It seems that the role of MSCs in the tumor niche is determined based on a spatiotemporally dependent process. When human MSCs were administered systemically to nude mice bearing tumors produced by the injection of TSA-pGL3 mouse adenocarcinoma cells or injected directly in contact with pre-established tumors, a significant reduction in tumor growth was achieved due to an inhibition of tumor cell proliferation [144]. The authors showed a significant decrease in the number of $CD31^+$ tumor vessels and increases in vessel length and in the percentage of $\alpha$-$SMA^+$ cells after MSC administration, indicating that MSCs may be useful for the treatment of established tumors and might be able to induce vascular remodeling in them [144] (Figure 26.3).

MSC-derived exosomes were also effective in the tumor niche through downregulation of the expression of VEGF in breast cancer cells, leading to inhibition of angiogenesis *in vitro* and *in vivo*, which may be in part mediated by miR-16, a microRNA known to target VEGF in exosomes [98] (Figure 26.3). The macromolecular content of MSC exosomes appears to differ in a context-dependent manner. A lower level of the tumor suppressor miR-15a and a higher level of CCL2 (also known as MCP-1) were detected in exosomes derived from bone marrow MSCs from people with myeloma compared to those from normal controls, suggesting that exosomes from myeloma MSCs promoted tumor growth in contrast to exosomes from normal bone-marrow-derived MSCs [111] (Figure 26.3).

Co-transplantation of human bone marrow MSCs and glioma cells into immunodeficient mice resulted in a significant reduction in tumor volume and microvessel density. The antiangiogenic property of MSCs was ascribed to reduced expression of PDGF-BB, PDGFR-β, and IL-1β [145]. The antitumor effect of MSCs in this model might have been due to suppression of tumor angiogenesis though the downregulation of the PDGF/PDGFR axis (Figure 26.3). Upregulation of the tumor suppressor phosphatase and tensin homolog (PTEN) with subsequent downregulation of Akt and PI3K signaling pathways was induced in glioma cells after co-culture with human umbilical-cord-blood-derived MSCs and glioma cells [146].

## 26.5 Endothelial differentiation of mesenchymal stromal cells

Transdifferentiation of MSCs into multiple mesodermal lineages, including differentiation into endothelial-like cells, has been demonstrated using *in vivo* and *in vitro* systems [147–151] (Figure 26.4).

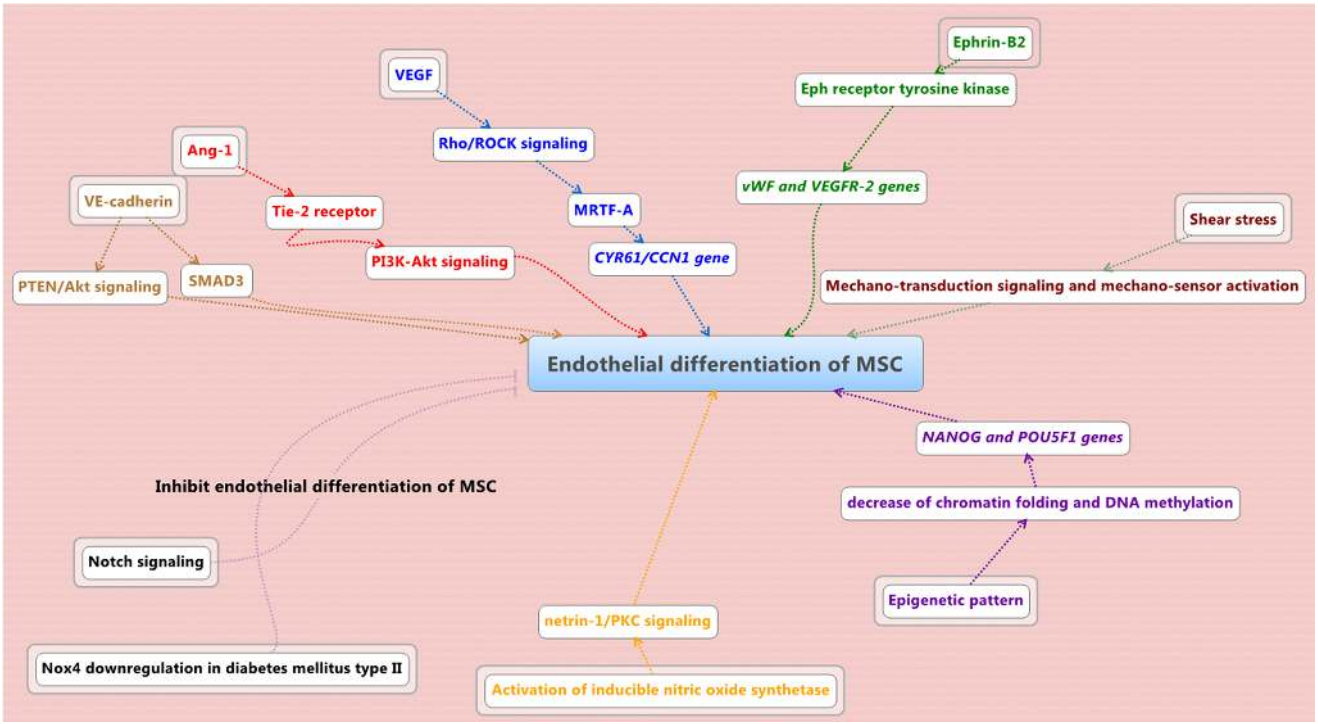

**Figure 26.4** Endothelial differentiation of MSCs and the switching on of EC-specific genes in MSCs is controlled by different signaling pathways. Multiple signaling pathways in addition to mechanical stimulation may trigger differentiation of MSCs into ECs.

However, the exact mechanisms mediating the endothelial differentiation of MSCs including stimulatory or inhibitory factors, intracellular signaling molecules or extracellular nano-mechanical signals is still being determined [152,153]. Because of the importance of neoangiogenesis in regenerative medicine together with the potential of MSCs to repair damaged tissues of the musculoskeletal system, many attempts have been made to use MSCs both as a source of cells for such tissue repair as well as precursors of ECs [56,149,154]. There is debate, however, with regard to the endothelial differentiation of MSCs. Issues include culture conditions, the tissue microenvironment of the recipient, and subpopulations of MSCs [153].

Differentiation of MSCs into endothelial-like cells has been associated with the expression of EC-specific markers on MSCs – including kinase insert domain receptor (KDR – a type III receptor tyrosine kinase also known as VEGFR2), FMS-like tyrosine kinase 1 (FLT-1), vWF, VEGFR1, endothelial differentiation-related factor 1, angio-associated, migratory cell protein, CD31, CD34, and cadherin 5, type 2 (vascular endothelium) (CDH5) – together with integrins such as ICAM-2 and down-regulation of stemness markers, including CD9, E-cadherin, podocalyxin-like protein, and stage-specific embryonic antigen-4. This has resulted in an extensive change in the behavior of these cells toward endothelial-like cells [147,155–157]. However, König *et al.* failed to detect amnion-derived MSCs with complete differentiation to mature ECs because of downregulation of proangiogenic factors such as tenascin C, Tie-2, VEGF, and FGF2 and upregulation of the antiangiogenic factors serpin F1, sprouty1, angioarrestin, and endostatin [154]. Furthermore, some *in vitro* experiments have cast doubts on the endothelial differentiation potential of some tissue-specific MSCs; for example, Wharton's jelly MSCs, with which *in vitro* cell manipulation or passage number altered the expression of EC-related markers, such as CD31, CD34, vWF, VE-cadherin (CD144), Tie-2, VEGFR-1, and VEGFR-2 [158,159]. Alaminos *et al.* also reported incomplete transdifferentiation of Wharton's jelly MSCs into ECs with no or only partial induction of genes related to endothelial function, including *CD36* (fatty acid translocase), *ECE2* (endothelin-converting enzyme), *vWF*, *THBD* (Thrombomodulin), *PGI2* (proliferation-inducing gene), *ECE1*, and *ACE* (angiotensin-converting enzyme) [157].

Conversely, a number of *in vitro* studies using specific experimental conditions, such as hypoxia or osteogenic differentiation, induced MSCs to secrete VEGF and its receptor VEGFR1 (FLT-1) [160]. Moreover, the potency of MSCs showing an endothelial-like phenotype has been confirmed in a number of studies in which MSCs were used for regenerative purposes [2,161]. We demonstrated the contribution of $CD31^+$ MSCs to the structure of myocardial capillaries as early as 7 days after their transplantation into infarcted myocardium [2].

As alternative inducers of differentiation, extracellular mechanical signals can actively direct EC differentiation of MSCs at both genotypic and phenotypic levels. In this context, the interaction of ECM proteins with MSC surface receptors and subsequent induction of intracellular mechano-transduction signaling resulted in endothelial differentiation of MSCs [153,162].

Mechano-sensors and mechano-transduction signaling pathways also support the fate of MSCs to an endothelial-like phenotype under shear stress [163] (Figure 26.4). A steady exposure of canine bone-marrow-derived MSCs to shear stress in a pulsatile bioreactor promoted MSC differentiation into endothelial-like cells after 4 days [164]. The authors found a profound increase in CD31, VE-cadherin, and CD34 at both mRNA and protein levels, while protein levels of α-SMA and calponin were reduced. Concurrently there was a change in cell morphology from a fibroblast-like appearance to an elongated fusiform shape in MSCs seeded onto poly-ε-caprolactone and lactic acid scaffolds [164]. In addition to soluble induction factors that promoted initial lineage differentiation of MSCs, ECM stiffness or elasticity has also been shown to be involved in commitment of MSCs to a specific lineage [165,166]. As an example, microarray profiling of MSC transcripts in cells cultured under 0.1, 1, 11, or 34 kPa matrices yielded neurogenic markers at 0.1–1 kPa, while myogenic and osteogenic markers were increased at 11 kPa and 34 kPa pressures respectively [165].

It has been demonstrated that adaptation of MSCs to a specific shape plays an important role in the fate of these cells [167]. Mahmoudi *et al.* demonstrated that the imprinted topography of silicon-made templates altered the gene expression profile of rabbit adipose-tissue-derived MSCs, while the imprinted patterns of mature chondrocytes induced both collagen type II and aggrecan expression in these cells. The imprinted pattern of spindle-shaped fibroblast-like cells did not induce collagen II expression and decreased aggrecan expression [167].

Numerous factors and their downstream signaling pathways have been reported to orchestrate MSC differentiation into EC-like cells. Both human and rat MSC differentiation to endothelial-like cells was achieved via the VEGF Rho/myocardin-related transcription factor-A (MRTF-A) signaling pathway [59] (Figure 24.4). It was shown that the activation of the Rho/ROCK signaling pathway promoted the nuclear translocation of MRTF-A, and knockdown of MRTF-A selectively reduced VEGF-derived differentiation of MSCs into endothelial-like cells [59]. VEGF can upregulate the promoter activity of cysteine-rich angiogenic inducer 61 (CYR61), a regulator of vascular development and angiogenesis. MRTF-A knockdown resulted in reduction of the VEGF-induced activation of the CYR61 promoter [59] (Figure 26.4). In contrast, it was found that upregulation of the myocardin transcription factor prompted MSCs to differentiate into smooth muscle cells and thwarted the differentiation of human MSCs into other lineages, such as ECs [168,169]. VEGF inhibited the non-EC differentiation of rat MSCs. As an example, VEGF hampered osteogenic differentiation of MSCs via BMP2 mRNA reduction *in vitro* [170]. Conversely, genetic modification of bone marrow MSCs via adenoviral delivery of Ang-1 accelerated both epidermal and dermal reconstitution by induction of an EC-like phenotype and increased CD31 expression [171]. Ang-1 had the strongest influence on endothelial differentiation of stem cells, especially embryonic stem cells, via activation of Tie2–PI3K–Akt as a major downstream signaling pathway responsible for Ang-1-induced $CD31^+/CD144^+$ EC expansion [172] (Figure 26.4). SMAD3, a downstream effector of TGF-β2 and inhibition of the PTEN/Akt pathway, participated actively in differentiation into EC-like cells from induced pluripotent stem cells, and this was associated with upregulation of VE-cadherin [173] (Figure 26.4).

In addition to extrinsic factors, distinct epigenetic patterns, including chromatin folding and DNA methylation, can change the expression of some genes, which ultimately contributes to cell reprogramming and phenotypic change [174]. Culmes *et al.* pretreated human adipose-tissue-derived MSCs for 48 h with the epigenetic drug BIX-01294 (BIX), a novel methyltransferase and a histone G9a inhibitor, with subsequent differentiation in endothelial inductive medium for 7 and 14 days [175]. By this method, a pronounced decrease of total DNA methylation along with increased expression of pluripotency-related genes *POU5F1* and *NANOG* was achieved, which was associated with subsequent improvement in the differentiation capacity of MSCs into ECs [175] (Figure 26.4).

It is well established that NO signaling has an important role in the endothelial differentiation and maturation of EPCs [176,177]. In this context there is some evidence that NO signaling participates in the differentiation of MSCs to ECs, although the precise mechanisms behind the proangiogenic effects of NO require further clarification [178]. The homozygous knockout of *S*-nitrosoglutathione reductase (GSNOR) gene ($GSNOR^{-/-}$), a denitrosylase that regulates *S*-nitrosylation in murine MSCs, strongly inhibited the vasculogenesis potential of these cells both in an *in vitro* Matrigel tube-formation assay and in an *in vivo* Matrigel plug assay performed in immunocompromised mice. This was consistent with NO/GSNOR imbalance [178]. The activation of the inducible NO synthase/netrin-1/PKC signaling pathway in rat MSCs that had been subjected to reprogramming with Sonic Hedgehog (*SHH*) resulted in enhanced viability and angiogenic properties of these cells in the heart after myocardial infarction [179]. In addition to the NO-derived angiogenic activity of MSCs, NO-mediated osteogenic differentiation was obtained in physically activated rat marrow MSCs *in vitro* [180]. Moreover, the mechanical stimulation of MSCs also promoted both NO and prostaglandin $E_2$ release, which was associated with osteogenic differentiation [181]. It was also shown that prostaglandin $E_2$ secretion by transplanted MSCs in mice induced a switch from a proinflammatory phenotype to an anti-inflammatory phenotypic in macrophages, which was followed by the recruitment of EPCs and osteogenesis-promoting cells [182]. Molecular crosstalk has been reported between osteogenesis and angiogenesis in the skeletal system [183,184]. Notch signaling exerted an inductive effect for the release of Noggin from bone ECs, which was required for normal osteogenesis. In addition to impaired bone vessel morphology and growth, disruption of Notch signaling resulted in a reduction of osteogenesis, shortening of long bones, chondrocyte defects, and loss of bone trabeculae [184].

Overexpression of Ephrin-B2, a transmembrane ligand for Eph receptor tyrosine kinases, in human MSCs also induced an early EC-like phenotype with upregulation of vWF and VEGFR-2 (KDR/Flk-1) under EC culture conditions [86,185] (Figure 26.4). In contrast, Notch signaling induced smooth muscle cell markers in human MSCs as well as in human embryonic stem cells together with a decrease in endothelial markers in embryonic stem cells [185] (Figure 26.4). Activation of Notch-1 signaling under oxidative stress was shown to promote cardiogenic differentiation of rat MSCs. Yan and colleagues also demonstrated that oxidant stress, induced in type 2 diabetes mellitus restricted the differentiation of murine MSCs to EC-like cells by downregulation of Nox4 expression [186] (Figure 26.4).

## 26.6 Development of a biologically active niche through bidirectional endothelial cell–stromal cell crosstalk

Crosstalk between MSCs and ECs influences the tissue microenvironment (the niche) in various physiologic and pathologic conditions. Physiologically normal lung stem cells (LSCs) recruited ECs by a mechanism involving fibroblasts [187] (Figure 26.5A). A basal level of SDF-1 was released by LSCs that resulted in the activation of lung fibroblasts, leading to the production of paracrine signals, including TNF-α. This cytokine induced a positive feedback loop in LSCs, which ultimately enhanced the expression of SDF-1, thereby promoting the recruitment and further activation of fibroblasts. Lung fibroblasts activated by high levels of SDF-1 then expressed the angiogenic factors VEGF and IL-8, leading to the recruitment of ECs that created the functional microenvironment required for normal self-renewal and differentiation of LSCs into bronchiolar and alveolar lineage cells (see Figure 26.5A). MSCs and ECs also constitute major components of the tissue microenvironment in pathologic conditions. MSC–EC crosstalk plays an important role in the development of the tumor niche [188], which allows maintenance and expansion of the tumor by protection of cancer stem cells (CSCs). Thus, the tumor niche may be a target for novel therapies [189,190]. For example, a number of acute myeloid leukemia (AML) cells express the tyrosine kinase receptor Axl and are able to induce expression and secretion of the Axl ligand growth-arrest-specific gene 6 (*GAS6*) by marrow MSCs in the tumor niche [191]. Gas6–Axl paracrine interaction between AML cells and MSCs creates a chemoprotective tumor niche, resulting in proliferation, survival, and chemoresistance of Axl-expressing AML cells (Figure 26.3). Targeting this tumor niche through Axl inhibition is a potential therapeutic strategy for AML. Furthermore, development of a new niche is a prerequisite for the dissemination of neoplastic cells in many tumor types. An example is the establishment of the SDF-1/CXCR4 axis through interaction of $CXCR4^+$ acute lymphoblastic leukemia (ALL) cells and $SDF\text{-}1^+$ bile duct epithelial cells, which provides a hepatic niche that supports the extramedullary dissemination of ALL cells to the liver. Inhibition of the SDF-1/CXCR4 axis may be another novel therapeutic approach to ALL [192] (Figure 26.5B). It has also been demonstrated that the expression of SDF-1 by liver sinusoidal ECs and establishment of the SDF-1/CXCR4 axis created an extramedullary vascular niche for hematopoietic stem cells (HSCs), regulating their trafficking and homing of HSCs during extramedullary hematopoiesis in the liver [193]. The SDF-1/CXCR4 axis was also used by murine lymphatic ECs to develop a metastatic lymphatic niche in organs such as lymph nodes and lung. This facilitated the dissemination of $CXCR4^+$/$CD133^+$ progenitor cells in malignant melanomas [194] (Figure 26.3). SDF-1 may be expressed by lymph node stromal cells to support the formation of a microenvironment for lymph node metastasis [195]. In addition, the SDF-1/CXCR4 signaling is involved in the homing and localization of neural progenitor cells (NPCs) in the vascular niche of the adult subventricular zone in the brain [196] (Figure 26.3). The properties of the vascular niche seem to be context dependent. When subventricular zone NPC-derived neurospheres were cultured with intact or oxygen–glucose-deprived ECs, the normal ECs increased self-renewal of the NPCs and maintained these cells in their stem-cell-like state, whereas deprived ECs prompted migration and differentiation of neural stem/progenitor cells to serve as an endogenous repair mechanism for neuronal replacement after injury [197] (Figure 26.5C).

As indicated earlier, ECs provide a protective vascular niche for cancer stem cells (CSC) [198]. In the highly aggressive brain tumor glioblastoma multiforme, elimination of the EC niche resulted in a decrease in the self-renewal of tumor stem cells as well as a reduction in neurosphere-forming ability of neoplastic cells. This was due to the loss of EC-mediated CSC maintenance, which was mediated in part by Notch signaling [199]. Juxtacrine (close proximity) signaling between tumor cells and their surrounding ECs in the tumor niche occurred by interaction between Notch ligands (which included JAG1, DLL1, and DLL4 expressed by tumor ECs) and the Notch receptors, including Notch1 and Notch2. The latter were expressed by CSCs and the interaction increased self-renewal of CSCs and promoted tumor growth [200] (Figure 26.3). Inhibition of Notch signaling from the tumor vascular niche resulted in depletion of CSCs and inhibition of tumor growth. The existence of a tumor vascular niche has also been shown for head and neck cancer stem-like cells with approximately 80% of the CSCs located in close proximity (within 100 μm radius) of blood vessels in human squamous cell carcinoma (SCC) [201].

It seems that a contact-dependent juxtacrine interaction of neural CSCs with their niche is required to preserve the self-renewal potential of tumor stem cells. Assessment of interactions between primary brain tumor microvascular ECs (tMVECs) and glioma-propagating cells showed that only direct contact between the two cell types stimulated proliferation and expansion of the glioma cells as opposed to paracrine interactions between tMVECs and glioma cells when they were co-cultured in transwell chambers or ECM secreted by tMVECs. Only tMVECs

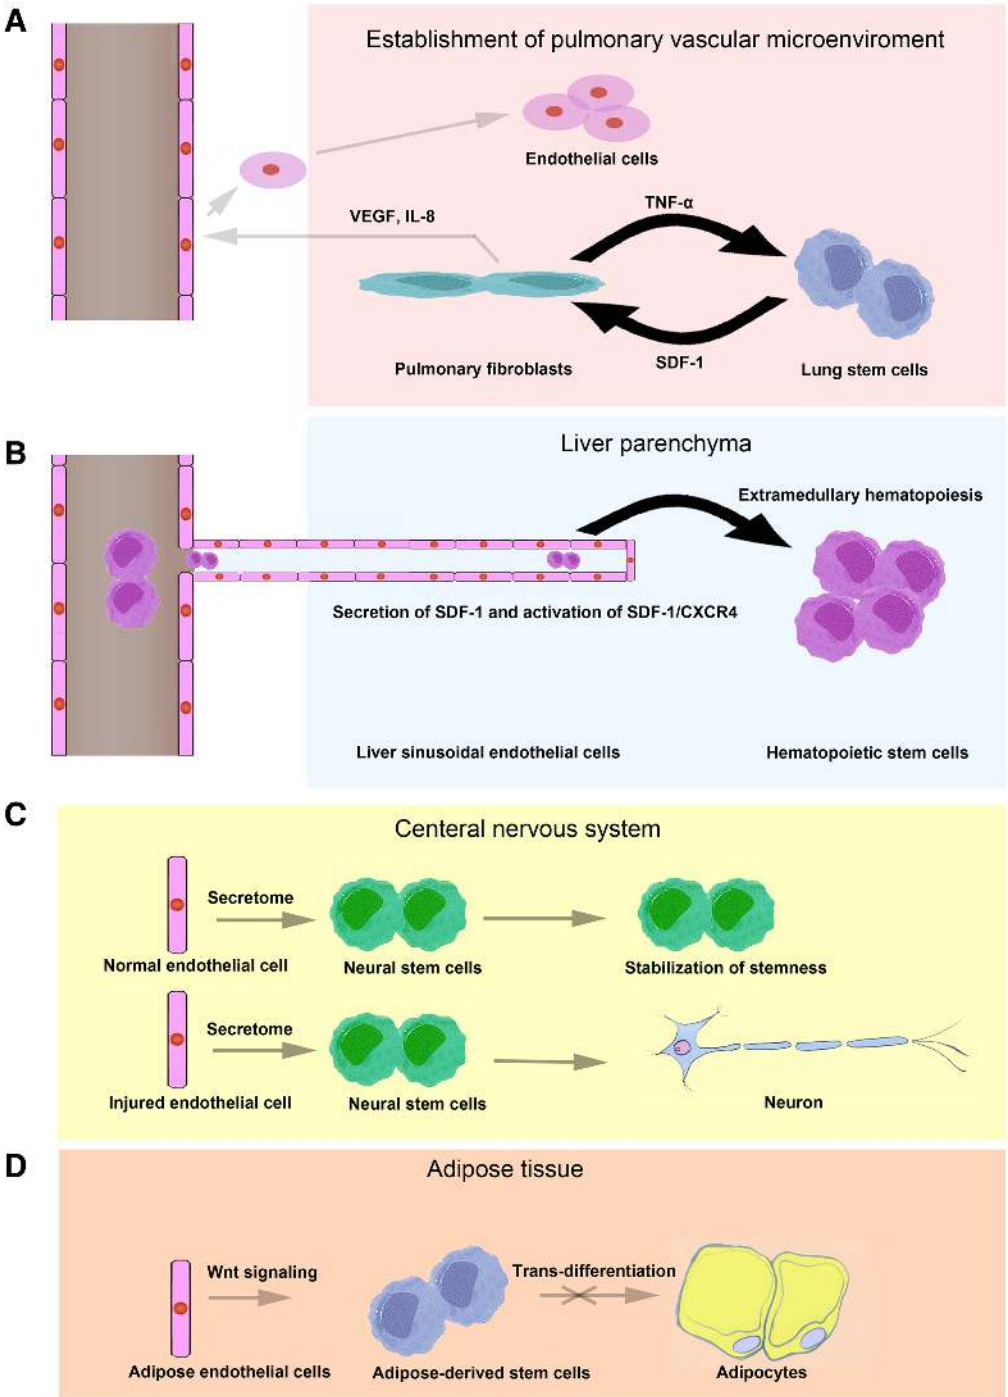

**Figure 26.5** Bidirectional EC–stem cell crosstalk leads to the development of niches with biological activity in different tissues under physiologic and pathologic conditions. (A) In the lung, development of a vascular niche by LSCs and fibroblasts directs stem cell growth and differentiation. (B) EC–progenitor cell interaction through SDF-1/CXCR4 controls physiologic and pathologic extramedullary hematopoiesis in the liver. (C) In the brain, a vascular niche exhibits different interactions with neural stem cells during physiologic and pathologic conditions. (D) In adipose tissue, a vascular niche maintains stem cell quiescence by Wnt signaling. (See color plate section.)

supported the expansion of glioma-propagating cells isolated from primary tumor specimens. HUVECs did not have a significant effect on the proliferation of the tumor cells [202]. Again, the SDF-1 (CXCL12)–CXCR4 signaling pathway was reported to direct the localization of glioma tumor cells in the vascular niche and mediate EC trophic function in glioblastoma multiforme, while depletion of CXCR4 in the glioma cell line U87 blocked its growth in xenografts transplanted intracranially [203].

It appears that there is bidirectional interplay between ECs and their surrounding cells in the vascular niche. Evidence shows that bidirectional interaction of tumor stem cells and ECs is an intricate microstructure that, on the one hand, supports the proliferation and expansion of neoplastic cells and, on the other hand, protects ECs. Brain tumor stem cells, which are supported in a protective vascular niche, stimulate angiogenesis through production of proangiogenic growth factors or directly contribute to tumor microvasculature through plasticity toward an endothelial lineage [204]. In gliomas, the tumor stem cells induced the synthesis of VEGF, which was associated with the development of aggressive neoplastic subpopulations in advanced stages of disease [205]. Moreover, crosstalk between ECs and their surrounding cells in the vascular niche is discernible in other situations. It has been demonstrated in injury to the white matter of the brain that secretion of MMP-9 by oligodendrocytes following upregulation of the proinflammatory cytokine IL-1β accelerated the angiogenic response in the oligovascular niche, which may have contributed to recovery of the white matter after brain injury [206]. There was coupled angiogenesis/neurogenesis crosstalk between cerebral ECs and subventricular zone NPCs after stroke injury, which was likely mediated by VEGF since blockage of VEGFR2 diminished the effect of the ischemia-activated ECs on NPC neurogenesis. Additionally, NPC-conditioned medium had an effect on endothelial angiogenesis [207]. Interactions between tumor cells and ECs in the vascular niche may influence other elements of the tumor. Crosstalk between tumor cells and ECs in medulloblastoma resulted in the secretion of macrophage migration inhibitory factor by tumor cells, which induced the tumor ECs to secrete the potent T lymphocyte chemoattractant RANTES, thus creating a chemotactic gradient guiding RANTES-receptor-expressing T cells to the tumor [208]. (Medulloblastoma is the most common malignant primary brain tumor in children, originating in the cerebellum or posterior fossa.)

MSCs have been shown to be capable of protecting the perivascular niche through stabilizing the vascular basement membrane [209]. MSCs undertake a supportive role for ECs in the vascular niche similar to that of pericytes [68,210,211]. MSCs secrete high levels of TIMP-1 and TIMP-2, while ECs mainly secrete TIMP-2 [209] (Figure 26.3). TIMPs are considered key protectors against degradation by MMP-2 and MMP-9 of the main matrix components of the vascular basement membrane, including laminins and collagen type IV [212,213]. Unlike ECs, MSCs increased TIMP-1 -expression when stressed by the proinflammatory cytokines IL-1β and TNF-α or by hypoxia. Secreted TIMP-1 in addition to TIMP-2 efficiently bound and inhibited MMP-2 under pathological conditions, highlighting the fact that MSCs as uniquely able to augment protection of the perivascular niche with secretion of multiple TIMPs [209].

Microparticles secreted by mesenchymal cell lines, but not microparticles from epithelial cell lines, contained high levels of angiogenic molecules, including PDGF, IL-8, and angiogenin, with the capability of endothelial activation and development of a vascular niche that promoted cancer cell proliferation, invasiveness, stem cell phenotype, and chemoresistance [214] (Figure 26.3). Moreover, induction of angiogenesis and promotion of a premetastatic niche was found during release of microvesicles by a $CD105^+$ MSC-like subset of human renal CSCs [215]. Microvesicles derived from $CD105^+$ CSCs modified the lung microenvironment after intravenous administration into SCID mice by enhancing the expression of VEGFR1, VEGF, MMP9, and MMP2 in lung tissue or in lung ECs, leading to the formation of a premetastatic niche [215–217]. Several microRNAs associated with tumor invasion and metastasis, including miR-29a, miR-650, and miR-151, were found to be shuttled by the $CD105^+$ microvesicles. A variety of mechanisms, including ligand–receptor interaction [134,218], direct cell–cell contact by gap junctions [219], or cell-to-cell communication through tunneling nanotubes [220,221] and exosome-mediated cell communication [222] have all been shown to be involved in cell–cell crosstalk in the tumor niche.

## 26.7 Determination of stem cell fate through crosstalk with endothelial cells

The fate of stem/stromal cells can be determined through bilateral interaction with ECs, which seems to be context dependent. In the central nervous system, actively proliferating type B and type C subventricular zone neural stem cells were found in close proximity to the vascular niche in the subventricular zone of the brain [223,224]. Activated type B and type C stem cells expressed high levels of EGFR and $\alpha_6$ integrin, which was mediated by SDF-1 secreted in the niche, resulting in migration of quiescent type B stem cells from the ependymal surface toward the blood vessel surface along with activation and proliferation of these cells and the generation of type C cells [196]. (Quiescent neural stem cells are type B. They are able to remain in the quiescent state due to the specific niches composed of blood vessels, astrocytes, microglia, ependymal cells, and ECM present within the brain. These niches provide nourishment, structural support, and protection for the stem cells until they are activated by external stimuli. Once activated, type B cells develop into type C cells, which are active proliferating intermediate cells, which then divide into neuroblasts consisting of type A cells.)

Co-culture of the human embryonic stem cell lines H1 and H9, as well as human induced pluripotent stem cells, with the transformed brain EC line bEnd.3 retained their pluripotency [225]. bEnd.3 and its conditioned medium, which is similar to that of primary mouse embryonic fibroblasts, expanded H9 ESCs with correct morphology and maintenance of expression of pluripotency markers. This makes bEnd.3 an appropriate feeder layer for prolonged culture of human pluripotent cells. In glioblastoma multiforme, brain ECs and their conditioned media protected the stemness of CSCs and the neurosphere-forming

ability of the tumor stem cells was sustained in the presence of the EC secretome but not with epithelial cell conditioned media [226]. These authors demonstrated a role for the mammalian target of rapamycin pathway as the means of active communication between ECs and CSCs and showed that the EC secretome supported the maintenance of glioblastoma stem-like cells. A combination of an anti-angiogenic agent (anti-VEGFR2) targeting the tumor vascular niche and chemotherapy was used in nude mice bearing subcutaneous xenografts of the C6 rat glioma cell line. A significant reduction in the fraction of tumor sphere-forming units was attained in the tumor, indicating that selective eradication of tumor stem cells can be achieved by targeting the tumor vascular niche, attesting to the ability of anti-angiogenic therapy to augment the efficacy of chemotherapy [227]. Similar results were obtained using the combination of the vascular disrupting agent combretastatin A1 diphosphate (OXi4503 or CA1P) with low-dose metronomic cyclophosphamide chemotherapy in xenografts of human breast cancer and melanoma that developed after injection of the 231/LM2-4 breast cancer cell line and MeWo melanoma cell line respectively [228]. Significant decreases in microvessel density, perfusion, and proliferation, accompanied by significant increases in tumor cell necrosis and apoptosis, were achieved by this protocol. (Metronomic chemotherapy refers mainly to the schedule of the chemotherapy, which consists of chronic, equally spaced, and (generally) low doses of various chemotherapeutic drugs without extended rest periods. This is markedly different from the current chemotherapy approach, which normally uses maximally tolerated doses of chemotherapeutic agents usually given as a number of courses over a period of months.)

Other studies, however, have reported that crosstalk between ECs and MSCs may prompt MSCs to exit the niche through induction of differentiation. Saleh *et al.* reported that paracrine factors secreted by HUVECs stimulated the proliferation of human MSCs and significantly enhanced their osteogenic differentiation [76]. Bioinformatic integration of gene expression datasets from HUVECs and MSCs suggested that a number of signaling pathways, including FGF, Wnt, BMP, PDGF, TGFβ, Notch, and Ephrin, might be involved in MSC–EC crosstalk [76]. A similar effect on the proliferation and osteogenic differentiation of MSCs by HUVECs has also been reported by others [87,229,230]. When different ratios of human MSCs and HUVECs were used in a co-culture system, a significant increase in the proliferation and osteogenic differentiation of MSCs was observed: augmentation in MSC proliferation occurred independently of relative cell ratios, whereas osteogenic induction, as assessed by alkaline phosphatase activity, was dependent on the cell : cell ratio. The highest alkaline phosphatase activity occurred in the 3 : 1 ratio of MSCs : HUVECs under nonosteogenic conditions [87]. Significantly enhanced MSC expansion with induction of osteogenesis using different ratios of MSCs to HUVECs was shown in another study with the highest proliferation rate of MSCs at a 1 : 4 MSC : HUVEC co-culture ratio [230].

VEGF appears important in osteoblastic differentiation of MSCs co-cultured with ECs, since inhibition of its receptors reduced the co-culture-induced osteoblastic activity [231]. Genetic modification of MSCs to overexpress VEGF resulted in inhibition of BMP2 expression in MSCs and inhibited osteogenesis *in vitro* and ectopic bone formation *in vivo*, highlighting VEGF as a potential inhibitor of BMP2 expression in MSCs' capability of altering the osteogenesis of MSCs [170]. Scrutiny of the role of VEGF in MSC differentiation showed that there is an intracrine mechanism by which VEGF regulates osteoblastic differentiation of MSCs [232]. Marrow MSCs from mice with conditional VEGF deficiency in osteoblastic precursor cells, or MSCs in which VEGF had been knocked down *in vitro*, exhibited a significant reduction in osteoblast differentiation and increased adipocyte differentiation that was independent of exogenous VEGF. Furthermore, there was a reciprocal interaction between VEGF and the nuclear envelope proteins lamin A/C in bone-marrow-derived MSCs in which lamin A stimulated VEGF protein expression while VEGF repressed levels of lamin A. The authors concluded that VEGF may induce osteoblastic differentiation of MSCs by stimulating the transcription factor RUNX2 and may control adipogenesis by suppressing the expression of peroxisome proliferator-activated receptor-γ2 (PPAR-γ2) [232]. In an attempt to further investigate the crosstalk between ECs and bone cells, noncontact co-culture of human osteoblast-like cells with HUVECs showed that osteoblasts released VEGF in response to prostaglandins, and ECs subsequently responded to VEGF with phosphorylation of VEGFR2, activation of ERK1/2, cyclooxygenase-2 induction, and release of prostanoids such as prostacyclin. These prostanoids may be key mediators in facilitating osteoblast–EC communication by enhancing the release of VEGF from osteoblasts [233]. However, interactions between these cells also appeared to depend on other factors, such as juxtacrine interactions or the distance of cells from each other. An osteoblast–EC contact co-culture model showed that the loss of VEGF sensitivity as well as abrogation of VEGF-mediated osteoblastic differentiation might be mediated by the action of prostaglandin $E_2$ with the possibility of restricting VEGF signaling to those ECs that were already in close proximity to osteoblasts [234].

Co-culture of human MSCs with HUVECs in a 3D spheroid system inhibited the proliferation and adipogenic differentiation of MSCs while selectively promoting osteogenic differentiation of MSCs. This indicated that, in an *in vivo* simulated 3D system, ECs maintained quiescence and facilitated niche exit via osteogenic differentiation [79]. Activation of endogenous Wnt and BMP signaling was demonstrated in MSCs by increased levels of immunoreactivity against downstream mediators of these signaling pathways. However, direct interactions with distinct differentiated cells may be a critical determinant of MSC fate. Although co-culture of MSCs with both ECs and dermal fibroblasts resulted in the appearance of α-SMA filaments in MSCs, these cells showed a pericyte-like morphology when co-cultured with ECs. A spindle-shaped myofibroblast-like morphology was

observed after co-culture with fibroblasts [78]. Direct cell–cell contact between MSCs and adult cardiomyocytes and smooth muscle cells specifically directed the fate of MSCs toward cardiomyocyte-like and smooth-muscle-like cells [235,236].

Endothelial interaction of human adipose-derived MSCs in the perivascular niche was found to maintain the stemness phenotype and inhibited the adipogenic differentiation of stem cells [237] (Figure 26.5D). Purified human perivascular stem cells from adipose tissue were shown to possess properties of MSCs [238,239]. Juxtacrine and paracrine interactions of ECs and adipose-derived MSCs resulted in modulation of stem cell fate through canonical Wnt signaling, predominantly by Wnt1, highlighting the relationship between MSCs and ECs in the regulation of adipogenesis in adipose tissue [237] (Figure 26.5D). Moreover, in porcine adipose-derived MSCs, inhibition of adipogenic differentiation was demonstrated by the activation of Wnt signaling via Wnt3a, which was shown to repress the mutual activation of CCAAT/enhancer-binding protein-α and PPAR-γ [240].

EC–stem-cell crosstalk may determine the fate of CSCs during tumor expansion. It was shown that interaction between ECs and CSCs from SCCs of the head and neck protected CSCs against anoikis and induced proliferation of these cells by VEGF secretion from ECs. (Anoikis is a form of programmed cell death that is induced by anchorage-dependent cells detaching from the surrounding extracellular matrix.) These findings indicated that the survival and self-renewal of head and neck SCCs occurs via EC-derived signals [241]. EC-induced phosphorylation of signal transducer and activator of transcription 3, Akt, and ERK in SCCs of the head and neck was mediated through upregulation of IL-6, IL-8, and EGF in ECs co-cultured with head and neck SCC cells, leading to increase in migration and inhibition of anoikis of the tumor cells [242].

## 26.8 Beneficial effects of mesenchymal stromal cell–endothelial cell interactions in some tissue pathologies

Long-term repeat positron emission tomography/computed tomography monitoring with the novel imaging agent 2′-deoxy-2′-[$^{18}$F]-fluoro-5-ethyl-1-β-D-arabinofuranosyluracil of MSCs retrovirally transduced with the sr39HSV1-tk gene after their intramyocardial transplantation in pigs showed that the peak of cell proliferation occurred at 33–35 days after injection in peri-infarct regions and in the major cardiac lymphatic vessels and lymph nodes [243]. Histochemical staining showed sr39HSV1-tk-expressing fibromyoblasts, lymphovascular cells, and microvascular and arterial endothelium, indicative of integration of transplanted MSCs into both lymphatic and vascular endothelium [243]. In a sex-mismatched cell transplantation model in miniswine, Y-chromosome-positive transplanted cells exhibited vascular differentiation of both vascular smooth muscle cells and ECs, contributing to large and small vessel formation in recipient female hearts [244]. Improved regional contractility and myocardial blood flow resulted in reduction of infarct size and improvement of cardiac function. Intramyocardial transplantation of MSCs dynamically changed the milieu of the injured myocardium toward a proangiogenic microenvironment by activation of VEGF signaling in the infarction and an increase in the Ang-2 : Ang-1 ratio, which resulted in reduction of phosphorylated Tie-2 [2].

In a unilateral ureteric obstruction model in mice, accumulation of a variety of stem/progenitor cells, including MSCs, HSCs, and EPCs, attenuated the deleterious tubulointerstitial scarring and contributed to regeneration of the renal parenchyma after release of the ureteric obstruction. This was thought due to an EC–stem-cell interaction likely through the SDF-1/CXCR-4 axis [245]. In acute kidney injury, paracrine and microvesicle-mediated production of proangiogenic factors, including VEGF, IGF, FGF-2, as well as erythropoietin, has been proposed as an important mechanism in MSC-related renoprotection [246].

MSC–EC interactions, particularly those mediated by paracrine mechanisms, significantly enhanced recruitment of both VE-cadherin and β-catenin to the plasma membrane of ECs. This established a VE-cadherin–β-catenin interaction with eventual establishment of functional adherence junctions in these cells. This in turn led to a reduction in endothelial permeability [81] (Figure 26.2). This interaction between MSCs and ECs also reduced blood–brain barrier permeability in mice with traumatic brain injury. In a murine model of stroke injury, expression of Ang-1, Tie-2, VEGF/VEGFR2 and Occludin was induced by MSCs and led to promotion of angiogenesis and establishment of vascular integrity [247]. In this context, Ang-1/Tie-2 signaling was found to be capable of protecting MSCs and ECs against adverse conditions such as serum deprivation and hypoxia-induced apoptosis by Akt phosphorylation, decreased activation of caspase-9 and -3, and an increased Bcl-2 : Bax ratio [248].

## 27.1 Mesenchymal stromal cells: modulators of hematopoiesis

The bone marrow (BM) is the primary organ in adults in which blood cell formation (i.e., hematopoiesis) occurs. Hematopoiesis is orchestrated by a rare population of pluripotent stem cells, known as hematopoietic stem cells (HSCs). Within the BM, nonhematopoietic stromal cells and various mature immune cells form a specialized microenvironment known as the BM niche. The BM niche provides various developmental cues that instruct HSCs to either remain quiescent (i.e., noncycling), or to undergo cell division and subsequently differentiate into multipotent progenitors. These multipotent progenitors mature into specialized immune cells that comprise innate (e.g., neutrophils, macrophages, and dendritic cells (DCs)) and adaptive (e.g., B and T cells) immunity. Mature immune cells circulate in peripheral lymphoid organs (e.g., the spleen and lymph nodes) and in the blood to exert the various functions of the immune system. Under normal conditions the rates at which mature hematopoietic cells enter and leave the peripheral blood are balanced, a process known as hematopoietic homeostasis. For homeostasis to be achieved, HSC self-renewal and differentiation must be tightly regulated to ensure that mature peripheral blood cells are continuously generated without exhausting the HSC reservoir in the BM. Therefore, tight regulation of HSC self-renewal and differentiation by the BM niche is essential for normal hematopoiesis to be maintained throughout adult life.

The cells that comprise the BM niche are distributed between two compartments: (i) the endosteal niche, located between the bone and the marrow space, and (ii) the perivascular niche, located within the sinusoids of the BM cavity (Figure 27.1) [2–6]; and see Chapter 32.

MSCs are a fundamental component of the BM niche. They are traditionally defined as BM-derived fibroblast-like cells that adhere to plastic and generate colony-forming units (CFU-Fs)

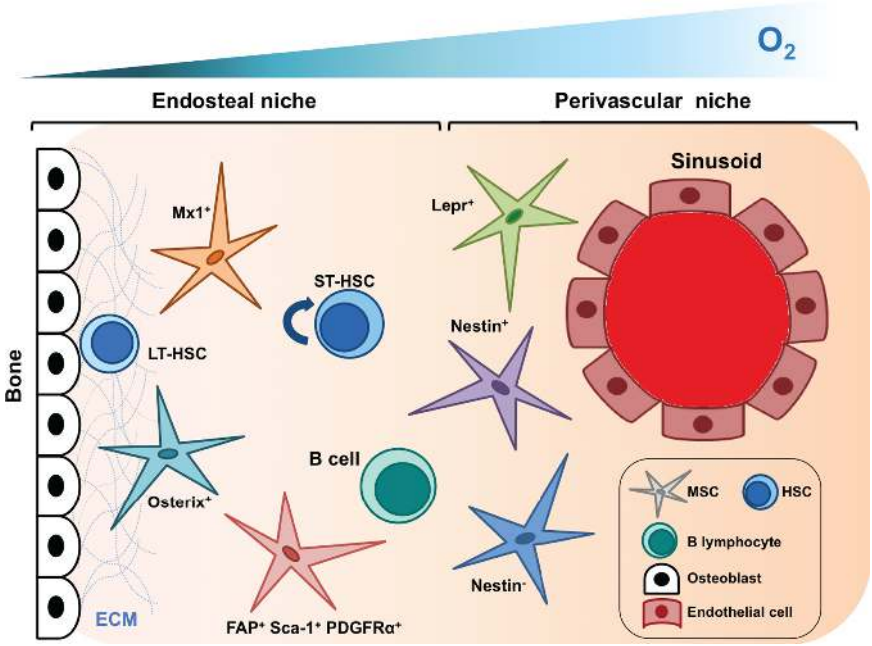

**Figure 27.1** The BM niche. This is segregated into two distinct compartments: (1) the endosteal niche, located proximal to bone, composed of osteoblasts and osteocytes (left); (2) the perivascular niche, located proximal to the vascular sinusoids (right). The BM niche is a hypoxic environment (2–8% $O_2$) with $O_2$ levels gradually decreasing with increasing proximity to the endosteal lining [1,2]. Various mesenchymal stromal cell (MSC) subpopulations of differing lineage potential, defined by specific cell surface marker expression, are distributed throughout the BM niche. These MSC subpopulations secrete a number of extracellular matrix (ECM) components, including cell adhesion molecules, growth factors, and cytokines that regulate defined stages of hematopoiesis, including HSC quiescence, self-renewal, and mobilization and B cell lymphopoiesis. FAP: fibroblast activation protein; LepR: leptin receptor; LT-HSC: long-term or dormant HSC; ST-HSC: short-term or cycling HSC (the gray-scale wedge indicates cycling activity); Mx1: myxovirus resistance protein 1; PDGFRα: platelet-derived growth factor-α; Sca-1: stem cell antigen-1.

*in vitro* [7,8]. They are also multipotent progenitors that differentiate along mesenchymal lineages to become adipocytes (fat cells), osteocytes (bone cells), and chondrocytes (cartilage cells) [9–13]. By flow cytometry, MSCs are distinguished by (1) the lack of hematopoietic cell surface markers such as cluster of differentiation (CD) CD45 (a pan-leukocyte marker), Ter119 (an erythroid marker), and CD3 (a pan T cell marker) and (2) by the presence of cell surface markers that include CD44, CD90, stem cell antigen 1 (Sca-1, in mice), and platelet-derived growth factor receptor (PDGFR)-α [13–15]. However, it is currently unclear whether MSCs express unique cell surface markers. As a result, the identification and isolation of purified MSC populations from the BM remains technically challenging.

Unlike HSCs, the origin(s), functions, and true lineage potential of MSCs in the BM remain poorly understood owing to the technical limitations described. However, the general concept of a stromal cell layer that supports hematopoietic cells *in vivo* coincided with the discovery of the HSC in 1961. In a landmark study by Till and McCulloch, HSCs were indirectly identified by demonstrating quantitative BM transplantation into lethally irradiated mice [16]. Later, hematopoietic colonies were observed in the spleen of reconstituted mice, so-called CFU-Ss, which were initially thought to represent clones of HSCs. However, later studies by Magli *et al.* indicated that CFU-Ss were transient, representing what we call today transient amplifying cells or proliferating precursor cells [17]. These findings also provided the first evidence that a stromal cell compartment capable of supporting hematopoiesis exists *in vivo*. Following this, a variety of MSC lines, such as ST-2, MS5, and OP9, were established *in vitro* from whole BM cultures, to enable the expansion of hematopoietic cells *ex vivo*. The ability to culture purified hematopoietic cell types on these MSC lines *in vitro* has greatly fueled our understanding of hematopoietic cell differentiation, and in particular of B cell development [18–20].

Transgenic Cre reporter mice have become a useful tool for studying specific cell populations *in vivo*. These reporter mice are genetically engineered to encode a fluorescent marker (e.g., green fluorescent protein) that is only expressed upon removal of a STOP codon cassette that is flanked by lox P sites that are recognized and excised by Cre recombinase. Therefore, the use of reporter mice that express Cre recombinase under the control of tissue-specific gene promoters has enabled the identification and lineage tracing of various stem cell types *in vivo*. In recent years, efforts have been made to use such transgenic mice to trace MSCs *in vivo*. These studies have revealed that MSC subpopulations of varying differentiation potential and function coexist within the BM niche. These MSC subpopulations coordinate various stages of hematopoiesis via (1) direct contact with HSCs and their progenitors and (2) the production of various cytokines, growth factors, and ECM molecules. For example, a population of MSC progenitors that express Mx1 has been demonstrated to strictly differentiate osteoblasts *in vivo* and to remodel the BM niche in response to injury [21].

Osteoblasts also closely interact with HSCs in the endosteal niche. Here, osteoblasts secrete ECM components (e.g., N-cadherin and vascular cell adhesion molecule-1), which provide physical support for HSCs. Osteoblasts also secrete various chemokines (e.g., C–X–C motif chemokine ligand (CXCL) 12 – also known as stromal cell-derived factor 1) that regulate HSC self-renewal in the BM [22–24]. CXCL12 production in the

BM is not confined to osteoblasts, however, as several MSC subpopulations that secrete CXCL12 have also recently been identified. CXCL12 production by Osterix-expressing MSCs maintains HSC progenitors and B lymphopoiesis in the endosteal niche [25]. Osterix is a transcription factor involved in osteogenesis. This MSC population also consists of a subset of adipo-osteogenic progenitors known as CXCL12-abundant reticular (CAR) cells. CAR cells produce large amounts of CXCL12 and stem cell factor (SCF) and function to promote HSC self-renewal [25,26]. In addition MSCs that express PDGFR-α, Sca-$1^+$, and FAP-α also produce CXCL12 and SCF and regulate B lymphopoiesis and erythropoiesis in the BM (Figure 27.1) [27,28].

Two distinct populations of MSCs distinguished by the expression of the leptin receptor ($LepR^+$ MSCs) and Nestin ($Nestin^+$ MSCs) have been identified in the perivascular niche (Figure 27.1). Nestin is an intermediate filament protein. These populations function (1) to maintain HSCs within the BM and (2) to suppress HSC mobilization to the spleen in response to injury or stress, a process known as extramedullary hematopoiesis [1,29]. Both $LepR^+$ MSCs and $Nestin^+$ MSCs can differentiate into osteoblasts, adipocytes, and chondrocytes *in vitro*. However, *in vivo* $LepR^+$ MSCs mainly give rise to osteocytes and adipocytes, whereas $Nestin^+$ MSCs have only osteogenic and chondrogenic potential. The discrepancy between the lineage potential of these MSC populations *in vitro* versus *in vivo* suggests that the differentiation potential of MSCs may be altered by growth conditions currently used to expand these cells *in vitro*. Therefore, it will be important to further characterize the differentiation capacity of identified MSC populations *in vivo* to determine the true lineage potential of these MSC subtypes in the physiological setting. Taken together, these findings indicate that interplay between MSC subpopulations and HSCs and their progenitors in the BM niche is likely required for the correct regulation of hematopoiesis *in vivo*.

Oxygen tension is emerging as an important environmental factor that modulates cell behavior, including that of stem cells. Cell lines, including MSC lines, are routinely established and expanded *in vitro* at the inhaled ambient oxygen concentration of 21% $O_2$, commonly referred to as "normoxia." However, the oxygen tension in most tissues is <21%, and therefore these growth conditions are physiologically hyperoxic for a multitude of cell types, including MSCs. The BM niche itself is a relatively hypoxic environment with an estimated oxygen concentration ranging between approximately 0.6% and 8% $O_2$ [2,30,31]. Cellular adaptation to hypoxia is primarily mediated by the transcription factor hypoxia inducible factor-1 (HIF-1). HIF-1 consists of a constitutively expressed HIF-1β subunit and an oxygen-responsive HIF-1α subunit (or their paralogs HIF-2α and HIF-3α). In normoxic conditions prolyl hydroxylase domain-containing proteins (PHDs) hydroxylate proline residues in the HIF-1α degradation domain, enabling the E3 ubiquitin ligase substrate, pVHL (product of the von Hippel-Lindau tumor suppressor), to target HIF-1α for proteasomal degradation. Additionally, factor-inhibiting HIF hydroxylates an asparagine residue in the C-terminal transactivation domain, rendering HIF-1α transcriptionally inactive. Since hydroxylation is dependent on $O_2$ availability, in hypoxic conditions these enzymes no longer posttranslationally modify HIF-1α, leading to HIF-1α stabilization. Stabilized HIF-1α is subsequently translocated to the nucleus, where it dimerizes with β subunits, enabling it to regulate the expression of hypoxia-responsive genes (Figure 27.2) [32–34].

HIF-1α regulates the expression of a myriad of genes involved in metabolism, including growth factor and cytokine production, cell growth and migration, ECM production and, in the DNA damage response, enables cells to functionally adapt to low oxygen environments [32–35]. Studies have demonstrated that, in HSCs, exposure to hypoxia activates transcriptional networks that promote HSC quiescence, differentiation potential, and reconstitutive capacity [2,30,36,37]. Although the effects of hypoxia on MSCs *in vivo* are largely unknown, *in vitro* studies indicate that hypoxia (1) increases the proliferation rate, (2) suppresses senescence, (3) induces pluripotency gene expression and telomerase activity, (4) improves differentiation potential, and (5) alters the cytokine and growth factor profile of MSCs [38–42]. Therefore, it is likely that oxygen tension impacts on MSC and HSC proliferation, differentiation, and function *in vivo*.

## 27.2 The response of mesenchymal stromal cells to ionizing radiation

Exposure to ionizing radiation (IR) (e.g., γ-rays and X-rays) has a multitude of adverse dose-dependent effects on human tissues, including skin burns, hair loss, and shedding of the epithelium lining the gastrointestinal tract. The hematopoietic system is one of the first cellular systems to fail following acute exposure to IR. Lymphocytes in general are highly radiosensitive and die within 24 h following exposure to even low IR doses, whereas granulocytes, erythrocytes, and platelets are more radioresistant [43,44]. HSCs and their progenitors are also radiosensitive, with a $D_0$ of 0.6–1.6 Gy, the dose required to reduce the proportion of surviving cells by 37% less than its previous value, thus preventing continuous renewal of functional blood and immune cell types in the periphery [43,45]. Allogeneic HSC transplantation remains the only practical treatment available for hematopoietic failure following IR exposure. In this process, patients are transplanted with HSCs isolated from a healthy living donor or with umbilical cord blood cells containing HSCs that have been cryopreserved in a cord blood bank. After appropriate pretransplant conditioning, treatment of the recipient (to ablate any residual immune cells that might reject the donor's cells) normal donor HSCs can engraft in the BM of the transplant recipient and reconstitute their hematopoietic and immune systems. Without HSC transplantation, exposed patients will usually die from

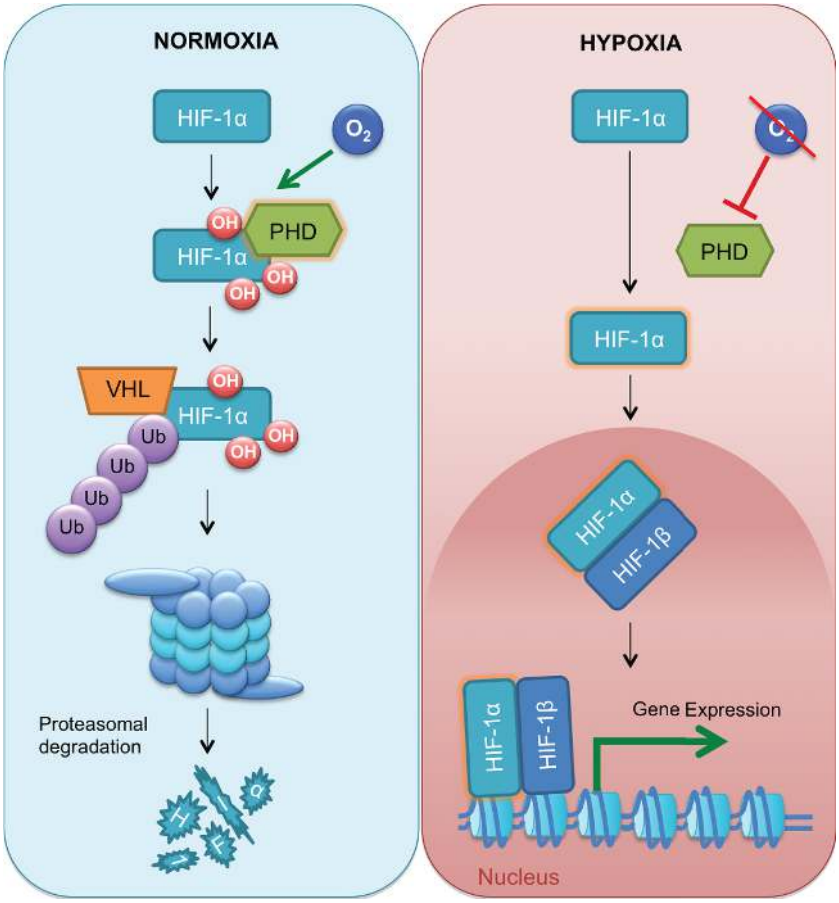

**Figure 27.2** Oxygen-dependent regulation of HIF-1 activity. In normoxia (left panel) the presence of oxygen allows the hydroxylation of HIF-1α by prolyl hydroxylase domain-containing proteins (PHDs), allowing product of the von Hippel–Lindau tumor suppressor (pVHL) to target it for proteasomal degradation. In hypoxia (right panel) the low oxygen levels prevent HIF-1α hydroxylation, allowing its stabilization and translocation to the nucleus, where it dimerizes with HIF-1β and promotes the expression of oxygen-responsive genes. Ub: ubiquitin; OH: hydroxyl groups. (See color plate section.)

complications of hematopoietic failure, which results in anemia, thrombocytopenia, agranulocytosis, and lymphopenia (no red cells, no platelets, no granulocytes (neutrophils), and no lymphocytes) [43,44].

However, unlike hematopoietic cells, MSCs are relatively radioresistant. Studies performed in mice and in humans have demonstrated that MSCs isolated from HSC transplant recipients originate from the irradiated host, rather than from the engrafted donor HSCs [46–51]. In addition MSCs isolated from these recipients can subsequently be expanded *in vitro* to generate cell lines such as MS-5, which (1) retain mesenchymal differentiation capacity, (2) continue to support hematopoiesis *in vitro*, and (3) do not give rise to tumors when injected into mice [46–51]. These findings demonstrate that MSCs within the BM can survive doses of irradiation that are detrimental to the hematopoietic system.

## 27.3 The DNA damage response

The maintenance of genomic stability is essential for cell survival and for preventing malignant transformation. The genome of the cell is continuously challenged by both extrinsic and intrinsic genotoxic stresses that damage DNA, such as environmental mutagens (e.g., IR and ultraviolet light) and reactive metabolic byproducts (e.g., reactive oxygen intermediates). The cellular responses to IR are mostly due to its destructive effects on the genome [52,53]. In general, IR-induced DNA damage can arise (1) from energy deposited directly on to DNA or (2) indirectly from free radicals generated by the ionization of other molecules, such as oxygen and water, that modify and/or break chemical bonds within DNA strands [54]. Cells have evolved a complex signaling network that senses DNA damage and they activate biological responses that promote cell survival or, if the DNA damage present in the cell is too extensive, can stimulate the cell to die. These pathways are collectively known as the DNA damage response (DDR). Conceptually, the DDR consists of (1) sensor proteins that monitor DNA for structural abnormalities such as DNA breaks; (2) transducer proteins that transmit and amplify the DNA damage signal; and (3) effector proteins that orchestrate the desired biological response(s) following the triggering of the DDR [55,56]. These pathways can ultimately lead to either a temporary or permanent halt in cell growth and division, the activation of DNA repair mechanisms and/or the activation of cell death mechanisms (Figure 27.3). Therefore, the activation of specific DDR pathways ultimately determines whether a damaged cell will survive or die in response to genotoxic stress.

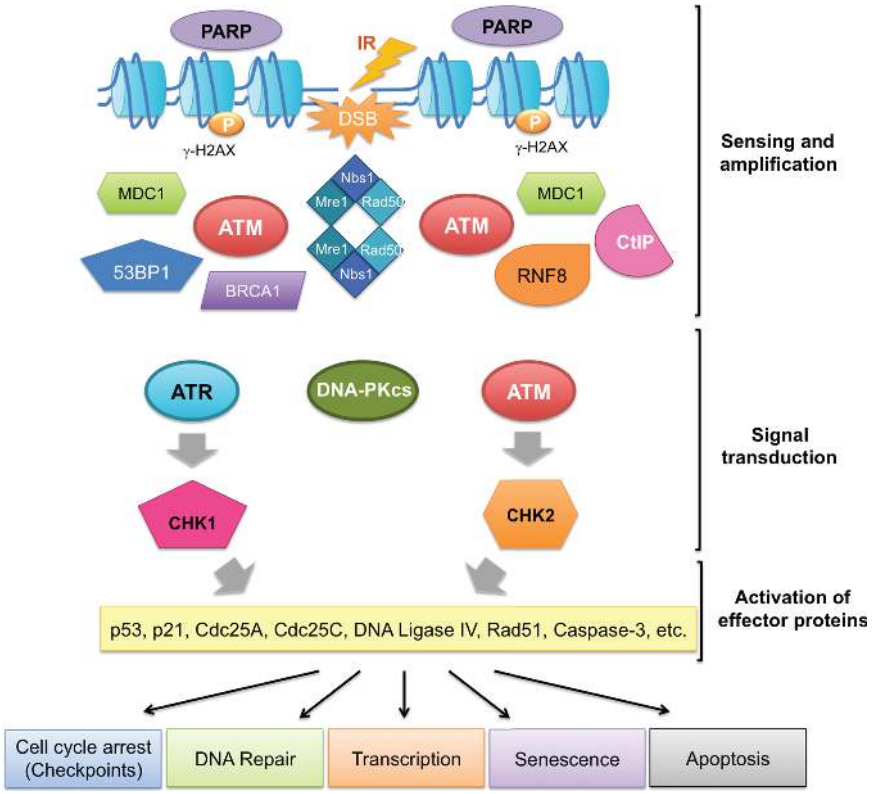

**Figure 27.3** The DDR is composed of sensor, transducer, and effector proteins whose activities induce biological responses to DNA damage. DNA double-strand breaks (DSBs) are initially sensed by poly-(ADP-ribose) polymerase (PARP) and the Mre11–Rad50–Nbs1 (MRN) complex, resulting in the recruitment and activation of the phosphoinositide-3-kinase (PI3K)-related protein kinases, ataxia–telangiectasia-mutated (ATM), and DNA-PKcs (DNA-dependent protein kinase, catalytic subunit – see text for details). Posttranslational modifications to histones surrounding DNA DSBs, including ATM-dependent H2AX Ser139 phosphorylation (γ-H2AX), stimulate the recruitment of DDR mediators, including mediator of DNA damage checkpoint protein 1 (MDC1), p53 binding protein 1 (53BP1), breast cancer type 1 (BRCA1), C-terminus interacting protein (CtIP), and E3 ubiquitin ligase RING finger protein 8 (RNF8), which act to amplify the DDR signal and to modulate ATM-dependent phosphorylation of target substrates. ATM-mediated DNA DSB resection to generate single-stranded DNA (ssDNA) tails also results in ATM and RAD3 related (ATR) activation. Activated ATM and ATR phosphorylate and activate the DDR transducers checkpoint kinase (CHK)2 and CHK1 respectively, which relay the damage signal downstream to effector proteins involved in various biological responses. These include p53 and p21: DNA damage checkpoints, DNA damage-induced transcription, DNA repair, apoptosis, and senescence; Cdc25a: DNA damage checkpoints; DNA ligase IV and Rad51: DNA DSB repair; caspase-3: apoptosis. See text for details.

The most genotoxic lesions caused by IR are DNA DSBs. These can arise when breaks in sister DNA strands occur either directly opposite or within a few base pairs of each other, causing the chromatin to be segregated into two pieces. The lack of a DNA template at the damage site renders these lesions difficult to repair, increasing cellular susceptibility to chromosomal instability and to the induction of cell death mechanisms [54]. It is estimated that each gray of IR introduces 33 DSBs into the mammalian genome [57]. DNA DSBs can also occur endogenously due to telomere uncapping or during DNA replication as a result of the collapse of a stalled replication fork. Replication fork stalling can occur due to presence of various lesions, including single base lesions, cross-links, and single DNA strand breaks (SSBs). It can also occur at natural replication pause sites known as fragile sites, which are frequently associated with chromosome breakage and genomic rearrangements [58–60]. Despite being a major threat to the genome, DNA DSBs also have defined biological purposes and are introduced deliberately, in a well-controlled manner, during meiotic recombination. In developing T and B lymphocytes, DNA DSBs are also induced during V(D)J recombination and class switch recombination, and are essential for generating the extensive repertoire of immunoglobulins and T cell receptors expressed on B cells and T cells respectively, which are central to the adaptive immune response [61,62].

The DDR is primarily regulated by the PI3K-related protein kinase family, which includes ATM, ATR, and DNA-PKcs [54,63–65]. All members share a common PI3K domain that phosphorylates a serine or threonine residue that is followed by glutamine (i.e., an SQ or TQ motif) in target substrates in order to transduce DNA damage signals to various transducer and effector proteins [64]. ATM is the master regulator of DNA DSB signaling pathways, whereas DNA-PKcs are primarily involved in the DNA DSB repair pathway or nonhomologous end-joining (NHEJ), which will be discussed later in further detail. ATR is primarily activated by ssDNA structures that are generated by a range of DNA lesions, including base adducts, cross-links, or single-strand breaks. Such DNA lesions are generated naturally during DNA replication and artificially by various agents that inhibit DNA replication, such as ultraviolet

light and hydroxyurea [58–60,63]. We will mainly focus on the branches of the DDR that mediate the cellular response to DNA DSBs as they represent the most deleterious DNA lesions caused by IR.

### 27.3.1 Sensing damage: DNA damage response initiation

The DDR is activated when DNA lesions such as DNA DSBs are recognized by sensor proteins. DNA DSBs are initially recognized by members of PARP family of proteins. Of the 17 members of the PARP family, only PARP1–3 have so far been demonstrated to be involved in the DDR, with each member having a different specificity. PARP1 is activated by multiple types of DNA lesions, including SSBs, DNA cross-links, stalled replication forks, and DSBs. PARP2 is thought to recognize gaps and flap structures, while PARP3 responds selectively to DNA DSBs, most likely in cooperation with PARP1 [53,66,67]. PARPs catalyze the addition of poly-(ADP) ribose (PAR) chains (i.e., PARylation) to histone tails flanking DNA DSBs. These chains provide a platform for recruiting the MRN complex, which forms a physical bridge between DNA DSB ends and acts as a primary sensor of DNA DSBs [66,68]. The MRN complex is a hexameric structure consisting of dimers of each of its three subunits. The Mre11, Rad50, and Nbs1 subunits collectively function to initiate the DDR, to stimulate the activation of downstream signaling pathways, and also to aid in the repair of DNA DSBs. Mre11 is a U-shaped nuclease that binds to short 3′OH overhangs at DNA DSB termini to form synaptic DNA complexes. Rad50 contains an adenosine-5′-triphosphate-binding cassette that binds and unwinds DNA DSB termini. While Mre11 facilitates short-range synapsis of the two ends at a DNA DSB, the current model suggests that Rad50 mediates long-range tethering of two different DNA molecules; for example, a broken chromosome and its sister chromatid. Nbs1 acts as a flexible adaptor between Mre11 and Rad50 and mediates the assembly and nuclease activity of MRN complexes at DNA DSB sites [69–72]. Recruitment of the MRN complex to DNA DSBs is essential for activating DDR signaling pathways.

As previously mentioned, the PI3K kinases ATM, ATR, and DNA protein kinase, catalytic subunit (DNA-PKcs) are key regulators of DDR signaling. ATM is rapidly recruited to DNA DSBs by the MRN complex and physically interacts with Nbs1. Interaction with the MRN complex stimulates ATM to be posttranslationally modified on multiple residues that (1) activate (e.g., S1981 autophosphorylation) and (2) modulate its function (e.g., TIP60 acetyltransferase-dependent K3016 acetylation). The components of the MRN complex itself are subsequently phosphorylated by activated ATM, which is thought to create a positive feedback loop in order to maintain ATM activity [61,69–76].

### 27.3.2 Sending an SOS: DNA damage response signal transduction and amplification

Following recruitment of PARPs, the MRN complex, and ATM to DNA DSBs, the surrounding chromatin is remodeled in order to amplify the DDR signal downstream. DNA compaction in "closed" heterochromatin obstructs DNA metabolism and repair. Therefore, a more "open" state of chromatin (i.e., euchromatin) is desirable in order to facilitate DNA repair processes. Consequently, immediately following DNA damage, chromatin surrounding DNA DSBs undergoes an energy-dependent local expansion, mediated by adenosine-5′-triphosphate-dependent chromatin remodelers (such as PARP1), in order to facilitate the recruitment of multiple DDR factors to damaged sites [77–79]. During the chromatin remodeling process histones are also posttranslationally modified in order to create docking sites for a family of BRCA1 C-terminal (BRCT)-domain-containing DDR scaffold or "mediator" proteins. DDR mediators are essential for (1) retaining sensor proteins at DNA DSB sites; (2) modulating ATM activation and function; and (3) facilitating DNA repair. DDR mediators are being identified on a continuing basis and include MDC1, RNF8, 53BP1, and BRCA1 [53,80–83].

A well-characterized histone modification generated in response to IR-induced DNA DSBs is γ-H2AX. The γ-H2AX modification is an important signal for DDR activation in response to DNA DSBs and is generally recognized as a marker of DNA DSBs [84–87]. γ-H2AX combined with Tyr143 dephosphorylation (via eyes absent homolog 1/3 [EYA1/3] phosphatases) facilitates the docking of MDC1 on to chromatin at DNA DSB sites where it interacts with ATM and Nbs1. This stimulates the recruitment of additional ATM–MRN complexes and further ATM activation, resulting in H2AX phosphorylation over several megabases (Figure 27.3) [61,88]. Other histone modifications, – for example, acetylation, ubiquitination, and methylation – also stimulate the recruitment of other DDR mediators, such as 53BP1 and BRCA1. This complex assembly of DDR sensors and mediators at DNA DSBs results in the formation of supramolecular structures known as DNA DSB-associated foci, or IR-induced foci (IRIF), which act to amplify the DDR signal downstream and to facilitate DNA DSB repair [68,88–90].

Crosstalk between DDR mediators and ATM at DNA DSBs enables ATM to phosphorylate numerous target substrates, including the DDR transducer Chk2. To facilitate DNA repair, various endonucleases are recruited to DNA DSBs to generate ssDNA tails, a process known as DNA DSB resection. As previously mentioned, ssDNA structures at damage sites are normally recognized by ATR. During DNA DSB resection, ATM mediates replication protein A (RPA) coating of ssDNA tails, which subsequently triggers ATR activation and ATR-dependent phosphorylation of another DDR transducer, Chk1 [65,91–93]. Thus, the DDR is modulated by a crosstalk between ATM–Chk2 and ATR–Chk1 pathways, which together transmit the damage signal to multiple effector proteins that orchestrate biological outcome(s) to DNA DSBs. These outcomes include transient delays in cell cycle progression (termed DNA damage checkpoints), DNA DSB repair, apoptosis, and senescence (Figure 27.3). These processes will now be discussed in further detail.

### 27.3.3 DNA damage checkpoints

The cell cycle comprises the series of events that enable the replication of the genetic material and its subsequent segregation into two new cells. It is composed of four discrete phases: mitosis (M), gap 1 ($G_1$), DNA synthesis (S), and gap 2 ($G_2$). $G_0$ refers to cells that are quiescent (i.e., out of cycle). These are detailed as follows: (1) $G_1$, in which the cell is stimulated to increase in mass by extracellular mitogens and growth factors and prepares for DNA synthesis; (2) S phase, in which DNA synthesis occurs; (3) $G_2$, in which the cell continues to increase in mass and prepares for mitosis; and (4) M phase, in which the cell segregates its newly copied chromosomes and divides [94,95]. Cell cycle progression is driven by a series of protein kinases known as cyclin-dependent kinases (CDKs). The activity of each CDK is regulated by the binding of specific cyclins whose expression levels fluctuate throughout the cell cycle, allowing different CDKs to be only active during specific cell cycle phases. Cyclin D–CDK4/6 and cyclin E–CDK2 complexes promote $G_1$ progression into S phase; cyclin A–CDK2 complexes are required for DNA synthesis and cyclin A– and cyclin B–CDK1 complexes regulate progression through $G_2$ and mitosis (Figure 27.4A). CDK activity is also modulated by (1) phosphorylation on conserved threonine and tyrosine residues by various enzymes, which induce conformational changes that can either promote or inhibit cyclin binding, and (2) by CDK inhibitors (CKIs), which can bind CDKs either alone or in cyclin–CDK complexes, thereby inhibiting CDK activity [52,96–99].

Activation of the DDR signal cascade can induce transient delays at specific cell cycle transitions (such as $G_1$-to-S phase or $G_2$-to-M) or during phases (intra-S phase;, i.e., during DNA replication), and these are known as the DNA damage checkpoints (Figure 27.4A) [52]. These checkpoints function as regulatory systems that ensure all processes in the cell required to replicate the genome are correctly completed before allowing subsequent division into two new daughter cells. In the presence of genotoxic or other cellular stresses, these checkpoints are activated to provide time for pathways required for the resolution of this stress to be activated.

#### 27.3.3.1 $G_1$/S checkpoint

Cells need to ensure that the genome is stable before committing to cell cycle entry. Therefore, the $G_1$/S checkpoint functions to prevent the initiation of DNA synthesis (i.e., entry into S phase) in the presence of DNA damage. The $G_1$/S checkpoint can be activated by ATM- and ATR-dependent phosphorylation of the DDR signal transducers, Chk1 and Chk2. Activated Chk1 and Chk2 in turn target two critical effectors operating in distinct branches of the $G_1$/S checkpoint, the Cdc25a phosphatase and the transcription factor p53. Cdc25a phosphatase activates CDK2, which is involved in the loading on to chromatin of Cdc45, a protein necessary for the activation of prereplication complexes during the initiation of DNA replication. In response to DNA DSBs, ATM-dependent Chk2 phosphorylation of Cdc25a targets it for ubiquitin-dependent proteasomal degradation, preventing

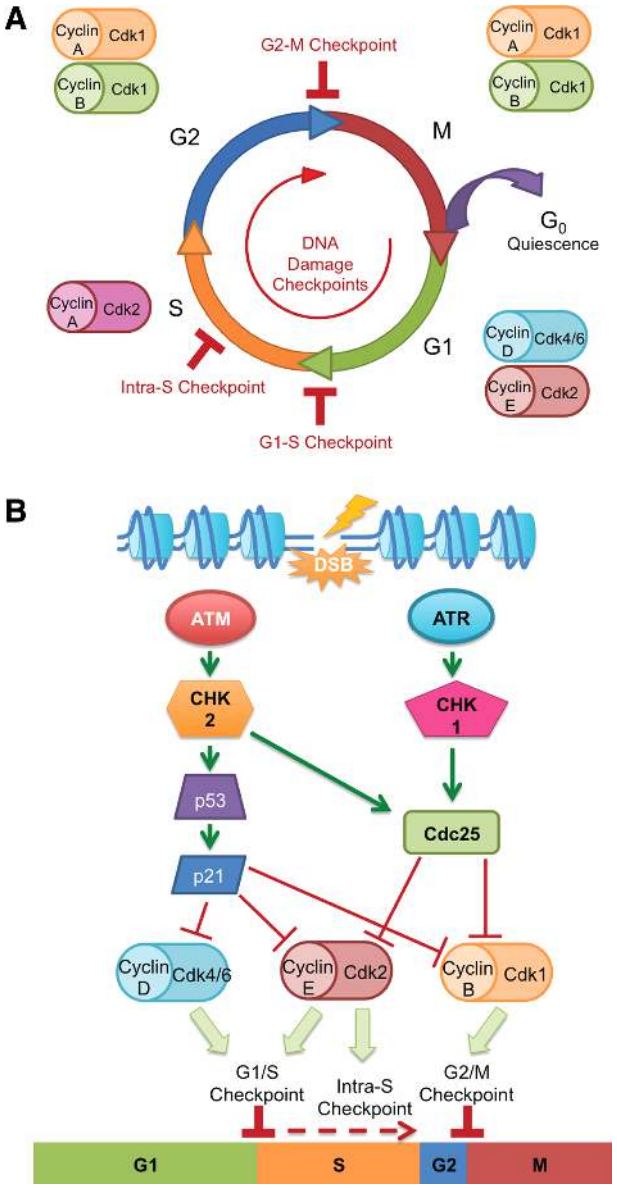

**Figure 27.4** DNA damage checkpoints. (A) The cell cycle is composed by four discrete phases: $G_1$, S, $G_2$, and M. The transition from one phase to the next is controlled by different cyclins and CDKs. These transitions can be delayed by the DDR in response to DNA damage through the activation of specific mechanisms known as DNA damage checkpoints, which are named according to the cell cycle transition that they affect: $G_1$/S, intra-S, or $G_2$/M checkpoints. (B) In response to DNA DSBs, ATM and Chk2 activation leads to downstream p53 stabilization and subsequent induction of p21 transcription. p21 is a potent CDK inhibitor that prevents the activation of cyclin D–Cdk4/6, cyclin E–Cdk2 and cyclin B–Cdk1 complexes, resulting in (1) a block in S-phase entry (i.e., the $G_1$/S checkpoint); (2) a reduction in the rate of DNA synthesis (i.e., the intra-S-phase checkpoint); and (3) a block in mitotic entry (i.e., the $G_2$/M checkpoint). Both ATM–Chk2 and ATR–Chk1 signaling pathways lead to the phosphorylation and targeted degradation of Cdc25a and Cdc25c phosphatases. Cdc25a and Cdc25c degradation prevent the downstream activation of cyclin E–Cdk2 and cyclin B–Cdk1 complexes respectively, inhibiting DNA replication (i.e., the intra-S-phase checkpoint) and blocking entry into mitosis (M) (i.e., the $G_2$/M checkpoint); see text for further details. Cdc: cell division control (protein). (See color plate section.)

CDK2 activation and thereby inhibiting DNA replication. This pathway is rapidly implemented, but is only capable of delaying cell cycle progression for several hours [100–103].

The other branch of the $G_1$/S checkpoint is regulated by the ATM–p53–p21 signaling axis. This pathway is activated slowly as the transcription and translation of downstream proteins are required to induce prolonged $G_1$ arrest. p53 and p21 are two key tumor suppressors that inhibit the proliferation of genetically unstable cells by regulating the expression of genes involved in multiple DDR mechanisms, including cell cycle arrest, DNA repair, and apoptosis. Under normal conditions, p53's function is constitutively maintained at low levels by the E3 ubiquitin ligase, mouse double minute 2 (Mdm2), which targets p53 for proteasomal degradation. However, in response to DNA DSBs, p53 and Mdm2 become posttranslationally modified by various DDR proteins, including ATM and Chk2, leading to p53 stabilization and accumulation. This results in an increase in its transcriptional activity. p21, a CKI, is the key effector of p53-mediated $G_1$ arrest. p53 positively regulates the expression of the CKI, p21, which inhibits (1) cyclin D–CDK4/6 and cyclin E–CDK2 complexes required for the $G_1$/S transition and (2) proliferating cell nuclear antigen (PCNA) activity required for DNA replication, thereby blocking S-phase entry (Figure 27.4B) [52,100–107].

#### 27.3.3.2 Intra-S-phase checkpoint

The intra-S-phase checkpoint is activated in response to replication stress and DNA damage. It is characterized by a reduction in the rate of DNA synthesis. This occurs due to the inhibition of late origin firing, caused by the presence of replication inhibitors and by DNA damaging agents. This checkpoint is also instigated as a result of replication fork stalling, which occurs due to an arrest in DNA elongation caused by the failure of replication complexes to bind to damaged template DNA. This checkpoint functions to protect stalled replication forks from aberrant recombination, promoting the relaxation of chromosomal torsional stress and the completion of replication via upregulation of deoxyribonucleotide (dNTP) production [108]. There are likely two effector cascades that contribute to the IR-induced intra-S-phase checkpoint. The blockade of replication origin firing in response to DNA DSBs is primarily mediated by the previously described ATM–Chk2–Cdc25a signaling axis (Figure 27.4B) [109,110]. The mechanism(s) underlying replication fork stalling in response to DNA DSBs is currently poorly understood. However, cohesin, a protein complex consisting of Structural Maintenance of Chromosome (SMC)1, SMC3, and double-strand-break repair protein RAD21 (known as Sister Chromatid Cohesion protein 1 (SCC1)) that forms a ring around sister chromatids as they are being synthesized during DNA replication, has emerged as an important substrate of ATM signaling in this process. The pairing of sister chromatids, (i.e., cohesion) is essential for accurate chromosome condensation and segregation in mitosis and for DNA DSB repair by homologous recombination (HR) [111,112]. Nbs1–BRCA1–ATM-dependent phosphorylation of SMC1 and ATM–Chk2-dependent phosphorylation of SMC3 are known to be required for replication fork stalling in response to DNA DSBs [113,114]. The molecular mechanism(s) linking ATM-mediated posttranslational modification of cohesin and replication fork stalling remains to be determined.

#### 27.3.3.3 $G_2$/M checkpoint

The $G_2$/M checkpoint prevents cells from initiating mitosis in the presence of DNA damage. This process is essential for preventing chromosomal instability and for ensuring that potentially harmful mutations are not inherited by daughter progeny. In response to DNA DSBs, ATM and Chk2 phosphorylate Cdc25c phosphatase, targeting Cdc25c for proteasomal degradation. As a result, Cdc25c does not remove inhibitory threonine 14/tyrosine 15 phosphorylations present on CDK1, preventing activation of CDK1–cyclin B complexes, thereby blocking entry into mitosis. ATR–Chk1-dependent phosphorylation and subsequent degradation of Cdc25C in response to resected DNA DSBs also contributes to the activation of $G_2$/M arrest in response to resected DSBs as described earlier (Figure 27.4B) [115,116]. The $G_2$/M checkpoint is maintained by two MDC1–53BP1-dependent pathways, depending on the nature of the DNA DSB. 53BP1 and MDC1 sustain activated ATM–Chk2 signaling in response to persisting DNA DSBs, whereas they promote the activation of ATR–Chk1 signaling in response to resected DNA DSBs [116,117]. Overall, activation of DNA damage checkpoints is critical to provide time for persisting DNA damage within the cell to be repaired before undergoing cell division.

## 27.4 DNA double-strand break repair

As previously discussed, DNA DSBs are extremely destructive for the genome. Therefore, failure to repair DNA DSBs, or their misrepair, can result in chromosomal aberrations and subsequently cell death or cell transformation and malignancy. Cells have evolved DNA repair pathways to effectively resolve DNA lesions in order to prevent these biological outcomes. DNA DSBs are primarily repaired via two distinct pathways, known as HR and NHEJ. HR requires a complementary DNA strand within a sister chromatid as a homologous template for DNA DSB repair, whereas NHEJ consists of tethering broken DNA ends together followed by their religation. The requirement of a sister chromatid for repair by HR results in this pathway being restricted only to S and $G_2$ phases of the cell cycle, whereas NHEJ can be activated throughout the cell cycle (Figure 27.5). Therefore, NHEJ is responsible for the repair of the majority of DNA DSBs, while only approximately 15–20% DNA DSBs are repaired via HR [118–121].

### 27.4.1 Nonhomologous end joining

NHEJ is initiated by the binding of each DNA end at the DSB by the ring-shaped Ku70–Ku80 heterodimeric complex.

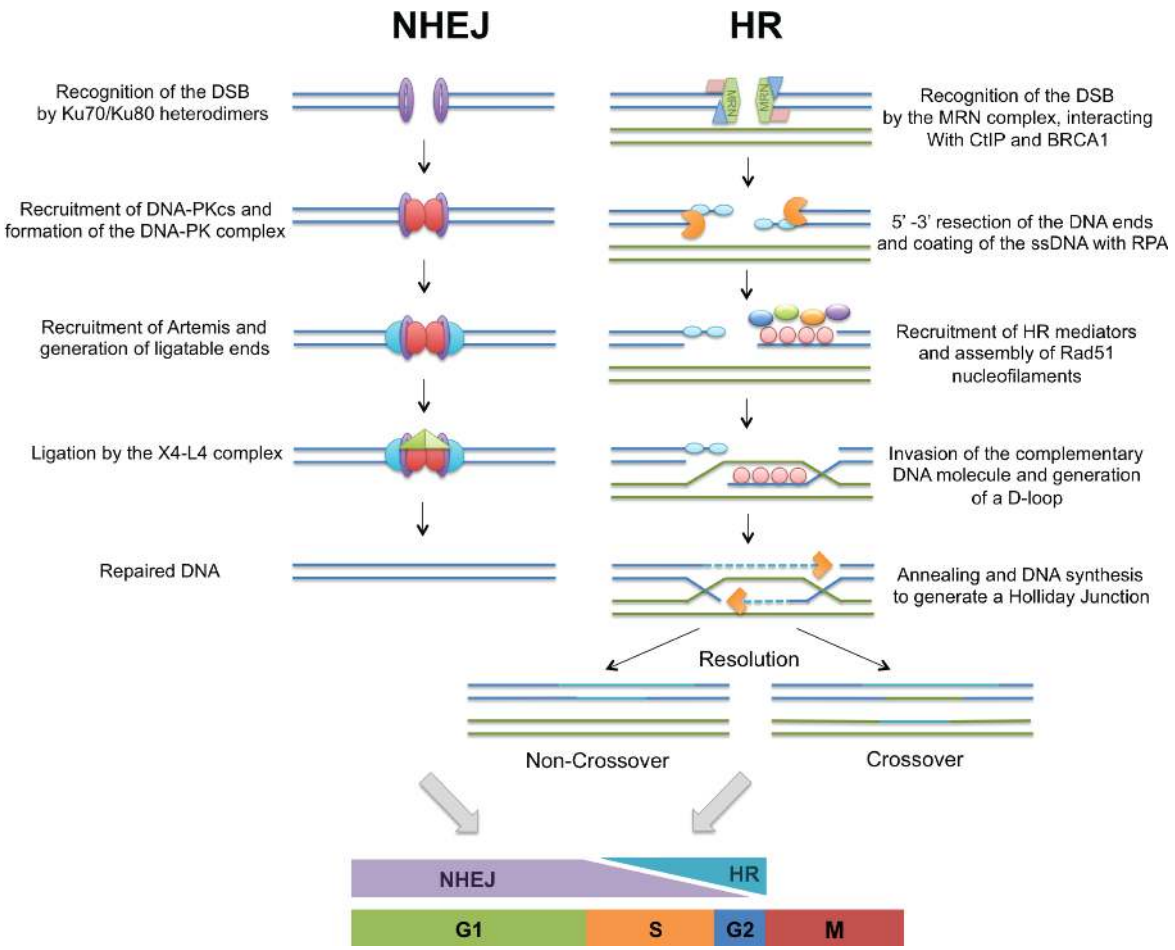

**Figure 27.5** DSB repair mechanisms. In NHEJ (left panel), DNA DSBs are recognized by the Ku70/Ku80 complex that forms a synaptic complex with DNA DSB termini and recruits DNA-PKcs to form the DNA-PK holoenzyme. DNA-PKcs is activated and the 5′–3′ endonuclease Artemis is recruited. Subsequent processing of DNA DSB ends facilitates the recruitment of the X4–L4 complex in which DNA ligase IV is activated and ligates the processed DNA DSB ends, resolving the DSB. In HR (right panel) DNA DSBs are resected by the 5′–3′ endonuclease activity of the MRN/–CtIP–BRCA1 complex, generating ssDNA tails that are subsequently bound by RPA. RPA unwinds DNA secondary structure, facilitating further resection and the recruitment of HR proteins, including BRCA2, X-ray repair cross-complementing protein (XRCC)3, Rad52, and Rad54. These proteins assemble Rad51 molecules along ssDNA tails, generating a Rad51 nucleofilament that displaces RPA oligomers. The Rad51 nucleofilament invades the sister chromatid and facilitates complementary binding between the resected DNA strand (generated at the DNA DSB) and the unprocessed sister DNA strand, resulting in the formation of a displacement (D) loop DNA intermediate. Subsequent annealing of the unresected DNA strand at the DNA DSB to the D loop and DNA synthesis generates a four-stranded DNA structure known as a double Holliday junction. These Holliday junctions can be repaired by either (1) sister chromatid dissociation, forming a non-crossover product or (2) cleavage and subsequent resolution of the cleaved products, generating a crossover product. While NHEJ can take place throughout the entire cell cycle, HR is restricted to S and G2 phases owing to the need for a homologous template (see text for further details). Rad51: a DNA repair protein; X4–L4: a complex consisting of XRCC4, XRCC4-like factor (XLF), and DNA ligase IV.

Ku70–Ku80 heterodimers hold the two ends in close proximity (a process known as synapsis) and recruit DNA-PKcs to DSB termini, together forming the DNA-PK complex in which DNA-PKcs is activated. Depending on the nature of the DNA ends and the complexity of the DSB, different processing factors are subsequently recruited to the DNA DSB. These factors include Artemis (a 5′–3′ endonuclease), polynucleotide kinase, and DNA polymerase X family members that process DNA DSBs to generate 5′ and 3′ ligatable DNA ends. The processed DNA ends are subsequently religated by the X4–L4 complex, consisting of XRCC4, XLF, and DNA ligase IV. XRCC4 and XLF create a scaffold for DNA Ligase IV at the DNA DSB site, resulting in the activation of DNA ligase IV and the resolution of the DNA DSB (Figure 27.5). 53BP1 has emerged as an important mediator and effector in the DDR with roles in DDR initiation, checkpoint signaling, and in DNA repair [119,120,122–125]. Interestingly, 53BP1 has been shown to interact with Rap1-interacting factor (RIF1) at DNA DSBs to block 5′ end resection, thereby promoting DNA DSB repair by NHEJ and inhibiting HR [119,126]. 53BP1 is also involved in long-range end-joining of antigen receptor loci segments in V (D) J recombination and in class switch recombination [127–129].

### 27.4.2 Homologous recombination

Unlike NHEJ, HR employs a complementary DNA strand within a sister chromatid as a homologous template for DNA DSB repair. First, 5′–3′ DNA DSB resection is carried out to create 3′ ssDNA overhangs that are necessary for strand exchange. This process is initiated by the interaction of the MRN complex with CTBP (C-terminus binding protein of adenovirus E1A-interacting protein (CtIP) and BRCA1, and continued by various exonucleases, including Exo1 and the Bloom syndrome helicase. These ssDNA tails are subsequently bound and stabilized by RPA oligomers, which unwind DNA secondary structures, facilitating the recruitment of HR factors. Rad51 recombinase translocates to the nucleus where various mediators, including BRCA2, XRCC3, Rad52, and Rad54, recruit and assemble Rad51 molecules along ssDNA strands, forming a nucleoprotein filament that displaces RPA. BRCA2-dependent loading of Rad51 at processed DNA DSBs results in Rad51 IRIF formation, which can be used experimentally as a marker of DNA DSB repair by HR. The Rad51 nucleoprotein filament then captures the duplex DNA of the intact homologous DNA region in the sister chromatid and invades a single DNA strand, generating a displacement loop intermediate within the sister chromatid. The invasion is followed by extension along both broken DNA strands by a DNA polymerase, most likely Poln, resulting in the formation of a four-stranded DNA structure known as a double Holliday junction. These complex DNA structures are resolved by resolvase complexes, such as Bloom syndrome protein–topoisomerase IIIα complex, resulting in the generation of repaired crossover (reciprocal exchange of DNA sequences) or noncrossover DNA products (Figure 27.5). The type of DNA product generated by HR is tightly regulated. In mitotic cells, the generation of crossover DNA products is disfavored when the DNA template selected fails to locate the identical sister chromatid. This is important for preventing genomic instability, as loss of heterozygosity and translocations can occur due to invasion of the wrong chromosome, and copy number changes may arise as a consequence of inaccurate template selection in repetitive DNA sequence regions such as ribosomal DNA sequences [122,124,130–135].

### 27.4.3 DNA double-strand break repair pathway choice

The choice between NHEJ and HR pathway activation needs to be tightly regulated in order to ensure maintenance of genomic stability. Repair pathway choice is critically influenced by the decision to initiate 5′–3′ DNA DSB end resection, which is now known to be regulated by the DDR mediators 53BP1 and BRCA1. This resection process is necessary for the activation of HR and simultaneous suppression of NHEJ [119,133]. At DNA DSBs, 53BP1 collaborates with RIF1 and paired box transactivation activation domain-interacting protein (PTIP) to inhibit the association of BRCA1 with MRN complex-bound CtIP, preventing DNA DSB resection. Once the cell enters S phase, CtIP is phosphorylated by CDKs, enabling the formation of the MRN–CtIP–BRCA1 complex. This complex displaces 53BP1, RIF1, and PTIP at DNA DSB sites, enabling DNA DSB resection to be initiated, subsequently leading to the activation of HR [119,132–138]. Together, NHEJ and HR enable cells to effectively repair DNA DSBs, contributing to the restoration of genomic integrity and promoting cell survival.

## 27.5 Apoptosis

DNA damage checkpoints and DNA repair mechanisms cooperate to restore genomic stability following genotoxic insult. However, when DNA damage is too extensive within the cell or cannot be repaired, cells can activate mechanisms to ensure that cells harboring potentially harmful genetic mutations are eliminated, or at least lose their proliferative capacity. Apoptosis is a type of programmed cell death that eliminates damaged and stressed cells and is the most prominent type of cell death activated in the presence of DNA damage [139,140]. Apoptosis is characterized by cellular and nuclear shrinkage (pyknosis), chromatin condensation, nuclear fragmentation, blebbing, and the formation of apoptotic bodies. Apoptosis is mainly executed by a family of cysteine proteases known as caspases, which coordinate two main apoptotic signaling pathways known as (1) the intrinsic or mitochondrial pathway and (2) the extrinsic or death receptor-mediated pathway. Caspases are synthesized as inactive zymogens that become functionally active upon cleavage. (A zymogen (or proenzyme) is an inactive enzyme precursor.) Each pathway consists of initiator caspases (e.g., caspase-8, -9, and -10) that cleave and activate executioner caspases (caspase-3, -6, and -7) that act on various proteins involved in multiple biological processes. While the extrinsic apoptotic pathway is initiated by the binding of extracellular signals to death receptors on the cell surface, the intrinsic apoptotic pathway is activated by intracellular stresses including DNA damage [141–144].

The intrinsic apoptotic pathway is regulated by the B cell lymphoma-2 (Bcl-2) family of proteins that are characterized by the presence of one to four conserved Bcl-2 homology (BH) domains. The Bcl-2 family consists of antiapoptotic proteins such as Bcl-2, Bcl-xl, and myeloid cell leukemia 1) and proapoptotic proteins divided into two subfamilies: (1) the BH3-only family, which includes Bid, Bim, Noxa, and Puma; and (2) the Bax family, which includes Bax, Bok, and Bak [141,145–147]. The Bcl-2 family acts as a "life/death" switch that is orchestrated via interactions between the antiapoptotic and proapoptotic members to ensure cell death is activated at the appropriate time and in a well-controlled manner. Under normal conditions, antiapoptotic Bcl-2 family members bind and sequester proapoptotic Bax family members, preventing the induction of apoptosis. In response to DNA DSBs, ATM–Chk2-dependent p53 stabilization can lead to the transcription of the p53 target genes, Puma and Noxa. Although Bim is not a direct transcriptional target of p53, it also plays a key role in activating apoptosis in response to DNA DSBs [148,149]. These activated BH3-only

proteins insert their BH3 domain into the hydrophobic groove of antiapoptotic Bcl-2 proteins, releasing Bax and Bak molecules. Bax, Bak, and other activated BH3-only proteins subsequently oligomerize at the outer mitochondrial membrane, forming pores that facilitate the release of proapoptotic factors from the mitochondrial intermembrane space into the cytosol [141,144–147].

Cytochrome C is one of the most important proapoptotic factors released in this process that interacts with apoptotic protease-activating factor 1 and deoxyadenosine triphosphate in the cytosol, collectively forming the apoptosome. Formation of the apoptosome initiates a signaling cascade in which a sequential series of initiator caspases (e.g., caspase-9) and downstream executioner caspases (e.g., caspase-3) cleave and inactivate target proteins. Thus, executioner caspase-3 can cleave PARP (normally involved in DNA SSB repair) in the presence of extensive DNA damage, preventing PARP-dependent recruitment of other DNA repair proteins to DNA damage sites, ultimately resulting in DNA degradation. Caspase-3 also cleaves and activates the negative regulatory subunit of the caspase-activated DNAse, resulting in DNA cleavage. Cleavage of nuclear lamina results in nuclear shrinking and blebbing, and cleavage of cytoskeletal proteins and cell adhesion molecules contributes to the loss of cell shape. These processes altogether culminate in cellular disassembly and death [144,146,150].

## 27.6 Cellular senescence

Cellular senescence is defined as an irreversible cell cycle arrest that is restricted to proliferating cells. The causes of cellular senescence are still under investigation and include (1) telomere dysfunction, (2) unrepaired DNA damage, (3) oxidative stress, and (4) excessive mitogenic signals, such as overactivation of oncogene expression [151–154]. Senescent cells remain alive and metabolically active, but are characterized by a stable loss of proliferative capacity and altered gene expression that results in multiple cellular changes, including enlarged and defective mitochondria, increased β-galactosidase production in lysosomes, protein aggregation in the endoplasmic reticulum, and an enlarged flattened morphology [154]. In response to DNA DSBs, cellular senescence can be activated by the ATM–Chk2 signaling axis via the phosphorylation and stabilization of p53 [152]. As previously described, in response to DNA damage, p53 can induce the expression of the tumor suppressor p21. p21, in turn, inhibits cyclin D–Cdk4/6, cyclin E–Cdk2, and PCNA activity, halting $G_1$ progression into S phase. The exact mechanisms that underlie the decision to either transiently arrest (i.e., checkpoint) or permanently arrest (i.e., cellular senescence) cell cycle progression at the $G_1$/S transition are poorly understood. However, it is hypothesized that the presence of unrepaired DNA damage within cells may cause p53–p21 signaling to be sustained long term, ultimately leading to permanent cell cycle arrest (i.e., senescence) [151].

Cellular senescence can also be activated via the $p16^{INK4A}$-pRb (retinoblastoma protein) pathway in response to DNA damage. This pathway controls the $G_1$/S phase transition via the regulation of the transcription factor E2F1, whose target genes regulate passage through the restriction point in late $G_1$ and stimulate entry into S phase. $p16^{INK4a}$ is a CKI encoded by the the *ink4a/arf* locus. In response to DNA damage $p16^{INK4a}$ binds to the cyclin D–CDK4/6 complex, preventing it from phosphorylating and inactivating pRb. As a result, pRb remains active and suppresses the activity of E2F1, preventing it from activating target genes required to transit from $G_1$ to S phase, thereby halting cell cycle progression in $G_1$ [99,152,154]. Overall, apoptosis and senescence are key tumor-suppressive mechanisms that prevent the survival and/or growth of cells harboring persistent DNA damage.

## 27.7 Stem cells exhibit a mixed response to DNA damage

The maintenance of genomic integrity in stem cells is indispensable for development and for maintaining tissues throughout adult life. The deleterious effects of DNA damaging agents, such as IR, on tissue viability and regeneration have fueled mounting interest in the DDR of stem cells and their progenitors. Interestingly, these studies have collectively demonstrated that the level of radiosensitivity varies widely between different stem cell types. For example, embryonic stem cells, HSCs, and intestinal stem cells are highly radiosensitive and undergo extensive apoptosis following irradiation (IR) [155–157]. However, other stem cell types, such as keratinocyte stem cells (KSCs) and hair follicle bulge stem cells (BSCs), are relatively resistant to IR-induced cell death [158,159]. Interestingly, radioresistant stem cells such as BSCs and KSCs can repair IR-induced DNA DSBs, whereas radiosensitive stem cells such as HSCs have a poor DNA DSB repair capacity [157,158,160]. IR-induced DNA damage can also stimulate the differentiation of certain stem cell types; for example, (1) of melanocyte stem cells into mature melanocytes and (2) of HSCs into lymphocytes [161,162]. However, the differentiation of other stem cell types, including BSCs and KSCs, is unaffected by irradiation [158,159]. These studies collectively indicate that the response of stem cells to DNA damaging agents is cell type dependent. The individual response of each stem cell type is strongly linked to the differential activation of specific DDR pathways that can either promote survival or induce cell death.

## 27.8 The DNA damage response of mesenchymal stromal cells

Studies to date clearly indicate that MSCs are radioresistant [46–51]. However, the mechanisms that underlie MSC radioresistance are poorly understood. Long-term proliferation

of primary human MSCs *in vitro* following exposure to high-dose irradiation is comparable to that of known radioresistant cell types, such as the A549 lung cancer cell line [163]. Irradiated human MSCs phosphorylate and activate ATM and induce γ-H2AX formation, which is abrogated in the presence of inhibitors that target ATM and DNA-PKcs [163,164]. Thus, the DDR is activated by irradiated human MSCs *in vitro*. The radioresistance of murine MSCs is comparable to that of human MSCs. However, primary mouse MSC cultures exhibit variable induction of γ-H2AX expression and foci formation following irradiation [165]. This suggests that primary mouse MSC cultures exhibit a heterogeneous response to IR-induced DNA damage. Primary MSC cultures can be established from whole BM aspirates previously depleted of hematopoietic cells. However, as described earlier, different stromal cell populations of varying function and differentiation potential are present within the BM. These "'bulk" uncloned MSC cultures are highly heterogeneous, with phenotypic characteristics varying with passage number and also between independent isolations. The inherent heterogeneity of these MSC cultures makes it difficult to extensively characterize the mechanisms that contribute to MSC radioresistance.

To overcome the difficulties presented by using bulk MSC cultures, recent studies have been performed on clonal mouse MSC lines in order to investigate MSC radiobiology in greater detail [165,166]. The radioresistance of the MSC lines MS-5 and ST-2 is comparable to that of primary mouse MSCs [165]. Detailed investigation into the response of these MSC lines to irradiation has demonstrated that several aspects of DDR signaling are likely to contribute to MSC radioresistance. As described previously, γ-H2AX on chromatin surrounding DNA DSBs facilitates the recruitment of various DDR mediator proteins to damage sites, leading to the activation of DDR signaling cascades. Thus, γ-H2AX is a well-defined marker of DDR activation in response to DNA DSBs. The kinetics of γ-H2AX formation were compared between irradiated MSC lines and a radiosensitive immature ($CD4^+$ $CD8^+$) thymocyte line known as ST4.5. These experiments demonstrated that irradiated MSCs induced maximal H2AX phosphorylation and γ-H2AX IRIF formation at a faster rate than radiosensitive ST4.5 thymocytes. ATM and DNA-PKcs function redundantly to phosphorylate H2AX, and chemical inhibition of their kinase activity delays H2AX phosphorylation [167,168]. Interestingly, MSCs were found to endogenously express higher levels of the key DNA DSB response proteins ATM and DNA-PKcs than ST4.5 thymocytes do. Taken together, these findings may indicate that the abundance of important DDR initiator proteins promotes rapid γ-H2AX formation at DNA DSB sites in irradiated MSCs, enabling robust activation of DDR signaling pathways that promote MSC survival.

The resolution of γ-H2AX and/or γ-H2AX foci in irradiated cells over time is an indirect indicator of DNA DSB repair. Following low-dose irradiation (1 Gy), γ-H2AX was resolved at a faster rate in irradiated MSCs than in ST4.5 thymocytes. Furthermore, while γ-H2AX was resolved in MSCs following high-dose irradiation (10 Gy), γ-H2AX persisted long term in irradiated ST4.5 thymocytes. These findings indicate that MSCs have an enhanced ability to repair IR-induced DNA DSBs compared with immature thymocytes [165]. Similar to human MSCs, mouse MSC lines can repair IR-induced DNA DSBs using both NHEJ and HR pathways [163–166]. It has been shown that the majority of IR-induced DNA DSBs are repaired at early time-points after IR, primarily via NHEJ [121]. Similarly, DNA DSBs are largely repaired in MSCs by 4–8 h after high-dose (10 Gy) irradiation [166]. Interestingly, the MSC line MS-5 exhibited an increased capacity to repair DNA DSBs via NHEJ compared with radiosensitive ST4.5 thymocytes [165]. In addition, mouse MSCs expressed higher levels of key DNA DSB repair proteins such as ATM, DNA-PKcs, DNA ligase IV, and Rad51 than ST4.5 thymocytes did. Overall, these findings indicate that MSCs have a robust capacity to repair IR-induced DNA DSBs that is likely promoted by expressing high endogenous levels of key DNA DSB repair proteins.

The presence of DNA damage, including DNA DSBs, can lead to the activation of signaling pathways that results in either delayed cell cycle progression or transient arrest at transitions between cell cycle phases, known as DNA damage checkpoints. In response to DNA DSBs, activation of the $G_1$/S DNA damage checkpoint is primarily mediated via p53-dependent induction of p21, as previously described. Irradiated human MSCs maintain p53 stabilization over time and strongly induce p21 expression after IR, indicating robust activation of the $G_1$/S checkpoint [163,164,169]. However, both primary and clonal murine MSCs only transiently activate the $G_1$/S checkpoint, indicated by (1) transient p53 stabilization and (2) progression of irradiated $G_1$ cells into S phase after high-dose irradiation [165,166]. The lack of a definitive $G_1$/S checkpoint response in mouse MSCs may be correlated with p53 dysfunction in these cultured cells. However, in the presence of persisting DNA DSBs, which can be induced in cells using specific chemotherapeutic drugs such as etoposide, persistent p53 stabilization and downstream induction of p53 target proteins p21 and Puma are readily detectable in mouse MSC lines. Interestingly, transient activation of the $G_1$/S checkpoint has also been reported to occur in irradiated hair follicle BSCs, embryonic stem cells, and human induced pluripotent stem cells [158,169,170]. Like MSCs, BSCs also have a high capacity for repairing IR-induced DNA DSBs via NHEJ and repair DSBs at a similar rate to that of MSCs [158]. Taken together, these findings suggest that the transient activation of the $G_1$/S checkpoint in irradiated mouse MSCs may be correlated with their ability to rapidly resolve DNA DSBs, thereby permitting $G_1$ cells to progress through the cell cycle after irradiation.

Induction of DNA DSBs in S-phase cells can activate the intra-S-phase checkpoint that is characterized by a reduction in the rate of DNA replication, delaying S-phase progression. Cells that accumulate DNA damage during $G_2$ or carry remaining DNA damage from S phase can activate the poorly

understood $G_2$/M checkpoint, which inhibits mitosis in the presence of DNA DSBs.

Activation of the intra-S and $G_2$/M checkpoints can be assessed by monitoring the cell cycle progression of 5′-bromodeoxyuridine (BrdU)-labeled cells. BrdU is a thymidine analog that is incorporated into cells' DNA during DNA replication. Flow cytometric analysis of BrdU-labeled cells with an anti-BrdU antibody and a DNA marker, such as propidium iodide, enables one to distinguish BrdU-labeled S-phase cells from BrdU-unlabeled $G_1$, $G_2$, and mitotic cells. Analysis of BrdU-labeled MSCs demonstrated that both primary and cloned murine MSCs delay S-phase progression and subsequently accumulate in $G_2$ for at least 12 h after high-dose irradiation *in vitro* [165]. These observations indicate that although irradiated mouse MSCs only transiently activate the $G_1$/S checkpoint, the intra-S-phase and $G_2$/M checkpoints are robustly activated by this cell type. The reason(s) why irradiated mouse MSCs preferentially activate intra-S and $G_2$/M checkpoints whereas irradiated human MSCs induce a robust $G_1$/S checkpoint are unclear. It is evident that both mouse and human MSCs can repair DNA DSBs via NHEJ and HR [163–166]. However, whether the capacity of MSCs to repair DNA DSBs by these two pathways is comparable between mouse and human is unknown and may account for the preferential activation of specific DNA damage checkpoints in these cell types.

Importantly, irradiated MSCs can subsequently recover from $G_2$/M arrest and reenter cell cycle. In addition, irradiated MSCs retain the ability to differentiate along mesenchymal-derived lineages [165,171]. These findings indicate that the proliferative capacity and differentiation potential of MSCs remain intact long term after irradiation. However, radiosensitive ST4.5 thymocytes undergo rapid cell death after irradiation, independent of cell cycle phase status. This is due to the rapid activation of apoptosis, indicated by strong p53 stabilization and extensive cleavage of caspase-3 and of PARP in this cell type after irradiation [165]. This phenomenon, previously coined "rapid interphase death," occurs commonly in irradiated lymphocytes. However, unlike ST4.5 cells, and despite harboring intact apoptotic machinery, apoptosis is weakly activated by irradiated mouse MSCs, and cell death mainly only occurs when these cells attempt to reenter the cell cycle following $G_2$/M arrest [165]. In addition, MSCs express high levels of the antiapoptotic proteins Bcl-2 and Bcl-xl, and low levels of the potent proapoptotic proteins Bim and Puma [165]. The intrinsic expression levels of various apoptotic proteins are known to influence the therapeutic sensitivity of various cell types, including HSCs, BSCs, KSCs, and lymphocytes [149,158,172,173]. Therefore, abundant expression of antiapoptotic proteins in MSCs may also enhance their ability to activate prosurvival mechanisms by suppressing the activation of cell death.

Overall, these findings demonstrate that, in response to IR, MSCs preferentially activate DNA damage signaling pathways that promote cell survival. Rapid induction of γ-H2AX in irradiated MSC nuclei, probably promoted by high expression levels of key DDR proteins, is likely to aid MSCs in rapidly initiating protective DNA damage checkpoints and DNA DSB repair. DNA damage checkpoints enable cells to extend the time frame in which DNA damage can be repaired before entering the next phase of the cell cycle. Therefore, coordinated activation of DNA damage checkpoints and DNA repair mechanisms is likely important for efficient resolution of genomic instability in MSCs.

Why MSCs preferentially activate prosurvival pathways in response to DNA damage is unknown. However, mounting evidence indicates that the DDR plays fundamental roles in stem cell biology. The DDR functions in stem cells to monitor endogenous DNA damage caused by environmental factors, such as reactive oxygen species production, and by telomere shortening, preventing stem cell dysfunction and exhaustion *in vivo* [174–177]. In addition, several key DDR proteins, such as ATM, p53, and p21, and DNA DSB repair proteins are also required in stem cells for (1) maintaining self-renewal, (2) inhibiting senescence, and (3) regulating their differentiation potential [160–162,174–180]. Interestingly, proteins involved in genome stability and cell cycle control have also been directly implicated in MSC biology. For example, loss of (1) the cell cycle regulator pRb, (2) the microRNA processor Dicer, and (3) telomerase, which is required for telomere maintenance and stability, impairs the ability of MSCs to regulate hematopoiesis, resulting in myeloproliferation and the development of leukemia [181–183]. In addition, deletion or loss-of-function mutations in several DDR genes, including ATM, ATR, and DNA ligase IV, can result in growth delay, skeletal abnormalities, and osteoporosis [184–186]. Overall, these findings suggest that MSC radioresistance may perhaps be a consequence of the importance of (1) the maintenance of genomic stability for stem cell homeostasis and (2) DDR components in regulating MSC self-renewal, differentiation and function in the BM.

## 27.9 Effects of hypoxia on mesenchymal stromal cell radioresistance

MSCs are radioresistant progenitors that reside in hypoxic niches *in vivo*, particularly in the BM [4,30,31,166,187]. In cancer, hypoxia within tumors and HIF-1α overexpression in tumor cells are associated with increased malignancy and metastatic potential and with poor patient outcome [188,189]. This prognosis is highly correlated with the increased resistance of hypoxic cancer cells to cancer therapies, including radiotherapy [189,190]. Mounting evidence indicates that exposure to hypoxia can alter the DDR of cancer cells, contributing to their increased resistance to DNA-damaging agents, including IR [192,193]. In addition, cellular exposure to severe hypoxia (<1% $O_2$) can activate the DDR independently of DNA damage, indicating that DDR signaling may contribute to adaptation to low oxygen environments [193–197]. Hyperbaric oxygen treatment involves the administration of 100% oxygen above normal atmospheric pressure to increase the amount of dissolved oxygen in

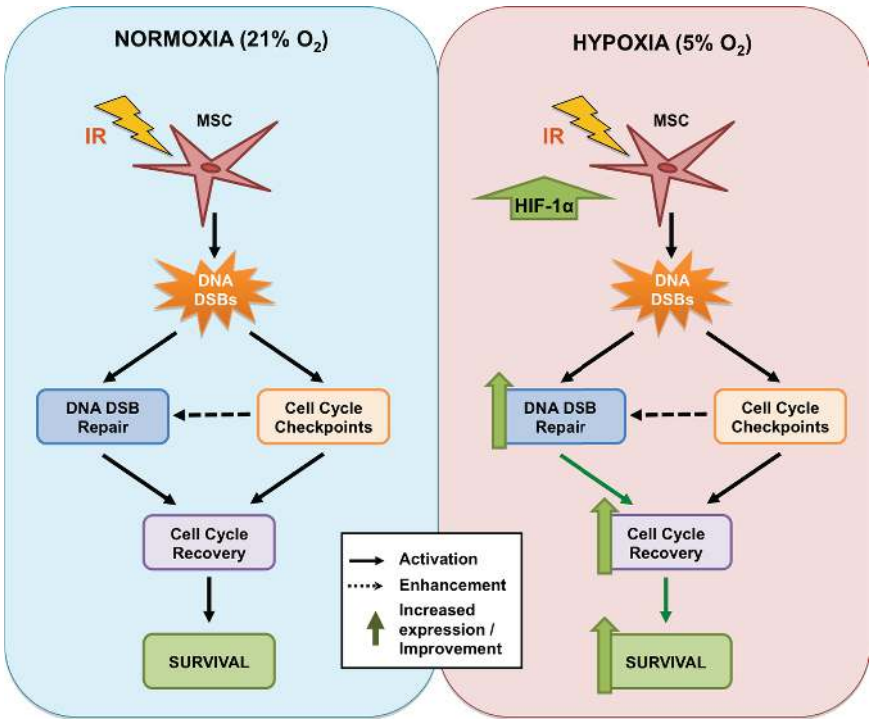

**Figure 27.6** The DDR of mouse MSCs. In normoxia (left panel) and hypoxia (right panel), irradiated MSCs activate DNA damage checkpoints and DNA DSB repair (NHEJ and HR) to resolve genotoxic DNA DSBs. Resolution of DNA DSBs likely enables irradiated MSCs to recover from cell cycle arrest and promotes MSC survival. In hypoxia (right panel), HIF-1α stabilization resulted in (1) increased endogenous expression of the two key NHEJ enzymes, DNA-PKcs and DNA ligase IV, and (2) accelerated recruitment of Rad51 to DNA DSBs, an essential component of repair by HR. Consequently, the DNA DSB repair capacity of MSCs is increased in hypoxia, accelerating recovery from cell cycle arrest and improving long-term survival.

plasma [198]. This treatment has been proposed as a means of increasing oxygen levels within tumors in the hope of augmenting the efficacy of anticancer treatments. However, a recent review indicated that various tumor types respond differentially to the effect of hyperbaric oxygen treatment [198]. Further studies in this area are clearly necessary. Whether exposure to hypoxia affects the resistance of MSCs to irradiation is largely unknown.

In one study, the effect of γ-irradiation on mouse MSCs cultured in normoxia (21% $O_2$) and hypoxia (5% $O_2$) was directly compared. This study demonstrated that both primary mouse MSCs and MSC lines displayed increased resistance to γ-irradiation *in vitro* when cultured in hypoxia [166]. DDR activation, indicated by γ-H2AX formation, was comparable between normoxic and hypoxic MSCs. In addition, MSCs also activated potent intra-S-phase and $G_2$/M checkpoints in hypoxia. However, irradiated MSCs were found to recover from cell cycle arrest at a faster rate in hypoxia than in normoxia [166]. Furthermore, γ-H2AX and γ-H2AX IRIF were resolved at a faster rate in MSC nuclei in hypoxia than with normoxia. Interestingly, MSCs were found to upregulate the expression of key NHEJ repair proteins, including DNA-PKcs and DNA ligase IV in hypoxia. The increased expression of these repair proteins coincided with HIF-1α stabilization in MSCs upon exposure to hypoxia. dsDNA break repairs are reconstituted using proteins of homologous recombination. Rad51 IRIF formation, a key step in the activation of homologous reconstitution, was also accelerated in hypoxic MSCs. Small-interfering-RNA-mediated depletion of HIF-1α in MSCs prevented the upregulated expression of these DNA repair proteins in hypoxic MSCs [166]. These results indicate that HIF-1α may function as a transcriptional modulator of DNA DSB repair in mouse MSCs. Importantly, depletion of HIF-1α rendered MSC lines more radiosensitive. Overall, this study demonstrated that enhanced MSC radioresistance in hypoxia is likely due to alterations in the DDR of MSCs to IR-induced DNA DSBs. These alterations include an enhanced DNA DSB repair capacity that is mediated, at least in part, by the activation of HIF-1α signaling in hypoxic MSCs (Figure 27.6) [166].

Overall, *in vitro* studies to date demonstrate that the DDR plays a major role in mediating the radioresistance of MSCs. Multiple aspects of the DDR are likely to collectively contribute to MSC radioresistance, including (1) rapid activation of DDR signaling, (2) robust DNA damage checkpoints, (3) efficient DNA DSB repair, and (4) suppression of apoptosis (Figure 27.6). The ability to restore the hematopoietic system of an irradiated mouse or human by transplanting donor HSCs into the recipient BM microenvironment is strong evidence that MSCs are also resistant to irradiation *in vivo*. However, as previously described, the BM niche consists of several MSC subpopulations of varying function, proliferative capacity, and differentiation potential. Therefore, it is likely that individual MSC subpopulations exhibit differential DDR signaling responses to IR-induced DNA damage. Mouse MSCs isolated from flushed BM aspirates (BM-MSCs) were reported to be more radiosensitive than MSCs isolated from collagenase-digested bone [199]. Interestingly, $p16^{INK4A}$ tumor suppressor protein was expressed at higher levels in irradiated MSCs from

collagenase-digested bone than in BM-MSCs, whereas $p19^{ARF}$ expression levels were only increased in irradiated BM-MSCs. Furthermore, BM-MSC numbers were significantly reduced in irradiated mouse femurs, and this reduction was rescued in *ink4a/arf*-deficient mice, whereas MSC numbers from collagenase-digested bone were unaffected by irradiation [199]. In addition, human MSCs derived from maxillary and mandibular trabecular bones (orofacial MSCs) were reported to be more radioresistant than MSCs derived from the iliac crest [169]. Orofacial bone MSCs induced higher p21 expression and harbored less DNA damage than iliac crest MSCs after IR treatment. Furthermore, injection of irradiated MSCs into mice demonstrated that bone formation by iliac crest MSCs *in vivo* was delayed in comparison with that of MSCs derived from oro-facial bone [169]. Interestingly, it has also been shown that irradiation stimulates the expansion of the osteoblast compartment in mouse BM, suggested to be due to the proliferation of a currently unidentified osteogenic MSC population in an attempt to repair the BM niche [200]. Taken together, these findings suggest that MSC subpopulations are likely to differentially execute the DDR following genotoxic insult in the BM niche.

## 27.10 Clinical relevance of mesenchymal stromal cells in radiation injury: two sides to the coin

### 27.10.1 Mesenchymal stromal cells and hematopoietic stem cell transplantation

In an allogeneic HSC transplant (HSCT) the recipient receives chemotherapy or chemotherapy and total body irradiation followed by an inoculum of donor cells that contain hematopoietic stem and progenitor cells. The source of the donor HSCs can be BM, mobilized peripheral blood stem cells, or umbilical cord blood stem cells. These cells subsequently reconstitute the hematopoietic and immune systems of the recipient. Such transplants can be genotypically matched for the antigens of the major histocompatibility complex (MHC) if a sibling is used as the donor, or phenotypically MHC-matched if a living unrelated volunteer donor is used. Additionally, an MHC antigen-mismatched HSCT can be used if an MHC-matched donor is unavailable. Even larger degrees of MHC disparity between HSC donor and HSC recipient can be tolerated if umbilical cord blood stem cells are used.

For the past 50 years, allogeneic HSCT has remained the most effective treatment for a number of lymphoid and myeloid malignancies. HSCT can also be used as treatment for some genetic disorders, including severe combined immunodeficiency disease, sickle cell anemia, and thalassemia major. Prior to transplantation, as already indicated, the recipient must undergo treatment known as a conditioning or preparative regimen, which consists of chemotherapy or chemotherapy and radiotherapy [201]. This treatment is required to eliminate any malignant cells, as well as any residual recipient immune cells that could mount an immune response to donor cells, leading to allograft rejection and BM failure. Total body irradiation is frequently used prior to allogeneic HSCT because it covers all sites of hematopoiesis and lymphopoiesis, as well as all sites in the body that harbor malignant cells [201,202]. However, there remains a 30% mortality rate from the procedure for those receiving myeloablative chemotherapy or chemoradiation followed by an allogeneic HSCT for advanced hematologic malignancy. Thus, new strategies focused on reducing complications associated with allogeneic HSCT are required to improve clinical outcomes [201,203–207].

The critical role of MSCs as an instructive support system for hematopoiesis suggests that MSCs may be of therapeutic benefit in allogeneic HSCT. It is well established that irradiated MSCs can support hematopoiesis long term *in vitro*. In addition, conditional depletion of MSC subtypes within mouse BM *in vivo* leads to impaired HSC maintenance and function [1,27–29,208]. Therefore, host MSCs within the BM are likely to contribute to hematopoietic engraftment and reconstitution following HSCT. However, high doses of total body irradiation (10 Gy or above) are known to cause damage to the BM microenvironment, particularly to the perivascular niche [31,209]. In addition, IR-induced damage to the BM vasculature can impede MSC recovery in mouse femurs [209]. Therefore, while irradiated MSCs can support hematopoiesis, loss of the overall BM architecture due to the radiosensitivy of other non-hematopoietic cell types within the niche may indirectly impede hematopoietic recovery following HSCT. Therefore, improving our understanding of the radiation response of the BM niche could enable preconditioning regimens to be improved so that treatments would adequately deplete host hematopoietic cells while maintaining MSCs and other supportive BM niche cells in the BM. In this way it may be possible to improve HSC engraftment and reconstitution without increasing the risk of allograft rejection, thereby potentially increasing the success rates of allogeneic HSC transplantation.

One of the most adverse complications of allogeneic HSC transplantation is graft-versus-host disease (GVHD), which occurs due to the recognition of host tissues as foreign by transplanted donor T cells. Donor T cells mount an immune response against host tissues even in MHC genotypically matched recipients because of the presence of non-MHC histocompatibility antigens present on the cells of the recipient but not on those of the donor. Acute GVHD (defined as occurring during the first 100 days posttransplant) is characterized by excessive production of proinflammatory cytokines and the activation of different immune cells against recipient (or host) tissues, leading to tissue damage in the recipient, which can be fatal and which occurs in spite of prophylactic immune suppressive treatment given to the recipient to minimize the activity of the donor T cells. Acute GVHD mainly affects the recipient's skin, gastrointestinal tract, and liver. Additionally, more than 50% of patients who survive beyond 100 days after allogeneic HSCT require

immunosuppressive treatment for 2 years or more because of chronic (late) GVHD [203,210].

As well as regulating hematopoiesis, MSCs are potent modulators of innate and adaptive immune cell function (see Chapters 33 and 34). MSCs home to sites of inflammation (see Chapters 22 and 23), where they function to suppress the immune response through various mechanisms, including direct cell–cell contact and the production of immunomodulatory factors.

MSCs suppress the functions of various immune cell types implicated in allograft rejection and in GVHD, particularly T cells, DCs, and natural killer (NK) cells. DCs display antigenic peptides to T lymphocytes, promoting T cell activation in an adaptive immune system response [211]. NK cells are cytotoxic lymphocytes that produce proinflammatory cytokines such as tumor necrosis factor-α and interferon-γ during an innate immune system response, which stimulates the recruitment and activation of other immune cells, thus further driving inflammation [211,212]. MSCs inhibit NK cell proliferation, cytotoxic activity, and secretion of proinflammatory cytokines by cell-mediated interactions and via soluble factors, including indoleamine 2,3-dioxygenase and prostaglandin $E_2$ [213]. MSCs also inhibit (1) the differentiation of myeloid precursors into DCs and (2) interactions between DCs and lymphocytes, thus again suppressing the immune response [212–214]. T cells, which are responsible for adaptive cell-mediated immunity, interact directly with DCs, which express histocompatability or other peptide antigens on their surface. This interaction results in T cells mediating antigen-specific cytotoxicity and producing cytokines that activate other immune cell types, leading to damage of histoincompatible cells (the GVHD response), virally infected cells, or residual malignant cells (the graft-versus-leukemia effect) [211]. MSCs suppress the proliferation of mature $CD4^+$ helper and $CD8^+$ cytotoxic T lymphocytes by secreting paracrine factors, including indoleamine 2,3-dioxygenase, prostaglandin $E_2$, nitric oxide, and transforming growth factor-β. MSCs also skew the maturation of naive $CD4^+$ T lymphocytes toward immunosuppressive/regulatory T cell subsets, including T helper 2 cells and regulatory T cells [214–217].

Co-administration of MSCs with donor HSCs has been demonstrated to improve hematopoietic engraftment and reconstitution in irradiated mice and in human allogeneic HSCT recipients [217–222]. Interestingly, MSCs have been shown to home toward radiation-injured non-hematopoietic tissues in which they likely promote wound healing via the production of anti-inflammatory cytokines (such as interleukin-10), growth factors (such as fibroblast growth factor and hepatocyte growth factor), and proangiogenic factors (such as vascular endothelial growth factor) [213,221–224]. Improved hematopoietic recovery observed with MSC co-administration of MSCs and HSCs may be due to the capacity of MSCs to (1) suppress inflammation during allogeneic immune responses such as GVHD and (2) to promote wound healing and tissue regeneration occurring as a result of the pretransplant chemotherapy or chemoradiation. MSC administration is now emerging as a possible therapeutic option for both acute and chronic GVHD. Several phase I and II clinical trials have suggested that MSC administration prevents allograft rejection, improves hematopoietic engraftment, and reduces the severity of GVHD [225–230] and see Chapter 57.

Whether transplanted MSCs directly support and instruct donor hematopoietic cells within the irradiated BM niche is largely unknown. Currently, the study of MSCs in transplantation settings remains technically challenging. When injected intravenously into mice, MSC engraftment in the BM is often poor due to their lodgment in other organs, particularly the lungs. To what extent donor MSCs (1) engraft in the irradiated host BM microenvironment and (2) whether donor MSCs improve hematopoietic reconstitution in comparison with irradiated host MSCs remain to be elucidated.

While several small-scale early phase clinical trials have shown encouraging results, and while MSC administration appears safe, large double-blind, randomized, placebo-controlled phase III clinical trials need to mature before the utility of MSCs in the setting of allogeneic HSCT can be determined.

### 27.10.2 Mesenchymal stromal cells and the tumor microenvironment

The capacity of MSCs to (1) home to sites of injury and inflammation, (2) to repair damaged tissues, and (3) to modulate immune responses is likely to be beneficial for tissue recovery following IR. However, these characteristics could equally prove to be detrimental in the context of cancer therapy. Solid tumors consist of neoplastic cells that are supported by a heterogeneous population of stromal and immune cells, comprising the tumor microenvironment. Tumor formation causes changes in the tissue environment that mimic those of a chronic wound site with tissue injury and inflammation. Inflammatory signals (such as interleukin-6 and interferon-γ) and chemokines (including CXCL8, monocyte chemoattractant protein 1, and CXCL12) that are produced at the tumor site stimulate MSC recruitment into the tumor microenvironment [231–235]. Once integrated in a tumor, MSCs are transformed into cancer-associated fibroblasts (CAFs) through currently unknown mechanisms [236,237]. CAFs promote tumorigenesis by (1) inhibiting apoptosis of cancer cells, (2) secreting growth factors that stimulate cancer cell growth, (3) secreting angiogenic factors and differentiating into pericytes, contributing to the tumor vasculature, (4) suppressing the activity of antitumor immune cells that normally act to eliminate cancerous cells, and (5) producing ECM molecules such as collagen and periostin and promigratory chemokines such CCL5 that promote tissue invasion and metastasis [234–239]. Since MSCs are radioresistant, MSC-derived CAFs within the tumor microenvironment may not be ablated by conventional radiotherapy. Consequently, these CAFs may continue to support the growth of therapy-resistant cancer cells and cancer stem cells, preventing tumor elimination and subsequently leading to tumor recurrence and spread.

MSCs within the BM niche are implicated in promoting the development and treatment resistance of hematological malignancies, particularly leukemias. MSCs produce cell–cell adhesion molecules such as vascular cell adhesion molecule-1 and fibronectin and factors such as CXCL12 and SCF that stimulate the homing and engraftment of leukemic cells. Leukemic cells establish malignant niches in which leukemic stem cells enter a quiescent state and in which they are highly resistant to antileukemia treatments [240–247]. MSCs also contribute to the treatment resistance of leukemic cells by suppressing apoptosis. For example, the interaction of MSC-derived CXCL12 with CXCR4 expressed on leukemic cells can (1) suppress chemotherapy-induced caspase-3 activation and (2) induce increased expression of antiapoptotic proteins such as Bcl-2, Bcl-xl, and myeloid cell leukemia 1 in leukemic cells [248–250].

Solid tumors often contain an abnormal, disorganized vascular network, resulting in heterogeneously distributed hypoxic regions within the tumor mass. Intratumor hypoxia is an adverse prognostic factor in cancer associated with increased malignancy, therapeutic resistance, and metastasis. The increased radioresistance of hypoxic cancer cells is thought to be mediated by two factors: (1) a reduction in IR-induced reactive oxygen species production, which causes chemical alterations in DNA that contribute to the generation of DNA damage; and (2) the activation of signaling cascades, mainly regulated by HIF-1α and HIF-2α, which lead to biological alterations in hypoxic cancer cells that promote resistance to treatment and genomic instability [45,191]. Hypoxia has been shown to enhance MSC radioresistance, particularly by upregulating DNA DSB repair in an HIF-1α-dependent manner [166]. These findings suggest that hypoxia may also contribute to tumorigenesis by altering the radioresistance of the tumor stroma, including MSC-derived CAFs. Similar to the tumor microenvironment, the BM niche is also relatively hypoxic. Hypoxia has been shown to improve the ability of MSCs to support leukemic cells in the BM and to promote leukemic stem cell survival and therapeutic resistance [251,252]. Thus, the enhanced resistance of hypoxic MSCs to DNA-damaging agents, including IR, may also promote the survival of leukemic cells in the BM, potentially contributing to clonal outgrowth of treatment-refractory cells and recurrence of disease.

Although MSCs play important roles in supporting tumorigenesis and leukemogenesis, there is little evidence to suggest that MSCs themselves undergo malignant transformation [253]. Currently, malignant transformation of MSCs has only been directly implicated in osteogenic sarcoma [254]. This rare form of sarcoma mainly occurs in children and young adults and exhibits osteoblastic differentiation and the production of osteoid tissue with a high density of malignant cells within bone. Mutations in the cell cycle regulator genes *p53* and *Rb* are frequently found in osteosarcoma cells and accelerate tumor development in mouse models [254–256]. Ewing's sarcoma is another rare form of bone tumor thought to be derived from neuroectodermal cells, although they are sometimes classified as mesodermal in origin [257]. These findings suggest that the maintenance of an intact DDR in MSCs is likely to be important for regulating MSC growth, differentiation, and function *in vivo*.

In conclusion, the radioresistance of MSCs has several significant implications for the clinic. It is evident that MSC radioresistance can be either beneficial or harmful, and this should be taken into account when designing therapeutic regimens using MSCs. MSCs may have beneficial effects in treating GVHD and improving allogeneic HSCT outcomes. Continued investigation into MSC radioresistance will have an impact on our understanding of how MSCs (1) restore hematopoiesis, (2) modulate the immune system, and (3) sustain cancer development in response to DNA-damaging agents such as IR. It is thus possible that they help develop more effective therapies for cancer.

## 28.1 Introduction

Multipotent mesenchymal stromal cells (MSCs) are able to differentiate *in vitro* into adipocytes, osteoblasts and chondrocytes [1] and into bone *in vivo*. MSCs have now been isolated from multiple organs and they form part of the endothelial wall of blood vessels [2,3]. In addition, they are a key component of tumor stroma and have been found to play important roles in various cancers [4]. Tumors, having many of the characteristics of injured tissue, may attract MSCs from their local tissue or from the circulation. The tumor tropism property of MSCs has suggested the possibility of their use as vehicles to deliver anticancer drugs or genes. However, extensive experimental research has demonstrated both anti- and procancer roles of MSCs in a context-dependent manner. It is now generally assumed that within this microenvironment reciprocal tumor–stroma crosstalk influences the phenotype of tumor cells, their progression, and their metastasis [5]. Various studies have reported the tumor-promoting effects of MSCs [6–8]. Others have provided evidence for an anti-oncogenic role of these cells [9–12]. MSCs are emerging as vehicles for anticancer drug/gene delivery [7]. This chapter aims to dissect this observed discrepancy in different experimental settings of human cancer so as to provide possible guidance to the appropriateness of clinical applications.

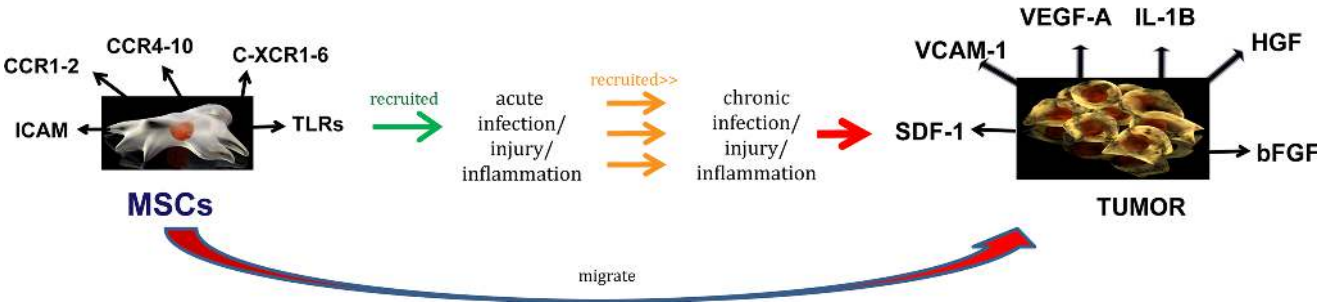

**Figure 28.1** Mechanisms for the recruitment of MSCs into tumors. MSCs express chemokine receptors, intercellular adhesion molecule (ICAM), C–C motif chemokine receptor (CCR)1–2, CCR4–10, C–X–C motif chemokine receptor (CXCR)1–6, and toll-like receptors (TLRs). Tumors release various cytokines, chemokines, and growth factors, including basic fibroblast growth factor (bFGF), stromal cell-derived factor 1 (SDF-1), hepatocyte growth factor (HGF), interleukin (IL)-1β, vascular cell adhesion molecule 1 (VCAM-1), and vascular endothelial growth factor (VEGF)-A, acting as chemoattractants for MSCs. MSCs in the local organ or tissue or circulating MSCs may be recruited into the tumor. MSCs may be constantly recruited in different stages from chronic infection, injury, and inflammation to cancer development.

expansion of a rare population of plastic-adherent cells [13,14]. The spatial distribution and properties of MSCs within their organ/tissue *in vivo* are relatively unclear [15]. MSCs have been isolated from most organs, including kidney, umbilical cord, brain, liver, lung, and bone marrow [16–18], and may have unique properties depending on their source. Recruited by the inflammatory milieu, MSCs migrate to the microenvironment of tumors and orchestrate the hallmarks of cancer cells [19]. The enrichment of MSCs in the tumor environment has been reported in both primary human cancers [20,21] and in metastases [22–24]. A resident population of MSCs has also been identified in the human adult liver and express a unique gene signature [25]. Additionally, MSCs share a molecular signature with mesenchymal tumor cells and favor early tumor growth in mice [26].

In response to injury or infection, MSCs can be released from the bone marrow and migrate toward sites of injury to promote tissue regeneration [27]. High frequencies of MSCs have been found in tumors with extensive inflammation, suggesting the recruitment of MSCs in response to inflammation [20]. Additionally, high circulating levels of endothelial progenitor cells have been observed in many cancer patients, which might also home to the site of tumors and promote tumor growth [28–30]. MSCs may be recruited locally and/or from the circulation to tumor sites (Figure 28.1). Future studies using somatic genomic signatures may provide a definite answer.

## 28.3 The migratory capacity of mesenchymal stromal cells

MSCs tend to be recruited by injured tissue, where they are thought to contribute to tissue repair and wound healing [31]. As tumors are often considered to have many characteristics of injured tissues, it is not surprising to find MSCs enriched within tumors. Various preclinical models have confirmed that MSCs can migrate to certain types of tumors, and this is one of the rationales of using MSCs as vehicles for anticancer drug/gene delivery [7,32]. MSCs are also relatively resistant to ischemia, because in the absence of oxygen they can survive by anaerobic adenosine triphosphate production [33], which may give them a competitive advantage in a tumor microenvironment. The tumor-tropic migratory property of MSCs is attributed to two main mechanisms [34,35].

### 28.3.1 Intrinsic migratory properties of mesenchymal stromal cells

Activated human MSCs express adhesion molecules such as integrins, ICAM-1, ICAM-2, and VCAM-1, which enable these cells to migrate [36]. MSCs also express chemokine receptors, including CCR1, CCR2, CCR4, CCR6, CCR7, CCR8, CCR9, CCR10, CXCR1, CXCR2, CXCR3, CXCR4, CXCR5, CXCR6, and CX3CR [31]. Production of their respective ligands is a characteristic of inflamed tissue and malignant tissue, and thus these receptors are likely involved in the specific accumulation of MSCs in both processes. Thus, the cognate ligands of these receptors are efficient chemotactic stimuli for MSCs. Additional receptors implicated in MSC migration are the TLRs. TLR1–6 have been identified in human MSCs and it has been reported that TLR stimulation enhanced the migratory function of MSCs [37].

### 28.3.2 Stimuli produced by the tumor

Malignant cells have been shown to produce relatively high amounts of MSC chemoattractants, including HGF, SDF-1 (also known as CXCL12), bFGF, VEGF-A, and VCAM-1 [38,39]. Tumor-derived IL-1β has been found to be a mediator of the proinflammatory response in MSCs exposed to tumor conditioned media, a mechanism that is regulated by focal adhesion kinase and mitogen-activated protein kinase signaling [40].

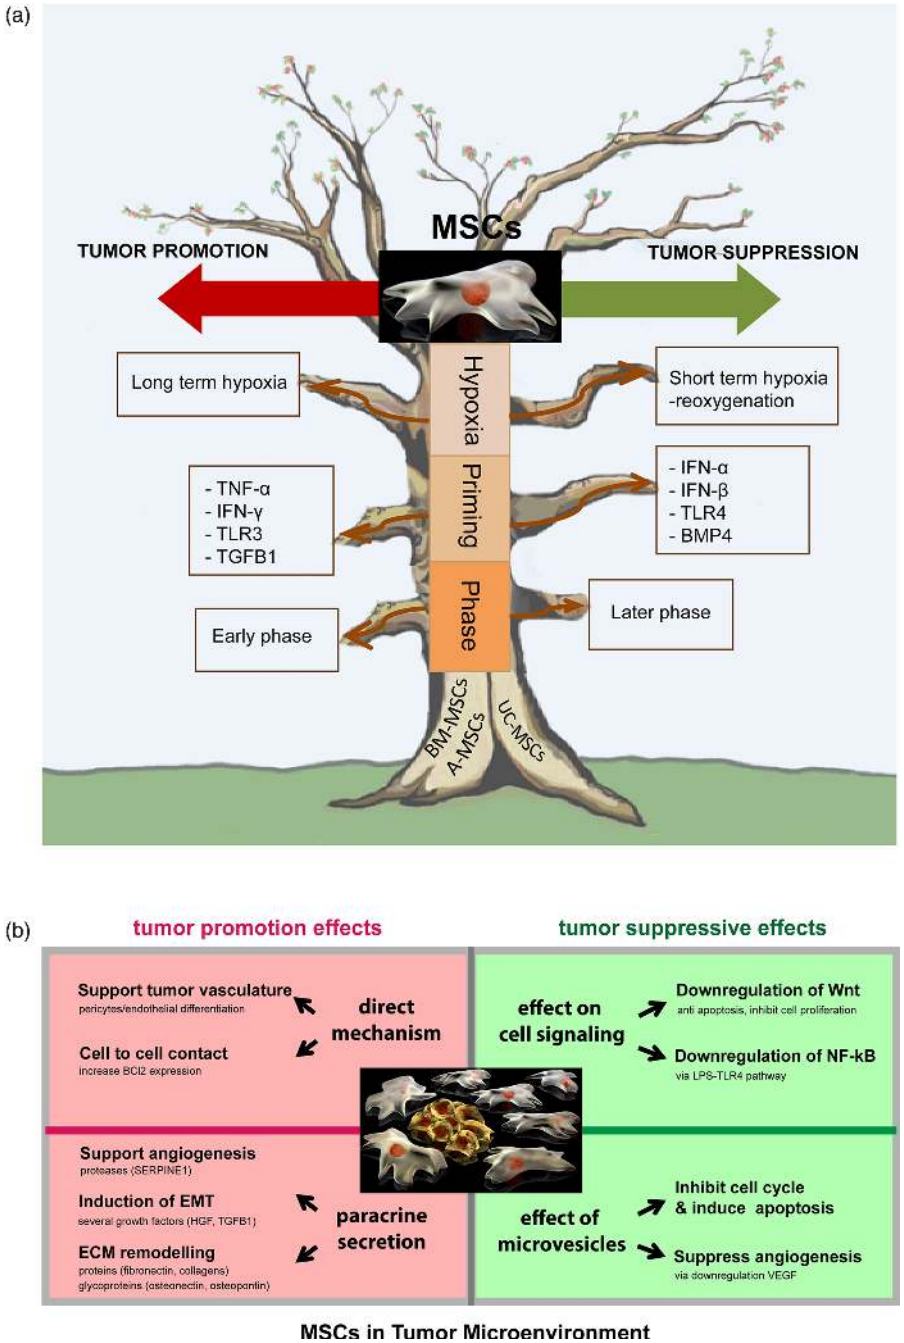

**Figure 28.2** Context-dependent role of MSCs in the tumor microenvironment. MSCs can exert tumor-promoting or tumor-limiting effects, which depend on the context in which the MSCs are present. (a) Different sources of MSCs, the presence of ligands, cytokine-primed MSCs, and the hypoxic microenvironment may lead to different effects of MSCs in the tumor microenvironment. The properties of the MSCs and the particular tumor microenvironment may result in dual roles for MSCs that can either suppress or promote tumor progression. (b) The tumor-suppressive mechanisms are mainly mediated by MSC microvesicles and downregulation of the Wnt and nuclear factor kappa light chain-enhancer of activated B cells (NF-κB) pathway. The tumor-promoting mechanisms are mainly attributed to factors secreted by MSCs and direct effects such as support of tumor vasculature, epithelial to mesenchymal transition (EMT) transition, and extracellular matrix (ECM) remodeling. BM-MSCs,: bone-marrow-derived MSCs; A-MSCs: adipose-derived MSCs; UC-MSCs: umbilical-cord-derived MSCs; BMP4: bone morphogenetic protein 4; IFN: interferon; LPS: lipopolysaccharide; TNF-α: tumor necrosis factor-α.

## 28.4 Context-dependent role of mesenchymal stromal cells in the tumor microenvironment

The tumor microenviroment is substantially different from that of normal organs and this is a mechanism in cancer development [41]. Depending on the experimental conditions, MSCs can exert tumor-promoting [20,24,42,43] or tumor-limiting effects [9,11,12,44,45]. Various hypotheses have been postulated to explain the context-dependent role of MSCs in cancer (Figure 28.2a).

### 28.4.1 Hypotheses on context-dependent roles of mesenchymal stromal cells in cancer

#### 28.4.1.1 Phase-dependent hypothesis

MSCs appear to promote tumor growth when co-injected with tumor cells, but inhibit tumor progression when administered into established tumors [4]. Thus, the presence of MSCs during

the early phase of tumorigenesis may contribute to angiogenesis that is required for tumor initiation. An increase in blood vessel density was observed when MSCs were co-injected with tumor cell lines [8,46].

#### 28.4.1.2 Priming-dependent hypothesis

MSCs express several TLRs, and their ability to migrate, invade, and secrete immune modulating factors is tightly regulated by specific TLR-agonist engagement [47]. TLR4-primed MSCs are polarized into a proinflammatory MSC type 1 (MSC1) phenotype, whereas TLR3-primed MSCs are polarized into the classical immunosuppressive MSC2 phenotype [47]. MSC1-based treatment of established tumors in an immune competent model attenuated tumor growth and metastasis, but MSC2-treated animals displayed increased tumor growth and metastasis [48]. The priming of all MSC types with inflammatory cytokines such as IFN-γ and TNF-α results in higher levels of VEGF [19] and induction of inhibition of runt-related transcription factor 2, one of the pivotal factors driving osteoblast differentiation [49]. These effects, in turn, can enhance tumor progression. However, stimulation of MSCs with IFN-α and IFN-β decreased tumor cell proliferation and induced tumor cell apoptosis in a mouse model of melanoma [50,51]. BMP4-differentiated bone marrow MSCs became less suppressive of T cell and natural killer (NK) cell proliferation and switched on their suppressive machinery by activating both indolamine 2,3-dioxygenase (IDO) and cyclooxygenase 2 (COX-2), promoting the differentiation of neighboring MSCs and triggering the anti-inflammatory effect [52]. In contrast, preconditioning of MSCs with TGF-β1 resulted in proinvasive MSCs in the progression of colon cancer [53].

#### 28.4.1.3 Hypoxic-dependent hypothesis

A long-term hypoxic microenvironment may lead to undifferentiated tumor cells and stromal cells, providing essential cellular interactions accompanied by the upregulation of the stemness genes [54,55]. Permanent hypoxia-stimulated MSCs proliferated and reduced their capacity to differentiate [56,57]. However, short-term oxygen limitation increased the number of apoptotic MSCs after 3–24 h of hypoxic treatment [58,59]. Moreover, oxygen limitation in hypoxia–reoxygenation-induced cell apoptosis was mediated in part by the reduction of phosphorylation of Akt and extracellular signal-regulated kinase 1/2 (ERK1/2) in MSCs [60]. ERK1/2 belongs to the class of protein kinase signal transduction pathways that are used to relay numerous extracellular signals within cells and have been reported to be involved in various cellular functions, including apoptosis and proliferation [61]. Hypoxia switches on various signaling pathways, and its context dependency determines the overall cell response and alterations in MSC functions.

Collectively, tumor cells and the tumor microenvironment will affect the ultimate function of recruited MSCs. However, there are some factors that drive MSCs to suppress or promote tumor growth (Figure 28.2b).

### 28.4.2 The tumor-suppressing roles of mesenchymal stromal cells

Extensive studies have reported tumor-suppressing effects of MSCs in various experimental cancer models. A variety of processes and mechanisms possibly implicated in MSC-dependent tumor suppression have been studied.

#### 28.4.2.1 Effect on cell signaling

Several signaling pathways have been reported to be associated with MSC suppression of tumor growth. Wnt signaling is aberrantly activated in many types of tumors. In chemically induced murine liver tumors the administration of MSCs has been demonstrated to have tumor suppressive effects associated with Wnt signaling. Its target genes were downregulated, especially those related to antiapoptosis, mitogenesis, cell proliferation, and cell cycle regulation [62]. MSCs can secrete Wnt inhibitors, such as Dickkopf-1 [52,63]. MSC-dependent inhibition of NF-κB signaling in cancer cells also occurs [64]. In addition, TLR signals can stimulate downstream effectors that may interfere with the LPS–TLR4 pathway and inhibit NF-κB activation during liver fibrosis [65].

#### 28.4.2.2 Effects of mesenchymal stromal cell microvesicles

Microvesicles are fragments of plasma membrane ranging from 100 to 1000 nm secreted by many cell types. They play an important role in intercellular communication and are capable of modifying the activity of target cells through surface receptor interactions and the transfer of proteins, mRNA, and microRNA (miRNA). Microvesicles have been implicated in tumor–stroma interactions [66]. Microvesicles released by MSCs have been associated with tumor inhibition in several preclinical studies [67] and have been shown to inhibit cell cycling and induce apoptosis or necrosis *in vitro* and to inhibit growth of established tumors *in vivo* [66,68,69], providing a further antioncogenic effect. Exosomes, a smaller type of intracellular vesicle derived from MSCs, suppress angiogenesis by downregulating VEGF expression in breast cancer cells [70], and MSCs pulsed with tumor-derived microvesicles exert an enhanced antitumor activity against hepatocellular cancer [71]. Thus, the secretome of MSCs appears to play an important role in their tumor suppressive function.

### 28.4.3 The tumor-promoting roles of mesenchymal stromal cells

The tumor-promoting role of MSCs has been attributed to direct mechanisms and paracrine secretion, including modulation of the immune response.

#### 28.4.3.1 Direct mechanisms

MSCs have been shown to directly differentiate into pericytes or possibly endothelial cells [72], thus supporting tumor angiogenesis, which in turn can promote tumor growth. MSC and

tumor cell contact is another important direct mechanism. In lymphoma models, direct cell–cell contact was the major mechanism of promoting tumor cell proliferation and survival rather than secretion of soluble factors by MSCs [73]. It is well recognized that adhesion to the bone marrow of the malignant cells of the B cell neoplasm, multiple myeloma, provides the myeloma cells with protection against chemotherapy. Bortezomib is a proteasome inhibitor used in the treatment of multiple myeloma and mantle cell lymphoma. MSCs can suppress bortezomib-induced multiple myeloma cell growth inhibition in a cell–cell contact-dependent manner by increasing Bcl2 expression in the myeloma cells [74]. Cell–cell contact with MSCs was reported to protect chronic lymphocytic leukemia cells, another B cell neoplasm, from spontaneous and drug-induced apoptosis [75]. Bone-marrow-derived MSCs have been reported to fuse with non-small cell lung cancer cells, resulting in highly malignant subpopulations with stem-cell-like properties [76].

#### 28.4.3.2 Paracrine mechanisms

MSC promotion of tumor growth via paracrine mechanisms is mainly attributed to supporting angiogenesis, promoting tumor growth, and metastasis. Secreted factors from patient tumor-derived MSCs have been shown to promote tumor growth in a xenograft mouse model associated with upregulation of cell growth and proliferation-related processes and downregulation of cell-death-related pathways in tumor cells [20]. Several growth factors secreted by MSCs, including HGF and TGF-β1, induce proinvasive signals in cancer [77,78]. A large number of proteases that have proangiogenic properties secreted by MSCs may inhibit apoptosis in vascular smooth muscle cells and endothelial cells [79]. The protease named serpin e1, a member of the serine proteinase inhibitor superfamily, is abundantly secreted by MSCs and has been shown to regulate proliferation, migration, and apoptosis of vascular smooth muscle cells and endothelial cells [80]. Transplantation of MSCs promoted microvascular growth in a mouse model [46,81], suggesting that angiogenesis plays an important role in support of tumor growth by MSCs.

A tumor-promoting effect attributed to remodeling of ECM via a paracrine secretion of MSCs also occurs. The ECM is a major component of the cellular microenvironment and is composed of diverse proteins such as collagens, elastins, fibronectin, proteoglycans, and glycoproteins [82]. Glycoproteins, such as osteonectin (also known as secreted protein acidic and rich in cysteine, SPARC), are highly expressed in stromal fibroblast cells that have been reported to promote tumor progression in several cancers [83–86]. Abundantly produced soluble fibronectin [83,87] by MSCs also plays an active role in the invasive process of human colon and liver cancer [88]. Matrix metalloproteinase proteases and hyaluronan, as well as various others factors secreted by MSCs, are capable of remodeling the ECM and facilitating tumor progression [20,89–91].

In contrast, human MSC-secreted microvesicles have been reported to have a striking antitumor effect in cancer [92] and tumor immune suppression [93], in which they transport mRNA, miRNA, and proteins between cells.

A functional role in neoplastic development and metastases has been attributed to the presence of miRNAs, small non-coding RNA molecules composed of approximately 22 nucleotides. They participate in RNA silencing and gene regulation [94]. In breast cancer, miR-21 and miR-205 were associated with tumor development, while miR-126 and miR-335 were related to metastases [37,95]. The promotion of progression of hepatocellular cancer by MSCs was attributed to miR-155 [89].

The effect of MSCs on tumor cells has also been reported to be associated with the induction of EMT [96], an effect that is further enhanced by the inflammatory milieu that characterizes many cancers. Initiation of metastasis requires invasion, and this is enabled by EMT: carcinoma cells in the primary tumor lose cell–cell adhesion mediated by repression of E-cadherin and break through the basement membrane with increased invasive properties and enter the bloodstream by intravasation. Later, when these circulating tumor cells exit the bloodstream to form micrometastases, they undergo the reverse process – mesothelial to epithelial transition. Evidence of a role for MSCs in EMT is the observation of increased expression of cancer-associated fibroblast and EMT markers in a co-culture model of hepatoma cells and MSCs [97]. There is also evidence that there are intricate links between EMT-type cells and drug resistance in tumors [98]. MSC-dependent EMT induction has been associated with shorter tumor-free survival and poorer overall survival, demonstrating the clinical relevance of this effect [96,99]. MSCs might also promote tumor progression or invasion via inducing regulation of secretion of IL-6 and secretion of SDF-1α in EMT [53,100].

## 28.5 The potential immunomodulation by mesenchymal stromal cells in the tumor microenvironment

MSCs can influence both the innate and adaptive immune systems, including the function of antigen-presenting cells [79,101], natural killer cells [102], B cells, and T cells [103,104] (and see Chapters 33 and 34). Immune suppressive cells accumulate in some tumors, which can impede immune surveillance and facilitate tumor growth [105]. The number and function of anti-tumor immune cells are decreased [54,106].

### 28.5.1 Mesenchymal stromal cells inhibit natural killer cells and macrophages

MSCs can modulate the function of NK cells [107] and macrophages [108]. NK cells are a type of lymphocyte that plays a role in the rejection of both tumors and virally infected cells. MSCs can inhibit the proliferation, cytotoxity, and cytokine production of NK cells through secretion of IDO and prostaglandin $E_2$ ($PGE_2$) [107,109]. In addition to IDO and $PGE_2$, cancer-

associated stromal cells produce other soluble factors, such as VEGF and platelet-derived growth factor, which enhance tumor progression by promoting or attracting M2 macrophages, which are characterized by their production of high levels of the suppressive cytokine IL-10 and low levels of the proinflammatory cytokines IFN-γ and TNF-α [110]. M2 macrophages activate T helper 2 cell activity and also promote angiogenesis, tissue remodeling, and repair. Proinflammatory stimulation by IFN-γ, TNF-α, or LPS increases the expression of COX-2 and IDO in MSCs and these enzymes promote further M2 macrophage polarization [108]. Macrophages also play an important role in the innate immune response to virus infections. Innate immune responses, including TLRs, are important for viral clearance [111].

### 28.5.2 Mesenchymal stromal cells inhibit T cell proliferation

T cells are the major player of the adaptive immune response and are important in controlling malignant disease, mediating both cytotoxicity of cancer cells and releasing anti-oncogenic cytokines [112,113]. MSCs can inhibit T cell function through multiple pathways [114,115]. MSC suppression of T cell responses can be mediated by cell contact and soluble factors, including TGF-β, HGF, $PGE_2$, soluble human leukocyte antigen (HLA)-G5, IDO, and inducible nitric oxide synthetase [112,113,116–118]. Inhibition of T cell function by MSCs affects T cell proliferation and IFN-γ production and induces the production of IL-4, resulting in a shift from a proinflammatory T cells to anti-inflammatory T cells [114,115]. Cell–cell contact T cell inhibition by MSCs can be mediated by surface expression of HLA-G [119], a nonclassical major histocompatibility complex class I molecule with tolerogenic functions that contribute to fetal graft tolerance and human allograft acceptance [120]. Fas ligand and programmed death-ligand 1 also play significant roles in immunomodulation mediated by MSCs [121].

### 28.5.3 Mesenchymal stromal cells promote the expansion and function of regulatory T cells

Regulatory T cells (Tregs) are a subset of T cells that suppress activation of the immune system to maintain homeostasis and tolerance to self-antigens. An increased number of highly activated Tregs were found to infiltrate the tumor milieu of liver tumors in which they were mainly localized in the stromal compartment of the tumors [106]. The frequency of Tregs has been associated with poor prognosis [122–124]. MSCs can induce the generation and expansion of Tregs by the secretion of TGF-β [125], IDO [126] and the release of soluble HLA-G5 [113]. In contrast to their suppression of cytotoxic T cells, MSCs can induce the generation and expansion of Tregs [127]. Additionally, MSCs have been reported to induce the production of IL-10 by plasmacytoid dendritic cells (DCs), which in turn triggered the generation of Tregs [114].

### 28.5.4 Mesenchymal stromal cells inhibit the function of dendritic cells

It has been found that MSCs also display immunosuppressive potential through inhibiting the differentiation of DCs. DCs are the most efficient cells in presenting antigen to T cells. They play a key role in the initiation of the primary immune responses and in tolerance, depending on their activation and maturation status [128]. MSCs are capable of modulating the differentiation, activation, and function of DCs [129]. MSCs reduce the production of several cytokines by DCs, including IL-12 and TNF-α [130]. MSCs isolated from different tissue sources present distinct immunomodulatory profiles [131], so it will be important to more closely study MSCs present in tumors.

## 28.6 Therapeutic application of mesenchymal stromal cells in cancer

### 28.6.1 Potential therapeutic application

Several studies have demonstrated that MSCs have the capacity to reverse acute and chronic injury in different experimental settings [132–135]. MSCs have been reported to attenuate inflammation [136–138] and ameliorate autoimmune diseases [10,139–141]. The fact that MSCs can migrate into certain types of tumors has led to their use as vehicles for tumor-specific delivery of anticancer drugs or genes.

Genetically modified MSCs have been used to deliver anticancer genes and inhibit cancer cell proliferation *in vitro* and *in vivo* [95,142–144]; and see Chapter 62. Several studies have demonstrated that MSCs have anticancer effects in different experimental settings [62,96,145–147]. MSCs have been extensively investigated in clinical trials as potential therapy in a number of different diseases [148,149]. Approximately 18 trials have been registered at ClinicalTrials.gov involving the use of MSCs in various cancers. These include ovarian cancer (NCT02068794), prostate cancer (NCT01983709), and hematologic malignancy (NCT01854567).

### 28.6.2 Reasons for caution

Given the context-dependent role of MSCs, it appears possible that MSCs in the tumor microenvironment could promote tumor growth [150]. MSCs may facilitate malignant development in patients at high risk of developing cancer, such as those with chronic hepatitis B or C patients or recipients of organ transplants [19,151,152]. In addition, MSCs have the potential for malignant transformation during *ex vivo* expansion [153].

Furthermore, although MSCs can be detected by magnetic resonance imaging or radioactive labeling [154] for up to 25 days [25], the cellular fate and distribution *in vivo* of transplanted MSCs remain unclear because techniques for tracking infused MSCs have low sensitivity [155]. Because of unclear clinical benefits of MSCs in patients with cancer [156–158] and because of the role of MSCs in the tumor microenvironment, it would be

wise to be cautious in the use of MSCs in patients with malignant diseases.

## Acknowledgments

We thank the Dutch Digestive Foundation (MLDS) for a career development grant (No. CDG 1304), the Netherlands Organization for Scientific Research (NWO/ZonMw) for a VENI grant (No. 916-13-032), and the Daniel den Hoed Foundation for a Centennial Award Fellowship to QP.

## 29.1 Mesenchymal stem/stromal cells

Although the earliest identification of putative mesenchymal stem or stromal cells (MSCs) was described over 50 years ago by Alexander Friedenstein [1] closely following the emergence of the hematopoietic stem cell (HSC) field with the seminal work of Till and McCulloch in bone marrow [2], the MSC field has lagged behind somewhat in terms of defining the stem cell properties of differentiation, multipotentiality, and self-renewal. Friedenstein first isolated adherent fibroblastic cells from the stromal compartment of bone marrow. These cells were able to differentiate into osteocytes and establish colonies from a single cell *in vitro*, referred to as colony-forming units fibroblastic (CFU-F) [1,3,4]. More critically to defining their stem cell phenotype, the colony-forming cells were also capable of generating multiple skeletal tissues *in vivo* [5,6].

The earliest terminology describing these cells used either marrow stromal cells or mesenchymal stromal cells. Caplan first coined the phrase "mesenchymal stem cells" to associate the "stemness" shown by the capacity of the cells to form tissues of the mesenchymal lineage [7]. This has led to some confusion and controversy in the field, with Bianco and Robey using the term "skeletal stem cells" to describe the mesenchymal cell co-existing with HSCs in marrow [8]. These authors identified that human cells associated with a subendothelial location in marrow stroma and high surface expression of melanoma-associated cell adhesion molecule (MCAM or CD146) were capable of promoting the establishment of the hematopoietic microenvironment (HME) and self-renewing as identical subendothelial cells in an immunocompromised mouse *in vivo*. The cellular components of the bone marrow formed in the heterotopic bone ossicles were of host origin, but CD146-positive cells also formed bone, with human fibroblastic tissue, osteocytes, and osteoblasts identified in these chimeric ossicles [9]. Furthermore, the human $CD146^+$ adventitial reticular cells produced angiopoietin-1, a molecule associated with angiogenesis [9]. Another study defined the isolation and phenotype of murine skeletal stem cells. Additionally, these authors identified some progenitor populations involved in the differentiation pathways to bone, cartilage, and stromal tissue as well as potential regulators of lineage commitment [10].

Since the original work in human bone marrow, MSCs have been isolated and characterized from many other human sources and species. The isolated cells demonstrate the capacity to differentiate into bone, fat, cartilage, and other cells of connective tissue lineages *in vitro* [11,12]. The most commonly used sources other than marrow include adipose tissue [13–15], umbilical cord sources [16–19], and skeletal muscle [20]. However, MSCs

have also been isolated from tissues such as synovium [21], articular cartilage [22,23], and ligament [24–27]. MSCs isolated from ligaments displayed similar properties to bone-marrow-derived MSCs but were also capable of *in vitro* differentiation to cells with characteristics of the ligaments themselves [25,28]. In a similar manner, MSCs isolated from synovium, perhaps the source of cartilage cells during development, are more chondrogenic than bone-marrow-derived cells or from MSCs isolated from joint-associated fat tissue [29,30]. Therefore, it is clear that MSCs seem to have the capacity to differentiate into cells of connective tissue lineages, such as cartilage, bone, and fat, *in vitro* whatever the tissue of origin but may have some tissue-specific characteristics.

Multipotential, pericyte-like cells with the capacity of *in vitro* differentiation to a number of lineages have also been isolated from blood vessels [31–35]. In addition to the work from Sachetti *et al.* described above, a number of other reports had suggested a perivascular niche as the source of MSCs derived from skeletal muscle, brain and adipose tissue [9,36–38]. This work, along with the wide tissue distribution of MSCs, led to the idea that MSCs derive from a perivascular niche [20] and a proposal from Caplan that although all MSCs are pericytes, not all pericytes are MSCs [39]. However, elegant work using a double-nucleoside-labeling strategy to examine distribution of stem cells before and after cartilage injury in the joint showed that MSCs in the joint were not pericytes. Proliferating, label-retaining cells after injury did not express hematopoietic and endothelial markers but showed a surface marker profile characteristic of MSCs [40].

Recent data looking at genome-wide methylation, transcription, and *in vivo* assessment of MSCs from various sources indicated that development potential differs depending on the cell source [41]. Despite very similar *in vitro* characteristics, only bone-marrow-derived MSCs, with a chondrogenic transcriptional program, were capable of establishing HME and forming bone. This report added to earlier data that regeneration of the mouse distal digit was mediated by local tissue-resident stem or progenitor cells that were lineage restricted [42]. Fracture repair is also associated with an MSC subpopulation from bone marrow: $Mx1^+$ cells exhibited a fate-restricted bone potential *in vivo* but underwent multilineage differentiation *in vitro* [43].

In addition to expanding knowledge on defining *in vivo* reparative cells it is also critical to establish the developmental origin of postnatal stem cells in order to advance the field of MSCs [10,44,45]. Mendez-Ferrer *et al.* have used the intermediate filament protein nestin to investigate the relationships between MSCs and HSCs in bone marrow [46]. This group recently showed that distinct biological functions ascribed to MSCs were associated with specific developmental origins and generated definitive data to indicate that not all MSCs are alike. MSCs negative for the neural marker nestin with an osteochondroprogenitor phenotype originated from mesoderm. However, nestin-positive cells derived from the neural crest contributed to the HSC niche in neonatal bone marrow [44] (and see also Chapter 32). This work added to an earlier study by Takashima *et al.* that showed a neural epithelium origin for early MSCs, some of which developed through a neural crest intermediate stage. These cells were replaced in early neonatal tissues [47]. Data on the developmental origin of MSCs is a significant advance in explaining the known heterogeneity of MSC preparations [48–50]. This heterogeneity in ancestral MSCs that may be present in source tissue is further compounded by the presence of multiple progenitor populations derived from the stem cells. *In vitro* culture could also add to this heterogeneity (see Chapter 7). This issue is highlighted by the reports on clonal heterogeneity of MSC preparations from many sources [51–55]. The use of MSCs for therapeutic applications may be compromised by this heterogeneity and the inability to specifically define the clinical population. It is also unknown whether the well-described clinical utility of MSCs is dependent on this heterogeneity or impacted negatively by the phenomenon.

Whatever the eventual outcome of research in this area, it is interesting to make the following speculations. HME-associated MSCs of neural origin may function as trophic mediators of repair, reflecting their capacity to provide a stromal support system for HSCs and to establish the HME in marrow [9,11,56,57]. These cells with a perivascular location will have widespread application in many tissue processes and provide the rationale for MSC-mediated effects in disease scenarios currently under investigation. Mesodermally derived MSCs or other tissue-specific stem cells will function to replace or regenerate damaged tissues. Furthermore, the perivascular MSC may act to recruit, activate, and direct differentiation.

## 29.2 Therapeutic application of mesenchymal stem/stromal cells

The use of MSC transplantation for tissue repair has received a great deal of attention in recent years, and these cells stand at the forefront of successful strategies in regenerative medicine [12,58–62]. Progress in preclinical models over the past decade and more recent evidence from clinical trials have led to some optimism that MSC therapy has the potential to be a transformative technology in medicine, although definitive and unambiguous proof of this is not yet forthcoming. Despite the surge of interest in this technology, there are very significant questions still unanswered, and several hurdles relating to biological understanding and translation that need to be overcome. While clinical proof of concept will emerge as trials are completed, technical deficits remain relating to both biology and logistics (Figure 29.1). In the biological context, three issues of great importance remain: potency, mechanism of action, and immune modulation. In logistical terms, issues of supply and delivery need to be addressed if the field is to develop unimpeded. Specifically, these include the incorporation of cell expansion protocols that include fully xeno-free growth media, bioreactors capable of industrial-scale cell manufacturing, and

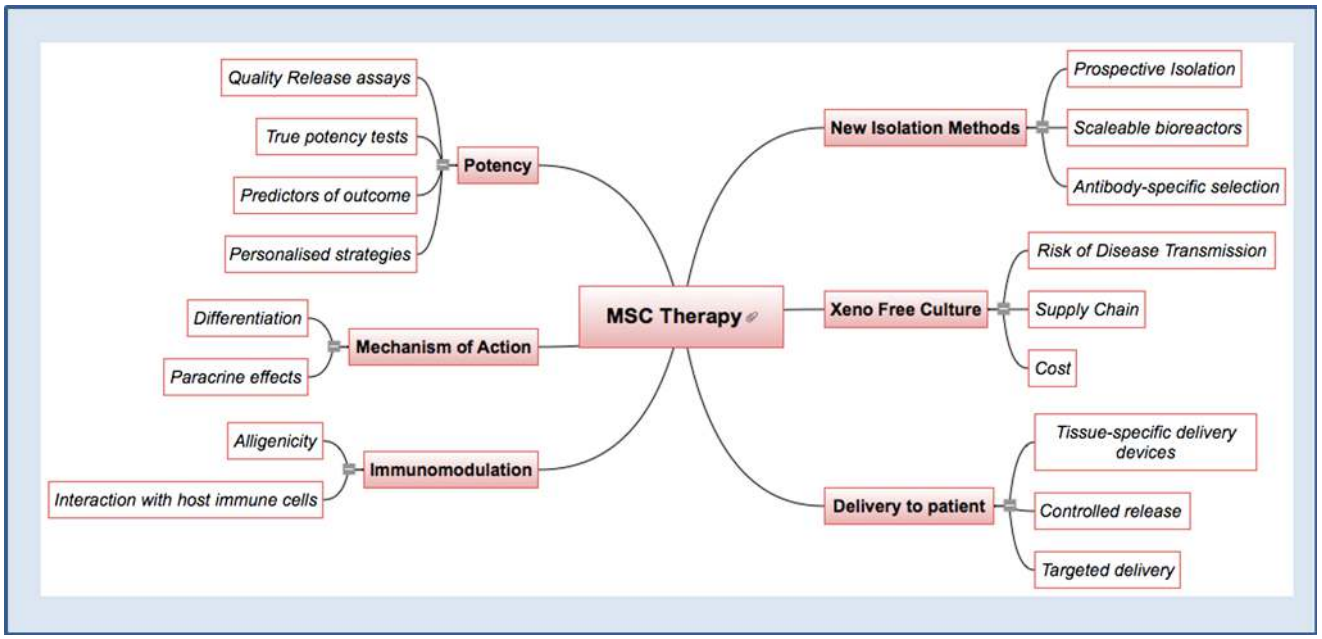

**Figure 29.1** MSC therapy: obstacles to translation. The translation of MSC therapy requires further development in the areas of isolation methods, xeno-free culture, potency assessment, mechanisms of action, immune modulation, and delivery to the patient.

tissue-specific device technologies for delivery of cell doses to patients [58,61,63].

The concept of potency is widely misapplied in the field of MSC therapy. The term is used in pharmacology to refer to the amount of the therapeutic agent needed to produce a specific measured outcome. It implies an understanding of both dose and mechanism, neither of which is available in the case of MSC therapy. Currently used markers of cell potency, such as those proposed by the International Society for Cell Therapy, are of limited value because they lack cell specificity and relationship to clinical outcome. In the context of quality control, product release testing, and dose adjustment, potency will need to be rigorously and fully addressed.

A complete understanding of mechanism of action is needed in order to optimize cell dose and develop next-generation products, including disease-specific and personalized therapies. This understanding will only emerge if the activity of cells *in situ* is understood; that is, the molecular and cellular impact that transplanted MSCs have on the host within the injury niche. This impact will relate possibly to differentiation of the delivered cells to the local phenotype and their structural contribution to tissue repair. It may also relate to the paracrine effects that the transplanted cells have, mediated through one or many secreted factors that evoke a host response that leads to a repair outcome. It is not likely that a complete understanding of mechanism of action will come from studying cells *in vitro* but will require instead probing the phenotype of cells delivered to the injured host. This will require sophisticated experiments in cell tracking and retrieval.

The interaction between transplanted cells and cells of the host immune system needs to be fully understood. It is also necessary to fully understand allogenicity – the use of mismatched donor rather than patient-derived (autologous) cells. This is likely to represent a more useful commercial manufacturing model and will make product more widely available for rapid use. Although allogeneic MSCs are widely used in preclinical and clinical applications, there are aspects of allogenicity that require greater understanding. These include, among others, a fuller understanding of the impact of delivered allogeneic cells on the host immune system, whether these effects change if the cells differentiate, and what are the consequences of the presence of alloantibodies in the MSC recipient in terms of future transplants.

In the logistical area, steps are urgently needed to guarantee the consistency, quality, and safety of MSC products. There is a need for serum-free and animal-protein-free culture systems that will remove the dependence on fetal bovine serum. This is an issue of safety relating to the risk of disease transmission associated with products of bovine origin, and one of supply chain relating to limited availability of these materials. In addition, there is a need for new and efficient isolation methods that are biologically specific and more reproducible. There is a risk associated with plastic adherence as a method for isolating MSCs from tissues. This is associated with the heterogeneity of cell populations isolated in this way, and a more defined method that relies on specific biological characteristics of the cells may be more desirable as mentioned earlier. Such a method might involve prospective isolation using antibody selection as

an example. Lastly, but by no means least, there is a need now to focus on delivery devices for cell therapy. This has received little attention to date, but it is unlikely that cell transplantation will be widely used unless there are target-specific, controlled devices for cell delivery. These are likely to be sterile, single-use closed systems that will allow cryopreserved MSC-to-patient delivery with minimal or no manipulation of the cells at the clinical site and thus minimal risk of contamination and operator error.

The interaction between the transplanted cells and the host is critical and is addressed in this chapter. This critical aspect of the therapeutic effect of MSCs is considered both from the point of view of tissue repair and immune modulation.

## 29.3 Mechanism of action

As mentioned earlier, MSCs were first isolated from bone marrow by Friedenstein and described as adherent, colony-forming fibroblastic cells with bone-forming activity [1,64]. The notion that MSCs could be delivered to injured tissues to effect a repair process was first proposed by Caplan [7]. Early efforts focused on conditions that were related to the mesenchymal nature of the cells and included bone repair [65–69], tendon repair [70,71], cartilage resurfacing [72,73], spine fusion [74–76], treatment of osteogenesis imperfecta [77–80], and osteoarthritis [81]. In recent years that focus has shifted to many other conditions, including vascular disease, myocardial infarction, diabetes, Crohn's disease, graft-versus-host disease (GvHD), spinal cord injury, and stroke. Currently, approximately 400 clinical trials are listed on the clinical trials website of the US National Institutes of Health (Clinicaltrials.gov).

There are two major paradigms of tissue regeneration associated with MSC transplantation. The first, which is the founding premise of cellular therapy, states that MSCs act as multipotent competent cells capable of migration, engraftment, and differentiation to the appropriate lineage, and that the newly formed tissue is populated by transplanted cells. This was the basis of many earlier efforts in cardiac repair, where it was assumed that differentiation of the transplanted cells to a cardiomyocyte phenotype was the central element of repair [82]. It is also presumed to be an element in MSC-mediated cartilage resurfacing [72]. However, in the earliest report describing protection by MSCs from development of osteoarthritis after meniscectomy, no implanted cells were detected in the cartilage. Cells were detected at the surface of regenerated menisci; however, the vast majority of cells in the neo-tissue were host derived [81]. This differentiation paradigm has been added to, or replaced by, a second paradigm involving trophic mechanisms where the transplanted cells secrete immunomodulatory and repair factors that stimulate a host repair response [83]. This concept suggests that MSCs have the capacity to recognize and respond to the injured or inflamed environment by becoming activated, and several mechanism have been proposed that underpin this concept. The undeniable consequence of this is that the phenotype of culture-expanded MSCs measured *in vitro* may bear little relationship to their activity *in vivo*.

Many efforts have been made to dissect the molecular pathways and signals that are activated by transplanted MSCs. This effort has identified several putative candidates that may mediate the repair effects. Little has been done, however, to validate these *in vivo*.

One approach has led to the identification of the anti-inflammatory protein, tumor necrosis factor (TNF)-α-stimulated gene 6 protein (TSG-6). When human MSCs were delivered to infarcted rat hearts the transplanted cells showed high levels of expression of this gene [84]. In these experiments, the effect of delivery of MSCs was a decrease in matrix metalloproteinase activity and decreased infiltration of monocytes and granulocytes in the infarcted hearts. These effects were reduced when MSCs were treated with small interfering RNA to block TSG-6 expression. Also, when recombinant TSG6 was delivered to the hearts the therapeutic effects of MSCs were recapitulated. This work suggested that TSG-6 is a major mediator of the anti-inflammatory effects of MSCs. Further, in zymosan-induced peritonitis in mice it has been suggested that delivered MSCs are activated by the inflammatory environment to produce TSG-6, which then exerts an effect on macrophages and other cells to reduce this inflammatory cascade. Thus, the therapeutic mechanism depicted in these experiments involves a bidirectional signaling mechanism whereby MSCs transplanted to the injured or inflamed environment are activated or "licensed" to increase production of TSG-6, which then binds CD44 on macrophages and causes a decrease in nuclear translocation of nuclear factor kappa light chain-enhancer of activated B cells (NF-κB).

TSG-6 is an extracellular hyaluronan-binding protein, likely to have roles in cell–matrix interactions [85]. It is also a C–X–C motif chemokine ligand (CXCL)8-binding protein and suppresses CXCL8-mediated chemotaxis of neutrophils [86]. Furthermore, in the mouse model of zymosan-induced peritonitis, TSG-6 binds the CD44 receptor on resident macrophages to decrease the zymosan/toll-like receptor (TLR)2-mediated nuclear translocation of NF-κB [87]. The consequence of this may be profound in terms of attenuating the inflammatory response.

A number of other paracrine factors have been associated with MSC-mediated repair. For example, MSCs overexpressing Akt showed dramatic improvement in mediating a positive repair response in infarcted myocardium [88]. Factors such as vascular endothelial growth factor (VEGF), fibroblast-derived growth factor 2, hepatocyte growth factor (HGF), and insulin-like growth factor-1 (IGF-1) were implicated in this effect, and further work focused on secreted frizzled related protein 2, which acts to modulate Wnt signaling, increase cellular β-catenin and upregulates expression of antiapoptotic genes [89,90]. Thrombospondin (TSP)-2, described in 2002 as a secreted factor involved in autocrine regulation of MSC growth [91], was subsequently implicated in mediating cartilage repair in a rabbit

osteochondral model. TSP-2 was selected from an antibody array analysis of human umbilical-cord-derived MSC conditioned media (CM) collected after the cells were exposed to human osteoarthritic synovial fluid. Recombinant TSP-2 was able to improve *in vivo* cartilage repair, although not to the same extent as the umbilical-cord-derived MSCs themselves, with mechanistic insights suggesting the stimulation of endogenous chondroprogenitor cells [92]. Secreted factors from stromal cells isolated from adipose tissue have also been shown to impact hypertrophy and dedifferentiation of human chondrocytes *in vitro*, an effect that was partially mediated by hepatocyte growth factor [93]. In an *in vivo* study, mouse stromal cells isolated from adipose tissue activated by the inflammatory osteoarthritic environment were also shown to be chondroprotective, a phenomenon associated with a decrease in the calcium binding protein S100A8/A9 alarmin levels [94]. (The term "alarmin" has been proposed to categorize endogenous molecules that signal tissue and cell damage. Effector cells of both innate and adaptive immunity can secrete alarmins when they are activated by pathogen-associated molecular patterns or other alarmins. Endogenous alarmins and exogenous pathogen-associated molecular patterns therefore convey a similar message and elicit similar responses. They can be considered subgroups of a larger set, the damage-associated molecular patterns.)

Further insight into potential mechanisms of MSC-mediated repair has come from studies of cell-derived exosomes, which are nanovesicles derived from cell membranes. These secreted vesicles have a phospholipid bilayer membrane rich in cholesterol and are capable of transferring proteins, mRNA, and microRNA to adjacent cells. They are widely understood to be important for intercellular communication. They carry membrane-bound proteins that mediate interactions with ligands on other cells and matrix molecules. Examples include the transferrin receptor (CD9), tumor necrosis factor receptors, lactadherin, integrins, and tetraspanin (CD63, CD81) proteins. These membrane-bound molecules provide a potential mechanism for the homing of exosomes to a specific tissue or microenvironment.

One study evaluated the effects of MSC CM on repair of myocardial ischemia in pigs. Both intravenous and intracoronary delivery of the CM resulted in a 60% reduction in infarct size and marked improvement of systolic and diastolic cardiac performance. Fractionation of the CM indicated that the active component was an exosomal fraction complex of 50–200 nm in diameter. Electron microscopy showed that these complexes were phospholipid vesicles. They contained co-immunoprecipitating exosome-associated proteins CD81, CD9, and ALIX (also known as programmed cell death 6-interacting protein) and could be purified with a hydrodynamic radius of 55–65 nm by size exclusion fractionation using high-performance liquid chromatography. Purified exosomes administered in a mouse myocardial ischemia–reperfusion injury model revealed that MSCs mediate their cardioprotective paracrine effect by exosome secretion [47]. These results suggested that exosomes are a highly efficacious therapeutic agent that neutralizes myocardial ischemia–reperfusion injury and will likely be an effective adjuvant to complement current reperfusion therapy.

## 29.4 Host immune response to autologous mesenchymal stem/stromal cells transplantation

Following the initial identification of MSCs from the bone marrow [95], studies focused on the regenerative capacity of MSCs based on their potential to transdifferentiate to cells of mesenchymal lineages [55,81,96]. However, the discovery of the immunomodulatory potential of MSCs just over a decade ago revolutionized interest in MSCs as a cellular therapy for tissue regeneration [97,98]. Understanding the mechanisms by which MSCs modulate an inflammatory microenvironment has been the focus of intense research since then [99]. It has become apparent that MSCs can exert effects on cells of both the innate and adaptive immune systems [99] through cell-contact, cytokines, chemokines, and TLR-mediated mechanisms (see Chapters 33 and 34). MSCs can suppress the activation and function of various immune system cells, including macrophages, natural killer (NK) cells, T cells, and B cells [100–103]. These distinctive regenerative and immunomodulatory characteristics have seen their application in a wide variety of diseases, including GVHD [104–106] (see Chapter 57), cardiovascular diseases [107] (see Chapters 45 and 46), neurological diseases [108–110] (see Chapters 48 and 49), organ transplantation [111,112] (see Chapter 56), experimental autoimmune encephalomyelitis (EAE) [108–110], autoimmune diseases (see Chapter 54), rheumatoid arthritis [113], osteoarthritis [81], bone and cartilage defects [114] (and see Chapter 47), inflammatory bowel disease [115–117] (see Chapter 50), inflammatory lung disease [118] (Chapter 52), and allergic airway disease [119] (see Chapter 39).

## 29.5 Mesenchymal stromal cells in an inflammatory microenvironment

The ability of MSCs to home to sites of inflammation and adopt a distinct phenotype in response to the inflammatory microenvironment is crucial to our understanding of their therapeutic potential in acute and immune-mediated diseases. MSCs migrate to sites of tissue injury and suppress inflammation, which enables tissue-resident stromal cells to proliferate, modulate inflammation, support angiogenesis, and reconstruct the extracellular matrix, thus enabling wound healing [120–122] (Figure 29.2).

Additionally, an emerging concept is that MSCs become "licensed" or "activated" by exposure to inflammatory cytokines in the microenvironment, further emphasizing their distinctive phenotype [99]. Activation of MSCs by the inflammatory cytokines interferon (IFN)-γ, TNF-α, and IL-1β has been shown to enhance their ability to modulate immune responses [123].

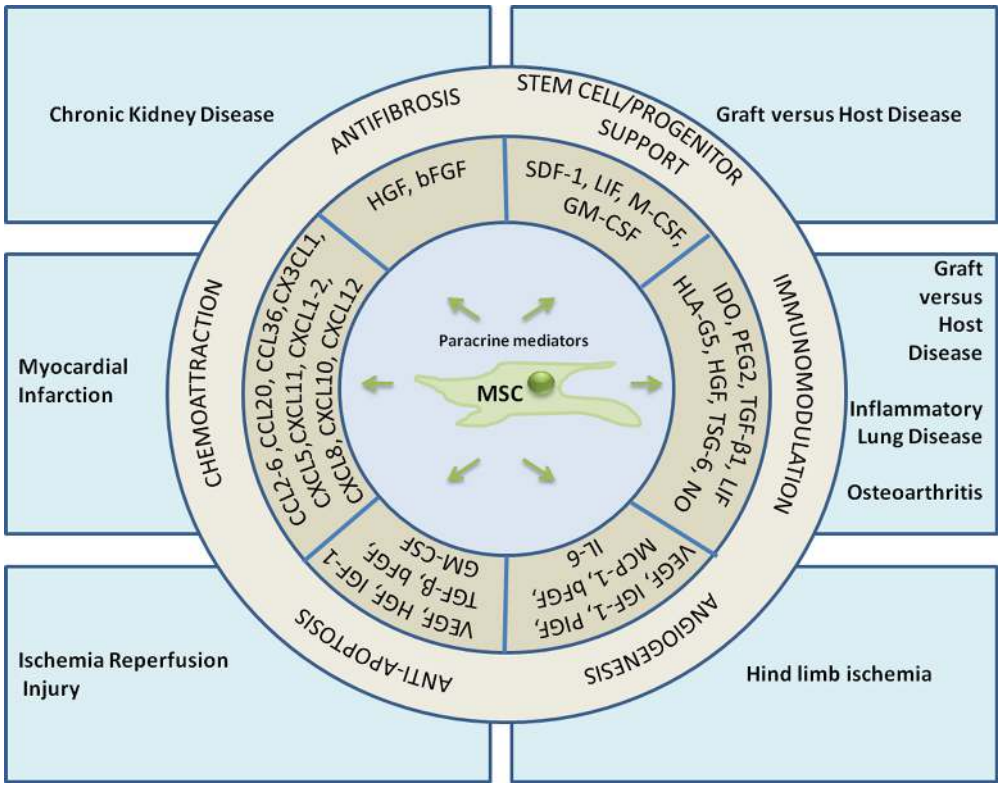

**Figure 29.2** MSC paracrine-mediated mechanisms of action and their therapeutic relevance. The therapeutic effects of MSCs are mediated in a large part through the release of paracrine factors. MSCs, as a result of their mechanisms of action, have potential in the treatment of diseases such as GvHD, inflammatory lung disease, osteoarthritis, hind limb ischemia, ischemia–reperfusion injury, myocardial infarction, and chronic kidney disease (outer boxes). Mechanisms of potential therapeutic relevance include the ability of MSCs to support stem cell/progenitor cells, immune modulation, angiogenesis, antiapoptosis, antifibrosis, and chemoattraction (indicated in the outer circle). MSCs can stimulate mitosis of tissue intrinsic progenitor or stem cells by secretion of stem cell factor, macrophage colony-stimulating factor (M-CSF), stromal cell-derived factor-1 (SDF-1, also known as CXCL12), leukemia inhibitory factor (LIF), and angiopoietin 1. The immunomodulatory effects of MSCs are mediated by indoleamine 2,3-dioxygenase (IDO), prostaglandin $E_2$ ($PGE_2$), transforming growth factor (TGF)-β1, LIF, human leukocyte antigen G5 (HLA-G5), HGF, TSG-6, and nitrous oxide (NO). MSCs can stimulate local angiogenesis by secretion of extracellular matrix, VEGF, IGF-1, placenta growth factor (PLGF), monocyte chemoattractant protein 1 (MCP-1, also known as CCL2), basic fibroblast growth factor (bFGF), and interleukin (IL)-6. MSCs have been shown to prevent apoptosis through HGF, TGF-β, IGF-1, bFGF, VEGF, and granulocyte M-CSF (GM-CSF). MSCs can elicit leukocyte and monocyte migration to sites of tissue injury to restore normal tissue homeostasis. Lastly, MSCs contribute to inhibition of scarring through the release of soluble factors, including HGF and bFGF.

Interestingly, activated MSCs have an enhanced homing potential and tissue regeneration properties [116,124]. This enhanced immunosuppressive ability has been attributed to the differential regulation of a number of key molecules, including IDO, NO, $PGE_2$, TGF-β, and TSG-6 by MSCs following proinflammatory stimulation. Other factors besides inflammatory cytokines also participate in "licensing" the immunomodulatory ability of MSCs [101]. Microbe-associated molecular patterns can activate MSCs through TLRs such as TLR3 and TLR4 [102,125]. TLR signaling has been shown to alter MSC-mediated immune modulation. TLR3 and TLR4 ligation may differentially induce MSCs to anti- and proinflammatory phenotypes respectively [125]. The emerging concepts that MSCs can sense their microenvironment and become differentially polarized depending on the nature and intensity of the inflammatory signals present adds another layer of complexity to our understanding of how the local microenvironment influences MSC activation and MSC-mediated immune modulatory functions [99,101,126] (Figure 29.3).

The nature of the inflammatory tissue microenvironment consequently influences and determines the fate of administered MSCs and may result in different therapeutic outcomes [123,127]. A complete understanding of MSC response to different phases and intensities of inflammation is necessary to guide strategies that will enable precise manipulation of therapeutic outcomes. Knowledge of how to control and regulate the immunomodulatory effects in variable inflammatory environments, both endogenously and exogenously, may provide an important new modality for improved clinical application.

MSC modulation of the immune system occurs as a multistage process involving MSC migration to the site of injury and response to inflammation, their response and activation by

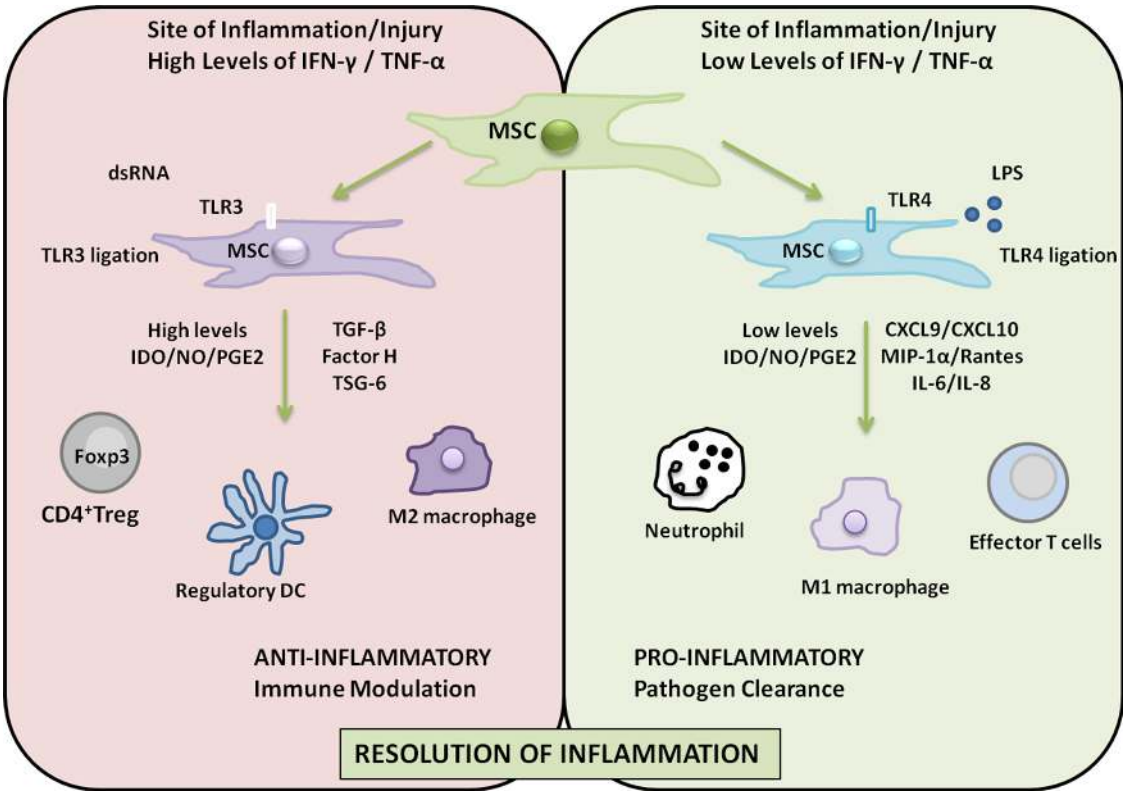

**Figure 29.3** MSC responses to diverse inflammatory microenvironments. Proinflammatory cytokines such as IFN-γ, TNF-α, or IL-1β are present in high concentrations at sites of acute or relapsing phases of inflammatory diseases. In response to high concentrations of these cytokines, and/or following ligation of TLR3 on MSCs, they produce large amounts of NO, IDO, and $PGE_2$, which participate in MSC-mediated immune modulation by induction of regulatory T cells (Tregs), regulatory dendritic cells (DCs), and M2 macrophages (left panel). In the context of chronic inflammation, in the presence of low concentration of proinflammatory cytokines and/or TLR4 ligation, MSCs secrete low levels of NO, $PGE_2$, and IDO, as well as CXCL9/10, IL-8, and IL-6. MSCs may promote pathogen clearance in this context by polarization of proinflammatory M1 macrophages, antimicrobial activity, and through promotion of the survival of neutrophils. This differential ability to respond to inflammation enables MSCs to promote pathogen clearance followed by suppression of an immune response in the resolution of inflammation. LPS: lipopolysaccharide; MIP-1α: macrophage inflammatory protein 1α.

inflammatory mediators, promotion of pathogen clearance, and subsequent modulation of inflammation [99]. MSCs exert effects that are both contact dependent and independent and influence cells of both the innate and adaptive immune systems (Figure 29.4).

## 29.6 Mesenchymal stem/stromal cells-mediated immunomodulation of the innate immune system

Innate immune cells have important roles in tissue homeostasis and are the first line of defense against invading pathogens. MSC and innate immune cell interactions shape inflammatory and regenerative environments [103]. Monocytes, macrophages, DCs, neutrophils, mast cells, and NK cells are all components of the innate immune system. MSCs can modulate the effector functions of each of these innate cellular subsets, which have been reviewed in great detail previously [99–103,121,122,128,129].

