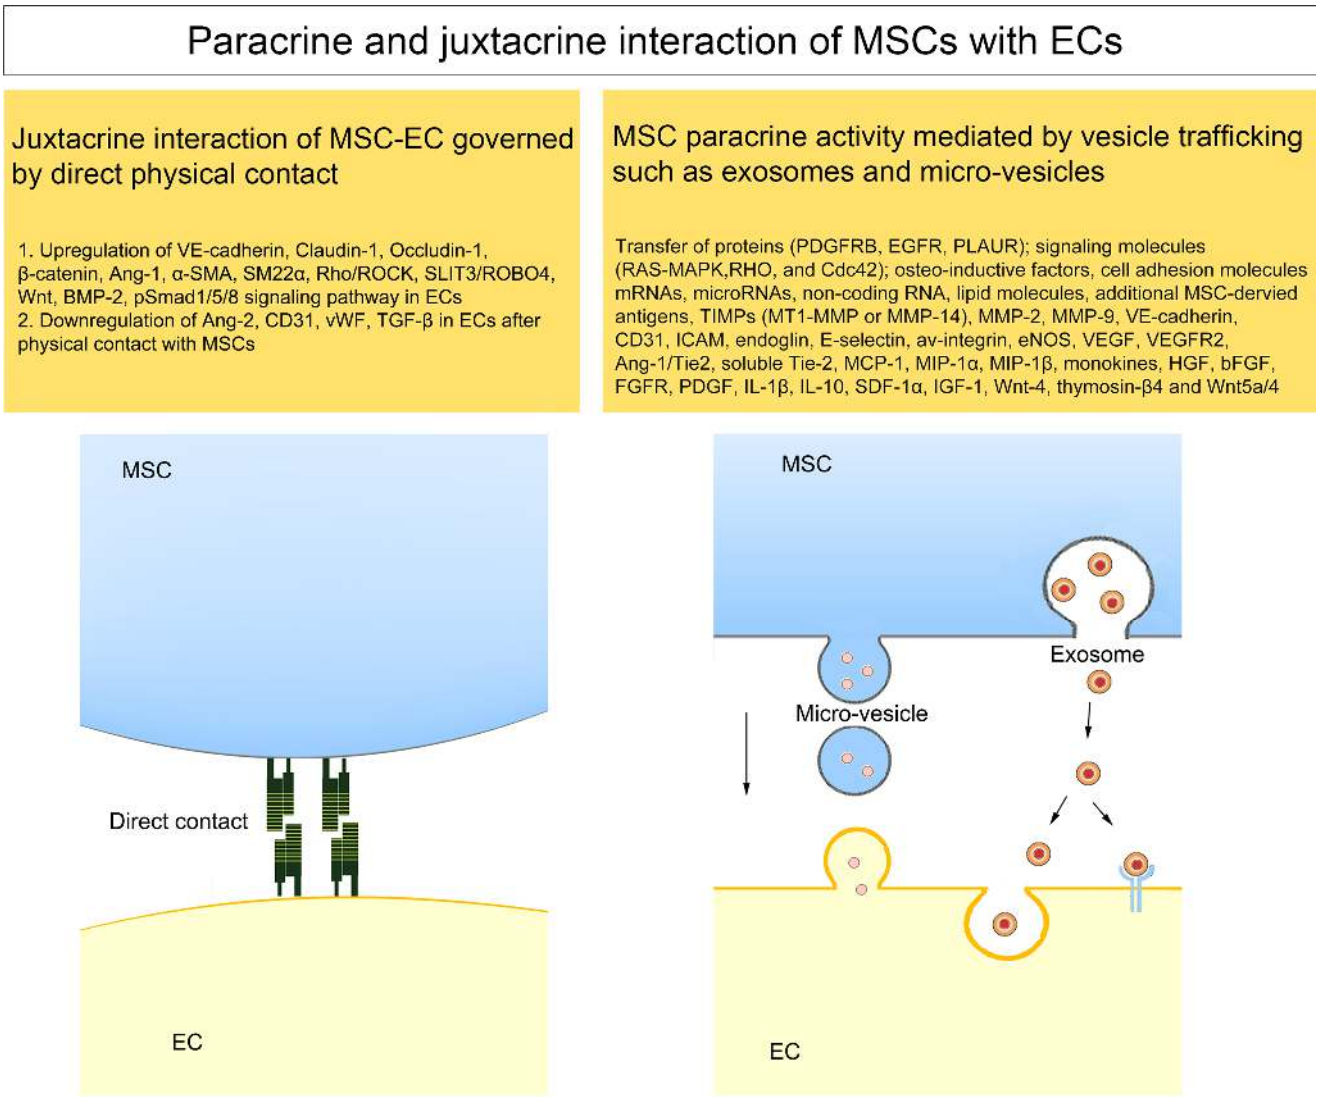

**Figure 26.2** MSC–EC interactions occur via different juxtacrine and paracrine mechanisms. A variety of signaling molecules participate in juxtacrine interaction between MSCs and ECs. In addition, many molecules are transferred between MSCs and ECs in a paracrine manner through vesicle trafficking, such as exosomes and microvesicles. Ang: angiopoietin; bFGF: basic fibroblast growth factor; Cdc42: cell division control 42; EGFR: endothelial growth factor receptor; FGFR: fibroblast growth factor receptor; HGF: hepatocyte growth factor; MCP-1: monocyte chemoattractant protein-1; MIP: macrophage inflammatory protein; PDGFR: platelet-derived growth factor receptor; PLAUR: urokinase-type plasminogen activator receptor; Tie-2: tyrosine kinase with immunoglobulin-like and EGF-like domains 2; TIMPs: tissue inhibitors of MMPs; VEGF: vascular endothelial growth factor; VEGF receptor (VEGFR)2.

expression, such as α-smooth muscle actin (α-SMA) and SM22α, whereas a pronounced reduction in Ang-2, CD31, and vWF was apparent [71]. Moreover, MSCs that expressed stemness markers, such as CD146, Sca-1, and PDGFRα, were identified in close proximity to vessels with a propensity to express the pericyte-like markers NG2, CD146, and PDGFRβ. It has been demonstrated that $CD146^+$ pericytes represent a subpopulation of bone marrow MSCs that supports neoangiogenesis [72]. *In vivo* perivascular homing of MSCs along the vessel wall was observed after intravenous injection of MSCs in an ischemic murine skin flap model [73]. *In vivo* co-implantation of MSCs isolated from four murine tissues – bone marrow, white adipose tissue, skeletal muscle, and myocardium – with human blood-derived endothelial colony-forming cells led to the development of a complex network of blood vessels with ECs lining the lumens and MSCs present in the perivascular space immediately adjacent to the luminal structures [74]. Immunofluorescence assays by our group revealed the localization of green-fluorescent-protein-labeled