Macrophages have key roles at sites of inflammation and can be polarized by the microenvironment into classically activated M1 macrophages, which are proinflammatory and involved in antimicrobial activity, or alternatively activated M2 macrophages, which are involved in tissue repair and resolution of inflammation [103]. MSCs recruit monocytes and macrophages into inflamed tissue in a CCL3-, CXCL2-, and CCL12-dependent manner. MSCs induce M2 macrophage polarization. M2 macrophages have high levels of CD206, IL-10, and phagocytic activity and low levels of TNF-α and IFN-γ. (CD206, also known as mannose receptor, is a pattern recognition receptor belonging to the C-type lectin superfamily. It is expressed on macrophages, DCs, Langerhans cells, and hepatic or lymphatic endothelial cells.)

These effects have been shown to be mediated by both cell-to-cell contact (EP2/4 ($PGE_2$ receptors), CD44, TLR2 on macrophages) and soluble factor ($PGE_2$, TGF-β, and TSG-6) mechanisms [87,130]. Macrophage-secreted TNF-α can activate MSCs to secrete TSG-6, thereby inhibiting inflammation through CD44-receptor-mediated negative feedback on macrophages [87]. The relevance of MSC-mediated modulation of macrophages has been validated in various models of sepsis and zymosan-induced peritonitis, in which MSCs promoted

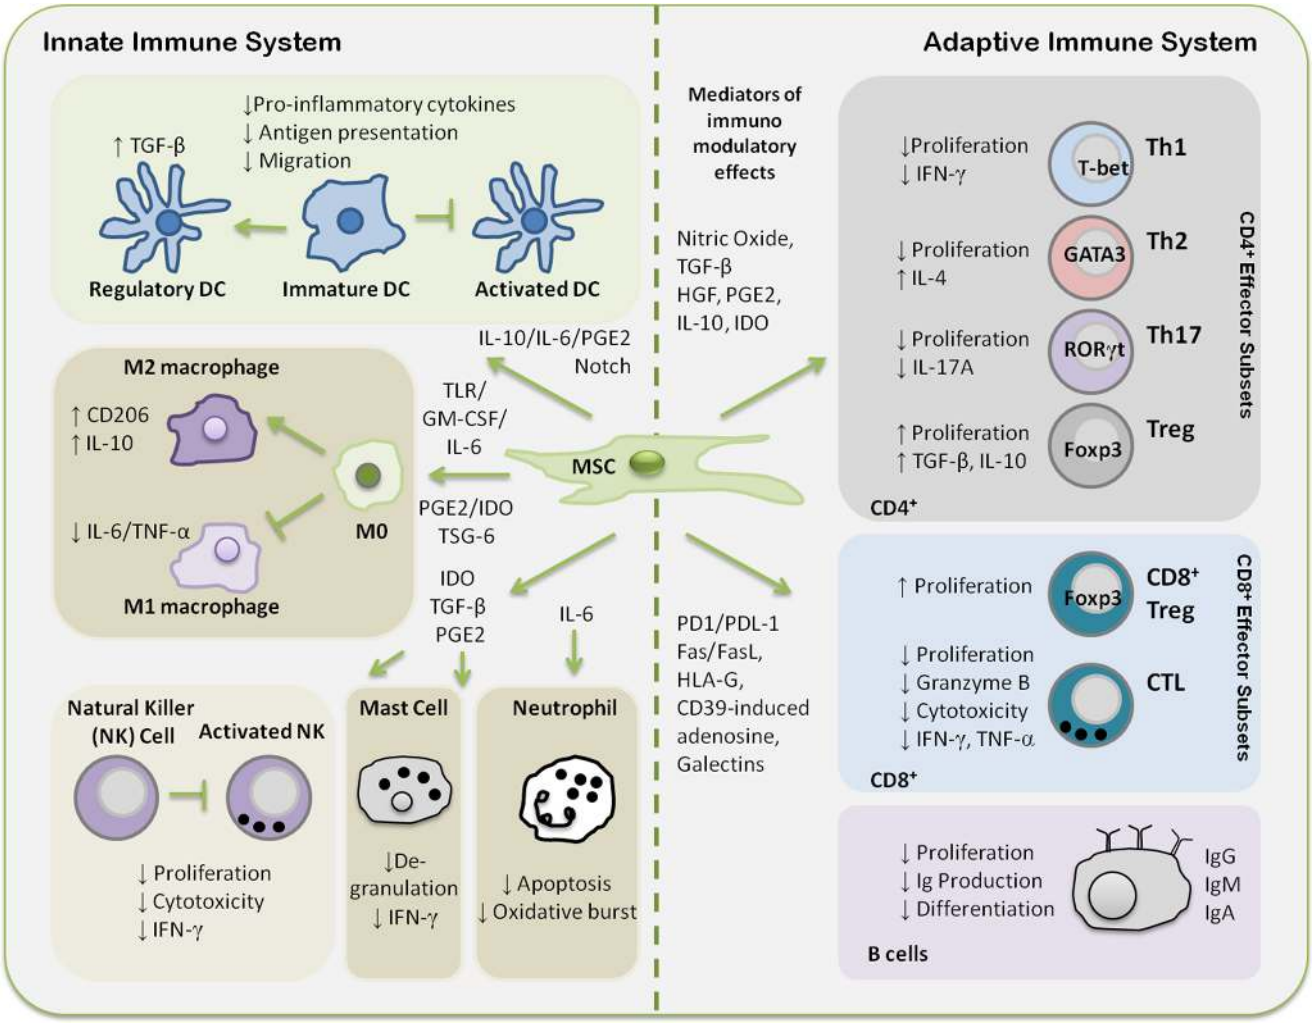

**Figure 29.4** MSC-mediated mechanisms of immune modulation. A summary of MSC-mediated effects on components of the innate and adaptive immune system is shown. These effects are mediated by soluble and cell-surface protein interactions. MSCs can modulate the effector functions of innate cellular subsets. MSCs inhibit DC maturation, migration, and antigen presentation ability, as well as promotion of regulatory DC subsets. MSCs promote the differentiation of monocytes to an anti-inflammatory M2 macrophage phenotype, while inhibiting the development of M1 proinflammatory macrophages. MSCs inhibit NK cell activation and cytotoxicity, mast cell degranulation, and neutrophil apoptosis and oxidative burst. MSC secretion of IL-6, IL-10, $PGE_2$, TGF-β, TSG-6, and GM-CSF, as well as Notch and TLR signaling, have been shown to modulate these MSC-mediated effects on innate immune cell responses. In the context of the adaptive immune system, MSCs inhibit the proliferation of T cell effector subsets, including $CD4^+$TH1, TH2, and TH17 effectors and can promote the expansion of Tregs in an antigen-specific manner. MSCs inhibit the activation and proliferation of $CD8^+$ cytotoxic T lymphocytes (CTLs) but induce the expansion of $CD8^+$ Tregs. MSCs can inhibit B cell proliferation and suppress the production of immunoglobulin (Ig)G, IgA, and IgM *in vitro*. Programmed cell death protein 1 (PD1)/programmed death ligand 1 (PDL-1), Fas/FasL interactions, as well as MSC secretion of NO, TGF-β, IDO, HGF, $PGE_2$, and IL-10 have been shown to modulate these MSC-mediated effects on adaptive immune cell responses. (See color plate section.)

resolution of inflammation that was dependent on monocyte/macrophage recruitment [87,130]. In the context of chronic inflammation and in the presence of low concentrations of proinflammatory cytokines and/or TLR4 ligation, MSCs secrete low levels of NO, $PGE_2$, and IDO, as well as CXCL9/10, IL-8, and IL-6. MSCs may promote pathogen clearance in such a microenvironment by polarization of antimicrobial activity [99] by proinflammatory M1 macrophages and through promotion of neutrophil survival. Neutrophils, another key facilitator of antimicrobial responses, produce a large quantity of microbicidal oxidative products in response to the detection of microbial molecules in the so-called "respiratory burst." During early-stage inflammation the proinflammatory activities of MSCs can facilitate neutrophil recruitment, accumulation, and phagocytosis to enable pathogen clearance, which is IL-6, IFN-β, and GM-CSF dependent [102]. MSCs inhibit neutrophil apoptosis even under IL-8-mediated activation conditions via MSC-derived IL-6 [131]. MSCs also prevent respiratory bursts from neutrophils,

although chemotaxis is unaffected. MSCs also inhibit mast cell functions, including migration, TNF production, and IgE-cross-linking-mediated degranulation, in a $PGE_2$-dependent-manner [132,133]. These findings are particularly interesting in the context of allergy and autoimmunity, in which MSC administration has been therapeutically efficacious. NK cells have a critical role in eliminating intracellular pathogen-infected cells, stressed cells, and cancer cells. NK cytotoxicity is regulated by both inhibitory and activating receptors, as well as by target cell major histocompatibility complex (MHC) expression levels and antibody-dependent cellular cytotoxicity. MSCs inhibit NK cell proliferation and suppress the expression of activating receptors in a $PGE_2$-, IDO-, and TGF-β-dependent manner, although these effects are context dependent [121]. DCs bridge the innate and adaptive immune systems and have a critical role in host defense and generation of immune responses. MSCs inhibit maturation of DCs by contact-dependent and -independent mechanisms [134–136]. MSCs have been shown to influence key features of DC function both *in vitro* [134] and *in vivo* [137], including migration, maturation, and antigen presentation [134,137]. MSCs can also reprogram conventional lymphocyte stimulatory DCs into anti-inflammatory DCs with a tolerogenic phenotype [138], which has implications in the context of solid organ transplantation (Chapter 56). In fact, tolerogenic DCs induced by MSCs inhibit delayed-type hypersensitivity responses, prevent $CD4^+$ T cell activation, and promote the survival of cardiac allografts [137,139,140] (Figure 29.3). Emerging evidence demonstrates that MSCs modulate the function of innate immune cells to establish a fine balance between pathogen elimination, resolution of inflammation, and tissue repair.

## 29.7 Mesenchymal stem/stromal cells-mediated immune modulation of the adaptive immune system

The adaptive immune system functions in an antigen-specific manner and is critical to the development of immunological memory [102]. The adaptive immune system is composed of $CD4^+$ helper T lymphocytes and $CD8^+$ CTLs that facilitate an antigen-specific immune response following presentation of antigen by antigen-presenting cells. It is now well documented that MSCs have potent immunomodulatory effects on most cellular subsets of the adaptive immune system, including $CD4^+$ TH1, TH2, and TH17 cells, CD8 CTLs, $CD4^+$ Tregs, $CD8^+$ Tregs, and B cells, and these mechanisms have been reviewed in detail previously [99–103,121,122,128,129,141]. MSCs suppress $CD4^+$ helper T cell proliferation (TH1/TH2/TH17) *in vitro* by contact-dependent (Fas/FasL, PD1/PDL1) and -independent mechanisms (TGF-β, HGF, $PGE_2$, IDO, and NO), which can be enhanced by MSC activation with proinflammatory cytokines [126,141]. This inhibition occurs as a result of cell cycle phase arrest in $G_0/G_1$ [99], regardless of the type of stimulation. Although it is evident that MSCs can suppress T cell proliferation and activation directly, it has recently been suggested that this suppression is dependent on the presence of monocytes [142]. MSCs can suppress activation and cytotoxicity of CTLs [141]. Several studies have shown that MSCs can polarize T cells toward a regulatory phenotype that represents another mechanism by which MSCs can suppress inflammation. Tregs are a subpopulation of helper T cells that are characterized by the expression of the forkhead box P3 (Foxp3) transcription factor and are specialized in suppressing T-cell-mediated immune responses. The generation of MSC-induced Tregs is both contact dependent (with helper T cells) and independent (through $PGE_2$, TGF-β, and HLA-G5) [102,143], and has also been shown to be dependent on the presence of monocytes [144,145]. Additionally, studies have shown that depletion of Tregs abrogates the anti-inflammatory effect mediated by MSCs [139,146]. Moreover, MSC-mediated induction of $CD8^+$ Tregs has been demonstrated to be immunosuppressive in human allo-antigen-stimulated cultures [141]. Treg expansion has been associated with protection in a number of disease models, including allergic airway disease [147] and inflammatory bowel disease [148]. MSCs also suppress B cell proliferation, chemokine receptor expression, and the production of IgG, IgM, and IgA *in vitro*. In transplantation studies, MSCs suppressed allo-specific antibodies and promoted long-term graft acceptance [139]. These effects are both contact dependent through the PD1/PDL1 pathway and independent. Together, these mechanisms clearly demonstrate immense potential for the use of MSCs in modulating the host adaptive immune response, particularly in the context of transplantation and allergic, inflammatory, and autoimmune diseases.

## 29.8 Host immune response to transplantation of allogeneic mesenchymal stem/stromal cells

Identification of the potent immunosuppressive properties of MSCs has led to the broadly accepted principle that MSCs from genetically unrelated individuals (allogeneic MSCs) could be used therapeutically with equal efficacy to autologous MSCs and without triggering a specific response against the donor MSCs typically associated with allogeneic organ transplants [149,150]. While the use of autologous MSCs may be thought more desirable from the perspective of safety of administration and avoiding the possibility of an allogeneic immune response, certain clinical situations, in which autologous MSCs are unattainable, dysfunctional, and/or less effective owing to disease [151–153], require the availability of "off-the-shelf" allogeneic MSCs. As a result, allogeneic MSCs from young healthy donors are an attractive source of cells for such clinical situations.

A range of studies have investigated the efficacy of allogeneic MSCs in preclinical disease models [154–165], both with and without direct comparison to autologous MSCs [149]. These

studies have provided insight into the range of antidonor responses that may be encountered in various clinical applications for allogeneic MSCs [149] and which have increased dramatically over the past several years [149,166–169]. Allogeneic MSC immunogenicity and the functional nature of antidonor immune responses generated following the administration of allogeneic MSCs have been determined using many approaches, including *in vivo* persistence of allogeneic MSCs after their administration, immune cell infiltration, therapeutic efficacy, analysis of antidonor T cell and B cell responsiveness, measurement of serum alloantibodies, *in vitro* "recall" of T cell responses to donor-specific alloantigens, and *in vivo* rechallenge experiments involving readministration of cells from the same or a different donor. Griffin *et al.* reviewed numerous experimental studies showing that allogeneic MSCs trigger donor-specific cellular and humoral immune responses [149]. These findings bring into question whether allogeneic MSCs are as immune privileged as initially hoped and whether antidonor immune responses limit their efficacy. Various preclinical and clinical studies provide evidence for a therapeutic benefit of allogeneic MSCs. However, the anti-inflammatory and immune modulatory properties of MSCs do not prevent the generation of active donor-specific T and B cell responses against allogeneic MSCs *in vivo*. The consequences of these observations have not been fully investigated. It is worth noting that allogeneic MSCs have been administered in human trials by multiple routes without severe immunological complications. However, large-scale therapeutic application of allogeneic MSCs will require a broader understanding of the nature and future consequences of the resulting antidonor responses. It is necessary to consider whether alloantibodies or memory T cells generated following the administration of allogeneic MSCs will represent a significant barrier to their successful administration [149,169]. A better understanding of the underlying mechanisms of the immune responses generated in response to the administration of allogeneic MSCs may be useful to either prevent or modify them in order to optimize clinical benefit.

There is a growing interest in the use of "activated" or "licensed" allogeneic MSCs based on the premise that MSC immunosuppressive properties are enhanced by pretreatment with inflammatory mediators such as IFN-γ [128,170] and TNF-α [126]. However, in the context of allogeneic MSCs, the increased anti-inflammatory potency of IFN-γ-activated MSCs may be counterbalanced *in vivo* by increased immunogenicity. Several studies have shown upregulation of key surface proteins, including MHC class I antigens, MHC class II antigens, intracellular cell adhesion molecule, and costimulatory molecules following activation of allogeneic MSCs with IFN-γ [149]. This increased immunogenicity was confirmed by observations of enhanced T cell responses and production of donor-specific antibodies, which resulted in accelerated clearance of a second injection of allogeneic MSCs *in vivo* [171]. Nevertheless, enhanced therapeutic efficacy has been observed with activated allogeneic MSCs in a model of GVHD [172]. These findings highlight the need to better understand how the potential for increased efficacy and enhanced immunogenicity can be balanced in the context of inflammatory disease. It has been suggested that protecting MSCs from immune detection and prolonging their persistence *in vivo* may improve clinical outcomes and prevent patient sensitization toward donor antigens [173].

The immunogenicity of MSCs following differentiation to chondrocytes, osteocytes, or other lineages is also poorly characterized and may be of fundamental importance for cell therapy for myocardial, bone, or joint disease [174,175]. Even weak immunogenicity may hamper successful translation for clinical applications that may require MSC engraftment, such as myocardial infarction (but see Chapter 45) or osteoarthritis. Recent evidence suggests that MSCs become more immunogenic and lose their immunosuppressive properties after differentiation [107,174–176]. Heightened immune responses have been confirmed *in vivo* [107,175,176]. Studies have shown that lack of immunosuppression was associated with a loss of $PGE_2$ and that immunosuppressive ability could be reestablished with addition of exogenous $PGE_2$ [176]. These findings raise important questions regarding the immunogenic properties of allogeneic MSCs following *ex vivo* or *in vivo* differentiation that are likely to become more clinically relevant as cellular therapies become established for specific acute and chronic diseases. It is necessary to determine if allogeneic immune responses limit therapeutic efficacy or long-term survival of MSCs *in vivo*, or whether these limitations can be overcome by genetic modification or the use of immunosuppression agents after administration of allogeneic MSCs.

## 29.9 Summary

It is becoming increasingly apparent that MSCs, although initially thought to be potent suppressors of immune cells, are distinctively responsive to crosstalk within the host microenvironment. Exploiting the potential of MSCs will involve a thorough understanding of the crosstalk between MSCs and endogenous immune cells in both physiological and pathological situations. Our current level of understanding of the host response with regard to allogeneic MSCs, although incomplete, suggests that the concept of immune privilege should be reevaluated. Emerging evidence indicates that MSC-associated alloantigens are actively recognized by the recipient's immune system with a range of potential outcomes [149]. With the increased number of disease models being investigated to assess the potential of allogeneic MSC treatment, and the increased sensitivity of techniques being utilized, the limits of immune modulation by allogeneic MSCs are emerging. These limits will most likely influence the disease targets suitable for cell therapy and help guide the next generation of enhanced allogeneic MSC therapies [177].

## 30.1 Introduction

Cellular therapy is a promising tool to treat a wide plethora of human diseases. So far, extensive studies have been done, and are still continuing to be done, to better characterize many aspects of cellular therapy for regenerative medicine purposes. Cell types proposed as potential candidates for cellular therapy can be classified into three groups: embryonic stem cells (ESCs) [1], induced pluripotent stem cells (iPSCs) [2], and adult mesenchymal stromal cells (MSCs) [3]. Although derived in different ways, both ECSs and iPSCs are capable of extensive self-renewal and expansion, and have the potential to differentiate into any type of somatic cell [4,5]. However, there are limitations to be considered for their clinical use, ranging from the ethical issues surrounding ESCs – primarily the destruction of the embryo by harvesting the cells early in embryonic development – difficulties in genetically manipulating iPSCs, immune reactions to the differentiated progeny of ESCs and iPSCs if derived from an MHC-incompatible donor, and, importantly, teratoma formation after transplantation of the differentiated progeny of ESCs or iPSCs if they are contaminated with undifferentiated ESCs or iPSCs [6,7].

MSCs were first isolated by Friedenstein from bone marrow (BM) [8]. Later, these cells were also isolated from multiple different human adult tissues, including umbilical cord blood (UCB) [9], skeletal muscle [10], skin [11], periodontal ligament [12], and adipose tissue (AT) [13]. MSCs are considered an optimal candidate cell population for cellular therapy as they have been reported to possess multipotent differentiation potential of mesodermal lineages [14], paracrine functions [15], genetic stability after *in vitro* manipulation [16], and, most importantly, MSCs have no ethical or manufacturing issues compared with ESCs and iPSCs.

One unsolved issue to ensure an efficient and reproducible use of MSCs in clinical practice is evaluation of their purity. The absence of specific markers that characterize MSCs is responsible for this. The presence of different cell types other than MSCs in a given preparation of cells such as hematopoietic and endothelial cells can be easily evaluated by the expression of CD34, CD45, and CD31 markers that are not present in MSCs [17]. In contrast, the occurrence of contaminating fibroblasts is hard to establish; thus, the assessment of the homogeneity and purity of an MSC preparation remains difficult. In contrast to MSCs, fibroblasts are considered mature MSCs that are particularly abundant in the connective tissue of each organ. Several findings have indicated

that MSCs and fibroblasts share many phenotypic and functional characteristics besides their morphology and origin [18–20]. For this reason, ready discrimination between MSCs and fibroblasts is difficult. It has been demonstrated that the presence of contaminating fibroblasts can represent a serious obstacle in determining the therapeutic potential of MSCs. It has been recently shown that co-administration of MSCs with contaminating fibroblasts in an experimental model of Parkinson's disease could have detrimental effects [21]. It is thus important to further distinguish the phenotypic and functional characteristics of MSCs and their differences compared with fibroblasts.

Although both cell populations have similarities, in this chapter we will describe some aspects and properties that can lead to a better definition of the differences between MSCs and fibroblasts.

## 30.2 Phenotypic similarities and differences between mesenchymal stromal cells and fibroblasts

Three important features have been suggested as characteristics of human MSCs: adherence to plastic in tissue culture, a characteristic cell surface antigen expression, and multipotent differentiation potential along the mesodermal lineages [22]. It is immediately apparent that the first criterion is not useful for distinguishing MSCs from fibroblasts. Indeed, as shown in Figure 30.1, both fibroblasts and MSCs adhere to plastic and have a spindle-shaped morphology.

Additionally, mesodermal lineage transdifferentiation potential is not an exclusive property of MSCs, since many studies have demonstrated that both MSCs and fibroblasts show a similar capacity to differentiate mesodermally.

## 30.3 Cell surface membrane markers

A minimum set of phenotypic criteria have been proposed to define MSCs: the presence (≥95%) of the three surface markers CD105, CD73, and CD90 and the absence (≤2% positive) of CD45, CD34, CD31, CD14 or CD11b, CD79a or CD19, and human leukocyte antigen (HLA) class II [22]. Other surface markers, such as CD13, CD29, CD44, and CD10, are variably expressed on MSCs [23]. However, these minimal criteria are insufficient to ascertain the purity of an MSC population because it has been shown that fibroblasts, at various stages, express all these surface markers [19,24]. For this reason, many investigators have tried to identify other markers that could be used to better define an MSC population [25]. Table 30.1 lists some cell surface membrane molecules that appear to be expressed on MSCs but not on fibroblasts.

Stro-1 is one of the best known markers for MSCs but it is not universally expressed on all MSC populations. Indeed, AT-derived MSCs, UCB-derived MSCs, and peripheral blood-derived MSCs have no or low Stro-1 expression [26–28]. Controversial data exist about Stro-1 expression by fibroblasts. Chen *et al* [29]. reported that Stro-1 was expressed by fibroblasts, albeit at low levels. Conversely, other authors demonstrated that fibroblasts do not express Stro-1 [19,30].

CD271 is an MSC marker used to select fibroblastic colony-forming units (CFU-Fs) from BM mononuclear cells. Similar to Stro-1, CD271 is not expressed by all MSCs. Indeed, its expression was found elevated in BM-MSCs and AT-MSCs [31,32], but at low levels in placenta-derived MSCs and totally absent in peripheral blood-derived MSCs [33]. Interestingly, Wirths *et al.* found that CD271 was expressed on BM-MSCs but not on foreskin fibroblasts [34].

The CD146 cell adhesion protein plays a pivotal role in vascular endothelial cell activity and angiogenesis. CD146 is

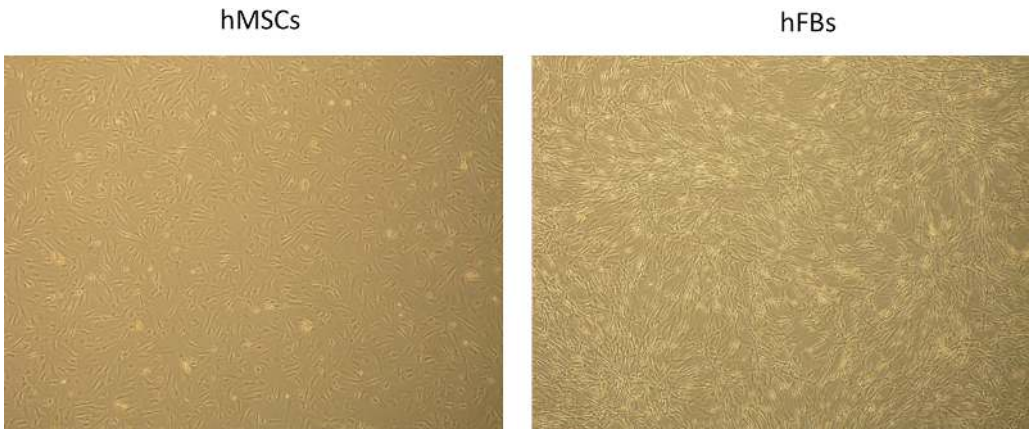

**Figure 30.1** Cell morphology of human MSCs (hMSCs) and human fibroblasts (hFBs). Representative photographs of MSCs isolated from AT and an available commercial line of foreskin fibroblasts. MSCs share a splindle-shaped fibroblasts-like morphology. Cell culture photographs were acquired at passage 5 for both cell populations.

**Table 30.1** Surface molecules identified on MSC cell populations and absent on fibroblasts.

| Marker | Main function or description | MSCs | Fibroblasts |
|---|---|---|---|
| Stro-1 | Cell membrane stromal cell antigen 1, which translocates from the endoplasmic reticulum to the cell membrane in response to a depletion of intracellular calcium | Yes [26–28] | No [19,29,30][a] |
| CD271 | Receptor for neurotrophin (low-affinity nerve growth factor receptor), which stimulates neuronal cells to survive and differentiate | Yes [31–33] | No [34] |
| CD146 | Plays a role in cell adhesion, and in cohesion of the endothelial monolayer at intercellular junctions in vascular tissue. Also known as melanoma cell adhesion molecule or cell surface glycoprotein MUC18 | Yes [35–40] | No [24] |
| CD49f | $\alpha_6$-Integrin, involved in cell adhesion as well as cell-surface-mediated signaling | Yes [41–43] | No [44] |
| GD2 | Neural ganglioside | Yes [45,46] | No [45] |
| MSCA-1 (TNAP, W8B2) | MSCA-1 is identical to TNAP | Yes [23,35,47] | No [34] |
| CD200 | Type-1 membrane glycoprotein that may regulate myeloid cell activity and delivers an inhibitory signal for the macrophage lineage in diverse tissues | Yes [48] | No [49] |
| TM4SF1 | Protein belonging to the tetraspanin family. Mediates signal transduction events that play a role in the regulation of cell development, activation, growth, and motility | Yes [50] | No [50] |

MSCA-1: mesenchymal stem cell antigen-1; Stro-1: stromal precursor antigen-1; TM4SF1: transmembrane 4 L6 super family member; TNAP: tissue nonspecific alkaline phosphatase.
[a] According to [29], Stro-1 is expressed in fibroblasts.

expressed by several MSC populations, including BM-MSCs [35], AT-MSCs [36], UCB-MSCs [37], and MSCs isolated from placenta [38], dermis [39], and periodontal ligament [40], but not by fibroblasts [24].

CD49f ($\alpha_6$-integrin) expression has been detected in BM-MSCs [41], fetal urinary-bladder-derived MSCs [42], and UC-MSCs [43]. It seems not to be expressed by fibroblasts [44].

The neural ganglioside GD2 was reported by Martinez *et al.* to be expressed on BM-MSCs and AT-MSCs but not on foreskin fibroblasts [45]. Moreover, GD2 identified a subpopulation of UC-MSCs [46].

MSCA-1 (also named TNAP [47] or W8B8 [35]) has been reported as a suitable marker for the prospective isolation of highly purified BM-MSCs [23]. MSCA-1 expression is probably limited to BM-MSC subpopulations. Fibroblasts do not express this surface antigen [34].

CD200 is expressed on the surface of human MSCs. However, it also is not detected on fibroblasts [48,49].

TM4SF1 was recently described as being highly expressed by BM-, UC-, and AT-MSCs but not on fibroblasts [50].

Thus, in summary, some of the surface antigens described here, specifically CD271, CD146, GD2, MSCA-1, and CD200, appear to represent, at least in part, cell surface markers expressed by MSC or MSC subpopulations, but not by fibroblasts.

## 30.4 Gene expression profile of mesenchymal stromal cells and fibroblasts

The development of techniques such as microarray technology, quantitative real-time reverse transcriptase polymerase chain

reaction (qRT-PCR) and proteomics has allowed an in-depth analysis of cellular gene and protein profiling. Several studies have examined differential gene expression between MSCs and fibroblasts. Using DNA microarrays probing for 9400 genes, Ishii *et al* [51]. found that approximately 100 genes were differentially expressed between MSCs and fibroblasts and that these differences were not related to age, donor gender or cell culture conditions. Reverse transcriptase polymerase chain reaction (RT-PCR) and qRT-PCR showed that mRNA levels were expressed at a lower level in MSCs compared with fibroblasts for the following: matrix metalloproteinase (MMP)-1, adrenomedullin, CUG triplet repeat RNA-binding protein, collagen type XV α-1, KH domain-containing RNA-binding signal transduction-associated protein 3 (KHDRBS3), C-type lectin superfamily member-2, and apolipoprotein D.

The genes related to these mRNAs encode proteins with the following functions:

- Adrenomedullin is a ubiquitously expressed peptide hormone initially isolated from a pheochromyctoma, a tumor of the adrenal medulla.
- CUG triplet repeat RNA-binding protein is involved in the regulation of pre-mRNA alternative splicing and possibly in mRNA editing and translation.
- Collagen type XV α-1 is a member of the FACIT collagen family (fibril-associated collagens with interrupted helices). It has a wide tissue distribution, with its strongest expression being localized to basement membrane zones; thus, it may function to adhere basement membranes to underlying connective tissue stroma.
- KHDRBS3 (also known as Sam68-like phosphotyrosine protein/T-STAR) is an RNA-binding protein that plays a role in the regulation of alternative splicing and influences mRNA splice site selection and exon inclusion, which may play a role as a negative regulator of cell growth, inhibits cell proliferation, is involved in splice site selection of vascular endothelial growth factor (VEGF), and which induces an increased concentration-dependent incorporation of exon in CD44 pre-mRNA by direct binding to purine-rich exonic enhancer.
- C-type lectin superfamily member-2 includes proteins with diverse functions, including cell adhesion, cell–cell signalling, and glycoprotein turnover, which have roles in inflammation and the immune response.
- Apolipoprotein D is a protein closely associated with the enzyme lecithin:cholesterol acyltransferase, an enzyme involved in lipoprotein metabolism.

mRNA was more highly expressed in MSCs than in fibroblasts for the following: tissue factor pathway inhibitor-2, HLA class II histocompatibility antigen DR α chain (MHC-DR-α), MHC-DR-β, MHC-DR-associated protein CD74, and neuroserpin. Proteins encoded by the genes related to these mRNAs are as follows:

- Tissue factor pathway inhibitor-2 is a single-chain polypeptide that can reversibly inhibit the blood clotting protein factor Xa, which is the activated form of the coagulation factor thrombokinase.
- MHC-DR-α is a protein that forms the α subunit of HLA-DR.
- MHC-DR-β, the protein produced from the *HLA-DRB1* gene, called the β chain, attaches to the α chain. Together, they form a functional protein complex called the HLA-DR antigen-binding heterodimer. This complex displays foreign peptides to the immune system to trigger the body's immune response.
- MHC-DR-associated protein CD74 (also known as HLA class II histocompatibility antigen γ chain and as HLA-DR antigens-associated invariant chain or CD74) is a polypeptide involved in the formation and transport of MHC class II protein. The cell surface form of the invariant chain is known as CD74.
- Neuroserpin is a protein secreted from the axons of dorsal root ganglion neurons and is expressed in the late stages of neurogenesis during the process of synapse formation.

Interestingly, these authors used this differential gene expression pattern to define the degree of purity of MSCs that were transplanted in patients undergoing periodontal therapy [51].

A similar approach employing a cDNA microarray of 9600 genes led to the identification of 80 genes that were more than threefold more highly expressed in BM-MSCs than in mature skin fibroblasts [52]. cDNAs highly expressed by MSCs were associated with developmental processes, including embryogenesis, as well as with stem cell function. Strangely, mesenchymal lineage genes were downregulated in MSCs compared with skin fibroblasts.

Another study comparing the gene expression of human AT-MSCs, UCB-MSCs, and BM-MSCs with that of terminally differentiated human fibroblasts showed that 25 and 30 genes, respectively, were found up- and downregulated in MSCs [53]. These included genes that contribute to extracellular matrix (ECM) formation and transcription factors that are mostly involved in collagen and other ECM protein synthesis and degradation. Furthermore, several genes involved in the Wnt pathway were found differentially expressed in MSCs in comparison with fibroblasts. In particular, higher levels of Wnt pathway inhibitors were found in fibroblasts, while in MSCs the downstream activators of the same pathway were found to be upregulated.

Kubo *et al.* used 54 675 DNA microarray probes to analyze the differences in expression levels of undifferentiated MSCs, differentiated MSCs (osteoblasts, chondrocytes, and adipocytes), and fibroblasts [54]; 148 genes were found more than twofold upregulated in MSCs compared with differentiated MSCs or fibroblasts. Furthermore, using qRT-PCR, it was found that the expression level of all 71 genes examined was selectively enhanced compared with differentiated cells and fibroblasts. Among these were genes encoding nine transcriptional factors: *ETV1*, *ETV5*, *FOXP1*, *GATA6*, *HMGA2*, *KLF12*, *PRDM16*, *SIM2*, and *SOX11*. Interestingly, small interfering RNA knockdown of *ETV1*, *ETV5*, *FOXP1*, *GATA6 HMGA2*, *SIM2*, or *SOX11* suppressed the self-renewal capacity of MSCs, whereas those of *FOXP1*, *SOX11*, *ETV1*, *SIM2*, or *PRDM16* reduced their

osteogenic and/or adipogenic differentiation potential. Additionally, the genes for *IL-6*, *VEGF*, *HGF*, and *MET* (the hepatocyte growth factor (HGF) receptor) were highly expressed by undifferentiated MSCs compared with differentiated MSCs and fibroblasts.

Other findings partially corroborate the role of transcriptional factors as genes that discriminate between MSCs and fibroblasts. Sachs *et al.* analyzed the expression of the transcription factors involved in pluripotency – SOX2, OCT-4, and NANOG – in AT-derived MSCs, fibroblasts, and iPSCs generated from fibroblasts [55]. They found that *SOX2* expression level was 10- to 100-fold higher in MSCs than in fibroblasts, but approximately 10-fold lower in MSCs than in iPSCs. *OCT-4* expression was ~10- to 100-fold lower than in iPSCs, but again was significantly higher than in fibroblasts. *NANOG* was also 10- to 100-fold higher in AT-derived MSCs than in fibroblasts and approximately 20-fold lower than in iPSCs.

A wider analysis of the transcriptome profiles of AT-derived MSCs and dermal fibroblasts found 62 genes that were differentially expressed between the two cell populations. Several genes remained expressed after differentiation of AT-derived MSCs and fibroblasts to adipogenic, osteogenic, and chondrogenic lineages: *COL1A1*, *COL1A2*, *EFEMP1*, *FN1*, *GGT5*, and *TPM2* were highly expressed in AT-derived MSCs, while *S100A4* and *TK1* were specific for fibroblasts and fibroblast-derived iPSCs. Proteins encoded by the genes that give rise to the mRNAs listed are collagen type 1 alpha 1, collagen type 1 alpha 2, epidermal growth factor (EGF)-containing fibulin-like ECM protein, fibronectin 1, γ-glutamyltransferase 5, tropomyosin β chain, S100A4 (which has been shown to interact with S100 calcium binding protein A1), and thymidine kinase 1 respectively. It is conceivable that such closely related stromal cells retain "memory" genes able to distinguish both cell populations [56].

An interesting approach to further define the differences between MSCs and fibroblasts may be their microRNA (miRNA) expression profiles. Discovered in early 1990s, these small RNA sequences of approximately 22 nucleotides in length possess regulatory activities, different sequence and expression patterns, and are evolutionarily widespread [57]. Moreover, these noncoding RNA molecules are known to occur in a cell-type-specific manner and to modulate gene expression and/or protein synthesis [58,59]. Recently, Bae *et al.* performed an elegant study to identify genetic elements that can reliably discriminate MSCs from fibroblasts [60]. By comparative gene and miRNA expression profiling analyses, the authors found 64 genes (56 known and 8 uncharacterized) and 21 miRNAs, the expression of which were at least 10-fold and twofold higher respectively in MSCs than in fibroblasts. Approximately one-third of the known genes encoded integral membrane proteins and membrane-associated proteins, suggesting that the cell surface membrane might be a cellular component that is divergent between MSCs and fibroblasts. Additionally, a large number of genes previously associated with cancers were identified as signature genes of MSCs rather than of fibroblasts. Among 21 miRNAs identified, miR-335 was approximately 44-fold higher in MSCs than in fibroblasts. The latter observation is of particular interest since miR-335 expression may also help elucidate some functional differences between MSCs and fibroblasts. Indeed, Tomé *et al.* recently demonstrated that miR-335 expression regulates MSC proliferation, migration, and differentiation [61]. The same authors proposed a working model for miR-335 control and MSC activation. In healthy tissues, Wnt signaling, in coordination with other stimuli, maintains miR-335 expression levels high in MSCs. When tissue damage occurs, interferon-γ (INF-γ) and probably other proinflammatory signals induce miR-335 downregulation, which in turn causes the de-repression of its target genes and leads to "activation" of MSCs by stimulating their proliferative, migratory, and differentiation capacities.

Overall, these findings illustrate that gene profiling has already expanded our knowledge of the molecular specificities of MSCs and fibroblasts. It is likely that new technologies, including next-generation sequencing (NGS), will further define molecular differences between the two cell types. NGS, or second-generation sequencing, also known as massive parallel sequencing or massively parallel sequencing, refers to any of several high-throughput approaches to DNA sequencing using the concept of massively parallel processing. Some of these technologies emerged in 1994–1998 and have been commercially available since 2005. These technologies use miniaturized and parallelized platforms for sequencing of 1 million to 43 billion short reads (50–400 bases each) per instrument run. Many NGS platforms differ in engineering configurations and sequencing chemistry. They share the technical paradigm of massive parallel sequencing via spatially separated, clonally amplified DNA templates or single DNA molecules in a flow cell. This design is very different from that of Sanger sequencing, also known as capillary sequencing or first-generation sequencing, that is based on electrophoretic separation of chain-termination products produced in individual sequencing reactions.

## 30.5 Differentiation potential of mesenchymal stromal cells and fibroblasts

One of the criteria formalized by the International Society for Cellular Therapy in 2006 for the characterization of MSCs was their ability to differentiate *in vitro* into osteoblasts, adipocytes, and chondrocytes [22]. This feature, however, cannot be used to distinguish MSCs and fibroblasts, since, on the one hand, there are reports that fibroblasts are unable to undergo mesenchymal differentiation [52,53,60] but, on the other hand, there are studies that show that fibroblasts do possess the ability to undergo *in vitro* mesenchymal differentiation potential [20,62]. In our own experience, the comparison between AT-derived MSCs and two different commercially available fibroblast cell lines showed no substantial differences in their *in vitro* mesenchymal differentiation capacity [19]. As shown in Figure 30.2, MSCs and

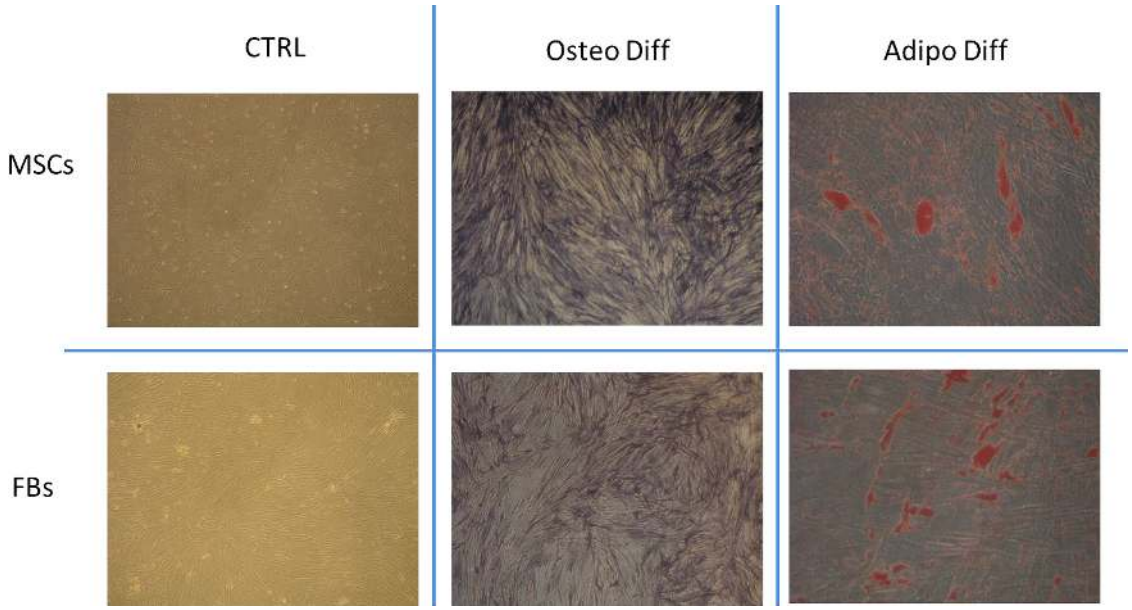

**Figure 30.2** Differentiation potential of MSCs and fibroblasts. Representative photographs of MSCs and fibroblasts assayed for osteogenic and adipogenic differentiation. Left panel: cells grown in control medium. Middle panel: cells cultured in osteogenic medium for 2 weeks were assessed by alkaline phosphatase staining. Right panel: cells cultured in adipogenic medium for 3 weeks were assessed by Oil Red O staining. (See color plate section.)

fibroblasts display comparable capabilities to undergo osteogenic and adipogenic differentiation.

However, to add further complexity to this topic is the discovery that MSC multipotency seems, at least in part, linked to particular MSC subsets. Battula *et al.* sorted two different BM-MSC cell populations by their phenotypic expression of MSCA-$1^+$ $CD56^-$ and MSCA-$1^+$ $CD56^+$ [63]. Interestingly, adipocytes differentiated from MSCs were exclusively derived from the MSCA-$1^+$ $CD56^-$ population, while chondrocytes and pancreatic-like islets were predominantly derived from the MSCA-$1^+$ $CD56^{+/-}$ population. Vaculik *et al.* examined human dermal MSCs using cell surface expression of CD271 and stage-specific embryonic antigen (SSEA) [39]. Adherent dermal cells with increased adipogenic, osteogenic, and chondrogenic potential were enriched in the $CD271^+$ population. The differentiation potential of dermal SSEA-$4^+$ cells, in contrast, appeared to be limited to adipogenesis.

Several aspects of fibroblasts' differentiation potential have also been elucidated. First, it may be related to the age of the cells. Covas *et al.* found that fetal fibroblasts showed a homogeneous capacity to differentiate into adipocytes, chondrocytes and osteocytes, whereas adult foreskin fibroblasts did not differentiate [64]. Contrary to this, another study reported that foreskin fibroblasts exhibited chondrocyte and rare adipocyte and osteocyte differentiation [65].

Hepatocyte differentiation potential of adult human dermal fibroblasts has also been described: in one study, where the *in vitro* and *in vivo* differentiation profile of fibroblasts was comparable to that of mesenchymal-derived hepatocyte-like cells [66].

Another study analyzed the molecular dynamics of differentiation of two closely related stromal cell types, AT-derived MSCs and dermal fibroblasts along adipogenic, osteogenic, and chondrogenic lineages using multiplex RNA-seq technology. They found that undifferentiated donor-matched AT-MSCs and dermal fibroblasts were distinct populations that remained different upon differentiation into adipocytes, osteoblasts, and chondrocytes. The changes in lineage-specific gene expression occurred early in differentiation and persisted over time in both AT-MSCs and dermal fibroblasts. AT-MSCs and dermal fibroblasts exhibited similar dynamics of adipogenic and osteogenic differentiation but different dynamics of chondrogenic differentiation [56].

In conclusion, two facts emerge. First, *in vitro* differentiation along the osteogenic, chondrogenic, and adipogenic lineages is not a useful parameter for distinguishing MSCs from fibroblasts. Second, the evidence for functional differentiation of either MSCs or fibroblasts to cell types outside the mesenchymal lineage is scanty and remains highly controversial.

## 30.6 Immune modulation capability of mesenchymal stromal cells and fibroblasts

The immune system is a very complex cellular and molecular network that requires tight regulation to guarantee a balance between immune surveillance and immune tolerance. Immune modulation by the interaction of a number of cell types and paracrine mechanisms is of great importance. Cell–cell contacts

involved in the immune modulation process include both co-stimulatory and co-inhibitory molecules.

Co-stimulatory molecules include CD80 (B7-1), CD86 (B7-2), CD40, and B7-H4 (B7 homolog 4, also known as V-set domain-containing T-cell activation inhibitor 1). CD80 works in tandem with CD86 to prime T cells.

Co-inhibitory molecules include programmed death-ligand 1 (PD-L1, also known as CD274 or B7 homolog 1). It has been speculated that PD-L1 plays a major role in suppressing the immune system during events such as pregnancy, tissue or organ allografting, and autoimmune diseases. Normally, the immune system reacts to foreign antigens where there is accumulation of the antigen in lymph nodes or spleen, which then triggers a proliferation of antigen-specific $CD8^+$ T cells.

The formation of programmed cell death protein 1 (PD-1) receptor/PD-L1 or B7.1 receptor/PD-L1 ligand complex transmits an inhibitory signal that reduces the proliferation of such $CD8^+$ T cells in the lymph nodes; and supplementary to that, PD-1 is also able to control the accumulation of foreign antigen-specific T cells in the lymph nodes through apoptosis, which is further mediated by a lower regulation of the gene *BCL-2*. B7-H4 is a protein that also belongs to the B7 family of proteins that are expressed on the surface of antigen-presenting cells and interact with ligands such as CD28 on T cells.

In addition, numerous secreted growth factors, cytokines, chemokines, and hormones are also required to promote or inhibit an immune-response. HGF, indoleamine 2,3-dioxygenase (IDO), prostaglandin E2 ($PGE_2$), INF-γ, tumor growth factor-beta (TGF-β), interleukin (IL)-1, -6, and -10, and nitric oxide constitute only a small example of biologically active secreted factors involved in immunological responses.

Immune-modulatory properties have been reported for both fibroblasts and MSCs. Fibroblasts have been shown to interact with the immune system as alternative antigen-presenting cells, either activating or downregulating T cells [67,68] and mediating an indirect antiproliferative effects on lymphocytes [69]. A potent effect of fibroblasts on dendritic cell differentiation has also been observed [70].

MSCs were demonstrated to have pleiotropic immune modulatory activities both *in vitro* and *in vivo*, mediated by complex mechanisms that inhibit the function of different immune cell subpopulations of the innate and adaptive immune systems [71].

In general, the immune modulatory effects of MSCs and fibroblasts are mediated by the mechanisms described earlier; namely, cell–cell contact and paracrine activity.

The immune-regulatory role of MSCs and fibroblasts is widely recognized. Haniffa *et al.* compared the immune-suppressive properties of human BM-MSCs and fibroblasts and found that, although both cell populations were equally effective in suppressing T cell proliferation, MSCs were more effective than fibroblasts at inducing T cell cytokine reprogramming [20]. The authors demonstrated that T cells induced INF-γ-dependent IDO expression in fibroblasts, causing a negative-feedback loop that subsequently inhibited T cell proliferation. A molecular mechanism common to fibroblasts and MSCs has been described [72]. Both MSCs and fibroblasts were able to modulate T cell cytokine secretion on stimulation, leading to a marked type 2 helper T cell (Th2) cytokine signature (IL-4 and IL-10), although MSCs appeared more potent in this respect.

Recently, it was demonstrated that indomethacin, a $PGE_2$ inhibitor, affected the immunosuppressive properties of MSCs, but not fibroblasts, on peripheral blood mononuclear cells (PBMCs). When PBMCs were induced to proliferate using the T cell mitogen phytohemaglutinin, both fibroblasts and MSCs inhibited PBMC proliferation. However, indomethacin significantly impaired the inhibitory effect on PBMC proliferation by BM-MSCs but not by fibroblasts [73]. Therefore, it is possible that fibroblasts inhibit PBMC proliferation through a $PGE_2$-independent mechanism. Wada *et al.* confirmed that both MSCs and fibroblasts induce immune suppression, but by different mechanisms. IFN-γ was the key molecule mediating the immunosuppressive activity of fibroblasts [74]. There remains some discrepancy between these findings and those reported by Haniffa *et al.* [20].

These observations could reflect a difference in behavior of MSCs and fibroblasts regarding the activation of immunosuppressive regulatory T cells (Tregs), which are responsible for inhibiting allogeneic T cell proliferation. It was demonstrated that MSCs induced the activation of Tregs through cell-to-cell contact and secretion of soluble factors such $PGE_2$, TGF-β, IL-10, IDO, and galectin [75–77], whereas fibroblasts did not [78,79]. Finally, regarding co-stimulatory molecules, it has been demonstrated that MSCs lack cell surface expression of CD80, CD86, and CD40 [19,80,81]. Likewise, fibroblasts do not express CD80 or CD86 [19,82], but, contrary to MSCs, they do express CD40 [19,65,83]. CD40 binds its ligand CD40L, also known as CD154, which is transiently expressed on T cells and on nonimmune cells under inflammatory conditions. Many molecular and cellular immunological processes are regulated by CD40 engagement, including the initiation and progression of cellular and humoral adaptive immunity [84]. Therefore, the presence of this receptor on fibroblasts may partially explain their different degree of immunosuppressive activity compared with that of MSCs [85]. Skin fibroblasts from patients with the autoimmune disease systemic sclerosis (or scleroderma) had increased levels of CD40 expression [86]. We hypothesize that the lack of CD40 expression on MSCs may help them establish functional immunological activity and help to distinguish MSCs from fibroblasts.

The differences in immune regulation between MSCs and fibroblasts (Figure 30.3) may reflect their behavior in physiological and pathological processes, including homing, inflammation, and fibrosis, where a tight balance between immune stimulatory and immune suppressive stimuli is required.

In summary, further studies are needed to better elucidate the immune modulatory role of different stromal cells populations. To date, the evidence seems to indicate that MSCs possess an enhanced immune suppressive capacity compared with that of fibroblasts.

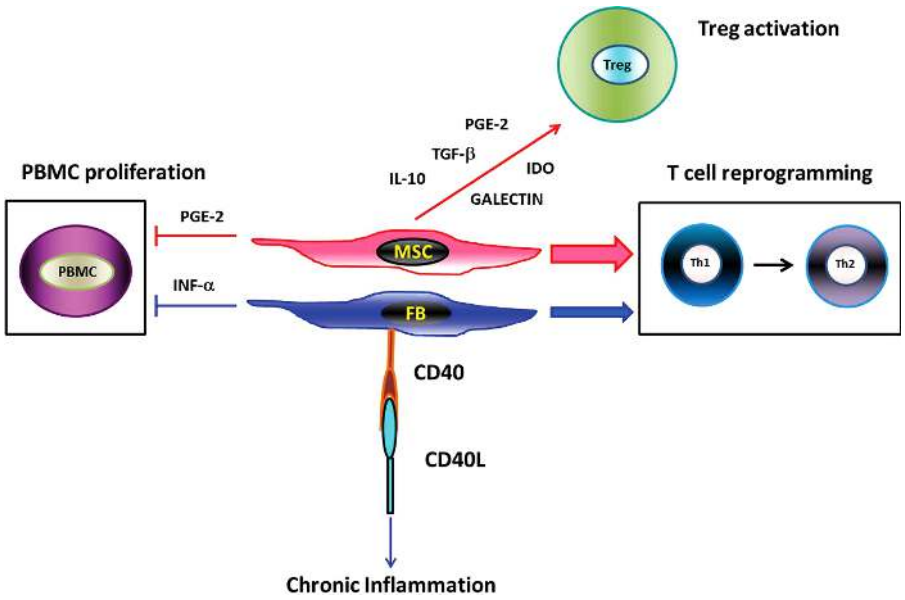

**Figure 30.3** Differences between MSCs and fibroblasts for immune-regulatory properties. Schematic representation of the immune-regulatory properties of MSCs and fibroblasts. Left: MSCs and fibroblasts inhibit PBMC proliferation by distinct mechanisms. Upper: MSCs, but not fibroblasts, induce Treg activation by secreting several factors. Right: MSCs and fibroblasts induce Th cell reprogramming; however, MSCs are twofold more effective than fibroblasts. Lower: fibroblasts, but not MSCs, express the co-stimulatory molecule CD40. CD40–CD40L interaction may lead to chronic inflammation.

## 30.7 Modulation of inflammation by mesenchymal stromal cells and fibroblasts

Strictly related to the immune system, inflammation can be defined as a fundamental defense mechanism aimed at removing harmful stimuli, including damaged cells, irritants, or pathogens, and thus enabling the healing process. Inflammation is a complex process involving sensor and effector cells, expression of surface receptors, and the release of soluble molecules, including cytokines and chemokines. Inflammation has to be tightly regulated in order to achieve a balance between activation and blocking signals. This balance is particularly important, since its dysfunction can lead to the development of chronic inflammation, abnormal pathological tissue remodeling, and autoimmune disorders.

The inflammatory microenvironment includes a complex cell population of both the activators of inflammation comprising macrophages, dendritic cells, and lymphocytes, and the regulating and controlling cells of inflammation comprised of resident fibroblasts, vascular cells, and MSCs, acting mainly by paracrine activity.

Fibroblasts, besides supplying ECM proteins such as collagens and fibronectin, play a role as initiators, modulators, and maintainers of inflammation [87]. During inflammation, fibroblasts are activated and display a proinflammatory phenotype secreting chemokines and cytokines, and acquiring migratory and contractile properties [88–90]. Molecules secreted by activated fibroblasts, such as C–X–C motif chemokine ligand (CXCL)1, CXCL5, IL-8, CXCL12, chemokine (C–C motif) ligand 21, and IL-15, promote the recruitment, survival, and activation of lymphocytes and macrophages. These cells, in turn, augment the activation of fibroblasts, triggering a loop that leads to the enhancement of inflammation. Thus, inhibiting fibroblast activation could reduce inflammation. The presence of proinflammatory signals predisposes to the development of chronic inflammation, which is a pathological condition underlying a wide range of diseases, including myocardial fibrosis after acute myocardial infarction and autoimmune diseases such as rheumatoid arthritis, psoriasis, and inflammatory bowel disease. Consistent reports indicate a preeminent role for fibroblasts in sustaining chronic inflammatory diseases [91,92]. Blockade of the CD40 receptor specifically expressed on fibroblasts, but not MSCs, has been proposed as a potential therapeutic approach to treat chronic inflammation [93].

In contrast to fibroblasts, MSCs have been widely reported to possess anti-inflammatory characteristics [94–96]. It has been demonstrated that, after homing to a site of inflammation (see Chapters 22 and 23), MSCs interact with immune cells, promoting anti-inflammatory pathways [97]. Studies have, in part, elucidated how MSCs exert their anti-inflammatory activity. It has been shown that MSCs are activated by proinflammatory stimuli such as tumor necrosis factor α (TNF-α), secrete $PGE_2$, and upregulate TNF-α-induced protein-6 (TSG-6). $PGE_2$ drives resident macrophages with an M1 proinflammatory phenotype toward an M2 anti-inflammatory phenotype. TSG-6 interacts with CD44 expressed on resident macrophages, decreases toll-like receptor (TLR)2/nuclear factor κ light chain-enhancer of activated B cell signaling, which in turn leads to a reduction of secreted mediators of inflammation [98]. Other mechanisms involving MSCs in controlling macrophage activation have been described [99]: MSCs suppress the generation of mitochondrial reactive oxygen species and inhibit the NOD-like receptor family, pyrin domain containing 3 (NLRP3) inflammasome activation in immune cells by increasing secretion of stanniocalcin-1 in response to activated macrophages [99]. The NLRP3

gene encodes the protein NACHT, LRR, and PYD domains-containing protein (NALP)3 or cryopyrin. This protein interacts with the apoptosis-associated speck-like protein PYCARD/ASC, which contains a caspase recruitment domain, and is a member of the NALP3 inflammasome complex.

An inflammasome is a multiprotein oligomer consisting of caspase 1, PYCARD, NALP, and sometimes caspase 5 (also known as caspase 11 or ICH-3). It is expressed in myeloid cells and is a component of the innate immune system. The exact composition of an inflammasome depends on the activator that initiates inflammasome assembly; for example, dsRNA will trigger one inflammasome composition, whereas asbestos will assemble a different variant. The inflammasome promotes the maturation of the inflammatory cytokines IL-1β and IL-18. The inflammasome is responsible for activation of inflammatory processes and has been shown to induce cell pyroptosis, a process of programmed cell death distinct from apoptosis. During an infection, one of the first forms of defense employed by the innate immune response is a group of pattern recognition receptors encoded in the germline to recognize molecular patterns expressed by invading pathogens. These may either be on the membrane surface (e.g., TLRs and C-type lectin receptors) or inside the cytoplasm (e.g., Nod-like receptors (NLRs) and RIG-I-like receptors). In 2002, a subset of NLRs named NLRP1 were found able to assemble and oligomerize into a common structure that collectively activated the caspase-1 cascade, thereby leading to the production of proinflammatory cytokines, especially IL-1β and IL-18. This NLRP1 multimolecular complex was called the inflammasome and spurred much interest in the following years. Since then, several other inflammasomes have been discovered, two of which are also NLR subsets: NLRP3 and NLRC4. Analogous to the apoptosome, which activates apoptotic cascades, the inflammasome activates an inflammatory cascade. Once active, the inflammasome binds to pro-caspase-1 (the precursor molecule of caspase-1), either homotypically via its own caspase activation and recruitment domain (CARD) or via the CARD of the adaptor protein ASC, which it binds to during inflammasome formation. In its full form, the inflammasome appositions together many p45 pro-caspase-1 molecules, inducing their autocatalytic cleavage into p20 and p10 subunits. Caspase-1 then assembles into its active form consisting of two heterodimers with a p20 and p10 subunit each. Once active, it can then carry out a variety of processes in response to the initial inflammatory signal. These include the proteolytic cleavage of pro-IL-1β at Asp116 into IL1-β, cleavage of pro-IL-18 into IL-18 to induce IFN-γ secretion and natural killer cell activation, cleavage and inactivation of IL-33, DNA fragmentation and cell pore formation, inhibition of glycolytic enzymes, activation of lipid biosynthesis, and secretion of tissue-repair mediators such as pro-IL-1α.

In summary, a review of the literature regarding the role of fibroblasts and MSCs in controlling inflammation shows them to have opposite effects. However, few studies have compared the anti-inflammatory activity of these cells side by side. One of these studies, recently published by our group, analyzed the anti-inflammatory capacity of MSCs derived from AT in comparison with two commercially available fibroblast cell lines [19]. We demonstrated that MSCs, but not dermal fibroblasts, were able to reduce the expression of adhesion molecules and inhibit the levels of inflammatory chemokines RANTES and MCP-1 secreted by the U937 monocytic cell line. Furthermore, we observed that, after priming of both types of stromal cells with TNF-α to mimic the presence of inflammatory stimuli, MSCs increased their inhibitory effect on U937, while fibroblasts increased their proinflammatory characteristics, causing significant augmented release of RANTES and MCP-1 by U937. Other researchers have confirmed our results, using pancreatic islets exposed to inflammatory injury. They demonstrated that MSCs, but not fibroblasts, exerted protective effects. In fact, human islets co-cultured with MSCs and subsequently exposed to a cocktail of proinflammatory cytokines maintained their functionality, as evidenced by glucose-stimulated insulin secretion. This protective effect was not observed in co-cultures with fibroblasts, indicating that the preservation of human islet glucose-stimulated insulin secretion is MSC-dependent [100].

Further data supporting the anti-inflammatory activity of MSCs compared with fibroblasts have been reported by Chen *et al.* [101]. They studied the difference between fibroblasts and MSCs in stimulating the regenerative process and in controlling inflammation in an *in vivo* wound healing model. They examined the differences between MSCs and dermal fibroblasts in releasing paracrine factors. Analysis of MSC- and fibroblast-conditioned media (CM) indicated that the former held greater amounts of cytokines and chemokines involved in wound healing process, such as VEGF, insulin-like growth factor-1, EGF, keratinocyte growth factor, angiopoietin-1 (Ang-1), stromal cell-derived factor-1, macrophage inflammatory protein-1α and -1β, and erythropoietin. In addition, MSC-CM significantly enhanced the migration of macrophages and proliferation and migration of keratinocytes and endothelial cells compared with fibroblast-CM. Moreover, *in vivo* treatment with MSC-CM accelerated wound healing when compared with the administration of fibroblast-CM [101].

Finally, it has been suggested that MSCs control inflammation because they were found to possess an antimicrobial effect whereas fibroblasts did not [102] (and see Chapter 55). In this study, MSCs secreted LL-37, a peptide with a wide array of antimicrobial properties. Conversely, fibroblasts secreted very low levels of LL-37 [102]. The authors speculated that this feature of MSCs might enable them to prevent excess or overexuberant inflammation caused by the presence of bacterial products that occur during wound healing. We wish to emphasize that the processes of scar formation and fibrosis are both linked to inflammation, but are differently regulated by MSCs and fibroblasts. Fibroblasts may negatively regulate these phenomena, probably by depositing excessive amounts of ECM. MSCs, on the other hand, seem to have an antifibrotic activity, probably mediated by anti-inflammatory mechanisms that lead to a

reduction of scar formation following normal wound healing [103] (and see Chapters 58 and 59).

In conclusion, these data demonstrate a clear functional difference between fibroblasts and MSCs as regulators of inflammation. While the former behave as proinflammatory cells, the latter act as anti-inflammatory cells. Although considerable work needs to be done to better understand the mechanisms and molecules involved in such differences, both fibroblasts and MSCs can be considered as sentinel cells in the inflammatory process. Fibroblasts are able to initiate and sustain inflammation when necessary. In contrast, MSCs adopt an anti-inflammatory phenotype and rescue tissues from an excessive inflammatory response. Thus, fibroblasts and MSCs participate synergistically in the inflammatory process to produce a fine balance between pro- and anti-inflammatory stimuli.

## 30.8 Angiogenic properties of mesenchymal stromal cells and fibroblasts

Angiogenesis is the process of new blood vessel formation. Adult angiogenesis usually occurs in the process of tissue regeneration, such as wound healing, and in many pathological situations, such as diabetes mellitus and cancer. Owing to its importance in many pathological processes, much effort has been made to understand the mechanism of neovasculogenesis and, in particular, to evaluate how endothelial cells respond to the angiogenic or anti-angiogenic microenvironment generated during wound healing or by a malignant neoplasm [104].

The interaction of endothelial cells with the microenvironment plays a pivotal role in determining the initiation of angiogenesis, control of progression and maturation of the new vessels. For this reason stromal cells, including fibroblasts and MSCs, and cells of the immune system including macrophages, neutrophils and lymphocytes, have been widely studied in the regulation of endothelial cell activity. In this Chapter we will focus on the involvement of fibroblasts and MSCs in angiogenesis. We will present some comparative studies, showing differences between MSCs and fibroblasts in their contribution to angiogenesis.

There are controversial data in the literature regarding the contribution of fibroblasts to the angiogenic process. Some studies describe a pro-angiogenic effect, while others report an anti-angiogenic effect of fibroblasts [105–108]. Additionally, different populations of fibroblasts have differences in their angiogenic potential [105,109]. In general terms, fibroblasts are able to modulate angiogenesis through a paracrine mechanism and ECM remodeling. Fibroblasts can secrete pro-angiogenic molecules such as VEGF, TGF-β, platelet-derived growth factor, and Ang-1. In addition, fibroblasts produce ECM proteins such as collagens, fibronectin, laminin, and also MMPs, as well as the counteracting tissue inhibitors of metalloproteinases (TIMPs). MMPs have been shown to both enhance and inhibit angiogenesis, including modulation of endothelial cell proliferation, adhesion, and survival, as well as governing tube morphogenesis and regression. ECM remodeling ultimately allows endothelial cell migration, sprouting, and new vessel formation. One study showing a high angiogenic potential of supernatants from fibroblast cultures with an overabundance of proteins associated with ECM constituents [110]. Fibroblasts exert their pro-angiogenic properties by secreting TIMP-1 [111]. Fibroblast-derived matrix proteins are essential for endothelial cell lumen formation as the angiogenic cocktail of Ang-1, angiogenin, HGF, TGF-β, and TNF-α alone failed to form lumens [112].

The pro-angiogenic potential of MSCs has been explored extensively [113–116]. Although a transdifferentiation mechanism was initially proposed as a mechanism by which MSCs mediated angiogenesis, accumulating evidence suggests that MSCs promote angiogenesis by secreting a number of angiogenic factors as well as proteins that regulate endothelial cell motility [117–120]. Additionally, a role has also been ascribed to MSC-derived extracellular vesicles in the *in vitro* and *in vivo* promotion of angiogenesis [121,122].

MSCs also directly interact with endothelial cells to increase tubule numbers, vascular stabilization, and complexity. MSCs are capable of aligning with vessel structure and efficiently stabilize nascent blood vessels *in vivo* by functioning as perivascular precursor cells [123,124]. MSCs are pericytes – they are present in the endothelial wall of all vascularized organs and tissues. Not all pericytes, however, are MSCs: all blood vessels have an endothelium and arteries; arterioles and larger veins have smooth muscle cells in their vessel wall.

Han *et al.* compared the angiogenic activity of MSCs and fibroblasts [125]. They demonstrated that *in vitro* levels of basic fibroblast growth factor were higher in MSCs than in fibroblasts. An *in vivo* model of angiogenesis demonstrated that MSCs induced a significantly higher number of microvessels than fibroblasts did. Similar results were obtained using an excisional wound splinting model in mice: MSCs, but not fibroblasts, significantly enhanced wound healing in both normal and diabetic mice by promoting re-epithelialization, cell infiltration, and angiogenesis. MSC treatment resulted in significantly higher amounts of Ang-1 and VEGF and enhanced capillary density [126].

MSCs, but not fibroblasts, are able to home to perivascular sites in ischemic tissue and promote vascular regeneration. Intriguingly, MSCs aligned along the vessel walls, released pro-angiogenic factors, and augmented microhemodynamics. This led to a reduction of arteriolar vascular resistance and an increase in functional capillary density, thus rescuing the tissue from critical ischemia [127].

In an immunodeficient rat femur nonunion model, human multipotent adipose-derived stromal cells accelerated fracture healing, whereas fibroblasts were not able to do so. In the MSC-treated group this effect was related, at least in part, to a greater capillary density and to an incremental increase in blood flow compared with the fibroblast-treated group. Furthermore,

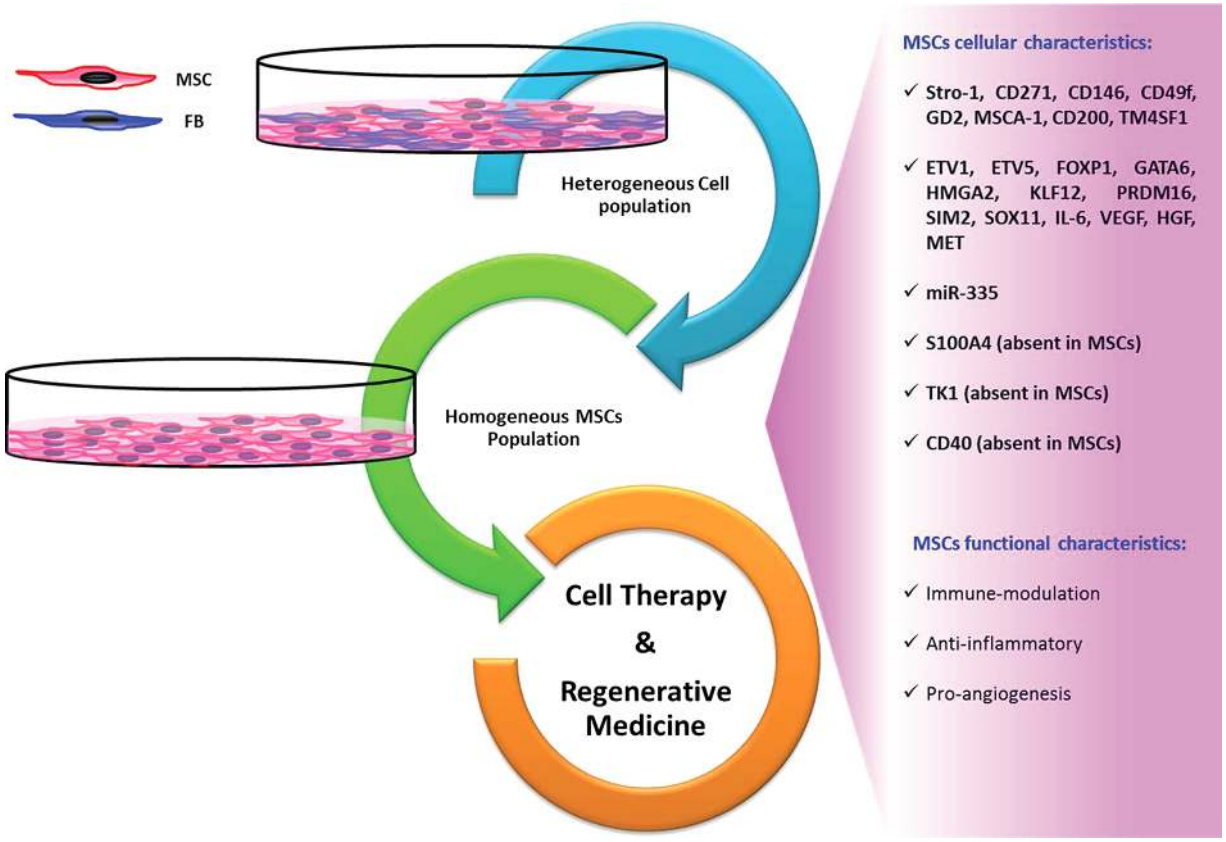

**Figure 30.4** Different molecular markers (genes and miRNAs) as well as surface antigens may be valuable for distinguishing MSCs from fibroblasts.

MSCs, but not fibroblasts, upregulated the expression of the rat pro-angiogenic factors bone morphogenetic protein-2, VEGF, and Ang-1 [128].

In summary, MSCs produce higher levels of pro-angiogenic cytokines than fibroblasts do, as assessed by both mRNA expression and protein [19,125,126]. Extracellular vesicles secreted by MSCs play an important role in angiogenesis promotion [129].

Additionally, MSCs, but not fibroblasts, preferentially home to sites of inflammation [130,131], although a pericytic behavior for fibroblasts has been reported; however, there was a qualitative reduction in vessel coverage by fibroblasts compared with MSCs in this study [132]. Thus, increased angiogenic potential is another parameter for distinguishing MSCs from fibroblasts.

## 30.9 Conclusions

In conclusion, MSCs can be distinguished from fibroblasts by cell surface markers, miRNA activity, immunomodulatory and anti-inflammatory capabilities, and pro-angiogenic activity, but not by the ability to differentiate to osteoblasts, chondrocytes, and adipocytes *in vitro*. These differences are summarized in Figure 30.4.

## 31.1 Introduction

Mesenchymal stem/stromal cells (MSCs) are readily isolated from many tissues and capable of extensive *ex vivo* expansion [1,2]. MSCs can typically be differentiated into cells of the mesodermal lineage, while some investigators have also reported MSC differentiation into cells of ectodermal lineage [3,4]. MSCs have low immunogenicity and can be transplanted across major histocompatibility complex (MHC) barriers, making them candidates for both patient-specific and "off-the-shelf" tissue regeneration therapies [5]. Administration of MSCs is associated with very little toxicity, perhaps in part owing to their anti-inflammatory and immunomodulatory properties [6,7]. Understanding the effects of the age, quality, and quantity of *ex vivo* expanded MSCs is of relevance to their potential future widespread clinic use [6].

The doses of MSC required for human transplantations can be as high as 6 billion cells. Potential targets for their use include modulation of organ transplant rejection (see Chapter 56), autoimmune disease (see Chapter 54), regeneration of bone and cartilage (Chapter 47), repair of cardiac muscle (Chapter 45), inflammatory bowel disease (Chapter 50), and neurological disorders (Chapters 48 and 49) [6,8,9]. However, as people age, bone marrow MSCs *in vivo* decline in quantity and quality [10]. MSCs harvested from adult bone marrow comprise only around 0.001–0.01% of total bone marrow mononuclear cells and proliferate only for a short duration [11]. This decline is disadvantageous in the elderly, who are the population most in need of tissue repair therapies. There is thus a major unmet

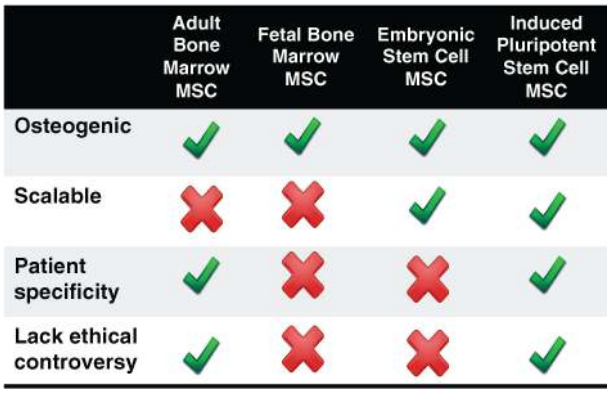

**Figure 31.1** Summary of the positive and negative aspects of different sources of MSCs for future regenerative medicine applications.

requirement for either a technology to improve the current properties of adult MSCs or to develop renewable, superior sources of MSCs.

MSC have been isolated from almost every organ in the mouse and human [1,12,13] with usually minor "organ-specific" or "niche" differences reported [14–19]. For example, bone marrow MSCs are excellent at forming bone, cartilage, and adipose tissue *in vitro* but have a short-term *ex vivo* proliferative capacity, whereas MSCs from term placenta are poor at adipose differentiation *in vitro* but have superior long-term proliferation [18]. Thus, MSCs from different organs may be suited for different clinical purposes, and this must be clearly elucidated prior to their clinical use [6,20].

## 31.2 Mesenchymal stem/stromal cells as candidates for cellular therapy

There is a major unmet need for a robust source of osteogenic stem cells that could be patient specific or, if derived from an unrelated MHC-unmatched donor, used as an "off the shelf" cellular therapy for nonuniting bone fractures (see Chapter 47). This has instigated the search for a source of stem or progenitor cells that could be used in conjunction with synthetic bone graft materials as a treatment to optimize fracture healing [21] (Figure 31.1).

## 31.3 Mesenchymal stem/stromal cells

MSCs are multipotent cells with the ability to differentiate into cells of the mesenchymal lineage [11,22], rendering them a potentially ideal cell source for use in a range of clinical applications, including bone repair [23,24]. MSCs were originally described as originating from bone marrow [25], but they have subsequently been isolated from adipose tissue [26], umbilical cord blood [27], peripheral blood [28], skeletal muscle [29], placenta [18], dental tissue [30], fetal tissue [31], and synovial fluid [32]. Owing to the tissue distribution of MSCs and variation in isolation methods, MSCs derived from the primary tissue result in a heterogeneous population of cells, leading to inconsistencies in the characteristics of MSCs with no specific cell surface marker to unequivocally identify them.

For these reasons the International Society for Cellular Therapy (ISCT) proposed minimal criteria for the classification of adult bone marrow MSCs [33,34]. These criteria were (1) MSCs must display a fibroblast-like morphology, (2) be plastic-adherent *in vitro*, (3) be able to undergo *in vitro* mesodermal differentiation into osteocytes, adipocytes, and chondrocytes, and (4) must express a panel of markers characteristic of, but not unique to, MSCs, including CD105, CD73, and CD90, as well as lacking expression of hematopoietic and endothelial markers such as CD45, CD11b, and CD31 [33,34].

This area took another significant step forward with the publication in 2013 of a joint statement from the International Federation for Adipose Therapeutics and Science and the ISCT on stromal cells from the adipose tissue-derived stromal vascular fraction and culture-expanded adipose tissue-derived stromal/stem cells (see Chapter 1).

The centrifuged but uncultured stromal vascular fraction was identified as being $CD45^-$, $CD235a^-$ (glycophorin A), $CD31^-$ (platelet endothelial cell adhesion molecule), and $CD34^+$, while cell surface positivity for CD13 (alanine aminopeptidase), CD73, CD90, and CD105 were best used in conjunction with CD45, CD235a, and CD31.

*Ex vivo*-expanded adipose tissue-derived stromal/stem cells retain cell surface markers expressed by other MSCs, including CD44 (the hyaluronic acid receptor), CD73, CD90, and CD105 and are also negative for CD45 and CD31, but can be distinguished from bone-marrow-derived MSCs by being $CD36^+$ (fatty acid translocase, also known as glycoprotein IIIb) and $CD106^-$ (vascular cell-adhesion molecule 1).

## 31.4 Adult bone-marrow-derived mesenchymal stem/stromal cells

Adult bone marrow-derived MSCs have been used clinically in the treatment of fractures [23]. However, they are limited by their rarity, the associated invasive harvesting technique required and their finite proliferative capacity in *ex vivo* expansion cultures, which is a necessary for obtaining enough cells for clinical translation [35].

## 31.5 Fetal tissue-derived mesenchymal stem/stromal cells

Another potential source of MSCs for bone repair is fetal bone marrow tissue [2,31]. These cells have been shown to possess ontological advantages over MSCs from adult tissues, with fetal bone-marrow-derived MSCs possessing more primitive

characteristics, such as faster proliferation and higher stromal precursor antigen-1 expression, indicative of colony forming and differentiative capacity [31]. Fetal bone-marrow-derived MSCs have also been shown to produce greater osteogenic matrix deposition *in vitro* and *in vivo* compared with adult bone-marrow-derived MSCs [17,36]. Despite these properties, fetal bone-marrow-derived MSCs are not scalable because of the paucity of source material and their isolation entails tissues being derived from aborted fetuses.

## 31.6 Embryonic stem cells

Human embryonic stem cells (ESCs) hold promise for regenerative medicine and tissue engineering applications. They provide a potentially unlimited source of pluripotent cells capable of undergoing differentiation into any cell type [37,38]. Human ESCs are characterized by the expression of the nuclear transcription factors *Oct4*, Nanog, and *SOX2* and the surface markers Tra-1-60, Tra-1-81, stage-specific embryonic antigen (SSEA)3, and SSEA4. However, undifferentiated ESCs form teratomas *in vivo*. This has hindered their clinical use, although a search of ClinicalTrials.gov in August 2015 listed five clinical trials using them or their differentiated progeny. An alternative approach would be to differentiate ESCs to committed progenitor cells, capable of expansion and differentiation to the desired mature cell type under environmental or niche influences, while negating the possibility of tumor formation *in vivo*.

## 31.7 Embryonic stem-cell-derived mesenchymal stem/stromal cells

To date, a number of studies have differentiated ESCs into MSCs using one or more of four methods. These are (1) immortalization, (2) co-culture with mouse MSCs, (3) epitope selection, or (4) physical selection [39–43]. However, these methods are not ideal for clinical translation, owing to the requirement of genetic modification, the use of xenogeneic tissues (mouse feeder cell layer), low throughput, labor intensity, or multiple culture steps.

A standard method of differentiating ESCs into MSCs involves an intermediate stage using embryoid body (EB) formation, an *in vitro* replication of early embryonic development [44], followed by physical selection of the cell type of interest. Undifferentiated ESCs are cultured as EBs for 10 days, at which point the cells are transferred to an extracellular-matrix-coated tissue culture plate. After further culture the outgrowth cells are physically selected and cultured in MSC growth medium [44,45]. The resulting cells expressed standard MSC markers, lacked expression of hematopoietic markers, and displayed greater *in vitro* and *in vivo* osteogenicity than that of adult bone-marrow-derived MSCs [44]. Unfortunately, a heterogeneous population of cells results from EB differentiation, rendering this physical selection method undesirable.

More recently, methods have been developed that provide feeder-free, sorting-free, and EB-free alternatives [37,46]. For example, Boyd *et al*. developed a method for differentiating human ESCs into a monolayer by culturing them in a commercial endothelial growth medium [37]. After 30–40 days the cells had differentiated into an epithelial monolayer, and with subsequent passaging under MSC culture conditions the cells further differentiated into MSCs. The resulting cells showed the characteristic MSC surface phenotype and displayed *in vitro* osteogenic and chondrogenic, but not adipogenic, differentiation.

Owing to the change in cell morphology it was hypothesized that the cells were undergoing epithelial-to-mesenchymal transition (EMT). However, the classic E-cadherin to N-cadherin switching mechanism, observed with definitive EMT [47], was not observed, as E-cadherin was present at all stages of differentiation. Although other mesodermal genes, such as *Gata4*, *Runx1*, and *BMP4*, were induced during the differentiation process, an increase in N-cadherin was not examined. However, this technique is scalable, uses defined medium to induce ESC to MSC differentiation, and avoids clinically untranslatable methods of co-culture, physical selection, and epitope selection. It is a very low throughput and time-consuming process, which limits its clinical applicability.

## 31.8 Induced pluripotent stem cells

In 2006, Yamanaka's group in Japan discovered that normal murine adult cells could be reprogrammed in the laboratory and converted into pluripotent ESC-like cells capable of unlimited proliferation and differentiation [48]. This was done by transducing terminally differentiated adult somatic cells such as fibroblasts with the four genes *Oct3/4*, *SOX2*, *Klf4* and *c-Myc*. This revolutionized the field of cell and developmental biology, with significant implications for regenerative medicine and tissue engineering.

In 2007, Thomson and colleagues demonstrated reprogramming of somatic cells into induced pluripotent stem cells (iPSCs) by transducing adult cells with a different quartet of four reprogramming factors: *Oct4*, *SOX2*, *Nanog*, and *LIN28* [49]. The iPSCs were morphologically similar to ESCs, were karyotypically normal, expressed telomerase activity, indicating their indefinite proliferative ability, and expressed cell surface markers and proteins characteristic of human ESCs: *SSEA3*, *SSEA4*, *Tra-1-60*, *Tra-1-80*, *Oct4*, *SOX2*, and *Nanog*. Like ESCs, these iPSCs had the capacity to differentiate into cells of all three primary germ layers in a teratoma assay [49].

Initially, iPSCs were derived using viral transduction reprogramming technology, which is clinically untranslatable [48–50]. However, with rapid advances in reprogramming technology, iPSC lines have been generated using episomal (nonviral) vectors, chemicals, and soluble proteins, which are more suitable for clinical translation [51].

The generation of patient-specific iPSCs obviates the need to harvest tissues enmeshed in ethical or controversial issues, such as embryonic or fetal sources. The starting material can potentially be any tissue in the adult body. iPSCs would be a scalable source of patient-specific stem cells, rendering them an ideal future source to exploit for tissue repair applications.

## 31.9 Small-molecule methods for differentiating pluripotent stem cells into mesenchymal stem/stromal cells

Watabe *et al.* developed a method to differentiate human ESCs into an epithelial monolayer using the small-molecule inhibitor SB431542 [52]. Recently, it has been established that Activin/Nodal signaling can block differentiation of ESCs, suggesting that members of the transforming growth factor-β (TGF-β) family are involved in cell fate decisions of ESCs and in the maintenance of pluripotency (Figure 31.2) [55].

Nodal acts by binding heteromeric complexes between type I (ALK4 and -7) and type II (ActRIIB) Activin receptors, which in turn act through the Smad2/Smad3 signaling pathway (Table 31.1). Nodal and Activin share type I and II receptors (ALK4, ActRIIB) and have the same Smad signaling pathway (Smad2/Smad3) [56,57]. Thus, a competitive inhibitor of the ATP binding site of ALK4/5/7 was used to induce differentiation

**Table 31.1** Signaling pathway of Activin and selected members of the TGF-β superfamily blocked by SB431542.

| Ligand | Receptor | | Smad Pathway |
|---|---|---|---|
| | Type II | Type I | |
| Activin A | ActRII | ALK4 (ActRIB) | Smad2 |
| Activin B | ActRIIB | ALK7 | Smad3 |
| Inhibin A | ActRII | ALK7 | Smad3 |
| Inhibin B | ActRIIB | ALK7 | Smad3 |

BMP: bone morphogenetic protein; ActR: Activin receptor kinase; ALK: activin-like kinase; ATP: adenosine triphosphate.

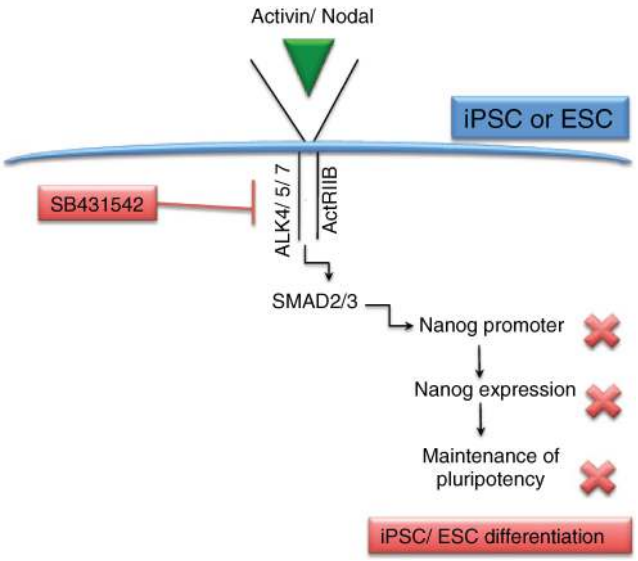

**Figure 31.2** Overview of the antagonism of Activin/Nodal-activated signaling pathways by SB431542. Cascades of downstream targets in the Activin/Nodal signaling pathway are shown. The inhibitory effects of the small-molecule inhibitor SB431542 are also indicated. Binding of heteromeric complexes between type I (ALK4/5/7) and type II (ActRIIB) Activin receptor is activated by ligand binding and signals through the Smad2/Smad3 pathway. The small-molecule inhibitor SB431542 acts as a competitive inhibitor of the ATP-binding site of ALK4/5/7 and is known to have the effect of inducing differentiation of human ESCs. *Source*: adapted from Harrison 2005 [53] and Vallier 2009 [54].

of human ESCs [55,58]. The application of the small molecule inhibitor SB431542 was shown to promote differentiation by inhibiting Nanog promoter activity and thus downregulating other genes responsible for maintaining pluripotency [53,58,59].

SB431542 has also been used in conjunction with the standard EB method to enhance differentiation of human ESCs, applying it to the outgrowth cells from the center of the attached EB [60]. The resulting cells were shown to upregulate genes associated with myogenic development and function and showed contraction ability *in vivo*. The cells also expressed markers characteristic of MSCs with mesodermal differentiation ability. Despite this advance, the methodology utilized still involves physical selection and the formation of the intermediate EB structure, again limiting its clinical applicability.

## 31.10 Derivation of induced pluripotent stem cell–mesenchymal stem/stromal cells through a novel transforming growth factor-β inhibitor method

As previously outlined, a sorting-free, EB-free monolayer method has been developed to differentiate ESCs into an epithelial monolayer and further into MSCs [37]. This is a desirable method as it avoids clinically untranslatable issues of co-culture

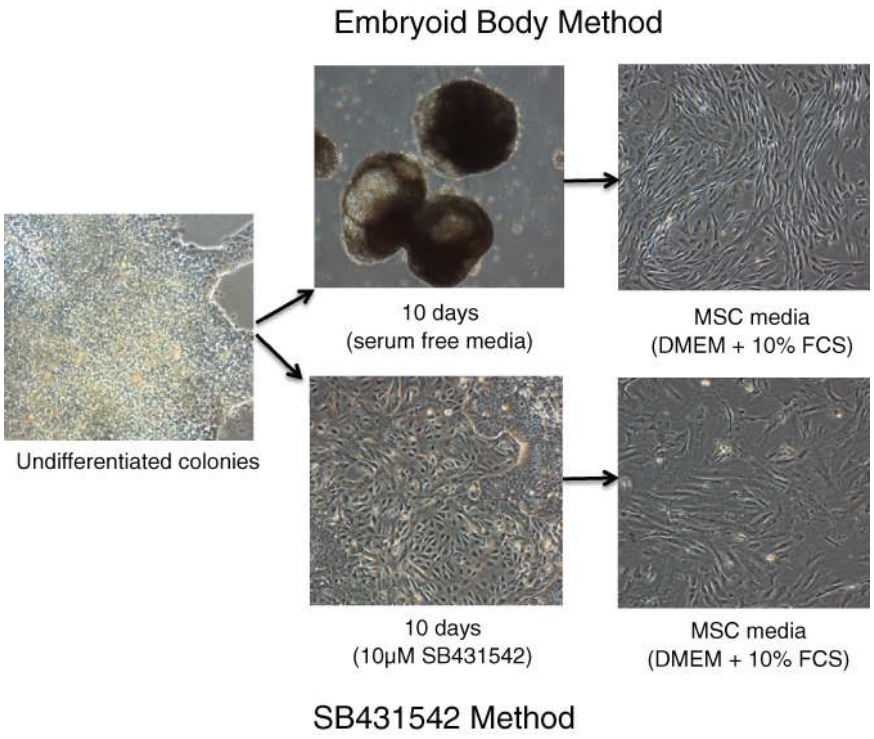

**Figure 31.3** Experimental outline for differentiating iPSCs to MSCs. To differentiate iPSCs to MSCs two methods were utilized. The first was an EB method, which involves culturing undifferentiated iPSC colonies (upper panel) in suspension for 10 days in noncoated dishes until EBs develop (upper left). The EBs are then transferred to a standard tissue culture flask in MSC medium consisting of Dulbecco's modified Eagle medium (DMEM) plus 10% fetal calf serum (FCS). After adhering to the plastic, the differentiated MSC-like cells grow out from the EB and are further cultured in MSC medium (upper right). The second method involved adding a small molecule SB431542, which is an inhibitor of the TGF-β pathway, each day for 10 days to the iPSCs (lower panel). The resulting cells display an epithelial-like morphology (lower left) and when subsequently cultured in MSC medium the cells differentiate into cells with a fibroblast-like morphology (lower right). (See color plate section.)

and physical and epitope selection, but does involve a prolonged differentiation period.

Our laboratory developed a novel method combining the methods of Watabe *et al.* [52] and Boyd *et al.* [37] using the SB431542 inhibitor. This procedure has been shown to induce differentiation of pluripotent stem cells into a uniform epithelial monolayer in only 10 days [61]. Subsequent culture in MSC medium resulted in fibroblast-like cells that displayed MSC markers, lacked pluripotency markers, and were capable of undergoing mesodermal differentiation. In a direct comparison we found that this method was more rapid and less likely to produce non-mesodermal cells than the standard EB method (Figure 31.3), even though similar MSC-like cells were produced.

Through analyzing the morphological changes occurring during the differentiation of MSCs from iPSCs and ESCs using the inhibitor method, it was evident that the resulting MSC-like cells formed a homogeneous monolayer. This finding enhances the clinical amenability of this method for iPSC–MSC derivation, as it negates the need for the physical selection of desired cell types, which is a requirement of the standard EB method and which was used as a comparison method in this study. The application of the TGF-β pathway inhibitor, SB431542, blocked maintenance of pluripotency by preventing activation of the Smad2/Smad3 signaling pathway and subsequent Nanog promoter activity. This resulted in inhibition of pluripotency, inducing differentiation of iPSCs through an EMT-like process. iPSCs and ESCs differentiated into homogeneous monolayers of epithelial-like cells expressing E-cadherin, which when cultured further in fetal MSC medium differentiated into MSC-like cells with a decrease in E-cadherin but an increase in N-cadherin. The observed E-cadherin to N-cadherin expression switching has been documented in definitive EMT [47]. This mechanism was supported by the fact that, during the course of our initial study, two independent studies found that a reverse mechanism, involving mesenchymal-to-epithelial-like transition is, indeed, crucial in the initiation phase of the reprogramming of fibroblasts to iPSCs [62,63] (Figure 31.4).

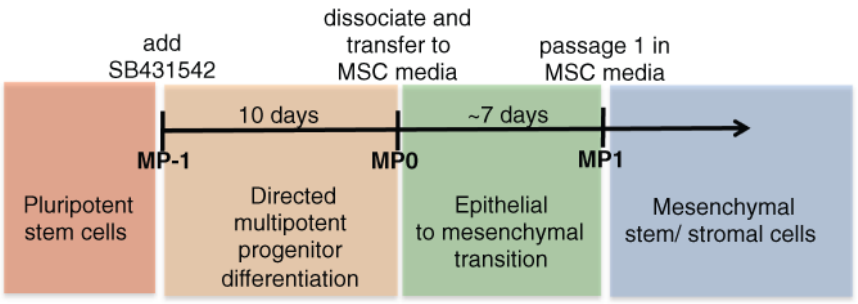

**Figure 31.4** A timeline of the proposed EMT occurring during the differentiation of pluripotent stem cells into MSCs. The differently shaded areas represent discrete steps of differentiation during SB431542 treatment and differentiation into MSCs. MP: mesenchymal passage.

Thus, MSC-like cells were derived from iPSCs using a sorting-free, EB-free monolayer method, circumventing the use of clinically untranslatable methods such as co-culture, physical selection, epitope selection, and viral transduction. Furthermore, the derivation required a rapid 10-day incubation period with SB431542 before differentiation was induced, unlike other methods requiring 40 days incubation [37]. We therefore believe that this method could be employed for the large-scale manufacturing of pluripotent stem-cell-derived MSCs, free of ethical concerns, for clinical use.

## 31.11 Mesenchymal characterization of induced pluripotent stem cell–mesenchymal stem/stromal cells derived through the inhibitor method

The various sources of MSCs used in this study were subjected to identical culture conditions in the same laboratory to control for the differences that occur when samples are processed in different laboratories. The fetal bone-marrow-derived MSCs, iPSC–MSC-derived MSCs (inhibitor and EB), and, where appropriate, ESC-derived MSCs (by both the inhibitor and EB methods) were fully characterized in accordance with the criteria of the ISCT for the classification of MSCs [33]. They were all found to be adherent fibroblast-like cells, possessing mesodermal differentiative capacity under permissive conditions, expressing various MSC markers and adhesion molecules, and lacking hematopoietic and endothelial markers.

The iPSC–MSCs derived through the novel inhibitor method expressed an immunophenotype similar to that of fetal bone-marrow-derived MSCs with positive expression of the markers CD73, CD90, and CD105 used to identify MSCs according to the ISCT criteria [33] at equivalent levels to those of fetal bone-marrow-derived MSCs. The iPSC–MSCs also lacked expression of hematopoietic, macrophage, and monocyte markers (CD11b, CD14, human leukocyte antigen (HLA)-DR, CD45, and CD34), again consistent with the ISCT criteria [33]. Other markers commonly expressed by MSCs were also expressed by iPSC–MSCs (inhibitor), including CD29, CD13, CD44, and CD146. Interestingly, iPSC–MSCs (EB) lacked expression of the fibroblast marker (CD13), which was positively expressed by iPSC–MSCs (inhibitor) and fetal bone-marrow-derived MSCs, suggesting the novel inhibitor method may facilitate the derivation of MSCs more similar to fetal bone-marrow-derived MSCs than to adult MSCs.

Immunofluorescence was used assess the loss of pluripotency markers expressed by iPSCs and ESCs as differentiation proceeded. Fetal bone-marrow-derived MSCs and iPSC–MSCs (inhibitor and EB) lacked expression of pluripotency markers such as *Oct4*, Nanog, Stella, SSEA3, Tra-1-60 and Tra-1-81. For the future therapeutic use of these cells it is critical that they are fully differentiated and do not express markers associated with pluripotency, and thus tumorigenicity. During the differentiation from iPSCs to iPSC–MSCs (inhibitor), cells gained expression of mesodermal markers, including vimentin, confirming that the iPSCs had undergone differentiation into MSCs using the inhibitor method. Interestingly, SSEA4 was expressed by undifferentiated iPSCs and iPSC–MSCs at mesenchymal passage 2 after differentiating through the inhibitor method. Although considered a typically archetypal pluripotent cell marker, SSEA4 expression by adult MSC populations has been documented by others [64].

The *in vitro* mesodermal differentiative capacity of iPSC–MSCs (inhibitor) was found to be comparable to that of fetal bone-marrow-derived MSCs, with both sources of MSCs readily undergoing osteogenic, adipogenic, and chondrogenic differentiation after 28 days' culture in permissive conditions. The ESC–MSCs derived through the novel inhibitor method displayed greater osteogenic differentiation than those derived through the standard EB method, as visualized by von Kossa and Alizarin red S staining. This increase in osteogenic differentiative ability supports the use of this method over the standard EB method for deriving MSCs with superior osteogenic capacity for clinical use for facilitating the healing of bone fractures.

## 31.12 Immune tolerance to induced pluripotent stem cell–mesenchymal stem/stromal cells

Another finding that would render the use of these cells clinically advantageous was the fact that iPSC–MSCs (inhibitor and EB methods) were found to express low levels of HLA-ABC and completely lacked expression of HLA-DR. This pattern of expression is consistent with that of fetal bone-marrow-derived MSCs. This could be indicative of low immunogenicity of iPSC–MSCs *in vivo*, similar to that of fetal bone-marrow-derived MSCs [65], which would be useful for clinical application.

## 31.13 Kinetics of the proliferation of induced pluripotent stem cell–mesenchymal stem/stromal cells

The iPSC–MSCs (inhibitor) and iPSC–MSCs (EB) did not proliferate as rapidly as fetal bone-marrow-derived MSCs. However, their population doubling time indicates their suitability for scale-up, as is required for clinical use. The growth kinetics of fetal bone-marrow-derived MSCs was in agreement with other studies of fetal bone-marrow-derived MSCs, confirming their rapid cumulative population doublings [36]. The growth kinetics of iPSC–MSCs (inhibitor) indicated that the cumulative population doublings were comparable to those of adult MSCs as described in literature [31,36]. The kinetics of proliferation of iPSC–MSCs were found to be comparable to those of ESC-derived MSCs [43]. Thus, the finding that these kinetics were

slower than those of fetal bone-marrow-derived MSCs was not surprising.

## 31.14 Tumorigenic potential of induced pluripotent stem cell–mesenchymal stem/stromal cells

The clinical use of MSCs derived from pluripotent stem cells such as ESCs and iPSCs has been limited by the fact that undifferentiated cells (iPSCs and ESCs) are known to form teratomas *in vivo* [49,66]. Thus, to explore the safety of using these cells in future clinical applications, iPSC–MSCs (inhibitor and EB) were injected intramuscularly into immunosuppressed mice and monitored for tumor formation at the injection site. Three mice were injected per cell type and it was expected that for undifferentiated stem cells one teratoma would form in every two mice injected [49]. We found that two out of the three NOD/SCID mice injected with iPSCs did form teratomas. Hematoxylin and esosin staining showed the presence of cells derived from all three primitive germ layers [49].

Since recent studies have focused attention on identifying and classifying chromosomal aberrations that have the potential to affect the safe use of these cells in future clinical applications [67], chromosomal stability was investigated by karyotyping. All samples tested, including fetal bone-marrow-derived MSCs, iPSC–MSCs (inhibitor), and iPSC–MSCs (EB), were found to be karyotypically normal.

**Table 31.2** MSC and pluripotency markers used to characterize iPSC–MSCs.

| Markers | |
|---|---|
| **Positive** | **Negative** |
| *MSC* | |
| CD73 | CD45 |
| CD90 | CD34 |
| CD105 | CD11b or CD14 |
| CD44 | CD19 or CD79 |
| CD146 | HLA-DR |
| CD29 | CD31 |
| HLA-ABC | |
| *Pluripotency* | |
| *Oct4* | Vimentin |
| *SOX2* | Collagen1 |
| Rex1 | N-cadherin |
| Nanog | |
| Lin28 | |
| CD24 | |
| SSEA3 and 4 | |
| Tra-1-60 or -81 | |
| E-cadherin | |

## 31.15 Critical parameters for future preclinical production of induced pluripotent stem cell–mesenchymal stem/stromal cells

Although pluripotent stem-cell-derived MSCs can be generated easily by a number of methods, deficiencies in the literature make it difficult to assess the efficiency of the differentiation. First, most papers do not compare cell surface markers with those of undifferentiated iPSCs or ESCs, nor with primary MSCs derived from adult tissues. It is important to determine that the cells are indeed differentiating from pluripotent stem cells to MSCs. We found that only CD73 changed expression. CD105 and CD90 are commonly expressed on different pluripotent stem cell lines [68]. Proposed minimal markers to assess mesenchymal, non-mesenchymal, and pluripotent markers are shown in Table 31.2.

Second, the ISCT criteria were often not used to confirm the presence of the four key MSC-defining parameters of plastic adherence, fibroblastic morphology, positivity for characteristic cell surface marker, and negativity for hematopoietic and endothelial markers. However, the ISCT criteria are based on adult bone-marrow-derived MSCs. It is now clear that MSCs from different organs, donors, donor ages, and different culture conditions may have different patterns of marker expression or differentiation potential (see Chapters 1 and 7). For example, we found that iPSC–MSCs and ESC–MSCs derived using the EB method had extremely limited adipogenic capacity, similar to that of human term-placenta-derived MSCs [49].

Third, limited evidence has been provided on pluripotent stem cell markers, *in vivo* tumorgenicity assays, or karyotype stability early and late in culture for pluripotent stem-cell-derived MSCs. We found that a number of lines of both ESC–MSCs and iPSC–MSCs, derived via both the EB and SB431542 method, developed karyotypic abnormalities in long-term culture (passage 3 and above). This is not due to the methods of production but to the inherent nature of pluripotent stem cells in *in vitro* culture conditions. Recently, this method has been used by our collaborators to derive canine iPSC–MSCs for potential uses in veterinary regenerative medicine applications [69]. This could provide critical *in vivo* safety information prior to the clinical use of the differentiated progeny of iPSC–MSCs.

## 31.16 Plasticity of lineage commitment: reprogramming, deprogramming and dedifferentiation

Cells undergoing fate changes do so either by incorporating molecular or functional changes [70]. Primitive MSCs can be

obtained by isolating MSCs from fetal tissue, reprogramming committed cells to pluripotent cells followed by partial differentiation, or partial reprogramming (or dedifferentiation) of a committed MSC to enhance the desired fetal MSC-like phenotype [71]. For example, indirect conversion of a cell type will change its fate to another cell type, bypassing dedifferentiation and reprogramming. During human development, stem cells are destined to differentiate to a committed cell type, such as cardiomyocytes, neurons, or fibroblasts, whereas during reprogramming, a laboratory-induced phenomenon, committed fibroblasts change their cell fate from a differentiated cell type to a pluripotent stem cell.

## 31.17 How to develop "young" mesenchymal stem/stromal cells: going backward to go forward?

The generation of a pluripotent cell type might seem to be the first option for deriving a renewable source of MSCs from an adult source and then differentiating them to a primitive cell type. However, iPSC generation usually involves the complete reprogramming of a fully differentiated cell (e.g., a fibroblast) using retroviral, transposomal, or episomal transfer systems. Now chemical factors alone have enabled the reprogramming of cells to a pluripotent phenotype. Treatment with valproic acid (VPA) allows not only pluripotency gene expression but also drives the cell toward pluripotency [72,73]. VPA treatment of c-kit$^+$ amniotic fluid cells resulted in a cell population that was pluripotent and gave rise to all germ layers upon differentiation [72,73], although it lacked the ability to form teratomas, regarded as the gold standard for pluripotency but favorable for clinical translation.

VPA has histone-deacetylase-inhibiting effects. Histone deacetylases are known to repress pluripotency genes like *Oct4* while inhibiting GSK3b by phosphorylation of Sox and activatation of Wnt signalling [72]. This method, however, involved a long culture period and is more time consuming than other methods for deriving MSCs from primitive stem cells.

## 31.18 Small-molecules inhibitors for generating "young" stem cells

In addition to the use of transgenic systems, cells have been reprogrammed to pluripotency by many small molecules or chemical inhibitors. These small molecules are safer than viral transduction methods as no genetic information is integrated into the cell genome. While transforming a cell type to pluripotency is termed reprogramming, the transformation of a more mature cell type to a less mature cell type is termed de-differentiation. Complete reprogramming has been achieved in MSCs by reprogramming MSCs to iPSCs [74,75]. However, partial reprogramming or de-differentiation of a more mature cell type, like a myocyte or fibroblast, to a less mature cell type, like an MSC, has been attempted in only a few cases with small molecules [76–78]. Chen *et al.* showed that the small molecule reversine reverted lineage-committed murine myoblasts to an MSC-like stage [61]. Further studies reported that short-term treatment of primary murine and human dermal fibroblasts with reversine allowed them to revert to a progenitor capable of differentiating into skeletal muscle both *in vitro* and *in vivo* [76]. Interestingly, these studies described how reversine initially increased cell size up to nine times, but, once removed, the cells reverted back to their original size, function, and growth kinetics. These changes were attributed to reversine being a mitogen-activated protein kinase 1 and non-muscle myosin II inhibitor.

Other small molecules have been reported to induce de-differentiation and change stem cell potency and self-renewal. (2′*Z*,3′*E*)-6-bromoindirubin-3′-oxime has been shown to be responsible for enhancing ESC self-renewal [79–81], a characteristic of primitive stem cells. Platelet-derived growth factor receptor inhibitor-IV increased pluripotency gene expression in human adult bone-marrow-derived MSCs [82]. The activities of these molecules are together suggestive of a de-differentiation process whereby (1) a cell type with higher potency is achieved, (2) cells self-renew more quickly, and (3) pluripotent stem cell marker expression is enhanced.

## 31.19 Primitive stem cells and mesenchymal stem/stromal cell generation by physical factors

Hypoxia has also been shown to improve the stemness of MSCs by increasing the fraction of rapidly self-renewing cells [83] or stemness markers in progenitor cells [84]. Three-dimensional culture, culture in ESC media, and selecting for c-kit$^+$ or CD34$^+$ cells have been reported to enhance or produce more pluripotent MSCs [72,73,83,85–87].

## 31.20 Conclusions

There is a major unmet need for an effective method of supplying a large source of MSCs for clinical use [36]. The identification of various MSC types from different organs and of different ages (fetal to adult) has raised the question as to the optimal cellular source of MSCs (and see Chapters 3–5 and 7).

Pluripotent stem-cell-derived-MSCs have been obtained through a number of methods. We have detailed our results for developing a novel clinically applicable method, using the TGF-β signaling pathway inhibitor (SB431542), to produce patient-specific MSCs from a source free from ethical concerns. The iPSC-derived MSCs showed standard MSC characteristics, adhering to the criteria outlined by the ISCT for the identification of MSCs. Their potential for scale-up with growth kinetics ideal

for practical utility and their lack of teratoma-forming ability *in vivo* support further therapeutic development of these cells. They readily undergo mesodermal differentiation, with a strong propensity for osteogenic differentiation. Further investigation of these cells at an appropriate passage number to avoid loss of primitiveness and osteogenicity could position these cells as an alternative MSC source for future tissue repair and tissue engineering applications.

## 31.21 Future directions

The fields of stem cell biology and tissue engineering are increasingly converging at the forefront of regenerative medicine. Investigation into the derivation of potential cell sources suitable for clinical use is currently offering more realistic approaches to therapy. The refinement of derivation methods, and potential manipulation of these, could derive more fetal-like MSCs and would ensure optimal osteogenic differentiative capacity and the fastest kinetics of proliferation. An off-the-shelf tissue matching therapy is a reality, with 98% of the Caucasian population being covered by approximately 200 homozygous donors. Further experimentation is required to determine the homing and engraftment characteristics of iPSC–MSCs. This exciting and novel area of research is beginning to be therapeutically promising in areas of regenerative medicine and tissue repair.

## 32.1 Introduction

Hematopoiesis, or the continual renewal of blood cells that takes place in the bone marrow after birth, must face two conflicting demands. The most obvious demand is the continuous and balanced replacement of blood leukocytes, erythrocytes, and platelets, since blood cells can have a rapid turnover from 45 days for erythrocytes to less than 24 h for platelets. As a consequence, approximately $2.5 \times 10^6$ erythrocytes, $0.5 \times 10^6$ granulocytes, and $15–20 \times 10^6$ platelets are produced every second in an average adult human. This equates to approximately 500 billion blood leukocytes, erythrocytes, and platelets produced per day in an average human adult to simply maintain healthy levels of these cells in the circulation. This astounding replacement rate is the product of a hierarchy of progressive differentiation and lineage commitment from the rare multipotent hematopoietic stem cells (HSCs), to the highly proliferative hematopoietic progenitor cells (HPCs). Owing to their multipotentiality and their high capacity to self-renew, HSCs are the only cells able to fully reconstitute the whole hematopoietic and immune systems life-long upon transplantation, whereas the more mature HPCs actively proliferate and differentiate to rapidly repopulate the blood and immune cells but are incapable of self-renewing in the long term and only maintain the hematopoietic system for a few weeks. Owing to the rarity of HSCs in the adult bone marrow (approximately 1 in 10 000–20 000 cells), their genomic and functional integrity must be preserved to maintain efficient life-long hematopoiesis and avoid premature hematopoietic exhaustion and bone marrow failure. The second demand that hematopoiesis must face is the preservation of these rare HSCs from cellular damage, oxidative stress, and increased rates of DNA replication errors associated with extensive proliferation.

In rodents and humans these two conflicting demands are resolved by the maintenance of a dormant pool of HSCs that divide rarely in steady-state adults with approximately one division every 145 days in mice [1] and every 40 weeks in humans [2]. A population of less dormant HSCs replicate more frequently to replace the pool of actively dividing multipotent progenitors (MPPs) [1]. Although MPPs generate the whole hierarchy of actively dividing lineage-restricted HPCs that subsequently regenerate the large number of blood cells consumed by the body, MPPs are not stem cells and, as such, have a very limited self-renewal capacity. Consequently, they cannot reconstitute the whole hematopoietic system beyond a few weeks after transplantation.

The maintenance of this rare pool of highly dormant HSCs has led to some seemingly counterintuitive observations. A recent

technique involving tagging single clonal HSCs with a doxycycline-inducible hyperactive sleeping beauty (HSB) transposase enables the random integration of a DNA sequence tag into the HSC genome, thus allowing the tracking of sequential HSC clones and their progenies according to the integration sites of the tags. The advantage of this technique over conventional HSC barcoding methods is that it is performed on mice in steady-state hematopoiesis and does not require HSC isolation, retroviral barcoding, and transplantation after lethal irradiation of recipients, which forces barcoded HSCs to proliferate in order to reconstitute the bone marrow of myeloablated recipients.

This HSB-mediated HSC tagging in mice in steady state hematopoiesis has shown that granulocytes, which have a short half-life (10 h to 5–6 days depending on the method used [3]), are renewed by more proliferative progenitors, not the dormant HSCs over a long period of 45 weeks in steady state, an unexpected feature unique to granulocytes and not shared with lymphocytes or monocytes, which are renewed from common HSC clones [4]. While the coexistence of deeply dormant HSCs with more active HSCs is observed during steady-state hematopoiesis, this system is highly adaptable in response to stress, resulting in the activation of dormant HSCs to proliferate when rapid expansion is required, such as during early life when the body grows or to repair the hematopoietic system following myeloablation [1], infections [5,6], or HSC transplantation [4].

## 32.2 Hematopoietic stem cells need a niche

The dynamics of the hematopoietic system in steady state requires precise tuning to maintain the pool of deeply dormant HSCs, while allowing the more proliferative HSCs to actively regenerate hematopoietic tissue. Moreover, this system needs to be adaptable and sensitive to external demands, to reversibly activate dormant HSCs into a proliferative state in response to stress, and return them to a dormant state once the system has normalized. This exquisite balance of HSC quiescence versus proliferation, and self-renewal versus differentiation, is in large part regulated by specific HSC niches within the bone marrow. HSCs cannot be maintained for very long periods of time outside these specialized environments.

While *in vitro* cultures of HSCs with soluble recombinant cytokines generate a large number of proliferative HPCs and leukocytes at various maturational stages [7–10], human or mouse HSCs that maintain their self-renewal potential and their capacity to reconstitute the whole hematopoietic system upon transplantation are lost over extended periods of culture in the absence of stromal cells [11–16]. The rare occasions of successful maintenance or expansion of transplantable human or mouse HSCs have been performed in co-cultures with mesenchymal progenitor cells [17] or immortalized endothelial cells [18,19].

Earlier studies have shown that autologous transplantation of large pieces of bone marrow fragments into various extramedullary tissues in rats resulted in engraftment of the stromal tissue, followed by complete reconstitution of the hematopoietic bone marrow [20], demonstrating that bone marrow stromal elements are necessary to support HSC survival *in vivo*. This clearly demonstrated that the intricate cellular and physical interactions taking place *in situ* in the bone marrow between HSCs, HPCs, and the medullary stroma are required to maintain hematopoiesis *in vivo*. Subsequent studies have shown that niche cellular components, the extracellular matrix [21], and physicochemical cues such as oxygenation [22–25] critically regulate HSC dormancy, self-renewal, and reconstituting potential.

Although the nature and the components of HSC niches remained elusive for over two decades after their conceptualization by Schofield in 1978 [26], recent technical advances in the last decade have allowed further insights into this. In particular, (a) novel genetic tools in the mouse and (b) large panels of antibodies against human antigens together with potent human–mouse xenotransplantation systems have revealed the basic characteristics of HSC niches. It is increasingly clear that while mesenchymal stem cells (MSCs) in the bone marrow are pivotal components of HSC niches, they do not act alone to regulate HSCs in their niches but in concert with many other cell types. An increasing collection of other bone marrow stromal cells, such as endothelial cells, more mature mesenchymal progenitors, megakaryocytes, and Schwann cells, also play important roles in directly regulating HSCs, while neurons and macrophages are important regulators of the niche. This chapter will review some recent advances in dissecting the interactions between MSCs and HSCs firstly in mice and then in humans.

## 32.3 A mesenchymal hierarchy

In the literature the term "mesenchymal stem cell" has often been incorrectly used to refer to mesenchymal progenitor cells, defined by a set of phenotypic cell surface markers and the capacity to proliferate in culture and differentiate into cells of mesenchymal lineages, such as osteoblasts, chondrocytes, or adipocytes. However, these characteristics are not sufficient to define these cells as "stem cells." Multilineage differentiation from a population of cells may be due to the presence of a mixture of different lineage-restricted progenitors with limited self-renewal and reconstitution capacity *in vivo* rather than a single multipotent self-renewing stem cell. As a "stem cell," a single MSC must be able both self-renew into daughter stem cells and to generate a clone with the ability to differentiate into a variety of mesenchymal lineages and robustly reconstitute a mesenchymal tissue such as a bone or an ossicle once transplanted [27]. Initial characterization of mesenchymal progenitor cells included assays such the colony-forming unit–fibroblast (CFU-F) assay that defined nonhematopoietic fibroblast-shaped progenitor cells able to form colonies in clonal conditions, to be serially replatable, and to differentiate into different mesenchymal lineages (such as osteoblasts, chondrocytes, or adipocytes) when

cultured in appropriate conducive conditions [28,29]. The discovery of monoclonal antibodies such as STRO-1 and CD146 that could be used to enrich human bone marrow stromal cells for CFU-F and mesenchymal progenitors provided the first tool to further characterize mesenchymal progenitor cells [30,31]. It is, however, in the mouse that the clearest demonstration of clonal MSCs with multilineage mesenchymal differentiation potential and the ability to support the formation of an ossicle containing an active hematopoietic bone marrow was performed, as discussed herein.

## 32.4 Identification of mesenchymal stem cells and their relationship with hematopoietic stem cells in the mouse

In a seminal work, Paul Frenette's group found a rare population of bone marrow stromal cells expressing the intermediate filament protein nestin, which is abundantly expressed by neuroectoderm stem cells during central nervous system development [32,33]. These cells were multipotent, self-renewing, and capable of forming ossicles with functional hematopoietic marrow following subcutaneous transplantation [34]. Using a transgenic mouse strain in which green fluorescent protein (GFP) reporter expression was driven by a *Nestin* gene promoter (Nes-GFP mice), they noticed that the adult mouse bone marrow contained rare nestin$^+$ GFP$^+$ stromal cells that were negative for the pan-leukocyte marker CD45, as well as endothelial markers such as VE-cadherin (CD144) and platelet endothelium adhesion molecule-1 (CD31). These nestin$^+$ GFP$^+$ cells represented approximately 0.08% of bone marrow nucleated cells and were wrapped around endothelial sinusoids in the bone marrow, suggesting they may be pericytes. Using fluorescence-activated cell sorting (FACS), these cells were sorted from the bone marrow of Nes-GFP mice. Subsequent two-dimensional culture of GFP$^+$ nestin$^+$ cells on plastic wells showed these cells could not self-renew and rapidly differentiated into osteoblastic and chondrogenic lineage progenitors, resulting in a rapid loss of all GFP$^+$ nestin$^+$ cells. However, in three-dimensional (3D) cultures supplemented with appropriate growth factors and chicken embryo extracts, these GFP$^+$ nestin$^+$ cells could spontaneously assemble into spheres called mesenspheres and expand. These mesenspheres, clonally grown from single GFP$^+$ nestin$^+$ cells, contained a mixture of osteoblasts, chondrocytes, and adipocytes at different maturational stages as well as maintained a pool of undifferentiated GFP$^+$ nestin$^+$ cells. Remarkably, when these clonal mesenspheres were attached to a phosphocalcic implant and transplanted subcutaneously, they developed into ossicles containing osteoblastic and chondrocytic cells derived from the initial GFP$^+$ nestin$^+$ donor cells. Furthermore, nestin$^+$ GFP$^+$ cells from these mesensphere-derived ossicles were re-sorted and formed new mesenspheres that could be transplanted into secondary recipient mice and form ossicles with functional hematopoietic marrow [34]. Therefore, under the most stringent clonal conditions, a proportion of nestin$^+$ GFP$^+$ cells in the bone marrow of adult Nes-GFP mice are capable of self-renewal and trilineage differentiation *in vitro* and *in vivo*, thus fulfilling the functional characteristic of true MSCs [27].

Intriguingly, despite the rarity of nestin$^+$ cells and even rarer HSCs rigorously defined as lineage-negative, 60% of HSCs were within five cell diameters of a nestin$^+$ cell, suggesting a close physical proximity between these two stem cell populations in mouse bone marrow.

(Lineage negativity is defined as absence of the following lineage markers: CD3 (a pan T cell marker), CD45R (the common leukocyte antigen), CD11b (integrin $\alpha_M$ on monocytes, granulocytes, macrophages, and natural killer cells), Ly6C/G (granulocyte receptor Gr-1 expressed on most myeloid cells in the bone marrow and all peripheral granulocytes), CD41 (integrin $\alpha_{IIb}$ or platelet GPIIb on megakaryocytes), Ter119 (erythroid cells), CD48 (B lymphocyte activation marker also known as BLAST-1 and signaling lymphocyte activation molecule 2, SLAMF2), and CD150 (signaling lymphocyte activation molecule 1, SLAMF1) [35].)

Importantly, these nestin$^+$ MSCs had the highest expression levels of chemokines (such as CXCL12), growth factors (such as kit ligand and angiopoietin-1), cell adhesion molecules (such as vascular cell adhesion molecule-1 – VCAM-1; CD106), and connexin 43 [34] necessary to maintain HSCs within their bone marrow niches [36]. Taken together, these findings suggest that these nestin$^+$ MSCs are pivotal to maintain viable HSCs in their niche. However, definitive proof that these nestin$^+$ MSCs are essential to HSC maintenance was provided by selectively ablating nestin$^+$ MSCs *in vivo*. As germinal ablation of nestin$^+$ cells is embryo-lethal due to its expression in the embryonic neuroectoderm, MSCs were selectively depleted in adult mice using diphtheria toxin. As mice do not express receptors for diphtheria toxin and are consequently resistant to this very potent toxin [37], a classic strategy of inducing expression of simian diphtheria toxin receptor (DTR) specifically in nestin$^+$ cells was developed in which DTR$^+$ cells could then be selectively ablated *in vivo* by administration of diphtheria toxin [34]. Generation of these mice involved crossing two different strains of mutant mice. The first strain expressed a fusion chimera between Cre recombinase and a mutant estrogen receptor that binds the estrogen antagonist tamoxifen but not endogenous estrogen (Cre$^{ERT2}$). In order to restrict its expression to nestin$^+$ cells, this chimeric construct was placed under the control of the *Nestin* gene enhancer (*Nes-Cre$^{ERT2}$* mice). These mice were crossed with a strain containing a Cre-inducible simian DTR (iDTR) (Figure 32.1). In the resulting *Nes-Cre$^{ERT2}$ iDTR* mice, the Cre$^{ERT2}$ fusion protein is specifically expressed in nestin$^+$ cells but trapped in the cytoplasm in the absence of tamoxifen. However when tamoxifen is administered to the mice it binds to Cre$^{ERT2}$, resulting in its translocation to the nucleus where it can recombine DNA between two loxP sequences. As the simian DTR transgene is preceded by a few STOP codons flanked by two

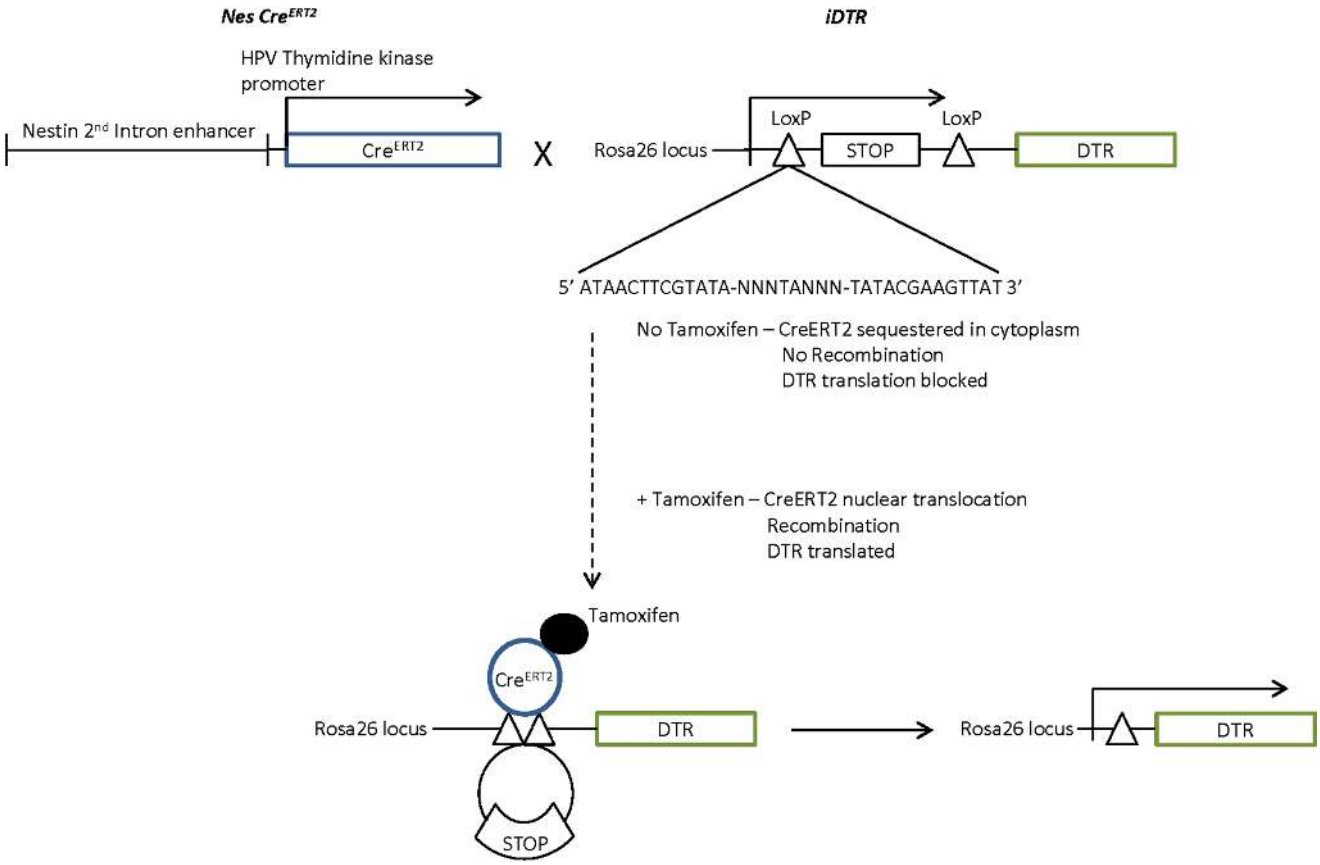

**Figure 32.1** Example of use of the Cre–Lox system to study the role of MSCs and other niche cells in regulating HSCs. In this particular example taken from reference [34], mice carrying the *Nes-CreER*$^{T2}$ transgene are crossed with iDTR mice containing a tamoxifen-inducible simian diphtheria toxin receptor cDNA downstream of a STOP codon flanked by two LoxP sites (floxed) inserted in the Rosa-26 gene trap locus. An example of loxP sequence with typical palindromes at both ends is shown. In the absence of tamoxifen, the CreER$^{T2}$ protein remains sequestered in the cytoplasm and cannot recombine genomic DNA in the cell nucleus. Consequently, the mRNA transcribed from the Rosa-26 gene trap locus in iDTR mice cannot be translated into DTR protein. Cells are resistant to diphtheria toxin. When mice are treated with tamoxifen, the drug crosses plasma membranes, binds to CreER$^{T2}$ protein, and induces its translocation to the nucleus via the estrogen-binding domain of the CreER$^{T2}$ protein. Once in the nucleus, CreER$^{T2}$ recombines DNA between loxP sequences and removes the STOP codon upstream of the DTR cDNA. As a consequence, the mRNA transcribed from the Rosa-26 is translated into DTR protein and cells become sensitive to diphtheria-toxin-mediated killing. By choosing Cre mice in which Cre is expressed in a specific cell type, in a constitutive or inducible manner (see examples in Tables 32.1 and 32.2), it is possible to induce gene expression (e.g., fluorescent reporter genes to track cells or toxins or toxin receptors to ablate cells) or to delete a particular gene in a cell-specific manner.

loxP sequences, translation of the DTIR protein is blocked in iDTR mice.

However, administration of tamoxifen activates Cre$^{ERT2}$ exclusively in nestin$^{+}$ cells (as they are the only cells to express Cre$^{ERT2}$ in *Nes-Cre$^{ERT2}$* mice), unlocking expression of DTR and rendering nestin$^{+}$ cells sensitive to diphtheria toxin (see Figure 32.1). Using this classic genetic approach, Mendez-Ferrer *et al.* were able to specifically deplete nestin$^{+}$ MSCs *in vivo* in adult *Nes-Cre$^{ERT2}$ iDTR* mice by co-administration of tamoxifen and diphtheria toxin. Two weeks following diphtheria-toxin-mediated nestin$^{+}$ cell ablation, the number of phenotypic Lin$^{-}$ Sca1$^{+}$ Kit$^{+}$ CD48$^{-}$ CD50$^{+}$ HSCs was reduced by 50% in the bone marrow, and hematopoietic activity in the bone marrow, as measured by long-term culture initiating cell assay, was reduced by 75%. Furthermore, homing of wild-type HSCs in recipients with nestin$^{+}$ cell depletion was reduced by 90% [34]. Taken together, these experiments suggest that rare nestin$^{+}$ cells in the adult mouse bone marrow are (1) bona fide MSCs capable of self-renewal and mesenchymal reconstitution *in vivo*, (2) physically associated with rare HSCs, and (3) supportive of HSC homing and maintenance in the bone marrow.

## 32.5 More than one nestin$^{+}$ cell type and hematopoietic stem cell niche exist in the mouse bone marrow

More refined flow cytometry and 3D confocal fluorescent microscopy analyses of *Nes-GFP* transgenic mice revealed GFP positivity did not define a single population of bone marrow MSCs. The first population identified exhibited very high expression of nestin and GFP and consisted of much scarcer elongated

cells (called $Nes^{peri}$) wrapped around arterioles. A second population with moderate expression of nestin and GFP were more reticular and found associated with sinusoids (called $Nes^{retic}$) [38]. Despite the varying locations, shapes, and GFP expression, both sorted populations contained CFU-F activity and expressed HSC-supportive genes such as *CXCL12*, *KITL*, *ANGPT1* or *VCAM1*. However, the $Nes^{peri}$ cells had higher levels of CFU-F activity as well as CXCL12, KITL, ANGPT1, or VCAM1 mRNA expression than $Nes^{retic}$ cells. This suggested that different types of $GFP^+$ $nestin^+$ MSCs reside in two different perivascular locations, either peri-arteriolar or peri-sinusoidal. As it had been inferred by several studies that dormant HSCs and more active HSCs reside in distinct niches according to their position relative to vascular beds, blood perfusion, and oxygenation of the surrounding milieu [1,22,25,39–43], the possibility that arteriolar and sinusoidal niches could segregate dormant from active HSCs was further explored. Dormant HSCs can be detected by oral administration of 5-bromo-2′-deoxyuridine (BrdU) or 5-ethynyl-2′-deoxyuridine (EdU), two thymidine analogs that incorporate into the DNA of dividing cells and can be easily detected with specific monoclonal antibodies. When mice drink water containing BrdU or EdU over a 2-week period, most HSCs (dormant or active) are labelled with these nucleotide analogs *in vivo* as their slight cytotoxicity forces HSCs to divide [1,44]. However, after a long chase over 70 days with plain drinking water, dividing cells will rapidly lose BrdU or EdU staining in the genomic DNA whereas dormant cells will retain these two nucleotide analogs during this long chase period, enabling their identification by flow cytometry or immunohistofluorescence [1,25]. Using this approach in *Nes-GFP* mice, 60% of dormant HSCs were found to reside within 20 μm of $Nes^{peri}$ cells in arterioles. As quiescent HSCs are not necessarily dormant (dormancy implies quiescence over several months), the proportion of quiescent HSCs defined by the absence of expression of the cell cycling nuclear marker Ki67 was also measured. Similar to dormant HSCs, 40% of quiescent HSCs were within 20 μm of $Nes^{peri}$ cells in these arteriolar niches. Conversely, cycling $Ki67^+$ HSCs were more distant from $Nes^{peri}$ [38].

It was also noted that peri-arteriolar $Nes^{peri}$ MSCs expressed the pericyte marker NG2 but not the leptin receptor (LEPR), which was previously found to be expressed by perivascular cells presenting Kit ligand to HSCs [45]. Conversely, peri-sinusoidal $Nes^{retic}$ MSCs were negative for NG2 and positive for LEPR [38]. Finally, in mice expressing both *iDTR* (Cre-inducible DTR) and *NG2-CreERT2* transgene (tamoxifen-inducible Cre recombinase fusion protein under the promoter of the gene encoding the pericytes marker NG2), diphtheria toxin treatment depleted approximately 50% of $Nes^{peri}$ MSCs in the mouse bone marrow, decreased the frequency of HSCs within 20 μm of an arteriole, and decreased the frequency of quiescent $Ki67^-$ HSCs [38]. From these findings it was concluded that dormant HSCs reside preferentially in peri-arteriolar niches close to $Nes^{peri}$ MSCs. It must be noted, however, that the frequency of dormant or quiescent HSCs in the proximity of peri-sinusoidal $Nes^{retic}$ MSCs was not shown. Therefore, while EdU-label-retaining dormant and $Ki67^-$ quiescent HSCs may be enriched in peri-arteriolar niches compared with the rest of the bone marrow space, their frequency in peri-sinusoidal niches close to $Nes^{retic}$ MSCs was not measured. Therefore, whether peri-sinusoidal niches preferentially harbor active or proliferative HSCs remains unclear.

Nevertheless, as nestin is an intracellular intermediate filament protein, the use of specific anti-nestin antibody to prospectively isolate viable MSCs by FACS from human or genetically unmodified mice is not possible. Screening of previously known cell surface markers of mesenchymal progenitor cells identified platelet-derived growth factor receptor-α (PDGFRα or CD140a) and integrin $\alpha_V$ (CD51) as the most abundantly expressed markers on $nestin^+$ $GFP^+$ bone marrow MSCs. Sixty percent of $nestin^+$ cells are double positive for both PDGFRα and CD51. Reciprocally, 75% of $CD45^-$ $Ter119^-$ $CD31^-$ $PDGR\alpha^+$ $CD51^+$ cells are $nestin^+$ and express the highest levels of CXCL12, VCAM1, ANGPT1, and SCF mRNA [46], factors all supportive of HSCs. Furthermore, sorted bone marrow $CD45^-$ $Ter119^-$ $CD31^-$ $PDGFR\alpha^+$ $CD51^+$ cells recapitulated all the properties of sorted $nestin^+$ $GFP^+$ MSCs, such as the formation of clonal mesenspheres, self-renewal *in vitro* and *in vivo*, and formation of ossicles containing a hematopoietic bone marrow when transplanted subcutaneously [46]. Therefore, double positivity for PDGFRα and CD51 within the $CD45^-$ $Ter119^-$ $CD31^-$ nonendothelial and nonhematopoietic gate is a good surrogate of nestin expression in adult bone marrow cells and is, to date, the best phenotypic profile to prospectively isolate mouse MSCs from mice that do not carry the *Nes-GFP* transgene. Of note, Pinho *et al.* found that the Sca-1 antigen was not present in these $nestin^+$ MSCs. Therefore, it should be possible to isolate MSCs from any mouse strain, especially from those that do not express Sca-1, such as BALB/c mice.

## 32.6 Controversies surrounding $nestin^+$ mesenchymal stem cells and other genetic models for alternative mesenchymal stem cells

The characterization of $nestin^+$ MSCs in the mouse bone marrow and its role in hematopoiesis has, however, been challenged by a recent report from Sean Morrison's group. As the tyrosine kinase receptor c-Kit (CD117) expressed by all hematopoietic stem and progenitor cells (HSPCs) and the Kit ligand (also called stem cell factor) expressed in the bone marrow stroma are both critical to HSC survival, self-renewal, and proliferation [47–49], *Nes-Cre* mice were crossed with mice carrying floxed *Kitl* alleles (flanked by two loxP sites, enabling conditional gene excision with Cre recombinase) to specifically delete the *Kitl* gene in $nestin^+$ cells [45]. This did not cause a reduction of HSC frequency in the bone marrow, but instead reduced their frequency in the spleen [45]. This result is at odds with previous findings showing that HSC frequency in the bone marrow was reduced

following acute depletion of nestin$^+$ MSCs in adult mice [34]. A possible explanation for this discrepancy is that in the *Nes-Cre$^{ERT2}$ iDTR* mouse model, ablation of nestin$^+$ MSCs was not constitutive but induced after administration of tamoxifen and diphtheria toxin in adult mice, whereas in Morrison's model the *Kitl* deletion in nestin$^+$ cells was constitutive throughout embryonic development. Indeed, it has recently been shown that, in the developing limb buds in the mouse embryo, a proportion of nestin$^+$ cells are endothelial cells expressing CD31. Similarly, at day 3 after birth, many nestin$^+$ cells gave rise to CD31 endothelial cells that persisted for up to a month, whereas at this stage their contribution to osteoblasts and chondrocytes was relatively minor, with no contribution to adipocytes [50]. Therefore, the cell specificity of nestin expression varies with developmental stages as nestin specifically labels MSCs only in the adult bone marrow [51], not in the embryo or perinatally [50]. Thus, conditional deletion or ablation in the adult mouse to study effects in adult bone marrow MSCs should be performed with tamoxifen-inducible *Nes-CreERT2* mice rather than *Nes-Cre* mice.

A second controversy is the observation by Morrison's group that HSC frequency in the bone marrow was decreased in mice in which *Kitl* was deleted by LEPR$^+$ cells (*Lepr-Cre* mice) [45], thus suggesting that LEPR$^+$ mesenchymal cells are critical to HSC development and survival, whereas Frenette's group could not detect LEPR in peri-arteriolar Nes$^{peri}$ MSCs. Instead, this group detected LEPR in peri-sinusoidal Nes$^{retic}$ MSCs [45]. However, a recent study shows that LEPR is also expressed in different bone marrow stromal subsets during development [51] and that osteoblasts in the embryo and adults emerge from distinct waves of mesenchymal differentiation from distinct MSCs depending on the developmental stage [50,51]. Therefore, as with nestin, LEPR is expressed in different cell types depending on developmental stage, underpinning the need for inducible gene deletions in adults rather than constitutive deletions during early embryonic development. Consequently, the precise role of nestin$^+$ versus LEPR$^+$ MSCs in the adult bone marrow, and the extent to which they overlap or segregate to arteriolar versus sinusoidal niches and dormant versus proliferative HSC niches, needs further clarification.

Besides models targeting nestin and LEPR, other genetic tools have become available to test MSC function in the mouse bone marrow (Tables 32.1 and 32.2).

One such model targets the transcription factor Prrx1 that is expressed by the limb bud mesooderm in the developing embryo and is critical to skeletal development [52,53]. Crossing these *Prrx1-Cre* mice with a Cre inducible fluorescent reporter showed that most mesenchymal cells expressing CXCL12 in the bone marrow are derived from Prrx1$^+$ MSCs. Furthermore, conditional deletion of the *CXCL12* gene in Prrx1$^+$ mesenchymal cells led to a dramatic reduction in the frequency of HSCs, as well as common lymphoid progenitors and B cell progenitors in the bone marrow and increased cycling of the remaining HSCs [54]. *Prrx1-Cre* mice are therefore a useful tool to test the role of the mesenchymal lineage in regulating hematopoiesis. However, they do not enable the different contributions of the various differentiation stages of MSCs to be distinguished for their respective contribution.

**Table 32.1** Cre mouse strains used to study HSC niche cells.

| Strain | Induction system | Cell specificity |
|---|---|---|
| *Mx1-Cre* | pI:pC inducible | All cells |
| *Nes-Cre$^{ERT2}$* | Tamoxifen inducible | Nestin$^+$ cells |
| *Nes-Cre* | Constitutive | Nestin$^+$ cells |
| *NG2-Cre* | Constitutive | Pericytes |
| *LEPR-Cre* | Constitutive | Mesenchymal LEPR$^+$ cells |
| *Prrx1-Cre* | Constitutive | MSCs |
| *Osx-Cre* | Constitutive | Immature osteoprogenitors |
| *Col2.3-Cre* | Constitutive | Maturing osteoprogenitors |
| *Osteocalcin-Cre* | Constitutive | Mature osteoblasts |
| *Tie-2-Cre* | Constitutive | Endothelial and hematopoietic cells |
| *VE-cadh-Cre$^{ERT2}$* | Tamoxifen inducible | Endothelial cells |
| *VE-cadh-Cre* | Constitutive | Endothelial cells |
| *Cxcl4-Cre* | Constitutive | Megakaryocytes |
| *Th-Cre* | Constitutive | Dopaminergic, adrenergic nerves |

## 32.7 Other stromal cells regulate hematopoietic stem cells and additional tools to study their role in regulating hematopoiesis

The last decade of research has shown that in both mice and humans an increasing variety of cell types regulate HSCs in the

**Table 32.2** Genes targeted by Cre mouse strains to study HSC niches.

| Gene | |
|---|---|
| *iDTR* | Inducible diphtheria toxin receptor |
| *iGFP* | Inducible GFP |
| *iYFP* | Inducible yellow fluorescent protein |
| *iRFP* | Inducible red fluorescent protein |
| *KITL* | Kit-ligand |
| *JAG1* | Jagged-1 |
| *CXCL12* | Stromal derived factor 1 (SDF-1) |

bone marrow. With the increasing availability of genetically modified mouse strains expressing the Cre recombinase under the control of cell-specific gene promoters (Tables 32.1 and 32.2) the precise function of some of these cell types has been revealed.

### 32.7.1 Osteoblastic lineage and osteoblasts

Cells of the osteoblastic lineage and osteoblasts have long been suspected to play an important role in regulating hematopoiesis. This notion arose from observations by Brian Lord four decades ago that short-term reconstituting HPCs detected in the colony-forming unit–spleen assay were more abundant close to the endosteum than in the central bone marrow [55]. Subsequent studies showed that $Lin^-$ $Sca1^+$ $Kit^+$ cells, which not only encompass HSCs but also a large proportion of MPPs and lineage-restricted HPCs, homed preferentially within 100 μm of the endosteum in lethally irradiated and nonmyeloablated recipients [56,57]. Conditional overexpression of a constitutively active parathyroid hormone receptor (PTHR1) or inactivation of the bone morphogenetic protein receptor 1A in maturing osteoblasts in which the 2.3 kb fragment of the collagen IA gene promoter is active (*Col2.3*-Cre mice) led to increased frequency of $Lin^-$ $Sca1^+$ $Kit^+$ HPCs and HSCs in the bone marrow [58,59]. Conversely, *in vivo* depletion of maturing osteoblasts using the *Col2.3* promoter led to the progressive relocation of hematopoiesis from the bone marrow to the spleen [60] and an arrest of medullary B lymphopoiesis [61]. However, with publications refining the phenotype identifying HSCs, MPPs, and lineage-restricted HPCs more precisely and the availability of additional Cre transgenic strains, the role of mature osteoblasts in directly regulating HSCs has become more controversial. Mature osteoblasts are not the main source of Kit ligand and CXCL12 in the bone marrow, as they are both abundantly expressed by more immature mesenchymal cells such as MSCs [38], as well as pericytes and CXCL12-abundant reticular cells [62]. Furthermore, conditional deletion of the *KITL* or *CXCL12* genes in maturing or mature osteoblasts using *Col2.3-Cre* mice or *osteocalcin-Cre* mice did not alter the frequency of HSCs in the bone marrow [54,63], suggesting that other cellular sources of Kit ligand and CXCL12 (such as from MSCs and endothelial cells) are more important to support medullary HSCs. However, it must be noted that maturing osteoblasts play an important role in maintaining medullary lymphopoiesis. Conditional deletion of the *CXCL12* gene in maturing osteoblasts (using *Col2.3-Cre* mice) led to a loss of medullary lymphopoiesis [63], an effect also observed following *in vivo* genetic ablation or granulocyte colony-stimulating factor (G-CSF)-mediated ablation of osteoblasts [60,61,64]. It is also possible that more primitive osteoprogenitors expressing the osterix/Sp7 transcription factor play an important role in regulating the proliferation of MPPs and HSCs. While deletion of *CXCL12* gene in $osterix^+$ osteoprogenitors did not alter HSC frequency or cycling in the bone marrow, it did increase their exit from quiescence and entry into the $G_1$ phase of the cell cycle and their mobilization into the blood and spleen [54]. Furthermore, blockage of microRNA synthesis in osteoprogenitors by conditionally deleting the *DICER1* gene in $osterix^+$ osteoprogenitors led to severe hematopoietic insufficiency and myelodysplasia evolving to secondary acute myeloid leukemia. However, conditional deletion of the *DICER1* gene in mature osteoblasts expressing osteocalcin did not lead to hematopoietic abnormalities [65]. Likewise, deletion of the *Sbds* gene, involved in ribosome regulation, in $osterix^+$ osteoprogenitors also leads to severe hematopoietic insufficiency and myelodysplasia evolving to secondary acute myeloid leukemia [65]. Therefore, dysregulation of osteoprogenitors can cause hematopoietic deficiencies or abnormal HSC trafficking and mobilization into the blood.

### 32.7.2 Endothelial cells

Visualization of rare HSCs (using the $Lin^-$ $CD48^-$ $CD150^+$ phenotype) by confocal immunofluorescence microscopy in sections of adult mouse long bones or calvaria or whole mount adult marrows *in situ* revealed that a large proportion of these rare HSCs are located adjacent to a blood vessel often reported as a sinusoid [35,62]. This raised the question as to whether this perivascular location of HSCs is due to the perivascular location of MSCs that support HSCs or whether endothelial cells are also directly supporting HSCs. There is strong evidence that both human [18] and mouse [19] endothelial cells can support expansion of human and mouse HSCs in co-cultures. Furthermore, many chemokines, cell adhesion molecules, and growth factors critical to the retention of HSCs within the bone marrow tissue, such as CXCL12 [54,63,66,67], VCAM-1 [68,69], and kit ligand [45], were not only expressed by perivascular mesenchymal cells but also by some endothelial cells in the bone marrow (Figure 32.2).

Furthermore, E-selectin, an endothelial cell-specific adhesion molecule expressed by a subset of bone marrow endothelial cells, promotes HSC proliferation in the bone marrow *in vivo* as deletion of the E-selectin gene *SELE*, or administration of selective antagonists of E-selectin, increases HSC quiescence and resistance to cytotoxic drugs and irradiation *in vivo* [40]. Taken together, this strongly suggests that endothelial cells, independent of MSCs, are important regulators of HSCs and hematopoiesis. Proof of a direct role of endothelial cells in regulating HSCs was recently provided by crossing transgenic mice with endothelial-cell-specific expression of Cre recombinase or tamoxifen-inducible $Cre^{ERT2}$ with mice in which either the *KITL* or *JAG1* (encoding the Notch 1 ligand and Jagged 1) genes were floxed (Tables 32.1 and 32.2). Constitutive excision of the *KITL* gene in endothelial cells reduced the frequency of HSCs in the bone marrow and spleen, and this reduction worsened with age [45]. Therefore, ongoing endothelial expression of Kit ligand is required for full maintenance of HSCs. Likewise, constitutive deletion of the *JAG1* gene in endothelial cells reduced HSC frequency in the bone marrow, self-renewal potential upon serial transplantation, and impaired recovery and survival from sublethal irradiation or cytotoxic injury with 5-fluorouracyl [70]. Taken together, these models demonstrate that, concomitantly to

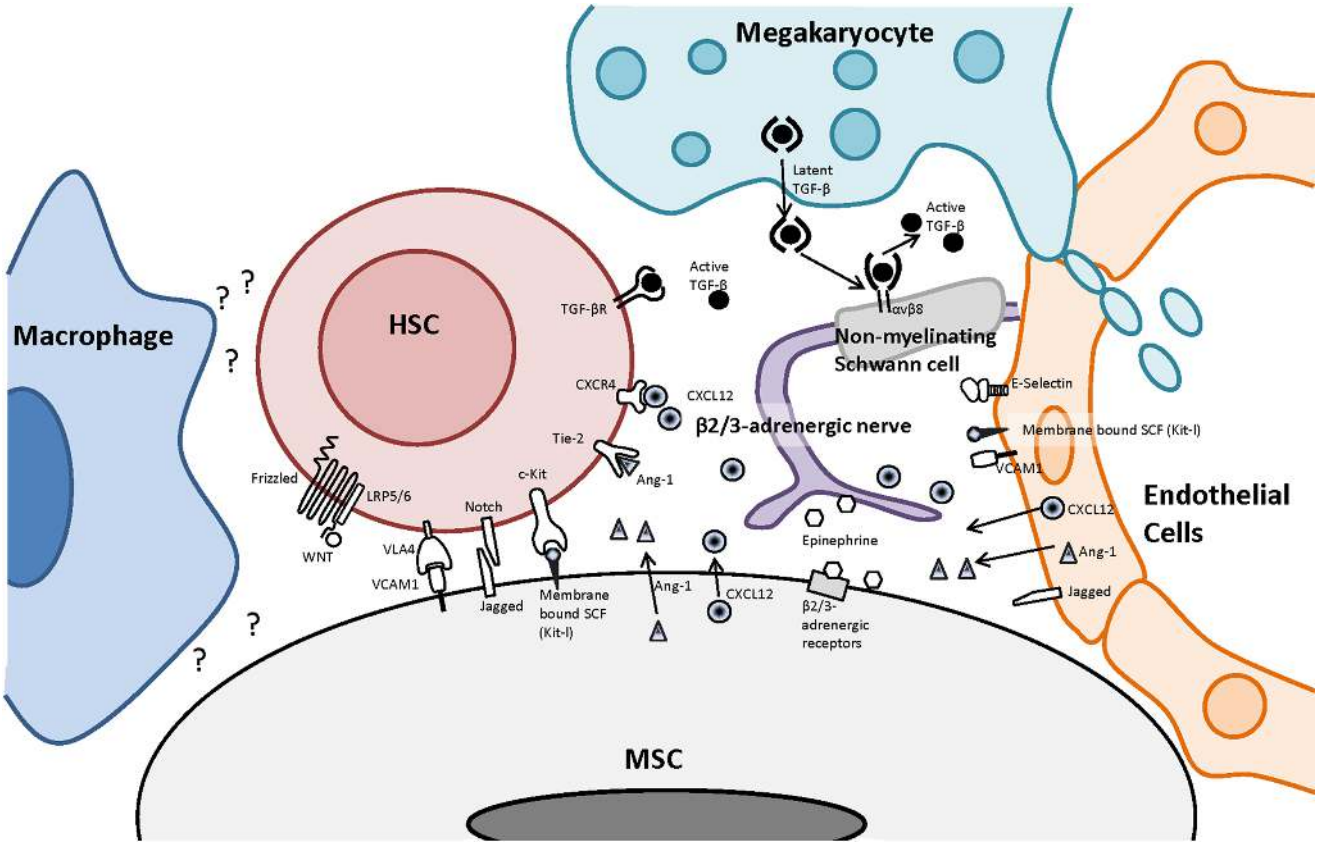

**Figure 32.2** Schematic view of HSC niches. MSCs expressing nestin play a central role in the HSC niche. MSCs are perivascular and can be present in bone marrow arterioles (arteriolar niches with nestin$^{bright}$ MSCs) or sinusoids (sinusoidal niches with nestin$^{dim}$ MSCs). MSCs, together with bone marrow endothelial cells, express key regulators of HSCs, such as kit ligand, angiopoietin-1 (Ang-1), CXCL12, or Jagged-1, as well as VCAM-1, which anchors HSCs within their niches. CXCL12 expression by MSCs and MSC quiescence are regulated by norepinephrine and epinephrine released from β2- and β3-adrenergic nerves. Specific macrophages also regulate MSCs and the niche via unknown mechanisms. E-selectin specifically expressed by bone marrow endothelial cells promotes HSC proliferation. Latent transforming growth factor-β (TGF-β) released by megakaryocytes binds to $\alpha_v\beta_8$ integrin on Schwann cells, enabling its activation. Active TGF-β maintains HSCs in a quiescent state.

MSCs, subsets of bone marrow endothelial cells independently support HSCs and hematopoiesis in the bone marrow.

### 32.7.3 Megakaryocytes, Schwann cells, and the transforming growth factor-β connection

It has been known for two decades that the three isoforms of TGF-β, particularly TGF-β1, are critical regulators of HSC quiescence and self-renewal potential by blocking HSC entry into the cell cycle [71–73] via the SMAD signaling pathway [74,75]. Following biosynthesis, TGF-β is secreted in a dimeric proform called small latent complex, which contains a latency associated peptide (LAP). This small latent complex is further bound to a latent TGF-β binding protein to form a large latent complex. Active dimeric TGF-β is released from a small or large latent complex by proteolysis or acidification. Megakaryocytes in the bone marrow are perivascular in order to shed platelets into the circulation [76] and are an important source of TGF-β [77]. Fifteen hours following HSC transplantation in nonablated recipients, 80% of HSCs are lodged within two cell diameters of a megakaryocyte [78], whereas in the naive bone marrow 20–25% of HSCs are within 5 μm or directly in contact with a megakaryocyte [79,80]. This close proximity is not fortuitous, as specific ablation of megakaryocytes resulted in HSC expansion in the bone marrow. Indeed, in two recent independent studies, *Cxcl4-Cre* (also called *Pf4-Cre*) transgenic mice with Cre-recombinase driven by the promoter of the *CXCL4* gene (also called platelet factor 4, specific for megakaryocytes) were crossed with *iDTR* mice (Tables 32.1 and 32.2). In these mice, administration of diphtheria toxin ablated megakaryocytes, resulting in thrombocytopenia and a 10-fold increase in phenotypic HSCs due to their exit from quiescence, and subsequent proliferation [79,80]. Furthermore increased proliferation of phenotypic HSCs was not associated with decreased self-renewal but rather with increased long-term reconstitution potential upon transplantation. Therefore megakaryocytes play an important role in maintaining HSC quiescence in the bone marrow. This effect was mediated by both TGF-β1 and CXCL4. Injection of active recombinant TGF-β1 could restore HSC quiescence and decrease HSC numbers to normal levels in megakaryocyte-ablated *Cxcl4-Cre iDTR* mice [80]. Similarly

deletion of the *CXCL4* gene in *Cxcl4*$^{-/-}$ mice recapitulated the increase in HSC proliferation and number observed in the bone marrow of megakaryocyte-ablated *Cxcl4-Cre iDTR* mice [79]. Whether TGF-β is produced by megakaryocytes in its active or latent form was not determined in these two studies [79,80]; however, antibodies specific for active TGF-β or for LAP stain distinct cell types in the mouse bone marrow. In particular, antibodies specific for active TGF-β do not stain megakaryocytes but exclusively long elongated nonmyelinated Schwann cells expressing glial fibrillary acidic protein which ensheath nerves around blood vessels in the bone marrow [81]. Furthermore, these Schawnn cells express integrin $\alpha_v\beta_8$, a cell adhesion molecule that binds LAP [81], causing a conformational change in latent TGF-β that enables its subsequent cleavage activation by matrix metalloproteinases [82]. Therefore, the perivascular co-location of megakaryocytes and Schwann cells may enable secretion of latent TGF-β by the former and subsequent TGF-β activation by the latter, a crucial duo to maintain HSCs in quiescence in perivascular niches (Figure 32.2). (Schwann cells were discovered by Theodor Schwann (1810–1882), a German physiologist.)

### 32.7.4 Adrenergic neurons

The bone marrow is innervated in particular with adrenergic nerves that secrete epinephrine and norepinephrine that bind to β2- and β3-adrenergic receptors expressed by MSCs in HSC niches. This β-adrenergic pathway regulates CXCL12 expression by MSCs as well as MSC quiescence and proliferation. Indeed, the β3-adrenergic pathway regulates the circadian oscillation of CXCL12 expression by MSCs and consequently circadian release of HSCs from bone marrow niches into the circulation in steady state [83]. In addition to this, both the β2- and β3-adrenergic pathways are necessary for maintaining MSCs and for functionality of HSC niches following cytotoxic injury. To demonstrate this, two models of *in vivo* ablation of peripheral adrenergic nerves were used: (1) chemical ablation of adrenergic nerves by injecting 6-hydroxy dopamine and (2) genetic ablation by injecting diphtheria toxin into *Th-Cre iDTR* mice in which Cre recombinase is driven by the promoter of the tyrosine hydroxylase gene. Tyrosine hydroxylase is the enzyme that converts tyrosine into L-dopamine and is specific for catecholaminergic nerves. In both models of adrenergic nerve ablation the recovery of nestin$^+$ MSCs and HSCs following cytotoxic injury with 5-fluorouracyl was compromised, leading to increased incidence of bone marrow failure and death [84]. Lucas *et al.* found that β2- and β3-adrenergic receptors present on MSCs block their proliferation and protect them from the cytotoxic effect of 5-fluorouracyl [84]. In the absence of adrenergic nerves, or following administration of β2- and β3-adrenergic antagonists, nestin$^+$ MSC proliferation was induced, resulting in increasing MSC sensitivity to cytotoxic drugs. Interestingly, cytotoxic drugs with peripheral neurotoxicity, such as cisplatin and vincristine, also killed adrenergic nerves in the bone marrow, sensitizing nestin$^+$ MSCs to subsequent irradiation or cytotoxic drug treatment. As a consequence of the enhanced destruction of MSCs, the number of HSCs surviving chemotherapy was significantly reduced [84]. Remarkably, administration of neuroprotective drugs, such as glial cell derived neurotrophic factor or 4-methylcatechol, prevented death of adrenergic nerves in response to cisplatin or vincristine, increasing MSC survival and hematopoietic recovery following treatment with these two drugs [84]. The clinical relevance of these findings is illustrated by the fact that cisplatin and vincristine are used to treat some types of lymphoma and acute leukemia. Up to 20% of patients so treated experience hematopoietic dysfunction and treatment-related mortality [85,86]. Therefore, adjuvant treatment with neuroprotective drugs may reduce the incidence of treatment-related bone marrow failure and the side effects and mortality in patients treated with cisplatin or vincristine.

### 32.7.5 Macrophages

Macrophages include a very diverse array of mononucleated myeloid cells with wide-ranging immune and homeostatic functions, from the phagocytosis and elimination of pathogens and tissue debris to the maintenance and homeostasis of a variety of tissues, such as the brain, liver, and lung [87]. Although monocytes are produced in the bone marrow from myeloid progenitors, the function of macrophages residing in the bone marrow is not fully understood. It has recently emerged that specific subsets of bone marrow macrophages are critical to the maintenance of HSC niches and osteoblasts in the bone marrow. Indeed, CD169$^+$ macrophages are found adjacent to nestin$^+$ MSCs in the mouse bone marrow [88]. Furthermore, a canopy of F4/80$^+$ macrophages lies just above osteoblasts at the endosteum [89,90]. Interestingly, *in vivo* ablation of these bone marrow macrophages by three independent methods, namely (1) the injection of G-CSF, (2) the administration of liposomes loaded with the cell-impermeable drug clodronate, and (3) genetic macrophage ablation using macrophage Fas-induced apoptosis, results in loss of osteoblasts, reduced expression of CXCL12 by MSCs, and induced mobilization of HSCs from their bone marrow niche into the circulation [88,90,91]. Therefore, together with adrenergic nerves, macrophages are key regulators of MSC function and HSC retention within their bone marrow niches. The mechanisms by which macrophages regulates MSCs remains unknown.

Studies in the mouse have revealed a complex picture of the HSC niche in which MSCs play a critical role by the secretion of factors essential to maintain HSC survival, quiescence, or proliferation (Figure 32.2). Although there is now consensus that many HSC niches and HSC-supportive MSCs are perivascular, whether they will promote quiescence or proliferation of HSCs depends on the balance between proliferative factors (such as E-selectin) and anti-proliferative factors (such as TGF-β or CXCL4), and which may ultimately depend on the location of these niches (peri-arteriolar or peri-sinusoidal) or the presence or absence of additional cells, such as endothelial cells, megakaryocytes, and Schwann cells (Figure 32.2).

## 32.8 Human mesenchymal stem cells and human hematopoiesis

Despite the complexity of HSC niches in the mouse bone marrow and the fact that exquisitely sensitive genetic studies with conditional gene induction or ablation *in vivo* in mice cannot be repeated in humans, progress has been made to better characterize genuine clonal multipotent MSCs and their HSC-supportive role in human bone marrow. There are similarities in marrow MSCs between mouse and man (Table 32.3).

In another seminal study, Sacchetti *et al.* compared the engraftment potential of cultured nonhematopoietic stromal cells derived from a variety of human tissues. In their model, plastic-adherent cells from two-dimensional cultures were harvested, cells adhered to a 3D support of hydroxyapatite/tricalcium phosphate matrix, and then packed in fibrin glue before subcutaneous implantation in immunodeficient mice. Eight weeks after implantation, mesenchymal cells isolated from the periosteum or from trabecular bones could form a compact ectopic bone but without a marrow cavity, whereas only stromal cells derived from whole human bone marrow could form an ectopic bone with a hematopoietic bone marrow inside it [92]. They further identified CD146, also called melanoma cell adhesion molecule or MUC18, as a marker of the bone marrow stromal cells able to develop an ectopic bone containing a bone marrow upon transplantation. In the human bone marrow, CD146 identifies cells that do not express hematopoietic or endothelial cell-specific molecules. This population of $CD146^+$ cells contains the whole CFU-F activity *in vitro* and contains complete potential to engraft in immunodeficient mice and forms an ectopic bone marrow, whereas $CD146^-$ cells have none of these abilities [92]. CFU-F derived from single $CD146^+$ cells can form ectopic ossicles with bone marrow upon implantation into mice. Furthermore, only $CD146^+$ cells at the single cell level could generate CFU-F that could serially replate to form secondary CFU-F. This suggested that $CD146^+$ cells can self-renew, at least *in vitro*, although *in vivo* self-renewal to serially regenerate ossicles and bone marrow was not demonstrated [92]. Nevertheless, these data are the first to pinpoint human mesenchymal cells from the bone marrow able to develop an ectopic bone containing a hematopoietic bone marrow upon transplantation *in vivo* and self-renew *in vitro*, thus fulfilling many attributes of MSCs capable of reforming an HSC niche upon transplantation in a recipient mouse. Like $nestin^+$ MSCs identified in the mouse bone marrow [34,38], human $CD146^+$ MSCs in the human bone marrow are perivascular and project long processes within the hematopoietic bone marrow tissue [92,93]. These $CD146^+$ cells also express PDGFR [92], nestin and LEPR [93], the HSC supportive chemokine CXCL12 [93], and HSC-supportive cytokines such as Jagged-1 and angiopoietin-1 [92] (Table 32.3). Although $CD146^+$ MSCs support the formation of an ectopic bone with bone marrow, the initial study from Sacchetti *et al.* did not show whether $CD146^+$ cell were capable of supporting HSCs directly. This was recently demonstrated using co-cultures of sorted $CD146^+$ cells and human $CD34^+$ HSPCs sorted from cord blood. Indeed, only $CD146^+$ cells could support the survival and maintenance of human HSCs capable of reconstituting human hematopoiesis upon transplantation in immunodeficient mice. After 2 weeks of co-culture without additional exogenous growth factors, hematopoietic cells co-cultured with $CD146^+$ MSCs were still capable of engrafting and generating human B lymphocytes and monocytes upon transplantation in immunodeficient mice, whereas cells recovered from co-cultures of HSPCs with nonsorted plastic-adherent bone marrow stromal cells were incapable of hematopoietic reconstitution upon transplantation [93]. Therefore, taken together, these two studies demonstrate that $CD146^+$ cells isolated from the human bone marrow are MSCs capable of regenerating an ectopic bone containing a bone marrow with HSC niches and directly supporting HSC maintenance [92–94].

Of note is that perivascular $CD146^+$ cells are not exclusively found in the bone marrow as they have been identified in, and isolated from, human adipose tissue, skeletal muscle, pancreas, and placenta [93,95]. Similar to $CD146^+$ MSCs isolated from the bone marrow, these MSCs isolated from alternative tissues were also perivascular and could support the formation of ectopic bones containing a hematopoietic bone marrow upon transplantation into immunodeficient mice [93,95].

While the direct role of human $CD146^+$ MSCs in regenerating a human bone containing a hematopoietic bone marrow and directly supporting human HSCs is now well documented, the potential roles of alternative niche cells have not been extensively

studied in human bone marrow. In the case of endothelial cells there is indirect evidence that human endothelial cells may also support human HSCs. However, the evidence is indirect because it is very difficult to culture bone marrow endothelial cells. Human umbilical vein endothelial cells can be immortalized following transfection with the E4ORF1 gene of adenoviruses, which enables long-term culture of these endothelial cells in serum-free medium without addition of exogenous angiogenic factors [18]. Compared with monocultures of human cord blood $CD34^+$ HSPCs with purified recombinant human kit ligand, thrombopoietin, and Flt-3 ligand, co-cultures of human HSPCs with this cytokine supplement together with immortalized human endothelial cells supported a much greater expansion of phenotypic human HSCs ($Lin^-$ $CD34^+$ $CD45RA^-$ $CD49f^+$) and greater expansion of HSCs able to reconstitute human hematopoiesis upon transplantation into immunodeficient mice [18], demonstrating that immortalized human endothelial cells can directly support human HSCs. The mechanisms by which immortalized human endothelial cells support HSCs has, however, not been reported.

## 32.9 Conclusions

Recent experimental evidence demonstrates that clonal multipotent MSCs in the adult bone marrow directly support HSCs in mice and humans and are capable of reforming a bone containing a functional hematopoietic bone marrow when transplanted onto an appropriate scaffold to support ectopic bone formation. Although the ontogeny of MSCs in the bone marrow is complex and may undergo several waves [50,51], MSCs in the adult bone marrow are perivascular, express nestin, and produce HSC-supportive chemokines and growth factors in both humans and mice (Table 32.3). It is also clear that MSCs are not alone in regulating HSCs in bone marrow niches but act in concert with endothelial cells, and in the mouse with megakaryocytes, Schwann cells, and macrophages (Figure 32.2). Elucidation of the many mechanisms deployed by MSCs and other niche cells to regulate HSCs in the bone marrow enables the design of novel therapeutic strategies specifically targeting these HSC–niche interactions to improve therapeutic outcomes. Several of these "nichotherapies" already exist [96]. For instance, G-CSF mobilizes HSCs from the bone marrow into the circulation by inhibiting macrophages that regulate HSC niches, causing the downregulation of CXCL12 and VCAM-1 [88,90,91], two key proteins expressed by mesenchymal progenitor cells and endothelial cells to retain HSCs within the bone marrow. G-CSF also causes a reduction of oxygen availability in the bone marrow, which contributes to HSC mobilization [97,98]. These discoveries have enabled the development of drugs targeting these niche interactions (also called nichotherapies), such as CXCR4 inhibitors [99–101] and prolylhydoxylase inhibitors [98] to further boost HSC mobilization for transplantation, particularly in patients undergoing autologous transplantation after prior successive rounds of chemotherapy that often compromise subsequent HSC mobilization and collection for transplantation [102]. Furthermore, it has recently emerged that leukemia-initiating cells, which represent a small subset of leukemia cells that self-renew and clonally reinitiate the leukemia [103,104], hijack HSC niches in the leukemic bone marrow where they are sheltered and protected from the cytotoxic effects of chemotherapy [105,106]. The poor response of leukemia-initiating cells to cytoxic chemotherapy and tyrosine kinase inhibitors can lead to recurrence of the leukemia once the chemotherapy regimen has ended. Hence, the concept of dislodging chemotherapy-resistant leukemia-initiating cells from their chemoprotective niches by mobilizing them with CXCR4 antagonists prior to chemotherapy in order to sensitize them to chemotherapies has emerged. This approach has been successfully employed in mice to sensitize acute myeloid leukemia-initiating cells to the chemotherapeutic agents cytosine arabinoside and doxorubicin [107,108], reduce leukemia burden, and increase mouse survival [107,108]. Likewise, L-ribose-based L-RNA aptamers (called spiegelmers because L-ribose L-RNA are mirror-image enantiomers of naturally occurring D-RNA based on D-ribose – *spiegel* is German for mirror) specifically block CXCL12 and have been reported to mobilize and chemosentitize mouse and human multiple myeloma cells *in vivo* [109]. These encouraging results in the mouse have prompted the initiation of approximately a dozen clinical trials to test the efficacy of CXCR4 inhibitors in increasing the sensitivity of malignant cells to chemotherapy treatment.

## 33.1 Introduction to the innate immune system

The innate immune system is broadly present in all organisms, including both plant and animal species. Also known as the nonspecific immune system, components of innate immunity are responsible for the initial immunological response toward pathogens and foreign material, which is usually in the form of an immediate and antigen-nonspecific response. In contrast to the evolutionarily younger adaptive immune system, this "first line" defense system does not confer long-lasting, protective immunity for the host. However, specific cell types within the innate immune system are responsible for activation of the adaptive immune system, and thus cells of this system also act as the bridge to link the two arms of the immune response together.

Despite the universality of the innate immune system, research on mesenchymal stem/stromal cell (MSC) interactions with this more ancient arm of the immune system has lagged behind that of MSCs and adaptive immune cells. Moreover, the largest proportion of reports of innate immune interactions with MSCs centers on dendritic cells (DCs), whose effector outcomes affect the adaptive immune system, especially T cell responses. Increasingly, however, targeting of the innate immune system has yielded new and effective treatments toward inflammatory diseases and conditions, thus shifting interest into further understanding of the myriad of leukocytes within this branch of the immune system [1]. It is anticipated, therefore, that insights into MSC interactions with the wide range of innate immune cells will be rapidly forthcoming.

A schema illustrating the immunomodulatory mechanisms of MSCs on the innate immune system is shown in Figure 33.1.

## 33.2 Interactions with dendritic cells

DCs are the quintessential antigen-presenting cell (APC) and considered the sentinels of the immune system. Derived from both myeloid and lymphoid precursors, DCs phagocytose pathogens and then present components of these pathogens as antigens to T lymphocytes, which then leads to lymphocyte activation. These key regulators also secrete cytokines to activate natural killer (NK) lymphocytes. Thus, DCs are messengers of the immune system and activate both adaptive and innate immune responses. Even more remarkably, DCs can fine-tune the immune response from being robustly immunogenic to being frankly tolerogenic. This depends on many parameters, including their own differentiation status [2]. Given the crucial role of DCs in the immune system, it is not surprising that the majority of publications of MSC interactions with innate leukocytes are focused on these leukocytes.

In general, reports show that MSCs inhibit the immunostimulatory capacity of DCs, inducing DCs into more tolerogenic phenotypes either by blocking differentiation or through other mechanisms. Co-culture of MSCs with monocytes, the precursors of DCs in the peripheral blood, or of bone marrow hematopoietic stem cells in the presences of cytokines and factors to induce differentiation into DCs, generally appears to halt the process, so that DCs remain in a more immature and immunoregulatory state [3–5]. DCs co-cultured with MSCs show reduced surface expression of a number of maturation markers, including CD83, HLA-DR, CD1a, CD11c, and the costimulatory molecules CD80 and CD86 [3,6–9], and may even generate novel populations of regulatory DCs [7]. Moreover, MSCs modulate DCs to decrease secretion of many proinflammatory cytokines, including TNF-α, IFN-γ, and IL-12 [3,8–11], while increasing secretion of immunomodulatory cytokines such as IL-10 [8,9,11,12]. Interestingly, DCs co-cultured with MSCs show enhanced endocytic ability, which paradoxically does not translate to increased functional capacity [6,7,9]. The effects of MSCs on DCs appear to be largely mediated by MSC-secreted paracrine factors [4,13], the most consistent being $PGE_2$ [13,14] and IL-6 [8,14,15], but there is some evidence that cell–cell contact may at least play a partial role in these processes [5,7,15]. The ability of DCs to home to regional lymph nodes is also decreased by the administration of MSCs as demonstrated in *in vivo* studies. In a mouse model of acute graft-versus-host disease, infusion of MSCs delayed disease onset by decreasing the ability of DCs to home to secondary lymphoid organs [16].

Given the known role of DCs in T lymphocyte activation, it is not surprising that at least some of the immunomodulatory effects of MSCs on T cells appear to require or at least involve DCs [17]. A number of reports show that MSC suppression of T cell proliferation is through the modulation of mature DCs by MSCs to more immature tolerogenic phenotypes, thereby decreasing the capacity to activate T cells [3,4,8,9,11,13]. This results in the alteration of the cytokine milieu from a Th1 into a Th2 axis [6,8], as well as the expansion of regulatory T cells (Tregs), a population of immunomodulatory $CD4^+$ T lymphocytes [8,11,18]. These *in vitro* findings are corroborated by *in vivo* studies in which infusion of MSCs affects the capacity of DCs to prime T cells by blocking DC homing to draining lymph nodes [19].

Remarkably, adult bone marrow MSCs have been shown to harbor functions similar to the antigen presentation function of DCs. It has been shown that IFN-γ-stimulated bone marrow MSCs can present exogenous antigens through the upregulation of surface major histocompatibility class (MHC) II molecules, which then induce $CD4^+$ T cell activation [20–22]. Moreover, adult bone marrow MSCs can also cross-present exogenous antigens to activate $CD8^+$ T cells [23,24]. These results differ from those of fetal-source MSCs, which express low or limited levels of MHC II molecules even after IFN-γ stimulation, rendering these MSCs poor APCs [25–27].

Increasingly more reports demonstrate that MSCs express high levels of toll-like receptors (TLRs), including TLR1, TLR3, TLR4, and TLR5. Highly expressed on APCs, TLRs are receptors that recognize conserved pathogen-derived components found on microbial pathogens. Triggering of TLR3 (which binds double-stranded RNA) and TLR4 (which binds lipopolysaccharide) on bone marrow and nasal MSCs has been reported to lead to a more proinflammatory phenotype inducing production of cytokines such as IL-1β, IL-6, and IL-8 [23,28–32]. Conversely, others have reported that triggering of TLR on bone marrow MSCs actually increases downmodulation of immunity through the induction of indoleamine 3,4-dioxygenase-1 (IDO1) and production of immunosuppressive kynurenines [33]. Even more interesting are reports showing induction of either a proinflammatory or an immunosuppressive phenotype in bone marrow and umbilical cord MSCs depending on the specific TLR stimulated [34–37]. These conflicting findings may be due to tissue-specific differences of MSCs [38], heterogeneity due to differences in isolation methods [39], and differences in

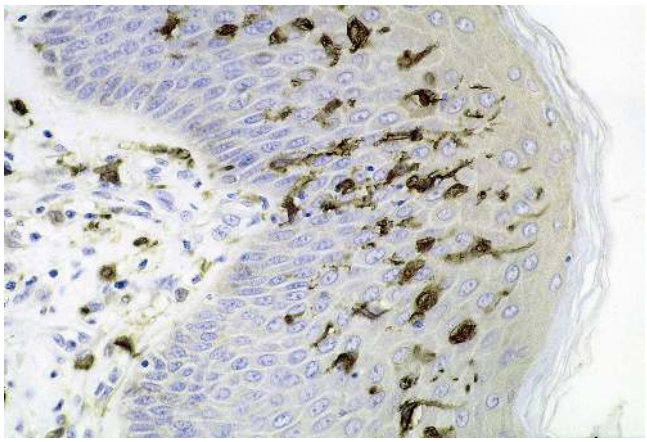

**Figure 33.2** Section of skin showing large numbers of dendritic (Langerhans) cells stained with S100 immunoperoxidase stain in the epidermis of a person with *Mycobacterium ulcerans* infection. *M. ulcerans* is a slow-growing mycobacterium that classically infects the skin and subcutaneous tissues, giving rise to indolent nonulcerated nodules and plaques and ulcerated lesions. The latter are known as Buruli or Bairnsdale ulcers. The Langerhans cell is named after Paul Langerhans, a German physician and anatomist, who discovered the cells at the age of 21 while he was a medical student. (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:Dendritic_cells.jpg#/media/File:Dendritic_cells.jpg. (See color plate section.)

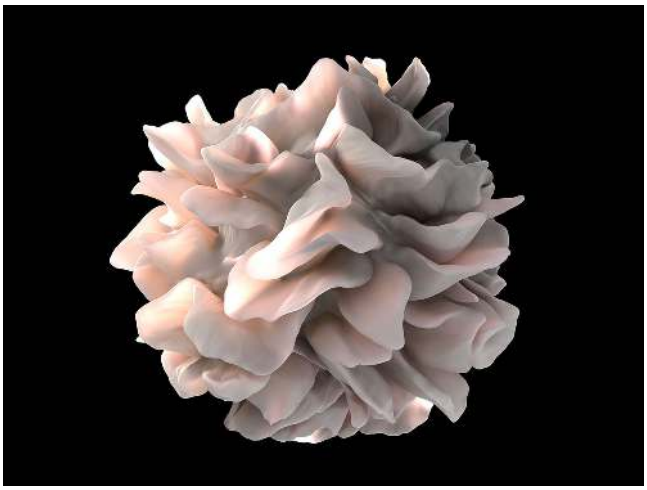

**Figure 33.3** Ion-abrasion scanning electron micrograph of a DC. Artistic rendering of the surface of a human dendritic cell illustrating the unexpected discovery of sheet-like processes that fold back onto the membrane surface. When exposed to viruses, for example, these sheets entrap them in the vicinity and focus them to contact zones with T cells targeted for infection. These studies were carried out using ion-abrasion scanning electron microscopy, a new technology developed and applied for three-dimensional cellular imaging. (See color plate section.) *Source:* dendritic cell revealed by National Institutes of Health (NIH). (See color plate section.)

the stimulator used, including dose and timing. More comparative studies on tissue-specific MSCs, better standardization of MSCs, and more concise experimental descriptions are necessary for a clear understanding of the role of TLRs in MSC immunomodulation and biology.

Figure 33.2 shows an infiltrate of DCs in the skin (where they are known as Langerhans cells) in a person with *Mycobacterium ulcerans* infection. Figure 33.3 shows the astonishing appearance of DCs obtained by ion-abrasion scanning electron microscopy.

## 33.3 Interactions with monocytes, macrophages, and immature myeloid cells

Approximately 10–15% of circulating leukocytes in human peripheral blood consist of monoyctes. Best known for being the precursor cells for macrophages and DCs, the effector function of monocytes have only recently been reported [40]. Correspondingly, while there are relatively more reports on interactions of MSCs with monocyte progenitors of DCs and macrophages, reports of monocyte and MSC interactions have lagged behind. One of the first reports in the MSC immunomodulation literature to mention monocyte interactions was with regard to T cell responses, in which monocytes were found to secrete IL-1β and induce MSCs to produce TGF-β, thereby suppressing T cell responses [41]. Further reports confirmed that monocytes often act as an intermediary in MSC modulation of T cell responses [42,43]. Interactions between MSCs and monocytes appear to be mediated by soluble factors, including MSC-secreted HGF, inducing monocytes into a tolerogenic phenotype that then results in the modulation of both $CD8^+$ T cell responses as well as $CD4^+$ T cell responses, thus altering the cytokine milieu from a Th1 to a Th2 axis [43,44]. MSC-secreted HGF also contributes to the expansion of myeloid-derived suppressor cells (MDSCs) [45], which are a population of immature myeloid cells critical in providing an immunomodulatory environment for cancer growth, including suppressing effector T cell responses and expanding Tregs [46–48]. Interestingly, early reports studying the role of MSC-secreted HGF, which is also highly secreted by other stromal cells and by many cancers [49], yielded mixed results with regard to T cell interactions [50,51]. The demonstration of MET expression (the receptor for HGF) on myeloid cells but not T lymphocytes [44,45,52] could explain the inconsistent data with regard to immunomodulation of T cells, as well as highlighting the complex interplay that exists between leukocyte populations.

Along with DCs, macrophages are one of the two progenies of monocytes. The prototypical phagocyte, macrophages are found throughout the tissues of the body and are important as part of the initial defense of the immune system. These leukocytes can also recruit adaptive immune cells, such as T lymphocytes, through secretion of cytokines as well as present antigen, similar to DCs. Like T cells and DCs, it is now evident that macrophages can exist in a more proinflammatory phenotype, termed M1 macrophages, or in a more immunomodulatory phenotype, termed M2 macrophages [40]. The importance of the M2 phenotype is increasingly appreciated, especially in the context

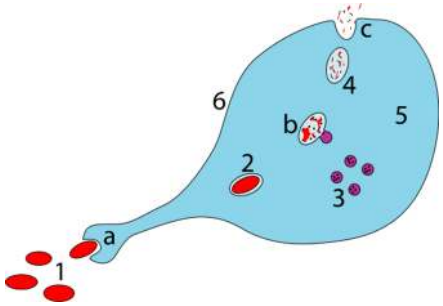

**Figure 33.4** Steps of a macrophage ingesting a pathogen. (a) Ingestion through phagocytosis, a phagosome is formed. (b) The fusion of lysosomes with the phagosome creates a phagolysosome; the pathogen is broken down by enzymes. (c) Waste material is expelled or assimilated (the latter not pictured). Parts: (1) pathogens; (2) phagosome; (3) lysosomes; (4) waste material; (5) cytoplasm; (6) cell membrane. *Source:* http://commons.wikimedia.org/wiki/File:Phagocytosis_ZP.svg#/media/File:Phagocytosis_ZP.svg.

of solid cancers, since tumor-associated macrophages contribute to tumor growth and immune evasion [53]. One of the earliest reports on MSC–macrophage interactions showed that $PGE_2$ secreted by MSCs modulates macrophages from a proinflammatory phenotype to a more immunomodulatory phenotype in a mouse model of sepsis [54]. Subsequent reports generally show that MSCs modulate macrophages into an immunomodulatory M2 phenotype through both cell–cell contact and paracrine mechanisms [55–57]. A recent report demonstrated that MSCs can inhibit activation in macrophages of the NOD-like receptor family pyrin domain containing 3 inflammasome by secretion of stanniocalcin in response to lipopolysaccharide-activated macrophages [58]. Macrophages can also modulate MSC phenotype. Using synovium from patients with osteoarthritis containing both M1 and M2 macrophages, the chondrogenic ability of MSCs can be altered by the M1 macrophage [59]. Furthermore, MSCs co-cultured with conditioned medium of proinflammatory macrophages acquire a proinflammatory phenotype, increasing IL-6 and CXCL10 secretion [60]. These reports collectively demonstrate that MSCs modulate diverse populations of myeloid and monocytic leukocytes. With increasing evidence demonstrating the important roles of these leukocytes in inflammation and cancer, it is anticipated that MSC interactions with these innate leukocyte populations will be further clarified.

Figure 33.4 shows a cartoon of the mechanism by which macrophages ingest pathogens.

## 33.4 Interactions with natural killer lymphocytes

NK cells are an important component of the innate immune system, targeting virus-infected cells and tumor cells. With few exceptions, NK cells comprise the bulk of innate leukocytes derived from the lymphoid progenitor. These innate lymphocytes are highly cytotoxic and secrete large amounts of proinflammatory cytokines, such as TNF-α and IFN-γ, recognizing and responding to MHC molecules signifying "self" versus "non-self", rather than specific antigens which T and B lymphocytes of the adaptive immune system recognize [61]. MSCs appear to be able to suppress the proliferation and cytokine production of NK cells, as well as modulate NK cytolytic functions [62–64]. While stimulated NK cells can efficiently lyse autologous and allogeneic MSCs, MSCs are still more resistant to NK cytolysis than other cell types [25,63,65,66], and this resistance to NK cytolysis can be further augmented by either stimulation of MSCs by IFN-γ and upregulation of surface expression of MHC class I molecules on MSCs [65] or by TLR3 stimulation [67]. The suppressive effects of MSCs on NK cells are detrimental with regard to tumor cytolysis [68,69] and result in protection of cancer cells in both *in vitro* and *in vivo* studies [70,71].

The inhibitory effects of MSCs on NK cells involve both cell–cell contact and secreted paracrine factors, including $PGE_2$, TGF-β, and IDO [63,64]. It has been found that constitutive expression of serine protease inhibitor 9 by MSCs was involved in MSC suppression of NK cytolysis [72]. In terms of cell–cell contact mechanisms, NK cells have a large repertoire of activating and inhibitory surface receptors, and the overall expression levels of all of these receptors determine the final phenotype of the NK cells: to be more cytotoxic or secretory [61]. MSCs suppress NK activity through interacting with a number of NK receptors, including downregulation of activating receptors NKp30, NKp46, NKp44, and most consistently NKG2D [64,69,73] as well as upregulation of the inhibitor receptor, KIR [74].

The nonclassical MHC class I molecule HLA-G, in both its secreted and surface isoforms, has a distinct role in MSC suppression of NK functions [74,75]. First identified in choriocarcinoma and migratory trophoblasts, HLA-G is thought to confer protective effects for the fetus from the maternal immune system, including directly suppressing maternal NK cytotoxicity [76]. HLA-G can exist in several forms, with the best characterized being one of the four complete transmembrane forms, HLA-G1, the predominant *in vivo* form (the others being HLA-G2, HLA-G3, and HLA-G4) and one of the three soluble truncated forms, HLA-G5 (the others being HLA-G6 and HLA-G7). Unlike most MHC class I molecules, HLA-G has very low polymorphism and its expression in the adult is highly restricted. However, in certain pathologic states, including cancer and inflammatory diseases, expression of sHLA-G has been observed [77]. The receptors for HLA-G include immunoglobulin-like transcript (ILT)-2, ILT-4, and CD94 and are found on a number of leukocytes, most prominently on NK cells [78]. Interestingly, embryonic and fetal MSCs can express HLA-G as a surface protein constitutively, and this ability has been speculated to be due to the earlier developmental stage of these cells [73,79]. Compared with adult bone marrow MSCs, fetal MSCs have a different expression profile of MHC molecules and responsiveness to IFN-γ stimulation [26]. Placental MSCs were

shown to preferentially upregulate surface HLA-G but not HLA-DR (an MHC class II molecule) after IFN-γ stimulation in contrast to adult bone marrow MSCs [74]. In embryonic and fetal MSCs, surface HLA-G expression appears to play a role in mediating modulation of NK responses [73,74]. There is still a role for HLA-G in adult bone marrow MSC suppression of NK cells, but it is in the form of sHLA-G rather than surface HLA-G [75]. The placenta is known to have unique immunomodulatory interactions with maternal uterine NK cells, which have a different effector profile than peripheral blood NK cells [80]. Thus, interactions of fetal MSCs with NK cells may differ from those of adult MSCs. Both fetal and adult gestational products are good sources of MSCs, and NK interactions may be quite varied depending on the developmental stage of the MSCs used. Mechanisms found for MSC immunomodulation of NK cells resemble those utilized by placental trophoblasts [81]. Research in this area of MSC-immune cell modulation will likely not only have clinical implications, but may also shed light on maternal–fetal immunodulation.

## 33.5 Interactions with neutrophils, other granulocytes, and mast cells

Neutrophils are the most abundant leukocyte in the human immune system [82]. A major type of granulocyte and an essential component of the innate immune system, these abundant but short-lived cells are the first leukocytes to arrive at sites of inflammation, especially if bacterial pathogens are involved. Along with the basophil granulocytes and eosinophil granulocytes, neutrophils are also known as polymorphonuclear cells due to their multilobed nucleus. Given the abundance and critical role of neutrophils in the acute inflammatory response, it is surprising that there are so few reports of MSC interactions with this leukocyte. In the few reports using co-culture of MSCs with freshly isolated human neutrophils, it appears that diverse sources of MSCs, including bone marrow, adipose tissue, and placenta, can suppress neutrophil apoptosis or prolong its viability [83,84] with mechanisms involving MSC-secreted IL-6 [85,86]. However, the effects of MSCs on functional and antibacterial activities of neutrophils, including phagocytosis and respiratory burst activity, appear to vary depending on the tissue source of MSCs utilized in the studies. Neutrophil migration and proinflammatory cytokine expression is enhanced after co-culture with salivary gland MSCs [87], and antibacterial activity, including phagocytosis, is enhanced after co-culture with either bone marrow or salivary gland MSCs [83,88] but not placental MSCs [85]. In murine models of bacteria-mediated lung injury, addition of MSCs reduced neutrophil influx and numbers, resulting in a significant decrease of inflammation and injury [89,90]. Neutrophils develop in the bone marrow from the common myeloid progenitor. However, only a few reports so far have begun to assess the niche/microenvironment aspect of MSC–neutrophil interactions [86,91]. Studies of the role of MSCs in the *in vivo* niche for neutrophil development can be anticipated to yield important insights into the physiological role of MSCs.

Reports of MSC interactions with other granulocytes (eosinophils and basophils) and with mast cells are scarce. These three types of innate immune system cells are prominent in allergic diseases, such as asthma. These leukocytes are mentioned in animal studies evaluating MSC treatment for asthma. It appears that MSC infusion in models of allergic airway inflammation generally results in decreased influx and degranulation of granulocytes and mast cells, leading to suppression of symptoms [92–94]. Decreased mast cell degranulation was also noted in a mouse model of contact dermatitis after treatment with MSCs isolated from the gingiva [95]. As shown by these few studies, the overall effect of MSCs on granulocytes and mast cells, and on allergic reactions in general, appears to be suppressive. Allergic responses are well known to be mediated by Th2 lymphocytes, and an important outcome of MSC immunomodulation is to induce Th1 lymphocytes into a Th2 fate [43,44]. Yet surprisingly, these *in vivo* studies of asthma models do not show exacerbation of symptoms after MSC treatment. The alleviation of Th2 allergic responses by MSCs in asthma may be due to the strong capacity of MSCs to modulate other aspects of inflammation in these allergic diseases, including increasing Treg numbers and the suppression of mast cell responses, known in asthma to be the most critical and dominant cell on lymphocyte/Th2 responses [96]. This could explain the numerous and generally efficacious reports of MSC application in animal models of asthma/allergic airway disease and in studies using asthma patient samples [97–101] (and see Chapters 39 and 53). A phase 1b study using intravenous infusions of human placenta MSCs in people with idiopathic pulmonary fibrosis was shown to be safe, demonstrating that MSCs, which are concentrated in the lungs immediately after intravenous infusion, do not appear to exacerbate underlying lung disease [102]. Clearly, it will be interesting for future studies to clarify the mechanisms by which MSCs modulate mast cell and granulocyte function for effective application in allergic diseases in general.

## 33.6 Interactions with complement

Unique to the innate immune system is the complement system, which is a noncellular component of the immune system. This system consists of proteins and glycoproteins mainly synthesized by the liver, with significant amounts produced by tissue macrophages, blood monocytes, and epithelial cells of the genitourinal tract and gastrointestinal tract. The functions of the complement system are to opsonize and enhance phagocytosis of antigens, to aid in chemotaxis of macrophages and neutrophils, to aid in cell lysis and membrane rupture of foreign cells, and to agglutinate pathogens. While studies on MSC–complement interactions are very scarce, findings so far demonstrate that MSCs inhibit complement activation [103,104]. MSCs can

be lysed by complement as well [105,106], and cryopreservation and increased passaging worsens complement-mediated elimination of MSCs, which would decrease therapeutic efficacy [107]. Given the varied interactions of MSCs with specific leukocyte populations, research on MSC–complement interactions is expected to be complex as well, and so reaching a consensus is premature at this time.

## 34.1 Introduction to the adaptive immune system

The adaptive arm of the immune system is comprised of T and B lymphocytes. In contrast to the evolutionarily older innate immune system, the adaptive immune system is highly specific and able to confer immunological memory, which allows for an enhanced response when the same pathogen is encountered again. This is achieved through the ability of T and B lymphocytes to recognize an enormous array of highly specific antigens, another advantage compared with the innate immune response. However, the adaptive immune response is slower than innate leukocyte responses. These differences between the two arms of the immune system are clearly complementary to each other, and complete the powerful armamentarium that humans and other mammals have against pathogens and disease. A schema of the immunomodulatory mechanisms of mesenchymal stromal cells (MSCs) on lymphocytes of the adaptive immune system is shown in Figure 34.1.

## 34.2 Interactions with T lymphocytes

T lymphocytes are responsible for the cell-mediated responses of the adaptive immune system. The importance of this class of leukocytes is clearly demonstrated by the wide range and types of diseases due to abnormalities in this area, including autoimmune diseases, allergies, and some immunodeficiencies. Moreover, recipient and donor cytotoxic $CD8^+$ T lymphocytes play a major role in the rejection of transplanted organs and in the mediation of graft-versus-host-disease respectively. On the other hand, immunomodulatory T lymphocytes have been found in solid tumors and contribute to the immunosuppressive niche. It is no surprise, then, that of all the leukocyte subpopulations, MSC interactions with T lymphocytes are the best studied to date. Current understanding of MSC interactions with T lymphocytes demonstrates that MSCs can strongly suppress effector T cell functions [1,2]. The evidence is best demonstrated for adult bone-marrow-derived MSCs (BM-MSCs), but fetal source and adipose-tissue MSCs also appear to harbor similar properties [3,4]. Concomitantly, and a nearly universal finding in MSC–T-cell studies, is the resulting decrease in secretion of proinflammatory cytokines, most consistently being tumor necrosis factor-α and IFN-γ, which are also considered to be part of the Th1 response [5–7]. Most of these studies examined T effector cells in general, encompassing both $CD4^+$ helper and $CD8^+$ cytotoxic T cells, but a few reports have focused on $CD8^+$ cytotoxic T cells and found that MSCs efficiently suppress the proliferation and cytolytic potential of these T cells as well [6,8–15]. MSC suppression of T lymphocyte proliferation has been demonstrated to be due to cell cycle arrest of activated T cells in the in the $G_0/G_1$ phase [16], and not involving apoptosis [15,17,18]. However, a few reports have shown that MSCs preferentially induce apoptosis of activated T cell subpopulations [19], and a more recent study in mouse models

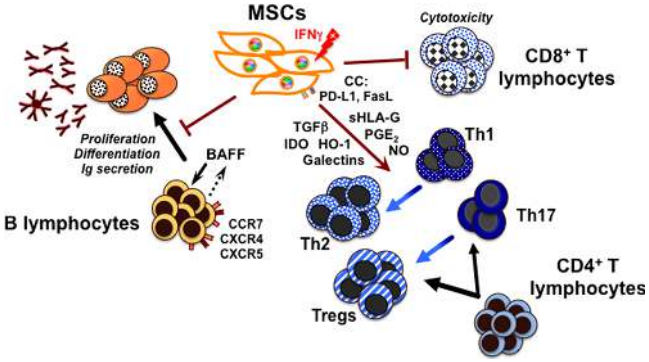

**Figure 34.1** Immunomodulatory mechanisms of MSCs on lymphocytes of the adaptive immune system. IFN-γ:, interferon-γ; Ig: immunoglobulin; BAFF: B-cell activating factor (dotted arrow indicates secretion by B lymphocytes); CC: cell contact; PD-L1: programmed death-ligand 1; FasL: Fas ligand; TGF-β: transforming growth factor-β; IDO: indoleamine 2,3-dioxyenase; HO-1: heme oxygenase-1; $PGE_2$: prostaglandin $E_2$; sHLA-G: soluble human leukocyte antigen-G; NO: nitric oxide; Th: T helper; Tregs: regulatory T cells.

demonstrated that systemic infusion of allogeneic murine BM-MSCs induced transient T cell apoptosis via FasL. The authors found that the presence of FasL on MSCs was critical to its therapeutic efficacy in mouse disease models of systemic sclerosis (scleroderma) and colitis [20]. Downregulation of the Fas receptor/FasL axis on T cells by MSCs has also been shown to prolong the survival of unstimulated T cells in a quiescent state [21]. Interestingly, a recent study found that telomerase can induce upregulation of FasL in MSCs, which affects immunomodulatory properties [22]. Despite mechanistic differences found for the role of the Fas/FasL axis in MSC-mediated suppression of T lymphocytes, the overall effect appears to be one of immunomodulation and T cell quiescence/nonproliferation.

The interactions of MSCs with T cells can modulate the fate of these lymphocytes, and reports are most consistent in showing MSC modulation of $CD4^+$ T cells toward Tregs [23,24]. Tregs, noted as being $CD4^+$ $CD25^{high}$ cells, are a population of immunomodulatory lymphocytes that play an important role in the induction of peripheral tolerance and the inhibition of proinflammatory immune responses [25]. Tregs are known to secrete interleukin (IL)-10 and TGF-β (two immunomodulatory factors), and lack of this $CD4^+$ population results in the development of severe, multiple organ autoimmune diseases in a number of mouse models [26,27]. A critical transcription factor involved in the differentiation of $CD4^+$ naive T cells to Tregs is $Foxp3^+$, and most studies show that co-culture of MSCs with peripheral blood mononuclear cells or with $CD4^+$ cells can induce the expansion of functional $Foxp3^+$ $CD4^+$ $CD25^{high}$ Tregs [18,28–34]. MSCs have also been shown in a few studies to induce a subpopulation of Tregs, the type 1 Tregs (Tr1), which secrete IFN-γ and IL-10 [35,36]. In studies with animal disease models of autoimmune disease or organ transplantation, the induction of Tregs by MSCs is clearly involved in mediating therapeutic responses [33,37–39]. Thus, both *in vitro* and *in vivo* data support the capacity of MSCs to induce Tregs and the critical role of this effect in ameliorating disease.

One population of $CD4^+$ T lymphocytes that has become prominent recently is the IL-17A-secreting T cell population [40]. Also known as Th17 cells, this T helper cell subpopulation is important in mediating host responses toward microbial infections as well as participating in the pathogenesis of many autoimmune and chronic inflammatory diseases that had long been believed to be caused by Th1 cells [41]. Th17 lineages are also linked to Tregs, and it is currently believed that one lineage is chosen over another to maintain immune homeostasis [42]. With the majority of studies demonstrating the induction of Tregs by MSCs, it should come as no surprise that many reports show that MSCs suppress the formation of Th17 cells both in *in vitro* studies and in *in vivo* disease models [23,43–47]. In fact, a study using a *Helicobacter pylori* model of gastric cancer in mice found that MSC modulation of $CD4^+$ cells away from Th17 cells and toward Tregs may create a permissive environment for the development of gastric cancer [48]. However, some studies have found that MSCs actually enhance Th17 responses [49–51]. This may be dependent on the specific molecules expressed by MSCs [52]. Given the importance of the Th17 population in the pathogenesis of many diseases, further investigation is warranted to elucidate the complexities of MSC interactions with this critical $CD4^+$ subpopulation.

Numerous studies have attempted to delineate whether MSC–T-cell interactions are mediated through cell–cell contact or by secretion of factors. Cell contact appears to play a partial role [30,53,54], but specific ligand–receptor interaction has been surprisingly difficult to discern with the exception of the programmed cell death (PD) PD-1/PD-L1 pathway [47,55,56]. This may be due to the overwhelming effects of MSC paracrine factors on T cell function [3,57]. One of the first paracrine molecules found to mediate MSC immunomodulatory effects on T cells was TGF-β, itself an immunomodulatory molecule [8,17,18,30]. MSCs can also induce leukocytes to express TGF-β, further enhancing the overall immunosuppressive environment [15,56,58,59]. Many studies have also demonstrated the involvement of other MSC-secreted factors, including IDO [1,8,19,36,60,61], $PGE_2$ [8,23,30,62], sHLA-G5 [28,63], HO-1 [35,64], NO [65–67], and various galectins [68–71]. MSC secretion of these many immunomodulatory molecules may be constitutive, but clearly is enhanced by the proinflammatory cytokine IFN-γ [1,13,18,60,69]. This may be one explanation for the strong capacity of MSCs to be therapeutic in highly inflammatory environments, such as graft-versus-host-disease [72].

Despite the overwhelming number of studies showing MSC downmodulation of T cell effector functions, there are some reports showing enhancement of T cell responses [73]. One important reason for this contrasting study may be due to differences in data obtained from *in vitro* versus *in vivo* settings [74,75]. Another point to consider is the subtle phenotypic

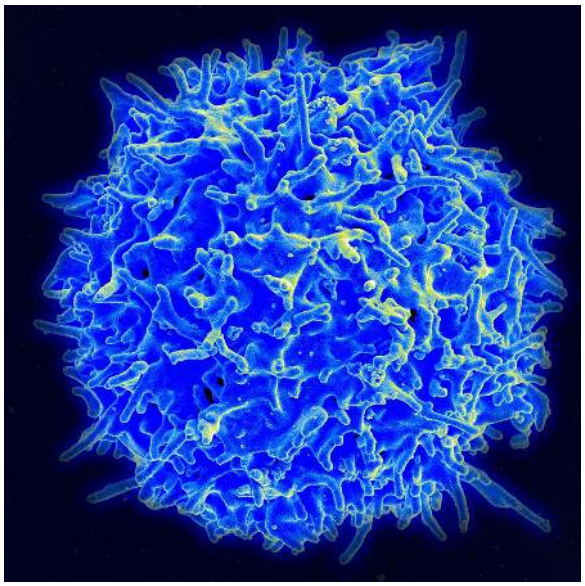

**Figure 34.2** Scanning electron micrograph of a human T cell of a healthy donor. *Source*: Healthy Human T Cell by NIAID/NIH.

variations due to the many methods available for isolation of MSCs [76]. An important caveat is that nearly all reported *in vitro* studies have used healthy donor T cells. In studies using patient T cells, decreased responsiveness can be observed [77,78]. This is a critical point to keep in mind and could be one reason why clinical trials using MSCs for immune-related diseases have not been as positive as might have been presumed [79]. Given the importance of the T lymphocyte in immune diseases and related conditions, it is crucial to establish a clear mechanistic understanding of MSC–T-cell interactions to obtain efficaceous clinical applications.

A scanning electomicraph of a normal human T cell is shown in Figure 34.2.

## 34.3 Interactions with B lymphocytes

B lymphocytes are responsible for the humoral response of the adaptive immune system. In contrast to T lymphocytes, which mediate cell-directed effector functions, B cells secrete proteins known as antibodies with high specificity for particular antigens. These lymphocytes can also be APCs, able to recognize cognate antigens in their native form, unlike T cells, which recognize antigens only after processing by an APC. Abnormalities in B cells result in a complete or partial absence of a particular class of antibodies, one or more immunoglobulin isotypes, with symptoms being recurrent infections with specific microorganisms.

One of the first reports on MSC–B-cell interactions demonstrated that MSCs, through paracrine factors, reduced B cell production of IgM, IgG, and IgA and affected B cell chemotaxis by downregulation of CXCR4, CXCR5, and CCR7 on B cells [80]. However, one report found that MSCs increased B cell production of IgG [81]. More consistently, most studies have shown that MSCs inhibit B cell differentiation, delaying maturation [80]. B cell proliferation was inhibited by MSCs through cell cycle arrest at the $G_0/G_1$ phase of the cell cycle and not through the induction of apoptosis [80]. MSC inhibition of B cell proliferation, differentiation, and antibody secretion has also been reported to require interactions with T cells first, involving both cell contact and secreted factors, as well as requiring both $CD4^+$ and $CD8^+$ T cells [82]. As with T cells, IFN-γ can also enhance MSC suppression of B cell function [83].

There are some convincing *in vivo* murine and human patient data showing suppressive effects of MSCs on B cell functions, and this involved decreasing B cell expression of BAFF, a potent B cell activator, by MSCs in a murine model of lupus nephritis [84] and in patients with chronic graft-versus-host disease who responded to the administration of MSCs [85].

B cells develop in the bone marrow and, as such, should have many interactions with BM-MSCs. It is therefore surprising that the number of studies on MSC–B-cell interactions lags far behind that of interactions with T cells. This may be due to the fact that pathologies in T cell biology dominate clinical disease entities. Moreover, developmental interactions may not be captured with *in vitro* studies (the predominant type of MSC–immune cell reports) and likely require *in vivo* modeling or complex *in vitro* systems [86,87]. A study using a genetically manipulated mouse model demonstrated that CCAAT/enhancer-binding protein β expression by BM-MSCs is essential in early B cell development [88]. It is anticipated that studies using such genetic *in vivo* models or complex *in vitro* models will yield further insights into MSC–B-lymphocyte niche interactions.

## 35.1 Effect of acute organ injury on the proliferative and functional activity of mesenchymal stromal cells

Acute organ injury markedly alters the microenvironment, which affects the proliferation, differentiation, and secretory activity of mesenchymal stromal cells (MSCs).

### 35.1.1 The effect of catecholamines on mesenchymal stromal cells

The pain accompanying acute organ injury activates the neuroendocrine system and, first and foremost, the hypophyseal portal system. This system is a system of blood vessels in the brain that connects the hypothalamus with the anterior pituitary. Its main function is the transport and exchange of hormones to allow fast communication between both glands. The *fenestrae* structure of the hypophyseal portal system needs only a small amount of hormones to allow a rapid exchange between the hypothalamus and the pituitary gland in order to stimulate an effect in the respective target organs in the body. Release of catecholamines directly affects

* The order of the authors' names indicates the relative contribution of each author to each section.

MSCs by increasing the level of DNA synthesis through the activation of α-1 adrenergic receptors [1]. It has been demonstrated that physiological doses of epinephrine (adrenaline) and norepinephrine (noradrenaline) augment MSC proliferation *in vitro* [2]. However, concentrations of these stress hormones increase abruptly in acute organ injury, resulting in almost complete inhibition of MSC colony growth to the level of 4–5% of normal [2]. We suggest that this inhibition of MSC proliferation may be induced by an acute increase in interleukin (IL)-6 levels, the synthesis of which is increased as the catecholamine level rises.

Dasu *et al.* demonstrated that the pathways of activation of adrenoreceptors and toll-like receptors (TLRs) are closely interrelated [3]. Treatment of MSCs with epinephrine increases the β2 adrenergic receptor level and expression of β adrenergic receptor kinase protein, disturbs cell migration of bone-marrow-derived MSCs by 21% and enhances IL-6 synthesis tenfold. This effect was significantly reduced when MSCs were cultured in the presence of the β2 adrenergic receptor antagonist [3]. Furthermore, it has been demonstrated that MSCs can synthesize catecholamines and their level can be regulated by activation of TLR2. We hypothesize that elevation of epinephrine secretion by MSCs in acute organ injury and activation of the MSCs' TLR-signaling system will lead to high production of proinflammatory cytokines and inhibition of injury recovery.

As discussed in Section 35.1.2, changes in tissue oxygen ($O_2$) tension are another crucial factor affecting the proliferation, differentiation, and paracrine function of MSCs in acute organ injury. Thus, increased levels of stress hormones in acute organ damage have a direct effect on the proliferation of MSCs. The observed decrease in proliferative activity is attributed to a protective mechanism that prevents cell death in the acute phase of the injury.

### 35.1.2 The impact of hypoxia as a factor of acute injury on mesenchymal stromal cell proliferation

Acute organ injury is accompanied by a severe inflammatory response and microcirculatory and metabolic abnormalities, which almost always cause tissue hypoxia. The impact of this factor on the functional activity of MSCs is discussed herein.

According to the literature, $O_2$ tension ranges from as high as 12% in blood to as low as 1% in cartilage [4]. Oxygen tension in the bone marrow has been reported to vary from 3% to 7% [5]. It has been demonstrated that a 2-week cell culture at an $O_2$ concentration reduced to 2% stimulates strong proliferative activity of MSCs, resulting in an over 30-fold increase in the number of MSCs compared with those cultured under normoxic conditions [6]. The authors of this study showed that hypoxia also affected MSC morphology and the expression level of certain genes. Thus, enhanced expression of *OCT-4* and *HIF-2α* genes was clearly detected. The *OCT-4* level increased as early as 24 h under hypoxic conditions and reached its maximum level on day 3. Enhanced expression of *OCT-4* is indicative of the increased pluripotency level in embryonic stem cells, and this also appears to apply to adult multilineage inducible cells [7].

D'Ippolito *et al.* reported data suggesting that culture of marrow-isolated adult multilineage inducible cells derived from murine bone marrow at 3% $O_2$ level accelerated proliferation, which caused a threefold increase in cell number within 7 days of culturing [8]. These cellular changes were also accompanied by enhanced expression of *REX-1* (a gene expressed in blastocyst cells) and *OCT-4* (one of the genes expressed during embryogenesis). Berniakovich and Giorgio demonstrated that culturing MSCs derived from murine bone marrow for 7 days at 3% $O_2$ level enhanced *OCT-4* and *REX-1* expression levels four- and six-fold respectively [9].

Thus, under hypoxic conditions, MSCs may be able to retain an undifferentiated phenotype and allow self-renewal [10]. In contrast, another study demonstrated that hypoxia stimulated differentiation of rat MSCs along the osteogenic pathway [11]. Ren *et al.* demonstrated that expression of major histocompatibility complex (MHC) proteins is significantly enhanced by culturing murine MSCs in the presence of 8% $O_2$ [12], which in turn was indicative of intensive differentiation. It was also shown that culturing MSCs in the presence of 8% $O_2$ inhibited *OCT-4* expression in MSCs.

Such discrepancy in the data from these studies may be due to the heterogeneity of the MSC population used. Hence, Nagano *et al.* demonstrated that MSCs derived from human umbilical cord blood and capable of differentiating along the adipogenic and chondrogenic lineages were populations characterized by different activity of aldehyde dehydrogenase [13]. The cells with high activity of this enzyme exhibited a higher proliferation rate and better differentiation ability under hypoxic conditions. This subtype of cells had higher levels of synthesis of FLT-1, CXCR4, and angiopoetin-2 proteins. The initial difference in metabolic activity may offer an advantage for proliferation of a certain MSC subpopulation under hypoxic conditions.

Ren *et al.* also reported that, in murine bone-marrow-derived MSC cultures, two cell types could be distinguished morphologically: spindle-shaped cells and large flat cells. Furthermore, early colonies also contained very small round cells that rapidly self-renewed [12]. Preferential proliferation of large flat cells compared with other cell types was observed when $O_2$ tension in the culture was reduced to 8%.

A number of chemokines responsible for MSC migration to sites of inflammation are produced during the inflammatory response and concomitant hypoxia [14]. Migration or transplantation of MSCs into hypoxic tissues can be accompanied by activation of cellular apoptosis [15–17].

The level of growth factors maintaining cellular metabolism becomes the limiting factor under hypoxic conditions. Thus, MSC viability is reduced under hypoxic conditions if MSCs are cultured in a serum-free medium [17]. Cell culturing in a serum-free medium (serum deprivation) increases the degree of apoptosis. Its combination with hypoxia increases it even more. We hypothesize that growth factors that provide cell adaptation to the new environment are required for MSCs to survive under hypoxic conditions. MSCs have been shown to be able to

rearrange their metabolism when adjusting to new microenvironmental conditions.

Hypoxia-preconditioned MSCs showed increased expression of antiapoptotic factors, including BCL-2 and BCL-XL [18], thus reducing caspase-3 activity and blocking apoptosis. MSCs preconditioned in a hypoxic environment and transplanted into the heart reduced cardiomyocyte apoptosis by increasing BCL-2 production [19–21]. Lavrentieva *et al.* reported that reduction in $O_2$ tension during culture of human MSCs to 1.5% increased expression of hypoxia-inducible factor (HIF)-1-dependent genes such as *GLUT1*, *LDHA*, and *PDK1* [22]. A significantly higher glucose consumption by cells and increased lactate production was observed at 1.5% $O_2$. These metabolic changes reduced the MSC necrosis level under hypoxic conditions, while the apoptotic level did not change significantly.

HIF is one of the key transcription factors involved in adaptation of MSCs to reduced $O_2$ tension. This factor is inactivated at increased $O_2$ tension levels and is stabilized under hypoxic conditions [23]. HIF activation induces expression of the genes determining the pro-survival ability of MSCs under hypoxic conditions (in particular, glucose-6-phosphate transporter) [24].

Data concerning the impact of $O_2$ tension levels lower than 2% on MSC proliferation vary. Martin-Rendon *et al.* observed augmented proliferation even after short-term culture at 1.5 $pO_2$ [25]. Rosová *et al.* did not observe this effect [26], while Hung *et al.* reported reduced proliferation level during cell culturing at 1% $O_2$ [27].

Thus, hypoxia occurring during acute organ injury is a powerful factor that triggers the adaptation processes of MSCs. Changes in biochemical indicators and gene expression contribute to the conditions essential for the survival of MSCs in the acute phase of injury and create the necessary conditions for subsequent MSC proliferation in the regeneration required for healing of the acute injury.

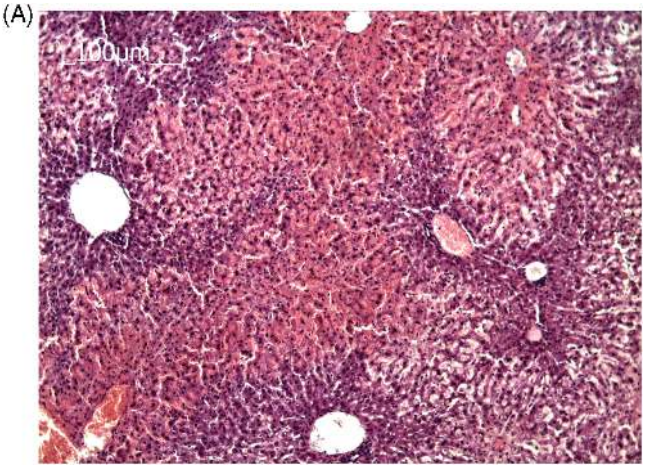
### 35.1.3 Effect of hypoxia as a factor of acute injury on the paracrine function of mesenchymal stromal cells

Hypoxia also alters production of paracrine factors secreted by stromal cells. The activation of HIF-1α production induces transcription of angiogenic factors [28,29]. Ohnishi *et al.* demonstrated that expression of 135 genes (many of which regulate glycolysis and metabolism) was augmented more than threefold by culturing MSCs in 1% $O_2$ for 24 h compared with normoxic culture conditions. Such genes as *VEGF-D*, *PGF*, *PBEF1*, *HB-EGF*, and *MMP-9* are some of those involved in the proliferation of MSCs [30]. It has repeatedly been shown that hypoxia enhances production of such factors as vascular endothelial growth factor (VEGF), fibroblast-derived growth factor (FGF), hepatocyte growth factor (HGF), and insulin-like growth factor (IGF) by MSCs [31–35].

Hypoxia affects the production of trophic, pro-angiogenic and anti-inflammatory factors by MSCs, while the use of the conditioned medium (CM) obtained by culturing MSCs under hypoxic conditions is more effective for treating a number of pathologic conditions compared with medium obtained by culturing MSCs at normal $O_2$ tension [36–39]. We demonstrated that the CM obtained by culturing MSCs isolated from cluster of differentiation 1 (CD1) mice for 3 days, when combined with lysate of these cells, had a protective effect in mice with acetaminophen-induced acute liver failure. (CD1 is a family of glycoproteins expressed on the surface of various antigen-presenting cells. They are related to the class I MHC molecules and are involved in the presentation of lipid antigens to T cells. However, their precise function is unknown. CD1 mice lack group 1 CD1 molecules and instead have two copies of CD1d.) Acetominophen is paracetamol and causes acute liver failure in humans and animals if overdoses are taken. In this experiment, MSCs were cultured at normal $O_2$ tension (21%) and under hypoxic conditions (10%). Biochemical analysis demonstrated that MSC-CM cultured both under hypoxic and normoxic conditions in combination with lysate significantly reduced the degree of acute liver failure. Liver damage was assessed by measuring alanine transaminsase and aspartate aminotransferase levels in the blood; liver damage results in elevation of theses enzymes.

The CM and the lysate obtained from normoxic MSC cultures showed the highest level of efficacy in the early stage of liver damage, with the mean alanine transaminsase level being 2508 U/L in the control group, 54.025 U/L in the normoxic group, and 223.16 U/L in the hypoxic group; the mean aspartate aminotransferase levels were 1275.75 U/L in the control group, 105.95 U/L in the normoxic group, and 621.4 U/L in the hypoxic group. In contrast, at later stages of liver damage the enzyme levels decreased more significantly in animals that received a combination of lysate and CM obtained from MSCs cultured under hypoxic conditions.

Histological data are shown in Figures 35.1, 35.2, 35.3, and 35.4.



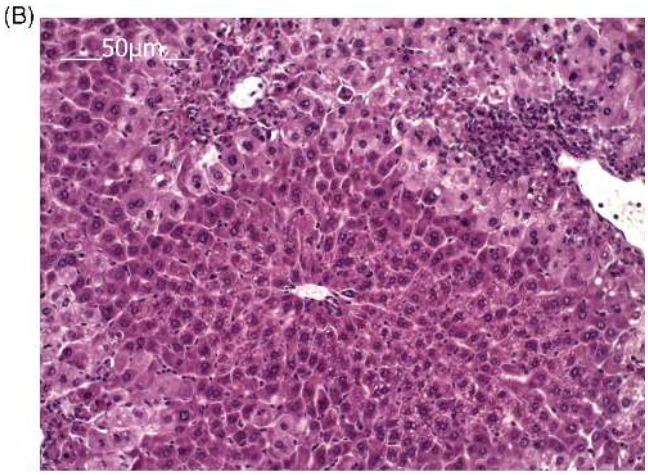


**Figure 35.1** Histopathologic findings in the liver of control mice after injection of acetaminophen (300 mg/kg) and Dulbecco's modified Eagle medium with 10% fetal bovine serum (1 mL). (A) 4 h: hepatocyte injury; necrosis of cells with plasma membrane disruption. (B) 24 h: adipose and protein dystrophy of hepatocytes; hepatocyte necrosis, leukocyte infiltration. (C) 48 h: adipose dystrophy of cells and chromatin margination; inflammatory infiltration.

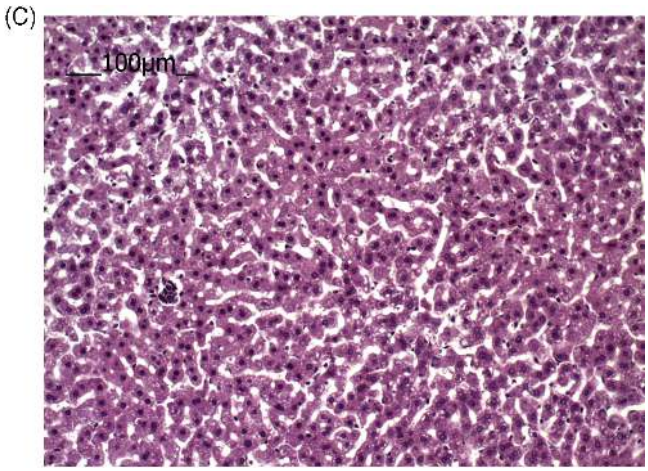

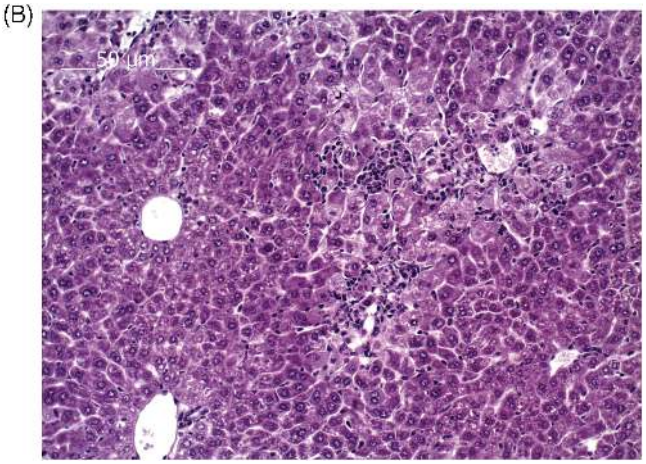

**Figure 35.1** (*Continued*)

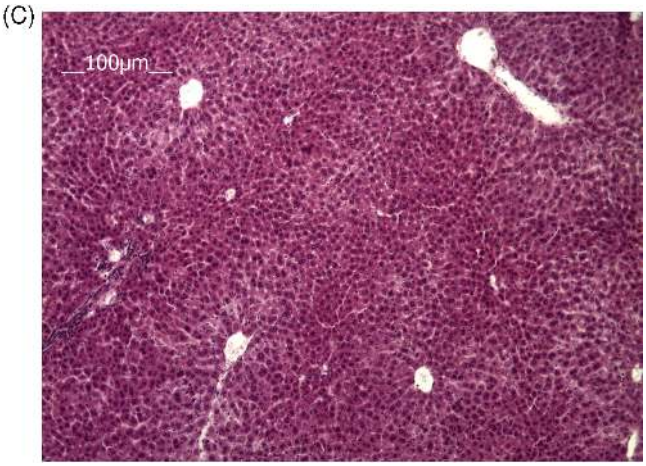

**Figure 35.2** (*Continued*)

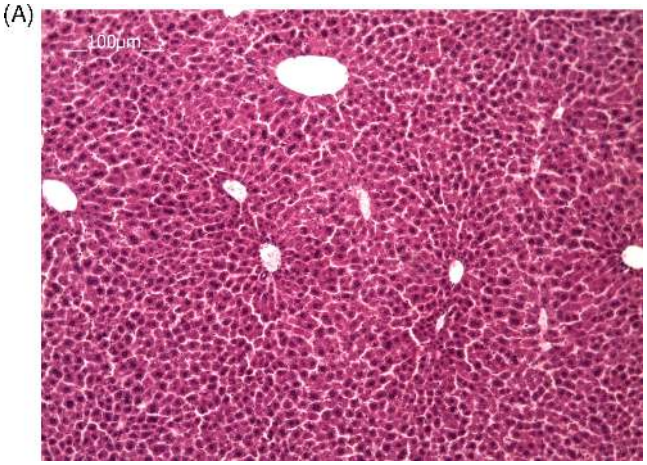

**Figure 35.2** Histopathologic findings in the liver of mice after injection of acetaminophen (300 mg/kg) and normoxic conditioned-medium MSCs (1 mL). (A) 4 h: hepatic lobules retain their trabecular structure; no signs of venous congestion or inflammatory infiltration are observed. (B) 24 h: the trabecular structure is retained in the periportal lobular regions; hepatocyte necrosis, leukocyte and macrophage infiltration. (C) 48 h: recovery of the injured tissues; hepatocyte dystrophy.

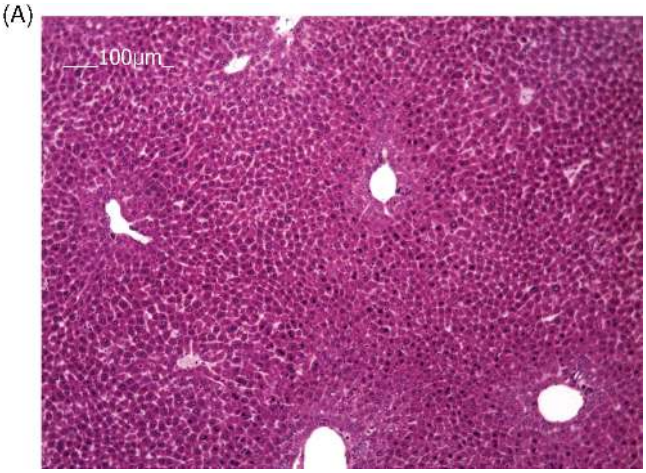

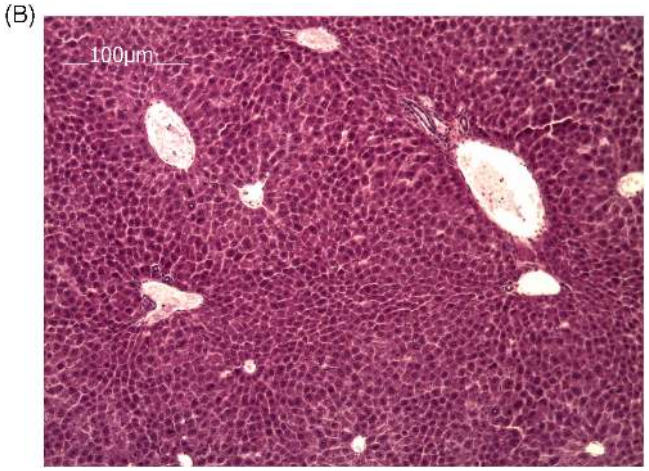

**Figure 35.3** Histopathologic findings in the liver of mice after injection of acetaminophen (300 mg/kg) and hypoxic conditioned-medium MSCs (1 mL). (A) 4 h: minimal tissue damage; no signs of circulation disruption or inflammatory infiltration were observed. (B) 24 h: macrovesicular adipose dystrophy in hepatocytes and cellular necrosis; no signs of inflammatory infiltration or circulation disruption were detected. (C) 48 h: no nuclear disruption is revealed; rather, regenerating cells with large hyperchromatic nuclei and binuclear hepatocytes were detected.

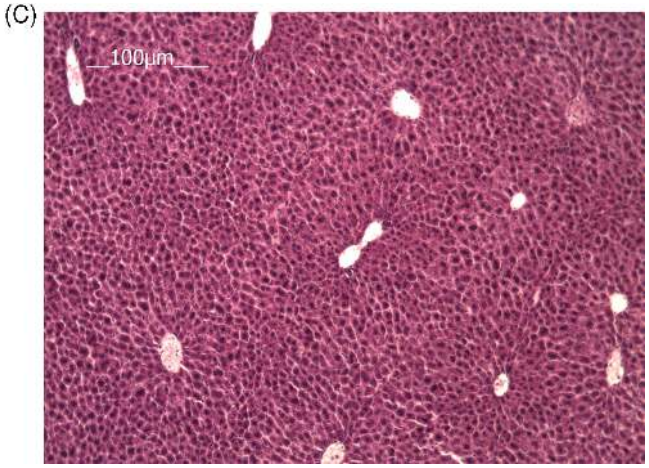

**Figure 35.3** (*Continued*)

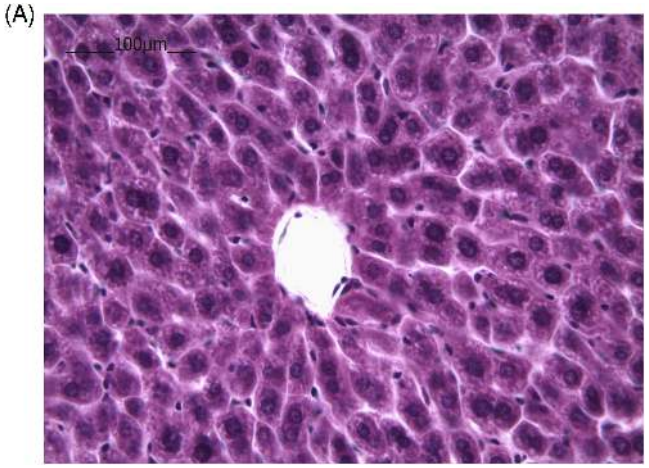

**Figure 35.4** Marked hepatocyte proliferative activity 48 h after administration of acetaminophen and hypoxic cMSC; (B) is a 20-fold magnified view of (A).

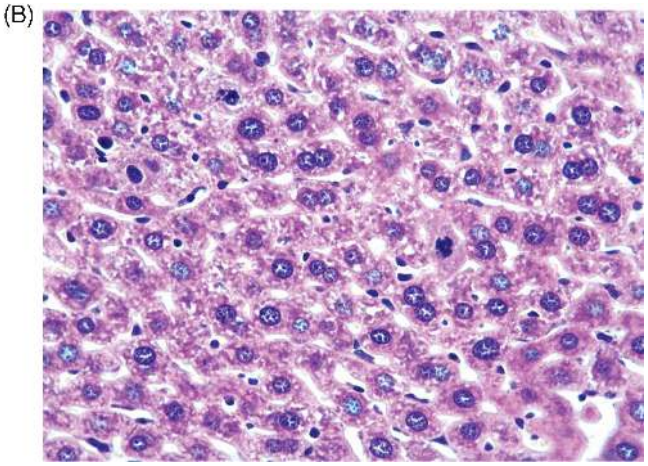

**Figure 35.4** (*Continued*)

Oxygen tension in tissues containing MSCs *in vivo* is known to vary from 1 to 7% depending on how far the tissues lie from blood vessels. Inflammation, edema, or disruption of blood supply can reduce $O_2$ tension to 0.4–2.3%. Hence, the conditions of MSC culture at $O_2$ tensions between 2.5 and 7% can be regarded as "physiological normoxia."

Centralization of blood flow takes place in the acute phase of injury due to neurohumoral transmission. Neurohumoral transmission is the transmission of a nervous impulse from neuron to neuron or from neuron to effector organ or tissue by means of a neurohumoral substance, such epinephrine, norepinephrine, acetylcholine, and possibly histamine, serotonin, and γ-aminobutyric acid. This results in reduction of blood flow in tissues containing stromal cells and the induction of hypoxia in these cells. A gradual decrease in $O_2$ tension to 2.5–5% might activate proliferation of stromal cells whose metabolic activity is best adapted to such conditions [13]. Analysis of published data allows the consideration of 2.5–3% $O_2$ level to be this point; the highest proliferative activity was observed by a number of groups under these conditions [6,8,40]. Hung *et al.* recorded either reduced MSC proliferation or no significant change after $O_2$ tension was reduced below 2.5% [27]. Studies using MSCs derived from rats, animals with the most active metabolism, demonstrated that an increase in $O_2$ tension to 5% enhanced proliferation by 40% [11]. A reduction in tissue $O_2$ tension to 0.4–1% is a direct death threat to cells, in which proliferative processes will be replaced by metabolic adaptation accompanied by enhanced expression of glucose transporter 1 and other molecules [22]. Maximum gene expression is observed at an $O_2$ tension of 1.5% compared with 2.5 and 5%.

Thus, changes in the production of paracrine factors by MSCs affected by hypoxia is aimed at minimizing tissue and cell damage and the creation of optimal conditions for subsequent regeneration.

### 35.1.4 Effect of tissue-specific proteins released after acute tissue injury on mesenchymal stromal cells

Acute injury induces a release of intracellular proteins liberated during cell and tissue degradation. It has been shown in a number of studies that these tissue-specific proteins can affect stromal cell differentiation along the appropriate lineage, ensuring recovery of the injured organ.

Choi *et al.* cultured bone-marrow-derived MSCs with pancreatic tissue extract and found that MSCs started expressing four hormones (insulin, glucagon, pancreatic polypeptide, and somatostatin) after 7 days. The cells also secreted insulin in response to supplementation of growth medium with glucose [41].

Chang *et al.* demonstrated that rat MSCs treated with proteins derived from post-infarction myocardium were capable of expressing cardiac-specific markers. The expression level was enhanced by using an extract from ischemic myocardium compared with that from uninfarcted myocardium [42]. The extract from ischemic tissue was found to contain higher transforming growth factor-β (TGF-β) and bone morphogenetic protein-2 (BMP-2) concentrations, while supplementation of growth medium with inhibitors of TGF-β or BMP-2 inhibitors blocked the expression of cardiac-specific proteins by MSCs.

Human MSCs treated with methylating agents, such as 5-azacitidine at a concentration of 10 μM, can differentiate along the cardiomyocyte lineage and express tissue-specific desmin, troponin I, sarco/endoplasmic reticulum $Ca^{2+}$-ATPase 2 (a calcium ATPase-type P-ATPase), and cardiac myosin heavy chain antigens. The same differentiation level could be obtained by culturing cells with an extract from neonatal rat cardiomyocytes [43].

Human cardiac explant-CM contains a high level of proteins capable of reprogramming the MSC genome and promoting their differentiation along the cardiomyocyte lineage. About 20 of these proteins are growth factors and cytokines [44]. *In vitro* supplementation of MSCs with this medium enhances their proliferative activity so that 3–5% of cells start to express cardiac-specific proteins. It should also be mentioned that an extract derived from injured brain tissue reduced *OKT-4* expression, enhanced *nestin* expression in MSCs, and increased the level of apoptosis in the cell culture. The extract derived from injured brain exhibited higher toxicity than that derived from healthy brain tissue [45].

Human macrophages are divided into M1 and M2 types. M1/M2 describes the two major and opposing activities of macrophages. M1 activity inhibits cell proliferation and causes tissue damage, while M2 activity promotes cell proliferation and tissue repair. The molecules primarily responsible for these "Fight" (nitric acid) or "Fix" (ornithine) activities both arise from arginine and via enzymatic pathways (inducible nitric oxide synthetase and arginase) that downregulate each other. The names M1 and M2 were chosen because M1 and M2 macrophages promote helper T cells type-1 and -2 responses respectively. M2 macrophages seem to play a crucial role in reprogramming the MSC genome induced by tissue-specific proteins released after acute tissue damage as they actively consume necrotic and apoptotic cells in the injured areas and secrete the anti-inflammatory cytokines TGF-β and IL-10 [46]. Furthermore, M2 macrophages release growth factors, such as IGF-1, in the injured area [47]. It has been demonstrated that IL-10 secreted by macrophages is required to sustain viability, differentiation, and fusion of mesoangioblast-like myogenic progenitors in toxin-induced skeletal muscle injury [48].

Additionally, injection of the CM from human placenta-derived MSCs increased the number of M2 macrophages near the wound [49]. Thus, tissue-specific factors released from damaged tissues is one of the signaling mechanisms underlying the tissue-specific regeneration process of MSCs.

## 35.2 Paracrine effect of mesenchymal stromal cells in acute organ injury

### 35.2.1 Background

The beneficial effect of MSCs in various pathological settings has been demonstrated in numerous experimental and clinical studies. Many years have passed since Friedenstein and his colleagues first isolated MSCs from bone marrow in 1968 and described them as a culture of fibroblast-like cells that could transdifferentiate into bone cells [50]. He used the term colony-forming unit–fibroblast (CFU-F) to describe colonies of these cells because of their superficial microscopic resemblance to fibroblasts.

The understanding of the mechanism of action of MSCs has significantly changed since then. While the effect of injecting MSCs was initially attributed to their ability to differentiate into cells of the surrounding tissue (and remains so today with regard to disorders of the musculoskeletal system), the paracrine mechanism (i.e., the ability of MSCs to synthesize and secrete a large number of proteins – including a number of cytokines and growth factors – that can affect the course of the pathological process in which the MSCs themselves are physically involved) is considered to be one of the key aspects of their mechanism of action. Paracrine signaling is a form of cell–cell communication in which a cell produces a signal to induce changes in *nearby* cells, altering the behavior or differentiation of those cells. It is different from endocrine signaling, in which one organ (e.g., the pituitary gland) secretes proteins, such as thyroid-stimulating hormone or adrenocorticotropic hormone, that have their effects on organs *distant* from the secretory organ – the thyroid gland in the case of thyroid-stimulating hormone and the adrenal glands in the case of adrenocorticotropic hormone.

It should be mentioned that the secretory activity of MSCs was reported in 1996 by Haynesworth *et al* [51]. and has been confirmed by a number of reports. First, injection of acellular MSC-CM has an effect similar to that of MSCs themselves. This has been demonstrated using preclinical models of injury of numerous organs, including kidney, heart, lung, liver, skeletal muscle, and urinary bladder [52–60]. Furthermore, the effect of

MSCs can often be observed as early as several hours after they are administered [61], which is insufficient time for them to differentiate. Thus, the short-term effect of MSC injection is most likely to be due to the paracrine mechanism. This aspect is especially relevant when considering a rapidly developing acute organ injury. Of note is the fact that the MSC migration pathways and the area of injury often do not coincide. For example, it has been demonstrated in the model of ischemia–reperfusion injury (IRI) in rats that most MSCs accumulated in the periportal zone, while the most profound antiapoptotic effect of injecting MSCs was observed in the centrolobular region, as shown by immunohistochemistry [62]. This clearly indicates that MSCs exhibit a paracrine effect. In this part of the chapter we will thoroughly describe the paracrine factors secreted by MSCs and discuss their main biological effect in acute organ injury.

### 35.2.2 Paracrine factors secreted by mesenchymal stromal cells

MSCs secrete a broad range of paracrine factors. Proteomic analysis has demonstrated that microvesicles (MVs) derived from MSCs contain over 730 different proteins [63]. These include cell adhesion and signaling molecules, cell surface receptors, ILs, and growth factors. We will discuss the production of MVs by MSCs. The key soluble paracrine factors that are likely responsible for the effects observed after MSC administration are shown in Table 35.1.

### 35.2.3 Immunosuppressive and anti-inflammatory effects of mesenchymal stromal cells

MSCs are both relatively nonimmunogenic as well as being actively suppressive of T cell, B cell, and natural killer cell activity. MSCs do not appear to be recognized by the immune system of immunocompetent recipients due, at least in part, to their lack of expression of MHC class II antigens as well as lack of the co-stimulatory molecules CD28 and CD80.

The immunosuppressive effect of MSCs has been known for some time. In 2002, Bartholomew *et al.* demonstrated that MSCs could reduce T-cell proliferation in response to an allogeneic stimulus by more than 50% [64]. The first description of the use of MSCs to treat acute graft-versus-host disease (GVHD) refractory to conventional therapy in humans was described in 2004 [65]. GVHD is mediated by donor T cells that recognize histocompatibility antigens present in the hematopoietic stem cell transplant recipient that are absent in the hematopoietic stem cell donor. In this report, haploidentical (maternal) MSC administration resulted in resolution of the GVHD in a recipient of an allogeneic hematopoietic stem cell transplant from an unrelated hematopoietic stem cell donor [65].

The anti-inflammatory effect of MSCs has also been demonstrated in preclinical models of endotoxic shock, lipopolysaccharide (LPS)-induced lung and liver injury, and in burns models [56,57,60,61,66,67].

It appears that both the immunosuppressive and anti-inflammatory effects of MSCs are mostly caused by the ability of MSCs to influence the expression and secretion of different cytokines. Hence, we will refer to these two effects together rather than discussing them separately. For example, the ability of MSCs to reduce concentrations of MCP-1 and MIP-1 [68,69], the powerful chemoattractants of the granulocyte-macrophage component of the innate immune system, abruptly inhibits the inflammatory infiltrate and thus reduces the severity of the inflammatory response, in particular during its early phase. MSCs secrete TGF-β and $PGE_2$, which inhibit synthesis of proinflammatory cytokines and T cell activation [70–73], thus downmodulating the inflammatory response in its later stages.

However, MSCs are also active producers of powerful proinflammatory agents, such as IL-1, IL-6, IL-8, IFN-γ, and TNF-α in

**Table 35.1** Most important paracrine factors secreted by MSCs.

| Group | Paracrine agents |
|---|---|
| Growth factors | TGF-β, HGF, VEGF, KGF, FGF, IGF-1, G-CSF, GM-CSF, IGF-2, M-CSF, PDGF-AA, EGF, NGF, BDNF, NT3, NT4 |
| Chemokines | MIP-2, MCP-1, MIP-1b, SDF-1, monokine induced by IFN-γ |
| Tumor necrosis factor | TNF-α,β |
| Interleukins | IL-1, IL-6, IL-8, IL-10 |
| Prostaglandins | $PGE_2$ |
| Cell adhesion molecule | ICAM-1 |
| Other proteins and enzymes | Adiponectin, IDO, MMP-9, IL-1 receptor antagonist, protein kinase B, sTNFR1, angiopoietin 1, TSG-6, NO, human leukocyte antigen-G5, IP-10, RANTES, IL-1RA |

BDNF: brain-derived neurotrophic factor; EGF: epidermal growth factor; G-CSF: granulocyte colony-stimulating factor; GM-CSF: granulocyte-macrophage colony-stimulating factor; ICAM: intercellular adhesion molecule; IDO: indolamine 2,3-dioxygenase; IFN-γ: interferon-γ; IP-10: interferon-γ-induced protein 10; KGF: keratinocyte growth factor; IL-1RA: interleukin-1 receptor antagonist; M-CSF: macrophage colony-stimulating factor; MCP-1: monocyte chemoattractant protein 1; MIP: macrophage inflammatory protein; MMP: matrix metalloproteinase; NGF: nerve growth factor; NO: nitric oxide; NT: neurotrophin; PDGF: platelet-derived growth factor; $PGE_2$: prostaglandin $E_2$; RANTES: regulation on activation, normal T cell expressed and secreted; SDF: stromal cell-derived factor; sTNFR1: soluble tumor necrosis factor receptor 1; TNF: tumor necrosis factor; TSG-6: tumor necrosis factor α-induced protein-6.

some settings [74,75]. Furthermore, MSCs can also express TLRs, one of the main targets for proinflammatory cytokines, on their surface [75,76]. Thus, a discussion on MSCs and both pro- and anti-inflammatory cytokines is warranted.

TNF-α is a powerful inflammatory agent secreted by many cells (including MSCs), but mostly by monocytes and macrophages. This agent is pyrogenic, acts as a chemoattractant for most inflammatory cells, induces apoptosis and secretion of other proinflammatory agents (IL-1, IL-6, and IL-8), and inhibits lipoprotein lipase activity. In addition, TNF-α can independently cause lysis of certain cells [70]. TNF is often secreted by cells in response to activation of surface TLRs (TLR 1, 2, 4, and 6) by such ligands as LPS, fibrinogen, hyaluronic acid, and diacyl peptides. After surface TLRs become activated, nuclear factor kappa light chain-enhancer of activated B cells (NF-κB) is no longer controlled by its inhibiting agent the IκB kinase, which induces transcription of controlled genes and the production of proinflammatory cytokines.

The reported data on the ability of MSCs to affect TNF-α are variable. Lee *et al.* detected no statistically significant changes in the TNF-α level after administration of allogeneic human MSCs and MSC-CM using a model of *Escherichia coli* endotoxin-induced acute lung injury [66]. In contrast, the ability of MSCs to reduce TNF-α levels, either directly or indirectly, has been reported in most studies. Thus, a profound decrease in TNF-α produced by human umbilical-cord-blood-derived MSCs has been reported in a model of *in vitro* cisplatin-induced acute kidney injury [52]. The ability of MSCs to reduce the TNF-α level has also been demonstrated in preclinical models of colitis [77], antigen-induced arthritis [78], albumin-induced renal tubular inflammation [79], and acute lung injury [56,69].

Much attention has recently been focused on TSG-6. Increased expression of this gene enhances production of TNF-α-induced protein 6, which has anti-inflammatory properties. This protein activates inter-α-inhibitor, which, in turn, inhibits serine proteases, a key link in the development of inflammation [80].

It was demonstrated in a model of LPS-induced acute lung injury that administration of human MSCs by oropharyngeal aspiration 4 h after the exposure to LPS considerably reduced the inflammation and edema of pulmonary tissues. It was clearly demonstrated in the same study that secretion of TSG-6 by MSCs increased abruptly 12 h after their administration. Blockage of TSG-6 expression by RNA interference significantly reduced the anti-inflammatory activity of MSCs [69].

In a murine model of acute myocardial infarction the intravenous injection of human MSCs reduced the inflammatory response in the myocardium, in particular the activity of proinflammatory MMP-9, decreased the infarction border zone, and preserved myocardial function. Inhibition of TSG-6 significantly reduced this effect [81].

Wang *et al.* used a peritonitis model to demonstrate that the intraperitoneal injection of MSCs and MSC-CM significantly reduced the inflammatory cell infiltrate and cell adhesion. A significant increase in expression and secretion of TSG-6 was demonstrated. The outcome was substantially reduced by blockage of TSG-6 [82]. Similar data on the effect of TSG-6 were also obtained in a rat model of chemical burns of the cornea [83].

Albumin-induced inflammation of tubular epithelium was modeled *in vitro* in another study. Bone-marrow-derived MSCs were cultured together with the cells of the renal proximal tubules. The investigators demonstrated high expression of TSG-6, which was activated by adding human serum albumin to the medium. However, in this case the enhanced expression of TSG-6 reduced the level of such factors as α-smooth muscle actin, fibronectin, and type IV collagen. Blockade of TSG-6 increased the level of these factors. Thus, TSG-6 was regarded in this study as an antifibrotic agent rather than an anti-inflammatory one [79].

sTNFR1 is believed to play a crucial role in TNF neutralization. The circulating receptor is capable of binding TNF-α, thus preventing its proinflammatory effect [84]. Furthermore, data indicate that sTNFR1 facilitates TGF-β1 formation, which reduces the proliferation of T cells [56]. Hence, the similarity between the anti-inflammatory and immunosuppressive effect of MSCs was again demonstrated. Yagi *et al.* clearly demonstrated that bone-marrow-derived MSCs can secrete sTNFR1. Moreover, this secretory activity considerably increased LPS-induced inflammation. Administration of anti-sTNFR1 monoclonal antibodies reduced the positive *in vivo* effect of MSCs, while the level of proinflammatory cytokines (TNF-α, IL-6, IFN-γ) in animal serum increased [56]. The authors thought that a negative feedback mechanism was induced in this case: increased concentration of TNF-α or LPS led to increased production of sTNFR1.

Another study compared the ability to secrete sTNFR1 between bone-marrow-derived MSCs and adipose-tissue-derived MSCs [67]. Bone-marrow-derived MSCs were shown to secrete a higher level of sTNFR1 than adipose-tissue-derived MSCs. Furthermore, it was demonstrated that neutralization of sTNFR1 did not significantly reduce the positive effect of bone-marrow-derived MSCs. Thus, the role of sTNFR1 in the anti-inflammatory effect remains unclear.

The role of different types of TLRs in the anti-inflammatory properties of MSCs is controversial. MSCs express several different types of TLRs (e.g., TLR 2, 3, and 4) [85]. Enhanced expression of certain TLRs in MSCs can be stimulated by adding the corresponding agents (e.g., LPS to stimulate expression of TLR 4 or polyinosinic:polycytidylic acid (polyI:C) to stimulate expression of TLR 3). Stimulation of monocytes with TLR agonists caused their transformation into the M1 phenotype involved in the inflammatory response, while stimulation of IL-4 gave rise to monocytes with the M2 phenotype, which exhibit anti-inflammatory properties [86]. Waterman *et al.* hypothesized that this polarization is possible for MSCs as well. However, the MSC response depended on the type of TLR (TLR 3 or TLR 4) the MSCs expressed. Thus, stimulation of TLR 4 expression induced greater secretion of proinflammatory cytokines (IL-6, IL-8), while TLR 3 expression enhanced secretion of anti-

inflammatory factors (IP-10, RANTES, IL-1RA) and, to a lesser degree, IL-4 and IL-10 [76]. It was also demonstrated in this study that MSCs with enhanced expression of TLR 3 significantly reduced secretion of TGF-β1 and TGF-β3, two key immunosuppressive factors, which may be involved in a negative feedback mechanism.

Hwang *et al.* studied the expression of different types of TLRs in MSCs derived from human nasal mucosa. They demonstrated that these cells mostly expressed TLR 3 and TLR 4, while expressing TLR 2 and TLR 5 to a lesser extent. In turn, exposure to TLR agonists (LPS and polyI:C) did not significantly increase expression of TLR 3 and TLR 5 in these cells but enhanced expression of TLR 2 and TLR 4. Exposure to LPS stimulated these MSCs to secrete both pro- and anti-inflammatory cytokines, while exposure to polyI:C had no effect on secretion of these cytokines by the cells, demonstrating that TLR 4 was more active than TLR 3 in this case [75].

The respiratory tract mucous membranes are exposed to significant antigenic stresses *in vivo*, which may induce phenotypic changes in cells in the mucosa, including MSCs. High expression of TLR 4 in the MSCs of nasal mucosa is likely associated with the need to provide a timely immune response to antigenic irritants.

The ability of MSCs to modulate the level of anti-inflammatory cytokines is also important. IL-10 is a powerful anti-inflammatory agent whose effect is mediated by a suppressive action on the effector functions of macrophages, T cells, dendritic cells, and natural killer cells. It also inhibits synthesis of some proinflammatory cytokines. Yagi *et al.* detected a threefold increase in the level of IL-10 gene expression in MSCs co-cultured with "inflammatory" serum derived from animals with an LPS-induced inflammatory syndrome or with thermal burns compared with control animals [60]. Danchuk *et al.* also found an increased level of IL-10 using the LPS-induced lung injury model [69]. Qui *et al.* demonstrated that administration of human umbilical cord-derived MSCs increased IL-10 and TGF-β levels in a rat model of cardiac transplantation [87]. An increased IL-10 level due to the effect of MSCs was also found in the model of ischemia–reperfusion-induced kidney injury, which will be discussed later in this chapter [88].

Peng *et al.* studied the effect of MSCs in patients with chronic GVHD and found that $CD5^+$ B cells in these patients showed greater gene expression for IL-10 after MSCs had been administered. IL-10 secretion is likely one of the key factors responsible for the clinical effect of MSCs [89].

It was shown in another study that co-culturing MSCs with peripheral blood mononuclear cells increased IL-10 mRNA production by mononuclear cells. An increased level of another anti-inflammatory cytokine, IL-4, was also observed [90]. Nevertheless, a number of authors reported no significant changes in IL-10 gene values when using MSCs or MSC-CM in different models *ex vivo* and *in vitro* [66,91,92]. Production of this factor may depends on external factors and medium conditions.

In the studies just described [89–92] and in many other studies, an important role has been attributed to induction of IDO secretion by MSCs. Furthermore, stimulation of MSCs with proinflammatory agents such as IFN-γ significantly enhanced secretion of this factor [93]. This enzyme induces L-tryptophan degradation via a kynurenine pathway, thus depriving T cells of an essential amino acid, thereby starving them to death and exerting a strong immunosuppressive and anti-inflammatory effect.

In another study, MSCs were cultured in medium supplemented with 20% synovial fluid collected from three groups of volunteers: those without any pathologies of joint disease, those with osteoarthritis, and those with rheumatoid arthritis. Under these conditions, expression levels of IDO mRNA and IL-6 were increased in MSCs in all three groups. Interestingly, however, expression of these factors after synovial fluid from patients with osteoarthritis and rheumatoid arthritis had been added to the culture was much higher. Furthermore, the MSC-CM derived from MSCs cultured in this manner profoundly reduced proliferation of $CD3^+$ $CD28^+$ T lymphocytes [94]. However, it was also demonstrated that MSCs can inhibit IDO synthesis by other cells. Thus, expression of this agent was enhanced in corneal epithelial cells stimulated by IFN-γ and TNF-α, while co-culturing these cells with bone-marrow-derived MSCs noticeably suppressed expression [95].

The secretion of another key immunosuppressive factor, TGF-β, by MSCs has also been described [95]. In particular, stimulation of bone-marrow-derived MSCs by IFN-γ or TNF-α abruptly increased secretion of this cytokine. The high secretory activity of MSCs with respect to TGF-β is associated with reduced expression of IDO by cells of the surrounding tissue. TGF-β has long been known for its powerful immunosuppressive activity and, in particular, its ability to inhibit proliferation and activation of lymphocytes and macrophages. MSCs can produce different amounts of this agent [87,96]. Expression of this factor is enhanced with inflammation and can mediate, at least in part, the anti-inflammatory effect of MSCs.

MSCs secrete a number of other anti-inflammatory agents, including $PGE_2$ [72], adiponectin (which can reduce TNF-α expression in adipose-tissue-derived MSCs), HGF, IGF, and endothelial nitrous oxide synthase [88].

The anti-inflammatory effect of HGF has been demonstrated in the preclinical model of albumin-induced renal tubular inflammation, in which it was found to inhibit transcription of TNF-α and the chemokines CCL-2 and CCL-5. The anti-inflammatory effect of MSCs notably decreased when HGF was neutralized [79].

The IGF family also have anti-inflammatory properties. In the LPS-induced lung injury model, IGF-2 contributed to the emergence of the anti-inflammatory M2 macrophage population, thus reducing the severity of inflammation [47].

Despite the fact that MSCs can produce some proinflammatory cytokines, it has been demonstrated in most studies that administration of MSCs reduces the total level of proinflammatory cytokines. It has been shown using various models that administration

of MSCs or MSC-CM profoundly reduced the expression and concentration of the following inflammatory agents: IL-1α and β, IL-6, IL-17, IFN-γ, G-CSF, GM-CSF, MIP-2α, and MCP-1 [52,56,60,68]. Secretion by MSCs of antagonists of some inflammatory cytokine receptors is likely one of the ways by which MSCs mediate their immune suppressive and anti-inflammatory properties. Thus, secretion of IL-1 receptor antagonist (IL-1RA) by MSCs increased more than fivefold after LPS was administered, although the basal expression level of this cytokine is low [69]. Secretion of IL-1RA by MSCs is significantly enhanced by culturing them in the presence of TNF, IFN-γ, and IL-1β [97].

IL-6 at high concentrations also appears to have an anti-inflammatory effect. Interestingly, intratracheal administration of 200 ng of IL-6 reduced the severity of inflammation in acute lung injury, decreased IL-1β, C–X–C motif chemokine ligand (CXCL)1, and TNF-α concentrations, and inhibited activity of lung myeloperoxidase, while it behaved as a typical proinflammatory cytokine when injected at the lower dose of 25 ng [98]. Since MSCs can produce high concentrations of IL-6 in inflammation, this factor can be regarded as an anti-inflammatory agent that reduces the levels of other proinflammatory cytokines.

MSCs can also reduce concentrations of granulocyte-macrophage chemoattractants, including MCP-1 and neutrophil-activation factor-3 (KC) [69].

The paracrine activity of MSCs may depend on different factors, including their tissue of origin and the health, gender, and age of the MSC donor. Crisostomo *et al.* studied the secretion of various proteins by MSCs *in vivo*. The level of VEGF secretion in female rats after activation of MSCs with LPS or hypoxia was higher in female rats, while the levels of TNF-α and IL-6 secretion were significantly lower than those in male rats [99]. Thus, MSCs from female rats exhibited lower proinflammatory activity and increased proliferative and regenerative activity compared with male rats. The authors hypothesized that estrogens might contribute to this effect. Exogenous estrogen has been reported to increase the activity of MSCs [100]. MSCs have the estrogen receptor alpha, which probably plays a role in their growth and differentiation [101], while mitogen-activated protein kinases (MAPKs) and cyclin-dependent kinases can mediate the proliferative effect of estrogens on murine embryonic stem cells [102].

We have shed light only on some tentative mechanisms of the immune suppressive and anti-inflammatory effect of MSCs. Nevertheless, we can infer that these abilities are mediated both by the secretion of anti-inflammatory and immunosuppressive agents by MSCs and by the influence of MSCs on the surrounding cells as they inhibit synthesis or reception of proinflammatory agents. In both settings, paracrine mechanisms are involved [71,72,103–107].

### 35.2.4 The pro-angiogenic and tissue regenerative effects of mesenchymal stromal cells in acute organ injury

In this section we will discuss the pro-angiogenic and tissue regenerative effects of MSCs as a component of their paracrine activities and will not focus on *de novo* differentiation of MSCs into cells of the appropriate mesodermal lineage, since it is paracrine mechanisms that are responsible for the early stages of angiogenesis and regeneration after MSCs are administered. Administration of MSCs caused enhanced proliferative activity [52] and angiogenesis [107] several days after acute organ injury had been induced.

It has been demonstrated in many studies that MSCs secrete significant levels of growth factors, including VEGF, HGF, FGF, heparin-binding EGF-like growth factor (HB-EGF), and placental growth factor (PLGF), which can stimulate angiogenesis in addition to induction of proliferation [108]. Furthermore, as with the secretion by MSCs of anti-inflammatory cytokines, secretion of these growth factors is in a dynamic equilibrium and can change in response to differing ambient conditions. An increase in secretion of cytokines by umbilical-cord-blood-derived MSCs was observed in response to cisplatin-induced injury: VEGF (fivefold), HGF (12-fold), FGF (twofold), and HB-EGF (sevenfold) [52]. It was noted in another study of bone-marrow-derived MSCs that expression of HGF, NGF, and SDF-1 significantly increased in response to administration of LPS, while expression of VEGF, NT3, and NT4 decreased [74]. Thus, the degree of growth factor secretion can vary depending on the injuring agent, health status of the MSC donor [74], and origin of the MSCs.

VEGF and HGF appear to play a crucial role in the regenerative and protective effects of MSCs, as well as in angiogenesis. High levels of these factors are observed with MSC-CM. When the effect of these factors was blocked by an appropriate monoclonal antibody, the effect of MSCs and MSC-CM was significantly reduced and cell survival *in vitro* decreased [68]. It has been demonstrated for angiogenesis that culturing umbilical-vein-derived endothelial cells in the absence of HGF significantly reduces their proliferative activity. The same effect is observed when HGF-depleted MSC-CM is added to an endothelial cell culture, while CM from intact MSCs stimulated endothelial proliferation [109].

The role of VEGF in angiogenesis cannot be overemphasized. Wu *et al.* demonstrated that the use of MSCs significantly accelerated wound recovery due to enhanced angiogenesis. A significant increase in VEGF expression by MSCs was demonstrated and was considered the most likely reason for the enhanced angiogenesis [107].

The preclinical model of cyclophosphamide-induced acute ovarian injury was used in another study. Cyclophosphamide abruptly reduced the $CD34^+$ cell count, suggesting inhibition of angiogenesis, while administration of adipose-tissue-derived MSCs considerably increased the survival rate of the cells compared with the untreated control group and with administration of fibroblasts. Cells expressing CD34 are normally found on early hematopoietic progenitor cells in the umbilical cord and bone marrow, a subset of mesenchymal stem cells, endothelial progenitor cells, and endothelial cells of blood vessels. It was also demonstrated in this study that MSCs secreted high levels of VEGF, IGF-1, and HGF, both *in vitro* and when transplanted

into the ovary [110]. Administration of these growth factors without MSCs was less effective.

It was shown in another study that MSC-CM contained high levels of VEGF, basic fibroblast growth factor (bFGF), PLGF, and MCP-1 and markedly enhanced proliferation of endothelium and smooth muscle cells. VEGF blockade inhibited endothelial proliferation, while FGF blockade inhibited proliferation of smooth muscle cells [108].

Genetic modification enables the regulation of production of some growth factors by MSCs. Thus, MSCs overexpressing GATA-4 produced more VEGF and IGF-1 than unmodified MSCs and contributed to a greater extent to the proliferation of endothelial cells, increased capillary density, and increased blood flow rate in a model of myocardial infarction. Neutralization of VEGF and IGF-1 significantly reduced the angiogenic effect of MSCs [111]. The *GATA-4* gene encodes a member of the GATA family of zinc finger transcription factors. Members of this family recognize the *GATA* motif that is present in the promoters of many genes. GATA-4 protein is thought to regulate genes involved in embryogenesis and in myocardial differentiation and function.

MSC-CM was also found to contain high levels of angipoietin (Ang)-1. This protein plays a crucial role in blood vessel formation and maturation and regulates the relationship between the endothelium and the extracellular matrix. On the contrary, Ang-2 is an Ang-1 antagonist as it inhibits binding of Ang-1 to the tyrosine kinase with immunoglobulin-like and EGF-like domains 1 (TIE-2) receptor. An increased Ang-1 level compared with the untreated control was detected in the lysate derived from wounds treated with MSC-CM, while the Ang-2 level remained intact. Hence, the Ang-1/Ang-2 ratio increased, which indirectly indicated induction of angiogenesis [107].

*In vitro* experiments have shown that co-culturing MSCs with endothelium noticeably enhances endothelial proliferation and facilitates formation of new capillaries. Endothelium is known to synthesize high levels of PDGF, while MSCs express receptors to this factor. This may be one of the mechanisms of interaction between the endothelium and MSCs [110].

However, it has also been demonstrated in the chemical corneal burn injury model that MSCs and MSC-CM can exhibit a negative effect on angiogenesis. The use of MSCs resulted in regression of vascularization [111], high expression of thrombospondin 1, an agent that induces endothelial apoptosis and reduces VEGF production. Reduced expression of the pro-angiogenic factor MMP-2 was also detected.

Thus, there is some disparity of results in studies of the angiogenic effect of MSCs, which seem related to the preclinical model employed.

A study be Lee *et al.* reported a profound decrease in the protective effect of MSCs after keratinocyte growth factor (KGF) knockdown by RNA interference. This was manifested as increased alveolar fluid clearance in the lungs. The effect was restored when recombinant KGF was added. KGF can increase the expression of epithelial sodium channels on the apical epithelial membrane, thus reducing the alveolar fluid level. Amiloride, a specific blocker of these channels, also reduced the effect of MSCs and MSC-CM, thus confirming the hypothesis concerning the mechanism of action of KGF [66].

The activity of growth factors derived from MSCs plays a crucial role in their protective effect. It is not only restricted to the regenerative and angiogenic effects. As mentioned earlier, HGF and IGF-1 exhibit anti-inflammatory properties. Some investigators believe that growth factors exhibit an antiapoptotic effect. This is discussed next.

### 35.2.5 The antiapoptotic activity of mesenchymal stromal cells

Kumar *et al.* induced apoptosis of human dermal microvascular endothelial cells by γ-radiation and found that treatment with VEGF significantly reduced the degree of apoptosis. The VEGF-treated endothelial cells showed markedly increased expression of B-cell lymphoma (Bcl)-2, an antiapoptotic agent, while expression of Bcl-2 in untreated cells subjected to radiation significantly decreased. Addition of phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K) inhibitors to the VEGF-treated cell culture reduced Bcl-2 expression. This fact indicates that VEGF inhibits apoptosis by affecting the PI3K–Akt–Bcl-2 signaling pathway [112]. It was also demonstrated using the model of cisplatin-induced acute kidney failure that treatment with anti-VEGF antibodies reduced expression of protein kinase B (Akt), a powerful antiapoptotic agent [68].

The antiapoptotic effect of Akt is related to its ability to phosphorylate the Bcl-associated death promoter (BAD). BAD can form pores in the outer mitochondrial membrane, which results in cytochrome c release from mitochondria into the cytoplasm and activation of the cytoplasmic caspase cascade, causing cell death. When phosphorylated, BAD is dissociated and loses its pro-apoptotic activity [113].

The effect of MSCs on Akt is unlikely to be the only pathway by which they mediate inhibition of apoptosis. Oxidative stress is known to be another powerful factor inducing apoptosis [114]. MSCs and some MSC-secreted growth factors, in particular HGF, can inhibit oxidative stress by normalizing the functional activity of mitochondria and oxidative enzymes [115,116].

Despite the fact that its mechanism of action still remains subject to debate, the antiapoptotic effect of MSCs has been repeatedly demonstrated in a number of studies. Thus, Yin *et al.* used a rat preclinical model of acute spinal cord IRI to demonstrate that transplantation of bone-marrow-derived MSCs restored motor function to the forelegs [117]. The effect was observed as early as 4 days after the transplant. Function was almost completely restored by day 7 using the Basso, Beattie, and Bresnahan locomotor rating scale for evaluation. Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) staining revealed a significantly smaller number of apoptotic cells in animals that received MSCs. (TUNEL is a method for detecting DNA fragmentation by labeling the terminal end of nucleic acids and is a common method for detecting DNA fragmentation

that results from apoptotic signaling cascades.) Reduction of apoptosis was also confirmed by immunohistochemistry (decreased caspase-3 level and the BAX/Bcl-2 ratio – BAX is Bcl-2-associated X protein).

The effect of MSCs on apoptosis has been studied in kidney, liver, and lung tissues [53,54,60,68]. Eliopoulos *et al.* used the model of cisplatin-induced acute kidney injury to demonstrate that MSCs both reduced the caspase-3 level and enhanced expression of the proliferation marker Ki-67 [68]. A significant reduction in caspase-3 level and degree of apoptosis was also revealed in a model of adriamycin-induced chronic renal failure [118]. While the antiapoptotic effect of MSCs in the model of acute renal injury could be detected as soon as several days after the injury, a model of chronic renal failure has shown that the effect of MSC administration persisted for 12 weeks.

Yagi *et al.* demonstrated that administration of MSCs noticeably reduced the number of apoptotic cells, and Akt overexpression was observed, after MSCs were introduced into the inflammatory medium (when "inflammatory serum" was added) in models of LPS-induced acute respiratory failure and thermal burns [60]. The antiapoptotic effect of human umbilical-cord-blood-derived MSCs in a model of acute optic nerve injury was observed at an early stage: caspase-3 level was assessed and TUNEL staining was performed. However, this effect was transient, since no differences were observed between the experimental and control groups at a later stage after the injury [119].

Thus, it is clear that MSCs exhibit an anti-apoptotic effect. This effect is most likely based on several pathways including the ability of MSCs to affect the PI3K–Akt–Bcl-2 signaling pathway and their ability to suppress oxidative stress.

### 35.2.6 Mesenchymal stromal-cell-derived microvesicles: an essential part of the paracrine mechanism

Secretion of growth factors and cytokines is a key property of MSCs and contributes to the positive effect of MSCs in a number of disorders, except for those of the musculoskeletal system where they are able to mediate their effect by transdifferentiation to the tissue into which they are injected.

The concept of the paracrine effect of MSCs now includes their ability to secrete MVs into the surrounding environment. MVs are exosomes 50–100 nm in size that contain a broad range of protein molecules and lipids as well as nucleic acids, with mRNAs and microRNAs being of particular interest. The most probable precursors of MVs are early endosomes and/or Golgi vesicles. Internal membrane folds are subsequently formed in them, resulting in formation of a large number of intraluminal vesicles inside the endosome. This complex is known as a multivesicular body. The membrane of the multivesicular body then fuses with the outer membrane of the MSC. Numerous intraluminal vesicles enter the intercellular medium, where they are referred to as MVs [120].

The role of MVs made by MSCs has not been completely clarified. However, a number of studies have been published demonstrating that introduction of isolated MVs can reduce the level of organ injury and see Chapters 1, 20, 38 and 57.

Thus, Bruno and colleagues demonstrated that MVs isolated from bone-marrow-derived MSCs significantly reduced mortality after cisplatin-induced kidney injury, decreased a histological abnormalities, and resulted in improved renal function as measured by reduced blood creatinine and urea levels compared with the untreated control animals [121]. Repeated administration of MVs had a greater effect than a single administration. However, the positive effect of introducing MVs was reduced after they had been subjected to long-term treatment with RNase, which suggests that mRNA and probably microRNAs embedded in MVs play a critical role in the mediation of the effect of the MVs. RNase concentration was significantly higher than physiological concentration, and the microvesicular membrane failed to protect RNA against cleavage [122,123]. A positive effect of MVs has also been demonstrated in other models of acute kidney injury, including those caused by glycerol administration [122], gentamicin administration [124], and IRI [123].

The role of MVs has also been demonstrated in injury models involving other organs. Herrera *et al.* found that MVs isolated from human hepatic stromal cells induced hepatocyte proliferation, reduced apoptosis *in vitro*, and contributed to regeneration and recovery of liver function after partial (70%) hepatectomy [125]. No effect was observed if MVs were treated with RNase. A protective effect from the administration of MSC MVs was demonstrated in other preclinical models of liver injury, including those caused by administration of CCL4, acetaminophen, and hydrogen peroxide [125,126]. It was shown that MVs enhance proliferation, manifested as enhanced expression levels of proliferating cell nuclear antigen (PCNA), which is a DNA clamp that acts as a processivity factor for DNA polymerase δ in eukaryotic cells and is essential for replication, as well as on cyclin D1. Additionally, apoptosis was decreased through increasing expression of the antiapoptotic factor Bcl-xL [126].

Lai *et al.* demonstrated that MVs reduced infarct size in a model of myocardial IRI in mice [127], and Bian *et al.* reported that MVs stimulated angiogenesis after myocardial infarction [128]. There are also studies confirming the protective effect of MVs in a model of lung injury [129].

Thus, it is clear that MVs play an important role in the activity of MSCs. However, the composition of MSC MVs has been analyzed in only a few studies. Kim *et al.* conducted a proteomic analysis of isolated MVs and found that they contained over 730 different proteins [63]. Most of these proteins are typically found in all types of MVs. However, 122 proteins detected in MVs were characteristic of MSCs. For example, MVs from MSCs had positive markers typical of those of MSCs, including CD13, CD29, CD44, CD73, and CD105, as well as some markers that have variable expression in MSCs, such as CD10. Fifty-five proteins (8%) revealed in MSC MVs were also found in MSC-CM.

Cell surface receptors (such as platelet-derived growth factor-β, epidermal growth factor receptor, and urokinase-type plasminogen activator receptor), which have a significant effect on

cell differentiation and proliferation and enhance mobilization and migration of MSCs, may play a key role in the therapeutic effect of MSCs. Signaling molecules such as RAS (a family of GTPases), MAPK1 (a protein kinase), RHO (also a family of GTPases, of which Cdc42 is a member) also play a significant role. These signaling pathways eventually enhance MSC proliferation and differentiation. The presence of molecules involved in cell adhesion, including fibronectin 1, ezrin, IQGAP1, CD47 (also known as integrin associated protein), galectins 1 and 3, and integrins, also indicates that MVs contribute to cell adhesion, migration, endothelial proliferation, angiogenesis, and vascular remodeling.

However, the main role of MVs is now attributed to the mRNAs and microRNAs contained within them. Ratajczak *et al.* demonstrated that embryonic stem cells can transfer mRNAs into other cells [130], while Chen *et al.* showed that MVs derived from MSCs were enriched in pre-microRNAs. mRNA and microRNA molecules penetrate target cells, thus affecting the cell's genome and changing the expression of various genes within the cell [131]. In this way, they cause critical changes in cell function. Migration of microRNA into a cell causes the phenomenon of RNA interference, the formation of complementary complexes between the mRNAs of the cell and microRNAs. Binding of the mRNA to microRNA results in inhibition of translation of the genes encoded in the region involved in the binding. The mRNA–microRNA complex is rapidly degraded by the cell [132]. It has also been reported that microRNAs interact directly with the DNA of the target cell [133]. MVs are likely excellent carriers of microRNAs and mRNAs, since they protect them against RNase activity. Some data are available indicating that MVs can be found in most fluids of the body [120].

There is presumably a mechanism for the selection of microRNAs to be transferred to MVs. Collino *et al.* found that, while MSCs and the MVs derived from them contain appreciably high levels of microRNAs, some microRNAs are detected only in MVs but not in MSCs [134]. The selection mechanism remains unclear. However, it is likely that microRNAs not transferred to MVs are destroyed by intracellular RNase.

Bruno *et al.* used the preclinical model of cisplatin-induced kidney injury to confirm that MV transfer mRNAs to the tubular cells and that proteins are translated from the transferred mRNAs. In this study, MVs were isolated from human bone-marrow-derived MSCs and carried the polymerase (RNA) II (DNA-directed) polypeptide E (*POLR2E*) and small ubiquitin-related modifier 1 (*SUMO-1*) genes. No expression of these genes was observed in the renal tubular epithelium of normal mice. However, proteins encoded by the *POLR2E* and *SUMO-1* genes were found in the renal tubular cells of mice with acute kidney injury after administration of MVs. No proteins were found in cells of animals that did not receive MVs [121]. An *in vitro* experiment demonstrated that MV genes were found in renal tubular cells after co-incubating them with MVs for 1 h.

A number of studies have demonstrated the ability of MVs to reduce the degree of apoptosis. Herrera *et al* [125]. used TUNEL staining to show that MVs derived from human hepatic stromal cells significantly reduced apoptosis after hepatectomy and enhanced cell regeneration. Treatment with RNase neutralized this effect, which confirmed the role of mRNAs and microRNAs in this process. It was shown in the model of cisplatin-induced renal failure that treatment with MVs increased expression of antiapoptotic genes (*BCL-XL*, *BCL2*, and *BIRC8* (baculoviral inhibitor of apoptosis repeat containing protein 8)), while reducing expression of pro-apoptotic agents such as caspase 1, caspase 8, and lymphotoxin-α. Moreover, introduction of MVs significantly increased PCNA expression by tubular cells, attesting to the important effect of MVs on proliferation. Micro- and mRNAs clearly play the key role in this effect [121].

Zhu *et al.* demonstrated that MVs isolated from human bone-marrow-derived MSCs alleviated *E. coli* endotoxin-induced acute lung injury, reduced the amount of extravascular fluid in lungs by 43%, and reduced the total protein level in broncho-alveolar fluid by 35%. Introduction of MVs also inhibited neutrophil migration and reduced MIP-2 concentration by 49%. Additionally, KGF gene knockout by RNA interference profoundly reduced the effect of MVs. We believe that the transfer of KGF mRNAs by MVs plays a key role in the effect exerted by MVs, MSCs and MSC-CM in endotoxin-induced acute lung injury [135]. There is no doubt that production of MVs is one of the key mechanisms in the paracrine effect of MSCs, along with secretion of soluble growth factors and cytokines. It is probably the synergistic activity of these two sets of agents that provides the powerful positive effect that has been repeatedly observed when using MSCs-CM to treat a number of different disease models.

## 35.3 Mesenchymal-stromal cells in the treatment of acute ischemia–reperfusion injury

IRI is a pathological process in which cell injury of an ischemic organ is enhanced by the restoration of blood flow to it [136–138].

Girn *et al* [139]. proposed the following definition of IRI: "the paradoxical and complex phenomenon of exacerbation of cellular dysfunction and increase in cell death after the restoration of blood flow to previously ischemic tissues."

Organ or tissue injuries such as acute myocardial infarction, acute renal failure, ischemic stroke, and tissue damage due to shock (severe hypotension) are the main fatal conditions that are accompanied by IRI.

Current treatment regimens of IRI are not fully effective, and new approaches to IRI therapy are needed. The use of MSCs is one approach, but first we would like to provide an overview of the pathogenesis of IRI.

### 35.3.1 Ischemia–reperfusion injury pathogenesis

The processes underlying the reperfusion syndrome can be defined as follows:

1 A metabolic imbalance accompanied by damage to mitochondria and disturbance of calcium homeostasis
2 Increased production of reactive oxygen species and NO.
3 Disorders of the microcirculation.
4 Activation cells of the immune system with the subsequent release of proinflammatory and pro-apoptotic factors.

Inflammatory changes in the form of the increased secretion of proinflammatory cytokines such as TNF-α, IL-1, IL-6, IL-8, and others by the ischemic tissue as well as the activation of complement components (C5a) leads to the development of inflammation and the migration of leukocytes, primarily neutrophils, to the damaged area [140]. Neutrophils activate adhesion molecules and interact with the endothelium through the rolling, adhesion, diapedesis mechanism [141], which, in combination with an increase in the rigidity of their membrane and a consequent decrease in their ability to deform, leads to disruption of blood flow throughout the capillary bed and prolongation of ischemia during the acute reperfusion stage – the no-flow phenomenon [142]. Of the proinflammatory cytokines, TNF-α is of particular importance, since it has been demonstrated to be capable of inducing heart microvascular endothelial dysfunction in the myocardium independently of neutrophil infiltration [143]. Furthermore, the action of anti-TNF antibodies results in a significant reduction in coronary arteriolar endothelial dysfunction and in the size of the myocardial infarct [140]. A direct relationship between the level of TNF-α expression and endothelial dysfunction during reperfusion injury has been observed [144].

The release of reactive oxygen species and free radicals (in particular, those due to increasing lipid peroxidation) leads in turn to elevated transaminase levels in the blood, increased inflammatory infiltrate, chromatin fragmentation, and the development of apoptosis [145].

Metabolic disorders are associated with an excessive intake of electrolytes and tissue macroerg synthesis products into damaged and necrotic tissues. Damaged tissues are not able to metabolize the incoming substrate normally. This leads to disruption of cell excitability, the activation of cyclogenase and lipoxygenase with subsequent formation of prostaglandins and leukotrienes, and the activation of anaerobic metabolism, which in turn exacerbates the degree of metabolic acidosis [146]. These changes lead to pronounced changes in cells, with apoptosis and necrosis of cells during acute reperfusion.

### 35.3.2 The use of mesenchymal stromal cells in kidney ischemia–reperfusion injury

Kidney IRI is the most frequent cause of IRIs, leading to acute renal failure in both the native kidney and the transplanted kidney [147]. The beneficial effects of MSCs in acute renal insufficiency (in particular, cisplatin-induced kidney failure) have been demonstrated in both *in vivo* and *in vitro* models. Administration of MSCs produced a significant increase in cell viability *in vitro* [58], the degree of apoptosis level was decreased [68], animal survival in *in vivo* experiments was increased up to 80% compared with control animals [52,148], and the function of the damaged organs was largely retained [52,53,60].

Chen *et al.* modeled kidney IRI in rats by clamping the renal artery pedicles on both sides for 1 h [88]. Next, the experimental group was administered adipose-derived MSCs (ADMSCs) while the control group received the culture medium. The urea and creatinine parameters at different intervals after reperfusion were examined. A significant improvement in the levels of both parameters was observed in the experimental group compared to the control group [88]. Histological studies revealed more significant damage to the kidney tissue in the control group compared with the experimental group, which was demonstrated by large areas of tubular necrosis, glomerular dilatation, and the loss of brush border.

Further, a study of mRNA expression of endothelin-1 (an indicator of vasoconstriction and endothelial damage), and TNF-α, and MMP-9 (indicators of inflammation) was conducted using real-time polymerase chain reaction. The values of these parameters in the control group were significantly higher than those in the experimental one, whereas anti-inflammatory markers such as IL-10 were significantly higher in the experimental group compared with the control. In addition, the secretion of ICAM-1 adhesion molecules and NF-κB were investigated using Western blot. These markers were also significantly reduced in the experimental group compared with the control group. In addition, the expression of markers of oxidative stress and apoptosis was investigated: an apoptosis indicator, caspase-3, was significantly reduced, whereas an antiapoptotic indicator, BCL-2, was increased in the experimental group compared with the control group.

Chinese researchers also demonstrated a pronounced positive effect of MSCs in a kidney IRI model *in vivo* and *in vitro* [147]. They focused on the increased release of SDF-1 (or CXCL12) by the ischemic kidney tissue. This factor plays a crucial role in the chemotaxis and homing of MSCs to inflamed tissue. The interaction of SDF-1 with MSCs is mediated by two chemokine receptors: CXCR4 and CXCR7. These researchers found that the expression of SDF-1 receptors was significantly increased by culturing MSCs under hypoxic (3% $O_2$) conditions. They found that CXCR4 was required for the homing of MSCs to the ischemic tissue. CXCR7 was important for increasing the viability of MSCs in the ischemic tissue.

Considering hydrogen peroxide ($H_2O_2$) as one of the most important mediators of cell death in IRI, Sachse and Wolf treated MSCs with this agent [149]. MSCs cultured in hypoxic conditions had much higher viability than MSCs cultured in normoxic conditions. As indicated above, a relationship and the expression of CXCR4 and CXCR7 receptors has been described. Four major pro-regenerative factors secreted by MSCs are VEGF,

HGF, IGF-1, and bFGF [52,68,74]. Using enzyme-linked immunosorbent assay, it was shown that the secretion of these growth factors was increased under hypoxic conditions and/or upon adding SDF-1 to the culture. At the same time, when CXCR4 and CXCR7 were neutralized by monoclonal antibodies, the secretion of all growth factors studied was markedly decreased. Furthermore, the therapeutic effect of MSCs in an *in vivo* kidney IRI model was diminished.

This work demonstrated the ability of MSCs not only to adapt well to conditions of hypoxia and ischemia, but also to increase their functional activity, including protein secretion, in a renal model of IRI due to the expression of SDF-1 and its receptors.

Another group conducted a similar study, but, in contrast to previous studies, they used uncultured ADMSCs freshly isolated from the adipose tissue of rats or fresh ADMSCs that had been cryopreserved [150]. The intra-arterial administration of these cells into the IRI-affected kidney increased the survival rate of the experimental animals and reduced the serum level of creatinine and urea compared with the control group within the first 24 h. Additionally, it also significantly reduced the expression of the proinflammatory cytokines IL-6 and MIP-2α (CXCL2). Furthermore, a significant decrease in $CD68^+$ macrophage infiltration of the kidney tissue was observed, as well as an increase in the cell proliferation marker Ki-67 in the distal and proximal kidney tubules after the administration of both freshly isolated ADMSCs and after ADMSCs that had been previously cryopreserved [150].

Since these changes were detected within the first day of IRI, as well as the fact that ADMSCs were virtually absent in the kidney tissue 72 h after the introduction, it is likely that the therapeutic effect in ischemia–reperfusion kidney injury is mediated by paracrine factors secreted by the ADMSCs and not by transdifferentiation [150].

### 35.3.3 Mesenchymal stromal cells and myocardial ischemia–perfusion injury

Acute coronary syndrome is a form of coronary heart disease that is the leading cause of mortality in the developed world. Timely reperfusion is the most important treatment. However, reperfusion itself is accompanied by inflammatory changes, oxidative stress, and metabolic disorders that lead to further damage to the myocardium. MSC administration into the myocardium has been reported to significantly reduce pathological remodeling of the infarct area (to become fibrotic), and thus to improve ventricular function [151–153]. MSC administration significantly reduced infarct size and increased cell proliferation and neovascularization of the infarcted area compared with hematopoietic progenitor cells [154]. A minority of investigators have explained this positive MSC effect by their ability to differentiate into cardiomyocytes *in situ* [151,153]. However, this remains controversial [155] and has not been able to be confirmed by other groups.

In contrast, there are a number of studies that suggest that paracrine mechanisms are involved in this improvement in myocardial function [154,156–161]. For example, Angoulvant *et al.* demonstrated that MSC-CM significantly reduced myocardial IRI. The *in vitro* data were obtained using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) test and by measuring lactic dehydrogenase. The *in vivo* data were obtained by measuring blood levels of creatine phosphokinase and by measuring infarct area [162]. The MTT assay is a colorimetric assay for assessing cell viability: nicotinamide adenine dinucleotide phosphate (NADPH)-/reduced form of nicotinamide adenine dinucleotide-dependent cellular oxidoreductase enzymes may, under defined conditions, reflect the number of viable cells present. These enzymes are capable of reducing the tetrazolium dye MTT to its insoluble formazan, which has a purple color. Moreover, the main mechanism of the positive effect was attributed in this study to paracrine activation of the PI3K-dependent pathway.

In 2006, Gnecchi *et al.* demonstrated that the introduction of CM obtained from MSCs overexpressing the Akt gene into the myocardium considerably reduced infarct area and improved left ventricular systolic pressure [156]. It was shown *in vitro* that this MSC-CM enhanced the viability of cardiomyocytes cultured under hypoxic conditions. As an indicator of apoptosis, the caspase-3 level was markedly reduced upon the introduction of the CM from MSCs. Additionally, the levels of paracrine factors such as VEGF, HGF, IGF-1, and bFGF were quite high in the CM of unmanipulated MSCs grown under normoxic conditions, but lower than in the CM from cells cultured under hypoxic conditions and/or those with enhanced expression of the Akt gene [156].

In another study, American investigators demonstrated that the MSC cardioprotective effect increased with knockout of the *TLR4* gene [55]. TLR4 is known to be expressed by MSCs [163]. When interacting with its ligand, this receptor is capable of inducing apoptosis and reducing cellular proliferative capacity, while a deficiency in this receptor leads to a decrease in the secretion of proinflammatory cytokines by cells [163,164]. Using the isolated rat heart, an IRI model was developed and parameters including left ventricular diastolic pressure and end-diastolic pressure were measured. TLR4 knockout (TLR4KO) murine MSCs demonstrated a more pronounced cardioprotective effect.

It has also been shown that TLR4KO MSCs produce more growth factors and chemokines – such as tissue inhibitor of metalloproteinases-1, M-CSF, and factors encoded by the KC and JE genes – and enhance MSC proliferation to a greater extent than wild-type MSCs [55].

In addition, it was noted that the baseline level of signal transducer and activator of transcription-3 (STAT3) was significantly higher in TLR4KO MSCs than in wild-type MSCs, and that knockdown of STAT3 using RNA interference caused a significant decrease in the production of growth factors and chemokines by TLR4KO MSCs compared with TLR4KO MSCs without STAT3 knockdown. The cardioprotective effect upon STAT3 knockdown was also decreased. Thus, it has been suggested that the enhanced production of cytokines and the cardioprotective effect of TLR4KO MSCs occurred through the STAT3-dependent pathway [55].

In another interesting study, Webber *et al.* developed a gel composed of self-assembling nanofibers of glycosaminoglycans linked to heparin-binding peptide amphiphile (HBPA) [165]. This gel is capable of immobilizing and binding to heparin, which makes it possible to bind various proteins through their heparin-binding domains. For example, VEGF and HGF bind to heparin, and hence to the gel. The objective of this study was to bind growth factors from MSC-CM and to test this on an IRI model of myocardial infarction and an IRI model of hind limb ischemia *in vivo*. Introduction of the gel steeped in the MSC CM into the wall of the left ventricle promoted significant retention of myocardial function, including left ventricular contractility, relaxation ability, and average systolic pressure, in a rat model of acute myocardial infarction compared with the untreated controls as well as with rats that received the separate introduction of the CM and the gel not steeped in the CM [165]. The most pronounced effect was obtained when the gel was steeped in CM from MSCs cultured under hypoxic (5% $O_2$) conditions. Similar results were obtained in a hind limb ischemia model. In this model, angiogenesis was assessed using angiography [165].

### 35.3.4 Mesenchymal stromal cells and ischemia–reperfusion injury of other organs

There have also been attempts to use MSCs in modeling IRI of other organs. For example, Kanazawa *et al.* demonstrated in a rat model of ischemia–reperfusion liver injury that transplantation of MSCs immediately after the restoration of perfusion significantly reduced the level of hepatic transaminases (a rise above normal indicates hepatic damage) and the level of apoptosis. Apoptosis was observed mainly in the centrilobular area. Enhancement of liver regeneration was noted [62]. Most of the introduced MSCs were in the periportal area, and only a small fraction of the cells was found in the centrilobular area. Thus, the cell migration site and the apoptosis site did not coincide, indicating that the transplanted cells did not replace damaged hepatocytes and that the antiapoptotic effect was likely due to paracrine mechanisms. In addition, the presence of the MSCs was determined by their luciferase activity of cells using an *in vivo* imaging system (IVISTM; Xenogen, Alameda, CA). The number of MSCs significantly decreased with time, and virtually none were observed after 7 days [62]. The significant reduction in liver transaminases in the first 24 h after MSC administration suggests that their effect was mediated by paracrine mechanisms [62].

The administration of MSCs as treatment of ischemia–reperfusion lung injury has also been described in a number of studies [166–168]. Sun *et al.* demonstrated in a rat model of lung IRI that administration of ADMSCs markedly increased the $O_2$ saturation level in blood and lowered the systolic blood pressure in the right ventricle as early as 72 h after the start of reperfusion compared with the control group, indicating protection of lung function. They found a significant increase in the level of expression and secretion of proinflammatory cytokines, including TNF-α, IL-1β, MMP-9, NF-κB, VCAM-1 and ICAM-1, pro-apoptotic factors (caspase-3, BAX), and endothelin-1 in the control group compared with the experimental group. In contrast, the experimental group showed enhanced expression of anti-inflammatory agents (including adiponectin, endothelial NO synthetase, and IL-10), as well as the anti-apoptotic agent BCL-2 and the antioxidant factors heme oxygenase, NADPH oxidase, NADPH quinone reductase, and glutathione reductase. Additionally, there was enhanced expression in the experimental group of von Willebrand factor and $CD31^+$, indicating active angiogenesis [166]. Chen *et al.* obtained similar results, although they used MSCs derived from bone marrow rather than from adipose tissue [167].

In another study, bone-marrow-derived MSCs transduced with the IL-10 gene were used for treatment of lung IRI *in vivo*. There was a marked improvement in both structural and functional parameters of the lungs in the experimental group compared with an untreated control group and a group given unmodified MSCs. Parameters of inflammation and apoptosis were also significantly reduced in the experimental group [168].

Other studies have reported positive outcomes when MSCs were administered in preclinical models of IRI of the intestine [169], the retina [170], the brain [171], and the limbs [58].

### 35.3.5 Conclusions

MSCs appear to have a beneficial effect in a number of organs damaged by IRI, and this effect appears to be mediated by a paracrine function of the MSCs and not by transdifferentiation.

## 35.4 The use of mesenchymal stromal cells in acute lung and airway injury

Pulmonary epithelium is constantly exposed to pathogenic factors such as microorganisms, allergens, smoke, and occasionally to chemical gases. Physiologic repair and renewal of airway epithelial cells is a continuous process, although its rate is lower than that of renewal of skin or colonic epithelium.

Repair of airway epithelium after an acute injury depends on the intensity of a damaging factor, on the type of pathogenic agent, and the injured area, be it the trachea, the bronchi, or the alveoli.

The epithelium of mouse trachea consists of a number of different cell types. Ciliary cells express β-tubulin and forkhead protein J1 (FOXJ1). Club cells, also known as bronchoalveolar cells and originally known as Clara cells after their discoverer Max Clara (1899–1966), express secretoglobin family 1A member 1 (SCGB1A1, also known as uteroglobin) and mucin 5b. Goblet cells express Scg1a1, Muc5B, Muc5A/C, and SAM pointed domain-containing ETS transcription factor. Basal cells express transformation-related protein 63 (p63) and cytokeratin 5 and/or 14 [172–177].

The mucus-secreting glands of the tracheal mucosa are located between the epithelial layer and the cartilage tissue. These glands have been shown to contain ductal cells that express cytokeratin 5

and 14 and, together with basal cells, are involved in the regeneration of severe epithelial injury that can be caused by ischemia or tracheal transplantation [178,179].

Columnar ciliated epithelium is replaced by monolayer cubic epithelium closer to the distal regions of the lungs. The intralobular bronchi mostly contain club, ciliary, and neuroendocrine cells. The highest concentration of neuroendocrine cells is at the bronchial bifurcation zone [177].

In the distal regions of the lung, type I pneumocyte cells (also called type I alveolar cells or squamous alveolar cells) are extremely attenuated cells that line the alveolar surfaces of the lungs. They cover 97% of the alveolar surface, with type II pneumocytes covering the remainder. Type II pneumocytes, also called alveolar type II cells, great alveolar cells, or septal cells, are granular and roughly cuboidal in shape. Type II pneumocytes are typically found at the alveolar-septal junction. Although they comprise 60% of the alveolar lining cells, because of their shape they cover a much smaller surface area than type I cells (<5%). Type II pneumocytes secrete a surfactant that is composed of a group of phospholipids that reduce alveolar surface tension.

### 35.4.1 Repair of the proximal regions of the airways after acute injury

Chemical agents such as sulphur dioxide, hydrochloric acid and naphthalene damage the ciliary epithelium. Club cells and basal cells expressing p63 and keratin type II cytoskeletal 5 (KRT5) that are involved in repair are partially retained. Ciliary cells and goblet cells recover during the repair process [174,180–183]. Diphtheria toxin mostly kills basal cells, and the surviving club cells are involved in their regeneration. Ductal stromal cells expressing Krt5 and Krt14, which reside in submucosal glands and which repair all types of epithelial cells, are activated in severe tracheal injury caused by hypoxia or transplantation, when almost all epithelial cells are damaged [178,179].

Data on the repair of the distal bronchial regions were obtained using the naphthalene-induced injury model. Naphthalene injury selectively kills club cells in intralobular bronchi, while the pool of naphthalene-resistant club cells (known as variant club cells) is retained. The latter cells express SCGB1A1 and surfactant protein C and reside near neuroendocrine cells and the bronchoalveolar junction. Neuroendocrine cells express calcitonin gene related peptide and protein gene product 9.5. The surviving variant club cells begin to secrete Wnt7b, which induces active proliferation of airway smooth muscle cells. The cells secrete FGF10, which induces short-term epithelial to mesenchymal transition. As a result, club cells begin to proliferate and repair the injured sites. Inhibition of FGF10 significantly reduces the ability of bronchial epithelium to regenerate after naphthalene-induced injury. It should be mentioned that neuroendocrine cells can be transformed into club cells. However, their contribution to the repair process is insignificant, since their elimination does not have a noticeable effect on regeneration [177].

In addition to resident stromal cells in the lung tissue, the mouse bone marrow contains $KRT5^+$ cells that participate in the repair of tracheal epithelium. It has been demonstrated that $CD45^+$ $KRT5^+$ cells expressing CXCR4 maintained the circulating pool involved in epithelium repair after injury. The cells are mobilized by activation of the CXCL12/CXCR4 axis. $KRT5^+$ $CXCR4^+$ cells play a key role in tracheal graft re-epithelization, and blocking of CXCL12 prevents mobilization of these cells [184].

It has also been demonstrated that bone-marrow-derived endothelial progenitor cells express KGF receptor in addition to $KRT5^+$. Systemic administration of KGF significantly increased mobilization of circulating endothelial progenitor cells 6 h after injection. A more rapid repair was observed in mice with transplanted trachea that received KGF due to the increased number of circulating endothelial progenitor cells. This effect was inhibited by anti-CXCL12 antibodies [185].

The role of MSCs in the repair of tracheal epithelium has been shown in many studies. Gender mismatch (detection of the Y chromosome) or green fluorescent protein was used to demonstrate that bone-marrow-derived MSCs contributed to the repair of epithelium in the proximal and distal airways regions. However, the number of MSCs in the lung tissue was low, ranging from 1 to 14% [186,187].

The intratracheal administration of MSCs in a mouse model of LPS-induced lung injury showed that the transplanted cells reduce the TNF and MIP-2 levels, while increasing the IL-10 level in broncho-alveolar lavage fluid. The degree of pulmonary edema was decreased and survival increased from 42% to 80%. Although less than 5% of MSCs were detected in lung tissue, intratracheal administration of MSCs had a therapeutic effect [187]. Similar data were obtained with the intravenous injection of MSCs in a bleomycin-induced model of respiratory failure [188,189]. Bleomycin is a cytotoxic drug that can cause pulmonary fibrosis both in humans and in mice. Because of the low numbers of MSCs detectable in lung tissue, their therapeutic effect was likely mediated by a paracrine effect.

In 2014, a study showed that IL-6 stimulated regeneration of ciliary cells while STAT3 inhibitors reduced it. IL-6/STAT3 signaling facilitated activation of multiciliary genes and enhanced expression of the *FOXJ1* gene. Multiciliated cells are a specialized population of post-mitotic cells decorated with dozens of motile cilia that beat in a polarized and synchronized fashion to drive directed fluid flow across an epithelium. Suppression of the STAT3 signaling pathway increased the number of secretory and basal cells. IL-6 null mice with lung injury produced less ciliary cells and a greater number of secretory cells [190].

We studied the effect of MSC-CM plus MSC lysate (MSC-CM-L) on the repair of rat tracheal epithelium after burn injury resulting from steam inhalation. MSC-CM combined with rat MSC lysate has a marked regenerative effect in heat-induced burn of the tracheal epithelium. Twenty-four hours after heat-induced injury histological examination showed that the

epithelium in the upper portion of the trachea was damaged through to the submucous layer (Figure 35.5A and B).

In the middle portion of the trachea more than 50% of the mucous membrane was damaged. The integrity of the epithelial layer remained partially disrupted (Figure 35.5C).

The pathological changes observed included an expanded vascular network, increased permeability of blood vessels, red blood cells in the epithelial layer, and necrosis of a large number of columnar epithelial cells. There was intense inflammation in the epithelium. Goblet cells and mucous glands retained their secretory properties in the surviving regions of the mucosa.

In this preclinical burn model, the epithelium was partially repaired 2–3 weeks after the injury (Figure 35.5D).

Inhalation of MSC-CM-L after the burn increased the size of the submucosal layer and the structures it contained, such as the submucosal glands, as early as 3 days after the burn. The structures migrated toward the basement membrane to be incorporated into the tracheal epithelium (Figure 35.6A and B).

Analysis demonstrated that the resulting vesicles contained ciliary cells of respiratory epithelium (Figure 35.7).

The epithelial layer in the experimental group of animals was completely repaired by 5–7 days after the injury (Figure 35.6C).

The acceleration of tracheal epithelium repair in animals after inhalation injury combined with MSC-CM-L administration can be attributed to accelerated proliferation and differentiation of ductal stromal cells and to the protective effect of cytokines and growth factors contained in MSC-CM-L. We believe that a key aspect of the protective effect is the impact of VEGF, which exhibits both antiapoptotic and anti-inflammatory effects. Inhalation of IL-6 also played a role. When inhaled, this cytokine exhibited an anti-inflammatory effect and reduced the cytokine

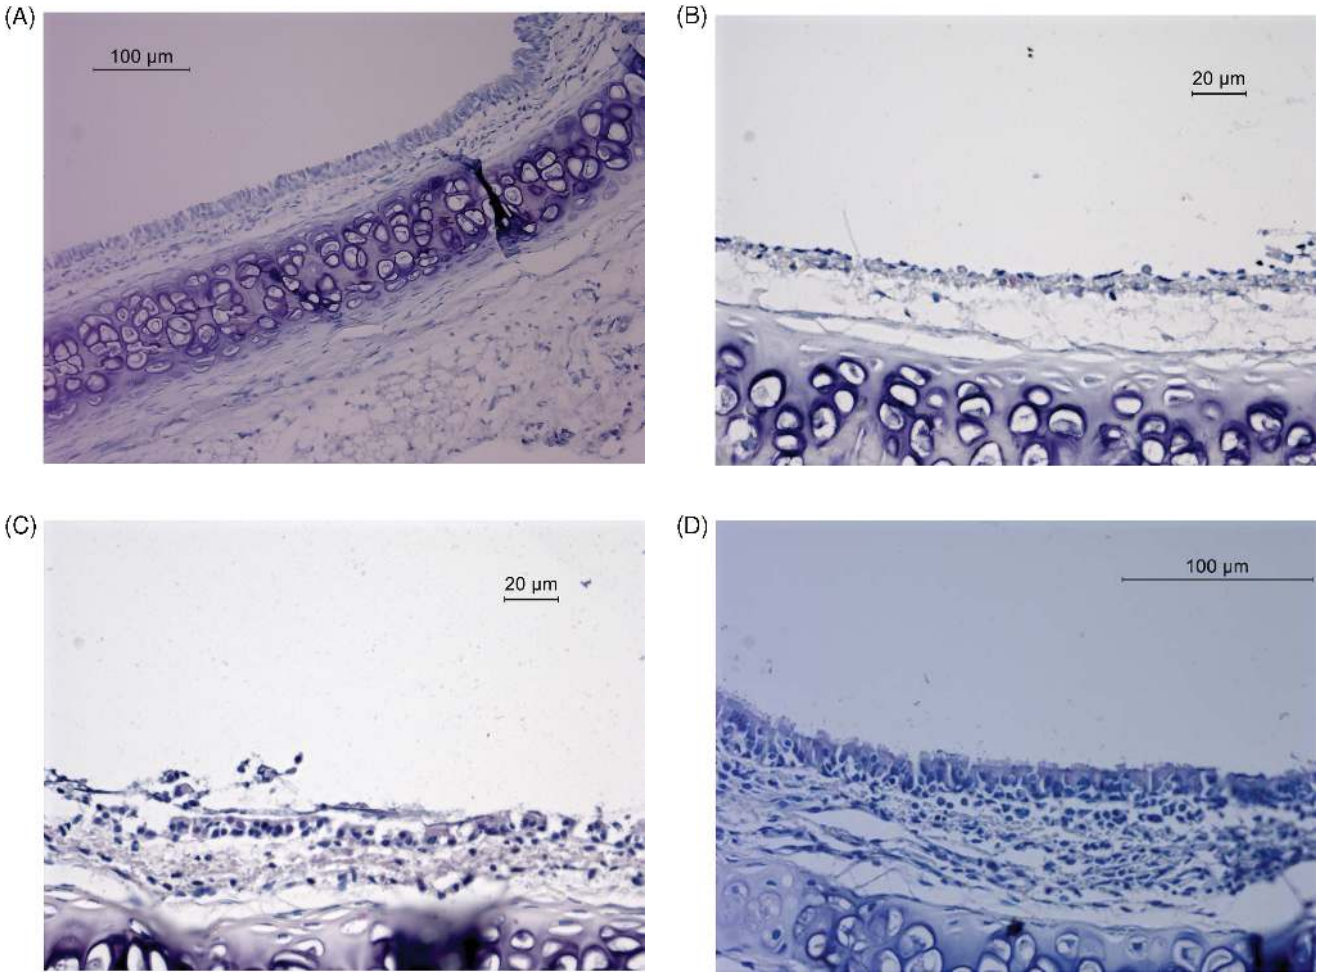

**Figure 35.5** Histopathologic findings in rat tracheal epithelium after a thermal burn:. (A) intact control; (B) 24 h after thermal burn; (C) 7 days after thermal burn; (D) 14 days after thermal burn. Mass epithelial cell death is observed following the burn (B); the epithelium is partly restored at 7 days (C), and complete or nearly complete epithelial recovery is seen at 14 days (D). Staining by haematoxylin–eosin.

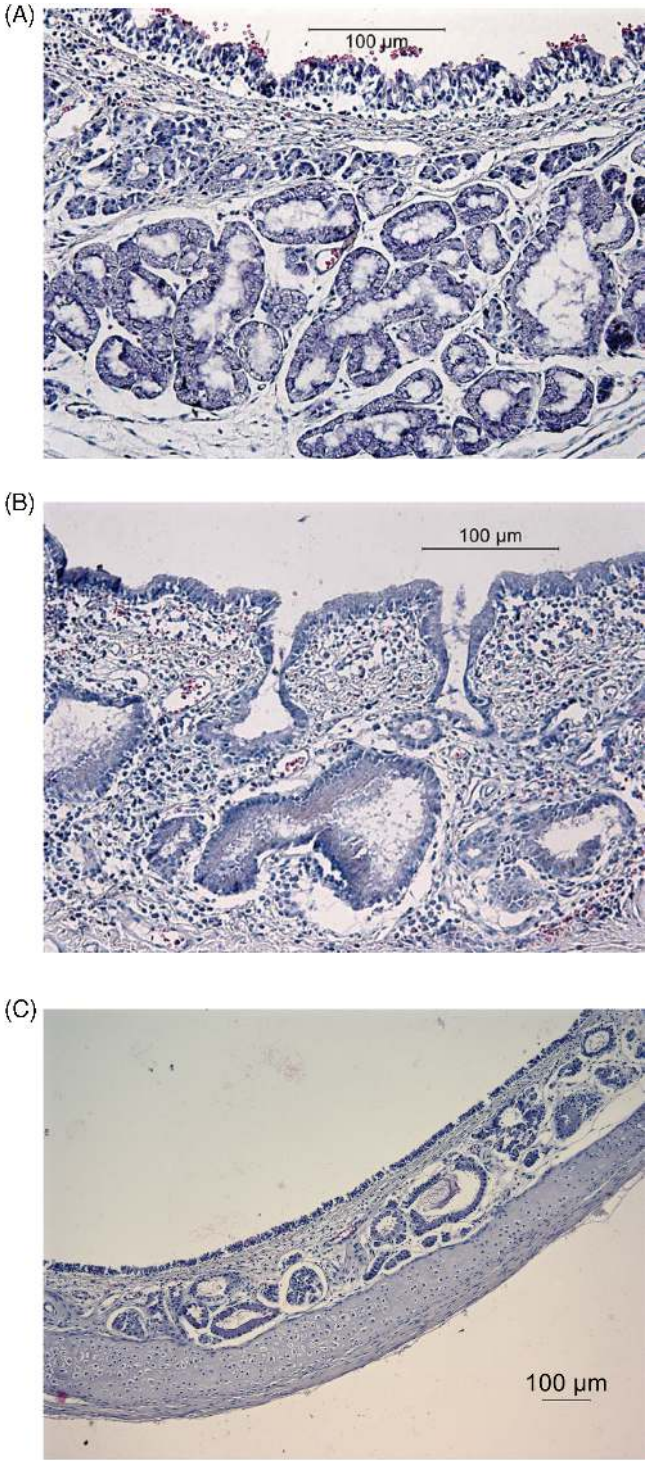

**Figure 35.6** Histopathologic findings in rat tracheal epithelium after thermal burn in combination with intratracheal administration of MSC-CM-L. Endotracheal introduction of MSC-CM-L after the burn resulted in vesicle formation in the submucosa of the trachea. (A, B) The greatest number of vesicles in the submucosa was observed on day 3 following the burn injury and MSC-CM-L administration. After this time point the vesicles reduced in number, reaching a minimum by day 7 (C). Moving toward the basal membrane, the vesicles became incorporated into the respiratory epithelium of the trachea (B). Staining by haematoxylin–eosin.

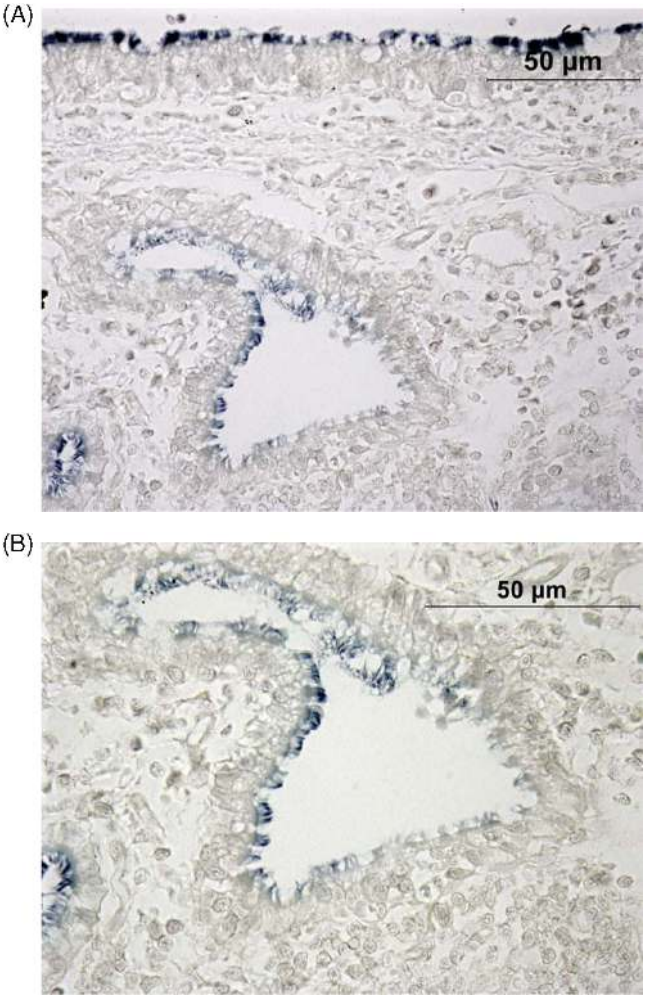

**Figure 35.7** Histopathologic findings in rat tracheal epithelium after a thermal burn in combination with intratracheal administration of MSC-CM-L. (A) Vesicles in the submucosa of the trachea after thermal burn at day 3 after MSC-CM-L administration. Staining by haematoxylin–eosin. (B) Immunohistochemical detection of ciliated cells of the epithelium. The primary antibody used was mouse monoclonal anti-tubulin; the secondary antibody was anti-mouse antibody conjugated with alkaline phosphatase.

level in inflamed lung caused by the intratracheal administration of LPS [98].

The IL-6 level in MSC-CM-L used was 1200 pg/mL. The increase in the IL-6 level in the tracheal lumen after heat-induced injury appeared to be a factor responsible for the predominant emergence of ciliary cells in the vesicles formed in the submucosal layer. This phenomenon might be caused by the effect of cytokines, as previously described by Tadokoro *et al* [190].

The findings demonstrate that paracrine mechanisms of MSCs play a crucial role in the repair of tracheal epithelium after acute injury. The acellular agent from stromal cells might be effective in treatment of acute lung injury in humans.

## 35.5 Current approaches to controlled transplantation of mesenchymal stromal cells in acute organ injury

The use of autologous MSCs is theoretically preferential to the use of allogeneic MSCs. Their transplantation does not induce immune rejection and minimizes the risks of viral contamination or reactivation. However, prolonged *ex vivo* cell culture increases the risk of malignant transformation and increases the risk of long-term complications [191,192]. In practical terms it is not possible to produce autologous MSCs soon after injury.

The limitations of using allogeneic MSCs also includes the risk of viral infection, although careful screening of the MSC donor similar to that applied to blood donors can minimize this risk. Transplantation of these cells, in particular in immune-compromised patients, could theoretically contribute to tumor development if the cells enter immune-privileged organs or may have a general negative effect on the immune status [193,194]. However, to date, the use of allogeneic MSCs appears to be safe.

Transplantation of MSCs exhibiting high secretory activity or MSCs transfected with genetic constructs and producing neurotrophic factors can be regarded as an alternative approach to therapy of a number of diseases, and retinal diseases in particular [195–204].

It is may be important to deliver nerve growth factor in neurodegenerative disorders of the eye. Successful transfection of human embryonic kidney (HEK) 293 cells with NGF has been reported: *in vitro* NGF expression from transfected HEK 293 cells was observed for 5 days [204] and up until 9 days [205].

As indicated earlier, one theoretical limitation of using MSC transplantation into immune-privileged organs (e.g., the eye or the central nervous system) is the potential risk of malignant transformation of the transplanted cells [206–209]. Again, no such events have been described of human MSCs in clinical trials.

There are a number of approaches to retain the transplanted cells within eye tissues; for example, the use of semipermeable capsules implanted into the vitreous body [210–212], which maintain diffusion of neurotrophic factors and prevent migration and uncontrolled proliferation of the transplanted cells, but may cause local inflammation and disrupt the translucency of the eye [212].

It is now possible to use magnetic technologies to anchor transplanted cells at the transplantation site. MSCs containing magnetic nanoparticles were used to deliver intravenously transplanted MSCs to the liver [213,214]. MSCs labeled with magnetic nanoparticles have also been delivered to the site of acute cardiovascular injury [215]. The directed and controlled migration of MSCs toward the injury site under an external magnetic field and local fixation of the material were attained during the observation period.

One disadvantage of such proposed methods is the high (up to 75%) percentage of MSC death within 24 h after their labeling with nanoparticles [215].

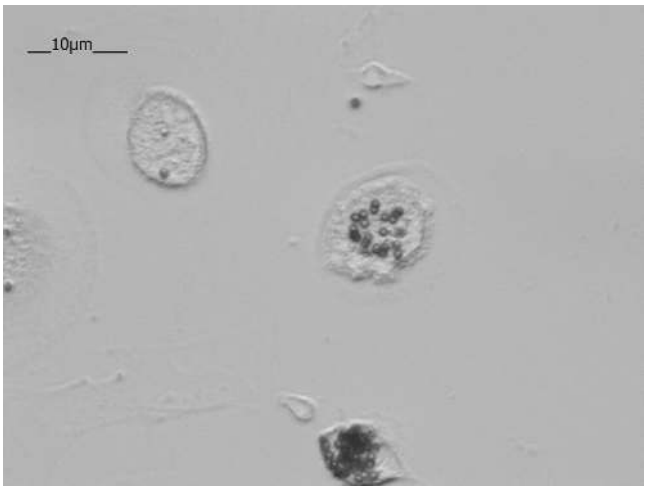

**Figure 35.8** MSC with magnetic particles. Using optical microscopy, different focal depths indicated that the magnetic particles were located in the cytoplasm.

In 2012, Yanai *et al.* successfully targeted delivery of MSCs labeled with superparamagnetic nanoparticles into the retina. However, the experimental duration was short and the study did not attempt to fix the transplanted cells at the transplantation site [216].

We have used micrometer-sized magnetic particles (Invitrogen) treated with Pluronic (a triblock copolymer) surfactants to produce MSCs containing micro-sized magnetic particles within their cytoplasm (Figure 35.8).

The transplanted cells were transfected with the enhanced green fluorescent protein gene using a Clontech kit for visualization. After a magnetic implant was added to a Petri dish, the cells were securely attached to its surface (Figure 35.9).

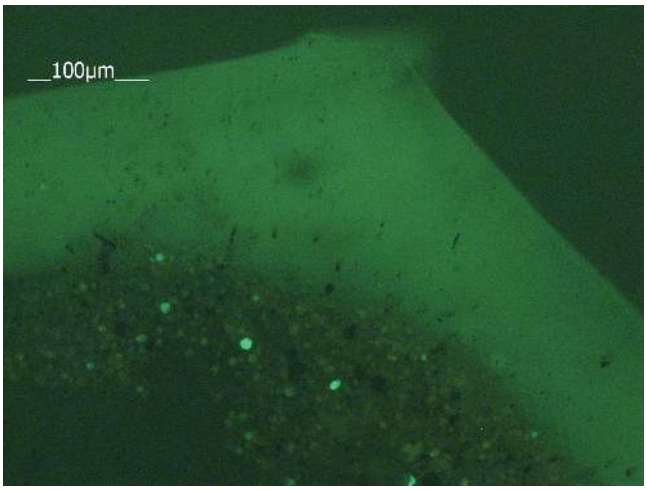

**Figure 35.9** Attachment of MSCs containing magnetic particles in their cytoplasm to the surface of a magnetic implant with a magnetic field intensity of 5 mT.

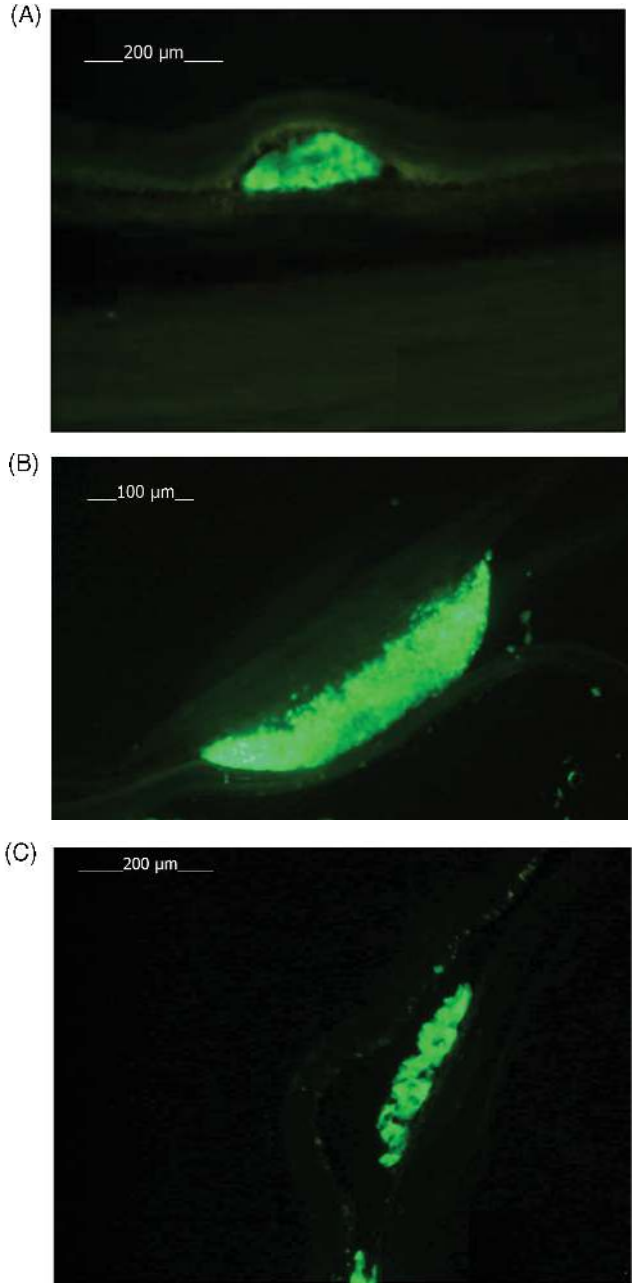

**Figure 35.10** MSCs with magnetic particles fixed by magnetic implant. The cells were located subretinally. Fluorescent microscopy was optimized for detection of green fluorescent protein. The transplantation site of the cells was fixed with a magnetic implant on day 5 (A), day 14 (B), and day 21 (C).

MSCs labeled with magnetic particles and retained by a magnetic implant were transplanted into the retina of rabbits. At 5, 14, and 21 days after the procedure the cells remained at the transplantation site (Figure 35.10). The cells could not be detected after 1 month.

When MSCs were transplanted into the retina without fixation using a magnetic implant, they started migrating to the vitreous body as soon as 3 days after transplantation and could not be detected in the retina by day 5 (Figure 35.11).

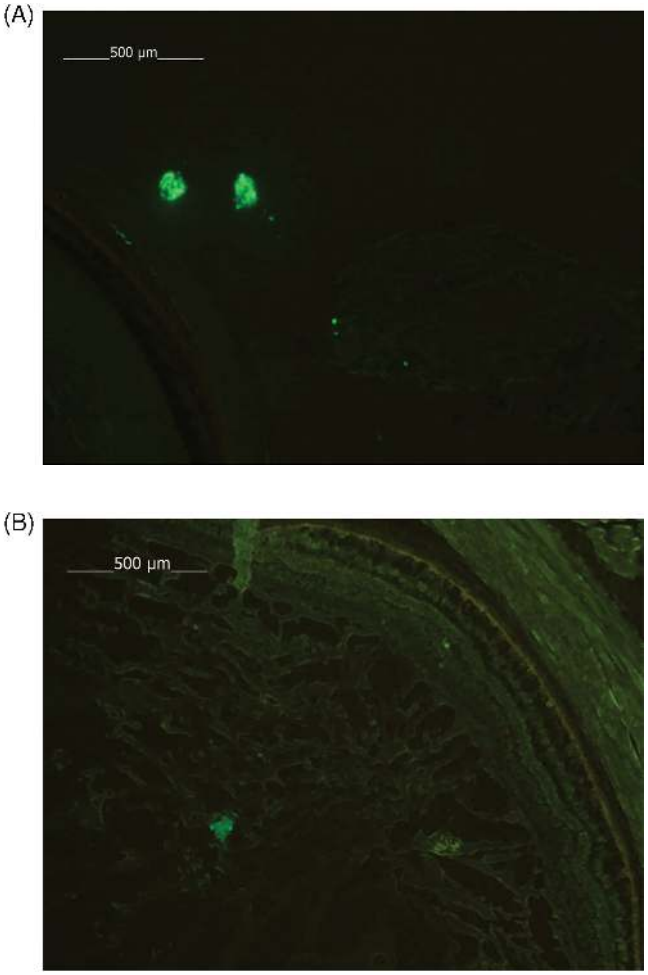

**Figure 35.11** Transplantation of MSCs with magnetic particles without a magnetic implant. The cells are located subretinally. Fluorescent microscopy was optimized for detection of green fluorescent protein. (A) The transplantation site of unfixed cells on day 3. Cells are located in the vitreous body cavity. (B) The transplantation site of unfixed cells on day 5.

These studies demonstrated that the proposed procedure ensured attachment of MSCs at the transplantation site for up to 21 days. This duration was seven times longer than that in the control group. This procedure opens up new avenues for studying the mechanisms of action of MSCs and designing new promising strategies for treating acute organ injury using allogeneic MSCs.

## 35.6 Conclusions

It is clear that the paracrine factors secreted by MSCs contribute to their protective and regenerative effects on acutely injured tissues and organs. Separation of their anti-inflammatory, immunomodulatory, regenerative, antiapoptotic, and antioxidant effects requires further elucidation. All these effects are interrelated and are often caused by similar processes.

## 36.1 Introduction

As a key component of the ocular surface required for vision, the cornea has been extensively studied as a site for cell and tissue-based therapies. Historically, these treatments have consisted of donor corneal tissue transplants [1], but cultivated epithelial autografts have become established over the last 15 years as a routine treatment for ocular surface disease [2–7]. Ultimately, these treatments are performed with the intention of restoring corneal transparency and a smooth ocular surface. The degree of success, however, is often dependent upon the inherent level of corneal inflammation at time of treatment [6,7]. In this regard, the anti-inflammatory and immunomodulatory properties of mesenchymal stromal cells (MSCs) have drawn attention to these cells as potential therapeutic agents for corneal repair.

The origins for MSC-based therapies are founded in part on observations of the recruitment of endogenous bone-marrow-derived cells to injured corneas [8,9]. However, an increasing quantity of data is emerging for MSC administration following their isolation and *ex vivo* expansion from a variety of tissues, including bone marrow [10,11], adipose tissue [12], umbilical cord [13], and dental pulp [14]. In brief, evidence has emerged of cultured MSCs, or their secreted products, having a positive impact on corneal wound healing (Table 36.1) and on retention of corneal allografts (Table 36.2) in animal models.

Optimal dosage, route and timing of administration, however, all remain active areas of investigation. Intriguingly, amidst these studies have emerged reports of MSC transdifferentiation into corneal cells (Table 36.3). The clearest evidence has been obtained with respect to expression of markers associated with the phenotype of corneal stromal cells. In contrast, the evidence for MSC conversion to corneal epithelial cell types remains inconclusive. In neither case does the conversion of

**Table 36.1** Effect of MSCs on corneal wound healing.

| Reference | MSC source | Species | Treatment | Observations |
|---|---|---|---|---|
| Ye *et al.* [11] | Bone marrow | Rabbit | DiI-labeled cells were applied intravenously following alkali burn to cornea. | Labeled cells trafficked to all cell layers of the cornea within 14 days. Enhanced expression of epithelial regeneration markers observed in limbus and peripheral cornea. |
| Oh *et al.* [69] | Bone marrow | Rat | Applied topically to alcohol-denuded corneas. | Dose-dependent reduction in inflammation and neovascularization. Modulations in immune infiltrates were consistent with physiological remodeling and regeneration. Elevations in IL-10, TGF-β1, and TSP-1, coupled with decreases in IL-2, IFN-γ, and CD4, were indicative of reduced inflammatory load. |
| Monteiro *et al.* [14] | Dental pulp | Human | Cultured sheets applied to alkali-wounded rabbit corneas and covered with amniotic membrane. | MSC-treated eyes showed marked improvement compared with control eyes treated with amniotic membrane alone. |
| Liu *et al*. [13] | Umbilical cord | Human | Injected into thin and cloudy corneas of lumican null mutant and keratocan null mutant mice. | Increased corneal thickness and clarity. |
| Zajicova *et al.* [70] | Bone marrow | Mouse | Applied to surgically denuded ocular surface of mice in conjunction with polyamide scaffold and limbal epithelial cells. | Reduction in inflammatory cytokines (IFN-γ, IL-2, iNOS) observed by RT-qPCR. |
| Gomes *et al.* [71] | Dental pulp | Human | Cultured sheets applied to alkali-wounded rabbit corneas and covered with amniotic membrane. | Reduced neovascularization and improved re-epithelialization. |
| Roddy *et al.* [72] | Bone marrow | Human | Applied intravenously or via intraperitoneal injection into rats with alcohol-denuded corneal epithelium. | Reduction in corneal opacity and neutrophil recruitment. Reduction in production of proinflammatory cytokines (including IL-1β) and the angiogenic factor Tenascin C. Role identified for TSG-6. |
| Agorogianni *et al.* [19] | Adipose tissue (autologous) | Human | Applied topically to nonhealing ulcer. | Healing of ulcer observed. |
| Yao *et al.* [73] | Bone marrow | Rat | Subconjunctival injection into rats with alkali-wounded corneas. | Improved re-epithelialization. Reduced infiltration by $CD68^+$ macrophage. Reduced expression of MIP-1α and TNF-α. |
| Cejkova *et al.* [74] | Bone marrow | Rabbit | Applied to ocular surface of alkali-wounded corneas in conjunction with a nanoporous PLA scaffold. | Decreased expression of proinflammatory cytokines, including IL-1β, IL-2, and IFN-γ. Reduced corneal neovascularization accompanied by a reduction in VEGF expression. |
| Lin *et al.* [75] | Adipose tissue | Human | Subconjunctival injection into rabbits with alkali-wounded corneas. | Improved re-epithelialization. |
| Zeppieri *et al.* [76] | Adipose tissue | Human | Applied to ocular surface of alkali-wounded rat corneas. | Reduction in inflammatory cells and improved re-epithelialization. |
| Pinarli *et al.* [77] | Bone marrow | Rat | Grown on amniotic membrane and applied to denuded corneal surface. | Improved re-epithelialization. |
| Jarvorkova *et al.* [78] | Bone marrow | Rat | Systemic administration via an intravenous catheter | Evidence of homing to the site of ocular injury. MSCs pretreated with IFN-γ reduced levels of IL-1α, IL-6, and iNOS in the damaged eye. |
| Lee *et al.* [79] | Bone marrow | Mouse | Systemic administration via intraperitoneal injection | Reduction in $CD4^+$ and $CD8^+$ lymphocytes of the draining lymph nodes. |

CD4: cluster of differentiation 4; CD8: cluster of differentiation 8; CD68: cluster of differentiation 68; DiI: a fluorescent lipophilic dialkylcarbocyanine dye for labeling cells; iNOS: inducible nitric oxide synthase; MIP-1α: macrophage inflammatory protein 1 α; PLA: poly(lactic acid); RT-qPCR: reverse transcriptase–quantitative (real-time) polymerase chain reaction; TNF-α: tumor necrosis factor α; TSG-6: tumor necrosis factor α-stimulating gene/protein 6; TSP-1: thrombospondin 1; VEGF: vascular endothelial growth factor.

**Table 36.2** Effect of MSCs on corneal allograft survival, cytokine production, and immune cell activation.

| Reference | MSC source and treatment | Transplantation model | Effect on transplant | Effect on lymphokine profiles | Other comments |
|---|---|---|---|---|---|
| Oh *et al.* [80] | Allogeneic rat MSCs applied topically. | Xenograft. Pig into rat. | No effect | No effect on IL-2 and IFN-γ. Increase in IL-6 and IL-10. | PKH-26-labeled MSCs were identified in the cornea, but failed to suppress infiltration by immune cells. |
| Jia *et al.* [81] | Allogeneic rat MSCs applied intravenously with and without CSP. | Allograft. Wistar into Lewis rats. | Increased survival when MSC applied alone or with ≥2 mg/kg CSP A. | Reduction: IL-2 and IFN-γ. Increase: IL-4 and positive trend for IL-10. | MSC therapy preoperation or postrejection had no effect. Effect of MSC therapy altered by CSP dose: 1 mg/kg, accelerated rejection; 2 mg/kg, decreased rejection. |
| Oh *et al.* [82] | Xenogeneic. Human MSC applied intravenously. | Allograft. B6 into BALB/c mice. | Increased graft survival. | Reduction: IL-6, IL-1β, IL-12a, IL-2, and IFN-γ. | Majority of cells lodge in lungs. Marked reduction in inflammatory cells within cornea, including $CD3^+$ T cells. Reduced activation of APC in cornea and DLN. Results linked to expression of TSG-6. |
| Lee *et al.* [83] | Xenogeneic. Human bone marrow MSCs applied intravenously. | Allograft. B6 into BALB/c mice. | Increased survival. | Reduction of IL-12a and IL-12b expression in DLN. | Reduced numbers of inflammatory cells within the cornea. Reduced numbers of $CCR7^+$ cells in lymph nodes. Reduction in chemokines involved with trafficking of APC to lymph nodes. |
| Omoto *et al.* [84] | Syngeneic. GFP-B6 into B6 or BALBc into BALB/c, applied intravenously. | Allograft. BALB/c into B6 or B6 into BALB/c. | Increased survival. | Syngeneic MSCs inhibited activation of IFN-γ-producing T cells. | GFP-B6 MSCs recruited to cornea, conjunctiva and DLNs. Reduction in $CD11c^+$/MHC $II^+$ DC maturation. |
| Treacy *et al.* [85] | Syngeneic or IFN-γ-treated syngeneic, or allogeneic or third-party. Lewis into Lewis, or Dark Agouti into Lewis, or Wistar-Furth into Lewis rats. All treatments applied intravenously via the tail vein. | Allograft. Dark Agouti grafts into Lewis rats. | Allogeneic and third-party MSCs prolong graft survival | Significant decreases in IL-6 and IL-1β in rats treated with allogeneic and third-part MSCs. | Reduction in the natural killer T cell numbers as well as APCs and $CD4^+CD25^+$ Tregs cells in MSC-treated animals. Importantly, the percentage of $Foxp3^+CD4^+CD25^+$ was increased in all MSC treatments except the IFN-γ-pre-treated cohort, where this T cell population was preferentially located in the spleen. Significantly increased levels of alloantibodies IgG1 and IgG2 following allogeneic MSC treatment were not related to graft survival. |

B6: C57 black 6 mouse strain; BALB/c: albino mouse strain; CCR7: C–C chemokine receptor 7; CD3: cluster of differentiation 3; CD11c: cluster of differentiation 11c; CD25: cluster of differentiation 25; CSP: cyclosporine; DLN: drainage lymph nodes, Foxp3: fork head box p3/scurfin; GFP: green fluorescent protein; PKH-26: a proprietary lipophilic dye used for labeling cell membranes.

**Table 36.3** Evidence for keratogenic differentiation of MSCs.

| Study | Species of MSC origin | Tissue of MSC origin | Study design | Host species | Observations |
|---|---|---|---|---|---|
| *Evidence for and against conversion into corneal epithelial cells* | | | | | |
| Guo *et al.* [87] | Human | Bone marrow | *In vivo* | Rabbit | Transplanted cells were retained on ocular surface and were immunoreactive toward antibodies to K12 and human antigen. |
| Gu *et al.* [88] | Rabbit | Bone marrow | *In vivo* | Rabbit | Evidence of survival by positive staining for BrdU-labeled cells. |
| | | | *In vitro* | | 10% of cells display immunostaining for K3 (mab AE5). |
| Ma *et al.* [86] | Human | Bone marrow | *In vivo* | Rat | Transplanted cells were retained on ocular surface but failed to express cytokeratin. |
| Monteiro e*t al.* [14] | Human | Dental pulp | *In vivo* | Rabbit | Transplanted cells were retained (human antigen) and co-expressed K3 (determined by IHC using mab AE5). |
| | | | *In vitro* | | Traces of K3/K12 detected in cultured cells by ICC (mab AE5), but only K12 detected by RT-PCR. |
| Gomes *et al.* [71] | Human | Dental pulp | *In vivo* | Rabbit | Transplanted cells were retained (human antigen) and expressed both K3 and K12 (IHC). |
| Zhang *et al.* [89] | Rat | Bone marrow | Organ culture | Dog | K3 was detected by RT-PCR and WB for cells grown on decellularized canine corneas, but levels were less than that for cultured limbal epithelial cell cultures. |
| Rohaina *et al.* [90] | Human | Bone marrow | *In vivo* | Rat | Fate of administered cells not tracked. |
| | | | *In vitro* | | Traces of K3 expression detected by ICC (mab AE5). |
| Katikireddy *et al.* [91] | Human | Bone marrow $SSEA4^{+/-}$ fractions compared | *In vitro* | — | K3 expression confirmed for $SSEA4^{+}$ fraction grown under epithelial growth conditions by ICC (mab AE5). Both K3 and K12 detected by RT-qPCR, but fivefold less than control tissue. |
| *Evidence for conversion into corneal stromal cells (keratocytes)* | | | | | |
| Du *et al.* [92] | Human | Adipose tissue (SP fraction) | *In vitro* | — | SP cells, grown under conditions to promote keratocyte differentiation, expressed keratocan. Expression confirmed by WB, RT-PCR, and RT-qPCR. |
| Liu *et al.* [13] | Human | Umbilical cord | *In vivo* | Mice $Lum^{-/-}$ $Kera^{-/-}$ | Labeled human cells ($DiI^{+}$) adopted keratocyte morphology and phenotype (keratocan, lumican, CD34) when implanted into corneal stromas of null mutant mice. Keratocan and lumican expression confirmed by WB. |
| Liu *et al.* [93] | Mouse | Bone marrow | *In vivo* | Mouse $Kera^{-/-}$ | Labeled cells ($DiI^{+}$) detected in stroma and co-localized with keratocan expression. |

MSCs into corneal cells seems likely to be an essential requirement for their clinical use. This field of research has recently become more complex by reports of MSC-like properties from cultures established from the peripheral corneal stroma – the limbal stroma, the cells of which are known as keratocytes in distinction from the epithelial cells of the cornea, which are known as keratinocytes (Table 36.4). The relationship and relative value of corneal-MSCs compared with traditional sources of MSCs, such as bone marrow, are at present unclear.

After providing a concise overview of corneal structure and function, we will highlight the types of corneal diseases that are likely to benefit from the anti-inflammatory and immunomodulatory properties of MSCs. We will subsequently summarize the evidence supporting the case for MSC-based therapies in the treatment of corneal diseases. Then we will review the literature concerning the keratogenic potential of MSCs. Finally, we will review the more recent literature indicating the presence of MSC-like cells derived from corneal tissue.

## 36.2 Anatomy and physiology of the human cornea

The cornea is the primary refractive element in the visual pathway. It consists of a highly transparent corneal stroma sandwiched between two epithelial tissue layers (Figures 36.1 and 36.2).

The anterior corneal epithelium, like the epidermis of skin, arises, from the ectodermal germ layer of the primitive embryo but forms a nonkeratinized stratified squamous epithelium consisting of between five and seven layers of cells. This epithelium is distinguished from other epithelial tissues in the body by expression of cytokeratin (also known as keratin) 3 and cytokeratin 12 [15]. Renewal of this epithelial layer throughout life occurs by the division and differentiation of epithelial progenitor cells that reside within the peripheral margin of the cornea known as the corneal limbus. More specifically, these so-called corneal stem cells are concentrated deep within epithelial crypts (Figure 36.1D) that reside between undulations of vascularized stromal tissue known as the palisades of Vogt. These are named after Alfred Vogt (1879–1943), a Swiss ophthalmologist.

Immediately posterior to the basement membrane of the corneal epithelium resides an 8–10 μm wide acellular zone of randomly organized extracellular matrix (ECM) components known as Bowman's layer (BL – named after Sir William Bowman (1816–1892), an English physician, anatomist, and ophthalmologist, who discovered it) (Figure 36.1C). While the activities of BL remain unclear, it is interesting to note that the termination point for this structure coincides with the location of the limbal stem cell niche. The adjacent corneal stroma constitutes approximately 90% of the thickness for the entire cornea and contains resident cells known as keratocytes distributed within several layers of highly organized ECM components including collagen, keratocan and lumican. In addition to producing these ECM components, keratocytes are defined by expression of aldehyde dehydrogenase and the cell surface marker CD34 [16]. In some respects, keratocytes are analogous to fibroblasts found within the dermal layer of skin. However, keratocytes are derived from cranial neural crest, as opposed to somatic mesoderm, and form an interconnected syncytium, more akin to the arrangement of osteocytes observed in bone tissue. In normal healthy corneas keratocytes are considered to be relatively quiescent, but corneal damage promotes their conversion into wound repair fibroblasts ($CD34^-$ and $CD90^+$) and myofibroblasts ($CD34^-$, $CD90^+$, α-smooth muscle $actin^+$ (SMA)) typical of stromal cell responses in other tissues.

In addition to keratocytes, the anterior stroma is populated by a dense network of sensory nerve fibers that extend their

processes across BL and into the corneal epithelium. Under normal circumstances, blood vessels and lymphatic vessels are restricted to the corneal limbus, but small numbers of antigen-presenting cells (APCs) have been observed within the corneal stroma. The limited contact with cells of the immune system is often regarded as inferring a form of immune privilege for corneal tissue; but, as will be discussed later, this privilege is far from absolute (Sections 36.5.1 and 36.5.2).

Posterior to the corneal stroma resides a second population of neural-crest-derived cells known as the corneal endothelium (Figure 36.1E). The corneal endothelium, or posterior corneal epithelium, is a single layer of epithelial cells separated from the posterior stroma by a thick basement membrane known as Descemet's membrane (named after the French physician Jean Descemet (1732–1810)). Unlike corneal epithelial cells and stromal cells, corneal endothelial cells display far less capacity for self-renewal, and a gradual decline in the number and density of these cells is observed with age [17]. Loss of corneal endothelial cells through disease or trauma is therefore generally more problematic than the loss of corneal epithelial cells or keratocytes. Phenotypically, the corneal endothelium is generally defined by a collection of nonspecific markers, including N-cadherin, zonula occludens-1 (ZO-1), and sodium/potassium ATPase.

All three layers of the cornea contribute to the optical properties of this tissue. The corneal epithelium, in addition to its protective barrier function, maintains a smooth transparent ocular surface and contributes to the refractive power of the cornea. Transparency of the corneal stroma is essential for visual acuity, and this is enabled through the highly ordered arrangement of keratocytes and ECM components. The hygroscopic composition of ECM components within the corneal stroma encourages the diffusion of water and accompanying solutes from the anterior chamber of the eye. (Hygroscopy is the ability of a substance to attract and hold water molecules from the surrounding environment.) In doing so, however, the optimal spacing of ECM components required for transparency would soon be lost if not for the action of the corneal endothelium. The sodium/potassium ATPase produced by these cells actively transports ions out of the corneal stroma and back into the anterior chamber of the eye. The net movement of ions encourages water to follow by osmosis, and thus corneal transparency is maintained. A decline in number or activity of corneal endothelial cells through disease or trauma may therefore lead to corneal opacity.

## 36.3 Overview of corneal pathology

Diseases of the cornea and ocular surface cover a wide range of conditions, including microbial infections, disorders of the immune system, congenital and metabolic abnormalities,

dysplasia, and malignancies [18]. Moreover, trauma can result in significant pathology, especially when it involves significant loss of limbal epithelial progenitor cells or corneal endothelial cells. The conditions that are most relevant to a discussion of potential MSC-based therapies are those involving chronic inflammation of the ocular surface and those requiring a donor corneal transplant.

### 36.3.1 Ocular surface disease

The corneal epithelium, together with the conjunctival epithelium, tear film, and accessory glands, contributes to maintenance of a smooth and lubricated ocular surface. As stated earlier, the principle role of the corneal epithelium, beyond simply its barrier properties, is to maintain a smooth and transparent structure suited to the refraction of light. Naturally, any challenge to epithelial integrity resulting from biological, physical, or chemical agents can therefore impact significantly on corneal function. In the case of normal wear and tear the corneal epithelium heals itself through the division, differentiation, and migration of cells arising from limbal epithelial progenitor cells. Any disturbance to epithelial homeostasis or tear formation, however, can lead to conditions collectively referred to as ocular surface disease.

Pathologically dry eyes can normally be managed through administration of artificial tears or other treatments. However, people with impaired wound healing responses, such as those with diabetes mellitus, are also prone to nonhealing epithelial defects. Such relatively common forms of ocular surface disease, while debilitating, can be managed reasonably well without the need for surgery or cellular therapies. It remains possible, however, that products derived from MSCs could be beneficial as an adjunct therapy for recurrent epithelial defects, and there is already some anecdotal evidence to support this [19].

Corneal diseases and injuries that extend to the limbus can dramatically reduce the number of epithelial progenitor cells required to sustain the corneal epithelium. In the absence of a corneal epithelium, the surrounding *conjunctival* epithelium extends across the corneal surface. Given the reduced optical properties of the conjunctival epithelium, corneal clarity is reduced. Moreover, the conjunctivalized corneal surface is prone to epithelial defects that, in turn, promote chronic inflammation of the corneal stroma, including scarring and vascularization. Because of the common involvement of limbal dysfunction, conditions associated with a conjunctivalized ocular surface are collectively referred to as limbal stem cell deficiency (LSCD) [20]. Typical causes of LSCD include trauma resulting from alkali burns or surgery to remove limbal tumors. Disorders of the immune system such as Stevens–Johnson syndrome, while relatively rare, can also have devastating effects on the ocular surface, including the limbal stem cell niche. Similarly, the congenital disorder aniridia (absence of the iris), arising from mutations in the *PAX6* gene, obstructs development of several structures within the anterior segment of the eye, including the corneal limbus, thus resulting in pathology consistent with other forms of LSCD, including the overgrowth of conjunctival tissue and chronic inflammation leading to stromal scarring and vascularization. The iris is a thin circular structure responsible for controlling the diameter and size of the pupil, and thus the amount of light reaching the retina (Figure 36.2). The color of the iris gives the eye its color. In optical terms the pupil is the eye's aperture and the iris is the diaphragm that serves as the aperture stop. The iris controls the size of the pupil by its smooth muscles: these are the sphincter muscle (sphincter pupillae), which contracts the pupil in a circular motion, and a set of dilator muscles (dilator pupillae), which pull the iris radially to enlarge the pupil, pulling it in folds.

### 36.3.2 Diseases of the corneal stroma and endothelium

The corneal stroma may be directly affected, as in conditions such as keratoconus, or indirectly affected via diseases of the corneal endothelium that lead to swelling of the corneal stroma.

Keratoconus is a relatively common degenerative disease with an incidence of 1 in 2000 people in Australia and is characterized by gradual thinning and ectasia, or protrusion, of the corneal stroma [21]. While the exact causes of keratoconus are unclear, links have been made to behavioral traits such as eye rubbing. Additionally, genetic mutations have been implicated. Typically, the condition presents in early adulthood and can be managed initially by wearing spectacles. If the condition progresses, hard contact lenses may be required to overcome the high degree of irregular astigmatism (an optical defect in which vision is blurred due to the inability of the optics of the eye to focus a point object into a sharp focused image on the retina).

Advanced cases of keratoconus may require corneal transplantation. A more recent innovation involves removing the corneal epithelium to expose the corneal stroma, followed by chemical crosslinking of stromal collagen fibers. Riboflavin (vitamin $B_2$) has been used as the crosslinking agent. This is activated by exposure to ultraviolet light. Collagen crosslinking can slow or even halt the progression of corneal ectasia.

Examples of endothelial dysfunction fall into two main categories: corneal dystrophies, arising through congenital abnormalities, and reductions in corneal endothelial cell density, brought about through age and trauma. Fuch's dystrophy is a relatively common degenerative disorder (1 in 2000 people) associated with thickening of Descemet's membrane, increased apoptosis of corneal endothelial cells, stromal swelling, and eventually blistering of the ocular surface [22]. While the exact mechanism by which Fuch's dystrophy develops remains somewhat unclear, it displays an autosomal dominant pattern of inheritance and has been linked to missense mutations in the gene for the alpha-2 chain of type VIII collagen. Fuch's dystrophy is generally regarded as a primary defect in endothelial cell function, and thus treatments are based upon targeting this tissue through either medical or surgical techniques. Endothelial dysfunction can also occur as an unintended consequence of intraocular surgery. Historically, endothelial damage has been associated with surgery to treat cataracts; however,

improvements in surgical techniques have markedly reduced the degree of endothelial cell loss. Iatrogenic endothelial dysfunction (e.g., caused by surgery) is generally referred to as bullous keratopathy. Fuch's dystrophy was first described by the Austrian ophthalmologist Ernst Fuchs (1851–1930).

## 36.4 Corneal transplantation and cultivated epithelial autografts

The standard treatment for severe corneal diseases, including advanced keratoconus, Fuch's dystrophy, and bullous keratopathy, is to perform a donor corneal tissue transplant. Historically, corneal transplants involve complete replacement of the entire central cornea from epithelium through to endothelium by a procedure referred to as penetrating keratoplasty (PKP) [1]. In more recent times, however, surgeons have adopted partial-thickness transplantation techniques with the view to more specifically replacing only those areas of the cornea that are diseased [22]. For example, in cases of endothelial dysfunction, a surgeon may attempt to replace only the corneal endothelium along with Descemet's membrane. Alternatively, performing a lamellar graft, where only the anterior portion of the cornea is replaced with donor tissue, may be performed to retain a healthy corneal endothelium. This more conservative approach to corneal transplantation makes sense from the viewpoint of preserving healthy tissue structure. Moreover, the corresponding use of less donor tissue reduces the foreign antigenic load, theoretically reducing the risk of immunological rejection of the graft. Subsequently, the use of PKP has reduced significantly. Irrespective of the surgical technique used, transplants of the central cornea remain the most successful form of solid organ transplant, with most transplants expected to last approximately 10 years in the absence of tissue typing or immunosuppressive therapy [7,23]. Nevertheless, the survival curves for corneal transplants change dramatically when the margin of transplanted tissue is extended to include the limbus (Figure 36.3).

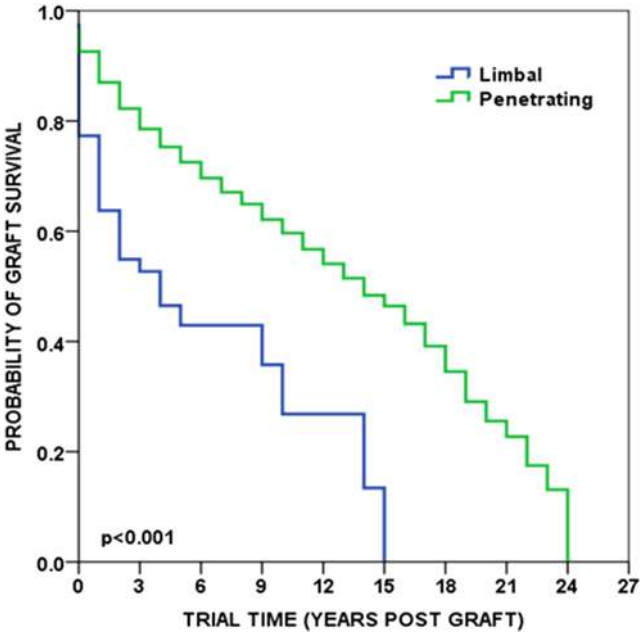

**Figure 36.3** Kaplan–Meier plots displaying the survival of full-thickness transplants of central donor cornea (penetrating keratoplasty) compared with transplants containing donor limbal tissue (log rank statistic = 50.799; df = 1; $P < 0.001$). *Source*: [24] Reprinted with permission from The Australian Corneal Graft Registry, Department of Ophthalmology, Flinders University, Adelaide, South Australia, Australia (taken from The Australian Corneal Graft Registry 2012 Report; KA Williams, MT Lowe, MC Keane, VJ Jones, RS Loh, DJ Coster (eds); 2012 pp. 1–246. URL: http://hdl.handle.net/2328/25859).

Two important points need to be made. First, while donor corneal transplants display relatively high survival rates, they will eventually fail due chronic immunological rejection (Figure 36.4). A failed corneal transplant is therefore a common reason for patients receiving a repeat corneal transplant. Techniques for improving the survival of corneal allografts are a priority area of research. Second, there are alternatives to donor tissue transplantation when diseases and injuries affect the corneal limbus, and especially in the case of LSCD.

Given the failure rate of donor limbal transplants, some surgeons have utilized small autologous transplants of one to two clock hours in shape, typically obtained from the contralateral healthy eye with limbal stem cells to spare [25]. Nevertheless, this technique risks creating localized stem cell deficiency in an otherwise healthy eye. As an alternative, therefore, many surgeons have switched to removing a much smaller piece of healthy limbal tissue from which a sheet of new corneal epithelium could be grown *ex vivo* before transplantation on to the surface of the injured eye [4,5]. Limbal epithelial cells and their progeny are first grown using a technique initially established for the cultivation of epidermal skin grafts developed by Rheinwald and Green in 1975 [26]. This technique relies on the use of growth-arrested mesenchymal cells in the form of embryonic murine 3T3 fibroblasts as a source of ECM proteins and growth factors to encourage the establishment of epithelial colonies from enzymatically dispersed patient tissue. More commonly, however, explants of limbal tissue have been grown intact while attached to a sheet of devitalized donor amniotic membrane [3,27]. In either case, some form of substrate is required to support the cultured epithelial sheet during its application to the ocular surface. A number of substrates have been successfully used, including donor amniotic membrane, fibrin glue, collagen membranes, and contact lenses. In many cases, surgeons have been able to improve the smoothness and transparency of severely injured corneas, with the best results often being obtained in conjunction with the use of PKP to remove stromal scarring at a later date [28]. Importantly, however, cultured sheets of limbal epithelial cells are not a permanent solution since long-term success relies on any progenitor cells remaining at the time of treatment and reestablishing themselves within a limbal stem niche. The treatment of severe corneal

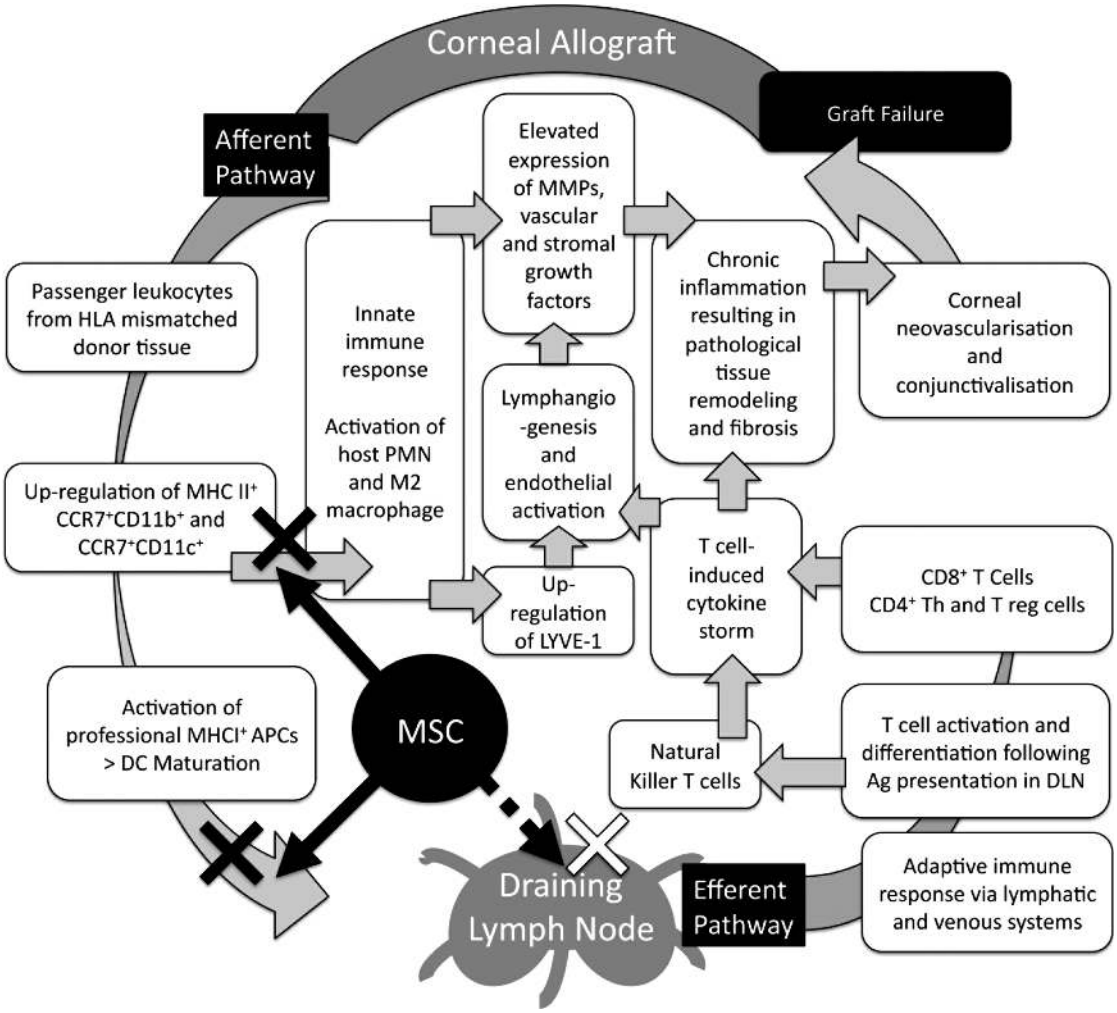

**Figure 36.4** Schematic illustrating the immune reflex arc involved with donor corneal transplant (corneal allograft) rejection. Potential sites of direct (full black arrows leading to black cross) and indirect (broken arrow leading to white cross) inhibitory actions of perioperative MSC-based therapies are illustrated.

disease could be enhanced significantly by finding ways to improve the survival of donor tissue transplants, especially those containing limbal tissue. Adjunct therapies based upon the use of MSCs therefore provide an attractive topic for investigation.

## 36.5 Evidence for mesenchymal stromal cells as modulators of corneal disease

Before considering a potential role for MSCs in treating corneal disease, it is helpful to explore the immunology of the cornea and the immune response to donor corneal transplants.

### 36.5.1 Immunology of the cornea

Both innate and adaptive immune systems play a role in preventing infection and repairing wounds to the corneal surface, although such mechanisms do not directly involve any lymphoid cells. Tear formation, corneal nerve reflexes, transforming growth factor-β1 (TGF-β1) production from keratocytes, and expression of interleukin (IL)-1α by epithelial cells, as well as interferons and the complement system, all operate to ensure that the epithelium remains impervious to external damage. The cells of the adaptive immune system are active within the corneal stroma and adjoining regions in the anterior segment of the eye. They respond to specific events such as infection, but they are also mediators of ongoing inflammatory damage and corneal transplant rejection. T cell precursors and some APCs residing in the anterior chamber are capable of responding to foreign antigens and initiating focal and systemic inflammatory responses. While there are no histamine-producing cells in the normal cornea because of its lack of a blood supply, it appears that there is a heterogeneous network of bone-marrow-derived cells that can be stimulated to function as APCs in certain conditions [29]. This unique population of both immature and mature cells includes epithelial Langerhans cells and anterior stromal dendritic cells (DCs), which are present in the peripheral cornea and to a lesser extent in the central

cornea [30]. Following an inflammatory insult, this population of DCs matures and in the process expresses major histocompatibility complex (MHC) class II antigens as well as the B7 antigens CD80, and CD86 and CD40 costimulatory molecules. This leads to downstream activation of T helper cells [31]. The corneal endothelial cells also contribute through weak expression of MHC class I antigens as well as Fas ligand (CD95L), resulting in apoptosis of lymphocytes [32].

Given its limited immune interaction the cornea is generally defined as being immune privileged, although this term is relative as, following major trauma or infection, bone-marrow-derived cells mature and infiltrate the cornea, producing keratitis and, in more chronic cases, diffuse vascularization and corneal fibrosis. Even in minor events, once the inflammation is mitigated, the cornea continues to retain a greater population of resident leukocytes than normal [33]. In part this is due to the involvement and proximity of the conjunctiva and the abundance of phagocytes and lymphocytes that circulate through the microvasculature of these tissue structures. The conjunctiva provides further immunological support to the cornea. However, in cases of severe focal trauma, it also provides a reservoir of cells from the innate immune system that stimulate angiogenesis, granuloma formation, fibrosis, and pathological conjunctivalization, creating a chronic inflammatory milieu that protects the corneal stroma without resolving the initial injury [34].

### 36.5.2 Immunology of corneal transplantation

For more than a century human corneal transplant procedures have been successfully performed to restore the corneal epithelial surface and reverse the optical disability. Typically, there is a 90% or better rate of graft survival within the first 12 months after corneal allograft surgery. This is quite remarkable compared with outcomes of other solid organ transplantation, such as lung transplants or pancreatic transplants. However, over the course of the next 15 years after a corneal transplant the failure rate is much higher (Figure 36.3), with as many as 55% of allografts failing [7]. It is of interest that the rate of primary graft failure appears to be directly proportional to the degree of focal inflammation and vascularization of the cornea prior to transplantation, even after accounting for confounding variables such as surgical approach, operator, comorbidities, and preexisting risk factors [7,35,36].

There are many reasons for graft dysfunction, including infection, inadequate immunosuppressive therapy regimens, poor human leukocyte antigen (HLA) matching, and most importantly the efferent immune response that is an irreversible reaction refractory to corticosteroid and other immune-modulating treatments (Figure 36.4). It is this focal host-versus-graft response that is the major cause of corneal allograft rejection [6].

In considering the pathophysiological mechanisms that lead to graft rejection, it is pertinent to note that there are two anatomically separate populations of APCs located in the iris and trabecular meshwork and in the conjunctiva and cornea [37]. Macrophages and MHC class II$^+$ DCs of the first group are well positioned to absorb soluble antigen shed from the posterior endothelial layer of the graft, and iris phagocytes are known to play a role in activating T cells during secondary responses [38]. MHC class II DCs of the conjunctiva and cornea appear to be specific to the local environment in which they reside in terms of phenotype and density [39]. Owing to the immunoprivileged nature of this anatomical region these cells do not normally encounter foreign antigens that stimulate the reactive T cell responses leading to a rejection process [33,40,41]. This is particularly noteworthy given that it has been reported in a preclinical murine model that donor cornea is a source of "passenger" leukocytes that migrate into cervical draining lymph nodes (DNLs) and start expressing MHC class II antigen after surgical implantation [33,41].

In considering the mechanisms of chronic rejection following corneal transplantation it is worth pondering how this process occurs given that the normal cornea is avascular and without a lymphatic drainage system. It is noteworthy that lymphatic vessels that express lymphatic vessel endothelial receptor 1 (LYVE-1) can invade an inflamed cornea and stimulate the process of neovascularization and lymphangiogenesis [42,43]. LYVE-1 is a CD44 homolog expressed by lymphatic endothelial cells. However, Xu *et al.* localized this marker to nonendothelial murine cells in the sclera, choroid, and iris where cell surface marker labeling was indicative of CD11b$^+$ F4/F80$^-$ bone marrow cells, CD11b$^+$ F4/F80$^+$ macrophages, and CD11b$^+$ F4/F80$^-$ macrophages [44]. The highest densities of LYVE-1$^+$ cells were observed in the limbus and conjunctiva. All LYVE-1$^+$ cells in the retina were CD11b$^+$ F4/80$^+$ macrophages. Cells in the limbus and the iris root also expressed the stem cell antigen Sca-1, suggesting that they are hematopoietic lymphatic vessel progenitor cells. Given that LYVE-1$^+$ CD11b$^+$ F4/F80$^+$ macrophages are present in the normal eye, they should be able to participate in the stimulus for lymphangiogenesis in response to any uncontrolled inflammatory challenge.

Immune privilege can be reversed due to the demonstrated presence of APCs in an avascular cornea prior to transplantation as well as by donor-derived APCs resident in the graft tissue at the time of surgery. The degree of major and minor histocompatibility matching between the corneal transplant donor and the corneal transplant recipient will also influence the risk of rejection. It has been suggested that the graft tissue is degraded overtime as a result of the inflammatory sequelae generated by histoincompatibility between donor and recipient, corneal angiogenesis, and lymphangiogenesis and the apoptosis that results from cytotoxic T-cell- and natural killer (NK)-cell-mediated mechanisms [45–48].

While the first corneal transplant was performed in 1906 and the first renal transplant in 1960, long-term improvements in clinical outcomes over the last 56 years in solid organ vascularized transplants have surpassed those in corneal transplantation [23]. This is largely a result of the improved immune suppression regimens used after vascularized solid organ transplantation. However, the location of the cornea makes it all the more

amenable to modern therapeutic strategies that utilize bioengineered antibodies and novel regenerative medicine approaches, such as mesenchymal stem/stromal cell administration.

### 36.5.3 Immunomodulatory properties of mesenchymal stromal cells

MSC administration is currently the subject of intense scientific investigation and clinical trials in an attempt to assess their safety and efficacy as both a novel immunomodulatory treatment and a potential wound healing and allograft alternative. These cells are relatively nonimmunogenic due to their lack of cell surface expression of CD40, CD80 and CD86 co-stimulatory molecules, and MHC class II molecules [49,50]. They are also actively suppressive of T cell alloproliferation as well as suppression of B cell, DC, and NK cell activity.

When MSCs are differentiated *in vitro* to the mesodermal adipogenic, osteogenic, and chrondrogenic lineages there is a slight increase in MHC class II expression, but not of the co-stimulatory molecules, indicating that these cells are capable of inducing tolerance and specifically T cell anergy [51–53].

MSCs also have an inhibitory effect on the expression of the proinflammatory cytokines TNF-α and IL-12 during DC differentiation [54,55]. In addition, MSCs can prevent peripheral blood mononuclear cells from differentiating into DCs [56]. When co-cultured with lymphocytes T cell growth kinetics were suppressed even after the addition of interferon (IFN)-γ [57]. MSCs have been reported to halve the expression of IFN-γ during T-cell differentiation and increase the production of IL-4 during type 2 helper T cell differentiation [54]. They can prevent cytotoxic T cell activation when added early to a mixed lymphocyte population [58].

MSCs are also capable of inhibiting the cell cycling behavior and chemotactic properties of B cells and can prevent their terminal differentiation into plasmacytes [59]. Factors in culture medium derived from MSCs inhibited immunoglobulin (Ig)G1 and IgM production in a murine model immunized with T-cell-dependent and -independent antigens [60].

MSCs are highly responsive to the endocrine and paracrine signaling cues within an inflammatory environment. The level of factors such as IFN-γ at low levels may induce MSCs to behave as APCs and promote the generation of cytotoxic $CD8^+$ T cells or, at higher concentrations, mediate immunosuppressive activities [61,62].

The local inflammatory environment is key in determining the behavior of MSCs. Van Poll *et al.* showed that the intravenous administration of MSC culture medium resulted in a 90% decrease in hepatic apoptosis and increased survival outcomes if administered before the systemic inflammatory response syndrome transitioned to multiple organ failure in a murine model in which acute liver failure was induced by D-galactosamine [63].

Other additional immunomodulatory mechanisms associated with MSCs include the ability to synergistically recruit and support anti-inflammatory processes instigated by regulatory T cells (Tregs). MSCs increased the numbers of Tregs when cultured with $CD4^+$ T cells [54]. Human adipocyte-derived MSCs can upregulate the anti-inflammatory mediator IL-10 as well as the numbers of $Foxp3^+$ $CD4^+$ $CD25^+$ Tregs [64]. MSCs play a role in directing the behavior of monocyte/macrophages populations in sepsis, where removal of these innate immune system cells impaired the ability of MSCs to attenuate systemic inflammatory and infectious processes [65].

The ability of MSCs to activate immunosuppressive networks and mediate adaptive and innate immune tolerance has led to the view that MSCs are an essential part of setting the background of tissue architecture and might reasonably be regarded as local stromal coordinators by ameliorating excessive focal and systemic immune responses [66]. It is for this reason that MSC administration has been explored as a potential treatment for both congenital and acquired causes of LSCD.

### 36.5.4 Mesenchymal stromal cells as modulators of corneal wound healing and tissue regeneration

MSCs have been found to positively influence the *in vitro* growth of corneal epithelial cells [67] and corneal endothelial cells [68]. It is reasonable, therefore, to assume that they could facilitate corneal wound healing *in vivo*. MSCs are being used clinically to treat persistent epithelial defects in patients refractory to conventional treatment [19]. The effect of MSCs on corneal wound healing in rodent models are presented in Table 36.1.

The majority of preclinical studies have examined the effects of MSC administration following chemical (alkali or alcohol) removal of the corneal–limbal epithelium [11,14,69,71–76]. Routes of MSC administration have included topical application as a cell suspension [69,76], intravenous injection [11], intraperitoneal injection [11], or subconjunctival injection [73,75].

MSCs have also been applied in conjunction with amniotic membrane [14,71,76] or synthetic scaffolds [70,74]. In these studies MSC administration generally led to marked clinical improvements, including reduced inflammation, reduced neovascularization, and improved re-epithelialization. The mechanism of MSC action has been linked in some cases to a reduction in production of proinflammatory cytokines [70,72–74].

Following intravenous or intraperitoneal injection of $1 \times 10^7$ human MSCs, Roddy *et al.* [72] determined that approximately 0.0001% of the cells were localized to the corneal tissue at 1 day or 3 days after the corneal injury and removal of limbal stem cells. While there was little evidence of engraftment, there was a significant reduction in the levels of focal inflammation and opacity within the cornea. MSC expression of the anti-inflammatory mediator TSG-6 was increased following corneal epithelial cell insult in *in vitro* experiments. These results were later validated in a TSG-6 small interfering RNA knockdown model. Together, these findings suggest that MSC administration activates a negative feedback loop to dampen inflammation and reduce leukocyte recruitment in tissue adjacent to the cornea.

The antiangiogenic and anti-inflammatory effects of MSCs in wound healing were explored by Oh *et al.* [69], where absolute ethanol was applied to denude the corneal surface in a rodent model. Animals were randomized to receive one of three MSC interventions or a control administered topically to the eye. The interventions were fresh culture medium (as control), MSC-conditioned medium (MSC-CM) once only for 2 h, MSC-CM once daily for 3 days (MSC-CM multiple), and direct MSC application. All treatment groups had evidence of peripheral neovascularization in conjunction with corneal opacity by 3 weeks after the injury, but there were significant differences in inflammatory cell infiltrates in the MSC-CM multiple and direct MSC application groups compared with the control group. The proinflammatory markers IL-2 and IFN-γ levels were decreased in the MSC-CM multiple and direct MSC treatment groups. The anti-inflammatory markers TGF-β1 and IL-10 were increased and TSP-1, a surrogate anti-angiogenic marker, was upregulated in the direct MSC and MSC-CM multiple cohorts. PKH26-labeled cells indicated that re-epithelialization occurred above the MSC layers in the direct MSC treatment group. Topical MSC application was thus the most efficacious approach in reducing the overall inflammatory burden 3 weeks after injury, presumably by the constant active expression of cytokines and growth factors that ameliorated chronic inflammation and potentially activated the function of remnant progenitor cells in the limbal stem cell niche.

Using an alkali burn murine model Javorkova *et al.* demonstrated that systemic administration of bone-marrow-derived MSCs homed to regional tissue damage and migrated preferentially to the eye that had been injured [78]. MSCs that had been pretreated with IFN-γ were the most effective at reducing the proinflammatory mediators IL-1α, IL-6 and nitric oxide during the first 24 h after the injury. Using sodium hydroxide to degrade the ocular surface in a rat model, it was observed that expression of the proinflammatory IL-17 was reduced in $CD3^+$ $CD4^-$ $CD8^-$ (T cells), $CD3^+$ $CD4^+$ $CD8^-$ (helper T cells), and $CD3^+$ $CD4^-$ $CD8^+$ (cytotoxic T cells) in the draining cervical lymph nodes after intraperitoneal injection of MSCs [79]. IL-17 secretion in double-negative T cells from the cornea was completely suppressed after MSC administration.

### 36.5.5 Mesenchymal stromal cells as modulators of corneal transplantation

In four of five separate rodent models investigating the changes in graft survival and lymphocyte profiles, it was found that intravenous or topical administration of MSCs resulted in significant improvements in corneal graft survival time as well decreasing the activation of pathological T cell populations and the expression of CCR7 from APCs (Table 36.2). Jia *et al.* [81] developed an MHC-mismatched rat corneal allograft model using Wistar rats as donors and Lewis rats as recipients in which bone-marrow-derived MSCs were derived from the Wistar corneal donor population. The recipient group randomly received either MSC administration alone or MSCs in addition to cyclosporine (CSP) as immune suppression. MSC administration was commenced 3 days prior to corneal surgery and continued for 2 days after grafting. CSP was administered for up to 9 days postoperatively at doses that ranged from 1 to 10 mg/kg.

The low-dose CSP/MSC group had increased graft rejection. However, when 2 mg/kg of CSP was combined with MSCs there appeared to be a synergistic response where graft survival was better than either treatment alone. At doses greater than 2 mg/kg the potential effect of MSC administration was obscured by the CSP treatment. This study highlights the importance of drug–MSC interactions and the need to consider dose-dependent effects when determining no observed adverse effect levels in preparation for phase I trials.

With the objective of investigating the effect of bone-marrow-derived MSCs on allosensitization following corneal allografting from C57BL/6 donors (MHC haplotype $H2^b$) to BALB/c recipients (MHC haplotype $H2^d$), Omoto *et al.* [84] identified that systemic administration of MSCs resulted in homing of $GFP^+$ MSCs to the ipsilateral (damaged) cornea and conjunctiva and DNLs. MSC administration resulted in a significant decrease in $CD11c^+$/MHC class $II^+$ mature DCs both in the corneal graft and the DNLs. At 14 days posttransplant, allosensitized type 1 helper T cells were substantially reduced both in the ipsilateral DNLs and in the graft, indicating that MSC administration can be used to modulate alloimmunity in high- and low-risk corneal grafting. In a follow-up study in which MSC administration was administered once only postoperatively or immediately after surgery and 7 days postoperatively, graft survival was more than twice as high in the latter compared with the control group. These findings suggest that MSCs can be used as a first-line or second-line immunomodulatory agent.

In a similar study by Lee *et al.* [83], specific attention was placed on the cytoplasmic expression levels of CCR7, a molecule critical in the migration of lymphocytes and DCs across the high endothelial venules in secondary lymphoid organs. Corneal transplantation was performed using C57BL/6 mice and BALB/c mice in which each animal was randomized to be either a donor or recipient for syngeneic or allogeneic procedures. Human bone-marrow-derived MSCs were infused preoperatively on day 0 or preoperatively as well as postoperatively on day 1. Follow-up was assessed at 7 and 28 days depending on randomization processes and were nominally referred to as early and late rejection respectively. $CD4^+$ T cells increased in allogeneic recipients by day 7 and $CD8^+$ T cells had expanded by day 28 compared with the syngeneic recipients, in which there was no change in these T cell subpopulations within cervical lymph nodes. To investigate the effect of human MSC administration, the numbers of CCR7-labeled $CD11c^+$ corneal epithelial DCs and $CD11b^+$ corneal stromal DCs were assessed using flow cytometry. MSCs were administered either postoperatively or preoperatively (day −1) and postoperatively (day 0). The second approach proved more successful in suppressing allograft rejection and ameliorating the adaptive immune response in which lower numbers of $CCR7^+$ DCs were detected. A single administration of intravenous MSCs

appeared to have no significant effect on the recipients' immune response following transplantation. While MSC administration did not completely inhibit MHC class $II^+$ $CCR7^+$ $CD11b^+$ from infiltrating the cornea, the number of these cells was significantly reduced compared with animals that received a corneal allograft and no MSCs.

The topical application of rat MSCs was evaluated in a preclinical trial by Oh *et al.* [80]. Using a pig-to-rat xenogeneic transplant model, all porcine corneal grafts had failed within 12 days of transplantation. There was no difference in graft survival time between those that received topical rat MSCs and those that did not. Histological examination of the grafts showed a massive infiltrate of neutrophils and macrophages as well as $CD8^+$ and NK T cells. The levels of IL-6 and IL-10 were significantly elevated in the MSC-treated graft tissue.

Subsequently, the same group tested the efficacy of human MSCs administered intravenously both pre- and postoperatively at a dose of $1 \times 10^6$ in a murine allogeneic corneal transplant model [82]. Only a small fraction of the administered cells was found in the cornea, with the majority residing in the lungs, as is normal after intravenous administration of MSCs. There was a significant reduction in the number of APCs in the cornea and DNLs in the allogeneic group compared with the syngeneic control group. The proinflammatory cytokines IL-2 and IFN-γ, as well as the $CD8^+$ cell effector molecules granzyme A, granzyme B, and perforin, were all decreased in MSC recipients. The human MSC administration was noted to significantly increase expression levels of TSG-6, with a 113.8-fold change reported. Using knockout mice for TSG-6, as well as intravenous administration of recombinant TSG-6, they were able to confirm the critical role of this downmodulator of inflammation in this model.

In a study by Treacy *et al.* [85], the effect of pretreating MSCs with IFN-γ was compared with nonpretreated syngeneic, allogeneic, and third-party MSCs. All MSCs were administered systemically via the tail vein at 7 days pretransplant and on the day of the procedure using a dose of $1 \times 10^6$ MSCs on each occasion. Graft opacity was used as the primary endpoint. The allogeneic (Dark Agouti) and third-party (Wistar-Furth) MSCs prolonged corneal allograft survival the longest in the Lewis rat recipients. Cell profiling and gene expression studies suggested a reduction in NK T cells, APCs, and $CD4^+$ $CD25^+$ Tregs as well as IL-1β mRNA levels in the recipients of allogeneic MSCs compared with recipients of syngeneic and IFN-γ-pretreated MSCs. MSCs were also found in the spleen, which had a significantly greater number of the $Foxp3^+$ $CD4^+$ $CD25^+$ Tregs in the allogeneic-MSC-treated cohort compared with the syngeneic MSC recipients. Interestingly, significantly elevated levels of IgG1 and IgG2 antibodies were generated against the allogeneic MSCs, but this did not result in a decrease in graft transparency or dysfunction.

It is clear from the studies just described that MSCs mediate their effects in corneal allografting by downmodulation of proinflammatory factors through an influence on both cells and proteins of the innate and adaptive immune systems, often by secreting anti-inflammatory proteins such as TSG-6 or tolerogenic proteins such as IL-10. In effect, they are unique circulating micro-pharmacies.

## 36.6 Evidence for mesenchymal stromal cells as a source of new corneal cells

One of the first papers to investigate the keratogenic potential of MSCs noted that MSCs derived from human bone marrow survived and formed an epithelial-like structure when applied *in vivo* to the ocular surface of wounded rat eyes [86]. Immunohistochemistry, however, using a monoclonal antibody raised against corneal epithelial cells that detects keratin 3 that also detects keratin 2p/76 (mab AE5) showed no evidence of staining. Negative results were also obtained using a pan-cytokeratin antibody, indicating that no epithelial cells of any type had been derived from the implanted bone marrow MSCs. Critically, these negative results were validated using positive controls and the MSC origin of the cells studied was confirmed by immunostaining for human nuclear antigen. On the basis of this negative result, it might have been expected that interest in the keratogenic potential of MSCs might have waned, but many papers have appeared over the subsequent years, some of which contain positive evidence of MSC differentiation into cornea-like cells (Table 36.3).

### 36.6.1 Mesenchymal stromal cell differentiation into corneal epithelium

While cultivated epithelial autografts have become a widely used method for ocular surface reconstruction, the sensitive location and limited supply of a patient's own corneal epithelial progenitor cells has prompted investigation of alternative sources of corneal epithelial progenitor cells. Mesenchymal cells are perhaps an odd choice for epithelial tissue repair, but mesenchymal-to-epithelial transition occurs during embryonic development. An example is neural crest differentiation into corneal endothelial cells. Thus, it is conceivable that a mesenchymal progenitor cell could perhaps be encouraged under the right circumstances to adopt an epithelial phenotype. In the case of the corneal epithelium, however, such a transition would presumably initially require reprogramming of MSCs to an ectodermal lineage, followed by an ocular tissue pathway of differentiation (defined by expression of Pax-6), and finally differentiation into corneal epithelial cells expressing keratin (K) 3 and K12. Interestingly, Pax-6 expression, which is also required for pancreatic islet development, has been reported in cultures of insulin-secreting cells derived from adipose tissue MSCs [96]. No studies, however, have examined Pax-6 expression by MSC-derived from any noncorneal tissue within the context of corneal differentiation. The case for MSC differentiation into corneal epithelial cells has so far been based largely on looking for evidence of K3/K12 expression on corneal cells either *in vitro* or *in vivo*. These studies

have often used the AE5 monoclonal antibody raised against corneal epithelial cells [15], but this antibody also reacts toward cytokeratin 2p/76, a keratin found in palate tissue. Additionally, a number of prior studies have relied solely on immunohistochemical staining [88,90]. Several reports of positive expression have not been validated because of lack of adequate controls [88,97–99]. Moreover, in the case of studies performed *in vivo*, the provenance of reported "corneal cells" is often unclear due to the fact that no marker was used to track the fate of administered MSCs [76,90,98,99]. Despite these shortcomings, several groups have reported a degree of K3 or K12 expression that has been validated through tracking of administered cells and/or use of appropriate experimental controls (Table 36.3) [14,71,87–91]. In most studies the degree of corneal-specific keratin expression was substantially less than that expressed by control samples of corneal epithelial cells [89,91] or noted to reside within only a small subpopulation of MSC-derived cells [14,88,90]. The ability of MSCs to generate corneal epithelial cells therefore remains inconclusive.

### 36.6.2 Mesenchymal stromal cell differentiation into keratocytes

Given their mesenchymal origin (cranial neural crest) and phenotype, keratocytes are perhaps the most likely candidate cell for MSC differentiation in the cornea. Reports of endogenous bone marrow MSC recruitment to injured corneal stroma have led to speculation that MSCs might naturally provide a source of cells for stromal repair. As with the case for studies of epitheliogenesis, prior studies of MSC differentiation into keratocytes have also often been hampered by inadequate use of appropriate cell phenotype markers [11,100] or experimental controls [101,102].

Three studies, however, have produced positive evidence of MSC conversion into keratocyte-like cells that have been appropriately validated. A study by Du *et al.* [92] reported positive evidence of keratocan expression confirmed by Western blotting, RT-PCR, and RT-qPCR when the side population obtained by flow cytometry of adipose-tissue-derived MSCs was grown under conditions designed to promote keratocyte differentiation. Stronger evidence was presented in two studies by Liu and colleagues [13,93] using two null mutant animal models. In the first study, human MSCs derived from umbilical cord were labeled with DiI and injected into the corneas of lumican deficient ($Lum^{-/-}$) and keratocan deficient ($Kera^{-/-}$) mice. As noted earlier (Table 36.1), these treatments led to improvements in corneal structure and function; but more importantly from a cell fate perspective, the implanted cells adopted a keratocyte-like morphology and produced keratocan and lumican, which was confirmed by Western blotting. The second study by this group used MSCs derived from mouse bone marrow and implanted into $Kera^{-/-}$ recipients. The results essentially produced similar results. Given the absence of endogenous keratocan in both studies, the subsequent discovery of this corneal ECM molecule following injection of MSCs is consistent with the theory that MSCs are capable of keratocyte differentiation.

### 36.6.3 Mesenchymal stromal cell differentiation into corneal endothelium

Liu and Zhao [94] reported reduced stromal edema when autologous, BrdU-labeled bone marrow MSCs were implanted onto the posterior surface of rabbit corneas *in vivo*. Survival of the implanted cells was later confirmed by immunostaining for BrdU, but traditional markers of endothelial function, such as ZO-1 and sodium–potassium ATPase, were not examined. The apparent reduction in edema suggests that at least implanted MSCs might provide a useful surrogate for corneal endothelial cells.

A subsequent study by Joyce *et al.* [95] utilizing GFP-labeled MSCs derived from human umbilical cord blood provided a detailed analysis of MSC fate when they were applied to wounded corneal endothelium in organ culture. The effect of growth medium derived from lens epithelial cell cultures was also examined. While these authors detected expression of ZO-1 and N-cadherin in cultures of control MSCs, both proteins became more distributed to cell boundaries in response to CM. A microarray analysis of over 250 genes indicated a shift in MSC phenotype toward that of corneal endothelial cells. Incorporation of MSCs into organ cultures of corneal endothelium appeared to be facilitated by attachment to wounded endothelial cells rather than to exposed sections of Descemet's membrane. These findings support the theory of "licensing," whereby MSCs are activated by local signals such as those produced by damaged cells. Further studies are clearly required to determine the potential of MSCs to produce corneal endothelial cells.

## 36.7 The biology of cornea-derived mesenchymal stromal cells

Following the discovery of epithelial progenitor cells in the corneal limbus and their successful clinical application, speculation began about the potential presence of progenitor cells for other corneal cell types, including corneal stromal cells [103–105]. These studies were motivated in part by the fact that cultivated epithelial autografts, while useful, do not contain the cellular elements required to repair the corneal stroma. Additionally, there has been interest in replacing embryonic murine 3T3 cells with a human mesenchymal cell equivalent, as feeder cells for the *ex vivo* expansion of limbal epithelial progenitor cells.

The foundation for our understanding of corneal stromal cell biology is derived from the work of Elizabeth Fini [16]. She and her colleagues described a population of $CD34^+$ keratocytes, which, upon wounding of the cornea, developed into $CD90^+$ wound repair fibroblasts and myofibroblasts expressing both CD90 and α-SMA. Thus, the $CD34^+$ keratocyte could be considered to represent the endogenous stromal progenitor cell population, with expression of CD90 perhaps representing their immediate progeny of transient amplifying cells. Since the peripheral edge of the corneal stroma extends a short distance (0.5 mm) into the deep limbus, it is likely that a similar pattern of

cellular differentiation occurs in this region. Nevertheless, the superficial limbal stroma contains a variety of additional cell types, including melanocytes, APCs, vascular endothelial cells, pericytes, and glial cells (Schwann cells) [106]. We grew cells from human limbal stroma using Dulbecco's modification of Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and analyzed the resulting cultures by flow cytometry using a panel of antibodies designed to detect a broad range of cell types, including those of corneal origin ($CD34^+$, $CD90^+$, $\alpha$-$SMA^+$), myeloid origin ($CD45^+$), glial origin ($CD271^+$), and vascular/pericyte origin ($CD141^+$, $\alpha$-$SMA^+$). Comparison cultures were established from central corneal stroma, as well as scleral stroma sampled a few millimeters beyond the limbus [107]. Despite the distinct regional differences in tissues acquired, greater than 95% of cells in all cultures expressed CD90 with negligible levels of other cell surface markers. A gradient of $\alpha$-SMA expression was observed ranging from approximately 10% of cells in corneal cultures to up to 80% in cultures established from scleral stroma. Distinct differences were also noted in the ability of cultures established from each region to serve as a feeder layer for limbal epithelial cells, with limbal stromal cells being judged on the number and size of epithelial colonies generated in colony-forming assays. Parallel cultures established from scleral tissue, only a few millimeters away from the limbus, failed to support epithelial growth beyond that seen in the absence of feeder cells.

These findings suggested that cultures established from the limbal stroma are remarkably homogeneous $CD90^+$ fibroblasts and could be used clinically as feeder cells for *ex vivo* expansion of limbal epithelial progenitor cells. The inherent stem cell properties of cells isolated from the corneal and limbal stroma were also becoming understood at this time, with some studies using stem cell markers and culture conditions used successfully for other tissues [104,105]. A different approach, however, was taken by Polisetty *et al.*, who reported that cultures established from the limbal stroma had similar properties to MSC cultures established from bone marrow [108]. This seminal work led to a series of recent publications exploring the phenotype and properties of limbal stromal cell cultures through the prism of MSC biology [109–114] (Table 36.4).

The premise for the initial study by Polisetty *et al.* [108] was that spindle-shaped cells observed as contaminants in cultures of limbal epithelial cells might share phenotypic and differentiation characteristics with bone-marrow-derived MSCs. As summarized in Table 36.4, there was expression of several characteristic MSC cell surface markers, including CD29, CD90, and HLA-ABC, as well as lack of expression of CD34, CD45, and HLA-DR – again the same as for bone marrow MSCs. A subsequent study by this group [109] added CD44 as a further positive MSC marker to this list, but other characteristic MSC markers such as CD105 did not feature prominently in this group's analysis [108]. A subsequent study by Branch *et al.* [110], however, using a panel of MSC markers recommended by the International Society for Cellular Therapies, confirmed that limbal stromal cell cultures established in serum-supplemented growth medium predominantly express a characteristic MSC cell surface phenotype by being positive for CD29, CD44, CD73, CD105, CD90, and HLA-ABC and negative for CD34, CD45, and HLA-DR [110]. Other studies have confirmed these findings, with the exception of a study by Garfias *et al.* [112], who noted marked expression of CD34 despite using cultures between passage numbers 3 and 5. We have demonstrated that subtle changes in limbal stromal cell phenotype occur according to the culture conditions used [111]. While cells in cultures supplemented with serum expressed high levels of CD146 (80%), cells in parallel cultures established using a commercial serum-free culture system (MesenCult-XF®, StemCell Technologies) expressed negligible levels. This disparity in CD146 expression is difficult to explain in view of the acknowledged utility of CD146 as a marker of MSCs that form part of blood vessel walls [115].

A second important observation in the initial study by Polisetty *et al.* was that cultures established from limbal stroma displayed histochemical evidence of differentiation into cells of osteogenic and adipogenic lineages when cultured under appropriate culture conditions [108]. Subsequent histochemical and immunocytochemical studies have provided evidence of chondrogenic differentiation [110–112] and neurogenic differentiation [112] potential. The classic trilineage mesenchymal differentiation potential (osetogenic, lipogenic, and chondrogenic) has been confirmed by RT-qPCR [110].

The apparent multipotency of cultured limbal stromal cells, however, presents a dilemma. While the classic trilineage potential of MSCs derived from bone or bone marrow fits well with intended musculoskeletal applications, most clinical applications for limbal stromal cells would presumably not require, or indeed would not desire, this type of activity. Further studies are therefore required to confirm the degree of true plasticity for limbal stromal cells and to better define the conditions under which nonkeratogenic differentiation occurs.

While multipotency may well be a less desirable activity for cultured limbal stromal cells to share with traditional sources of MSCs, the ability to evade immune detection and suppress inflammation and immunity are clearly desirable traits. To this end, it is encouraging that all studies to date have noted that passaged cultures of limbal stromal cells express low to negligible levels of HLA-DR on their cell surface (Table 36.4). Cultured allogeneic limbal stromal cells are therefore less likely to be rejected compared with conventional donor limbal tissue transplants. In addition, Garfias *et al.* have demonstrated that cultured limbal stromal cells, like MSCs, suppress proliferation of peripheral blood lymphocytes in a dose-dependent manner [112]. Further analysis indicated that this immune suppression activity of limbal stromal cells is mediated through the release of TGF-$\beta$1. We have recently confirmed immunosuppressive properties for human limbal stromal cells cultured in either serum-supplemented or serum-free growth media [113]. We have achieved similar results for cells cultivated from the limbal stroma of rabbit corneas, thus providing the foundation

for a preclinical study in this animal model [112]. Interestingly, the abilities to suppress lymphocyte activation and support epithelial colony formation are displayed both within and across species boundaries.

## 36.8 Conclusions and future directions

The delicate and highly organized structure of the cornea means that even low levels of inflammation caused by disease and trauma can lead to significant loss of vision. Restoration of corneal structure, and thus vision, is therefore acutely tied to the inflammatory status of this tissue. The negative effects of inflammation and antigenic load are especially apparent in the case of traditional and emerging cell- and tissue-based therapies for corneal repair, including donor corneal transplants and cultivated epithelial autografts. It is not surprising, therefore, that MSCs have shown significant potential as agents for improving corneal wound healing and improving retention of corneal allografts in animal models. In particular, the mechanism of MSC action appears highly dependent upon the perioperative timing of their administration. Moreover, significant progress has been made in identifying soluble factors responsible for MSC action, including TSG-6. These results encourage advancing to human trials using MSCs or MSC-derived products, especially with respect to improving the retention of donor corneal allografts.

MSC-based therapy also has significant potential to repair the corneal epithelial stem cell niche by grafting whole segments of donor corneal limbus. However, there remain issues for further exploration, including the optimization of MSC dosage and the route of administration in human patients. The question of whether or not MSCs display keratogenic differentiation is interesting, but we consider this to be less important than progressing to clinical development of this new therapy.

Additionally, the apparent existence of limbal stromal cells with MSC-like properties paves the way for novel therapies based on the isolation and expansion of MSCs from donor limbal tissue that would otherwise be discarded. Further research is required to evaluate the efficacy of these potential limbal MSCs in comparison with *bona fide* MSCs derived from traditional tissue sources such as bone marrow and adipose tissue.

Given that the limbus has a resident stem/stromal cell niche and that several laboratories have already developed different techniques for culturing small explanted biopsies on either biological or synthetic scaffolds prior to implanting them in place of traditional corneal grafts, the ophthalmologic field is already well advanced in the application of novel tissue-engineered approaches that use autologous or allogeneic MSC-differentiated cells *ex vivo*. It will be important to apply good manufacturing practice to the manufacturing of such new treatments with the safety that standard operating procedures and protocols, quality control, and quality assurance provide for the product, the donor, the recipient, the manufacturers of the product, and the institutions sponsoring clinical trials with them.

## Acknowledgments

We thank Professor Kerry Atkinson (Editor) for his guidance and mentorship within the field of MSC research and for inviting us to contribute this book chapter. The process of researching and writing this chapter has proved to be a valuable opportunity for critical reflection. Our sincere thanks are also extended to Professor Keryn Williams and Dr Miriam Keane of the Australian Corneal Graft Registry (Department of Ophthalmology, Flinders University) for generously supplying us with a high-resolution copy of the image presented in Figure 36.3. This image was originally published as Figure 1.2 in the 2012 Annual Report of the Australian Corneal Graft Registry. The full version of this report is available for download free of charge at http://hdl.handle.net/2328/25859. Finally, we wish to acknowledge the following funding agencies and professional bodies for their ongoing financial support of our work: The National Health & Medical Research Council of Australia, The Ophthalmic Research Institute of Australia, and the Queensland Eye Institute Foundation supported through Viertel's Vision.

## 37.1 Introduction

True mesenchymal *stem* cells are defined by their self-renewal ability and their differentiation potential into mesodermal cell types. They are, however, rare cells with a frequency in bone marrow of between 1 in $10^4$ and 1 in $10^5$. This makes it difficult to obtain sufficient numbers of them for most experimental purposes, and certainly for clinical trials. Therefore, their progeny, undifferentiated mesenchymal *stromal* cells (MSCs), which can be readily expanded in large numbers, have been used for these purposes. MSCs form part of the endothelial wall of blood vessels and thus can be isolated from any vascularized organ or tissue.

MSCs are believed to hold great promise in cell replacement therapy. Recent studies, however, have shown that cell empowerment, rather than replacement, is more critical. This notion has increasingly attracted attention and is thought to be a key for understanding MSC-based therapy other than that aimed at regenerating musculoskeletal tissues, in which bone and tendon transdifferentiation has been shown to be the mechanism of action. It is envisioned that concerted actions of MSCs on immune responses and tissue repair are exerted through paracrine factors, including immunoregulatory factors, cell mobility factors, and growth factors. In this chapter we discuss the key roles of these paracrine factors in tissue repair and regeneration.

## 37.2 Cell replacement and cell empowerment

Preclinical studies have suggested that MSCs are effective in a number of acute tissue injuries, including myocardial infarction [1–4], sepsis [5,6], hepatic failure [7], lung injuries [8–15], peritonitis [16] and acute experimental autoimmune encephalomyelitis (EAE) [17]. In experiments tracing *ex vivo* expanded MSCs infused intravenously, it was shown that MSCs became trapped in the lungs initially, but were subsequently recruited to damaged tissues such as infarcted myocardium, traumatic brain injury, fibrotic liver, damaged lung, and tumors [18].