rabbit bone-marrow-derived MSCs both in the lumen and in the wall of newly formed microvessels after injection of these cells into the border zone of infarcted myocardium [2]. The existence of MSCs in the peri-endothelial space highlights that the endothelium, as an important component of the MSC niche, can regulate the biological activity of MSCs [75–77].

MSC-derived spindle-shaped myofibroblastoid cells containing organized smooth muscle α-actin filaments were also detected in the EC–MSC co-culture [78]. With respect to intracellular signaling, HUVECs, in a 3D spheroid co-culture system, activated endogenous Wnt as well as bone morphogenetic protein (BMP) signaling in human MSCs with an increased level of nuclear β-catenin and pSmad1/5/8 under osteogenic conditions [79] (Figure 26.2). MSC–EC interaction resulted in the expression and co-localization of VE-cadherin and β-catenin at the cell membrane, vascular tube breakdown, and inhibition of endothelial permeability with the preservation of VE-cadherin, Claudin-1, and Occludin-1 in pulmonary ECs in a rat model of hemorrhagic shock-induced acute lung injury [80] as well as in an *in vitro* study using a human MSC–EC co-culture system [81,82] (Figure 26.2). As the soluble modulator of Wnt signaling, secreted frizzled-related protein (sFRP)-1 upregulated PDGF-BB in murine MSCs and facilitated β-catenin-dependent MSC–MSC, MSC–EC, and MSC–smooth muscle cell adhesions *in vitro* [83]. After subcutaneous injection of MSCs mixed with Matrigel in mice this pathway in turn triggered MSC glycogen-synthase-kinase-3β-dependent induction of angiogenesis along with vessel maturation and functionality, but not endothelial differentiation of MSCs [83,84]. Other studies have implicated sFRP-2 as a key molecule for the regenerative potential of murine MSCs following their transplantation into myocardial infarction tissue [85]. Likewise, specific knockdown of sFRP-2 in murine MSCs decreased the MSC engraftment and vascular density in the tissue [85].