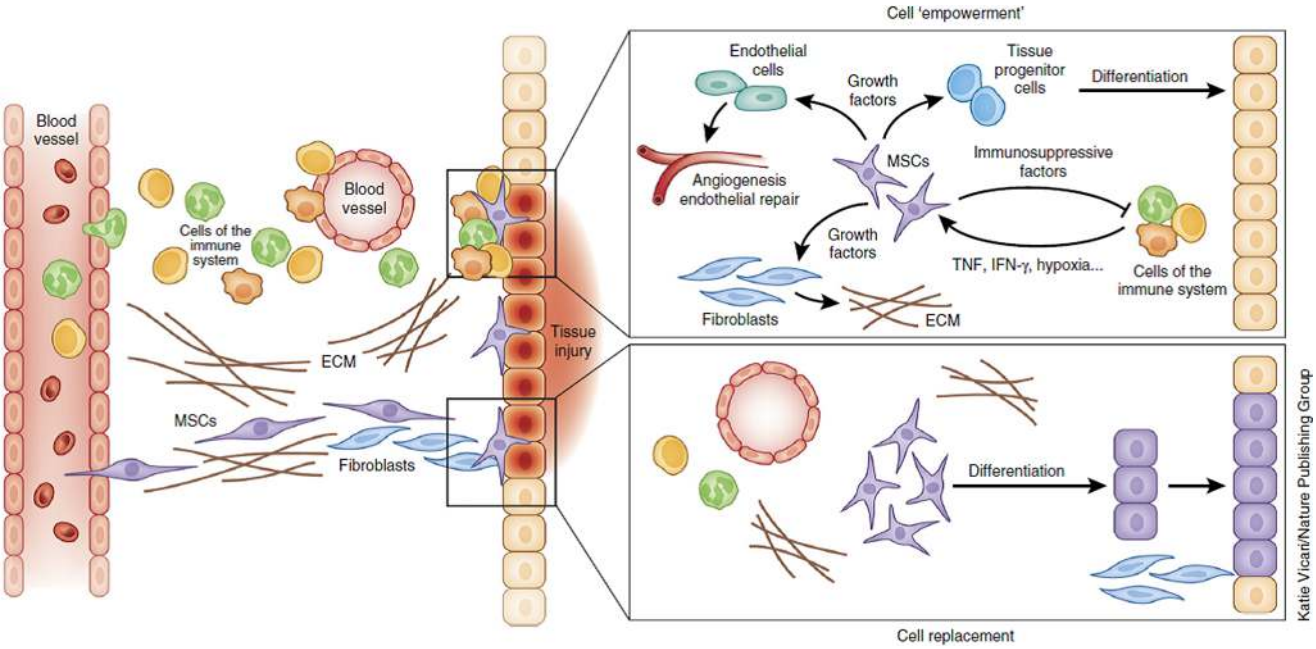

**Figure 37.1** Modes of MSC-based therapy: cell replacement versus cell "empowerment." When tissue is damaged, inflammation occurs and MSCs are mobilized to the site. Since they have multipotent differentiation potential, the recruited MSCs are believed to differentiate into functional cells to replace damaged cells. However, in response to inflammatory cytokines, MSCs also help prepare the microenvironment by producing immunoregulatory factors that modulate the progression of inflammation. MSCs also produce large amounts of growth factors that subsequently stimulate endothelial cells, fibroblasts, and, most importantly, tissue progenitor cells *in situ*. The concerted action of these factors and cells facilitates tissue repair through angiogenesis, remodeling of the extracellular matrix (ECM), and the differentiation of tissue progenitor cells. (See color plate section.) *Source*: Wang *et al. Nature Immunology* 2014; 15:1009–1016. Reproduced with permission.

Importantly, endogenous nestin$^+$ MSCs have been observed to migrate from bone marrow to asthmatic lungs [19]. After homing to injured tissues, MSC-based therapy can be achieved in two ways: cell replacement and cell "empowerment" (Figure 37.1) [20].

Based on their proliferative and mesodermal differentiation capability, MSCs are being used for their potential to replace damaged cells such as cardiomyocytes, hepatocytes, and endothelial cells, thereby promoting tissue regeneration in various organs, such as the heart, lung, and liver [21–24]. Growing evidence from both clinical and preclinical studies in arthritis, liver cirrhosis, myocardial infarction, renal degeneration, and neural degeneration have demonstrated that the beneficial role of MSCs in disease treatment is not related to the efficiency of cell engraftment and the longevity of MSCs [4,25–29]. Rather, factors such as hepatic growth factor (HGF) and tumor-necrosis-factor-(TNF)-inducible gene 6 (TSG-6) protein, which form part of the MSC secretome, or MSC conditioned medium alone, may substitute for the presence of MSCs themselves and exert beneficial effects on various inflammatory diseases [4,29,30]. Furthermore, in preclinical models, autologous, allogeneic, and xenogeneic MSCs are effective in treating tissue injuries, even in immunocompetent recipients, suggesting that MSC engraftment is not necessary for the mediation of therapeutic benefit in many circumstances [25,31]. Thus, the cell empowerment model is more important than the cell replacement model for MSC-based therapy, at least when diseases other than those of the musculoskeletal system are involved.

Through concerted actions of their secreted immunosuppressive factors, cytokines, growth factors, and differentiation factors, MSCs suppress inflammation, promote tissue progenitor cell proliferation and differentiation, facilitate endothelial cell function and fibroblast activity, and maintain tissue homeostasis [20]. Various studies have demonstrated that the production of paracrine factors is dependent on inflammatory responses.

## 37.3 Paracrine factors produced by mesenchymal stromal cells

Damaged tissue is always accompanied by infiltration of cells of the innate immune system, including macrophages and neutrophils, as well as those of the adaptive immune system, including T cells and B cells (see Chapters 33 and 34). These cells are recruited by chemotactic factors released from apoptotic cells, necrotic cells, damaged microvasculature and stroma [32,33]. Accumulation of these immune cells subsequently induces the production of inflammatory mediators, such as TNF-α, interleukin (IL)-1β, interferon (IFN)-γ, IL-17, free radicals, and chemokines, depending on the nature of the inflammatory stimulus [34]. These inflammatory molecules and immune system cells,

together with endothelial cells and fibroblasts, constitute the tissue microenvironment that influences the properties of MSCs during tissue repair [35]. The mechanisms by which MSCs are recruited, survive, and differentiate in damaged tissues have not been well understood until recently. However, investigations have found that MSCs stimulated by inflammatory signals such as cytokines, toxins of infectious agents, hypoxia, and toll-like receptor (TLR) ligands can secrete an array of growth factors and distinct soluble immunosuppressive factors [35,36]. We here summarize the effects of these paracrine factors on tissue repair processes.

### 37.3.1 Growth factors and mesenchymal-stromal-cell-mediated tissue repair

During acute tissue damage the endothelial cell barrier is broken down, allowing infiltration of leukocytes and the release of protein-rich plasma from blood into the damaged area [35]. The supporting function of fibroblasts becomes abnormal, resulting in aberrant extracellular matrix deposition and tissue integrity. Some studies have indicated that growth factors produced by MSCs are important in treating wounds and in improving recovery from myocardial infarction [37–39]. There is accumulating evidence that MSCs stimulated by inflammatory signals can secrete many growth factors, including epidermal growth factor (EGF), fibroblast growth factor (FGF), platelet-derived growth factor, transforming growth factor-β (TGF-β), vascular endothelial growth factor, HGF, insulin growth factor-1, angiopoietin-1 (Ang-1), keratinocyte growth factor, and stromal cell-derived factor-1 (also known as C–X–C motif chemokine ligand 12) [36,40–42]. These factors have been linked to the tissue repair functions of MSCs by promoting the activation and differentiation of tissue progenitor cells and the development of endothelial cells and fibroblasts. Among these growth factors, Ang-1, vascular endothelial growth factor, HGF, EGF, platelet-derived growth factor, FGF, keratinocyte growth factor, and TGF-β can directly regulate endothelial cells. Through promoting endothelial cell proliferation, regulating ECM production, decreasing endothelial permeability, and inhibiting the interaction between leukocytes and endothelial cells, these factors can maintain endothelial integrity and promote angiogenesis [43,44]. Additionally, they can influence fibroblasts to maintain tissue integrity and promote wound healing.

In addition to their functions on endothelial cells and fibroblasts, growth factors secreted by MSCs have also been demonstrated to have a role in the restoration of intrinsic tissue progenitor cells. For instance, it has been reported that HGF secreted by MSCs is effective in modulating endogenous neural cell remyelination, enabling recovery from EAE and spinal cord demyelination [29]. Other factors, such as FGF, stem cell factor, macrophage colony-stimulating factor, stromal cell-derived factor-1, leukemia inhibitory factor, Ang-1, and chemokines can also stimulate intrinsic tissue repair. Taken together, these observations demonstrate the complicated interactions between MSCs and damaged tissue during the process of tissue repair. The multitude of paracrine factors produced by MSCs, which provoke tissue resident progenitor cells or other relevant cells to initiate tissue repair, are in part responsible for the therapeutic effects of MSCs on tissue repair, even in the absence of local MSC engraftment [29,35,45].

### 37.3.2 Soluble immunosuppressive factors and mesenchymal-stromal-cell-mediated tissue repair

Cellular components released from necrotic cells in injured tissue are first sensed by resident immune cells such as macrophages, which are activated and subsequently produce various inflammatory molecules to initiate and promote local inflammation. Additional innate immune system cells, such as neutrophils, and adaptive immune system cells, such as B cells, $CD4^+$ T cells, and $CD8^+$ T cells, are also attracted to the site of tissue injury and augment the inflammation. Thus, downmodulating an exuberant and excessive inflammatory infiltrate, such as the massive infiltration by neutrophils and macrophages that occurs in infarcted myocardium, can prevent the subsequent replacement of myocardial muscle by fibroblasts and help avoid the consequent hypokinesis of the left ventricular wall that unchecked will lead to refractory heart failure.

One of the properties of MSC-based tissue repair is their immunosuppressive ability. MSCs have been shown to inhibit several types of immune cells, including T cells, B cells, dendritic cells, and natural killer (NK) cells at several key steps [36,46–48] (Figure 37.2).

Since the discovery that bone-marrow-derived MSCs could suppress T cell proliferation in 1998, the immunosuppressive ability of those cells on T cells has been actively investigated [48–50]. The inhibitory effects of MSCs on general T cell activation have been reported in both *in vitro* and *in vivo* experimental systems. Recent studies showed that MSCs can specifically inhibit T cell differentiation into Th1 and Th17 subsets of helper T cells and enhance the generation of Tregs [51]. Their regulation of Tregs involves induction of dendritic cells to a tolerogenic phenotype, which subsequently elicits the generation of Tregs [52]. Moreover, the induction of Tregs by MSCs can result from high levels of TGF-β production by macrophages that are activated by apoptotic T cells [53]. The switching from a proinflammatory to an anti-inflammatory status can also be observed in macrophages. In MSC-based sepsis treatment, MSCs can promote proinflammatory macrophages to switch into anti-inflammatory macrophages [5,54]. Also, MSCs can retain dendritic cells in an immature state via suppressing the expression of MHC class II, CD1α, CD40, CD80, and CD86, and decreasing proinflammatory cytokine production [55,56]. NK cells, one type of innate immune cell, can also be suppressed by MSCs through soluble factors, such as TGF-β and $PGE_2$ [57]. In the human system, similar suppression of IL-2- or IL-15-driven NK cells by MSCs has been observed [58]. Other suppression such as that mediated by MSCs on B cell proliferation are also found [59]. Taken together, MSCs possess extensive immunosuppression

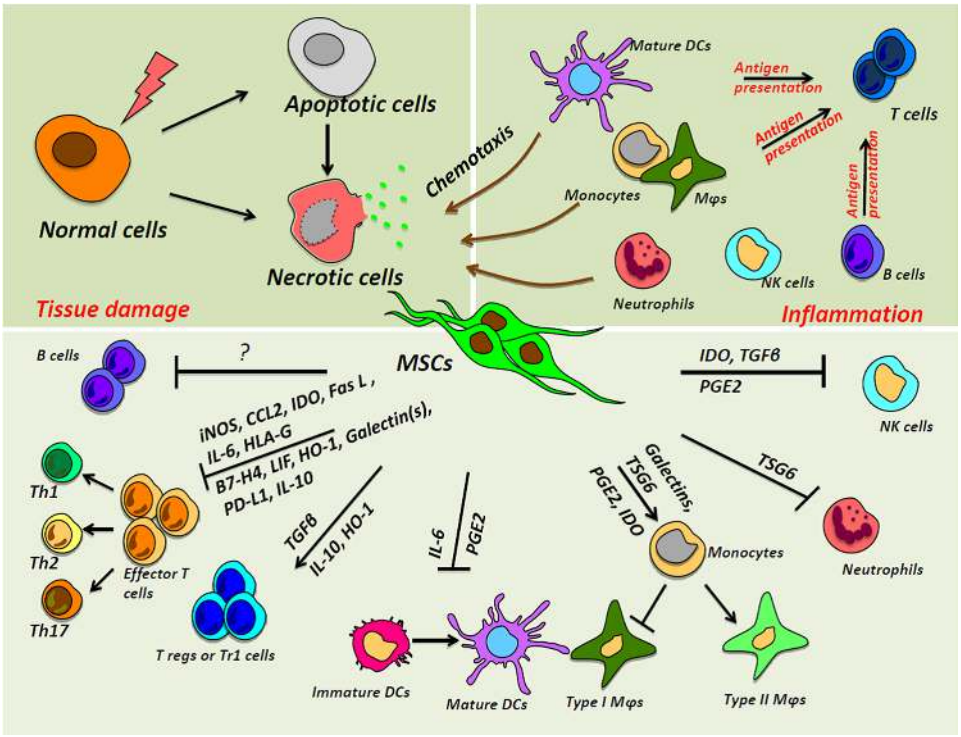

**Figure 37.2** Immunoregulation by MSCs. Immune cells accumulate in damaged tissues and release signals to recruit MSCs. At damaged tissue sites, MSCs have been reported to exert immunosuppressive effects on distinct types of immune cells by expression of immunosuppressive molecules. MSCs inhibit T cell activation and Th1/Th2/Th17 cell differentiation, induce regulatory T cells, render dendritic cells tolerogenic, and induce anti-inflammatory macrophages as well as suppress the activity of B cells, neutrophils, and NK cells. The mechanisms by which MSCs block inflammatory cell activity are shown by the T-shaped symbols. The mechanisms by which MSCs promote effective tissue repair are shown by the arrows. CCL2: chemokine (C–C motif) ligand 2; HLA-G: human leukocyte antigen G; HO-1: heme oxygenase-1; IDO: indoleamine 2,3-dioxygenased; iNOS: inducible nitric oxide synthase; LIF: leukemia inhibitory factor; PD-L1: programmed death ligand 1; PGE2: prostaglandin $E_2$; Th: helper T cell; Tregs: regulatory T cells. (See color plate section.)

ability on immune cells and so have attracted great interest from basic and clinical researchers. Recent investigations have suggested that the immunosuppressive function of MSCs can be enacted through a paracrine effect in a cell–cell contact manner.

MSCs are benign and cannot inhibit immune responses unless they are first activated by certain combinations of inflammatory cytokines. In the presence of IFN-γ, combined with one (or more) other cytokine(s), including TNF-α, IL-1α, or IL-1β, MSCs are licensed to exert their immunosuppressive function [60]. The vital role of IFN-γ and it receptor IFN-γR has been investigated in experiments with antibodies to IFN-γ or to IFN-γR, as well as IFN-γR1-deficient MSCs [60,61]. Under appropriate inflammatory stimulation, MSCs express large amounts of immunoregulatory factors, such as IDO and iNOS, as well as chemokines, including ligands for chemokine receptors CXCR3 and CCR5, which are critical for T cell chemotaxis [60,62]. Through the concerted action of chemokines and immunoregulatory factors, MSCs exert suppressive effects on these recruited T cells. Investigations on the mechanisms of MSC-mediated immunosuppression have demonstrated that not only are cell–cell contact molecules, including FasL and PD-L1/2, important for the functions of these cells, but soluble factors such as nitric oxide (NO), IDO metabolites, and immunosuppressive cytokines are critical for their immunosuppressive effects [35]. These factors are detailed in the following subsections.

### 37.3.3 Inducible nitric oxide synthase/ indoleamine 2,3-dioxygenase

NO in high concentrations has been shown to inhibit immune responses through yet largely undefined mechanisms. iNOS is expressed in murine MSCs when stimulated with the proinflammatory cytokine IFN-γ in combination with either TNF-α or IL-1 [60]. The high concentration of NO suppresses signal transducer and activator of transcription (STAT)5 phosphorylation in T cells and induces immune cell apoptosis [63]. Suppression of iNOS activity by either chemical inhibitors or genetic ablation in MSCs reverses the immunosuppression mediated by MSCs and abolishes the therapeutic effect of MSCs in several immune abnormality models [64]. However, NO is a highly labile oxidative species and can only act on target cells that are in close proximity to cells producing it. Experiments using permeable

membrane to separate lymphocytes and MSCs have demonstrated that the immunosuppressive factor works over a short distance. Indeed, MSC-mediated immunosuppression on T cells through NO is dependent on high chemokine production, which recruits T cells to the vicinity of MSCs and facilitates the suppression by NO on T cells.

Importantly, analysis of immunosuppressive factors between different species shows that MSCs derived from rodents and rabbit use iNOS to exert their immunosuppressive effect, while MSCs derived from human, monkey, and pig employ IDO instead [61,62,65]. IDO is an enzyme that catalyzes tryptophan into kynurenine. The depletion of tryptophan and accumulation of metabolites account for the immunosuppression mediated by IDO [66]. However, the mechanism of IDO-mediated immunosuppression remains unclear. Studies have revealed that IDO is involved in suppressing T cell proliferation, promoting type 2 macrophage differentiation, and impairing NK cell activity [62,67,68].

iNOS and IDO are key factors in mediating the immunoregulation of MSCs. Promoting their expression in MSCs by inflammatory cytokines can license or optimize MSC-mediated immunosuppression, while inhibiting or downregulating their expression in MSCs will enhance the immune response. Thus, strategies targeting iNOS or IDO can modulate the plasticity of MSCs in immune disorders, thereby facilitating MSC-based treatment via decreasing or increasing immune responses [20].

### 37.3.4 Prostaglandin $E_2$

$PGE_2$ is another molecule involved in the immunosuppressive role of MSCs that can be induced by inflammatory cytokines. It has been reported that IL-6-induced $PGE_2$ plays a major role in the therapeutic effect of MSCs in an experimental model of arthritis [69]. Also, $PGE_2$ produced by MSCs is critical for the attenuation of sepsis, which can promote macrophages to produce high levels of IL-10 [5]. Several studies demonstrated that $PGE_2$ secreted by mouse or human MSCs can inhibit dendritic cell maturation, reprogram macrophages to secrete IL-10, shift the balance between Th1 and Th2 T cells, induce Treg cells, and suppress NK cell function [5,57,68,70–72]. Of note, $PGE_2$ can promote IDO-mediated MSC immunosuppression of T cells and NK cells [68,73]. Further studies on the mechanism of $PGE_2$ expression in MSCs and its role in immunosuppression will help facilitate clinical application of MSCs.

### 37.3.5 Tumor-necrosis-factor-inducible gene 6 protein

TSG-6 is an anti-inflammatory protein that is inducible by a subset of inflammatory cytokines, such as TNF-α and IL-1. In patients with inflammatory or autoimmune disorders, TSG-6 has been found to be highly expressed in a variety of cells, suggesting that TSG-6 is involved in the pathogenesis of autoimmune diseases. In MSC-based treatment of myocardial infarction, intravenously injected MSCs accumulate in the lung and form microemboli, which can induce the production of TSG-6 by MSCs. TSG-6 is important in MSC-mediated suppression of the inflammatory response, reduction of infarct size, and improvement of cardiac function [4]. Similarly, immunosuppression mediated by TSG-6 has also been observed in MSC-based treatment of zymosan-induced mouse peritonitis, in which TSG-6 alleviates inflammation through dampening TLR 2/NF-κB signaling in resident macrophages [16]. However, the exact role of TSG-6 in human MSC-mediated immunoregulation requires detailed further investigations.

### 37.3.6 Chemokine (C–C motif) ligand 2

CCL2 is a low molecular weight chemokine. Classically, it is regarded as a molecule that mediates chemotaxis of myeloid cells to inflammatory sites by ligating its receptor, CCR2. An *in vitro* investigation showed that matrix metalloprotease (MMP)-cleaved CCL2 can dramatically decrease monocyte migration [74]. In an experiment using MSCs to treat EAE, it was shown that MSCs could inhibit disease progression via a paracrine conversion of CCL2 from agonist to antagonist to suppress Th17 cells [17]. Similarly, cleaved CCL2 processed by MMP has been demonstrated to mediate the suppression of MSCs on immunoglobulin production by plasma cells. In this process, cleaved CCL2 suppresses the activation of STAT3 and induces the activity of paired box protein 5 in plasma cells [75]. Additionally, intact CCL2 is also important in MSC-mediated tissue repair, especially in tissue injuries that need monocytes and macrophages to help to eliminate bacteria and promote wound healing.

### 37.3.7 Interleukin-6

IL-6 is a pleiotropic cytokine. It has dual properties in proinflammation and anti-inflammation. Murine MSCs produce a high level of IL-6 even in resting status. Under inflammatory stimulation, IL-6 production can be further enhanced. When IL-6 is blocked by neutralizing antibody, it was demonstrated to be crucial in mediating the immunosuppression of MSCs on T cells [76]. Additionally, IL-6 produced by MSCs is important in suppressing the differentiation of bone marrow progenitors into dendritic cells [52].

### 37.3.8 Interleukin-10

Soon after the discovery of the immunosuppressive role of MSCs, IL-10 was found to mediate the suppressive effect of MSCs on T cell proliferation and Th17 cell differentiation. However, IL-10 production by non-stimulated MSCs does not occur, nor does it occur after stimulation with lipopolysaccharide/IL-3 [77–79]. Rather, IL-10 production in antigen-presenting cells such as dendritic cells and monocytes is upregulated when those cells interact with MSCs through cell–cell contact. Further investigation is required to determine whether such production of IL-10 is derived from MSCs or from the co-cultured immune cells. IL-10 blockade did not reverse MSC-mediated immunosuppression of lymphocytes [80].

### 37.3.9 Transforming growth factor-β

TGF-β is an immunosuppressive cytokine that counterbalances proinflammatory effects in a number of disease models. TGF-β has a direct effect in maintaining tissue homeostasis. It is a key factor in the induction of Tregs. Both *in vitro* and *in vivo* studies have demonstrated that TGF-β is important in mediating MSC suppression of T cells and NK cells in preclinical disease models including EAE, asthma and experimental autoimmune uveitis through Treg induction [57,81,82,83]. TGF-β secreted by MSCs can serve as a feedback loop to reverse the immunosuppression of MSCs on T cells via TGF-β receptors I and II, thus indicating a switching function of MSCs in converting from an immunosupressive role into an immune-enhancing one [84].

### 37.3.10 Human leukocyte antigen G

HLA-G is a nonclassical HLA class I molecule that is selectively expressed in cytotrophoblast cells at the maternal–fetal interface. It has been implicated in the mediation of maternal–fetal tolerance, since it is a ligand for inhibitory receptors of uterine NK cells. MSCs were recently reported to secrete a soluble (s) HLA-G5 isoform. Blockade of HLA-G5 reduces immunomodulatory functions of MSCs, including the *in vivo* expansion of $CD4^+CD25^+Foxp3^+$ Tregs, inhibition of T cell proliferation and suppression of NK-mediated cytolysis [16,85]. Thus HLA-G molecules play an important role in the modulation of immune response by MSCs.

### 37.3.11 Galectins

The human galectin family consists of 15 members. They are widely expressed by both immune cells and non-immune cells and play an important role in the maintenance of tissue homeostasis and regulation of the innate and adaptive immune responses. Galectin-1 has been shown to be a negative regulator of inflammation. It has two forms; one is soluble and the other is expressed on the cell surface membrane. Both forms can be detected in MSCs. Galectin-1 is released into the supernatant of MSCs in culture. Knockdown of galectin-1 on MSCs inhibits their immunosuppressive effect and restores T cell proliferation and IFN-γ production [86,87]. Galectin-9 has been reported to mediate an inhibitory role of MSCs in immune responses. On exposure to TLR ligands and inflammatory stimuli, MSCs can secrete galectin-9 to suppress T cell activation. Galectin-9 knockdown MSCs have a much lower immunosuppressive effect on mixed lymphocyte cultures than normal MSCs [88].

### 37.3.12 Other soluble immunosuppressive factors secreted by MSCs

Semaphorin-3A and leukemia inhibitory facor (LIF) are also involved in suppressing human T cell responses [87,89]. LL-37, an antimicrobial peptide secreted by MSCs, is upregulated by bacterial stimulation [90]. In a mouse model of *Escherichia coli* pneumonia, LL-37 secreted by MSCs increased bacterial clearance, suggesting that this is another paracrine effect of MSCs [90].

## 37.4 Conclusions

Investigations over the past several decades have dramatically increased our understanding of the potential therapeutic effects of MSCs. In addition to their function in cell replacement in certain circumstances, many studies have demonstrated that they produce a large number of soluble factors, especially in inflammation. They can orchestrate tissue repair by decreasing the effect of bacterial infection, by suppressing vigorous immune responses, and by promoting tissue regeneration. Further investigation of the potential mechanisms of these soluble factors is required. It would be desirable if paracrine factors alone could accomplish the same therapeutic effects as those of MSCs.

## 38.1 Introduction

Mesenchymal stromal cells (MSCs) may potentially be an innovative treatment for acute and chronic lung disease owing to their ability to secrete paracrine factors such as growth factors, anti-inflammatory cytokines, and antimicrobial peptides [1–9]. This is in addition to the "immuno-privileged" property of MSCs allowing allogeneic transplantation and lack of evidence of tumor formation *in vivo*. Based on significant preclinical data, multiple phase I and II clinical trials (listed in ClinicalTrial.gov) have been performed or are ongoing in a variety of acute and chronic lung diseases, such as acute respiratory distress syndrome (ARDS; NCT01775774, NCT01902082, NCT02215811), severe bronchopulmonary dysplasia (NCT01207869, NCT01297205), asthma (NCT02192736), chronic obstructive pulmonary disease (COPD; NCT00683722), emphysema (NCT01849159), and

idiopathic pulmonary fibrosis (NCT02135380). However, concerns still remain as to whether MSCs can become tumorigenic or promote preexisting tumors, such as breast cancer [10–12].

Recently, MSCs have been found to release extracellular vesicles such as exosomes and microvesicles (MV) that are as biologically active as the cells themselves in a variety of inflammatory syndromes. In this chapter we review the current preclinical studies on the use of exosomes or MVs derived from MSCs as a therapeutic agent in both acute and chronic lung diseases.

## 38.2 Definitions and characterization of extracellular vesicles

Once considered cellular debris or dust, increasing evidence now demonstrates that secreted extracellular vesicles play important roles in biology (e.g., in intercellular traffic and communication) and in disease (e.g., in inflammation or cancer). Multiple cell types, including but not limited to platelets, megakaryocytes, monocytes, epithelial and endothelial cells, lymphocytes, polymorphonuclear leukocytes, stem cells, and cancer cells, secrete vesicles following diverse physiological or pathophysiological processes or triggers or in response to external stimuli. Vesicles can be found in blood, urine, organs, and tissues or cavities such as the alveolar space. Currently, research into the biological importance of vesicles ranges from potential biomarkers of disease to mechanisms for injury or repair in part through the transfer of proteins or peptides, mRNA, microRNA, and/or organelles contained in the vesicles of the targeted tissue [13,14].

However, owing to the ubiquitous nature of vesicles in normal physiology and pathophysiology, there is no broad agreement on classification or nomenclature of vesicles. In the first meeting of the International Society of Extracellular Vesicles in 2012 no

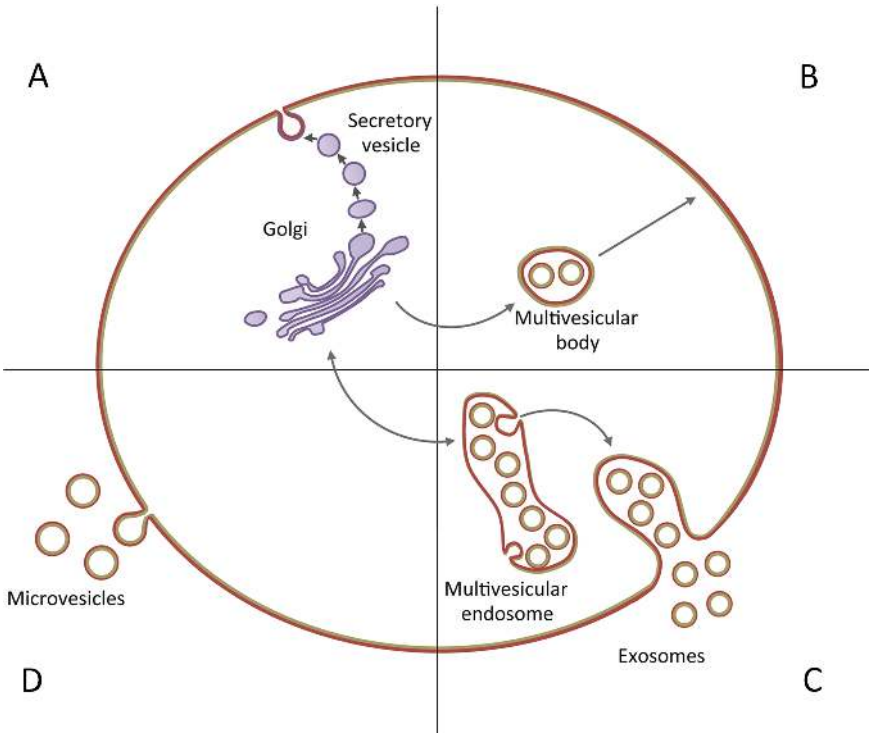

**Figure 38.1** Extracellular vesicles: diversity of origins and mechanisms of interactions with recipient cells.
Extracellular vesicles originate from different subcellular compartments. (A) Intracellular trafficking toward the plasma membrane for secretion of soluble components (e.g., proteins, lipids, RNA) occurs via secretory vesicles that contain intraluminal components. (B, C) Alternatively, extracellular vesicles can form inside internal compartments such as early endosomes, through the invagination of the endosomal membrane to generate intraluminal vesicles within either multivesicular bodies (B) or multivesicular endosomes (C). The intraluminal vesicles are then released by fusion of these compartments with the plasma membrane. Vesicles generated in either multivesicular bodies or endosomes are called exosomes once secreted. (D) By contrast, secreted extracellular vesicles contain cytoplasmic components. Secreted extracellular vesicles can form at the plasma membrane by direct budding into the extracellular space, giving rise to microvesicles and membrane particles.
Mechanisms of interactions between extracellular vesicles and recipient cells. (E) Extracellular vesicles can deliver their bioactive cargo through the fusion-mediated transfer of surface receptors, proteins, lipids, and genetic material (e.g., DNA and RNA). (F) They can also initiate transduction of a cell-signaling pathway through either a ligand–receptor interaction or (G) through a paracrine effect from a secreted factor. (H) Lastly, internalization and lysosomal processing of extracellular vesicles represents another mechanism of interaction, which can lead to both the expression of the content of the extracellular vesicles on the surface of the recipient cell and the delivery of their bioactive cargo.

consensus was reached on vesicle nomenclature, but a general agreement was made "that investigators should not be forced to concede their scientific independence" [15]. In an attempt to cope with "imperfect nomenclature," Gould and Raposo recommended that scientists should state their use of the terms for vesicles explicitly based on precedent or logical argument and the method of collection of the vesicles in their publications [16].

## 38.3 Nomenclature defined by size and morphology

For research purposes, vesicles can now be broadly defined by their size and morphology as exosomes, MVs, and apoptotic bodies. Exosomes are vesicles 50–100 nm in size that arise from endosomal membrane compartments and are released into the extracellular space after fusion of multivesicular bodies with the cell membrane [17–21]. Exosomes are rich in annexins, tetraspanins (CD63, CD81, CD9), and heat-shock proteins (Hsp60, Hsp70, and Hsp90) and express low amounts of phosphatidylserine. In addition, tumor susceptibility gene 101 (Tsg101), Alix, and clathrin are frequently present in exosomes. More importantly, exosomes carry proteins and RNAs unique to their cell source and their pathophysiological state [22,23]. The list of proteins and RNAs reported to be present in exosomes is freely accessible at Exocarta [24] (http://www.exocarta.org) or Vesiclepedia [25] (http://www.microvesicles.org).

MVs (often referred to as ectosomes, microparticles, or shed vesicles/particles) originate by direct budding off the plasma membrane and range in size from 100 to 1000 nm [26–28]. These vesicles express high amounts of phosphatidylserine, contain proteins associated with lipid rafts, and are enriched in cholesterol, sphingomyelin, and ceramide.

Apoptotic bodies (also called apobodies) are larger sealed membrane vesicles that are produced from cells undergoing programmed cell death and are generally >800 nm in size. The formation of apoptotic bodies is a mechanism by which dying cells prevent leakage of potentially toxic or immunogenic cellular content, preventing inflammation and tissue destruction, by coordinated uptake by phagocytes. In contrast, exosomes and MVs are constitutively released and can be induced by multiple cell types and often serve as a means of intercellular communication, whether through normal physiological processes or in response to injury (Figure 38.1).

Both exosomes and MVs may communicate with target cells by specific receptor–ligand interactions and transfer receptors and biologically active molecules to these target cells following internalization [29]. Moreover, besides proteins and lipids, both exosomes and MVs also carry mRNA and microRNA and thus may play a role in the exchange of genetic material between cells [27–30].

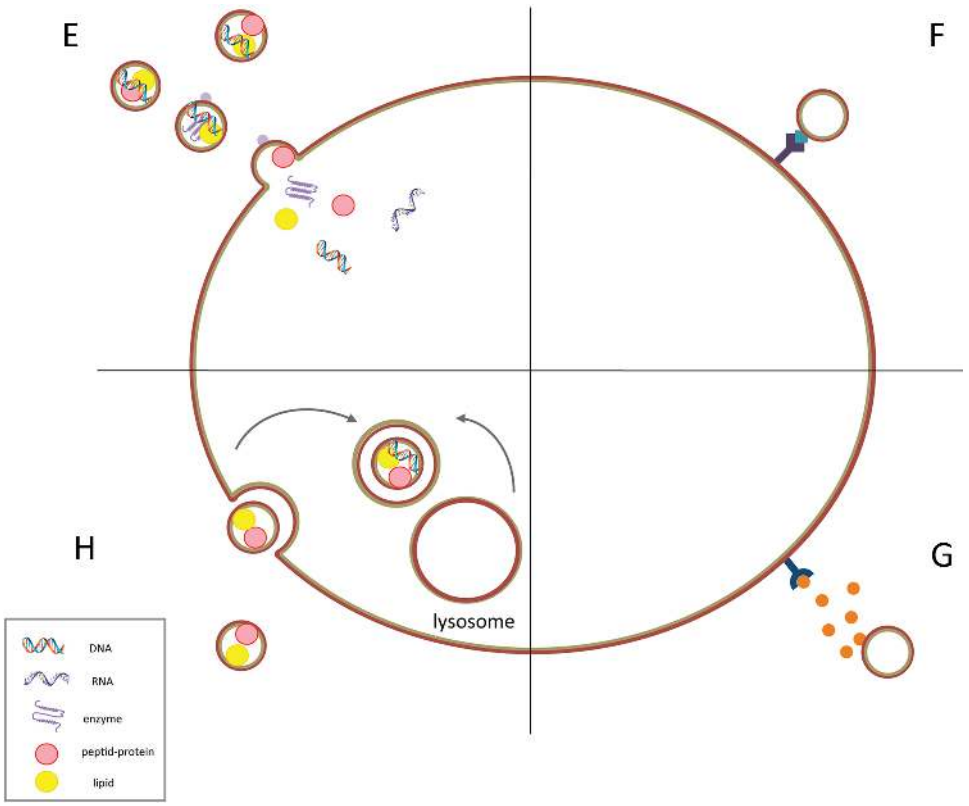

**Figure 38.1** (*Continued*)

## 38.4 Common methods of collection of extracellular vesicles

Common methods used to isolate extracellular vesicles include techniques such as ultracentrifugation, filtration, and immunoaffinity isolation [15].

### 38.4.1 Ultracentrifugation

Vesicle isolation by differential centrifugation is the most commonly used technique utilized in the literature. Body fluid samples such as plasma or serum or from culture medium are depleted first of cells, platelets, and large apoptotic bodies by low-speed centrifugation steps and/or size exclusion filters (e.g., 800 nm filters). Forces commonly reported for this step are in the 10 000–20 000*g* range. Smaller vesicles are then pelleted at higher speeds (100 000–120 000*g*). However, these sequential ultracentrifugation steps cannot achieve absolute separation of vesicles by size because sedimentation also depends on the density of the vesicle and the distance a vesicle travels. Vesicle pellets from high-speed ultracentrifugation will also contain extravascular protein complexes or aggregates, lipoprotein particles, and other contaminants. Although used frequently to quantitate vesicles (as discussed later), protein concentration measurement of vesicles may be inaccurate due to these contaminations. To separate contaminating protein and/or protein–RNA aggregates from the lipid-containing vesicles, density sucrose gradients or sucrose cushions are used to float the relatively low-density vesicles, classically reported in the range between 1.1 and 1.19 g/mL, away from other contaminants. Although density separation is more precise, such separation can require centrifugation of a sample for up to 90 h. Consequently, when reporting methods utilized to isolate the vesicles, it is important to specify the *g* force, rotor type (fixed angle, swinging bucket), pelleting efficiency (rotor *k*-factor), sample viscosity, and gradient characteristics.

### 38.4.2 Size exclusion

Using filters, separation of vesicles based on size can be achieved. Filters of 0.8 μm are often used to remove large cell fragments and platelets prior to vesicle isolation, while 0.2 μm filters may be used for the isolation of smaller vesicles. However, some concerns remain that forcing vesicles through filter pores may cause deformation and breakup of larger particles or platelets, thereby changing the characteristics of the recovered vesicles. To prevent this, size exclusion should be performed by gravity. Column chromatography may allow sequential elution of vesicles of different size fractions from a single column. However, filter-based methods will not enrich vesicle populations unless low molecular weight filters (e.g., Centricon) are used for concentration.

### 38.4.3 Immunoaffinity isolation

The presence of characteristic surface proteins on certain vesicles is the basis for immunoaffinity isolation in which antibodies to surface proteins are used to select desired vesicle populations (immuno-enrichment) or to trap unwanted vesicle populations (immuno-depletion). Antibodies are attached to beads or other matrices through covalent or high-affinity interactions, facilitating physical separation by low-speed centrifugation or magnetic techniques. Immunologic techniques have the potential for high specificity of the collected vesicles. However, high selectivity may result in lower yields of the vesicles because not all vesicles will express the marker or protein of interest.

### 38.4.4 Polymeric precipitation

Commercial kits containing polymeric precipitation mixtures are incubated with the fluid containing the vesicles overnight and low-speed ultracentrifugation is then used to collect the precipitate containing vesicles. By tying up water molecules, the reagent in theory forces less-soluble components, such as vesicles, out of solution, which allows them to be collected by low-speed centrifugation. However, as with ultracentrifugation, isolation of vesicles by polymer-based precipitation methods may include numerous contaminants, such as lipoproteins. In general, this technique may produce a higher yield of RNA at the cost of inclusion of impurities.

Research studies into exosomes or MVs derived from MSCs often use ultracentrifugation and size exclusion filters to isolate the vesicles.

## 38.5 Quantification of extracellular vesicles

Several methods have been developed to quantify vesicles from different preparation methods. Often, the major limitation to the quantification technique used by investigators is the cost or lack of availability of the instruments required.

### 38.5.1 Optical single-particle tracking: nanoparticle tracking analyses

Nanoparticle tracking analyses (NTA) is the commercial name of an optical particle tracking method. In this method, a laser beam is scattered by particles in the sample of interest and the mean velocity of each particle is calculated by the Stokes–Einstein equation on the basis of Brownian motion as recorded by a charge-coupled-device camera. This technique is used to obtain the concentration and size distribution of vesicle populations. Prior to use, vesicles should be isolated from the fluid of interest in order to remove contaminating lipoprotein particles, protein complexes, and other particles of similar size. Although standard light scatter NTA does not detect the cellular origin of vesicles, such analyses can be made using fluorescent-labeled antibodies to surface proteins on vesicles of interest. It may be useful to compare samples treated with and without detergents to eliminate the vesicles to check for the amount of debris in the sample.

### 38.5.2 Flow cytometry

Conventional flow cytometry has a lower detection threshold around 500 nm and is suited for analysis of large vesicles. Newer instruments, such as Gallios (Beckman Coulter), BD-Influx or LSR Fortessa (Becton Dickinson), and Apogee (Apogee Flow Systems), can discriminate particles as small as 100–200 nm. The International Society on Thrombosis and Haemostasis Scientific Standardization Committee proposed a protocol that uses 500 nm and 900 nm polystyrene beads from Megamix to define a vesicle size gate. However, even with the use of appropriate standards such as polystyrene beads or silica particles to quantitate the number of vesicles, it remains difficult by flow cytometry to distinguish single vesicles from "swarm" detection (i.e., multiple vesicles are simultaneously illuminated by the laser beam and counted as a single event), underestimating the concentration of vesicles [31]. The current recommendation is to analyze serial dilutions of the vesicle sample to define the proper dilution at which "swarm" signals are minimized. As with NTA, detergents can be used to estimate the amount of debris contaminating the sample. Recently, investigators have used fluorescent-labeled antibodies to surface receptors such as CD44 and CD29 on vesicles to determine the concentration. Although specific enough to quantitate the number of fluorescent hits, the technique in general may underestimate the true number of vesicles due to low to moderate sensitivity of the surface protein on the vesicle.

### 38.5.3 Electron microscopy

Using heavy metal stains such as osmium tetroxide and uranyl acetate, transmission electron microscopy has been used to characterize membrane-bound vesicles in cells and in isolation of pure vesicles. Transmission electron microscopy has also been used with immunoglobulin coupled to nanogold particles that detect specific vesicle features (immuno-EM). Electron microscopy is valuable for the assessment of morphology, size, and presence of markers (immuno-EM). However, the technique is of limited use for the determination of concentration of vesicles.

### 38.5.4 Protein concentration

Protein concentration using a standard protein assay (i.e., Bradford) for both the membrane and intracellular components of the vesicles has been used to quantitate and compare vesicles from different isolation techniques. However, the use of protein concentration will not reveal the number of cells from which the vesicles were released and may also be affected by any preconditioning steps the cells undergo prior to the release of the vesicles.

### 38.5.5 Cell count

For *in vitro* experiments, preconditioning the cells of interest (e.g., by serum starvation, inflammation, or hypoxia) prior to isolation of the released vesicles can dramatically change the phenotype and the surface and/or intracellular compositions of the vesicles released. An example is vesicles derived from M1 or M2 macrophages. Consequently, many investigators have quantified the number of vesicles by the number of cells from which they are derived and the preconditioning steps used to release the vesicles. Benefits of using cell count to quantify the vesicles are (1) the ability to compare the released vesicles with the parent cells as in cell-based therapy and (2) the lack of need for expensive equipment.

Research studies into exosomes or MVs derived from mesenchymal stromal cells have used all of these techniques equally.

## 38.6 Interaction of extracellular vesicles with targeted cells

Extracellular vesicles may influence the behavior of recipient cells by several different mechanisms. First, vesicles may act as signaling complexes by direct stimulation of target cells. Vesicles may express several types of receptors and surface molecules, such as tissue factor (TF), tumor necrosis factor (TNF), major histocompatibility complex class I/II molecules, chemokine receptor CCR5 [32], intercellular adhesion molecule 1 (ICAM-1) [33], and delta-like ligand 4 [34]. These molecules may directly activate cells bearing the respective ligands and/or transfer receptors and/or bioactive lipids between cells after fusion with the target cell membrane [35]. For MVs derived from MSCs, Camussi and colleagues found that the membrane receptors CD44 and CD29 were critical for targeting MSC MVs to injured renal epithelium in a mouse model of acute kidney injury (AKI). Prior trypsinization of the MSC MVs eliminated trafficking toward the targeted cell and the therapeutic effects of the MVs [36].

Second, vesicles may modulate target cells by delivering their intracellular protein cargo. For example, vesicles can activate angiogenesis through the transfer of proangiogenic molecules such as vascular endothelial growth factor, basic fibroblast growth factor, TNF-α, and transforming growth factor (TGF)-β [37] along with proteases such as matrix metalloproteases 2/9 and membrane type 1 metalloprotease [38] and their respective activators [39]. Exosomes can reverse the depletion of key enzymes such as peroxiredoxins and glutathione *S*-transferase involved in reactive oxygen species metabolism and reduce the resultant accumulation of toxic products from the electron transport chain by direct transfer into injured cells during oxidative stress-induced injury [40]. Exosomes also contain key enzymes involved in the adenosine-5′-triphosphate (ATP)-generating stage of glycolysis, potentially restoring proteomic alterations in injured tissues [41,42]. For MVs derived from MSCs, Islam *et al.* found that one of the therapeutic effects of MSC MVs was through the transfer of mitochondria to the injured alveolar epithelium with subsequent restoration of ATP levels in a mouse model of acute lung injury [43]. In contrast to a beneficial biological effect, vesicles can also induce apoptosis in target cells by transferring caspase-1, caspase-8, or lymphotoxin-α [44].

Third, vesicles can transfer mRNAs and small noncoding RNA species between cells as a mechanism for cell-to-cell communication [45]. It has become evident that vesicles contain a distinct cargo that not only represents the cell of origin but also are enriched in specific nucleic acid or lipid species that can be transferred to target cells and subsequently translated into proteins [30,46]. In several studies, pretreatment of vesicles with RNase inhibited the observed biological effects of the vesicles, demonstrating the important contributions of vesicle-derived RNA [27,28]. These nucleic acids can be transferred to recipient cells and induce functional/phenotypic changes in the recipient cells [47,48]. Zhu *et al.* found that one of the therapeutic properties of MSC MVs was through the transfer of mRNA for keratinocyte growth factor to the injured alveolus with subsequent expression of the protein in a mouse model of acute lung injury [14] (Figure 38.1).

## 38.7 Endogenous extracellular vesicles in lung disease

Occupying a pivotal interface between the internal milieus of the body with the external environment, the lung is a unique organ composed of multiple cellular lineages forming its parenchyma and circulating within the alveolar space. Among the cells that occupy the alveolus are epithelial cells, endothelial cells, fibroblasts, monocytes and macrophages, polymorphonuclear neutrophils (PMNs), dendritic cells, and lymphocytes. There is intense cell-to-cell communication to maintain homeostasis or to become involved in inflammatory lung diseases such as ARDS, asthma, and COPD. Interestingly, most cell types have been shown capable of secreting in their environment a wide array of extracellular vesicles, ranging from exosomes to the larger MVs [49]. Far from "cell garbage" as originally thought [50], released extracellular vesicles are *sine qua non* (essential) for cell-to-cell communication, which in turn is critical for homeostasis and for generating an efficient response to lung injury [13]. In the following sections we will provide a brief overview of the main characteristics of endogenous extracellular vesicles and review the available body of knowledge on their role in ARDS, COPD, and asthma, describing both their detrimental and beneficial effects in lung injury. Then we will demonstrate how endogenous extracellular vesicles may serve as biomarker in lung disease, potentially representing a therapeutic target (Figure 38.2).

### 38.7.1 Endogenous extracellular vesicles in acute respiratory distress syndrome

Clinically, ARDS, the most common cause of respiratory failure in intensive care units, is defined by bilateral chest infiltrates without evidence of left heart failure and a $PaO_2/FIO_2$ ratio <300 [51]. Depending on the etiology, pneumonia and sepsis being most the common, the mortality rate can reach 40%. The pathophysiology of ARDS involves complex crosstalk between both the immune and coagulation systems with the alveolo-capillary lung barrier, leading to an excessive proinflammatory response, increase in lung protein permeability, and formation of pulmonary edema, which eventually results in impaired gas exchange and hypoxemia [52]. A growing body of research has revealed the critical role of extracellular vesicles as a means of communication between the multiple different cells involved in ARDS.

Extracellular vesicles released by platelets (PEVs) have been shown to interact with key players in ARDS, leading to the activation of endothelial cells, PMNs, and platelets themselves [53–55]. Exposure to PEVs was found to stimulate lung endothelial cells to secrete proinflammatory cytokines such as interleukin (IL)-1, IL-6, IL-8, monocyte chemoattractant protein-1 (also known CCL2), monocyte-derived IL-1, TNF-α, and IL-8. In addition, IL-1β-enriched PEVs increased the expression of vascular cell adhesion molecule-1 (VCAM-1) on the endothelium [53]. Interaction between PEVs and PMNs appeared to be mediated by different ligand–receptor linkage, such as the platelet glycoprotein Ib–the leukocyte interin Mac-1, β2-integrins (CD11b)–Mac-1, or P-selectin–P-selectin glycoprotein ligand-1, promoting IL-8 secretion, oxidative burst, degranulation, and enhanced leukocyte rolling [54,55]. The arachidonic acid (AA)–thromboxane A2 (TXA2) signaling pathway largely underlies the proinflammatory properties of PEVs. PEVs activated by either soluble phospholipase A2 or ExoU (a *Pseudomonas aeruginosa* toxin with phospholipase A2 activity), converts the newly formed AA to TXA2, promoting platelet activation and, more importantly, resulting in a hypercoagulable state with increased lung protein permeability [56,57]. Overall, these studies demonstrated that platelets, monocytes, and endothelial cells were activated through either AA or one of its downstream prostanoid metabolites released by PEVs [58–60]. As with PEVs, PMN extracellular vesicles (NEVs) were also found to stimulate platelets, endothelial cells, and other immune cells directly or indirectly through platelet-activating factor secretion. Multiple studies have demonstrated the capacity of NEVs to stimulate endothelial cells to increase IL-6 secretion, leading to vascular dysfunction by altering the balance between nitric oxide and reactive oxygen species production, which results in oxidative stress [61–63]. Injured endothelial cells in turn subsequently release extracellular vesicles, which further modulates inflammation and coagulation.

Coagulation disorders characterized by hypercoagulability and hypofibrinolytic states are key features of ARDS [52,64]. TF (also known as platelet TF, factor III, thromboplastin, and CD142), which is a key initiator in the coagulation cascade, is widely expressed by diverse extracellular vesicles in ARDS [65,66] such as PEVs [67,68] and is critically involved in the coagulation abnormality. While some extracellular vesicles (such as those released by monocytes) decrease the expression of the TF pathway inhibitor and thrombomodulin (which promotes thrombogenicity *in vitro* [69]), most of the procoagulant effect is mediated through TF extracellular vesicles during inflammation [65,70]. In addition, the large amount of

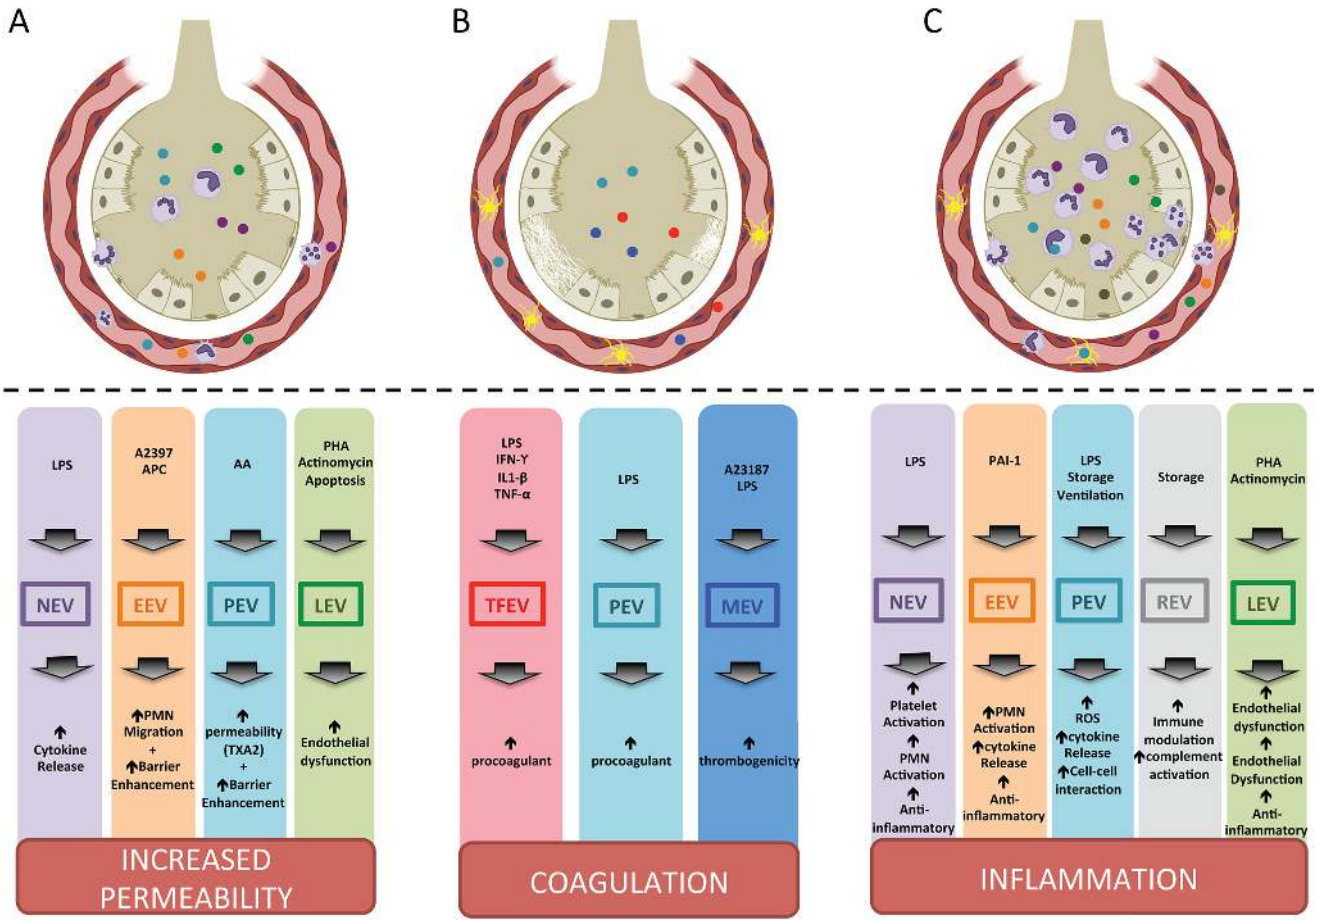

**Figure 38.2** Schematic representation of endogenous extracellular vesicles and their involvement in acute lung injury. The pathological effects of endogenous extracellular vesicles in acute lung injury are depicted under three major pathways: increased lung protein permeability (A), a hypercoagulable state (B), and inflammation (C). Extracellular vesicles (color coded) released by specific cells are capable of impacting these three pathways of lung injury at multiple levels. As described further in the text, the different extracellular vesicle populations are in turn activated or released upon specific stimuli. (See color plate section.)
AA: arachidonic acid; APC: activated protein C; EEV: endothelial extracellular vesicles (orange); IFN: interferon; IL-1: interleukin 1; LEV: lymphocyte extracellular vesicles (green); LPS: lipopolysaccharide; MEV: monocyte extracellular vesicles (dark blue); NEV: neutrophil extracellular vesicles (purple); PAI-1: plasminogen activator inhibitor 1; PEV: platelet extracellular vesicles (light blue); PHA: phytohemagglutinin; PMN: polymorphonuclear neutrophil; REV: red blood cell extracellular vesicles (grey); ROS: reactive oxygen species; TFEV: tissue factor expressing extracellular vesicles (red); TNF: tumor necrosis factor; TXA2: thromboxane A2.

phosphatidylserine present on the surface as well as the amount of thrombin and von Willebrand factor multimers expressed and released by extracellular vesicles also contribute to the procoagulant effects during inflammation [71–73]. In a study comparing bronchoalveolar lavage (BAL) fluid from ARDS patients with patients with cardiogenic pulmonary edema, TF-enriched extracellular vesicle concentration was significantly higher in the BAL fluid of ARDS patients [74]. Lastly, aside from platelets, alveolar epithelial cells can also generate procoagulant extracellular vesicles in inflammation [74,75].

Disruption of alveolar epithelial and endothelial barriers, leading to altered lung protein permeability, is another hallmark of ARDS. As described earlier, TXA2, which is one of the mediators responsible for an increase in lung vascular permeability [76,77], can be generated and released by PEVs, especially during inflammation. A direct link between high levels of circulating PEVs and TXA2 with increased lung vascular permeability was shown in infection-induced acute lung injury in mice [57]. Moreover, several studies clearly demonstrated that extracellular vesicles released by endothelial cells upon inflammation altered local nitric oxide production, leading to increased barrier permeability [71]. This capacity of endothelial-cell-derived extracellular vesicles (EEVs) to induce lung injury through the alteration of endothelial function has been found in several additional *in vivo* acute lung injury animal models [78–80]. Interestingly, although in these studies investigators used EEVs produced from human lung endothelial cells exposed to either physiologic or mechanical stress or to molecular triggers such as lipopolysaccharide or plasminogen activator inhibitor 1, extracellular vesicles released by direct acute lung injury

produced similar features, such as neutrophil infiltration with increased lung vascular permeability and proinflammatory cytokines release. Overall, these studies demonstrated that extracellular vesicles from diverse cell types during injury are able to promote inflammation, a hypercoagulable state, and endothelial dysfunction, which can lead to ARDS.

Clinically, however, patients with higher levels of circulating leukocyte extracellular vesicles or EEVs have been associated with better outcomes with a lower mortality rate in both sepsis and ARDS [81,82], suggesting a more complex role of these extracellular vesicles in lung injury. This important finding demonstrating some beneficial advantages from higher extracellular vesicles deserves further investigation. For example, PEVs have been found to express lipoxygenase 12, which once transferred into mast cells promotes synthesis and secretion of lipoxin $A_4$ [83], a factor known to exert anti-inflammatory properties that are able to attenuate acute lung injury [84,85]. Other investigators have shown the capacity of NEVs to express annexin A1 [86] or to stimulate the secretion of TGF-β [87], both of which have anti-inflammatory properties and can also exert increased bactericidal activity [88]. Timár *et al.* found that neutrophils prestimulated with opsonized particles were able to release extracellular vesicles that exerted increased bactericidal activity through cytoskeletal reorganization and impairment of bacterial growth. These effects might contribute to their anti-inflammatory effect in lung injury induced by infection. Concerning the impact of extracellular vesicles on coagulation in ARDS, studies have found that extracellular vesicles can also exhibit anticoagulant properties through protease-activated receptor-1 and -2 signaling pathways [89] and increased expression of anticoagulant factors such as thrombomodulin and protein S [90]. Finally, although extracellular vesicles have been associated with endothelial dysfunction in ARDS, some authors have demonstrated that extracellular vesicles carrying sonic hedgehog protein might be beneficial for the endothelium by increasing nitric oxide release and reducing reactive oxygen species production [91–93].

In summary, endogenous extracellular vesicles released by diverse cell types are involved in the pathophysiology of ARDS and are able to exert both detrimental and beneficial effects on inflammation, coagulation, and endothelial function. Thus, any strategy aiming at using extracellular vesicles as a potential therapeutic target will need to identify the phenotype of the released extracellular vesicles first.

### 38.7.2 Endogenous extracellular vesicles in chronic obstructive pulmonary disease

COPD is characterized by progressive destruction of lung parenchyma, resulting in airflow reduction [94]. A growing body of evidence indicates that cell injury, increased apoptosis, and accelerated senescence of both epithelial and endothelial cells contribute significantly to the lung destruction encountered in COPD [95–101]. Since the release of extracellular vesicles constitutes an important response of endothelial cells to injury, EEVs have represented the main focus of the majority of studies in COPD. Eight cell surface markers have been found to be expressed on the surface of EEVs in COPD [102]. They are vascular endothelial-cadherin (CD144), platelet endothelial cell adhesion molecule-1 (CD31), melanoma cell adhesion molecule (CD146), E-selectin (CD62E), integrin $\alpha_V$ chain (CD51), endoglin (CD105), von Willebrand factor, and angiotensin-converting enzyme (CD143). Based on preclinical evidence, EEVs in COPD appear to be involved in endothelial junction preservation or disruption [103], platelet function, angiogenesis, T and B cell activation, endothelial cell permeability and signal transduction, transmigration across the endothelium, and leukocyte recruitment to the site of injury [104–110]. Unlike extracellular vesicles in ARDS described earlier, which can both exacerbate and suppress inflammation, EEVs appear to primarily propagate inflammatory injury. However, further studies investigating the impact of EEVs released in COPD on other cells are needed. Notably, to our knowledge, no studies have been carried out on the biological cargo of EEVs (such as mRNA, microRNA, or proteins), the impact of which on the epithelium, endothelium, and immune cells involved in COPD may be important. Nevertheless, smoking exposure [111–113], oxidative stress [113], and infection [114–117] are known to trigger EEV release, suggesting an involvement of EEVs in an early stage of the mechanisms underlying the disease. In addition, two different research teams have demonstrated a differential pattern of EEV release, enabling the distinction of COPD patients from non-COPD healthy volunteers as well as demonstrating different levels at different stages of the disease [118–120]. These studies showed first that in EEVs the levels of circulating vascular endothelial-cadherin-, platelet endothelial cell adhesion molecule-1-, and E-selectin-positive were higher in stable COPD patients than in non-COPD patients [118]. Second, they showed that the levels of circulating vascular endothelial-cadherin-, platelet endothelial cell adhesion molecule-1-, and E-selectin-positive EEVs were increased during exacerbations of COPD compared with stable COPD [118]. Third, they showed that even patients with a mild or moderate COPD had a higher systemic level of platelet endothelial cell adhesion molecule-1-positive EEVs than control subjects did [120]. And fourth, they showed that E-selectin-positive EEVs were associated with severe COPD and hyperinflation of the lungs (emphysema) [120]. Importantly, these results were found to be independent of other factors associated with endothelial injury, such as smoking status, sepsis, or the stage of the disease as classified by the Global Initiative on Obstructive Lung Disease. In addition, several studies demonstrated that the increased EEVs in COPD originated from the lung capillary endothelium [111], suggesting an initial regional dysfunction rather than a systemic process.

Although the main findings of these preclinical studies suggest that EEVs are a pathological trigger promoting endothelial injury in COPD, questions remain. Since COPD is an inflammatory lung disease in which multiple cells are involved, extracellular vesicles released by endothelial cells upon injury cannot be

viewed in isolation. As previously seen in ARDS, leukocytes, platelets, red blood cells, and epithelial cells also release extracellular vesicles with both beneficial and detrimental impacts on the endothelium, epithelium, coagulation, and immune cells. Further investigations are needed to shed new light on the complex array of extracellular vesicles involved in the pathogenesis of COPD, clarifying the potential use of EEVs as accurate biomarkers and as possible therapeutic targets.

### 38.7.3 Endogenous extracellular vesicles in asthma

Asthma is a common chronic inflammatory disease characterized by smooth muscle airway constriction and inflammation and reversible airflow obstruction. Multiple stimuli, such as allergens, infection, and air pollution, are potential triggers of exacerbations in asthma. Genetic factors also contribute to the severity of the symptoms. Immunopathology in asthma is characterized by a hyperresponsiveness of type 2 $CD4^+$ T helper cells which secrete proinflammatory cytokines such as IL-4, IL-5, and IL-13, which promote the influx of mast cells, type 2 $CD4^+$ T helper cells, and eosinophils. This specific shift toward a type 2 T helper proinflammatory response drives airway remodeling characterized by reversible airway hyperresponsiveness and airway obstruction [121–124]. As with other lung diseases, key cells involved in the pathology of asthma, such as mast cells, dendritic cells, T lymphocytes, and bronchial epithelial cells, are capable of releasing a broad spectrum of extracellular vesicles into their environment. Some of these vesicles promote the progression of the allergic reaction, whereas others exhibit a capacity for attenuating or blocking the allergic response.

Torregrosa Paredes *et al.* found that vesicles isolated from BAL fluid of asthmatic patients increased IL-8 and leukotriene C4 secretion in bronchial epithelial cells *in vitro*, suggesting a direct role of these vesicles in propagating the type 2 T helper cell proinflammatory response [125]. In addition, the authors speculated that the extracellular vesicles present in BAL fluid of asthmatic patients might originate mainly from the bronchial epithelium. This finding was in line with another study demonstrating that bronchial epithelial cells and lung macrophages were the main sources of vesicles in asthmatic patients. These investigators showed that IL-13-treated epithelial cells produced vesicles promoting macrophage expansion. Blocking vesicle generation protected mice from developing airway remodeling in a murine model of asthma [126]. In contrast, Prado *et al.* found that extracellular vesicles harvested from tolerized mice were capable of attenuating allergic sensitization, the immunoglobulin E response, and the type 2 T helper proinflammatory response, ultimately decreasing airway inflammation [127].

Unlike the situation in ARDS or COPD, where the biological effects of extracellular vesicles are mediated by multiple mechanisms, including proteins, receptors, mRNA, and microRNA, a growing body of preclinical evidence suggests that in asthma these effects are mainly driven by microRNA transfer from vesicles to the recipient cells. Multiple studies have found that microRNA was transferred from mast cells, dendritic cells, or T lymphocytes to other mast cells, dendritic cells, or antigen-presenting cells using extracellular vesicles as shuttle vectors [45,128,129]. Furthermore, there were significant differences in the microRNA content of exosomes involved in the IL-13 pathway. These included differences in members of the LETHAL-7 (LET-7) and miRNA-200 families in the BAL fluid of asthmatic patients compared with healthy controls [130]. Thus, overall endogenous extracellular vesicles appear to play an important role in asthma exacerbation, supporting the recent ongoing research using vesicles as biomarkers or as potential therapeutic targets.

### 38.7.4 Endogenous extracellular vesicles as biomarkers in lung disease

The composition of circulating extracellular vesicles in healthy humans can often be changed significantly by both physiological and pathological conditions. Normally, circulating extracellular vesicles are mainly derived from platelets and, to a lesser extent, from leukocytes and endothelial cells [131,132]. However, even physiological changes such as exercise, menstrual cycle, or age are capable of impacting the pattern of extracellular vesicle release in terms of quantity, size, heterogeneity, and phenotype [131,133,134]. Thus, extracellular vesicles have been studied as potential biomarkers in a wide variety of systemic inflammatory diseases, including atherosclerosis, vasculitis, pulmonary hypertension, cardiopulmonary resuscitation, systemic lupus erythematosus, Crohn's disease, rheumatoid arthritis, systemic inflammatory response syndrome, sepsis, and multi-organ dysfunction syndrome [90,132,135–142]. For example, based on the extensive preclinical studies of extracellular vesicles in ARDS pathophysiology, several groups have studied the potential use of extracellular vesicles as biomarker measured either in blood or BAL fluid from ARDS patients [13]. Since different proinflammatory stimuli (e.g., endotoxin, *N*-formylmethionyl-leucyl-phenylalanine, and phorbol myristate acetate) have increased the amount of extracellular vesicles released by diverse cell types, we can speculate that the amount of vesicles released into the blood and the alveolar space of ARDS patients would be higher. Although this field of research is still expanding, some studies have already found that a high circulating concentration of leukocyte extracellular vesicles was associated with better outcomes [81], whereas a high level of extracellular-vesicle-associated TF was associated with progression of the disease [13]. More studies investigating the possibility of exploiting extracellular vesicles as biomarkers in ARDS are expected soon. Likewise, higher circulating levels of vascular endothelial-cadherin, platelet endothelial cell adhesion molecule-1, and E-selectin-positive EEVs have been found in stable COPD patients than in non-COPD patients [118]. Furthermore, the same investigators suggested that E-selectin-positive EEV levels may be used as a biomarker of the severity of COPD, since they correlated with the acceleration of loss of lung function and the number of exacerbations [102,118]. Also, different levels of extracellular-vesicle-associated microRNA involved in the IL-13 pathway

measured in BAL fluid have been used to distinguish asthmatic patients from healthy controls [130], suggesting a potential use of extracellular vesicles as a biomarker in asthma.

However, as discussed earlier, extracellular vesicles are not inert particles released by cells upon specific stimuli, with minimal or no role in the progression of lung diseases. These vesicles also carry a large amount of bioactive molecules capable of impacting critical pathways involved in inflammation, coagulation, lung permeability, and endothelial function. Their multiple interactions with epithelial cells, endothelial cells, PMNs, monocytes, macrophages, lymphocytes, and platelets give rise to the possibility of modulating their functional effect as a therapeutic target for a number of lung diseases.

### 38.7.5 Endogenous extracellular vesicles as potential therapeutic targets for lung diseases

Because of their considerable heterogeneity in terms of origin and functional properties, extracellular vesicles may either stimulate or inhibit the characteristic pathological features of ARDS. Removal or inhibition of extracellular vesicles with pathological effects [143,144] and/or administration or stimulation of extracellular vesicles that attenuate multiple pathways involved in inflammatory lung diseases may give rise to new therapeutic strategies to modulate coagulation, inflammation, and endothelial injury with increased permeability.

One strategy demonstrated in a clinical study involved removal of significant amount of PEVs using a membrane plasma separator [145]. Although the method may be challenging and with an incomplete effect, advanced plasmapheresis technologies may enable a more selective separation allowing targeted removal of extracellular vesicles with pathological effects. Currently, pharmacological modulation of the deleterious extracellular vesicles may represent a more accessible goal. For example, glucocorticoids have been used to decrease the circulating level of PEVs in the nonpulmonary inflammatory diseases dermatomyositis and polymyositis [146]. Given the controversies around corticosteroid treatment and their frequent use as a therapeutic agent in many cases of persistent (>14 days) ARDS and COPD exacerbations, further investigation on the impact of corticosteroids on extracellular vesicles is needed. Furthermore, agonists of peroxisome proliferator-activated receptor-γ, such as rosiglitazone, have been found to inhibit important extracellular-vesicle-related inflammatory pathways involved in monocyte-associated extracellular vesicles and lymphocyte extracellular vesicles [90,147,148]. Although peroxisome proliferator-activated receptor-γ can attenuate experimental ARDS [149–151], the therapeutic effect on extracellular vesicle activity is still unknown. Finally, although statin and polyunsaturated fatty acids have been shown to modulate PEV formation [70,152], they were unsuccessful in preventing ARDS [153] or COPD exacerbations [154], suggesting that their impact on extracellular vesicle activity might be insufficient for contributing to a therapeutic effect.

As described in the previous sections, some of the endogenous released extracellular vesicles can exert beneficial effects on inflammation, coagulation, and endothelial function during lung injury. The concept of exploiting these capacities by administering anti-inflammatory, anticoagulant, and endothelial barrier-protective extracellular vesicles is appealing but still needs to be investigated. In addition, enhancement of their therapeutic effect by either upstream preconditioning of the parent cells prior to the release of the extracellular vesicles or by loading exogenous extracellular vesicles with bioactive molecules might also be part of their pharmacological engineering worth considering in the future.

Lastly, one specific endogenous cell type still needs to be addressed: the MSCs. Although their number is limited at baseline in multiple organs, including the lung, MSCs are capable of releasing a wide array of extracellular vesicles exhibiting largely an anti-inflammatory phenotype, which may be beneficial for lung diseases [155–158]. We will review in the next sections studies focused on the effect of MSC extracellular vesicle administration in organ injury, and more specifically in lung diseases.

## 38.8 Therapeutic properties of extracellular vesicles derived from mesenchymal stromal cells

In various organ injury models, MSC-derived vesicles, whether exosomes or MVs, have been shown to be as potent as the parent cell as a therapeutic agent in both tissue repair and/or regeneration (Figure 38.3).

The mechanisms have been primarily through the transfer of bioactive content from the vesicles to the recipient cells, changing the function and/or phenotype of the recipient cell. A systematic review [159] summarized the existing preclinical data with regard to the reparative and regenerative properties of MSC vesicles following injuries to the kidney, heart, liver, brain,and hind limb ischemia injury [160]. Based on such promising preclinical data, there is currently one phase 2/3 clinical trial using umbilical-cord-blood-derived MSC MVs in type 1 diabetes mellitus (NCT02138331).

### 38.8.1 Mesenchymal stromal cell vesicles for kidney injury

MSC-derived vesicles have been studied as a potential therapeutic agent in AKI models induced by cisplatin [161,162], glycerol [36], ischemia–reperfusion injury [163,164], nephrectomy [165], and drug toxicity (gentamicin) [166]. Overall, in comparisons with controls, MSC exosomes or MVs improved renal function and reduced the extent of kidney injury [18,167,168]. In an AKI model in severe combined immunodeficiency mice, Bruno *et al.* [36] found that MSC MV administration improved recovery from AKI in part by preventing apoptosis and increasing renal tubular epithelial cell proliferation. A single administration of MSC MVs immediately following cisplatin [161] or ischemia–

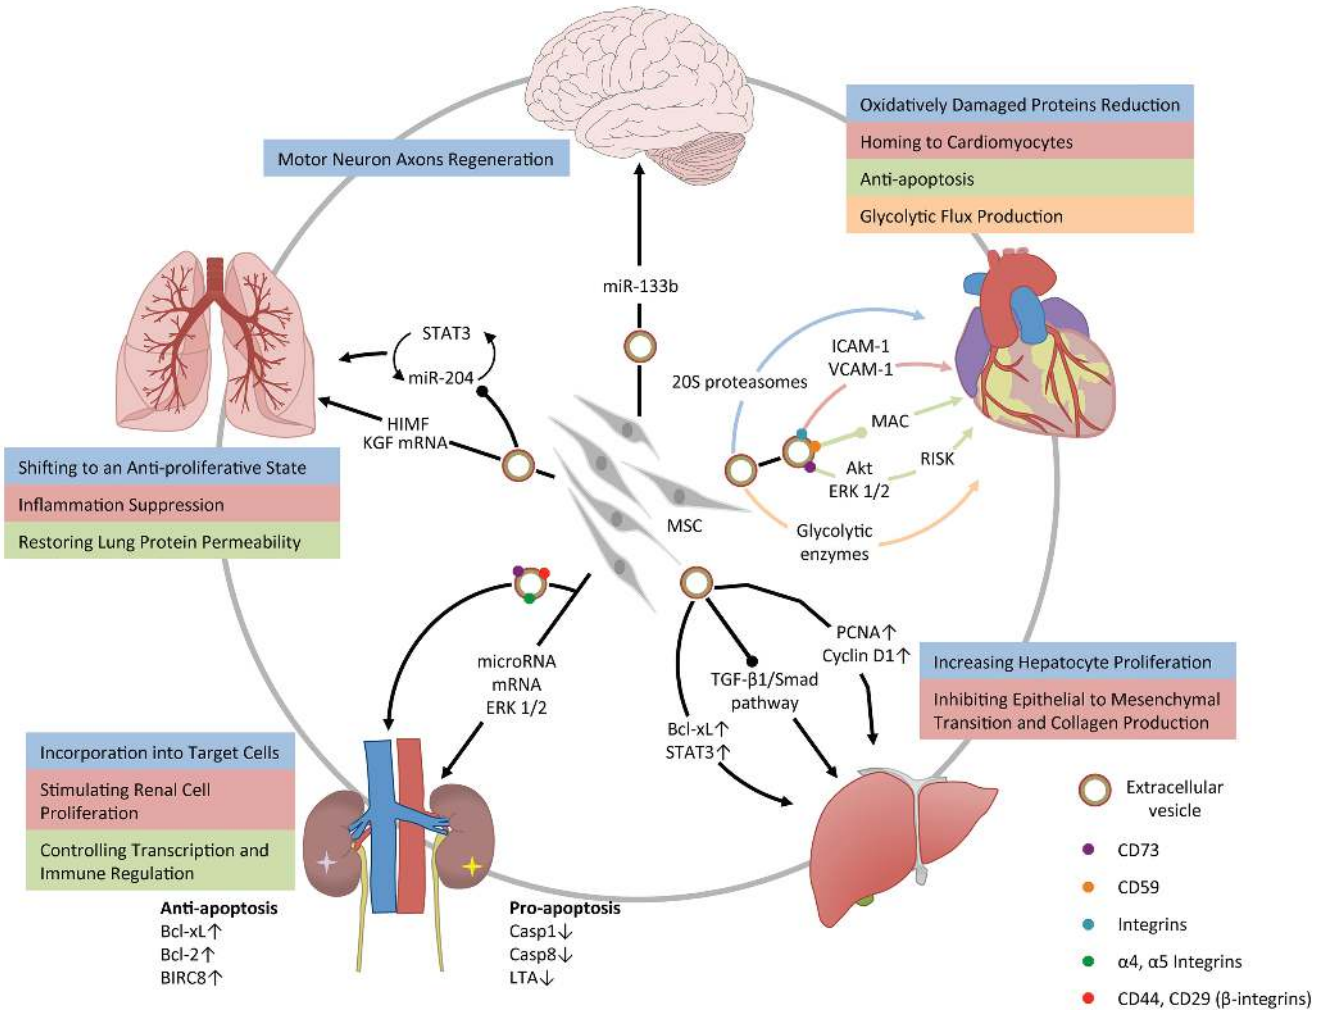

**Figure 38.3** Mechanisms underlying the therapeutic properties of extracellular vesicles derived from MSCs following different organ injuries. (See color plate section.)
*Kidney.* MSC-derived vesicles expressed several adhesion molecules, such as CD44, CD29 ($\beta_1$-integrin), $\alpha_4$ and $\alpha_5$ integrins, and CD73, which were critical for the incorporation into target cells. MSC MVs shuttled microRNA and mRNA into recipient cells and stimulated renal cell proliferation by activation of ERK1/2. In addition, MSC MVs conferred an antiapoptotic phenotype necessary for tissue repair by inducing the expression of anti-apoptotic genes (*BCL-XL*, *BCL2*, and *BIRC8*) in renal tubular epithelial cells while downregulating pro-apoptotic genes (*CASP1*, *CASP8*, and *LTA*).
*Heart.* MSC exosomes contained (1) integrins that could channel exosomes to cardiomyocytes that expressed ICAM-1, a ligand for integrins, or to VCAM-1 on endothelial cells; (2) CD73, present on the surface of exosomes, that activated RISK by increased expression of pro-survival protein kinases such as AKT and ERK1/2; (3) CD59 (protectin), a widely expressed glycosylphosphatidylinositol-anchored membrane protein that prevented the formation of MAC and inhibited complement-mediated lysis; (4) a significant clustering of enzymes involved in glycolysis, which could ameliorate a glycolytic deficit and potentially increase glycolytic flux and ATP production; additionally, they mediated the transfer of functionally active 20S proteasomes, which were responsible for the degradation of intracellular protein damaged by oxidation.
*Liver.* MSC exosomes inhibited epithelial-to-mesenchymal transition and collagen production by suppressing the activation of the TGF-β1/SMAD signaling pathway. MSC exosomes were also associated with higher expression of proliferation proteins (PCNA and cyclin D1), the antiapoptosis gene (*BCL-XL*), and higher expression of STAT3.
*Brain.* MSC exosomes transferred functional microRNAs, such as miR-133b, involved in regeneration of motor neuron axons to injured neural cells.
*Lung.* In acute lung injury, MSC exosomes suppressed inflammation by upregulating HIMF transcription and restored lung protein permeability by transferring KGF mRNA. In a model of PAH, MSC exosomes suppressed the hypoxic induction of STAT3 and upregulated miR-204 levels, interfering with the STAT3–miR-204–STAT3 feed-forward loop and shifting the balance to an antiproliferative state.
AKT: protein kinase B; BCL2: B-cell lymphoma 2; BCL-XL: B-cell lymphoma-extra large; BIRC8: baculoviral inhibitor of apoptosis repeat containing protein 8; Casp1: caspase 1; Casp8: caspase 8; CD: cluster of differentiation; ERK: extracellular regulated kinase; HIMF: hypoxia-induced mitogenic factor; ICAM-1: intercellular adhesion molecule-1; KGF: keratinocyte growth factor; LTA: lymphotoxin-α; MAC: membrane attack complex; MSC: mesenchymal stromal cell; PCNA: proliferating cell nuclear antigen; RISK: reperfusion injury salvage kinases; STAT3: signal transducer and activator of transcription 3; TGF-β1: transforming growth factor-β1; VCAM-1: vascular cell adhesion molecule 1.

reperfusion-injury-induced AKI [164] alleviated inflammation, mitigated renal cell apoptosis, and enhanced proliferation of the renal epithelial cells [164]. In addition, multiple injections of MSC MVs further improved renal function and morphology, abrogated renal fibrosis, and decreased mortality. When compared with MSCs, MVs were found to mimic the beneficial effects of the adult parent cells. The effects appeared to be mediated in part by the transfer of RNA by MSC MVs to the injured renal epithelium, as indicated by the loss of reparative effects after RNase pretreatment of the MVs [17,36,169]. Specifically, Bruno *et al.* demonstrated that MSC MVs shuttled RNA associated with control of transcription, proliferation, and immune regulation to the injured epithelium. The effective transfer of specific MV-derived microRNA and mRNA and the translation of MV-shuttled mRNA into proteins within recipient cells were shown both *in vitro* and *in vivo* [30,36]. In the AKI model, MSC MVs conferred an antiapoptotic phenotype necessary for tissue repair by inducing the expression of the antiapoptotic genes *BCL-XL*, *BCL2*, and *BIRC8* in renal tubular epithelial cells while simultaneously downregulating the pro-apoptotic genes *CASP1*, *CASP8*, and *LTA* [161]. In addition, MSC MVs stimulated renal cell proliferation by inducing the phosphorylation and subsequent activation of extracellular regulated kinase (ERK) 1/2 [162]. The authors found that MSC MVs expressed several adhesion molecules, such as CD44, CD29 ($\beta_1$-integrin), $\alpha_4$ and $\alpha_5$ integrins, and CD73, which were critical for the incorporation of the MVs into the target cells [36,169–171]. These data demonstrate the ability of MSC MVs to modulate simultaneously several different pathways to stimulate renal repair and/or regeneration.

### 38.8.2 Mesenchymal stromal cell vesicles for cardiac injury

The therapeutic effects of MSC vesicles have also been reported in several experimental models of myocardial ischemia–reperfusion injury [41,172–174]. For example, Timmers *et al.* previously found that conditioned medium from human embryonic stem-cell-derived MSCs significantly reduced infarct size in pig and mouse models of myocardial ischemia–reperfusion injury [175]. Using electron microscopy, ultracentrifugation, mass spectrometry, and biochemical assays the authors demonstrated that the active components of the conditioned medium were exosomes [172,176]. Administration of purified MSC exosomes 5 min before reperfusion significantly reduced infarct size and improved left ventricular function.

Several mechanisms for the therapeutic effect of MSC exosomes in myocardial ischemia–reperfusion injury were postulated.

First, exosomes contained membrane proteins that have significant binding affinity to other ligands on cell membranes or to the extracellular matrix. Specifically, integrins could channel exosomes to cardiomyocytes that expressed ICAM-1, a ligand for integrins, after myocardial ischemia–reperfusion injury [177] or to VCAM-1 on endothelial cells [178]. Tetraspanin proteins, which function primarily to mediate cellular penetration, invasion, and fusion events [179], could also facilitate cellular uptake of exosomes. Interestingly, it was observed that the efficiency of exosome uptake correlated directly with intracellular and microenvironmental acidity [180]. This may be a mechanism by which MSC exosomes exert their cardio-protective effects on ischemic cardiomyocytes that have a low intracellular pH [181].

Second, exosomes contain enzymes, and since enzyme activities are catalytic rather than stoichiometric and are dictated by their microenvironment (e.g., substrate concentration or pH), enzyme-based therapeutic activities of exosomes could be activated or attenuated according to the release of injury-associated substrates, which is directly proportional to the severity of the injured microenvironment [176]. Lai *et al.* interrogated the proteome of MSC exosomes by mass spectrometry and antibody array and found a significant clustering of enzymes involved in glycolysis. These enzymes from MSC exosomes could ameliorate the glycolytic deficit and potentially increase glycolytic flux and ATP production in the reperfused myocardium [42]. The intracellular transfer of glycolytic enzymes from MSC exosomes across the plasma membrane is likely to be sufficient for the enzymes to exert their biochemical activity, as glycolysis is a cytosolic process, unlike fatty acid oxidation and the tricarboxylic acid cycle, which are mitochondrial processes. An important corollary of this hypothesis is that MSC exosomes increased ATP production in reperfused myocardium and/or in cells where oxidative phosphorylation was inhibited [41,42]. However, Islam *et al.* found MSCs using connexin43 gap junctions were able to restore ATP levels in injured alveolar epithelium through the transfer of mitochondria in a mouse model of acute lung injury [43].

Third, activation of some pro-survival protein kinases such as AKT and ERK 1/2, which prevent apoptosis, has been demonstrated to be protective against myocardial ischemia–reperfusion injury when stimulated at the time of myocardial reperfusion [182,183]. These kinases are termed the reperfusion-injury salvage kinases (RISKs) [184]. From the proteomic study of MSC exosomes, Lai *et al.* also postulated that CD73, which was present on the surface of MSC exosomes, was the most likely protein candidate to overcome the pro-apoptotic proteome of reperfused myocardium through the activation of RISKs [42].

Fourth, MSC exosomes may possess additional therapeutic activities to prevent other complications of myocardial ischemia–reperfusion injury by reducing misfolded or oligomerized proteins in reperfused hearts through the transfer of functionally active 20S proteasomes, which are responsible for the degradation of ~90% of all intracellular protein damaged by oxidation [185]. In addition, CD59 (protectin), a widely expressed glycosylphosphatidylinositol-anchored membrane protein, is also present on MSC exosomes [186]. This principal molecule inhibits the terminal pathway of complement preventing the formation of the membrane attack complex (MAC). Thus, exosome-associated CD59 may contribute to cell protection by inhibition of complement-mediated lysis.

### 38.8.3 Mesenchymal stromal cell vesicles for liver injury

Two studies have focused on the therapeutic effects of MSC exosomes in a mouse model of liver injury. Using a carbon-tetrachloride-induced liver injury model [187,188], the investigators demonstrated that MSC exosomes ameliorated liver fibrosis by inhibiting the epithelial-to-mesenchymal transition of hepatocytes and collagen production. Exosomes were found to significantly restore the hepatic enzyme aspartate aminotransferase activity in serum and decrease collagen type I/III, TGF-β1 and phosphorylation of SMAD2 expression *in vivo*, suggesting the inactivation of TGF-β1/SMAD signaling pathway. In another study [188], the investigators found that MSC exosomes elicited hepatoprotective effects in acetaminophen and hydrogen-peroxide-induced liver injury primarily through an increase in hepatocyte proliferation, as demonstrated by elevation of the proliferating cell nuclear antigen (PCNA) and higher cell viability. The increased survival rate was associated with upregulation of the priming phase genes involved during liver regeneration, which subsequently led to higher expression of proliferation proteins (PCNA and cyclin D1) and the anti-apoptosis gene *BCL-XL* and higher expression of STAT3. Surprisingly, however, the therapeutic effect of MSC exosomes was not mediated through modulation of oxidative stress during hepatic injury.

### 38.8.4 Mesenchymal stromal cell vesicles for neural injury

The therapeutic role of MSC exosomes has been studied in a few models of neural ischemia. Yu *et al.* demonstrated that functional microRNAs, such as miR-133b, which is involved in regeneration of motor neuron axons [189], are transferred from MSCs to injured neural cells via exosomes, and Xin *et al.* found that exosome-encapsulated transfer of microRNAs promoted neurite remodeling and functional recovery following stroke in rats [190,191]. In a following study, the latter investigators administered cell-free MSC exosomes to rats subjected to middle cerebral artery occlusion and assessed functional recovery and enhancement of neurite remodeling, neurogenesis, and angiogenesis [192]. By evaluating functional recovery with a foot fault test [193] and a modified neurologic severity score [194] it was concluded that MSC exosomes contributed to significant functional improvement following middle cerebral artery occlusion. MSC exosome treatment also significantly increased axonal density and synaptophysin-positive areas along the ischemic boundary zone of the cortex and striatum, as well as the number of newly formed doublecortin$^+$ cells (neuroblasts) and von Willebrand factor$^+$ cells (endothelial cells).

Another group investigated the protective effects of rat bone marrow-derived MSC MVs against apoptosis in glutamate-induced injury in rat pheochromocytoma PC12 cells [195]. They demonstrated that MVs reversed both the glutamate-induced downregulation of AKT phosphorylation and Bcl-2 expression and the glutamate-induced upregulation of Bax expression and the level of cleaved caspase-3, suggesting that MVs act as cell-protective effects via the PI3K/AKT signaling pathway.

### 38.8.5 Mesenchymal stromal cell vesicles for lung diseases

To date, only a few groups have studied the effects of MSC vesicles in lung diseases such as pulmonary artery hypertension (PAH) [196,197] and acute lung injury [14]. Although the mechanisms of action have not been fully defined, these groups have demonstrated that MSC vesicles are as potent as their parent cells as therapy, suggesting a novel cell-derived preparation without the limitations of using live cells.

Lee *et al.* [196] demonstrated that exosomes mediated the cytoprotective effect of bone-marrow-derived MSCs in hypoxia-induced PAH in mice. In this model, administration of MSC-derived exosomes protected against the elevation of right ventricular systolic pressure and the development of right ventricular hypertrophy after 3 weeks of hypoxic exposure. Specifically, treatment with MSC exosomes interfered with the early hypoxic signal in the lung, suppressed inflammation, and upregulated HIMF transcription and alveolar macrophage activation. Surprisingly, exosome-depleted conditioned media had no therapeutic effect, suggesting a limited role for soluble factors released by MSCs. MSC exosomes also suppressed the hypoxic induction of STAT3 in primary cultures of pulmonary artery endothelial cells and upregulated miR-204 levels, interfering with the STAT3–miR-204–STAT3 feed-forward loop and shifting the balance to an antiproliferative state. Similarly, Chen *et al.* demonstrated that MSC MVs decreased pulmonary pressure and right ventricular pressure and reduced right ventricular hypertrophy and pulmonary arteriole remodeling during the development of PAH in rats [197].

Zhu *et al.* demonstrated a biologic effect of MVs derived from human bone marrow MSCs in a mouse model of endotoxin-induced acute lung injury [14]. Treatment with MSC MVs was effective in restoring lung protein permeability, reduced inflammation (such as an influx of neutrophils and elevation of macrophage inflammatory protein-2 levels), and prevented the formation of pulmonary edema in the injured alveoli. Moreover, KGF small interfering RNA pretreatment of MSCs partially eliminated the therapeutic effects of MSC MVs, suggesting that KGF protein expression was an important component of the underlying mechanism. Previously, KGF secretion by MSCs had been found to be involved in restoring both vectorial ion and fluid transport in injured human alveolar epithelial type II cells and in increasing the antimicrobial properties of monocytes and macrophages [6].

Although the few preclinical studies are promising, more work is needed to better understand the mechanisms underlying the therapeutic effects of MSC vesicles. For instance, it is unclear whether MSC vesicles retain the antimicrobial properties of MSCs or whether MSC vesicles can be used in other acute or chronic lung diseases, such as asthma and idiopathic pulmonary fibrosis, where the pathophysiology is different.

## 38.9 Remaining questions on the therapeutic use of mesenchymal stromal cell extracellular vesicles

The use of MSC-derived extracellular vesicles as a cell-free therapeutic agent in lung disease offers several advantages compared with using the parent cell from which the vesicles are derived. First, extracellular vesicles are non-self-replicating and can easily be stored at −80 °C for several months while maintaining their functional effect [198]. The risk of ectopic tissue formation or malignant transformation by MSC-derived extracellular vesicles is minimal. Second, extracellular vesicles in theory could be harvested from immortalized or prestimulated MSCs, which would drastically reduce the total number of MSCs needed. This approach could also lead to specific phenotypes of extracellular vesicles with enhanced therapeutic properties. Lastly, owing to their lower expression of membrane-bound proteins, extracellular vesicles may be less immunogenic than their parent cells [199]. However, multiple questions remain that must be addressed before effective translation to the clinic can take place.

### 38.9.1 Isolation and quantification techniques

Based on current preclinical studies on the therapeutic use of extracellular vesicles derived from MSCs, there are clear limitations using the current isolation and quantification techniques that require further research. First, the use of ultracentrifugation to isolate MSC vesicles does not differentiate them based on the size of the vesicles. Although both MVs and exosomes have therapeutic properties [161,196], further studies are needed to determine the contribution of each to the overall therapeutic effect. Second, as with MSCs themselves, it remains unclear whether there is a dose-dependent response based on the quantity of the extracellular vesicles released. For example, one of the functional effects of extracellular vesicles may be through direct stimulation of a target cell by a surface ligand on the extracellular vesicles. However, not all vesicles will have the same surface composition, despite being released from the same parent cell.

### 38.9.2 Extracellular vesicle characterization

The available techniques used for characterizing extracellular vesicles, such as proteomics, mass spectrometry, and microarrays, have evolved [13]; unfortunately, there is still no uniform standard for characterizing extracellular vesicles isolated by different investigators. More importantly, the different methods used to precondition MSCs in order to stimulate vesicle release, such as serum starvation, hypoxia, and inflammation, will change the surface and intracellular content of the released vesicles. Whether it will change the phenotype or effect of the released vesicles needs to be studied further. In addition, soluble factors released by MSCs appear to have therapeutic efficacy in a variety of inflammatory disorders, and released vesicles do contain these proteins [1–9]. However, the role of these proteins within the vesicles is unclear. In order to proceed toward translational application of extracellular vesicles in human lung disease, it is essential that optimal characterization methods be developed that will give rise to a consensus for standardizing the potency of these vesicles.

### 38.9.3 Feasibility of large-scale generation of extracellular vesicles

Based on the few studies using extracellular vesicles as treatment in preclinical animal models, roughly a 10-fold higher dose of extracellular vesicles was required to generate an effect equivalent to the parent cells [14,161,196]. Since the average therapeutic dose of MSCs administered systemically in the majority of ongoing clinical trials is between $1 \times 10^6$ and $2 \times 10^6$ MSCs/kg, there may be a need to harvest extracellular vesicles released in the region of $10–20 \times 10^6$ of MSCs/kg of body weight to get an equivalent effect. Consequently, large-scale generation of extracellular vesicles remains challenging. However, one published [200] and several ongoing clinical trials (NCT01159288, NCT01550523, NCT01779583 [201–203]) have demonstrated that this is feasible. Although several high-throughput techniques – such as centrifugation combined with either ultrafiltration or high-pressure liquid chromatography, or differential ultracentrifugation combined with a sucrose cushion, – have been proposed as viable manufacturing processes, large-scale extracellular vesicle production needs to be further developed, especially if prestimulation of the parent cells is used to generate a unique phenotype.

## 38.10 Regulatory considerations for the clinical use of extracellular vesicles

It is likely that extracellular vesicles will soon be considered as a biotherapy and, therefore, will need to comply with the rules and standards of regulatory authorities. Written protocols, standard operating procedures, quality control, and quality assurance methods have been in place for some time to govern the use of *ex vivo* expanded MSCs and other cellular therapies in clinical trials, including the need for appropriately licensed good manufacturing practice laboratory facilities (see Chapters 42–44). Similar demands will be placed on the clinical trial use of extracellular vesicles, which will need to demonstrate their safety for systemic distribution, purity, viability, sterility, potency, lack of toxicity, and half-life studies.

## 38.11 Conclusions

Although still in its infancy compared with MSC-based administration, there are potential advantages of using MSC-derived extracellular vesicles in a variety of inflammatory lung diseases, including asthma, ARDS, and COPD. However, questions remain concerning their characterization, potency, and quantification, making a direct comparison with MSCs difficult. More

research is needed on the mechanisms underlying the apparent beneficial effects of MSC-derived extracellular vesicles before making assumptions that extracellular vesicles are equivalent in potential efficacy to that of their parent stromal cells.

## 39.1 Summary

Asthma is a disease marked by reversible airway obstruction, persistent airway inflammation, and airway hyperresponsiveness. The remodeling of asthmatic airways is a complex process that represents a safe method of preventing chronic inflammation. Mesenchymal stem/stromal cells (MSCs) have been overwhelmingly shown to suppress inflammation. MSCs can be licensed to become immune suppressor cells within an inflamed microenvironment. Such an environment can be established by allergen-mediated airway contraction, edema, and mucus secretion. However, the molecular and cellular pathways by which MSCs suppress inflammation is complex and may depend on the cause of the inflammation. Specifically, experimental evidence has shown different responses by MSCs in the milieu created by activated T cells from allergic asthma and allergic rhinitis. This chapter discusses the complex inflammation caused by allergic diseases. We argue for more robust studies to effectively use MSCs. Another major unanswered question is whether a specific source of MSCs would be more effective in the treatment of allergic diseases.

## 39.2 Introduction

Asthma is a disease marked by reversible airway obstruction, persistent airway inflammation, and airway hyperresponsiveness. The World Health Organization reported that approximately 235 million people suffer from asthma, spanning high-, middle-, and low-income countries. Asthma is a major public health concern and is still underdiagnosed and undertreated. It is a heterogeneous disease with many physiologic and clinical phenotypes. Allergic asthma is triggered by exposure to allergens, the effects of which are mediated primarily via pathways involving T helper (Th)2 cells, mast cells, and eosinophils. Nonallergic asthma, associated with nonallergen triggers such as fumes, typically do not involve the Th2 pathway. This will be discussed further later. The development of allergic diseases involves interplay between genetic predispositions and environmental exposures to triggers. The expanding insights into the mechanisms underlying asthma pathology have resulted in a broadening of available therapeutic modalities.

## 39.3 Early and late asthma response

Key mediators have been described in the pathogenesis of early inflammatory response as well as for late and chronic stages of asthma. Mediators such as histamine, leukotriene $D_4$ and $E_4$, and

prostaglandin $D_2$ can mediate the early phase of asthma, which manifests as bronchospasm. Increased vascular permeability allows cells to leave the bloodstream and enter pulmonary tissue, thereby contributing further to inflammation.

Mast cells are one of the cells of the innate immune system implicated in asthma pathogenesis. Antigens cause crosslinking of the high-affinity FcεRI receptors on mast cells, resulting in degranulation and release of preformed inflammatory cytokines such as histamine and tryptase, as well as newly synthesized inflammatory mediators that include leukotriene $C_4$, prostaglandin $D_2$, platelet activating factor, and cytokines. Basophils, through their immunoglobulin (Ig)E receptors, can enable cross-linking by allergens to release histamine and leukotriene mediators. Basophils also secrete interleukin (IL)-4, which can cause Th2 differentiation. Innate lymphoid cells, sharing the same progenitor as T cells, are capable of skewing the immune response. Specifically, innate lymphoid cells 2 express IL-13 that can further promote Th2-driven inflammation. The late/chronic response is mediated by Th2 polarization, along with eosinophil- and neutrophil-mediated cytokine inflammation [1].

## 39.4 Airway remodeling

Asthmatic airway remodeling is a complex process that is the result of chronic inflammation. Allergen exposure and subsequent release of mediators cause airway contraction, edema, and mucus secretion. Chronic damage to the epithelial layer develops over time and exaggerates extracellular matrix deposition, causing subepithelial fibrosis and thickening of the basement membrane [2]. An imbalance in cytokine signaling results in altered extracellular matrix composition and increased smooth muscle. This results in abnormal airway remodeling that causes airflow obstruction and increased airway hyperresponsiveness. Additionally, smooth muscle hypertrophy serves as a nidus of proinflammatory cytokine production as well as mechanical bronchoconstriction. The process of basement membrane thickening occurs via increased collagen deposition. Collagen, produced by fibroblasts, is the primary component of the basement membrane. Metalloproteinase-9 can digest type IV collagen, thereby preventing excess collagen deposition. Tissue inhibitors of matrix metalloproteinase 1 (TIMP-1) interfere with metalloproteinase-9-mediated collagen degradation, resulting, as indicated earlier, in an exaggerated collagen deposition and thickening of the basement membrane. Transforming growth factor-β (TGF-β), synthesized by macrophages, lymphocytes, fibroblasts, airway epithelial cells, eosinophils, and mast cells, induces TIMP-1 expression. Furthermore, IL-13, a cytokine that is prominent in Th2-driven inflammation, promotes TIMP-1 production [3]. Cytokine-driven angiogenesis causes airway edema, which is a known contributor of asthma fatalities. Vascular endothelial growth factor is responsible for increased angiogenesis in asthmatic airways and is thought to be able to modulate smooth muscle cell proliferation [4].

## 39.5 Innate immunity of the airway

The airway is a rich repository of immune cells. Epithelial cells, monocytes, mast cells, neutrophils, and eosinophils are the innate immunity's sentinels in host defense (see also Chapter 33). Lymphocytes, members of the adaptive immune response, can mount antigen-specific defense. A fine balance between both arms of the immune system is necessary for mounting and maintaining a controlled immune response. A dysregulation of these systems results in asthmatic disease.

Epithelial cells lining the airway serve a physical barrier function to prevent invasion of pathogens and allergen sensitization. A compromised epithelial layer can allow allergen presentation to antigen-presenting cells (APCs) that can then sensitize the host's immune response. Additionally, epithelial cells secrete important inflammatory mediators. Thymic stromal lymphopoietin (TSLP) is an epithelial-derived cytokine that upregulates the APC function of dendritic cells in the Th2 pathway, thereby driving Th2-mediated inflammation [5].

Macrophages, another subset of innate immune cells, serve as an important cellular component in airway function. Macrophage-derived cytokines can polarize the immune response to Th1 or Th2 pathways. The M1 class of macrophages, when stimulated by interferon (IFN)-γ, causes a Th1 response. In contrast, M2 macrophages, when activated by IL-4 and IL-13, result in a Th2 response, which is a central pathway for allergic inflammation [6]. Of note, macrophages are sources of IL-10, which can suppress inflammation and promote the expansion of regulatory T cells (Tregs) [7].

In the lungs, dendritic cells can be located at the basolateral side of epithelial cells and sample luminal antigens. After antigen uptake, the dendritic cells migrate to the draining lymph nodes where they present the antigens to T cells. Dendritic cells can support Th2 polarization by decreasing Th1 and Th17, resulting in the production of IL-12, TGF-β, IL-23, and IL-6 [8].

Granulocytes are also an important component of airway physiology. There are few resident mast cells within the airways. Mast cells release both preformed mediators, such as histamine and tryptase, as well as newly synthesized mediators, such as bradykinin, in response to stimuli. Mast cells also secrete IL-4, IL-5, IL-9, IL-13, TSLP, and tumor necrosis factor (TNF)-α. Mast cells are a prominent source of vascular endothelial growth factor and fibroblast growth factor-2, promoting airway remodeling and edema [9]. Eosinophils are recruited to the airway during inflammation. *In vitro* studies have shown that eosinophils can promote IL-17 production through the release of IL-1β. As will be discussed further, IL-17 is an important mediator of inflammation in asthmatic airways [10]. Although eosinophil-mediated killing of invasive pathogens can serve a useful function, their recruitment during an allergic response can result in the release of cationic proteins. The release of proteins by eosinophils has been attributed to physiological and inflammatory damage seen in asthmatic airways.

## 39.6 Adaptive immunity of the respiratory tract

Epithelial integrity is one the foremost methods for maintaining intact tolerance. If compromised, this can predispose to the development of allergic disease. Frequent viral and bacterial infections can lead to damage of the epithelial membrane. Allergens can also compromise the integrity of the airway epithelial membrane, since certain allergens, such as dust mites' Der p 1, have proteolytic activity that can enzymatically cleave the epithelial layer. Der p 1, a cysteine protease found in dust mites, can degrade cellular adhesion molecules to cause mucosal permeability [11].

Allergen-mediated stimulation of the innate immune system can trigger an inflammatory response. Activation of dendritic cells caused by presentation of allergens can activate both the innate and adaptive immune systems. The allergic antigens are presented within the groove of the major histocompatibility complex (MHC) of dendritic cells. Co-stimulation through CD80 or CD86 on the dendritic cells is critical for naive T cells to be activated. These co-receptors interact with CD28 on T cells. The ensuing response (Th1 versus Th2) is determined by the cytokine milieu. As an example, IL-12 will favor Th1 differentiation and IL-4 will favor Th2 differentiation.

Anergy can occur when T cells are presented with the antigen–MHC complex in the absence of co-stimulation. This is a major mechanism through which tolerance occurs. In our *in vitro* studies, small amounts of MSCs with a low dose of allergen when added intermittently to the cultures resulted in tolerance when the T cells were washed and then re-exposed to the optimal dose of the allergen [12]. Th2 polarization is the predominant mechanism underlying allergic asthma inflammation. IL-25 and IL-33 produced by airway epithelial cells activate lymphoid cells that can then produce IL-4, IL-5, and IL-13, which are the primary cytokines driving allergic inflammation and promoting Th2 production. IL-4 and IL-13 also induce IgE class switch in B cells. IL-13 promotes airway hyperresponsiveness. Although Th2 is the predominant lymphocyte responsible for asthma pathology, other T cell types have been implicated in the disease. Th1 cells have been identified in chronic exacerbations. Th9 cells, the differentiation of which is mediated by IL-4 and TFG-β, increase mucus hypersecretion in asthmatic patients and further promotes Th2 activation [13]. Th17 cells secrete the proinflammatory cytokines IL-17 and IL-22 as well as IL-8, a neutrophil chemotactic factor. IL-17 promotes goblet cell hyperplasia and smooth muscle contraction. IL-22 can contribute to smooth muscle proliferation and subsequent airway remodeling [14]. Although the role of neutrophils in asthma is not yet well defined, a predominance of neutrophils in asthma results in more severe asthma, and the presence of atopy does not exclude this non-eosinophilic asthma variant [15]. (Atopy (atopic syndrome) is a syndrome characterized by a tendency to be "hyperallergic." A person with atopy typically presents with one or more of the following: eczema (atopic dermatitis), allergic rhinitis (hay fever), or allergic asthma.)

## 39.7 Toll-like receptors

Inflammation is characterized by redness, pain, swelling, heat and loss of tissue function. It is a protective response to various factors including microbial infection and tissue injury [16,17]. The symptoms related to inflammation increase vascular endothelium permeability, resulting in access for immune cells. The major contributor to acute inflammation induced by microbial infection or tissue damage is caused by the innate immune response, commonly referred to as the first line of defense [16–20]. Germline-encoded pattern recognition receptors (PRRs) sense the presence of microorganisms by identifying microbial structures called pathogen-associated molecular patterns (PAMPs). One class of the PRR family is the transmembrane protein toll-like receptors (TLRs).

TLR-mediated defense is critical for the host's response to invading pathogens [16–19]. Eleven TLRs have been identified in humans. Their differential expression and regulation has led to the identification of various ligands [16]. Besides activated immune cells such as dendritic cells and macrophages, PRRs are also expressed on nonprofessional APCs (such as epithelial cells), and other cells, such as human MSCs, have been shown to express the intracellular receptor TLR3 and cell surface receptor TLR4, which recognize PAMPs' nucleic acid and lipopolysaccharide respectively [17]. The stimulation of human MSCs with lipopolysaccharide or poly(I:C) leads to the production of inflammatory mediators [21]. Expression of TLRs is further increased by stimulation of IFN-α and IFN-γ, resulting in the conversion of the MSCs to immune suppressor cells [21].

This section briefly discusses the role of MSCs as a therapeutic strategy for allergic responses. MSCs can modulate an immune response by direct regulation of the cellular response at the site of infection or injury [22]. In order to exert immunomodulatory properties, MSCs rely on intercellular communication, partly through the secretion of soluble factors such as autonomous cytokines and/or chemokines from neighboring activated immune cells [23]. The effects of MSCs on the innate and adaptive immune response can be mediated by the TLRs. Thus, these effects need to be considered when considering cellular therapies.

## 39.8 Allergic rhinitis and immunology

Allergic rhinitis is an inflammatory disease of the nasal mucosa characterized by nasal pruritus, sneezing, rhinorrhea, and nasal congestion [24]. It is associated with other inflammatory disorders, including asthma, rhinosinusitis, and allergic conjunctivitis. Although boys are more likely to have allergic rhinitis during childhood, this tendency reverses in puberty, and by adulthood both men and women are affected equally [25]. Atopy

is the abnormal development of specific IgE in response to harmless and ubiquitous environmental allergens. Allergic rhinitis is often associated with other atopic diseases, including allergic rhinoconjunctivitis, asthma, atopic dermatitis, and food allergies. These disorders have been linked to genetic loci on chromosomes 2, 5, 6, 7, 11, 13, 16, and 20 [26]. Allergic rhinitis has been traditionally classified as seasonal or perennial, based on sensitization to seasonal or year-round allergens. On exposure to an allergen, symptoms arise within minutes and can last 1–2 h before resolution as an immediate hypersensitivity reaction via mast cells and basophils. Late-phase symptoms include nasal obstruction, hyposmia, postnasal mucous discharge, and nasal hyper-reactivity [27].

Allergic conjunctivitis differentiates allergic rhinitis from other forms of rhinitis. It is characterized by intense itching, hyperemia, watering of the eyes, and periorbital edema. Pollen-induced allergic rhinitis can have an associated oral allergy syndrome, including oral and pharyngeal itchiness, tingling, erythema, and angioedema of the tongue, lip, and soft palate after oral contact with fruits and vegetables [28]. To determine the cause, a detailed history is necessary to identify potential triggers and reveal other allergic diseases. To confirm the diagnosis, either skin-prick testing or serum levels of specific IgE are used to record specific IgE reactivity to airborne allergens. Although IgE is the mainstay in the pathogenesis of allergic rhinitis, new developments have started to elucidate the underlying complex mechanism. This section will focus on the immunologic basis behind allergic rhinitis.

Individuals with allergic rhinitis are sensitized to an antigen via activation of dendritic cells and T lymphocytes [29]. Dendritic cells at the mucosal surfaces capture allergens and act as APCs to the T lymphocytes in the draining lymph nodes. $CD4^+$ T cells secrete cytokines, including ILs, to initiate and coordinate the allergic immune response. Regulatory T lymphocytes that express the surface markers CD4 and CD25, and Tr1 cells that produce IL-10, normally suppress the Th2 response to allergens, but this inhibition is decreased in allergic diseases [29]. IL-4 and IL-13, along with CD40 ligation, induce IgE class switch in B lymphocytes, driving sensitization to allergens [30]. IgE molecules are released into the bloodstream and bind to mast cells and basophils. When an allergen binds to surface IgE on mast cells in the nasal mucosa, there is a rapid release of preformed mediators such as histamine, which cause symptoms associated with early allergic response. Histamine, along with TNF-α, leukotriene $C_4$, and prostaglandin $D_2$, stimulate the expression of adhesion molecules on endothelial cells and contribute to the influx of inflammatory cells comprised of eosinophils, $CD4^+$ T lymphocytes, and basophils. The influx of these inflammatory cells creates the late allergic response [29].

IgE is a well-known mediator of allergic reactions, including allergic rhinitis and asthma. It differs from other antibodies as it is primarily located in the tissues, tightly bound to mast cells and basophils via a high-affinity receptor. IgE does not bind complement and functions mainly through its receptors. It can be produced in the regional lymph nodes or bone marrow, as well as locally in the mucosa, by plasma cells. At least half of patients with allergic rhinitis have positive skin tests, and a higher degree of peripheral eosinophilia is associated with an increased risk of more severe sinus disease [31,32]. However, a positive allergy test does not necessary prove a causal relationship with allergic rhinitis [33]. Based on previous studies, there is insufficient evidence to associate classical IgE-mediated allergy as the major mechanism behind allergic rhinitis [34].

In contrast, there is little disagreement with local inflammation and production of IgE in allergic rhinitis. The concentration of IgE in nasal secretions was higher than in serum [35]. After intranasal exposure to an allergen, specific IgE was elevated in nasal washings, suggesting local intranasal IgE production [36,37]. In addition, secondary lymphoid follicles with T cells, B cells, and plasma cells associated with IgE were found in nasal tissue [36]. ILs and CD40, elements needed for IgE production, were discovered in the sinonasal mucosa [35]. Heavy-chain class-switching and IgE induction in response to antigen was also demonstrated in the sinonasal tissue, further supporting local production of IgE [38]. IgE also plays a central role in immediate hypersensitivity. Cross-linking of bound IgE with an allergen on mast cells and basophils triggers degranulation and the release of inflammatory mediators. IgE receptors on dendritic cells facilitate the presentation of allergens to T cells, and low-affinity IgE receptors on B cells augment cellular and humoral immune responses [39].

B cells are integral to IgE production and allergen sensitization via IgE class switching. A subset, B regulatory cells 1 (Br1), produce high amounts of IL-10, inhibiting proliferation and differentiation of Th1 and Th2 cells and altering TNF expression in effector $CD4^+$ T cells. Activated Bregs can enhance Treg properties by increasing Foxp3 expression and increase the suppressive co-receptor, cytotoxic T lymphocyte antigen 4 [40]. Semaphorin3A (sema3A) is a soluble molecule involved in immune system modulation and maintenance of self-tolerance. It is present on Tregs as a suppressor marker. In addition, sema3A was found on Bregs, along with its receptor NP-1 and CD72, a regulatory molecule on B cells that inhibits B cell receptor pathway activation signals. In allergic rhinitis there is hyperinnervation of sensory neurons in the nasal turbinate, possibly associated with itching and sneezing. Sema3A inhibits sprouting of nerve fibers and restricts innervation of sensory neurons. There is a decreased expression of sema3A in the nasal epithelium, accompanied by an increase in nerve fiber density in a murine allergic rhinitis model. Treating the mice with recombinant sema3A, a possible therapeutic option, decreased the density of nerve fibers compared with untreated mice with allergic rhinitis [41].

Accumulation of basophils is present in allergic inflammation. Basophils are myeloid hematopoietic cells. Basophil maturation is not well understood, but transcription factors, microbial-derived signals, and IgE regulate their development. Th2 cytokine-mediated inflammatory responses, via IL-3 and thymic stromal lymphopoietin, increase basophil development, and cause peripheral basophilia. Basophils can be activated through

multiple signals, including cytokines, antibodies, proteases and directly by antigens. Local infiltration of immune cells into the nasal mucosa of patients with allergic rhinitis includes basophils. Basophils are a major source of histamine in the late-phase responses to allergen challenge. They also provide leukotriene $C_4$, important in the activation of mast cells [42].

Cytokines are major mediators in the pathogenesis of allergic rhinitis. Cytokines can be produced by immune, structural, and other cells within an organ, where they coordinate inflammatory responses. The effects of cytokines can be triggered by any insult, but are exacerbated by infection, trauma, allergic challenges, and autoimmune diseases, among others. In allergic rhinitis, a Th2-mediated response with associated cytokines such as IL-4, IL-5, and IL-13 are elevated in the nasal mucosa [43]. The levels of these cytokines generally correlate with symptom severity [43]. IL-10, a regulatory cytokine, is also increased in nasal fluid after an allergen challenge. The Th2-linked chemokines, eotaxin, RANTES (regulation on activation, normal T cell expressed and secreted and also known as CCL5), monocyte chemoattractant protein 1 (also known as CCL2), and macrophage inflammatory protein 1α, are reportedly increased in allergic rhinitis. The Th1-mediated inflammatory cytokine IFN-γ was not significantly increased in nasal fluid after an allergen challenge. The role of IL-17 in allergic rhinitis is unclear, and its elevation, may depend on the specific allergen, such as dust mite. Epithelial-derived cytokines, TSLP, IL-33, and IL-25 are released by allergen exposure and affect Th2 cells directly or via innate lymphoid cells that produce cytokines to activate Th2 cells. The role of epithelial-derived cytokines in allergic rhinitis is unclear, and studies have been inconclusive to date [44]. IL-33 is released upon structural cell damage and activates multiple immune cells, leading to the production of Th2-like cytokines. It has been postulated that IL-33 exacerbates allergic rhinitis via the activation of mast cells to produce proinflammatory cytokines and chemokines [45].

The innate immune system has an important role in allergic rhinitis. The sinonasal epithelium is an interface for pathogens via their PAMPs, and the innate immune system via PRRs. TLRs have a dual role in allergic diseases. Some cause sensitization and break tolerance, while others promote tolerance to allergens. TLRs impact adaptive immunity by deviating Th2 to Th1 and maturation of Tregs [35]. TLR9, a bacterial DNA receptor in the nasal mucosa, is decreased in allergic rhinitis [46]. Given its role in the pathogenesis of allergic rhinitis, TLR9 has been the aim of research as a possible therapeutic target to block TLR9-mediated immune activation [47]. TLR4 is upregulated in allergic rhinitis, and the goal of targeting TLR4 using adjuvants of allergy vaccines is to induce tolerance and the inhibition of its inflammatory function [48].

## 39.9 Immune modulation by mesenchymal stem/stromal cells

MSCs first emerged as immune-related cells when it was observed that MSCs inhibited T cell proliferation *in vitro* [49]. This observation was validated *in vivo*, when MSCs were co-administered during the transplantation of allogeneic bone marrow hematopoietic stem cells and progenitors. MSCs were given to reduce the risk of graft rejection, a recipient T cell-mediated host-versus-graft response [50]. They have more commonly been used to treat or prevent graft-versus-host disease, another complication of allogeneic hematopoietic stem cell transplantation, in this case mediated by donor T cells reacting against recipient (host) tissues (see Chapter 57). These studies led to further research on the broader immunomodulatory properties of MSCs. Over the past decade, MSCs have been found capable of exerting either immune-suppressing or immune-enhancing functions (reviewed in [51] and [52]), as well as releasing various cytokines capable of acting in an autocrine or paracrine fashion [53].

MSCs have been shown to suppress T cell proliferation [49,54]. Although the exact mechanism is unknown, MSCs induce cell cycle arrest in the $G_0/G_1$ phase in T cells, possibly through the production of indoleamine-pyrrole 2,3-dioxygenase (IDO), prostaglandin $E_2$ ($PGE_2$), or by the induction of the inhibitory molecule programmed cell death protein 1 (PD-1, also known as CD279) [55,56]. MSCs do not always act as immune suppressor cells. They can act as APCs [57]. In other studies, MSCs have been shown to lack the co-stimulatory molecules CD80 and CD86 that are needed to stimulate T cells together with specific antigen. Because of this, MSCs could lead to T cell anergy [58]. MSCs can secrete cytokines to influence T cell differentiation. These include hepatocyte growth factor, IL-6, IL-10, and TGF-β1 [59]. Specifically, MSCs can suppress the differentiation into Th1 and Th17 cells and enhance Th2 and Treg differentiation [60].

MSCs can arrest B cells in the $G_0/G_1$ phase of the cell cycle, and further reduce B cell chemotaxis [61]. The mechanism of B cell arrest is unclear, but may be based on the PD-1 pathway [55], as reported for T cell arrest, or could occur from MSC-mediated production of soluble factors [61]. Conversely, some studies have shown that MSCs can stimulate B cell proliferation and differentiation [62].

MSC-derived IDO and $PGE_2$ have major roles in the suppression of MSCs on natural killer (NK) cell proliferation [63,64]. In addition, MSCs can further inhibit NK cell activity by down-regulating the NK-activating receptors NKG2D, NKp30, and NKp44 [64]. Down-modulation of these activating receptors involves reduced production of proinflammatory cytokines, resulting in suppression of NK cell function [64]. MSCs inhibit dendritic cell differentiation and maturation *in vitro*. Studies have shown that this occurs through the production of $PGE_2$ by MSCs [65].

Macrophages normally differentiate into proinflammatory M1 or anti-inflammatory M2 subtypes. In the presence of MSCs, macrophages selectively differentiate into the anti-inflammatory M2 macrophage subtype [66,67]. Again, the IDO and $PGE_2$ pathways have been implicated in this anti-inflammatory modulation, as has the MSC-secreted cytokine IL-10, among other cytokines [68].

MSCs have been shown to suppress neutrophil infiltration [69,70]. IL-10 and TGF-β secreted by MSCs reduce E-

selectins on endothelial cells to minimize the extravasation of neutrophils [70]. Meanwhile, MSCs secrete IL-6, IL-8, and macrophage inhibitory protein [71], which have been implicated in the activation of neutrophils, while IL-6 also inhibits neutrophil respiratory bursts [72], thus suppressing neutrophil function and subsequent tissue damage.

## 39.10 The future of mesenchymal stem/stromal cells as therapy for allergic diseases

MSCs appear to be primarily anti-inflammatory effector cells, making them an ideal candidate for cell therapy. This immune suppression relies on multiple pathways and secreted factors. Before transitioning MSCs to the clinic, however, we must more fully understand the microenvironment in which these cells will find themselves, and how that environment will act on the MSCs. Experimental evidence has shown different responses by MSCs in the milieu created by activated T cells in allergic asthma compared with allergic rhinitis [12,73]. The brief discussion in this chapter shows that allergic diseases are complex. Despite the inflammatory milieu formed by allergic disease, experimental evidence indicates that the triggers cause different outcomes in MSCs. Our studies used bone-marrow-derived MSCs. The results indicate that the molecular and cellular methods by which allergic rhinitis and allergic asthma triggered MSCs to respond might be different. These findings indicate that additional research studies are required before introducing MSCs to the clinic for these two allergic disorders.

Because of their immune modulatory properties, MSCs remain a good candidate for the cellular treatment of allergic diseases. Additionally, since MHC matching between MSC donors and MSC recipients does not appear to be required, banks of allogeneic MSCs from a number of unrelated donors can be cryopreserved, allowing direct access to MSCs as needed. Thus far, there have been no overt pathological problems reported from the use of allogeneic MSCs for inflammatory diseases. However, the pathogenesis of inflammatory airway diseases, such as allergic asthma and allergic rhinitis, are complex, although there is some overlap due to the involvement of the innate and adaptive immune responses in each. (Figure 39.1).

It will be important to understand what happens to MSCs when they act as immune-suppressive cells, how they will react to the local environment in which they are placed, and what happens when the inflammation becomes chronic.

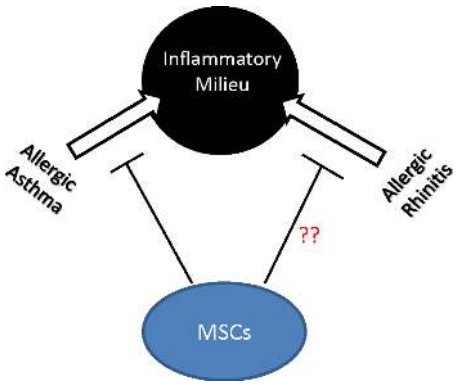

**Figure 39.1** Shown are seemingly similar inflammatory milieu after an allergic response by subjects with asthma and rhinitis. The experimental results thus far show that MSCs can induce tolerance and reverse the inflammation in allergic asthma [12]. However, a similar response has not been noted for allergic rhinitis [73]. The "??" depicts an unknown method by which MSCs can be used for allergic rhinitis.

## 40.1 Introduction

Huntington's disease (HD) is a hereditary neurodegenerative disorder in which a mutation of a single gene leads to the progressive loss of neurons throughout the brain resulting in the loss of both cognitive and physical faculties. The onset of HD symptoms occurs at about 40 years of age, and these patients usually succumb to the disease approximately 20 years after the emergence of these symptoms. Currently, there is no treatment to delay the onset of the disease or to halt its progression. Early clinical and preclinical studies in which stem cells were transplanted into a degenerated environment have provided therapeutically relevant benefits, establishing a proof of principle in which stem cells or their progeny are a viable therapy. However, the optimal approach for cell therapy to treat HD has not been established. In this chapter we will first outline the multifaceted nature of HD. We will also describe the types of cells being studied, with a focus on their ability to protect against further degeneration, as well as which types of cells may be more suitable for replacing neurons. The disease was initially called Huntington's chorea. Choreiform movements are involuntary, quick, sudden, random, jerky, purposeless spasmodic movements that can occur in any part of the body, often in the shoulders, arms or hands, or in the face and tongue.

## 40.2 Huntington's disease

Written accounts of the characteristics of HD have been available for centuries. One of the first accounts of what researchers believe to be related to HD was in the 14th century, when the epidemic "dancing mania" was described. Around the turn of the 17th century English colonists in the Americas used the terms "that disorder" or "Saint Vitus's Dance" to describe the involuntary movements, which were believed to be a result of possession by the devil and possibly led to one execution during the Salem witch trials in the 1690s [1]. In 1872, Dr. George Huntington gave his paper "On Chorea" to the Mason Academy of Medicine in Middleport, Ohio, which was published in *The Medical and Surgical Reporter* 2 months later [2]. In this paper Huntington began by describing many of the already known features of chorea. However, apart from his predecessors, Huntington describes in great detail what he considered a strikingly different form of chorea based upon observations of a small community in

Long Island, New York. This new form of chorea, according to Huntington, was hereditary in nature with patterns of inheritance, as well as being of adult onset and progressive in nature. Huntington also described the tendencies toward insanity, leading to suicide.

Having established HD as being hereditary in nature, it was not until the Venezuela Project when a more comprehensive understanding of the genetic patterns of HD was elucidated. Beginning with the discovery of an isolated population with an inordinately high frequency of HD on the shores of Lake Maracaibo in Venezuela [3], researchers were able to establish a pedigree of over 10 000 individuals, all stemming from a single ancestor. Various samples taken from these individuals helped to locate the DNA polymorphism situated on chromosome 4 [4].

It was not until 10 years after the discovery of the location of the mutation that a multi-institutional collaborative effort led to finding the exact gene, IT15 (now termed *huntingtin*; *HTT*), which is responsible for HD [5]. In addition, these investigators discovered that the mutation of this gene involved an increase in the numbers of CAG trinucleotide repeats on exon 1 [5]. The vast majority of cases of HD involve an expansion of CAG repeats of the *HTT* gene on one allele. Alleles can be classified as healthy, mutable, and penetrant [6]. Healthy alleles are ones in which fewer than 26 CAG repeats are observed and no symptoms will appear [5]. Individuals with a mutable allele (27–35 CAG repeats) will show no symptoms of HD but have the risk of passing a penetrant allele to their offspring [7]. Penetrant alleles can be broken down into reduced penetrance (36–39) or full penetrance (40 or more CAG repeats). Individuals with a reduced penetrant allele are at risk for developing HD but may never develop symptoms, while individuals with fully penetrant alleles are associated with fully developed symptoms [8].

Anticipation is also observed in HD, a phenomenon whereby successive generations show increased disease severity at a reduced age of onset, commonly by paternal transmission through CAG repeat instability during spermatogenesis [9]. The number of CAG repeats has also been suggested to play a role in the age of onset [8,10] as well as the variability of progression [11]. Individuals with a greater number of CAG repeats (>60 CAG) will show the less common Westphal variant (or juvenile onset) of HD, while fewer repeats are associated with adult onset. Similarly, higher CAG repeats are correlated with an increase in the deterioration of cognitive and motor function [12,13].

### 40.2.1 Prevalence and symptomology

Based on a meta-analysis of 13 different studies on the incidence of HD worldwide, Pringsheim *et al.* estimated the prevalence of HD in the western world at about 5.7 cases per 100 000 and a prevalence of 0.4 cases per 100 000 in Asia [14]. Apart from the Lake Maracaibo community, high frequencies of HD are also observed in certain regions of western Europe [15]. Approximately 5–10% of all cases of HD are of the Westphal variant, in which the onset of symptoms appears before the age of 20 [9,16].

The progression of HD is highly variable, with the severity of symptoms correlating with the age of onset [10]. This is usually between the ages of 35 and 40 in adult-onset HD. Whereas death of individuals with adult-onset HD is approximately 20 years after the initial emergence of symptoms, juveniles with the Westphal variant of HD (a hypokinetic rigid form of the disease) have a much shorter life expectancy [17].

Symptoms of HD can be characterized as motor, nonmotor, and hypothalamus-related dysfunction. The progression of HD symptoms can be divided into early, mid, and late stage. Prior to the self-reported symptom of involuntary movements, patients slowly merge from the healthy phase to a prediagnostic phase in which the first subtle symptoms appear. This early stage has been extensively studied through the Predict HD study, a multi-institutional collaborative study designed to elucidate the earliest signs of HD [18,19]. Reports from these studies show changes in olfactory sensation and finger-tapping motor scores one to two decades prior to diagnosis [18]. Between high-risk HD carriers and noncarriers, significant differences appear in verbal and logistical memory [18,20]. Included in these early-stage symptoms are clumsiness, irritability, delusions, and depression with ideations toward suicide [21].

Symptoms developing during mid-stage HD are increasingly motor in nature [6,22]. Involuntary movements and difficulty initiating movement emerge during this stage, as well as a continuation of cognitive impairments and emotional disturbances and increases in sleeping difficulties and sexual decline. The mid to end stages are characterized by increased weight loss, chorea, inability to maintain balance, general weakness, speech difficulty, and loss of bladder and bowel control [6,23]. As the progression of the disease continues, most patients suffer from rigidity and bradykinesia and lose the ability to care for themselves. They usually die due to complications from falls, dysphagia, or pneumonia, often as a result of difficulties in aspiration, such as inhaling a foreign substance (e.g., food) into the lungs [1,15].

### 40.2.2 Neuronal pathology

From a neuropathological perspective HD is unique, in that the mutation primarily leads to an early, massive degeneration of medium spiny neurons (MSNs) within the striatum, with most of the extrastriatal neuronal loss occurring in later stages of the disease [24,25]. The striatum is a structure within the interconnected nuclei of the basal ganglia, which includes the caudate nucleus, putamen, globus pallidus, substantia nigra, and thalamus. The striatum, also known as the neostriatum or striate nucleus, is a subcortical part of the forebrain. It receives input from the cerebral cortex and is the primary input to the basal ganglia system. In all primates, the striatum is divided by a white-matter tract called the internal capsule into two sectors called the caudate nucleus and the putamen (Figure 40.1).

Functionally, the striatum helps coordinate body movements. The caudate nucleus and the putamen receive the majority of input from cortical glutamatergic neurons as well as dopaminergic afferents of the substantia nigra, pars compacta, and

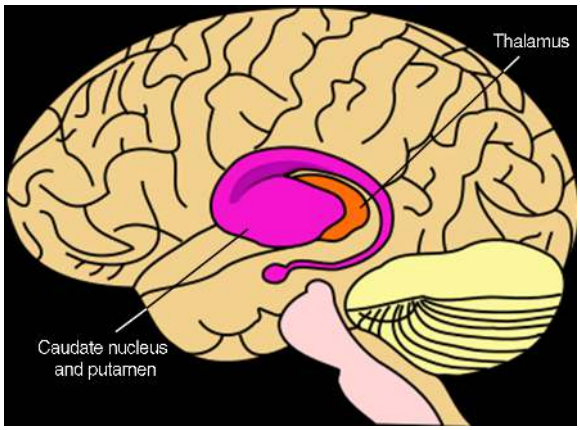

**Figure 40.1** Image showing the basal ganglia and related structures. The caudate nucleus and putamen and the thalamus are shown. *Source*: John Henkel, US Food and Drug Administration.

glutamatergic afferents of the thalamus [24]. Glutamate (glutamic acid) is abundant in the human body, but particularly in the nervous system, and is especially prominent in the human brain, where it is the body's most prominent neurotransmitter, the brain's main excitatory neurotransmitter, and also the precursor for γ-aminobutyric acid, the brain's main inhibitory neurotransmitter. Glutamate receptors are responsible for the glutamate-mediated postsynaptic excitation of neural cells and are important for neural communication, memory formation, learning, and regulation.

Analysis of several imaging studies has revealed four stages of neuropathology in HD. Beginning at stage 1 prior to the onset of symptoms, there appears to be selective cortical thinning [26] and alterations in the white matter of the corpus callosum [27]. Functional magnetic resonance imaging has revealed a decrease in the activity of the dorsolateral prefrontal cortex and reductions in grey-matter volume [28,29]. Autoradiographic techniques have also revealed a decrease in binding for cannabinoid, $D_2$ dopamine, and adenosine receptors, with a slight increase of γ-aminobutyric acid receptor binding [30]. An autoradiograph is an image on an X-ray film or nuclear emulsion produced by the pattern of decay emissions (e.g., β-particles or γ-rays) from a distribution of a radioactive substance. Alternatively, an autoradiograph may also be available as a digital image (digital autoradiography), due to the recent development of scintillation gas detectors or rare earth phosphorimaging systems.

At stage 2 of HD a selective degeneration of encephalin-containing striatal neurons projecting to the external segment of the globus pallidus is observed, as well as an increase in degeneration of substance-P-containing striatal neurons, projecting to the substantia nigra and pars reticulate [25]. Encephalins are related to the endorphins and have similar physiological effects.

At stage 3 of HD there is a progressive and severe loss of striatal projection neurons as well as thinning of cortical layers III, V, and VI.

Stage 4 is characterized by 95% loss of all striatal neurons and marked decreases in the size of the subthalamic nucleus, hypothalamus, white matter, and the cerebellum [31].

### 40.2.3 Mechanisms of neurodegeneration

Understanding the mechanism of degeneration in HD is difficult. The huntingtin protein HTT is ubiquitously expressed throughout the body, but is highly expressed in the central nervous system, particularly in corticostriatal projection neurons in layers III and V with projections to the striatum [32,33]. At the cellular level HTT is found in many subcellular compartments including the nucleus, dendrites, axons, and synapses of neurons, as well as in intracellular organelles [34,35]. Given its cellular diversity, the exact function of HTT remains unclear. However, the interactions of HTT with proteins involved in vesicle transport and cytoskeletal and synaptic structure suggest that HTT promotes cellular health and function.

The expanded CAG repeat near the N-terminus of *HTT*, leading to the formation of mutant HTT (mHTT), results in a gain-of-function disruption in a variety of cellular processes, including transcriptional dysregulation and transport of brain-derived neurotrophic factor (BDNF) [1,36], hypersensitivity of MSNs [37], and mitochondrial dysfunction [38].

Reductions of BDNF within the HD brain have been well documented [39,40]. Brain-derived neurotrophic factor is a member of the neurotrophin family of growth factors, which are related to the canonical nerve growth factor.

Produced in cortical neurons with afferent projections to the striatum, BDNF is transported via corticostriatal tracts to MSNs and is necessary for MSN survival [41,42]. Protein–protein interactions with mHTT occur at the stages of BDNF production, transport, release, and uptake [1]. It has been observed that symptomatic HD patients with lowered levels of BDNF had significantly worse motor and cognitive performances than individuals with normal BDNF levels, highlighting the importance of BDNF in the prevention of neuronal degeneration in HD [43,44].

Similarly, mHTT is involved in corticostriatal glutamatergic signaling. In particular, mHTT seems to impart a hypersensitivity of *N*-methyl-D-aspartate (NMDA) receptors to glutamate released from cortical projection neurons [45]. Coupled with reductions of mHTT-dependent reuptake of glutamate from the extracellular space [46], a cascade of events is initiated leading to the death of MSNs, termed excitotoxicity [37,47]. This increased excitability at the level of NMDA receptors creates an increase in the levels of intracellular calcium, leading to activation of proteases and lipases, generation of free radicals and constitutive nitric oxide synthase, disruption of mitochondrial oxidative phosphorylation, and enhanced brain lipid peroxidation, culminating in cell death by the release of apoptotic factors and oxidative stress [48,49].

The excitotoxicity hypothesis of HD is supported by evidence in which mHTT interacts with the surface of mitochondria to exhibit a defect in regulating intracellular calcium [50].

Mitochondria of HD patients also exhibit a defect in energy metabolism [38]. Additionally, reports indicate that glucose metabolism is altered beginning in the early stages of HD [51]. Molecular analysis of mitochondria of HD-affected individuals suggests dysfunction in complexes I, II, III, and IV of the electron transport chain that reduces oxidative phosphorylation, thereby reducing succinate oxidation and ATP synthesis [38,51,52].

## 40.3 Animal models

Several animal models of HD have been developed, many of which allow for the study of the behavioral deficits mimicking the progressive nature of HD. Animal models range from transgenic mice, in which a copy of *mHTT* is introduced into the animal's genome (Table 40.1), to chemical models, in which toxins are introduced to mimic the degeneration which occurs in HD (Table 40.2). These models have led to greater understanding of the molecular mechanisms of HD and have also allowed for the testing of potential therapies that are designed to slow the degeneration or, perhaps, replace MSNs lost during the progression of the disease.

### 40.3.1 Transgenic models

Amongst a myriad of mouse models in which a transgene with an expanded CAG has been inserted into the genome, or in which an insertion of CAG repeats on the endogenous *HTT* has been made, two mouse models are predominantly used in HD research: the R6/2 and YAC128 mice [1]. The R6/2 transgenic mouse expresses only the first exon of the human *HTT* gene with an expanded CAG repeat length of approximately 140–160 CAG repeats [53]. This model presents with a rapidly progressing phenotype in which robust motor deficits that include dyskinesia, irregular gait, and clasping are observed. The onset of the deficits appears between 6 and 8 weeks of age, with a lifespan of 13–15 weeks of age [59,60] in comparison with a normal murine lifespan of 2 years. However, aside from intranuclear inclusions of mHTT aggregates and striatal atrophy, many of the hallmark neuropathological symptoms of HD are not observed [1,53]. Unlike the R6/2 mouse, the YAC128 transgenic mouse expresses full-length *mHTT* with 128 CAG repeats [54,61]. These mice display a mild phenotype with forelimb and hindlimb coordination deficits appearing at 24 weeks of age [61], as well as robust striatal and cortical atrophy which includes a significantly reduced number of neurons and formation of mHTT aggregates within the striatum by 48 weeks of age [1,54].

Owing to technological and logistical issues, development of transgenic rat models of HD have lagged behind those of transgenic mouse models [62]. The tgHD (transgenic Huntington disease) 51CAG rat carries *mHTT* with 51 CAG repeats and exhibits a progressive phenotype resembling adult-onset HD [55]. These rats display early cognitive deficits [63] followed by motor dysfunction [55]. Similar to the R6/2 transgenic mouse model, the tgHD 51CAG rat displays minor neuropathological deficits with enlargement of the lateral ventricles as well as aggregation of mHTT [1,55].

**Table 40.1** Transgenic models of HD.

| | R6/2 mouse | YAC128 mouse | tgHD rat |
|---|---|---|---|
| Reference | [53] | [54] | [55] |
| CAG repeat | 140–160 | 128 | 51 |
| Onset | 5–6 weeks | 8–12 weeks | 40–50 weeks |
| Neuropathology | Atrophy of the striatum; aggregation of mHTT | Atrophy of the striatum and cell loss (48 weeks); aggregation of mHTT | Enlarged lateral ventricles; aggregation of mHTT |
| Motor deficits | 5–6 weeks | 24 weeks | 40–50 weeks |
| Weight loss | Yes | No | Yes |
| Lifespan | 13–15 weeks | Normal | 98 weeks |

**Table 40.2** Chemical models of HD.

| | Quinolinic acid | 3-Nitropropionic acid |
|---|---|---|
| Reference | [56] | [57,58] |
| Mechanism | NMDA receptor agonist | MSN mycotoxin |
| Administration | Single intrastriatal injection (unilateral or bilateral) | Progressive peripheral |
| Neuropathology | Immediate loss of MSNs | Progressive |
| Motor deficits | Immediate apomorphine/paw placement (unilateral lesions) and staircase test/rotarod (bilateral lesion) | Rotarod (2 weeks) |

## 40.4 *In vitro* models

Chemical models of HD were among the first to be used, and had a high degree of reproducibility that mimicked the neuropathology observed in HD (Table 40.2). Glutamate agonists such as kainic acid and quinolinic acid are able to selectively kill striatal MSNs through overactivation of NMDA receptors on the MSNs, which, in turn, causes lethal increases in intracellular calcium, a phenomenon that led to the development of the excitotoxic hypothesis of HD [32,56,64]. Single intrastriatal administration of quinolinic acid has shown immediate and selective degeneration of MSNs as well as motor and memory dysfunction, similar to what is observed in people with HD [65,66].

The mitochondrial toxin 3-nitropropionic acid (3-NP) was also an early chemical used to model HD [66–69]. Peripheral injections of 3-NP have been shown to cross the blood–brain barrier and irreversibly inhibit complexes II and III of the electron transport chain, inhibiting succinate dehydrogenase, and specifically reducing available energy within the striatum, similar to what is observed in HD [68,70,71]. Systematic intraperitoneal injections can replicate the progressive nature of HD, in which animals present with weight loss, motor dysfunction, and cell death [66,72].

## 40.5 Experimental therapies

Currently, no cure exists for HD, and only palliative treatments for reducing the motor symptoms of HD are available. The only therapy for HD approved by the US Food and Drug Administration to date is tetrabenazine, which acts to inhibit the hyperactive dopamine pathway, thereby reducing the severity of choreic movements [73,74]. Various pharmaceutical agents aimed at inhibiting the dopamine pathway, reducing excitotoxicity, or enhancing mitochondrial metabolism have shown promise in preclinical trials, but none has been able to progress beyond phase III clinical trials. Various gene therapies have also shown promise in preclinical settings. Among the more promising avenues for gene therapy is increasing expression of BDNF production from endogenous cells within the striatum via adenoviral or adeno-associated virus vector injections into the striatum [75–77]. These approaches were shown to be neuroprotective, with preservation of striatal MSNs following injection of quinalonic acid [76] and an increase in recruitment of neural stem cells to the striatum [75]. These methods also reduced motor deficits and prolonged lifespan in the transgenic R6/2 mouse model of HD [78,79].

Another target of gene therapy is to reduce transcription of *mHTT* through RNA interference. Most commonly, *HTT*-specific RNA interference has been introduced using viral vectors [80–82]. These studies were able to show nonspecific reduction of *HTT* expression in various mouse models of HD, as well as in healthy nonhuman primates [83]. A second method being explored is the use of antisense oligonucleotides that target common single nucleotide polymorphisms located on the *mHTT* allele. This method of gene therapy has been shown to specifically reduce mHTT expression in a humanized mouse model of HD (97 CAG/18 CAG) [84,85]. While these potential therapies hold promise, they lack the ability to replace cells that have been lost to the disease.

## 40.6 Cell transplantation

Transplantation of cells falls into two separate strategies: either to provide protection against neurodegeneration, or to replace the neurons lost because of the disease. Transplantation of mesenchymal stem/stromal cells (MSCs) has been traditionally used in the first (prophylactic) strategy, because of their ability to release neurotrophic factors that promote neuronal survival. Transplants of fetal or adult neural stem cells (NSCs) and the differentiated progeny of induced pluripotent stem cells (iPSCs) have been used in the second (replacement) strategy, since these cells can differentiate into neurons.

### 40.6.1 Mesenchymal stem/stromal cells

A true adult mesenchymal stem cell that fulfills the criteria of both self-renewal and lineage differentiation has been documented, but it is a rare cell, being present at a frequency of 1 in $10^4$ to 1 in $10^5$ in murine bone marrow. To get sufficient mesenchymal cells for laboratory experiments or for clinical trials, their progeny need to be expanded in *ex vivo* culture. These culture-expanded cells are known as mesenchymal stromal cells.

Transplantation of MSCs early in disease progression provides an option for intervention that can help protect against further degeneration. Originally described by Friedenstein *et al.* [86], MSCs are multipotent stromal cells that have since been defined by three main characteristics: (1) plastic adherence and proliferation in *ex vivo* tissue culture; (2) ability to differentiate into a diverse set of mesodermal lineages *in vitro*, and (3) expression of characteristic but not unique cell surface markers [87]. Mesenchymal stromal cells cannot dedifferentiate to mesenchymal stem cells. However, since mesenchymal stromal cells are pericytes, forming part of the blood vessel wall in all vascularized tissues, they can therefore be derived from many tissue sources, including bone marrow, umbilical cord blood, and adipose tissue. They can then expanded in *ex vivo* tissue culture. Other characteristics of human MSCs, defined by the International Society for Cellular Therapy, include positive expression of the cell surface proteins CD73, CD90, and CD105 and lack of expression of CD34, CD45, and major histocompatibility complex class II molecules [88].

The intrinsic characteristics of MSCs, such as immunomodulation and neurotrophic factor release, have made these cells a candidate for cell-based therapies in HD. The ability of MSCs to modulate the local immune environment comes from cell-to-cell contact and through the release of interleukins and cytokines that interact with a wide range of immune cells, which in turn help to protect transplanted MSCs from acute and prolonged immune responses and rejection [89–92]. MSCs secrete many neurotrophic factors, including BDNF, glial-derived neurotrophic factor (GDNF), and nerve growth factor (NGF) [93,94]. Recent advances in cell characterization techniques have allowed researchers to explore the secretome of MSCs with the aim of identifying all secreted molecules, which may provide insight into the mechanisms mediating the benefits of transplanted MSCs [95].

As MSCs can be isolated from various sources, it is important to determine if MSCs maintain similar characteristics regardless of their source. For example, MSCs isolated from the bone

marrow may express proteins implicated in neuroprotection at different levels relative to MSCs isolated from the umbilical cord. To test this hypothesis we isolated mRNA transcripts from these two MSC types and assayed them using reverse transcriptase polymerase chain reaction. Results from this study suggested that the expression of neurotrophic factors and anti-inflammatory cytokines are highly variable. Furthermore, it is apparent that the length of time MSCs are kept in culture will also alter expression of these genes and cell surface proteins (Figure 40.2). Given the degree of variability, it is unclear as to which MSC source and what the optimal duration of culture (number of passages) are that will produce the greatest benefit in a transplantation paradigm.

Early transplantation studies in animal models of HD focused on isolating MSCs derived from bone marrow, as these cells were particularly easy to isolate and expand in numbers sufficient for transplantation [94,96,97]. In 2003 we transplanted autologous whole bone marrow into the brains of rats treated with quinalonic acid [97]. Although reduction in working memory errors were observed, no evidence of neuronal differentiation of the transplanted cells was found, suggesting that the beneficial effects were the result of some mechanism other than cell replacement. We later observed that MSCs transplanted into the 3-NP rat model of HD had improved performance on the rotarod test, as well as a reduction in the size of the lesion in the striatum. We hypothesized that this was a result of release of neurotrophic

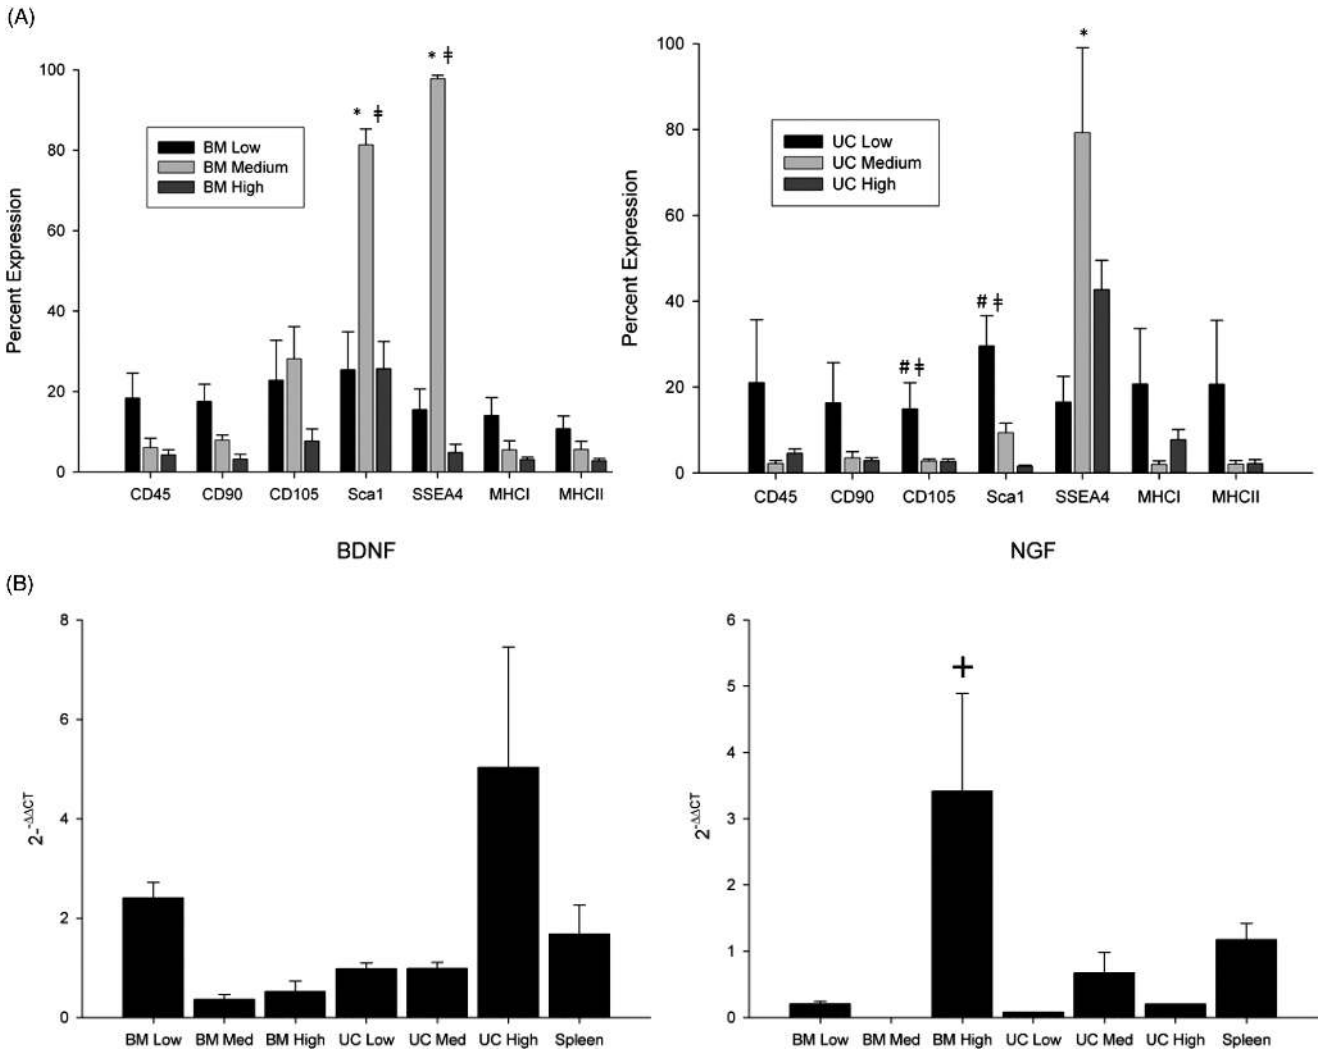

**Figure 40.2** (A) Expression of cell surface markers on MSCs derived from the bone marrow (BM) or umbilical cord (UC) over multiple passages and analyzed by flow cytometry. Changes in protein expression were observed across low passage (P) number (P4–P10), medium passage number (P40–P60), or high passage number (P100–P130). (B).Similarly, a high degree of variability was observed in mRNA transcripts for BDNF and NGF. These data indicate that different populations of MSCs exist, which may be able to be distinguished according to tissue sources or by duration in culture. Symbols: ∗, significantly different from low-passage cells; #, significantly different from medium-passage cells; ǂ, significantly different from high-passage cells; +, significantly different from all groups.

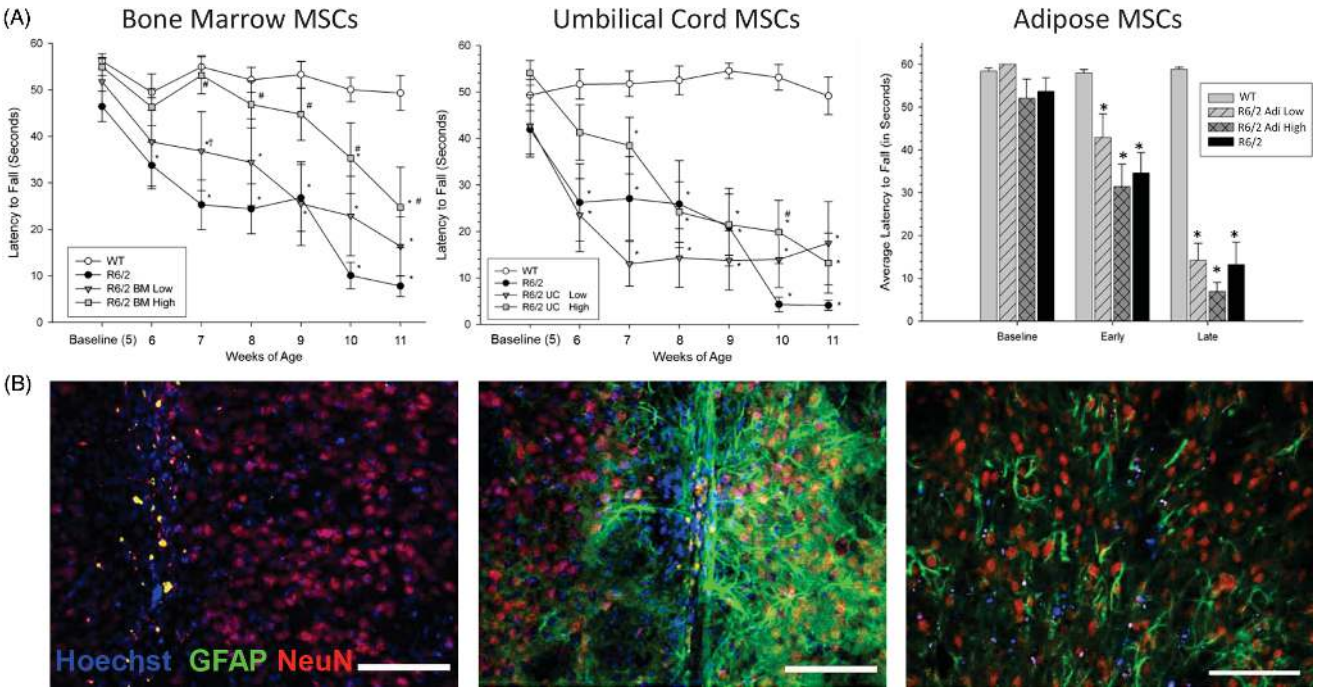

**Figure 40.3** Behavioral and histological evaluation following intrastriatal transplantation of low-passage (P4–10) or high-passage (P40–P60) MSCs derived from bone marrow (BM), umbilical cord (UC), and adipose tissue (Adi) in the R6/2 mouse model of HD. (A) It was observed that R6/2 mice transplanted with high-passage BM MSCs demonstrated greater behavioral sparing on the rotarod task, whereas R6/2 mice transplanted with UC MSCs or Adi MSCs did not display the same degree of benefit. (B) At 6.5 weeks following transplantation, Hoechst-labeled MSCs (blue) were observed at the site of transplantation in all groups. Activation of reactive astrocytes (green) was observed surrounding the site of transplantation in R6/2 mice transplanted with UC MSCs (center) and Adi MSCs (right) but not BM MSCs (left). There was no indication of neuronal differentiation of transplanted MSCs into neurons (red) in any of the three groups. (See color plate section.) Symbols: ∗, significantly different from wild type; #, significantly different from R6/2; †, significantly different from high passage. Scale bars represent 100 μm. *Source*: adapted from Fink 2013 [98], p. 130.

factors from the MSCs [94]. The rotarod test is a performance test based on a rotating rod with forced motor activity being applied, usually by a rodent. The test measures parameters such as riding time (seconds) or endurance. Some of the functions of the test include evaluating balance, grip strength, and motor coordination.

As mentioned above, MSCs have been derived from many tissues and organs, including the umbilical cord and adipose tissue, and these have provided additional MSC types for transplantation. As the R6/2 transgenic mouse model of HD presents with early symptoms and rapid progression, transplantation of MSCs derived from bone marrow, umbilical cord, and adipose tissue have provided high-throughput validation of the neuroprotective effects of these cells [98]. In three separate studies, results suggested that bone-marrow-derived MSCs may provide the greatest degree of behavioral and neuroanotomical sparing (Figure 40.3). Using immunohistochemistry, MSCs were detected in R6/2 mice transplanted with MSCs from bone marrow, umbilical cord, or adipose tissue for up to 6.5 weeks after transplantation. Furthermore, histological examination of the brains of R6/2 mice transplanted with bone-marrow-derived MSCs revealed a reduction in reactive astrocyte response. While the mechanisms behind the observed beneficial effects are still unclear, it has been suggested that neurotrophic factor support and immunomodulation provide a favorable microenvironment to sustain the function of endogenous MSNs [94].

### 40.6.2 Genetic engineering of mesenchymal stem/stromal cells

The direct correlation between intrastriatal levels of BDNF and disease progression led one group to alter cell culture conditions in order to induce MSCs to release enhanced amounts of BDNF and GDNF (Figure 40.4) [99,100]. When transplanted prior to quinolinic acid injection these neurotrophic-factor-releasing MSCs were able to reduce lesion size relative to nontransplanted controls [99]. This technique of enhancing neurotrophic factor release was also utilized in MSCs derived from human bone marrow and subsequently transplanted into R6/2 mice. This resulted in a transient reduction in rotarod deficits [100].

In an effort to overexpress neurotrophic factors in MSCs we used a retrovirus to transfect MSCs with the *BDNF* gene on a cytomegalovirus promoter, which led to the overexpression of BDNF [101]. Analysis of BDNF production in these cells revealed a sixfold increase in the amount of intracellular BDNF and a fourfold increase in secreted BDNF relative to production by nontransfected MSCs. These cells were then transplanted into

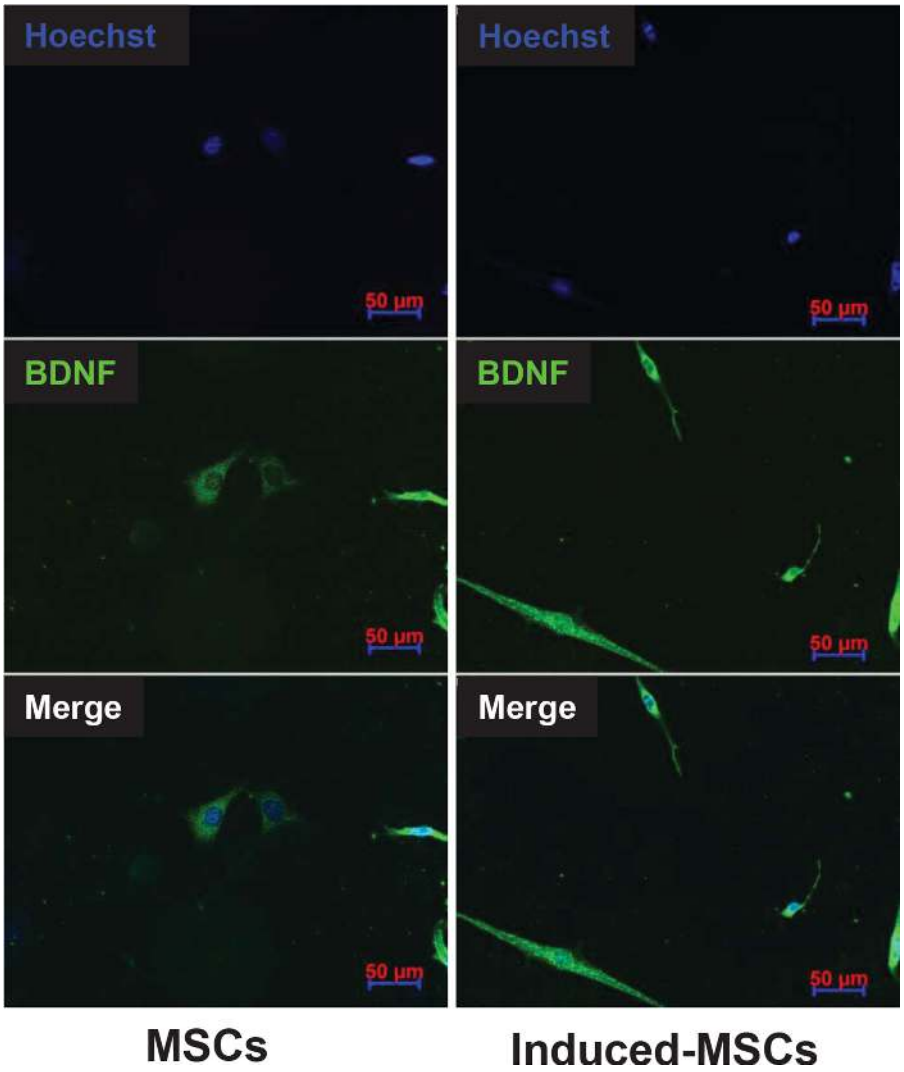

**Figure 40.4** Immunocytochemical analysis of intracellular BDNF of MSCs or MSCs induced to release neurotrophic factors (induced-MSCs). Following treatment with mitogens, basic fibroblast-derived growth factor, and epidermal growth factor, an increase in the fluorescent signal of immunolabeled BDNF (green) in induced-MSCs was observed relative to noninduced MSCs. (See color plate section.)

the YAC128 transgenic mouse model of HD and observed for 9 months. All YAC128 mice that were transplanted with the BDNF-engineered MSCs displayed an increased latency to fall from the rotarod and reduced clasping scores (Figure 40.5). Compared with R6/2 mice transplanted with unmodified MSCs, BDNF-expressing MSCs showed the highest amount of behavioral protection. Histological analysis revealed that YAC128 mice transplanted with BDNF-expressing MSCs had complete preservation of neurons in the striatum as well as protection against significant losses in the number of MSNs.

Viral transfection of MSCs has now progressed beyond the ability to increase levels of neurotrophic factors. Given that MSCs can establish cell-to-cell interactions to transfer mitochondria as well as RNA and other nucleic acids through extensions of the cytoplasm [102–105], Olson *et al.* measured the ability for short hairpin (sh)RNA produced by viral transfection in MSCs to reduce expression of HTT in neighboring cells [106]. Results from this *in vitro* study demonstrated that shRNA-expressing MSCs co-cultured with mHTT-expressing cells were able to reduce levels of the mutated mRNA within the cell as well as the expression of the mutated protein.

### 40.6.3 Embryonic and fetal stem cells

Pluripotent stem cells have garnered much attention in the study of neurodegenerative disorders primarily because of their potential to differentiate into any tissue of the three germ lineages: ectoderm (which includes neurons), endoderm, and mesoderm. Embryonic stem cells are derived from the inner cell mass of a blastocyst and express the transcription factors OCT4 and SOX2 [107,108]. Obtaining true pluripotent stem cells suitable for therapeutic transplantation has raised ethical concerns because the embryo is destroyed in the process.

Cells derived from fetal tissue have been utilized for transplantation with the hope that the fetal ganglionic eminence – cells

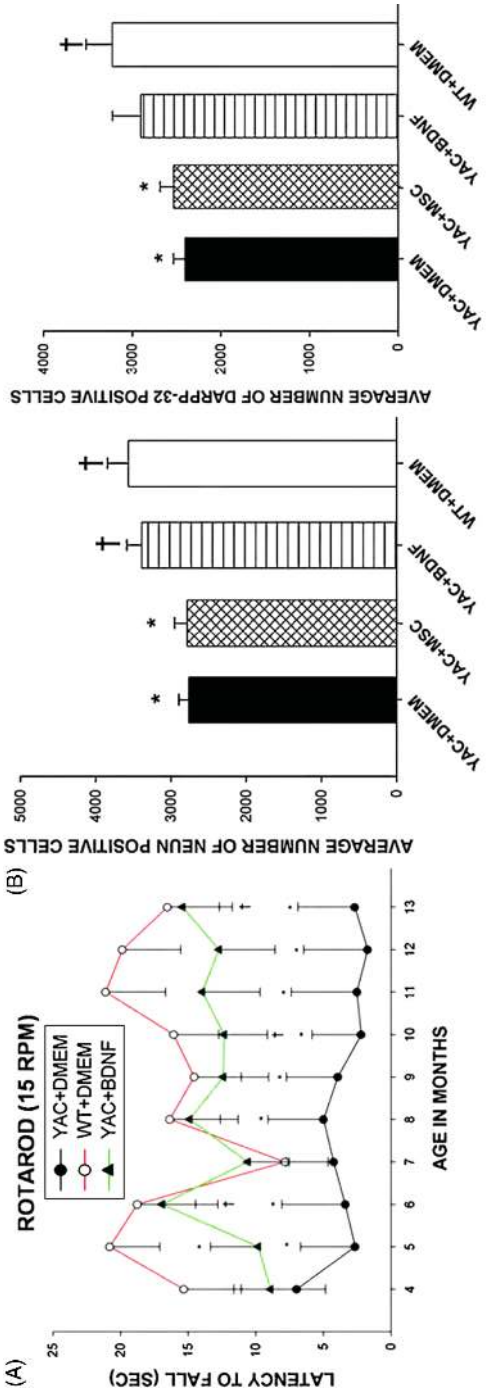

**Figure 40.5** Behavioral and histological evaluation following intrastriatal transplantation of MSCs genetically engineered to overexpress BDNF in the YAC128 mouse model of HD. (A) Following transplantation, a significant reduction of deficits in rotarod performance was observed in YAC128 mice transplanted with BDNF-MSCs relative to YAC128 mice receiving intrastriatal vehicle injections alone. (B). Relative to vehicle-injected YAC128 mice and YAC128 mice transplanted with unmodified MSCs, a preservation of striatal neurons (left) and MSNs (right) was observed in YAC128 mice transplanted with BDNF-MSCs. Symbols: *, significantly different from wild type; †, significantly different from YAC128 mice. DMEM: Dulbecco's modified Eagle's medium. *Source*: adapted from Dey 2010 [101], pp. 193–200. Reproduced with permission of Elsevier.

destined to become MSNs of the basal ganglia – will differentiate into MSNs following transplantation. Long-term clinical studies in which cells from the ganglionic eminence were transplanted into HD patients have shed light on the variability associated with fetal cell transplants. In 2000, Bachoud-Lévi and colleagues transplanted HD patients with ganglionic eminence tissue and found that three of the five patients receiving the transplants had a delay in the progression of their disease and that transplanted tissue was metabolically active up to 10 years after transplantation [109–111]. These beneficial effects, however, were not seen in all patients receiving transplantation of fetal ganglionic eminence tissue. Other groups observed short-term graft survival, HD-related neurodegeneration, and aggregate formation within the graft or formation of cysts at the site of transplantation [112–114]. These findings offer insight into clinical applications of fetal grafts, but the logistical challenges of their transplantation into HD patients provided the impetus to investigate other cell types suitable for such transplantation.

### 40.6.4 Neural stem cells

When large populations of proliferating cells were discovered in the adult subgranular zone of the hippocampus and subventricular zone or the lateral ventricles, the dogma that only a fixed number of cells exist in the brain was no longer tenable [115–117]. The extraction and expansion of NSCs has allowed researchers to obtain small quantities of tissue and produce large enough numbers of cells for *in vivo* transplantation. Culturing of NSCs *in vitro* requires defined growth medium supplemented with mitogens to maintain proliferation, at which point NSCs will begin to form free-floating multicellular neurospheres (Figure 40.6) [118]. Removal of growth mitogens from culture conditions induces NSCs to differentiate into cells within the neural lineage such as neurons, glial cells, and oligodendrocytes.

The potential for NSCs to form new neurons following transplantation into animal models of HD has garnered much attention. Transplantation of immortalized human, mouse, and rat NSCs have all shown considerable promise, with reductions in behavioral deficits being observed in several animal models of HD, including measures of apomorphine-induced rotation, beam walking, and latency to fall off the rotarod [119–126]. Several laboratories have observed that, following transplantation, NSCs maintain protein markers for immature neurons, as well as markers of mature neurons, astrocytes, and even MSNs [122,126]. However, Johann *et al.* found that the majority of the transplanted NSCs differentiated into astrocytes and not into mature neuronal phenotypes [127]. The ability of transplanted NSCs to evade rejection by the immune system is limited. While one study found few transplanted NSCs surviving up to 20 weeks posttransplant [128], another study observed that transplanted NSCs were rapidly rejected after 14 days in a quinolinic acid mouse model of HD and after 28 days in the R6/2 model of HD [127]. Although local immune suppression

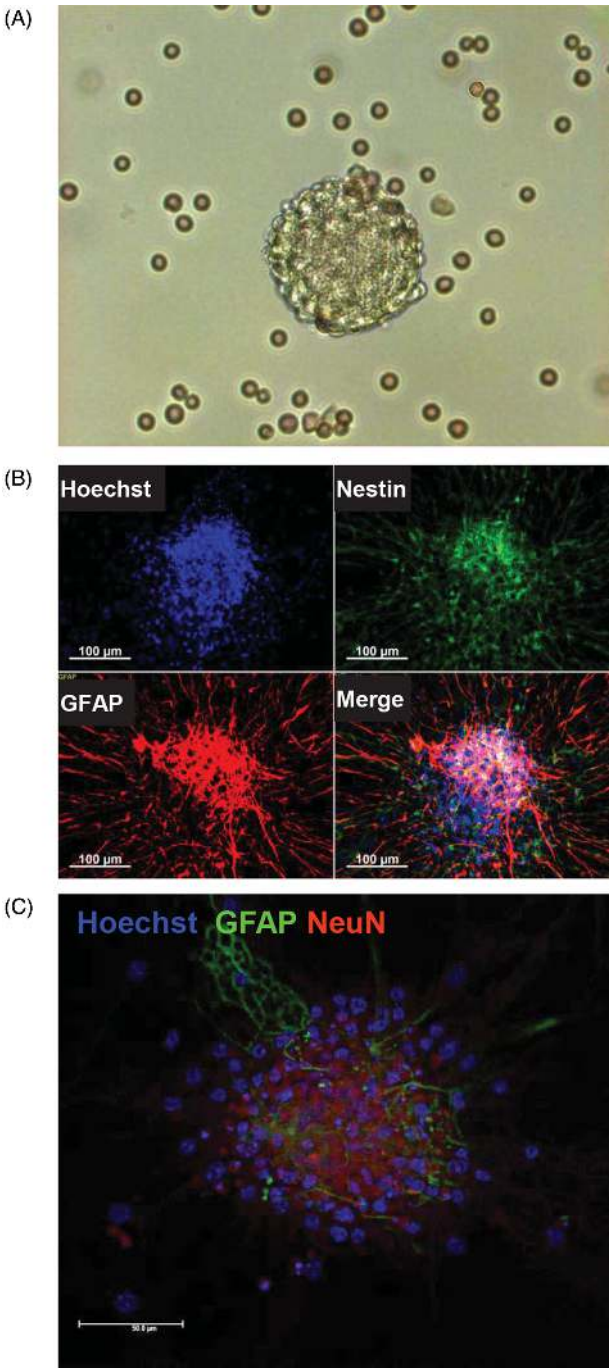

**Figure 40.6** Bright-field and fluorescent imaging of NSCs. (A) Phase-contrast image revealing that free-floating neurospheres are formed from cultured NSCs. (B). The Hoechst-labeled neurosphere (blue) is also labeled by the neural precursor marker nestin (green) and the astrocyte marker GFAP (red). (C). When cultured in the absence of growth mitogens the Hoechst-labeled neurosphere (blue) differentiates into astrocytes (green) and neurons (red). (See color plate section.)

can enhance graft survival, there are significant side effects associated with long-term immune suppression [129]. Identifying cells that can evade the host's immune response is of great value for cell-based transplantation approaches.

### 40.6.5 Induced pluripotent stem cells

In 2006, a team in Japan led by Shinya Yamanaka published a seminal paper showing that somatic cells could be reprogrammed by retroviral transfection of the genes for the embryonic transcription factors OCT3/4 and SOX2 together with the embryonic stem cell maintenance transcription factors KLF4 and c-MYC (commonly termed the "Yamanaka factors") [130]. These iPSCs exhibited many of the same characteristics of embryonic stem cells, including morphology, gene expression, and ability to differentiate into cells of all three germ lines. For HD, iPSCs have become a powerful research tool that has helped elucidate the mechanisms of mHTT at the single cell level, as well as providing a pluripotent cell that can be transplanted into the HD brain [131,132] (Figure 40.7).

Transplantation of neurally differentiated progeny of iPSCs into the central nervous system for therapeutic use remains a major topic of interest. Many practical hurdles remain, including the potential of transplanted iPSC progeny to develop the HD phenotype, as seen in fetal graft transplants [112], as well as their rejection by the recipient's immune system. Another major concern is the ability of undifferentiated iPSCs to form teratomas [133]. Controversy surrounds this issue, as some groups have observed teratomas [134–136] while other groups have not [132,137–139]. Techniques for reducing the tumorigenicity of iPSCs are being pursued and include lineage restriction toward NSCs or MSN progenitor cells prior to transplantation [133].

In 2012, Jeon *et al.* generated iPSCs from a patient with juvenile-onset HD (72 CAG repeats) and tested the potential of these cells to differentiate into MSNs *in vitro* and *in vivo* [140]. Following a standard *in vitro* multistage differentiation protocol, iPSCs were first differentiated into neural progenitors, which expressed markers for immature neural cells, as well as mature neural cells. When neural progenitor cells were transplanted into the quinolinic acid rat model and the YAC128 mouse model of HD [140,141] it was observed that the transplanted cells were able to express markers specific for MSNs as well as reducing behavioral deficits associated with these models. Interestingly, these HD-derived iPSCs did not show aggregates of mHTT, a hallmark of the HD brain.

The development of therapeutically relevant iPSCs for the treatment of HD is still in its infancy. We have established a line of iPSCs derived from healthy rat tail-tip-derived fibroblasts and transfected with a pair of nonintegrating adenoviruses expressing genes for the Yamanaka factors OCT4, KLF4, SOX2, and c-MYC [137]. The transfected fibroblasts formed iPSC colonies and expressed markers of pluripotency. To test the safety of adenovirus-generated iPSCs, undifferentiated iPSCs were bilaterally transplanted into the striata of immune-competent syngeneic rats. Transplanted iPSCs were observed up to 90 days posttransplant and expressed markers of mature region-specific neural cells. Formation of tumors was not observed.

To test the efficacy of adenovirus-generated iPSC transplantation in the HD brain we transplanted this line of cells into both

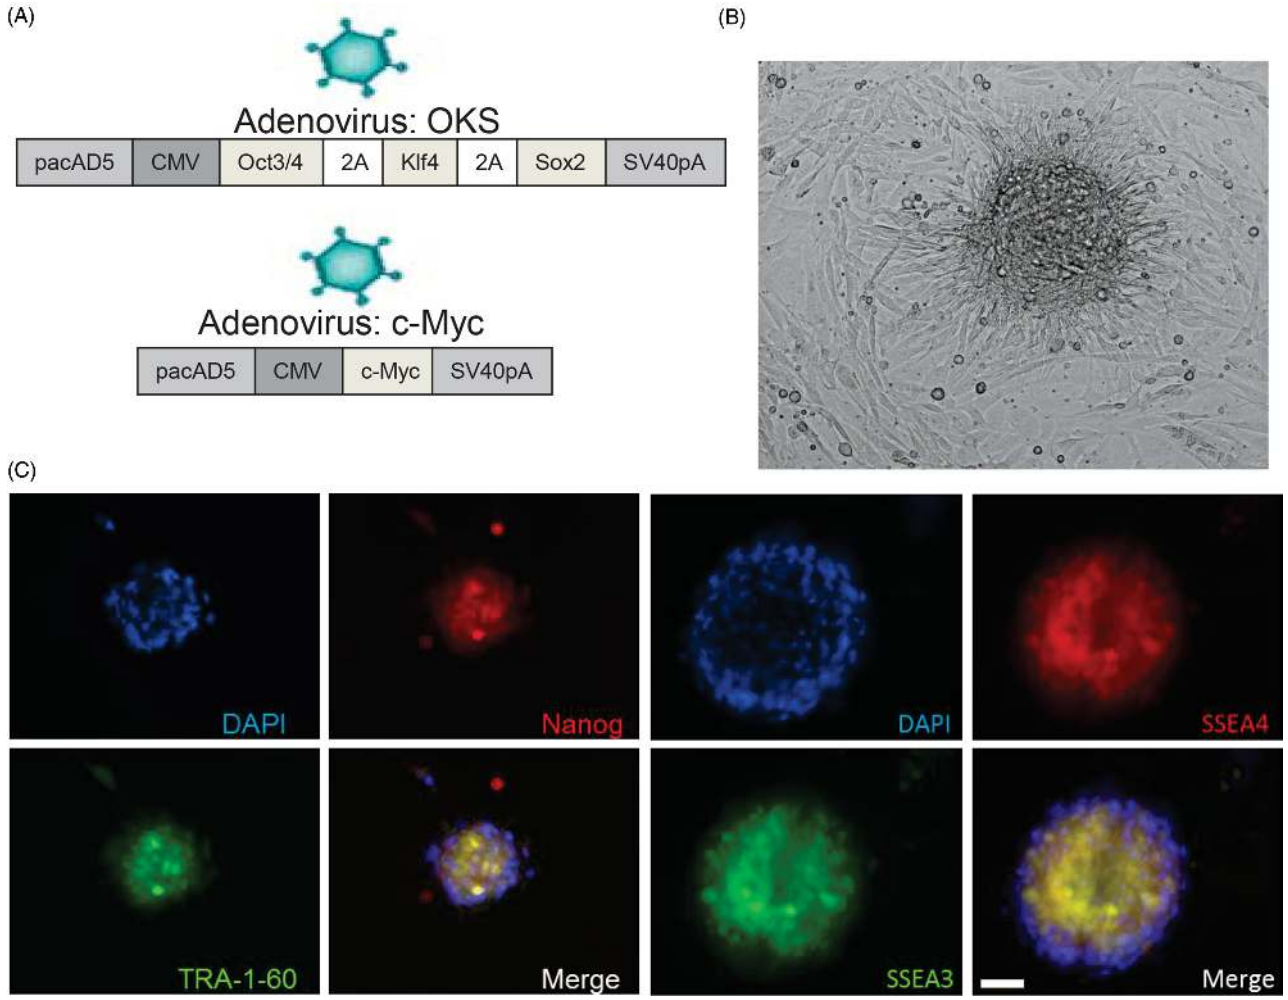

**Figure 40.7** Generation and characterization of iPSCs. (A). Schematic of the Yamanaka factors placed into two separate adenoviral vectors. The first adenoviral vector codes for Oct3/4, Klf4, and Sox2 and the second vector codes for c-Myc, each under the cytomegalovirus promoter. (B). When both adenoviral vectors are incorporated into rat tail-tip fibroblasts colonies are observed, which are then isolated and expanded on a monolayer of deactivated rat embryonic fibroblasts. (C). Immunocytochemical analysis of Hoechst-labeled iPSCs (blue) expressing pluripotency-related proteins, including Nanog, Tra-1-60, SSEA3, and SSEA4; scale bar: 50 µm. (See color plate section.) *Source*: adapted from Fink 2014 [132].

young and aged rats treated with 3-NP as well as the transgenic Huntington disease (tgHD) transgenic rat.

In the first study adenovirus-generated iPSCs were transplanted into syngeneic young adult (2 months of age) rats progressively dosed with 3-NP [132]. 3-NP is an inhibitor of the mitochondrial citric acid cycle and its administration results in a progressive locomotor deterioration resembling that of HD. In 3-NP rats that received transplants at stages mimicking early- and mid-stage HD, behavioral sparing on the accelerod test was observed (Figure 40.8). The accelerod test measures performance on the rod during acceleration at approximately 1 rev/s compared with that obtained using the rotarod when the same rod is operated at a constant speed of 20 rev/min. Surprisingly, a recovery of function was observed when 3-NP rats with end-stage disease were transplanted. Histological analysis of brains following transplantation showed survival of iPSCs with mature neuronal phenotypes as well as a reduction in neuronal loss due to 3-NP administration (Figure 40.9A).

However, in a second study aimed at better mimicking transplantation into adult-onset HD brain, the same line of iPSCs was transplanted into syngeneic older (6–8 months of age) rats treated with 3-NP. Six weeks after transplantation, histological analysis of these older 3-NP-treated rats given undifferentiated iPSCs revealed the presence of tumors and cystic lesions (Figure 40.9B). It is possible that an aged 3-NP rat model may not be an optimal choice for testing the efficacy of cell-based treatments, likely due to an enhanced inflammatory response to the 3-NP.

A third study was designed to determine whether iPSCs are effective in a transgenic rat model of HD. We transplanted the same line of iPSCs into allogeneic tgHD 51CAG rats. Results from this study indicated that survival of transplanted iPSCs was

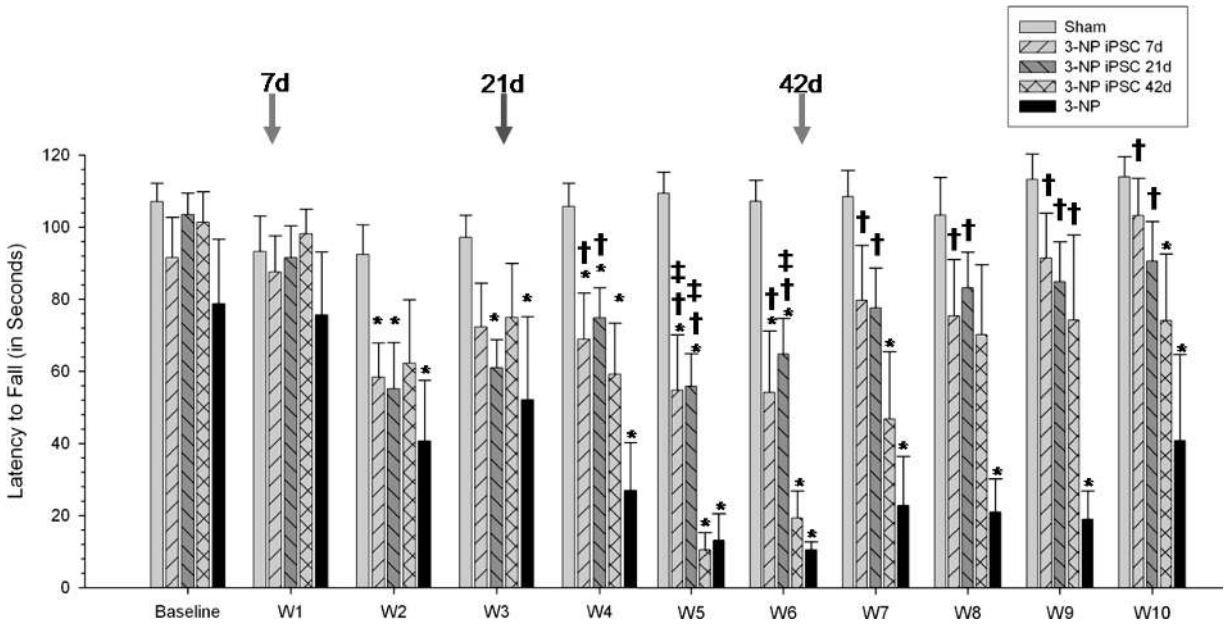

**Figure 40.8** Analysis of motor coordination in 3-NP-injected rats transplanted with undifferentiated iPSCs. Following a schedule of progressive 3-NP injections, rats were transplanted with undifferentiated iPSCs at 7, 21, and 42 days, representing early-, mid-, and late-stage HD. 3-NP rats transplanted at 7 and 21 days maintained motor coordination as observed by a significantly longer latency on the rotarod, relative to 3-NP rats injected with vehicle alone (black bars). Recovery of motor coordination deficits was observed in 3-NP rats transplanted with iPSCs 42 days after the start of the 3-NP injections. Symbols: ∗, significantly different from sham-treated control rats; †, significantly different from 3-NP-treated rats; ‡, significantly different from rats given 3-NP and iPSC 42 days previously. *Source*: adapted from Fink 2014 [132].

limited, with increased inflammation surrounding the transplant site (Figure 40.9C). However, no tumors were observed. Taken together, these studies suggest that the effectiveness of transplantation may be dependent upon age of the recipient, the genetic relatedness between iPSC donor and iPSC recipient (syngeneic versus allogeneic), and the choice of model.

Building on this, we then generated a similar line of iPSCs derived from healthy mouse tail-tip fibroblasts. Similar to

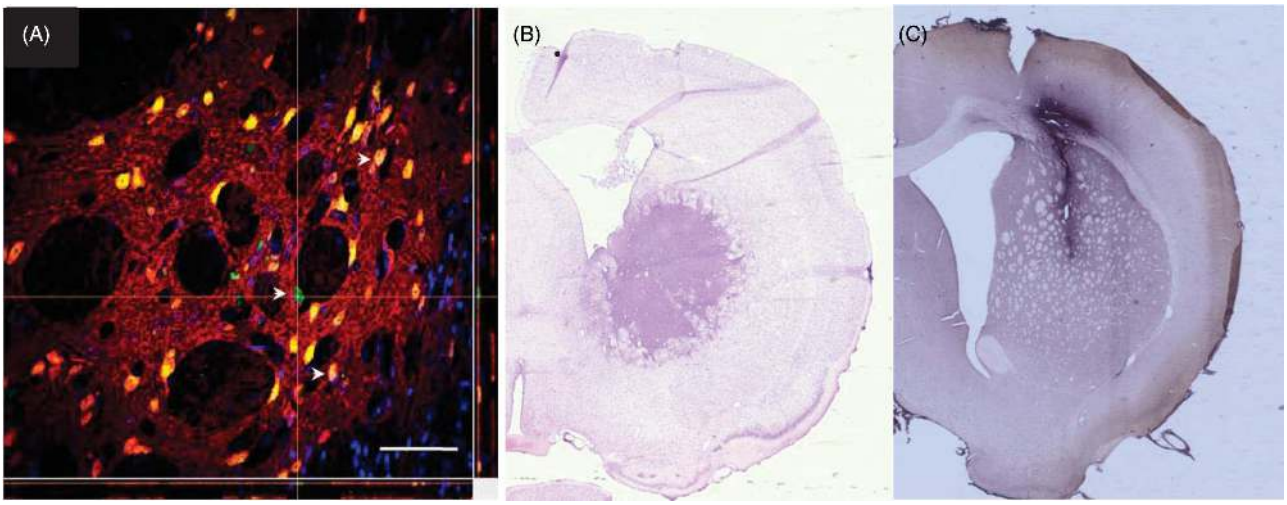

**Figure 40.9** Photomicrographs of tissue containing iPSCs that were transplanted into younger (2 months) and older (6–8 months) rats that had been treated with 3-NP as well as tgHD rats. (A). Immunohistochemical analysis of syngeneic transplantation of iPSCs in a young 3-NP-treated rat revealed that the Hoechst-prelabeled iPSCs (blue) survived and differentiated into mature neurons (green) or MSNs (yellow). (B). Following syngeneic transplantation of iPSCs into older 3-NP-treated rats, tumor-like masses were observed in the striatal tissue, which was stained with cresyl violet. (C). No prelabeled iPSCs were observed in the brains of tgHD rats 20 weeks after allogeneic transplantation of iPSCs, although a marked increase in macrophage activity (measured by IBA1 labeling) was observed at the site of transplantation. (See color plate section.)

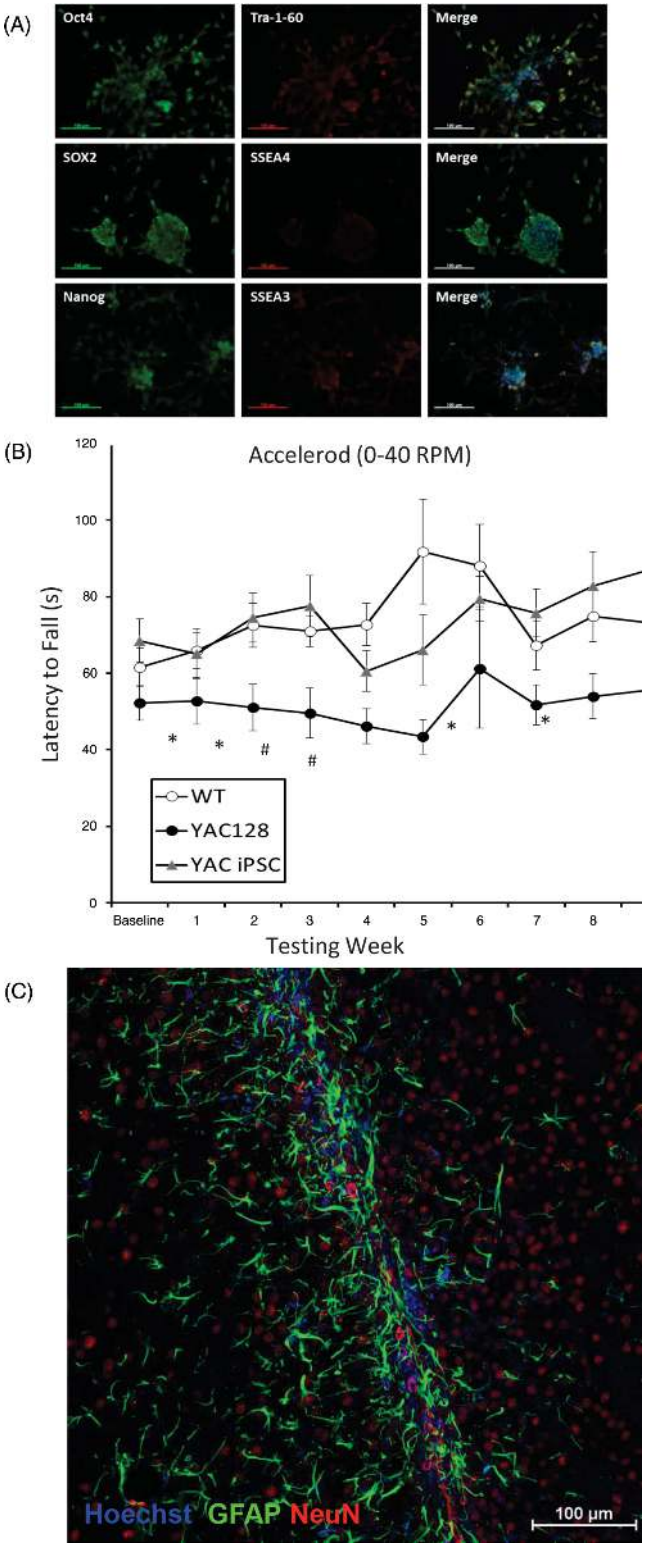

**Figure 40.10** Characterization and transplantation of adenovirus-generated iPSCs derived from mouse tail-tip fibroblasts. (A). Immunocytochemical analysis of Hoechst-labeled iPSCs (blue) shows that they express pluripotency proteins including OCT-4, SOX2, Nanog, Tra-1-60, SSEA3 m and SSEA4. (B). Accelerod analysis of YAC128 mice transplanted with iPSCs at 10.5 months of age revealed preservation of motor coordination for up to 10 weeks after transplantation. (C). Immunohistochemical analysis of iPSCs injected into the striatum of YAC128 mice showed the survival of Hoechst-prelabeled iPSCs (blue) and the differentiation of these cells into mature neurons (red) as well as astrocytes (green). (See color plate section.) Symbols: ∗, significantly different from all groups; #, significantly different from wild type mice.

rat-derived iPSCs, mouse-derived iPSCs express markers of pluripotency detectable by both flow cytometry and immunocytochemistry (Figure 40.10). When transplanted into syngeneic YAC128 mice at 12 months of age we observed a significant improvement in behavioral deficits and survival and differentiation of transplanted iPSCs up to 8 weeks following transplantation.

While the exact mechanisms for the observed effects of transplantation of iPSCs into the HD brain are unknown, it is encouraging that iPSCs can survive and differentiate into region-specific neurons in rodent models of HD. The recovery of function in late-stage 3-NP-treated rats, as well as improved function in aged transgenic mice, suggests that iPSCs are best suited toward transplantation when the HD brain is in a degenerated state.

### 40.6.6 Co-transplantation paradigm

To enhance the survival and differentiation of transplanted cells we have utilized the immunomodulatory and neurotrophic support of MSCs and co-transplanted them with NSCs into the tgHD rat model of HD [128]. It was observed that HD rats receiving transplants of both MSCs and NSCs had a greater degree of behavioral sparing as measured by the rotarod task relative to HD rats receiving transplants of NSCs alone. We also found that transplants of MSCs preserved the number of surviving NSCs, as determined by the larger graft size in the rats receiving the co-transplants (Figure 40.11). These findings suggest that the microenvironment provided by the co-transplanted MSCs allowed a greater survival of NSCs.

## 40.7 Conclusions

Although the genetic mutation underlying HD was identified more than 20 years ago, a unifying hypothesis to explain the mechanism for the selective degeneration of MSNs has yet to be elucidated. This has been a limiting factor in the development of targeted therapeutic agents for this disease. Presently, two treatment strategies for HD are being explored. The first strategy involves using cells prophylactically to slow the progression of the disease-induced deficits. With this approach the primary focus has been on the ability of transplanted MSCs to secrete an array of proteins that can alter the microenvironment and provide niche support for the local MSNs. Genetic engineering of MSCs to overexpress such proteins is in its early stages but has provided a proof of principle to serve as the basis for future work.

The second strategy focuses on replacing the cells already lost due to the disease. For this, the potential of fetal tissue, NSCs, and

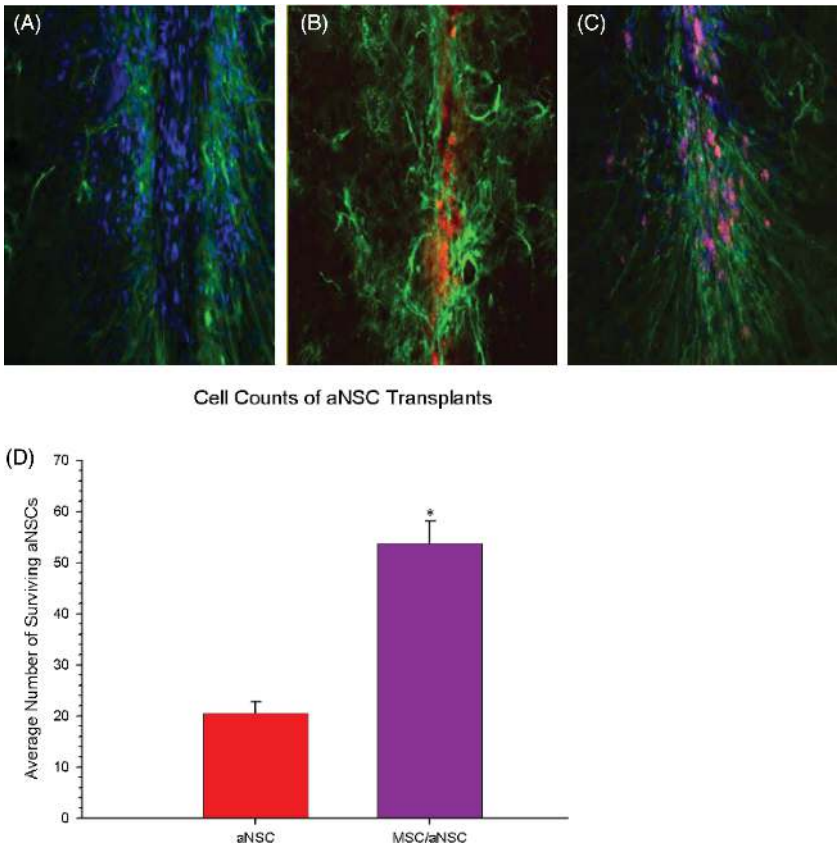

**Figure 40.11** Co-transplantation of adult NSCs (aNSCs) and MSCs in the tgHD rat model of HD. At 20 weeks after intrastriatal transplantation, (A) Hoechst-prelabeled MSCs (blue), (B) PKH-26-prelabeled aNSCs (red), or (C) co-transplanted MSCs and adult NSCs were observed. Reactive astrocytes (green) were also observed in all groups, although infiltration within the graft site was observed in NSC-transplanted animals; scale bar: 50 μm. (D). Rare event stereology at the site of transplantation demonstrated an increase in the number of positively labeled adult NSCs when co-transplanted with MSCs compared with tgHD rats transplanted with adult NSCs alone. Stereology is the three-dimensional interpretation of two-dimensional cross-sections of materials or tissues. (See color plate section.) Symbol: ∗, significantly different from adult NSCs. *Source*: adapted from Rossignol 2014 [128].

iPSCs has been harnessed, all of which have been shown capable of differentiating into MSNs. iPSCs offer an alternative to embryonic tissue but share the ability to differentiate into all cells of the body, including MSNs of the striatum. Results of early studies indicate that transplantation of iPSCs can reduce behavioral deficits and differentiate into mature neurons.

Combining the beneficial effects associated with each of these two strategies, such as co-transplantation of MSCs and NSCs, has provided another avenue for future therapeutic approaches. This could protect endogenous MSNs while enhancing the differentiation of transplanted NSCs or iPSCs to replace cells already lost. Understanding the characteristics of the various cell types, as well as determining how they exert their beneficial effects in animal models of HD, will provide valuable information toward ultimately using them clinically to improve both the longevity and quality of life for the individuals affected by this devastating disorder.

## 41.1 Introduction

Pelvic organ prolapse (POP) is a very common condition affecting millions of women worldwide. Recent notifications by the US Food and Drug Administration (FDA) warning of the high rate of complications with transvaginal placement of polypropylene (PP) mesh have led to withdrawal of many vaginal meshes from the market. This now severely limits the available treatment options for large numbers of women with POP. There is an urgent need for an effective therapy for this major hidden disease burden of women. This chapter will review recent studies in an emerging field in regenerative medicine that suggest a tissue engineering (TE) approach for the treatment of POP. It will detail new mesh designs that are more likely to succeed than the present PP meshes. It will describe the potential of cell-based therapy for POP, highlighting a newly identified source of mesenchymal stem/stromal cells (MSCs) from human endometrium. Characterization of endometrial MSCs (eMSCs) and the use of specific markers for their enrichment will be discussed. Approaches undertaken to produce eMSCs under good manufacturing practice conditions will be emphasized. Finally, the need for a large animal model of vaginal repair that can assess new TE constructs for a longer duration will be highlighted as a necessary step before the first clinical trials of a cell-based therapy can be commenced in women with POP. Figure 41.1 shows the anatomy of the human uterus, fallopian tubes, ovaries and vagina.

The uterus is made up of an external layer of smooth muscle called the myometrium and an internal layer called the endometrium. The endometrium has three layers: the stratum compactum, the stratum spongiosum (which make up the stratum functionalis), and the stratum basalis. The stratum compactum and stratum spongialis develop into the stratum functionalis during the first half of the menstrual cycle (proliferative phase).

## 41.2 Pelvic floor disorders

Pelvic floor disorders (PFDs) encompass stress urinary incontinence, fecal incontinence, and POP. The overall

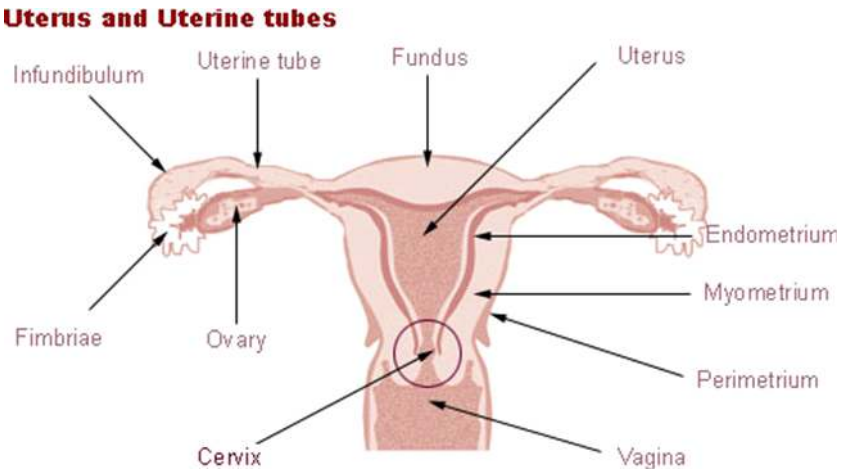

**Figure 41.1** Anatomy of the human uterus, fallopian tubes, and vagina. This work is in the public domain in the USA because it is a work prepared by an officer or employee of the United States Government as part of that person's official duties under the terms of Title 17, Chapter 1, Section 105 of the US Code. http://training.seer.cancer.gov/ss_module09_cervix_corpus/cervix_unit01_sec01_intro.html.

prevalence of PFD in women is 35%, which increases to 52% for women above 70 years of age [1–3]. Women as young as 18 years of age are affected by this condition, and the prevalence increases significantly with age [4,5]. Major risk factors include pregnancy, vaginal delivery, and obesity. Although many pregnant women seek elective cesarean section to prevent PFDs, compelling evidence suggests that the incidence of PFD in women undergoing this elective procedure does not decrease compared with nulliparous women or those undergoing vaginal birth delivery [1,6].

## 41.3 Pelvic organ prolapse

POP is a major hidden burden affecting millions of women worldwide. POP is the downward descent or herniation of pelvic organs, including the bladder, bowel, and/or uterus, into the vagina due to a weakened or damaged pelvic floor support structures [7]. POP accounts for over two-thirds of PFDs [7]. The support structures of female pelvic organs comprise the endopelvic fascia of the vaginal wall, the suspensory ligaments, and the levator ani muscles (pelvic floor muscles) [3,7]. Pregnancy and vaginal delivery can injure these support structures, through damage or denervation to muscles [8], overstretching or tearing of the ligaments, and weakening of the endopelvic fascia. In addition to the immense stretching of the pelvic floor during vaginal delivery, 10–20% of women giving birth to their first child have prolonged labor, instrument delivery, a large infant weight, or an episiotomy, all of which contribute to pelvic floor injury leading to POP [9]. Subsequent pregnancies and child birth and aging further weaken these tissues. Symptoms of POP include urinary incontinence, bowel incontinence, and/or sexual dysfunction [9].

One in four women suffer from POP, for which surgical reconstruction is frequently required. Women have an 11–20% probability of requiring an operation for POP repair in their lifetime [4,10–12]. POP is the leading indication for hysterectomy in postmenopausal women [13], and in Australia approximately 22 000 POP repair operations are conducted every year. In the USA the figure is 300 000 per year [7]. Although the lifetime risk for POP is higher than breast or lung cancer [14], most women suffer in silence because of the embarrassing symptoms [15]. A survey showed that only one in three US women had reluctantly discussed bladder issues with their doctor because of a perceived stigma and associated embarrassment. With increasing rates of obesity, delayed first childbirth, and rising life expectancy, the disease burden related to POP in terms of decreased quality of life, social isolation, lost productivity, and the effects on families and health-care systems will be substantial [3]. A comparative study in the USA estimated that 17 million women were affected by urinary incontinence, and the cost was estimated to be $19.5 billion [16]. Long-term, safe, and more effective therapies and earlier interventions are needed for affected women in order to improve their quality of life.

### 41.3.1 Surgical treatment for pelvic organ prolapse

Depending on which organs and support structures are affected and the severity of POP, the ultimate treatment is reconstructive surgical repair of the vaginal wall transvaginally (colporrhaphy). Native tissue surgical treatment has a high failure rate, with 30% of cases requiring further surgery for recurrent POP and with the time frame between surgeries decreasing with increasing age [4]. This high failure rate of native tissue repair prompted clinicians to adapt commercial synthetic abdominal hernia meshes for POP repair. These meshes aimed to provide additional support of the damaged pelvic tissues and to improve long-term outcomes. Synthetic PP meshes were introduced in 1997 and gained FDA approval in 2004. Since then, surgical methods for repair of POP have increased in number and complexity. In the USA, mesh had

been used in a third of POP surgeries and inserted transvaginally in ~75% of cases [17]. These mesh-augmented repair operations delivered seemingly higher "cure" rates, particularly for anterior vaginal wall damage, compared with colporrhaphy using native tissue surgery [18–20]. More recently, however, serious complications, such as mesh exposure into the vagina, bladder, or bowel, mesh shrinkage, vaginal shortening, pain, dyspareunia, and infections, have been reported in as many as 10–15% of cases [21–23]. This alarming complication rate led to two notifications by the FDA in 2008 and 2011 warning of the complications with transvaginal placement of surgical mesh [17,24]. These notifications have led to the withdrawal of some vaginal meshes from the market by several leading device companies. There is now a real risk that successful treatment options for women will be reduced and ineffective for a large number of women with POP.

### 41.3.2 New meshes for treatment of pelvic organ prolapse

Meshes used for clinical purposes may either be biological or synthetic. Biological scaffolds are typically natural tissues such as autologous rectal fascia and fascia lata (the deep fascia of the thigh that encloses the thigh muscles), allogeneic, such as cadaveric tissue, or decellularized xenografts, such as porcine small intestinal submucosa (SIS). Synthetic meshes, predominantly fabricated from PP, are the most commonly used for POP repair. Biological materials can be used as an untreated, decellularized matrix or can be further stabilized by chemical cross-linking. In either case, they are largely biodegradable and have limited efficacy due to their variable degradation rate, lack of longevity, variable tissue integration and host response, and concerns over transmission of diseases. Synthetic meshes are often preferred over biological meshes for applications requiring long-term support of tissues because they have more consistent properties and there is a more predictable host response [25]. While currently used PP meshes provide good mechanical tensile support for the damaged vaginal wall, they are generally stiffer than the natural tissue, resulting in compromised distensibility, poor compliance, and less integration into vaginal fascial tissues [26]. In addition, synthetic materials, while normally inert and nonimmunogenic, can induce a relatively vigorous foreign-body reaction leading to fibrotic tissue deposition [27].

The ideal mesh for POP has not yet been designed [28]. Adverse effects associated with current meshes can lead to erosion where the implanted material protrudes into the vaginal, bladder, or bowel lumen. POP meshes should be biocompatible and provide sufficient mechanical strength to support damaged tissue, but should also be elastic and flexible enough to allow compliance, movement, and integration with the natural tissue [25,26].

The physical properties of mesh depend upon polymer composition of the material, filament type, weaving or knit pattern, pore size, weight, and coating [26,27]. The current range of meshes will vary in one or more of these properties. Evolution of mesh design has largely focused on reduced weight with accompanying large pore diameter, which is conducive to cell infiltration, new fibro-collagenous deposition, and tissue remodeling [26,29].

Our recent work has used these current design strategies to further improve the biomechanical and biological performance of new fabricated polymer mesh types. The *in vitro* structural and mechanical properties of three commercially available PP meshes were compared with these new fabricated meshes from alternative polymers [26]. One of these meshes fabricated from polyamide (PA) monofilament yarn was optimized with a pore size of 1000 μm and dip-coated with 12% porcine gelatin (PA/G) to provide a platform for delivering cells to the surgical site (Figure 41.2D). The new PA/G meshes were less stiff on uniaxial biomechanical testing, more flexible and elastic on multiaxial testing, and with lower bending rigidity than commercial PP meshes. These favorable properties allow the mesh to conform to the highly mobile human vaginal tissue, with a less predictable likelihood to erode into neighboring organs. *In vivo* evaluation of the fibronectin-coated PA/G mesh designs in a rat abdominal hernia model showed significantly improved tissue integration by promoting angiogenesis, exerting a moderate foreign body reaction and generating good collagen deposition for up to 90 days compared with commercial PP mesh [27]. This new mesh with superior biomechanical and biocompatibility properties may be a more suitable starting point for developing a TE construct for POP therapy.

## 41.4 Tissue engineering

TE is an emerging field in regenerative medicine that uses a combination of cells and biomaterials of synthetic or natural origin (Figure 41.2D and E) The goal is to replace or regenerate damaged or diseased human tissues and restore or improve the long-term outcomes of surgical therapy [26]. In the urogynecological field, preclinical studies using animal models and clinical trials are scarce and have predominantly focused on the use of cell-based therapies for stress urinary incontinence. There are few studies that have explored the potential use of cell-based or TE approaches as potential therapies for POP. We are proposing to use a novel cell source with newly designed meshes to generate a TE approach for treating women with POP (Figure 41.2). The following summarizes the *in vitro* studies and studies in preclinical animal models (Figure 41.2F).

### 41.4.1 Candidate cells for tissue engineering applications for pelvic organ disorders

#### 41.4.1.1 Skeletal muscle-derived cells and muscle fibers

Murine skeletal muscle-derived stem cells (MDSCs) can differentiate into smooth muscle cells (SMCs) *in vitro* and express the pluripotency genes *OCT4* and *NANOG* [30]. MDSCs were grown on porcine SIS (Cook, Biotech®) and on a polymeric Vicryl mesh, and were found to stimulate vaginal tissue repair with reduced fibrosis in a rat model. It was postulated that MDSCs had

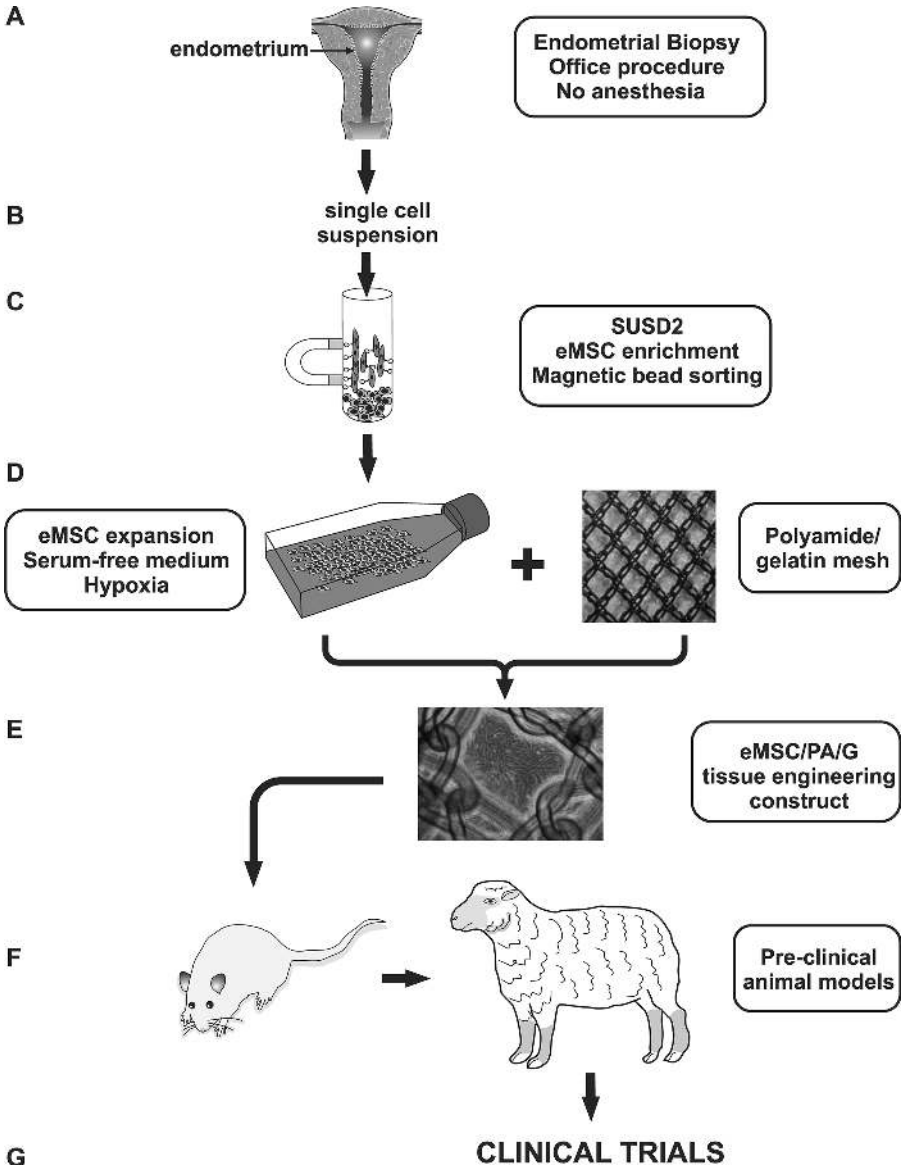

**Figure 41.2** Schematic showing a TE approach for the treatment of POP with eMSCs. Endometrium is the mucosal lining of the uterus. It can be collected (A) by biopsy in an office-based procedure without the need for anesthesia. (B) Endometrial tissue is mechanically and enzymatically dissociated into a single-cell suspension and (C) eMSCs immunoselected using SUSD2 (W5C5) antibody by magnetic bead sorting. (D) eMSCs are culture expanded in serum-free medium in physiological (5% $O_2$) hypoxia and (E) seeded on fibronectin-coated PA/G composite mesh, which is cultured for a further 48 h before transplanting into (F) small animal models (rats) and a preclinical large animal model (sheep) for proof of concept and then (G) human clinical trials.

transdifferentiated into SMCs and stratified keratin $5^+$ squamous epithelium when implanted into the injured vaginal tissue as a TE construct. α-smooth muscle actin (α-SMA) was used to evaluate the resulting tissue generated, but it could not discriminate between SMCs and myofibroblast differentiation. This is important, because the latter mediates the fibrotic process. In addition, it is unclear whether the differentiated cells had arisen from a stem cell precursor or a mixed population of heterogeneous cells. Further studies on the functional properties of the implants and their effects *in vivo* are required.

Fresh skeletal muscle fibers or cultured autologous skeletal-muscle-derived cells have also been seeded on synthetic biodegradable methoxy(polyethylene glycol)–poly(lactic–co-glycolic acid) meshes and implanted subcutaneously into the rat abdomen [31]. The TE constructs were well tolerated, and in contrast to the previous study the cultured skeletal muscle cells had disappeared by 8 weeks. However, there was generation of fragmented striated muscle tissue in the skeletal muscle fiber tissue construct [31], indicating superiority of fresh skeletal muscle fibers to culture-expanded skeletal muscle cells for surgical reconstruction in an animal abdominal wall model of POP repair surgery [31].

#### 41.4.1.2 Fibroblasts

Human vaginal fibroblasts have also been suggested as an alternative cell source for a TE approach to treat POP. Vaginal

fibroblasts were expanded, added to a collagen solution, labeled with the fluorescent dye DiL and applied to biodegradable poly (D,L-lactic–co-glycolic acid) meshes [32]. The TE construct was implanted subcutaneously into mice, where a well-organized multilayered neofascia of collagen was generated. The DiL-labeled cells survived and were identified within the construct after 12 weeks, indicating the contribution from the human vaginal fibroblasts.

The feasibility of using autologous vaginal fibroblasts for the treatment of POP is attractive; however, POP vaginal fibroblasts are less than ideal. Vaginal fibroblasts from the prolapsed site in women with POP showed delayed collagen contractility and lower matrix metalloproteinase-2 production compared with fibroblasts from normal premenopausal women [33]. The immunoreactive collagen and elastin scores of the vaginal connective tissue from women with POP were higher than with normal vaginal tissue but contained fewer fibroblasts [34]. This increased collagen staining does not accurately reflect total collagen content, nor does it take into account alterations in the ratio of type III/type I collagen. A higher ratio, as found in women with POP, is characterized by mechanically inferior tissue, suggesting that pathological changes in vaginal wall connective tissue composition changes the quality and the functional ability of the vaginal fibroblasts, and this should be considered when opting to use them [33].

Buccal mucosal fibroblasts are a readily available cell source for TE. They express the typical MSC/fibroblast surface markers, but do not differentiate into adiopogenic and chondrocyte lineages and have limited osteogenic differentiation ability. Despite this, buccal mucosal fibroblasts produce collagen I *in vitro*, an important component of extracellular matrix [35]. Cultured buccal fibroblasts attach well in heat-annealed poly(L-lactic acid) (PLA) scaffold, produce collagen and elastin under intermediate stress forces *in vitro*, and have been suggested as a cell type for use in the treatment of POP [36]. However, *in vivo* work in an appropriate animal model is required to assess the utility and long term effects of buccal fibroblasts for tissue repair.

#### 41.4.1.3 Mesenchymal stem/stromal cells

MSCs were first discovered in the bone marrow as an adherent, clonogenic, nonhematopoietic cell population that undergoes extensive proliferation in culture and differentiates into multiple mesodermal lineages, including fat, bone, cartilage, stroma, tendon, and muscle [37]. MSCs have since been identified in multiple organs, including adipose tissue, dental pulp, umbilical cord tissue, placenta, and endometrium [38,39]. MSCs are an attractive source of cells for regenerative medicine, as evidenced by the ~400 clinical trials now listed on clinical trial websites (such as ClinicalTrials.gov) and the 2000 or more patients who have received varying forms of MSC as experimental therapy without any serious adverse events [40,41]. A systematic review and meta-analysis of clinical trials involving MSCs given intravenously or intra-arterially showed systemically delivered MSCs to be safe [41]. Thus far there have been no clinical trials of MSC or cell-based therapy for POP. MSCs home to sites of tissue damage and act in a paracrine manner, secreting bioactive signaling molecules that promote angiogenesis, limit fibrosis, enhance anti-inflammatory and immune suppressive function, inhibit apoptosis, and induce tissue-specific progenitor cells to proliferate – processes that collectively repair damaged tissue [40,42]. In preclinical animal models, MSCs have also been delivered directly to damaged tissue in scaffolds as TE constructs for repairing bone, cartilage, fat, tendon, muscle, and connective tissues. Scaffolds provide structural support and sites for cell adhesion, allowing delivery and retention of large numbers of cells at the site of tissue injury [43]. In this mode the MSCs integrate and proliferate in the neotissue and/or have paracrine effects, modulating tissue repair without long-term engraftment [44]. MSCs seeded on to a scaffold deliver larger doses of secreted bioactive molecules locally to an injury site compared with systemic delivery of MSCs [42]. Preclinical studies are required to determine the efficacy of MSCs, their mechanism of action, and whether MSC-seeded materials are superior in regenerating tissues than materials alone [40].

In order to provide consistency among investigators in the definition of MSCs, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy proposed minimal criteria in 2007 to minimize experimental variability in MSC research [45]. MSCs should be more than 95% positive for the surface markers CD90, CD105, and CD73 and negative for the hematopoietic lineage markers CD45, CD14, and CD11 as well as for the co-stimulatory molecules CD80 and CD40. However, MSCs defined by such methods still include heterogeneous populations with different levels of "stemness." Thus, the markers defined above are not suitable for the prospective isolation of MSCs from tissues. Furthermore, MSCs undergo spontaneous replicative differentiation and senescence during culture expansion, losing their stemness and regenerative ability despite expression of the listed phenotypic markers [46,47]. These markers fail to discriminate between undifferentiated MSCs and differentiated mature fibroblasts (see Chapter 30). Culture conditions, including seeding density, confluency, and growth factors, also have the potential to influence MSC phenotype marker expression.

Clinical translation of MSCs for cell-based therapies includes autologous and allogeneic sources. For autologous use, the easy accessibility of a cell source is vital. Common sources, such as bone marrow and adipose tissue biopsy, involve painful procedures for procurement and require some form of anesthesia. These sources often produce low yields. A new source of MSCs from human endometrium (i.e., eMSCs) has been proposed as an alternative autologous (or allogeneic) source because of their easy accessibility (Figure 41.2E). eMSCs can be obtained via endometrial biopsy in an office-based procedure, incurring minimal pain, scarring, or morbidity, and generally do not require an anesthetic [48–50].

## 41.5 Endometrium is highly regenerative and contains stem/stromal cells

The endometrium or mucosal lining of the uterus is a dynamic tissue. Following menstruation as much as 10 mm of endometrium is regenerated in the first half of the subsequent menstrual cycle. The endometrium then differentiates in preparation to receive an embryo in the second half of the cycle, and sheds if there is no pregnancy [51,52]. This repeats for 400–500 cycles of growth, differentiation, and shedding during a woman's reproductive life. Endometrial regeneration also occurs in the postpartum period and in postmenopausal women taking estrogen therapy [53,54]. This level of cellular turnover and scarless mucosal regeneration in the endometrium is similar to that observed in other highly regenerative tissues, such as the skin, gastrointestinal tract, and bone marrow [52], where resident stem/progenitor cells have known roles in maintaining tissue homeostasis [50].

### 41.5.1 Human endometrial mesenchymal stem/stromal cells

Key properties of any stem cell include the ability to form colonies from single cells, to self-renew into daughter stem cells, and to differentiate into one or more lineages and reconstitute tissue *in vivo*. Colony-forming unit (CFU) cells were first identified in stromal cell suspensions from human endometrium in 2004 [55]. These CFUs–fibroblast (CFU-Fs) comprised 1.25% of stromal cells. There was a range of clone sizes, but only the rarer large CFUs demonstrated classic MSC properties: self-renewal *in vitro* assessed in serial cloning assays, mesodermal lineage differentiation to adipocytes, chondrocytes, osteoblasts, and myocytes, and a characteristic surface phenotype [56]. There were variations in the clonogenic activity at different stages of the menstrual cycle and in noncycling endometrium, but these differences were not statistically significant [57]. Nonetheless, 0.02% of freshly isolated endometrial stromal cells generated large colonies. Cells initiating a large colony could be serially cloned four or five times at low seeding densities (10 cells/cm$^2$) before CFU activity was exhausted, indicating extensive self-renewal capacity *in vitro* [56]. Single cells initiating the large colonies also demonstrated high proliferative ability, undergoing 30 population doublings and generating several billion cells. The culture-expanded cells from the large colonies expressed the characteristic but not unique MSC markers CD29, CD44, CD73, CD105, and CD146 and were negative for CD45, CD34, CD31, and stromal precursor antigen-1 (Stro-1) [56]. Freshly isolated endometrial stromal cells also generated colonies in serum-free medium supplemented with fibroblast-derived growth factor (FGF)-2, epidermal growth factor, platelet-derived growth factor (PDGF)-BB, or transforming growth factor (TGF)-α, although the cloning efficiency was lower in the absence of serum [55]. These findings indicate that multiple factors are likely to act as niche factors *in vivo*.

#### 41.5.1.1 Prospective isolation and functional properties of human endometrial mesenchymal stem/stromal cells

Efforts are in progress to find markers to identify MSCs in many tissues and in different species. Identification of markers for the prospective isolation of MSCs is important in order to demonstrate their location in tissues, characterize their properties and genomic signature, and to harness them for their therapeutic properties. To identify markers of human endometrial stromal CFUs, stromal cells were flow-sorted using four commonly used MSC markers (CD90, CD146, CD133, and Stro-1) and examined for CFU activity [58]. CD90$^{high}$ and CD146$^{+}$ individually enriched for stromal CFUs and immunostaining identified their perivascular location in human endometrium. Stro-1, a bone marrow MSC marker, did not enrich for endometrial stromal CFUs despite its perivascular location. Importantly, endometrial stromal cells co-expressing two markers, CD140b and CD146, contained almost all stromal CFUs and accounted for 1.5% of the total stromal cells [38]. Single CD140b$^{+}$ CD146$^{+}$ cells underwent multilineage differentiation into the typical MSC mesodermal lineages of adipocytes, chondrocytes, osteocytes, and myocytes [38]. They had the characteristic MSC surface marker phenotype and were negative for the hematopoietic markers CD34, CD31, and CD45. Together, these data showed that almost all eMSCs are found in the CD140b$^{+}$ CD146$^{+}$ subpopulation. Examining the co-expression of these two markers by immunofluorescence revealed the perivascular location of eMSCs in the layer that is shed at menstruation and in the remaining basal layer of human endometrium. Their close association with endothelial cells pointed to the likely pericyte identity of eMSCs. It was also noted that the CFU ability of the cells following flow cytometry was threefold less compared with unsorted cells, indicating that flow cytometry sorting adversely affects cell viability [58]. Therefore, it was important to find a single marker of eMSCs to enable a simpler method of enrichment using magnetic bead sorting (Figure 41.2C) [59]. Screening endometrial stromal cell suspensions with several novel antibodies with perivascular specificity [60] by flow cytometry and immunohistochemistry identified a single marker detected by the W5C5 antibody [59].

The W5C5 antibody targets the extracellular domain of Sushi domain containing 2 (SUSD2), a type I transmembrane adhesion molecule. SUSD2 has a large extracellular region containing a somatomedin B, adhesion-associated domain in MUC4 and other proteins (AMOP), a von Willebrand factor (vWF), and a Sushi domain. Although the biological function of SUSD2 is not fully known, somatomedin B, AMOP, and von Willebrand factor domains are components of proteins that participate in cell adhesion, homodimerization, migration, homing, and signal transduction [60]. Large-scale mapping of human protein–protein interactions by mass spectrometry indicates that SUSD2 may be involved in cell-to-cell binding [61]. Clonogenic bone marrow MSCs reside in the CD271$^{bright}$ but not in the CD271$^{dim}$ population. Furthermore, the W5C5 antibody

exclusively identified the CD271$^{bright}$ bone marrow MSCs but not the dim population [62]. Apart from functional and phenotypic differences, the CD271$^{bright}$/W5C5$^+$ bone marrow MSCs have bright nuclear staining compared with the dark immature lymphoblastic appearance of the CD271$^{dim}$ cells. This supports W5C5 as a promising marker candidate for isolating MSCs.

As with bone marrow MSCs, the majority of endometrial CFU-Fs are found in the W5C5$^+$ fraction. W5C5$^+$ magnetic-bead-sorted endometrial stromal cells generated more colonies than flow-cytometry-sorted W5C5$^+$ cells and flow-cytometry-sorted CD140b$^+$ CD146$^+$ cells, indicating the utility of magnetic bead sorting with a single marker. Exploring the relationship between W5C5 and existing eMSCs markers showed that 85% of fresh W5C5$^+$ cells expressed CD140b and 60% expressed Stro-1, while all the W5C5$^+$ CD146$^+$ cells were positive for CD140b. There was no difference in the colony-forming ability between the W5C5$^{hi}$ and W5C5$^+$ CD146$^+$ cells [59]. W5C5$^+$ stromal cells demonstrated typical MSC properties: mesodermal lineage differentiation into Oil Red O-stained adipocytes that expressed peroxisome proliferator-activated receptor gamma 2, osteogenic cells which stained for alkaline phosphatase and expressed core binding factor-α1, also known as RUNX, and chondrocytes surrounded by Alcian blue-positive cartilage matrix expressing collagen X. In addition, W5C5$^+$ endometrial stromal cells differentiated into early stage SMCs staining for α-SMA as well as later differentiation stages by staining for smooth muscle myosin heavy chain and to CD31$^+$ endothelial cells [59]. The surface phenotype of the W5C5$^+$ beaded population showed that they predominantly expressed CD146 and CD90, endometrial perivascular and stromal markers respectively [59]. The identification of CD140b$^+$ CD146$^+$ and W5C5$^+$ as potential markers of eMSCs and their presence in the endometrial layer that is shed during menses indicates that eMSCs can be harvested from endometrial biopsy samples as well as from menstrual blood [50]. The ultimate proof of the regenerative capability of stem/progenitor cells is their ability to reconstitute the parent tissue from which they were derived. Human vimentin-positive endometrial stromal-like tissue was generated when W5C5$^+$ eMSCs were transplanted under the kidney capsule of severely immunodeficient NOD SCID GAMMA mice [59]. In addition to the stromal-like tissue, migratory cells were also observed in the mouse kidney parenchyma, which were morphologically similar to CD31$^+$ endothelial cells demonstrated in xenografts from endometrial side population cells [63]. Therefore, both *in vitro* and *in vivo* studies have demonstrated that W5C5$^+$ eMSCs differentiate into endometrial fibroblasts and vascular cells [59,64].

Other surface markers have also been identified for isolating eMSC-like cells. Mesenchymal stem cell antigen-1 (MSCA-1) is a novel molecule on the surface of MSCs that is suitable for their prospective isolation [65]. The molecular identity of MSCA-1 is tissue nonspecific alkaline phosphatase (TNAP) [65]. TNAP/MSCA-1 co-localized with a subpopulation of CD146$^+$ endometrial cells at a similar percentage as for CD146$^+$ CD140b$^+$ eMSCs [58], but not in differentiated stromal fibroblasts from bone marrow or endometrium. TNAP/MSCA-1 is not a suitable single marker for isolating eMSCs as immuno-localization showed not only endometrial perivascular cell staining but also the luminal surface of the glandular epithelium [65]. However, co-expression of TNAP/MSCA-1 with CD146 can be used to prospectively sort and isolate eMSCs.

All specific markers identified for eMSCs (CD140b$^+$, CD146$^+$, SUSD2, and TNAP/CD146) show that eMSCs are present in both stratum functionalis and stratum basalis layers of the endometrium and are located perivascularly. Thus, it was anticipated that menstrual blood would also contain a subpopulation of eMSCs. Indeed, adherent menstrual blood cells cultured for five passages have been immunoselected with CD117 (c-kit) beads but yielded only 9% [66]. Further culturing for three more passages increased this yield to 77% of CD117$^+$ cells. However, the existence of fresh c-kit-expressing stromal cells in menstrual blood still remains to be demonstrated. Immunostaining of endometrial tissue over the lifespan from the female fetus to the atrophied tissue of postmenopausal women demonstrated that the CD117$^+$ stromal cells were present as scattered single cells in the endometrial stroma and myometrial stroma, but mostly in the endometrial glands in adult life [67]. As with TNAP, CD117 is also expressed on endometrial glandular epithelial cells. Thus, a simple isolation procedure of eMSCs without epithelial contamination is not possible with TNAP or CD117.

#### 41.5.1.2 Endometrial mesenchymal stem/stromal cell phenotype and gene expression profile

Gene expression profiling on freshly isolated endometrial stromal cells sorted using flow cytometry on the basis of CD146 and CD140b expression has provided insight into the global state of eMSCs' gene expression and their inferred functions [64]. The three cell types compared were CD146$^+$ CD140b$^+$ (eMSCs), CD146$^-$ CD140b$^+$ (fibroblasts), and CD146$^+$ CD140b$^-$ (endothelial cells) [64]. Hierarchical clustering and principle component analysis showed greater similarity of gene profiles between eMSCs and stromal fibroblasts, which were distinct from endothelial cells. Despite the relatively similar profiles of eMSCs and endometrial fibroblasts, 762 genes were differentially expressed between these cell types, approximately half the number of differences observed between eMSCs and endometrial endothelial cells. This study indicated a relatively close relationship between eMSCs and endometrial stromal fibroblasts, and that endometrial fibroblasts are a lineage cell of eMSCs. Importantly, the CD146$^+$ CD140b$^+$ population expressed significantly greater levels of the single marker SUSD2 now used to enrich for eMSCs [68].

The pericyte phenotype of eMSCs was confirmed by the expression of pericyte markers such as the regulator of G-protein signaling (*RGS5*), α-smooth muscle actin-2 (*ACTA2*), angiopoietin 2 (*ANGPT2*), insulin-like growth factors (*IGFs*), nerve growth factor (*NGF*), platelet-derived growth factor (*PDGF*), transforming growth factor-β (*TGF-β*), parathyroid hormone-like hormone (*PTHLH*), and syndecan. Gene families responsible for

self-renewal and differentiation, such as Notch, TGFB, Wnt, IGF, FGF, Hedgehog members, and cyclic adenosine-monophosphate-mediated and G-protein-coupled receptor-mediated signaling were also upregulated in eMSCs [64]. Furthermore, this study confirmed that endometrial CD140b$^+$ CD146$^+$ cells are clonogenic and can differentiate into mesodermal lineages.

Gene profiling of passage 2 culture-expanded SUSD2$^+$ eMSCs identified 12 perivascular genes upregulated in SUSD2$^+$ eMSCs. Perivascular markers, including melanoma cell adhesion molecule (CD146), vascular endothelial protein 1 (also known as amine oxidase, copper containing 3 (*AOC3*)), *NOTCH3*, a smooth muscle myosin (*MYTH11*), and elastin (*ELN*) were enriched in cultured SUSD2$^+$ eMSCs. These genes translated as the proteins were also identified around endometrial arterioles by immunostaining [69]. Desmin (DES), α-SMA (ACTA2), and chondroitin sulfate proteoglycan 4 (CSPG4), which are essential for regulating pericyte recruitment and sprouting during angiogenesis, were also highly expressed, indicative that the pericyte signature genes of the primary cells were retained in cultured eMSCs [68,69].

The Notch target genes *HEY2* and *HEYL*, but not *HEY1*, were found to be highly expressed in SUSD2$^+$ eMSCs compared with SUSD2$^-$ fibroblasts [69]. These *HEY2* and *HEYL* transcripts were significantly downregulated in human SUSD2$^+$ eMSCs treated with γ-secretase Notch inhibitor, DAPT. This was reflected by decreased SUSD2 mRNA expression and SUSD2$^+$ eMSC number to 53% and 64% respectively. This study showed for the first time that *SUSD2* is a downstream target gene in the Notch pathway in human eMSCs. Further knockdown and overexpression assays are required to confirm the involvement of Notch signaling in eMSC function. However, other signaling pathways may also be involved in eMSC regulation.

Gene profiling of freshly isolated CD140b$^+$ CD146$^+$ eMSCs did not detect the pluripotency genes *OCT4* (*POU5F1*), *SOX2*, and *NANOG* when compared with the National Institutes of Health-approved human embryonic stem cell line H7 using quantitative real time reverse transcriptase polymerase chain reaction [64]. In contrast, others have demonstrated the expression of OCT4 (POU5F1) but not NANOG [70] and the embryonic stem cell markers SSEA-4 and c-KIT (CD117) [66] using flow cytometry in culture-expanded endometrial regenerative cells cultured from menstrual blood. Some studies suggest that the *OCT4* gene is expressed by adult stem/progenitor cells and primarily regulates self-renewal, but others have shown that only pluripotent stem cells such as human embryonic stem cells and induced pluripotent stem cells express these pluripotency genes. There are at least three *OCT4* transcripts (*OCT4A*, *OCT4B*, and *OCT4B1*) and four protein isoforms (OCT4A, OCT4B-190, OCT4B-265, and OCT4B-164). OCT4A is the transcription factor responsible for the pluripotency properties in human embryonic stem cells, while *OCT4B* has no such role [71]. Many studies showing the expression of pluripotency genes, especially *OCT4* in adult stem cells, including endometrium, have failed to distinguish the *OCT4* isoforms or did not exclude the possibility of pseudogene artefacts [71].

Recently, much interest has focused on the soluble factors secreted by MSCs, the homing capacity of bone marrow MSCs to sites of injury, and their immune modulatory and paracrine properties. These include secretion of vascular endothelial growth factor, hepatocyte growth factor, TGF, and prostaglandin $E_2$.

A recent *in vitro* study highlighted the role of eMSCs in endometrial stromal cell decidualization (differentiation) and potentially in placentation [68]. A secretome analysis on passage 2 of SUSD2$^+$ eMSCs and SUSD2$^-$ endometrial fibroblasts following induction of decidualization (differentiation) *in vitro* with a cyclic adenosine monophosphate analogue and a stable progesterone (medroxy progesterone acetate) showed that decidualized eMSCs differentially secreted 12 immunomodulatory and trophic factors compared with SUSD2$^-$ fibroblasts. There was a 43-fold increase in secretion of chemokine ligand-7 (capable of attracting monocytes, lymphocytes, granulocytes, natural killer cells, and dendritic cells) and an 18-fold increase in secretion of leukemia inhibitory factor (which is a multifactorial cytokine indispensable for embryo implantation and stromal cell decidualization, as well as having roles in trophoblast attraction and differentiation). In contrast, the SUSD2$^-$ fibroblasts had only a fivefold and fourfold increase of these cytokines respectively. Therefore, eMSCs may not only have a role in the decidual response but may also function as a key immune modulator, particularly for the establishment of pregnancy given that the fetus is an allograft.

It is likely that eMSCs also have a homing capacity as they show high levels of CXCR4, a chemokine receptor for stromal-cell-derived factor 1, which is a potent chemoattractant that enables migratory activity through tissues and is upregulated in eMSCs. Furthermore, eMSCs display low levels of major histocompatibility complex class I antigens and lack major histocompatibility complex class II molecules, indicating their likely low immunogenicity. Because of these characteristics, eMSCs have been suggested as a possible source of cells for cell-based therapies and TE.

## 41.6 Culture expansion of endometrial mesenchymal stem/stromal cells toward current good manufacturing practice conditions

Adult stem/progenitor cells in the tissues are rare and account for around 1% of the total tissue. In bone marrow, MSCs account for less than 0.01% of marrow cells, which decreases even further with age [72,73]. In the endometrium, clonogenic MSCs account for around 1–5% of the stromal cells [38,59]. Owing to their limited number in tissues, MSCs need to be enriched using specific markers (see earlier) and then expanded in tissue culture to obtain sufficient numbers of cells for clinical trials. To date, there are no standard culture conditions that satisfy the growth of

MSCs from all tissue types. For clinical translation, culture of MSCs ideally requires serum and xeno-free conditions compliant with current good manufacturing practice. Using Xcelligence and cell viability assays, fibronectin was identified as a superior attachment factor for eMSCs compared with collagen, gelatin, or Cell Start XF [74]. In comparison with various serum-free media (designed for bone marrow MSC culture), an in-house serum-free medium supplemented with FGF-2 and epidermal growth factor and cultured in physiological oxygen concentration (5% $O_2$) was found optimal for eMSC growth. Under these conditions the cultured eMSCs retained their surface phenotype, cloning efficiency, and multilineage differentiation ability [74]. Substitutes for fetal calf serum include human serum, human platelet lysate, or chemically defined serum-free media [75–77]. However, serum and platelet lysates are complex products with many undefined components and significant lot-to-lot variation, hindering the development of a uniform approach to MSC expansion. Serum-free medium supplemented with chemically defined growth factors and other small molecules is the likely approach for future eMSC expansion.

Not all serum-free media support MSC growth equally [74,78,79]. For example, eMSCs grew well in Lonza-TP-SF medium, but underwent early differentiation, as demonstrated by loss of the MSC markers CD140b, CD146, and SUSD2 but not the characteristic MSC markers CD73, CD90, and CD105, highlighting the inability of classic MSC markers to distinguish MSCs from fibroblasts [74] (and see Chapter 30). Similarly, MSCs derived from umbilical cord and from adipose tissue were supported by StemPro XF medium containing 2% human serum supplementation and by xeno-free medium (RegES) respectively [75,80]. This suggests that optimal culture conditions may need to be defined for each MSC source because MSCs from different tissues have subtly different microenvironments *in situ* by which they maintain tissue homeostasis [74].

## 41.7 Tissue engineering for pelvic organ prolapse repair

Having developed a new mesh material more closely simulating vaginal tissue biomechanics and having characterized a new source of easily obtainable eMSCs, a TE construct comprising eMSCs and PA/G was developed (Figure 41.2E). *In vivo* evaluation of this TE construct comprising passage 6 eMSCs labeled with Vybrant DiO dye showed that eMSCs attached well on the PA/G mesh (Figure 41.2E). The labeled cells could be identified *in vitro* for up to 35 days and *in vivo* for at least 14 days [49]. In a wound-healing fascial defect model the PA/G–eMSCs TE construct (Figure 41.2E) was implanted subcutaneously in the dorsal region of a nude rat and studied for 3 months (Figure 41.2F). PA/G–eMSCs mesh promoted early neovascularization at 7 days, as assessed by α-SMA immunostaining and image analysis. A greater initial influx of $CD45^+$ leucocytes, predominantly proinflammatory type M1 $CCR7^+$ macrophages, was observed at 7 days in the PA/G–eMSCs mesh, but by 30 days a prohealing M2 $CD263^+$ macrophage phenotype predominated. (CD263, otherwise known as TRAIL-R3, is present on neutrophils and macrophages and is a glycophosphatidylinositol-anchored protein that lacks the cytoplasmic death domain. Thus, it is unable to induce apoptosis and serves as a negative regulator of apoptotic signaling by competing for binding of TRAIL with death receptor 5.) In comparison, the PA/G mesh alone elicited a smaller M1 response at 7 days, which was still predominant at 30 days [49]. By 90 days, significantly fewer $CD68^+$ macrophages surrounded the PA/G–eMSCs mesh filaments compared with PA/G mesh alone. The collagen deposited around the mesh was of rat origin identified by a specific anti-rat-collagen antibody. There was no difference between the total collagen production in the mesh with or without cells or in the ratio of collagen III/collagen I + III over 90 days of implantation (Figure 41.3A). Picrosirius red (Figure 41.3B) also showed similar total collagen content, but birefringence analysis showed that the quality of collagen fibrils laid down differed between the mesh alone and the eMSC-seeded mesh, which comprised well-organized physiological thin fine fibrils (Figure 41.3D) with crimping (Figure 41.3F) [81]. In comparison, the PA/G alone resulted in a greater proportion of dense bands of scar-like fibrils (Figure 41.3C) and without crimping (Figure 41.3E) [49,81]. These differences may have contributed to the biomechanically less stiff and more extensible mesh/tissue complex generated from the eMSC-seeded mesh, suggesting greater compliance and matching to the soft tissue of the vaginal wall than those without cells (Figure 41.4). Such new tissue deposition and biomechanical properties in the eMSC-seeded mesh implants are likely to be more favorable for vaginal tissue repair by allowing greater mobility [49].

The PA mesh with gelatin (10% w/v in $H_2O$) cross-linked with glutaraldehyde (0.025% w/v) was optimized for eMSCs growth and gelatin degradation *in vitro* [82]. Endometrial eMSCs differentiated into SM22-α (a marker of adult smooth muscle) and smooth muscle myosin-heavy-chain-expressing SMCs on the PA/G mesh in serum-free induction medium containing TGF-β1 and PDGF. eMSCs also differentiated into fibroblast-like cells on the PA/G mesh in 10% serum-supplemented induction media containing connective tissue growth factor (CTGF) and ascorbic acid. CTGF, also known as CCN2, is a matricellular protein of the CCN family of extracellular-matrix-associated heparin-binding proteins. The CTGF-differentiated cells produced collagen I and Tenascin-C, with total collagen production and Masson's trichrome staining indicative of new tissue formation. Tenascin-C is important in regulating cell proliferation and migration, especially during developmental differentiation and wound healing.

SMCs and fibroblasts are vital cellular components required for regenerating the fibromuscular wall of the human vagina, to provide elasticity and strength [82]. However, in the *in vivo* rat model of fascial repair the SMCs and collagen produced were of rat origin, suggesting that the human eMSCs mediated their effects by an induced paracrine mechanism [49]; this is possible given the secretome of cultured W5C5/$SUSD2^+$ eMSCs [68]. To

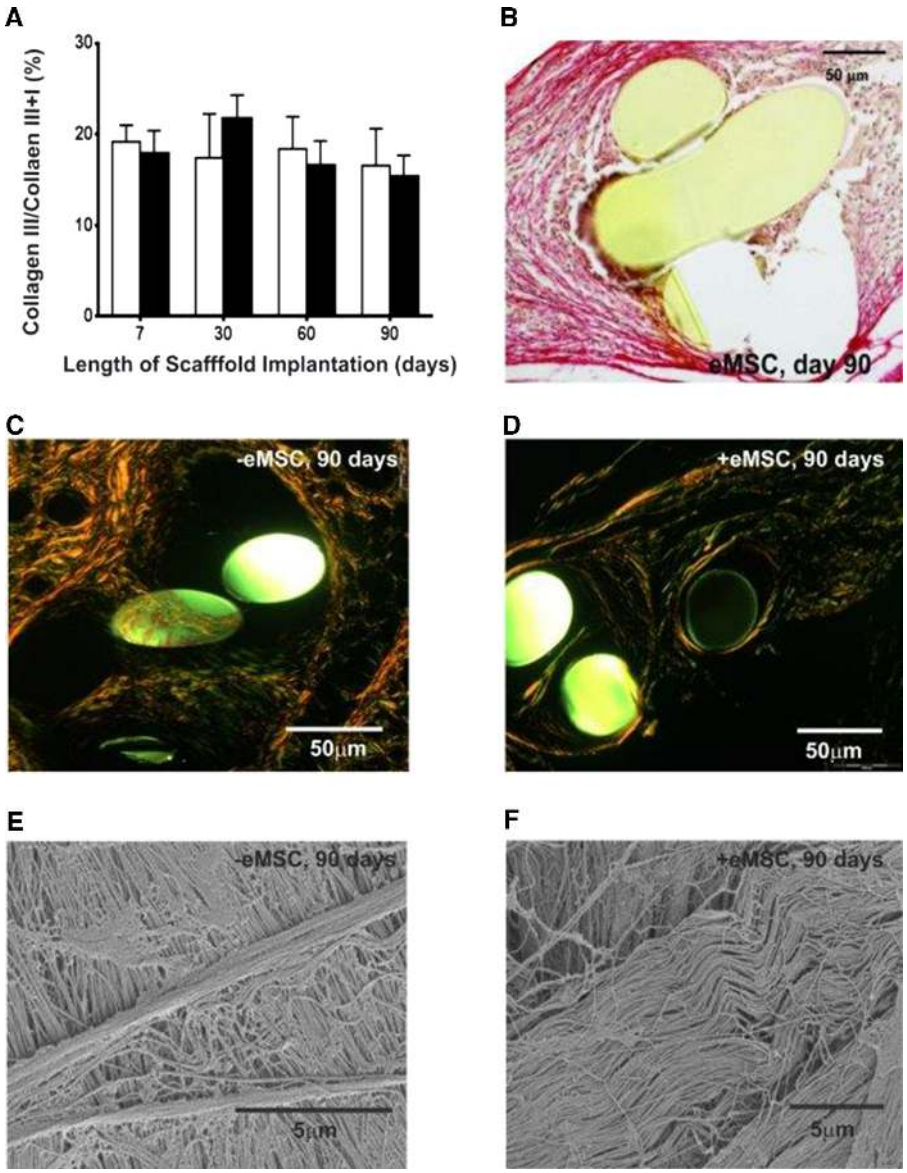

**Figure 41.3** Collagen assessment in explanted PA/G meshes with or without eMSCs. (A) PA/G meshes with (black bars) or without (white bars) eMSCs were subcutaneously implanted in the dorsal region of immunodeficient nude rats. The tissue constructs were explanted and the percentage of total collagen III within and around the meshes was determined by sodium dodecyl sulfate polyacrylamide gel electrophoresis. The percentage of collagen III changed little over the period of time in the two groups. Data are mean plus/minus standard error of the mean of $n = 8$ animals/group. (B) Conventional light microscopy image of Sirius-red-stained section to show collagen in explanted PA/G–eMSC mesh construct after 90 days. (C,D) Birefringence microscopy images of Sirius-red-stained sections from explanted PA/G mesh (C) and PA/G–eMSC mesh (D) after 90 days assessed using and scored according to the presence of predominantly thick (orange, red) or thin (green) birefringent collagen fibers. Rats implanted with PA/G–eMSC mesh had a greater number of thin collagen fibers, while the mesh alone had more dense and thick collagen fibers. (E,F) The explanted PA/G meshes with (F) or without (E) eMSCs were carefully extracted from the surrounding muscle and processed for scanning electron microscopy. The micrographs were taken at 1.2 kV using a Schottky field-emission variable pressure scanning electron microscope. Unseeded mesh had relatively narrow collagen bundles (up to 1.3 mm in width) with straight collagen fibrils. Seeded mesh consisted of wider collagen fiber bundles (up to 8 mm in width) with crimped configuration. (See color plate section.) *Source*: reproduced with permission from Mary Ann Liebert Inc. publishers from Ulrich *et al.* [49] *Tissue Engineering A* 2014 and Elsevier from Edwards *et al.* [81] *Acta Biomateriala* 2015.

confirm whether eMSCs are capable of producing collagen and modulating biocompatibility of the PA/G mesh *in vivo* in the vaginal environment, a preclinical large animal model of vaginal repair was required (Figure 41.2F). Currently, this new PA/G–eMSCs TE construct appears promising for POP corrective surgery.

In another study, seven different candidate materials, both biological and synthetic (AlloDerm, porcine dermis, PP, sheep

forestomach, small intestine submucosa, acellular cadaveric dermis, and PLA scaffold), were assessed *in vitro* for cell attachment, contracture, and extracellular matrix production [83]. Alloderm is a commercially produced acellular dermal matrix. Among these materials, biodegradable PLA and SIS meshes seeded with human buccal fibroblasts showed favorable *in vitro* properties for potential clinical use. For example, these TE constructs increased new extracellular matrix production, particularly collagens I and III and elastin. Both collagen types are a vital component of the extracellular matrix, but the ratio of collagens I and III was not addressed. The biomechanical properties of the PLA mesh with or without buccal fibroblast seeding showed that strength, strain, and Young's modulus for the PLA tissue construct were similar to the biomechanical properties of native tissue from women without pelvic dysfunction [84]. Similar findings were observed when adipose-derived MSCs were used with the PLA mesh [36]. Young's modulus, also known as the tensile modulus or elastic modulus, is a measure of the stiffness of an elastic material. It is defined as the ratio of the stress (force per unit area) along an axis to the strain (ratio of deformation over initial length) along that axis. A rubber band, for example, has an extremely low Young's modulus.

In a rat model with PLA mesh seeded with or without cultured human or rat adipose-derived MSCs and implanted for 7 days, angiogenesis was only promoted in the cell-seeded mesh, as demonstrated by CD31 (platelet endothelium adhesion molecule-1, an endothelial marker) immunostaining [85]. Deposition of collagens III and I was demonstrated qualitatively by immunohistochemistry, and increased macrophage infiltration and foreign body reaction was shown by CD68 immunohistochemistry. CD68 is a glycoprotein that binds to low-density lipoprotein and is only expressed on monocytes and macrophages. There was no difference in the macrophage infiltration in the seeded and unseeded meshes, and macrophages enclosed the PLA fibers, indicating an innate immune response to the synthetic material. This 7-day study with PLA examined the short-term acute effects of fibroblasts on implanted meshes; the long-term effect of the scaffold plus cells still needs to be demonstrated. In both these studies, extracellular matrix deposition increased when fibroblasts were delivered on meshes, but there is a need for long-term *in vivo* studies to assess whether the cells make a difference in extracellular matrix production and strength and longevity of the implant. All these studies highlight that cellular therapy may significantly improve mesh biocompatibility for POP by modifying the host response to the mesh material.

### 41.7.1 A large animal preclinical model for pelvic organ proplapse

Animal models of POP are vital in providing preclinical data prior to testing any new TE approach in women. There is no perfect animal model to study POP owing to its multifactorial etiology. Humans are bipedal with a unique pelvic orientation, not recapitulated in most mammalian species. Nonhuman primates, including rhesus and squirrel monkeys, are the best animal model for POP study as they develop spontaneous prolapse similar to women [86]. These nonhuman primates are bipedal for some of the time and have similar anatomical and histological pelvic structures to humans. Their reproductive cycle and pregnancy outcome closely match those of humans. However, nonhuman primate models are limited by ethical issues, their short life span, lengthy pregnancy duration before developing POP, and prohibitive costs [86].

The sheep is a quadripedal large animal that has similar pelvic tissue anatomy, histology, size, and vaginal dimensions but a larger fetal head/maternal pelvis ratio than women [86,87]. Ewes have the same three pelvic support structures as women and their pelvises experience increased internal pressures due to their ruminant anatomy, offsetting some of the disadvantage of being quadrupedal [86]. Like humans, sheep have prolonged labors with relatively large fetuses and spontaneously develop antepartum uterovaginal prolapse at the same frequency (8–12%) as women develop chronic POP. Ovine prolapse is associated with age and pregnancy, similar to the situation in women [86]. Regional variation in the biochemical composition of the ovine vagina was discovered in a comparative study of the posterior vaginal wall in postmenopausal women and in a sheep model [88]. Total collagen and elastin tissue-associated protein content in the vaginal wall in the two species were similar. The proximal region near the cervix of the ovine vagina had significantly higher collagen and glycosaminoglycan content compared with the distal region. The proximal ovine vagina was also much

stiffer, stronger, and more elastic than more distal regions, in contrast to human vaginal tissues. There was a significantly increased percentage of type III to type I collagen (40%) in human compared with ovine vagina [88]. The increase in type III collagen in postmenopausal women correlates with their propensity to develop prolapse. The similarity between women and sheep in the biochemical composition and histology of the vaginal wall complements the similarity in the biomechanical properties and therefore makes the sheep a good preclinical model for vaginal studies involving POP (Figure 41.2F).

## 41.8 Conclusions

Endometrium is a highly regenerative tissue and it is likely that adult stem/progenitor cells are responsible for its cyclical growth, differentiation, and regression. Rare populations of perivascular human MSCs have been identified in both the functional (shed) and germinal layers of the endometrium. These eMSCs are present at all stages of the menstrual cycle, as well as in inactive and atrophic postmenopausal endometrium. eMSCs can be harvested from endometrial biopsies in an office-based procedure with minimal discomfort and without the use of anesthesia, making the endometrium an attractive, although still underrecognized, alternative source of MSCs. Importantly, eMSCs can be enriched by magnetic bead selection using the W5C5 antibody or by flow cytometry sorting using CD140b and CD146 antibodies, removing contaminating stromal cells or leucocytes not possible when using plastic adherence for MSC isolation. eMSCs are clonogenic, can self-renew *in vitro*, display multipotent differentiation into mesodermal lineages *in vitro*, and generate endometrial stromal-like tissues and vascular cells *in vivo*.

Newly fabricated polyamide–gelatin composite meshes are superior to commercially available PP meshes, promoting neovascularization, collagen deposition, and minimizing inflammatory cell infiltration. These properties were further augmented when eMSCs were integrated with PA/G mesh as a TE construct and implanted into a fascial defect in rats. The eMSCs initiated a vigorous M1 macrophage influx and promoted their differentiation to a wound-healing M2 phenotype. eMSCs promoted the deposition of physiological fibrilar, crimped nonscarring collagen fibers, significantly improving the biocompatibility and the biomechanical properties of the explanted mesh–tissue complex. These are favorable and promising profiles of the PA/G–eMSCs TE construct.

Substantial progress has been made in examining the utility of these TE constructs in a small animal model, but to take this approach to the clinic for the treatment of POP, more studies examining the mechanism of how eMSCs exert their anti-inflammatory effects are required. Finally, an autologous large animal model using the sheep will provide the necessary preclinical data for translation as a potential treatment for POP in women.

## 42.1 Introduction

Over 600 clinical trials using mesenchymal stromal cells (MSCs) or mesenchymal stem cells have been listed on ClinicalTrials.gov if you type into the search box either mesenchymal stromal cells or mesenchymal stem cells. This site is run by the United States National Library of Medicine (NLM) at the National Institutes of Health. Obtaining MSCs for clinical trials is a cumbersome, time-consuming, and laborious process when done manually (see Chapters 3–5 and 7). In addition, the prolonged period of *ex vivo* expansion includes the risk of the cells becoming microbially infected. Thus, we attempted to develop an automated closed system that could be scaled up for manufacturing MSCs for clinical trials. We chose term placenta obtained at elective cesarean section, since this provides a large amount of biomaterial rich in these cells that would otherwise have been discarded. The rate of elective cesarean sections performed at term in Australia is between 30 and 50%, making access feasible. We had shown previously that adult human MSCs derived from term placenta were similar to those derived from adult human bone marrow in terms of cell surface phenotype, ability to suppress T cell alloproliferation in *vitro*, and with similar differentiation ability *in vitro* to chondrogenic and osteogenic lineages [1,2]. They did not differentiate to adipogenesis to the same degree as that of marrow-derived MSCs [1], and the gene expression profiles differed to some extent [3]. However, we have found them safe when injected intravenously in people with idiopathic pulmonary fibrosis in a phase I clinical trial [4] and capable of regenerating new tendon tissue when injected directly into the Achilles tendon in people with chronic Achilles tendinopathy refractory to surgery or exercise programs (Young *et al.*, unpublished results, and see Chapter 47).

## 42.2 Design of a semi-automated closed-system bioreactor capable of manufacturing mesenchymal stromal cells for clinical use

We employed a noncontact paddle blender for semi-automated processing of term placentas. In these blenders the tissue was placed into a sterile sample bag that was then subjected to a crushing action by alternating compression of the contents by mechanical paddles. An enzyme digest solution was added to the bag prior to blending in order to facilitate the release of cells from tissue fragments [5].

Various seeding and culture formats were explored. These included static dishes/flasks, static tubes, shake tubes, shake flasks, and spinner flasks. The most consistent performance was ultimately achieved by overnight seeding under

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.
© 2017 John Wiley & Sons, Inc. Published 2017 by John Wiley & Sons, Inc.

static conditions in a minimum amount of complete medium. After 6–7 days culture in the same medium as above, microcarriers were collected into sterile tubes, washed with Hanks' balanced salt solution, and the cells released by enzymatic treatment. Microcarriers screened for placental MSC culture included Cytodex 1, Cytodex 3, CultiSpher-S, Hillex II, MicroHex, Cytopore 1, and Cytopore 2. CulltiSphere-S was selected for subsequent experiments. Following further washing in Hanks' balanced salt solution to remove enzymes, cells were reseeded on to fresh microcarriers. Wave-type bioreactor microcarrier culture CultiSpher-S microcarriers were introduced to 2 L CultiBags or Cellbags. Cells were then similarly introduced in a minimal volume of medium and the bag gently rocked several times in order to distribute the cells amongst the microcarriers. Following incubation of cells with microcarriers for 18 h, culture medium was collected by decanting [5].

The blender-based approach was capable of processing an entire placenta in 1.5–4 h. We found that neither our blender-based approach to isolation, nor subsequent cultivation on CultiSpher-S microcarriers altered the MSC phenotype relative to standard flask expansion. There was no indication that cultivation of human placental MSCs on CultiSpher-S was detrimental to the final cell product. Although simple, our isolation and culture methods were highly effective. We found that cultivation of MSCs from a single 500 g placenta over four serial passages would have the potential to produce more than 7000 doses per placenta in a scaled-up version of this bioreactor system.

## 42.3 A commercially available closed-system bioreactor for manufacturing mesenchymal stromal cells for clinical use

Terumo BCT sell a machine called the Quantum™ specifically for manufacturing cells, including MSCs, for clinical purposes. The Quantum system's 3D, functionally closed bioreactor contains about 11 500 hollow fibers with a surface area of 2.1 $m^2$, which is equivalent to the surface area of 120 T175 flasks. The bioreactor's design and small footprint of 0.3 $m^2$ footprint allow more effective use of laboratory space. The Quantum system can replace the need for an incubator, a biosafety cabinet, and a clean room, which are typically required for flask-based culture methods and which are expensive to operate. It is a functionally closed system with temperature and gas control.

The large surface area is designed to maximize adherent cell expansion in a minimal amount of space. The bioreactor provides a defined and stable geometry that allows for the control and management of the cell culture environment. The closed environment of the bioreactor remains intact during the cell culture process, removing open events and hands-on tasks associated with manual flask-based culture methods. The Quantum system uses a number of predefined tasks that can be customized to replicate the manual cell culture process for a range of adherent cell types, including mesenchymal stromal cells. These tasks include automated cell seeding, reagent addition, feeding, and harvest. Continuous temperature control, cell feeding, and waste removal provide process control over the cell culture environment. A direct gas connection allows operators to control the cell culture environment, enabling any gas blend connection to the Quantum system.

An internal investigation by Terumo BCT demonstrated that hypoxic and normoxic conditions had no significant difference on cell yield, viability, phenotypic, morphologic, or differentiation potential. The Quantum system is controlled by a touchscreen user interface, which allows operators to monitor and adjust cell culture process parameters. The Quantum system provides reporting, remote alarms, user authentication, and power failure recovery features, providing more control over the cell culture process, aiding in current good manufacturing practice and associated compliance.

The system includes four primary phases. First, the Quantum system is primed as the nutrients, metabolites, and gases diffuse across the fibers in the bioreactor. Second, cells are loaded into the bioreactor. Third, media exchange begins with the continuous control of temperature, cell feeding, and waste removal. Finally, cells are harvested in as little as 20 min.

The National Institutes of Health analyzed bone marrow stromal cells (BMSCs) from the Quantum system to determine if they retained their differentiation potential. It was found, first, that cell yields in all test cases were higher when cells were grown in the Quantum system compared with cell factories. Second, BMSCs grown in the Quantum system were found to have similar phenotypes when compared with BMSCs grown in cell factories. Lastly, BMSCs from both the Quantum system and cell factories were able to differentiate into adipocytes.

Lechanteur *et al.* compared the Quantum device with traditional clinical culture system in flasks [6]. They found that the Quantum device reproducibly produced therapeutic MSC doses that fulfilled the International Society for Cell Therapy release criteria, were sterile, devoid of mycoplasma and endotoxin, had normal karyotypes, and demonstrated immunosuppressive and differentiation capacities *in vitro*. Cells grew faster in the bioreactor than in flasks during passage P1 (doubling time 40 h compared with 56 h in flasks) and P2 expansions but not during the primary expansion phase (P0). Seeding $20 \times 10^6$ thawed P2-preselected cells on the device allowed harvesting of $110–276 \times 10^6$ MSCs after a 7-day expansion. Seeding $50 \times 10^6$ cells resulted in $291–334 \times 10^6$ harvested MSCs. If MSCs become part of mainstream medicine, it appears that such a system will be infinitely cheaper and safer to use than the manual methods currently still used at many institutions for manufacturing MSCs.

## 43.1 Source of mesenchymal stromal cells for use in clinical trials

Bone marrow has been the traditional source of mesenchymal stromal cells (MSCs), but, because MSCs are components of blood vessel walls, they can be isolated from any vascularized organ or tissue [1]. Ideally, sources that are easily accessible and contain large amounts of tissue are the most useful. MSCs have been isolated from blood and bone marrow, adipose tissue, amniotic fluid, umbilical cord blood, umbilical cord including Wharton's jelly and perivascular tissue, first trimester fetal liver, and second trimester fetal liver, lung, bone marrow, and pancreas, as well as from term placenta and amniotic and chorionic placental membranes. Gestational sources can be collected at delivery or from prenatal diagnostic specimens such as amniotic fluid. The latter can be sourced by the minimally invasive technique of amniocentesis, or obtained peripartum from otherwise discarded tissue.

We compared human term placenta-derived MSCs with human bone-marrow-derived MSCs and could find no significant difference in their ability to suppress T cell alloproliferation *in vitro* [2], cell surface phenotype, cytokine receptor display, or mesodermal lineage differentiation to osteogenic and cartilage lineages *in vitro* [3]. Placenta-derived MSCs, however, consistently showed less differentiation ability to adipogenesis *in vitro* compared with marrow MSCs [3]. Additionally, gene array expression has revealed differences between human MSCs derived from adult bone marrow and those derived from term placenta [4]. Whether these differences affect functional outcome when the placental MSCs are administered for a specific indication is currently unknown, although the results of trials in which our placenta-derived MSCs have been used have been encouraging (see later).

Since obtaining 50 mL of bone marrow from a normal volunteer donor is a painful procedure, and because we had on campus

a maternity hospital in which 10 000 babies were born each year, 40% of them by elective cesarean section (C section) at term, we elected to use term placenta-derived MSCs for our MSC clinical trials program.

## 43.2 Inclusion criteria for mothers wishing to donate their term placenta for isolation and expansion of mesenchymal stromal cells for use in clinical trials approved by a human research ethics committee

All mothers giving birth by elective lower segment C section at the Mater Mothers Hospital, Brisbane, Australia, who had signed informed consent and who did not fulfill any of the exclusion criteria listed in Section 43.3 were included in the phase 1 clinical trials described later in this chapter.

## 43.3 Exclusion criteria for mothers wishing to donate their term placenta for isolation and expansion of mesenchymal stromal cells for use in clinical trials approved by a human research ethics committee

We imposed strict exclusion criteria on the selection of mothers who agreed to donate their term placenta. First, we included all the exclusion criteria used by the Australian Red Cross for excluding blood donors. Second, because term placenta includes tissues of fetal origin (the amniotic and chorionic membranes) as well as tissues of maternal origin (the decidual placenta), we added all the exclusion criteria of the Australian Cord Blood Registry (AusCord) not listed by the Australian Red Cross.

Donors of placenta were required to undergo a blood test to determine their serological status of the following: the presence of hepatitis B surface antigen, and antibodies against hepatitis A, hepatitis B, hepatitis C, human immunodeficiency virus (HIV) I/II, human T cell leukemia virus I/II, Epstein–Barr virus, cytomegalovirus (CMV), herpes simplex virus, varicella-zoster virus, syphilis, and toxoplasmosis.

Maternal donors had to be seronegative for all of the serological tests with the exception of CMV, Epstein–Barr virus, herpes simplex virus, varicella-zoster virus, and toxoplasmosis. However, MSCs manufactured from CMV-seropositive mothers were not given to clinical trial subjects who were CMV seronegative.

In addition, the following exclusion criteria were applied.

- A previous or current serious blood disorder.
- A previous or current cancer, except adequately treated basal cell carcinomas of the skin or adequately treated carcinoma *in situ* of the uterine cervix.
- Known carriers for, or mothers with partners who were considered to have, risk factors for any infectious disease transmissible by blood product transfusion, including hepatitis B and C, HIV, human T cell leukemia virus I/II, and syphilis.
- A serious infections during pregnancy.
- Residence in the United Kingdom during the period between January 1, 1980, and December 31, 1996, for a period of more than 6 months or if visits on several occasions during those years added up to a total of more than 6 months.
- Age less than 18 years old or more than 45 years old.
- Less than 36 weeks' gestation at the time of delivery or with a multiple pregnancy.
- Refusal to have their blood tested for sexually transmitted diseases or the serology tests described earlier.
- Use of intravenous drugs not prescribed by a doctor.
- Prior treatment with clotting factors such as factor VIII or factor IX.
- An inherited blood disorder, such as Fanconi anemia, Blackfan–Diamond syndrome, pyruvate kinase deficiency, thalassemia, hereditary spherocytosis, or hereditary ellliptocytosis.
- Multiple sclerosis, myasthenia gravis, or polymyositis.
- Receipt of injections of human pituitary hormone for infertility injections or human growth hormones for short stature before 1986.
- A previous allogeneic organ or tissue transplant (e.g., a corneal transplant, a skin graft, a hematopoietic stem cell transplant, a kidney, liver, lung, heart, or pancreas transplant) or a dura mater patch.
- Creutzfeldt Jakob disease (or its variant), familial insomnia or Gerstmann Staussler Scheinker disease, or Chagas' disease.
- Sexual contact with a person known to have been exposed to HIV.
- Sexual contact with a male who had sexual contact with another male in the preceding 5 years.
- Sexual contact with a person who had had sexual contact with a male or female sex worker.
- Shared needles or syringes for drug abuse, or had
  - a blood products transfusion or an intra-uterine transfusion within the preceding 12 months;
  - injury with a used needle/syringe;
  - a blood/body fluid splash to eyes, mouth, nose, or broken skin;
  - jaundice or hepatitis or contact with a person who had had malaria, Ross River fever, dengue fever, leptospirosis, Q fever, brucellosis, or worked in an abattoir.
- Serious heart disease, including cardiomyopathy, myocarditis, pericarditis, or rheumatic heart disease.
- On immunosuppressive therapy during pregnancy (such as corticosteroids for autoimmune disorders, including ankylosing spondylitis, multisystem autoimmune disease, systemic lupus erythematosus, polymyositis, or rheumatoid arthritis).
- A history within the last 6 months of persistent fevers, night sweats, diarrhea, or lymphadenopathy.
- Infectious mononucleosis or pancreatitis within 1 month.
- Active genital herpes, chicken pox, herpes zoster, meningitis, amebic dysentery, shigella or salmonella infections, food

poisoning, giardia infection, viral infection of unknown cause, Coxsackie virus, or yersinia infection within the last 2 weeks.
- Antibiotic therapy for any named or other illness within the last 2 weeks.
- Refusal to sign the Placenta Donation Declaration form.

## 43.4 Mesenchymal stromal cell manufacturing

### 43.4.1 The good manufacturing process facility

This must be a facility approved by the Therapeutic Goods of Australia for cell manufacturing and cell banking. While the current federal law does not mandate the use of such a facility for phase 1 clinical trials, we elected to use such a facility in order to maximize the safety and reproducibility of the MSC product, as well as maximally protecting the manufacturing scientists and the reputation of the institution.

Significant preparation is required before starting the manufacturing procedure. Gowning including double gloving is required (Figures 43.1 and 43.2).

The anteroom and the clean room must have been prepared before the gowned scientists and quality control personnel enter the facility.

Environmental monitoring takes place before and during the manufacturing procedure (Figure 43.3).

**Figure 43.1** Gowning prior to entering the clean room.

Finger swabs taken from each person entering the anteroom or the clean room were an important part of this monitoring (Figure 43.4).

### 43.4.2 Quality control and quality assurance

Quality control (QC) and quality assurance (QA) are pivotal to current good manufacturing practice (GMP). We wrapped our MSC manufacturing procedure in a tight series of standard operating procedures and protocols. Any deviation from one of these documents raised an immediate warning that was investigated and dealt with as quickly as possible. Our QC/QA program contained over 2000 documents and required a 0.5 full-time equivalent person to build it and manage it.

### 43.4.3 Isolating and expanding mesenchymal stromal cells from human term placenta

The MSCs isolated and manufactured in *ex vivo* expansion cultures were obtained from the term placenta of women undergoing elective C section delivery at term. Using good clinical practice, good laboratory practice, and GMP, the placental tissue was received in the clean room of the GMP facility (day 0). The umbilical cord was drained. The whole placenta was then cut into small pieces using scalpels and scissors (Figure 43.5).

Dissected pieces of placental tissue were washed in Hanks' buffered salt solution to remove excess blood, transferred to tubes and digested for 3 h at 37 °C with collagenase I and DNase I. The tissue was then passed through a cell strainer and washed. Red cells were removed using a red cell lysis agent and the remaining cells were resuspended and cultured in Dulbecco's minimal essential medium/10% fetal calf serum. After 24 h, nonadherent cells were washed off and the remaining cells maintained in culture at 37 °C in 5% $CO_2$ and 20% $O_2$. At 80–90% confluence the cells were passaged. This occurred approximately once weekly (Figures 43.6 and 43.7).

At the end of each passage the cells were harvested; all cells from a given passage were pooled and were frozen using a controlled-rate freezer to −90 °C, when they were cryopreserved in the vapor phase of liquid nitrogen. A sample from each pooled passage was sent for the tests indicated in Section 43.3.4. In addition, a small cryovial was attached to each bag or vial intended for use in a clinical trial. Three weeks prior to the planned MSC administration date, this vial was thawed and tested, again as indicated in Section 43.3.4. MSCs obtained by this procedure expressed CD29, CD44, CD73, CD90, CD105, CD166, and major histocompatibility complex (MHC) class I and did not express CD34, CD45, CD14, or MHC class II. An overview of the manufacturing process is shown in Figure 43.8.

### 43.4.4 Testing performed on mesenchymal stromal cells manufactured for clinical use

Tests performed on each passage of manufactured MSCs at the time of cryopreservation and criteria for their acceptability were as follows:

**Figure 43.2** The anteroom and clean room.

**Figure 43.3** Environmental monitoring.

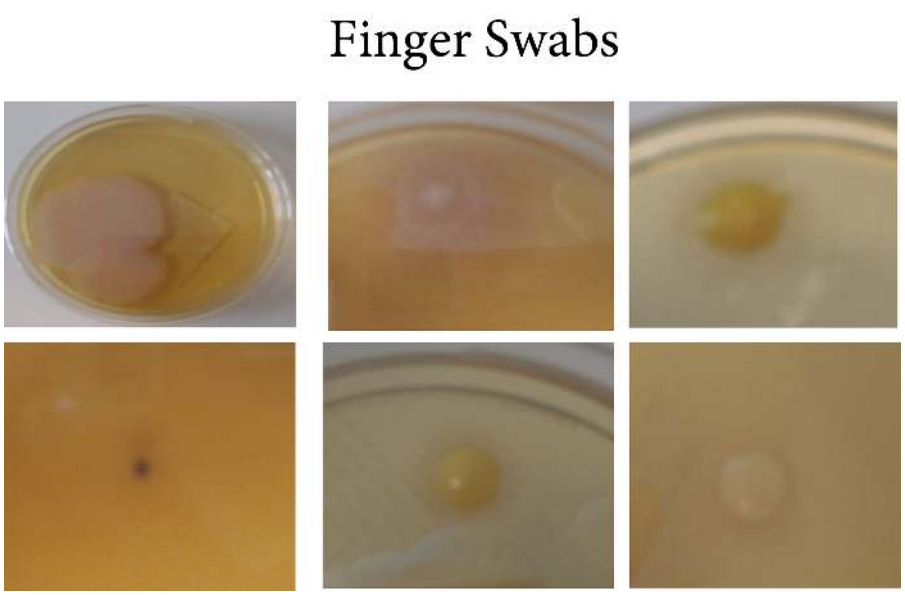

**Figure 43.4** Microbial cultures of finger swabs from the production scientists.

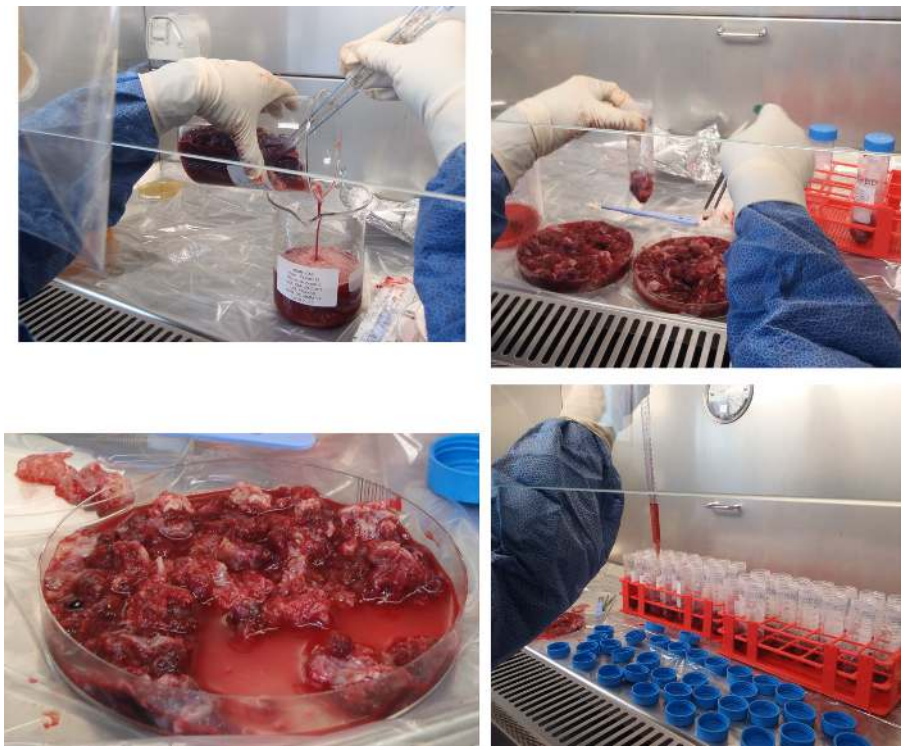

**Figure 43.5** Dissection of human placenta using scissors and scalpels prior to enzyme digestion.

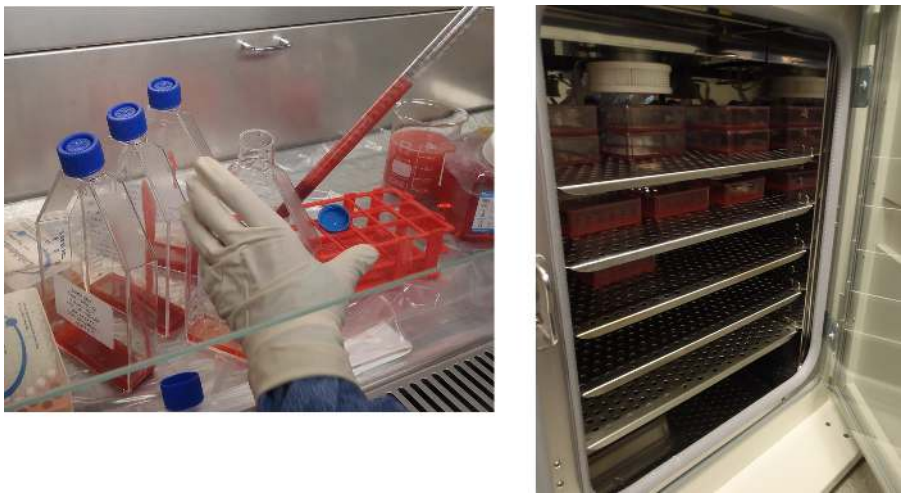

**Figure 43.6** *Ex vivo* expansion at 37 °C in 5% $CO_2$ and 20% $O_2$.

**1** Viability tested by Trypan blue dye exclusion >70%
**2** Purity as defined by >90% $CD73^+/CD105^+$ and CD45 <1%
**3** Sterility on 14-day microbial culture
**4** Mycoplasma test negative
**5** Endotoxin level <2 EU/mL
**6** 16s rRNA test (for microbial elements) negative
**7** Karyotype normal on cytogenetic testing.

Tests performed on the cryovial accompanying each cryovial or cryobag intended for use in a clinical trial and thawed 3 weeks before the planned administration of the corresponding MSCs included the following:

**1** Viability by Trypan blue dye exclusion >70%
**2** Sterility on 14-day microbial culture
**3** Mycoplasma test negative
**4** 16s rRNA test (for microbial elements) negative.

## 43.5 Phase 1 trials using placenta-derived mesenchymal stromal cells

Our laboratory generated enough placental MSCs for three phase 1 clinical trials using two maternal donors who were unrelated to, and MHC-unmatched with, the MSC recipients.

**Figure 43.7** Human placental MSCs in a tissue culture flask at day 3 of expansion culture.

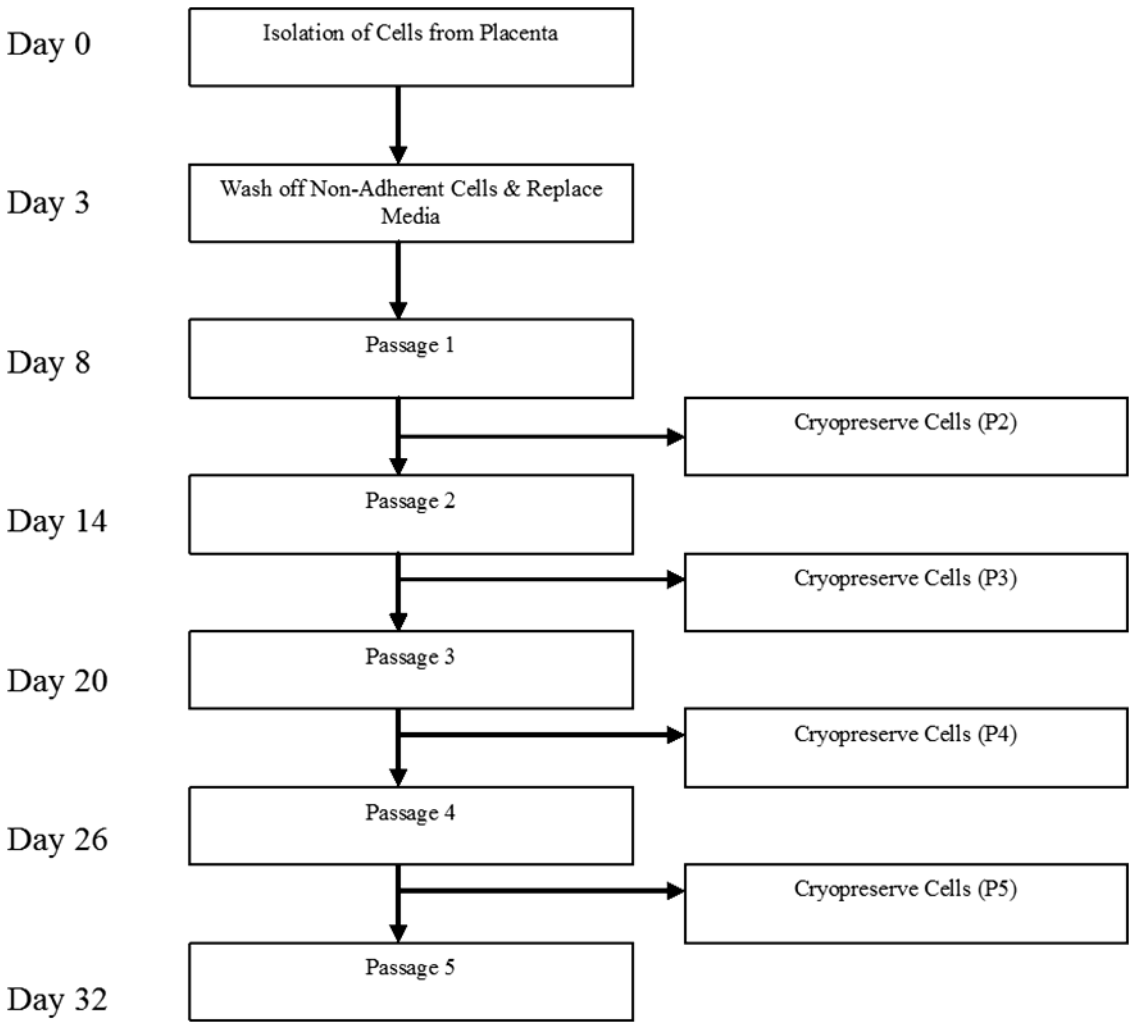

**Figure 43.8** An overview of the manufacturing process for isolating MSCs from human term placenta.

Our first trial was a phase 1 multicenter open-label dose-escalation study of unrelated, MHC-unmatched placenta-derived MSCs in recipients of unrelated umbilical cord blood hematopoietic stem cell transplants. No adverse events related to the MSCs were reported [5].

The second trial was a phase 1 trial of unrelated MHC-unmatched placenta-derived MSCs administered intravenously in patients with idiopathic pulmonary fibrosis. This disease affects middle-aged individuals and there is no effective treatment other than lung transplantation. It is usually fatal after 3–5 years. The primary objective of this trial was to establish the feasibility and safety of intravenous infusions of placental MSCs in people with this serious lung disease. No serious adverse events related to the MSCs were noted [6].

The third trial was a phase 1 trial of placenta-derived MSCs administered intratendinously in recipients with treatment-refractory Achilles tendinopathy. Two of the three planned dose-escalation cohorts with MSCs injected directly into the tendon under ultrasound guidance have been performed. No serious adverse events related to the MSCs were noted and a remarkable improvement in symptoms and exercise performance was noted (Young *et al.*, unpublished results; and see Chapter 47).

## 44.1 Introduction

The development of a wide range of regulatory standards applicable to the production and use of tissues, cells (including mesenchymal stromal cells) and other biologics (or biologicals) as advanced therapies indicates considerable interest in governmental regulation of these products. In this chapter, high-tier documents within the Australian, European, and US biologic drug regulatory environments have been analyzed and compared using qualitative methodology. Cohort 1 of the selected 18 high-tier regulatory documents from the European Medicine Agency (EMA), the US Food and Drug Administration (FDA). and the Australian Therapeutic Goods Administration (TGA) were subject to a manual documentary analysis. These documents are consistent with the legal requirements for the manufacturing and use of biologic drugs in humans and fall into six different categories. Manual analysis included a terminology search. The occurrence, frequency, and interchangeable use of different terms and phrases were recorded in the manual documentary analysis. Despite obvious differences, manual documentary analysis revealed general consistency in the use of terminology across frameworks analyzed. Phrase search frequencies showed less uniformity than the search of terms. The EMA framework's documents referred to "medicinal products" and "marketing authorisation(s)," the FDA documents discussed "drug(s)" or "biologic(s)," and the TGA documents referred to "biological(s)." Although high-tier documents often utilized different terminology, they shared concepts and themes. Documents originating from the same source have more conjunction in their terminology, although they belong to different frameworks (e.g., good clinical practice requirements based on the Declaration of Helsinki, 1964). Automated (software-based) documentary analysis can also be obtained for conceptual and relational analysis.

## 44.2 Background

The recent development of a wide range of regulatory standards applicable to the production and use of tissues, cells, and other biologics (or biologicals) – as new therapies – has stimulated considerable interest in the regulation of biologic drugs (including, but not limited to, human cell and tissue therapies) as part of the vast array of biopharmaceutical agents available or becoming available. Mesenchymal stromal cells are an example of this. Governmental regulation of biological therapeutic agents has been widely developed by mature regulatory agencies such as the Australian framework administered by the TGA, the European Union's EMA levied framework, and the US framework imposed by the FDA [1].

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.
© 2017 John Wiley & Sons, Inc. Published 2017 by John Wiley & Sons, Inc.

A significant number of documents are currently available in these regulatory frameworks in the form of standards, guidelines, recommendations, or regulations [2]. Conditions of product manufacturing and release have been established and outlined in a spectrum of documents from high-tier regulatory documents down to procedural documents. However, one of the major issues facing manufacturers, clinical practitioners, patients, patient advocacy groups, investors, and the general public is confusion over terminology at various levels and in types of documents applicable to specific products (e.g., stem cells versus progenitor cells versus biologics versus biologicals) [2–6]. Additional misconceptions can be attributed to the unclear level of regulatory oversight required, different levels of scrutiny (e.g., control of an entire manufacturing facility versus control of a manufacturing process), differences in availability of specific formal written procedures (e.g., some regulatory documents are deemed overly prescriptive or overly generic), and different product testing and release requirements [2–6]. Nonetheless, complex regulations are meant to be adhered to at all times and in every aspect of the manufacturing of biologic drugs (including, but not limited to, human cell and tissue therapies).

For the purpose of this chapter, all the aforementioned products, including mesenchymal stromal cells, will be referred to as biologic drugs, although other terminology may be used in the literature [3]; however, it should be noted that consensus has not been reached entirely on the use of the term "drug" [4], the regulatory oversight required [5], and established industry models [6]. An overview of the regulatory documents available on the websites of these three regulatory agencies is shown in Table 44.1.

The intention of this chapter is to compare and contrast the content and terminology in high-tier regulatory documents related to biologic drugs in Australia, Europe, and the USA, where these products are also referred to as biologicals, Advanced Therapy Medicinal Products (ATMPs), and biologics respectively. Since stem cells and their progeny are "biologics," these regulations are of major importance to all those attempting to translate stem cells or progenitor cells into clinical trials and clinical practice.

To accomplish this, an assessment of specific documents was made. The scope of the study included regulations of biologic drugs in Australia, Europe, and USA, while the objective was to derive data shared between the regulatory frameworks in order to make them usable in a harmonization process. Exploiting the shared terminology and mutually recognized scope or aim of the regulations was easiest to define via documentary analysis of high-tier documents in each regulatory scheme. It was hypothesized that there are similarities between high-tier regulatory documents related to biologic drugs in Australia, Europe, and the USA, although the terminology and focus of these regulatory frameworks differ to some extent. It was also anticipated that high-tier regulatory documents could be taken as a central representation of the regulatory frameworks from which they were drawn. The overall aim of this chapter is to assess the use of a qualitative methodology in this highly specialized area of regulatory science.

## 44.3 Definitions used by the Australian Therapeutic Goods Administration, the European Medicine Agency, and the US Food and Drug Administration for "biologicals"

The following definitions were used by the three regulatory agencies. The TGA regulatory documents refer to biologicals as [7]:

> Essentially a biological comprises, contains or is derived from human cells or human tissues . . . and is used to treat or prevent disease, ailment, defect or injury; or to diagnose the condition of a person; or to influence, inhibit or modify a physiological process in persons; or to test the susceptibility of persons to a disease or ailment; or to replace or modify parts of the anatomy in persons.

The official FDA definition of biological products or biologics can be summarized as "any virus, therapeutic serum, toxin, antitoxin or analogous product applicable to the prevention, treatment or cure of diseases or injuries of man," while the FDA Consumer Information page states [8]:

> Biological products include a wide range of products such as vaccines, blood and blood components, allergenics, somatic cells, gene therapy, tissues, and recombinant therapeutic proteins. Biologics can be composed of sugars, proteins, or nucleic acids or complex combinations of these substances, or may be living entities such as cells and tissues. Biologics are isolated from a variety of natural sources – humans, animals, or microorganisms – and may be produced by biotechnology methods and other cutting-edge technologies. Gene-based and cellular biologics, for example, often are at the forefront of biomedical research, and may be used to treat a variety of medical conditions for which no other treatments are available.

The lengthy official definition (codified in 21 CFR 600.3) vaguely defines biologics on the basis of analogies (i.e., products similar to viruses, serums, toxins and antitoxins) [9]. This definition avoids terms and concepts in use for generations (i.e., proteins, antibodies, genes, microbes, cells, viruses, and DNA/RNA). In practice, biologics include "a wide range of products such as vaccines, blood and blood components, allergenics, somatic cells, gene therapy, tissues and recombinant therapeutic proteins" [9].

The European Parliament Regulation 1394/2007 (amending directive 2001/83/EC and Regulation 726/2004) identifies an ATMP as [10]:

> . . . a medicinal product as defined in Directive 2001/83/EC of the European Parliament and of the Council of 6 November 2001 on the Community code relating to medicinal products for human use (the Directive), as amended to reflect new innovative therapeutic products. Specifically, an ATMP is a biological medicinal product which is either: - a gene therapy medicinal product as defined in Part IV of Annex I to Directive 2001/83/EC; a somatic cell therapy medicinal product as defined in Part IV of Annex I to Directive 2001/83/EC; or a tissue engineered product as defined in Article 2 1 (b) of the ATMP Regulation (1394/2007/EC).

*The EU: overview of the EMA website references to ATMPs Regulations as of December 10, 2011* [a]

**Regulation of medicines**

Human medicines

This section of the website provides information for companies and individuals involved in developing and marketing medicines for use in the EU.

**Table 44.1** (*Continued*)

For further information on EU legislation and procedures for the regulation of medicines, see also Volumes 1–4, 9, and 10 of the rules governing medicinal products in the EU.*

*__Eudralex__

The body of EU legislation in the pharmaceutical sector is compiled in Volume 1 and Volume 5 of the publication *The rules governing medicinal products in the European Union*.

Volume 1 – EU pharmaceutical legislation for medicinal products for human use

Volume 5 – EU pharmaceutical legislation for medicinal products for veterinary use

The basic legislation is supported by a series of guidelines that are also published in the following volumes of *The rules governing medicinal products in the European Union*:

Volume 2 – Notice to applicants and regulatory guidelines for medicinal products for human use

Volume 3 – Scientific guidelines for medicinal products for human use

Volume 4 – Guidelines for good manufacturing practices for medicinal products for human and veterinary use

Volume 6 – Notice to applicants and regulatory guidelines for medicinal products for veterinary use

Volume 7 – Scientific guidelines for medicinal products for veterinary use

Volume 8 – Maximum residue limits

Volume 9 – Guidelines for pharmacovigilance for medicinal products for human and veterinary use

Volume 10 – Guidelines for clinical trial

Medicinal products for pediatric use, orphan, herbal medicinal products, and advanced therapies are governed by specific rules.

**Advanced therapies**

Advanced-therapy medicinal products (ATMPs) are medicines for human use that are based on gene therapy, somatic-cell therapy or tissue engineering. They offer groundbreaking new opportunities for the treatment of disease and injury.

The regulatory framework for ATMPs is established in Regulation (EC) No 1394/2007.

These pages provide information for applicants on:
- the classification of ATMP marketing-authorization applications;
- certification of the quality of ATMPs;
- nonclinical data submitted by small and medium-sized enterprises (SMEs) developing ATMPs.

**Support to companies**

The Innovation Task Force (ITF) provides a forum for informal dialogue between the EMA and companies or individuals in the early stages of the medicine development process.

In addition, the agency can provide support to companies through:
- the SME office; scientific advice and protocol assistance; orphan designation.
- EU regulation on advanced therapies ATMP classification (includes scientific recommendations), certification procedure for SMEs, marketing-authorization application submission, scientific guidelines, risk management, interested parties guidance.

**Procedural advice**

Procedural advice on the provision of scientific recommendation on classification of ATMPs in accordance with article 17 of regulation (EC) No 1394/2007.

**Other information**

EU regulation on advanced therapies

ATMP classification

Certification procedure for SMEs

*USA: overview of the FDA regulations applicable to biologic drugs since 2004* [21]

21 CFR 1271.10(a) sets out the criteria that form the foundation of our tiered, risk-based approach to regulating HCT/Ps. HCT/Ps that meet all of these criteria are subject only to regulation under section 361 of the PHS Act. These HCT/Ps are subject to the regulations in Part 1271, and no pre-market approval is required. HCT/Ps that do not meet all of the criteria in 21 CFR 1271.10(a) are regulated as drugs, devices, and/or biological products. These HCT/Ps are subject to the regulations specific to drugs, biological products, or medical devices, in addition to applicable sections of Part 1271. Bone (including demineralized bone), Ligaments, Tendons, Fascia, Cartilage, Ocular Tissue (Corneas and Sclera), Skin, Arteries and Veins (except umbilical cord

**Table 44.1** (*Continued*)

veins), Pericardium, Amniotic membrane (when used alone, without added cells for ocular repair), Dura mater, Heart valve allografts, Semen, Oocytes, Embryos and Hematopoietic stem/progenitor cells derived from peripheral and cord blood.
On 25 May 2004, the FDA disseminated regulations requiring most cell and tissue donors to be tested and screened for relevant communicable diseases (donor-eligibility final rule, 69 FR 29786). On 18 November 2004, the FDA issued regulations that require establishments that manufacture human cell and tissue products (HCT/Ps) to comply with Current Good Tissue Practices (CGTP), which include proper handling, processing, labelling, and record-keeping procedures. At the same time, FDA also published an interim final rule to revise certain regulations regarding the screening and testing of HCT/P donors and related labelling (interim final rule, 70 FR29949). The FDA took this action in response to comments from interested persons regarding the impracticability of complying with certain regulations as they affect particular HCT/Ps. The CGTP and other regulations are contained in 21 CFR Part 1271, along with provisions relating to establishment registration. These regulations apply to HCT/Ps recovered on or after the rule's effective date. HCT/Ps that were recovered before the effective date of the new rules are subject to 21 CFR 1270, and subparts A and B of Part 1271, as appropriate. In addition, 21 CFR Part 1271 subparts A, B, C, F, 21 CFR 1271.150(c) and 21 CFR 1271.155 of subpart D apply to reproductive HCT/Ps. The new Part 1271 is made up of six subparts: general provisions pertaining to the scope and purpose of Part 1271, as well as definitions; registration and listing procedures; provisions for the screening and testing of donors to determine their eligibility; current Good Tissue Practice (cGTP) requirements; certain labelling and reporting requirements; inspection and enforcement provisions. Those HCT/Ps that do not meet all 21 CFR 1271.10(a) criteria and are regulated as drugs, devices or biological products are covered under separate compliance programs:

- Blood and blood products are covered under CP 7342.001 Inspection of Licensed and Unlicensed Blood Banks, Brokers, Reference Laboratories, and Contractors; and CP 7342.002 Inspection of Source Plasma Establishments;
- HCT/Ps that do not meet all 21 CFR 1271.10(a) criteria and are regulated as Medical Devices are covered under CP 7382.845 Inspection of Medical Device Manufacturers;
- HCT/Ps that do not meet all 21 CFR 1271.10 (a) criteria i.e. autologous, allogeneic or xenogeneic cells whose biological characteristics have been altered (i.e. propagated, pharmacologically treated) *and ex vivo* and gene therapy products are regulated as biological drugs and are covered under CP 7345.848 Inspection of Biological Drug Products;
- HCT/Ps recovered before 25 May 2005 and regulated under 21 CFR 1270 and subparts A and B of Part 1271 are covered under CP 7341.002A Inspection of Tissue Establishments.

The above HCT/Ps are regulated solely under section 361of the PHS Act and the regulations in 21 CFR Part 1271 if they meet all of the following criteria: minimally manipulated; intended for a homologous use only as reflected by the labelling, advertising, or other indications of the manufacturer's objective intent; not combined with another article, (except for water, crystalloids, or a sterilizing, preserving, or storage agent, if the addition of the agent does not raise new clinical safety concerns with respect to the HCT/P); and either:

- Do not have a systemic effect and are not dependent upon the metabolic activity of living cells for the primary function; OR
- Have a systemic effect or are dependent upon the metabolic activity of the other cells for the primary function, AND:
- Are for autologous use; Are for allogeneic use in a first or second-degree relative; OR Are for reproductive use.

HCT/P establishments must follow CGTP requirements to prevent the introduction, transmission, or spread of communicable diseases by ensuring that the HCT/Ps do not contain communicable disease agents, that they are not contaminated, and that they do not become contaminated during manufacturing. The following are Core CGTP requirements as referenced in 21 CFR 1271.150(b):

- Requirements relating to facilities (21 CFR 1271.190(a) and (b))
- Requirements relating to environmental controls (21 CFR 1271.195(a))
- Requirements relating to equipment (21 CFR 1271.200(a))
- Requirements relating to supplies and reagents (21 CFR 1271.210(a) and (b))
- Requirements relating to recovery (21 CFR 1271.215)
- Requirements relating to processing and process controls (21 CFR 1271.220)
- Requirements relating to labeling controls (21 CFR 1271.250(a) and (b))
- Requirements relating to storage (21 CFR 1271.260(a) - (d))
- Requirements relating to receipt, pre-distribution shipment, and distribution of an HCT/P (21 CFR 1271.265(a)–(d)).
- Requirements relating to donor eligibility determinations, donor screening, and donor testing (sections 1271.50, 1271.75, 1271.80 and 1271.85).

ATMP, advanced therapy medicinal product; ARTG, Australian Register of Therapeutic Goods; CFR, Code of Federal Regulation; GMP, good manufacturing practice; HCT/P, human cell and tissue products.

## 44.4 Complexity of the area

Taking newly created biomedical discoveries from the bench to the bedside has proven to be a complex, highly challenging, and costly exercise [11]. It has been defined as translational research and recognized by researchers, funding agencies, and more recently by regulatory agencies as an imminent need [11]. Success in translational research requires not only highly trained experts and complex skill sets within a team, but also an understanding of the application of data in different sets of regulatory principles [12]. The independent development of regulatory authorities in Australia, Europe, and the USA has led to differences in the regional approach to biopharmaceutical manufacturing. Some of these were favorable for the conduct of early clinical trials with a minimal requirement for supporting data. Other developments have been affected by external factors or have expanded their scope through the years. Recent efforts have been made to harmonize the three frameworks, mostly in the area of active pharmaceutical ingredient inspections [13], and are expected to be followed by other joint programs.

Although therapeutic agents derived from biological sources have been subject to regulatory oversight for some time (e.g., monoclonal antibodies), biologic products used in transplantation procedures such as cells and tissues have historically been exempted from such oversight [14]. The unique source of the "active ingredients" renders cell and tissue therapies difficult for assessment by the traditional regulatory approaches, which have been geared to support traditional pharmaceutical manufacturing practice [15]. It has been recognized that therapeutic claims for biologics need to be supported by strong scientific evidence [16], as well as their manufacturing being governed by comprehensive regulatory principles. New considerations have led the existing regulatory agencies to propound new regulatory approaches for the sector of biologic drugs or biopharmaceuticals that "has become one of the most research-intensive sectors with great potential for delivering innovative human medicines in the future" [17].

The biopharmaceutical industry is defined as business activities related to the development of new biopharmaceutical drugs and medicines [18]. Defining the term "biopharmaceutical" for the industry's stakeholders, including the regulatory agencies, has proven to be a difficult task. Regulatory definitions of biopharmaceuticals are generally based on a broad biotechnology definition but often use other terms with their own intricate definitions (e.g., "biologicals" in Australia, ATMPs in Europe, and "biologics" in the USA) [9]. Documentary analysis is a useful methodology to clarify the complexity of biologic drugs regulations, as part of the complex regulatory arena of biopharmaceuticals [19].

Regulation of cell and tissue products is closely linked not only to sensitive areas of public health policy and funding, but also to the development of novel disciplines such as regulatory science [18,20]. This positions regulators in a challenging position as they attempt to reconcile their roles as independent assessors with public health needs and perceptions [18,20]. The historical background of the development of regulatory agencies of interest has been explored previously [21], and regional differences were illustrated by observations pertinent to their clinical trial requirements.[1] These differences inevitably contribute to the complexity of the regulations applicable to the development of biologic drugs.

## 44.5 Analysis of documents

Documents and written material used in this chapter provide a way of gaining access to sets of processes that cannot be observed or documented otherwise and are not easily described in verbal or other reconstructions [19]. Documents used were readily available on the websites of the three regulatory agencies used for comparison. They were complete, well constructed, and clearly presented. The main tasks in the manual document analysis were (1) the selection process of documents to be analyzed – necessary because of the vastness of the material available – and (2) thorough reading and analysis of selected documents. The type of sampling used in this research was theoretical or purposive sampling of high-tier regulatory documents that are, for the purpose of this chapter, taken as the central representation of the regulatory frameworks from which they were drawn. The sampling approach is outlined in Table 44.2, indicating the inclusion and exclusion criteria. An extensive list of the documents analyzed is presented in Table 44.3.

Manual analysis of selected documents identified main terms and phrases in individual documents. While undertaking data analysis, important consideration was given to selectivity and the perspective of the research, in order to maintain focus in the process of documentary analysis. This related back to asking the question of what the documents were expected to provide in an ontological and epistemological sense. Ontology in this chapter is used to indicate a rigorous and exhaustive organization of the knowledge domain of regulatory science. Epistemology in this chapter is used to indicate a philosophical approach to the nature of regulatory science, including its presuppositions, its foundation, its extent, and its validity. The process of analysis involved several steps. First, the context was established while the complexity and historical background were explored for each of the sets of regulatory principles analyzed. Second, extensive preparation for analysis and selection of documents was obtained. Third, selected documents were copied from the official regulatory agencies' websites and examined. Since the intent of this chapter is to focus predominantly on the literal wording and terminology as an examination of the documents' focus and intent, a manual method (Table 44.4) was devised to record these.

An overview of the TGA website structure and content is presented in Table 44.1. It includes only the new Biologicals Framework as established in July 2011 from which relevant documents were selected.[2] In terms of the EU regulatory requirements, selection of the documents was not straightforward owing to the complexity of national and EMA regulations (Table 44.1). It is acknowledged by the EMA that new technologies, therapies, and medicines are emerging in the form of regenerative medicine and more personalized medical treatments.[3] The lack of an EU-wide regulatory framework in the past led to divergent national approaches in Europe that hindered patient access to products; as

**Table 44.2** Inclusion and exclusion criteria for selection of documents.

| Parameters | Inclusion criteria | Exclusion criteria |
|---|---|---|
| Location | EU | Regions other than EU, USA, and Australia |
| | USA | |
| | Australia | |
| Language | English | Documents not written in English |
| Type of the document | High-tier legal and regulatory domain | Documents other than high-tier legal and regulatory domain |
| Purpose of the document | Legal requirements for manufacture and use of biologic drugs for human use, including definitions and scope | Documents concerned with issues other than legal requirements for manufacture, GMP, and GCP applicable to medicinal products and biologic drugs for human use |
| | Good manufacturing practice (GMP) for manufacture of medicinal products and biologic drugs for human use | |
| | Good clinical practice (GCP) for use of medicinal products and biologic drugs in clinical trials involving humans | |
| Scope of the document | Medicinal products, biologics, biologicals, and ATMPs for human use | Documents concerned with other than medicinal products, biologics, biologicals, and ATMPs for human use |
| Time frame | Most recent documents published from 2000 (inclusive) | Documents published prior to 2000[a] |

[a] Only one document was exempt as it was originally published in 1996 (see Table 44.4).

a result, the central procedure agency was established.[4] As a further illustration of the complexity and vastness of written material available in the area of biologic drug regulations, an overview of the relevant FDA regulations since 2004 [22–24] is also presented briefly in Table 44.1. Some of these documents were selected for the analysis, based on the inclusion and exclusion criteria, while provision was made in relation to so-called nonbinding documents in the form of guidances (see the Disclaimer footnote in Table 44.3).

In terms of sampling, it was important to decide what was significant in the context of the research, its theoretical and empirical impacts, and how it related to the broader universe and the ongoing development in the field [25–29].

The data presented in Tables 44.5 and 44.6 were derived from the manual analysis, using the PDF search feature to assess the documents in Cohort 1 (see Table 44.3). Rather than treating the data as an end product, it was classified and subsequently parts or "slices" were treated as unfinished resources for further use [19]. Manual analysis included a terminology search with a list of 10 specific terms (Table 44.5) and 16 phrases (Table 44.6). The frequencies of terms and phrases in the documents are also illustrated in Figures 44.1 and 44.2.

The frequency of terms presented in Table 44.5 revealed some consistency across regions in the use of "manufacturing" (58, 71, and 113 occurrences in EMA, FDA, and TGA documents respectively) and "human" (137, 55, and 89 rates respectively). The terms "drug(s)," "cell(s)," and "biologic/biological(s)" were also to some extent used across the entire spectrum of documents analyzed.

More frequent and specific use of "medicinal" was observed in the EMA documents (a total of 1092 occurrences in three documents), while "pharmaceutical" was very sporadically utilized in any documents other than in EMA DOC1 (54 occurrences). The term "therapy(ies)" was not mentioned in any of the FDA documents and was seldom used in the TGA documents (13 times in total), while it was mentioned 141 times in EMA DOC3, likely due to the definition by the EMA of cell therapies as ATMPs.

While the most frequent words used in the EMA documents were "product(s)" along with "medicinal," the term "drug(s)" was consistently mentioned within all FDA documents (84, 34, and 36 times) but seldom mentioned in the other two frameworks (a total of five occasions). The TGA documents featured "biologic/biological(s)" most consistently, while "cell(s)" was most utilized in a document from the FDA framework (78 occurrences in FDA DOC3) and the TGA framework (100 occurrences in TGA DOC1). Considering the relevant definitions, these search terms were expected to be dominant[5] [22–24].

The definitions of cell therapies by each of the regulatory agencies are as follows.

PIC/S: Pharmaceutical Inspection Convention (PIC) and Pharmaceutical Inspection Co-operation Scheme; n/a: not applicable.
[a] Subsequently amended.
[b] Disclaimer: major, specific, and updated FDA guidances relating to key subsets of biologics were not included in Cohort 1 and 2 documents. Although the basic FDA regulations have not been changed much since the expansion of biologic drugs, including vaccines, the guidances have really become more like interim regulations. Owing to the research sampling criteria, guidances (including the key manufacturing guidances for biologics that the FDA does enforce in a way similar to that for regulations) have not been analyzed here. These documents can be found at http://www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/default.htm.
[c] In process of being amended.
[d] Document was exempt from the timeframe.

**Table 44.4** Literal wording, form, and sequence of manual recording in the documents.

| Manual document analysis | Considerations | Questions raised | Result |
|---|---|---|---|
| Stage 1:<br>Selection of documents (including comparison with other frameworks/areas) | Regulatory frameworks (by region) – areas of regulatory frameworks | What to analyze? | List of documents to be analyzed |
| Stage 2:<br>Reading and "interpretation" | Purpose and aim of documents.<br>Understanding of the content | How to analyze? | Thorough understanding of aim, scope and depth of documents.<br>List of terms and phrases to search |

| | Consistency and quality assurance<br>Presenting results in an adequate manner | Reliability of results? | Tables and diagrams outlining results of the manual analysis |

- Somatic cell therapy and gene therapy related definitions and considerations by the FDA (http://www.fda.gov) [24]:

> Somatic cell therapy is the administration to humans of autologous, allogeneic, or xenogeneic living cells which have been manipulated or processed ex vivo. Manufacture of products for somatic cell therapy involves the ex vivo propagation, expansion, selection (see: "A Proposed Approach to the Regulation of Cellular and Tissue-based Products," Feb. 28, 1997, (62 FR 9721)), or pharmacologic treatment of cells, or other alteration of their biological characteristics. Such cellular products might also be used for diagnostic or preventive purposes. Recently, various innovative therapies involving the introduction of somatic cells into humans have been used or proposed. For the purpose of this Guidance, the term somatic cell therapy refers to the administration to humans of autologous, allogeneic, or xenogeneic living non-germline cells, other than transfusable blood products, for therapeutic, diagnostic, or preventive purposes. . . . Examples of somatic cell therapies include implantation of cells as an in vivo source of a molecular species such as an enzyme, cytokine or coagulation factor; infusion of activated lymphoid cells such as lymphokine-activated killer cells and tumor-infiltrating lymphocytes (addressed in a separate Points to Consider document: see below); and implantation of manipulated cell populations, such as hepatocytes, myoblasts, or pancreatic islet cells, intended to perform a complex biological function. Because of the complexities of potential interactions with the cells and other constituents, additional components should be considered as part of the final biological product for purposes of preclinical evaluation.

**Table 44.5** Terminology search: frequency of terms in documents (cohort 1).

| Terminology search | Frequency in the documents | | | | | | | | |

[a] Frequency of term "manufacturing quality."

- Human cell and tissue-based therapeutic goods-related definitions and considerations by the Australian TGA (https://www.tga.gov.au/regulation-basics):

> The Australian Regulatory Guidelines for Biologicals (Aclr1) provide information for manufacturers, sponsors, healthcare professionals and the general public on the legal arrangements in Australia for the supply and use of human cell and tissue-based therapeutic goods. These products are collectively defined as "biologicals." . . . The Biologicals Regulatory Framework is the term for legislation that came into force in 2011 to regulate human cell and tissue-based products as a distinct group of therapeutic goods called "biologicals." The framework is administered by the Therapeutic Goods Administration (TGA), which has produced this document - the Australian Regulatory Guidelines for Biologicals (Aclr1) – to inform manufacturers, sponsors, healthcare professionals and all other interested parties about the framework. . . . The Biologicals Regulatory Framework provides a comprehensive system of assessment and controls that must be completed before products are allowed to be marketed in Australia (premarket), and follow-up and further controls after they are marketed (post-market) . . . or included on the Australian Register of Therapeutic Goods (ARTG) otherwise exempted, approved or authorised.

- ATMPs-related definitions and considerations by the EMA:

> Advanced therapy medicinal products (ATMPs) are medicines for human use that are based on gene therapy, somatic cell therapy or tissue engineering. They offer groundbreaking new opportunities for the treatment of disease and injury. The regulatory framework for ATMPs is established in Regulation (EC) No 1394/2007. (http://www.ema.europa.eu/ema/index.jsp?curl=/pages/home/Home_Page.jsp).
>
> For reasons of clarity, complex therapeutic products require precise legal definitions. Gene therapy medicinal products and somatic cell therapy medicinal products have been defined in Annex 1 to Directive 2001/83/EC, but a legal definition of tissue engineered products remains to be laid down. When products are based on viable cells or tissues, the pharmacological, immunological or metabolic action should be considered as the principle mode of action. It should also be clarified that products which do not meet the definition of a medicinal product, such as products made exclusively of non-viable materials which act primarily by physical means, cannot by definition be advanced therapy medicinal products [10].

Phrase search results are shown in Table 44.6. The phrase "access to" was the one most uniformly present in all documents across the frameworks, although not frequently used altogether (a total of 31 occurrences across all frameworks' documents). The phrases "clinical investigation" and "clinical

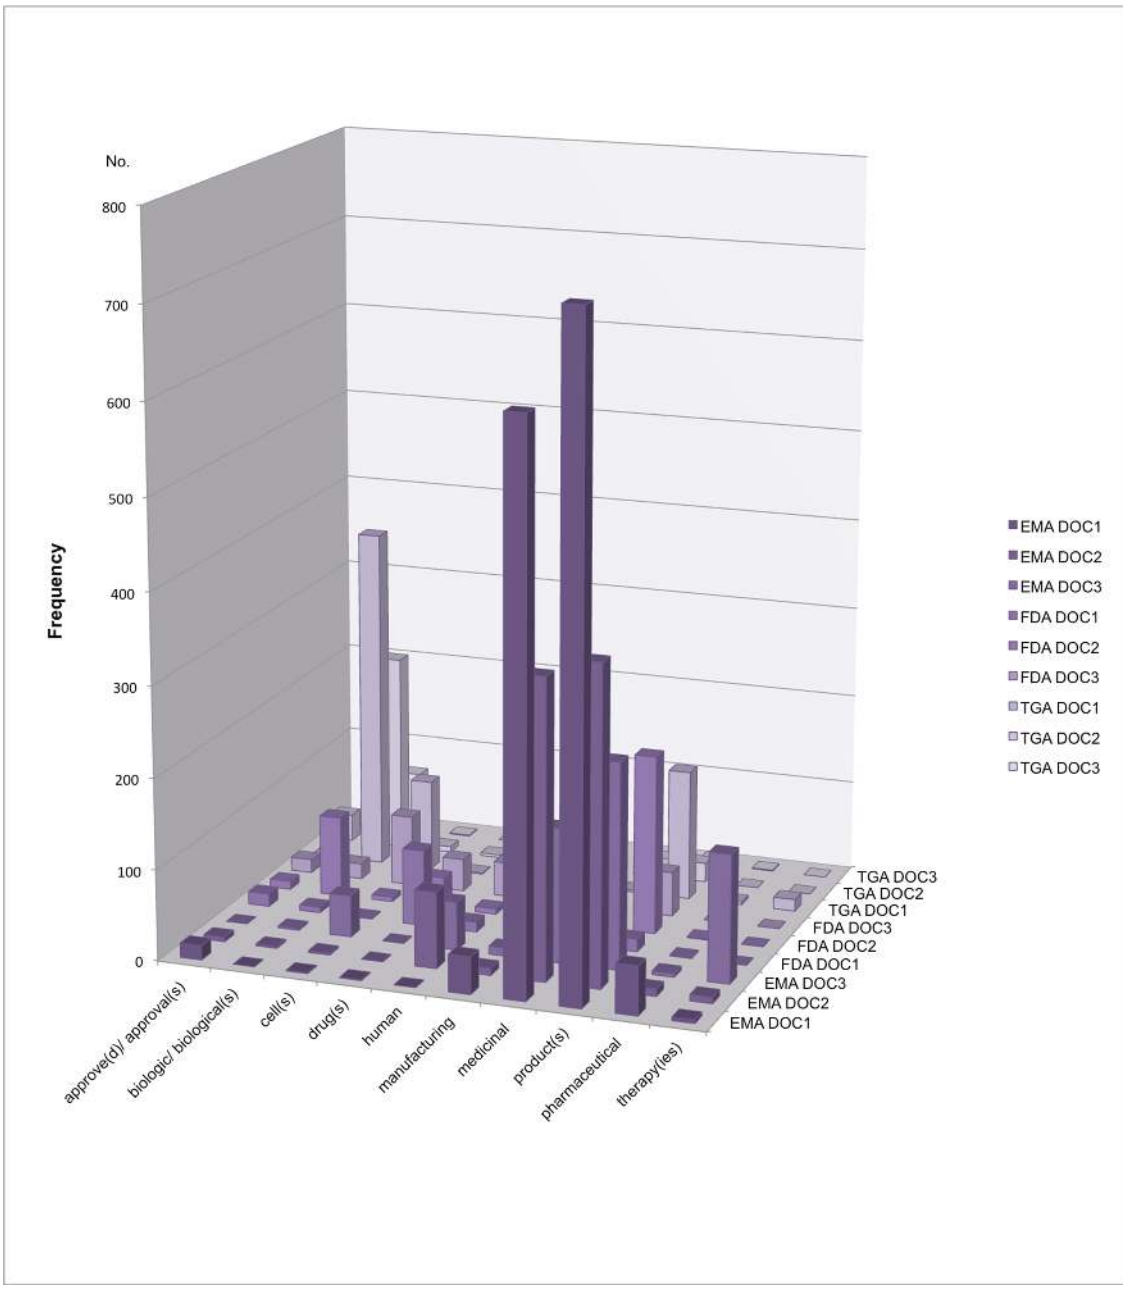

**Figure 44.1** Terminology search graph: frequency of terms in documents (cohort 1).

trial" were interchangeably used by FDA documents, while EMA and TGA documents referred only to "clinical trial." "Human cell(s) and tissue(s)" and "human cells" were only referred to by a single document in each framework (9 occasions in EMA DOC3, 12 in FDA DOC3, and 12 in TGA DOC1), while "investigational new drug" was mentioned only in two FDA documents (a total of 32 occasions in FDA DOC1 and DOC2).

The TGA documents referred often to "manufacturing" (along with the other two frameworks' documents to a lesser extent) and "approved/unapproved," while mentioning "cell(s)" over 100 times in only one of the TGA documents (TGA DOC1). The TGA framework relied heavily on the terms "product(s)" and "risk management," on 171 and 27 occasions respectively. "Risk management" was mentioned less frequently in the EMA documents and only twice in all FDA documents. The term "therapy/ies" was not mentioned in any of the FDA documents and was seldom used in the TGA documents (13 times in total), while it was mentioned 141 times in the EMA DOC3.

Overall, the EMA framework's documents referred to "medicinal products" and "marketing authorisation(s)," the FDA documents discussed "drug(s)" or "biologic(s)," and the TGA

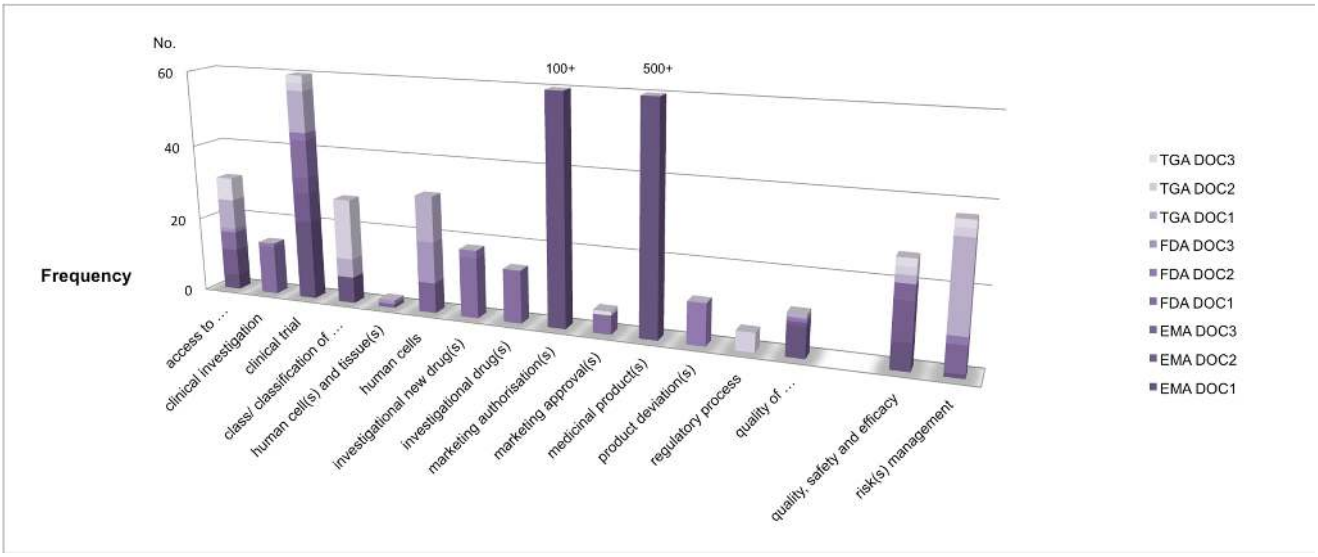

**Figure 44.2** Terminology search graph: frequency of phrases in documents (cohort 1).

documents mentioned "biological(s)." Hence, all the documents signified "product" as such – although referred to it using different terminology ("medicinal product" versus "drug/biologic" versus "biological"). Furthermore, the EMA documents were mostly concerned with "marketing authorisation(s)" while mentioning "quality, safety and efficacy." In the same manner, the FDA documents discussed "drug(s)" or "investigational drug (s)" that were not cited in the other two frameworks at all. They also utilized "product deviation" exclusively and used "clinical investigation" and "clinical trial" interchangeably.

The results reported in this chapter reveal numerous differences between the regulatory frameworks' high-tier documents and the terminology they employ. For instance, "marketing authorisation" was exclusively utilized by the EMA regulatory framework, as well as the phrase "medicinal products." Neither of these was mentioned at all in the FDA and the TGA frameworks' documents. "Class" or "classification of" were not mentioned at all in the FDA documents, while the same phrases were utilized minimally in the EMA documents (seven occurrences) but more frequently in the TGA documents (54 occurrences).

"Quality, safety and efficacy" was a phrase barely used in the EMA and the TGA documents,and it was not present in any of the FDA documents. This also applied to the phrases "quality of" or "manufacturing quality."

## 44.6 Regulatory science

Biologic drugs must be developed and manufactured through disciplined and specific mechanisms [3]. This is the case even when full compliance with traditional concepts of pharmaceutical manufacturing practice is sometimes not possible (although strived for), particularly for life-saving therapies and new modalities in investigational drug development [12]. These systems incorporate considerations of risk/benefit ratios and include mechanisms for transparent and accountable release of products [16].

Conditions of product requirements and release are established and outlined in a spectrum of documents from the high-tier regulatory documents down to the procedural documents. Hence, the documents outlining the highest level of regulatory requirements in three mature regulatory frameworks were analyzed by a documentary analysis method in order to establish concomitance between different regional regulations applicable to biologic drugs as a source of a specialized knowledge in regulatory science.

The Commissioner of the FDA stated "that a failure to invest 'adequately' in regulatory science has been one of the reasons why fewer new drugs have been making it to the market" [30]. In October 2010 the FDA promised to bring its "regulatory science" into the 21st century [31], and in August 2011 it issued its strategic plan for regulatory science [32] called Advancing Regulatory Science at FDA [18]. The Common Fund's Regulatory Science program was initiated in the second half of 2010 as a partnership between the US National Institutes of Health and the FDA [33]. At the same time, the EMA stated on its website that "the European Medicines Agency is a key leader in the development and application of regulatory science" [34] and referred to the conference hosted by the agency in December 2010, which resulted in the report "Regulatory science: are regulators leaders or followers?" [35].

The origin of the term regulatory science is unknown, but it is believed that it was created in the 1970s when the newly formed US Environmental Protection Agency was required to make decisions based on incomplete and sometimes nonexistent scientific information [36]. Although there is still some debate as to

whether it is necessary to use this new terminology "as 'science is science' regardless how it is applied" [36], the FDA currently defines regulatory science as "the science of developing new tools, standards, and approaches to assess safety, efficacy, quality, and performance of all (FDA) regulated products" [37]. There is an undeniable need to capture regulatory knowledge and expertise required for the development of future regulatory policies to enable safe application of new biologic drugs [38].

## 44.7 Interpretation of the analysis of the documents

This chapter has described the processes that were used to develop a method of manual documentary analysis for high-tier regulatory documents. Although the data were studied out of context and the selectiveness of the data or representativeness of the sample can be questioned, this approach to documentary analysis is particularly useful when the researcher is faced with a vast number of complex documents with no common format, scope, or terminology.

Similar studies aimed at analyzing or comparing regulatory documents have been performed in the pharmaceutical industry, and other industries such as aviation and education [39–42]. Irrespective of the area and a specific methodology (manual or automated documentary analysis) employed in each study, they have added benefit to their respective areas. The purpose of these studies was either to provide a procedure for assessing connections between the current regulations and incorporation of new requirements [39], to increase understanding and knowledge about the trends in success of regulatory submissions [40], or to compare the regulatory versus the educational value of documents – for example, guidances for undergraduate education for medical practitioners [41]. Some of the research looked into establishing a clear definition of requirements or identifying inconsistencies between those definitions [42].

In the process of choosing the documents for the study, an ontological approach was adopted that assumed written words, texts, and documents are meaningful constituents of the process in the way in which they are changed and utilized [17]. In addition, an epistemological position was adopted that suggested that texts, documents, and written material can provide or count toward evidence of these ontological properties. The benefits of studies aimed at analyzing or comparing regulatory documents have been already recognized in the health care [39], the pharmaceutical industry [40,42], and the aviation and education [41] fields, while qualitative documentary review and analysis has demonstrated benefits to a number of other sectors, such as political science [43], environmental health research [44], ethics [45], and the World Health Organization's health economics and policy-making research [46].

It was observed that the main tasks in documentary analysis are a thorough understanding of documents analyzed, familiarity with relevant terminological differences, and robust quality assurance of the methodology [47–49]. The main advantages for the use of existing documents in a research study are that the data are usually easy to access, it takes a relatively short period of time to collect the data, and to some extent it provides a relatively inexpensive form of data collection [27]. In addition, the documents are unbiased by the data collection process (i.e., nonreactive) and may be useful for hypothesis and problem formulation. Nonreactivity is one of the methodological strengths of documentary analysis – "the data selection method itself generally does not change the data being collected" [28]. The stability of a measure refers to the extent to which the same results are obtained on repeated administrations of the instrument and it focuses on the instrument's susceptibility to "extraneous factors from one administration to the next" [49]. It was considered appropriate to rely on the "stability" of the documents as a retest measurement facility due to the nature of high-tier documents available to the public and researchers. Reliability refers to the accuracy of the research methods and techniques [50,51]. The process of reading, understanding, selecting, and comparing documents added a further dimension of construction as well as reflexivity [52]:

> textual analysis involves the mediation between the frames of reference of the researcher and those who produced the text . . . the researcher's own frame of reference becomes the springboard from which the circle is entered, and so the circles reaches back to encompass the dialogue between the researcher and the text.

Careful consideration of the validity of data generation requires a precise application of the logic used previously in determining methodological approaches – the chosen methodology has to be more valid than other methodological approaches [19]. To some extent there is a blurring of the distinction between validity and reliability. The main question posed here was how well the documents analyzed represented the concepts of the research or the hypothesis in an accurate, authentic, and relevant manner [29]. Since the issue of similarities and differences between the regulatory approaches was examined, it appears appropriate to use high-tier regulatory documents that have established the hallmark of these frameworks. It would be difficult to justify use of any other documentary sources for this type of research since the other documents, such as lower tier procedural texts or guidelines, are either overly specialized in their aim or scope or not considered as mandatory for every product.

Generally, qualitative research cannot entirely rely on standardized procedures to deal with concepts such as bias and reproducibility [50]. In this process, reproducibility is often replaced with transparency or an audit trail (a record of the researcher's design decision) about gaining access, collecting, and analyzing the data or about the actual research design [51]. Manual analysis with its quantified data (i.e., frequencies of terms and phrases) can be repeated accurately on many occasions and with no operator dependency. The only variable potentially influencing the reproducibility of the study relies upon selection

of the documents to be analyzed. Construct validity concerns the degree to which results of documentary analysis of documents reflects the underlying theoretical concepts or exposure pointers. This would be "the extent to which the theoretical concepts have been successfully operationalised" and "the process of translating research concepts into measurable phenomena" [27]. Validity of the construct was established by the assumption that differences in the regulatory frameworks were dictated by different historical and cultural backgrounds, regional dynamics, and various complexities of the biologic drug development. Nevertheless, some shared concerns were considered an underpinning factor for similarities among the regulatory frameworks, such as public and individual safety and a uniform scientific knowledge. Validity of interpretation is another way to think about the validity of the research. It is concerned with the data analysis validity and the interpretation on which it is based; it is contingent upon the end result, including how that interpretation was reached [19]. The validity of interpretation was established in two ways. First, by making the process of reaching interpretations as transparent as possible. Second, by following the same logic in making methodological choices and identifying the sources to be used – the documents analyzed.

Furthermore, the intent of the research was to provide some level of generalization, since it examined a broad set of regulations in three areas of the developed world: Europe, the USA, and Australia. Generalization is sometimes perceived in two distinct ways: empirical (i.e., one empirical population is representative of a wider population) and theoretical [19]. Theoretical generalization is often seen as more productive since it encompasses a range of strategies based on different logics, some of which are more "theoretical" than others (i.e., attaining a wider perspective) [19]. The aim of the theoretical generalization of this research was to demonstrate that high-tier regulatory documents are a central representation of the regulatory frameworks from which they are drawn. The comparison aimed to contribute more to the generalization than a simple statement of similarity or discrepancy.

It was also designed to pose questions for future regulatory studies. What questions do all regulatory agencies want answered? What are the specific areas that they wish to emphasize? In what specific areas do they converge or diverge and how can the lessons learned from a conventional pharmaceutical model be applied to biopharmaceutical development? It is well known that the biggest risk in drug development is failure to convince a regulator that a given therapeutic product meets the requirements for the next stage of development or marketing approval. It is also becoming clear that regulatory education and precedence information analysis, along with thorough knowledge of regulatory framework(s) and their focus, are the most acceptable development strategies for a smarter product development pathway. Not only does it require fewer clinical and nonclinical trials while reducing time and related cost [53], but it also potentially brings development of a biologic drug closer to market approval stage in different regions [54,55].

## 44.8 Conclusions

This chapter draws attention to the importance of understanding the complexity of a global regulatory environment applicable to biologic drugs, including stem cells and their progeny. It demonstrates considerable differences in the regulatory approach to biologic drugs' development and application, particularly with respect to terminology and definitions used in different regional regulatory frameworks. The EMA documents were mostly concerned with "marketing authorisation(s)," while occasionally mentioning "quality, safety and efficacy"; the FDA documents discussed "drug(s)" or "investigational drug(s)" that were not cited in the other two frameworks at all, utilized "product deviation" exclusively, and used "clinical investigation" and "clinical trial" interchangeably. While the most frequent words used in the EMA documents were "product(s)" along with "medicinal," the term "drug(s)" was consistently mentioned within all FDA documents but seldom mentioned in the other two frameworks. The TGA documents featured "biologic/biological(s)" most consistently, while "cell(s)" was most utilized in a document from the FDA framework and the TGA framework.

Regardless of these disparities between the three frameworks, this study identifies some conjoint aspects: the focus on the "product," whether it is referred to as "medicinal product," "drug/biologic" or "biological" is an example. Similarly, the terms "drug(s)," "cell(s)," and "biologic/biological(s)" were to some extent used across the entire spectrum of documents analyzed. All documents use the term "human" in a comparable manner.

Although the data were studied out of context and the selectiveness of the data or representativeness of the samples can be questioned, this approach to documentary analysis is particularly useful when the researcher is faced with a huge number of complex documents with no common format, scope, and terminology.

## 45.1 Introduction

Despite the recent decline in deaths attributable to cardiovascular disease (CVD), it remains the leading cause of death not only in the USA but alsothe entire developed world [1]. More Americans die each year from CVD than cancer and chronic lower respiratory diseases combined, and the economic burden in medical costs alone is projected to reach $918 billion by the year 2030 [1]. Therefore, innovative, cost-effective treatments are needed. The heart is one of the least regenerative organs, and the standard of care for the treatment of CVD has been restricted to either mitigating further damage or heart transplantation. However, in the past several years there has been an increased focus on overcoming this lack of regenerative potential by the therapeutic use of stem/progenitor cells. Mesenchymal stromal/stem cells (MSCs) are a particularly attractive candidate due to their ease of isolation [2], immune privilege [3], ability to stimulate endogenous cardiac stem cells (CSCs) [4], and the release of beneficial paracrine factors [5]. In this chapter we will examine the therapeutic use of MSCs for acute and chronic ischemic heart disease in the preclinical and clinical setting as well as the possible mechanisms involved in their reversal of cardiac remodeling.

## 45.2 The biology of acute and chronic ischemic cardiomyopathy

Occlusion of one or more major coronary arteries, even if temporary, produces myocardial ischemia, and the resulting lack of oxygen and subsequent depletion of creatine phosphate inevitably leads to a shift from aerobic metabolism to anaerobic glycolysis in order to meet the energy demands of the heart [6]. This shift in the energy-generating pathway is characterized by a severely hypoxic environment leading to acidosis due to the accumulation of glycolytic intermediates, primarily lactate [6]. As the energy demand of the cardiomyocytes exceeds supply, adenine diphosphate increases and

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.
© 2017 John Wiley & Sons, Inc. Published 2017 by John Wiley & Sons, Inc.

adenylate kinase is activated, leading to a buildup of adenosine monophosphate (AMP) [7]. As AMP accumulates it is progressively degraded into nucleosides and bases, which eventually efflux from cardiomyocytes. The progressive catabolism of ATP, glycogen stores, and more catabolites during cardiomyocyte metabolism leads to an increased osmolar load, and therefore cell swelling [6]. As a consequence of this increased load, $Na^+/K^+$-ATPase, $Na^+/H^+$, and $Na^+/Ca^{2+}$ ion gradients are disrupted, leading to the influx of calcium. When intracellular calcium reaches a threshold level, the activation of specific phospholipases and proteases ensues, leading to autolysis of the cytoskeletal attachment complexes, subsequent breaks in the plasmalemma (cell membrane), and myocyte leakage [6]. If ischemia continues for 40–60 min without reperfusion, cardiomyocytes begin the transition from reversible to irreversible injury [7], beginning in the subendocardial layer and proceeding to the subepicardial layer [8]. While the precise transition point from reversible to irreversible injury remains unknown, it is the disruption of the sarcolemma, the fine transparent tubular sheath that envelops the fibers of striated muscles, that indicates definitive myocardial death [8]. Therefore, the lack of oxygen to myocardial tissue following a myocardial infarction (MI) leads to hypoxia followed by acidosis, which contributes to massive cell death of all cardiac cell types, including cardiomyocytes, vascular smooth muscle cells, fibroblasts, and endothelial cells. A collagenous avascular scar replaces necrotic tissue, causing adverse cardiac remodeling and eventually heart failure.

The structural and functional effects of the aforementioned myocardial ischemia were originally considered permanent, as the heart was thought to be a terminally differentiated postmitotic organ [9]. However, evidence of native myocyte proliferation [10] and the discovery of endogenous CSCs [11] highlighted the potential for reversal of CVD damage by optimizing the heart's regenerative potential. Exogenous stem cell therapy seeks to reverse cardiac remodeling by engraftment into the myocardium and differentiation as well as promoting resident cardiomyocyte cell cycling and endogenous CSC proliferation and differentiation. While early *in vitro* and preclinical studies focused on pluripotent stem cells, including embryonic stem cells and induced pluripotent stem cells because of their multipotential differentiation capacity, the ethical concerns of the former and teratoma formation by both, shifted the focus toward other viable cell options, including unfractionated bone-marrow-derived mononuclear cells (BM-MNCs) [12,13]. While early clinical trials utilizing BM-MNCs provided promising results [14,15], more recent clinical trials have failed to document the regenerative capability of these cells [16–19]. These conflicting results have shifted the focus again toward other bone marrow stem cell populations, with one of the most promising being MSCs. In addition to the ability of MSCs to engraft [20] and to contribute to reverse cardiac remodeling [4,20,21], MSCs provide the possibility for use as an allogeneic off-the-shelf product because of their immunosuppressive properties [22–24].

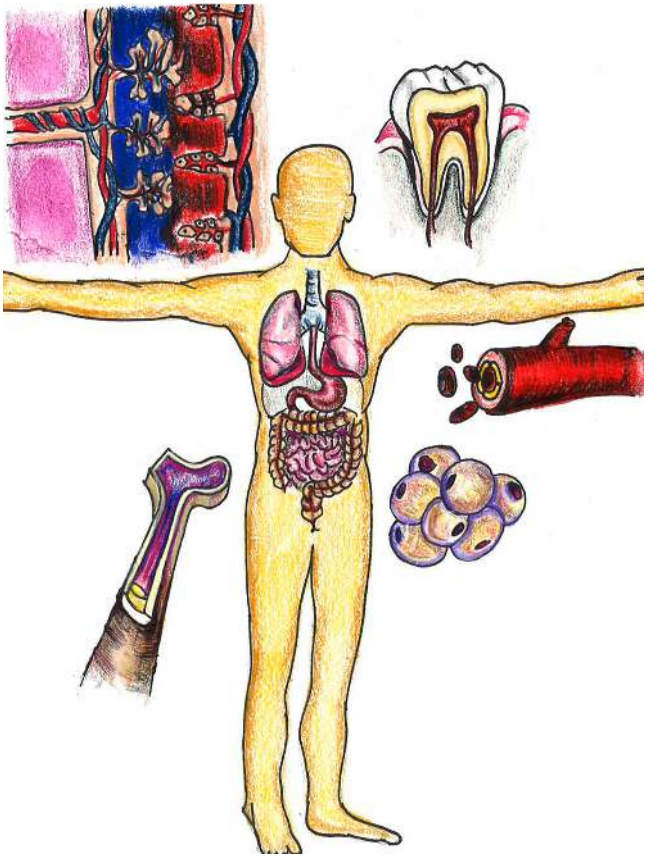

**Figure 45.1** MSCs reside in nearly every tissue of the body, including, but not limited to, bone marrow, adipose, lung, gut, amniotic fluid, placenta, umbilical cord, Wharton's jelly, dental pulp, and also in the circulation. (See color plate section.)

## 45.3 Characterization of mesenchymal stromal/stem cells

MSCs were originally isolated from the bone marrow [25] but have recently been shown to reside in virtually every tissue, including fat, lung, gut, amniotic fluid, placenta, umbilical cord, Wharton's jelly, dental pulp, and also in the circulation [26,27] (Figure 45.1).

In 1970, Friedenstein *et al.* discovered a population of adult stem cells that comprised 0.001% of the bone marrow of guinea-pigs [25]. These cells exhibit the necessary characteristics of stem cells, in that they have the capacity for self-renewal and multilineage differentiation and also exhibited plastic adherence *ex vivo* [28,29]. Their ease of isolation and therapeutic potential led to a swift transition from early preclinical studies into clinical trials in a variety of diseases. In 2006 the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy established the minimal criteria for MSC characterization in order to provide consistency and clarification as the cell field progressed. These criteria included (1) adherence to plastic when maintained in standard culture conditions; (2) expression of surface markers CD105, CD73, and CD90 while

lacking expression of CD45, CD34, CD14, CD11b, CD79α, CD19, and human leukocyte antigen (HLA)-DR; and (3) the ability to differentiate into osteoblasts, adipocytes, and chondroblasts *in vitro* [30]. However, it is important to note that these standards are the minimal defining characteristics. MSCs may differentiate into a variety of both mesoderm- [31–33] and non-mesoderm-derived tissues [34], although the latter is controversial, particularly with regard to efficacy. MSCs have become one of the most prominent contenders as a therapeutic treatment for acute and chronic heart disease for a variety of reasons, perhaps the most distinct being their capacity for immunomodulation.

### 45.3.1 Immunomodulatory properties

MSCs are particularly effective in preventing abnormal cardiac remodeling in the setting of acute MI (AMI) owing to their potent immunomodulatory properties (Figure 45.2), which are particularly important for the use of allogeneic MSCs.

The basis of MSC immune privilege is their low to moderate expression of HLA and major histocompatibility complex (MHC) class I and their lack of MHC class II molecules, which are involved in mediating interactions with leukocytes [35]. They also lack Fas ligand and co-stimulatory molecules, including CD80 and CD86 (B7.1 and B7.2 respectively) and CD40 ligand [36]. These properties have enabled the therapeutic use of MSCs as a convenient off-the-shelf ready-to-go therapeutic product in a number of conditions, including treatment-refractory graft-versus-host disease and acute and chronic ischemic cardiomyopathy. Their ability to hide from the immune system enables MSCs to survive/differentiate as both an allograft and a xenograft [36,37].

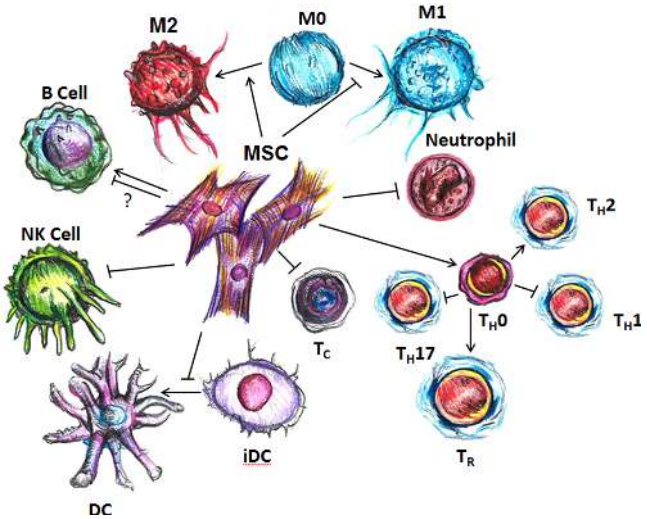

**Figure 45.2** The immunomodulatory properties of MSCs. An overview of the relationship between MSCs and the immune system. MSCs suppress natural killer (NK) cell activity through the secretion of soluble factors and downregulation of their activating receptors. The maturation of dendritic cells (DCs) is inhibited through the secretion of interleukin (IL)-6, which indirectly inhibits T cell activation. T cell activity is regulated by MSCs via multiple pathways. While MSCs inhibit the proliferation of both cytotoxic T ($T_C$) and helper T ($T_H$) cells by inducing cell cycle arrest, they promote differentiation of regulatory T ($T_R$) cells and the anti-inflammatory $T_H2$ cells. Additionally, MSCs preferentially promote monocyte differentiation into the anti-inflammatory M2 macrophage phenotype while inhibiting M1 macrophage differentiation. MSCs delay neutrophil apoptosis through the release of IL-6 while simultaneously decreasing the production of reactive oxygen species. The effect of MSCs on the humoral adaptive immune system remains unclear, with some studies indicating that MSCs inhibit B cell proliferation and subsequent antibody production, while others have found that MSCs elicit the opposite effects. (See color plate section.)

MSCs exert their immunomodulatory effects by interacting with both the innate immune system (macrophages, neutrophils, NK cells, and DCs) and adaptive immune system (T cells and B cells). After AMI, macrophage colony-stimulating factor promotes the maturation of monocytes to macrophages [38]. M1 macrophages, activated in the presence of nitric oxide (NO), secrete proinflammatory cytokines and are involved in debris cleaning in the initial stages of an AMI [39]. MSCs promote monocyte differentiation into the alternatively activated anti-inflammatory M2 phenotype involved in cardiac repair and angiogenesis, while still retaining the debris cleaning properties of the M1 phenotype [39]. Neutrophils are activated in response to tissue damage following MI, and produce reactive oxygen species to kill microorganisms [40]. MSCs secrete IL-6, which decreases the production of reactive oxygen species (thus decreasing the respiratory burst) and delays neutrophil apoptosis, therefore preventing further tissue damage while maintaining microbial phagocytic activity [40]. (The respiratory burst is the rapid release of reactive oxygen species, such as superoxide radical and hydrogen peroxide.) After an AMI, DCs activate the adaptive immune system through presentation of antigens to T cells. MSCs not only inhibit the maturation of monocytes to DCs but also indirectly inhibit T cell activation, breaking the link between the innate and adaptive immune systems [41]. NK cells are cytotoxic leukocytes that respond to a viral infection or stressed cells, such as those affected by an AMI. MSCs suppress NK cell activity by secretion of soluble factors and by downregulating their activating receptors, which in turn leads to further NK suppression [3].

T cells involved in the adaptive immune system consist of $T_H$ cells, $T_R$ cells, and $T_C$ cells. While $T_H$ and $T_C$ cells are involved in the apoptosis of antigen-presenting cells, regulatory T cells mediate the immune response. MSCs suppress the proliferation of $T_H$ and $T_C$ cells by inducing cell cycle arrest in the $G_0/G_1$ phase through various pathways. They also exert their effects through lineage commitment by inhibiting proinflammatory $T_H1$ and $T_H17$ differentiation [42], while promoting the differentiation of anti-inflammatory $T_H2$ cells [43]. Finally, MSCs also induce $T_R$ cell differentiation, which creates a negative feedback loop to inhibit T cell maturation [42,44]. Therefore, MSCs suppress the adaptive immune system both directly and indirectly.

B cells are also involved in the adaptive immune system and are responsible for antibody production, which leads to macrophage and neutrophil phagocytosis of antigen-presenting cells. In an AMI, inflammation leads to antibody production,

macrophage recruitment, and subsequent tissue damage. Similar to T cells, MSCs are capable of arresting B cells in the $G_0/G_1$ phase, thereby halting proliferation and continued myocardial destruction [45]. However, while some researchers have demonstrated that MSCs inhibit B cell-mediated antibody production [45], others have shown the opposite [46]. Therefore, the effect of MSCs on the humoral adaptive immune system requires further investigation.

Thus, MSCs can play a significant immunomodulatory role after MI through cell–cell interaction and the secretion of multiple soluble factors (the paracrine effect) and are potent cardio-protective agents. They also secrete a variety of cytokines and growth factors involved in scar reduction and activation of matrix metalloproteinases (MMPs) involved in degradation of the extracellular matrix. Therefore, MSCs play an important role in both the prevention and reduction of fibrosis.

### 45.3.2 Antifibrotic effects

One of the most significant factors leading to adverse cardiac remodeling following an AMI is fibrosis [47]. As stated earlier, after an AMI, if the tissue is not quickly reperfused, irreversible cell death occurs, leading to the replacement of necrotic myocardium with scar tissue. This process entails the destruction of the myocardial extracellular matrix followed by the formation of a provisional matrix composed of fibronectin, laminin, collagen, and other proteins and finally the maturation of a collagen-based scar [48]. While the antifibrotic effect of MSCs in both the preclinical and clinical settings has been well described, the exact mechanism is poorly understood. *In vitro* studies have shown that MSCs decrease the viability of myofibroblasts and subsequently increase their ability to degrade the extracellular matrix [49]. Decreased fibroblast viability was assessed by reduced expression of α-smooth muscle actin, a marker of myofibroblast differentiation. MSC-conditioned medium stimulates the activity of MMP2/MMP9 in cardiac fibroblasts, while decreasing the expression of tissue inhibitor metalloproteinases (TIMPs), namely TIMP-2. This expression demonstrates a shift in ECM remodeling from production to degradation, which therefore inhibits the subsequent deposition of collagen. Mias *et al.* also demonstrated that MSC-treated mice presented with decreased type I and type III collagen deposits at 2 months after MI [49]. MSCs also secrete specific growth factors and cytokines involved in the reduction of scar tissue, including hepatocyte growth factor (HGF) and heme oxygenase, both possible key factors involved in MMP and TIMP regulation [49–51]. Cumulatively, these studies in addition to the results of preclinical and clinical studies have led us closer to understanding the mechanisms involved in MSC-induced scar reduction.

### 45.3.3 Cardiomyogenesis *in vitro* and *in vivo*

The antifibrotic effects of MSCs are accompanied by both cardiomyogenesis and neovascularization. MSCs promote cardiomyogenesis by engrafting into the myocardium and differentiating into cardiomyocytes as well as by stimulating endogenous CSC differentiation and promoting resident cardiomyocyte cell turnover. The ability of MSCs to differentiate into cardiomyocytes *in vitro* [52] inspired subsequent small and large animal studies [4,20,53]. *In vitro* studies demonstrated the capacity of cardiomyocytes to adopt a cardiac phenotype by co-culture with 5-azacytidine, other cardiac myocytes, or pro-cardiogenic factors, including bone morphogenetic protein (BMP)-2, HGF, transforming growth factor beta (TGF-β), and Jagged1 [5,54–57]. Xu *et al.* co-cultured MSCs with 5-azacytidine and demonstrated differentiation into cardiomyocytes as noted by the expression of known myogenic markers, including α-cardiac actin, β-myosin heavy chain, and desmin, as well as the appearance of cytoplasmic myofilaments [57]. The induced myogenic cells also displayed functional characteristics consistent with cardiac myocytes, such as rhythmic $Ca^{2+}$ fluctuations [57]. Another study not only showed that 5-azacytidine induces myocyte differentiation, but also that these induced cardiac myocytes can connect with adjoining cells and beat spontaneously 2 weeks later [58]. Additional *in vitro* experiments revealed the ability of MSCs to transdifferentiate into cardiomyocytes when co-cultured with other myocytes. Xu *et al.* showed that direct cell–cell contact is necessary for transdifferentiation to occur through formation of connexin-43-mediated gap junctions between bone-marrow-derived MSCs (BM-MSCs) and native myocytes. When cells were cultured in a dual chamber system separated by a semipermeable membrane, BM-MSCs failed to differentiate into cardiomyocytes, as noted by a lack of α-actinin expression. However, in a separate study, Li *et al.* showed that physical contact between cells is not necessary for cardiomyocyte differentiation [55]. Cumulatively, these findings suggest that cell–cell contact, the local microenvironment, and soluble factors secreted by both native myocytes and MSCs all play a role in the ability of MSCs to contribute to cardiomyogenesis.

*In vivo* experiments provide evidence of MSC engraftment as well as endogenous CSC proliferation/differentiation and resident cardiomyocyte cell signaling. In 2002, Toma *et al.* injected human MSCs transfected with β-galactosidase into the left ventricle through the diaphragm of immune-deficient mice and reported that at 4 days 0.44% of the injected cells could be found in the myocardium, while the majority of cells resided in the spleen, liver, and lungs [53]. While even fewer cells were found in the myocardium at 60 days postinjection, all the mice that survived expressed desmin, a marker of cardiac differentiation, as well as cardiac-specific troponin T, β-MHC, α-actinin, and phospholamban. In a swine model of chronic ischemic cardiomyopathy, Quevedo *et al.* further demonstrated the ability of MSCs to engraft and differentiate into cardiomyocytes [20]. In this study, female swine received either placebo or male allogeneic MSCs by transendocardial injections. Engraftment of MSCs was determined by co-localization of the Y chromosome (Ypos) and cardiomyocyte differentiation was determined by co-localization with GATA-4, Nkx2.5, and α-sarcomeric actin. Cell engraftment and subsequent differentiation were found in both

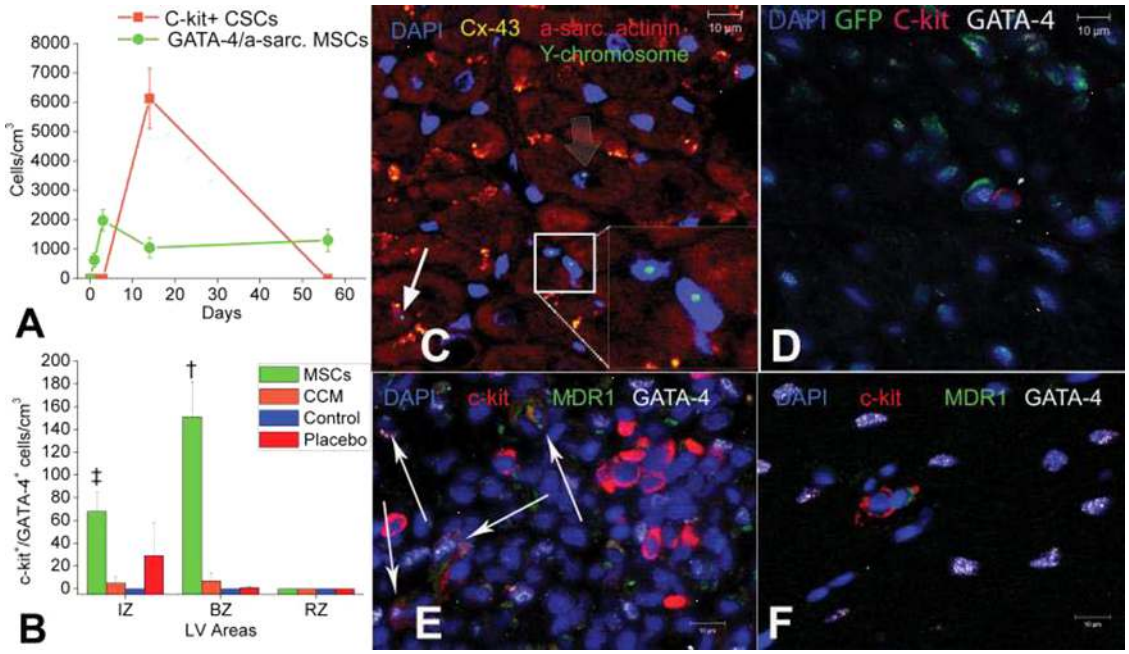

**Figure 45.3** Direct MSC stimulation of endogenous repair. (A) A graph depicting the contribution of cardiomyocyte precursors following exogenous administration of MSCs (green line) and endogenous CSCs (orange line), during cardiac repair after MI. MSC differentiation occurs rapidly after delivery. At 2 weeks, MSCs activate endogenous expansion of c-kit$^+$ CSCs (orange line). (B) Two weeks following transendocardial injection the number of c-kit$^+$ cells co-expressing GATA-4 is greater in MSC-treated hearts compared with non-MSC treated hearts. The cardiac precursors are preferentially located in the infarct zone (IZ) and border zone (BZ) of the MI, indicating an active process of endogenous regeneration (‡ $P = 0.019$ and †$P < 0.0001$). (C, D) The 2-week-old chimeric myocardium contains mature cardiomyocytes (open arrow), immature MSCs (arrowheads, inset), and cardiac precursors of MSC origin (arrow), coupled to host myocardium by connexin-43 gap junctions. Interestingly, endogenous c-kit$^+$ CSCs are found in close proximity to MSCs (D). (E) Cluster of c-kit$^+$ CSCs in an MSC-treated heart; numerous CSCs are committed to cardiac lineage documented by GATA-4 and MDR-1 co-expression (arrows). (F) A few isolated c-kit$^+$ cells were found in non-MSC-treated animals. (See color plate section.) *Source:* Hatzistergos *et al.* 2010 [4]. Reproduced with permission of American Heart Association.

the infarct and border zones of treated animals. Interestingly, engraftment correlated with increased contractile function and global left ventricular (LV) function in the infarct and border zones of treated animals compared with the placebo-treated group. These results demonstrated not only the ability of MSCs to engraft and differentiate into cardiomyocytes, but also their direct contribution to improved cardiac function.

Despite significant cardiac structural and functional improvements, the low rates of MSC engraftment and differentiation found in these studies have underscored the role of paracrine effects in cardiomyogenesis. However, a comparison of injection of allogeneic MSCs, concentrated conditioned medium (CCM) or placebo by Hatzistergos *et al.* highlighted the cell autonomous effects of MSC treatment in a porcine model of AMI. This study demonstrated that MSCs contributed to myogenesis by additional mechanisms, stimulation of endogenous CSC recruitment, proliferation, and myocardial lineage commitment (Figure 45.3) [4].

MSC-treated animals exhibited a 20-fold increase in c-kit$^+$ endogenous CSCs compared with those treated with CCM. This difference could be attributed to the ability of MSCs to form connexin-43-mediated gap junctions and N-cadherin mechanical connections with ckit$^+$ CSCs and adult cardiomyocytes as well as other MSCs. In addition to the stimulation of endogenous CSCs, MSC-treated animals exhibited a fourfold increase in cardiomyocyte turnover after MSC administration compared with CCM-treated animals as measured by the presence of the mitotic marker phospho-histone H3. These results indicated that while paracrine factor secretion does indeed play a distinct role in cardiomyocyte regeneration, MSC engraftment, differentiation, and interaction with the local milieu provides for a more complete recovery.

### 45.3.4 Neovascularization

Similar to the process of cardiomyogenesis, MSC-induced neovascularization is both multifaceted and synergistic. Possible mechanisms leading to vasculogenesis include the differentiation of MSCs into vascular smooth muscle cells and endothelial cells, the release of pro-angiogenic and pro-arteriogenic paracrine factors, as well as the recruitment of endothelial progenitor cells (EPCs). Several *in vitro* and *in vivo* studies have demonstrated the ability of MSCs to differentiate into endothelial and vascular smooth muscle cells [20,59,60]. However, substantial increases in perfusion, capillary density, and cardiac function, despite low rates of MSC engraftment, have highlighted the role of paracrine factor secretion in neovascularization. Vascular endothelial growth factor (VEGF), one of the first pro-angiogenic factors described, is of particular interest [61]. Several small and large

animal models of AMI have demonstrated increased VEGF expression in the myocardium of MSC-treated animals along with significant increases in angiogenesis, capillary density, tissue perfusion, and improvement in LV function [62,63]. Additionally, Markel *et al.* demonstrated that reducing VEGF in MSCs using small interfering RNA technology impaired both VEGF production and prevented MSC-mediated improvement in cardiac function following transplantation in a rat model of AMI [64]. However, while the administration of VEGF as a protein and as a DNA plasmid promotes angiogenesis, Shyu *et al.* showed that MSCs are superior to both angiopoietin-1 (Ang-1) and VEGF therapy in promoting cardiac regeneration [65]. Thus, MSC-induced neovascularization is mediated by the interaction of MSCs with multiple factors produced within the ischemic microenvironment. For example, NO, present after an AMI, promotes peripheral EPC mobilization to sites of injury and subsequent differentiation into mature endothelium [66]. In contrast, NO production inhibits MSC differentiation into endothelial cells [67] through a mechanism of upregulating VEGF receptor 2 present on EPCs, allowing VEGF-A to induce differentiation but downregulating the platelet-derived growth factor receptor on MSCs responsible for VEGF-A-induced endothelial cell differentiation. Therefore, it appears that the accumulation of NO in the inflammatory environment after MI allows for the recruitment of EPCs through VEGF-A production and subsequent vasculogenesis. After the release of anti-inflammatory factors by MSCs and the subsequent decrease in NO, MSC-mediated vasculogenesis can commence. Cumulatively, these results demonstrate the multifaceted nature of MSC-induced neovascularization and the need to prolong cell survival and engraftment in order to reap the full benefits of their use.

### 45.3.5 Paracrine effects

The robust cardiac structural and functional improvements demonstrated by MSC administration despite low MSC retention and engraftment rates have led to the hypothesis that MSCs secrete a variety of soluble factors, including cytokines, chemokines, and growth factors, which act both locally and systemically, leading to cardioprotective as well as cardioreparative effects. MSC-secreted proteins include those that promote angiogenesis, such as VEGF, stromal cell-derived factor 1 (also known as CXCL12), granulocyte colony-stimulating factor, TGF-β1, HGF, and Ang-1 [68,69]. Secreted pro-cardiogenic factors include BMP-2, HGF, TGF-β, and Jagged1 [5,70,71]. Those that promote cell homing and recruitment include thymosin-β4 and stromal cell-derived factor 1 [72,73]. Immunomodulatory factors include heme oxygenase-1, HGF, and IL-6 [73–75]. The antifibrotic actions of MSCs are mediated by MMP-1, -2 and, -9, as well as tumor necrosis factor-α [72]. Owing to the plethora of beneficial cardioprotective and regenerative effects generated by paracrine factor secretion, there has been an increased attempt to augment secretion of these factors through preconditioning, genetic modification, and pharmacotherapy.

### 45.3.6 Exosomes

Some of the cell autonomous paracrine effects of MSCs have been attributed to their release of exosomes or microvesicles derived from intracellular endosomes [76]. These membrane-bound vesicles range in size from 40 to 100 nm and can influence cellular activity through antigen presentation and the transfer of proteins, mRNA, and microRNA [77]. These characteristics allow exosomes to play an important role in a variety of cell processes, including, but not limited to, immune response, cell death, and angiogenesis [78–80]. Various studies have demonstrated a role for MSC-derived exosomes in tissue regeneration, including the treatment of acute kidney injury, liver fibrosis, hind limb ischemia, MI, and reperfusion injury [81–84]. In 2010 Lai *et al.* isolated a homogeneous population of 50–65 nm MSC-derived vesicles and were the first to demonstrate that these exosomes reduced infarct size in a mouse model of myocardial ischemia–reperfusion injury compared with saline-injected animals [85]. While the results attributed to exosomal therapy reveal a novel and exciting intercellular communication involved in MSC treatment, future studies are still needed to assess the safety and efficacy of MSC-derived exosomes in large animal models (see also Chapters 1, 20, and 38).

### 45.3.7 Mitochondrial transfer

In addition to the release of membrane-bound exosomes, MSCs have the capacity to transfer mitochondria between cells, thereby prolonging cellular lifespan and rescuing damaged cells by improving aerobic respiration. Spees *et al.* elegantly displayed the capacity for MSC-mediated mitochondrial transfer by co-culturing human MSCs with A549 $p^0$, cells that lack mitochondrial DNA and which are incapable of aerobic respiration due to pretreatment with ethidium bromide [86]. While aerobic respiration was restored and the functionality of the newly transferred mitochondria was determined, it was not understood whether the mitochondria had been transmitted as discrete vesicles or via direct cytoplasmic transfer. Various experiments have now provided compelling evidence that this process occurs through connexin-43-mediated gap junctions and actin-containing tunneling nanotubes [87,88]. Together, the evidence from exosome release and mitochondrial transfer experiments underscores the importance of MSC autonomous mechanisms of action and necessitates continued emphasis on the ability of MSCs to transfer therapeutic factors in a paracrine or direct cell-to-cell manner (see Chapters 10 and 21).

### 45.3.8 Preconditioning

The preconditioning of MSCs through stress induction, co-culture, and pharmacotherapy has emerged as a possible route to promote the cardioregenerative effects of MSCs. Preconditioning enhances paracrine factor secretion and improves cardiac structure and function in both small and large animal models and has already been the subject of clinical trials. Chacko *et al.* demonstrated that hypoxic preconditioning of MSCs in 0.5% oxygen for 24 or 48 h increased the expression of

pro-survival, pro-angiogenic, and pro-differentiation proteins [89]. Additionally, there was an upregulation of hypoxia-inducible factor-1α, a key angiogenic mediator, and phospho-AKT, a molecule involved in a cell signaling pathway that leads to cell survival by blocking apoptosis. Chacko *et al.* expanded on these results by demonstrating that multiple episodes of ischemic preconditioning of MSCs prior to longer periods of anoxia increased cell survival in a rat model of AMI compared with a single cycle of anoxia. Ischemic preconditioning significantly reduced apoptosis and increased cell engraftment through activation of AKT and hypoxia-inducible factor-1α pathways [89].

Co-culturing MSCs with various growth factors, including Ang-1 or a cocktail of growth factors (basic fibroblast growth factor, insulin-like growth factor (IGF)-1, and BMP2), increased cell survival, reduced scar size, and improved functional recovery in a rat model of AMI [90]. Interestingly, MSCs preconditioned with a cocktail of growth factors displayed enhanced connexin-43-mediated gap junction formation as well as increased cardiac-specific markers [5]. Finally, combined administration of simvastatin, a cardioprotective statin, in a swine model of AMI resulted in statistically significant improvements in MSC survival and differentiation compared with untreated MSCs, and this led to decreased fibrosis and improved cardiac function.

Statins, which are HMG-CoA reductase inhibitors, are a class of drugs used to lower cholesterol levels by inhibiting the enzyme HMG-CoA reductase, which plays a central role in the production of cholesterol in the liver. As indicated earlier, statins have also been found to prevent cardiovascular disease and mortality in those who are at high risk.

The improvements in cardiac structure and function described can be attributed to reduced inflammatory markers present in the local microenvironment of the swine hearts after infarction, providing an environment more conducive to cell engraftment, survival and differentiation [91].

### 45.3.9 Genetic modification

Genetic modification of MSCs has demonstrated promising results in various small and large animal models of ischemic cardiomyopathy. For example, several studies utilizing retroviral transduction of MSCs in order to overexpress the anti-apoptotic/cell survival gene *AKT* have demonstrated increased cell survival, engraftment, and cardiac function as well as reduced infarct size compared with control cells [92,93]. Gnecchi and colleagues overexpressed *AKT* in mouse or rat MSCs (Akt-MSCs) and showed that the administration of conditioned medium from hypoxia-preconditioned Akt-MSCs generated similar effects to the injection of the Akt-MSCs themselves, including significant reduction in fibrosis as well as restoration of ventricular function [73,94]. Studies suggest that a variety of paracrine factors mediate the therapeutic effect of Akt-MSCs, including secreted frizzled-related proteins 1 and 2 and IGF-1 [73,95,96]. *In vitro*, the Akt-MSC conditioned medium was able to induce spontaneous contraction of isolated rat cardiomyocytes. Additionally,

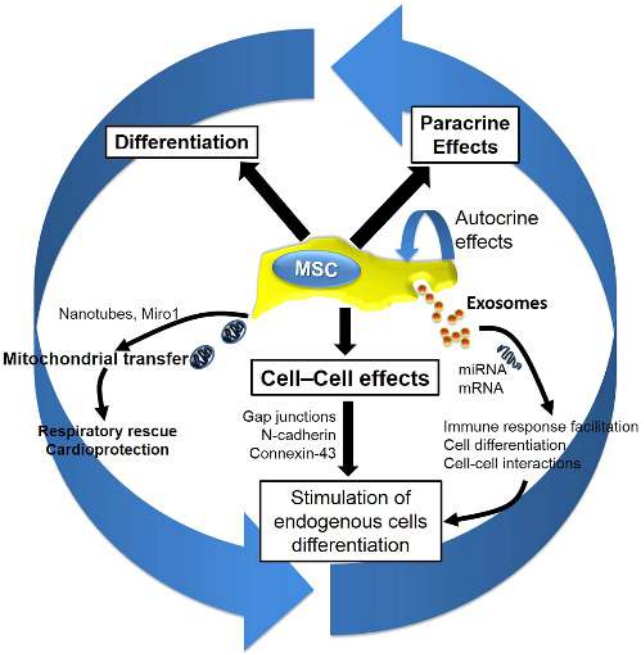

**Figure 45.4** MSC mechanisms of action. The proposed mechanism of action of MSCs forms an intertwined cycle of paracrine, autocrine, and direct effects that include vascular regeneration, myocardial protection, and cardiomyocyte regeneration that ultimately lead to cardiac action repair. *Source:* Karantalis and Hare 2015 [100]. Reproduced with permission of Wolters Kluwer Health.

expression of VEGF, fibroblast growth factor-2, HGF, IGF-1, and thymosin-β4 were all significantly upregulated in the Akt-MSCs compared with control MSCs. Combining Akt overexpression and another gene product has also proven effective. Shujia *et al.* showed that MSCs transduced to overexpress both Akt and Ang-1 led to increased engraftment and long-term survival, increased vascular density, and decreased infarct size compared with nontransduced MSCs and placebo in a rat model of AMI [97]. Furthermore, the transduced MSCs showed an increased capacity for vascular smooth muscle and cardiomyocyte differentiation, leading to improved LV function and reverse remodeling. Together, these and other results [98,99] suggest that genetic modification of MSCs is an exciting strategy to bolster the cardiac regenerative effects of MSCs, to circumvent the problem of poor cell survival in the proinflammatory post-infarction environment, and provide compelling evidence to move forward with additional preclinical studies with longer follow-up in order to ensure safety prior to clinical trials.

The many ways that MSCs mediate their therapeutic benefit are summarized in Figure 45.4.

## 45.4 Cell combination therapy

In addition to preconditioning and genetic modification, another novel approach to cell-based therapy involves cell combination therapy. As previously noted, *ex vivo* co-culturing of MSCs with

cardiomyocytes enhances MSC lineage commitment into a cardiac phenotype, and MSCs alone are able to stimulate proliferation and differentiation of endogenous CSCs *in vivo* [4]. These results prompted the exploration of combining MSCs and CSCs in hopes of capitalizing on the immunomodulatory and paracrine effects of MSCs while enhancing their differentiation capacity through interaction with CSCs. Williams *et al.* tested this approach in a swine model of AMI. Yorkshire swine were administered either a combination of human MSCs and human CSCs (200 million cells/1 million cells, $n = 5$) or human CSCs alone (1 million cells, $n = 5$), or human MSCs alone (200 million cells, $n = 5$) or placebo (phosphate-buffered saline, $n = 5$) by intramyocardial (transepicardial) injection [21]. One of the most exciting results of this study was the sevenfold increase in engraftment of the combination stem cell group compared with either cell group alone. Additionally, while all cell groups exhibited reduced infarct size, the antifibrotic effect was twofold greater in the cell combination group compared with the single cell groups. The combination cell group also showed the greatest improvement in both diastolic and systolic function, while all cell-treated animals exhibited similar improvements in LV ejection fraction (LVEF) and stroke volume compared with placebo-treated animals. Surprisingly, while both single cell-treated groups demonstrated a significant improvement in cardiac output in the combination group, the improvement was not significantly different from the placebo group. This study showed that combination stem cell therapy is safe and produces (in most cases) statistically significant improvements in cardiac structure and function compared with single cell therapy. This positive effect prompted its testing in a chronic model of ischemic cardiomyopathy using both autologous and allogeneic combination therapy without immunosuppressive agents. The autologous study has proven to be very promising, while the allogeneic preclinical trial is ongoing. Both studies compared a combination of MSCs and CSCs with either MSCs alone or placebo injection. While scar size reduced substantially with either cell treatment, functional improvements, including LVEF, cardiac output, and circumferential strain, were markedly greater in the combination-treated animals. These results have convinced the US Food and Drug Administration to approve a phase I clinical trial, The **C**ombination **O**f c-kit$^+$ cells and mesenchymal cells: a **N**ovel **C**ell study **E**valuating single and dual cell **R**egenerative **T**herapy in **C**hronic **H**eart **F**ailure Trial (The CONCERT-CHF Trial), that will be administrated by the National Institutes of Health-sponsored Cardiovascular Cell Therapy Research Network.

## 45.5 Clinical trials utilizing bone-marrow-derived mesenchymal stromal/stem cells

### 45.5.1 Acute myocardial infarction

The combination of safety and efficacy as determined from preclinical trials involving MSCs in both the acute and chronic settings of ischemic cardiomyopathy led to a swift transition into the clinical trial realm. While the exact mechanisms of action are not fully understood, the therapeutic potential of MSCs offers patients with heart failure, and a variety of other illnesses, the potential not only to halt but also to reverse their disease. The first clinical trial utilizing autologous human BM-MSCs for treatment of AMI was published in 2004 [101]. This groundbreaking study enrolled 69 patients who underwent primary percutaneous coronary intervention within 12 h after the onset of AMI. Patients were randomized, and 3 weeks after their balloon angioplasty/stenting they received intracoronary injections of either $8–10 \times 10^9$ autologous BM-MSCs or saline. This trial not only demonstrated safety, but also efficacy. Several imaging techniques were utilized to show significant improvements in LV hemodynamic measurements and cardiac functional indices between the two groups at 3 and 6 months follow-up. MSC-treated patients had a 14% increase in LVEF compared with placebo-treated patients at 3 months postinjection and exhibited an additional 10% increase at 6 months postinjection. Additionally, real-time cardiac electromechanical NOGA® mapping in the MSC group demonstrated significant improvements in cardiac mechanical capability 3 months after injection compared with pre-injection [101].

The NOGA system is a catheter-based, nonfluoroscopic, three-dimensional electromechanical mapping system that simultaneously registers the electrical and mechanical activities of the left ventricle, enabling online assessment of myocardial viability. The system distinguishes between viable, nonviable, stunned, and hibernating myocardium and can assess wall motion. By steering the deflectable mapping catheter tip gradually to the LV endocardial sites, the NOGA processing system reconstructs the shape of the left ventricle in three dimensions in real time.

In 2009, Hare *et al.* published the first study using allogeneic human BM-MSCs in a double-blinded, placebo-controlled, dose-ranging phase I study for the treatment of 53 patients with AMI [102]. Patients were randomized to receive an intravenous infusion of one of the three cell-doses ($0.5 \times 10^6$, $1.6 \times 10^6$ and $5.0 \times 10^6$ allogeneic human MSCs/kg) or vehicle 7–10 days after AMI. This study not only provided groundbreaking evidence that the intravenous infusion of allogeneic human MSCs was safe, but demonstrated efficacy as well. The MSC-treated group had an increased LVEF relative to baseline when measured at 3, 6, and 12 months after the injection. Pulmonary function, as assessed by forced expiratory volume in 1 s results, also improved in the MSC group but not in the placebo group. Lastly, fewer cardiac arrhythmias were reported in the MSC group, and overall clinical status at 6 months after treatment was improved. These encouraging results paved the way for additional allogeneic MSC clinical trials, resulting in equal numbers of trials using autologous or allogeneic MSCs by 2014. Additionally, the safety and efficacy of intravenous administration led to questions concerning the optimal mode of delivery.

### 45.5.2 Chronic myocardial infarction

The exciting results from clinical trials assessing the therapeutic potential of MSCs for AMI have encouraged researchers to focus on chronic MI, for which there are six published and/or ongoing clinical trials. A clinical trial by Mohyeddin-Bonab *et al.* was designed to assess the optimal mode of cell delivery. This trial was not only the first clinical pilot study of autologous MSCs for chronic MI but also sought to determine whether injection into the myocardium or intracoronary administration provided superior results [103]. Eight patients (mean age of 49 years) who had been living with heart failure for an average of 72 months received MSCs either by intramyocardial injection during coronary artery bypass grafting ($n = 5$) or by percutaneous intervention ($n = 3$). The control group consisted of eight matched patients who received the same treatment but without MSC injection. The study provided evidence that MSCs, regardless of the mode of injection, were safe, increased LVEF at 12–25 months (mean 18 months) after injection, improved New York Heart Association class, increased viable myocardium, and decreased infarction size at 6 months follow-up. However, the study did not provide data determining which mode of delivery was more beneficial, likely due to the small sample size. MSCs thus improve cardiac structure and function as well as quality of life for patients with chronic MI. While Mohyeddin-Bonab *et al.* demonstrated improvements in various cardiac parameters following MSC treatment, the concurrent administration of MSCs with coronary artery bypass grafting did not allow them to assess MSC autonomous effects.

The Prospective Randomized Study of Mesenchymal Stem Cell Therapy in Patients Undergoing Cardiac Surgery (PROMETHEUS) trial showed scar reduction, tissue perfusion and regional function improvements in patients with chronic ischemic cardiomyopathy who received autologous MSCs by intramyocardial injections into akinetic/hypokinetic nonrevascularized myocardial territories. Antifibrotic effects were seen in both the MSC-only treated segments as well as the revascularized-only segments. However, corresponding increases in viable tissue, improved regional contractility, and wall motion, as well as increased perfusion, were only seen in the MSC-treated group [104]. These improvements collectively contributed to a global increase in LVEF. Results from this study provide compelling evidence for MSC-induced neoangiogenesis, although whether it occurs through stimulation of endogenous CSCs or other resident cells, differentiation of MSCs into vascular smooth muscle/endothelial cells, or a combination of the two is unclear.

It is important to note that improvements in the previously mentioned parameters occurred to the greatest extent at the site of injection, suggesting that MSCs exert their greatest effects at the regional level, thus underscoring the significance of both the mode and the location of cell delivery.

Although the PROMETHEUS trial provided compelling evidence for the therapeutic application of MSCs in the clinical setting, the size of the trial and the lack of a placebo control were definite limitations. The Transendocardial Autologous Cells (human MSCs or BM-MNCs) in Ischemic Heart Failure Trial (TAC-HFT) trial, on the other hand, compared transendocardial injections of autologous MSCs, BM-MNCs, and placebo in 65 patients with chronic ischemic cardiomyopathy [105]. This study showed safety of delivery in all three groups, while only the MSC-treated and BM-MNC-treated patients displayed improvements in clinical measurements of quality of life using the Minnesota Living With Heart Failure (MLWHF) score and the 6 min walk test. Interestingly, infarct size as a percentage of LV mass was reduced and regional contractility improved in only the MSC-treated group. In contrast to the PROMETHEUS trial, LVEF was not increased by transendocardial MSC injections.

Another recent clinical trial by Hare and colleagues, The PercutaneOus StEm Cell Injection Delivery Effects On Neomyogenesis (POSEIDON) trial, not only compared allogeneic and autologous human BM-MSCs, but also explored the effect of cell dosage [106]. The 30 patients enrolled in this study were equally divided to randomly receive $2 \times 10^7$, $1 \times 10^8$, or $2 \times 10^8$ MSCs. Within each group of 10, five patients received autologous MSCs while the other five received allogeneic cells, although all patients underwent bone marrow aspiration. Interestingly, while there was an inverse relationship between cell dosage and improved cardiac structure and function, there was no significant difference between efficacy of allogeneic and autologous cells. This finding unveiled another important question about cell potency versus cell dosage.

Similar to the TAC-HFT trial, the POSEIDON trial utilized a transendocardial method of delivery. Using multidetector computed tomography and biplane left ventriculography, this study reported scar size reduction of approximately 44% in treated (allogeneic or autologous) segments versus a 25% reduction in nontreated segments [106]. Furthermore, while minimal scar reduction was evident in nontreated scar segments, an improvement in segmental LVEF was only seen in the MSC-treated segments. The primary endpoint for the TAC-HFT study was safety, which was satisfied, but while the lack of improved LVEF in the TAC-HFT trial is inconsistent with the similar improvements in LVEF in the PROMETHEUS and POSEIDON trials, the small sample size precludes definitive conclusions of efficacy.

Further proof of reverse remodeling in the POSEIDON trial is provided by the improved sphericity index (i.e., the ratio of the long and short axes of the left ventricle) in treated groups, as well as reduced diastolic and systolic volumes. However, end-diastolic volume and end-systolic volume reductions were only seen in the allogeneic-treated groups. In addition to the previously stated structural and functional improvements, the POSEIDON trial also reported improvements in New York Heart Association classification, 6 min walk tests, and MLWHF scores. Clinical improvements in treated patients, in addition to statistically significant evidence of reverse remodeling, further substantiate the role of MSCs in improving functional status and quality of life for patients with chronic ischemic cardiomyopathy.

**Figure 45.5** Twelve-lead electrocardiogram showing ST segment elevation (orange) in leads I, aVL, and V1–V5 with reciprocal changes (blue) in the inferior leads, indicative of an anterior wall MI. (See color plate section.) *Source:* this image, reproduced here from Wikimedia Commons, is in the public domain and is attributed as follows: "12 Lead EKG ST Elevation tracing color coded" by Displaced – Own work. Cumulatively, the results of these clinical trials demonstrate the safety and efficacy of MSCs as a therapeutic agent for acute and chronic ischemic cardiomyopathy.

## 45.6 Clinical trials utilizing adipose-derived mesenchymal stromal/stem cells

Adipose-tissue-derived MSCs have garnered attention not only due to their ease of isolation using a liposuction technique, but also because adipose tissue contains 500-fold more MSCs than adult bone marrow does [107], thereby reducing the time needed for cell expansion [108]. The vast array of tissues containing MSCs and the success of adipose-tissue-derived MSC transplantation in preclinical trials of acute ischemic cardiomyopathy [109] prompted swift transition to the clinical setting. In the Randomized Clinical Trial of Adipose-Derived Stem Cells in the Treatment of Patients With ST-elevation Myocardial Infarction (APOLLO trial), 14 patients with ST-segment elevation AMI were randomized 3 : 1 to receive intracoronary infusion of either $2 \times 10^7$ adipose-derived MSCs or placebo. Not only did this trial demonstrate the safety of adipose-derived MSCs for the first time in the acute setting of an MI, but it also provided evidence of a 50% infarct reduction, a significant improvement in perfusion defect, although there was no significant improvement in cardiac function. (A characteristic elevation of the ST segment of the electrocardiogram occurs in some cases of severe AMI, an example of which is shown in Figure 45.5.)

Together, the clinical trials described here that utilized both bone-marrow- and adipose-derived MSCs demonstrate safety and efficacy in the acute setting of an MI, necessitating additional and larger scale clinical trials.

The success of adipose-tissue-derived MSC transplantation in preclinical trials of chronic ischemic cardiomyopathy in addition to the APOLLO clinical trial prompted the Randomized Clinical Trial of Adipose-derived Stem Cells in Treatment of Non Revascularizable Ischemic Myocardium (PRECISE) clinical trial. In this study, adipose-derived MSCs were administered transendocardially to 21 patients with chronic ischemic cardiomyopathy, while six patients received placebo injections [108]. Results included improved $MVO_2$ values between groups from baseline to 6 and 18 months posttreatment, as well as significantly improved total LV mass measurements and wall motion score index values. Interestingly, neither scar size reduction nor increased LVEF were seen in either the APOLLO or the PRECISE trials. These results suggest that MSCs from different tissues are

not identical and produce their therapeutic effects by a different mechanism(s).

## 45.7 Preconditioning in the clinical setting

Promising results from a previously mentioned preclinical trial [110] prompted the Cardiopoietic Stem Cell Therapy in Heart Failure (C-CURE) trial. The underlying rationale and driving force for this study was that the induction of MSCs toward a cardiopoietic lineage should optimize repair potency [111]. The C-CURE trial ultimately enrolled 47 patients with chronic ischemic cardiomyopathy, 15 of whom received standard of care (control group) and 32 of whom received stromal cell injections. Autologous human BM-MSCs were harvested and isolated from the iliac crest of heart-failure patients followed by their *ex vivo* expansion. The MSCs were subsequently exposed to a cardiogenic growth factor cocktail to induce expression and nuclear translocation of certain cardiac transcription factors and thereby promote cardiopoietic lineage specification of the MSCs. The cells were further culture-expanded and the cardiopoietic cells were delivered by trans-endocardial injection. Cell-treated patients exhibited statistically significant increases in LVEF as well as decreased end-systolic volume values compared with patients treated with the standard of care. Additionally, the cell therapy group demonstrated significantly improved 6 min walk test values, but the MLWHF questionnaire results were not improved significantly. Along with the establishment of safety, these results provide evidence of improved cardiac structure and function and quality of life. As the first clinical trial to demonstrate the efficacy of lineage specification without the need for cardiac tissue harvesting, the C-CURE trial undeniably advances the field of cell therapy for heart disease. Further clinical validation is needed to compare nonlineage-specified MSC treatment as well as allogeneic lineage-specified cells.

## 45.8 Conclusions

MSCs have proven to be safe and effective in the treatment of acute and chronic heart disease. The unique immunomodulatory properties of MSCs and their secretion of a wide array of soluble factors sets them apart from other readily available or inducible cells. Additionally, preclinical and clinical trials demonstrating improved cardiac structure and function in the acute and chronic settings of ischemic cardiomyopathy encourage the eventual widespread use of MSCs as a therapeutic agent for the reversal of heart disease. Future clinical trials should address optimization of mode, location, and time of cell delivery, as well as the combination of different cells. Once preclinical trials establish the safety of using genetically modified MSCs, these experiments should move cautiously into the clinical realm. The future of MSC therapy lies in optimizing their efficacy, whether by cell survival, engraftment, secretion, and/or differentiation capacity.

## 46.1 Introduction

Peripheral arterial occlusive disease, also commonly known as peripheral artery disease (PAD), is a manifestation of atherosclerosis caused by obstruction of peripheral arteries (Figure 46.1). Critical limb ischemia (CLI) is the severe subset and end stage of PAD and is characterized by severe pain at rest, nonhealing ischemic skin lesions, and, finally, gangrene of the extremity due to inadequate blood supply to the limb [1]. If no therapeutic intervention is made during this stage of the disease the inevitable outcome is limb amputation [2]. The blockage of arteries is primarily due to atherosclerosis.

Another cause of PAD, especially in Mediterranean and Asian countries, is thromboangitis obliterans, also known as Buerger's disease. This is a recurring progressive inflammation and thrombosis of small and medium arteries and veins of the hands and feet. It is thought to be an autoimmune disease that is strongly associated with use of tobacco products, primarily from smoking, but also from smokeless tobacco [3]. Buerger's disease was first reported by Felix von Winiwarter in 1879 in Austria, but it was not until 1908 that the disease was given its first accurate pathological description by Leo Buerger of Mount Sinai Hospital in New York City.

Other causes of PAD include other autoimmune disorders like systemic lupus erythematosus and acute conditions such as arterial embolism. The prevalence of PAD has been estimated to be around 27 million in Europe and North America [4]. It occurs in approximately 3–12% of the general population and increases with age [5–7]. Buerger's disease accounts for a variable proportion of patients with peripheral vascular disease throughout the world: 0.75% in North America, 0.5–5.6% in western Europe, 16–66% in Korea and Japan, 45–63% in India, and 80% in Israel among Jews of Ashkenazi descent [3,8]. Various risk factors causally related to PAD include diabetes mellitus, hyperlipidemia, hypertension, and smoking. Coexisting coronary artery disease and cerebrovascular disease are highly prevalent in patients with PAD, particularly in the elderly population. CLI, which is the most severe form of the disease, is seen in 1% of the general population [9].

Diagnostic studies include measurement of hemodynamic changes by ankle–brachial pressure index (ABPI) (Figure 46.2), transcutaneous partial oxygen pressure (TcPO2), toe brachial

pressure index, exercise testing to elicit symptoms, segmental pressure monitoring, and Doppler examination of the vascular system.

Magnetic resonance angiogram and computed tomography angiography can also aid in the diagnosis [10]. The management of CLI is based on risk factor management and surgical or endovascular revascularization aiming to improve blood flow to the affected extremity [11]. Most patients with CLI are managed with analgesics and medications that inhibit platelet aggregation, such as cilostazol, in addition to lipid-lowering drugs. Cilostazol is a phosphodiesterase inhibitor with a therapeutic focus on cyclic adenosine monophosphate. It inhibits platelet aggregation and is a direct arterial vasodilator. Its main effects are dilation of the arteries supplying blood to the legs and decreasing platelet coagulation.

If revascularization has failed or is not possible, amputation is often necessary. Approximately 10% of CLI patients will undergo primary amputation, with healing rates varying between 30 and 90% and re-amputation rate at between 4 and 30%. Overall, approximately 40–50% of CLI patients will lose their leg within 6–12 months and approximately 15% will also require contralateral amputation within 2 years [12]. In CLI patients cardiovascular mortality increases substantially with approximately 20% of patients dying during the first 6 to 12 months after the onset of CLI, and 2, 5 and 10 year mortality rates of approximately 35%, 70% and 100% respectively [12]. It has therefore become urgent to develop new modalities of therapy that will induce revascularization, including neoangiogenesis and remodeling of the vascular system, to prevent the complications of CLI, thus improving limb salvage and increasing the overall survival of these patients.

## 46.2 Mesenchymal stem/stromal cells and angiogenesis

Several types of cells, particularly bone-marrow-derived mesenchymal stromal cells (BM-MSCs), have been shown to differentiate in the presence of appropriate growth stimuli along specific pathways including endothelial cells and perivascular cells. Mesenchymal stromal cells (MSCs) were isolated first from the bone marrow [13] and subsequently from a variety of other tissues, including adipose tissue, placenta, umbilical cord and cord blood, dental pulp, and amnion. MSCs are usually isolated by their plastic adherence property and can be expanded in large-scale culture for clinical use. Although no specific marker has been identified to isolate the MSC population, the International Society of Cell Therapy has defined these cells as being positive for CD73, CD105, CD90, and major histocompatibility complex class I antigens (human leukocyte antigen (HLA)-A, -B, and -C) and being negative for the hematopoietic markers CD45, CD34, CD14, CD19, and CD11b as well as major histocompatibility complex class II antigens (such as HLA-DR) [14]. The lack of a specific marker to identify MSCs has made it difficult to categorically determine the similarities or differences between the biological properties of these cells isolated from different tissues. Interestingly, BM-MSCs have been shown to possess several unique biological properties that are potentially beneficial for their use in both autologous and allogeneic cell therapy. Their intrinsic self-renewing ability and differentiation potential into chondrocytes, adipocytes, and osteocytes have been well documented [15,16].

Furthermore, MSCs are able to migrate and home to injured tissues, where they can act either by differentiating into cells of the musculoskeletal system if the injury is a musculoskeletal one and/or by secreting trophic factors that mediate paracrine signaling [16]. MSCs possess anti-inflammatory and immunomodulatory properties by a number of mechanisms, including inhibition of secretion of tumor necrosis factor-α (TNF-α) and interferon-γ and by increasing secretion of interleukin (IL)-10, indolamine 2,3 deoxygenase, prostaglandin $E_2$, and nitric oxide [17]. This unique immunomodulatory property makes these cells suitable for allogeneic, as well as autologous, use since they are nonimmunogenic as well as actively suppressive of T cells, B cells, natural killer cells, and macrophages and thus avoid rejection by the recipient's immune system [18].

It is now accepted that the myriad of growth factors and cytokines secreted by the MSCs *in vitro* and *in vivo* are critical for their therapeutic activity (Figure 46.3).

The major immunomodulatory cytokines secreted by MSCs include prostaglandin $E_2$, transforming growth factor-β1 (TGF-β1), hepatocyte growth factor (HGF), stromal derived factor-1, nitric oxide, indolamine 2,3-deoxygenase, IL-4, IL-6, IL-10, IL-1 receptor antagonist, and soluble tumor necrosis factor-α receptor.

With regard to angiogenesis, MSCs secrete vascular endothelial growth factor (VEGF), insulin-like growth factor-1 (IGF-1), epidermal growth factor, and angiopoietin (Ang)-1. These factors are released to recruit endothelial lineage cells and initiate vascularization [21]. MSCs also express mitogenic proteins such as TGF-α, TGF-β, HGF, epidermal growth factor, basic fibroblast growth factor, and IGF-1, which increase fibroblast, epithelial, and endothelial cell division [22]. These important factors are

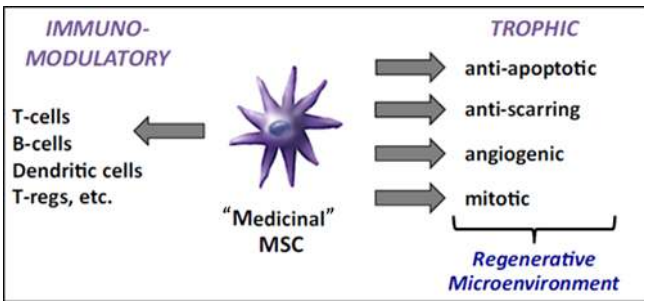

**Figure 46.3** The bioactive molecules secreted by medicinal MSCs are immunomodulatory and affect a variety of immune cell lineages [17]. Other secreted molecules establish a regenerative microenvironment by establishing a powerful trophic field [19]. *Source:* adapted from Caplan 2011 [20], pp. 11–15. Reproduced with permission of Elsevier.

known to play a key role in angiogenesis and act by a paracrine pathway [23,24]. Both VEGF and the angiopoietins (Ang-1 and Ang-2) play a crucial role in the process of neoangiogenesis. While Ang-1 and Ang-2 participate in the stabilization of the newly formed vessels, VEGF exerts its proangiogenic function by binding to one of its receptors, specifically VEGF receptor 2 (VEGFR2) also known as kinase insert domain receptor), which is expressed exclusively by endothelial cells and their precursors. This binding triggers a cascade of events leading to the formation of new blood vessels, including recruitment of support cells such as pericytes for small capillaries and smooth muscle cells for larger vessels [25]. MSCs have also been shown to possess anti-inflammatory, antiapoptotic, antifibrotic, mitogenic, and wound healing properties [26]. The anti-inflammatory properties of MSCs may be primarily responsible for the marked benefit of these cells in Buerger's disease, which is an inflammatory disease with a likely autoimmune basis affecting small and medium-sized arteries [27].