The proliferation rate of rat MSCs was reportedly reduced in MSC–EC co-culture as a result of the downregulation of a number of growth factors, particularly in members of the TGF-β family [55]. Duffy *et al.*, however, showed that human MSCs increased aortic EC proliferation in a noncontact co-culture system [86]. Bidarra *et al.* reported that human MSC–EC co-culture not only augmented the proliferation of MSCs but also triggered osteogenic differentiation via ECs-dependent BMP-2 signaling [87]. These authors used three ratios of MSC : EC (3 : 1, 1 : 1, and 1 : 3) and found that the relative number of ECs declined over time in all cell ratios, with the highest percentage of MSC : EC ratio (3 : 1) resulting in the lowest relative number of ECs. However, when rat MSCs were added to rat lung microvascular EC-derived capillaries on Matrigel at EC : MSC ratios of 1 : 1 or 3 : 1, degeneration of the capillaries was evident due to the production of reactive oxygen species by MSCs [32]. Such discrepancies may be partly related to culture conditions and difference in the origin of cells [87]. Adding human MSCs at increasing doses from 1 : 10 to 1 : 1 MSC : EC ratio, in order to pre-establish a human aortic endothelial lattice on Matrigel, resulted in a proportional increase in the thickness of vessel-like structures as well as in the size of junctions. In contrast, the addition of MSCs prior to EC seeding on Matrigel resulted in EC bunching and loss of lattice formation [86]. Thus, the addition of MSCs to the fully formed endothelial lattice led to the stabilization and maturation of pre-established vessel-like structures, whereas MSCs prompted EC migration and bunching at early time points during vessel formation [86,87].

Overall, it appears that the inhibitory or stimulatory effect of MSCs on the behavior of ECs on Matrigel is dependent not only on the MSC : EC ratio in co-culture systems, but also on the sequence of cell addition in different co-culture experiments. Distinct signaling mechanisms can change cell–cell ratios. An example is during development of the thymus, where change in the intrathymic CD4 : CD8 cell ratio from the fetal to adult thymus occurred as a result of differential expression of Notch signaling molecules by thymic stromal cells [88]. A change in cell : cell ratios may also activate distinct signaling mechanisms, with subsequent development of different phenotypic and genotypic profiles.

### 26.3.2 Paracrine interactions of mesenchymal stromal cells and endothelial cells

MSCs have a dynamic effect on their microenvironment through production of a variety of biomolecules, including cytokines, chemokines, growth factors, and ECM molecules in a paracrine (on nearby cells) or autocrine (on the same cell that secreted the molecule) manner (Figure 26.2). Among this heterogeneous mixture of proteins, a variety of proangiogenic, immunosuppressive, anti-inflammatory, and antifibrotic factors together with ECM homeostasis regulators, such as several types of collagens, as well as TIMPs, have been detected [89].

Membrane-derived or extracellular vesicles are important mediators of intercellular communication essential for exchanging information and transmission of biological signals, and now designated the signalosome [90] (Figure 26.2). Three classes of extracellular vesicles have been described: exosomes, microvesicles, and apoptotic bodies [90] (and see Chapters 20 and 38). Exosomes and microvesicles are enclosed by a lipid bilayer and constructed from the inward budding of an endosomal membrane and from budding of the plasma membrane respectively [90,91]. The extracellular vesicles of MSCs, including microvesicles and exosomes (or nanovesicles), contain many proteins [92]. MSC-derived exosomes are 30–100 nm in diameter, express characteristic exosomal markers, such as CD9, CD63, and CD81 [93], and serve to transfer molecules, including proteins, transcription factors, small and large non-coding regulatory RNAs, such as mRNAs, microRNAs, and lipid molecules (Figure 26.2). While therapeutic effects of MSC-derived exosomes have been detected in cancer and in regenerative medicine, including cardiovascular and hepatic regeneration [93,94], information on the role of exosomes in many pathophysiological processes is in its infancy. However, MSC exosomes have some proangiogenic properties [93,94]. Among the proteins identified by proteome analysis of human MSC exosomes are PDGFRB, EGFR, and PLAUR as well as signaling molecules such as RAS-MAPK and RHO. Other proteins identified in the MSC exosome include Cdc42 cell adhesion molecule, osteoinductive factors, and some characteristic MSC surface markers [95,96] (Figure 26.2). A variety of factors dynamically regulate the rate of

exosome secretion by MSCs [97]. For example, under hypoxic conditions of 1% and 3% $O_2$, the rate of exosome secretion by placental MSCs was enhanced by 3.3- and 6.7-fold respectively, resulting in enhancement of the migration and angiogenic tube formation of placental microvascular ECs *in vitro* [97]. By contrast, in the mouse breast cancer cell line 4T1 the expression of the proangiogenic molecule VEGF was significantly downregulated by murine MSC-derived exosomes [98]. In addition to the dynamic interactions via exosomes of MSCs with cells of other lineages, ECs were also found to release extracellular vesicles in response to cellular activation or apoptosis [99,100]. In this context, different kinds of soluble factors, such as VE-cadherin, PECAM-1 (CD31), ICAM-1, endoglin, E-selectin, S-endo or $\alpha_v$ integrin, eNOS, and VEGFR2 were transferred by EC-derived extracellular vesicles [101,102] (Figure 26.2).

By virtue of their versatility, MSC-derived exosomes are now considered as a potential cell-free therapeutic approach that may avoid the some of the difficulties associated with cell therapy. A beneficial effect of MSC exosomes has been demonstrated in preclinical models of stroke [103,104], ischemic heart disease [105], acute lung injury [106], liver fibrosis [93], rheumatologic diseases [107], and central and peripheral nerve degeneration [108,109], as well as in a number of malignancies, including glioma [110] and multiple myeloma [111]. MSC-derived exosomes have also been utilized for horizontal drug cargo sorting and transfer to recipient cells [112].

Large numbers of soluble factors have been identified in MSC-derived conditioned medium. These include VEGF, VEGFR2, Ang-1/Tie-2, MCP-1, MIP-1α, MIP-1β, fibroblast growth factor-2 (FGF-2), PDGF, IL-1β, IL-10, HGF, SDF-1, IGF-1, thymosin-β4, and Wnt5a [57,89]. MSC-derived VEGF can act as a stimulus for the survival and functional commitment of ECs [113]. In addition, a soluble Tie-2 receptor fragment generated by ectodomain proteolytic cleavage [114] was detected in rat MSC-conditioned medium, which appeared to be involved in the angiogenic axis [57].

The elimination of Wnt-4 signaling in murine MSCs preconditioned with hypoxia abolished the vasculogenic properties of these cells in a mouse ischemic hind limb model [115], suggesting that the Wnt signaling pathway possesses a critical role in the paracrine proangiogenic properties of MSCs. Overexpression of Wnt-4 induced osteogenic differentiation of human MSCs via the p38 MAPK in a novel noncanonical signaling pathway [116]. Induction of canonical Wnt signaling resulted in upregulation of the Wnt target gene Cyclin D1, which in turn led to an enhanced proliferative potential of murine MSCs [117]. Wnt-3a stimulation contributed to enhanced downregulation of MMP-2 and MMP-9 in MSCs, whereas Wnt signaling inhibition, by knockdown of the transcriptional activator β-catenin, diminished membrane type 1-matrix metalloproteinase (MT1-MMP or MMP-14), highlighting the regulatory role of Wnt signaling in MSC invasion and recruitment [117].