## 46.3 Potency assays for cells to be used in critical limb ischemia

The criteria for establishing the safety and quality of cellular therapies, both during production and at the time of lot release, are the use of potency assays to measure biologic activity appropriate to their intended clinical use. Potency testing, as stipulated by regulatory guidelines, should be a quantitative measure that reflects directly on the fundamental mechanistic pathway underlying the therapeutic response to verify the manufacturing process and is a measure of biological activity. A potency assay also provides the basis for comparability assessment after process changes, such as scale-up, site transfer, and new starting materials (e.g., a new MSC donor). Unlike defined component therapies with known molecular mechanisms, the therapeutic benefit of cellular therapies is often driven by its influence on a combination of mechanistic pathways and is often the result of a complex mixture of factors [28]. Cell viability is an important component of the potency of cell-based therapy. However, additional parameters of biological activity should also be tested [29] (and see Chapters 43 and 44).

Release specifications, which are acceptance criteria to be met by a product lot in order to allow administration to a patient, need to be defined in terms of identity, purity, and potency. Critical biological activity or potency for cell products can be defined by repeated testing of new cell lots in preclinical models. However, this is often not practical because the time taken for its execution is long and thus complicates lot release and clinical inventory requirements. Therefore, development of rapid, robust, consistent surrogate assays is required to ensure maintenance of biologic activity of cell therapies before their release for clinical use. Core requirements for potency testing as defined by the US Food and Drug Administration are presented in Table 46.1 [30].

**Table 46.1** US Food and Drug Administration core requirements for potency testing [30].

Potency testing of cell therapy product must:

- indicate product-specific biologic activity
- measure identity and activity of active component
- provide test results for product release
- provide data to establish stability specifications
- meet labeling requirements
- comply with biologics regulations and good manufacturing practice

Potency testing methods must:

- have predefined acceptance or rejection criteria
- include appropriate reference materials, standards, controls
- be amenable to validation
- have established and documented accuracy, sensitivity, specificity, and reproducibility
- provide quantitative data

Lehman *et al.* demonstrated that by using an *in vitro* endothelial tube formation assay a surrogate angiogenic potency assay could be developed that reflects the proangiogenic activity of multipotent adult progenitor cells (MAPCs) [28]. Serum-free conditioned media collected from MAPC culture induced endothelial tube formation. Three proteins, chemokine (C–X–C motif) ligand 5 (CXCL5), IL-8, and VEGF, were required and were linked to angiogenic potency. Depletion of any of these factors from the media prevented tube formation, while adding back increasing amounts of these cytokines into the depleted serum-free conditioned media established the lower limits of each of the cytokines required to induce angiogenesis. Thus, these markers were adopted as a surrogate potency assay for MAPC angiogenic activity.

### 46.3.1 Ixmyelocel-T

Ledford *et al.* demonstrated that ixmyelocel-T, which is an autologous patient-specific, expanded, multicellular therapy cultured from bone marrow mononuclear cells (BM-MNCs), contains a unique expanded population of M2-like macrophages that may limit tissue injury and promote repair [31]. It also contains large numbers of MSCs. M2 macrophages promote tissue repair and regeneration through various mechanisms, including immunomodulation and scavenging of tissue debris. It was proposed that delivering high numbers of these cells to ischemic tissues might limit tissue injury and promote repair. The authors demonstrated that macrophages in ixmyelocel-T therapy expressed the surface markers of M2 macrophages, CD206, and CD163. CD206 (also known as mannose receptor) is a 175 kDa type I membrane protein. It is a pattern recognition receptor belonging to the C-type lectin superfamily. CD163 is a scavenger receptor for the hemoglobin–haptoglobin complex.

After stimulation with lipopolysaccharide, they showed minimal secretion of the proinflammatory cytokines IL-12

and TNF-α compared with conventional M1 and M2 macrophages. Ixmyelocel-T macrophages efficiently ingested apoptotic BM-MNCs. They concluded that ixmyelocel-T therapy contained a unique population of M2-like macrophages that are characterized by expression of M2 markers, decreased secretion of proinflammatory cytokines after inflammatory stimuli, and efficient removal of apoptotic cells and that they may have a potential role in tissue repair and regeneration.

### 46.3.2 Stempeucel®

Stempeutics Research in Bangalore has developed a cell product called stempeucel®, which is an adult human bone-marrow-derived, cultured, pooled allogeneic MSC population. The cells show greater than 90% positivity for MSC-associated markers CD73, CD90, and CD105 and do not express CD34, CD45, or HLA-DR or co-stimulatory molecules (Figure 46.4) [32,33].

The probable mechanism of action of stempeucel in CLI is through secretion of growth factors, chemokines, and cytokines that are known for their pro-angiogenic, anti-inflammatory, and immunomodulatory functions [34]. BM-MSCs are known to secrete angiogenic cytokines such as VEGF, IL-6, IL-8, and Ang-1, and they have been shown to be potently angiogenic [35]. VEGF has a unique feature compared with the other growth factors in the regulation of new blood vessel formation in that it has a high degree of specificity for endothelial cells. VEGF treatment of cultured endothelial cells promotes cell survival, proliferation, migration, calcium influx, and branching morphogenesis [36]. In order to understand the exact mechanisms involved, stempeucel was initially screened for the expression of angiogenic genes such as VEGF A and its receptor VEGFR2, IL-6, Ang-1, HGF, keratinocyte growth factor (KGF), IGF-1, and TGF-β by reverse transcriptase polymerase chain reaction (Figure 46.5). The results clearly demonstrated that stempeucel expressed most of the angiogenic genes and that VEGF could potentially be a surrogate potency marker for stempeucel [31–33].

A possible potency assay for an MSC-based product for use in CLI could be its ability to initiate the process of neoangiogenesis. The potency assay could indicate the mechanism of action of the cellular product and could be used for quality control (stability) throughout the manufacturing process. Different studies [28,31] have demonstrated that various surrogate angiogenic markers can be established to demonstrate the potency of the product in CLI. These include VEGF, CXCL5, IL-8, endothelial tube formation, markers of M2 macrophages (CD206, CD163), IL-6, Ang-1, HGF, KGF, IGF-1, and TGF-β.

Selection of an angiogenic marker or markers is important in order to demonstrate the ability of the product to effect the desired therapeutic result. Developing at least two different methods increases the chances that one of them will be suitable for the product and will satisfy the requirements of the regulatory authorities [37].

## 46.4 Preclinical studies

### 46.4.1 Preclinical safety studies

Many studies have demonstrated that MSCs are nontoxic and nontumorigenic when tested in various preclinical animal models. MSCs from different tissue sources have been studied for potential side effects according to the regulatory criteria of respective countries (see Chapter 44). Studies involving both allogeneic and xenogeneic MSCs have shown that these cells are nontoxic. Similar results have been found in numerous clinical trials. Ra *et al.* studied the safety of human adipose-tissue-derived MSCs (ADMSCs) in humans and animals [38]. Immunodeficient mice were exposed to different doses of human ADMSCs intravenously and were observed for 13 weeks. There were no side effects and no mortality was observed. Tumorigenicity testing in BALB/c-nu (nude) immunodeficient mice showed no evidence of tumor formation even at the highest cell dose used.

Isakova *et al.* injected BM-MSCs into the central nervous system of young adult rhesus macaque monkeys to evaluate their safety and feasibility as vectors for direct intervention in neurologic disorders. The study demonstrated that the procedure of cell implantation was well tolerated and there was no observed toxicity attributable to the injected MSCs. Importantly, unlike the study by Ra *et al.*, in which xenogeneic cells were used, the study by Isakova *et al.* used syngeneic MSCs isolated from the iliac crest of a male rhesus macaque [39].

There have been concerns over the possibility of aggregation of these cells producing emboli in the lungs [40]. However, Eggenhofer *et al.* demonstrated the MSCs delivered by intravenous infusion have a short life and do not migrate to other organs [41], although other studies of intravenously injected MSCs have shown that after initial lodgment in the lungs they can subsequently migrate to sites of inflammation beyond the pulmonary capillary bed (see Chapters 22 and 23).

We have also conducted preclinical safety studies using BM-MSCs. These studies included acute toxicity studies (14 days single dose and 14 days repeat dose) by intravenous and intramuscular administration of stempeucel, as well as longer toxicity studies (90 days single dose) in two animal species (rats and rabbits) by two routes (intravenous and intramuscular) of administration. The toxicity studies were conducted using human-equivalent doses in respective animals to a maximum dose of $20 \times 10^6$ BM-MSCs/kg body weight. In addition, tumorigenicity and prenatal developmental toxicity studies have also been performed in immunocompromised mice and Sprague Dawley rats respectively. Results have shown that these cells are safe, nontumorigenic, nonteratogenic, and did not induce genotoxicity (Mathi *et al.* unpublished results).

Studies using a wide range of doses ($2 \times 10^6$ cells/kg body weight to $250 \times 10^6$ cells/kg body weight) of MSCs have been used in preclinical studies and have not shown signs of toxicity in rodents and large animal studies, including subhuman primates.

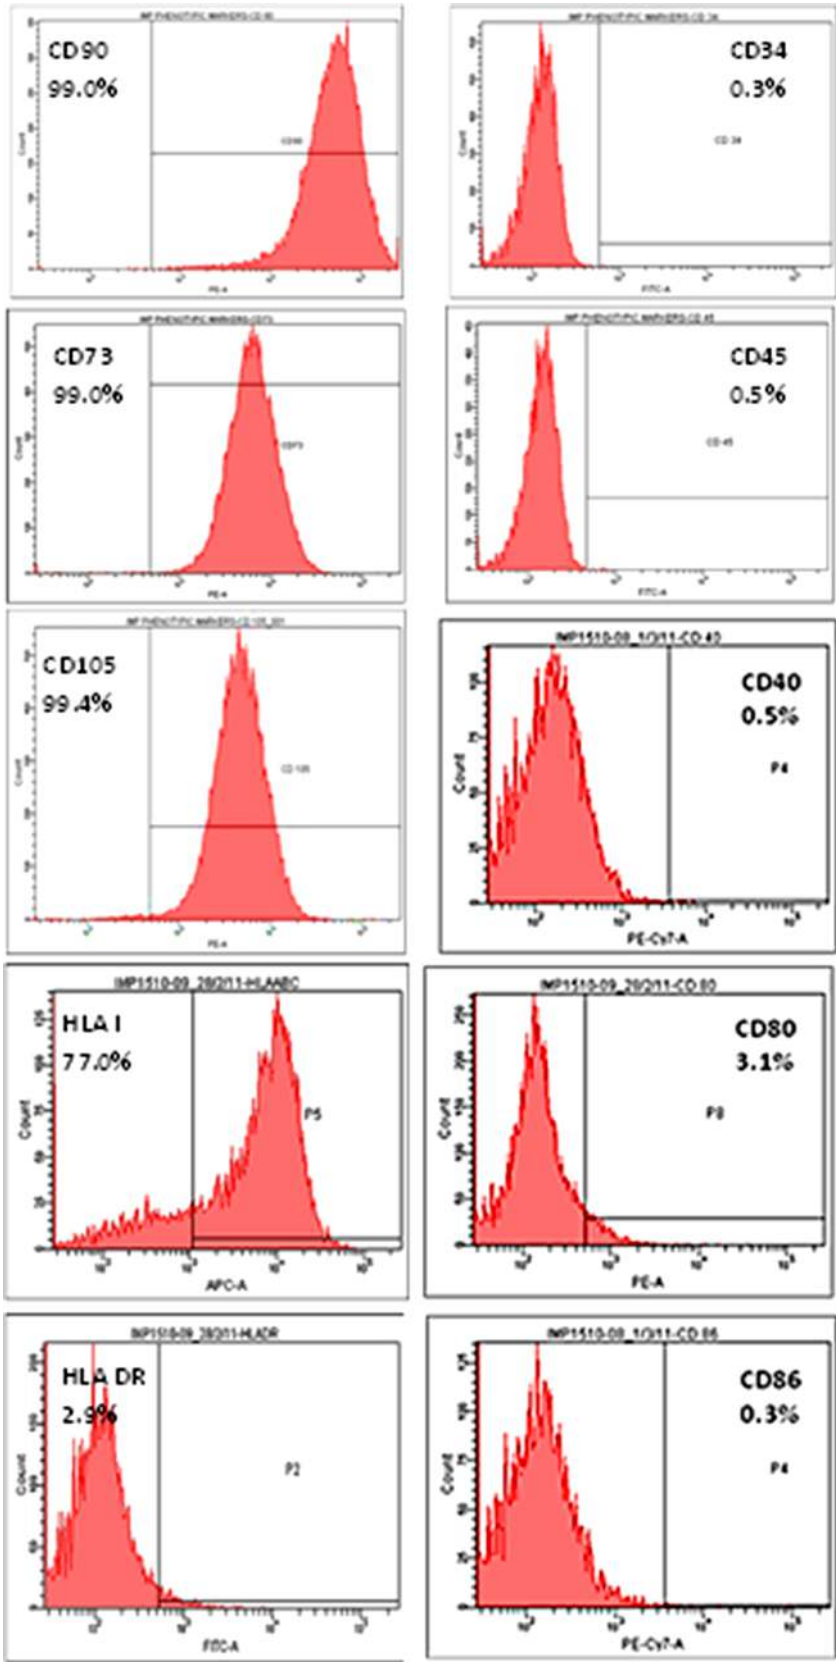

**Figure 46.4** Immunophenotype analysis of stempeucel. Stempeucel is positive for expression of the characteristic mesenchymal stromal cell markers CD90, CD73, and CD105 and negative for hematopoietic markers CD34 and CD45, as well as HLA-DR and the immune co-stimulatory markers CD80 and CD86.

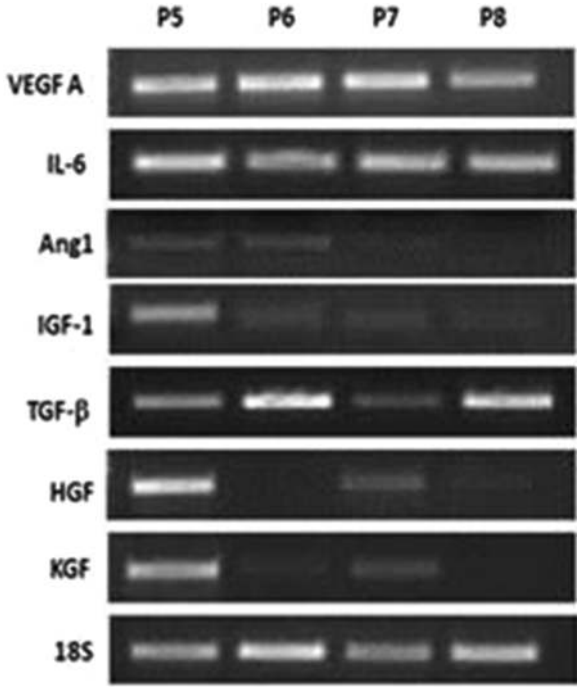

**Figure 46.5** Reverse transcriptase polymerase chain reaction showing that stempeucel expresses most of the angiogenic genes, including VEGF A, IL-6, Ang-1, IGF-1, TGF-β, HGF, and KGF from passage 3 to passage 7.

### 46.4.2 Preclinical efficacy studies

It is also important to demonstrate efficacy of any cell therapy product in an animal model of disease before administering the same cells to humans with the same disease. Unlike conventional small molecules, stem cell products face a unique challenge in this area. The disparity lies in determining the suitability of using animal stem cells in animals or human stem cells in immunocompromised/immunocompetent animals. A common regulatory requirement is to have animal data for the same test product that is intended to be tested in humans. This infers a regulatory preference for testing a human cell product in an animal disease model that closely resembles the human disease condition for which the product is intended. However, to validate the concept of efficacy, scientists have more commonly tested animal cells in animals.

In the context of this chapter, numerous animal models have shown that transplantation of MSCs or mononuclear cells (MNCs) from different sources augmented arteriogenesis in the ischemic limb of the animal [42,43]. Kim *et al.* compared the angiogenic potency of human mesenchymal stem/stromal cells derived from adipose tissues (ADSC) and bone marrow in a nude mouse model of hind limb ischemia [42]. Two weeks after transplantation the laser Doppler perfusion index was significantly higher in the ADSC group and BM-MSC groups compared with animals in the control group. The authors demonstrated that human MSCs can be a potential source for therapeutic angiogenesis.

Iwase *et al.* studied whether MSCs or MNCs would be a better option for treatment of CLI in a rat model of hind limb ischemia [43]. Three weeks after injection the laser Doppler perfusion index was noted to be significantly higher in the MNC group than in the control group. Capillary density was found to be higher in the MSC group than in the MNC-treated group. The numbers of endothelial cells and vascular smooth cells derived from the injected cells were also higher in the MSC group than in the MNC group. The study concluded that MSCs provided greater improvement in hind limb ischemia than MNCs.

We have performed preclinical efficacy studies in an animal model of hind limb ischemia in BALB/c nude mice to determine the efficacy of stempeucel. We used an extended femoral ligation method as the model and injected stempeucel intramuscularly at two different doses around the ligation. In the control group, all animals developed foot necrosis, whereas in the stempeucel group the highest dose of $5 \times 10^6$ MSC-treated animals showed 43% protection from foot necrosis. The results clearly demonstrated that animals treated with the highest dose of stempeucel had a better outcome than animals treated with the lower dose.

Based on this preliminary study a second efficacy study was performed with stempeucel at a dose of $5 \times 10^6$ cells. The results clearly showed a significant improvement in limb function, limb salvage, and histology scores, including muscle fiber area in animals treated with stempeucel, compared with the animals treated with the vehicle control (unpublished results). Histological analysis of limb muscles at day 28 after stempeucel injection revealed significant increase in the total muscle fiber area and significantly reduced muscle degeneration, inflammation, and muscle necrosis (Figure 46.6).

These findings suggest that allogeneic human BM-MSCs have the therapeutic potential to reduce inflammation and muscle degeneration and to promote neoangiogenesis for the healing of ischemic ulcers in CLI patients.

## 46.5 Clinical trials in critical limb ischemia

### 46.5.1 Safety of mesenchymal stromal cells in clinical trials

Lalu *et al.* conducted a systematic review of the literature and a meta-analysis of clinical trials to evaluate the safety of MSCs given intravenously or intra-arterially to humans [44]. A total of 1012 participants with various clinical conditions were included. Eight studies were randomized controlled clinical trials and enrolled 321 of the total 1012 patients studied. Both adult populations and mixed adult and pediatric populations were included. Studies using differentiated MSCs or additional cell types were excluded. There was a significant association between MSCs and transient fever at or shortly after MSC administration, which was not associated with long-term sequelae. Importantly, the pooled analysis recorded no serious adverse events due to administration of the MSCs and specifically found no association between MSCs and tumor formation. Other potential risks, such

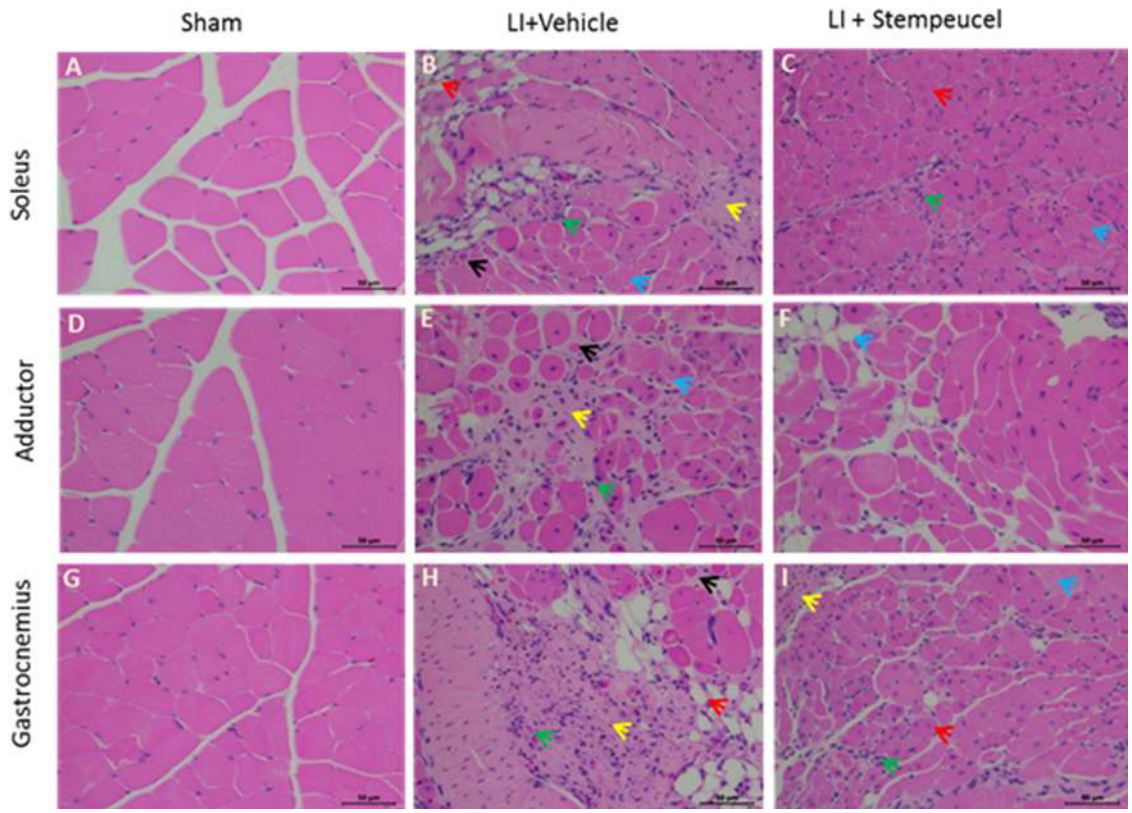

**Figure 46.6** Histology (hematoxylin and eosin stain) of sham-treated, arterial ligation+vehicle and arterial ligation+stempeucel animals after 28 days. (A, D, G) Cross-sections of skeletal muscles (A; soleus; D: adductor; G: gastrocnemius) of sham-treated animals showing the normal histology of muscle fibers with a peripheral nucleus arranged in muscle bundles with occasional blood vessels seen in between. (B, E, H) Cross-sections of the skeletal muscles (B; soleus; E: adductor; H: gastrocnemius) of animals after arterial ligation treated with vehicle showing severe vacuolar degeneration (red arrow), infiltration of inflammatory cells (green arrow), necrosis of muscle fibers (yellow arrow), degeneration of muscle fibers (blue arrow), and atrophy of muscle fibers (black arrow). (C, F, I) Cross-sections of the skeletal muscles (C; soleus; F: adductor; I: gastrocnemius) after arterial ligation in animals treated with stempeucel showing very mild degeneration of muscle fibers (blue arrow), infiltration of inflammatory cells (green arrow), and necrosis of muscle fibers (yellow arrow). Many regenerating muscle fibers (red arrow) with a centrally placed nucleus are observed. (See color plate section.)

as acute infusional toxicity, organ system complications, infection, or death, were also not associated with MSC administration. Hence, one can conclude that systemic administration of MSCs is safe.

### 46.5.2 Efficacy of mesenchymal stromal cells in clinical trials of critical limb ischemia

Several clinical trials have been conducted using AD- or BM-MSCs in CLI, both in atherosclerotic PAD and in Buerger's disease. Administration has been fairly standardized, with cells being administered in most studies by intramuscular injection into the gastrocnemius muscle. A few studies have also tried intra-arterial injections. There has been a preference for administering the MSCs locally around the ischemic ulcers for better healing.

On searching clinicaltrials.gov using the keywords "stem cells" and "CLI" we found 46 completed or ongoing clinical trials. Fifteen studies were using mesenchymal stem/stromal cells as the investigational agent, while other studies were using autologous MNCs from the bone marrow. TACT (Therapeutic Angiogenesis using Cell Transplantation) was the first large report on the use of BM-MNCs in the treatment of CLI [45]. In this pilot study they investigated the efficacy and safety of autologous implantation of BM-MNCs in patients with ischemic limbs because of PAD. They concluded that administration of autologous BM-MNCs was safe and effective for obtaining therapeutic angiogenesis, presumably because of the ability of marrow-derived cells to supply endothelial progenitor cells and to secrete various angiogenic factors or cytokines. They further suggested that the success of BM-MNCs transplantation was due to a higher number of $CD34^+$ hematopoietic stem cells and immature precursor cells in the bone marrow compared with peripheral blood. This was the first study using cells for the treatment of limb ischemia, and it was followed by a number of studies across the globe. The studies published in clinicaltrials.gov using mesenchymal stem cells are shown in Table 46.2.

Idei *et al.* assessed long-term clinical outcomes after BM-MNC administration in 51 patients with CLI, including 25 patients with PAD and 26 patients with Buerger's disease. Forty-six CLI

MNCs: mononuclear cells; MSCs: mesenchymal stromal cells; BM-MSCs: bone marrow-derived mesenchymal stromal cells; ADMSCs: adipose-tissue-derived mesenchymal stromal cells; EPCs: endothelial progenitor cells; UMSCs: umbilical-cord-derived mesenchymal stromal cells.

patients who had no BM-MNC injection served as control subjects. The median follow-up period was 4.8 years. The 4-year amputation-free rates after BM-MNC implantation were 48% in PAD patients and 95% in Buerger's disease, while they were 0% in control PAD patients and 6% in control Buerger's disease. The 4-year overall survival rates after BM-MNC implantation were 76% in PAD patients and 100% in Buerger's disease, while they were 67% in control PAD patients and 100% in control Buerger's disease. Multivariable Cox proportional hazards analysis revealed that BM-MNC implantation correlated with prevention of major amputation and that hemodialysis and diabetes mellitus correlated with major amputation. In the patients with Buerger's disease, ABPI and TcPO2 were significantly increased after 1 month and remained high during the 3-year follow-up period. However, in patients with PAD, ABPI and TcPO2 significantly increased after 1 month but then gradually decreased during the 3-year follow-up period and returned to baseline levels. The authors concluded that BM-MNC transplantation is safe and effective in patients with CLI, especially in patients with Buerger's disease [27].

We have earlier evaluated and reported the results of a study of 13 patients in a phase I trial to investigate the safety and efficacy of intra-arterial injection of BM-MSCs in CLI patients. There was significant pain relief in these patients at 6 months after cell administration compared with their baseline level. Visual analog scale scores decreased from $2.29 \pm 0.29$ to $0.5 \pm 0.34$ ($P < 0.05$), ABPI increased significantly from $0.56 \pm 0.02$ to $0.67 \pm 0.021$ ($P < 0.01$), and TcPO2 also increased significantly in the foot from $13.57 \pm 3.63$ to $38 \pm 3.47$ ($P < 0.05$). Similar improvements were seen in the leg as well as in the thigh region. There was 86% limb salvage and six of seven ulcers showed complete or partial healing. The authors concluded that intra-arterial MSCs could be safely administered to patients with CLI and that significant therapeutic benefits were observed in these patients [46]. (A visual analog scale is a psychometric response scale that can be used in questionnaires. It is a measurement instrument for subjective characteristics or attitudes that cannot be directly measured. When responding to a visual analog scale item, respondents specify their level of agreement to a statement by indicating a position along a continuous line between two endpoints.)

The ulcer healing properties of BM-MSCs was demonstrated by Dash *et al.* [47]. This study was undertaken to assess the efficacy and feasibility of autologous BM-MSCs in the treatment of chronic nonhealing ulcers in patients with diabetic foot ulcers or Buerger's disease of the lower extremities. A total of 24 patients with nonhealing ulcers of the lower limb were enrolled and randomized into cell and control groups. In the cell group the patients received autologous cultured BM-MSCs together with standard wound dressing. The control group received only the standard wound dressing regimen. Patients were followed up for at least a 12-week period. Wound size, pain-free walking distance, and biochemical parameters were measured before therapy and at 2-week intervals following the intervention. The cell group had a significant improvement in pain-free walking distance and a reduction in ulcer size compared with those in the control group. There was no significant alteration in biochemical parameters observed during the follow-up period, indicating normal liver and renal function following the intervention. The study indicated that autologous implantation of BM-derived MSCs in nonhealing ulcers accelerated the healing process and significantly improved clinical parameters.

Lu *et al.* conducted a study to compare autologous bone-marrow-derived mesenchymal stem/stromal cells with the BM-MNCs for the treatment of diabetic CLI and foot ulceration [48]. The ulcer healing rate in the BM-MSC group was significantly higher than that in the BM-MNC group at 6 weeks after injection and reached 100% 4 weeks earlier than in the BM-MNC group. After 24 weeks of follow-up the improvements in limb perfusion induced by BM-MSC administration were more significant than those receiving BM-MNCs in terms of painless walking time, ABPI, TcPO2, and magnetic resonance angiography analysis. There was no significant difference between the groups in terms of pain relief and amputation and there were no serious adverse events related to either type of cell injections. The authors concluded that BM-MSC administration may be better tolerated and more effective than BM-MNCs for increasing lower limb perfusion and promoting foot ulcer healing in diabetic patients with CLI.

Teraa *et al.* conducted a meta-analysis of all randomized controlled trials (RCTs) that studied bone-marrow-derived cell therapy compared with standard care with or without placebo in CLI patients. Major amputation and amputation-free survival were considered as the primary endpoints. A total of 12 RCTs cumulatively including 510 CLI patients were analyzed. The meta-analysis showed significant beneficial effects of bone-marrow-derived cell therapy on both subjective and surrogate objective endpoints, including pain score, pain-free walking distance, ABPI, and TcPO2 measurements. Overall, the RCTs showed reduced amputation rates in the therapeutic arms of the trials with a relative risk (RR) of major amputation of 0.58 (95% confidence interval (CI), 0.40–0.84;$P = 0.004$). However, when only the placebo-controlled RCTs were considered, the beneficial effect on major amputation rates was considerably reduced and no longer significantly different (RR = 0.78; 95% CI, 0.40–1.51; $P = 0.46$). Amputation-free survival did not significantly differ between the bone-marrow-cell-treated group and the control group. This meta-analysis underlined the promising potential of bone-marrow-derived cell therapy in CLI patients, but importantly indicated the need for placebo-controlled clinical trials once safety and feasibility issues were satisfactorily resolved in phase I trials [49].

### 46.5.3 Clinical trials in India

Few clinical trials using allogeneic or autologous MSCs or MNCs in CLI have been conducted in India. The first initiative was undertaken by the Department of Biotechnology, Government of India, which conducted a multicenter trial using autologous BM-MNCs in patients with CLI, the results of which are yet to be published.

Motukuru *et al.* enrolled 36 patients with nonreconstructible Buerger's disease and injected autologous BM-MNCs into the calf muscles of the affected limbs in a clinical trial conducted at Jain Institute of Vascular Sciences, Bhagwan Mahaveer Jain Hospital, Karnataka, India [48]. They reported no procedure-related complications. Three patients (12%) underwent major amputations within 6 months. The others had improvement in ulcer healing, an increase in the mean ABPI, and an improvement in mean TcPO2 levels, resulting in limb salvage in all at 6 months. They concluded that BM-MNCs transplantation into ischemic limbs was a relatively safe procedure with no demonstrable side-effects at 6 months follow-up.

### 46.5.4 Stempeutics research experience in critical limb ischemia

The off-the-shelf allogeneic BM-MSC product developed by Stempeutics has undergone two clinical trials in CLI. The phase I/II trial included all patients with CLI (both atherosclerotic CLI and Buerger's disease), while in the phase II trial we exclusively included patients with CLI due to Buerger's disease as per Shionoya's diagnostic criteria [51]. These criteria are a smoking history, onset before the age of 50 years, infrapopliteal arterial occlusions, either upper limb involvement or phlebitis migrans, and absence of atherosclerotic risk factors other than smoking. All five criteria need to be present in order to make a diagnosis of Buerger's disease. Phlebitis is inflammation of a vein. When it occurs repeatedly in different locations it is known as thrombophlebitis migrans or migrating thrombophlebitis and can be an early indicator of gastric or pancreatic cancer.

### 46.5.5 Phase I/II study in patients with critical limb ischemia

The phase I/II results of stempeucel in CLI patients have been published [52]. Briefly, 10 patients each were randomized to either the cell arm or the placebo arm. A BM-MSC dose of 2 million MSCs/kg body weight administered intramuscularly was shown to be safe in patients with CLI. Improvement was observed in the rest pain scores in both arms, and no measurable differences were observed between the two arms. A significant

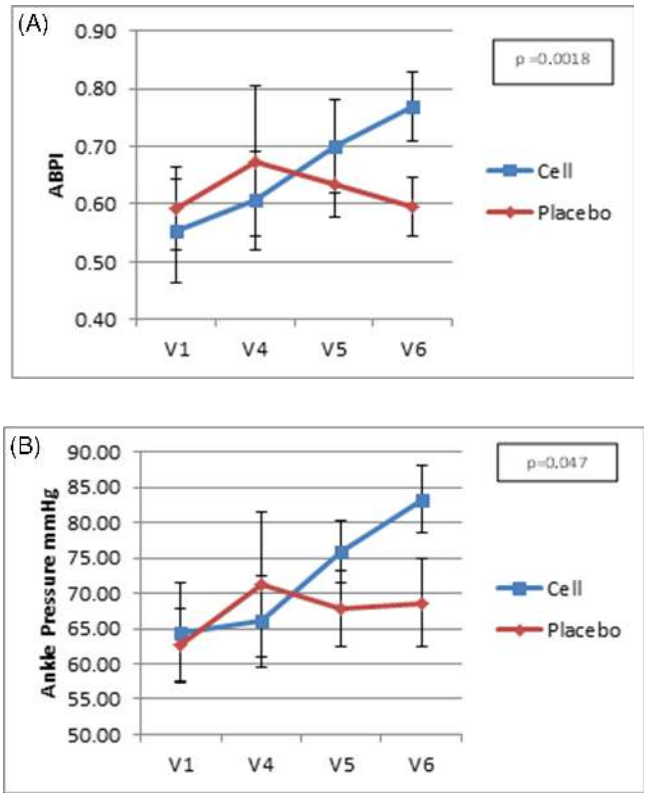

**Figure 46.7** Phase I/II study efficacy parameters. Results of the ankle-brachial index test (A) and ankle pressure (B) are shown as mean plus/minus standard deviation. VI: screening; V4: 1 month; V5: 3 months; V6: 6 months of follow-up.

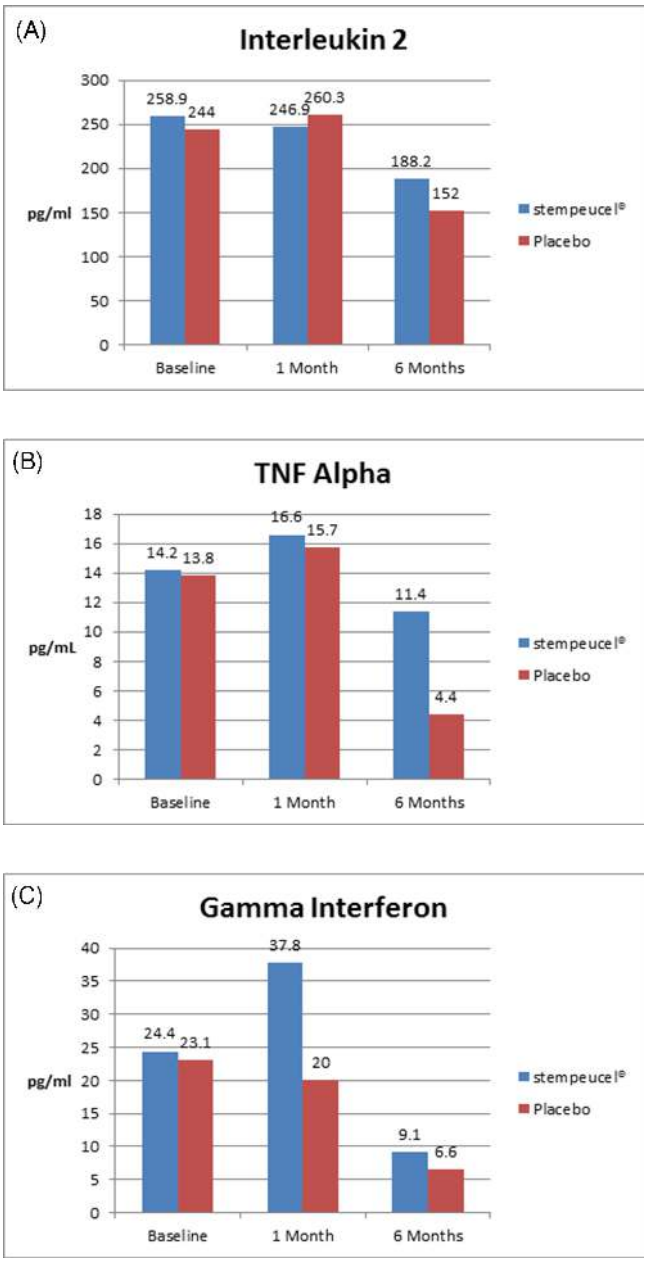

**Figure 46.8** Immunological response markers in stempeucel-treated arm and placebo arm at baseline, 1 month, and 6 months follow-up for IL-2 (A), TNF-α (B), and interferon-γ (C).

increase in ABPI and ankle pressure was seen in the MSC arm compared with the placebo group (Figure 46.7).

It is noteworthy that although a small group of 10 patients was recruited in each arm of the trial, we found a significant increase in the blood flow of patients in the lower limbs that received stempeucel. The incidence of adverse events in the BM-MSC arm was 13 versus 45 in the placebo arm, while the incidence of serious adverse events was similar in both the arms: five in the MSC group and four in the placebo group. The serious adverse events were related to disease progression and not related to the administration of cells or placebo.

In addition to routine safety laboratory parameters, such as measurement of parameters of renal and hepatic function, levels of the proinflammatory cytokines IL-2, TNF-α, and interferon-γ were documented. $CD4^+$, $CD8^+$, and $CD25^+$ lymphocyte numbers before and after stempeucel or placebo injection were measured by flow cytometry at baseline, 1 month, 3 months, and 6 months. Results showed that both immunological response (Figure 46.8) and CD markers (Figure 46.9) were comparable in both the placebo and cell arms.

No significant difference in blood lymphocyte profile or in serum cytokine level was observed between stempeucel and placebo-administered patients, suggesting that the administered allogeneic cells did not elicit a T cell proliferative response *in vivo*. With respect to the levels of the proinflammatory cytokines, we observed a possible difference between the MSC recipients and the placebo control patients at baseline, 1 month, and 6 months after treatment, but they were either comparable to the baseline values or were within the normal range of these cytokines. Collectively, these data indicate that allogeneic BM-MSC

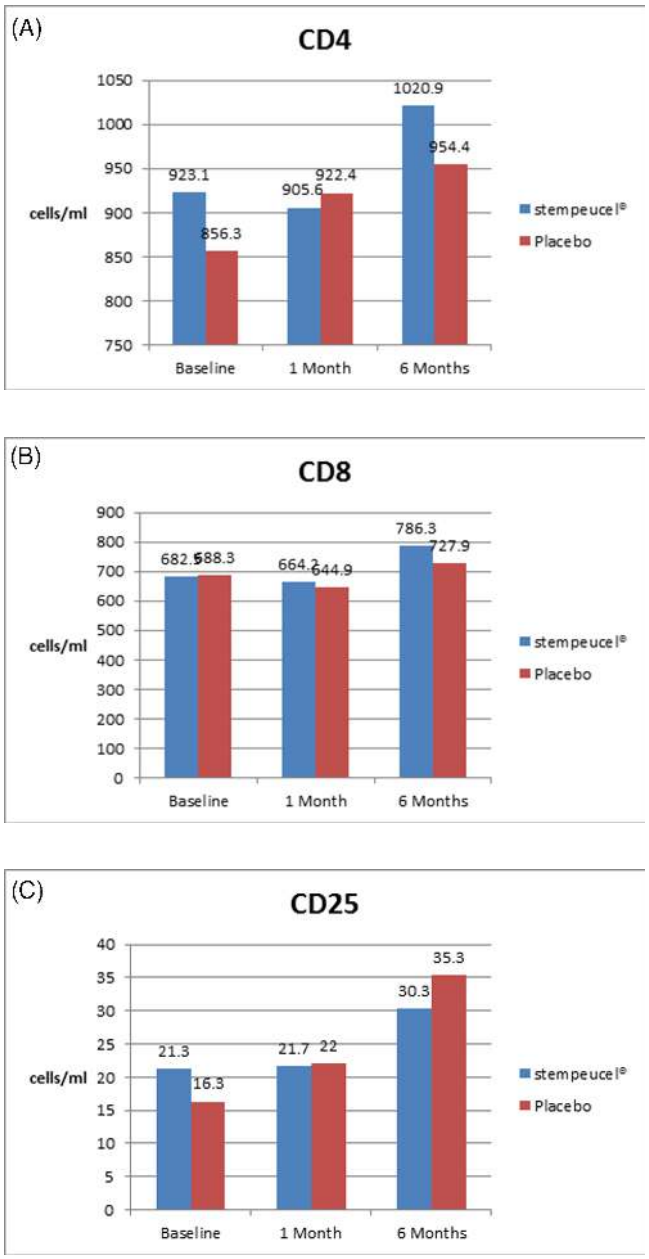

**Figure 46.9** CD markers in stempeucel arm and placebo arms at baseline, 1 month, and 6 months follow-up for $CD4^+$ cells (A), $CD8^+$ cells (B) and $CD25^+$ cells (C).

administration in CLI patients did not adversely alter the immunological profile.

It was concluded that BM-MSCs were safe when injected intramuscularly at a dose of 2 million cells/kg body weight. The safety profile exhibited by BM-MSCs, coupled with the observed improvements in some of the important clinical parameters in Buerger's disease, warranted a separate study with a larger number of patients. An open-label nonrandomized dose-finding phase II study was next conducted in patients with Buerger's disease.

### 46.5.6 Phase II study in patients with Buerger's disease

The second trial initiated in patients with CLI due to Buerger's disease was an open-label, nonrandomized, dose-finding phase II study evaluating different dose levels of stempeucel in patients with CLI due to Buerger's disease. Thirty-six patients were accrued to one arm of the study and received 1 million MSCs/kg, and 36 were accrued to the second arm of the study and received 2 million MSCs/kg. Eighteen patients were accrued to the control arm. Patients in the cell groups received the respective dose of stempeucel into the calf muscle of the affected limb and 2 mL of stempeucel around ischemic ulcers. Patients belonging to the control arm received standard of care only. Six months follow-up of the patients has been completed, and these patients will be followed up for 2 years.

The safety profiles of both the 1 million MSCs/kg and 2 million MSCs/kg groups were comparable to that of control group. All the adverse events were manifestations of the underlying disease. None of the serious adverse events reported were related to stempeucel as per the investigators' feedback and were due to progression of the disease. There was significant improvement in both the primary endpoints of the trial: relief of rest pain (Figure 46.10) and healing of ulceration.

Furthermore, stempeucel recipients showed a significant increase in blood flow in the lower limbs, as evidenced by a significant increase in ankle systolic pressure (Figure 46.11) and total walking distance in the 2 million MSCs/kg dose group.

Hence, it was concluded that BM-MSCs at a dose of 2 million MSCs/kg body weight has a role in alleviating the symptoms of CLI in Buerger's disease.

## 46.6 Conclusions

CLI represents the most severe manifestation of PAD, diminishes quality of life and global function, and is often associated with very high short-term mortality. Prompt clinical diagnosis, vasodilator agents, and surgical revascularization represent the current standard of care. However, in some patients this care is either not possible or ineffective in providing clinical benefit. Effective new biological and angiogenic therapies would fill a real clinical need. Current literature favors the administration of autologous BM-MNCs or allogeneic BM-MSCs; the latter are relatively safe, easy to expand *ex vivo*, and appear to be efficacious. Issues that remain unresolved include the optimal cell type, optimum cell dosage, and optimal route of administration. Cells that have immunomodulatory and proangiogenic properties appear likely to be the cell of choice for the treatment of CLI due to PAD.

## 47.1 Summary

Mesenchymal stromal cells (MSCs) are a population of progenitor cells that can be easily isolated from bone marrow, adipose tissue, and other sources and culture expanded for cell-based therapeutic applications. MSCs can be differentiated into various mesenchymal tissue types, including bone, cartilage, muscle, and tendon, and thus play a pivotal role in the regeneration of musculoskeletal tissues. This chapter describes the potential of MSCs for site-specific and systemic tissue regeneration applications and summarizes the current preclinical and clinical evidence.

## 47.2 Introduction

Cells are key players in the treatment of musculoskeletal disorders. Interest in basic and clinical research of MSCs has increased dramatically during the last two decades. MSCs have the potential to differentiate into various types of cells of mesenchymal lineage. They have provided hope for regenerative medicine in the future. The International Society for Cellular Therapy proposed minimal criteria to define human MSCs in 2008 [1]. First, MSCs are plastic-adherent when maintained in standard culture conditions. Second, MSCs express CD105, CD73, and CD90, and lack expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA-DR surface molecules. Third, MSCs are able to differentiate into osteoblasts, adipocytes, and chondroblasts *in vitro*.

MSCs were first isolated from murine bone marrow by Friedenstein *et al.* [2]. Since then they have been isolated from almost tissues, including adipose tissue [3], trabecular bone [4], periosteum [5], synovial membrane [6], skeletal muscle [7], dental pulp [8], placenta, and others [9]. However, the most commonly used sources for MSCs are bone marrow (Figure 47.1) and adipose tissue [11]. Tissue-specific stem-like cells and precursor cells from the bone marrow collaborate for tissue repair [12].

Currently, two strategies exist for preparing MSCs for clinical applications (Figure 47.2), each with its advantages and disadvantages.

Applying *instant* cell therapy, bone marrow aspirates containing approximately $1 \times 10^2$ MSCs/mL are harvested, usually from the iliac crest [13]. MSCs are then concentrated by centrifugation

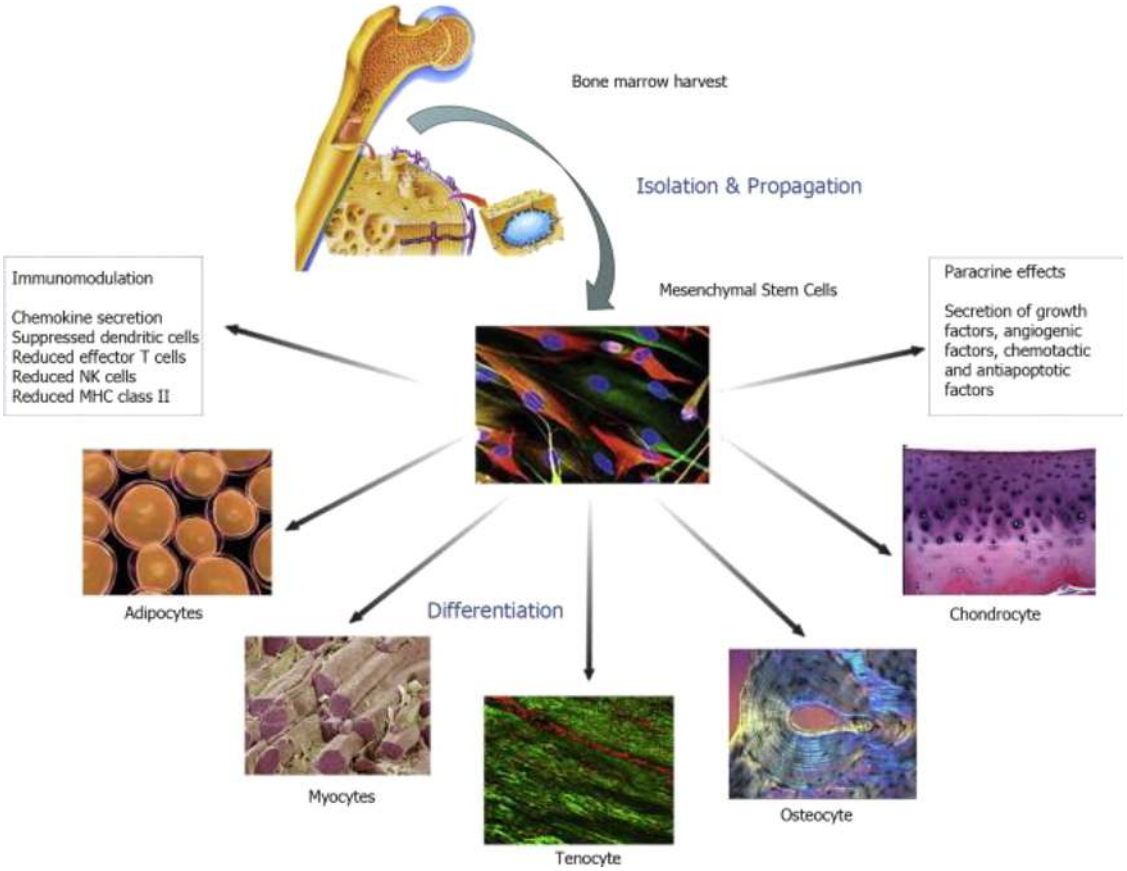

**Figure 47.1** MSCs can be isolated from numerous connective (and other) tissues, but bone marrow has been the most widely used source to date. The effects of MSCs may be mediated by differentiation toward the target cell lineage (at least in the case of the musculoskeletal system) and by their secretion of trophic (supportive) factors via paracrine and autocrine activity, including angiogenic, chemoattractant, antiapoptotic, and anti-inflammatory factors, as well as by immunomodulation of T cells, B cells, and natural killer cells. (See color plate section.) *Source:* Nixon [10], pp. 278–294. Reproduced with permission of Elsevier.

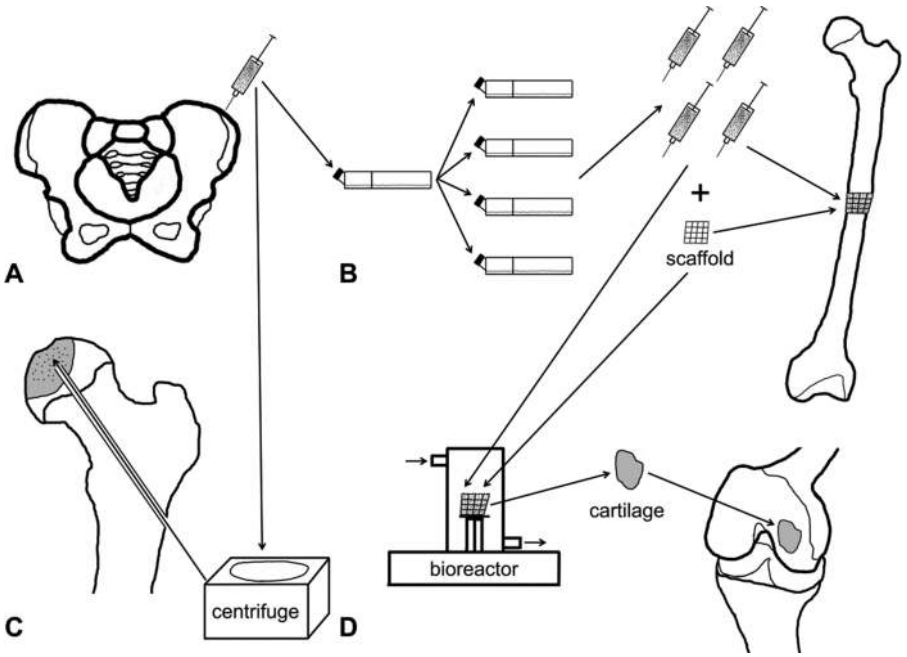

**Figure 47.2** Options for using MSCs in the treatment of musculoskeletal disorders. (A) Bone marrow is most commonly aspirated from the iliac crest. Thereafter, there are various ways to process the cells for their administration to the patient. For "immediate" administration the bone marrow aspirate is concentrated by centrifugation and placed directly at the site of injury. As an example, this is used clinically to treat early stages of osteonecrosis of the femoral head. (C) Cells concentrated by centrifugation are applied after core decompression. Alternatively, to generate large numbers of cells, MSCs are isolated from the bone marrow aspirate and expanded in *ex vivo* culture for several weeks (B). A large number of cells can be transplanted, often combined with a scaffold. A critical-size femoral bone defect would be approached in this way. Finally, MSCs can be isolated, expanded, and differentiated in culture. An example is the production of cartilage by culturing MSCs in chondrogenic media in a bioreactor (D).

by a factor of about 14 and directly administered to the site of injury [13]. The major advantage of this method is that only one operation is needed to harvest the cells and use them for treatment. The disadvantage is that only comparatively low absolute cell numbers can be generated by this process.

Alternatively, MSCs can be isolated and expanded *in vitro* before transplantation. Large numbers of cells can be generated. MSCs can be isolated from bone marrow by various methods, including the use of immunomagnetic beads, density gradient separation, and direct plating [14]. Polystyrene tissue culture flasks or factories are subsequently used for *ex vivo* expansion of the MSCs. After a certain number of passages MSCs start to lose their multilineage mesenchymal differentiation qualities [15]. First, their osteogenic and adipogenic, and later their chondrogenic, potentials are affected [16]. In contrast to the small number of MSCs obtained from a marrow aspirate that is administered immediately, about $1.0–4.8 \times 10^9$ MSCs can be harvested from 12 mL bone marrow after cell culture to passage 3 [17]. The two-step method has two disadvantages: first, one additional interventional step including some type of regional anesthesia is required for implantation of the cells into a musculoskeletal site; and second, there is a risk of infection during *ex vivo* expansion.

In preclinical and clinical studies, MSCs can be delivered locally [18–21] or systemically [22,23].

A promising future tool for differentiation into cells of any type are induced pluripotent stem cells. In 2006, Yamanaka *et al.* showed that somatic cells such as fibroblasts could be reprogrammed to pluripotent cells by the transfer of stem cell genes [24]. Although a small number of clinical trials have been initiated with the differentiated progeny of both induced pluripotent stem cells and embryonic stem cells, the technology required is infinitely greater than that required for the use of MSCs.

## 47.3 Stem cells for bone regeneration

Osteoblasts produce osteoid, an extracellular protein-based matrix, which mineralizes to become bone. MSCs are osteoprogenitors that can differentiate into osteoblasts and induce bone formation.

### 47.3.1 Bone defects

Treating and healing bone diseases is often challenging. Critical-size bone defects (Figure 47.3) are defects of a size and location that do not heal by themselves. They can occur due to trauma, infection, failure of total joint replacement, or tumor or be associated with other musculoskeletal disorders. The gold standard for treatment of these defects is autologous bone grafting. However, this procedure has limited availability and donor site morbidity. Numerous preclinical studies have demonstrated the advantages of MSCs for bone regeneration [25–29]. Human clinical trials employing MSCs are examining their potential for bone regeneration applications [30,31].

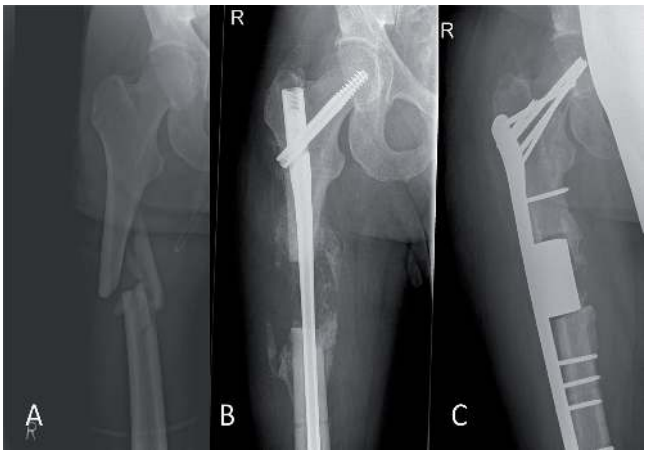

**Figure 47.3** (A) A critical-size femoral bone defect is shown. The 33-year-old male patient suffered a diaphyseal multifragmentary fracture of the femur. (B) After primary osteosynthesis failed, the two-stage Masquelet technique of membrane formation and bone grafting was applied. Unfortunately, the patient developed a deep wound infection requiring further revision surgery, including temporary external fixation and filling of the defect using antibiotic-releasing bone cement in addition to systemic antibiotic treatment. (C) In the next step a trabecular tantalum-coated void filler was implanted and stabilized by a locked plate. To achieve long-term regeneration of such extended bone defects, a strategy that includes an osteoconductive bioresorbable scaffold material in combination with osteoprogenitor cells (e.g., MSCs) and osteoinductive factors is needed.

Currently, various strategies are used to treat bone defects. The ideal bone graft material has osteoconductive, osteoinductive, and osteogenic properties [32].

For bone regeneration, MSCs provide osteoinductive and osteogenic properties because of their secretion of appropriate growth factors and cytokines and can differentiate into osteoblasts [32]. MSCs also have immune-modulating properties and can suppress excessive and damaging inflammation.

Treatment of critical-size bone defects with MSCs usually requires a biocompatible scaffold to support their growth and induce bone formation [33]. Bruder *et al.* isolated bone-marrow-derived MSCs, expanded them, and seeded them on to porous hydroxyapatite–tricalcium phosphate (TCP) ceramic scaffolds. The implants were transplanted into an 8 mm critical-size femoral bone defect in rats. After 4 weeks 2%, after 8 weeks 23%, and after 12 weeks 46% of the available void in the scaffolds was filled with bone [25]. Arinzeh *et al.* used expanded allogeneic MSCs loaded on to hollow TCP cylinders and transplanted this construct into a 21 mm (critical-size) femoral bone defect in dogs [26]. No adverse host response was detected after 16 weeks of observation. The MSC-loaded implants showed significantly more bone growth than the control implants without MSCs.

Total joint replacement is a common procedure for patients with severe osteoarthritis (OA) involving the hip. The majority of these patients have a successful outcome. However, for a number of reasons, including infection, aseptic loosening, osteolysis due to wear debris, and trauma, bone implants can become loose and result in major bone defects (Figure 47.4).

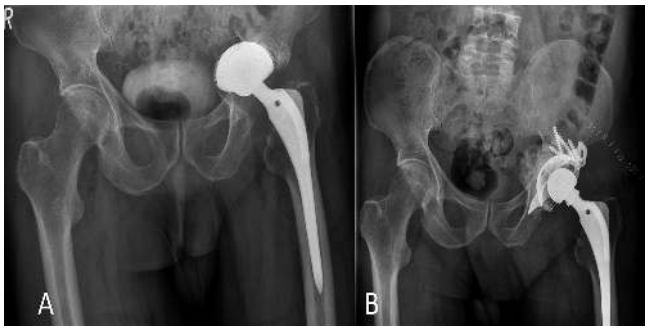

**Figure 47.4** (A) A large bony periprosthetic pelvic defect with acetabular implant loosening 2 years after total hip replacement for femoral neck fracture is shown. (B) Revision surgery was performed, implanting a cemented cup into an antiprotrusio ring supported with bone allograft. The use of one- or two-stage isolated autologous MSCs seeded on a bioresorbable scaffold material is a promising strategy to avoid the disadvantages associated with bone allografting, including reduced osteointegration of the implant and the risk for transmission of infectious agents.

Korda *et al.* investigated the impact of allografts enriched with MSCs in an ovine (sheep) hip hemiarthroplasty model [29]. Bone-marrow-derived MSCs were expanded and mixed with allograft bone prior to implantation into the defect. The distal part of the stem of the artificial joint was implanted with cement, whereas the proximal part was impaction-grafted by a mixture of allograft bone with or without MSCs. After 12 weeks there was significantly more bone formation surrounding the implants that were impaction-grafted with the mixture of MSCs and allograft bone compared with the group with bone allografts without MSCs.

Immediate cell therapy for the treatment of acetabular bone defects after failed total hip replacement was described by Ochs *et al.* [34]. Autologous bone marrow was used to enrich freeze-dried irradiated bone allografts for acetabular reconstruction. After an average of 31.4 months follow-up each hip showed evidence of trabeculation and incorporation of the allograft with no acetabular loosening.

Stromal cell-derived factor-1 plays a key role in the attraction of MSCs to sites of bony defects [35]. It also enhances the bone inductive capabilities of bone morphogenetic protein (BMP)-2 and thus reduces the necessary concentration of BMP-2. High BMP-2 concentrations can be associated with significant side-effects, such osteonecrosis [36].

Intervertebral disc degeneration with vertebral instability resulting in pain and sensorimotor deficits is one of the commonest causes of low back pain. Treatment options are limited to conservative treatment and surgical fusion to eliminate the instability. Preclinical studies and initial clinical trials have described the potential of MSCs to support disc regeneration or spinal fusion. Pang *et al.* expanded human umbilical-cord-tissue-derived MSCs to passages 6–8 and injected them locally into injured discs [37]. This resulted in improved function and reduced pain. Yang *et al.* developed a rabbit model for anterior spinal fusion using two biological matrix-assisted treatment groups of porous collagen sponge plus cultured and osteogenically differentiated MSCs versus porous collagen sponge alone. They compared bone regeneration with an autologous bone graft and no implant as positive and negative controls respectively [38]. The autologous bone graft resulted in a 70% fusion rate after 12 weeks, while the collagen sponge with MSCs had a 40% fusion rate. The collagen sponge alone and no implant control groups did not result in any bony fusion. The authors suggested that ongoing research on MSC differentiation and scaffold composition may further improve the outcome of MSC-seeded scaffolds for spinal fusion.

Despite promising animal studies and clinical trials, Khashan *et al.* concluded in a systematic review of the literature that there is not sufficient evidence to support the use of a bone marrow aspirate combined with an allograft, or synthetic scaffold as a substitute for iliac crest grafts or as a supplement for any autologous bone grafts, for thoracolumbar spinal fusion [39]. Weak evidence was found to support the use of bone marrow aspirates as a substitute for local bone grafts during thoracolumbar spinal fusion procedures [39].

### 47.3.2 Osteonecrosis

The pathophysiology of osteonecrosis (also known as avascular necrosis or aseptic necrosis) is controversial. Different theories include a disorder in lipid metabolism, abnormal clotting disorders, genetic abnormalities, or increased intraosseous pressure that leads to decreased blood flow and cell death [40]. Risk factors include the systemic use of corticosteroids, chemotherapy, alcoholism, trauma, decompression sickness, vascular compression, hypertension, vasculitis, arterial embolism and thrombosis, radiation, bisphosphonates (particularly affecting the mandible), sickle cell anemia, systemic lupus erythematosus, and Gaucher's disease. In some cases it is idiopathic (no cause found). Osteonecrosis results in severe pain and functional deficits, especially when the disease is located at the hip or knee. Early stages of the disease are only detectable by magnetic resonance imaging (MRI) or bone scan. Treatment with core decompression is recommended for stages prior to subchondral bone collapse. For example, core decompression for osteonecrosis of the femoral head involves drilling one larger hole or several smaller holes into the femoral head to relieve pressure in the bone and create channels for new blood vessels to supply the affected areas of the hip. If the subchondral bone collapse has already occurred, total joint replacement is the only long-term therapeutic option.

A combination of core decompression and concentrated bone marrow aspirate application was successful for cases up to Ficat and Arlet stage II osteonecrosis of the femoral head (Figure 47.5) [41–44]. The Ficat staging system ranges from stage 0 (in which the patient has no symptoms, a normal X-ray, and a normal magnetic resonance image) to stage IV (in which patients walk with a painful limp and both X-rays and MRI show secondary degenerative changes).

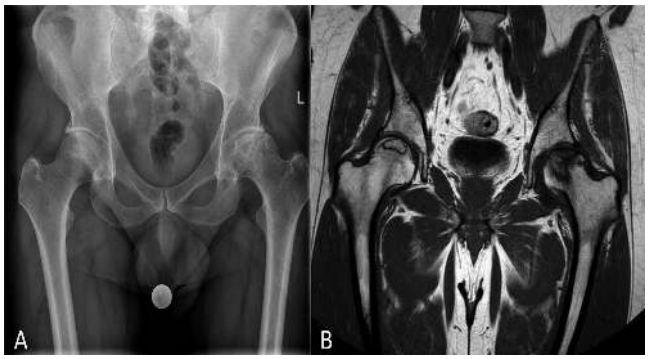

**Figure 47.5** (A) An anteroposterior X-ray of the pelvis and (B) a magnetic resonance image of a 36-year-old male patient with osteonecrosis of the femoral head. The right hip shows subchondral edema only detectable by MRI and corresponding to Association Research Circulation Osseous (ARCO) stage I. ARCO staging primarily uses X-ray and MRI to determine the stage of osteonecrosis. Core decompression combined with autologous bone marrow concentrate or expanded osteoprogenitor cells is a promising treatment option. (B) The left hip (L) shows stage IV osteonecrosis of the femoral head with complete destruction of the femoral head. Total joint replacement is the only current treatment to improve function and pain of the collapsed femoral head.

Ma *et al.* performed a randomized double-blinded study of 53 people with avascular necrosis of the femoral head [42]. Patients in the treatment group received core decompression combined with implantation of concentrated autologous bone marrow cells. The control group received only the core decompression. After 2 years the nonprogression rate for those with stage I/II disease was 100% in the treatment group compared with 66.7% in the control group. Hernigou *et al.* treated 38 patients – who had a total of 56 osteonecrotic hips associated with sickle cell disease – with core decompression and implantation of autologous bone marrow concentrate [45]. They found that autologous bone marrow grafting was a safe and effective treatment for early stage disease related to sickle cell disease compared with other studies describing the natural history of osteonecrosis of the femoral head.

### 47.3.3 Wear-particle-related osteolysis

The term osteolysis generally refers to a problem common to artificial joint replacements, such as total hip replacements, total knee replacements, and total shoulder replacements. Osteolysis can also be associated with the radiographic changes seen in a person with bisphosphonate-related osteonecrosis of the jaw. There are several biological mechanisms that may lead to osteolysis. In total hip replacement, the generally accepted explanation for osteolysis involves wear particles (worn off the contact surface of the artificial ball and socket joint). As the body attempts to clean up these wear particles (typically consisting of plastic or metal) it triggers an autoimmune reaction that causes resorption of bone tissue.

Total hip replacement achieves excellent long-term results and cost-effective improvement in pain and functional outcome [46]. Depending on the materials used for the bearing couple, metal, ceramic, conventional polyethylene, or highly crosslinked polyethylene particles are generated. Gibon *et al.* reported that chemokine C–C motif receptor 1 mediates the systemic recruitment of MSCs to ultra-high molecular weight polyethylene particles and recruited MSCs that were able to differentiate into functional osteoblasts and decrease particle-associated bone loss [47].

### 47.3.4 Systemic bone diseases

#### 47.3.4.1 Osteoporosis

Osteoporosis is a disorder of excessive skeletal fragility that results from a combination of a reduction in bone mass and bone strength. Its severity is measured by bone mineral density testing. This can be assessed in a number of ways, of which dual-energy X-ray absorptiometry is one of the most commonly used. The two most significant determinants of osteoporosis are estrogen deficiency and aging [48]. Zhang *et al.* compared the effect of systemic and local injection of gene-modified BMP-4-overexpressing MSCs on bone mineral density in osteoporotic mice [49]. Twenty-four hours after systemic administration only 0.02–0.29% of the cells were present in the femoral bone marrow. In contrast, 7 to 100 times more MSCs were present when the cells were injected locally. While bone volume and bone mineral density after systemic therapy remained unchanged, local injection of MSCs increased bone mineral density by 10.4% after 56 days [49]. MSCs injected systemically were found in the upper metaphysis, epiphysis, bone marrow sinusoids, or the osteon/Haversian systems and were usually removed from the bone marrow within a few weeks [48]. The osteon or Haversian system is the fundamental functional unit of much compact bone. Osteons are roughly cylindrical structures that are typically several millimeters long and around 0.2 mm in diameter. Each osteon consists of concentric layers, or lamellae, of compact bone tissue that surround a central canal, the Haversian canal. The Haversian canal contains the bone's nerve and blood supplies. The boundary of an osteon is the cement line (Figure 47.6).

Yao and Lane described a method of directing MSCs to the osteoporotic bone of both young and aged mice [48]. The synthetic high affinity and specific peptidomimetic ligand LLP2A, which targets integrin 1, a molecule highly expressed on MSCs, was linked to a bisphosphonate. Mice treated with the combination of LLP2A linked to the bisphosphonate and MSCs resulted in significant gains in both trabecular and cortical bone mass and strength.

#### 47.3.4.2 Osteogenesis imperfecta

Osteogenesis imperfecta is a congenital bone disorder characterized by brittle bones that are prone to fracture (Figure 47.7). Children with osteogenesis imperfecta are born with defective connective tissue, usually because of a deficiency of type-I collagen [50].

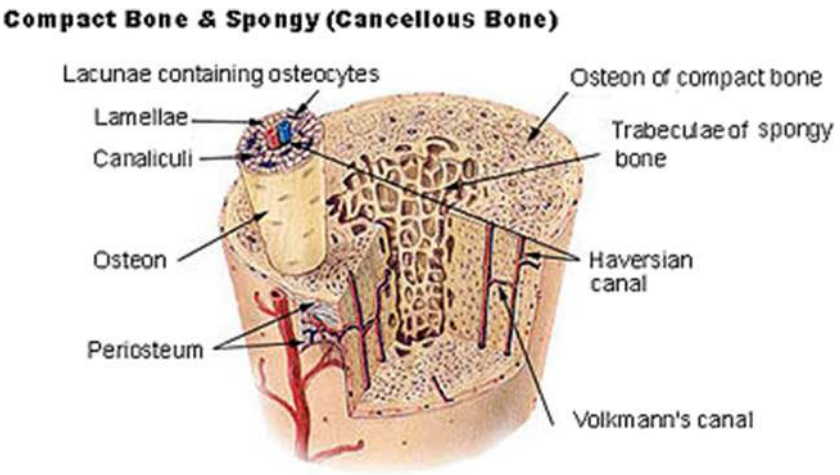

**Figure 47.6** Diagram of a typical long bone showing both compact (cortical) and cancellous (spongy) bone. *Source:* this image, reproduced here from Wikimedia Commons, is in the public domain. Its attribution is as follows: "Illu compact spongy bone" by SEER – US National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) Program (http://training.seer.cancer.gov/anatomy/skeletal/tissue.html). Licensed under Public Domain via Wikimedia Commons – https://commons.wikimedia.org/wiki/File:Illu_compact_spongy_bone.jpg#/media/File:Illu_compact_spongy_bone.jpg.

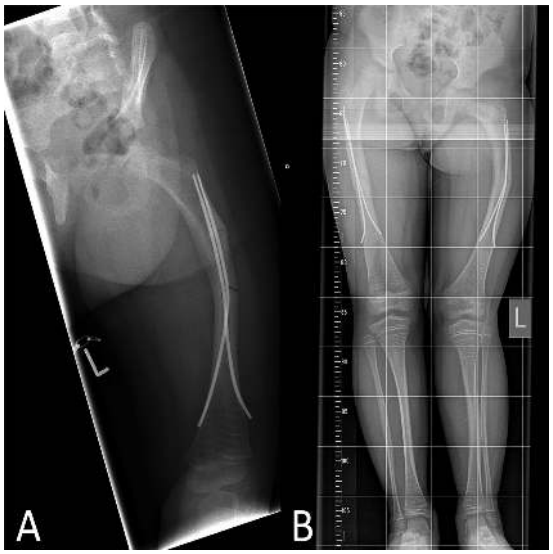

**Figure 47.7** Anteroposterior X-rays of a 5-year-old child with osteogenesis imperfecta. Two diaphyseal fractures were stabilized by intramedullary nails after closed reduction. Five years later multiple fractures had occurred. Stem/progenitor cell administration, either as an intravenous infusion of allogeneic MSCs or allogeneic bone marrow, has the potential to improve bone metabolism in this disease.

Horwitz *et al.* showed that allogeneic bone marrow transplantation in children with osteogenesis imperfecta led to donor-derived osteopoiesis and consequent improvement in the microscopic structure of bone [22]. Although MSC transplantation is a successful treatment of osteogenesis imperfecta, MSCs do not substantially engraft in bone; rather, they secrete a soluble mediator that indirectly stimulates bone growth [51].

## 47.4 Stem cells for cartilage regeneration

Articular cartilage is a simple avascular, aneural connective tissue that covers the ends of the articulating surfaces of bones [52,53]. It facilitates smooth joint movement in addition to dissipating biomechanical loads of the diarthrodial (synovial) joints [54–56]. It is composed primarily of chondrocytes that synthesize an abundant extracellular matrix under the direction of the chondrogenic transcription factors SOX9, L-SOX5, and SOX6 [57–60]. In addition, the extracellular matrix is specific for hyaline cartilage, half of which is made up of type II collagen, and different proteoglycans [60]. This composition confers on cartilage its viscoelastic property.

After cartilage injury (Figure 47.8), whether focal or widespread, the ability of native cartilage to heal itself is limited.

Historically, cartilage injuries have undergone a wide range of treatments, from a conservative approach to surgical

**Figure 47.8** A localized large posttraumatic chondral defect of the lateral femoral condyle of the right knee of a 32-year-old male patient as viewed by arthroscopy. Current surgical treatment includes microfracturing to induce bone marrow stem cell migration, leading to the formation of a fibrous cartilage substitute, or autologous chondrocyte transplantation. Stem/progenitor cell administration may be a future option for the treatment of localized cartilage defects. *Source:* courtesy of Dr J. Lützner.

interventions. Surgical modalities have included abrasion, drilling, microfracture, mosaicplasty, and autologous chondrocyte implantation, each of them having potential benefits and risks. (Mosaicplasty is a technique in which small circular (4–8 mm) autologous tissues are harvested from non-weight-bearing regions of the knee and then transplanted in a mosaic pattern until the osteochondral defect is filled.)

MSCs now are a promising cell source for cartilage regeneration that can be relatively easily obtained and then expanded in *ex vivo* culture to obtain high numbers of cells [61,62]. MSCs have been shown to have a chondrogenic differentiation potential when placed into chondrogenic media [11]. Johnstone *et al.* used the micro-mass culture system and centrifuged this into a condensed aggregate to which chondrogenic medium was added. Transforming growth factor (TGF)-β3 was the most important factor in the medium [63]. Other growth factors with the capacity to enhance the chondrogenic potential of MSCs have been identified, including BMPs [64], insulin-like growth factor-1 [65], and fibroblast growth factor-2 [66]. MSCs also have immune modulatory potential, including the ability to suppress the proliferation and activity of $CD4^+$ T cells, $CD8^+$ T cells, and memory T cells [67,68]. In spite of the potential advantages of MSCs in cartilage regeneration, there are some potential drawbacks to their use after chondrogenic differentiation, including expression of cartilage hypertrophy markers such as collagen type X, matrix metalloproteinase-13, parathyroid-hormone-related protein receptor, vascular endothelial growth factor (VEGF), and alkaline phosphatase, which could lead to ossification of the neocartilage tissue [69–72]. Additionally, regenerated cartilage has reduced thickness compared with mature native cartilage [73]. However, promising attempts at overcoming these hurdles have been made; for example, co-culture of MSCs with mature chondrocytes has been shown to reduce the expression of the hypertrophic markers [74]. Furthermore, addition of fibroblast-derived growth factor-2 and TGF-β1 to the MSC-induced cartilage tissue has also been shown to promote increased compressive stiffness, decreased surface tension, decreased water content, and increased collagen content – all characteristics of mature cartilage [75].

In an attempt to repair articular cartilage defects in goats, Guo *et al.* seeded culture-expanded MSCs derived from autologous bone marrow on bioceramic TCP scaffolds [76]. The study showed increased proteoglycan content of the neocartilage at 12–24 months after implantation. At 24 weeks the defects were resurfaced with a hyaline-like tissue with good incorporation into the normal cartilage and bone. Wakitani *et al.* treated full thickness articular cartilage defects on the weight-bearing surface of the medial femoral condyle of rabbits using bone marrow-derived MSCs [77]. The cells were seeded into a type I collagen gel before transplantation into the defect. Cell differentiation into chondrocytes was noted at 2 weeks, while complete regeneration of the defect without loss of overlying cartilage was documented at 24 weeks after transplantation. Yan and Yu transplanted MSC-seeded polylactic acid matrices in a full cartilage defect in rabbits and showed hyaline cartilage regeneration [78].

### 47.4.1 Osteoarthritis

MSCs have been the focus of attention in regenerating articular cartilage defects in OA in humans [79,80]. The first use of transplanted MSCs seeded on type I collagen gel to regenerate isolated, full-thickness articular cartilage defects in humans was reported by Wakitani *et al.* [79]. This study involved 24 patients with OA of the knees who had undergone tibial osteotomy. (Knee osteotomy is commonly used to realign arthritic damage on one side of the knee. The goal is to shift the patient's body weight off the damaged area to the other side of the knee where the cartilage is still healthy. Surgeons remove a wedge of the tibia from underneath the healthy side of the knee, which allows the tibia and femur to bend away from the damaged cartilage.) In the Wakitani *et al.* study 12 patients received bone-marrow-derived MSCs that were embedded in a collagen gel and transplanted on to the articular cartilage defect at the femoral condyle and covered with a periosteal flap, while the other 12 patients served as controls. At 42 weeks after transplantation the defects were covered with hyaline cartilage-like tissue in the MSC-transplanted group. Two years later, the treated group had a significantly greater amount of hyaline cartilage formation compared with the control group. In a later study the authors also demonstrated clinical and histological improvement in patients treated with autologous bone-marrow-derived MSCs for repair of articular cartilage defects in comparison with the control group [80]. Two patients with patellar cartilage defects were treated with cultured MSCs embedded in collagen gel and covered with autologous periosteum [80]. Even though histological analysis showed that the regenerated defect consisted of fibrocartilaginous new tissue, pain and walking ability improved 2 years postoperatively in the treatment group. Kuroda *et al.* reported on a 31-year-old male with a 20 mm × 30 mm full-thickness cartilage defect who was implanted with autologous bone-marrow-derived MSCs [81]. One year postoperatively there was significant improvement in clinical symptoms. Currently, there are 20 ongoing clinical trials registered at www.clinicaltrials.gov, recruiting patients to assess the efficacy of MSC-injection in OA, including a phase II multicenter study for OA of the knee [82]. However, clinical evidence of benefit in humans is still limited [82].

On the premise that articular cartilage defects are best repaired with autologous engineered cartilage tissue, there has been substantial research on ways to improve the outcome of cartilage regeneration [83]. These preclinical studies have focused on the efficacy of cartilage regeneration. However, the translation of these treatments into clinical practice has been slow [83].

## 47.5 Stem cells for tendon regeneration

Tendons are viscoelastic dense fibrous connective tissues that attach muscles to bone [84]. They are composed of fibroblasts, fibrocartilage cells, and occasionally fat cells. Collagen – especially type I – and cells constitute 85% of their dry weight,

water 55% of their wet weight, and proteoglycans <1% [84]. Tendon injuries can be divided into tendon rupture and tendinopathy [85]. Tendon injuries are common in athletes and people with jobs involving highly repetitive movements [86–89]. Irrespective of the type of injury, damaged tendons usually do not recover to the pre-injury status [85,90,91]. Tendinopathy, or overuse of tendons [88], has been described as the most frequent type of tendon injury, commonly found in the Achilles, patellar, shoulder rotator cuff, and forearm extensor tendons [92]. Various therapeutic modalities for treating tendon disorders include the use of nonsteroidal anti-inflammatory drugs [93–95], eccentric exercises [96–100], sclerosing injection treatment [101–104], low-intensity pulsed ultrasound [105,106], topical glyceryl trinitrate [18,107], shock-wave therapy [109–111], autografts, allografts, and prosthetic devices [112–114]. However, these approaches have had limited long-term benefits, and thus the development of tissue- or cell-engineered substitutes is being explored [84,115], including the use of MSCs [116]. MSCs have been shown in animal studies to significantly improve the structure and function of injured tendons [116,117]. Ohtera *et al.* conducted a study on the effect of fresh periosteum wrapped around tendons in a bone tunnel and found that the pullout strength of such tendons was significantly greater in the periosteal-tendon flap group than in a group that received frozen grafts 4 weeks postoperatively [118]. The authors concluded that the result was due to the presence of viable cells in the fresh periosteum. Goh *et al.* demonstrated the efficacy of bone-marrow-derived MSCs injected into the hallucis longus tendon using a calcaneal bone tunnel rabbit model [84]. Another study demonstrated structural and biomechanical improvement of Achilles tendons injected with allogeneic MSCs loaded on to a knitted poly-lactide-co-glycolide scaffold with fibrin glue [119]. These results were corroborated by two similar studies by Ouyang and co-workers [119,120]. A study by Awad *et al.* demonstrated a 15–40% increase in biomechanical properties of regenerated rabbit tendon defects implanted with bone-marrow-derived MSCs [116]. Young *et al.* suspended MSCs in a type I collagen gel on a biodegradable suture and then implanted the composite into rabbit Achilles tendon gap defects. Four weeks after implantation the MSC–collagen-grafted tendons were twice as stiff as the contralateral control tendons that received suture only [117]. Awad *et al.* implanted composites made from MSCs, collagen gels, and suture scaffolds into surgically created patellar tendon defects in rabbits [121]. The results at 12 and 26 weeks after surgery showed significant improvement in biomechanical properties compared with natural repair.

Animal and human studies have examined the use of MSCs in regeneration of rotator cuff tendon injury. The animal studies conducted by Chen *et al.* and Gullota *et al.* using MSC–collagen in a fibrin glue failed to show histological or biomechanical improvement [122,123]. However, in a clinical study by Ellera Gomes *et al.*, which included 14 patients with complete rotator cuff tears, the injured tendons were repaired and supplemented with autologous bone-marrow-derived MSCs [124]. The patients were monitored for 1 year. The University of California, Los Angeles scores were significantly improved in the treated patients, and healing was shown by MRI [125]. Although there was no control group in their study, the results demonstrated the potential benefit of MSCs in tendon repair [126]. In a small Phase I study, six patients with chronic Achilles tendinopathy refractory to conventionial treatment received an ultrasound-guided intratendinous injection of unrelated MHC-unmatched MSCs derived from term placenta. Symptomatic and functional improvement was rapid, and at 18 months after injection Doppler ultrasound imaging showed a marked decrease in the abnormal vasculature in the tendon compared with baseline, as well as slow regrowth of tendon tissue (Young *et al.*, unpublished data).

In a study by Smith and Webbon, in conjunction with VetCell Bioscience Ltd, more than 100 horses with acute tendon injuries had their tendons injected with bone-marrow-derived MSCs under tenoscopic and ultrasonographic control [91]. The results showed that the horses were back in full training after 48 weeks. However, the authors concluded that, despite the encouraging outcome, the efficacy for treating acute tendon lesions with MSCs has yet to be proven.

Although there may be potential benefits using MSC-based techniques in tendon regeneration, there are still fundamental issues that need to be resolved [116]. First, it has been observed that the majority of tissue-engineered tendons failed to reach the expected *in vivo* strength. Second, there are constraints in the clinical application of this technology by the interface between the newly developed tendon tissue and host bone. Third, the rate of tendon regeneration is often slow [84]. Future studies should explore (1) the use of mechanical stimulation, hormones, and growth factors to enhance the cellular differentiation process; (2) the cell concentration that prevents ectopic bone formation, and (3) the exploration of new matrices that can withstand the initial biomechanical loads after implantation [121].

## 47.6 Stem cells for skeletal muscle regeneration

After muscle injury, healing occurs in three different phases [127]. First, degeneration and inflammation continues for up to 2 weeks after the injury. Second, muscle regeneration begins 1 week after injury and peaks at about 14 days after the injury. Third, fibrosis occurs 2 weeks after the injury and increases over time until the fourth week after injury. The processes are interrelated and time dependent. There can be no full recovery if scar tissue occurs [127]. Thus, the goal of research in the regeneration of muscle is to optimize the process of regeneration and to minimize fibrosis. Satellite cells are essential for skeletal muscle regeneration. They are located in a niche on the surface of the muscle fiber beneath the ensheathing basal lamina [128]. During skeletal muscle healing satellite cells are activated under the influence of growth factors. They proliferate and differentiate into multinucleated myotubes and

eventually into regenerated myofibers [127]. Satellite cells have myogenic, adipogenic, and osteogenic differentiation potential. They are considered to be muscle-resident myogenic stem/progenitor cells [128].

Both acute and chronic muscle injuries lead to a systemic mobilization of MSCs increasing their number in the bloodstream [129]. Using a rat soleus muscle open crush model, Von Roth *et al.* demonstrated that the administration of $2.5 \times 10^6$ MSCs into the femoral artery significantly improved muscle forces (fast twitch and tetanus strength) after 3 weeks compared with the control group [130]. Nakabayashi *et al.* used a model of acute trauma to the tibialis anterior muscle in rats. They injected MSCs at the site of injury [131]. After 1 and 4 weeks muscle forces (fast twitch and tetanus strength) were significantly higher compared with the control group not given cells, and there was less than 50% fibrosis in the treated group. Using an external magnetic targeting system, the number of MSCs at the site of injury was increased, muscle force was enhanced, and fibrosis was reduced.

Muscle injury also occurs in systemic neurovascular diseases, and cell administration in these settings also showed improved outcomes after local [132,133] and systemic [134,135] administration of cells. A combination of insulin-like growth factor-1 and intravenous injection of MSCs in dystrophic mice enhanced muscle strength [134]. Jeong *et al.* differentiated induced pluripotent stem cells into MSCs and transplanted these cells locally into the tibialis anterior muscle of mice with a muscular dystrophy phenotype [133]. After 6 weeks, reduced levels of oxidative stress and increased dystrophin expression were detected in the MSC-treated group. Furthermore, the nuclei of transplanted MSCs were detected in the mouse muscle tissue.

## 47.7 Stem cells for wound repair

Injury and trauma initiate the mobilization of MSCs into the peripheral blood [136,137]. MSCs play a key role in wound healing, coordinating the repair response by recruiting cells and secreting growth factors as well as matrix proteins [138]. Wound healing is a complex process involving a series of coordinated events, including bleeding and coagulation, acute inflammation, cell migration, cell proliferation, cell differentiation, angiogenesis, re-epithelialization, and synthesis and remodeling of the extracellular matrix [138]. The process occurs in three overlapping phases in which MSCs play different roles: first, the inflammatory phase; second, the proliferative phase; and third, the remodeling phase [138].

The inflammatory phase begins after injury and lasts for 1–3 days. MSCs decrease secretion of the proinflammatory cytokines tumor necrosis factor-α and interferon-γ while increasing the production of the anti-inflammatory cytokines interleukin-10 and interleukin-4 [139]. The anti-inflammatory effect is particularly beneficial for chronic wound healing since MSCs can help shift the chronic inflammatory state to the next stage of healing [138,140,141]. Paracrine mechanisms reduce inflammation, promote angiogenesis, and induce cell migration and proliferation [142].

The proliferative phase starts on the third day after the trauma and lasts for approximately 2 weeks. MSCs enhance tissue repair by the production of growth factors (including VEGF, hepatocyte growth factor, and platelet-derived growth factor) and recruit keratinocytes, dermal fibroblasts, and host progenitor cells [138]. To restore the structure of the tissue, fibroblasts attach to the fibrin matrix and begin to produce collagen [143].

Remodeling is the final phase of wound healing and lasts 1–2 years or longer [144]. During this phase the degradation and remodeling processes lead to organized collagen bundles, resulting in better adaptation of the tissue to its function. MSCs produce soluble factors such as TGF-β3 and others that stimulate proliferation and migration of cells into the wound [138]. Paracrine signaling of MSCs provides antiscarring properties through secretion of VEGF and hepatocyte growth factor, as well as maintaining the balance between TGF-β1 and TGF-β3 [145–147].

Early clinical trials have shown enhanced healing of acute and chronic wounds treated with bone-marrow-derived MSCs injected or applied topically [148–152].

## 47.8 Conclusions

The potential of MSCs in the treatment of musculoskeletal and other disorders is promising. Preliminary data obtained from limited *in vitro* and *in vivo* studies are encouraging. Further preclinical and clinical studies demonstrating safety, efficacy, and cost effectiveness are necessary in order to substantiate a definitive role for MSCs in clinical practice.

## 48.1 Introduction

### 48.1.1 Stroke

In the 1970s the World Health Organization defined stroke as a neurological deficit of cerebrovascular cause that persists beyond 24 h or is interrupted by death within 24 h. A stroke, also known as a cerebrovascular accident, occurs is when the brain is damaged either by poor blood flow to the brain or by hemorrhage into the brain, both resulting in death of brain cells. Strokes result in part or parts of the brain not performing normally and can lead to major functional neurological deficits such as hemiparesis – paralysis of one side of the body, a condition first noted by Hippocrates (Figure 48.1).

There are two main types of stroke: ischemic stroke due to lack of blood flow to the brain and hemorrhagic stroke due to bleeding into the brain or into the ventricular system within the brain, or both. Ischemic strokes are caused by interruption of the blood supply to the brain, while hemorrhagic strokes result from the rupture of a blood vessel or an abnormal vascular structure in the brain such as an arterial aneurysm. A schema depicting how a cerebral hemorrhage can occur from such a vascular abnormality is shown in Figure 48.2.

About 87% of strokes are ischemic, the rest being hemorrhagic. Hemorrhagic strokes can be associated with a severe headache as well as severe functional impairment [1]. A computed tomography (CT) scan showing brain hemorrhage is shown in Figure 48.3.

This chapter deals only with ischemic stroke. In an ischemic stroke, blood supply to part of the brain is decreased, leading to dysfunction of the brain tissue in that area. This causes cerebral infarction. There are three main ways by which this can happen:

1. Thrombosis – obstruction of a cerebral artery by a blood clot forming locally.
2. Embolism – obstruction of a cerebral artery due to an embolus from elsewhere in the body, such as the heart in atrial fibrillation.
3. Systemic hypoperfusion – underperfusion of the arterial blood supply to the brain (e.g., due to low blood pressure, as can occur in severe infection or severe hemorrhage).

Hippocrates (circa 460–circa 370 BC) was a Greek physician in the age of Pericles (Classical Greece) and is considered one of the most outstanding figures in the history of medicine. He first described the sudden paralysis that is often associated with stroke. He is referred to as the "Father of Western Medicine." *Source:* this image, reproduced here from Wikimedia Commons, is in the public domain (PD 1923). Ischemic stroke is a leading cause of death in the world [2] and also one of the primary causes for adult-acquired disability [1,3]. Signs and symptoms of a stroke may include an inability to move or problems in understanding or speaking, feeling like the world is spinning, or loss of vision on one side, among others. Signs and symptoms often appear soon after the stroke has occurred. The symptoms of a stroke can be permanent. If symptoms last less than 1 or 2 h it is known as a transient ischemic attack.

The diagnosis of stroke is typically made clinically and confirmed with medical imaging such as CT scanning or magnetic resonance imaging (MRI). Optimal treatment utilizes recombinant tissue plasminogen activator (tPA) to lyse the thrombus or embolism causing an ischemic stroke [4–7].

In 2010, approximately 17 million people had a stroke and 33 million people had previously had a stroke and were still alive. Between 1990 and 2010 the number of strokes that occurred each year decreased by approximately 10% in the developed world and increased by 10% in the developing world [8]. In 2013, stroke was the second most frequent cause of death after coronary artery disease, accounting for 6.4 million deaths (12% of the total) [9]. About 3.3 million deaths resulted from ischemic stroke, while 3.2 million deaths resulted from hemorrhagic stroke [9]. About half of people who have had a stroke live less than 1 year [3]. Overall, two-thirds of strokes occurred in those over 65 years of age.

Currently, recombinant tPA is the major pharmacologic agent used to treat acute ischemic stroke [4], but its efficacy is limited by a short therapeutic time window for administration of only 4.5 h from the time of the stroke event [5]. In the USA, only 5% of patients with acute ischemic stroke receive therapy with tPA [6].

Even when thrombolytic therapy or percutaneous vascular intervention is administered in time, many patients still experience deficits in neurological function. Currently, the primary treatment goals for ischemic stroke are recovery of cerebral perfusion in the acute stage and promotion of reestablishment of the cerebral circulation to avoid death of brain cells [7]. Comparatively little attention has been paid to enhancing long-term repair and recovery of brain function after ischemic stroke. Current thinking in treatment is guided by the principle of prophylaxis, with a focus on avoiding risk factors for cerebrovascular disease by developing healthy living habits and taking drugs such as statins prophylactically to prevent the occurrence of ischemic stroke. More recently, cell therapy has been studied in the treatment of ischemic stroke.

### 48.1.2 Stem/stromal cells

In the treatment of cerebral ischemic disease stem/stromal cells provide trophic support, enhance angiogenesis, replace dead neurons or stimulate the regeneration of endogenous cells in the ischemic area [8]. A number of different types of cell have been listed as candidates for cell therapy of cerebral ischemia, including embryonic stem cells, neural stem cells, induced pluripotent stem cells, umbilical cord blood cells, and bone-marrow-derived mesenchymal stromal cells (BM-MSCs) [9]. BM-MSCs appear especially promising as a potential avenue for treatment for several reasons: they are relatively easy to obtain from the patient's own body and they can be expanded in numbers by *in vitro* culture. They do not pose ethical issues or cause immunological side effects [10].

Bone-marrow-derived stem/progenitor cells include BM-MSCs [11], hematopoietic stem cells [12], and endothelial progenitor cells [13]. Hematopoietic stem cells are the stem cells for the hematopoietic and immune systems [13]. Endothelial progenitor cells play an important role in angiogenesis, and may differentiate into endothelial cells [14].

### 48.1.3 Mesenchymal stromal cells

Mesenchymal stromal cells (MSCs) can be derived from a wide variety of tissues, including bone marrow, adipose tissue, umbilical cord blood, Wharton's jelly, placental tissue, tooth buds, and hepatic tissue [15,16]. MSCs can differentiate into cells of mesodermal lineage, and under certain conditions they are capable of differentiating into cells that have the phenotypic

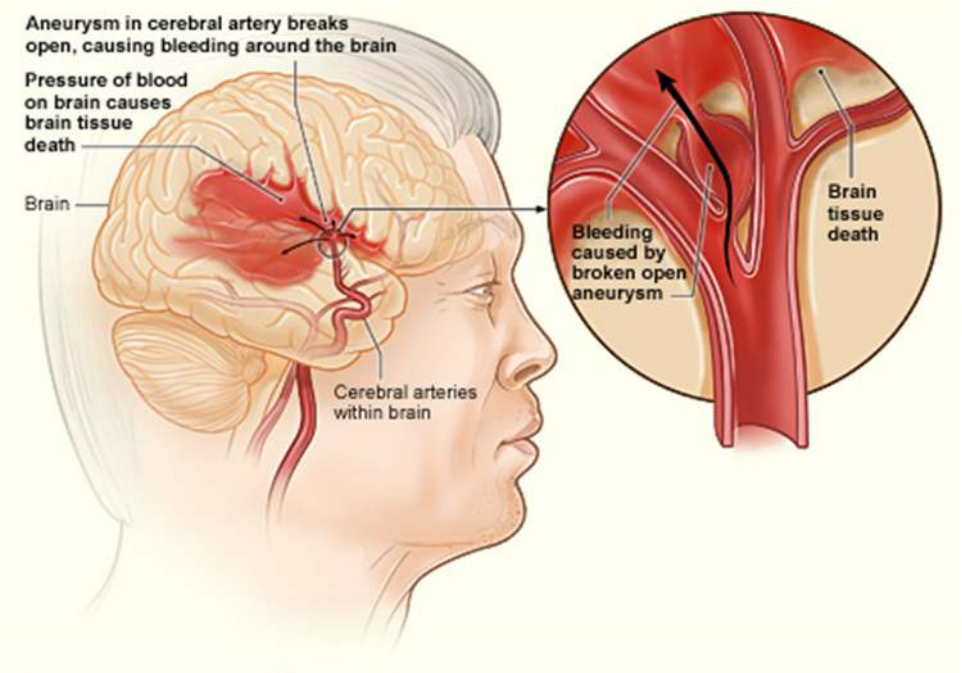

**Figure 48.2** The illustration shows how a hemorrhagic stroke can occur in the brain. An aneurysm in a cerebral artery breaks open, which causes bleeding in the brain. The pressure of the blood causes brain tissue death. *Source:* this image, reproduced here from Wikimedia Commons, is in the public domain because it has been placed there by its creator. characteristics of neurons, glial cells, and endothelial cells [11,17,18], although there are few reports that after phenotypic differentiation to neural cells they can *function* as neural cells. Human BM-MSCs do not normally express markers of hematopoietic cells, such as CD11, CD14, CD34, or CD45, or costimulatory molecules such as CD40 ligand (CD154), CD80, or CD86. BM-MSCs can express CD105, CD73, CD44, CD90 (Thy-1), CD71, and stromal precursor antigen-1, as well as the adhesion molecules CD106, CD166, intercellular adhesion molecular-1, and CD29 [19]. However, no specific markers for BM-MSCs have yet been identified. Differences in the methods used for isolation and expansion can affect the expression of the surface markers of BM-MSCs [11,20–24] (and see Chapter 7).

As indicated previously, cerebrovascular disease is one of the major causes of death worldwide [25], and it is possible that BM-MSCs can provide therapeutic benefit after an ischemic stroke. Regenerative processes are usually initiated in the brain within a few days to a few weeks after the occurrence of cerebral ischemia, providing a window of opportunity for the use BM-MSCs [26]. We suggest that these neurorestorative processes may include trophic support, angiogenesis, synaptic plasticity, and neurogenesis and contribute to functional recovery [27]. In experiments using animal models of cerebral ischemia it has been found that the ischemic cerebral tissue induces BM-MSCs to migrate into the ischemic area [28]. BM-MSCs secrete cytokines and trophic factors [29], promote angiogenesis and neurogenesis [30,31], and regulate the acute and chronic pathological process of ischemic stroke by means of anti-inflammatory, antiapoptotic, and immunoregulatory mechanisms [11].

BM-MSCs can be transplanted in animal experiments by either stereotactically guided intracranial (IC) injection or by intravascular injection [32]. Several clinical trials have administered BM-MSCs to ischemic stroke patients and the preliminarily findings have suggested that the transplantation of BM-MSCs in a clinical setting is safe and feasible [33–36].

## 48.2 Transplantation route and mechanisms of migration

BM-MSC administration by the IC route can be into the striatum or into the lateral ventricle [37]. The striatum is divided by a white matter tract called the internal capsule into two sectors called the caudate nucleus and the putamen (Figure 48.4). The ventricular system is a set of four interconnected cavities (ventricles) in the brain, where the cerebrospinal fluid (CSF) is produced (Figures 48.5 and 48.6). The intravascular route can be by either intra-arterial (IA) or intravenous (IV) injection [38].

In early studies MSCs were transplanted intracranially by directly injecting them into the injured brain or into the nearby ventricular system. Several studies have shown that the same therapeutic effects can be achieved by administering BM-MSCs outside the central nervous system (CNS) by IA or IV injection [38]. Neurological function improved after transplantation

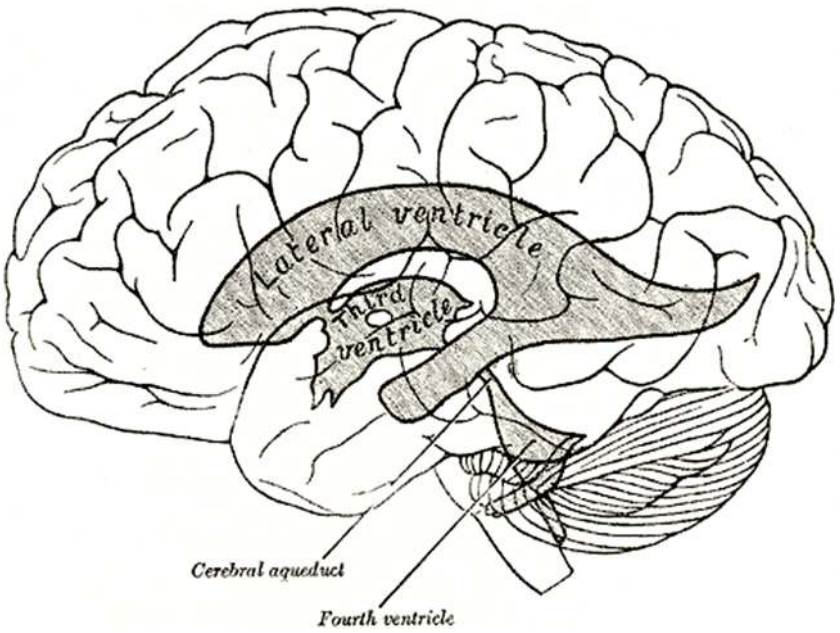

**Figure 48.6** Scheme showing relations of the ventricles to the surface of the brain. *Source:* this image, reproduced here from Wikimedia Commons, is in the public domain (PD 1923). The author was Henry Vandyke Carter (1831–1897) and the source was Henry Gray (1918) *Anatomy of the Human Body*. The attribution is as follows: "Gray734" by Henry Vandyke Carter – Henry Gray (1918) *Anatomy of the Human Body* (See "Book" section below) Bartleby.com: Gray's Anatomy, Plate 734. of BM-MSCs by different routes and at different times in experiments using animal models of cerebral ischemia. However, there is still a lack of a comprehensive and thorough comparison between the various routes of BM-MSC transplantation (Table 48.1).

Transplantation directly into the striatum may be the best way of targeting of BM-MSCs to the ischemic area of the brain [80]. BM-MSCs transplanted into the striatum reduce NVU disruption caused by tPA after MCAO [62] (see legend of Table 48.1 for abbreviations). The MCA is the artery most often occluded in

**Table 48.1** Optimum delivery routes and timing of MSC transplantation in animal models of ischemic stroke.

| Stroke model | Delivery route | Timing | Results | Reference |
|---|---|---|---|---|
| Permanent MCAO | IC (striatum) | 3/4/7 days | MSCs survived, migrated toward IBZ, expressed neuronal or astrocytic markers, increased axonal sprouting, produced many trophic factors, and remyelination occurred in the cortical penumbra | [39–42] |
| Transient MCAO (2 h) | IC (IBZ) | 24 h/3 days | Enhanced endogenous neurogenesis; increased MMP-9 activation, stimulation of neurons to modulate CBF | [30,43] |
| Transient MCAO (2 h)/ permanent MCAO | IC (striatum) | 24 h/7 days | Inhibited pathologic upregulation of brain-isoform glucose transporters types 1 and 3, and promoted recovery of local glucose metabolism in peri-infarct area | [44,45] |
| Permanent MCAO | IC (lateral ventricle) | 24 h | MSCs survived, adhered to ventricular wall, and reduced behavioral functional deficits | [46] |
| Cortical ischemia | IC | 7 days | Human MSCs survived, expressed markers of neuroectodermal cells and ameliorated neurological deficits | [47] |
| Transient MCAO (2 h) | IA | 24 h | MSCs distributed throughout the area of MCA, upregulated the expression of BMP2 and BMP4, gap junction protein CX-43, and synaptophysin | [48,49] |
| Transient MCAO (2 h) | IA | 24 h/2 h | Reduced lesion size, increased axon–myelin remodeling | [50,51] |
| Transient MCAO (2 h) | IV | 24 h | Produced many trophic factors; MCP-1 levels significantly increased from 6 h, peaked at 48 h after MCAO, and enhanced MSC migration and tissue repair | [43,52] |
| Transient MCAO (2 h)/ permanent MCAO | IV | 24 h | Human MSCs expressed bFGF and VEGF, promoted expression of IGF-1 and receptor, which contributed to improved recovery and increased neurogenesis | [29,53,54] |
| Transient MCAO (2 h) | IV | 24 h | Cell-free MSC-derived exosomes survived, enhanced neurite remodeling and angiogenesis, and improved functional recovery; male MSCs increased bFGF expression, reduced apoptosis, and improved functional recovery in female rats | [55,56] |
| Transient MCAO (90 min) | IV | 3 h | Downregulated expression of survivin and Bcl-2, prevented apoptosis and cell death | [57] |
| Global cerebral ischemia | IV | 3 h | Reduced infarct volume and neuronal loss, increased BDNF expression, ameliorated functional deficits | [58] |
| Lacunar stroke | IC (striatum) | 7 days | Enhanced the recovery of motor function, migrated towards the lesion, enhanced neurogenesis, expressed neuronal or astrocytic phenotypes | [59] |
| Permanent MCAO | IV (tail vein) | 3 h | MSCs reduced the infarct size, improved functional deficits, attenuated IL-23/IL-17 expression | [60] |
| Barrel cortex stroke | IC | 1/7 days | Restored the thalamocortical circuit connections; increased the density of neurons, axons, and blood vessels; enhanced local blood flow; produced cytokines/trophic factors | [61] |
| Transient MCAO (90 min) | IC | 24 h | MSCs ameliorated MMP-9 activation, improved NVU disruption | [62] |
| SHR-SP | IC (striatum) | 8 weeks | MSCs ameliorated ventricular dilatation, reduced the breakdown of neurovascular integrity | [63] |
| Permanent MCAO | IC/IV | 7 days | MSCs enhanced functional recovery (IC), expressed neural cell makers (IV) | [64,65] |
| Transient MCAO (2 h) | IV (tail vein) | 24 h | MSCs produced cytokines (GDNF) | [66] |

**Table 48.1** (*Continued*)

| Stroke model | Delivery route | Timing | Results | Reference |
|---|---|---|---|---|
| Permanent MCAO | IV | 1 day | Enhanced functional recovery, increased axonal density in both contralateral motor cortex and ipsilateral rostral forelimb area, enhanced interhemispheric and intracortical connections, regulated cytokines (TGF-β) | [67,68] |
| Transient MCAO (60 min) | IA | 2/7 days | MSCs did not improve functional recovery, but enhanced angiogenesis | [69] |
| Transient MCAO (2 h) | IC (striatum) | 3 days | MSCs secreted TGF-β to suppress immune propagation | [70] |
| Permanent MCAO | IV (tail vein) | 7 days | Enhanced brain plasticity, increased synaptophysin, synapse density, and myelinated axons, increased tPA and SHH expression | [71] |
| Permanent MCAO | IV | 24 h | Increased angiogenesis by activation of the Notch signaling pathway | [31] |
| Transient MCAO (90 min) | IC | 8 days | Human MSCs modified cerebral microvasculation, abolished CBV increase and delayed VSI increase | [72] |
| Permanent MCAO | IV | 1 day | Improved functional deficits, increased corticospinal tract axonal density | [73] |
| Transient MCAO (60 min/2 h) | IV (tail vein) | 1/7 days | MSCs reduced infarct volume, expressed cytokines/chemokines/growth factors/neurotropic factors | [74,75] |
| Transient MCAO (1 h) | IC (striatum) | 15 min | BMSCs restored CBF and BBB to normal levels, elevated levels of growth factors/neurotrophic factors | [76] |
| Transient MCAO | IV | 24 h | Migrated towards the scar area and border zone of the ischemic region, expressed the neuronal marker NeuN, reduced scar size, limited apoptosis, enhanced angiogenic factor expression and vascular density, improved functional recovery | [28] |
| Transient MCAO (90 min) | IA | 24 h | MSCs improved functional recovery and reduced the mean infarct volume at the maximum tolerated dose of $1 \times 10^5$ delivered at 24 h | [77] |
| Transient MCAO (90 min) | IA | Immediate | MSCs displayed less reduced amplitude of MEP after monopolar stimulation; 40% of the MSC group had measureable MEP induced by bipolar stimulation and displayed I wave | [78] |

stroke. The rodent model of MCAO involves transecting the external carotid artery, temporarily tying off the common carotid artery, and using the external carotid artery trunk as a side path to pass a suture through the internal carotid artery to lodge in the junction of the anterior cerebral artery and MCA. The suture can be left in place for a variable duration of time and then removed to produce reperfusion. The most common durations of suture occlusion of the MCA in the rat are 60, 90, 120 min, or permanent occlusion. This technique does not require craniotomy, produces focal occlusion of a large cerebral artery, as seen in human stroke, and can be done in a high-throughput manner. The network of cerebral arteries is shown in Figure 48.7, and the area of brain supplied by the MCA is shown in Figure 48.8.

MCAO produces primary ischemic cell death in the striatum and overlying frontal, parietal, temporal, and portions of the occipital cortex, but also variable damage in the thalamus, cervicomedullary junction, substantia nigra, and hypothalamus. The most consistent pattern of cell death in MCAO follows a progression from early infarction in the striatum to delayed infarction in the dorsolateral cortex overlying the striatum. Striatal infarction is mostly necrotic and occurs rapidly. Cortical infarction is more delayed, involves a prolonged and biphasic opening of the BBB, and contains a greater degree of apoptotic cell death than in striatal infarction.

Transplantation of BM-MSCs into striatum has the advantages of requiring lower doses (usually $1–2 \times 10^5$ cells) [39,76] and achieving more rapid effects [50,76]. One study demonstrated that BM-MSCs transplanted into the striatum of rats 15 min after MCAO resulted in recovery of CBF in the infarct area and promoted the recovery of neurological function [76]. Miyamoto *et al.* transplanted BM-MSCs into the striatum 7 days after MCAO using a permanent model of brain damage. Results from $^{18}$F-fluorodeoxyglucose positron emission tomography suggested that BM-MSCs improved the glucose metabolism in the region containing new cortex around the infarct [44]. Li *et al.* found that transplantation of BM-MSCs labeled by

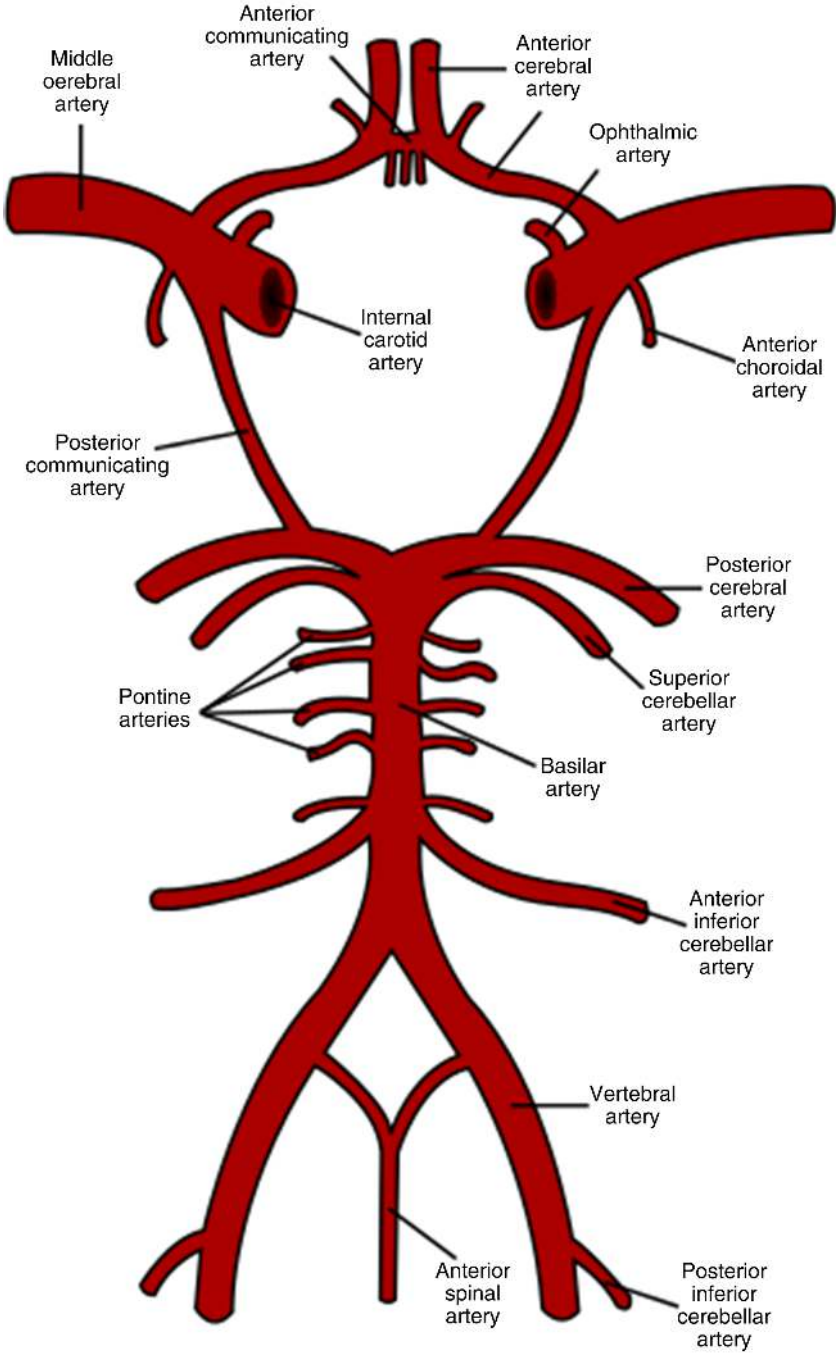

**Figure 48.7** The arteries of the brain. The middle cerebral arteries (top of figure) arise from the internal carotid arteries. *Source:* https://commons.wikimedia.org/wiki/File:Circle_of_Willis_es.svg#/media/File:Circle_of_Willis_es.svg.

bromodeoxyuridine (BrdU) to the striatum of MCAO mice promoted axonal sprouting and remyelination in the ischemic penumbra of the cortex, significantly improved performance on the rotarod test, and modified neurologic severity score tests [39]. (The penumbra is the brain region adjacent to the earliest region of ischemic cell death that will itself progress to infarction over time unless treated.) IC transplantation is relatively invasive and may lead to functional disorders of brain cells. In 14 patients given BM-MSCs into their striatum, seizure, syncopal (fainting) events, or subdural hematoma occurred in three of them [33].

Lateral ventricle injection is another method of IC transplantation in which the transplanted BM-MSCs first adhere to the wall of the lateral ventricle and then penetrate the wall of the ventricle into the ischemic area [37]. Compared with intrastriatal injection, lateral ventricle injection is thought to be less invasive. More BM-MSCs can be transplanted using this method, and the distribution of cells is more extensive [80]. However, the success of lateral ventricle transplantation depends primarily on the properties of the grafted cells, specifically their ability to adapt to CSF and their ability to penetrate the blood–CSF barrier [81].

The optimum timing and dosage for the transplantation of BM-MSCs via the IC route is not yet clear. Wan *et al.* suggested that the guiding principle behind current treatment approaches for ischemic stroke is "the earlier the better" [82]. Kawabori *et al.* transplanted BM-MSCs into the striatum of MCAO rats at 1 week or 4 weeks after induction of ischemia. Both low-dose and high-dose BM-MSCs significantly improved motor function when BM-MSCs were transplanted at 1 week, whereas only high-dose BM-MSCs improved motor function at 4 weeks. In order to reach the same level of improvement, the number of BM-MSCs transplanted when used early was significantly smaller than the number required at later time points [83].

Increasing evidence supports the conclusion that intravascular transplantation rather than IC transplantation of BM-MSCs is preferable after ischemic stroke [84]. Although IC injection of BM-MSCs is helpful for targeting the transplantation of cells, the therapeutic effect of IV injection is superior for global cerebral ischemia. IV transplantation of BM-MSCs not only allows the cells to distribute more extensively around the lesion [85], but also has the benefits of being a simpler and less invasive procedure and generates cells that can fully interact with various neurotrophic factors and migratory signals [84]. Wu *et al.* suggested that the IV route allowed BM-MSCs to better adapt to an adverse microenvironment [28]. Studies have shown that the use of IV transplantation of BM-MSCs promoted cellular expression of the antiapoptotic proteins Survivin and Bcl-2 and improved sensorimotor function in MCAO rats [57,86]. Transplantation of BM-MSCs via the tail vein promoted the expression of BMP2 and BMP4, gap junction protein CX-43, and synaptophysin [48]. The neurological deficits in rats were significantly alleviated 2 weeks after IV injection and the therapeutic effects of BM-MSCs lasted for at least 1 year [48]. MSCs were intravenously administered at 6 h after a unilateral MCAO in a rat model resulting in bilateral cortical hyperactivity detected by functional MRI and associated with improved motor function [87].

After IV injection the cells become trapped, at least temporarily, in organs such as the lungs and the liver [88]. It is still not clear whether BM-MSCs that localize outside the CNS will cause changes in physiological function in the CNS [79]. Various attempts have been made to improve the therapeutic effects of intravenously transplanted BM-MSCs [28,88]. MSCs have been given in two boluses, blocked with anti-CD49d antibody or infused with multipotent adult progenitor cells, neural stem cells, or bone-marrow-derived mononuclear cells. All of these approaches resulted in an increase in MSCs crossing the pulmonary microvascular barrier [88]. Although the number of BM-MSCs that migrated to the ischemic area was quite small after IV injection, neurological functional deficits improved significantly [84,89]. Goldmacher *et al.* concluded that the functional recovery observed after IV administration of BM-MSCs was likely due to changes in blood and/or brain cell number or their cytokine and growth factor products [90]. Previous studies also indicated that, even with IC administration, the distance of the graft to the lesion may not be important [85,91]. It remains unclear whether enhancing the targeting of BM-MSCs is critical for functional neurological recovery.

IA transplantation of BM-MSCs via the ipsilateral (same side as the ischemic lesion) carotid artery showed a higher survival rate of grafted cells in the ischemic area. This method is easy to use and avoids pterygopalatine artery occlusion [92]. (The pterygopalatine artery is a branch of the maxillary artery, which in turn is the larger of the two terminal branches of the external carotid artery). Compared with the IV route, the IA route is also more suitable for treating transient cerebral ischemia because the transplanted BM-MSCs can travel through the appropriate arteries and reach the ischemic area in a short period of time [48,85]. When the MCAO rat was subjected to 2 h of ischemia followed by 24 h of arterial reperfusion (ischemia–reperfusion (I/R) injury), BM-MSCs transplanted intra-arterially were distributed in the territory of MCA (Figure 48.8), and the transplantated cells led to a significant improvement in neurological deficits and recovery of sensorimotor function [49]. In addition, Ishizaka *et al.* found that IA transplantation provided timing-dependent cell distribution and functional recovery [93]. IA infusion of human MSCs in rats resulted in immediate cell entrapment in the brain, but the majority of the transplanted cells relocated to the internal organs during the next 24 h [94]. Keimpema *et al.* showed that IA injection of a syngeneic suspension of hematopoietic and mesenchymal cells 2 h after MCAO onset resulted in cell migration to the lesion 6 h after transplantation and microglial cells were activated. Despite the difference in the quantities of BM-MSCs detected around the infarct at each time point, the cumulative number of BM-MSCs increased

gradually within 12 h after transplantation and began to decrease at 24 h due to phagocytosis by activated microglial cells. The majority of BM-MSCs (>95%) were eventually trapped in the spleen [51]. Keimpema *et al.* also showed that IA transplantation of BM-MSCs reduced the size of infarct, promoted angiogenesis and neurogenesis, and increased synaptic plasticity by secreting growth factors such as VEGF, bFGF, and BDNF [51]. Jang *et al.* indicated that rats with transient ischemia receiving an IA injection of BM-MSCs displayed less reduced amplitude MEPs after monopolar stimulation. Forty percent of the MSC group had measureable motor-evoked potentials (MEPs) induced by bipolar stimulation and displayed an I wave that was not detected in the control group [78]. Although animal experiments have demonstrated the effectiveness of IA transplantation of BM-MSCs for cerebral ischemia, mortality in the animal model was greatly increased due to arterial microthrombosis [85]. One study showed that the dose of transplanted MSCs was a major determinant of the safety of intracarotid transplantation [95]. This study suggested that an infusion of MSCs (diameter 25 μm) resulted in a significant decrease ($75 \pm 17\%$) in CBF. Stroke lesions occurred frequently (12 out of 15 animals) when injecting $2 \times 10^6$ MSCs, but not after lowering the dose to $1 \times 10^6$ MSCs [95]. Yavagal *et al.* showed that IA delivery of MSCs can be performed safely and effectively at the maximum tolerated dose of $1 \times 10^5$ delivered at 24 h after MCAO [77].

Another delivery method for the transplantation of BM-MSCs is the use of a cell sheet applied to the brain surface [96]. The cell sheet was $27.9 \pm 8.0$ μm thick and contained $9.8 \pm 2.4 \times 10^5$ BM-MSCs. The cells maintained their ability to migrate and to differentiate neurally. This less invasive method of transplantation was also associated with an improvement in neurologic deficits [96].

In the cerebral I/R rat model, the expression of stromal-cell-derived factor-1α (SDF-1α) increased around the ischemic penumbra [97], and chemokine (C–X–C motif) receptor 4 (CXCR4) and chemokine (C–X–C motif) receptor 7 (CXCR7) were expressed mainly by BM-MSCs [98,99]. SDF-1α and CXCR4 played an important role in the migration of BM-MSCs [98], and the effect of SDF-1α/CXCR7 was stronger than that of SDF-1α/CXCR4 [99]. Wang *et al.* showed that treating rats with cerebral ischemia with BM-MSCs led to the expression of SDF-1α, reaching its peak value within 3–7 days and being maintained for at least 14 days after transplantation [100]. Both CXCR4 and CXCR7 bound SDF-1α to synergistically mediate the migration of BM-MSCs to the ischemic area [99,100]. When the expression of CXCR4, CXCR7, or SDF-1α decreased, the number of migrating BM-MSCs decreased correspondingly [99,101,102]. MCP-1 also plays a role in the migration of BM-MSCs. The expression of MCP-1 significantly increased from 6 h and peaked at 48 h after MCAO [52]. In order to evaluate the role of MCP-1, Wang *et al.* added anti-MCP-1 antibody to an extract of the rat ischemic brain tissue and found that the migration of BM-MSCs was reduced [52]. Selectins regulate the distribution of BM-MSCs in the microvascular system after I/R injury. It was considered that cerebral vascular endothelium had a proadhesive role after I/R injury. BM-MSCs adhered to the cerebral vascular endothelium via P- and E-selectin expression by the vasculature and were distributed around the infarct site [103]. CD44, a critical ligand, also participates in selectin-mediated BM-MSC migration. When CD44-deficent BM-MSCs were transplanted into MCAO rats, the targeted migration of BM-MSCs decreased significantly [103].

Other techniques have been described. Migration of BM-MSCs to an ischemic area was improved by using a long course of hyperbaric oxygen treatment [104].

The ultrasound microbubble technique induced the blood-brain barrier (BBB) to open and significantly promoted the migration of MSCs to ischemic brain, leading to an improvement in neurological function of rats [105].

In cerebral ischemia, the infarct tissue eventually becomes necrotic and a cavity forms. This was detrimental to BM-MSC homing [106]. In order to distribute more BM-MSCs around the infarct, an artificial scaffold was transplanted into the ischemic brain [106]. The scaffold was able to encourage new tissues composed of endothelial cells, astrocytes, and microglial cells to grow. Trophic factors produced by these cells promoted BM-MSC migration to the scaffold [107]. One study showed that a fibrin matrix might also improve the survival and migration of BM-MSCs, and therefore be a useful material for injured CNS tissue [108]. A thermoreversible gelation polymer hydrogel could also be a promising candidate for scaffold formation [109].

## 48.3 Tracking techniques for transplanted mesenchymal stromal cells

It is important to develop techniques to serially and non-invasively track the fate of the transplanted cells in the host CNS. Potential tracking technologies of transplanted MSCs include MRI, nuclear imaging, and optical imaging [110].

MRI can be used to observe MSCs labeled by superparamagnetic iron oxide (SPIO) [111–113]. Lu *et al.* showed that *in vivo* MRI was useful for tracking intra-arterially delivered MSCs after SPIO labeling [113]. *In vitro*, high-dose SPIO labeling may affect human MSC survival under serum and oxygen withdrawal conditions [114]. Micrometer-sized SPIOs provided efficient intracellular labeling of human MSCs and did not modify cell viability, phenotype, or *in vitro* differentiation capacity [115]. Detante *et al.* showed that labeled human MSCs can die and release iron particles *in vivo* [115], while Tarulli *et al.* suggested that the use of micrometer-sized SPIOs as labeling agents was insufficient to conclusively determine the localization of iron within cells in regions of ischemia or hemorrhage [116].

Nuclear imaging can detect transplanted cells by labeling them with radioactive tracers [103,117]. Correa *et al.* labeled MSCs with $^{99m}$Tc-hexamethylpropylene and injected them into a patient with an ischemic stroke. The transplanted cells were

visualized using single-photon emission CT [117]. $^{18}$F-fluorodeoxyglucose positron emission tomography may also be a useful tool to visualize the effects of MSC transplantation for ischemic brain lesions [44,118].

The herpes simplex virus thymidine kinase $^{131}$I-5-iodo-2-fluoro-1-β-D-arabinofuranosyluracil (HSV1-TK-$^{131}$I-FIAU) reporter gene-probe system has also been used to track BM-MSC activity in ischemic stroke rat models [119]. Currently, $^{123}$I-iomazenil (IMZ) single-photon emission CT has emerged as a promising technique to track the effects of BM-MSC transplantation on the brain [120].

Optical imaging can also be used to visualize MSCs engrafted in the damaged CNS [29,40,103,121,122]. Shichinohe *et al.* stereotactically transplanted BM-MSCs labeled with green fluorescent protein into the ipsilateral striatum of MCAO mice. Twelve weeks after transplantation the skull was exposed and green fluorescence emitted from the brain surface was sequentially observed using *in vivo* fluorescence optical microscopy [40].

Quantum dots emit near-infrared fluorescence with a longer wavelength (800 nm) and can easily penetrate living tissue. BM-MSCs labeled with quantum dots can be serially visualized by *in vivo* fluorescence imaging for at least 8 weeks after transplantation [121].

Organic nanoparticles with aggregation-induced emission have also been used successfully for tracking MSCs in rats with ischemic stroke, suggesting the potential of fluorescent nanoparticles to help understand the fate of transplanted MSCs [123].

## 48.4 Cytokines and neurotrophic factors

Li and Chopp [124] and others have described MSCs as small molecule factories: they can secrete cytokines, trophic factors, and growth factors. Such factors may be important in the recovery of neurological function after ischemic stroke injury by inducing the migration of BM-MSCs to the ischemic area, providing trophic support, promoting angiogenesis, reducing the apoptosis of neural cells, inducing the differentiation of neural cells, and promoting remodeling of synapses [82].

To induce the migration of BM-MSCs the expression of SDF-1α around the ischemic penumbra and CXCR4 and CXCR7 on the surface of BM-MSCs is upregulated [99,100,125]. Cui *et al.* showed that the molecule nitric oxide donor (DETA NONOate) significantly upregulated CXCR4 and MMPs' expression in BM-MSCs, promoting the migration of BM-MSCs into the periphery of the ischemic area [126]. During the early stage of cerebral infarction, BM-MSCs transplanted into the ischemic area stimulate the expression of many trophic and growth factors, including BDNF, nerve growth factor (NGF), epidermal growth factor, bFGF, IGF-1, hepatocyte growth factor (HGF), VEGF, TGF, angiogenic factor, and stem cell factor [28,29,41,55,82,127–130]. These secreted factors can suppress the local immune system, inhibit fibrosis and apoptosis, enhance angiogenesis, and stimulate mitosis and differentiation of reparative cells. These effects are referred to as trophic effects and are distinct from the direct differentiation of MSCs for the repair of damaged tissues. Shichinohe *et al.* demonstrated that BDNF may be a key trophic factor for BM-MSCs. Treatment with anti-BDNF antibody significantly reduced the trophic effects of BM-MSCs [41]. Transient receptor potential canonical 6 (TRPC6) is the downstream molecular target of BDNF. The neuroprotective effect of BDNF was significantly suppressed when the TRPC6 channels were blocked or the expression of TRPC6 was reduced [131]. In ischemic stroke, the increased expression of TRPC6 contributed to the protection of neurons [132]. We transplanted MSCs into the striatum of MCAO rats using a 2 h/24 h I/R model. The neurological function of rats was significantly improved. This study suggested that BM-MSCs might increase the expression of BDNF, activate TRPC6 channels, and protect neurons after ischemic stroke. Yilmaz *et al.* showed that angiopoietin (Ang)-1 and -4 were highly expressed in BM-MSCs isolated from post-ischemic brains [133]. The transplantation of human BM-MSCs stimulated the expression of VEGF, which was beneficial for angiogenesis following cerebral ischemia [130]. Sun *et al.* suggested that VEGF also had anti-inflammatatory effects and the ability to promote the migration and differentiation of BM-MSCs in addition to its ability to promote angiogenesis [134–136]. Bcl-2 is a protein capable of inhibiting apoptosis. We transplanted MSCs into the MCAO rat again using the 2 h/24 h I/R model and found that the expression of Bcl-2 protein in areas of cerebral ischemia was increased. Upregulation of Bcl-2 resulted in a decrease of apoptosis [86]. BM-MSCs may upregulate soluble factors, such as BMP2 and BMP4. Both soluble factors play key roles in the differentiation process of astrocytes [48]. It has been shown that the expression of BMP2 and BMP4 is increased through co-culture with BM-MSCs and ischemic astrocytes *in vitro* [137]. Astrocytes express CX-43, which promotes the exchange of small molecules in the brain and improves synaptic function [48]. Intracarotid arterial injection of BM-MSCs improved neurological function and promoted the expression of synaptophysin through increasing the expression of BMP2, BMP4, and CX-43 in astrocytes [48].

Zacharek *et al.* compared the therapeutic effects of BM-MSCs harvested from rats that had stroke-induced cerebral ischemia. The data suggested that BM-MSCs from these rats were superior to those from normal rats, and this may have been due to the enhanced secretion of trophic factors and angiogenic factors by BM-MSCs of rats after a stroke [138]. Hypoxia and reoxygenation pretreatment of human BM-MSCs before their administration increased their ability to rescue ischemic cortical neurons by enhancing trophic factors' release, including VEGF, fibroblast growth factor (FGF) and BDNF [139].

## 48.5 Angiogenesis

Transplantation of BM-MSCs significantly protected NVUs [63] and increased angiogenesis in ischemic brain [31,140]. Ito *et al.*

showed that in stroke-prone spontaneously hypertensive rats (SHR-SP) the transplantation of BM-MSCs protected the neurovascular integrity between basement membrane and astrocyte end-feet, which alleviated the ischemic cerebral injury [63]. Chen *et al.* transplanted human BM-MSCs intravenously into MCAO rats at 24 h after the stroke and showed that the number of new capillaries in the periphery of the infarcts increased significantly [53]. Three-dimensional analysis indicated that the capillary vessel volume in the ischemic region was increased [141]. When MSCs were injected intravenously at 1 month after the MCAO, rats still showed clear improvement of neurological function, suggesting that the systemic delivery of MSCs in the later phase of cerebral ischemia may have beneficial effects through an angiogenic mechanism [142,143].

MSCs may mediate angiogenesis by upregulation of factors such as VEGF, VEGF receptor-2 [53], fetal liver kinase-1, the Ang-1/Tie2 system [144] (the Ang-1 receptor Tie2 is a tyrosine kinase of the Tie family), and erythropoietin (EPO) and EPO receptor (EPOR) [145]. Guo *et al.* transplanted MSCs intravenously at 24 h after MCAO and showed that activation of the Notch signaling pathway was also related to angiogenesis [31]. MSCs [53], MSCs combined with DETA NONOate [144], and human MSCs modified by the Ang-1 gene [146] can all promote functional angiogenesis in the ischemic zone and facilitate recovery of the cerebral blood circulation. The mechanisms by which these cell populations mediated their effect was different. Human BM-MSCs enhanced angiogenesis by increasing the levels of endogenous VEGF and VEGFR2 [53]. Combination treatment of stroke with MSCs and DETA NONOate promoted neovascularization partially by upregulation of the Ang-1/Tie 2 axis [141]. Human MSCs modified by the Ang-1 gene increased angiogenesis at the border of the lesion by hypersecretion of Ang-1 [146].

## 48.6 Neurogenesis

The beneficial effect of MSC administration in stroke animals has been reported to be mediated either by differentiation into neurons and expression of neuronal or glial markers and replacement of dying cells [142,147], or by amplifying endogenous neurogenesis [30].

Li *et al.* transplanted BM-MSCs prelabeled by BrdU into the striatum of MCAO mice and showed that 1% of BrdU-positive cells expressed NeuN, a neuron-specific marker, while 8% of BrdU-positive cells expressed glial fibrillary acid protein (GFAP), an astrocyte-specific protein, at 28 days after the infusion [39]. Schichinohe *et al.* confirmed these findings *in vivo* by tracking transplanted MSCs labeled with green fluorescent protein [40]. MSCs administered by the IC, IV [43], and IA [49] routes in some studies showed similar results. However, Kawabori *et al.* reported that IC, but not IV, administration of bone marrow stromal cells enhanced functional recovery in rat cerebral infarcts [64]. Shichinohe *et al.* transplanted MSCs into the brain after the induction of small deep (lacunar) strokes using a stereotactic technique and suggested that some MSCs expressed neuronal or astrocytic phenotypes in the neocortex, subventricular zone (SVZ), corpus callosum, and perilesional area [59]. Shen *et al.* injected MSCs 1 month after the stroke; subsequent double staining revealed that approximately 13% and 6% of MSCs expressed the astrocyte marker GFAP and the neuronal marker microtubule-associated protein-2 (MAP-2) respectively [142].

Hypoxia pretreatment of MSCs may enhance their ability to differentiate [148]. Wei *et al.* showed that significantly more $NeuN^+$ cells and glucose transporter protein $(Glut\text{-}1)^+$ cells were seen in the ischemic core and peri-infarct regions of animals which received anoxic (0.5%) human MSCs, possibly suggesting that anoxic MSCs differentiated into neuronal and vascular endothelial cells more readily compared with normoxic (20%) MSCs [145]. Rat MSCs transfected with Notch 1 were transplanted into the striatum of rats 1 month after MCAO. Subsequent histological staining showed a 9–15% graft survival rate, with 5% of cells $GFAP^+$ and 23% $NeuN^+$ at 12 weeks after transplantation [149]. When human BM-MSCs transfected with Notch 1 were transplanted into the striatum of rats at 1 month after MCAO, histological analysis revealed a modest 5–7% graft survival rate, and few (<1%) MSCs expressed the MAP-2 neuronal marker [149]. Marrow stromal-cell-derived neuronal cells (MSDNCs) can be specifically induced from BM-MSCs with extremely high efficiency using gene transfection of the Notch intracellular domain and subsequent treatment with bFGF, forskolin, and ciliary neurotrophic factor [150]. Both MSDNCs and BM-MSCs migrated from the injection site into the ischemic boundary area, including the cortex, corpus callosum, striatum, and hippocampus. One month later the survival rates of MSDNCs and BM-MSCs were 45% and 10% respectively [150]; 84% of transplanted MSDNCs were positive for MAP-2 at 41 days after transplantation, whereas only a small number of cells were positive for GFAP [150].

By using a highly hydrophobic diphenylamino-*s*-triazine-bridged *p*-phenylene-coated surface and adopting a procedure for the propagation of neural stem cells, Heo *et al.* efficiently converted MSCs into neurosphere (NS)-like cellular aggregates (NS-MSCs) that were subsequently induced to differentiate into neural cells expressing neuroectodermal markers. NS-MSCs exhibited stronger therapeutic effects than MSCs in rat brains with permanent MCAO [151]. Another study showed that light-depolarization of astrocytes can stimulate the release of endogenous adenosine-5′-triphosphate in rats with cerebral ischemia. The released adenosine-5′-triphosphate acted on transplanted MSCs in the ischemic zone and promoted their differentiation into neurons, with improvement in neurological deficits [152].

The administration of MSCs enhanced endogenous neurogenesis in the SVZ [48,54,59,127], which is one of the sites in the brain where endogenous neural stem cells develop. Zhang *et al.* transplanted human BM-MSCs via the IA route 24 h after an ischemic stroke and found that there were more $BrdU^+$ and $Ki\text{-}67^+$ cells in the SVZ, as well as more $BrdU^+/GFAP^+$ cells in the

IBZ [48]. Similarly, Li *et al.* and Chen *et al.* showed enhanced neurogenesis in the SVZ by transplanting either human BM-MSCs or human BM-MSCs with DETA NONOate [54,127].

## 48.7 Axonal sprouting and remyelination

Studies have shown that, after stroke, transplanted MSCs can facilitate the recovery of neural function, enhance interhemisphere and intercortical connections, and restore connections between different cerebral areas by axonal sprouting and remyelination of surviving cortical neurons around the IBZ [67,153]. Axonal sprouting and remyelination may be responsible for the neurological functional improvement observed after MSC administration [50]. Li *et al.* transplanted allogeneic and syngeneic MSCs intravenously into rats 24 h after ischemia and found significant increases in the thickness of axons and myelin, areas of the contralateral corpus callosum, and the number of white matter bundles in the striatum [154]. Song *et al.* provided novel evidence that the transplantation of MSCs has the potential to repair ischemia-damaged neural networks and restore lost neuronal connections. The expression of the axonal growth-associated protein-43 was significantly increased, whereas expression of the axonal growth inhibiting proteins Rho-associated protein kinase II and neural/glial antigen 2 were suppressed in MSCs-treated brains [61].

Ding *et al.* showed that MSCs significantly enhanced brain plasticity after ischemia, and also led to increases in synaptophysin, synapse density, myelinated axons along the IBZ, and endogenous tPA and SHH expression [71]. tPA plays a pivotal role in neurite outgrowth via the SHH signaling pathway [71]. (A neurite refers to any projection from the cell body of a neuron. This projection can be either an axon or a dendrite). Co-culture of MSCs with oxygen–glucose-deprived cortical neurons confirmed the effect of SHH on MSC-mediated neurite outgrowth [71]. Plasminogen activator inhibitor 1, the inhibitor of tPA, also participates in regulating neurite outgrowth [68]. Xin *et al.* showed that MSCs decreased TGF-β1 expression in the IBZ, which contributed to downregulation of plasminogen activator inhibitor 1, thus inducing neurite outgrowth after stroke [68].

Cultured neurons treated with exosome-enriched fractions from MSC-exposed rat brain extracts 72 h after MCAO showed significantly increased neurite branch number and total neurite length [155]. Futher, Xin *et al.* demonstrated that the therapeutic benefit of MSC treatment in ischemic stroke is mediated by miR-133b via exosomes to neural cells that improve neurite remodeling and brain plasticity [156].

## 48.8 Antiapoptotic effects

One of the benefits of MSC administration after stroke injury is a reduction in apoptosis in the penumbral zone of the ischemic lesion. Apoptosis is the process of programmed cell death that occurs in multicellular organisms. Biochemical events lead to characteristic cell changes and death. These changes include blebbing, cell shrinkage, nuclear fragmentation, chromatin condensation, chromosomal DNA fragmentation, and global mRNA decay. A diagram of the process of apoptosis is shown in Figure 48.9.

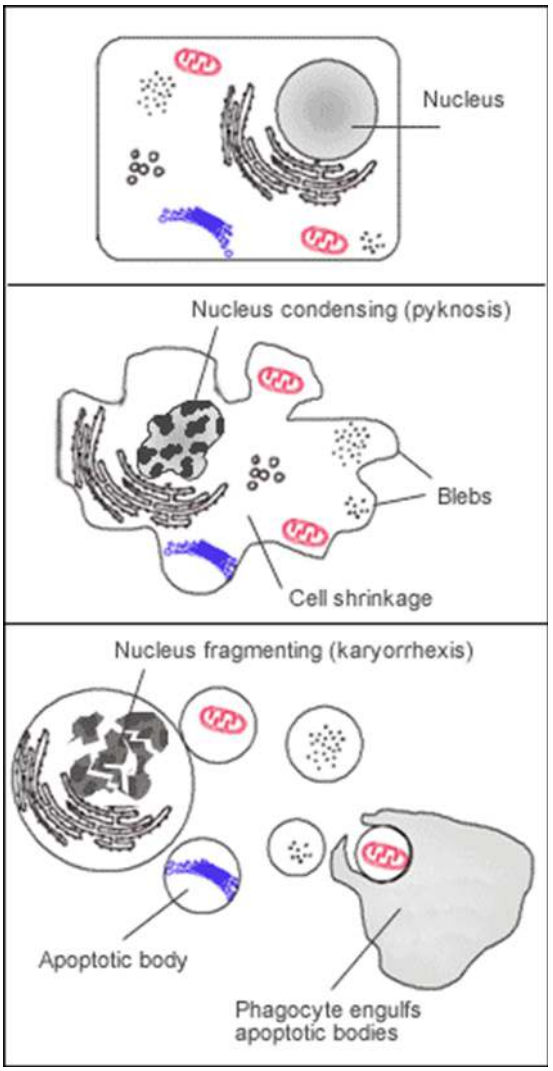

**Figure 48.9** Labeled diagram of a cell undergoing apoptosis. *Source:* https://commons.wikimedia.org/wiki/File:Apoptosis.png#/media/File:Apoptosis.png/

Several studies have shown that IV administration of MSCs to MCAO rats reduced apoptosis along the IBZ [28,55,66,157]. MSCs protected the integrity of the BBB by reducing apoptosis of astrocytes after ischemic stroke [158]. Calió *et al.* suggested that the transplantation of MSCs decreases apoptosis in the brain of SHR-SPs by increasing expression of the antiapoptotic gene *Bcl-2* [159]. In our study, upregulation of *Bcl-2* resulted in a decrease of apoptosis, and may be one of the therapeutic mechanisms by which MSCs mediate a benefit in cerebral ischemic stroke injury [86].

The *in vitro* proliferation of neuronal cells was significantly decreased, and the rate of apoptosis increased, after exposure to oxygen–glucose deprivation. These effects could be alleviated by co-culture with MSCs which had the capacity to decrease apoptosis [160]. Scheibe *et al.* investigated the mechanism through which MSCs protect neurons from apoptosis in oxygen–glucose deprivation. They showed that MSCs activate signal transducer and activator of transcription-3- and Akt-dependent antiapoptotic pathways that enhance the survival of neurons after oxygen–glucose deprivation [161].

Genetically modified MSCs showed greater potential of an antiapoptotic effect. Kurozumi *et al.* used a fiber-mutant F/RGD adenovirus vector to transfect the BDNF gene to human MSCs (BDNF-hMSCs) [162]. Rats receiving BDNF-hMSCs exhibited greater functional recovery, and the number of terminal deoxynucleotidyl transferase dUTP nick-end labeling-positive apoptotic cells in the IBZ was significantly decreased [162]. Zhao *et al.* suggested that MSCs transfected with HGF also had an antiapoptotic effect [163].

## 48.9 Immunomodulation

Another mechanism by which MSCs may mediate a beneficial effect in stroke injury is by their immunoregulatory effects. Xenotransplantation of MSCs is feasible since MSCs are relatively nonimmunogenic [42]. In the early stage of ischemic stroke, cell death results in a release of antigens. Oxidative stress and inflammation mediators activate T cells that cross the BBB [164]. T cells probably exert detrimental effects by antigen recognition [165]. The infiltrating T cells generate large quantities of interferon-γ (IFN-γ), which mediates delayed neurotoxicity in ischemic areas [165]. Transplantation of MSCs inhibits T cell proliferation and cytotoxicity and reduces IFN-γ production by hindering the T cell response to cognate peptides [166]. MSCs also significantly reduce the infiltration of gamma delta T cells, which are detrimental to the ischemic brain, and increase levels of regulatory T cells (Tregs) and Treg-associated cytokines in the ischemic brain [167]. IL-10 induces the protective effect of Tregs by limiting the activation of proinflammatory T cells and decreasing inflammatory cytokines such as IFN-γ [168]. Liu *et al.* suggested that MSCs could increase the expression of IL-10 and decrease tumor necrosis factor-α and thus limit ischemic brain injury [46]. IL-23/IL-17 induce inflammation in cerebral ischemia [60]. MSCs play an immunomodulatory role by reducing IL-23/IL-17 levels, both in serum and around the infarct lesion [60]. Yoo *et al.* demonstrated that the transplantation of MSCs enhanced the recovery of brain functions by secreting TGF-β1, which could block the upregulation of MCP-1 and reduce the infiltration of $CD68^+$ cells and thus limit immune propagation in the ischemic rat brain [70].

However, levels of the inflammatory cytokines IL-6, tumor necrosis factor-α, IFN-γ, and MCP-1 remained unchanged in the sera of mice after cerebral ischemia and transplantation of MSCs [169].

No negative effects of MSCs transplantation on the immune system after stroke have been observed, which may reduce safety concerns about the administration of MSCs in ongoing clinical trials in people who have had an ischemic stroke [169].

## 48.10 Pretreatment of mesenchymal stromal cells prior to their administration in animal models of ischemic stroke

In animals with cerebral ischemia, transplanted MSCs migrate to the ischemic area [28], express trophic factors [29], increase angiogenesis [31], promote neurogenesis [30], improve synaptic plasticity [67], and inhibit apoptosis [66]. To achieve a better treatment effect, different ways of pretreating the MSCs prior to their administration in animal models of ischemic stroke have been explored [26,79] (Table 48.2).

**Table 48.2** Pretreatment of MSCs prior to their administration in animal models of ischemic stroke.

| Stroke model | Cell delivery route | Cells administered | Timing | Results | References |
|---|---|---|---|---|---|
| Transient MCAO (2 h) | IC | FGF-2/HGF–MSCs | 2 h/24 h | Remarkable decrease of infarct volume, neuroprotective or vasodilating effect of FGF-2 and HGF | [163,170] |
| Permanent MCAO | IC | G-CSF–MSCs | 7 days | Upregulated expression of SDF-1α, HGF, and NGF | [129] |
| Permanent MCAO | IV | BDNF/GDNF/PLGF/VEGF–human MSCs (modified to hypersecrete neurotropic factors) | 6 h/3 h | Decreased infarct size and promoted functional recovery | [146,171–173] |
| Permanent MCAO | IC | MSDNCs–bFGF/CNF | 7 days | Behavioral functional recovery in beam balance test, limb placing test, and Morris water maze tests | [150] |

**Table 48.2** (*Continued*)

| Stroke model | Cell delivery route | Cells administered | Timing | Results | References |
|---|---|---|---|---|---|
| Barrel cortex ischemia | IC | Hypoxic MSCs | 24 h | MSCs decreased infarct size and restored thalamocortical circuit connections | [61,174] |
| Focal cerebral ischemia | Intra-nasal | Hypoxic MSCs | 24 h | MSCs decreased cell death in IBZ and reduced infarct volume. Hypoxic preconditioning enhanced cell homing and optimized therapeutic efficacy | [175] |
| Permanent MCAO | IV | Noggin–MSCs | 5 days | Promoted neurogenesis and decreased infarct volume, and ameliorated neurological deficits | [176] |
| Permanent MCAO | IV | CXCR4–MSCs | 24 h | Promoted mobilization and migration, enhanced neuroprotection | [98] |
| Permanent MCAO | IV | NGF/Noggin–MSCs | 5 days | Improved neurological function, upregulated neuron-like cell differentiation and increased synaptophysin expression | [177] |
| Permanent MCAO | IC striatum | PL/G-CSF–human MSCs | 7 days | Enhanced proliferation | [178] |
| Transient MCAO | IV | BDNF–MSCs | 48 h | Improved neurological deficits, reduced infarct volume, improved BBB dysfunction, inhibited neuronal apoptosis | [179] |
| Transient MCAO | IV | VEGF–MSCs | 1 day | Promoted angiogenesis and increased CBF in the ischemic areas, improved neurological deficits | [180] |
| Transient MCAO (2 h) | IV | MCI-186–MSCs | Immediate | Upregulated secretion of BDNF, VEGF, superoxide dismutase; inhibited apoptosis; improved functional deficits; reduced infarct volume; increased the number of neurons | [181] |
| Transient MCAO (90 min) | IV | Hypoxic MSCs | 24 h | Enhanced survival of transplanted cells, improved regenerative properties, upregulated trophic/growth factors, downregulated proinflammatory cytokines and chemokines, expressed more $NeuN^+$ cells | [145] |
| Transient MCAO (1 h) | IV | VPA/lithium–MSCs | 24 h | Improved functional recovery, reduced brain infarct volume, enhanced angiogenesis, migrated toward IBZ | [182] |
| Transient MCAO (2 h) | IV | MSCs | 24 h | Improved transplanted cells' survival capacity and upregulated the expression of protective cytokines | [183] |
| Transient MCAO (2 h) | IC | FlK-1–human SCs | 3 days | Exhibited significant behavioral recovery, increased glucose metabolic activity and reduced infarct volume, increased expression of VEGF and BDNF, promoted angiogenesis, facilitated CBF | [184] |
| Transient MCAO (2 h) | IC | EPO–MSCs | 14 days | Improved neurological function and reduced infarct volume, secreted various trophic factors | [185] |
| Permanent MCAO | IC striatum | NS-MSCs | 3 days | Highly distributed throughout the area of lesion; expressed dopaminergic, glutaminergic and GABA neuronal makers, extended neurites, expressed synaptophysin, improved functional recovery | [186] |
| Permanent MCAO | IV | Ang–VEGF–human MSCs | 6 h | Reduced infarct volume, increased angiogenesis, improved functional recovery | [187] |
| Transient MCAO 2 h | IV | HIF 1α–MSCs | 6 h | Significantly improved motor function, reduced infarct volume and increased VEGF expression | [188] |

Modified, with permission, from [79].
G-CSF: granulocyte-colony stimulating factor; PLGF: placental growth factor; CNF: ciliary neurotrophic factor; CXCR4: chemokine (C–X–C motif) receptor 4; VPA: valproic acid; HIF-1α: hypoxia inducible factor-1α; GABA: γ-aminobutyric acid; PL: platelet lysate.

### 48.10.1 Administration of genetically engineered mesenchymal stromal cells

The IV injection of human MSCs transfected with genes of various growth and neurotrophic factors significantly improved neurological function in ischemic stroke. These factors include BDNF, GDNF, FGF, VEGF, and PLGF [170–173,180]. Ikeda *et al.* showed that intrastriatal delivery of MSCs transfected with FGF-2 improved neurological function and reduced infarct volume in MCAO rats [170]. This improvement was mainly attributed to the transfected FGF-2 playing a neuroprotective or vasodilatory effect [170]. Human MSCs transfected with PLGF were transplanted intravenously into MCAO rats and showed greater therapeutic effect [173]. PLGF promoted neuroprotection and angiogenesis in cerebral ischemia [173]. The modified MSCs were able to overexpress corresponding growth and neurotrophic factors and had a greater effect in reducing infarct volume and improving neurological function [170–173,180]. A positive correlation between the expression levels of modified genes and the therapeutic effect of modified MSCs was found [172,173]. Factors such as Ang-1, Ang-2, and VEGF play important roles in angiogenesis [146,180,187]. MSCs transfected with the gene for VEGF upregulated the level of endogenous Ang-2, which promoted angiogenesis in MCAO rats [180]. The IV administration of human MSCs transfected with the genes for Ang-1 and VEGF (Ang-1–VEGF–human MSCs) showed greater structural–functional recovery than Ang–human MSCs or VEGF–human MSCs [187].

HIF-1α plays a stimulatory role in revascularization in cerebral ischemia. MSCs transfected with a HIF-1α mutant gene were transplanted into MCAO rats and showed significantly improved motor function, reduced infarct volume, and increased VEGF protein expression [188]. The interaction between SDF-1α (CXCL12) and its cognate receptor CXCR4 is crucial for BM-MSC homing and migration [97,98]. MSCs transfected with the gene for CXCR4 promoted the migration of MSCs to the ischemic zone and enhanced neuroprotective effects, which contributed to increasing capillary vascular volume of the peri-infarct area, reduced infarct volume, and improved neurological function in MCAO rats [98].

Hypoxic pretreatment of MSCs before transplantation improved the survival rate of the grafted cells [145]. Hypoxia exposure upregulated endogenous HIF-1α and neurotrophic and growth factors in MSCs, including BDNF, GDNF, VEGF, EPO and EPOR, SDF-1, and CXCR4, and reduced the secretion of many proinflammatory cytokines and chemokines [145]. The transplantation of human MSCs in MCAO rats resulted in better locomotion recovery in the rotarod test [145].

The barrel cortex ischemic stroke model in rodents is generally used to evaluate the recovery of damaged neuronal loop connectivity [174]. The cortical representation of each facial whisker in a rodent forms a structural module, or barrel, that is easily visualized in the adult brain. Together, these modules constitute the barrel cortex, which forms a significant part of the entire rodent cortex. To generate reproducible stroke and a component of reperfusion injury, arterial branches to the barrel cortex are permanently interrupted and both common carotids are occluded for 1 h. The outcome of this technique is a small cortical stroke in a specific functionally defined region of the rat barrel field. Human MSCs (cultured for 24 h in 0.5% $O_2$) transplanted to adult mice 1 and 7 days after focal barrel cortex stroke promoted angiogenesis and axonal growth [61]. Six weeks after the stroke, the ischemia-damaged intracortical activity showed noticeable recovery and the thalamocortical connections were partially restored [61]. Kim *et al.* administered autologous MSCs intravenously in patients with ischemic stroke. The autologous MSCs were cultured *in vitro* with autologous ischemic serum obtained at the time of the acute phase of the stroke [189]. Tsai *et al.* showed that there was no difference in the effectiveness of MSC conditioned medium (CM) derived from ischemic or normal animals [190]. The IV infusion of MSCs grown in normal CM and those grown in ischemia CM were both associated with improved functional recovery, increased neurogenesis, and attenuated microglia and macrophage infiltration in MCAO rat brains [190]. *In vitro*, both populations of MSCs effectively increased neuronal connections and enhanced survival in mixed neuron–glial cultures [190].

Noggin, an antagonist of BMP, regulates the differentiation of stem cells into neurons [191]. BM-MSCs transfected with Noggin and then injected intravenously into MCAO rats promoted neurogenesis in the ipsilateral SVZ, enhanced neuroprotective effects, reduced infarct volume, and improved functional deficits [176]. The cotransfection of NGF and Noggin in BM-MSCs induced synergistic effects on functional recovery and brain plasticity after ischemic stroke [177].

Previous studies have confirmed the therapeutic effects of the transplantation of BM-MSCs on cerebral ischemia. However, the proliferative, differentiation, and homing capacities of BM-MSCs from an elderly population are significantly reduced, especially after several rounds of expansion *in vitro*. By introducing lentivirus-mediated human telomerase reverse transcriptase and VEGF genes into human BM-MSCs from aged donors, Tang *et al.* observed extended lifespan and increased angiogenic capacity [192].

Thus, different pretreatment regimens of BM-MSCs can promote the migration of MSCs toward the ischemic area, provide trophic support to ischemic brain, increase functional angiogenesis, and induce neurogenesis.

### 48.10.2 Administration of mesenchymal stromal cells in combination with chemical agents

Several studies have demonstrated that the application of a number of agents can induce BM-MSCs to migrate to the ischemic area, modulate the expression of cytokines and trophic factors, promote angiogenesis, inhibit apoptosis of the transplanted BM-MSCs, and enhance their therapeutic effect [109,125,144,193].

Intracranial transplantation of BM-MSCs in combination with SDF-1α promotes the migration of BM-MSCs to the ischemic region, increases the density of blood vessels in the ischemic cortex, enhances the plasticity of neurons, and upregulates the expression of antiapoptosis proteins [102].

MCI-186 (3-methyl-1-phenyl-2-pyrazolin-5-one) is a free-radical scavenger that enhances NGF protein levels via the c-Jun NH2-terminal kinase pathway. When BM-MSCs combined with MCI-186 were transplanted, MCI-186 enhanced the survival of the BM-MSCs, promoted the migration of BM-MSCs to the ischemic area, and promoted neurogenesis around the ischemic penumbra [181].

Osanai *et al.* grafted a BM-MSC–thermoreversible gelation polymer (TGP) hydrogel construct on to the ipsilateral intact neocortex of adult mice 7 days after MCAO [109]. The TGP hydrogel promoted the migration of BM-MSCs to the cerebral infarct zone as well as the adjacent dorsal neocortex. TGP hydrogel is biodegradable and provoked no inflammation in the host brain [109].

The IV infusion of human MSCs with DETA NONOate significantly improved functional recovery in transient (2 h) MCAO rats [54]. After this combination therapy, cell proliferation in the SVZ and the expression of VEGF and bFGF in the IBZ increased [54]. DETA NONOate induced high expression of CXCR4 and MMP in BM-MSCs, which promoted their migration and adhesion to ischemic brain [126]. The combination of BM-MSCs and DETA NONOate also increased the expression of Ang-1 and its receptor Tie2, prompted angiogenesis, and restored cerebral blood circulation [144].

Sodium ferulate, the sodium salt of ferulic acid, is a compound used in traditional Chinese medicine for the treatment of cardiovascular and cerebrovascular diseases and to prevent thrombosis. It is considered safe and effective. The coadministration of BM-MSCs and sodium ferulate promoted the expression of SDF-1α/CXCR4 and improved the homing of BM-MSCs toward the ischemic zone [125]. This study showed that serum ferulate induced the differentiation of BM-MSCs to Nestin$^+$ cells, promoted the migration of Nestin$^+$ cells to the ischemic area, and improved functional recovery [125]. Zhao *et al.* also suggested that the administration of BM-MSCs and sodium ferulate facilitated the differentiation of BM-MSCs into neural- and astrocyte-like cells, as well as enhancing the repair capacity of cerebral parenchymal cells by promoting glucose metabolism and endogenous neurogenesis after stroke [194].

*Z*-Val-Ala-DL-Asp-FMK (Z-VAD) is a caspase family inhibitor and cell permeable apoptotic protease. When BM-MSCs were transplanted in combination with Z-VAD into I/R MCAO rats, the survival rate of BM-MSCs significantly increased while the apoptotic rate decreased [193].

Massive intracerebral hemorrhages were observed in the ischemic hemispheres with tPA treatment after MCAO. Edaravone is a nootropic and neuroprotective agent used for the purpose of aiding neurological recovery following acute brain ischemia and subsequent cerebral infarction. Nootropic is a term given to memory enhancers, neurological enhancers, cognitive enhancers, and intelligence enhancers. Nootropics are drugs, supplements, nutraceuticals, and functional foods that improve one or more aspects of mental function, such as working memory, motivation and attention. They act as a potent antioxidant and strongly scavenge free radicals, protecting against oxidative stress and neuronal apoptosis. The combination of BM-MSCs and edaravone protected the ischemic brain against the risk of tPA. Only small hemorrhages were found in recipients of BM-MSCs and edaravone [195].

Oxiracetam is a nootropic drug of the racetam family. The proven effects of the drug are limited to beneficial effects that lead to higher scores in tests for logical performance, attention, concentration, memory, and spatial orientation. Oxiracetam has a protective effect in cerebrovascular impairment [196]. The coadministration of BM-MSCs and oxiracetam showed a synergic effect in improving neurologic function, increasing the expression of Bcl-2, and inhibiting apoptosis in MCAO rats [86].

Minocycline is a broad-spectrum antibiotic that is also a neuroprotective agent and may lead to greater histological and functional improvement when combined with BM-MSCs [197]. Statins, a commonly prescribed type of medication used to lower cholesterol levels, also prevent thrombosis and arteriosclerosis and protect endothelium [198]. The combination of BM-MSCs and simvastatin improved neurological function primarily due to the pharmacological effects of simvastatin that reduce infarct volume and alleviate brain edema [198]. Recent studies showed that BM-MSCs in combination with Chinese medicines, including Bing Pian (Borneolum), She Xiang (Moschus), Naomai Tong, and Dihuang Yinzi, promoted the homing of BM-MSCs, induced angiogenesis, and removed blood clots in ischemic stroke [199,200].

Balseanu *et al.* tested the hypothesis that administration of BM-MSCs in G-CSF-treated animals improved long-term functional outcome in aged rodents. However, the studies showed that, in post-stroke aged rats, daily treatment with G-CSF alone led to a robust and consistent improvement of neurological function. The combination of BM-MSCs with G-CSF may not have any impact on the spatial reference–memory task or infarct volume and did not further improve recovery after stroke injury [201].

## 48.11 Clinical trials involving bone-marrow-derived mesenchymal stromal cells in the treatment of ischemic stroke

The transplantation of BM-MSCs has had a useful therapeutic effect on cerebral ischemia in animal models [138]. In 2005, Bang *et al.* administered autologous MSCs intravenously to five patients with ischemic stroke [202]. One year after transplantation the patients receiving MSCs showed a lower modified Rankin scale score corresponding with improvement in

**Table 48.3** Classification severity of stroke.

| Score | Stroke severity |
|---|---|
| 0 | No stroke symptoms |
| 0–4 | Minor stroke |
| 5–15 | Moderate stroke |
| 16–20 | Moderate to severe stroke |
| 21–42 | Severe stroke |

neuroimaging. No side effects from the MSC infusions were detected [202]. This study suggested that IV administration of autologous MSCs for ischemic stroke is safe. However, because the number of patients receiving MSC treatment was small, Lee *et al.* administered autologous MSCs intravenously to 16 patients with ischemic stroke and followed them up for as long as 5 years [34]. The mortality rate during the follow-up period decreased in the MSC group. Again, it was found that IV MSC administration was safe in stroke patients [34]. Friedrich *et al.* administrated autologous MSCs intra-arterially to patients who had had an ischemic stroke within the preceding 3–7 days [203]. Serial clinical, laboratory, electroencephalogram, and imaging evaluations showed no procedure-related adverse events. The USA National Institutes of Health Stroke Scale (NIHSS) is a tool used by health-care providers to objectively quantify the impairment caused by a stroke (Table 48.3).

Lower NIHSS scores occurred in 6/20 (30%) patients at 90 days after the stroke [203]. Moniche *et al.* administrated autologous MSCs intra-arterially to patients who had an ischemic stroke within the preceding 5–9 days and reported improved neurological function [36]. Battistella *et al.* administrated autologous MSCs intra-arterially to patients with an MCA ischemic stroke within 90 days of symptom onset [35]. No patients exhibited any adverse events during the procedure. There was no worsening in the neurological scales during the follow-up period [35]. These studies indicate that transplantation of MSCs for an ischemic stroke is safe regardless of the time of administration of the MSCs [35,36,203].

In the majority of animal experiments BM-MSCs have generally been transplanted 24 h to 7 days after the stroke [44,45], whereas in clinical trials the timing has usually been several weeks to several months after the stroke [34,35,202,204]. Changes are required in the way clinical trials for ischemic stroke are carried out [205]. Importantly, larger numbers of patients should be recruited to both further phase I and to phase II trials.

G-CSF may be useful for accelerating BM-MSC expansion in order to shorten the interval between the stroke and the administration of MSCs [129,178]. An appropriate concentration of G-CSF significantly enhances BM-MSC proliferation by modulating their cell cycle and also upregulates production of NGF, HGF, and SDF-1α [129,178]. One study showed that G-CSF activated the proliferative capacity of BM-MSCs in aged animals [206]. The Quantum cell expansion system is a novel method of generating high numbers of MSCs in a shorter period of time and requires fewer passages than current conventional methods [207].

## 48.12 Controversies and safety analysis of bone-marrow-derived mesenchymal stromal cells in the treatment of ischemic stroke

### 48.12.1 Conflicting results in animal models

Whether transplantation of BM-MSCs into the ischemic brain can cause adverse effects remains controversial in spite of the numerous animal models and the early clinical trials described previously. Chen *et al.* showed that the administration of BM-MSCs in a type 1 diabetic MCAO (T1DM-MCAO) rat model did not improve neurological deficits but rather resulted in leakage of the BBB and promoted the occurrence of arteriosclerosis [208]. However, Ye *et al.* showed that the transplantation of BM-MSCs combined with extended-release nicotinic acid (Niaspan), also known as vitamin B3, to T1DM-MCAO rats improved white matter remodeling, promoted myelination, and enhanced synaptic plasticity [209]. Yan *et al.* suggested that BM-MSCs with Niaspan may alleviate leakage of the BBB and arteriosclerosis-like changes by decreasing the expression of angiogenin, MMP9, and ED1 (a cellular marker specific for activated rat microglia, monocytes, and macrophages) in T1DM-MCAO rats [210]. Mitkari *et al.* showed that BM-MSCs, although they could migrate to the ischemic penumbra and promote angiogenesis around the lesion, could not improve neurological function of rats after an ischemic stroke [69]. Steiner *et al.* found that IV administration of human BM-MSCs in mice at 24 h after MCAO did not result in any significant differences in mortality between the treatment group and the control group [211]. The majority of the MSCs localized in lung, spleen, kidney, and intestine but not in the brain [211]. Boltze *et al.* observed that, although many studies have indicated that the delivery of MSCs in stroke improves functional outcomes, commonly applied functional tests may not be suitable for discriminating real functional recovery from compensation, which is a frequently encountered phenomenon in rodents. Consequently, these workers highlighted some alternative tests that might determine specific functions, including the cylinder task, tapered/ledged beam walking, and Montoya's staircase test, all of which are relatively easy to perform [212].

### 48.12.2 Combined transplantation of mesenchymal stromal cells and neural stem/precursor cells

Eight patients with cerebral ischemia were enrolled in a clinical trial to assess the safety and feasibility of the cotransplantation of neural stem/precursor cells and MSCs [213]. The results indicated that the most common side effect of cell

transplantation was low fever, which usually lasted for 2–4 days after each administration of cells. All side effects appeared within the first 2–24 h after cell transplantation and resolved spontaneously. There was no evidence of neurological deterioration or infection, and no tumor formation was found at 2-year follow-up. These observations support the use of the combination transplantation of neural stem/precursor cells and MSCs as a safe and feasible method of improving neurological function [213]. Lalu *et al.* performed a systematic review of the literature reporting on over 1000 patients who had received MSCs by either the IV or the IA route. They did not identify any adverse events other than transient fever [214].

## 48.13 Conclusions and perspectives

BM-MSCs are remarkable cells with potential for treating a wide variety of human diseases, including ischemic stroke. They have the ability to improve repair of cerebral ischemic damage by neuroprotection, angiogenesis, neurogenesis, axonal sprouting and myelin remodeling, antiapoptosis, and immunoregulation. A large number of preclinical studies have consistently shown that BM-MSCs are safe and improve neurological function after stroke. Initial human trials have also indicated that they are safe. Much further preclinical work remains to be done, but preclinical animal models and early clinical trials support the value of administration of BM-MSCs as a treatment for ischemic stroke.

## Acknowledgments

## 49.1 The central nervous system

The central nervous system (CNS) comprises the brain and spinal cord and is divided into white and grey matter. The white matter consists of axons (nerve fibers) and oligodendrocytes, while the grey matter consists chiefly of neurons (nerve cells). Both tissues include a number of glial cells, which are often referred to as the supporting cells of the CNS. Different forms of glial cells have different functions, some acting almost as scaffolding for neuroblasts to climb during neurogenesis, while others such as microglia are a specialized form of macrophage involved in the immune system of the brain as well as in the clearance of various metabolites from brain tissue. Oligodendrocytes are a type of neuroglia. Their main functions are to provides support and insulation to axons in the CNS. Astrocytes may be involved with both clearance of metabolites and transport of nutrients to neurons from the capillaries of the brain. When the CNS is injured, astrocytes will proliferate, causing gliosis, a form of neuronal scar tissue, lacking in functional neurons.

## 49.2 Spinal cord injury

Spinal cord injury (SCI) is one of the most devastating diseases that affects patients and their families for the rest of their lives. Most of the cases are caused by traffic accidents, falls, sports, and assaults and therefore often involve young people. The costs of SCI to society include a reduction in quality of life and productivity, lower life expectancy, and high medical costs. In 2007 the medical and related expenses for a 25-year-old tetraplegic patient in the USA were estimated at $3 million [1]. Patients with SCI also face increased risk of cardiovascular complications, deep-vein thrombosis, osteoporosis, pressure ulcers, autonomic dysreflexia, and neuropathic pain [2].

SCI is a complex event with a variety of accompanying factors. Mechanical trauma to the spinal cord triggers an immediate cascade of cellular and biochemical events that leads to lesion progression. Primary injury results in blood vessel disruption and extensive cell death, followed by edema, ischemia, and release of cytotoxic chemicals and proinflammatory cytokines (Figure 49.1). In response, macrophages, neutrophils, and other leukocytes are attracted to the lesion and are recruited to phagocytose cell debris and create a local inflammatory environment. Further lesions develop due to secondary processes, which include ischemia, lipid peroxidation, the production of free radicals, disruption of ion channels, axonal demyelination, necrosis, and apoptosis [3]. In a matter of days to weeks a fluid-filled cyst forms at the injury site surrounded by a glial scar, which consists mainly of reactive astrocytes. These astrocytes increase their metabolism and form processes, preventing the further spread of the aggressive environment both up and down the spinal cord [4,5]. They also secrete several inhibitory proteins, including chondroitin sulfate proteoglycans and axonal growth inhibitors (Figure 49.1). This barrier blocks axonal

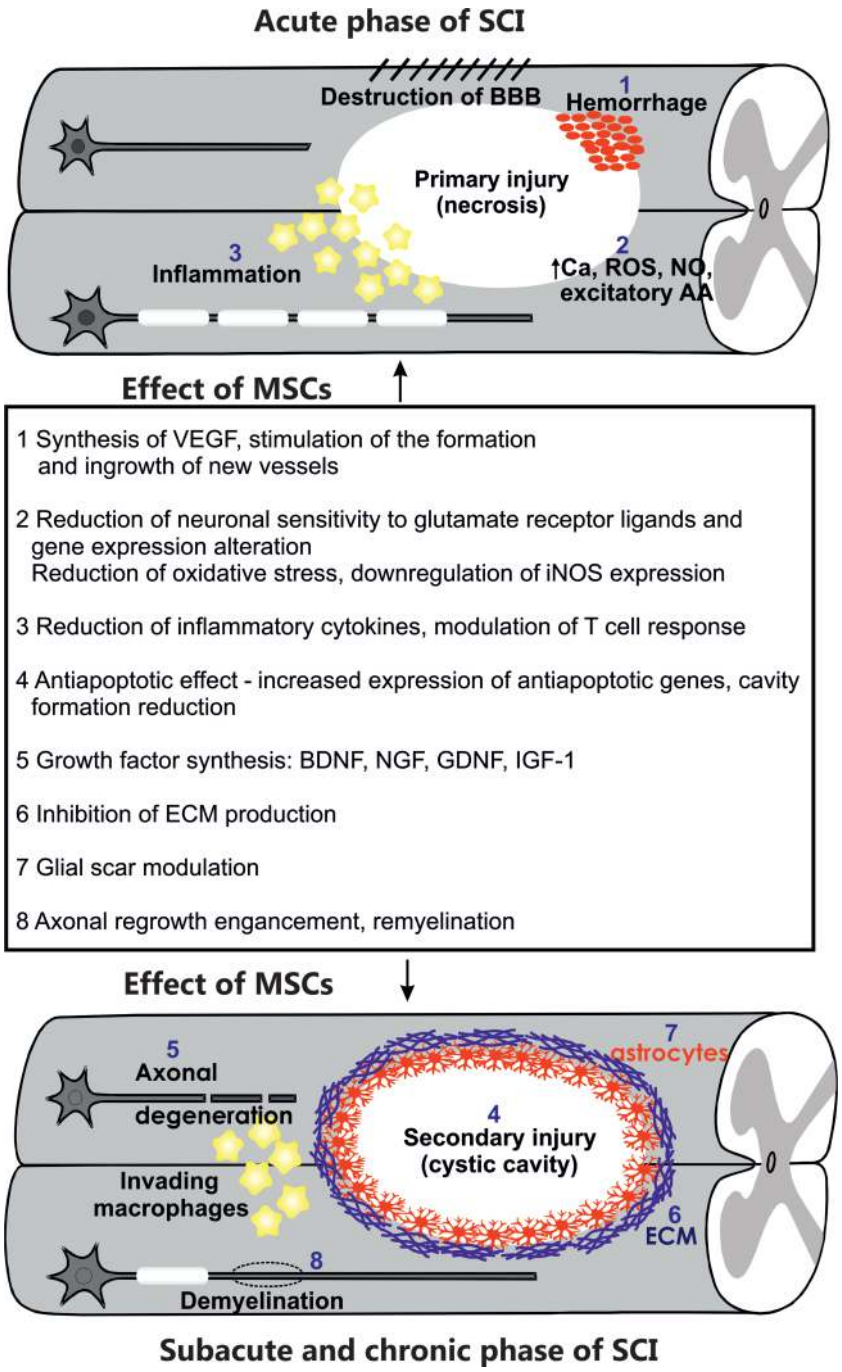

**Figure 49.1** Scheme of pathological events accompanying SCI and the therapeutic effects of MSCs on its pathobiology. BBB: blood–brain barrier; Ca: calcium; ROS: reactive oxygen species; NO nitric oxide; AA: amino acids; iNOS: inducible nitric oxide synthase; VEGF: vascular endothelial growth factor; BDNF: brain-derived neurotrophic factor; NGF: nerve growth factor; GDNF: glial cell-derived neurotrophic factor; IGF-1: insulin-like growth factor 1; ECM: extracellular matrix.

sprouting across the lesion [6]. Additionally, the activation of oligodendrocytes leads to the synthesis of oligodenrocyte-myelin glycoprotein and myelin-associated glycoprotein, both of which have neurite growth inhibitory activity [7–9].

As a result, the nonpermissive environment in the lesion prevents axons from regenerating and crossing the lesion cavity. Any novel therapeutic strategy should confront these obstacles by creating an anti-inflammatory environment that minimizes the glial scar component and provides neuroprotective support for the remaining host cells. It should also stimulate regeneration of the adult CNS and improve neurological functions. Cell therapy has the potential to enhance the quality of life of SCI patients.

## 49.3 Cell therapy

Among many treatments being developed for SCI, the placement of different types of grafts embedded with cell populations into areas of damage has been one of the most commonly used

regenerative approaches, attracting scientists and physicians for the last 15 years [10]. Initially, stem/stromal cells were used mainly because of their differentiation potential. However, it has been shown that they are able to secrete a large repertoire of signaling molecules, including anti-inflammatory cytokines and growth factors, which may modulate the inhibitory environment of SCI while increasing trophic support to the resident cells [10–12]. Trophic factors in the CNS that regulate the survival of neurons include NGF, BDNF, ciliary neurotrophic factor, and GDNF.

In addition, stem/stromal cells can be pro-oligodendrogliogenic, reduce scar formation, and secrete various anti-apoptotic and proangiogenic factors. Different sources and types of cells, including neural progenitor cells derived from embryonic stem cells, induced pluripotent cells, glial restricted precursors, mesenchymal stromal cells, olfactory ensheathing glia (OEG), and Schwann cells have all been examined in preclinical studies and in some cases in clinical studies.

Neural stem cells (NSCs), as well as neural progenitor cells derived from embryonic stem cells or from induced pluripotent stem cells, were tested for their ability to facilitate nerve regeneration and restore the neuronal circuitry when integrated into the injured site [13–15]. It was shown, that neural precursors of human origin can survive in the lesion, express neurotrophins, and facilitate the sprouting of endogenous axons. All of these actions lead to rapid improvements in locomotor functions and to the sparing of white and grey matter within 2–3 weeks of their transplantation. In the long term, transplanted neural precursor cells can slowly mature into region-specific mature neurons and can participate to some extent in tissue reconstruction [13,15].

OEGs are glial cells that ensheath olfactory axons within both the peripheral nervous system and the CNS portions of the primary olfactory pathway. They are responsible for the successful regeneration of olfactory axons throughout the life of adult mammals [16]. OEGs can create a permissive environment for axonal regeneration in the hostile environment of an SCI, supporting axonal growth and remyelination via the secretion of NGF, BDNF, neuregulins, and GDNF [17].

## 49.3.1 Mesenchymal stromal cells

Among cell populations tested, mesenchymal stromal cells (MSCs) have drawn the attention of many research groups. MSCs are self-renewing multipotent progenitor cells with the ability to differentiate into several mesenchymal phenotypes. Although they are not neuroectodermal in origin, and therefore do not normally differentiate into cells of neural lineages, they have been explored for the treatment of SCI. These multipotent adult stem cells are present in many tissues, including bone marrow, fat, placenta, umbilical cord (UC), UC blood, dental pulp, chorionic villi, amniotic membrane and fluid, and the spinal ligament, the ligamentum flavum. The sources that have been explored most commonly for SCI treatment are the bone marrow, adipose tissue, and the UC.

### 49.3.1.1 Bone-marrow-derived mesenchymal stromal cells

Traditionally, MSCs have been isolated from bone marrow even though bone marrow MSCs (BM-MSCs) have been shown to represent less than 1% of marrow mononuclear cells. Isolation of MSCs from the bone marrow is primarily by adhesion to plastic, but these cells can also be concentrated using Percoll gradient centrifugation.

BM-MSCs express a number of phenotypic markers. However, none of them are specific to these cells. According to the International Society for Cellular Therapy, human BM-MSCs under standard culture conditions must meet at least three criteria: (1) they must be plastic-adherent; (2) they must express C105, CD73, and CD90 and not CD45, CD34, CD14, CD11b, CD79 or CD19, or human leukocyte antigen (HLA)-DR surface molecules using flow cytometry; and (3) they must be capable of differentiating into osteoblasts, adipocytes, and chondroblasts *in vitro* [18]. Other markers that are generally accepted to be present on the surface of MSCs include CD44, CD71, stromal precursor antigen (Stro)-1 and adhesion molecules such as CD 106, CD166, and CD29 [19]. Human MSCs express class I major histocompatibility complex (MHC) antigens, HLA-A, -B and -C, but not MHC class II antigens such as HLA-DR as indicated above. They also lack the costimulatory molecules CD40, CD80, and CD86 [20].

Oliveri *et al.* performed a meta-analysis of the use of MSCs in animal models of SCI. Bone marrow was the most frequently used MSC tissue source (84%) and human MSCs were used in 36% of the studies. The majority of studies used the thoracic region as the site of induction of the SCI lesion [21], while only a few studies utilized cervical spinal cord lesions. In one study, BM-MSCs were injected into the lateral funiculus at 1 mm rostral and caudal to the lesion. The lateral funiculus is comprised of bundles of the anterior nerve roots emanating from the spinal cord and transmits nerve messages from the contralateral corticospinal and spinothalamic tracts. Grafted cells promoted extensive ingrowth of serotonin-positive raphespinal axons in the raphespinal tract, which is a tract of the spinal cord located in the lateral funiculus. The cells also promoted the growth of calcitonin-gene-related peptide (CGRP)-positive dorsal root sensory axons into the trauma zone, and significantly attenuated astroglial and microglial cell reactions. However, they also induced aberrant sprouting of CGRP-immunoreactive axons in Rexed's lamina III [22]. The Rexed laminae comprise a system of 10 layers of grey matter that label portions of the grey columns of the spinal cord.

Bone marrow contains different subpopulations of cells. Therefore, Urdzikova *et al.* compared the effect of MSCs with that of cells in the bone marrow mononuclear fraction as well as that of granulocyte colony-stimulating-factor-stimulated mobilized bone marrow cells. All three cell populations reduced locomotor deficits and cavity formation and spared white matter, regardless of the type of treatment [23]. Nearly all studies reporting on the use of BM-MSCs in SCI have observed such locomotor function improvement, although different

mechanisms of action have been put forward. Most often the effect was thought to be mediated by the release of growth factors, facilitating recovery by remyelinating spared white matter tracts, enhancing axonal growth, or by neuroprotective effects via the sparing of white and grey matter tissue in the lesion or by the downregulation of caspase-3-mediated apoptosis (Figure 49.1). Studies from Neuhuber's group reported a reduction of the acute inflammatory response to SCI, as well as a reduction of the cavity formation together with attenuation of microglia and macrophage reactivity [24,25]. Similarly, Hofstetter *et al.* observed not only less acute inflammation, but also the formation of guiding strands through the lesion [26]. BM-MSCs, when applied without *in vitro* predifferentiation, usually do not differentiate into either astrocytes or neurons. However, they can reduce lesion volume without altering astroglial or microglial activation [27]. BM-MSCs transplanted into rats with contusion lesions to the spinal cord exhibited significant improvements in motor and sensorimotor functions, which were strongly correlated with spared tissue volumes. Retrograde tracing revealed that rats given BM-MSCs had twice as many descending brainstem neurons with an axon projecting beyond the contused spinal cord segment. This correlated strongly with improved motor/sensorimotor functions but not with sensory functions [28]. Electrophysiological recordings showed that the latency of somatosensory evoked potentials and motor evoked potentials in MSC recipients were shorter than those of control animals [29,30].

The delivery route of cells is an important factor in the translation to clinical practice. Several studies have compared the intraspinal, intrathecal (or intracisternal), intra-arterial, and intravenous administration of BM-MSCs. Regardless of the delivery route, BM-MSC administration improved functional recovery after SCI. While engraftment of the transplanted cells was higher in animals given MSCs by the intraspinal route [29,31], injections into the parenchyma carry a risk of further damage to the spinal cord tissue; therefore, less invasive routes, such as intrathecal or intravenous delivery, are preferable. Cells administered via lumbar puncture, or intracisternally, showed the best functional recovery, even though the cells often remained in the intrathecal space [32,33] or accumulated around the anterior spinal artery [34]. Rats administered human BM-MSCs intrathecally had reduced inflammatory reactions and apoptosis, improved functional recovery, and rearranged glial scar formation after SCI, although no cells were detected in the spinal cord parenchyma 2 months after transplantation [33]. Repeated delivery of BM-MSCs may prolong the beneficial effects [34].

#### 49.3.1.2 Adipose-tissue-derived stromal cells

Adipose tissue is abundant in the body of most people. It is discarded after liposuction, and centrifugation of the lipoaspirate can isolate a stromal vascular fraction that is rich in stromal progenitor cells and endothelial cells as well as adipocytes. The stromal (mesenchymal) progenitor cells can differentiate *in vitro* into osteogenic, chondrogenic, and adipogenic cells. The *in vitro* and *in vivo* properties of adipose-tissue-derived stromal cells (ADSCs) are similar, although not identical, to those of BM-MSCs [35]. ADSCs in the stromal vascular fraction are identified phenotypically as follows: $CD45^-$, $CD235a^-$ (glycophorin A), $CD31^-$, and $CD34^+$. The colony-forming unit assay for fibroblasts permits the evaluation of progenitor frequency in the stromal vascular fraction population. In culture, ADSCs retain markers in common with other MSC populations, including CD90, CD73, CD105, and CD44 and remain negative for CD45 and CD31. They can be distinguished from BM-MSCs by their positivity for CD36 and negativity for CD106 [36]. In models of SCI, ADSCs provide functional benefits by mechanisms similar to those of BM-MSCs, influencing angiogenesis, axonal outgrowth, inflammation, and gliosis. In one study, three-dimensional cell clusters of human ADSCs were transplanted into an SCI model [37]. The three-dimensional ADSCs differentiated *in vivo* into $CD31^+$ endothelial cells and remained differentiated. The grafted cells significantly elevated the density of vessel formation through angiogenic factors released at the site of the lesion and enhanced axonal outgrowth at the lesion site.

After direct delivery of human ADSCs in a rat spinal contusion model, abundant depositions of laminin of human origin were detected at the lesion site. Laminins are fibrous proteins present in the basal lamina of epithelia, one of the layers of the basement membrane. In neural development, laminin-111 is a major substrate along which nerve axons grow, both *in vivo* and *in vitro*. At the lesion site of rats given human ADSCs, clusters of neural precursors and blood vessels were found. Thus, laminin can be considered a factor mediating the proregenerative effect of human ADSCs in this animal model of SCI [38]. In experiments directly comparing the effect of direct injection of BM-MSCs and ADSCs in SCI models, the ADSC recipients had a significantly increased level of BDNF, which was associated with increased angiogenesis, preservation of axons, a decreased number of ED1 macrophages, and reduced cavity formation. These changes were accompanied with improved functional recovery [39]. (ED1 is a cellular marker specific for activated rat microglia, monocytes and macrophages).

#### 49.3.1.3 Umbilical cord mesenchymal stromal cells

Wharton's jelly is the mucoid connective tissue surrounding the two arteries and vein of the UC. It is composed of myofibroblast-like stromal cells, collagen fibers, and mucopolysaccharides, including hyaluronic acid and chondroitin sulfate. Human UCMSCs share many characteristics with BM-MSCs, including fibroblastic morphology, characteristic cell surface markers, cell cycle status, adipogenic and osteogenic differentiation capacity *in vitro*, secretion of a wide range of proteins, and support of hematopoiesis [40]. Several studies, however, have shown some differences between the two populations. The frequency of colony-forming units was significantly higher in UC-derived nucleated cells than in bone-marrow-derived nucleated cells, suggesting a higher frequency of MSCs in Wharton's jelly

compared with bone marrow. In addition, human UCMSCs have a faster doubling time than human BM-MSCs. This proliferative characteristic did not change after 30 passages [40]. There are also several potentially clinically important advantages of the use of UCMSCs. Unlike BM-MSCs, UCMSCs can undergo repeated freeze–thaw cycles without significant loss of viability or accumulating karyotypic abnormalities [41]. UCMSCs are readily obtainable after birth with no ethical constraints and can be reliably isolated. Like BM-MSCs, they can be engineered to express exogenous proteins. They may be less immunogenic than BM-MSCs. UCMSCs secrete a wide range of immunomodulatory and trophic factors known to promote neural cell survival, including fibroblast growth factor (FGF)2 and stromal cell-derived factor-1α, and neural differentiation (GDNF, BDNF, and NGF), making them a useful tool for neural rescue and support [3]. In a complete spinal cord transection model, transplanted UCMSCs survived for 16 weeks and produced large amounts of human neutrophil-activating protein-2, neurotrophin-3, basic FGF, glucocorticoid-induced tumor necrosis factor receptor, and VEGF receptor 3 [42]. Park and colleagues examined the potential effect of UCMSCs on endogenous cell proliferation and oligodendrogenesis after SCI. UCMSCs were transplanted into the boundary zone of the injured rat spinal cord. Newly synthesized ependymal and periependymal cells, which immunohistochemically resembled stem/progenitor cells because of their expression of neural/glial antigen 2, 2′,3′-cyclic-nucleotide 3′-phosphodiesterase (also known as CNPase), myelin basic protein, and glial fibrillary acid protein, were detected in the spinal cord tissue of grafted rats. CNPase is expressed exclusively by oligodendrocytes in the CNS, and the appearance of CNPase seems to be one of the earliest events of oligodendrocyte differentiation. CNPase is thought to play a critical role in the events leading up to myelination. (Ependyma is the thin epithelium-like lining of the ventricular system of the brain and the central canal of the spinal cord.) Behavioral analysis in this model showed that locomotor functions of the UCMSC group were significantly restored, the spinal cavity volumes were smaller, and the number of $TUNEL^+$ (apoptotic) cells was lower than in the control group [43] (TUNEL: terminal deoxynucleotidyl transferase dUTP nick end labeling). When canine UCMSCs were compared with BM-MSCs and ADSCs in the same experiment, the application of UCMSCs led to more nerve regeneration, neuroprotection, and less inflammation compared with the other populations of MSCs [43].

#### 49.3.1.4 Neural differentiation of mesenchymal stromal cells

Several attempts have been made to transdifferentiate BM-MSCs or UCMSCs into neuron-like cells, oligodendrocytes, or Schwann cells. Many differentiation protocols have been published [44,45]. However, detailed examination of the protocols revealed that the morphological and immunocytochemical changes of MSCs following treatment with a neuronal induction and differentiation medium were not the result of neuronal differentiation, but represented cellular responses to chemical stress [46]. Neuronal differentiation of MSCs would require not only the adoption of neuronal morphology and gene expression, but also the acquisition of the electrophysiological properties of neurons. Experiments with β-mercaptoethanol-induced MSCs have shown that the neuron-resembling cells lacked action potentials and voltage-gated sodium and potassium currents 48 h after induction. The ability of MSCs to differentiate into cells of all three germ layers must be carefully examined as they have been reported to spontaneously express neural markers even in the undifferentiated state [47]. Electrophysiological evidence is essential for proving full differentiation to neuronal lineages.

#### 49.3.1.5 Pretreatment of mesenchymal stromal cells

In an attempt to enhance the therapeutic effectiveness of MSCs transplanted into rats with an acute SCI, several methods of pretreating the MSCs have been employed (Figure 49.2).

BM-MSCs were pretreated with valproic acid (VPA) before transplantation and then injected intravenously 1 week after SCI [48]. In animals, VPA raises cerebral and cerebellar levels of the inhibitory synaptic neurotransmitter γ-aminobutyric acid. This study demonstrated that pretreatment with VPA before transplantation enhanced the benefits of BM-MSCs in terms of greater cell migration and better neurological outcomes after traumatic SCI. The mechanism of this enhancement may have been related to an influence on the stromal cell-derived factor-1/CXCR4 axis [48]. In another study BM-MSCs were exposed simultaneously to inhibitors of DNA methylation, histone deacetylation, and pharmacological agents that increased cyclic adenosine monophosphate levels in an attempt to induce neural differentiation. The transplanted human MSCs survived, differentiated, and significantly improved locomotor recovery of SCI rats. Transplantation also reduced the volume of the lesion cavity and the loss of white matter [49]. UCMSC-derived neurospheres

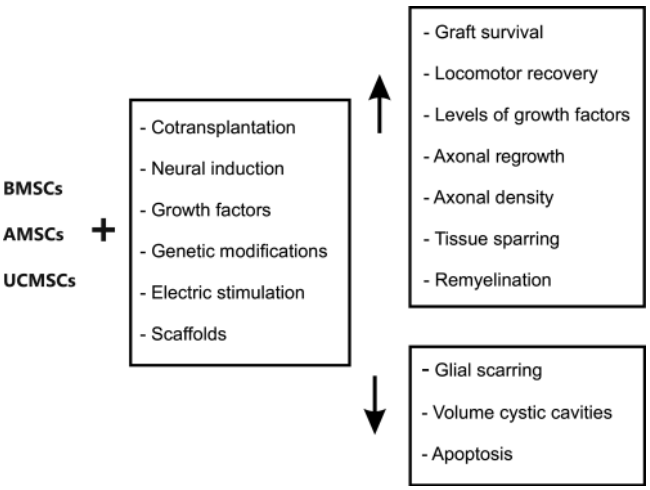

**Figure 49.2** Scheme showing modalities for enhancing MSC effects.

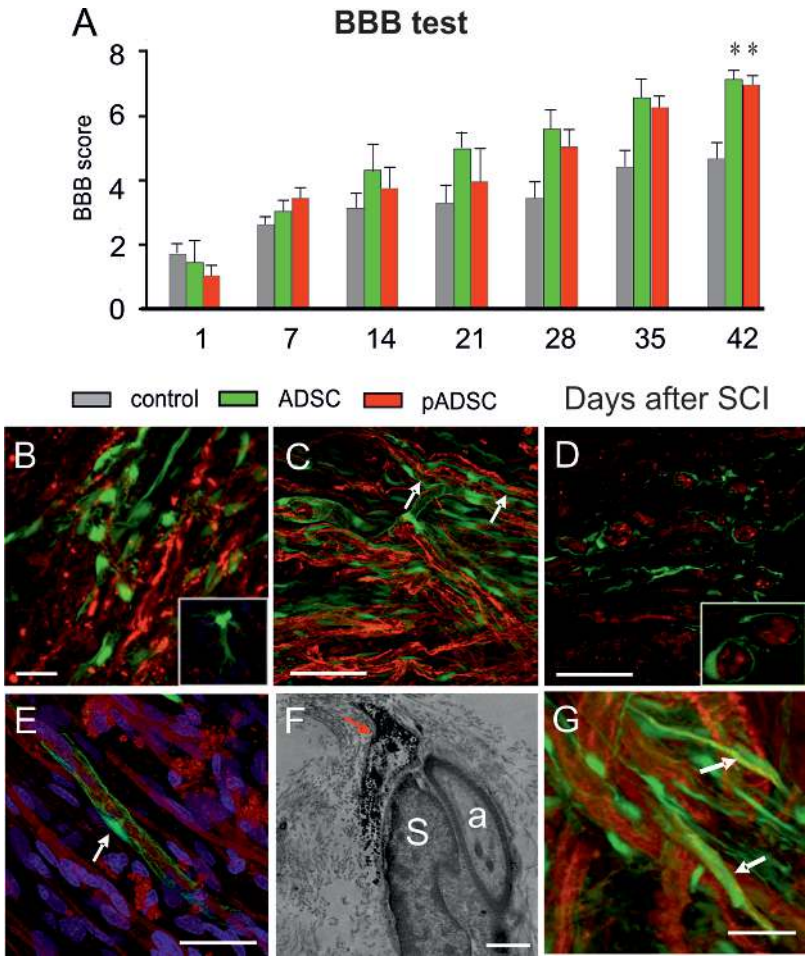

**Figure 49.3** Transplantation of ADSCs into SCI injury. (A) The Basso, Beattie, Bresnahan (BBB) test of rats with SCI grafted with predifferentiated (pADSCs) and naive ADSCs. Grafted animals showed better recovery regardless of the type of implanted cells. (B) Naive ADSCs did not form any interactions with host tissue 2 months after grafting into the SCI. (C, D) Predifferentiated pADSCs form tubules wrapping around the remaining filaments. (NF160, red; green fluorescent protein (GFP), green). (E) The myelinated fibers were covered (O1, red; GFP, green; 4′,6-diamidino-2-phenylindole, blue). (F) Transmission electron microphotograph showing a $GFP^+$ cell in close contact with a Schwann cell (S) and axon (a). (G) Transplanted cells expressed endothelial markers CD31 (CD31, red; GFP, green). Scale bar: B–D 20 μm; E, G, 25 μm; F, 1 μm. (See color plate section.) *Source:* adapted from Arboleda *et al.* 2011 [51], pp. 1113–1122.

supported by BDNF promoted morphologic and functional recovery in an animal model of transected spinal cord [50]. Treatment of BM-MSCs with the Schwann-cell-differentiating factors FGF, platelet-derived growth factor, and glial growth factor 2 significantly increased the production of BDNF *in vitro*.