Dynamic mechanical signal transduction by compressive loading has also been considered to have an effect on gene expression and function of MSCs [118]. Stretch-activated ion channels, cell adhesion molecules with activation of second messenger pathways, and downstream signaling cascades such as growth factor tyrosine kinases, G protein-coupled receptors, p21ras, MAPK, ribosomal S6 kinases (pp90RSK), protein kinase C, phospholipase C, and phospholipase D participated in the transduction of mechanical stimuli from the external environment to the interior of the cells [119,120]. Interestingly, both autocrine and paracrine mechanisms were shown to be involved in such stretch responses, since stretch-conditioned medium mimicked the effect of stretch on nonstretched cells, especially cardiomyocytes [119]. Furthermore, in a bioreactor system for modeling the fracture gap, mechanical loading induced the upregulation of a battery of proangiogenic molecules, such as FGF-2, FGF receptor, VEGFR, TGF-β, MMP-2, MMP-9, and MT1-MMP (or MMP-14) in human MSCs during the early phase of bone healing [120,121]. In general, it can be concluded from this set of data that milieu-dependent conditions, including cell–cell contact, soluble paracrine factors, and mechanical stimulation, ultimately determine the biological activity of MSCs in physiological and pathological conditions.

## 26.4 Mesenchymal stromal cell–endothelial cell crosstalk in tumor angiogenesis

Tumor angiogenesis is a critical component of tumor progression and metastasis. It is under the control of a number of endogenous and exogenous factors that influence the tumor microenvironment. There is controversy on the role of MSCs in tumor angiogenesis, with both stimulatory and inhibitory effects having been reported for tumor neoangiogenesis [56].

### 26.4.1 Stimulation

Subcutaneous co-injection of MSCs and c26 colon cancer cells in mice resulted in the development of larger tumors with enhanced cancer angiogenesis compared with the injection of the cell line alone. This growth-promoting effect was further enhanced after pretreatment of MSCs with inflammatory factors IFN-γ and TNF-α [122]. Enhanced angiogenesis in this system was achieved by upregulation of VEGF through activation of the hypoxia-inducible factor (HIF)-1α signaling pathway in MSCs. In another study, co-transplantation of the mouse breast cancer cell line 4T1 and murine MSCs, or co-injection of the human prostate cancer cell line DU145 and human MSCs, into nude mice led to increased tumor size with a greater vascular area [123]. Increased expression of the proangiogenic factors TGF-β, VEGF, IL-6, and MIP-2 was detected in human MSCs exposed to DU145-conditioned medium or co-cultured with DU145 (Figure 26.3).

Co-cultures of murine MSCs and B16 melanoma cells also resulted in secretion of higher concentrations of the cytokines LIF, M-CSF, MIP-2, and VEGF [124]. Moreover, co-transplantation of MSCs and B16 melanoma cells or Lewis lung carcinoma cells into