Differentiated Schwann-like BM-MSCs transplanted into cervical spinal cord lesions remained at the injection sites, and in the trauma zone they were often associated with neurofilament-positive fibers and increased levels of VEGF. Differentiated BM-MSCs provided neuroprotection to axotomized rubrospinal neurons and increased the density of rubrospinal axons in the dorsolateral funiculus rostral to the injury site [22]. (Axotomy is the cutting or otherwise severing of the axon of a neuron. The rubrospinal tract is one of several major motor control pathways.) It is smaller and has fewer axons than the corticospinal tract, suggesting that it is less important in motor control. It is one of the pathways for the mediation of voluntary movement. The tract is responsible for large muscle movement as well as fine motor control.

As with BM-MSCs, ADSCs have also been also the subject of predifferentiation. ADSCs were predifferentiated into spheres prior to transplantation and their behavior was compared *in vivo* with naive ADSCs after transplantation into an SCI site. Both studies observed increased survival of predifferentiated ADSCs [51,52] (Figure 49.3). However, functional improvements were comparable in both groups, indicating that repair was mediated mainly through paracrine mechanisms.

#### 49.3.1.6 Co-transplantation

Owing to their anti-inflammatory and immunomodulatory effects, as well as their secretion of several neurotrophic factors, MSCs have been used as a cellular source of trophic support for endogenous and co-transplanted cells. The viability of mouse NSCs when they were co-transplanted with ADSCs was examined [53]. It was found that ADSCs preconditioned with hypoxia inhibited the apoptosis of murine NSCs in several *in vitro* injury models. Consistent with these *in vitro* results, murine NSCs transplanted into rat spinal cords with ADSCs showed better survival rates than murine NSCs transplanted alone [53]. Co-transplantation of Schwann cells and BM-MSCs promoted functional recovery in rat hind limbs, reduced the extent of the glial scar, and remyelinated the injured axons to a greater degree than single cell treatments and controls [54]. However, Amemori *et al.* co-transplanted OEGs and BM-MSCs and did

not observe a synergistic effect in the treatment of balloon-induced spinal cord compression [29].

#### 49.3.1.7 Mesenchymal stromal cells, growth factors, and neuroprotective factors

In order to promote survival of transplanted MSCs, the cells can be pretreated in culture prior to transplantation, or a neuroprotective agent can be administered at the same time as the cells. Salvianolic acid can alleviate oxidative stress and improve endothelial function. Salvianolic acid applied intraperitoneally with transplanted BM-MSCs provided neuroprotection to SCI and promoted the survival of the MSCs transplanted into the SCI [55]. Immunosuppression with the calcineurin inhibitor tacrolimus (originally known as FK506) also improved the survival of transplanted BM-MSCs [56]. Immortalized human BM-MSCs and neuropeptide pituitary adenylate cyclase-activating polypeptide (PACAP) had synergistic protective effects that increased the number of remaining neuronal fibers in the injured spinal cord, leading to better locomotor functional recovery in SCI rats compared with administration of PACAP or human BM-MSCs alone [57].

Although MSCs secrete a large number of proteins, the level of these proteins is not sufficient for SCI repair. Poly(lactic-co-glycolic acid) (PLGA) is a copolymer that is used in a large number of therapeutic devices approved by the US Food and Drug Administration because of its biodegradability and biocompatibility. The sustained long-term release of FGF-2 from heparin-conjugated PLGA-conjugated nanospheres co-transplantated with BM-MSCs following rat SCI led to increased functional improvement, greater survival of the human BM-MSCs, and a greater density of neurofilament-positive cells in the center of the injury [58].

Animals co-transplanted with human UCMSC-derived neurospheres (HUMSC-NSs) and BDNF had greatly improved BBB test scores compared with HUMSC-NSs-treated and vehicle-treated control groups. The BBB scoring system was devised by Drs Basso, Beattie, and Bresnahan in 1995 in order to study the sequence of locomotor recovery patterns. It takes into consideration the early (BBB score from 0 to 7), intermediate (8–13), and late phases (14–21) of recovery. Any treatment which increases the BBB score may be considered neuroprotective in animal models. Additionally, axonal regeneration showed significant improvement in rats receiving HUMSC-NSs and BDNF compared with HUMSC-NSs-treated and medium-treated groups as demonstrated by staining for the 200 kDa neurofilament protein NF-200$^{+}$ and fluorogold retrograde tracing [50]. The retrograde fluorescent tracer fluorogold is useful, first, because it is not only detectable by fluorescence microscopy but also immunocytochemically, resulting in an almost complete staining of the dendritic arbor. Second, it is visible in lysosome-like structures allowing for the identification of projection neurons at the ultrastructural level and, third, it remains in the labeled neurons for extended periods of time.

Genetically modified neurotrophin 3 (NT-3) UCMSCs were transplanted following a clip injury to the rat spinal cord. A clip injury is produced by clipping the spinal cord extradurally with a modified aneurysm clip. NT-3-UCMSCs recipients achieved better functional recovery with an increased intensity of 5-hydoxytryptamine (serotonin) fibers, increased volume of spared myelination, and decreased area of the cystic cavity in the NT-3-UCMSCs group compared with the UCMSCs group. Moreover, transplanted NT-3-UCMSCs survived and produced larger amounts of NT-3 than the UCMSCs in the spinal cord of the recipients [59].

Zeng and colleagues have performed several studies with BM-MSCs overexpressing tropomyosin receptor kinase C (TrkC), indicating that TrkC may play a role in BM-MSC homing [60,61]. TrkC is also known as NT-3 growth factor receptor, neurotrophic tyrosine kinase receptor type 3 or TrkC tyrosine kinase. TrkC is the high-affinity receptor for NT-3. As such, TrkC mediates the multiple effects of this neurotrophic factor, which include neuronal differentiation and survival.

Rats with combined treatments comprising of platelet-rich plasma and BDNF-overexpressing BM-MSC implants showed enhanced hind limb locomotor performance with more axonal remyelination and less accumulation of astrocytes at the transplant site at 8 weeks compared with control animals [62].

MSCs that overexpressed basic FGF produced enhanced myelination, axonal regeneration in the lesion, and recovery of neurological function after SCI in rats [63].

Hepatocyte growth factor (HGF) has antiglial scar effects. Transplantation of HGF-overexpressing BM-MSCs (HGF-BM-MSCs) into the cervical hemisection reduced scar formation. Animals treated with HGF-BM-MSCs showed axonal growth promotion beyond the glial scars and improved recovery of forepaw function [64].

#### 49.3.1.8 Mesenchymal stromal cells and external physical forces

Electrical stimulation has been reported to promote the survival and differentiation of the BM-MSCs. The number and ratio of BM-MSCs surviving near the lesion site were significantly increased in the BM-MSC and electrical stimulation group compared with groups treated with either BM-MSCs alone or electrical stimulation alone. This suggested that the implanted spike wave evoked by electrical stimulation could promote the bioactivity of BM-MSCs as well as their survival [65]. Zeng and colleagues reported in several studies that electric acupuncture promoted the differentiation of BM-MSCs into neuron-like and oligodendrocyte-like cells as well as the regeneration of 5-hydroxytryptamine (serotonin)-positive nerve fibers in injured spinal cords via the induction of endogenous NT-3. A combination of electric acupuncture and BM-MSC transplantation can improve the partial functionality of paralyzed hind limbs in transected rats [61,66,67].

The efficiency of cell delivery in SCI can be increased using magnetic systems with tunable geometric parameters. The effects

of a pulsed electromagnetic field (PEMF) on injured rat spinal cords were investigated using human MSCs into which magnetic nanoparticles had been incorporated. The MSCs were guided by the PEMF toward the injured site; following exposure for 8 h each day over a period of 4 weeks, behavioral recovery occurred in SCI rats, suggesting that PEMF enhanced the action of the transplanted cells [68].

Vanecek *et al.* showed that intrathecally transplanted cells labeled with superparamagnetic iron oxide (SPIO) nanoparticles could be guided by a magnetic field and successfully targeted to a position near the lesion site in the rat spinal cord. Cell distribution correlated well with the calculated distribution of magnetic forces exerted on the transplanted cells in the subarachnoid space and lesion site [69].

To follow the migration and fate of transplanted cells, an SPIO labeling technique was successfully used with *in vivo* magnetic resonance imaging (MRI) in stroke or SCI models [23,70]. MRI cell detection *in vivo* was confirmed by histologically using iron staining or fluorescent cellular markers that were be coupled to SPIO nanoparticles [71].

#### 49.3.1.9 Mesenchymal stromal cells and scaffolds

The standard method of MSC delivery for SCI is intraspinal injection, but this can result in additional injury and provides little control over how the cells integrate into the tissue. Moreover, in the case of large SCI or chronic spinal cord lesion, when cystic cavities are common, it is necessary to reconstruct the damaged tissue with a growth-promoting environment that can bridge the lesion and stimulate host tissue regeneration. One approach is to fill the cavity with a bioengineered scaffold that can provide structural and/or chemical support for axonal regrowth and concomitantly serve as a matrix for the delivery of cells or drugs and bioactive substances [72,73]. Scaffolds are available for the treatment of subacute and chronic lesions. Poly(2-hydroxyethyl methacrylate) (PHEMA) is a polymer that forms a hydrogel in water. Delayed implantation of positively charged PHEMA hydrogels 1 week after a spinal cord transection was shown to be more effective than immediate hydrogel implantation, as it significantly reduced cavity volume [74].

The survival time of BM-MSCs or UCMSCs was assessed by grafting acellular spinal cord scaffolds seeded with BM-MSCs or UCMSCs in a rat model of acute hemisected SCI. Spinal cord scaffolds seeded with MSCs enhanced grafted cell survival, improved differentiation, promoted axonal regeneration at the site of the lesion, promoted migration of host oligodendrocytes into the graft, and reduced endogenous nerve tissue apoptosis, thus protecting the host tissue as well as improving functional recovery from the implant [75,76].

MSC survival was improved 6 months after the implantation of poly[*N*-(2-hydroxypropyl) methacrylamide with the attached amino acid sequence Arg–Gly–Asp] (HPMA-RGD) that had been seeded with MSCs. A cell polymer scaffold bridged the lesion, reduced atrophy, and facilitated the ingrowth of axons, vessels, Schwann cells, and astrocytes into the lesion [77].

PLGA scaffolds seeded with human BM-MSCs were implanted into a completely transected spinal cord. BM-MSCs were detected at the implanted site 4 and 8 weeks after transplantation, indicating *in vivo* survival of implanted human BM-MSCs. Immunostained images showed clear evidence of axonal regeneration in human BM-MSC-seeded PLGA scaffolds only, and this resulted in functional recovery of a completely transected SCI [78].

## 49.4 Chronic spinal cord injury

Although the acute and subacute phases of SCI have been extensively studied, there have only been a limited number of preclinical studies in chronic animal models; as a result, it is more difficult to evaluate the efficacy of an MSC-based approach. Studies reported to date have not been as encouraging as studies performed in the acute or subacute phases of SCI. The effects of BM-MSCs alone was compared with that of BM-MSCs and the immunosuppressive agent tacrolimus. The findings indicated that immunosuppression improved the survival of the grafted cells. A cell-dose effect was found regarding locomotion recovery and tissue protection independent of immunosuppression. Nevertheless, immunosuppression enhanced the electrophysiological outcomes and allowed filling of the cavity formed after injury by new regenerative tissue and axons [56].

Highly purified Stro-1-positive human mesenchymal precursor cells were assessed for their ability to repair injured spinal cord at 3 or 6 weeks after the SCI [79]. Behavioral and anatomical analysis showed a statistically significant improvement in functional recovery, tissue sparing, and cyst volume reduction following cell therapy. This was due to an increased presence of serotonergic and sensory (CGRP) axons. Zurita *et al.* observed progressive functional recovery 3 months after SCI in paraplegic pigs that had been injected with autologous BM-MSCs suspended in autologous plasma into the lesion zone and adjacent subarachnoid space. Intramedullary cavities caused by the injury were filled with a newly formed tissue containing several axons together with surviving BM-MSCs. In the treated animals, recovery of the previously abolished somatosensory-evoked potentials was detected [80].

NT-3 BM-MSCs were injected into the lesion site of rats with cervical SCI 6 weeks after induction of the lesion [81]. A modest number of axons penetrated through the chronic scar that contained a mixture of inhibitory and growth-stimulating factors.

Behavioral analysis showed a statistically significant improvement in rats implanted with HPMA-RGD hydrogels seeded with BM-MSCs 5 weeks after SCI. The combined approach prevented tissue atrophy, and the hydrogels were infiltrated with axons myelinated with Schwann cells, blood vessels and astrocytes [77] (Figure 49.4).

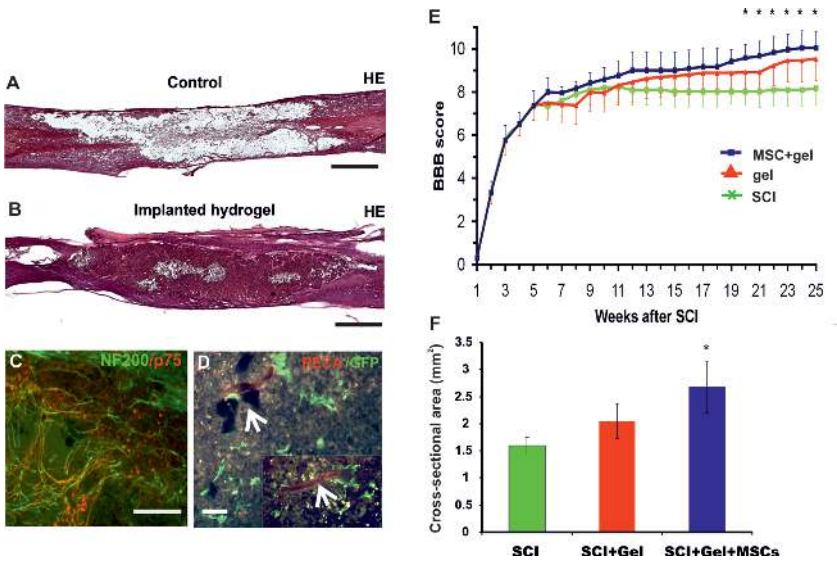

**Figure 49.4** Hydrogel scaffold seeded with BM-MSCs implanted into a chronic lesion 6 months after SCI. (A) A cavity developed at the lesion site 6 months after induction of the lesion. (B) The implanted hydrogel adhered well to the surrounding tissue and completely bridged the posttraumatic cavity. (C) The porous structure of the hydrogel was completely infiltrated with axons ($NF200^+$) and Schwann cells ($p75^+$). (D) Transplanted cells survived for 6 months in the hydrogel. Blood vessels stained with rat endothelial cell antigen (RECA) infiltrated the hydrogel. (E) Animals transplanted with the hydrogels seeded with cells showed improved in locomotor activity. (F) Tissue atrophy was reduced in animals with a cell–polymer construct. Scale bar: A, B: 500 µm; C: 50 µm; D: 15 µm. (See color plate section.) *Source*: adapted from Hejcl 2010 [77], pp. 1535–1546.

## 49.5 Cellular transplants for spinal cord injury

The annual total incidence of SCI ranges from 12 to 71 per million people in different populations, and approximately $700 \pm 500$ per million patients are living with SCI [82–86]. The most frequent causes of SCI are motor vehicle accidents, falls, and acts of violence. SCI has been considered an untreatable condition for a very long time. Initial references to it come from the Edwin Smith papyrus (Figure 49.5). This document is an Ancient Egyptian medical text, named after the dealer who bought it in 1862, and is the oldest known surgical treatise on trauma. This document, which may have been a manual of military surgery, describes 48 cases of injuries, fractures, wounds, dislocations, and tumors. It dates to Dynasties 16–17 of the Second Intermediate Period in Ancient Egypt, *circa* 1500 BC.

**Figure 49.5** Plates VI and VII of the Edwin Smith Papyrus at the Rare Book Room, New York Academy of Medicine. *Source:* https://commons.wikimedia.org/wiki/File:Edwin_Smith_Papyrus_v2.jpg#/media/File:Edwin_Smith_Papyrus_v2.jpg.

The document described two cases of SCI and determined them as "an ailment not to be treated" [87]. The idea that axons have an intrinsic ability to regrow comes from the work of Ramon y Cajal in the 1920s, who described how the capacity to regenerate is inhibited by scar tissue formation at the site of injury. Despite a long history of spinal cord regeneration research, the progress of therapeutic intervention has been limited.

Current management of SCI is based on two multicenter controlled studies, the STASCIS [88] and NASCIS trials [89] that advocated early decompression and corticosteroid therapy respectively. Both clinical trials have engendered controversies. However, these are more related to the framework of the clinical trials as opposed to the treatments advocated [90]. Despite the modest therapeutic approaches available, 679 clinical trials related to SCI have been registered at clinicaltrials.gov. The trials are mostly related to rehabilitation, electrostimulation, pharmacological repair strategies, surgical management, cell therapies, and treatments of accompanying diseases such as pain management or hypertension. Rehabilitation after SCI plays an increasingly important role in recovery. Its primary goals are the prevention of secondary complications, maximization of physical functioning, and reintegration of the patient into the community.

### 49.5.1 Use of hematopoietic stem/progenitor cells for spinal cord injury

The rationale for cellular transplants as a strategy for SCI is based on the idea that living cells will respond better than a drug to the wide spectrum of pathological events that occur after injury. The proposed mechanisms include minimalization of cell loss

through immunomodulation, neuroprotection through trophic support, tissue modification, and cell replacement. Cells can be administered effectively by lumbar puncture into the cerebrospinal fluid; thus, no additional surgical intervention is required and there is the possibility of repeated applications. Selective intra-arterial and intravenous administrations are other routes that have been used in clinical studies to treat SCI. The first clinical trials in SCI patients based on cell therapy used an unmanipulated mononuclear cell fraction isolated from bone marrow (BMCs) or sorted $CD34^+$ hematopoietic stem cells isolated from mobilized peripheral blood. We compared intra-arterial administration (using the vertebral artery, $n = 6$) versus intravenous administration of bone marrow nucleated cells ($n = 14$) in a group of subacute (10–33 days after SCI, $n = 8$) and chronic patients (2–18 months after SCI, $n = 12$) [91]. Motor evoked potentials, sensory evoked potentials, MRI, and the American Spinal Injury Association (ASIA) scores were used for monitoring patient follow-up. The ASIA scoring system is a system of tests used to define and describe the extent and severity of a patient's SCI and help determine future rehabilitation and recovery needs. It is ideally completed within 72 h after the initial injury. The patient's grade is based on how much sensation they can feel at multiple points on the body as well as on tests of motor function. We found that the administration of bone marrow mononuclear cells after SCI was safe. A partial improvement in the ASIA score and partial recovery of motor evoked potentials or sensory evoked potentials were observed in all subacute patients who received the cells via the vertebral artery ($n = 4$) and in one of four patients with subacute SCI who received the cells intravenously. Improvement also occurred in one patient with chronic SCI who received cells via the vertebral artery [91].

Park *et al.* evaluated the therapeutic efficacy of autologous bone marrow cells implanted at the site of the SCI in combination with granulocyte-macrophage colony-stimulating factor (GM-CSF) given by subcutaneous injection [92]. No serious side effects were observed. There were improvements in the ASIA score, and MRI 4–6 months after injury showed a slight improvement at the site of cell injection [92].

Yoon *et al.* implanted autologous bone marrow cells directly into the spinal cord and reported that neurological improvement occurred in acute and subacute SCI patients, but not in those in the chronic period [93].

The study performed by Callera and do Nascimento demonstrated the feasibility and safety of delivering autologous bone marrow mononuclear cells after GM-CSF administration via lumbar puncture to patients with SCI. Interestingly, there was an absence of cells in cerebrospinal fluid samples obtained 7 days after their administration [94], an observation made also in rodent models of SCI [33]. Similarly, Kumar *et al.* injected autologous bone marrow cells by lumbar puncture and reported improvements in neurological function in one-third of SCI patients [95]. The time elapsed between injury and the administration of cells and the number of $CD34^+$ cells injected influenced the outcome of the approach. Deda *et al.* administered autologous hematopoietic stem/progenitor cells cells to nine chronic patients and concluded that their application was safe regardless of the route of administration (intrathecally, directly into the cord, and intravenously) [96]. Geffner *et al.* administered autologous bone marrow stem cells directly into the spinal cord, into the spinal canal, and intravenously [97].

### 49.5.2 Use of mesenchymal stromal cells for spinal cord injury

BM-MSCs have been used in a number of studies. Kishk *et al.* administered MSCs intrathecally monthly within 6 months of injury [98]. Dai *et al* administered MSCs intrathecally [99]. Each reported improvements after BM-MSC administration.

Karamouzian *et al.* reported a marked recovery in three patients after intrathecal application of MSCs but the results were statistically borderline [100]. Pal *et al.* did not find any neurological or electrophysiological improvements after BM-MSC administration [101]. Bhanot *et al.* used autologous MSCs to treat chronic SCI that were administrated directly to the injury site. They concluded that the administration of such cells was safe, but may not have been efficacious [102].

Ra *et al.* administered adipose-tissue-derived MSCs intravenously to eight male patients who had had an SCI >12 months previously. No serious adverse events related to administration of the cells during the 3-month follow-up period were reported [103].

Clinical studies involving MSCs derived from UC blood are still limited. Cheng *et al.* transplanted UCMSCs into the subarachnoid space by lumbar puncture and compared the outcome with that with rehabilitation therapy. They concluded that MSCs from the umbilical matrix improved recovery of neurological functional after SCI and that their efficacy was superior to that of rehabilitation therapy [104].

The safety and efficacy of umbilical MSCs administered by intrathecal injection have been reported by Liu *et al.* Treatment was effective in 13 of 22 patients and no treatment-related adverse events occurred during a follow-up period ranging from 3 months to 3 years [105]. All published clinical studies are summarized in Table 49.1.

## 49.6 Conclusions

The application of cells represents a promising approach in the treatment of SCI. From experimental studies in rats with traumatic SCI it is evident that MSCs applied during the subacute phase of SCI decrease the size of the lesion, prevent cavity formation, and have a substantial beneficial effect on locomotor recovery. There are several possible mechanisms underlying these effects, including the production of growth factors, a decrease in anti-inflammatory cytokines, glial scar remodeling, and support of revascularization. Their effects are observed mainly in the rescue of endogenous tissue and support of neuroregeneration, and can be enhanced by genetic engineering to

**Table 49.1** Published clinical trials using bone marrow mononuclear cells or mesenchymal stromal cells for the treatment patients with SCI.

| Authors | Number of patients in the study | Type of cells/routes | Follow-up period | Results | Complications |
|---|---|---|---|---|---|
| Park *et al.* [92] | 4 acute patients, 2 chronic patients | $1.1 \times 10^6$/μL autologous BMCs IS, GM-CSF SC for 5 days | 6–12 months | 1 × ASIA A–B, 4 × ASIA A–C | Fever, myalgia, leukocytosis after GM-CSF injections |
| Callera *et al.* [94] | 10 chronic patients | $2 \times 10^9$ BMCs IT | Not provided | No detailed assessment of the results | No complications |
| Syková *et al.* [91] | 7 acute/ subacute patients, 13 chronic patients | $10^{12}$ BMCs IA 6 patients; IV 14 patients | 3–12 months | IA: 4 patients ASIA improvement; IV: 1 patient ASIA improvement | No complications |
| Yoon *et al.* [93] | 17 acute patients, 6 subacute, 12 chronic patients | $2 \times 10^9$ BMCs IS, once daily for 5 days, GM-CSF SC | 10 months | 29.5% acute, 33.3% subacute, and no chronic patients improved | Fever, headache after GM-CSF application, neuropathic pain |
| Deda *et al.* [96] | 9 chronic patients | $10–67 \times 10^6$ autologous BMCs IS, IV into gel covering the spinal lesion | 1 year | 100% improvement 1 × A–B, 8 × A–C | No complications |
| Geffner *et al.* [97] | 4 acute, 4 chronic patients | $4 \times 10^8$ autologous BM-MSCs, repeated injections IT, IV, and IS | 2 years | Acute SCI: 3 × ASIA A–C Chronic SCI: 1 × ASIA A–C, 1 × B–C, 1 × C–D | No complications |
| Pal *et al.* [101] | 15 acute, 10 chronic | $10^6$ culture-expanded BM-MSCs, two doses IT | 1–3 years | No ASIA improvement | No complications |
| Hammadi *et al.* [106] | 277 chronic patients | $5 \times 10^8$ hematopoietic stem cells IT, repetitive 1–4 times after 6–8 weeks | 4 weeks | Improvement in 120 patients (43%); 88 × A–B, 32 × A–C 157 patients no improvement | 90% temporary back pain, meningism |
| Saito *et al.* [107] | 5 acute patients | $3–5 \times 10^7$ culture-expanded autologous BMSCs IT | 6 months | 3 × ASIA A 1 × ASIA B–D 1 × ASIA C–D | No complications |
| Kishk *et al.* [98] | 44 chronic patients | $5–10 \times 10^6$/kg BM-MSCs IT once per month for 6 doses | 18 months | 18 × improvement of motor score | Spasticity, neuropathic pain, myelitis, and encephalomyelitis in 1 patient |
| Park *et al.* [108] | 10 chronic patients | $8 \times 10^6$ culture-expanded BM-MSCs IS + $4 \times 10^7$ ID + $5 \times 10^7$ IT | 6–62 months | Improvement in strength tests in 3 patients; 7 patients no improvement | |
| Karamouzian *et al.* [100] | 11 acute/ subacute patients | From $7 \times 10^5$ to $1.2 \times 10^6$ BM-MSCs IT | 12–33 months | 5 patients improvement | No complications |
| Jiang *et al.* [109] | 20 chronic patients | $1 \times 10^8$ BM-MSCs IT, IL | 30 days | 75% of patients ASIA improvement | Fever, headache |
| Amr *et al.* [110] | 14 chronic patients | BM-MSCs in combination with chitosan–laminin-based scaffold and peripheral nerve grafts | 2 years | 14 × ASIA A–C, 2 × ASIA A–B | Seroma after degradation of chitosan, 1 × hematoma as a result of healing process |
| Moviglia *et al.* [111] | 8 chronic | BMCs IA; effector T cells IV; NSCs IA | 12 months | 5 × ASIA A–D | Fever, headache, and a tingling sensation |
| Kumar *et al.* [95] | 297 patients | Unmanipulated BMCs via lumbar puncture (IT) | 3 months | 32.6% of patients sensory and motor improvement | No complications |
| Cristante *et al.* [112] | 39 chronic patients | Autologous undifferentiated hematopoietic stem/ progenitor cells mobilized by GM-CSF IA | 2.5 years | 66.7% patients recovery of somatosensory evoked response | No complications from cell therapy |

**Table 49.1** (*Continued*)

| Authors | Number of patients in the study | Type of cells/routes | Follow-up period | Results | Complications |
|---|---|---|---|---|---|
| Dai *et al.* [99] | 40 chronic patients | Autologous BM-MSCs IS | 6 months | 10 patients improved in terms of motor, light touch, pin prick sensation, and residual urine volume | No complications |
| Ra *et al.* [103] | 8 chronic patients | ADSCs IV | 3 months | Cell treatment appeared safe; no tumor development | No complications |
| Cheng *et al.* [104] | 34 chronic patients | $2 \times 10^7$ double injections of UCMSCs IS | 6 months | 7 patients had significant and stable improvement in movement, self-care ability, and muscular tension | Radiating neuralgia |
| Liu *et al.* [105] | 22 patients | UCMSCs cells IT | 3 months–3 years | 13 patients improved in motor or sensory functions | Headache and low back pain |

IA: intra-arterially; ID: intradurally; IL: intralesionally; IS: intraspinally; IT: intrathecally; IV: intravenously; SC: subcutaneously.

oversecrete specific molecules. Unlike neural progenitors, MSCs do not differentiate; therefore, they cannot replace lost populations of neural cells. Unfortunately, patients with SCI often suffer from multiple injuries and consequently the application of cell therapy in the acute or subacute phase is not always possible. The consequent severe degeneration, cavity formation (syringomyelia), and atrophy of grey and white matter prevents regeneration. Bridging the defect with a suitable artificial or biological scaffold is therefore needed. Future approaches to chronic SCI treatment should focus on the development of multifaceted therapeutic approaches that would stimulate the regeneration process. These would comprise of scaffolds as cell carriers, enzymes that can digest glial scarring, growth factors to support cell survival and axonal regeneration, and blockers of molecules that adversely affect the SCI milieu. The optimal combination and timing of these processes may result in a synergistic effect in spinal cord treatment.

## Acknowledgments

This work was supported by project LO1309 of the MEYS of the CR under the NPU I program from the European Regional Development Fund.

## 50.1 Inflammatory bowel diseases

Inflammatory bowel diseases (IBDs) are chronic relapsing diseases associated with debilitating symptoms and leading to progressive intestinal tissue damage and disability (Figure 50.1).

Crohn's disease (CD) can affect any part of the gastrointestinal tract, and lesions are often segmental and transmural. The disease was named after gastroenterologist Dr Burrill Bernard Crohn, who, in 1932, together with two other colleagues at Mount Sinai Hospital in New York, described a series of patients with inflammation of the terminal ileum of the small intestine, the area most commonly affected by the illness. Active CD is characterized by focal inflammation with granulomas and formation of fistula tracts or abscesses, and chronic lesions include fibrosis and stricture of the bowel (Figure 50.2).

In ulcerative colitis (UC), mucosal inflammation is continuous and limited to the mucosa and superficial submucosa. Lesions can affect the rectum and to a variable extent the colon, without granulomas or fistulas. The age of onset of IBD is most frequently in late adolescence or early adulthood, and the disease is equally

distributed between the sexes. The incidence and prevalence are stable in high-incidence areas (northern Europe and North America), and rising in low-incidence areas (southern Europe, Asia, and most developing countries) [1,2].

Symptoms of CD are heterogeneous, but commonly include chronic diarrhea, abdominal pain, weight loss, anorexia, and/or fever. Rectal bleeding occurs commonly in UC, while perianal fissures, fistulas, or abscesses can occur in CD. Extraintestinal features can be related to extraintestinal inflammation, such as joint inflammation (spondyloarthritis, peripheral arthritis),

**Figure 50.2** A portion of resected jejunum showing the typical cobblestone appearance of CD affecting the jejunum. *Source:* http://commons.wikimedia.org/wiki/File:Crohn_Jejunum.PNG#mediaviewer/File:Crohn_Jejunum.PNG.

**Figure 50.3** Erythema nodosum is an inflammatory condition characterized by inflammation of the fat cells under the skin, resulting in tender red nodules or lumps. It can be caused by a variety of conditions and typically resolves spontaneously within 3–6 weeks. The commonest distribution of erythema nodosum is on the shins – the anterior aspect of the lower legs. *Source:* 1905, William Wood and Company.

cutaneous manifestations – erythema nodosum (Figure 50.3), pyoderma gangrenosum (Figure 50.4) – ocular inflammation (uveitis, episcleritis, sclero-conjunctivitis), and primary sclerosing cholangitis, or are consequences of malabsorption (cholelithiasis, nephrolithiasis, and osteoporosis) [3].

The diagnosis is based on clinical evaluation and a combination of endoscopic, histological, radiological (computed tomography scan, magnetic resonance imaging (MRI)), and/or biochemical (C-reactive protein (CRP), full blood count, and fecal calprotectin) investigations. The histologic diagnosis is based on the presence of discontinuous chronic inflammation, focal crypt irregularity, and granulomas in CD [4].

## 50.2 Pathogenesis of inflammatory bowel diseases

The etiology of IBD is multifactorial, polygenic [5], and environmental [6] and includes an abnormal systemic and mucosal

**Figure 50.4** Pyoderma gangrenosum affecting the lower leg of a person with CD. This is a condition that causes tissue to become necrotic, resulting in deep ulcers that usually occur on the legs. Ulcers usually initially look like small bug bites or papules and then progress to larger ulcers. While the ulcers rarely lead to death, they can cause pain and scarring. Although the etiology is not well understood, the disease is thought to be due to immune system dysfunction, and particularly abnormal functioning of neutrophils. The commonest diseases associated with pyoderma gangrenosum are the IBDs (CD and UC), followed by the arthritides such as rheumatoid arthritis, followed by malignant hematological disorders. (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:Crohnie_Pyoderma_gangrenosum.jpg#file.

immune response against intraluminal antigens, favored by microbial factors [7] and alteration of the mucosal barrier [8]. A key role in the pathogenesis of IBD seems to be played by enhanced proliferation and defective apoptosis of immune cells, attributed to an imbalance of the antiapoptotic protein BCL-2 and the pro-apoptotic protein BAX [9,10]), as well as by proinflammatory cytokines arising from T helper cells (Th)1 and Th17 CD4 T cell differentiation in CD, and Th2 T cell differentiation in UC [11–13]. The loss of balance between proliferation and apoptosis is responsible for the presence of an abnormal population of T cells with extended lifespan, which remains in the mucosal compartment and secretes proinflammatory cytokines. The result is an activation of other inflammatory cells, including macrophages and B cells, and a recruitment of circulating leukocytes into the gut through interactions between homing receptors (e.g., $\alpha_4\beta_7$ integrin) and addressins on vascular endothelium, such as the mucosal vascular addressin cell adhesion molecule (MAdCAM)-1 or the vascular cell adhesion molecule (VCAM)-1.

In CD the initial phase of the inflammation seems to be predominantly driven by a Th1 response. Interleukin (IL)-12, a proinflammatory cytokine produced by dendritic cells (DCs), promotes the conversion of T cells into Th1 cells, secreting interferon (INF)-γ and tumor necrosis factor (TNF)-α, two major actors in the induction and propagation of inflammation [14–18]. In a later phase, the importance of the Th17 response increases. Th17 cells are induced by IL-6 and transforming growth factor (TGF)-β, and secrete IL-17 and IL-22. IL-23, produced by DCs, interacts with Th17 cells and increases the secretion of IL-6 and IL-17 by T cells, thus enhancing the inflammatory response [19–24]. This overactive immune response can lead to the development of mucosal lesions. Defective apoptosis also promotes autoimmunity, by a reduced autoantibody clearance. Interestingly, almost all drugs with clinical efficacy, including infliximab [25], are able to induce apoptosis of immune cells *in vitro*, while etanercept, an anti-TNF-fusion protein that does not induce apoptosis of immune cells [26], is not efficacious in the treatment of CD [27]. Nevertheless, certolizumab pegol, another anti-TNF agent, is unable to induce cell apoptosis [28], and yet is effective for inducing and maintaining remission in active CD [29,30]. Eventually, chronic inflammation induces intestinal fibroblasts to proliferate and produce a greater amount of extracellular matrix, resulting in local intestinal fibrosis [31].

Endoscopic appearances are shown in Figure 50.5.

In UC, inflammation is mainly driven by IL-5 and IL-13, while production of INF-γ is normal. The disease is qualified as "Th2-like" given the normal production of IL-4, the most defining Th2 cytokine [11]. A Th17 response may also play a role, but its importance is probably lower than in CD.

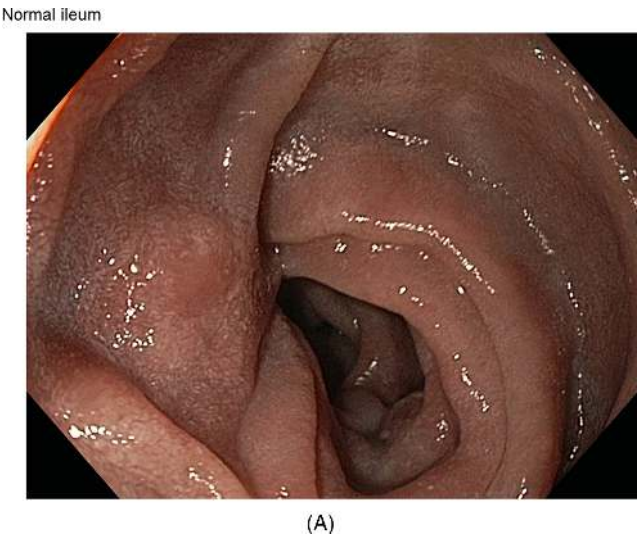

**Figure 50.5** (A) Normal ileum: the mucosa is homogeneously pink and the villi are regular and well developed. (B) Crohn's ileitis: diffuse inflammation characterized by erythema and mucosal hemorrhage. (C) Crohn's ileitis: presence of erythema and ulcers; red dots indicate mucosal hemorrhages. (D) Normal colon: colonic folds are present and regular. The vascular pattern is also readily visible. (E, F) Crohn's colitis: presence of diffuse inflammation with erythema and superficial ulcers. (G) Healed colon. (See color plate section.)

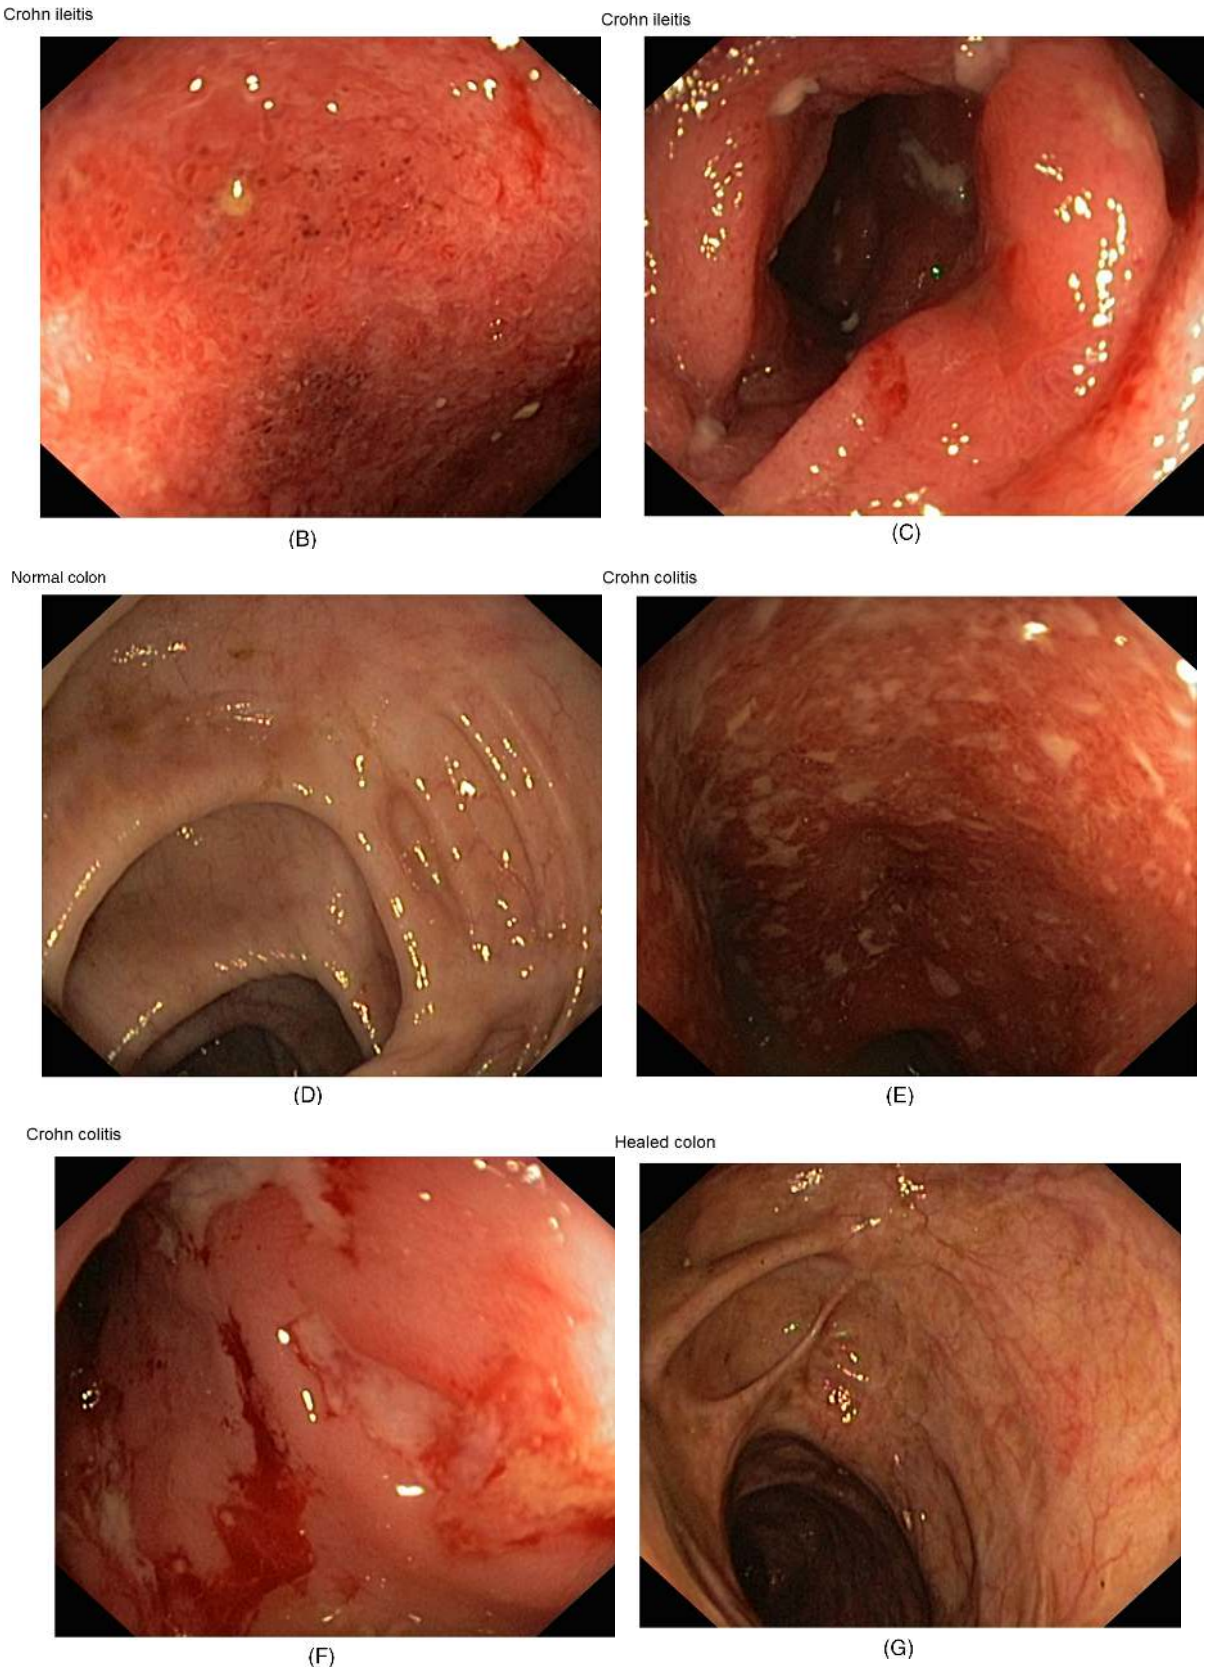

**Figure 50.5** (*Continued*)

**Table 50.1** The CDAI is a research tool used to quantify the symptoms of patients with CD.

| Clinical or laboratory variable | Weighting factor |
|---|---|
| Number of liquid or soft stools each day for 7 days | ×2 |
| Abdominal pain (graded from 0 to 3 on severity) each day for 7 days | ×5 |
| General wellbeing, subjectively assessed from 0 (well) to 4 (terrible) each day for 7 days | ×7 |
| Presence of complications[a] | ×20 |
| Taking Lomotil or opiates for diarrhea | ×30 |
| Presence of an abdominal mass (0 as none, 2 as questionable, 5 as definite) | ×10 |
| Hematocrit of <0.47 in men and <0.42 in women | ×6 |
| Percentage deviation from standard weight | ×1 |

Source: Best et al. [32].
Remission of CD is defined as CDAI below 150. Severe disease is defined as a value of greater than 450.
[a] One point each is added for each set of complications: (a) the presence of joint pains (arthralgia) or frank arthritis; (b) inflammation of the iris or uveitis; (c) the presence of erythema nodosum, pyoderma gangrenosum, or aphthous ulcers; (d) the presence anal fissures, fistulae, or abscesses; (e) the presence of other fistulae; (f). Fever during the previous week.

## 50.3 Treatment of Crohn's disease

The choice of therapy is based on anatomic location, severity, and behavior of disease. Severity can be assessed by the CD activity index (CDAI), a score based on daily symptoms and repercussions of CD such as hematocrit, weight, and other factors (Table 50.1).

CD can be classified as mild or mild–moderate (CDAI between 150 and 220), moderate or moderate–severe (CDAI between 220 and 450), or severe or severe/fulminant (CDAI >450). There is a current trend to use CRP levels in conjunction with the CDAI to evaluate severity of the disease [4,33]. Disease remission is defined in the majority of clinical trials as a CDAI of less than 150 [34]. Response is often defined by a variation of CDAI of 100 points or more, although a variation of 70 points or more has been used in some studies. The perineal disease activity index (PDAI) is sometimes used if perineal lesions are predominant. Endoscopic evaluation can be standardized using the CD endoscopic index of severity (CDEIS) or a simplified variant, the simple endoscopic score for CD (SESCD) [35].

### 50.3.1 Current treatment options for Crohn's disease

Current treatment strategies include oral 5-aminosalicylates (sulfasalazine, mesalamine), antibiotics (metronidazole, ciprofloxacin), topically or systemically acting steroids (controlled ileal release budesonide or prednisone), and immunomodulator therapy, including azothioprine, 6-mercaptopurine, methotrexate, calcineurin inhibitors (cyclosporine, tacrolimus) and anti-TNF antibodies (infliximab, adalimumab, certolizumab pegol). Nutritional therapy (elemental or polymeric diets) can be considered as an adjunct treatment. Mildly to moderately active localized ileocecal disease can often be managed with budesonide, while severe active or extensive disease generally requires systemic corticosteroids with or without an immunomodulator. Anti-TNF therapy, used alone or in adjunction to an immunomodulator, is recommended in moderate to severe or extensive relapsing disease or in previously steroid-refractory, -dependent, or -intolerant patients. All currently available anti-TNF therapies appear to have similar efficacy.

If there is loss of response to anti-TNF therapy, increasing doses or frequency of administration can be tried before switching to another anti-TNF agent. Surgery should be considered in localized disease. Treatment of relapse is essentially based upon previously successful therapies, but other factors such as patient preference, time to relapse, concurrent therapy, and adherence to therapy are taken into account. The choice of maintenance therapy is essentially based upon the course and extent of disease, and the effectiveness and tolerance of previously used treatments. Some patients do not need maintenance. Azathioprine is generally the first choice, followed by methotrexate and anti-TNF therapy [36].

Perianal and fistulizing disease can be treated by surgery, including surgical drainage, fistulotomy and setons, advancement flaps, antibiotics, or an immunomodulator (including anti-TNF agents) [33]. A seton or seton stitch is a procedure used to aid the healing of fistulas. The procedure involves running a surgical-grade cord through the fistula tract so that the cord creates a loop that joins up outside the fistula. The cord provides a path that allows the fistula to drain continuously while it is healing, rather than allowing the exterior of the wound to close over. Keeping the fistula tract open can help keep from trapping pus or other infectious material in the wound. The procedure was mentioned by Hippocrates in 400 BC. Flap surgery is a technique in plastic and reconstructive surgery where any type of tissue is lifted from a donor site and moved to a recipient site with an intact blood supply. Advancement flaps are used when the patient is in overall good health and the defect is free of tumor and obvious infection.

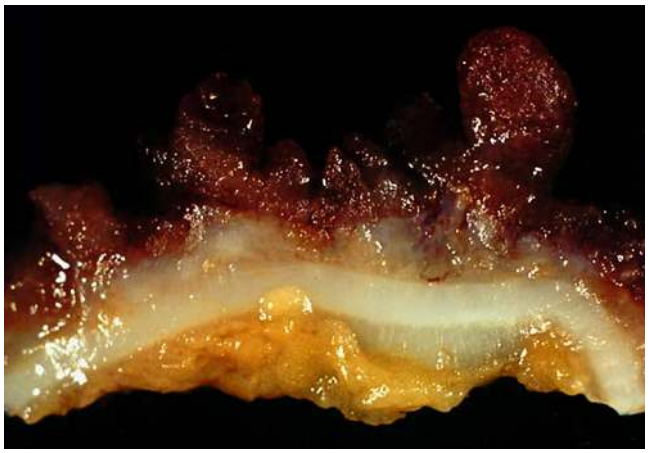

**Figure 50.6** Chronic UC. The image shows a view of a longitudinal section through the colon wall. This demonstrates not only the angry red mucosa but also the tendency for the inflamed tissue to throw itself up into inflammatory pseudopolyps. (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:Chronic_Ulcerative_Colitis_1.jpg#mediaviewer/File:Chronic_Ulcerative_Colitis_1.jpg.

Whereas 80–90% of the patients can be satisfactorily treated with these approaches, some patients are refractory, intolerant, or lose response to them. In this setting, few options are left apart from debilitating surgery with a permanent stoma or experimental treatments. Images of surgical resections are shown in Figures 50.6 and 50.7.

### 50.3.2 Potential treatment options

New therapies that have demonstrated some efficacy are inhibiting leucocyte migration, targeting inflammatory cytokines, enhancing immune regulatory mechanisms, and/or promoting tissue repair.

**Figure 50.7** Colonic pseudopolyps of a patient with chronic severe intractable UC. Colectomy specimen. (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:Chronic_Ulcerative_Colitis_1.jpg#mediaviewer/File:Chronic_Ulcerative_Colitis_1.jpg.

#### 50.3.2.1 Drugs targeting leucocyte homing

Alpha-4 integrins are members of the cell-surface adhesion family expressed by several cells, including leucocytes, and binding several ligands, including VCAM-1 expressed on endothelial cells, and extra-cellular matrix proteins such as fibronectin. These interactions lead to various cellular processes, such as activation, proliferation, and migration of $\alpha_4$-integrin-expressing cells toward sites of inflammation, including areas of the gut in CD [37]. Natalizumab, a humanized monoclonal antibody against the $\alpha_4$ subunit of both $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins, has demonstrated therapeutic benefit in patients with moderate to severe active CD. In the ENACT-1 randomized clinical trial (RCT) evaluating natalizumab versus placebo as induction therapy in 905 patients with active CD, similar rates of response (decrease in CDAI of ≥70 points) and remission (CDAI <150) were observed at week 10 (respectively 56% versus 49%, $P = 0.05$, and 37% versus 30%, $P = 0.12$). In a second part of the trial (ENACT-2) evaluating natalizumab versus placebo as maintenance therapy in 339 patients who had a response to natalizumab in the first trial, a significantly higher rate of sustained response (61% versus 28%, $P < 0.001$) and remission (44% versus 26%, $P = 0.003$) was observed at week 36 [38]. In ENCORE, an RCT evaluating the efficacy of natalizumab versus placebo as induction therapy in 509 patients with moderately to severely active CD and active inflammation (CRP >2.87 mg/L), significantly higher rates of response (decrease in CDAI of ≥70 points) at week 8 and remission (CDAI <150) were observed (respectively 48% versus 32%, $P < 0.001$, and 26% versus 16%, $P = 0.002$) [39]. In a meta-analysis of five trials comparing natalizumab with placebo, the relative risk (RR) of not achieving remission was reduced with natalizumab (0.88) [40]. In the USA, monotherapy with natalizumab is indicated for inducing and maintaining clinical response and remission in adult patients with moderately to severely active CD and evidence of inflammation who have had an inadequate response or who are unable to tolerate conventional CD therapies and anti-TNF agents [33]. The most dangerous adverse effect is progressive multifocal leukoencephalopathy caused by the JC virus.

Vedolizumab, a humanized anti-$\alpha_4\beta_7$ integrin monoclonal antibody, has also been approved by the US Food and Drug Administration and the European Medicine Agency for use in patients with moderate to severe CD. In the induction phase comparing intravenous vedolizumab therapy (300 mg) versus placebo in 368 adults with active CD, a higher rate of clinical remission (CDAI ≤150) was observed (14.5% versus 6.8%, $P = 0.02$), while CDAI-100 response was similar (31.4% versus 25.7%, $P = 0.23$). In the maintenance phase comparing intravenous vedolizumab therapy every 8 or 4 weeks versus placebo in 461 patients who had had a response to vedolizumab, there was a significantly higher rate of clinical remission (39.0% and 36.4% for the two vedolizumab groups, respectively, versus 21.6% for the placebo group; $P < 0.001$ and $P = 0.004$), but also a higher rate of serious adverse events (24.4% versus 15.3%) and infections (44.1% versus 40.2%) [41].

Chemokine receptor 9 (CCR9) is a highly specific receptor expressed predominately by T cells. Its overexpression leads to the migration of T cells to the small and large intestines. In PROTECT-1, an RCT with 436 subjects suffering from moderate to severe CD (CDAI between 250 and 450 and CRP >7.5 mg/L), a CCR9 antagonist (CCX282-b/Traficet-EN) given 250 mg twice daily for 36 weeks demonstrated efficacy in maintaining remission in patients identified as responders (decrease in CDAI of ≥70 points) after the induction phase (47% of subjects on CCX282-B in remission at 36 weeks versus 31% on placebo; $P = 0.01$). CCX282-B was also superior to placebo in normalizing CRP at week 36 (19% versus 9%; $P = 0.04$), and decreasing the number of subjects requiring corticosteroid rescue therapy (11% versus 21%, $P = 0.04$). Serious adverse events occurred in similar rates in the two groups [42].

Other molecules targeting T cells, but not interfering with homing, have been studied with less success. Visilizumab, a humanized monoclonal antibody directed at the cell surface marker CD3 expressed only by activated T cells, inducing selective apoptosis of these activated T cells, has shown some efficacy in an uncontrolled trial [43] but was associated with an increased rate of adverse events, including cytokine release syndrome and liver toxicity [44].

Cytokine release syndrome is a common immediate complication occurring with the use of anti-T cell antibody infusions such as antithymocyte globulin (ATG), OKT3 (muromonab-CD3), and TGN1412, and also with the CD-20 antibody rituximab against B cells. Severe cases are known as cytokine storms. The antibodies bind to the T cell receptor (TCR), activating the T cells before they are destroyed. The cytokines released by the activated T cells produce a type of systemic inflammatory response similar to that found in severe infections and characterized by hypotension, pyrexia, and rigors. The patient feels very unwell, as if in a high fever – indeed, the cytokine release syndrome *is* effectively a type of noninfective fever. Deaths due to cytokine release syndrome with OKT3 have been reported, and it can cause life-threatening pulmonary edema if the patient is fluid overloaded. However, if treated appropriately it is usually not dangerous, just extremely unpleasant for the patient.

Abatacept, a CTLA-Ig (cytotoxic T-lymphocyte-associated protein) that blocks the co-activation of T cells by competing with CD28 for CD80/CD86, and which is used in the treatment of rheumatoid arthritis, was not found to be effective in CD [45].

#### 50.3.2.2 Drugs targeting the proinflammatory cascade

The proinflammatory cytokines IL-12 and IL-23 are involved in Th1 and Th17 responses respectively, and both are implicated in the pathogenesis of CD [46]. Ustekinumab, a human monoclonal antibody blocking the p40 common subunit of IL-12 and IL-23, was evaluated in a phase II RCT with 526 adults suffering from moderate-to-severe CD that was resistant to TNF antagonists. In the induction phase, clinical response at 6 weeks was significantly higher in a subgroup of patients receiving 6 mg/kg of ustekinumab intravenously (39.7% versus 23.5% in the placebo group, $P = 0.005$), while there was no significant difference in clinical remission. In the maintenance phase of the trial, comparing 90 mg of ustekinumab subcutaneously versus placebo in 145 patients who had a response to ustekinumab at 6 weeks, significantly increased rates of clinical response (69.4% versus 42.5%, $P < 0.001$) and remission (41.7% versus 27.4%, $P = 0.03$) at 22 weeks [47]. Phase III trials are currently underway to evaluate the safety and efficacy of ustekinumab (www.clinicaltrials.gov; NCT01369355, NCT01369342, NCT01369329).

The proinflammatory cytokine IL-6 has been implicated in the pathogenesis of colitis in various animal models and in patients with CD [48,49]. In a small pilot study with 36 patients suffering from active CD, a biweekly 8 mg/kg infusion of tocilizumab, an anti-IL-6 receptor humanized monoclonal antibody used in rheumatoid arthritis, showed promising results with 8/10 (80%) patients experiencing a clinical response compared with 4/13 (31%) patients in the placebo group ($P = 0.019$), although only two patients achieved remission. The incidence of adverse events was similar in the two groups [50].

Thalidomide has anti-inflammatory effects, by decreasing the production of proinflammatory cytokines, including TNF-α and IL-12. It appears to be effective in inducing remission in refractory pediatric CD, as shown in a randomized controlled trial with 56 children with active CD despite immunosuppressive treatment (prolonged by an open-label extension of the study, where nonresponders to placebo received thalidomide). Overall, 32/49 (65.3%) patients treated with thalidomide achieved a response (reduction in pediatric CDAI by ≥75%) and 31/49 (63.3%) achieved clinical remission [51].

Since IL-17 and IFN-γ have been identified as major actors in the pathogenesis of CD, molecules inhibiting these agents have been developed. However, anti-IL-17 antibodies (secukinumab [52], brodalumab [53]) and anti-IFN-γ antibodies (fontolizumab [54]) all failed to demonstrate efficacy. Despite encouraging preliminary results, attempts to administer anti-inflammatory cytokines, such as IL-10 [55,56] and IL-11 [57,58], were also disappointing, as no significant improvement was observed.

#### 50.3.2.3 Other treatments

Some other treatments have been studied with encouraging preliminary results, including human growth hormone [59], linoleic acid [60], low-dose naltrexone [61], helminths [62,63], or extracorporeal photopheresis [64]. Larger studies are needed to confirm these results. Other agents have so far failed to demonstrate efficacy including granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) [65,66], probiotics [67–70], and prebiotics [71]. If intestinal failure occurs, home parenteral nutrition and intestinal transplantation can be discussed [72]. Interestingly, several cases of CD recurrence after intestinal transplantation have been reported [73–75], which may indicate that the immune system plays a more important role than the mucosal barrier in the pathogenesis of CD.

#### 50.3.2.4 Bone marrow transplantation and stem cell therapy

The first reported success of autologous hematopoietic stem cell transplantation (HSCT) in CD was published in 1993 in a patient with non-Hodgkin's lymphoma [76]. Since then, at least 19 cases of autologous or allogeneic HSCTs for malignancies in CD patients have been reported, with remission of CD achieved in most cases, even after discontinuation of any immunosuppressive therapy [77]. Given these results, HSCT trials in patients with CD refractory to conventional therapy were initiated. In 1995, the Autoimmune Diseases Working Party of the European Group for Blood and Marrow Transplantation recommended the use of autologous rather than allogeneic HSCT because of the lower risk of severe toxicity [78]. The largest study is a phase I–II trial on 24 patients with severe CD (CDAI >250 and/or Crohn Severity Index >16) despite anti-TNF therapy, who underwent autologous HSCT after mobilization of their peripheral blood hematopoietic stem cells (HSCs) with cyclophosphamide and G-CSF, *ex vivo* HSC enrichment by $CD34^+$ selection, and non-marrow ablative preparation with cyclophosphamide and equine or rabbit ATG.

All patients went into remission (CDAI <150). After 5 years, the percentage of clinical relapse-free survival was 19% and the percentage of patients in remission, steroid-free, or medication-free was at least 70%, 80%, and 60% respectively. Infectious complications were frequent, including early bacteremia and/or central venous line infection (six patients) and late infections (10 cases, including seven severe infections, in the first year after transplantation) [79]. A randomized phase III study was initiated, but recruitment was halted prematurely for safety reasons (http://clinicaltrials.gov/ct2/show/NCT00297193). Preliminary results on 48 patients after 1 year follow-up showed decreases in mean CDAI from 324 to 161, CRP from 16.6 to 6.5 mg/L, with six patients achieving a normal CDAI and three patients allowed to stop immune-suppressive medications. However, high rates of adverse events were observed (100 serious adverse events, among which 42 infective episodes requiring or prolonging hospitalization and eight patients with temporary flare of CD activity or a need for surgery) [80].

## 50.4 Treatment of ulcerative colitis

The choice of therapy is based on the activity, distribution, and pattern of disease. Disease activity can be evaluated by Truelove and Witts' criteria (number of bloody stools/day, pulse, temperature, hemoglobin, and erythrocyte sedimentation rate or CRP) or the Mayo score, and is classified as mild, moderate, or severe. Remission is defined as complete resolution of symptoms and endoscopic mucosal healing. Response is defined as clinical and endoscopic improvement (generally a decrease in the activity index of >30%, associated with a decrease in the rectal bleeding and endoscopic scores in the Mayo score) [2].

### 50.4.1 Current treatment options for ulcerative colitis

Current treatment strategies include oral 5-aminosalicylates (sulfasalazine, mesalamine), antibiotics (metronidazole, ciprofloxacin), topically or systemically acting steroids (prednisone, beclomethasone dipropionate), and immunomodulatory therapy, including azathioprine, 6-mercaptopurine, calcineurin inhibitors (cyclosporine, tacrolimus), and anti-TNF antibodies (infliximab, adalimumab, golimumab). Surgery (procolectomy with ileo-anal anastomosis) is an option to treat acute severe colitis or to manage refractory disease (see Figures 50.5 and 50.7) [81].

### 50.4.2 Potential new treatment options

The most promising therapies for UC are essentially acting through an inhibition of leukocyte migration or inflammatory cytokines. Several anti-integrin antibodies have been studied in UC, including vedolizumab [82], which has been recently approved by the US Food and Drug Administration, and etrolizumab, a humanized monoclonal antibody targeting the $\beta_7$ subunit of $\alpha_4\beta_7$ and $\alpha_E\beta_7$) [83,84] and PF-00547,659, a monoclonal antibody to MAdCAM [85], which have been found effective in preliminary trials.

Alicaforsen, an inhibitor of intracellular adhesion molecule-1 [86–88], and tofactinib, a Janus kinase-3 inhibitor [89], have also shown promising results in UC. The roles of methotrexate [90–94], probiotics, and fecal microbiota transplantation [95,96] in the treatment of UC are still debated, and randomized controlled trials are needed to evaluate their effectiveness. Despite encouraging preliminary results, anti-IL-2 receptor (daclizumab [97,98], basiliximab [99–101]) and anti-CD3 (visilizumab [102–104]) monoclonal antibodies have failed to demonstrate efficacy in larger trials. Rituximab (an anti-CD20 antibody against B cells) is ineffective and can even mediate exacerbation of UC [105–107].

## 50.5 Properties of mesenchymal stromal cells

Mesenchymal stromal cells (MSCs) are multipotent progenitors within the bone marrow and all other vascularized organs that are capable of differentiating into various cells and tissues, such as chondrocytes, osteoblasts, and adipocytes *in vitro* [108]. MSCs can be isolated after *ex vivo* culture of the plastic-adherent mononuclear cell fraction. After *ex vivo* expansion human MSCs have a fibroblast-like morphology, and are uniformly positive for CD29, CD44, CD71, CD73, CD90, CD105, CD106, CD120a, CD124, and CD166 but do not express common hematopoietic markers such as CD14, CD45, or CD34. No marker specific for MSCs has been found yet. The International Society for Cellular Therapy has proposed three minimal criteria to define MSCs: (1) adhesion to plastic in standard culture conditions, (2) expression of CD105, CD73, and CD90, and lack of expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, and human leukocyte antigen (HLA)-DR surface

molecules, and (3) *in vitro* differentiation into osteoblasts, adipocytes, and chondroblasts [109]. MSCs can be isolated from bone marrow and many other tissues, including umbilical cord [110], umbilical cord blood [111], placenta [112], adipose tissue [113], gingival tissue [114], skin [115], lung [116], liver [117], heart, and spleen [118]. They are pericytes residing in the endothelium in the connective tissues of most organs [119].

### 50.5.1 Immunomodulation

MSCs also exert powerful immunomodulatory effects, including inhibition of proliferation and function of T cells, B cells, and natural killer (NK) cells. These properties have been demonstrated *in vitro* with both murine and human cells, and *in vivo* in murine models of experimentally induced colitis. Dextran sodium sulfate (DSS) and trinitrobenzene sulfonate (TNBS) are commonly used to induce colitis in mice, by initiating epithelial cell lesions and altering the epithelial barrier integrity. Both acute DSS- and TNBS-induced colitis are characterized by a Th1–Th17-mediated acute inflammation with increased TNF-α, IL-6, IL-17 and increased IL-12, IL-17, IFN-γ respectively. However, while chronic TNBS-induced colitis is associated with an enhanced Th1/Th17 intensity of response, chronic DSS-induced colitis switches to a Th2-biased (IL-4, IL-10) profile. Similarly, histological DSS-colitis features are "UC-like" (epithelial disruption, focal lesions, superficial inflammation), while histological TNBS-colitis features are "CD-like" (transmural inflammation and edema) [120].

The first observed immunomodulatory effect of MSCs was their ability to inhibit T cell proliferation *in vitro* [121–123]. This phenomenon was observed independently of whether the T cells were $CD4^+$ or $CD8^+$, naive or memory T cells [124], stimulated with allogeneic cells or nonspecific mitogens [123], and regardless of their functional state or the type of TCR expressed [125]. The immunosuppressive activity of MSCs is independent of the major histocompatibility complex (MHC), as inhibition is similar using third-party MHC-unmatched MSCs or MSCs that are autologous to the responder or stimulating lymphocytes [121]. MSC-inhibited T cells do not undergo apoptosis [123], but are blocked in the $G_0/G_1$ phase of the cell cycle in a state of anergy by inhibition of cyclin D2 expression [126]. Whether *in vitro* addition of IL-2 can [122] or cannot [127] reverse this inhibition is controversial. However, a recent study found that the systemic infusion of murine BM-MSCs induced T cell apoptosis via the FAS ligand/FAS pathway, and that $FASL^{-/-}$ bone-marrow-derived MSCs (BM-MSCs) could not ameliorate DSS-induced colitis in mice [128]. Interestingly, it has been demonstrated that FAS-mediated apoptosis is lower in the T cells of people with CD than in control T cells [129]. However, another study demonstrated that *in vitro* MSCs prevented activation-induced cell death through downregulation of Fas receptor and Fas ligand on TCR-activated T cells [127]. It is important to note that the effect of MSCs on T cells seems dependent on the MSC/T cell ratio: a high MSC/T cell ratio exerts strong inhibitory effects, while low MSC/T cell ratios enhance T cell proliferation [130].

Other studies suggest that an important part of MSC-mediated immunomodulation results from the recruitment of immune-regulatory T cells (Tregs), which can be either $CD4^+$ $CD25^+$ $FoxP3^+$ or $CD8^+$ from both naive and memory T cells [131–133]. *In vivo*, MSC-mediated Treg expansion has been observed in several immune-mediated diseases, including experimental autoimmune encephalomyelitis [134], experimental arthritis [135], and type 1 diabetes mellitus [136]. Mechanisms of this T-reg expansion appear multiple and include secretion of soluble factors by MSCs, such as prostaglandin $E_2$ ($PGE_2$) and TGF-β1 [137–139] or HLA-G [140,141], interaction between MSCs and chemokine ligand 1 and chemokine receptor 8 on T cells [142], and induction of immature DC [143] and monocytes [144] to a regulatory profile. MSC-mediated T cell modulation was observed in several DSS- and TNBS-induced colitis mouse models, treated with intravenous or intraperitoneal injection of human adipose-derived MSCs (ASCs) [145], umbilical-cord-derived MSCs (UCMSCs) [146,147], or BM-MSCs [148]. In these studies, MSCs effectively treated colitis with both a clinical response and histological improvement, showing decreased infiltration of inflammatory cells in the lamina propria. The investigators mostly observed a decreased number of IFN-γ-producing Th1 cells and higher numbers of $CD4^+$ $CD25^+$ $Foxp3^+$ Tregs in mesenteric lymph nodes and the lower colon and systemic levels of Th1 and Th17 proinflammatory cytokines, including TNF-α, IFN-γ, IL6, IL-12, IL-17, and IL-23, as well as higher colonic and systemic levels of the anti-inflammatory/regulatory cytokine IL-10. In a murine model of TNBS-induced colitis, MSCs co-localized with $CD11b^+$ cells in the spleen, and these cells were essential to the expansion of Tregs in draining mesenteric lymph nodes [149]. In another murine model of TNBS-induced colitis, intravenous injection of murine BM-MSCs was followed not only by downregulation of both Th1 and Th17 responses and activation of regulatory T cells, but also by a significant upregulation of Th2 activities (IL-4, IL-10, GATA-3) [150].

The effect of MSCs on B cells remains controversial, and may depend on environmental signals. According to most authors, MSCs inhibit B cell activation, proliferation, chemotaxis, and immunoglobulin G secretion, both in murine [126,151,152] and human [153] studies. In these studies, B cells were enriched from the spleen or purified from peripheral blood and were exposed to various stimuli, including allogeneic cells, mitogenic agents and lipopolysaccharide. Inhibition of B cell function was mediated by soluble factors in transwell experiments. In another study, B-cell co-stimulatory molecule expression and cytokine production seemed unaffected by human MSCs [153]. However, in a study of highly purified B cells, MSCs promoted proliferation and differentiation into immunoglobulin-secreting cells of naive B cells isolated from healthy donors and total B cells from children with the autoimmune disease systemic lupus erythematosus (SLE), stimulated with an agonist of toll-like receptor (TLR) 9 in the absence of B cell receptor triggering [154].

The relationship between MSCs and NK cells is complex and also not yet fully understood. MSCs inhibit the IL-2- or

IL-15-driven proliferation of human resting NK cells and their production of IFN-γ, TNF-α, and IL-10 [155,156], but their effects on the cytotoxic activity of NK cells is controversial. Some authors report have reported MSC-mediated decreased NK cell cytotoxicity [140,156,157], while others have not observed this effect [158,159]. This discrepancy might depend on MSC/NK ratios or on whether NK cells were freshly isolated or not [155].

MSCs also interact with antigen-presenting cells, including DCs. MSCs inhibit differentiation of DC precursors, such as monocytes or $CD34^+$ hematopoietic progenitors into mature DCs, by blocking them in the $G_0/G_1$ phase of the cell cycle, through a downregulation of cyclin D2 and $p27^{Kip1}$ expression [160]. DCs cultured with MSCs have impaired antigen-presenting [161] and migration [162] functions and show increased secretion of IL-10 and decreased production of IL-12 [163]. These effects have been confirmed *in vivo* in murine models [164]. MSCs also induce DC precursors ($CD34^+$ hematopoietic progenitors) [165] and mature DCs [166] to differentiate into a regulatory DC population through the Notch signaling pathway.

MSCs may also modulate the functions of macrophages, for example, through increased IL-10 secretion [167] or induction into a regulatory-like profile [144]. *In vitro* addition of increasing numbers of monocytes or DCs into co-cultures of human ASCs and activated $CD4^+$ cells progressively inhibited T cell proliferation and IFN-γ production [145]. In murine models of DSS- and TNBS-induced colitis, the intraperitoneal injection of murine bone marrow macrophages co-cultured with ASCs was effective in treating both colitis and sepsis. *In vitro* these macrophages showed a regulatory phenotype that was different from activated macrophages and characterized by high arginase activity and increased expression of IL-10 and inducible nitric oxide synthetase (iNOS) upon restimulation with lipopolysaccharide, while secreting low levels of the inflammatory cytokines TNF-α and IL-12. They showed potent immunosuppressive activity on splenocytes that was significantly reversed by the iNOS inhibitor L-NG-nitroarginine methyl ester and IL-10-blocking antibodies [168].

Thus the mechanisms of MSC-mediated immunomodulation are not yet fully elucidated and probably vary among species [169]. They include direct cell-to-cell contact through the expression of adhesion molecules and secretion of soluble factors. Multiple factors are involved, including $PGE_2$ [156,167,170], indoleamine 2,3-dioxygenase [114,156,171], nitric oxide [172,173], HLA-G [140,174], TGF-β and hepatocyte growth factor [123], IL-1 receptor antagonist [175], TNF-stimulated gene 6 protein [176], and IL-10, which, although probably not secreted directly by MSCs, also participates in the immunosuppressive effect of MSCs, as IL-10 blockade partially reversed the colitis and sepsis in the murine model [145]. In the DSS murine models of DSS- or TNBS-induced colitis, $PGE_2$ produced by nucleotide-binding oligomerization domain-containing protein-2-activated human UCMSCs increased production of IL-10 and Tregs and was required to reduce the severity of colitis [177].

Transcriptional repression of the proinflammatory cytokine early T cell activation factor 1 (osteopontin) by the autoimmune regulator (AIRE) has also been implicated in MSC immunomodulation as it was required for the efficacy of BM-MSC administration in a model of chronic colitis by transfer of $CD4^+$ $CD45RB^{hi}$ T cells in $Rag^{-/-}$ mice. However, AIRE did not control MSC suppression of T cell proliferation *in vitro* [178].

The immunomodulatory effects of MSCs depend on the inflammatory environment and in some circumstances MSCs can act as immune-stimulating cells. TLRs have an important role in inducing MSCs into an immunosuppressive or immunostimulating pathway, as different TLR agonists influence MSC proliferation, differentiation, migration, and immunomodulatory functions in different ways [179–181]. Many inflammatory cytokines promote MSC-mediated immunosuppression, including IFN-γ, TNF-α, and IL-1β [173]. Pretreatment of human BM-MSCs with IFN-γ increased expression of MHC class II molecules, indoleamine 2,3-dioxygenase, and iNOS and significantly inhibited peripheral blood mononuclear cell (PBMC) proliferation at lower PBMC : MSC ratios. In murine models of DSS- and TNBS-induced colitis, intraperitoneal administration of INF-γ-pretreated MSCs was more effective in treating colitis, in reducing serum amyloid A levels, in reducing colonic inflammatory cytokines (TNF-α, IL-6, IFN-γ, and IL-17A), and in increasing migration into inflamed intestine [182]. Similarly, IL-1β-primed human UCMSCs significantly attenuated the development of DSS-induced murine colitis, increased the number of peritoneal M2 macrophages and splenic or mesenteric lymph node Tregs, and enabled migration more efficiently into the spleen, mesenteric lymph nodes, and colon, which was related to upregulation of CXCR4 expression. IL-1β stimulation elevated COX-2, IL-6, and IL-8 mRNA expression in MSCs [183].

### 50.5.2 Immune tolerance

Human MSCs are immunoprivileged cells because they express low levels of HLA class I molecules and do not express HLA class II molecules nor the co-stimulatory molecules CD80, CD86, and CD40 under normal circumstances [184,185]. However, expression of HLA class I antigens, even at a low level, may be responsible for vulnerability of MSCs to activated NK-cell lysis [186]. Moreover, a recent study observed the capacity of murine MSCs to present extracellular antigen through their MHC class I molecules by cross-presentation and to induce an effective $CD8^+$ T cell immune response [187]. In addition, it has been demonstrated *in vivo* that, in the presence of a narrow window of IFN-γ, MSCs upregulate expression of MHC class I and II molecules and are able to act as antigen-presenting cells and stimulate $CD4^+$ cell proliferation [188–190]. This immunogenicity has also been observed *in vivo* in animal models in which donor-derived MSCs, unlike autologous MSCs, could promote bone marrow [191] or skin graft [192] rejection. Systemic or local administration of allogeneic MSCs in rats resulted in the development of anti-donor T cell and antibody responses, which could

promote a rapid clearance of MSCs and a limitation of their long-term benefits [193,194].

### 50.5.3 Tissue regeneration

MSCs can differentiate *in vitro* to cells of the mesenchymal lineage. The relative importance of this property for the efficacy of MSCs in experimental colitis and IBD is still being investigated.

### 50.5.4 Homing

MSCs are able to selectively home to sites of tissue injury and inflammation, including intestine, kidney, lung, liver, thymus and skin [195] (and see Chapters 22–24). In murine models of colitis, MSCs have demonstrated their ability to migrate selectively into inflamed zones of the intestine, mesenteric lymph nodes, and spleen, whether they were murine or human, bone marrow, adipose, or umbilical cord derived, and whether administered intravenously or intraperitoneally [145,147–149,196]. MSCs have been found in the lamina propria [196], the muscular layer, and the submucosa of the inflamed intestine [197]. However, homing capacities may be altered in MSCs that have been cryopreserved. In a murine model of TNBS-induced colitis, intraperitoneally but not intravenously injected cryopreserved MSCs were found in the inflamed colon [197]. MSC migration is directed by a multitude of signals depending on the MCS source, type or environment, and growth factors and cytokines involved [198,199]. In order to better understand the selective migration of MSCs into the inflamed intestine, Gonzalez-Rey *et al.* [145] studied the expression of various chemokine receptors involved in cell recruitment to inflammatory sites and demonstrated that human ASCs expressed on their surface the chemokine receptors CCR1, CCR2, CCR4, CCR5, CCR7, CCR9, CXCR1, and CXCR5 and that most of these receptors were functional since human ASCs migrated in response to chemokines such as CCL5, CCL22, CCL19, CCL25, CXCL8, and CXCL13. Moreover, human ASCs expressed a panel of adhesion molecules involved in tissue transmigration, including CD54, CD49e, CD44, CD29, CD105, CD106, and CD166. Activation and targeting may improve delivery of MSCs into mesenteric lymph nodes and colon, and hence their efficacy in murine colitis, as demonstrated with IFN-γ- [182] or IL-1β-primed MSCs [183] and VCAM antibody-coated MSCs (AbVCAM-1-MSCs) [200]. IFN-γ upregulates expression of the chemokine receptor CXCR7, lectins LGALS3BP and LGALS9 and ADAM15, a matrix metalloproteinase involved in epithelial adhesion [182], while IL-1β upregulates CXCR4 expression [183]. How long MSCs do stay into the inflamed intestine is unknown, but it seems that they remain there for at least 2 weeks [147].

### 50.5.5 Differentiation and stimulation of tissue repair

In addition to their capacity to differentiate into chondrocytes, osteoblasts and adipocytes, MSCs can also differentiate into other cells of the mesenchymal lineage, such as myoblasts [201] or cardiomyocytes [202]. Moreover, UCMSCs [203] and BM-MSCs have shown an ability to differentiate *in vitro* into cells of ectodermal lineage, such as neuroglial cells [204,205], and of endodermal lineage, such as renal tubular epithelial cells [206] and hepatocytes [207–209], although this a controversial area; and while MSCs may take on the morphological and even the cell surface markers of, for example, neurons, there is little, if any, evidence that they function as neurons. This not to say that they are not beneficial in the treatment of diseases involving damaged neurons, but they most likely mediate this effect by secretion of paracrine factors and by modulation of the inflammatory reaction.

As indicated earlier, in response to inflammation or tissue injury, MSCs are capable of engrafting in many tissues [210], albeit transiently, and have demonstrated their efficacy in promoting tissue repair in myocardial infarction [211], kidney diseases [212,213], liver diseases [214], lung diseases [215] and injury [216], and neurological disorders [217]. In DSS-induced colitis in rats, intravenous injection of rat MSCs enabled significant healing of epithelial injuries, and the MSCs extracted from the lamina mucosa had upregulated their expression of α-smooth muscle actin, suggesting a reprogramming to myogenic lineage differentiation, possibly involved in intestinal repair. In TNBS-induced colitis in rats, topical implantation of rat BM-MSCs healed mucosal injuries. MSCs engrafted into the submucosal layers, but only a small proportion was positive for α-smooth muscle actin and desmin, indicating differentiation into myofibroblasts. A larger proportion of MSCs surrounding the lesion area expressed vascular endothelial growth factor and TGF-β1, two growth factors known to play important roles in gastrointestinal wound healing [218]. In a DSS-induced colitis model in rats, intravenous injection of allogeneic MSCs resulted in clinical improvement with markedly reduced epithelial injury and, significantly, restoration of expression of claudin-2, -12 and -15, proteins constituting tight junctions that play a major role in the paracellular permeability of the epithelial barrier [219].

Again, as indicated earlier, it is thought that the tissue repair properties of MSCs are mainly due to their ability to stimulate survival and recovery of local tissues, rather than to transdifferentiation ability [220]. MSCs have demonstrated their ability to stimulate angiogenesis [221] and to inhibit apoptosis and fibrosis in injured tissues [222].

## 50.6 Mesenchymal stromal cell administration in inflammatory bowel diseases

Two different applications of MSCs in IBDs have been evaluated in human trials: local injection of MSCs to treat fistulizing CD and intravenous injection of MSCs to treat luminal CD or UC. MSC administration has been studied in CD more than it has in UC.

### 50.6.1 Mesenchymal stromal cell administration for fistulizing Crohn's disease

Management of fistulas in patients with CD is an extremely challenging problem, because many such fistulas do not respond to available treatment, despite recent improvements using anti-TNF agents and improvements in surgical treatments. Endoanal advancement flap is the standard surgical technique, but anal incontinence and recurrence are not uncommon. Several trials have evaluated the efficacy of local injections of ASCs or BM-MSCs.

### 50.6.2 Autologous mesenchymal stromal cell administration for fistulizing Crohn's disease

#### 50.6.2.1 Adipose-tissue-derived mesenchymal stromal cells

In a phase I study García-Olmo *et al.* treated four patients with one or more refractory, complex Crohn's fistulas with a single intrafistular injection of MSCs. The fistulas were enterocutaneous, suprasphincteric, and/or rectovaginal fistulas, were unresponsive to medical treatment, and had been unsuccessfully treated by surgery at least twice. The injection consisted of $3–30 \times 10^6$ autologous ASCs from passages 1 to 3. Six of eight (75%) fistulas had healed 8 weeks after treatment, and the other two (25%) were incompletely closed with decreased output flow. No relationship was found between the number of injected MSCs and the success of the treatment. No adverse effects were observed within 12–22 months follow-up, and no aberrant differentiation was seen in biopsies [223].

In a phase IIb study the same group showed that ASCs were effective in healing 69% of complex perianal fistulas in patients with moderate to severe CD who were intolerant or resistant to the anti-TNF agent infliximab [224]. Forty-nine patients with complex perianal fistulas were included. Thirty-five of the fistulas were of cryptoglandular origin and 14 were associated with CD. Cryptoglandular anal fistulas arise from inflammation of the proctodeal glands of the intersphincteric space. The mucus secretions of the anal glands empty into the anal crypts, thereby lubricating the anus. Anal glands are present in the subepithelium and the internal sphincter, with a large number also deeply sited within the intersphincteric space. Infection of these intersphincteric glands is thought to give rise to an intersphincteric abscess if the draining duct is blocked by the resulting infectious debris. The abscess may resolve by spontaneous drainage into the anal canal or it may progress to an acute anorectal abscess that, in most cases, subsequently develops into a perianal fistula. This type of fistula is not associated with CD.

Patients were randomly assigned to the administration of an intrafistular injection of fibrin glue or fibrin glue containing 20 million ASCs. If fistula healing had not occurred by 8 weeks, a second double dose of ASCs was administered. Fistula healing was observed in 17/24 patients receiving ASCs (71%); 11 patients healed after the first injection and six patients healed after a second injection compared with 4/25 (16%) in the control group (RR 4.43, $P < 0.001$). A similar proportion was observed in the CD patients, with healing of the fistula in five out of seven patients receiving ASCs compared with one out of seven patients in the control group (RR 5.00, $P = 0.10$). Improvement of quality of life, assessed by a quality-of-life questionnaire, was significantly greater in the ASC group compared with the control group, even in patients whose fistula did not heal [225]. After an average long-term follow-up of approximately 40 months, 7 out of 12 patients treated with ASCs remained free of recurrence compared with two out of three in the control group. Perianal sepsis occurred more frequently in the control group than in the ASC group ($P = 0.04$). No adverse effects related to ASC administration were noted, confirming their excellent safety and tolerability profile, and no patient suffered from anal incontinence [226].

Another group performed a dose-escalation phase I study, in which 10 patients with a perianal fistula associated with CD were treated with an intrafistular injection of autologous ASCs from passages 3 and 4 at a dose of either $1 \times 10^7$ (group 1), $2 \times 10^7$ (group 2), or $4 \times 10^7$ ASCs/mL (group 3). The doses used were selected with regard to the size of the fistula. Eight weeks after injection, complete healing occurred in two out of four patients in group 2 and one out of three patients in group 3, while partial closure with no output drainage was observed in all other patients. After follow-up of 8 months the three patients whose fistula had been completely healed were free of recurrence and no adverse effects were observed [227]. The same group subsequently led a phase II trial studying the effects of the intrafistular injection of ASCs from passages 3 and 4 in 43 patients with perianal fistulas associated with CD. The first injection again contained a number of ASCs that was proportional to the size of the fistula: $3 \times 10^7$ ASCs per 1 cm length of fistula when the fistular diameter was less than 1 cm, and $6 \times 10^7$ ASCs per 1 cm length of fistula when the diameter was between 1 and 2 cm. The average number of ASCs was $15.8 \times 10^7$ cells per fistula. Patients without complete fistula closure at 8 weeks received a second injection of 1.5 times more cells than the first injection. The fistula tract was filled with a mixture of ASCs and fibrin glue. Complete fistula healing was observed in 27/42 patients (64.3%) by 8 weeks after the final ASC injection and was sustained after 1 year in 23/26 patients (88%). Six other patients showed incomplete closure of the fistula, of which five patients achieved closure of more than 50% of the fistula tract with a decrease in drainage of more than 50%. Five other patients discontinued the study before week 8. No relation was found between the outcome of the treatment and fistula type, length, or diameter or duration of CD. No adverse events related to ASCs were observed [228].

#### 50.6.2.2 Bone marrow-derived mesenchymal stromal cells

The safety and efficacy of serial intrafistular injections of autologous BM-MSCs in the treatment of fistulizing CD was studied by

Ciccocioppo *et al.* in 10 patients refractory to all previous medical treatments including anti-TNF agents or unsuccessfully treated by surgery. They administered intrafistular injections of $15–30 \times 10^6$ MSC from passage 3 every 4 weeks until improvement was obtained or when autologous MSCs were no longer available Patients received between two and five injections. Sustained complete closure of the fistula tract occurred in 7/10 patients and incomplete closure in 3/10 patients as assessed by surgical exploration and MRI. MRI provided images of regenerative tissue without fibrotic tissue. All patients had a significant reduction of their CDAI scores: pre- and posttreatment median values were $294 \pm 49$ and $99 \pm 32$ at 12 months after the last procedure ($P < 0.001$). Their median PDAI scores pre- and posttreatment were $13.0 \pm 2.2$ and $4.5 \pm 2.4$ at 12 months after the last procedure ($P < 0.001$). Patients who achieved remission had CDAI scores ≤150 and PDAI scores ≤8, usually after the second administration of ASCs. Lower endoscopic examination performed at the end of the follow-up period demonstrated rectal mucosal healing in seven out of seven patients. In addition, they observed a significant increase in the percentage of circulating $CD4^+$ $CD25^{bright}$ $FoxP3^+$ Tregs as soon as after the second injection of ASCs which was stable at 12 months ($P < 0.01$). Additionally, mucosal $FoxP3^+$ Tregs were present in the inflamed areas at 12 months ($P < 0.0001$). There were no adverse effects during the procedure nor during the 12-month follow-up period [229].

### 50.6.3 Allogeneic mesenchymal stromal cell administration for fistulizing Crohn's disease

García-Olmo and co-workers also explored the use of expanded allogeneic ASCs for the treatment of complex perianal fistulas in patients with nonactive luminal CD (CDAI ≤200) in a single-arm multicenter phase I/IIa clinical trial. Twenty-four patients received an intrafistular treatment with $20 \times 10^6$ allogeneic ASCs followed by a second administration of $40 \times 10^6$ ASCs if fistula closure was incomplete after 12 weeks. After 12 weeks, 12/20 patients (60.0%) had an improvement of at least one of their fistulas and complete closure occurred in 8/21 (38.1%) on clinical examination. After 24 weeks, these values were respectively 9/13 patients (69.2 %) and 9/16 patients (56.3%). Based on a combination of clinical and MRI assessment, fistula closure was seen in 6/24 patients (30%) at 24 weeks. A statistically significant decrease in the MRI score of severity was observed at week 12. PDAI significantly decreased by more than 37% compared with baseline ($P < 0.01$). No effect was observed on the CDAI scores. Luminal relapse was observed in 0/24 patients (0.0%) at week 12 and in 5/24 patients (20.8%) at week 24. After a 6-month follow-up period the safety profile was acceptable, with a low number of serious adverse events: anal abscess in three patients, pyrexia in one patient, and uterine leiomyoma in one patient [230].

### 50.6.4 Autologous mesenchymal stromal cell administration for luminal inflammatory bowel diseases

Intravenous injections of autologous BM-MSCs have been tested in a phase I trial. Nine adult patients with moderate to severe CD with a CDAI score between 220 and 450 and who were refractory to conventional standard treatment, including corticosteroids, immunosuppressive agents, or anti-TNF therapy, were treated with two intravenous injection of $1–2 \times 10^6$ cells/kg body weight 7 days apart. Three patients had a clinical response (defined as a decrease in CDAI score of ≥70 points) but none achieved remission (CDAI <150), and four patients experienced worsening of their disease, requiring surgery in three cases or rescue medication in one case within 14 weeks after BM-MSC administration. Endoscopic improvement using the SESCD was seen in two patients at week 6. Biopsies of inflamed mucosa showed a trend to lower $CD4^+$ T cell and higher $CD4^+$ $CD127^+$ Treg numbers [231]. CD127 is the receptor for IL-7.

### 50.6.5 Allogeneic mesenchymal stromal cell administration for luminal inflammatory bowel diseases

Intravenous injection of allogeneic BM-MSCs has also been evaluated with more success in a phase II pilot study. Nine patients with refractory moderate-to-severe CD with a CDAI score ≥220 and previously unsuccessful treatment with corticosteroids and immunomodulatory agents were randomized to receive either a low ($2 \times 10^6$ BM-MSCs/kg) or a high ($8 \times 10^6$ BM-MSCs/kg) dose of MSCs by intravenous infusion. After 28 days all patients had a decrease in their CDAI score, with a mean decrease of 105 ($P = 0.004$), and three patients had a clinical response (reduction in CDAI ≥100), one of whom entered clinical remission (CDAI <150). Patients reported an increased quality of life, as attested by a significant increase in mean Inflammatory Bowel Disease Questionnaire (IBDQ) score by day 28 ($P = 0.008$). No infusion reaction was observed, although five patients experienced mild to moderate adverse events [232].

The Nanjing group, who studied the use of MSCs in the autoimmune disease SLE, reported their experience of allogeneic MSC transplantation in seven patients with IBD, among whom four had CD and three had UC. They administered one intravenous infusion of BM-MSCs from healthy family members or UCMSCs at a dose of $1 \times 10^6$/kg body weight. Patients continued their treatment with corticosteroids and/or immunosuppressive agents after the transplant. After 3 months they observed a significant reduction in disease activity (CDAI or Clinical Activity Index) in all patients, with remission achieved in five out of seven patients (two out of four with CD and three out of three with UC) and endoscopic improvement with a decrease in Endoscopic Index of Severity score or in Endoscopic Activity Index in three out of seven patients, two out of four with CD and one out of three with UC. Remission lasted for more than 2 years in two patients, while two other patients relapsed at 6 and

7 months. One CD patient had a significant reduction in fistula size and drainage. Histological analysis of biopsy specimens showed a reduction in the extent of the inflamed area and in the lymphocytic infiltration in the mucosa propria. One patient had a significant reduction in fistula size and drainage. No serious adverse events were reported after a mean follow-up of 19 months (range 6–32 months) [233].

## 50.7 The future of mesenchymal stromal cell treatment in inflammatory bowel diseases

### 50.7.1 Ongoing protocols

#### 50.7.1.1 Mesenchymal stromal cell treatment for fistulizing Crohn's disease

##### *50.7.1.1.1 The Navarra study (NCT01157650)*

This phase I–II study is evaluating viability, safety, and tolerance of locally implanted autologous ASCs in 15 patients with non-active CD (CDAI ≤200) and one or more enterocutaneous, rectovaginal or complex perianal fistulas. Patients should not have perianal abscesses or rectal and/or anal stenosis, and should not have received anti-TNF therapy or have received tacrolimus or cyclosporine within 8 weeks and 4 weeks before MSC therapy respectively. Secondary outcomes include an evaluation of efficacy (fistula healing, quality of life, presence of systemic CD, relapse) and a biological characterization of the MSCs used in terms of their phenotype, immune suppressive capacities, and cytokine production. This study is ongoing, but is no longer recruiting participants (Figure 50.8).

##### *50.7.1.1.2 The Leiden study (NCT01144962)*

This dose-escalation phase I–II study aims to determine the safety and efficacy of intrafistular injection of allogeneic BM-MSCs for the induction of response of active fistulizing CD. The fistulas are peri-anal fistulas refractory to conventional medical treatment. Patients are randomized into one of four groups, receiving either placebo or MSCs at doses of 10 million, 30 million, or 90 million. Exclusion criteria include acute peri-anal infection, rectovaginal or complex peri-anal fistulas with more than two internal openings, and anti-TNF therapy less than 8 weeks prior to enrolment. Secondary outcomes at 12 weeks are improvement of clinical and endoscopic scores, quality of life details, and serum CRP. Safety is evaluated after 12 and 24 weeks. This study is ongoing, but is no longer recruiting participants.

##### *50.7.1.1.3 The Anterogen studies (NCT01314092, NCT01623453)*

In a phase II trial, patients with complex perianal fistulas are randomized to receive autologous ASCs at either low ($1 \times 10^9$/mL) or high ($2 \times 10^9$/mL) dose, followed by a second double-dose injection if complete closure is not achieved. Primary outcome is complete closure of the fistula at week 8. Safety is assessed by the reporting of all adverse events. Subsequently, an open follow-up clinical trial will evaluate the number of patients with sustained complete closure and the number of adverse events 6 months after the final dose injection.

##### *50.7.1.1.4 The TiGenix study (NCT01541579)*

This phase III randomized double-blind placebo-controlled multicenter study is evaluating the efficacy of allogeneic ASCs for the treatment of complex anal fistulas in patients with CD. Patients with nonactive or mildly active luminal CD (CDAI ≤220) and two or less complex perianal fistulas are randomized to receive either an intrafistular injection of $120 \times 10^6$ allogeneic ASCs or placebo. Patients with abscesses, rectovaginal fistulas, surgically treated fistulas, and ongoing corticosteroid treatment or corticosteroid within the preceding 4 weeks are excluded from

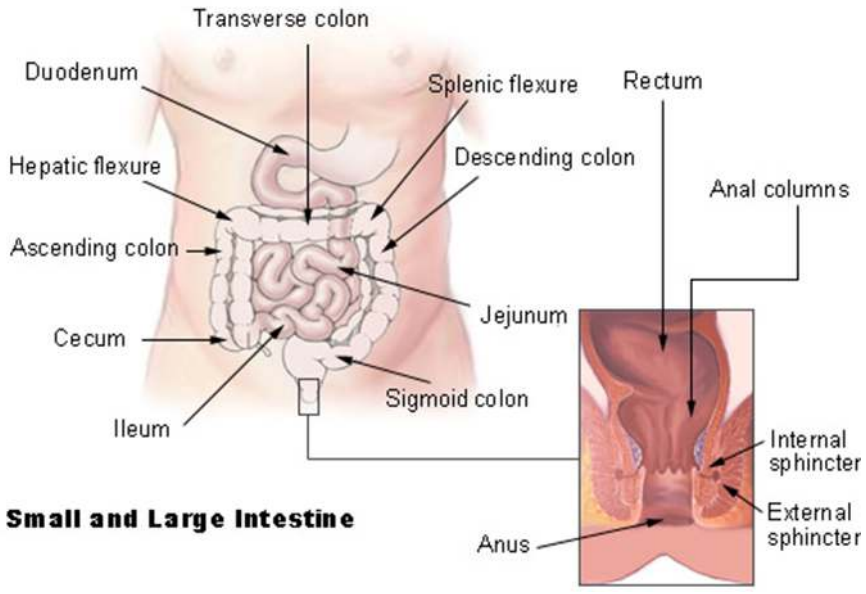

**Figure 50.8** The small and large intestine with an insert of the perianal anatomy, an area where perianal fistulas occur in persons with CD. *Source:* http://commons.wikimedia.org/wiki/File:Illu_intestine.jpg#mediaviewer/File:Illu_intestine.jpg.

the study. Primary outcomes include remission of perianal fistulizing CD at week 24 by clinical and MRI assessment. Other outcomes are efficacy, including response, time to response, and time to remission, and assessment using the PDAI and IBDQ criteria, as well as safety at weeks 24 and 52. This study is currently recruiting participants.

#### *50.7.1.1.5 The Royan study (NCT01874015)*

This study is a prospective, randomized, phase I trial in which patients with refractory CD, a CDAI score >220, and perineal fistulas are randomized to receive four monthly intrafistular injections of autologous BM-MSCs with or without fibroblasts. Outcomes are fistula closure and CDAI score at month 4. This study is currently recruiting participants.

### 50.7.1.2 Mesenchymal stromal cell administration for luminal inflammatory bowel diseases

#### *50.7.1.2.1 The Liège study (NCT01540292)*

This prospective open-label phase I–II pilot trial was initiated in 2013 to explore the safety and efficacy of allogeneic BM-MSC infusions in CD refractory or intolerant to conventional therapies. Twenty patients with active refractory CD defined by a CDAI >220 despite conventional treatment, including mesalazine, corticosteroids, purine analogues, methotrexate, infliximab, and adalimumab, are treated with two successive injections of $1.5–2.0 \times 10^6$ allogeneic BM-MSCs/kg at the beginning of the trial and 4 weeks later. Conventional treatments of CD, such as mesalazine, methylprednisolone, budesonide, azathioprine, 6-mercaptopurine, or methotrexate, are allowed, while anti-TNF antibodies are forbidden, and antibiotics are allowed only for the treatment of a concurrent infection. The primary endpoint is a clinical response defined by a 100-point decrease in the CDAI score at week 8. Secondary endpoints include clinical response, remission defined by a CDAI score <150, CDAI levels, CRP levels, and fecal calprotectin levels at weeks 2, 4, 8, and 12. Immune modulation is being investigated by monitoring of nucleated cell counts, leucocyte subpopulations, Treg numbers, immunoglobulin levels, Vβ repertoire of T lymphocytes, and the quantification of TRECS in T lymphocytes. TRECS are TCR excision circles, which are small circles of DNA created in T cells during their passage through the thymus as they rearrange their TCR genes. This is a measure of thymic function. Safety is being assessed by recording side effects, including infections.

#### *50.7.1.2.2 The Mesoblast international studies (NCT01233960 and NCT00543374)*

In a first phase III study, patients with moderate-to-severe CD (CDAI scores between 250 and 450) who are intolerant to, or who have previously failed, therapy with at least one corticosteroid course and at least one immunosuppressive agent course and an anti-TNF treatment are randomized into three groups to receive a placebo or an intravenous injection of allogeneic MSCs at low ($6 \times 10^6$ MSCs) or high ($1.2 \times 10^9$) doses on four occasions over 2 weeks. The primary outcome is disease remission (CDAI score ≤150) at day 28, and secondary outcomes are disease improvement (reduction in CDAI score of ≥100 points), improvement in quality of life (using the IBDQ), and reduction in number of draining fistulas. In a second phase III study, patients who successfully achieved clinical benefit in the first study will be enrolled and followed for duration and reinduction of clinical benefit using the CDAI questionnaire and improvement in quality of life using the IBDQ after 6 months.

#### *50.7.1.2.3 The Qingdao study (NCT01221428)*

This phase I–II study aims to determine the safety and efficacy of UCMSCs in refractory UC. First, $2 \times 10^7$ MSCs are injected intravenously followed 1 week later by $1 \times 10^7$ MSCs injected into the mesenteric artery. Outcomes evaluated after 3 months are improvement in endoscopy findings and histology and amelioration of clinical symptoms.

#### *50.7.1.2.4 The La Paz study (NCT01914887)*

In this phase I–II study, patients with left-sided colitis and moderate activity as assessed using a modified Truelove–Witts score between 11 and 21, who did not respond to 4 weeks of treatment with oral and/or topical 5-aminosalicylates, receive multiple endoscopic injections of allogeneic ASCs into the affected colonic submucosa at a total dose of $6 \times 10^7$ MSCs. Safety and efficacy assessed by the modified Truelove–Witts score, IBDQ, Mayo endoscopic index, CRP, and fecal calprotectin are evaluated at weeks 0, 4, 8, and 12. The study is currently recruiting.

#### *50.7.1.2.5 The Washington study (NCT02150551)*

In this phase I trial, pediatric patients with IBDs will be randomized into three dose groups and will receive eight weekly infusions of allogeneic BM-MSCs. Safety and efficacy will be assessed using the pediatric CDAI or Pediatric Ulcerative Colitis Activity Index questionnaires, quality of life using the Impact III IBD questionnaire, laboratory tests, including CRP, fecal calprotectin, and proinflammatory cytokines, as well as endoscopic healing evaluated at day 24 and day 77.

## 50.8 Issues to be resolved

### 50.8.1 Source of mesenchymal stromal cells

Most of the published human trials in people with CD have used ASCs. Only Ciccocioppo *et al.* used BM-MSCs [229]. ASCs have the advantage of being easily accessible in large numbers. MSC treatment requires a large number of cells, and, although MSCs have great proliferation potential, extended *ex vivo* expansion can alter their properties, resulting in reduced differentiation potential and senescence from the sixth passage onward [234].

Alternatively, expanded ASCs could be superior to nonexpanded ASCs, known as the stromal vascular fraction, for the treatment of enterocutaneous fistula in CD, as shown by García-Olmo *et al.* in eight patients: three of four fistulas healed in the ASC group compared to one of four in the stromal vascular

fraction group [235]. We lack information on differences on immunophenotype, differentiation potential, transcriptome, and proteome between BM-MSCs and ASCs. *In vitro* studies suggest that ASCs might be superior to BM-MSCs in suppressing immune responses [236,237]. In practice, both types of cells have demonstrated some efficacy, but formal studies comparing the efficacy of BM-MSCs and ASCs will be needed to resolve this question.

### 50.8.2 Autologous versus allogeneic mesenchymal stromal cells

The use of autologous MSCs has raised a debate on whether MSCs are affected by, or may contribute to, CD. MSCs from patients with other autoimmune diseases, such as SLE, have lower proliferation capacities [238], and the results in human studies on SLE were disappointing when autologous MSCs were used. However, several *in vitro* studies have demonstrated that MSCs from patients with CD have similar growth potential and T cell suppression properties to MSCs from healthy donors [231,239]. Moreover, both autologous and allogeneic MSCs seem promising in human trials, with the exception of a trial using autologous MSCs in SLE.

### 50.8.3 Dosage and modalities of administration

Because of the extent and dissemination of luminal lesions in CD, systemic administration seems required. In mice, intravenous and intraperitoneal routes of administration have been used with equal success, apart from a few studies in which MSCs did not appear to home to inflamed intestine [196,218]. In humans, intravenous infusion of cells is simple, minimally invasive, routinely performed, and safe. However, little is known about the optimal amount of MSCs and the proportion of MSCs that will reach an inflamed intestine. Duijvestein *et al.* used $1–2 \times 10^6$ autologous MSCs/kg body without much success [231], while Onken *et al.* observed no significant difference between low ($2 \times 10^6$ MSCs/kg) and high ($8 \times 10^6$ MSCs/kg) [232]. Administration of MSCs via selective mesenteric artery cannulation has been successfully performed in one patient, without any complication [240]. This route of administration may increase the number of MSCs reaching the inflamed organ, but its superiority over the intravenous administration is yet to be demonstrated.

Local injection of MSCs has been successfully used in several studies to treat CD fistulas. In studies showing efficacy of intrafistular injections, $10–60 \times 10^6$ MSCs were injected into each fistulous tract, and these injections were sometimes repeated. Ongoing trials are testing higher systemic doses: the Mesoblast international studies are testing the injection of $6 \times 10^8$ or $1.2 \times 10^9$ cells four times over a 2-week period. Several local dose-escalation trials are also currently ongoing.

### 50.8.4 Concomitant use of other drugs

MSCs are used concomitantly with immunosuppressive drugs, and, as they have common targets, it is important to know if the drugs can affect MSC function. MSCs exposed to physiological concentrations of azathioprine, methotrexate, 6-mercaptopurine, and anti-TNF-α antibodies had normal survival and inhibitory capacities on PBMC proliferation when tested *in vitro*. An additive effect could even exist with 6-mercaptopurine and anti-TNF-α antibodies [241].

## 50.9 Safety

So far there have been no reports of any serious adverse events or ectopic tissue growth in clinical trials using MSC-based therapy for CD, nor for graft-versus-host disease [242–244], solid-organ transplantation [245], cartilage disorders [246], or in many completed clinical trials for a variety of applications [247,248]. In some studies there was a mild and transient fever shortly after the time of administration, and this association was found to be statistically significant in a meta-analysis [248]. More experience is needed in order to confirm the long-term safety of MSCs.

The immunosuppressive properties of MSCs could theoretically increase susceptibility to infections and cancers. However, no infections or malignant diseases have been reported as serious adverse events in MSC-treated CD patients, and there is no evidence of any increased risk in other applications [248]. In the context of solid organ transplantation with MSC-based immunosuppression, one group has even observed a decreased infection risk compared with standard immunosuppressive drugs [245]. Another reason for concern for an increased risk of malignant disease is the need to expand MSCs *in vitro* in order to obtain a sufficient number of cells for MSC-based therapy. While murine MSCs have shown a potential for the development of chromosomal aberrations and tumor generation after long-term *in vitro* culture [249,250], human MSCs have not shown any of these risks so far [251–253]. Moreover, IBDs are associated with a higher risk of developing colorectal cancer. In a murine model of colitis-associated tumorigenesis induced by azoxymethane and DSS, MSC-treated animals showed a significant reduction in tumor number and tumor load compared with control mice, while tumor size remained comparable. This could be linked to a decreased expression of proinflammatory cytokines and down-regulation of STAT3 phosphorylation [254].

Finally, the effects of MSCs on preexisting cancers have also been studied. In animal studies some authors found that MSCs could promote tumor growth [255,256], while others observed a tumor-suppressive activity of MSCs [257–259]. This dual effect could be explained by a context-dependent role of MSCs in regulating tumor growth [260,261]. In a small human trial of 25 patients, co-transplantation of MSCs and HSCs was associated with a higher relapse rate compared with control patients (60% versus 20%). However, this observation has not been confirmed by other studies [262].

## 50.10 Conclusions

MSCs represent a promising therapy for IBD, especially for CD. They probably exert their effects through a combination of

immunomodulation, myogenic differentiation, and the promotion of epithelial repair. Both local injection of MSCs for fistulizing CD and intravenous injection of MSCs for luminal IBD have shown interesting results in several human trials. Unlike current surgical strategies, MSC administration is a minimally invasive procedure, which does not injure the anal sphincter and even promotes a nonfibrotic reparative process of fistulas, with no cases of incontinence reported after MSC treatment. MSCs seem superior to conventional drugs in term of side effects, such as opportunist infections. There are still many questions to answer concerning the optimal source of MSCs, as well as dosage and routes of administration.

The efficacy of MSCs compared with conventional treatments still needs to be demonstrated in randomized controlled trials, several studies of which are ongoing. They will also likely help us in the understanding and use of MSCs to treat IBDs.

## 51.1 Introduction

Mesenchymal stromal cells (MSCs) show great promise in ameliorating kidney disease. These multipotent fibroblast-like stromal cells can migrate to damaged kidneys, where they selectively home to inflammatory cues and alter the course of injury. MSCs can elicit endogenous repair through paracrine and/or endocrine mechanisms that modulate the immune response, ultimately allowing for cellular replacement. This chapter will discuss the features of MSCs and evidence for their homing and engraftment to sites of inflammation as well as their unique immunomodulatory properties and the factors they release that protect against kidney injury. New approaches using MSCs as delivery vehicles for secreted proteins and methods for improving efficacy will also be reviewed. Despite uncertainty over mechanisms mediating protection, MSCs are currently in clinical trials for a range of acute and chronic diseases, including kidney disorders. This chapter will discuss challenges in applying MSCs in a setting of chronic kidney disease (CKD). The potential of a combined therapeutic approach using MSCs and an antifibrotic, relaxin, to aid in MSC viability and the promotion of endogenous repair, cellular replacement, and attenuation of fibrosis will be highlighted.

## 51.2 Immune modulation and protective effects of mesenchymal stromal cells

Nonrenal stromal cells such as mesenchymal stromal cells (MSCs) have been identified as a potential therapy for kidney disease owing to their immunomodulatory properties and their ability to ameliorate acute kidney damage through endocrine and paracrine mechanisms [1]. MSCs have been characterized in a wide variety of fetal tissues during early gestation. However, by the third trimester of pregnancy MSC numbers rapidly decline in the periphery and eventually establish themselves in the bone marrow (BM) [2]. Postnatally, MSCs exist in virtually all organs, including the kidney. However, their immunophenotype and differentiation potential differ from MSCs isolated from other sources, such as the BM [3].

In the setting of experimental kidney disease, MSCs derived from the BM have been extensively studied. These cells are classified according to the expression of surface markers, including CD73, CD90, and CD105, and the lack of hematopoietic markers, adherence to plastic in culture with a fibroblast-like appearance, and the capacity to differentiate into linages of the mesoderm, such as bone, fat, and cartilage under appropriate culture conditions [4]. BM-MSCs are an attractive cell source for

therapeutic delivery as they are relatively easily obtained from BM, readily cultured into adequate numbers for administration, and have demonstrated immunomodulatory properties [5].

While the exact mechanisms of MSC-induced renal repair are yet to be fully elucidated, it has been established that, rather than direct transdifferentiation into kidney cells, MSCs exhibit unique immunomodulatory effects on both the innate and adaptive immune systems, while releasing many growth factors to elicit tissue repair [6,7] (Figure 51.1).

MSC administration in experimental settings of kidney disease results in the preservation of kidney architecture and an increase in kidney function (as measured by glomerular filtration rate (GFR)), and coinciding with an increase in tubular epithelial cell proliferation and decreased cell apoptosis [8]. (Kidney function impairment is indicated by a GFR value below the normal range, a serum creatinine value above the normal range, and a urea or blood urea nitrogen level above the normal range.) When cytokine and growth factor expression were analyzed from whole

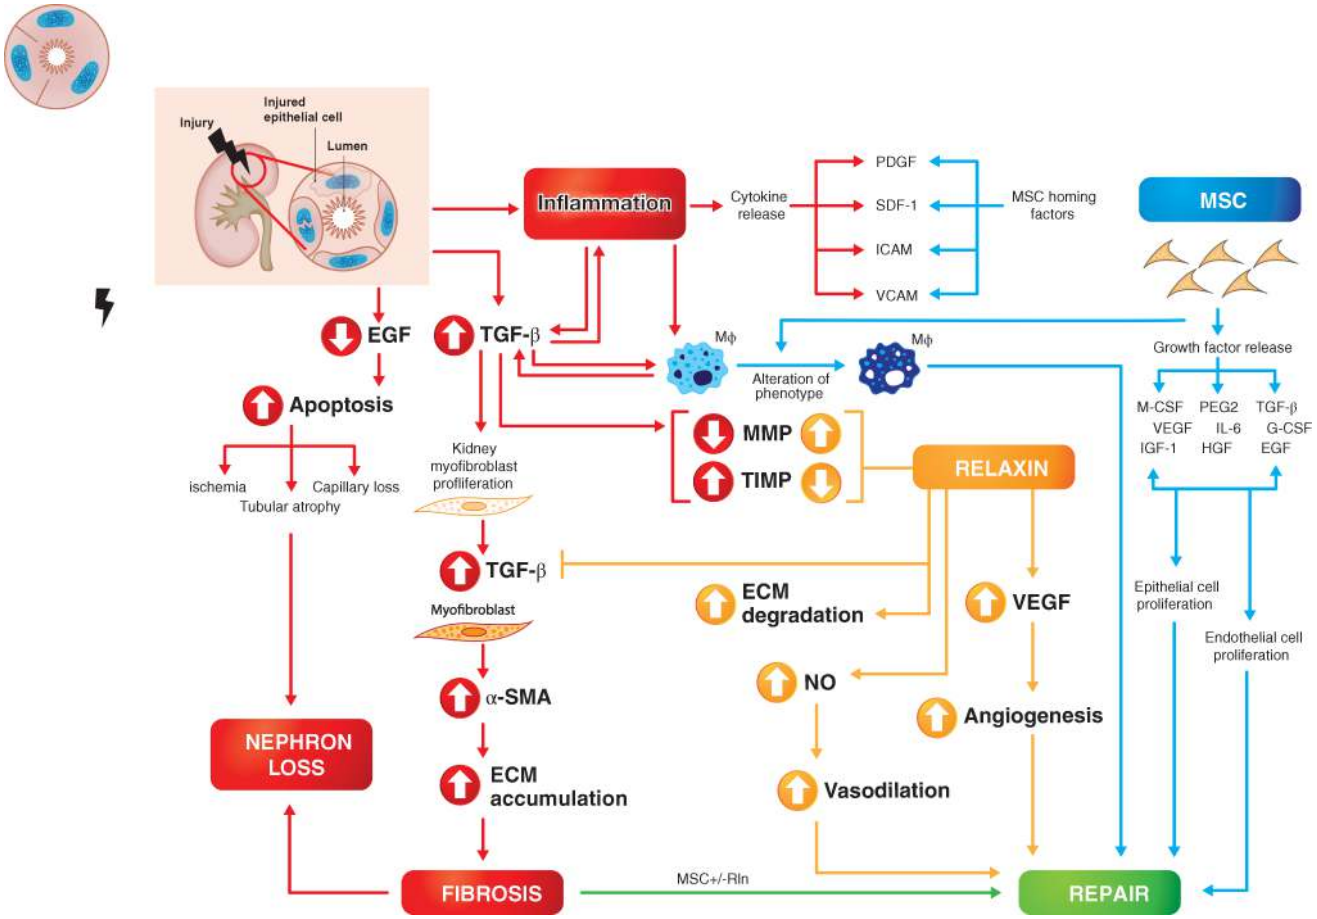

**Figure 51.1** The mechanisms of MSC-mediated repair after kidney injury. Diagrammatic representation of the progression of renal fibrosis and nephron loss, and the regulatory pathways targeted by MSCs and relaxin that promote structural and functional kidney repair. Following injury, tubular epithelial cells release a range of chemokines that alter the local kidney microenvironment. Epidermal growth factor (EGF) expression is decreased, causing apoptosis of endothelial and epithelial cells, leading to hypoxia and ultimately nephron loss. Transforming growth factor (TGF)-β is also released and serves as an important mediator of fibroblast transformation into myofibroblasts, the main collagen-producing cells in the injured kidney. Activated myofibroblasts express α-smooth muscle actin (α-SMA) and augment the deposition of extracellular matrix (ECM), exacerbating hypoxia and cell death, and ultimately leading to progressive interstitial fibrosis. This is compounded by TGF-β-induced inhibition of matrix metalloproteinases (MMPs) and the upregulation of tissue inhibitors of MMPs (TIMPs). Inflammation stimulates the release of TGF-β and other cytokines, leading to immune cell infiltration. Inflammatory release of cytokines, such as platelet-derived growth factor (PDGF), stromal cell-derived factor (SDF)-1, intracellular adhesion molecule (ICAM), and vascular cell adhesion molecule (VCAM), also serve as chemoattractants for MSC homing. At the site of kidney injury, MSCs alter the microenvironment of the kidney by interacting with macrophages, and by releasing trophic growth factors that result in the proliferation of epithelial and endothelial cells, resolving inflammation and promoting endogenous repair. If fibrosis is already established, the efficacy of MSCs may be reduced. Therefore, altering the local environment with an antifibrotic agent, such as relaxin (Rln), can aid in MSC-mediated repair. Exogenous relaxin (serelaxin) directly inhibits the downstream pathways of TGF-β, preventing fibrosis. Additionally, relaxin promotes MMP activity and downregulates TIMPs, leading to further ECM degradation. Additionally, relaxin promotes angiogenesis and vasodilation through the upregulation of vascular endothelial growth factor (VEGF) and nitric oxide (NO), contributing to kidney remodeling after injury. (See color plate section.)

kidneys, it was found that MSC administration resulted in an upregulation of anti-inflammatory cytokines, IL-10, basic fibroblast growth factor (bFGF), and TGF-α, and a decrease in the proinflammatory cytokines IL-1β, tumor necrosis factor (TNF)-α, interferon gamma (IFN-γ), and inducible nitric oxide synthase (iNOS) [8], suggesting that secreted factors released by MSCs influence the microenvironment of the injured kidney and mediate the reparative function. Further evidence for the protective paracrine mechanisms of MSCs in kidney disease emanates from experiments that administered MSC-conditioned media (CM) in a cisplatin model of kidney injury. Mice receiving CM had better survival outcomes, improved histopathology correlating with an increase in GFR, and a decrease in tubular apoptosis compared with vehicle-injected mice [9]. Furthermore, administration of MSCs in a rat remnant model of kidney disease influenced the immune system by downregulating IL-6 and TNF-α while increasing IL-4 and IL-10 expression levels [10]. Additionally, in obstructive nephropathy, expression of the proinflammatory cytokine IFN-γ was significantly decreased and IL-10 was significantly increased in MSC-treated animals when compared with sham- and saline-injected control mice [11].

The anti-inflammatory effects of MSCs may also be due to downstream effects on dendritic cells (DCs), antigen-presenting cells that can trigger either proinflammatory or anti-inflammatory pathways, and are involved in the early innate immune response [7]. MSCs may prevent the maturation of DCs by inhibiting the release of proinflammatory cytokines such as IL-12 and TNF-α, while also increasing secretion of IL-10, suggesting that MSCs can influence DCs and trigger a helper T (Th)2 anti-inflammatory profile [12,13]. Moreover, MSCs release a plethora of cytokines that are responsible for their therapeutic effect, with IL-6 [14] and $PGE_2$ [15] being implicated in preventing DC maturation. $PGE_2$, IL-10, and TGF-β released from MSCs are also seemingly important for the inhibition of natural killer (NK) cell proliferation, cytokine release, and lytic ability. However, this effect is lost if the NK cells had previously been exposed to IL-12 [16]. Of further significance, Spaggiari *et al.* characterized the ligands expressed on MSCs that were able to bind to specific receptors on IL-12-stimulated NK cells and induced lysis of both allogeneic and autologous MSCs [17], which may provide an explanation of the null effect on NK cells derived from human peripheral blood mononuclear cells (PBMCs) [18].

B and T cells are major players in the adaptive immune response, and MSCs may be involved in inhibiting the proliferation, differentiation, and activation of both. *In vitro* culture of MSCs and stimulated B cells caused a decrease in B cell proliferation, maturation, and immunoglobulin M production [19]. MSC-derived soluble factors may induce this effect as MSC-CM inhibited proliferation and immunoglobulin production to the same extent as that of MSCs [20]. Data have suggested that the release of IFN-γ from NK and T cells upregulates indoleamine 2,3-dioxygenase (IDO) expression from MSCs, which is responsible for the suppressive effects of MSCs on activated B, T, and NK cells [21,22]. While contrasting studies demonstrate that MSCs may enhance B cell proliferation and maturation [23], a study by Rosado *et al.* used MSCs and PBMCs from healthy and kidney transplant patients to show that the efficacy of MSC-mediated B cell inhibition was dependent on the presence of T cells and their cell-to-cell contact with MSCs *in vitro* [24]. In order for MSCs to modulate T cells, they first need to be activated by IFN-γ, and/or TNF-α, which may be released from the T cells themselves or the tissue microenvironment [25]. This in turn causes the release a myriad of growth factors and cytokines secreted from MSCs, such as IL-6, IL-10, $PGE_2$, TGF-β, HGF, and IDO [7]. As such, MSCs can inhibit T cell proliferation, cytokine production, and cytotoxicity, an effect that is abrogated by blocking the IFN-γ receptor on MSCs [22].

Of further note, a study performed by Aggarwal and Pittenger [26] suggested that the presence of MSCs in an inflammatory environment modulates inflammation by altering cytokine release from DCs, NK cells, and T cells. More specifically, the presence of MSCs induced naive T cells (Th1) to decrease IFN-γ release and helper T cells (Th2) to increase IL-4 secretion, suggesting a shift from a proinflammatory (Th1) to anti-inflammatory (Th2) microenvironment [26]. $PGE_2$ levels increased in the MSC/immune cell culture supernatant, in addition to vascular endothelial growth factor (VEGF), suggesting that these molecules are released by MSCs and likely involved in modulating inflammation [26]. Interestingly, when MSCs from living kidney donors were cultured with stimulated PBMCs from their organ recipients the proliferation and activation of T cells was significantly hampered and likely mediated by an upregulation of IL-10 and IDO [18]. The fact that MSCs can modulate the immune system potentially makes them an attractive therapy for immune-related diseases, such as graft-versus-host disease occurring after allogeneic hematopoietic stem cell transplantation (see Chapter 57) and in solid organ transplantation (see Chapter 56). Additionally, it is also an important characteristic when considering MSC therapy for chronic diseases where ensuing inflammation is present, such as the progression of CKD.

The direct interaction of MSCs and macrophages has been reported to be critical in the reparative effects of MSCs. While the ablation of macrophages in an ischemia reperfusion (IR) model of renal disease resulted in a significant attenuation of fibrosis [27], macrophages are increasingly being recognized as having a more complex role in tissue repair and remodeling, with both inflammatory and reparative phenotypes observed, dependent on cues within the microenvironment [28–30]. Németh *et al.* demonstrated that MSCs can reprogram macrophages and induce the release of IL-10 in a $PGE_2$-dependent manner inducing organ repair in a sepsis model of injury, yet the ablation of macrophages rendered MSCs ineffective [31]. Macrophage-dependent reparative effects have also been observed by alteration of the microenvironment using colony-stimulating factor (CSF)-1 [32]. Analysis of macrophages obtained from IR injured

kidneys treated with CSF-1 showed that they had an altered gene expression profile and were induced to release IGF-1, compared to macrophages not exposed to CSF-1 [32]. This may be one of the main mechanisms by which CSF-1 induces renal protection [32]. A study from our laboratory demonstrated that direct or indirect co-culture of human MSCs with stimulated murine-derived macrophages upregulated genes associated with an anti-inflammatory-like state [33]. The supernatant of these cultures was screened for human growth factors and cytokines that might have been responsible for this alteration, and EGF, granulocyte-macrophage CSF, chemokine motif C–X–C ligand 1, IL-6, monocyte chemotactic protein, platelet-derived growth factor (PDGF)-AA, and chemokine motif C–C ligand 5 were detected [33].

## 51.3 Mesenchymal stromal cell homing, recruitment, and tracking

Understanding the processes that control MSC homing, migration, and engraftment to injured tissues where they exert their reparative effects is of great importance for the development of more selective MSC therapies. First, the weak interaction between MSCs and P-selectin expressed on the endothelium likely facilitates MSC rolling and tethering along the endothelium toward a stromal-cell-derived growth factor (SDF)-1 and hyaluronic acid (HA) gradient originating from the inflamed tissue [1,34]. Following ischemic kidney injury in mice, Tögel *et al* were the first to demonstrate that surviving tubular epithelial cells upregulate SDF-1 and its receptor, C–X–C motif chemokine receptor 4 (CXCR4) [35]. MSCs also express CXCR4, which is critical for the migration and homing of MSCs toward SDF-1. Delivery of MSCs that were preincubated with an anti-CXCR4 blocking antibody has been reported to significantly reduce the number of MSCs localizing in the ischemic kidney [35]. CD44 is also expressed on MSCs [36], which is the surface receptor for HA, and it has also been suggested that it plays a role in MSC homing. Herrera *et al.* [37] used a model of glycerol-induced kidney injury to confirm that HA expression was increased in response to injury and that $CD44^{+}$ MSCs migrated to, and localized in, the injured kidney. However, MSCs that were obtained from the BM of CD44 knockout mice failed to localize in the damaged kidney. This effect could be reversed if the $CD44^{-/-}$ cells were transfected with wild-type CD44, indicating that the interactions between CD44 and HA are important in the successful homing of MSCs to sites of kidney injury [37].

To further elucidate the factors that might be responsible for the migration capacity of MSCs, Ponte *et al.* investigated the response of MSCs to 16 chemokines and growth factors *in vitro* and found that growth factors such as PDGF-AB and IGF-1, and to a lesser extent HGF and EGF, were the most potent chemoattractants of MSCs, rather than chemokines, including SDF-1 [38]. However, stimulation of MSCs with TNF-α significantly increased their migration capacity toward the chemokines RANTES (regulation on activation, normal T cell expressed and secreted), macrophage-derived chemokine, and SDF-1, which correlated with an increase of their membrane receptor expression on MSCs – chemokine receptor 3, chemokine receptor 4, and CXCR4 respectively [38]. These results demonstrate that the migration capacity of MSCs is controlled by a number of interactions between chemokines, growth factors, and receptors; and since MSC migration is increased when MSCs are primed with TNF-α, the homing of MSCs is likely dependent on the presence of inflammatory cues. In order for MSCs to enter the kidney, they must first adhere to and then migrate across the endothelium. The presence of inflammation has been reported to upregulate vascular cell adhesion molecule-1 on the endothelium [39], which binds MSCs via their expression of very late activation antigen (VLA)-4 [40], facilitating entry into the kidney interstitium.

The invasion of MSCs into damaged tissues also requires degradation of the basement membrane to which both endothelial and epithelial cells attach. This is likely mediated by protein-degrading enzymes; namely, MMPs. MMPs are a group of proteases that are responsible for the degradation of collagen and are regulated by TIMPs [41]. Transcript analysis of human BM-MSCs revealed that MMP-2, membrane-type 1 (MT1)-MMP, TIMP-1, and TIMP-2 are all expressed by MSCs, and when MMP-2, MT1-MMP, and TIMP-2 are knocked down the invasive capacity of MSCs is significantly hampered [42]. Furthermore, the presence of the inflammatory cytokines TGF-β1, IL-1β, and TNF-α served as chemoattractants for MSCs, significantly increasing their ability to migrate across basement membranes through the upregulation of MMP-2, MT1-MMP, and possibly MMP-9 [42].

While studies have demonstrated the successful homing of MSCs to the kidney, a "lung barrier" has been identified whereby MSCs initially accumulate in the small capillary beds of the lungs rather than the target organs when administered intravenously [43–45]. To overcome this, intra-arterial administration of MSCs [46,47] or the use of a vasodilator at the time of MSC administration have been used as a means of increasing MSC localization within the target organ [43,48].

However, identifying the location of MSCs after intravenous (IV) infusion will be important since the most commonly used route of MSC delivery in the clinic is likely to be by IV infusion [49]. Various methods to trace MSCs have been used, including magnetic resonance imaging of iron dextran-labeled MSCs [50–52], fluorescently tagged MSCs [53], and bioluminescent imaging [46]. Bioluminescence imaging is based on the principle that the firefly luciferase enzyme generates light, emitting photons when undergoing oxidation in the presence of adenosine-5′-triphosphate (ATP) [54]. The substrate for luciferase is D-luciferin, which can be injected intraperitoneally in experimental animals to activate the luciferase in an ATP-dependent manner [54]. In order to be detected, the photons released by the luciferase must pass through tissues and fluids before escaping through the skin of the animal, which is a

limitation of using any *in vivo* optical imaging to trace MSCs. Hemoglobin is responsible for absorbing blue and green light of wavelengths of 600 nm or below, and while some scattering of light occurs when it passes through tissue, the majority of red light (600–1100 nm) is emitted from the surface of the animal and is captured by a highly sensitive camera [54]. Studies have successfully utilized MSCs transduced with the luciferase gene [55] in order to determine their *in vivo* distribution, which offers advantages over other imaging techniques. For example, magnetic resonance imaging of MSCs can result in the identification of nonviable cells or even cells other than the labeled MSCs because of iron shedding [46]. However, because the generation of photons from the luciferase gene is dependent on ATP, only metabolically active cells will emit light and be detected using bioluminescence [54].

An additional advantage of this technique is that mammals do not emit a background bioluminescent signal; therefore, the sensitivity of bioluminescent tracking remains high. Importantly, the luciferase gene can be activated multiple times over an extended period of time; therefore, animals can be imaged over many time points and the localization of the MSCs identified, thus reducing the number of animals required. Conversely, fluorescence-based imaging techniques have inherent problems with background autofluorescence in mammalian tissue, significantly affecting the signal-to-noise ratio [54].

Our recent studies in a fibrotic model of experimental kidney injury have utilized bioluminescence imaging and demonstrated that venous administration of luciferase/green fluorescent protein (GFP)-tagged MSCs could overcome the "lung barrier" and home to the injured kidney (Figure 51.2).

Imaging at 1, 24 and 36 h after MSC administration to both injured and sham-operated mice demonstrated that MSCs were present only in the lungs of sham-operated mice, but in both the lungs and the kidney of injured mice after 1 h. By 24 h, however, MSCs were localized in the injured kidneys only (Figure 51.2a) and not in sham controls (Figure 51.2b) [56].

These results indicate that, following intravenous administration, MSCs are capable of homing out of the lungs and into the injured kidney. Of note also is that the MSCs remained for longer and in higher numbers in an inflammatory setting, as seen in

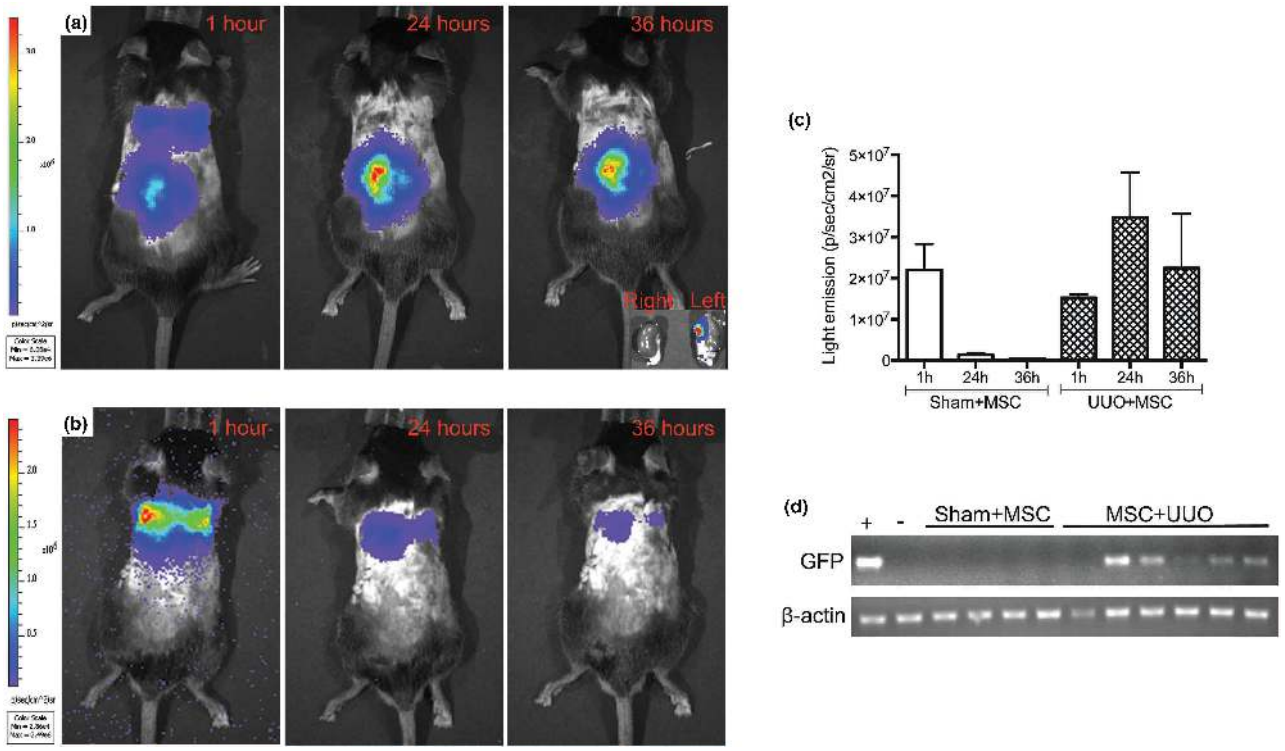

**Figure 51.2** MSCs can home to the injured kidney after intravenous transplantation. Luciferin/GFP+-tagged MSCs can be utilized to visualize MSC distribution *in vivo*. Luciferin requires ATP to produce photons and emit light; therefore, only viable MSCs will be detected using this method. Additionally, the amount of light produced is directly proportional to the amount of MSCs present. (a) After ureteric obstruction, MSCs can be observed in both the lung and the obstructed kidney as early as 1 h post MSC administration, yet after 24 h a strong bioluminescent signal originates from the area of the obstructed kidney only, where it remains for up to 36 h. Excision of the kidneys revealed that MSCs were located only in the injured kidney, and not the uninjured control. (b) In comparison, MSCs do not home to the kidneys in sham-operated controls. Instead, MSCs home to the lungs, where they remain for up to 36 h yet are hardly detectable. (c) When the bioluminescent signal is quantified from the area of the kidneys in injured mice, and the area of the lungs in sham-operated mice, the differences in light emission can be compared. (d) Polymerase chain reaction of genomic DNA extracted from whole kidneys showed that the GFP gene was present in MSC-treated groups, and not sham-operated controls. UUO, unilateral ureteric obstruction. (See color plate section.) *Source*: adapted from Huuskes 2015 [56].

Figure 51.2c: at 36 h the bioluminescent signal had almost completely diminished over the area of the lungs in sham-operated animals, but was still present in the injured kidney [56], suggesting that inflammation is an important cue for MSC homing and localization within the injured kidney. Similarly, in an experimental model of IR injury, MSCs were undetectable in sham-operated mice by 72 h, yet homed out of the lungs and engrafted into both unilateral and bilateral kidneys in IR mice [33].

This increased capacity of MSCs to migrate out of the lungs and into injured kidneys may be due to MSCs' ability to produce or influence MMP activity [42]. MSCs can stimulate MMP production from cultured cardiac fibroblasts [57], and increased MMP-2 activity is likely the major mechanism for reducing lung fibrosis when administering umbilical cord MSCs [58]. Of further significance, the migration of MSCs into injured tissues is reliant on MMP-2-dependent degradation of the basement membrane [42,59].

## 51.4 Mechanisms of kidney injury and capacity for repair

A growing body of evidence suggests that MSCs can attenuate or reverse kidney damage, dependent on the severity of injury. However, the efficacy of MSCs is limited following a more chronic insult, with the accumulation of ECM protein leading to the establishment of fibrosis. The challenge of reversing kidney fibrosis is, in part, due to the difficulties in adequate cell replacement in order to preserve structure and improve function. The highly specialized and complex structural architecture of the kidney makes cell replacement difficult. The functional unity of the kidney consists of nephrons (containing a glomerulus), which are mainly responsible for filtration, and a series of connecting tubules, which are responsible for reabsorption. The tubulointerstitium surrounding the glomerulus comprises approximately 80% of kidney volume, predominately containing the renal tubules, and performs the majority of the critical functions of the kidney [60]. As such, it has a high energy demand and is thus susceptible to injury resulting from ischemic or fibrotic environments [61].

After transient injury the kidney has a remarkable ability to undergo endogenous repair, yet the underlying mechanisms are still under debate. Cochrane *et al.* [62] demonstrated the regenerative potential of the adult mouse kidney by inducing kidney injury using a unilateral ureteric obstruction (UUO) model and then reversing the ureteric ligation (RUUO) after 10 days. Six weeks after the reversal of injury, kidney fibrosis and macrophage infiltration were significantly decreased, and this correlated with an increase in GFR [62]. The origins of the cells that are responsible for this endogenous repair are an ongoing debate; however, data have demonstrated that, rather than a kidney stromal/progenitor cell inducing tubular regeneration, existing tubule cells undergo self-duplication whereby they dedifferentiate and proliferate to replace damaged tubular epithelial cells [63]. Rinkevich *et al.* [64] confirmed previous findings by Humphreys *et al.* [63], but further elucidated that tubular regeneration happens in a fate-restricted fashion. By inducing IR injury in rainbow mice that express green, yellow, blue, or red epithelial reporters, long segments of epithelial cells expressing a single colored reporter were found in the cortex, medulla, and papilla 2 months after injury. This suggests that each segment of the tubule is responsible for its own repair through proliferation of existing tubular cells; for example, cells isolated from the papilla only formed collecting ducts and not proximal or distal tubules [64]. Interestingly, by 7 months, single clones were also found in long segments of tubules without changes in renal mass, indicating that tubulogenesis continues into adulthood with a subset of tubular epithelial cells responsible for this maintenance [64].

Despite endogenous repair in the short term, there is an inextricable link between the severity of disease and the ability for the kidney to undergo endogenous repair. Studies have demonstrated that UUO in neonatal mice not only impairs the growth and development of the kidney, but that fibrosis persists even 28 days after RUUO [65]. Further studies by the same group showed that obstructing one kidney in neonatal mice had a significant effect on the contralateral unobstructed kidney, resulting in delayed maturation and atubular glomeruli [66]. More significantly, a growing number of patients are progressing to CKD after acute kidney injury. Hence, there is urgent need for therapeutic agents that can promote endogenous repair of the kidney and restore renal function.

## 51.5 Kidney injury and repair in balance with fibrosis

A hallmark of all kidney diseases is fibrosis, which results from aberrant wound healing. Inflammation plays an important role in initiating the fibrotic pathway, as the release of TGF-β from local and infiltrating immune cells activates fibroblasts, transforming them into myofibroblasts, which are responsible for the extensive collagen production in the renal parenchyma that ultimately leads to fibrosis [67] (Figure 51.1). Myofibroblasts are identified by their expression of α-SMA, and studies have demonstrated that DNA methylation might be responsible for sustaining fibroblast activation [68]. Fibroblasts isolated from mouse kidneys exposed to TGF-β1 demonstrated hypermethylation of the promoter region of the transcription factor RAS protein activator like 1 (Rasal 1) after 5 days of culture. The hypermethlyation of Rasal 1 was concurrent with extensive fibrogenesis and was shown to be dependent on DNA-methyltransferase (Dnmt) 1 as Dnmt knockdown mice were resistant to kidney fibrosis [69]. The exact mechanism of how Dnmt can hypermethylate genes is yet to be elucidated. The origin of myofibroblasts during kidney fibrosis has been the subject of considerable debate [70,71]. Many investigations have suggested that myofibroblasts are derived from cells undergoing

epithelial-to-mesenchymal transition, or endothelial-to-mesenchymal transition, or that pericytes and BM recruitment give rise to these cells [72–74]. However, data using transgenic knockout mice demonstrated that pericytes do not contribute to myofibroblast accumulation in the injured kidney and that, together, epithelial-to-mesenchymal transition and endothelial-to-mesenchymal transition only contribute approximately 15% of the myofibroblast pool [75]. Of further significance is that the proliferation of local fibroblasts and subsequent conversion into myofibroblasts contributed around half of the total myofibroblast accumulation within the kidney, while the migration and differentiation of BM cells was found to be responsible for an additional 35% of the myofibroblast pool [75]. Conversely, a study has demonstrated that circulating infiltrating BM cells do not contribute to the myofibroblast pool [75]; rather, tissue-resident Gli1$^+$ (glioma-associated antigen 1) progenitor cells transformed into myofibroblasts, while ablation of the Gli1$^+$ pool resulted in the amelioration of the fibrosis in lung, liver, heart, and kidney damage [76]. Understanding the mechanisms that perpetuate fibrosis is therefore important for the development of novel therapeutic agents that can target progression of disease.

The deposition of ECM widens the interstitial space, increasing the distance between the tubules and capillaries, thereby limiting the diffusion of oxygen through the interstitium and is a major contributor to the progression of kidney disease [77]. In a model of UUO, renal expression of EGF was significantly decreased, further exacerbating ischemia and leading to tubular apoptosis and capillary loss [78]. The vascularization of the kidney after injury can be determined using immunohistochemical (IHC) techniques with a marker for endothelial cells such as von Willebrand factor or CD31 [79,80], or with genetically modified animals with reporter genes for endothelial cells [81]. These methods, however, do not provide information about the perfusion state of capillaries and may give an overrepresentation of surviving capillaries as embolized and collapsed capillaries remain identified. The identification of endothelial cells has also been determined using a novel technique called fluorescent migroangiography (FMA) and has been validated with a tdTomato genetic reporter of endothelial cells [82]. (tdTomato protein is a very bright red fluorescent protein). FMA is a technique in which experimental animals are perfusion fixed with an agarose/fluorescent microbead mixture, after which the organs can be harvested and imaged, allowing the microvascular architecture to be quantified and reconstructed into a three-dimensional image [83]. The comparison of FMA and IHC markers to identify endothelial cells was made in a moderate and severe model of IR injury, and results confirmed that while some capillaries are positive for IHC markers, they may not be well perfused [82]. Thus, FMA may provide a more sensitive method for determining the difference in moderate and severe vascular changes in response to IR injury [82]. Hence, a critical component of the regenerating kidney is to also target the interstitial vasculature.

MSCs have demonstrated vasculogeneic and angiogenic properties in experimental models of acute kidney injury. This was first recognized by Tögel *et al.* [8] when they suspended human placental alkaline phosphatase$^+$ (hPAP) MSCs in Matrigel and administered them subcutaneously to rats. After 7 days the Matrigel was removed and hPAP cells were stained to reveal vascular-like structures *in vivo*. Furthermore, gene analysis revealed that MSCs express similar vascular tropic factors to those by endothelial cells, including VEGF-C, bFGF, heparin-binding EGF-like growth factor, and TNF-α, as well as high expression levels of IGF-1, VEGF-A, and VEGF-D [8].

## 51.6 Mesenchymal stromal cells as delivery tools for therapies

Since studies have demonstrated that MSCs can home to sites of inflammation and injury, it is plausible that MSCs could be used as a delivery tool for other therapeutic agents. As such, efforts have been made to increase MSC homing and efficacy through the transduction of MSCs with IGF-1 [84] and HGF-1 [85], with results demonstrating increased MSC engraftment, correlating with improved renal architecture compared with MSC therapy alone. Studies have previously shown that transducing MSCs with vesicles or growth factors can facilitate their homing into target organs [84,86,87], which is important in promoting MSC-mediated repair and also when considering the use of MSCs as therapeutic delivery tools [88].

Extracellular vesicles such as exosomes and microvesicles (MVs) have been considered as critical components for cell-to-cell communication. They differ based on a range of properties, such as size, surface markers, and biosynthesis, but are similar in the sense that that they are both able to deliver mRNA, microRNA (miRNA), and proteins to a target cell [89]. Extracellular vesicles are present in almost all cells, including MSCs [90]. Bruno *et al.* isolated and characterized MVs derived from MSCs and determined that CD44 and CD29 were essential for the fusion of MVs with tubular epithelial cells *in vitro*, but it was the transfer of RNA that was responsible for tubular cell proliferation and inhibition of apoptosis [90]. Further studies have described a protective effect of MSC-derived MVs in both acute and progressive models of kidney disease. Markers of kidney injury, such as tubular lesions, cell apoptosis, and blood urea nitrogen levels, decreased at early time points, while markers of CKD progression, such as serum proteinuria and tubulointerstitial fibrosis, were decreased 6 months after MV delivery [91]. MVs derived from endothelial progenitor cells (EPCs) have similar effects on kidney repair to those derived from MSCs, both of which can be reversed if RNAse is co-administered with the MVs [91,92]. Furthermore, genomic screening from MVs derived from EPCs showed 26 miRNAs specific to the MV that was not detected in the EPCs. These miRNAs differed from those isolated from fibroblasts: specifically, fibroblasts lacked miR-126 and miR-296, which are known

proangiogenic and antiapoptotic miRNAs [92], indicating that the source of MVs is critical in determining their ability to repair.

Studies with MSCs in experimental models of kidney injury are continuing to expand our knowledge of the mechanisms by which MSCs induce repair in acute and chronic models of kidney disease and the ways in which MSC efficacy can be enhanced (Table 51.1).

## 51.7 Clinical trials with mesenchymal stromal cells

Clinical trials with mesenchymal stromal cells are well underway for a variety of diseases, with safety consistently demonstrated [103] (Table 51.2). Tubulointerstitial fibrosis is not only a common phenotype observed in end-stage renal disease

**Table 51.1** Preclinical studies investigating MSCs derived from various sources to treat acute and chronic forms of kidney disease.

| Injury model | MSC source | Administration | Features | Reference |
|---|---|---|---|---|
| UUO | $1 \times 10^6$ BM-MSCs transfected with HGF. male Sprague Dawley rats | IV via tail vein into female Sprague Dawley rats | MSC localization into tubular epithelial cells of injured kidney; both MSCs and MSC-HGF showed decreased α-SMA expression | [85] |
| 45 min unilateral IR with contralateral nephrectomy | 30 μg of MV protein derived from human BM-MSCs | IV into male Sprague Dawley rats | Acute setting (2 days postinjury): decreased serum creatinine and BUN, increased tubule proliferation, decreased apoptosis. Chronic setting (6 months postinjury): decreased serum creatinine, BUN, proteinuria, and fibrosis | [91] |
| UUO | $1 \times 10^6$ human MSCs | Into the renal artery of male Sprague Dawley rats | MSC localization into renal cortex of injured kidney, increased epithelial cell preservation, decreased α-SMA, fibroblasts, and fibrosis | [47] |
| 5/6 nephrectomy | $0.5 \times 10^6$ BM-MSCs from male Sprague Dawley rats | IV via tail vein into male Sprague Dawley rats | MSC localization into injured kidney; improved renal function, increased morphological recovery, increased expression of Pax-2, bFGF, BMP-7, VEGF, and Tie-2; decreased tubular injury | [93] |
| UUO | $1 \times 10^6$ BM-MSCs from male Wistar rats | IV into the inferior vena cava | Decreased fibrosis, macrophage infiltration, and IFN-γ; increased expression of Foxp3 and IL-10 | [11] |
| Chronic aristo-lochic acid nephropathy | $2 \times 10^7$ BM-MSCs from male Wistar rats | IV via tail vein into female Wistar rats | MSC localization in the injured kidney; decreased TGF-β, BUN, creatinine, and proteinuria; increased morphological recovery and upregulation of HGF | [94] |
| Kidney transplantation: male Lewis rats received a kidney from male Fischer-344 rats | $0.5 \times 10^6$ $GFP^+$ BM-MSCs from male Sprague Dawley rats | IV via tail vein after 11 weeks of transplantation | No immunosuppression given posttransplant. No difference between treatment groups 1 week post MSCs; decreased tubular atrophy, fibrosis, lymphocytes, and macrophages | [95] |
| Anti-glomerular basement membrane glomerulo-nephritis | $3 \times 10^6$ human BM-MSCs | IV 4 days after postinjury in female WKY rats | MSC localization in the glomeruli and tubulointerstitium of injured kidney 5–48 h after administration but were not detectable by 7 days; decreased proteinuria, serum creatinine at late time points, decreased kidney weight, glomerular injury, apoptosis, TNF-α, IL-1β, IL-17, TGF-β, Col1 and Col3; increased IL-4, Foxp3, IL-10 | [96] |
| Cisplatin-mediated kidney injury | $2 \times 10^5$ BM-MSCs from male C57BL/6 J mice | IV into female C57B/6 J mice | MSC localization into peritubular areas of injured kidney preconditioning with IGF-1 increased MSC migration, improved renal function, and preserved morphology | [84] |
| 5/6 nephrectomy | $0.5 \times 10^6$ human adipose tissue-derived MSCs | IV via tail vein of male Sprague Dawley rats | MSC localization in the injured kidney; decreased BUN; increased morphological recovery, VEGF, Pax-2, and BMP-7 | [97] |
| Cisplatin-mediated kidney injury | $5 \times 10^5$ IV, $4 \times 10^6$ IP, or $1 \times 10^6$ renal subcapsular space BM-MSCs from C56BL/6 J $GFP^+$ mice | IV, IP, or renal subcapsular space | Improved renal function and morphological recovery regardless of route of administration | [98] |

(*continued*)

**Table 51.1** (*Continued*)

| Injury model | MSC source | Administration | Features | Reference |
|---|---|---|---|---|
| Cisplatin-mediated kidney injury | $1 \times 10^6$ BM-MSCs – male Sprague Dawley rats | IV into male Sprague Dawley rats | MSC localization in the peritubular space of injured kidneys; decreased BUN, serum creatinine; increased tubule proliferation and improved morphological recovery; decreased apoptosis and MAPKs phosphorylation | [99] |
| 5/6 nephrectomy | $1 \times 10^7$ MSCs transfected with GFP into Sprague Dawley rats | IV via tail vein at 4, 8, 12, and 16 weeks after injury in male Sprague Dawley rats | MSC localization in the glomeruli, tubular epithelial cells, and interstitial space at all time points; decreased fibrosis and glomerular injury; improved renal function at 4 and 8 weeks only | [100] |
| Type 1 diabetes mellitus | $1 \times 10^6$ BM-MSCs from male albino rats | IV into female albino rats | Improved renal function; increased Blc2 and Bax gene expression; decreased TGF-β and TNF-α expression | [101] |
| 40 min unilateral and 25 min bilateral IR | $1 \times 10^6$ human BM-MSCs | IV into C57BL/6 J mice | MSC localization in injured kidney; improved renal function; morphological recovery and tubular proliferation, decreased fibrosis and Kim-1 expression; increased MMP-9 expression | [33] |
| Polycystic kidney disease | $2.5 \times 10^5$ BM-MSCs from male Sprague Dawley rats | IA into the renal artery in female Sprague Dawley rats | No change in cyst number or size; blood pressure normalized; increased vascular density; decreased fibrosis | [102] |
| UUO | $1 \times 10^6$ human BM-MSCs | IV into C57BL/6 J mice | MSC localization into the obstructed kidney; increased morphological preservation; decreased fibrosis; increased MMP-2 | [56] |

Bax: blc-2-like protein 4; Bcl: B cell lymphoma; BMP: bone morphogenetic protein; BUN: blood urea nitrogen; Col: collagen; Foxp3: forkhead box p3; IP: intraperitoneal; IA: intra-arterial; Kim: kidney injury molecule; MAPK: mitogen-activated protein kinase; Pax-2: paired box gene 2; Tie-2: angiopoietin receptor-2.

**Table 51.2** Published clinical trials investigating the use of MSCs derived from various sources in the setting of solid organ kidney transplantation.

| Timing | Cell number and source | Patient number | Main results | Reference |
|---|---|---|---|---|
| 7 days after kidney transplant | Autologous BM-MSCs $1.7 \times 10^6$/kg and $2 \times 10^6$/kg | 2 | Restricted memory T cell expansion; enlarged regulatory T cell population; renal insufficiency from 7 to 14 days after MSC infusion; good graft function at follow-up 360 and 180 days posttransplant | [104] |
| TIP using MSCs | Various cell numbers of adipose-tissue-derived MSCs and hematopoietic stem cells from kidney donors | 916<br>Group 1: MSCs and HLA-matched<br>Group 3: MSCs and not HLA-matched<br>310 controls<br>Group 2: HLA-matched<br>Group 4: not HLA-matched | Patients receiving TIP (groups 1 and 3) had 1- and 4-year follow-up outcomes similar to those of HLA-matched controls (group 2). Groups 1–3 had increased patient survival and graft function compared with group 4. A percentage of patients in groups 1 and 3 (17–21%) had rejection episodes and were placed on conventional triple immune suppression, yet a further 5% developed chronic rejection and half of these lost the graft. Conclusion: MSCs are feasible for induction therapy | [105] |
| Induction therapy using MSCs. Kidney transplants from living related donors | Autologous BM-MSCs $1–2 \times 10^6$/kg | 159<br>Group A: MSCs + standard CNI<br>Group B: MSCs + low-dose CNI<br>Group C: Controls | Increased GFR in groups A and B versus group C, but only for the first month posttransplant; early time points showed that groups A and B had decreased acute rejection, but at 1-year follow-up no difference between any groups was observed; opportunistic infection decreased in groups A and B at 1-year follow-up. Conclusion: MSCs were safe and well tolerated | [49] |

**Table 51.2** (*Continued*)

| Timing | Cell number and source | Patient number | Main results | Reference |
|---|---|---|---|---|
| 1 day pretransplant | Autologous BM-MSCs $2 \times 10^6$/kg | 8 (2 subjects and 6 controls) | Decreased donor-specific cytotoxic and $CD8^+$ T cells. MSC infusion did not affect the graft. MSCs had comparable immunomodulatory effects as standard induction therapy. Follow-up at 1 year | [106] |
| If signs of rejection on renal biopsy at 4 weeks and at 6 months posttransplant | Two doses of autologous BM-MSCs $1–2 \times 10^6$/kg 7 days apart | 6 | Decreased donor-specific PBMC proliferation; resolution of tubulitis; MSCs were well tolerated | [107] |
| Patients who had already received pretransplant MSCs and who had stable graft function at >2 years with serum creatinine <2 | Allogeneic hematopoietic stem cells $17.5 \pm 5.5 \times 10^8$/kg. In 55 patients, donor adipose-tissue-derived MSCs were additionally administered | 76 | All immune-suppressive medication except prednisone was withdrawn from patients, with no adverse effects. No adverse rejection episodes. Follow-up $5.5 \pm 3$ years | [108] |
| Pretransplant infusion after living related donor kidney transplant and 1 month posttransplant | Kidney-donor-derived BM-MSCs delivered twice: $5 \times 10^5$/kg pretransplant and 1 month later $2 \times 10^6$/kg | 12 (6 subjects and 6 controls) | Standard immune suppression was able to be reduced in MSC group; no chimerism detected at 3 months; MSC recipients showed significantly higher B cell levels at 3 months compared with controls; MSCs were safe and well tolerated. Follow-up 1 year | [109] |
| Induction therapy 16 days pretransplant | Donor adipose-tissue-derived MSCs ($2.5 \times 10^2$/μL – total of 3 mL infused) and BM-HSCs ($2.18 \times 10^4$/μL – total of 99 mL infused) | 1 | Stable graft function with no immunosuppressive therapy from 6 months onwards. Follow-up to 35 months. | [110] |

CNI: calcineurin inhibitor; HLA: human leukocyte antigen; TIP: tolerance induction protocol.

(ESRD), but is also a common cause for renal allograft rejection [111]; as such, a number of ongoing clinical trials are investigating the use of MSCs in the kidney transplant setting [107] (see Chapter 56). While long-term studies are yet to be concluded, early reports demonstrate that MSC therapy is well tolerated as a form of induction therapy [49] and can also reduce fibrosis when subclinical rejection has started [112]. It is important to note, however, that the timing of MSC administration is a key factor in determining the outcome of such an approach, since MSC administration pretransplant restricted T cell proliferation, but when they were administered 7 days posttransplant they induced graft dysfunction [104]. Of importance, BM-MSCs from patients with ESRD had similar morphology, growth characteristics, mRNA expression profiles, and immunosuppressive properties to BM-MSCs isolated from healthy individuals [112]. This is important when considering autologous MSCs as a potential treatment.

With the discovery of MSCs, and more recently of embryonic stem cells and induced pluripotent stem cells, regenerative medicine has the potential to repair damaged tissues *in vivo*. Ultimately, patient-specific differentiated stromal cell-derived progeny may be used to home to and/or engraft at the site of injury and differentiate into specialized functional cells, replacing scar tissue [113]. However, this is proving to be challenging due, in part, to the complex interplay of regulatory mechanisms governing cell replacement and tissue remodeling. In addition, the reversibility of fibrotic tissue damage is dependent on the progression of the injury. Cell-based therapy is likely to be advantageous when used as a complement to existing therapies [114]. Despite the regenerative capacity in settings of acute kidney disease, the development of fibrosis in chronic disease models has been shown to hamper MSC survival and limits integration of transplanted cells into the host tissue, thus significantly impacting MSC-dependent repair and restoration of function [115–118]. Thus, the use of MSCs in conjunction with an antifibrotic agent, such as relaxin, may enhance cell viability and increase MSC-mediated tissue repair.

## 51.8 The antifibrotic functions of relaxin

Relaxin is an endogenous hormone first identified in 1926, when it was shown to be important in the relaxation of pelvic ligaments during pregnancy [119]. More recently, humans have been shown to express three relaxin peptides (H1, H2 and H3),

with a further four insulin-like peptides classified as members of the relaxin peptide family of hormones and distinguished from insulin and IGF by their ability to act through G-protein-coupled receptors [120].

Studies with relaxin-null and relaxin family peptide receptor (RXFP1)-null mice have demonstrated that endogenous relaxin plays an important homeostatic role in collagen regulation, as age-related fibrosis is often observed in these knockout mice as well as an inability to undergo sexual maturation [121–126]. Furthermore, in experimental models of kidney disease, relaxin-null mice had significantly higher fibrosis scores than wild-type mice; however, this was normalized with the administration of exogenous relaxin (serelaxin) [127]. The administration of exogenous serelaxin, a recombinant form of human relaxin 2, in a variety experimental models of renal disease, including papillary necrosis, renal mass reduction, and, more recently, cisplatin toxicity and IR injury, has abrogated disease-induced fibrosis [73,128–132]. In a UUO model of fibrosis, exogenously administered serelaxin suppressed TGF-β1 expression, mothers against decapentaplegic homolog 2 (Smad2) phosphorylation, and myofibroblast differentiation, which resulted in a marked reduction in renal collagen accumulation [73]. Importantly, serelaxin only targets TGF-β-induced fibrosis; thus, basal levels of collagen are unaffected [133].

In a number of cell culture and animal models of disease (reviewed in [133]) serelaxin was able to antagonize the actions of TGF-β by inhibiting Smad2 phosphorylation, a protein involved in the regulation of TGF-β1 signal transduction and activity [134]. Through this inhibition serelaxin optimally inhibits myofibroblast differentiation and subsequent collagen synthesis, while promoting MMP activity when circulating levels mimicked physiological serum concentrations during pregnancy [134]. An extension of these studies confirmed that serelaxin acted via RXFP1 and the nitric oxide (NO) pathway, specifically via a neuronal NO synthase (nNOS)–NO–cyclic guanosine monophosphate (cGMP)-dependent mechanism to disrupt Smad2 phosphorylation as a means of interfering with TGF-β1 signal transduction [135]. Furthermore, a secondary mechanism of the antifibrotic action of serelaxin was found that promoted collagen degradation by suppressing TGF-β1 activity and increased the availability of iNOS, and therefore NO, which in turn upregulated MMP activity [136].

In addition to its potent antifibrotic actions, relaxin contributes to the homeostasis of vascular function in many organs. Administration of relaxin generally has a vasodilatory effect on the vasculature of most organ systems. In the kidney this is complemented by a decrease in vascular resistance and an increased GFR [137]. Serelaxin has shown angiogenic properties that can contribute to blood vessel formation in diabetic skin wounds [138] and ischemic wound sites in the heart [139], while antiapoptotic actions have been observed in the injured heart [140] and kidney [73], suggesting that relaxin may be beneficial in the attenuation of scarring.

## 51.9 Combination therapy using mesenchymal stromal cells and relaxin

We have demonstrated that delivery of exogenous serelaxin improves MSC-induced renal repair and promotes protection from fibrotic injury [56] (Figure 51.1). In a UUO model of kidney fibrosis this combined therapeutic approach resulted in a significant decrease in collagen content compared with either MSCs or serelaxin delivered alone [56]. Of further significance, the synergistic actions of MSCs and serelaxin in protecting the obstructed kidney from fibrosis were likely due to their combined effect on the matrix degradation pathway, as only the combined delivery of both MSCs and serelaxin resulted in a significant upregulation of MMP-2 [56]. Macrophage infiltration and the collagen synthesis pathway were also investigated in this study. However, there was no apparent effect of combination therapy on infiltrating macrophages, α-SMA, or TGF-β expression [56]. Importantly, *in vitro* studies suggest for the first time that serelaxin may be influencing MSCs, as both the migration and proliferation capacity of MSCs were significantly increased when serelaxin was present [56]. Therefore, manipulating the inflammatory kidney microenvironment through the synergistic delivery of antifibrotic agents may aid in MSC efficacy and viability, and thus improve renal function over the long term.

Supportive evidence that stromal cell viability can be increased in the presence of serelaxin originated from heart failure models in rats and pigs. In a myocardial infarction model of heart failure, administration of serelaxin was found to prevent the progression of fibrosis by 30–40% in the infarct region and promoted angiogenesis while inhibiting cadiomyocyte apoptosis [140]. Seemingly, these actions of relaxin were what facilitated the beneficial effects of skeletal myoblasts engineered to express relaxin when administered in a rat chronic heart failure model [141]. After this combination treatment, postinfarct fibrosis progression was attenuated, while an improvement of cardiac function was observed. Previous studies by the same group suggested that stromal cell viability was increased when relaxin was present [139].

## 51.10 Conclusions

The development of fibrosis is the inevitable consequence of ESRD, regardless of etiology. Current treatment options for patients living with CKD can only slow the progression of the disease, with a substantial number still progressing to ESRD, for which dialysis or solid organ transplantation remain the only treatment options. Recent advances in our understanding of MSC recruitment and capability in response to microenvironmental cues raise new and exciting therapeutic possibilities to attenuate or conceivably reverse progressive renal disease in the context of fibrosis. Future therapeutic approaches can be

envisaged that capitalize on a cell-based therapy in combination with antifibrotics or proteins such as relaxin, to dampen inflammation, provide immune modulation, and promote normal tissue remodeling. With MSCs and relaxin already individually in clinical trials in a number of other indications, future options may include the combination of both MSCs and relaxin as an alternative for patients that respond poorly to currently available treatment. Alternatively, they could be used in the solid organ transplantation setting, to extend the life of the graft by preventing the chronic rejection that results from fibrosis. In addition, the advent of identifying reliable biomarkers that provide a good indication of the progression of kidney disease will aid in the optimal timing of MSC delivery together with existing or novel therapeutic agents.

## 52.1 Introduction to lung disease

### 52.1.1 The global burden of lung disease

Chronic lung disease is responsible for approximately 7% of all deaths worldwide and represents 4% of the global burden of disease [1,2]. This is evidenced by the economic cost of chronic lung diseases in the USA, which is $154 billion in health-care costs each year [3]. Notably, chronic obstructive pulmonary disease (COPD) accounts for most of the disease burden of lung diseases and will be the third leading cause of death worldwide by 2020 [4].

### 52.1.2 The pathogenesis of lung diseases

The lung has a unique structure of a complex series of branches that end in alveoli (or the gas exchange units). This unique structure makes the lung the largest organ exposed to the environment [5]. This large surface area has allowed the lung in humans to adapt to fight or flight situations by increasing oxygen consumption from 250 to 5500 mL/min and blood flow from 4 to 40 L/min [5]. This significant capacity to adapt has conferred an evolutionary survival advantage for humans and other mammals. We pay a price for the large surface area of the lung, since it is always susceptible to injury.

Inflammation is usually the initial phase in an injury caused by either infective or noninfective causes. A generic insult incurred from cigarette smoke or infection results in infiltration by neutrophils, lymphocytes, and macrophages. Furthermore, injury damages epithelium, endothelium, and the mesenchymal tissue of the lung. Two major processes are

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.

required for normal repair to occur. These are (1) epithelial and endothelial reconstitution and (2) an intact basement membrane on which the epithelial and endothelial cells can proliferate and repair damaged tissue. However if, there is inadequate reconstitution of epithelium and endothelium a fibro-proliferative phase occurs in which the lung develops scar tissue [6,7]. The fibrotic tissue is composed of fibroblasts, myofibroblasts, and an extracellular matrix comprising predominantly of collagen I.

Chronic tissue-remodeled lung disease is a major cause of morbidity and mortality, and the mechanisms of disease progression remain the subject of intensive research. Factors that have been implicated are increased oxidative stress and cellular senescence. The latter results in impaired telomerase function, resulting in defective repair [8]. In addition, upregulation of adhesion molecules promotes ongoing inflammation.

### 52.1.3 The range of lung diseases

The respiratory tract commences at the nasal passages and ends at the alveoli. The extensive branching of the trachea to bronchioles serves to increase the area for gas exchange and to filter potentially harmful organic and inorganic environmental agents. Thus, anatomically specific conditions such as allergic rhinitis and sinusitis are distinct from bronchitis, bronchiolitis, or diseases affecting the alveoli, such as hypersensitivity pneumonitis. Furthermore, the pleura and mediastinum are additional sites for disease.

The major lung diseases include:

1 Airways disease, such as cystic fibrosis, chronic obstructive pulmonary disease (COPD), bronchiectasis, and asthma.
2 Distal lung disease, such as pneumonia, lung cancer, tuberculosis, acute lung injury (ALI), idiopathic pulmonary fibrosis (IPF), sarcoidosis, interstitial pneumonias, and occupational lung diseases.
3 Airways and distal lung disease, such as lung cancer, tuberculosis, and sarcoidosis.

Unfortunately, the therapeutic options for these diseases are limited to bronchodilators, antimicrobial agents, immunosuppressive agents, and chemotherapeutic agents, as well as lung transplantation for a very small minority. However, these treatments do not adequately address the pathological repair and the progressive tissue remodeling of these disorders. Cell therapies have become an increasing focus of research and can act at several therapeutic levels. Pluripotent cells such as embryonic stem cells and induced pluripotent stem cells can be differentiated *in vitro* into epithelium and endothelium, thereby making them theoretically very useful for the reconstitution of damaged tissue. Multipotent cells such mesenchymal stromal cells (MSCs) can enhance tissue repair and positively immunomodulate pathological inflammatory responses. Cell therapies may provide important treatment options for these lung diseases.

## 52.2 What are stem cells?

Stem cells possess the following characteristics [9]:

1 Derivation from a clonal population and the ability to self-renew, thus creating daughter stem cells.
2 Unlimited doubling capacity.
3 Differentiation into many cell types.

The archetypal human adult stem cell is the hematopoietic stem cell, which gives rise to daughter stem cells and is also capable of differentiating to the cells of the hematopoietic and immune systems.

True mesenchymal *stem* cells have been shown to exist in the bone marrow (see Chapter 32), but are very rare cells; in order to obtain enough mesenchymal cells for laboratory studies, preclinical animal model studies, and clinical trials the undifferentiated progenies of mesenchymal stem cells are produced by *ex vivo* expansion (see Chapters 3, 4, 5 and 7). These cells are most commonly called mesenchymal *stromal* cells, and the abbreviation "MSCs" will be used in this chapter to denote them.

MSCs have anti-inflammatory properties that can reduce inflammatory pathways as well as possibly replacing damaged lung tissue. MSCs derived from different sources [10], including the placenta [11], umbilical cord, and adipose tissue (see Chapters 3–5 and 7), have these anti-inflammatory actions. MSCs are part of the connective tissue framework that provides both structural and physiological support to parenchymal cells in multiple organs. Since they form part of the wall of blood vessels they can be obtained from any vascularized tissue or organ.

## 52.3 What are mesenchymal stromal cells?

MSCs were first isolated by Friedenstein and colleagues in 1966 from suspensions of bone marrow and spleen [12]. According to the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy Standards [9], MSCs have three key characteristics:

1 MSCs are plastic-adherent when cultured under standard conditions.
2 MSCs express the cell surface proteins CD73, CD90, and CD105 and do not express CD45, CD34, CD14, CD11b, CD79α, CD19, or human leukocyte antigen (HLA)-DR surface molecules (see Chapters 1–5 and 7 for further details).
3 MSCs are capable of differentiating into the mesodermal lineages of bone, cartilage, and adipose tissue.

The identification of MSCs is not without difficulty since the listed cell surface markers are ubiquitous and found on dermal fibroblasts [13–15], but see Chapter 30 for features that distinguish MSCs from fibroblasts. MSCs are not a homogeneous cell population since some bone-marrow-derived MSCs (BM-MSCs) may be unipotent, bipotent, or tripotent in terms of their ability to differentiate to osteoblasts, chondrocytes, or adipocytes *in vitro*. This heterogeneity of BM-MSCs likely applies to MSCs derived from other organs such as the lung [16].

## 52.4 Lung-resident mesenchymal stromal cells

MSCs in the lung may provide support for normal epithelial and endothelial homeostasis. Lung MSCs have been isolated from broncho-alveolar lavage fluid and lung tissue [17,18]. McQualter *et al.* demonstrated a stem cell common antigen-$1^+$ population of MSCs in mice responsible for proliferation and differentiation of a bronchiolar epithelial stem/progenitor cell into both airway and alveolar lineages. These actions are mediated by the secretion of fibroblast growth factor [10] and hepatocyte growth factor (HGF) [19]. These studies confirmed that MSCs are central to the maintenance of normal lung function and structure.

## 52.5 Tracking mesenchymal stromal cells in the body

When injected intravenously, many studies have shown that the extensive capillary circulation within the lung acts as a filter for the MSCs and that few of them enter the systemic circulation [20,21]. As an example, intravenously injected indium-labeled MSCs homed to the lung and remained concentrated there for 48 h (Figure 52.1) [22]. The initial signal was strong for the first 20 min, followed by a decline during the subsequent 48 h.

This localization in the lungs is likely due to their large size: their diameter in a single cell suspension is approximately 100 μm, which is considerably greater than the diameter of a pulmonary capillary.

Further studies have suggested that MSCs retained in the lungs appear to target areas of injured lung [23]. Direct intratracheal, intrapulmonary, and intrapleural administration are alternative routes for the administration of MSCs to the lung [23]. As shown in Chapter 22, MSCs are able to pass through the lung barrier and subsequently preferentially home to a site of inflammation – in this case to a small skin incision on one side of the abdomen made just prior to an intravenous injection of murine MSCs. A similar response has been shown for unilateral kidney damage (see Chapter 51).

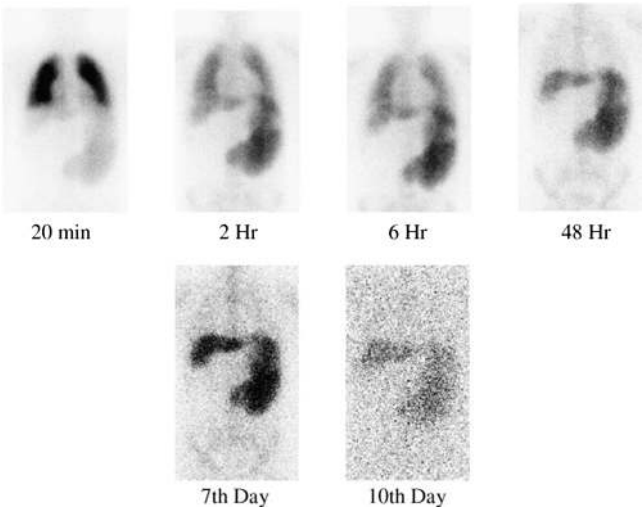

**Figure 52.1** Distribution of indium-labeled MSCs in the lungs, liver, and spleen over 10 days. *Source*: Gholamrezanezhad 2011 [22], pp. 961–967. Reproduced with permission of Elsevier. (See color plate section.)

## 52.6 The properties of mesenchymal stromal cells that favor repair

MSCs have several properties that make them a unique candidate for therapeutic use. They are relatively non-immunogenic, and direct injection into tissues or intravenous or intra-arterial infusion of MSCs in humans has not been associated with adverse events. The effects of MSCs may be dependent on tissue engraftment (although this is controversial), modulation of the immune system, and/or release of trophic (supportive) factors. (See Chapter 32 for an account of their critical role in the survival, growth, and differentiation of hematopoietic stem cells in the bone marrow.)

### 52.6.1 Avoidance of immune recognition

MSCs are able to evade the recipient's immune system (at least to some extent – see Chapter 29), thus enabling the administration of allogeneic MSCs from unrelated HLA-unmatched donors without need for immunosuppression of the recipient. Human MSCs express low levels of major histocompatibility complex (MHC) class I and do not express MHC class II [25]. However, there is a suggestion that MSCs that have differentiated into myocytes may demonstrate upregulation of MHC molecules, leading to their destruction by complement- and/or cell-mediated lysis [26,27]. Furthermore, evidence from a primate model described the development of alloantibodies in two of six animals following multiple administrations of high-dose allogeneic MSCs [28]. In addition, MSCs have also been reported to induce memory T cell responses [29] and activation of the natural killer (NK) cell receptor ligands NKG2D and UL16 [30] in a murine model, thus limiting their ability to avoid lysis by NK cells [31]. Caution must therefore be exercised in future clinical studies that utilize multiple injections of allogeneic MSCs.

### 52.6.2 Mechanisms of mesenchymal-stromal-cell-mediated immunomodulation

MSCs play a major role in immunomodulation and tissue homeostasis. MSCs protect the microenvironment from inflammatory insults by reciprocal regulation of innate and adaptive components of the immune system. These properties have sparked interest in their use as immunosuppressive agents to alleviate chronic inflammatory diseases and graft rejection. The overall regulatory effect of MSCs is a result of many mechanisms that rely on soluble mediators and/or cell-to-cell contact (see Table 52.1).

#### 52.6.2.1 Macrophages

Macrophages are capable of differentiating into pro-inflammatory (M1) and anti-inflammatory (M2) phenotypes. M1

**Table 52.1** Immunomodulatory effects of MSCs.

| Cell type | Mediators | Effects |
|---|---|---|
| *Innate immune system* | | |
| Macrophages | $PGE_2$, IL-6, GM-CSF | ↓ MHC class II, CD86 expression<br>↓ M1 differentiation<br>↑ M2 differentiation<br>↑ IL-10 production |
| Neutrophils | IL-6 | ↓ Oxidative metabolism<br>↓ Apoptosis |
| Mast cells | $PGE_2$, TGF-β1 | ↓ Degranulation<br>↓ Chemotaxis<br>↓ Cytokine production |
| DCs | IL-6, $PGE_2$ | ↓ Maturation<br>↓ Co-stimulatory molecule expression<br>↓ Lymph node migration<br>↓ Endocytosis<br>↑ Regulatory DC generation<br>↑ DC tolerance |
| NK cells | $PGE_2$, TGF-β1, IDO | ↓ Proliferation<br>↓ Cytotoxicity<br>↓ IFN-γ, TNF-α production<br>↓ Activating receptor expression |
| *Adaptive immune system* | | |
| T cells | NO, HGF, PD-1, $PGE_2$, TGF-β1, sHLA-G5 | ↓ Th1 activity<br>↑ Th2 activity<br>↓ Th17 activity<br>↓ $CD8^+$ T cell cytotoxicity<br>↑ IL-10-producing Tregs |
| B cells | PD-1, IDO | ↓ IgG, IgA, and IgM production<br>↓ Plasmablast differentiation<br>↓ Chemokine receptor expression<br>↑ IL-10-producing Bregs |

Breg: regulatory B cell; DC: dendritic cell; GM-CSF: granulocyte-macrophage colony-stimulating factor; IDO: indoleamine 2,3-dioxygenase; IFN: interferon; Ig: immunoglobulin; IL: interleukin; NO: nitric oxide; PD-1: programmed cell death protein 1; $PGE_2$: prostaglandin-$E_2$; TGF: transforming growth factor; Th: T helper; TNF: tumor necrosis factor; Treg: regulatory T cell.

macrophages possess an antimicrobial arsenal that enables them to engulf and destroy invading pathogens, as well the production of an array of proinflammatory cytokines and antimicrobial molecules such as NO. In contrast, M2 macrophages suppress the immune response by producing anti-inflammatory cytokines such as IL-10. MSCs thus favor the activity of M2 macrophages while antagonizing M1 activity. MSCs also downregulate the expression of CD86 and MHC class II on macrophages to reduce their responsiveness to inflammatory stimuli [32]. These effects been shown to occur in a process dependent on prostaglandin-$E_2$ ($PGE_2$), which is constitutively produced by MSCs but can be upregulated in response to proinflammatory cytokines. Moreover, MSC-derived IL-6 and granulocyte-macrophage colony-stimulating factor can synergistically favor the polarization of M2 macrophages. Further information on the interactions between MSCs in the innate and immune systems are given in Chapters 33 and 34.

#### 52.6.2.2 Neutrophils

Neutrophils play an important role in the first line of defense against pathogens. Neutrophils release an array of reactive oxygen species in a process called respiratory burst which is used as a defense mechanism against invading microbes. Accumulation of reactive oxygen species is highly inflammatory and is associated with the rapid apoptosis of neutrophils. In an IL-6-dependent manner, MSCs inhibit respiratory burst and rescue neutrophils from apoptosis. In contrast, the phagocytic capacity, expression of adhesion molecules, and chemotaxis of neutrophils in response to IL-8 are not affected, suggesting that MSCs may act to preserve critical neutrophil functions while preventing

excessive oxidative burst and subsequent inflammation or tissue damage [33].

#### 52.6.2.3 Mast cells

Mast cells play a critical role in allergic responses and anaphylaxis through the release of proinflammatory cytokines and the degranulation of histamine. After interacting with MSCs mast cell functions, including chemotaxis, degranulation, and cytokine production are severely inhibited. These processes were found to be dependent on MSC-derived $PGE_2$ [34]. Moreover, in response to IL-4, TGF-β1 produced by MSCs contributes to the attenuation of mast cell degranulation by reducing FcεRI expression [35]. The high-affinity receptor FcεRI is a member of the Ig superfamily. It has two Ig-like domains. FcεRI is found on epidermal Langerhans cells, eosinophils, mast cells, and basophils. As a result of its cellular distribution, it plays a major role in controlling allergic responses. FcεRI is also expressed on antigen-presenting cells and controls the production of cytokines that mediate immune reactions that promote inflammation. (ε is the Greek symbol epsilon and is the fifth letter in the Greek alphabet.)

#### 52.6.2.4 Natural killer cells

NK cells are cytotoxic cells of the innate immune system that are pivotal to immune surveillance against intracellular pathogens and malignant cells. The cytotoxic effects of NK cells are regulated by both activating and inhibiting receptors but can also be activated following antibody recognition during antibody-dependent cellular toxicity. Following stimulation by MSC-derived $PGE_2$ and TGF-β1, NK cell cytoxicity and proliferation were inhibited. Moreover, expression of proinflammatory cytokines, IFN-γ, and TNF-α and activation of the $PGE_2$ receptor 4 (EP4) and NKG2D were reduced [31]. (NKG2D is a transmembrane protein belonging to the CD94/NKG2 family of C-type lectin-like receptors. In humans it is expressed by NK cells, γδ T cells, and $CD8^+$ αβ T cells. NKG2D is an activating/costimulatory receptor.)

The activity of IDO in MSCs may also operate synergistically with $PGE_2$ to inhibit NK cell function [36]. IDO is an enzyme that produces the immune regulatory catabolite tryptophan. Although IDO is not the mediator, immune regulation via this pathway is dependent on IDO activity. Some mechanisms have been proposed but remain uncharacterized.

#### 52.6.2.5 Dendritic cells

Dendritic cells (DC) are classified as the interface between the innate and the adaptive immune systems by capturing, processing, and presenting antigens to T cells (see Chapters 33 and 34). DC activity is pivotal to the polarization of T cell responses. During DC maturation there is an upregulation of several signals that augment T cell priming. Culturing MSCs with DCs showed reduction of the activating potential of DCs by diminishing their endocytic activity, migration to lymph nodes, and expression of costimulatory molecules (CD40, CD80, CD83, and CD86) following stimulation [37]. Soluble factors produced by MSCs have also been shown to inhibit monocyte differentiation to DCs. Furthermore, the presence of MSCs skews DC differentiation to a regulatory phenotype to promote the expansion of Tregs, thus contributing to the state of immunosuppression. These effects are largely attributed to the action of IL-6 and $PGE_2$, but unknown contact-dependent mechanisms have also been suggested [38,39]. Overall, MSCs promote DC tolerance by attenuating their ability to prime the adaptive arm of the immune response.

#### 52.6.2.6 B cells

B cells play a protective role against pathogens by producing highly specific antibodies that serve to neutralize pathogens as well as to enhance effector cell functions. *In vitro* studies have demonstrated that MSCs inhibit B cell proliferation by cell cycle arrest [40]. In addition, MSCs downmodulate IgM, IgG, and IgA production and chemokine receptor expression [41]. A contact-dependent mechanism involving PD-1 (also known as CD279) has been implicated in this process. However, soluble factors also play a role [42]. More recently, the discovery of a new Breg subset has highlighted novel functions for B cells. Following MSC infusion the proportion of IL-10-producing Bregs was increased in a model for graft-versus-host disease. This was at least partially dependent on IDO expression [43].

#### 52.6.2.7 T cells

T cells are classified into several subsets that can directly kill pathogens (cytotoxic T lymphocytes (CTLs)) or help coordinate immune responses (T helper (Th)1, Th2, or Th17 cells). MSCs strongly inhibited T cell proliferation, which required MSC-derived HGF, TGF-β1, and NO produced by inducible NO synthase [44,45]. This effect was also exacerbated by the action of MSCs on other immune cells, including DCs for which T cell activation is dependent. In contrast to the effects on cytotoxic and Th cell subsets, MSCs increased the proportion of IL-10 producing Tregs, which are an immunosuppressive T-cell subset. MSC blocking studies confirmed soluble HLA G5 (sHLA-G5) to be a mediator of this effect. However, contact between cells was required to maximize the production of sHLA-G5 [46].

MSCs promote IL-4-producing Th2 cells, which exert an anti-inflammatory effect and inhibit IFN-γ-producing Th1 cells, which are generally considered proinflammatory. $PGE_2$ appears to be one of the strongest mediators for regulating this balance [47], although several other soluble factors, including IDO, may have additive effects [48]. Furthermore, Th17 development and subsequent IL-17 production are also markedly impaired; this is also dependent on $PGE_2$ production, PD-1/PD-L1 ligation, and other cell-to-cell contacts by MSCs [49,50]. Finally, MSCs also impair the activity of CTLs. *In vitro* studies have shown that co-culture with MSCs reduced the expression of IFN-γ, CD8, and granzyme-B production in CTLs, which markedly inhibited their cytotoxicity. It has been suggested that the inhibition of CTL activity is indirectly a result of diminished DC activity [51].

### 52.6.3 Mesenchymal-stromal-cell-mediated repair via trophic factors

There has been ongoing controversy as to whether MSCs engraft or release trophic factors that mediate their effects. Early studies demonstrated differentiation into mesodermal-derived tissue such as adipose and bone and muscle. In addition, there were reports that MSCs also differentiated into non-mesodermal-derived tissue, including bronchial epithelium, renal epithelium, neuronal tissue, and cardiomyocytes [52]. However, it is becoming increasingly evident that the effect of MSCs is not dependent on engraftment. The paradigm change was stimulated by a study of MSCs in people with osteogenesis imperfecta (brittle bone disease), a congenital disease of defective connective tissue usually because of a deficiency of type I collagen (see Chapter 47). In this study there was a very low level of engraftment in the bone marrow (<1%), while significant functional improvements were noted [53]. There are also studies that demonstrate a treatment effect without significant engraftment in other organs, including the brain [54], heart [55], and kidney [56].

#### 52.6.3.1 Growth factors

Several studies have shown that growth factors have a role in mediating repair. In an innovative explant (perfused) lung model, Lee *et al.* subjected the lung to lipopolysaccharide (LPS, also known as endotoxin) injury that increased alveolar permeability. MSCs inhibited the increase in capillary permeability. These researchers knocked-down several growth factors, including HGF, fibroblast growth factor, and keratinocyte growth factor (KGF), but found that only KGF knockdown inhibited the actions of MSCs [57]. Although HGF has not been noted to have mediated repair in the lungs, it has been found to mediate improvement in a model of acute kidney damage [58].

#### 52.6.3.2 Microvesicles

A compelling development in MSC research is the discovery that MSCs release microvesicles (MVs) (see Chapters 1, 10, 20 and 38). These MVs are biologically active and appear to mediate repair as effectively as MSCs themselves. MVs are nuclear plasma-membrane-bound circular fragments of 50–200 nm in size that are constitutively released from the endosomal compartment as exosomes or shed from the plasma membrane [38,59]. The MVs derived from MSCs also appear to be as immune-privileged MSCs themselves, since they express very low levels of MHC class I or class II antigens. A wide variety of molecules are carried by MVs, including microRNA (miRNA), mRNA, and proteins.

Studies have shown that MSC-derived MVs augmented repair in a murine glycerol-induced model of acute kidney injury by increasing the proliferation of renal tubular cells [60]. The hypothesized mechanism is that the MSC MVs homed to, and were incorporated into, the injured tubular cells via the surface receptor CD44 (the extracellular matrix receptor type III for hyaluronic acid), thus allowing for transfer of MSC MVs' mRNA. Another study found that MSC MVs attenuated pulmonary edema and lung protein permeability in an *Escherichia coli* endotoxin-induced ALI in mice through the expression of KGF mRNA in the injured alveoli [61]. In another study, Gennai *et al.* demonstrated that MSC MVs improved alveolar fluid clearance in an *ex vivo* perfusion model [62]. The administration of intravenous MSC MVs improved lung mechanics and induced a reduction of pulmonary artery pressure that was probably due to an increase in NO. The internalization of MVs into injured cells was mediated through the CD44 receptor [62]. This is further evidence that MSC MVs are a potentially important new tool in the treatment of lung diseases.

#### 52.6.3.3 Mitochondria

Another proposed mechanism for the reparative effects of MSCs is the transfer of normal MSC mitochondria to injured cells. In a seminal study, Islam *et al.* demonstrated that mitochondrial transfer rescued injured cells by improving their energetics [63] (see Chapters 10 and 21 for further details).

#### 52.6.3.4 mRNA and microRNA

The contents of MSC MVs extend to miRNA. Eirin *et al.* documented the contents of extracellular MVs derived from adipose-tissue-derived MSCs. MVs preferentially expressed mRNA for transcription factors such as MyoD family inhibitor domain containing (MDFIC), POU domain, class 3, transcription factor 1 (POU3F1), and nuclear receptor-interacting protein 1 (NRIP1), as well as genes involved in angiogenesis, such as HGF, transcription factor HES1 (hairy and enhancer of split-1) and TCF4 (sometimes referred to as immunoglobulin transcription factor 2TCF4). In addition, mRNA for genes involved in adipogenesis, such as CCAAT/enhancer binding protein alpha and Kruppel-like factor 7, were preferentially expressed in these MVs. In addition, they also carried miRNAs miR148a, miR532-5p, miR378, and let-7f. This study demonstrated that MSC MVs can carry miRNA with the potential to modify recipient tissue function [64].

In a mouse model of hypoxia-induced pulmonary hypertension, MVs downregulated miR-17 and upregulated miR-204. miR-17 is associated with signal transducer and activator of transcription 3 signaling and is upregulated in pulmonary hypertension [65]. MiR-204 is downregulated in IPF with pulmonary hypertension [66]. The change in the profile of miRNA following MV injection supports the potential therapeutic role of MVs in therapy.

## 52.7 Mesenchymal stromal cells as delivery agents for drugs

MSCs not only are used as direct therapy for lung disorders but may also be used as engineered vectors for drug delivery to specific sites (see Chapters 61 and 62).

### 52.7.1 Viral transduction

In a study by Sage *et al.* MSCs were transduced using a lentiviral vector to express TNF-related apoptosis-inducing ligand

(TRAIL) [67]. TRAIL is a proapoptotic molecule for cancer cells but does not affect healthy cells. These cells were used to treat pleural mesothelioma in mice. MSCs were delivered directly into the tumor or systemically in a mouse model of mesothelioma. Intravenously administered MSCs resulted in increased engraftment and tumor reduction due to elevated apoptosis. Of note was that intrapleural instillation of MSCs were not as effective [67]. This study elegantly illustrated that MSCs can be engineered to express therapeutic molecules for the treatment of specific diseases.

### 52.7.2 Genetic modulation

Several strategies to modify MSC protein expression include genetic modulation by viral and nonviral transduction. Viral transduction is potentially dangerous in human subjects. Therefore, nonviral strategies designed to increase the permeability of the cell membrane and nucleus have been utilized to improve transfection, including electroporation. Such techniques have been used to increase MSC survival by expression of the anti-apoptotic molecule Bcl-2, improve homing of cells to sites of injury via C–X–C motif chemokine ligand 4 and to deliver bone-forming molecules such as bone morphogenetic protein 2 and TGF-β to facilitate bone repair [68].

### 52.7.3 Nanoparticle incorporation

In addition to genetic manipulation, nanoparticles can be incorporated into MSCs to enable the expression of specific molecules via cellular internalization. Nanoparticles can be endocytosed. In addition, nanoparticles can be incorporated into cells by lipid fusion. Nanoparticles are taken up by the cell and released through endocytosis by fusion with the cell membrane [68].

### 52.7.4 Surface modification

The homing of MSCs can be enhanced by modifying their cell surface characteristics. Since selectins are upregulated on the endothelium of injured tissue, Xia *et al.* enzymatically modified umbilical cord blood cells to express selectin binding motifs and increased MSC delivery to sites of injury [69]. Increased delivery of MSCs can also be achieved through chemical modification by covalently coupling target ligands to the cell surface [70]. Another strategy is to chemically paint MSCs with palmitated-ischemia homing particles that also improve MSC trafficking to injured tissue [71].

### 52.7.5 Preconditioned mesenchymal stromal cells

MSCs can be further manipulated for their application in lung diseases. Lan *et al.* demonstrated that exposing MSCs to a hypoxic environment improved repair in a bleomycin-induced model of lung injury. The hypoxia exposure improved the homing characteristics of MSCs [72]. It is possible that MSCs alone may be surpassed by engineered MSCs for a variety of specific tasks in the treatment of cancer and tissue injury.

## 52.8 Preclinical and clinical studies of mesenchymal stromal cells in pulmonary diseases

MSCs have been the focus of a significant number of preclinical trials. Several different animal models have been used to test the efficacy and mechanisms of these cells. In this chapter we have limited our discussion to IPF, COPD, and acute respiratory distress syndrome (ARDS). However, we have included a summary of selected preclinical studies of pulmonary hypertension (Table 52.2), asthma (Table 52.3) and bronchopulmonary dysplasia (Table 52.4).

### 52.8.1 Idiopathic pulmonary fibrosis

#### 52.8.1.1 Epidemiology of idiopathic pulmonary fibrosis

Lung fibrosis is a term that applies to scarring of the lung. IPF is a severe and progressive lung disorder resulting from damage to

the lung tissue by inflammation and fibrosis with a median survival from diagnosis of 2–5 years [92]. IPF has an incidence ranging from 4/100 000 in persons aged 18–34 years to >200/100 000 among those above 75 years of age [93].

#### 52.8.1.2 Pathogenesis of idiopathic pulmonary fibrosis

The pathogenesis of IPF (Figure 52.2b) demonstrates the cycle of injury and remodeling of the distal lung. The process results in the characteristic radiology of bibasal honeycombing, reticular distortion, and traction bronchiectasis (Figure 52.2b) [94]. The histopathology of IPF typically shows the presence of fibroblastic foci, fibrosis and honeycombing (Figure 52.2c) [92]. Chronic remodeling of the lung results in the loss of gas-exchange units and the clinical features of IPF.

#### 52.8.1.3 Limitations of the preclinical model of idiopathic pulmonary fibrosis using bleomycin

Animal models have been predominantly used in bleomycin-induced lung injury (Table 52.5). This model has its limitations when compared with human IPF. The bleomycin-induced murine model is characterized by inflammation and fibrosis. In contrast, inflammation is not a major feature of IPF. Furthermore, the bleomycin model is a transient disease model with recovery over 6–8 weeks, and tissue remodeling such as honeycomb formation is not significant. Thus, the preclinical studies in mice may not reflect the outcomes for people with IPF. The timing of MSC administration in the bleomycin mouse model is important. MSCs administered within 24 h of bleomycin injury attenuated inflammation and fibrosis. MSCs administered 7 days after bleomycin injury did not attenuate fibrosis. This finding suggests that MSCs reduce inflammation and the downstream effects of fibrosis as opposed to having a direct antifibrotic effect. This was confirmed in a study by our group comparing the effects of several types of adult stem cells in which MSCs did not have a major impact on reducing established fibrosis.

#### 52.8.1.4 The safety of mesenchymal stromal cells in a clinical trial in patients with idiopathic pulmonary fibrosis

Human studies using MSCs in IPF have been performed. Chambers *et al.* demonstrated that placenta-derived MSCs were safe to administer systemically in IPF patients, although at 6 months the forced vital capacity, diffusing capacity for carbon monoxide, 6 min walk distance, and computed tomography fibrosis score were unchanged compared with baseline. There was no evidence of worsening fibrosis [99].

## 52.8.2 Chronic obstructive pulmonary disease

### 52.8.2.1 Chronic bronchitis and emphysema

COPD is the commonest respiratory condition in the world. It ranks amongst the top five causes of global morbidity and mortality, with 1.2 million patients in Australia [100]. COPD has two broad definitions that incorporate characteristics of the clinical features.

Chronic bronchitis is defined as daily sputum production for three consecutive months for two consecutive years and involves damage to the airways and the chronic production of mucus.

Emphysema is a radiological definition in which there is dilatation of the distal air spaces beyond the terminal bronchi. The damage to the distal lung in COPD is due to loss of elastin. These well-established definitions, however, do not take into account the complexity of COPD in which some patients deteriorate, lose weight, or have frequent acute exacerbations. A consensus statement released by the Global Initiative for Chronic Obstructive Lung Disease based on symptoms and lung function tests has been published [101].

### 52.8.2.2 Pathogenesis of chronic obstructive pulmonary disease

COPD is characterized by chronic irreversible inflammation and destruction of lung tissue leading to airflow obstruction and loss of gas-exchange units [102]. Smoking is the major risk factor for COPD, resulting in damage to the epithelium and endothelium in the lungs. There is increased oxidant and inflammatory damage resulting in infiltration and activation of immune cells, including neutrophils, macrophages, and $CD4^+$ and $CD8^+$ T cells in the airways of COPD patients [102]. Cell infiltration is driven by cytokines, chemokines, and growth factors. Other pathogenic features of COPD include the imbalance between matrix metalloproteinases (MMPs) and tissue inhibitors of MMPs. The increase in MMPs causes breakdown of the extracellular matrix in the lung, especially of elastin. This causes gas trapping, resulting in physical discomfort. In addition, there is increased apoptosis of alveolar epithelial cells that results in loss of gas-exchange units. The progressive inflammation in the lung also induces a heavy oxidant burden, resulting in cell death. COPD-associated injuries are not limited to the lung but also result in systemic inflammation with an increased incidence of ischemic heart disease, vascular disease, muscle wasting, and cachexia [102].