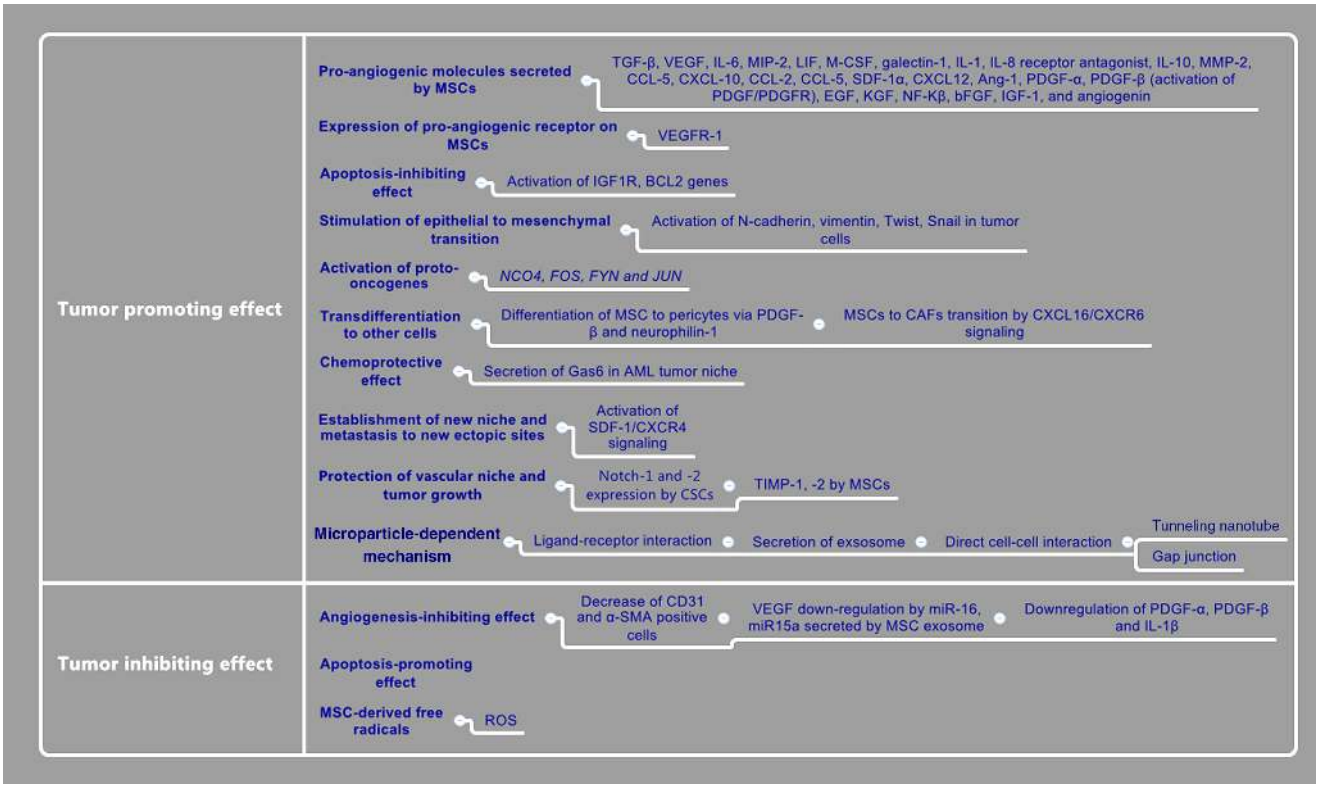

**Figure 26.3** Effects of MSCs on the biology of tumors. MSCs exert a large number of both stimulatory and inhibitory effects on tumor development and proliferation through multiple mechanisms. KGF: keratinocyte growth factor; LIF: leukemia inhibitory factor; M-CSF: macrophage colony-stimulating factor; NF-κB: nuclear factor kappa light chain-enhancer of activated B cells; ROS: reactive oxygen species.

mice led to increased tumor size with enhanced vessel density [124]. The transplanted MSCs were tracked near tumor vessels and attained a $CD31^+$ endothelial-like phenotype. MSC-secreted IL-6 and VEGF were shown to be paracrine migratory stimuli for breast cancer cells [125]. MSCs can also induce changes in the transcriptome of tumor cells. Direct co-culture of human MSCs with a number of breast cancer cell lines, including T47D, SK-Br3, and MDA-MB-231, resulted in upregulation of the proangiogenic gene *VEGF* and the antiapoptotic genes insulin-like growth factor 1 receptor (*IGF-1R*) and B cell lymphoma (*BCL2*) in breast cancer cells, as well as overexpression of the oncogenes nuclear receptor coactivator 4 (NCOA4) and FOS (see Glossary), the proto-oncogenes *FYN* and *JUN*, and genes involved in epithelial-to-mesenchymal transition (EMT), such as N-cadherin, vimentin, Twist, and Snail. These findings suggest that MSCs may act as a trigger to induce EMT in breast cancer cells and actively promote breast cancer metastasis [126] (Figure 26.3). Tumor-cell-derived proangiogenic factors may induce MSCs to take on an endothelial-like morphology. When MSCs were seeded on Matrigel in an indirect transwell co-culture with the MCF-7 breast cancer cell line, breast cancer cells stimulated MSCs to organize into capillary-like structures, which was similar to those observed when MSCs were cultured in the presence of VEGF [127].

It appears that galectin-1, an immunosuppressive and proangiogenic member of the β-galactoside-binding lectin family, is involved in regulation of tumor progression and angiogenesis by MSCs (Figure 26.3). Compared with control wild-type MSCs, orthotopic co-injection of galectin-1-deficient MSCs and 4T1 cells resulted in a reduction of tumor growth and development [128]. Consistent with these findings, it was demonstrated that galectin-1 stimulated the proliferation of B16F10 melanoma cells through a marked decrease in the expression of p53/p21, indicating that galectin-1 antagonists may be a useful therapeutic target in melanomas [129].

Tumor-cell-derived paracrine mechanisms play a key role in the fate of MSCs in the tumor. Conditioned media from different tumor cell lines directed MSCs to differentiate into mature pericytes by tumor-cell-secreted PDGF-B with recruitment of MSC-derived pericytes to the newly formed capillaries *in vitro* and *in vivo* [130]. In this context, conditioned media from more aggressive tumor cells had less abundant recruitment of pericytes, with potential correlation with metastatic spread of these cells. Tumor PDGF-B may induce mesenchymal to pericyte transition through an interaction with neuropilin-1 in MSCs [130] (Figure 26.3). In a murine model of vascular injury it was shown that interaction between CX3CR1 and fractalkine resulted in smooth muscle cell differentiation of $CX3CR1^+$ bone marrow progenitor cells at the site of injury [131].

The secretion of the proinflammatory peptide LL-37 (leucine, leucine-37), the C-terminal peptide of human cationic

antimicrobial protein 18, in a variety of carcinomas, including ovarian carcinoma, can induce MSCs to migrate into the tumor mass and augment MSC secretion of a number of cytokines and proangiogenic factors, including IL-1 receptor antagonist, IL-6, IL-10, CCL5 (also known as RANTES, regulated upon activation, normal T-cell expressed, and secreted), VEGF, and MMP-2, resulting in MSC-induced tumor progression [132] (Figure 26.3). HIFs were also shown to act as mediators of bidirectional paracrine signaling between MSCs and breast cancer cells [133]. HIF-dependent interaction between MSCs and breast cancer cells resulted in expression of CXCL10 and CCL5 in MSCs and their cognate receptors CXCR3 and CCR5 in breast cancer cells, as well as expression of placental growth factor and its cognate receptor VEGFR1 by breast cancer cells and MSCs respectively. This led to the expression of genes that promote invasion and metastasis of breast cancer cells.

Local and recruited MSCs also participate in the tumor niche through differentiation into cancer-associated fibroblasts (CAFs) with a capability of developing cytokine networks that promote tumor growth, progression, and metastasis and create chemotherapy resistance in many solid tumors, including brain cancer, breast cancer, and colon cancer [134–138]. In prostate cancer it has been shown that the expression of the CXC chemokine ligand 16 (CXCL16) by tumor cells resulted in the recruitment of bone-marrow-derived MSCs through interaction with its receptor CXCR6, which is expressed by marrow MSCs [139]. The CXCL16/CXCR6 signaling induced the conversion of MSCs into CAFs with subsequent secretion of a high level of SDF-1 (also known as CXCL12) (Figure 26.3). SDF-1 expression by CAFs promoted EMT of the prostate cancer cells and augmented the expression of its receptor CXCR4, resulting in enhanced tumor progression, extravasation, and metastasis [139]. Thus, MSCs and the CXCL16/CXCR6 axis may be a potential therapeutic strategy for curbing tumor progression and metastasis in prostate cancer. Activation of the PDGF/PDGFR axis through interactions of PDGF-expressing gastric and colon tumor cells and PDGFR-expressing CAFs was shown to play a critical role in the growth and metastasis of gastric and colon cancers in orthotopic transplantation models [140,141]. In a study of orthotopic transplantation and splenic injection of human MSCs together with KM12SM human colon cancer cells, blockade of PDGFR signaling with imatinib, which is a potent tyrosine kinase inhibitor of PDGFR, inhibited the tumor-promoting effect of MSC-derived CAFs and significantly reduced the migration and survival of MSCs in the tumor microenvironment [142].

MSCs from different tissues may have different biological effects on tumor growth and angiogenesis. While co-culture of glioma cells with human umbilical-cord-blood-derived MSCs resulted in inhibition of tumor growth and induction of apoptosis in tumor cells via TNF-related apoptosis-inducing ligand (TRAIL), adipose-tissue-derived MSCs promoted glioma growth, which was associated with the overexpression of the proangiogenic factors VEGF, Ang-1, PDGF-α, PDGF-β, IGF, and SDF-1 [143] (Figure 26.3). Because of the inhibition of TRAIL activation of the apoptotic pathway by SDF-1, the authors concluded that adipose-tissue-derived MSCs supported glioma development by both promotion of angiogenesis and inhibition of apoptosis.

### 26.4.2 Inhibition