### 52.8.2.3 A preclinical model of chronic obstructive pulmonary disease: the use of mesenchymal stromal cells in smoke and papain-induced emphysema

Several studies in animal models have demonstrated that MSCs may address the fundamental defects in COPD (Table 52.6).

MSC infusion in a rat model of smoking-induced emphysema reduced proinflammatory cytokines including IL-1β, IL-6, TNF-α and MCP-1 and proteases including MMP-9 and MMP-12, but increased anti-inflammatory cytokines such as TGF-β. In addition MSCs also decreased alveolar epithelial apoptosis. Mechanisms for this inhibition of apoptosis were likely down-regulation of Bax and upregulation of Bcl-2 in a papain-induced emphysema model [104]. MSCs reduce cleavage of caspase-3 and increase VEGF, which also inhibit cell apoptosis [103].

COPD is also characterized by an increase in the oxidant : antioxidant level induced by the transcription factors nuclear factor kappa light chain-enhancer of activated B cells and activator protein 1. The increase in oxidant levels in COPD results in increased inflammation, DNA damage, MMP levels, and cell apoptosis [107,108]. MSCs have been shown to decrease oxidant stress in an animal model [109,110]. Mechanisms include decreasing malondialdehyde and increasing heme oxygenase-1 levels in the lung with consequent cytoprotective effects. Thus, preclinical studies have shown that MSCs can improve pathogenic outcomes in COPD by addressing specific events in the course of the disease.

**Table 52.6** Therapeutic effects of MSC infusion on smoke- and papain-induced emphysema.

| Beneficial effects | Species | MSC source | Reference |
|---|---|---|---|
| ↑ Lung function | Sprague-Dawley rat | BM – Sprague-Dawley rat | [103] |
| ↓ Emphysema | Sprague-Dawley rat | BM – Sprague-Dawley rat | [103] |

| ↑ VEGF | Sprague-Dawley rat | BM – Sprague-Dawley rat | [103,106] |
| ↑ Anti-inflammatory cytokines (e.g., TGF-β) | Sprague-Dawley rat | BM – Sprague-Dawley rat | [103] |

BM: bone marrow.

#### 52.8.2.4 Safety of mesenchymal stromal cells in chronic obstructive pulmonary disease

Weiss *et al.* carried out studies on the safety of human MSCs in COPD patients [111]. Sixty-two patients were randomized to double-blinded intravenous infusions of either allogeneic MSCs or vehicle control. Patients received four monthly infusions ($100 \times 10^6$ cells/infusion) and were followed up for 2 years. All patients completed the trial protocol, and 74% completed the 2-year follow-up. There were no toxicity or adverse side effects noted. There was no difference in the frequency of COPD exacerbations or worsening of disease in patients treated with MSCs versus controls. There was also no difference in pulmonary function tests or quality-of-life indicators between MSC-treated patients and control patients. Interestingly, there was a drop in the inflammatory marker C-reactive protein in MSC-treated patients who had elevated C-reactive protein levels at entry of the study. The authors concluded that intravenous administration of MSCs was safe in patients with moderate to severe COPD [111]. There are several ongoing studies delineating a potential role of MSCs as a treatment for COPD.

### 52.8.3 Acute lung injury and acute respiratory distress syndrome

#### 52.8.3.1 Epidemiology of acute lung injury/acute respiratory distress syndrome

ALI and the more severe ARDS are the commonest cause of acute respiratory failure in hospitalized patients. ALI is defined as the ratio of arterial oxygen partial pressure to fractional inspired oxygen ($PaO_2 : FiO_2$) of <300, while the more severe ARDS is defined as a ratio of <200. ARDS is characterized by refractory hypoxemia in patients with bilateral lung infiltrates in the absence of cardiogenic pulmonary oedema [112,113]. A National Institutes of Health study estimated the incidence of ARDS to be 75 per 100 000 population in the USA with a mortality rate of 40–70% [114].

#### 52.8.3.2 Pathogenesis of acute lung injury/acute respiratory distress syndrome

ARDS can be caused by direct or indirect injuries to the lung, including aspiration of gastric contents and sepsis [115]. The early phase of lung injury is characterized by epithelial and endothelial cell damage leading to a compromised alveolar–capillary barrier and exudation of fluid into the alveolar space, followed by infiltration of inflammatory cells such as neutrophils. Progression from acute lung injury to fibrosis is observed 5–7 days after the injury [116], and this phase predicts a poor prognosis [117]. Current therapies, such as lung-protective ventilation and a fluid-conservative strategy, although useful, are of limited efficacy [118,119]. Thus, innovative therapies are needed to address the fundamental defects in ARDS. Human MSCs exhibit anti-inflammatory and proreparative properties that may be beneficial in ARDS.

#### 52.8.3.3 Preclinical model of acute lung injury/acute respiratory distress syndrome by endotoxin- or bleomycin-induced lung injury

To date MSCs have been studied extensively in preclinical lung injury models (Table 52.7) [118,130]. Most of the injuries involved intratracheal endotoxin exposure or bleomycin administration, and rodents were the main small animals studied. There have also been studies in larger animal models. In the sheep model of bacterial pneumonia Asmussen *et al.* used a cotton smoke inhalation model and infection with pseudomonas to determine if human MSCs could improve this sheep model of pneumonia [122]. At 24 h after the administration of human MSCs pulmonary artery pressures were reduced and the $PaO_2/FiO_2$ ratio was increased. There were no differences in airway pressure between control sheep and MSC-treated sheep. There were also no difference in any physiological parameters between controls and MSC-treated groups at time points before 24 h [122].

ARDS is also characterized by decreased alveolar fluid clearance due to increased epithelial permeability and high levels of proinflammatory molecules, which allows the influx of protein-rich fluid into the alveoli. MSCs secrete KGF, an epithelial growth factor that increases alveolar clearance by upregulating α-epithelial sodium channel gene expression and Na/K-ATPase activity or by enabling increased trafficking of sodium transport proteins to the cell surface [57,131–133]. Factors such as angiopoietin-1, a ligand for the endothelial Tie2 receptor, increase endothelial stabilization, thus reducing endothelial permeability. Angiopoietin-1 also inhibits leukocyte–endothelium interactions by modifying cell adhesion molecules and cell junctions [134,135].

Specific actions of MSCs in relation to ARDS that could modify the disease include immunomodulation: the anti-inflammatory stimulation of T regulatory lymphocytes (Tregs) and the increase of M2 macrophages could reduce the intense inflammation seen in ARDS. Sun *et al.* demonstrated prevention of ALI by MSC administration, and this correlated with increased levels of anti-inflammatory Tregs and the anti-inflammatory cytokine IL-10 while reducing levels of proinflammatory cytokines such as IFN-γ and TNF-α [129].

MSCs also secrete antimicrobial factors that could improve the outcome of sepsis as a cause for ARDS. MSCs have toll-like receptors and formyl peptide-like receptors that are activated in response to bacterial products [24,136]. MSCs can inhibit bacterial growth by secretion of antimicrobial peptides such as LL-37 [128] and antibacterial proteins such as lipocalin-2 [120]. These improved bacterial clearance in a mouse model of *Escherichia coli* pneumonia. MSCs can also improve bacterial clearance by enhanced phagocytic activity [137].

#### 52.8.3.4 Demonstration of the potential clinical use of mesenchymal stromal cells in an *ex vivo* human lung model of acute respiratory distress syndrome/acute lung injury

An *ex vivo* perfused human lung model has been used to assess the potential of MSC administration in human ALI/ARDS. MSC administration restored lung endothelial permeability, lung water level, and alveolar fluid clearance in lungs injured with endotoxin. MSCs also decreased inflammatory infiltration [57]. A randomized control trial (SMART) is underway using MSC administration in ARDS.

## 52.9 Challenges in mesenchymal stromal cell administration in lung diseases

Despite the large body of data showing the benefits of MSCs in preclinical models, challenges remain.

### 52.9.1 Optimal dosage of mesenchymal stromal cells

The optimal dose and route of delivery of MSCs remain to be determined and may be dependent on the lung disease itself. Preclinical animal models have shown significant variation. In

rodents, a dose of $20–30 \times 10^6$ cells/kg has been used. The average dose of MSCs derived from the bone marrow was $28.3 \pm 21.8 \times 10^6$ cells/kg. In clinical trials for lung disease, $1–2 \times 10^6$ cells/kg have been used. Clinical trials on the ClinicalTrials.gov website include conditions such as IPF (NCT01385644), bronchopulmonary dysplasia (NCT01632475), and ARDS (NCT01775774).

### 52.9.2 Timing of mesenchymal stromal cell administration

In preclinical models there appears to be an optimum window period in which to use MSCs. Most studies have treated animals within 6 h of acute lung injury. The optimum time from studies utilizing different animal models suggests MSC administration within 2–3 days of lung injury. Ortiz *et al.* showed that MSCs administrated 5 days after injury did not ameliorate fibrosis [95]. Thus, MSC administration for chronic lung disease may be limited in the management of established fibrosis and tissue remodeling.

## 52.10 Summary and conclusions

Lung diseases comprise a heterogeneous group of diseases with different pathogenic mechanisms. MSCs administered intravenously enter the lung in significant numbers but only remain in the lung for a short period in time. MSCs have been shown to have a variety of potentially useful actions in diseased lungs, including reduction in inflammation and improvement in repair mechanisms.

Goals for the use of MSCs in lung disorders include:

1 Determination the disease states (if any) for which MSCs could be effective.
2 Determination of the optimal dose and frequency of MSC administration in the management of lung disorders.
3 Consideration of the use of MSCs to deliver therapeutic agents.

Taken together, many questions remain, but the journey may yield outcomes that could have a significant impact on how a number of lung diseases are managed.

## 53.1 Introduction

The lungs are the perfect organ for the intravenous (IV) administration of mesenchymal stromal cells (MSCs) since they localize there within seconds of administration (see Chapters 22 and 23). They lodge there for approximately 3 days. This is likely due to their large size. In a cell suspension *in vitro* murine MSCs have a diameter of 15–19 μm [1] and murine pulmonary capillaries have a diameter of approximately 4 μm [1]. Human MSCs in a single cell suspension have a diameter of 100–120 μm [2], while human pulmonary capillaries have a diameter of 8–30 μm [3]. A human lymphocyte by comparison has a diameter of 7–8 μm and traverses the pulmonary capillary endothelial network unimpeded. The size of MSCs, however, does not prevent their subsequent transit out of the lungs, and they then home preferentially to sites of inflammation. An example of this is shown in Figure 22.5D and E. Immediately prior to IV injection a small incision was made on the right side of the abdominal wall and this area preferentially attracted the injected MSCs after their passage through the lungs.

* Email: m.atkinson1@uq.edu.au, K6.atkinson@qut.edu.au.

MSCs secrete a number of proteins that have anti-inflammatory, antiapoptosis, and immunomodulatory functions that may mediate some of their effects. The MSC secretome is described in detail in Chapters 1, 18, and 19. The way that paracrine function is mediated by tunneling nanotubes is described in Chapter 21. The MSC exosome is described in Chapters 1, 20, and 38.

This chapter will review lung diseases in which MSCs have been shown to be beneficial in preclinical murine models and will review clinical trials using MSCs for diseases of the lung.

## 53.2 Pulmonary fibrosis

Pulmonary fibrosis can be a primary disease of unknown etiology (idiopathic pulmonary fibrosis) or it may secondary to other diseases. Most of these are classified as interstitial lung diseases. Examples include autoimmune disorders, viral infections, and bacterial infections, including tuberculosis, which may cause fibrotic changes in both lungs, especially in the upper lobes. However, pulmonary fibrosis can also appear without any known cause and is diagnosed by lung biopsy and after all primary causes

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.

have been excluded. Diseases and conditions that may cause pulmonary fibrosis as a secondary effect include inhalation of environmental and occupational pollutants (e.g., asbestosis, silicosis, and exposure to certain gases), hypersensitivity pneumonitis (most often resulting from inhaling dust contaminated with bacterial, fungal, or animal products), some connective tissue diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus, scleroderma – also known as systemic sclerosis – and sarcoidosis), and some medications (e.g., bleomycin, busulfan, methotrexate, and amiodarone).

Pulmonary fibrosis involves a gradual replacement of normal lung parenchyma with fibrotic tissue. The replacement of normal lung with scar tissue causes an irreversible decrease in oxygen diffusion capacity, and the resulting stiffness or decreased compliance makes pulmonary fibrosis a restrictive lung disease. Pulmonary fibrosis is perpetuated by aberrant wound healing rather than chronic inflammation. Idiopathic pulmonary fibrosis occurs in middle age without a known cause. It is fatal without lung transplantation. The end result shows scarring and honeycombing of lung tissue, as shown in the example taken at autopsy in Figure 53.1.

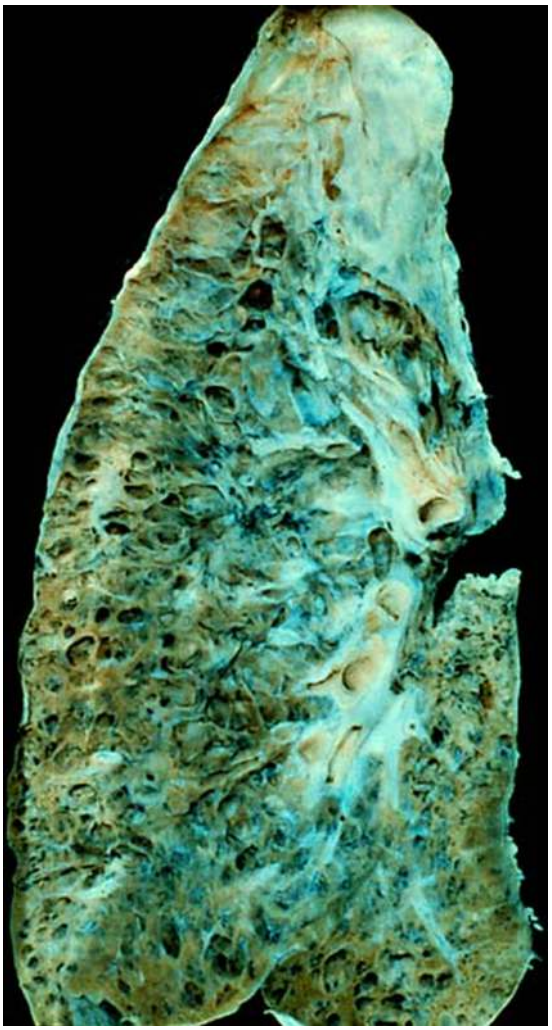

**Figure 53.1** Lung with end-stage pulmonary fibrosis at autopsy. *Source*: https://commons.wikimedia.org/wiki/File:End-stage_interstitial_lung_disease_(honeycomb_lung).jpg.

### 53.2.1 Animal models

One of the earliest models investigating MSCs in lung disease was a murine model of pulmonary fibrosis induced by the chemotherapeutic cytotoxic agent bleomycin [4]. It causes inflammatory and fibrotic reactions within a short period of time. An initial rise in the proinflammatory cytokines interleukin (IL)-1, tumor necrosis factor-α, IL-6, and interferon-γ is followed approximately 9 days later by increased expression of the profibrotic markers transforming growth factor-β1, fibronectin, and procollagen-1 with a peak around day 14 [5]. MSCs have been shown to be effective in ameliorating this disorder. Ortiz *et al.* demonstrated that bone marrow-derived murine MSCs homed to lung in response to injury, adopted an epithelium-like phenotype and reduced inflammation and collagen deposition in lung tissue of mice challenged with bleomycin [6]. In another study it was thought that MSCs produced their effect by downregulating matrix metalloproteinase 9, tissue inhibitor of metalloproteinases 1, interferon-γ, and transforming growth factor-β [7].

### 53.2.2 Clinical trials of mesenchymal stromal cells

Chambers *et al.* [8] performed a single-center, nonrandomized, dose-escalation phase 1 trial in patients with moderately severe idiopathic pulmonary fibrosis as defined by a diffusing capacity for carbon monoxide (DLCO) of ≥25% of predicted and a forced vital capacity (FVC) of ≥50% of predicted. They received intravenously either $1 \times 10^6$ ($n = 4$) or $2 \times 10^6$ ($n = 4$) MSCs/kg isolated from the term placenta of an unrelated, human-leukocyte-antigen-unmatched donor. They were followed for 6 months with lung function testing (FVC and DLCO), a 6-min walk distance, and computed tomography of the chest. Eight patients, four males and four females with an age range from 61 to 71 years and with a median (interquartile range) FVC 60% (52.5–74.5%) and DLCO 34.5% (29.5–40%) of predicted values were treated. Both dose schedules were well tolerated with only minor and transient acute adverse effects. The MSC infusion was associated with a transient (1% (0–2%)) fall in $SaO_2$ after 15 min, but without any hemodynamic changes. At 6 months, FVC, DLCO, 6-min walk distance, and computed tomography fibrosis scores were unchanged compared with baseline. There was no evidence of worsening fibrosis. The value of this study was that it demonstrated the safety of IV infusion of these doses of MSCs into people whose lung function was already significantly impaired.

## 53.3 Asthma

Asthma is a common chronic inflammatory disease of the airways characterized by variable and recurring symptoms,

reversible airflow obstruction, hyperresponsiveness of the small airways, and bronchospasm. Common symptoms include wheezing, coughing, chest tightness, and shortness of breath. Asthma is thought to be caused by a combination of genetic and environmental factors. Its diagnosis is usually based on the pattern of symptoms, response to therapy over time, and spirometry. It is clinically classified according to the frequency of symptoms, forced expiratory volume in 1 s (FEV1), and peak expiratory flow rate (Figure 53.2).

Asthma may also be classified as atopic (extrinsic) or non-atopic (intrinsic), where atopy refers to a predisposition toward developing type 1 hypersensitivity reactions. The combination of asthma, eczema, and allergic rhinitis is known as atopy. Treatment of acute symptoms is usually with an inhaled short-acting β-2 agonist (such as salbutamol), sometimes in combination with inhaled corticosteroids. In more severe cases oral corticosteroids may be required. In very severe cases, IV corticosteroids and hospitalization may be required. Symptoms can be prevented by avoiding triggers, such as allergens and irritants, and by the use of inhaled corticosteroids. Long-acting β agonists or antileukotriene agents may be used in addition to inhaled corticosteroids if asthma symptoms remain uncontrolled. Asthma is the result of chronic inflammation of the airways that subsequently results in increased contractility of the surrounding smooth muscles (Figure 53.3).

This among, other factors, leads to bouts of narrowing of the airway and the classic symptom of wheezing. The narrowing is typically reversible with or without treatment. Occasionally the airways themselves change. Typical changes in the airways include an increase in eosinophils and thickening of the lamina reticularis. Chronically, the airways' smooth muscle may increase in size along with an increase in the numbers of mucous glands. Other cell types involved include T cells, macrophages, and neutrophils. There may also be involvement of other components of the immune system, including cytokines,

**Figure 53.2** Peak flow meters are used to measure the peak expiratory flow rate, important in both monitoring and diagnosing asthma. (See color plate section.) *Source*: https://commons.wikimedia.org/wiki/File:Two_Peak_Flow_Meters.jpg#/media/File:Two_Peak_Flow_Meters.jpg.

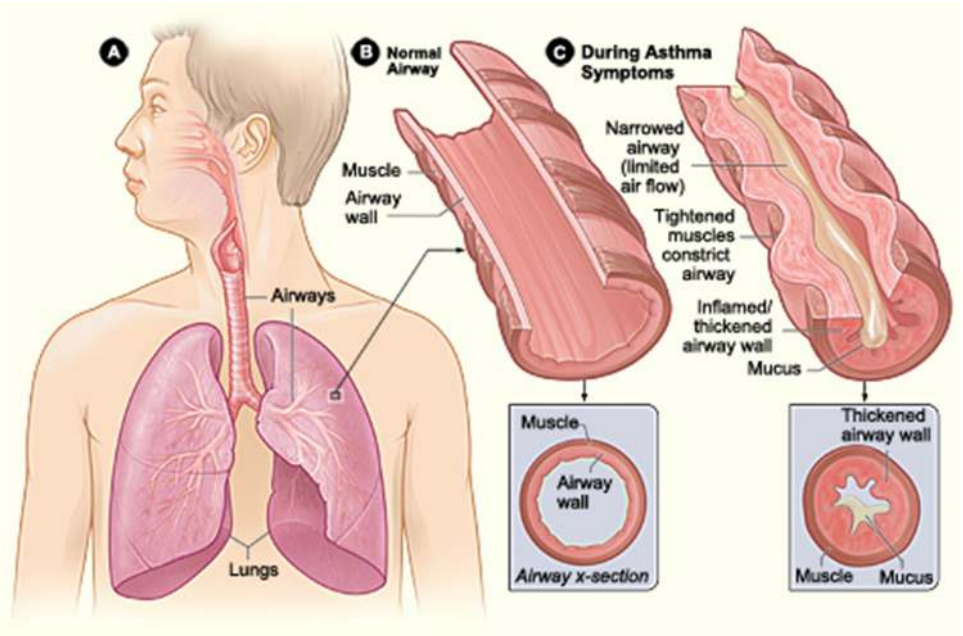

**Figure 53.3** (A) Location of the lungs and airways in the body. (B) Cross-section of a normal airway. (C) Cross-section of an airway during asthma symptoms. *Source*: NIH.

chemokines, histamine, and leukotrienes. A particularly severe form of asthma that is refractory to conventional treatment occurs in approximately 5% of people with asthma and may be associated with a marked neutrophilic infiltrate in the small airways.

A detailed description of the immunobiology of asthma is given in Chapter 39.

The commonest cause of allergic asthma in developed countries is the house dust mite (HDM). Asthma can also be precipitated by exercise, immersion in cold water, aspirin, and alcohol. Occupational asthma also occurs, and several hundred different agents have been implicated, with the most common being isocyanates, grain and wood dust, colophony, soldering flux, latex, animals, and aldehydes. Jobs associated with the highest risk of problems include those who spray paint, bakers and those who process food, nurses, chemical workers, those who work with animals, welders, hairdressers, and timber workers.

The occurrence of asthma has increased significantly since the 1970s. In 2011, 235–300 million people globally were diagnosed with asthma, and it caused 250 000 deaths.

### 53.3.1 Preclinical models

We conducted a study in which BALB/c mice were rendered allergic to HDM, the commonest allergen in Australia of allergic asthma. No adjuvant treatment was used [9]. It is known that allergic asthma is underpinned by T helper 2 (Th2) inflammation. Redundancy in Th2 cytokine function and production by both innate and adaptive immune cells suggested that strategies aimed at immunomodulation might prove beneficial. We sought to determine whether administration of MSCs to HDM-sensitized mice would suppress the development of Th2 inflammation and airway hyperresponsiveness (AHR) following HDM challenge. We found that the IV administration of allogeneic donor MSCs 1 h prior to allergen challenge significantly attenuated the features of allergic asthma in this model, including tissue eosinophilia, Th2 cytokine (IL-5 and IL-13) levels in bronchoalveolar lavage fluid, and AHR. The number of infiltrating type 2 innate lymphoid cells was not affected by MSC transfer, suggesting that MSCs may modulate the adaptive arm of Th2 immunity. The effect of MSC administration was long-lasting: all features of allergic airways disease were significantly suppressed in response to a second round of HDM challenge 4 weeks after MSC administration. We also observed that MSCs decreased the release of epithelial-cell-derived alarmins IL-1α and high-mobility group box-1 in an IL-1 receptor antagonist-dependent manner. This in turn decreased the expression of the pro-Th2 cytokine IL-25 and reduced the number of activated and antigen-acquiring $CD11c^+$ $CD11b^+$ dendritic cells in the lung and mediastinal lymph nodes. These findings suggested that MSC administration can ameliorate allergic airway inflammation by blunting the amplification of epithelial-derived inflammatory cytokines induced by exposure to HDM and may offer long-term protection against Th2-mediated allergic airway inflammation and AHR.

### 53.3.2 Clinical trials of mesenchymal stromal cells

The following trial was listed as recruiting when "mesenchymal stem cells and asthma" were searched in ClinicalTrials.gov: Safety and Feasibility Study of Intranasal Mesenchymal Trophic Factor (MTF) for Treatment of Asthma. No trials were found when the terms "mesenchymal stromal cells and asthma" were searched. In contrast, 4887 trials were listed when "asthma" alone was searched. When the terms "mesenchymal stem cells and lung diseases" were searched a total of 40 trials were listed.

## 53.4 Obliterative bronchiolitis

Obliterative bronchiolitis (OB), also known as bronchiolitis obliterans, is a rare and life-threatening form of nonreversible obstructive lung disease in which the bronchioles are compressed and narrowed by fibrosis and/or inflammation. OB has always been thought to be irreversible and progressive, but the use of inhaled cyclosporine has been shown to increase the FEV1 percentage, while patients are able to decrease their systemic corticosteroid doses.

### 53.4.1 Preclinical animal models

OB is a manifestation of chronic lung allograft rejection. A similar disease is a manifestation of chronic graft-versus-host disease occurring after allogeneic hematopoietic stem cell transplantation. It is characterized by small airway inflammation and occlusion by fibrous tissue. It is immune mediated. Al-Dessari and colleagues described a model of obliterative bronchiolitis occurring after lung transplantation using genetically defined miniature swine [10]. Group 1 ($n = 2$) received a left lung autograft; group 2 ($n = 7$) received a left lung allograft. Group 2 recipients were given cyclosporine, prednisone, and azathioprine for 3 months, and then immunosuppression was tapered and discontinued over 1 month. The animals were observed for an additional 5 months and then sacrificed. Lung grafts in both groups were monitored with serial bronchoalveolar lavages and transbronchial biopsies for 6 months. After sacrifice, lung grafts underwent histopathologic and immunohistochemical examination. No allograft had histologic evidence of acute rejection or peribronchiolar infiltrate during the first 3 months of immunosuppression. During the tapering period, airway changes characterized by severe peribronchiolar lymphocytic infiltrates were seen. Bronchoalveolar lavages of allografts showed significantly increased lymphocyte counts, with $CD8^+$ cells predominating. After the discontinuation of immunosuppression, transbronchial biopsy and autopsy specimens showed progressive fibrous inflammatory occlusion of bronchioles. Immunohistochemical staining demonstrated increased expression of major histocompatibility complex class II antigen on the bronchiolar epithelium and increased numbers of dendritic cells and $CD4^+$ lymphocytes. None of these changes were seen in the recipients of lung autografts (group 1). These findings indicated that OB is an

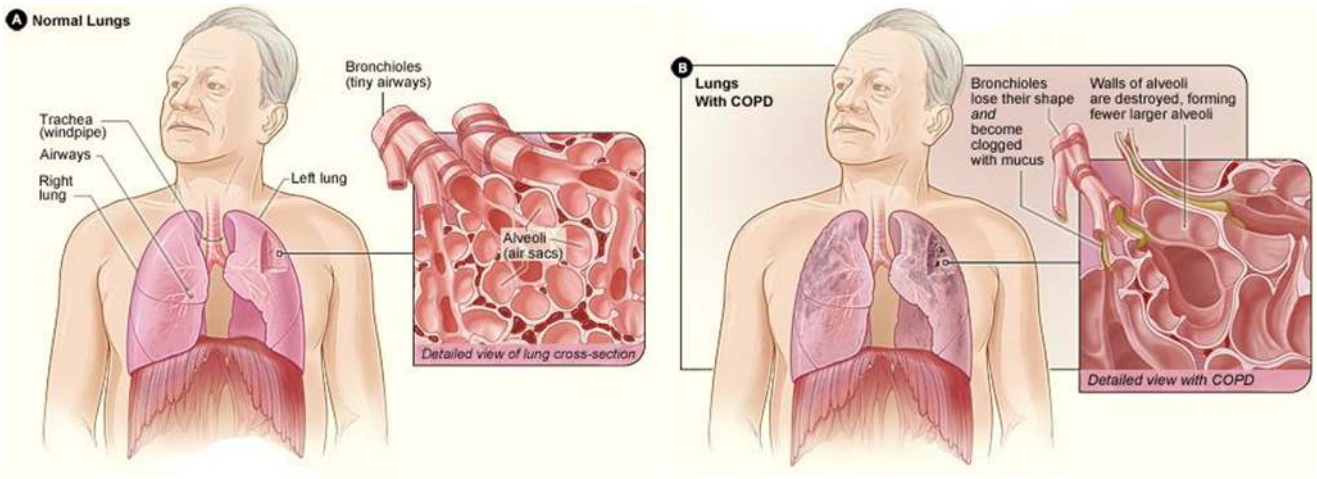

**Figure 53.4** (A) Location of the lungs and airways in the body. The inset image shows a detailed cross-section of the bronchioles and alveoli. (B) Lungs damaged by COPD. The inset image shows a detailed cross-section of the damaged bronchioles and alveolar walls. *Source*: NIH.

immunologically mediated phenomenon related to chronic graft rejection after lung transplantation. It is likely that a similar pathogenesis mediated by donor T cells present in the transplantant inoculum occurs after allogeneic hematopoietic stem cell transplantation as one manifestation of chronic graft-versus-host disease.

### 53.4.2 Clinical trials of mesenchymal stromal cells

Two trials were listed when the terms "mesenchymal stem cells and obliterative bronchiolitis" were searched in ClinicalTrials.gov. Both were in OB after lung allografting. One trial had been terminated because of loss of funding. The other was in the recruitment stage. When the terms "mesenchymal stromal cells and obliterative bronchiolitis" were searched, one additional study, again after lung transplantation, was listed as recruiting.

## 53.5 Chronic obstructive pulmonary disease and emphysema

Chronic obstructive pulmonary disease (COPD), also known as chronic obstructive airways disease, is characterized by chronically poor airflow in and out of the lungs. The main symptoms are shortness of breath, cough, and sputum production. Most people with chronic bronchitis have COPD.

Tobacco smoking is the most common cause of COPD, with other factors such as air pollution and genetics playing a smaller role. In the developing world, one of the common sources of air pollution is from poorly vented cooking and heating fires. Long-term exposure to these irritants causes an inflammatory response in the lungs, resulting in narrowing of the small airways and breakdown of lung tissue known as emphysema (Figure 53.4).

The diagnosis is based on poor airflow as measured by lung function tests. In contrast to asthma, the airflow reduction does not improve significantly with the administration of medications.

COPD can be prevented by reducing exposure to the known causes. This includes efforts to decrease rates of smoking and to improve indoor and outdoor air quality. COPD treatments include quitting smoking, influenza and pneumococcal vaccinations, rehabilitation, and often inhaled bronchodilators and corticosteroids. Some people may benefit from long-term oxygen therapy or lung transplantation.

Worldwide, COPD affects 329 million people, or nearly 5% of the population. In 2013, it resulted in 2.9 million deaths, up from 2.4 million deaths in 1990. The number of deaths is projected to increase due to higher smoking rates and an aging population in many countries. An image taken at autopsy of a human lung severely damaged by COPD is shown in Figure 53.5.

**Figure 53.5** Gross pathology of a human lung showing centrilobular-type emphysema characteristic of smoking. This close-up of the fixed, cut lung surface shows multiple cavities lined by heavy black carbon deposits. (See color plate section.) *Source*: www.cdc.gov.

### 53.5.1 Preclinical animal models

Many of the hallmark features of human COPD can be mimicked in animal models of the disease, including chronic lung inflammation with accumulation of macrophages, neutrophils, and lymphocytes, impaired lung function, emphysema, mucus hypersecretion, small airway wall thickening and remodeling with an increase in matrix components, inflammatory cells and goblet cell metaplasia in the airway wall, resulting in luminal narrowing, distortion, and obstruction by mucus, vascular remodeling, lymphoid aggregates, and pulmonary hypertension.

Churg *et al.* described an acute murine model of exposure to smoke from four cigarettes over 1 h. They observed that the resulting inflammation was associated with activation of the transcription factor nuclear factor κB and proposed that tumor necrosis factor-α, processed by matrix metalloproteinase 12, was largely responsible for the ensuing responses, especially upregulation of the vascular adhesion molecule E-selectin [11].

### 53.5.2 Clinical trials with mesenchymal stromal cells

A search of ClinicalTrials.gov using the terms "mesenchymal stem cells and chronic obstructive airways disease" showed one complete trial carried out by Mesoblast PTL, but no results were available. Using the terms "mesenchymal stem cells and emphysema," three are listed. The status of one was unknown, one was recruiting, and one was completed in 2012 but no results were available.

## 53.6 Bronchopulmonary dysplasia

Bronchopulmonary dysplasia is a chronic lung disorder of infants and children first described in 1967. It is more common in infants with low birth weight and those who receive prolonged mechanical ventilation and prolonged high oxygen delivery to treat respiratory distress syndrome. It results in significant morbidity and mortality. Management includes surfactant, antenatal glucocorticoid therapy, and less aggressive mechanical ventilation. Prolonged high oxygen delivery in premature infants causes necrotizing bronchiolitis and alveolar septal injury, with inflammation and scarring. This results in hypoxemia. Current practice using surfactant and high-frequency ventilation and oxygen supplementation results in a much milder injury without necrotizing bronchiolitis or alveolar septal fibrosis. Instead, there are usually uniformly dilated acini with thin alveolar septa and little or no interstitial fibrosis.

### 53.6.1 Preclinical animal models

Newborn animal models employing both premature and term animals have been used over the years to study various components of bronchopulmonary dysplasia. The similarities to lung injury in human premature infants include an acute inflammatory response with the production of cytokines, chemokines, and growth factors that have been implicated in human disease, abnormal pulmonary function, disordered lung architecture, alveolar simplification, development of fibrosis, and abnormal vascular growth factor expression [12].

### 53.6.2 Clinical trials using mesenchymal stromal cells

When the terms "mesenchymal stem cells and bronchopulmonary dysplasia" were searched in ClinicalTrials.gov, eight trials were listed. Their status was as follows: one was not yet recruiting, one was of unknown status, three were recruiting, two were active but not yet recruiting, and one was completed. No results were given for the completed trial. Six of the eight trials used PNEUMOSTEM®, a preparation of allogeneic umbilical-cord-blood-derived MSCs.

## 53.7 Acute respiratory distress syndrome and acute lung injury

Acute respiratory distress syndrome (ARDS), acute lung injury, adult respiratory distress syndrome, or shock lung is a severe, life-threatening medical condition characterized by widespread inflammation in the lungs. While ARDS may be triggered by trauma or lung infection, it is usually the result of sepsis (bacteria in the bloodstream).

ARDS is a disease of the microscopic air sacs of the lungs (alveoli) that leads to a decreased exchange of oxygen and carbon dioxide. ARDS is associated with several pathologic changes: the release of proinflammatory proteins, breakdown of the cells lining the blood vessels in the lungs, loss of surfactant, leading to increased surface tension in the lung, fluid accumulation in the lung, and excessive fibrous connective tissue formation.

The syndrome has a high mortality of between 20 and 50%.

The signs and symptoms of ARDS usually begins within 72 h of the initial insult or injury to the lung and include shortness of breath, tachypnea (fast breathing rate), and a low oxygen level in the blood. Chest X-ray frequently demonstrates generalized infiltrates or opacities in both lungs, which represent fluid accumulation in the lungs.

The predisposing factors of ARDS are numerous and varied. Common causes include sepsis, pneumonia, trauma, multiple blood transfusions, babesiosis, lung contusion, aspiration of stomach contents, and drug abuse or overdose. (Babesiosis is a malaria-like parasitic disease caused by infection with *Babesia*, a genus of protozoal piroplasms.) Other causes of ARDS include burns, pancreatitis, near drowning, or the inhalation of chemical irritants such as smoke, phosgene, or chlorine gas.

ARDS is an acute injury to the lungs that results in the flooding of the alveoli, the small air sacs within the lungs where the exchange of oxygen and carbon dioxide occurs, partial collapse of the lungs (atelectasis), and low levels of oxygen in the blood (hypoxemia). The triggering insult to the tissue usually results in an initial release of chemical signals and other inflammatory mediators secreted by local epithelial and endothelial cells. Neutrophils and T cells quickly migrate into the inflamed

lung tissue and contribute in the amplification of the phenomenon. Typical histolopathological changes include diffuse alveolar damage and hyaline membrane formation in alveolar walls. ARDS is usually treated with mechanical ventilation in a hospital intensive care unit. Ventilation is usually delivered through orotracheal intubation, or by tracheostomy whenever prolonged ventilation (≥2 weeks) is deemed inevitable.

### 53.7.1 Preclinical animal models

There are a number of animal models of ARDS, each focusing on different aspects of the disorder: lipopolysaccharide (LPS) delivered intra-tracheally is a good model for neutrophil recruitment; acid aspiration is a good model for epithelial barrier disruption; hyperoxia is a good model for hemorrhagic injury; surfactant depletion is a good model for lung injury induced by other agents, especially mechanical ventilation.

In one of the most dramatic reports LPS (*Escherichia coli* endotoxin) was instilled into the airway of mice. After this, murine bone-marrow-derived MSCs (BM-MSCs) were instilled into the airway. Live optical studies revealed that MSCs formed connexin-43-containing gap junctional channels (GJCs) with the alveolar epithelium, releasing mitochondria-containing microvesicles that the epithelium engulfed. The presence of MSC mitochondria in the epithelium was evident optically. The mitochondrial transfer increased alveolar adenosine triphosphate. This LPS-induced acute lung injury, indicated by alveolar leukocytosis and protein leak, inhibition of surfactant secretion and high mortality, was markedly abrogated by wild type murine BM-MSCs, but not by mutant, GJC-incompetent murine BM-MSCs or by murine BM-MSCs with dysfunctional mitochondria. It demonstrated that BM-MSCs can protect against acute lung injury by reconstituting alveolar bioenergetics through connexin-43-dependent alveolar attachment and mitochondrial transfer [13].

### 53.7.2 Clinical trials with mesenchymal stromal cells

Searching Clinical Trials.gov with the terms "mesenchymal stem cells and acute respiratory distress syndrome/acute lung injury" revealed five trials. Four were recruiting and the status of the fifth was unknown. Of those recruiting, two were using adult BM-MSCs and one was using umbilical-cord-derived MSCs.

## 53.8 Conclusions

The use of mesenchymal stromal cells to treat lung disease is in its infancy. It is encouraging that MSCs administered intravenously to people with impaired lung function and pulmonary fibrosis appeared safe and did not further impair lung function by their initial (presumed) lodgment in the lungs. The results of the ongoing trials are awaited.

## 54.1 Cell biology of endogenous mesenchymal stromal cells

In vertebrates, the majority of postnatal hematopoiesis occurs in the marrow of the long bones. Each day the marrow of adult humans releases hundreds of millions of new blood cells into the circulation [1], but the profound proliferative capacity of this system must be kept in check by a variety of mechanisms: dysregulated marrow is the genesis of autoimmune disease and hematologic dyscrasias, both benign and malignant. The hematopoietic stem cell (HSC) is the multipotent self-renewing progenitor that gives rise to all cells of the lymphoid (T cell, B cell, natural killer cell) and myeloid (erythrocyte, monocyte, granulocyte, platelet) lineages. The HSC functions in the context of a niche populated by nonhematopoietic cells of stromal origin. These stromal elements play a central role in marrow homeostasis and are the object of our current discussion.

A bone marrow aspirate reveals the stromal tissue of mammalian bone marrow to be a complex structure, punctuated by blood cell progenitors of varying maturity and interspersed with adipocytes as well as bone-remodeling osteoclasts and osteoblasts. In the highly vascularized endosteal niche the stromal cell network surrounds and coordinates the development of HSCs. If a healthy human bone marrow aspirate is put into tissue culture plates, after a week of culture a population of plastic-adherent spindle-shaped cells will become manifest. This process of *ex vivo*

expansion is necessary in order to generate appreciable amounts of cells, for in the native marrow true mesenchymal stem cells are vanishingly rare and can be found at a frequency of approximately 1 out of 10,000 cells [2]. By ex vivo expansion large numbers of mesenchymal stromal cells can be obtained, a progenitor population that can differentiate into a number of mesoderm-derived tissues such as adipose tissue, cartilage, and osteocytes. It is this mesenchymal progenitor feature that serves loosely as rationale for the term "stem cell"; but to prevent confusion with HSCs, and in reference to their stromal derivation, we and others refer to these as mesenchymal stromal cells, though the abbreviation "MSC" is used for both mesenchymal stem cells and mesenchymal stromal cells. In this chapter "MSC" will used solely to denote mesenchymal *stromal* cells.

### 54.1.1 Mesenchymal stromal cells coordinate hematopoietic stem cell development

Within the vascularized marrow compartment, fate mapping and parabiosis experiments have elucidated different MSC classes that interact with HSCs to coordinate hematopoiesis [3–7]. Although MSC surface and intracellular markers vary in the literature, such variance is thought to reflect the different microenvironments in which the cells reside (e.g., the skin, lung, fat, marrow) rather than distinct cell lineages [7]. One of the more well-described marrow-resident MSCs is the C–X–C motif chemokine ligand 12 (CXCL12)-abundant reticular (CAR) stromal cell. Named for their reticuloid processes as well as their chemokine production, CAR stromal cells have been shown to be essential for functional hematopoiesis. (Note that these CAR stromal cells are totally unrelated to T cells that have been genetically engineered to express specific receptors on their surface called chimeric antigen receptors and which are also known as CAR cells).

CXCL12 is produced by stromal cells in the marrow and is also required for normal lymphopoiesis – the development of a functionally mature T and B cell compartment. The use of conditional knockout mice has elucidated the connection between CAR stromal cells and committed lymphoid progenitors in the marrow. Using a *Cre–lox* system Greenbaum *et al.* showed that, when CXCL12 is deleted only from CAR stromal cells, animals exhibit a sharp drop in the numbers of pre-pro B cells and have fewer marrow committed lymphoid progenitors [6]. CAR stromal cells are also principal sources of stem cell factor (SCF, also known as kit ligand), a cytokine that is presented on the stromal cell membrane. SCF is the ligand for the receptor tyrosine kinase c-Kit (CD117), which transduces important pro-survival signals to developing HSCs [8,9]. As such, CAR stromal-cell-derived signals are indispensable for normal hematopoiesis. Using an inducible knockout system in mice, Omatsu *et al.* have shown that short-term ablation of CAR stromal cells decreases the self-renewing cell cycling of HSCs, as well as reducing the numbers of both lymphoid and erythroid progenitor cells [4].

Other work has described a rare population of CXCL12-producing cells referred to as nestin$^+$ stromal cells. These cells are named for their co-expression of the intermediate filament protein nestin and are found in perivascular bundles in close apposition to both HSCs and catecholaminergic nerve fibers. The mobilization of HSC progeny from the marrow has been observed to oscillate with circadian rhythms delivered via the sympathetic nervous system [3,10]. Work by Méndez-Ferrer has shown that these nestin$^+$ stromal cells express the $\beta_3$-adrenergic receptor and that, upon selective depletion, the mobilization and development of HSCs is significantly impaired [5]. These findings illustrate the ability of MSCs to coordinate hematopoiesis by integrating paracrine signals with long-range autonomic control (see also Chapter 32).

### 54.1.2 Mesenchymal stromal cells and central tolerance in the bone marrow

Lymphopoeisis is a complex process wherein T and B cell progenitors generate a unique antigen receptor via the recombination of hundreds of different gene segments. Immunologists have calculated that on the order of $10^{18}$ different antigen receptors could be made stochastically, although certain mechanisms (allelic exclusion, the preponderance of certain T cell receptor β-chains) revise this number downward [11]. Nonetheless, gene segment recombination endows a healthy vertebrate with an extremely diverse immune repertoire, poised to respond to a vast array of proteins, lipids, or carbohydrates. As a result of this combinatorial diversity, occasional lymphocytes are generated whose receptors target self-antigens. Left unchecked, such T or B cells may escape to the periphery, and under certain conditions initiate a pathologic autoimmune process. The body has a number of mechanisms whereby it evades autoimmune disease, but these can be grouped into two general classes: central tolerance and peripheral tolerance. By central tolerance, we refer to events occurring in the primary lymphoid organs – the bone marrow, thymus or spleen – whereas peripheral tolerance may be induced anywhere in the body that leukocytes are found.

In the marrow, lymphoid progenitors with newly generated antigen receptors are in constant contact with the stromal cell network. It is important to note that although lymphoid progenitors begin this process in the marrow, T cells migrate to the thymus in order to undergo maturation. In a process termed positive selection, new lymphocytes ensure that their receptor is capable of recognizing peptides presented by endogenous antigen-presenting cells (APCs).

In negative selection, lymphocytes that vigorously autoreact to self-antigens are neutralized to so-called clonal ignorance, anergy, or undergo apoptosis, here termed deletion. In the thymus, signals from both local tissue-resident and marrow-derived cells guide the developing T cells through the positive and negative selection processes [12]. Medullary thymic epithelial cells (mTECs) express the transcription factor autoimmune regulator (AIRE), enabling the cells to express self-derived antigens. Research has shown that mTECs can also transfer this antigen for indirect presentation by thymus-resident dendritic cells [13]. In the thymus, autoreactive T cells can be

converted to so-called natural regulatory T cells (Tregs), be deleted, or otherwise deprived of survival signals and become anergic. Figure 54.1 shows the structure of the AIRE molecule.

Studies using human cells as well as murine models have shown that MSCs can also be isolated from the thymus, and that they contribute to the development of a normal T cell compartment [14,15]. Toward the coordination of lymphopoiesis, MSCs, like professional APCs such as dendritic cells and macrophages, can express the diverse human leukocyte antigen (HLA) molecules: class I, presenting mainly intracellular-derived peptides, and class II, presenting extracellular-derived peptides. If the lymphocyte is unable to recognize, or if it autoreacts too vigorously to the HLA-presented peptides, that lymphocyte clone is deprived of pro-survival signals (e.g., CXCL12 and other growth factors) and is deleted.

These mechanisms of central tolerance, enforced by the thymus, suffice to keep a healthy individual free of autoimmune disease. Autoreactive T cells can be tolerized to self-antigen in the periphery, thereby becoming "induced" Tregs. The precise mechanisms by which these conversions occur, where they occur, and the principal inducers of Treg conversion are areas of intense interest, with changes in cellular metabolism and co-stimulatory and co-inhibitory surface molecules all being investigated [16,17].

In addition to classes I and II, less variable HLA molecules are expressed by MSCs, including HLA-G. Initially discovered on trophoblastic tissues in the placenta, HLA-G prevents maternal immune infiltration of the hemi-allogeneic fetus. When expressed by MSCs, HLA-G confers an immunosuppressive signal by activating immunotyrosine inhibitory motifs on lymphocytes and monocytes. In the marrow, HLA-G signaling dampens the activity of bone-remodeling osteoclasts that are derived from monocytes, whereas in the periphery lymphocytes respond to HLA-G on membranous vesicles [18,19].

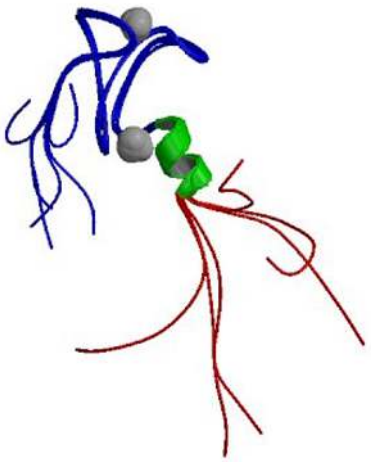

**Figure 54.1** Protein data base rendering based on 1xwh of the structure of the transcription factor AIRE. (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:PBB_Protein_AIRE_image.jpg#/media/File:PBB_Protein_AIRE_image.jpg.

*Ex vivo* MSCs have been defined using conventional flow cytometric techniques by the International Society for Cellular Therapy (ISCT) [20]. These cells must stain positively for CD73 (ecto-5′-nucleotidase), CD90, and CD105 (endoglin), but lack staining for the following lymphomyeloid markers: CD11b, CD14, CD19, CD34, CD45, CD79a, or of major histocompatibility complex (MHC) class II [21]. One other surface marker that has garnered considerable attention regarding MSC functionality is the surface marker CD271. Also known as low-affinity nerve growth factor receptor, expression of CD271 has been observed on primary MSCs that also produce large amounts of CXCL12 (the aforementioned CAR cells). $CD271^+$ MSCs have been shown to support the development of HSCs *in vitro* [22]; additionally, mouse models of HSC–MSC co-transplantation demonstrate CD271 as a prospective marker for the engraftment-promoting qualities of MSCs [23]. Apart from these markers, when studied in their endogenous setting MSCs can present other differences in surface markers, perhaps reflective of the varied cytokine milieu in peripheral tissues or the marrow. It must be stated that MSCs can be isolated from a variety of nonhematopoietic tissues, including lung, fat, kidney, skin, and muscle. Indeed, some reports indicate that MSCs can be derived and propagated from any organ tissue, and that the amount of MSCs present is proportional to the blood vessel density per end-organ [24]. The role of MSCs as precursors for angiogenesis has become appreciated as recent reports show a shared phenotype with vascular pericytes. Though beyond the scope of present discussion of immune-mediated application, MSCs have been much explored in the field of regenerative medicine, particularly in cardiovascular and wound healing models [25–29].

## 54.2 Cell biology of mesenchymal stromal cells in culture

Since their initial discovery in bone marrow, MSCs have been studied by translational scientists in attempts to harness their regenerative and immunomodulatory abilities. The progenitor nature of MSCs, and their proven ability to differentiate into cartilage, bone, and fat cells, has spurred research efforts to regenerate these tissues. A number of studies have utilized MSCs to regrow musculoskeletal tissues, including craniofacial defects [30], repair of ruptured tendons [31], or to correct the congenital bone disease osteogenesis imperfecta [32]. The regenerative nature of MSCs has not been without controversy, however, as published reports have claimed the ability to repair transected spinal cords (see Chapter 49), myocardial infarcts (see Chapter 45), and even autism. Such controversy may speak to the variability inherent to performing *in vitro* differentiation with progenitor cells, in which different laboratory culture media and cell-processing protocols can be at variance.

### 54.2.1 Mesenchymal stromal cells and B cell immunosuppression

Whereas the regenerative capacity of MSCs may remain a question of tissue culture recipes, the immunomodulatory capabilities of these cells have been borne out in a variety of assay systems. From a teleological perspective, the role of MSCs in hematopoiesis affords us the best lens to view the mechanisms by which stromal cells suppress the proliferation and effector function of potentially pathologic leukocytes. After an immature B cell has undergone gene recombination and expresses its novel antigen receptor, marrow stromal cells mediate positive and negative selection. Through this process autoreactive B cells are either silenced or deleted, thereby maintaining central tolerance. For autoreactive B cells that do escape the marrow, mechanisms of peripheral tolerance exist to limit immunopathology. Given the complexities of observing central and peripheral tolerance *in situ*, a number of techniques have been developed to model how MSCs and pathologic B cells interact.

Our group explored a mouse model of hemophilia A, a coagulopathy that arises from an inherited deficiency in clotting factor VIII (FVIII) [33]. After years of FVIII replacement therapy, it is common for human patients to develop allo-antibodies to FVIII, complicating treatment and causing significant morbidity. Both *in vivo* and *in vitro* techniques demonstrated that murine MSCs induced plasma cells to re-express paired box 5 via the protein-phosphatase-dependent inhibition of signal transducer and activator of transcription (STAT)3, causing a systemic decrease in anti-FVIII antibodies. Our protocol was repeated in healthy mice immunized to ovalbumin protein, after which we observed similarly decreased anti-ovalbumin-protein immunoglobulin (Ig) production by B cells. Other studies using B cells and MSCs from healthy human donors have shown that MSC co-culture attenuates the production of IgA, IgM, and IgG via *in vitro* assay systems [34]. A study by Ma *et al.* explored the utility of MSC administration for idiopathic thrombocytopenic purpura (ITP), a hematologic disease characterized by spontaneous bleeding, petechiae, and purpura [35]. Although not all cases of ITP are proven autoimmune in nature, both T and B cells with specificity for platelet surface antigens have been implicated in its pathogenesis [36]. Using *ex vivo* culture systems of primary cells from ITP patients, Ma *et al.* show a marked decrement in platelet destruction after MSC co-culture, although they were unable to pinpoint a specific causative relationship, instead citing a number of possibilities.

### 54.2.2 Mesenchymal stromal cell and T cell co-culture assays

Different *in vitro* systems have been utilized to observe the mechanisms whereby MSCs can regulate, suppress or limit the inflammatory damage of pathologic T cells. One of the principal ways that MSC-mediated immunosuppression can be observed is by co-culture with peripheral blood mononuclear cells (PBMCs) or purified T cells. In order to activate the T cells toward proliferation and effector differentiation, the T cell markers CD3 and CD28 must be ligand-stimulated. These stimuli reproduce the so-called Signal 1 and Signal 2 of T cell activation: Signal 1, in which a T cell receptor encounters its cognate antigen presented by the HLA molecule of an APC, and Signal 2, whereby CD80 or CD86 on the APC delivers co-stimulation to the CD28 on the T cell. Whether affixed to beads or in solution, anti-CD3/anti-CD28 stimulation of PBMCs or purified T cells induces activation and proliferation that is polyclonal in nature. We and others have used this technique in combination with *in vitro* co-culture to demonstrate the suppressive effects mediated by MSCs [37–39]. Other techniques for polyclonal activation of T cells include the use of mitogenic stimuli, such as phytohemagglutinin [40] and the superantigen staphylococcal enterotoxin B [39].

To assess proliferation, and thereby judge the degree of MSC immunosuppression, different groups have employed the generational dilution of carboxyfluorescein succinimidyl ester [41], an increase in $^{3}$H-thymidine incorporation [41], or intracellular flow cytometric staining for Ki67 [39]. The classical mixed lymphocyte reaction (MLR) has also been utilized to assess the degree by which MSCs modulate T cell allo-proliferation. Given a high degree of HLA mismatch, responder T cells proliferate in an allo-specific fashion, generationally diluting their carboxyfluorescein succinimidyl ester concentration. MSCs can be plated beneath the MLR, allowing the researcher to tease apart tolerance-conferring mechanisms [42].

MSCs have been shown to suppress the proliferation of activated T cells using a variety of mechanisms, and both cell-to-cell contact and soluble factors have been implicated. Soluble factors include prostaglandin $E_2$, transforming growth factor-β (TGF-β), hepatocyte growth factor, and HLA-G, released on membranous bodies as described earlier. These and other mechanisms have been reviewed by others [20,21,43–45], so our discussion will instead focus on translationally important findings whereby stromal cells suppress the activity of T cells.

For researchers in transplantation and autoimmune disease, the word "tolerance" evokes the categorical good; immunosuppressive pharmacotherapies are thus employed to avert rejection of allografted organs or host tissues undergoing autoimmune cellular infiltration. However, tolerance can also be maladaptive, a consequence engendered by the stromal environment in which benign tumors become malignant cancers. By understanding the mechanisms of cancer-associated maladaptive tolerance, immunologists stand to gain valuable insight for next-generation immunomodulatory therapies.

## 54.3 Immunosuppression: lessons from oncology

It is now appreciated that cancer is not one syndrome, but rather a collection of diseases marked by dysregulated proliferation of the body's endogenous cells. The last century has advanced our understanding of carcinogenic toxins, inherited or acquired

mutations, and chronic inflammatory changes that can all incite cells to become cancerous. In the process, one or all of the following systems becomes dysregulated: a cell can undergo loss of function (e.g., of a tumor-suppressing factor like the retinoblastoma gene *RB*), or it can gain a competetive growth advantage (e.g., the constitutive growth triggered by *BCR-ABL*, the oncogene responsible for chronic myeloid leukemia), or it can become ignorant to apoptotic signals (e.g., mutations in the B cell lymphoma gene *BCL-2*), or lastly it gains the ability to metastasize beyond its normal niche (e.g., by the loss of E-cadherin) [46]. These changes may not occur sequentially in every cancer, but *in vitro* each is sufficient for a human cell to acquire immortality. In the healthy body it is appreciated that such dysregulations occur at a basal level, but are kept in check by a variety of homeostatic mechanisms. The concept of immune surveillance has been described as the mechanisms by which circulating lymphocytes detect premalignant changes and subsequently kill the mutated cell [47]. A number of studies have demonstrated the ability of lymphocytes to perform tumoricidal immune surveillance [48,49]. However, in instances where cancer does arise, recent discoveries indicate that tumor stromal tissue exerts immunosuppressive mechanisms that neuter the potentially cancer-fighting effects of tumor-infiltrating lymphocytes (TILs) [50].

### 54.3.1 Programmed death ligand 1 and immunosuppression by tumors

After receiving Signal 1 and Signal 2 and being exposed to inflammatory cytokines, newly-activated T cells ($CD4^+$ T helper cells and $CD8^+$ cytotoxic lymphocytes) upregulate adhesion molecules and then traffic to inflamed areas by following chemokine gradients. The activation process for T cells involves the maturation of effector function (i.e., the ability to release cytokines such as interferon (IFN)-γ or granzyme B), after which they lose dependence on the co-stimulatory Signal 2. For example, when cytotoxic lymphocytes arrive at an inflamed area, they serially kill any cell that displays the cognate antigen–HLA complex. In addition to gaining effector function, T cell activation induces the upregulation of inhibitory receptors that include programmed death-1 (PD-1) [51]. Although we have described the process of T cell activation, it is important to note that PD-1 expression is also upregulated on activated B cells. PD-1 is a transmembrane protein that contains an immunotyrosine inhibitory motif, which upon ligation recruits tyrosine phosphatases that inactivate a number of signaling molecules, including spleen tyrosine kinase, zeta-chain-associated protein kinase 70, and phosphatidylinositide 3-kinase [51]. Such changes induce the anergy or apoptosis of T cells and B cells, tempering the late immune response toward resolution. The structure of programmed death ligand 1 (PD-L1) is shown in Figure 54.2.

The principal ligands for PD-1 are PD-L1 (also called B7 homolog and CD274) and PD-L2 (also called B7 dendritic cell and CD273). Early studies of PD-L1 indicated that the molecule was commonly found on primary human cancer cells [52], although subsequent work has also located the molecule on benign hematopoeitic and nonhematopoietic cells [51]. Likewise, PD-L2, first identified on human cancer cell lines [53], has been since identified on APCs and some nonhematopoietic cells [51]. The finding that PD-L1 was associated with cancerous human tissues generated a flurry of research in the first decade of the new millennium, as scientists explored new avenues of cancer immunotherapy. Antibodies to blockade PD-1 and PD-L1 have shown great promise in preclinical models [54,55], later spurring the development of clinical trials for cancer immunotherapy [56–58]. In late 2014, the US Food and Drug Administration approved pembrolizumab, a monoclonal antibody drug targeting PD-1, as the newest therapeutic agent for metastatic melanoma [59].

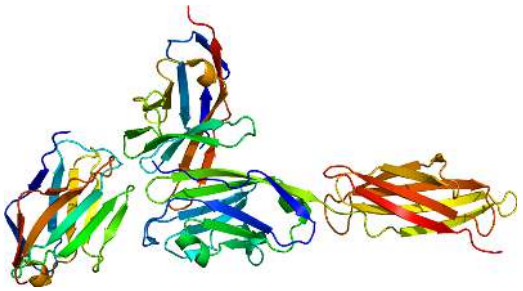

**Figure 54.2** Structure of PD-L1 (CD274). The rendering is based on PyMOL rendering of the Protein Data Bank 3BIK. (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:Protein_CD274_PDB_3BIK.png#/media/File:Protein_CD274_PDB_3BIK.png.

### 54.3.2 Programmed death ligand 1 and immunosuppression by mesenchymal stromal cells

Among the contact-dependent factors implicated in immunosuppression by MSCs, PD-L1 has emerged as a potentially important mediator. As discussed earlier, the role of PD-L1 has been explored in oncology research and found to dampen the effects of tumoricidal lymphocytes. Such findings have furthered efforts to improve immunomodulatory MSC therapy, via a deepened mechanistic understanding of immune tolerance. In 2005, just a few years after the first characterizations of PD-1, surface expression of PD-L1 by marrow-derived MSCs was described to mediate immunosuppression [60]. Augello *et al.* showed that resting, marrow-derived MSCs only contained mRNA for PD-L1, but could be induced to express the protein on the cell surface by inflammatory stimuli. These researchers showed that MSCs inhibited the proliferation of both B cells and T cells in an MLR or after phytohemagglutinin stimulation, and that this effect could be reversed by a blocking antibody to PD-L1. A 2008 study used MLR, mitogens, and also anti-CD3/anti-CD28 stimulation to show that lymphocyte-derived IFN-γ was responsible for the induction of PD-L1 on the surface of MSCs [61].

Other studies have further elucidated the role of PD-L1 in MSC immunosuppression. In a 2012 study, Luz-Crawford *et al.*

explored how MSCs utilize PD-L1 to inhibit both proliferation and effector capacity of T cells [62]. Using established protocols for *in vitro* T cell skewing, they generated inflammatory T helper (Th)1 and Th17 cells, confirmed by canonical transcription factors and cytokine expression (T-bet and *RORγt*, and IFN-γ and interleukin (IL)-17 respectively). They showed that MSCs are able to suppress cytokine release from both types of inflammatory T cells, which was reversed by antibody blockade of PD-L1. Of particular note was the finding that although soluble factors play a role in the immunosuppression, Th17 cells were especially sensitive to contact-dependent inhibition by PD-L1. Subsequent work by the same researchers suggested that MSCs can reprogram Th17 cells into Tregs [63], though the exact role of PD-L1 remains to be fully described. The crystallographic structure of retinoic acid receptor-related orphan receptor gamma (RORγ) is shown in Figure 54.3.

In a 2014 report our research group explored the differential effects of MSC immunosuppression after inhibition of indoleamine 2,3-dioxygenase (IDO) or PD-L1 [39]. Primary human MSCs were shown to be capable of inhibiting both the proliferation and effector function (cytokine release) of T cells after treatment with the superantigen staphylococcal enterotoxin B or anti-CD3/anti-CD28 stimulation. We showed that although IDO was associated with suppression, treatment with the enzymatic inhibitor 1-methyl-tryptophan did not fully reverse this effect. However, small-interfering-RNA-mediated knockdown of PD-L1 or PD-L2 was shown to reverse the inhibitory potential of MSCs. These results suggest that MSCs may rely on a number of factors – soluble factors, IDO catalysis, and PD-L1/PD-1 signaling – to mediate their immunosuppression by complementary nonoverlapping mechanisms.

### 54.3.3 Indoleamine 2,3-dioxygenase and immunosuppression by tumors

IDO is an important enzyme that is known to be associated with the conferrence of immunologic tolerance. It catalyzes the rate-limiting step in the biochemical degradation of tryptophan, yielding a group of metabolites collectively termed kynurenines [64]. A 2012 report identified IDO in trophoblast-derived macrophages, where it is associated with the maintenance of maternal–fetal tolerance [65]. IDO-expressing dendritic cells have likewise been found to be tolerance-inducing in a heart transplantation model [66]. Although these recent discoveries speak to the tolerogenic stimuli sought by the transplant field, the enzymatic activity of IDO was first indirectly observed in the field of oncology. In a 1956 study, patients with advanced bladder cancer were found to have abnormally high excretion of kynurenines, which could be modulated by supplementation of tryptophan or other chemical analogs [67]. Viewed through a modern lens, it is likely that IDO-expressing cells in the cancerous bladder wall augmented local tryptophan degradation, rendering any TILs impotent in their attempt to eradicate the tumor.

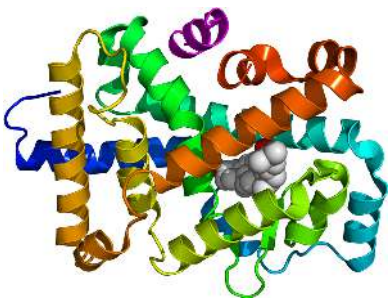

**Figure 54.3** Crystallographic structure of the ligand binding domain of RORγ (rainbow colored: N-terminus, blue; C-terminus, red) complexed with 25-hydroxycholesterol (space-filling model (carbon, white; oxygen, red) and the nuclear receptor coactivator 2 (magneta). (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:RORC_3L0L.png#/media/File:RORC_3L0L.png.

Various models have been proposed to explain how IDO can suppress the immune response and block the antitumor effect of TILs. One model holds that local deprivation of tryptophan prevents the phosphorylation of T cell receptor zeta chains, thereby preventing further activation of T cells [43]. Other studies have examined the role of IDO-generated kynurenines and how they may act directly or indirectly to reprogram effector T cells into tolerogenic Tregs [68]. Perhaps as an echo of the 1956 cancer studies, enzymatic inhibitors of IDO have been developed as an effort to abrogate its downstream immunosuppressive effects. The most promising of these inhibitors is 1-methyl-tryptophan, a structural analog that blocks the catalytic site of IDO, and is being tested in clinical trials for breast cancer, brain tumors and melanoma (http://www.clinicaltrials.gov). As such studies continue, the mechanistic switches that govern maladaptive tolerance to cancer will better inform future IDO-targeted therapies.

### 54.3.4 Indoleamine 2,3-dioxygenase and immunosuppression by mesenchymal stromal cells

Although not basally expressed in resting MSCs, upon treatment with IFN-γ the expression of IDO increases greatly in MSCs, as confirmed by mRNA levels and Western blot protein analysis [69,70] (see Section 54.4 on cytokine licensing of MSCs). A number of studies have shown that in human MSCs, the IDO enzyme is a key correlate of immunosuppressive ability [71,72]. Using bone-marrow-derived MSCs from a variety of different donors, we showed that immunosuppressive potency was correlated with the expression of IDO protein [72]. Others have explored the downstream effects of IDO-catalyzed changes in target cells and noted decreased levels of tryptophan as well as increased production of kynurenines [37]. The mechanisms whereby MSCs and kynurenines together suppress leukocyte inflammation are an area of active research [45]. In a 2011 study our group showed a link between IDO catalysis and MSC reprogramming of inflammatory macrophages (conventional or M1 macrophages) into anti-inflammatory (M2) macrophages. The contributions of M2 macrophages have become increasingly

appreciated as key players in wound healing and postinflammatory resolution [45]. Such reprogramming of peripheral macrophages may be a recapitulation of MSCs in the marrow, which are known to modulate the bone-resorptive activity of monocyte-derived osteoclasts [18]. Crosstalk between MSCs and M2 macrophages has been demonstrated by a number of studies [73–75], further suggesting this axis of immunosuppression may be important for *in vivo* efficacy.

In addition to monocytes, IDO catalysis has been found to an important factor in the reprogramming of inflammatory T cells into a regulatory phenotype. This was first suggested in a 2004 report in which MSCs were shown to inhibit the proliferation of T cells in a human MLR by IDO-catalyzed production of kynurenines [76]. These studies have been expanded through the use of animal models in which organs are co-transplanted with allogeneic MSCs [77]. The presence of IDO and the increased production of kynurenines were both shown to be associated with long-term graft tolerance as well as increased frequency of both peripheral and tissue-resident Tregs [78].

## 54.4 Mesenchymal stromal cell response to inflammatory signals: licensing and integration

Having considered the cellular biology of MSCs observed via *in vitro* methodologies, as well as appreciating their endogenous role in the normal hematopoietic niche, we now turn to how MSCs' functionality is altered by inflammatory signals. Much of the basic and clinical research occurring with MSCs explores these cells' unique immunomodulation, and how it changes before, during, and after *in vitro* culture expansion. Tissue culture experiments are vital to the furtherance of all MSC biology work, as rigorous reductionist methods teach us with each new data point obtained. When such work is predicated on endogenous observations, it affords a better perspective on how MSCs function in patients currently being treated with these cells.

We described earlier the role of MSCs in the hematopoietic niche, where they integrate a variety of signaling paradigms – CXCL12, SCF, and adrenergic stimuli – to regulate the development of lymphoid and myeloid cells that defend and oxygenate all tissues. In addition, MSCs have been observed to exert immune control in the peripheral tissues, suppressing immune activation and tipping the inflammatory milieu back toward therapeutically beneficial resolution. As stromal cells, MSCs are poised to respond to environmental cues in the marrow, adipose tissue, or other vascularized tissues, and thence exert their immunomodulatory abilities [7]. The mechanisms by which MSCs sense inflammation, integrate stimuli, and modulate the immune response depend upon basic cellular biology. That is to say, the response of MSCs is determined by the identity of activating ligands, the presence of the relevant receptor, and the activation state of diverse adaptors that transduce, amplify, or otherwise allow MSCs to coordinate the local immune response.

As tissue-resident stromal cells, MSCs can respond to inflammatory stimuli through a diversity of receptors. One of the most important classes of innate sensing molecules possessed by MSCs are the highly conserved pattern recognition receptors (PRRs). These are surface or intracellular sensing molecules that detect inflammatory changes early in the course of infection or injury. MSCs possess a number of PRRs that enable them to sense and migrate towards an inflammatory nidus and help coordinate the influx of innate and adaptive immune cells. We will sequentially discuss the effects of inflammatory signaling on MSC phenotype and behavior as it pertains to a number of different ligand classes. However, it is essential that it is understood that *in vivo* all such signaling happens simultaneously, and it is via the integration of local and long-range signals that stromal cells and leukocytes together cooperate to inflame, defend and then repair the tissue microenvironment.

Let us consider as an example a chronically nonhealing wound, such as a stasis ulcer that can arise in people with poorly controlled diabetes mellitus. Although a variety of endocrine and cardiovascular factors contribute to such pathology, over time endothelial cells and capillary-associated cells locally release inflammatory cytokines and chemokines in response to poor perfusion, leading to pathologic degradation of the extracellular matrix. One key cytokine in this process is TNF-α, which we will discuss at length later, but for now it should be noted that its local action in capillary beds causes vasodilatation, enabling the local diapedesis of leukocytes [79]. The exposed endothelium causes platelet activation, release of additional inflammatory mediators, and the formation of clots in the microvasculature, attempting containment of the insult. An increasing body of literature has appreciated the diverse secretome of platelet activation, including cytokine growth factors such as platelet-derived growth factor, vascular endothelial growth factor, and TGF-β, eicosanoids like thromboxane A2, and fibrinolytic and anti-fibrinolytic enzymes. Eicosanoids are signaling molecules made by oxidation of 20-carbon fatty acids. They exert complex control over many bodily systems, mainly in growth during and after physical activity, and in inflammation or immunity after the intake of toxic compounds or pathogens. Thromboxane A2 is a type of thromboxane that is produced by activated platelets and has prothrombotic properties. It stimulates activation of new platelets as well as increasing platelet aggregation. The structure of thromboxane A2 is shown in Figure 54.4.

### 54.4.1 Mesenchymal stromal cells and complement

The complement system is an early innate immune defense mechanism comprised of plasma proteins that interact with membrane surfaces. Elements of the complement system were first identified by their "complementary" role in antibody-mediated lysis of pathogens. However, a modern evolutionary understanding of these proteins reveals their early innate action, long before the adaptive immune system begins antibody production. Indeed, the alternative and lectin pathways demonstrate that

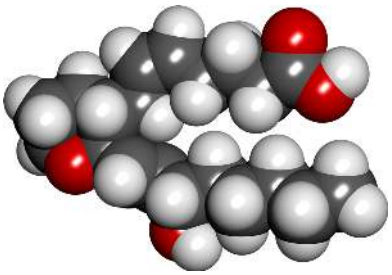

**Figure 54.4** A space-filling model of thromboxane A2. *Source:* http://commons.wikimedia.org/wiki/File:ThromboxaneA2_spacefill.png#/media/File:ThromboxaneA2_spacefill.png.

from sea urchins to humans the complement system functions to detect foreign invaders [80]. In the case of an inflammatory ulcer, a breach of the tissue with the outside environment introduces a host of pathogens. Complement proteins are deployed in the process of opsonization, to coat invading pathogens, either lysing or delivering them up to phagocytic cells for destruction. Through the deposition of complement proteins on to pathogen surfaces, the cleavage of reactive thioester bonds generates split products, such as C3a, C4a, and C5a. Listed in order of increasing inflammatory potential, these anaphylatoxins (complement peptides) ligate G-protein-coupled receptors on leukocytes to enhance phagocytosis, antigen-processing, and presentation.

MSCs have been shown to express the C3a and C5a receptors and to migrate chemotactically to *in vitro* gradients of C3a and C5a. The mechanisms of C3a receptor ligation were shown to be linked to receptor translocation and prolonged extracellular signal-regulated kinase 1/2 phosphorylation within primary human MSCs [81]. Others have shown that anaphylatoxin generation and even complement deposition on MSC surfaces is important in activating and enabling MSC immunosuppression in MLRs [82]. Moll *et al.* showed that this effect was associated with expression of the surface membrane protein CD59, which prevents complement-mediated lysis of MSCs. Together, such results suggest that MSCs are poised to respond to local complement activation and modulate the early inflammatory response to injury or infection.

### 54.4.2 Mesenchymal stromal cells and toll-like receptors

With the loss of epithelial integrity (such as in the lesions of inflammatory bowel disease – see Chapter 50), microbes entering into the wound may be of commensal origin, living in host tissues without causing overt disease, but upon entry to the subcutaneous niche become pathogenic. Such microbes are referred to as pathobionts, in that they have the ability to cause disease when in conjunction with other damage-associated markers [83]. The highly conserved molecular patterns of microbes are called pathogen-associated molecular patterns and those released from damaged tissues (such as heat shock proteins or uric acid) are called damage-associated molecular pattern molecules. A variety of immune competent cells, including MSCs, express receptors for such molecules, sensing microenvironmental changes to help coordinate the immune response [84]. In addition to the soluble defense mechanisms, including complement, ficolins (oligomeric lectins that activate the lectin pathway of complement activation), and C-reactive protein, invading pathogens are sensed by PRRs. Evolutionarily ancient in origin, PRRs recognize conserved patterns common in microbes, such as the formylated methionine residues found in bacteria, and detected by the formyl-methionyl-leucyl phenylalanine receptor.

In considering the role of PRRs in MSC biology, the best characterized class is the toll-like receptor (TLR) family. Initially discovered as innate sensing molecules in *Drosophila*, TLRs can be found on the cell surface or on intracellular membrane surfaces of a variety of vertebrate and invertebrate cells. There have been 11 TLRs described in humans and 13 in mice. These molecules are able to detect and transduce danger signals associated with pathogenic lipoproteins, lipopolysaccharide (LPS, also known as endotoxin), flagellin, double- or single-stranded RNA, and unmethylated cytosine–phosphate–guanosine DNA motifs [84,85]. It is important to note that TLRs do not just sense invading microbes but also host-derived molecules indicative of inflammatory or necrotic processes. Accordingly, TLRs have been described in the response to uric acid, heat shock proteins, intracellular cell debris, or fragments of extracellular matrix [84].

The pattern-sensing TLR domain contains about 20 leucine-rich repeats, which facilitate its ligand detection via homo- or heterodimerization. Depending on the class of ligand being sensed, a TLR will recruit different adaptor molecules to its signaling region; for example, the 200-residue toll–IL-1 receptor homology (TIR) domain, in which the toll domain is shared with the IL-1 receptor, demonstrates the importance of this cytokine in tuning and responding to inflammatory events. TLR dimerization patterns, as well as a diversity of adaptor molecules (myeloid differentiation primary response protein 88, TIR domain adaptor protein, TNF-receptor-associated factor (TRAF), and TIR-domain-containing adapter-inducing IFN-β-related adapter molecule), help to explain how only a dozen or so molecules can transduce a diversity of signals that vary according to the level of threat posed by each pathogen- or host-derived ligand. These signals feed into the nuclear factor κB (NF-κB), mitogen-activated protein kinase, or caspase pathways, resulting in immune activation, proliferation, or apoptosis [85].

The presence and function of TLRs on MSCs has been interrogated in a number of studies exploring primary murine and human MSCs derived from a variety of tissue sources. Such reports have identified some degree of expression for TLR families 1–6, although TLR3 and TLR4 are the only classes that reach expression levels comparable to that seen in hematopoietic-derived cells [86]. In one such study researchers identified that stimulation of MSCs with the well-characterized TLR4 ligand LPS abrogated the ability of MSCs to exert immunosuppressive modulation on *in vitro* T cell proliferation assays. Likewise, treatment of MSCs with poly(I:C) (a synthetic double-stranded RNA analog and TLR3 ligand) prevented the

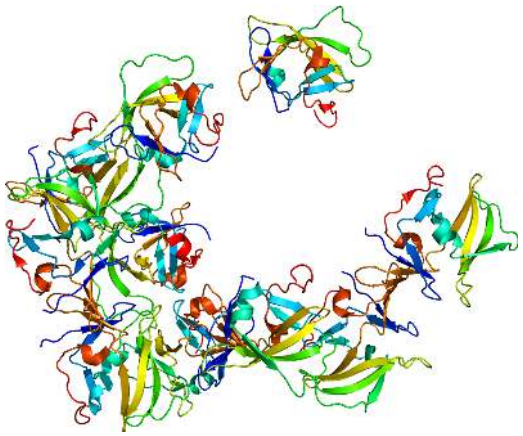

**Figure 54.5** Rendering of the structure of the DEAD box polypeptide 58 based on Protein Data Bank 2QFB. (See color plate section) *Source:* http://commons.wikimedia.org/wiki/File:Protein_DDX58_PDB_2QFB.png#/media/File:Protein_DDX58_PDB_2QFB.png.

immunosuppression observed in controls. Treatment of MSCs with either LPS or poly(I:C) induced NF-κB activation, as well MSC downregulation of the protein Jagged-1. Jagged-1 is a ligand for the T cell receptor Notch, and MSC signaling via Notch and Jagged-1 has been implicated in MSC immunosuppression of T cells [86]. Other studies show that TLR3 or TLR4 ligands cause MSCs to produce greater amounts of IL-1β, IL-6, CXCL8, chemokine (C–C motif) ligand (CCL)5, and IL-12p75 [87]. Furthermore, it was shown that treatment of MSCs with IFN-α increased expression of TLR3. Type I IFNs (IFN-α or IFN-β) function as early innate mediators and activate defenses, including protein kinase R and retinoic acid-inducible gene 1, key systems that block viral proliferation in host cells. Retinoic acid-inducible gene 1 contains an RNA helicase-DEAD (Asp–Glu–Ala–Asp) box motif and a caspase recruitment domain also known as a caspase activation and recruitment domain. The structure of DEAD box polypeptide DDX58 is shown in Figure 54.5, and a cartoon of the caspase recruitment domain RIP-associated protein with a death domain (RAIDD) is shown in Figure 54.6.

In the same experimental system we found that treatment with IFN-γ, the type II IFN, increased MSC expression of both TLR3 and TLR2. The observations that TLR ligands prevent MSC immunosuppression are nonetheless consistent with their coordinating role in the early immune response. By analogy, TLR ligands have been shown to activate dendritic cells, priming them to perform antigen-presentation to engage the adaptive immune system. Much as dendritic cells modulate the immune response, tissue-resident MSCs can be seen as responsive to microenvironmental cues, engendering early inflammation but later tipping the balance back to resolution and repair.

### 54.4.3 Interferon-γ in the immune response

The role of IFN-γ is most commonly understood as a cytokine involved in the coordination of the immune response, specifically that driven by Th1 cells. Its crystallographic structure is shown in Figure 54.7.

The first descriptions of Th1 and Th2 cells, performed by Mossman and Coffman in 1986, showed that T cell subsets respond to stimulation differently and can be characterized by their specific cytokine secretion [88]. Today, some degree of plasticity is appreciated to exist, wherein T cells may secrete multiple cytokines or be reprogrammed to different subsets. However, the role of IFN-γ derived from Th1 cells spurred many studies exploring this cytokine's effect on the immune response. Like the type I IFNs (IFN-α and IFN-β), IFN-γ was noted early on for its ability to "interfere" with viral replication. It is now thought that the Th1 response is most well adapted to a variety of intracellular pathogens, such as *Mycobacteria* and *Listeria* as well as protozoans and viruses. Since it is derived chiefly from activated T cells, it does not arise until later in the inflammatory process, after innate immune cells, both resident and immigrant, have sounded the alarm. This is an important point, for the persistence of IFN-γ in the cytokine milieu signifies ongoing inflammatory changes in the microenvironment.

In a successful immune response the immune infiltrates will defeat the pathogen, and a shift toward immune suppression, wound healing, and repair must occur, otherwise there is a risk of

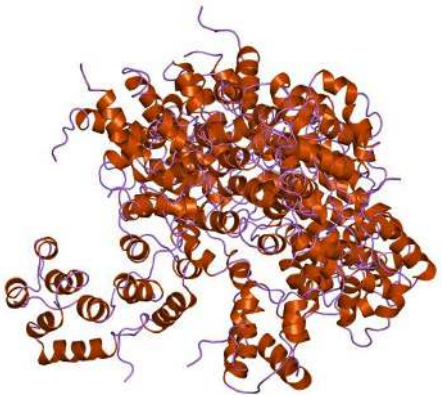

**Figure 54.6** A cartoon representing the structure of the caspase recruitment domain RAIDD. *Source:* http://commons.wikimedia.org/wiki/File:PDB_3crd_EBI.jpg#/media/File:PDB_3crd_EBI.jpg.

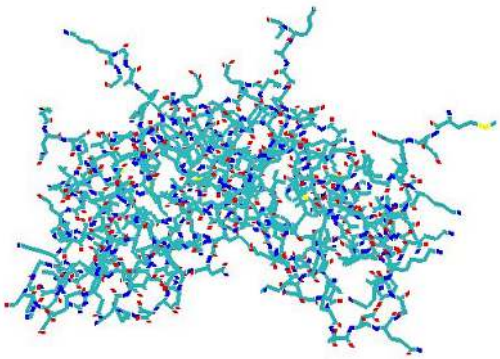

**Figure 54.7** Line representation of the crystallographic structure of IFN-γ. *Source:* http://commons.wikimedia.org/wiki/File:IFN.png#/media/File:IFN.png.

the development of a chronic nonhealing wound. From this perspective we can appreciate how and why inflammatory signals, such as IFN-γ, can deploy the anti-inflammatory effect of MSCs, both *in vitro* and *in vivo*.

### 54.4.4 Mesenchymal stromal cells and interferon-γ

In the past decade a number of studies have sought to identify the most important factors involved in immunomodulation by MSCs. Both IDO and PD-L1, described earlier, have been found to be essential in conferring on human MSCs the ability to suppress T cell proliferation and effector function. Resting MSCs – that is, cells derived from primary tissue sources and maintained in *in vitro* culture – are only partially effective at suppressing T cell proliferation. Pretreatment with an inflammatory mediator will "license," or greatly augment, the immune veto effects of the MSCs. Among the mediators described thus far, IFN-γ has been the most well explored and characterized MSC licensing agent. A number of studies have demonstrated that IFN-γ markedly enhances the ability of human MSCs to suppress allo-proliferation in MLRs, as well as mitogen-driven immune proliferation [70,89,90]. After ligating the receptor for IFN-γ (IFN-γR), Janus-family kinases 1 and 2 both associate with the intracytoplasmic tails of the receptor. Following this, STAT1 homodimerizes and is phosphorylated, enabling it to traffic to the nucleus to initiate transcription of IFN-γ-responsive genes. In MSCs, IFN-γ treatment results in STAT1 phosphorylation and the upregulation of a number of genes, including IDO. It has been shown that, in response to IFN-γ, primary human MSCs increase expression of class I HLA and begin to express *de novo* class II HLA as well as PD-L1 [39,91]. The importance of IFN-γ and IDO in enabling MSC immunosuppression has been demonstrated through the use of blocking antibodies to the IFN-γR, as well as small-interfering-RNA-mediated knockdown experiments targeting IDO, after which the MSCs are not able to suppress as well. The increased expression of HLA molecules is consistent with antigen presentation, which may be a way to recapitulate the endogenous role of MSCs as enforcers of self-tolerance as described earlier.

### 54.4.5 Tumor necrosis factor-α in the immune response

TNF-α is a cytokine that is classically associated with both acute and chronic inflammatory responses. As a component of the acute phase response, TNF-α signaling triggers containment of infection while also initiating vasodilatation in the area of inflammation. However, systemic release of TNF-α (either induced experimentally or observed in patients) results in a clinical syndrome not unlike septic shock. (Septic shock is a result of severe infection with sepsis; the latter term denotes the presence of pathogenic microorganisms in the bloodstream. Shock refers to the low blood pressure characteristic of this often catastrophic illness. It can cause multiple organ dysfunction syndrome and death.)

The discovery of TNF-α followed the characterization of a hormone known as cachectin, which had been found at high levels in the blood in patients with cachexia, a clinical syndrome with extreme muscle and fat wasting, common in late-stage cancer patients. In 1985, Bruce Beutler performed the first studies showing that TNF-α and cachectin were in fact the same molecule [92]. It is now appreciated that signaling via TNF receptors (TNFRs) is crucial for a vast array of processes, beyond the shaping of acute and chronic inflammation. As an example, TNFR signaling is essential during the development of secondary lymphoid organs, particularly those of the gut, including Peyer's patches and mesenteric lymph nodes, via the extrinsic and intrinsic transduction of apoptotic or survival cues [93,94].

We will only describe the extrinsic or death receptor pathway, as it is so vital to immune system function. Additionally, its membrane-bound activation affords a perspective on how cell-to-cell TNF signaling can induce target cell death. Upon ligation the TNFR homotrimerizes and its intracellular death domain moieties, in the case of TNFR-1, associate with TNFR-1-associated death domain (TRADD) protein. Depending on the ligand–receptor class, TRADD can then associate with Fas-associated protein with death domain and activate the initiator caspase CASP8, leading to eventual apoptosis driven by the executioner caspases CASP3, CASP6, and CASP7. Alternatively, recruitment of adaptor TRAF will instead lead to activation of the transcription factors NF-κB, as well as the kinase c-JUN, part of the activator protein 1 complex, which leads to cell survival, proliferation, or immune activation [95].

The relevance of TNFR signaling for MSC biology lies in the point that, depending on cellular context and ligand–receptor pairing, such signaling paradigms can lead to (a) activation of immune cell functions and (b) the deletion of lymphocytes during the resolution of inflammation. In order to understand the effects of inflammatory licensing of MSCs it is helpful to employ reductionist *in vitro* experiments informed by a thorough understanding of the cytokine milieu that characterizes the microenvironment. Although recognized as a key mediator of the inflammatory response, direct observations of the effects of TNF-α on MSC licensing and subsequent immunosuppression are still developing. In a 2014 paper, Dorronsoro *et al.* set out to characterize the role of TNF-α derived from T cells and its effect on the suppressive capacity of primary human MSCs [96]. They first noted that T cells activated by anti-CD3 and anti-CD28 monoclonal antibodies secreted large amounts of TNF-α in culture media and this induced robust NF-κB signaling in MSCs. Having observed both effects to correlate with immune suppression, they transduced MSCs with short hairpin RNA for the inhibitor of kappa kinase β. Forced expression of inhibitor of kappa kinase β causes constitutive repression of MSC NF-κB signaling and resultant failure to immunosuppress. In carefully designed experiments the team used transwells, anti-TNF-α antibodies, recombinant TNF-α, and a mutated form of the TNFR to show that T-cell-derived TNF-α is required for MSC immunosuppression.

Other recent work by Dorronsoro and team has explored the role of A20 zinc finger protein, which is an anti-inflammatory protein involved in signal integration downstream of TNF-α and NF-κB [97]. The protein A20 has a dual function, with a de-ubiquitinating motif as well as possessing E3 ligase activity. In cellular biology, ubiquitination is a complex process involving the enzymatic addition of ubiquitin chains to proteins, marking them for recycling via the proteosome or lysosomal degradation. (The proteasome is a multisubunit enzyme complex that plays a central role in the regulation of proteins that control cell cycle progression and apoptosis.) Multiple and redundant levels of regulation exist to tag, target, and process the ubiquitination of cell signaling proteins, any of which can go awry and lead to neurodegenerative diseases or some forms of cancer [98,99]. In APCs such as dendritic cells or macrophages, silencing of A20 leads to a hyperstimulatory effect by which these cells are able to overcome tumor-derived Treg cells, tipping the balance toward eradication by cytotoxic T cells [100]. Such studies have described A20 as an attenuator of antigen presentation, tempering the immune stimulatory effect via NF-κB degradation. Germane to MSCs, the team led by Dorronsoro found that, upon stimulation by TNF-α, MSCs rapidly degrade intracellular A20, perhaps consistent with the early inflammation of an immune response [97]. The precise regulation of TNF-α and A20 in MSC activation remains to be fully defined, but signs point toward a delicate balance of immune activation coupled to a compensatory immunosuppressive phenotype.

One last aspect of TNF-α signaling in MSCs that deserves special mention is TNF-α-stimulated gene 6 protein (TSG-6). This protein was first discovered by stimulating skin fibroblasts with TNF-α [101], but more recently its anti-inflammatory effects have been studied via its secretion from MSCs. A number of preclinical research models employing MSCs have sought to inject human MSCs into mice in order to study their engraftment and immunomodulatory potential. After the intravenous injection of MSCs in mice, the cells get lodged in the lung vasculature. However, therapeutic improvement is still observed, even after the cells are no longer present. Paracrine release of anti-inflammatory factors has been suggested to explain this effect, with TSG-6 as one likely candidate.

It was in one such study exploring the utility of MSCs to direct regeneration of myocardial tissue after infarction that Lee *et al.* [102] noted that human MSCs localized in the lungs and then upregulated mRNA for TSG-6 80-fold higher than controls. They noted that the amount of TSG-6 protein released by MSCs far exceeded that which has ever been observed from skin fibroblasts. Further experiments revealed that MSC-derived TSG-6 is involved in inhibition of matrix metalloproteinases and that its presence tips the balance toward resolution of post-infarction inflammation. One other recent study has explored the role of TSG-6 from MSCs and how this paracrine factor can temper the immune response. In a 2011 study, Choi *et al.* used a TLR2 agonist, zymosan, to induce inflammatory peritonitis in mice and then injected human MSCs intraperitoneally [103]. They noted that MSC-derived TSG-6 attenuated the inflammatory response by inhibiting NF-κB activation in peritoneal macrophages. From TSG-6, A20, and the growing number of studies on TNF-α, it is clear that this inflammatory cytokine primes MSCs, enabling them to perform their immunomodulatory function in a variety of settings.

### 54.4.6 Synergy of interferon-γ and tumor necrosis factor-α in mesenchymal stromal cells

MSC licensing has been explored through a number of studies utilizing both human and mouse MSCs in a variety of assay systems. The T cell suppression assay, described earlier, is perhaps the most reductionist method to study the pretreatments by which MSC immunomodulation can be altered. It was through such studies that Ren *et al.* demonstrated a synergistic effect after treating murine MSCs with both IFN-γ and TNF-α [104]. In this 2008 study, murine MSCs were found to depend on IFN-γ signals for activation, as MSCs lacking the IFN-γ receptor were unable to suppress T cell proliferation. It is important to note in the MSC field that murine MSCs do not utilize IDO at all. Rather, the enzyme best correlated with IFN-γ-induced licensing is inducible nitric oxide synthase. Ren *et al.* demonstrated that upon treatment with IFN-γ, plus addition of either TNF-α or IL-1, murine MSCs induced the highest levels of inducible nitric oxide synthase and chemoattracted and suppressed the proliferation of T cells more robustly than with pretreatment by a single proinflammatory cytokine. In 2010 our research group sought to explore the connection between synergistic cytokine licensing and the antigen-presenting capacity of MSCs [105]. As mentioned earlier, MSCs may be induced to express both class I and class II HLA molecules and have also been observed to perform cross-presentation, akin to dendritic cells. On treating MSCs with both IFN-γ and TNF-α we observed enhanced antigen-presenting capacity as well as reduced activation and proliferation among co-cultured T cells. As others have noted, and we described, Ren and team showed the source of these cytokines to be the activated T cells, leading to a feedback loop in which the inflammatory milieu primes MSCs into a regulatory, immunosuppressive phenotype. A schema summarizing our group's interpretation of MSC licensing is shown in Figure 54.8.

## 54.5 Strength of signal and integration

Some controversy has arisen regarding MSCs in clinical trials, as results have not been uniform in replicating promising *in vitro* findings. We and others have pointed out that this may be due to differences in cell source and processing between studies [106]. Such challenges could be inherent to cell therapeutics, suggesting they will remain the purview of academic or biomedical research centers equipped for such protocols.

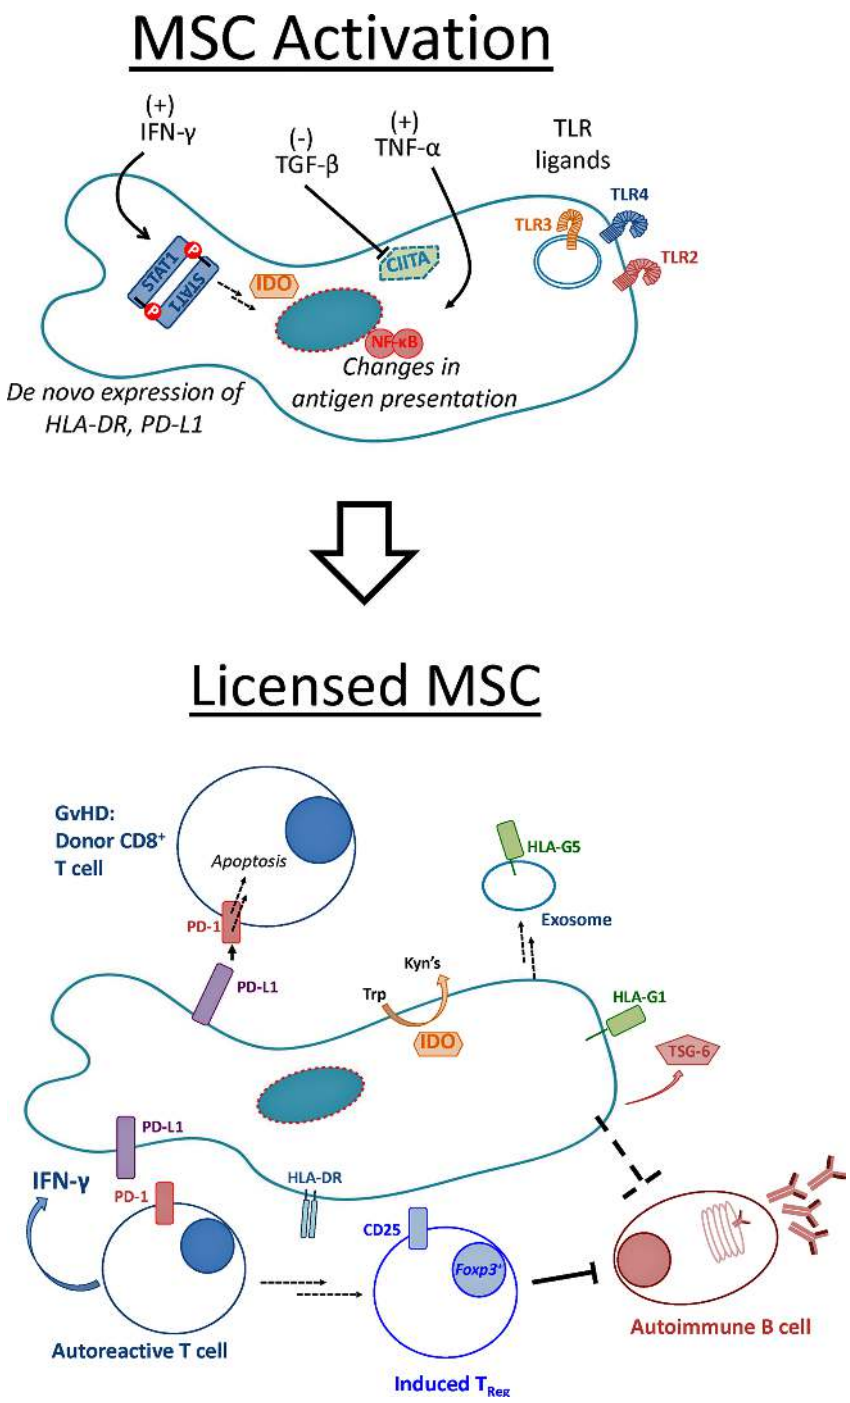

**Figure 54.8** Licensing of MSCs activates their immunomodulatory capabilities. Exposure to inflammatory stimuli causes MSCs to undergo a number of RNA- and protein-level changes, activating their immunomodulatory capabilities. This includes the *de novo* expression of PD-L1 and HLA-DR, as well as increased expression of class I HLA molecules. TNF-α signaling causes a number of NF-κB-mediated signaling events consistent with immune activation. TGF-β treatment abrogates expression of HLA-DR via inhibition of the class II transactivator CIITA [70]. After *in vitro* licensing, MSCs have been shown to more efficiently suppress the function and proliferative capacity of T and B cells. In the setting of cellular therapy it is thought that inflammatory factors in the patient can activate these same mechanisms, resulting in immunomodulation by the transfused MSCs.

However, some of these heterogeneous results may in fact be explained by the MSCs themselves. In a tissue culture system MSCs typically adopt a fibroblast-like morphology, but as culture conditions change, differences can be perceived. At low culture densities MSCs exhibit a small, round morphology characterized by rapid self-renewal. In this state MSCs express surface proteins that maintain the mesenchymal state, thereby promoting motility and inhibiting cell adhesion. After continued culture towards confluence, the cells adopt an extended fibrous shape while some of their mesenchymal plasticity and surface antigen expression is lost (see Chapter 7). This bimodal distribution of MSCs is referred to as Type 1 or Type 2 MSCs (MSC1 and MSC2 respectively). MSC1s are the smaller, self-renewing, and robustly pluripotent cells. MSC2s have reduced proliferative capacity and may be less desirable as a cellular therapeutic agent [20].

If MSC1 and MSC2 represent different temporal states of MSC populations *in vitro*, it may help to explain the differential behavior of MSCs on infusion into human patients. In the early

phases of an inflammatory insult, tissue-resident MSCs can behave like classical APCs. In response to acute-phase stimuli such as IL-1, TNF-α, or TLR agonists, MSCs upregulate HLA molecules to coordinate with the influx of first-responder leukocytes. MSCs have been shown *in vitro* to present both soluble and intracellular antigens on class I and class II molecules, in addition to cross-presentation, just as classically activated dendritic cells do [107–109]. Whether unmanipulated MSCs are capable of upregulating CCR7, and thereby trafficking to secondary lymphoid organs, remains controversial [110–112]. Nonetheless, their antigen-presenting role in the early inflammatory response plays an important role in tissue maintenance.

As inflammatory stimuli persist, the ingress of activated T cells, particularly IFN-γ-releasing Th1 cells, alter the stromal tissue cytokine milieu in which leukocytes and MSCs interact. Th1 cells are known to be pathologic in a number of chronic inflammatory conditions, and have been associated with aberrant wound repair and immune activation, as observed in sarcoidosis and cutaneous ulcers [113,114]. (Sarcoidosis is a disease involving abnormal collections of inflammatory cells (granulomas) that can form as nodules in multiple organs. The granulomas are most often located in the lungs or its associated lymph nodes, but any organ can be affected. Granulomatous inflammation is characterized primarily by accumulation of monocytes, macrophages, and activated T cells, with increased production of key inflammatory mediators such TNF, IFN-γ, IL-2, IL-8, IL-10, IL-12, IL-18, IL-23, and TGF-β, indicative of a Th1-mediated immune response.)

As discussed earlier, increasing levels of IFN-γ act on MSCs in a STAT1-dependent fashion, upregulating the enzyme IDO, the cell surface marker PD-L1, and other changes. Poised as stroma-resident immune coordinators, MSCs may integrate the signals initiated by inflammatory products, and, in physiologic conditions, tip the local balance back toward resolution and repair. Immunosuppression, so often demonstrated through *in vitro* assays, may play a crucial role *in vivo* by dampening the proliferative capacity of pathologic T cells (IDO-catalyzed changes), contact-dependent deletion (PD-L1), and the paracrine release of factors such as TSG-6, prostaglandin $E_2$, and antagonistic matrix metalloproteinase-processed CCL2 with anti-inflammatory properties.

## 54.6 Clinical applications of mesenchymal stromal cells for immune-mediated diseases

### 54.6.1 How *in vitro* data inform assessment of clinical efficacy

Discussion of the mechanistic cellular biology of MSCs is an important endeavor, for any efforts aimed at future development of these cells as a therapeutic agent must be based on scientific data. The studies described heretofore posit elegant models that seek to define the *modus operandi* for MSCs. We now turn our attention to recently generated data from larger scale clinical trials examining the therapeutic utility of MSCs in immune ailments sponsored by governmental and industry-based organizations in a variety of settings worldwide. We frame our discussion by the general platform by which clinical researchers are deploying the MSC product, and analyze these results vis-à-vis the putative mechanisms by which they are thought to act. It is our hope the reader may thereby gain a contextual framework to better understand the biology of these immunomodulatory cells.

### 54.6.2 Random donor, industrial scale

Osiris Therapeutics Inc. is a company based in Columbia, Maryland, USA, and their human bone-marrow-derived MSC product named Prochymal has been explored in a variety of clinical studies. Though much of their preclinical data have been encouraging, a recent phase III randomized placebo-controlled study failed to meet its primary endpoint in a study of severe acute graft-versus-host disease (GVHD) occurring after HSC transplantation (HSCT) [115]. In this study, overall 100-day response rate of patients receiving MSCs was 82% compared with 73% in the placebo group. Given other encouraging results using MSCs for immune-mediated diseases (notably from trials discussed later), it bears exploring some of the variations that may cause their product to achieve suboptimal results [106].

Recognizing that the development of autologous, or patient-derived, cells can sometimes be a challenge to generate in large-scale doses for patients in geographically diverse clinical trials, Osiris had sought to employ instead a so-called universal, or random donor, marrow source for their MSC product. According to the company's website and other papers published by the group [116], Osiris used MSCs from four different human sources, isolated, expanded, and archived according to good manufacturing practices as mandated by the US Food and Drug Administration for the handling of cell-based therapeutics. Many individualized dose units were then cryopreserved and shipped to health-care institutions participating in clinical trials using the Prochymal product. Given our earlier discussions regarding the differential behavior of MSCs in different cell niches, and their temporal abilities to respond to environmental cues, such a platform may be disadvantageous to clinical success. Using a massively expanded universal lot of cells could bias the overall population toward a clonal homogeneity that poorly reflects their *in vivo* niche. Clinical response in patients may therefore be blunted by infusion of suboptimal cells.

Lastly, and perhaps most importantly, for convenience of product distribution, Prochymal is shipped as a frozen bag and infused as a just-thawed product into patients. In their methods description [116], the study authors stated the cells are ascertained to have 70% viability, presumably by Trypan blue exclusion, though this was not specified. It remains an open question whether viability is the best determinant of MSC immunomodulatory abilities. This has been borne out in studies by our group and others showing that cryopreservation and

immediate infusion of thawed cells can cause dramatic loss of immune veto function [117–119].

Other studies have continued to explore the use of third-party MSCs in which the MSC donor is unrelated to, and MHC unmatched with, the MSC recipient for prophylaxis as well as treatment in GVHD occurring after HSCT. However, literature discrepancies exist regarding the definitions of response after treatment, including varied time-point assessment intervals, as well as different pharmacotherapy regimens before, after, and during MSC infusion, as well as patient age and severity of GVHD. GVHD is appreciated to be a complex syndrome, and each of the variables just mentioned can drastically alter the immunologic environment into which the MSCs are infused [120]. As perspective, the earlier described cellular biology research explored MSC function and effect through *in vitro* or animal models, but without addressing patient comorbidities or concomitant immunomodulatory therapy. Owing to variable GVHD presentations and cellular processing, it is difficult to truly compare large meta-analyses of MSC therapies [121]. A different approach may be to examine the results of such studies in consideration of their contextual framework.

One illustrative example comes from a European group in 2013 who treated a cohort of 37 children with severe grade III–IV GVHD using HLA-mismatched MSCs from cryopreserved third-party donor stocks [122]. These children had developed acute GVHD following HSCT and were treated with three doses of MSCs. Of these patients, 69% demonstrated a complete response, with the majority alive and well after a 3-year median follow-up period. The aforementioned review [121] by Introna and Rambaldi analyzes the recent developments in using MSCs immediately after HSCT as prophylaxis for GVHD, again in conjunction with standard pharmacotherapy regimens. One such study from a Russian group in 2012 infused MSCs sourced from the same donor as the transplanted HSCs as prophylaxis against GVHD [123]. Their cellular formulations are of interest. Some MSC doses were delivered fresh, others were given as thawed cellular preparations, but all cells were culture-expanded in human platelet lysate rather than fetal calf serum. Theirs was a randomized prospective study of 37 patients, mostly adults diagnosed with hematologic malignancies. The researchers demonstrate both safety and efficacy for prophylaxis, with 5% of the MSC-therapy group developing acute GVHD compared with 38% of the control group.

### 54.6.3 Allogeneic mesenchymal stromal cells, low passage

The function of MSCs in maintaining the hematopoietic niche in a healthy state and the multilevel signaling that maintains central tolerance was described mechanistically earlier. It is this very attribute of MSCs, their tolerance-enforcing role, that has motivated their application in a number of autoimmune diseases. Systemic lupus erythematosus is a complex disease with diverse symptomatology and prominent pathologic signs that imperil the gut, skin, kidneys, and nervous system (Figure 54.9).

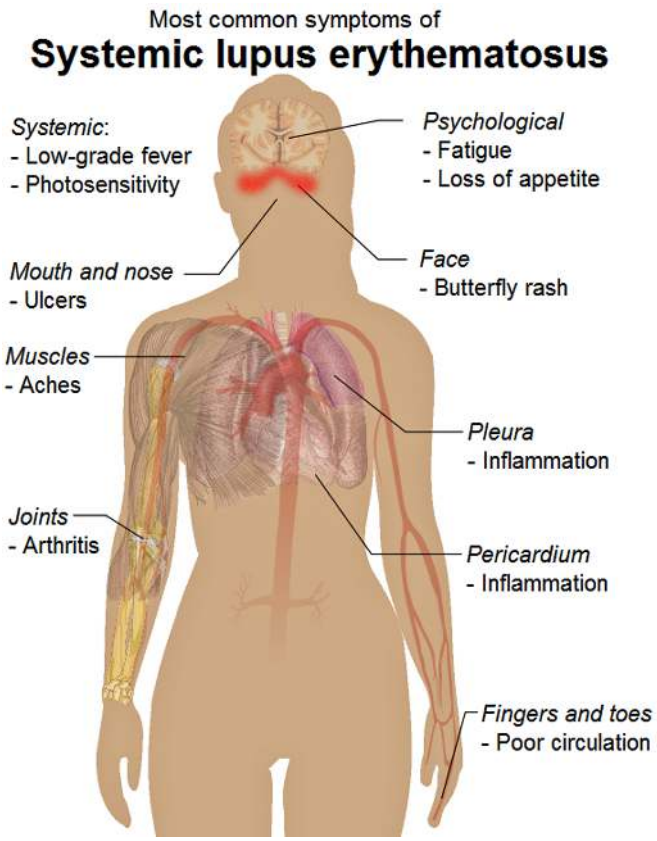

**Figure 54.9** The common symptoms of systemic lupus erythematosus, published in MedicineNet: Systemic Lupus (cont.). Last editorial review: 2009-01-30. *Source:* http://commons.wikimedia.org/wiki/File:Symptoms_of_SLE.png#/media/File:Symptoms_of_SLE.png.

Although not found in every case, antibodies that react with self-antigens have been shown to be critical to its pathogenesis. Either in the periphery or the marrow, lymphocytes that react against self-tissues are not reprogrammed into death or ignorance, and instead proliferate and wreak havoc across the body [124]. Given its immune-mediated nature, a number of research teams have sought to employ MSCs as a disease-modifying therapy in lupus.

One such study is a 2010 report that sought to treat lupus patients using autologous MSCs derived from the patients' own marrow. This study failed to show significant clinical benefit despite apparent increases in Tregs [125]. Hypothesizing that a tolerogenic defect may exist in the MSCs derived from lupus patients, a different team led by Lingyun Sun instead sought to utilize allogeneic MSCs. In a 2013 paper Sun and colleagues describe the results of 4 years' worth of clinical trial data conducted at their hospital in Nanjing, treating 87 patients with severe or drug-refractory lupus [126]. In their clinical trials, MSCs were harvested from marrow or umbilical cord, culture-expanded for no more than five *in vitro* passages and infused into patients while still in a fresh living state. Standard phenotyping and differentiation assays were performed to confirm MSC identity, but invasive studies aimed at mechanistic questions were not performed in these patients. Nonetheless, their data showed induction of clinical remission and improvement in renal function, irrespective of marrow or umbilical source.

These same researchers released a study in 2014 that sought to go further in identifying the mechanistic links whereby MSCs effect clinical improvement [127]. In a series of carefully reductionist experiments, the team replicated their allogeneic MSC data using *in vitro* assays of culture of lymphocytes and/or MSCs derived from healthy donors or patients with lupus. They demonstrated that it is the $CD8^+$ compartment of T cells that produces large amounts of IFN-γ, and that this in turn results in increased expression and enzymatic activity of IDO in healthy MSCs. Conversely, lupus-patient-derived MSCs were deficient in IDO activity, a measure that is defined as IDO catalysis of tryptophan into kynurenines. By careful comparisons of *in vitro* assays with the clinical trials, such reports demonstrate how basic cellular biology can synergize with clinical medicine to further our understanding of such cell-based therapies.

### 54.6.4 Autologous mesenchymal stromal cells for autoimmune diseases

Crohn's disease (CD) is an autoimmune disease characterized by inflammatory lesions that can occur anywhere along the gastrointestinal tract from mouth to anus. Along with ulcerative colitis, these two forms of inflammatory bowel disease (IBD) cause a spectrum of painful and damaging symptoms, including enterocutaneous fistulas, intestinal bleeding episodes, diarrhea, and malnourishment [128]; and see Chapter 50. Although the precise etiology has not been confirmed, it is generally accepted that CD arises in patients with a genetic predisposition and may represent a dysregulated immune response in the gut. The naturally tolerogenic balance of immune cells, gut tissues, and commensal flora is lost in these patients, and inflammatory cytokines such as IL-6, IL-23, and TNF-α have all been identified to play a role in its pathogenesis [129]. Although IBD can be described as an autoimmune disease, frankly self-reactive T cells or B cells are not uniformly found in all patients. Nonetheless, inflammatory damage to the gastrointestinal system is a hallmark of both ulcerative colitis and CD.

The immunologic component of IBD has been appreciated for some time, and a number of disease-modifying immunotherapies have been developed that are now in clinical use. These include anti-TNF-α antibodies such as infliximab and lymphocyte-depleting drugs drawn from the realm of chemotherapy, including azathioprine. Cell-based therapies have also been explored, including the transplantation of HSCs and MSC-based approaches. The rationale by which MSC administration is thought to improve IBD lies in their profound immunosuppressive effects, which have been described in a variety of *in vitro* and animal model systems. A number of ongoing clinical trials are now exploring MSC platforms as a therapy for CD. As has been said, interpreting these clinical data and the mechanisms by which the cells are thought to act affords us an excellent perspective on how to further improve MSC-based therapies for immune-mediated diseases.

In 2010 a Dutch group led by Hommes and Duijvestein released a report in which they described results from infusing ten CD patients with autologous bone marrow-derived MSCs [130]. Hommes and colleagues harvested MSCs from the patients, cultured the cells for no more than three passages, and then cryopreserved them prior to infusion. Patients received two infusions of cells 1 week apart. One of the distinctive aspects of this study was the battery of immunologic assays that the team employed to characterize patient responses. In addition to assessing symptom scores using the Crohn's disease activity index, the trial included endoscopic examination of lesional changes, as well as biopsies to assess T cell subsets and cytokine levels present in gut tissues. Additionally, they performed *ex vivo* T cell suppression assays, using PBMCs and MSCs derived from the same set of CD patients. Their *in vitro* experiments showed that MSCs derived from CD patients were not inferior to MSCs from healthy donors in suppressing the proliferation or cytokine secretion of CD3/CD28-stimulated PBMCs. As many of the patients received simultaneous pharmacologic treatments, the team added these drugs to co-culture systems, observing an additive effect on MSC immunosuppression. Biopsies from patients after MSC infusions showed a trend toward improvement, as suggested by Treg numbers and cytokine levels in lesional areas, but none of the patients in the study entered true long-term clinical remission. This study is nonetheless an important benchmark in MSC therapy for CD, in part because of the investigative mechanisms explored by the research team. By exploring *in vivo* the mechanisms by which MSCs have been shown to act *in vitro*, further insights are sure to follow.

## 54.7 Conclusions and next steps

It is our hope that by considering the cellular biology of the MSC we may be able to better understand the mechanisms by which these cells function in the human body, and thereby better develop cell-based therapies in the years to come. Though a number of encouraging clinical studies have been undertaken in recent years, key questions remain, most importantly regarding which immunologic mechanisms are the principal determinants of MSC bioactivity. If enzymatic catalysis of tryptophan by IDO is truly essential for their therapeutic effect, as observed in *in vitro* culture systems, then where and how is IDO activity optimized prior to giving MSCs to a patient? After intravenous injection does MSC entrapment by pulmonary vasculature stymy the cells' efficacy in modulating inflammation? And if so, does homing to diseased tissues play an important role? Although we have not discussed the genetic re-engineering approach, is expression of PD-L1, HLA-G, or CCR7 necessary for MSC efficacy and, if so, a worthwhile exploration, given the apprehension that still accompanies gene therapy?

One last consideration, but certainly not the least in terms of its priority, is how to culture MSCs *ex vivo* in order to ensure that the infused dose is as therapeutically active as possible. What are the factors that could be or should be added to culture media to make MSCs more effective? Administering cellular products with novel drug targets is already a translatable therapy in personalized cellular clinics. But which factors might exist – in the patient-derived platelet lysate, or perhaps in the conditioned media from MSCs with high IDO enzymatic activity, or the cytokines secreted by autoreactive T cells – that can ensure each infused dose of MSCs is biologically primed to exert its immune modifying effects?

The clinical studies described herein are making strong headway toward understanding MSC immunomodulation, examining peripheral and tissue-resident T cell compartments in patients after MSC administration, or subjecting MSCs to rigorous immunologic and biochemical analyses prior to infusion. Without standardized cellular processing protocols and companion potency assays, it will continue to be difficult to assess meta-analyses of MSC clinical trials. The challenge in advancing this cellular product will be to marshal enough support for one particular protocol to be consistently applied in large, statistically powerful, randomized controlled trials. As a plurality of institutes worldwide continue to utilize MSC therapies for a variety of ailments, it is essential to consider all such clinical data from the grounding perspective of molecular and cell biology and how it informs understanding and development of MSC-based therapeutics.

## 55.1 Introduction

Sepsis is a disease process representing the systemic response to severe infection. It is characterized by dysregulation of the host immune and inflammatory mechanisms [1]. The majority of cases of sepsis are due to bacterial infections. As a result, bacterial infections and sepsis represent a significant cause of mortality and morbidity [2]. The infectious insult activates the immune cells of the host, including neutrophils, monocytes/macrophages, and lymphocytes. This early activation of immune cells triggers a proinflammatory response that contributes to the eradication of the invading microorganisms [3]. Systemically, elevated levels of proinflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-1β, and IL-6 have been described in sepsis [4]. If the pathogens are not eradicated then sepsis can progress in severity with associated organ dysfunction and ultimately death. Even if the invading microorganism is eradicated the early proinflammatory response may also be followed by a later stage of immune paralysis, due in part to apoptosis of immune effector cells [5]. Despite an improved understanding of sepsis and its management, it still remains a significant and complex clinical problem. As a result, new and innovative treatment strategies are necessary to target each stage of sepsis [6].

One of the treatment strategies currently being investigated is the use of mesenchymal stromal cells (MSCs) for bacterial infections and sepsis [7]. MSCs are considered to be a promising platform for cell-based therapy. They possess a variety of anti-inflammatory and cytoprotective properties that could regulate the process of sepsis-induced inflammation and organ injury via several mechanisms targeting the various stages of sepsis [8]. MSCs express low levels of major histocompatibility complex (MHC) class I molecules but do not express MHC class II or costimulatory molecules such as CD80, CD86, and CD40. Therefore, they are considered to be immune-privileged cells and can be successfully transplanted across allogeneic barriers [9]. This chapter will review the properties of MSCs that can be used to target the harmful effects of bacterial infections as well as the data obtained from the use of MSCs in preclinical animal models of sepsis and the proposed mechanisms behind these findings. The proposed beneficial properties of MSCs against bacterial infection and sepsis are summarized in Figure 55.1.

ANG-1: angiopoietin-1; CXCR4: C—X—C chemokine receptor 4; FGF: fibroblast growth factor; HGF: hepatocyte growth factor; IDO: inoleamine 2,3-dioxygenase; IGF: insulin-like growth factor; KGF: keratinocyte growth factor; LL-37: human cathelicidin (also known as human cationic antimicrobial protein 18); MVs: microvesicles; NK: natural killer; NLRP3: NOD-like receptor family, pyrin domain containing 3; NO: nitric oxide; $PGE_2$: prostaglandin $E_2$; ROS: reactive oxygen species; SDF: stromal-cell-derived factor; TGF: transforming growth factor; TSG: TNF-α-stimulated gene/protein; TLR: toll-like receptor; VEGF: vascular endothelial growth factor.

## 55.2 Experimental models of bacterial infection and sepsis

MSCs have been tested in a variety of preclinical models of bacterial infection and sepsis. The complexity of these disease processes makes the clinical study of potential therapeutics difficult. As a result, animal models have been developed to help understand the pathogenesis of sepsis and to trial potential therapies such as MSCs. Sepsis models can be divided into three categories: exogenous administration of a toxin, exogenous administration of bacteria, or alteration of the animal's endogenous protective barrier [10]. As these models try to mimic the multistage picture of clinical sepsis, they each have their own limitations.

The lipopolysaccharide (LPS) or endotoxin model is an example of the exogenous administration of a toxin. LPS is the glycolipid that is present in the outer membrane of all Gram-negative bacteria. (Gram-staining was developed by Hans Christian Joachim Gram, a Danish bacteriologist, in 1884.) Exogenous administration of LPS causes a sepsis-like picture characterized by an elevated level of circulating proinflammatory cytokines without bacteremia [11]. This model is simple to perform and widely used. LPS has been given via a variety of routes and used in several species, including an *ex vivo* perfused human lung [12]. The LPS model has been criticized in that a bolus injection of LPS results in a rapid but transient host response that differs from the prolonged response of human disease [10]. Formylated peptides are a group of bacteria-derived components that are used to induce infection in preclinical models [13].

Animals can also be inoculated directly with bacteria. These models can be tailored by altering the route of infection; for example, into the blood, intraperitoneally, subcutaneously, or into the lung. The frequency of administration and the mode of administration, such as a bolus injection, a continuous infusion, or by an osmotic pump, can also be selected, as can the bacterial strain and the size of the inoculum. All of these parameters can affect progression and outcome. Direct inoculation has been used in a variety of animals, including mice, rats, and sheep [14,15].

The fibrin clot model is a variation of the direct inoculation model. It introduces a strain of bacteria into the peritoneal cavity and ultimately the bloodstream. It consists of entrapping a set dose of bacteria into a fibrin clot and performing a midline laparotomy to implant the fibrin clot into the peritoneal cavity. The benefits of this model are that it allows a slower release of bacteria and a more sustained infection [16]. Alternatives to a fibrin clot, such as a gelatin capsule, have also been used to introduce bacteria into the peritoneal cavity [17].

Host-barrier disruption models of sepsis involve disrupting the normal protective barriers that shield sterile compartments from pathogenesis. Cecal ligation and puncture (CLP) is an example of this type of model. It involves a midline laparotomy followed by externalizing, ligating, and puncturing the cecum. The perforated cecum then serves to leak fecal contents into the peritoneum, followed later by translocation of enteric bacteria into the blood. This establishes a polymicrobial model of infection as well as an inflammatory source of necrotic tissue. The amount of cecum ligated and the number and size of punctures can control the severity of the model [18]. The CLP technique is commonly employed owing to its ease of use. While the model is thought to be reproducible, there is operator variability as well as variability introduced from the amount of the load of fecal material in the ligated cecum. Despite its limitations, CLP is currently the most widely used animal model of sepsis [19].

The colon ascendens stent peritonitis is another example of a host-barrier disruption model of sepsis. It consists of a defined-diameter stent being placed into the ascending colon of mice, leading to persistent leakage of fecal content into the peritoneal cavity. Stent diameter is used to control the severity of disease induced. The stent can also be removed after defined time periods. Like CLP, it is also a model of acute polymicrobial septic peritonitis characterized by a rise in proinflammatory cytokines. However, systemic cytokine levels and bacterial blood counts are thought to be greater than in the CLP model. The colon ascendens stent peritonitis model has had limited usage as it involves a more challenging surgical procedure than CLP. MSCs have not yet been trialed in this model [10].

In order to develop a more clinically relevant model of sepsis, researchers have employed "two-hit" models. These models seek to mimic the changes in the host immunologic response with disease progression. For example, CLP is typically used as the "first hit" followed by bacterial pneumonia as the "second hit." This strategy seeks to encompass the early proinflammatory phase and the later state of immune paralysis [20].

All preclinical models differ from human sepsis because of age, comorbidity, and use of supportive therapy [19]. Despite these limitations, preclinical models have been a very important tool for studying the effects of MSCs on infection and sepsis. Bone marrow remains the most common source of MSCs. However, in recent years other sources of MSCs, such as compact bone and adipose-tissue-derived (AD)-MSCs, have shown similar effects [21]. Adipose-derived MSCs show promise, and they are much more readily available than bone-marrow-derived (BM)-MSCs [22]. MSCs can be given at various time points before, during, and after the infectious insult in all of these models. Their administration has conferred a survival benefit in many of these models. In addition to improving mortality, they also have been shown to have many other effects on the septic picture [23]. The remainder of this chapter will explore the potential mechanisms by which MSCs can improve outcomes in bacterial infections and sepsis. The findings from preclinical models are summarized in Table 55.1.

## 55.3 Effects of mesenchymal stromal cells on the innate immune response

In sepsis, patients surviving the initial infectious insult can develop features of immunosuppression that can result in secondary infection, organ dysfunction, and death. This immunosuppressive state is caused in part by apoptotic immune cell loss and immune cell dysfunction that occurs by a chronically excessive proinflammatory state [8]. MSCs interact with the innate immune system in several ways that may be beneficial in modulating this detrimental inflammatory response (and see Chapter 33).

Neutrophils are one of the important cells of the innate immune system and are considered a first line of defense against pathogens. These cells are rapidly mobilized in the setting of bacterial infections and are activated to kill microorganisms via a process known as the respiratory burst that occurs during phagocytosis. The respiratory burst (sometimes called the oxidative burst) is the rapid release of ROS (superoxide radical and hydrogen peroxide) from different types of cells. While neutrophils are critical for the clearance of bacteria, they can also result in collateral injury of normal tissue. MSCs have been shown to dampen the respiratory burst. In addition, MSCs have also been shown to inhibit neutrophil chemotaxis [26].

It has also been demonstrated that MSCs may promote the generation of ROS in neutrophils under direct *E. coli* stimulation to eliminate invading microbes. However, in the presence of MSCs, formylated-peptide-stimulated neutrophils demonstrated a decrease in ROS production [39,40]. These different outcomes may have been caused by different stimulators of the respiratory burst (e.g., live bacteria as opposed to bacteria-derived components), different incubation approaches, or the use of conditioned media (CM) instead of cells. In the former of these reports neutrophils were treated with CM, whereas in the latter report MSCs were co-cultured with neutrophils.

A harmful effect of excessive inflammation during sepsis is the apoptotic death of immune cells by activation of the caspase cascade. MSCs have been shown to delay the spontaneous apoptosis of resting and activated neutrophils through an IL-6-dependent mechanism [40]. This finding was seen in mice after CLP, in which MSCs were able to prevent apoptotic cell death in the lung and kidneys [25].

Finally, the importance of the MSC and neutrophil interaction in bacterial infections was demonstrated in a CLP-induced polymicrobial sepsis model in mice. Hall *et al.* demonstrated that the therapeutic effect of MSCs was dependent on endogenous neutrophils. In particular, MSC treatment failed to rescue neutropenic animals from CLP-induced septic death compared with normal mice. These investigators also found that MSCs may enhance bacterial phagocytosis in neutrophils in a significant manner. This phagocytic enhancement led to a further decrease in bacterial burden [36].

Macrophages and monocytes are another type of immune cell thought to play an important role in phagocytosis of invading

**Table 55.1** Publications on the use of MSCs in preclinical models of infection and sepsis.

| Model | Species | MSC methods | MSC effects | Reference |
|---|---|---|---|---|
| *Exogenous toxin* | | | | |
| *Escherichia coli* endotoxin ALI | Mouse | $7.5 \times 10^5$ mouse BM-MSCs, IT, 4 h post ALI | Increased survival<br>Decrease in excess lung water and BAL protein<br>Decreased proinflammatory cytokines and increased IL-10 | [24] |
| LPS-induced ALI | Mouse | $2 \times 10^5$ mouse BM-MSCs overexpressing ANG-1, IV, 30 min post LPS | Improvement in alveolar inflammation and permeability | [25] |
| Endotoxemia/LPS | Mouse | $5 \times 10^5$ mouse BM-MSCs, IV 1 h postLPS | Decreased proinflammatory cytokines | [26] |
| Endotoxemia/LPS | Mouse | $1 \times 10^5$–$10^6$ human AD-MSCs, IP, 30 min post LPS | Improved survival<br>Decreased proinflammatory cytokines and increased IL-10<br>Reduced inflammatory cell organ infiltration | [22] |
| *E. coli* endotoxin ALI | *Ex vivo* perfused human lung | $5 \times 10^6$ human BM-MSCs or MSC-CM, IB, 1 h post ALI | Decreased extravascular lung water<br>Improved lung endothelial barrier permeability<br>Restored alveolar fluid clearance<br>Reduced inflammatory cell lung infiltration and septal thickening | [12] |
| Endotoxemia/LPS | Rat | $2 \times 10^6$ mouse BM-MSCs IP, 1 h post LPS | Reduced proinflammatory cytokines in blood and myocardium<br>Increased IL-10<br>Attenuated myocardial functional depression | [27] |
| *E. coli* endotoxin ALI | Mouse | 30 μL MVs (from $3 \times 10^6$ human BM-MSCs), IT, with ALI | Decreased extravascular lung water<br>Reduced total protein in BAL fluid<br>Decreased lung inflammation<br>Reduced influx of neutrophils in lung | [28] |
| Staphylococcal enterotoxin B TSS | Mouse | $2 \times 10^5$ human BM-MSCs, IV, 1 h before TSS | Decreased proinflammatory cytokines<br>No improvement on survival | [29] |
| *Exogenous bacteria* | | | | |
| *E. coli* pneumonia | Mouse | $1 \times 10^6$ human BM-MSCs IT, 4 h post pneumonia | Reduced bacterial growth in lung and BAL fluid<br>Effects mediated by secretion of antimicrobial peptide LL-37 | [30] |
| *Pseudomonas aeruginosa* peritonitis | Mouse | $1 \times 10^6$ human BM-MSCs, IV, 1 h post bacteria | Improved survival<br>Decreased bacteremia<br>Enhanced phagocytosis by monocytes | [31] |
| *E. coli* pneumonia/ALI | *Ex vivo* perfused human lung | 5 or $10 \times 10^6$ human BM-MSCs, IB, 1–2 h post pneumonia | Restored alveolar fluid clearance<br>Decreased lung inflammation<br>Increased bacterial killing and reduced bacteremia<br>Increased alveolar macrophage phagocytosis | [32] |
| *P. aeruginosa* pneumonia | Sheep | 5 or $10 \times 10^6$ human BM-MSCs/kg, IV, 1 h post pneumonia | Improved $PaO_2/FiO_2$ ratio<br>Decreased lung water content | [33] |
| *E. coli* IP capsule | Mouse | $1 \times 10^6$ mouse AD-MSCs, retro-orbital injection, with capsule | Decreased splenocyte apoptosis<br>Decreased liver and pancreatic damage<br>Decreased proinflammatory cytokines<br>Increased IL-10 | [17] |
| *Host-barrier disruption* | | | | |
| CLP | Mouse | $1 \times 10^5$–$10^6$ human AD-MSCs, IP, 4 h post CLP | Improved survival<br>Decreased proinflammatory cytokines<br>Reduced inflammatory cell organ infiltration<br>Decreased bacterial burden in liver/spleen | [22] |
| CLP | Mouse | $1 \times 10^6$ mouse BM-MSCs, IV, 24 h before or 1 h post CLP | Reduced organ damage (dosed 24 h before CLP)<br>Decreased proinflammatory cytokines<br>Reprogrammed host macrophages to increase IL-10 production | [34] |

microbes, as well as in the production of inflammatory mediators during sepsis. They are also thought to contribute to the subsequent resolution of inflammation by releasing pro-resolving lipid mediators and clearing the site of injury of dead cells and debris to prevent further escalation of the inflammatory reaction [41]. Macrophages and monocytes also appear to be a major target in the protective effect of MSCs. In a Gram-negative model of peritoneal sepsis in mice, human MSCs reduced bacteremia in part by enhancing the phagocytic activity of blood monocytes [31].

MSCs have also been shown to alter cytokine production of macrophages. They were shown to induce IL-10-secreting macrophages in both *in vitro* and *in vivo* studies via $PGE_2$ signaling. In addition, they have been shown to decrease the production of the proinflammatory factors TNF-α, IL-1β, and IL-6 in macrophages by secreting soluble factors such as $PGE_2$ or TSG-6 [34,42]. The importance of the MSC and monocyte/macrophage interaction is highlighted by the fact that MSCs were no longer effective in CLP in mice lacking monocytes/macrophages [34].

It is well known that macrophages represent two different phenotypes: M1 and M2. The M1 or classically activated macrophages are considered to be proinflammatory macrophages with high expression of TNF-α, IL-1β, IL-6, and inducible NO synthase. In contrast, M2 or alternatively activated macrophages possess anti-inflammatory properties by releasing IL-10 and IL-4. Interestingly, several reports have indicated the ability of MSCs to change a macrophage phenotype from M1 to M2, which may explain the potential anti-inflammatory properties of MSCs [43–46]. Several other studies have further suggested that MSCs switch macrophages into a regulatory profile characterized by a low ability to produce inflammatory cytokines and a high ability to phagocytose apoptotic cells and bacteria [47]. Moreover, Dalli and Serhan demonstrated that M2 macrophages not only have anti-inflammatory actions but also pro-resolving properties by releasing pro-resolving lipid mediators such lipoxins, resolvins, protectins, and maresins [48]. However, the concept of MSCs effecting resolution of inflammation during infection needs further investigation.

The mechanisms by which MSCs regulate macrophages have not been full elucidated. It has been suggested that MSCs might act as regulators of the NLRP3 inflammasome. Inflammasomes are cytosolic multiprotein complexes that proteolytically activate caspase-1 in response to cellular "danger" signals [49]. Activated caspase-1 then processes proinflammatory cytokines, including IL-1β, into their biologically active and secreted forms. The best characterized inflammasome is the NLRP3 inflammasome. Human MSCs negatively regulated NLRP3 inflammasome activation in human and mouse macrophages that were exposed to LPS and adenosine-5′-triphosphate by decreasing mitochondrial ROS production that is critical for NLRP3 inflammasome activation [50].

Dendritic cells (DCs) are also a major part of the innate immune response. Upon maturation, DCs have an important role in antigen presentation to naive T lymphocytes. MSCs have been shown to affect DCs in several ways *in vitro*. MSCs can inhibit the maturation of DCs, impair the antigen-presenting function of mature DCs, and decrease the proinflammatory potential of DCs by inhibiting their production of

TNF-α [51]. Further *in vitro* effects of MSCs have been described. These include their ability to inhibit the proliferation and cytotoxicity of resting NK cells. These effects are largely mediated by $PGE_2$ and TGF-β [52]. However, it has recently been suggested that the tryptophan catabolizing enzyme IDO plays a role in the inhibition of NK cell proliferation. MSCs can express IDO that degrades essential tryptophan and results in accumulation of kynurenine breakdown products, resulting in reduced NK cell proliferation.

To summarize, it is clear that MSCs have profound and complex interactions with different types of innate immune system cells. The studies described here illustrate that MSCs play an important role in immune regulation during bacterial invasion.

## 55.4 Effects of mesenchymal stromal cells on the adaptive immune response

T lymphocytes are a major component of the adaptive immune system (see Chapter 34). Antigen-specific activation and differentiation of naive T cells results in the generation of a range of T cell phenotypes. Human BM-MSCs have been shown to suppress T cell proliferation *in vitro* [53]. This inhibition of T cell proliferation leads to a shift in T cells from a proinflammatory, interferon-γ-producing T cell to an anti-inflammatory, IL-4-producing state. MSCs have a similar effect on both memory and naive T cells, as well as on both $CD4^+$ T helper and $CD8^+$ cytotoxic T cell subsets. As with NK cells, TGF-β, IDO, and $PGE_2$ are thought to play a major role in inhibition of T cell proliferation by MSCs [54].

Another level at which MSCs modulate immune responses is through the induction of regulatory T cells. Regulatory T cells are a specialized population of T cells that suppress activation of the immune system and help to maintain a balance. MSCs have been reported to induce the production of IL-10 and to trigger the generation of regulatory T cells [55]. One study showed in rats subjected to CLP that the percentage of circulating regulatory T cells and the ratio of regulatory T cells/total T cells were elevated significantly in the group that received MSCs after CLP. In addition, it was demonstrated that the immunosuppressive capacity of regulatory T cells from rats with CLP-induced sepsis was diminished but could be restored by administration of MSCs [38].

The other major cell type involved in the adaptive immune response is the B cell, which produces antibodies. Most of the studies done to date indicate that MSCs inhibit B cell proliferation, chemotactic ability, and differentiation *in vitro*. In these experiments, B cell proliferation appeared to be inhibited by human MSCs through an arrest in the $G_0/G_1$ phase of the cell cycle and not through the induction of apoptosis [55,56].

The immunosuppressive properties of MSCs have been shown to be affected by specific disease-related tissue microenvironments [57]. These findings suggest that MSCs can modulate the intensity of the potentially harmful immune response without making the host susceptible to infections.

## 55.5 Antimicrobial activity of mesenchymal stromal cells

In addition to the bacterial clearance that occurs by enhanced monocyte and neutrophil phagocytosis, MSCs also exhibit benefit in models of sepsis via a direct antimicrobial activity. Several preclinical models have shown that MSC administration significantly reduced CLP-induced blood bacterial load [58]. In an *ex vivo* perfused human lung injured with live *E. coli* bacteria, alveolar fluid from lungs treated with MSCs had increased antimicrobial activity compared with lungs exposed to *E. coli* alone [32]. In addition, MSC CM was shown to possess direct antimicrobial activity in co-culture in *in vitro* experiments with *E. coli*, *P. aeruginosa*, and *Staphylococcus aureus*. These findings were confirmed in an *E. coli* pneumonia model in mice in which antimicrobial activity in the MSC CM was conserved, indicating the presence of a secreted soluble factor. The authors identified this factor as LL-37, a member of the cathelicidin peptide family [30].

## 55.6 Mesenchymal stromal cells and endothelial/epithelial dysfunction

Increasing evidence supports the substantial role of endothelial and/or epithelial cell dysfunction in the clinical deterioration that can be seen in sepsis. ANG-1 has been shown to enhance endothelial cell survival and barrier maintenance. Studies have shown that overexpression of ANG-1 in MSCs can lead to improvement in outcome after LPS-induced lung injury, including decreased inflammation and permeability [58]. In addition, not unlike leukocytes, MSCs express integrins and adhesion molecules and interact in a coordinated fashion with the vascular endothelium. These interactions allow MSCs to adhere and transmigrate into tissue at the site of injury [59]. While most MSC activity has been felt to be due to their secreted factors, MSCs have also been shown to differentiate to some degree after treatment with retinoic acid *in vitro* into epithelial cells [60]. This indicates that they may play a role in repair of the damaged epithelial barrier that can occur in sepsis.

## 55.7 Mesenchymal stromal cells and effect on organ injury in infection

Several interrelated mechanisms likely contribute to the pathogenesis of organ injury and dysfunction in sepsis. The early host response leads to the release of proinflammatory and procoagulant mediators. These mediators contribute to organ damage by priming immune cells, producing ROS and causing

circulatory derangement. The activation of these pathways also leads to endothelial and/or epithelial injury and dysfunction and microvasculature thrombosis [7]. In preclinical models, MSCs have shown benefit in organ injury caused by infection. These beneficial effects are now summarized by organ system.

The acute respiratory distress syndrome (ARDS) is a common cause of acute respiratory failure and is often caused by pneumonia and/or sepsis. Human MSCs or their CM were shown to restore lung protein permeability and reduce alveolar inflammation following *E. coli* endotoxin-induced lung injury in an *ex vivo* perfused human lung. This effect was mediated in part by the secretion of soluble factors, including KGF [12]. In addition, MSCs have been shown to reduce lung inflammation by inhibiting the transmigration of neutrophils into alveoli [26]. MSCs have also improved ALI in several other preclinical models of infection using live bacteria or following CLP in several species, including mice, rats, and sheep [28,33].

Islam *et al.* further investigated the molecular basis of the protective effect of MSCs in lung injury induced by LPS in mice. They demonstrated that mouse BM-MSCs infused into the trachea of mice attached to LPS-injured alveolar epithelial cells by forming connexin-43-containing gap junctions. They showed that, after attachment, labeled mitochondria were transferred from the MSCs to the LPS-injured alveolar cells through the formation of nanotubes and MVs. This was the first *in vivo* study to show that MSCs can repair tissue injury through the transfer of mitochondria [61,62] (and see Chapters 10, 20, 21, and 38).

In addition to the lung, MSCs have shown benefit on other organ injuries. Luo *et al.* showed that MSCs could ameliorate sepsis-associated acute kidney injury in mice undergoing CLP. The group of mice that received BM-MSCs intravenously after CLP had lower levels of kidney injury markers, improved tubular function, lower levels of proinflammatory cytokines and neutrophil infiltration in kidney tissue, and a higher survival rate than the control group [37].

Weil *et al.* showed that MSCs could attenuate decreased myocardial function and reduce myocardial inflammation in a model of endotoxemia in rats [27]. In a model of murine sepsis induced by IP placement of an *E. coli*-containing capsule, MSCs given intravenously after the infectious insult decreased splenic injury and splenic apoptosis. This study also demonstrated a reduction in liver damage as measured by serum alanine aminotransferase and in pancreatic damage as measured by serum amylase [17].

Németh *et al.* also showed that BM-MSCs reduced organ damage in the kidney, liver, and pancreas in a model of CLP. In this study, vascular permeability in the peritoneum, lung, liver, and kidney was also improved after CLP in the mice that were treated with MSCs [34].

Our laboratory has studied the effect of MSCs in a genetically modified mouse model that is susceptible to injury. These heme-oxygenase-1-deficient mice underwent CLP and were administered three doses of MSCs after the onset of polymicrobial sepsis. In these susceptible mice there was significantly less tissue injury seen on histological analysis of the bowel, kidney, liver, and spleen 24 h after CLP-induced sepsis in the group that received MSCs. The fact that MSCs could ameliorate CLP-associated organ injury in a mouse model that is more sensitive to organ injury further emphasizes the therapeutic impact they may have [36].

## 55.8 Mesenchymal stromal cell cytokine and growth factor production

The previous sections have described the ability of MSCs to alter the cytokine profile of resident cells such as macrophages. However, the potential beneficial activities of MSCs in sepsis may also be related to the MSC cytokine profile. MSCs are potent sources of the anti-inflammatory cytokines TGF-β, IL-10, and IL-13 [57]. The effects of MSCs on cytokine profiles have been seen in preclinical models of sepsis. MSC instillation decreased levels of the proinflammatory cytokine TNF-α and increased levels of the anti-inflammatory cytokines IL-10 and IL-13 in the BAL of mice undergoing endotoxin-induced lung injury [24]. In addition, injection of human AD-MSCs into mice that underwent CLP significantly ameliorated the clinical and histopathological severity of colitis, abrogating weight loss, diarrhea, and inflammation, and increasing survival. The therapeutic effect was associated with downregulation of type 1 T-helper-cell-driven inflammatory responses. AD-MSCs decreased a wide panel of inflammatory cytokines and chemokines and increased IL-10, acting on macrophages. The AD-MSCs also impaired type 1 T helper cell activation in both colonic mucosa and draining lymph nodes. The induction of IL-10-secreting regulatory T cells was partially involved in the therapeutic effect of the AD-MSCs. Moreover, AD-MSCs protected from severe sepsis by reducing the infiltration of inflammatory cells in various target organs and by downregulating the production of various inflammatory mediators [22].

The benefits of MSCs are further enhanced by MSC secretion of cytoprotective and proangiogenic factors such as VEGF, HGF, IGF-1, ANG-1, and FGF-2 [57]. Human MSCs have been shown to upregulate the production of these protective growth factors in response to noxious stimuli such as LPS. This process is largely mediated by MSC expression of TNF receptors [63].

The full extent of the neoangiogenic properties of MSCs continues to be investigated (see Chapters 25 and 26). Increased vasculature was found in MSC-treated wounds associated with elevated levels of VEGF-α and ANG-1. These data suggest that the high levels of proangiogenic growth factors and cytokines released by MSCs enhance neovascularization in the wound [64] (and see Chapters 58 and 59). In addition, the growth factors secreted by MSCs may be involved in mobilizing resident stem cell populations that exist in the adult heart, lung, liver, and kidney [65]. It is possible that MSCs can stimulate resident stem cell proliferation to aid in organ damage caused by sepsis.

## 55.9 Toll-like receptors and mesenchymal stromal cells

Inflammation in sepsis is largely initiated by TLRs that detect microbes, LPS shedding, and cellular contents released by injury to trigger an innate immune response. As a result, TLRs are an important part of the host response to infection. They are expressed by a variety of cells. It has been shown that their expression in human MSCs may play a role in mediating many of the beneficial actions of these cells [66]. This is further supported by the finding that the TLR3 ligand polyinosinic:polycytidylic acid could enhance the production of soluble factors in MSCs, including $PGE_2$ and IDO, and enhance the therapeutic effect of MSCs on CLP-induced sepsis [67]. Much remains to be learned about the role of TLRs in MSCs as there are contrasting and complex immune modulating effects reported thus far for TLR activation in MSCs. One group proposed a possible explanation for the different responses seen in MSCs after TLR signaling. They suggested that human MSCs, like monocytes, are polarized by downstream TLR signaling into two homogenously acting phenotypes that they classified as MSC1 (proinflammatory) and MSC2 (immunosuppressive) [68].

## 55.10 Mesenchymal stromal cell homing

MSCs have the ability to home to sites of tissue injury and inflammation when given via IV or IP routes [44]. For example, one study found that in response to CLP-induced polymicrobial sepsis, the greatest concentrations of MSCs were in the lung, kidney, and spleen [34]. This is a quality that makes them appealing for the treatment of infection and sepsis, where tissue injury and inflammation are widespread. While the mechanisms by which MSCs are recruited to tissues and cross the endothelial layer are not yet fully understood, chemokines and their receptors are involved. SDF-1 (also known as C—X—C motif chemokine ligand 12) and its corresponding receptor CXCR4 appear to be the most significant mediators of this process in MSCs [69]. In addition, many of the molecules known to be involved in the tethering, rolling, adhesion, and transmigration of leukocytes from the bloodstream into tissues are known to be expressed on MSCs. These include integrins, selectins, and chemokine receptors [54] (and see Chapters 22 and 23).

## 55.11 Mesenchymal stromal cell response to oxidative stress

ROS and reactive nitrogen species (RNS) are produced in the setting of infection and act as antimicrobial agents that can directly destroy microbial pathogens. However, during sepsis, excess production of ROS and RNS can be detrimental. It is not uncommon for the oxidative stress burden to persist after eradication of the organism. One study demonstrated that the *in vitro* treatment of MSCs with LPS induced production of ROS and RNS that ultimately resulted in redox stress. These events triggered in MSCs a cascade of responses driving adaptive remodeling and resistance to oxidative stress. (Oxidative stress reflects an imbalance between the systemic manifestation of ROS and a biological system's ability to readily detoxify the reactive intermediates or to repair the resulting damage. Disturbances in the normal redox state of cells can cause toxic effects through the production of peroxides and free radicals that damage all components of the cell, including proteins, lipids, and DNA. Further, some reactive oxidative species act as cellular messengers in redox signaling. Thus, oxidative stress can cause disruptions in normal mechanisms of cellular signaling.) The data described here suggested that MSCs are able to activate a prosurvival pathway under conditions of oxidative stress that may add to their ability to modulate septic conditions [70].

## 55.12 Paracrine effects of mesenchymal stromal cells

As described in this chapter, the beneficial effects of MSCs derive predominantly from their capacity to secrete paracrine factors that modulate immune responses and alter the responses of cells to injury (see also Chapter 37). However, it is poorly understood whether the cell itself is necessary for this therapeutic response or if the secreted factors alone would exert the same benefit. Studies suggest that the distribution of MSCs might be essential for the beneficial effect. As mentioned earlier, MSCs can home to damaged organs to protect them from injury. However, intravenously infused MSCs initially accumulate in the lungs, trapped in the first capillary bed that they encounter after IV infusion, probably due to their large size. This suggests that MSCs exert their protective effects via a paracrine effect. In one study, human MSCs were infused intravenously into mice and most of the cells were trapped in the lung. However, after myocardial infarction these MSCs decreased inflammatory responses in the heart and improved cardiac function by secreting the anti-inflammatory protein TSG-6 [71]. The paracrine effect of MSCs is further supported by the fact that MSC CM has shown benefit in some preclinical models of sepsis [37].

MSCs release circular membrane fragments called exosomes or MVs that are biologically active because of the presence in them of mRNA or microRNA [72]. Zhu *et al.* showed that MVs released from BM-MSCs improved several indices of endotoxin-induced ALI in mice. KGF appeared to be partially responsible for the MV effect [28]. There has been significant work done on MVs and exosomes in models of hypoxic pulmonary hypertension that may relate to the ARDS that can occur after sepsis. Lee *et al* showed that exosomes mediate the cytoprotective action of MSCs in these models [73]. This work suggests that MVs may be therapeutically effective. However, the cell itself may have further benefits, as it is able to respond to the complex and changing conditions of sepsis.

## 55.13 Transcriptomic analysis of mesenchymal stromal cell therapy in sepsis

Despite the benefits that MSCs have shown in experimental models of sepsis, the cellular and molecular mechanisms mediating their beneficial effects are complex. A recent network analysis of transcriptional responses of target organs in a CLP model of sepsis provided some insight into these mechanisms. In this study mice underwent CLP and 6 h later were treated with MSCs. Total RNA from the lungs, hearts, kidneys, livers, and spleens was analyzed for common transcriptional responses. These responses identified three common effects of MSC administration: attenuation of sepsis-induced mitochondrial-related functional derangement, downregulation of TLR innate immune proinflammatory responses, and preservation of endothelial/vascular integrity. This study illustrated that the protective effect of MSC therapy in sepsis likely involves a wide range of complementary activities [35].

## 55.14 Summary

Research utilizing preclinical models of sepsis has provided a greater understanding of the beneficial properties of MSCs for this serious disorder. MSCs show promise in the treatment of bacterial infections and sepsis by their ability to interact with the innate and adaptive immune responses, alter cytokine profiles, enhance bacterial clearance, home to injured tissue, limit inflammation and organ injury, decrease cell apoptosis, and improve endothelial/epithelial dysfunction [7]. While MSCs have been trialed in a variety of human disease conditions, clinical trials are just beginning in human sepsis and infection. There is currently a clinical trial of mesenchymal cells in patients with septic shock and severe neutropenia (https://clinicaltrials.gov/ct2/show/NCT01849237). In addition, as lung injury is a known complication of infection and sepsis, much information can be gained from the use of MSCs for ARDS. A recent phase I dose-escalation, multicenter trial was conducted to study the effects of human allogeneic BM-MSCs for the treatment of ARDS. The authors found that a single IV infusion of these cells was well tolerated. A phase II trial is ongoing [74]. While more mechanistic information is necessary to further understand how to translate these findings into clinical use, MSCs continue to show significant promise as a therapy for bacterial infections and sepsis.

## 56.1 Introduction

Organ transplantation is the only definitive treatment for many critical diseases of the liver, kidney, heart, pancreas, and lungs. Although it is the primary therapeutic option at present, transplanted patients have to deal with the numerous side effects of life-long dependence on immunosuppressive drugs, and these drugs still fail to prevent chronic rejection of the transplanted organ in many cases. The risk of developing cancer and opportunistic infections is also markedly increased in solid organ transplant (SOT) recipients receiving long-term immunosuppressive therapy. Cancer and opportunistic infections cannot be completely avoided since they result from the immunosuppressive drugs used posttransplant that affect not only the anti-graft response but also the entire immune response. Finding a way to establish donor-specific immunological tolerance without the need for nonspecific immunosuppression remains one of the major goals in transplantation medicine [1,2]. Another important aim is the improvement of graft survival and function. Overall, graft survival is about 15 years, but the increasing shortage of organs has led to the use of expanded criteria for donor organs often donated by older individuals, which are less robust organs than those donated by younger donors.

Mesenchymal stromal cells (MSCs) are currently being evaluated in SOT with the hope of achieving more selective immunosuppression, better graft function, and longer graft survival.

## 56.2 Potential effects of mesenchymal stromal cells in solid organ transplantation

Potential MSC benefits to SOT could be mediated through three main mechanisms: immunomodulation, tissue repair, and antioxidative effects. Moreover, MSCs are able to selectively home to the sites of tissue injury and inflammation, including the intestine, kidney, lung, liver, thymus, and skin [3]. Mechanisms underlying this homing include interactions between soluble mediators such as stromal cell-derived factor-1, hyaluronic acid, macrophage inflammatory protein-1(α), hepatocyte growth

factor (HGF) and their respective MSC receptors, C–X–C chemokine receptor type 4 (CXCR4), CD44, C–C chemokine receptor 1, and c-Met [4] (and see Chapters 22 and 23).

## 56.3 Immunomodulation

The immunosuppressive properties of MSCs have been widely studied and include inhibition of T cell proliferation and function, inhibition of dendritic cell (DC) maturation, and induction of regulatory T cells (Tregs), DCs, and macrophages. For example, Bartholomew *et al.* demonstrated the ability of MSCs to inhibit lymphocyte proliferation *in vitro* and to prolong skin graft survival *in vivo* [5]. The importance of immunomodulation by MSCs in SOT is illustrated by the fact that donor-derived, autologous, and unrelated third-party MSCs seem to have different effects in transplantation models [6]. Transplantation of human leukocyte antigen (HLA)-nonidentical MSCs is enabled by their low immunogenicity. However, while some authors performed mismatched allogeneic MSC transplantation with no signs of alloreactivity against donor MSCs [7,8], others observed induction of memory T cell responses and immune rejection of MSCs in major histocompatibility complex mismatched hosts [9–11]. Pretransplant infusion of donor-derived MSCs may lead to sensitization to donor antigens and hence to accelerated graft rejection, or, on the contrary, may desensitize the host to donor antigens. Dosing and timing of MSC infusion may play a role in this immune balancing act [12]. So far, some data suggest that MSCs sharing major histocompatibility complex antigens with the donor graft may be superior for inducing long-term tolerance [6]. The effects of MSCs on the innate immune system and the adaptive immune system are described in detail in Chapters 33 and 34 respectively.

## 56.4 Tissue and organ regeneration

The regenerative effects of MSCs were initially attributed to their multilineage differentiation capacity, such as in liver disease in which MSC administration enabled liver regeneration in animal models of terminal liver failure or metabolic diseases [13,14]. This could be useful in partial liver transplantation (LT) (split graft or living donor LT), a technique that is being increasingly used because of the shortage of donor organs. MSCs also demonstrated multiple beneficial effects in repairing acute kidney injury in animal models of acute renal failure through differentiation toward endothelial or smooth muscle cell lineages [15] or through a reduction of apoptosis and an increased proliferation of renal cells [16].

More recently it has been demonstrated that the beneficial effects of MSCs in these settings are mediated by their ability to secrete trophic factors that induce proliferation and differentiation of progenitor cells at the site of injury, rather than from transdifferentiation [6]. For example, allogeneic human MSCs are able to restore alveolar fluid clearance in human lungs through the secretion of keratinocyte growth factor [17]. The importance of these soluble factors secreted by MSCs is also illustrated by the fact that MSC-conditioned medium (MSC-CM) has been found effective in reducing inflammation and improving survival in an animal model of LT [18]. Further information on the MSC secretome is given in Chapters 18 and 19.

## 56.5 Prevention of ischemia–reperfusion injury

The term ischemia–reperfusion injury (IRI) defines inflammatory lesions observed when tissues are reperfused after an ischemic period, as happens after declamping in transplant surgery. Mechanisms involve endothelium dysfunction with increased permeability, production of oxygen radicals and inflammatory mediators, and expression of adhesion molecules. These phenomena lead to a stimulation of both innate and adaptive immune responses that are responsible for organ damage [19].

Because of their ability to migrate into hypoxic or inflamed tissues and to downregulate excessive immune responses, the potential beneficial effects of MSCs on IRI have been investigated in animal models of kidney [20–23], liver [24,25], and lung [26] IRI with promising results. For example, it has been demonstrated that hyaluronic acid accumulating in the kidney following ischemic injury stimulates the migration of MSCs through interaction with the surface receptor CD44 [27]. Complex paracrine interactions seem involved in this protective effect, with downregulation of proinflammatory signals such as tumor necrosis factor-α, transforming growth factor-β, interleukin (IL)-1β, and IL-6 and upregulation of anti-inflammatory cytokines such as IL-10 [24], resulting in MSC-mediated suppression of oxidative stress and inhibition of apoptosis [25].

## 56.6 Mesenchymal stromal cell administration in solid organ transplantation

### 56.6.1 Kidney transplantation

Kidney transplantation is the best option for patients suffering from end-stage kidney diseases, improving survival and quality of life compared with maintenance dialysis [28,29]. The site of placement of a transplanted kidney is shown in Figure 56.1.

However, long-term immunosuppressive treatments are necessary to prevent graft rejection. Induction therapy generally includes an IL-2 receptor antagonist such as basiliximab or a lymphocyte-depleting agent such as rabbit antithymocyte globulin (ATG) or muromonab-CD3 (OKT-3). A combination of immunosuppressive medications is used as maintenance therapy, including calcineurin inhibitors (CNIs) such as tacrolimus

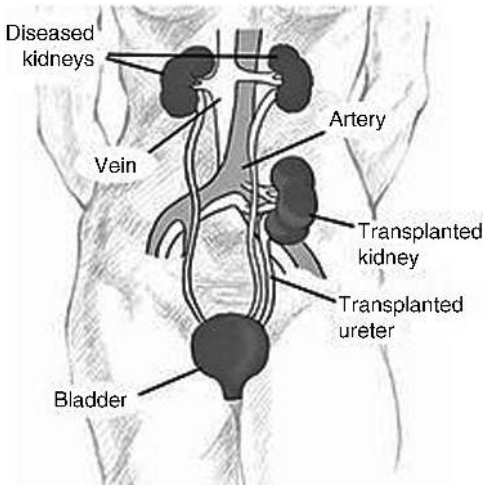

**Figure 56.1** Kidney location after transplantation. *Source:* nih.gov.

or cyclosporine (CSP), antiproliferative agents such as mycophenolate or azathioprine, corticosteroids (prednisolone) and/or mammalian target of rapamycin inhibitors such as sirolimus or everolimus. The main causes of posttransplant morbidity and mortality are cardiovascular diseases, infections, malignancies, and graft dysfunction.

#### 56.6.1.1 Animal studies

MSCs have demonstrated their ability to downregulate the immune response after kidney transplantation in several animal studies. Zhang *et al* transplanted Lewis rats with Wistar rat kidney and bone marrow (BM)-MSCs. Intravenous $1 \times 10^7$ BM-MSCs were given 1 week before transplantation, immediately after reperfusion, and 1 and 2 weeks posttransplant and compared with the effects of MSCs alone, CSP alone, and a combination of MSCs and CSP. They found that MSCs were able to preserve graft function, as assessed by serum creatinine level, and to prolong animal survival, but were not as effective as CSP [30].

Monotherapy with third-party BM-MSCs infused directly into the renal artery of the transplanted kidney ($3 \times 10^6$ cells injected soon after reperfusion) was studied in a syngeneic and allogeneic model of rat kidney transplantation. Compared with placebo, MSC-treated rats had better kidney function as assessed by serum creatinine level, creatinine clearance rate, proteinuria and diuresis, reduced histological damage as assessed by the degree of tubulitis and vasculitis, and a reduced inflammatory infiltrate with fewer $ED1^+$ and $CD8^+$ cells [31]. ED1 is a rat marker of activated monocytes, macrophages, DCs, and microglial cells and is also known as CD68. Tubulitis is a defining feature for the diagnosis and management of acute renal allograft rejection.

The efficacy of syngeneic MSCs to prevent IRI was also demonstrated in a rat kidney transplantation model with prolonged cold ischemia. Rats received CSP 1.5 mg/kg/per day for 2 days and three intravenous injections of $2.5 \times 10^6$ or $5.0 \times 10^6$ MSCs 7 days before, immediately after, and 1 day after transplantation. MSC administration resulted in reduced intragraft gene expression of proinflammatory cytokines, chemokines, and intercellular adhesion molecule-1, and in a reduced infiltration of antigen-presenting cells in the renal allograft [32].

The mechanisms of MSC-induced allograft tolerance are not yet fully elucidated, but generation of Tregs and tolerogenic DCs and production of indoleamine 2,3-dioxygenase appear to be involved in mice [33]. The importance of the route of administration has been pointed out in rats, as intra-arterial injection was shown to be more efficient than intravenous injection, with a more rapid functional recovery as assessed by serum creatinine levels and reduced inflammatory infiltrate in the graft [34]. These findings suggested that a high concentration of MSCs at the site of immunological injury may be crucial for the efficacy of MSCs in this setting.

With regard to the timing of MSC administration, experiments in mice have shown that syngeneic MSCs injected intravenously after transplantation 2 days posttransplant localized mainly in the graft, where they were responsible for local inflammatory reaction and failed to enhance graft survival, while MSCs injected 7 days and 1 day before transplantation localized in lymphoid organs, promoting Treg expansion and significantly prolonging allograft survival [35]. However, it has been shown in rats that a delayed third-party MSC injection was also beneficial, protecting the kidney allograft from injury development as shown by reduced interstitial fibrosis and tubular atrophy, lower inflammatory cell infiltration, and improved balance between proinflammatory and anti-inflammatory cytokines [36].

The long-term safety of MSC administration has been questioned by one group, who observed an unexpected increase in MSC-related life-threatening events in rats, including thrombotic microangiopathy, infarctions, and infections [37]. So far there has been no other report of such MSC-related adverse events in transplant recipients.

#### 56.6.1.2 Human studies

The first studies on human cells showed that *in vitro* donor-derived adipose MSCs were able to significantly inhibit recipient antidonor reactivity and proliferation of $CD4^+$ and $CD8^+$ T lymphocyte subsets in mixed lymphocyte reactions [38]. Combined MSC and hematopoietic stem cell co-transplantation compared with hematopoietic stem cell transplantation alone produced significantly higher peripheral blood chimerism, better kidney transplant function as assessed by serum creatinine levels, and improved survival [39]. Intra-osseous injection of donor MSCs into the BM at a dose of $1 \times 10^6$ cells/kg at the time of kidney transplantation was evaluated in a pilot study of seven patients undergoing living donor kidney transplantation. The procedure was safe, but three patients had biopsy-proven acute rejection that was controlled with corticosteroid pulse therapy. Donor-specific T cell proliferation was observed in two patients, while Treg priming responses were observed in two others associated with increased IL-10 levels in the peripheral blood [40].

#### 56.6.1.3 Mesenchymal stromal cells versus conventional induction therapy

Perico *et al.* evaluated the pretransplant infusion of autologous BM-MSCs in two living-related kidney transplant recipients. One patient had corticosteroid-sensitive acute cellular rejection of the kidney 2 weeks posttransplant, but both patients had excellent renal function at 1 year follow-up. Circulating memory $CD8^+$ T cell numbers and donor-specific $CD8^+$ T cell cytolytic responses were reduced. Compared with patients receiving basiliximab induction therapy, $CD4^+$ $FoxP3^+$ Treg expansion was not increased [41].

Tan *et al.* reported a randomized controlled trial of living donor kidney transplantation in 156 patients who were divided into three groups: a control group receiving antibody induction therapy versus two groups receiving autologous BM-MSCs at a dose of $1–2 \times 10^6$/kg administered at the time of kidney graft reperfusion and 2 weeks later plus either low-dose or standard-dose CNI treatment. Graft survival was similar, but MSC infusion resulted in fewer acute rejections at 6 months, no corticosteroid-resistant rejection, accelerated renal function recovery, and a reduced rate of opportunistic infections. However, acute rejection rates and glomerular filtration rates were not different at 1 year postransplant [42].

#### 56.6.1.4 Mesenchymal stromal cells versus conventional maintenance therapy

Perico *et al.* also investigated the effect of autologous BM-MSCs in two living-related kidney transplant recipients 7 days after transplantation. Increasing levels of $CD4^+$ $CD25^{high}$ $FoxP3^+$ $CD127^+$ Tregs and inhibition of memory/effector $CD8^+$ T cell expansion were observed, resulting in a long-term tolerogenic environment compared with the control group. However, patients suffered from engraftment syndrome with transient renal dysfunction a few days after MSC administration, and biopsies showed a focal inflammatory infiltrate with neutrophils and MSCs and complement C3 deposition [43]. (Engraftment syndrome characterized by fever, rash, pulmonary edema, weight gain, liver and renal dysfunction, and/or encephalopathy usually occurs at the time of neutrophil recovery after hematopoietic cell transplantation).

Another recent pilot study with 12 patients receiving living-donor related kidneys compared donor-derived BM-MSC infusions with a first dose of $5 \times 10^6$ cells into the renal allograft artery at the time of kidney transplantation and a second intravenous dose of $2 \times 10^6$ cells/kg 1 month later plus low-dose (50% of usual) tacrolimus versus a control group who received no MSCs and standard doses of tacrolimus. Patients also received mycophenolate mofetil (MMF) and methylprednisolone. All patients had stable renal function at 1 year posttransplant despite reduced tacrolimus doses in the MSC group, and only one episode of acute rejection occurred (in the control group). Significantly increased B cell levels were observed in the MSC group 3 months after transplantation. There were no MSC-related adverse events [44].

#### 56.6.1.5 Mesenchymal stromal cells as treatment for kidney rejection

In a phase I trial, Reinders *et al.* studied two intravenous infusions of $10^6$ autologous BM-MSCs per kilogram as treatment for kidney rejection in six patients. MSC infusions were well tolerated, and no treatment-related serious adverse events were reported. Biopsies were performed after MSC administration in two patients and showed resolution of tubulitis without interstitial fibrosis/tubular atrophy. Five patients had downregulation of peripheral blood mononuclear cell proliferation and three patients developed an opportunistic viral infection [45].

#### 56.6.1.6 Mesenchymal stromal cells as a desensitizing treatment

In a report of three cases, infusion of $50 \times 10^6$ donor-derived MSCs led to successful desensitization of patients with a positive lymphocyte cross-match before kidney transplantation [46].

#### 56.6.1.7 Ongoing trials

##### *56.6.1.7.1 Mesenchymal stromal cells in addition to conventional therapy*

The Liège trial (NCT01429038) is a single-center, open-label prospective phase I–II study that includes 10 kidney transplant recipients receiving a kidney from a deceased donor (and 10 liver transplant recipients who will be described later). In addition to induction therapy of standard immunosuppression with anti-IL-2 antibodies and maintenance therapy of tacrolimus, MMF, and corticosteroids, patients receive an intravenous infusion of third-party MSCs at a dose of $1.5–3.0 \times 10^6$/kg on postoperative day 3 ($\pm$2 days). The 10 study patients will be compared at 1 year posttransplant with a control group of 10 similar kidney transplant recipients. The primary endpoint is safety of the MSC infusion, including infusional toxicity and incidence of infections and cancers. Secondary endpoints are patient and graft survival; graft function assessed by the number of posttransplant hemodialysis episodes required and serum creatinine levels; biopsy-proven rejection rates using the Banff classification; feasibility and safety of weaning or decreasing immunosuppression, recipient immune function as assessed by T cell blood populations, including Tregs, T-cell receptor excision circle quantification, Vβ repertoire diversity, pathogen-specific T cells, anti-organ donor HLA antibodies; and potential development of anti-MSC donor HLA antibodies.

The first Bergamo trial (NCT00752479) is studying the effects of syngeneic *ex vivo* expanded MSCs in HLA-mismatched (one or two haplotype mismatches) living donor kidney transplantation. Patients are randomized into two groups. One group receives an intravenous injection of $2 \times 10^6$ MSCs/kg at the time of kidney transplantation. All patients receive conventional induction treatment with basiliximab, rabbit ATG and methylprednisolone and maintenance treatment with CSP and MMF. Patients will be followed for 12 months. Primary outcomes include percentage inhibition of memory and/or naive T cell responses, induction of donor-reactive T cell anergy, and levels of

circulating Tregs. Secondary outcomes are safety of the MSC infusion, graft function, and graft rejection.

The second Bergamo trial (NCT02012153) is investigating the effect of autologous *ex vivo* expanded BM-MSCs in HLA-mismatched (one or two haplotype mismatches) living donor kidney transplantation. MSCs are administered intravenously on the day before kidney transplantation at a dose of $2 \times 10^6$ MSCs/kg. Patients are followed for trial parameters for 1 year. Outcomes evaluated at 6 and 12 months include levels of circulating naive cells, memory cells, and Tregs, T cell function in mixed lymphocyte reaction, urinary forkhead box P3 (FOXP3) mRNA expression, and adverse events.

#### *56.6.1.7.2 Mesenchymal stromal cells versus conventional induction therapy*

The Fuzhou study (NCT00658073) is evaluating autologous MSCs as an alternative to antibody induction therapy in renal transplantation. Patients are randomized into three groups, two of them receiving two intravenous injections of MSCs immediately after releasing the renal artery clamp and 2 weeks after transplantation, while the third group receives standard induction therapy with anti-IL-2 receptor antibody. All patients will receive maintenance therapy with CNIs, MMF, and corticosteroids, but one of the MSC groups receives a reduced dose (80% less) of CNIs. Patients will be followed for trial parameters for 1 year. Primary outcomes are incidence of acute rejection and early renal function recovery. Secondary outcomes are patient and graft survival, and prevalence of adverse events.

#### *56.6.1.7.3 Mesenchymal stromal cells versus conventional maintenance therapy*

In a Leiden trial (NCT02057965), intravenous infusions of autologous BM-MSCs are being evaluated as maintenance therapy in renal transplantation with a kidney from a deceased, a living unrelated, or a HLA-nonidentical living-related donor older than 50 years of age. Patients are randomized into two groups. One group will receive MSCs and everolimus versus tacrolimus and everolimus. Patients in the MSC group will receive two injections of $1–2 \times 10^6$ MSCs/kilogram at 6 and 7 weeks after transplantation. After the second MSC infusion, tacrolimus is tapered off and withdrawn over a 2-week period. The primary outcome is kidney fibrosis at 6 months compared with 4 weeks posttransplant. Secondary outcomes evaluated at 6 months posttransplant are renal function and proteinuria, complications (including opportunistic infections and cardiovascular disease), adverse effects, a composite endpoint of efficacy failure (biopsy-proven acute rejection, graft loss, or death, and immunological parameters such as donor-specific antibodies.

#### *56.6.1.7.4 Mesenchymal stromal cells as treatment for kidney rejection*

Another Leiden trial (NCT00734396) is studying the safety and efficacy of autologous BM-MSCs to treat renal transplant rejection in HLA-DR mismatched kidney graft recipients. Patients with subclinical rejection and/or an increase in interstitial fibrosis/tubular atrophy in the renal biopsy at 4 weeks or 6 months receive two intravenous injections of $1–2 \times 10^6$ MSCs/kg 7 days apart. Primary outcomes are safety and feasibility of MSC administration at 2 years, while secondary outcomes are efficacy parameters, including the presence of late acute rejection in the 6-month biopsy compared with the 4-week biopsy, Sirius red staining for renal cortical matrix accumulation, and immunologic response before and after MSC infusion.

### 56.6.2 Liver transplantation

Since the pioneering experience in the 1960s LT has become established as the standard treatment of many end-stage liver diseases, including cirrhosis, primary liver cancer, fulminant hepatic failure, and a number of other metabolic or congenital hepatic diseases. Expected patient survival after LT is now more than 80% at 1 year and 60–70% at 5 years, dependent on the different indications for transplantation [47]. The excellent results of LT have led to a shortage of liver grafts that has been partially fulfilled by the development of living-related LT, and the procurement of liver grafts from brain-dead donors, aged cadaveric donors, or donors procured after cardiac death [48]. A human liver photographed at autopsy is shown in Figure 56.2.

Immunosuppressive regimens include CNIs, antimetabolites, mammalian target of rapamycin inhibitors, corticosteroids, and antibody-based therapies. A combination of CNIs and antimetabolites with tapering doses of corticosteroids during the first month is generally used to prevent graft rejection, while treatment of rejection usually comprises boluses of intravenous corticosteroids or ATG for corticosteroid-resistant rejection.

#### 56.6.2.1 Animal studies

Syngeneic BM-MSCs have shown their ability to home to the liver and to alleviate acute immunologic rejection in an orthotopic (normal location) rat LT model [49]. Similarly,

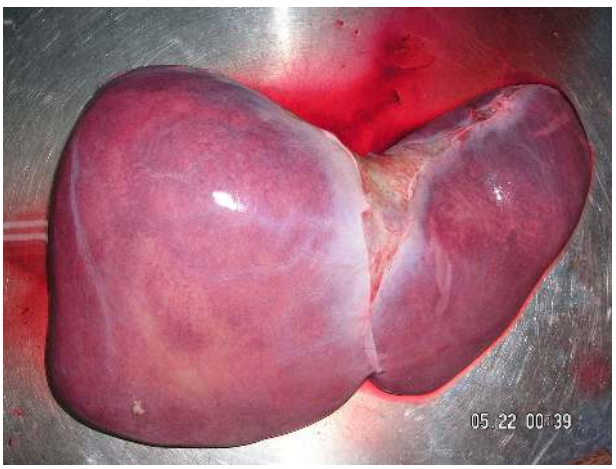

**Figure 56.2** Human liver. *Source:* http://commons.wikimedia.org/wiki/File:Human_Hepar.jpg#/media/File:Human_Hepar.jpg.

adipose-tissue-derived MSCs infused intravenously at day −7 and day +3 as well as during the operation via the portal vein were able to significantly decrease acute rejection as assessed by reduced serum IL-2 levels and increased serum IL-10 levels as well as reduced hepatocyte apoptosis [50]. MSCs also demonstrated their efficacy in a liver xenotransplantation model (orthotopic guinea pig to rat LT), enabling increased survival and alleviating acute rejection compared with placebo or with the powerful corticosteroid dexamethasone [51].

MSCs from different donors have shown equivalent effects in a rat LT model. Recipient-, donor-, or third-party-derived MSCs were infused intravenously at the time of surgery and once daily for 3 days thereafter. MSC administration resulted in significantly improved recipient survival, inhibition of allograft rejection based on histological analysis and induction of $CD4^+$ $CD25^+$ $Foxp3^+$ Tregs, with no significant difference between the three MSC-treated groups [52].

Du *et al.* studied the efficacy of the intravenous injection of MSC-CM in a 50% reduced-size rat LT model. In the MSC-CM group the authors observed a significantly lower release of liver injury biomarkers, a reduction in hepatocyte apoptosis, an increased proliferation of hepatocytes and sinusoidal endothelial cells, and reduced signs of inflammation in the graft as assessed by lower expression of several proinflammatory cytokines, reduced neutrophil infiltration and Kupffer cell activation and increased expression of vascular endothelial growth factor and matrix metallopeptidase (or metalloproteinase) 9. These observations were associated with increased survival in the MSC-CM group compared with the control group [18]. (Kuppfer cells were first observed by Karl Wilhelm von Kupffer in 1876 and are hepatic macrophages.)

In an attempt to improve MSC homing, the same group used MSCs overexpressing CXCR4 in a 50% reduced size rat LT model. MSCs reduced the release of liver injury biomarkers and apoptosis of hepatocytes. Although unable to further reduce liver injury, CXCR4 overexpression successfully enhanced MSC homing and hepatocyte proliferation, resulting in a significant survival benefit [53].

MSCs were also efficient in preventing, but not treating, acute graft-versus-host disease (GVHD) following LT. Rats that received donor- or recipient-derived BM-MSCs from day 0 to day 6 after LT ($5 \times 10^6$ MSCs/day) had a significantly longer survival and no typical LT-associated GVHD symptoms, while administration of MSCs after the onset of symptoms was ineffective for treating GVHD. The efficacy of MSC therapy was associated with higher Treg ratios in the peripheral blood [54].

Another use of MSCs in LT has been the *in vivo* delivery of engineered growth factors or cytokines. Intraportal infusion of $5 \times 10^6$ syngeneic HGF-expressing MSCs immediately after liver reperfusion was performed in a 30% small-for-size rat LT model. HGF-expressing MSCs prevented liver failure and improved liver function and liver weight recovery. Moreover, HGF enhanced the incorporation of MSCs into injured livers, and the engrafted cells and their progeny produced albumin [55]. In another study the same group showed that HGF-expressing MSCs significantly inhibited the formation of liver fibrosis in rats undergoing small-for-size rat LT with synergistic effects of the MSCs and HGF [56].

Similarly, genetic delivery of IL-10 by IL-10-engineered-MSCs has been tested. Compared with placebo, intravenous injection of syngeneic IL-10-transduced MSCs 30 min after transplantation resulted in longer survival, lower Banff scores, increased expression of the Treg-associated cytokines IL-10 and TGF-β1, and the transcription factor FOXP3, as well as decreased expression of T helper (Th)17 T-cell-related cytokines IL-17, IL-6, interferon-γ, tumor necrosis factor-α, and IL-23 and the retinoic-acid-related orphan receptor gamma (RORγ) transcription factor (RORγt) [57]. RORγ is a protein that in humans is encoded by the *RORC* (RAR-related orphan receptor C) gene. RORγ is member of the nuclear receptor family of transcription factors. It is essential for lymphoid organogenesis, in particular lymph nodes and Peyer's patches, but not the spleen. RORγ also plays an important regulatory role in thymopoiesis, by reducing apoptosis of thymocytes and promoting thymocyte differentiation into proinflammatory Th17 cells. It also plays a role in inhibiting apoptosis of undifferentiated T cells and promoting their differentiation into Th17 cells, possibly by downregulating the expression of Fas ligand and IL2 respectively. RORγt drives production of the cytokine granulocyte-macrophage colony-stimulating factor in Th cells, which is essential for the effector phase of autoimmune neuroinflammation.

#### 56.6.2.2 Ongoing trials in humans

The Liège trial (NCT01429038), mentioned earlier, is a single-center, open-label prospective phase I–II study that includes 10 liver transplant recipients (as well as the 10 kidney transplant recipients described earlier). In addition to standard immunosuppression with tacrolimus, MMF, and corticosteroids, patients receive an intravenous infusion of third-party MSCs at a dose of $1.5–3.0 \times 10^6$ MSCs/kg on the third postoperative day (±2 days). The 10 study patients will be followed for trial parameters for 1 year and compared with a control group of 10 similar liver recipients. The primary endpoints are safety of the MSC infusion and the incidence of infections and cancers. The secondary endpoints are patient and graft survival; graft function as assessed by serum bilirubin levels, prothrombin time, hepatic transaminase, and GGT levels; biopsy-proven (Banff classification) rejection rates; feasibility and safety of weaning or decreasing immunosuppression; recipient immune function as assessed by T cell blood populations, including Tregs, T-cell receptor excision circle quantification, Vβ repertoire diversity, pathogen-specific T cells, and anti-organ donor HLA antibodies; and potential development of anti-MSC donor HLA antibodies.

The Beijing trial (NCT01690247) and the Guangdong trial (NCT02223897) are studying the addition of intravenous injections of $1 \times 10^6$ umbilical cord MSCs/kg in addition to conventional therapy. MSCs are administered once every fourth week

for 12 weeks in the first trial and once per week for the first month followed by once per month for 6 months in the second trial. In the Beijing trial, patients are followed for trial parameters for 48 weeks. Outcomes are rates of acute rejection and early liver function recovery, patient and graft survival, and incidence of adverse events. The Guangdong trial is focused on ischemic-type biliary lesions, and outcomes after 18 months include the incidence of ischemic-type biliary lesions, and changes in hepatic enzymes and biliary blood supply as assessed by contrast-enhanced ultrasound examination.

### 56.6.3 Heart transplantation

Since the first human heart transplantation in 1967 this treatment has been the best option for selected patients with end-stage heart failure not remediable by more conservative measures. Despite significant improvements in survival since the introduction of current immunosuppression and better prevention and treatment of infections, there remain major complications, including allograft vasculopathy and other classical complications of solid organ transplantation, including graft failure, graft rejection, opportunistic infections, and malignancies.

#### 56.6.3.1 Animal studies

In rats, mesenchymal progenitor cells have demonstrated their ability to migrate into heart allografts after systemic administration [58] and to participate in tissue repair during chronic rejection [59]. The effects of MSC administration on heart allograft survival are still unknown. Some authors have shown that in rats MSCs did not prolong allograft survival [60] and even accelerated allograft rejection when used alone [61] or when added to low-dose CSP [62], while other studies demonstrated increased heart allograft survival using MSCs alone [63–66] or when MSCs were added to MMF [60,67]. A combination of MSCs and low-dose sirolimus has enabled long-term heart graft survival of more than 100 days with normal histology [65]. The mechanisms of MSC effects on heart allografts are not yet elucidated, but seem to include $CD4^+$ $CD25^+$ $Foxp3^+$ Treg and tolerogenic DC expansion [64,65], interferon-γ-induced suppression of T cell proliferation [60,61], and inhibition of endothelial activation with intercellular adhesion molecule 1 and E-selectin downregulation [61].

No trials in humans have been conducted yet.

### 56.6.4 Lung transplantation

Single or bilateral lung transplantation is a viable treatment option for patients with various end-stage lung diseases, such as chronic obstructive pulmonary disease, idiopathic pulmonary fibrosis, cystic fibrosis, emphysema due to alpha-1 antitrypsin deficiency, and idiopathic pulmonary arterial hypertension. Lung transplant recipients are exposed to complications that include primary graft dysfunction, infections, malignancies, and both acute and chronic rejection. Chronic lung allograft manifests as a bronchiolitis obliterans syndrome (BOS). Endothelin-1-stimulated MSCs may play a pathologic role in this phenomenon by differentiating locally into myofibroblastic cells [68]. However, another group demonstrated that resident lung MSCs isolated from human lung allografts inhibited T cell proliferation *in vitro* [69].

There is only one preclinical study of the administration of MSCs in lung transplantation, and this demonstrated the ability of IL-10-engineered MSCs to prevent lung IRI in mice [26].

The immunomodulatory properties of MSCs are currently being assessed in patients with BOS after lung transplantation. In the Prince Charles Hospital trial in Brisbane, Australia (NCT01175655), patients with BOS will receive MSCs from a third-party donor at a dose of $2 \times 10^6$/kg twice weekly for 2 weeks. Safety, pulmonary function, and survival will be evaluated at 12 months. In a Mayo Clinic trial (NCT02181712), patients with BOS will receive an intravenous injection of $2–4 \times 10^6$ allogeneic MSCs/kg. Adverse events and pulmonary function will be assessed after 2 weeks.

### 56.6.5 Pancreas and islet transplantation

Pancreas or islet transplantation is performed in order to restore glucose-regulated endogenous insulin secretion, which allows insulin independence and improves glycemic control in patients with diabetes mellitus. However, pancreas or islets available for transplantation are scarce, and long-term pancreatic transplant survival rates are unsatisfactory, partly due to the lack of markers for pancreas graft rejection. As in other organ transplantations, long-term immunosuppression with several drugs is often required posttransplant.

MSCs have the ability to differentiate into insulin-producing cells both *in vitro* [70] and *in vivo* in animals [71,72] and humans [73,74]. Moreover, autologous [75], syngeneic [76–78] or allogeneic [78–80] MSCs have demonstrated immunomodulatory properties in animal models of islet transplantation. Complex mechanisms are involved including secretion of soluble factors (such as matrix metalloproteinase-2 and -9 [76] and IL-10 [81]), improvement of graft revascularization [77], and effects on immune cells (including the inhibition of maturation and function of DCs [82], downregulation of memory T cells [80], and induction of regulatory T cells [83]). Moreover, in non-human primates, co-transplantation of allogeneic donor MSCs and islet cells led to significantly enhanced islet engraftment and function at 1 month posttransplant, and additional infusions of donor or third-party MSCs successfully treated rejection [84]. In addition to these effects, MSCs provide a supportive microenvironmental niche through the secretion of paracrine factors and the deposition of extracellular matrix *in vitro* [85,86], in pretransplantation co-cultures [87], and *in vivo* [88]. Finally, as in LT, MSCs are able to prevent IRI in animal models of islet transplantation [89,90].

There is only one ongoing clinical trial on co-transplantation of allogeneic islets and autologous MSCs. Primary outcomes are exogenous insulin requirement, glycated hemoglobin, and glucose and C-peptide levels. Secondary outcomes are liver and

kidney function, portal vein ultrasound appearance, autoantibodies, and complete blood count (NCT00646724).

### 56.6.6 Bowel transplantation

There is one case report of successful administration of third-party-derived BM-MSCs to treat severe refractory bowel dysfunction secondary to infection after bowel transplantation [91]. More recently, Doğan *et al.* gave an intra-arterial infusion of autologous BM-MSCs (three doses of $1 \times 10^6$ MSCs/kg) at the time of reperfusion and on days 15 and 30 posttransplant in six patients undergoing small intestine transplantation. All patients received anti-thymocyte immunoglobulin and corticosteroids as induction therapy and a CNI using low-dose tacrolimus as maintenance therapy. Four patients developed acute rejection. Three did not survive, of whom one did not respond to bolus corticosteroid therapy and two developed severe fungal and bacterial infections after corticosteroids. Two patients did not experience rejection and had no complications with good quality of life during the 30 months of trial follow-up [92].

## 56.7 Conclusions

Studies are providing increasing evidence of MSC benefits in solid organ transplantation. These benefits appear to be obtained by a combination of three major properties of MSCs: immunomodulation, tissue/organ repair, and prevention of IRI. Complex mechanisms are involved, and further research is required to elucidate them. Convincing animal studies in kidney transplantation and LT, and to a lesser extent in lung and islet transplantation, have led to the initiation of human trials. Initial results are promising in kidney transplantation. In heart transplantation, conflicting data have been obtained and more research is needed in animal models before human clinical trials can be initiated. Major goals in this field are reduction of graft rejection rates, improvement of organ and patient survival, and avoidance of treatment-related adverse effects through dose reduction or withdrawal of immunosuppressive drugs.

## 57.1 The immunobiology of allogeneic hematopoietic stem cell transplantation

There are four main immunologic processes that are associated with allogeneic hematopoietic stem cell transplantation (HSCT), regardless of whether or not the hematopoietic stem cell (HSC) donor is a family member who is genotypically or phenotypically identical with the recipient for the human leukocyte antigens (HLAs) of the major histocompatibility complex, or is a living unrelated volunteer who is phenotypically matched for all or most of the HLAs, or whether an umbilical cord blood (UCB) unit is used; in the latter case there is more tolerance for the degree of HLA mismatching. The four immunologic process are graft rejection, graft-versus-host disease (GVHD), the graft-versus-leukemia effect, and the recipient's response to infection.

### 57.1.1 Graft rejection and late marrow failure

Graft failure is when the donor marrow fails to engraft at all due to rejection by recipient T cells that have survived the pretransplant chemoradiation or chemotherapy. This is often a fatal event, but there may be a role for mesenchymal stromal cells (MSCs) in it. Marrow failure refers to a graft that has taken initially but subsequently peters out. One reason is a low number of HSCs infused. This is sometimes treated with retransplantation.

### 57.1.2 Graft-versus-host disease

Acute GVHD is defined as that occurring within 100 days of HSCT. After that it is called chronic GVHD. Both are serious and both can be fatal. Acute GVHD is thought to be due to the release of lipopolysaccharide (exotoxin) secondary to organ and tissue damage from the pretransplant preparative regimen. This results in a cascade-like release of proinflammatory factors, such as tumor necrosis factor-α, interleukin (IL)-1, and IL-6, which recruit T cells in particular, which in turn mediate an immune attack on the recipient's tissues. This occurs even if the donor and recipient are HLA-matched and is due to recognition by the donor T cells, infused with the stem cell inoculum, of minor (or non-HLA) histocompatibility antigens present on the recipient's cells but not on those of the donor. It is thought that minor histocompatibility antigens drive T cell activation via the CD40–CD154, the CD80–CD28, and the CD86–CTLA4 interactions, inducing proliferation and differentiation of effector T cells. (CTLA4 is cytotoxic T-lymphocyte-associated protein 4, also known as CD152.) It occurs even though the recipient is routinely given immunosuppressive treatment such as cyclosporine and

methotrexate to prevent it. Both acute and chronic GVHD usually require additional active immune suppressive medication, such as corticosteroids, and GVHD is itself immunosuppressive because it targets lymphoid organs such as the lymph nodes, thymus, and spleen in addition to the more clinically apparent target organs of skin, liver, and the gastrointestinal tract [1]. Thus, the allograft recipient is immune suppressed before the transplant due to conventional chemotherapy and further immune suppressed by the pretransplant regimen, the prophylactic drugs given to minimize GVHD, the immunosuppressive drugs given to treat GVHD, and GVHD itself.

### 57.1.3 The graft-versus-leukemia effect

The third immunologic process is the graft-versus-leukemia effect (or the graft-versus-malignancy effect if the recipient's diagnosis is a neoplasm other than leukemia). This is one of the major ways by which an allogeneic HSCT cures leukemia and other hematologic malignancies. As with GVHD, it too is mediated by donor T cells, and the respective populations are hard to separate. If relapse of the leukemia occurs it can sometimes be successfully treated simply by an infusion of lymphocytes from the marrow donor. Sensitivity to this procedure varies between different hematologic malignancies.

### 57.1.4 The recipient's response to infection

The fourth immunologic process is the recipient's response to infection. In view of the recipient's immune suppressed state it is not surprising that infections are common posttransplant. Prophylactic medication is routinely given with acyclovir, co-trimoxazole, an azole antifungal medication, and ganciclovir, to respectively minimize the risk of herpes simplex virus, *Pneumocystis jiroveci*, *Candida* and *Aspergillus* fungal infections, and cytomegalovirus. Happily, some elements of the innate immune system reconstitute quickly after the transplant. The most important of these is neutrophil recovery because of their importance in controlling bacterial diseases in conjunction with antibacterial antibiotics. The adaptive immune system, including both T cell and B cell function, reconstitutes much more slowly.

## 57.2 The immunobiology of mesenchymal stromal cells

The involvement of MSCs in both the innate and adaptive immune systems is multiple and complex and is described in Chapters 33 and 34.

## 57.3 The role of mesenchymal stromal cells in the expansion of hematopoietic stem cells

A major role of bone marrow mesenchymal stem and stromal cells is to support the function and survival of HSCs in the bone marrow. The two cell types are in close proximity to each in the marrow (Figure 57.1). The mechanisms underlying this are described in detail in Chapter 32.

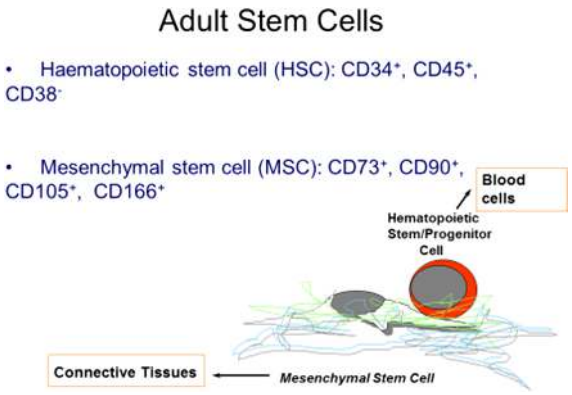

**Figure 57.1** HSCs are in close proximity to MSCs in the bone marrow and receive from them growth and differentiation signals. (See color plate section.)

This property of MSCs has been exploited clinically in patients undergoing UCB HSCT. While UCB HSCT works well in children, the number of HSCs present in one or two cord blood units is often insufficient to establish rapid or robust hematopoietic reconstitution in adults after UCB HSCT. After showing that expansion of both primitive and mature hematopoietic progenitors in unfractionated cord blood cells was markedly enhanced by co-culture with MSCs *in vitro*, de Lima *et al.* in Dr Shpall's group in Houston studied engraftment results in 31 adults with hematologic cancers who received transplants of two cord blood units, one of which contained cord blood that was expanded *ex vivo* in co-cultures with allogeneic MSCs [2]. The results in these patients were compared with those in 80 historical controls who received two units of unmanipulated cord blood. Co-culture with MSCs led to an expansion of total nucleated cells by a median factor of 12.2 and of $CD34^+$ cells by a median factor of 30.1. In patients in whom engraftment occurred, the median time to neutrophil engraftment was 15 days in the recipients of expanded cord blood compared with 24 days in controls who received unmanipulated cord blood only ($P < 0.001$). The median times to platelet engraftment were 42 days and 49 days respectively ($P = 0.03$). On day 26 posttransplant the cumulative incidence of neutrophil engraftment was 88% with expansion versus 53% without expansion ($P < 0.001$). On day 60 posttransplant the cumulative incidences of platelet engraftment were 71% and 31% respectively ($P < 0.001$). This was an encouraging result that needs confirmation in further trials.

## 57.4 The role of mesenchymal stromal cells in marrow graft rejection

Meuleman*et al.* evaluated the safety and efficiency of an infusion of donor MSCs that had been expanded in *ex vivo* culture in six patients with poor hematopoietic recovery after allogeneic HSCT [3]. The MSCs were infused without HSCs and without

conditioning at a dose of $1 \times 10^6$/kg weight. Two patients displayed rapid hematopoietic recovery on days 12 and 21 after the MSC infusion, while the other four patients showed no response. The two patients who showed hematopoietic recovery were in first complete remission, while the four who did not respond to MSCs had been more heavily pretreated. There were no toxic side effects from the MSC infusions. Thus, this small study of MSCs without HSC co-infusion suggests that MSCs can restore medullary function in some patients who have poor hematopoietic recovery after an allogeneic HSC transplant.

## 57.5 The role of mesenchymal stromal cells in the prevention of acute graft-versus-host disease

Three studies that included a randomization of MSCs or no MSCs to prevent GVHD after allogeneic HSCT have been reported [4–6]. Ning *et al.* performed a randomized clinical trial with 30 patients given marrow and/or peripheral blood stem cells from an HLA-identical sibling donor with ($n = 15$) or without ($n = 15$) added MSCs after myeloablative conditioning [4]. The authors compared the outcomes of the 10 evaluable patient given MSCs with those observed in the 15 patients randomized to the control arm. One of 10 patients in the MSC arm versus 8 of 15 in the control arm experienced grade II–IV acute GVHD. However, patients given MSCs had a higher risk of relapse (60% versus 20% at 3 years; $P = 0.02$), and lower disease-free survival (30% versus 67% at 3 years; $P = 0.035$) than those in the control arm, an outcome eerily reminiscent of T-cell-depleted allografts in the 1980s.

Bernardo *et al.* co-transplanted parental HLA-disparate MSCs in 13 children with hematological disorders undergoing unrelated cord blood transplantation after myeloablative conditioning [5]. HSCT outcomes were compared with those observed in a cohort of 39 matched historical controls. The cumulative incidence of graft rejection was 15% in the MSC group versus 3% in the historical group (not significantly different). The incidence of grade III–IV acute GVHD was 0% in the MSC group versus 26% in the historical group ($P = 0.05$), while the cumulative incidence of chronic GVHD was 0% in the MSC group versus 11% in the historical group (not significantly different). The 3-year overall survival was 63% and 64% in the MSC and control groups respectively, while the 3-year cumulative incidence of relapse was 25% and 23% respectively.

Baron *et al.* reported the results of a pilot study analyzing the safety of MSC co-transplantation in 20 patients given HLA-mismatched PBSCs after pretransplant conditioning with fludarabine and toal body irradiation [6]. MSCs were given at doses of 1–2 $\times$ $10^6$ MSCs/kg. Transplantation outcomes in these 20 patients were compared with those observed in a historical group of 16 patients given HLA-mismatched PBSCs (without MSCs) after the same nonmyeloablative conditioning. One of 20 patients in the MSC group versus 0 of 16 patients in the historical group experienced graft rejection. The 1- and 2-year probabilities of dying from GVHD or infection while on treatment for GVHD were 10% and 10% respectively in the MSC group, versus 31% and 38% respectively in the historical group ($P = 0.04$).

These three studies described lower risks of acute GVHD in patients co-transplanted with MSCs compared with historical or concurrent controls. However, the number of patients involved was relatively small. Large randomized, double-blinded, placebo-controlled studies are required to determine the potential utility of MSCs given as prophylaxis for GVHD while determining the effect, if any, on graft rejection, serious infection, and recurrence of the underlying hematological malignancy.

## 57.6 The role of mesenchymal cells in the treatment of corticosteroid-refractory acute graft-versus-host disease

One of the most dramatic single case reports in the history of allogeneic HSCT is of a 9-year-old boy with acute lymphoblastic leukemia in third remission who had received a transplant of blood stem cells from an HLA-A, HLA-B, HLA-DR-β1 identical, unrelated female donor after conditioning with cyclophosphamide (120 mg/kg) and fractionated total body irradiation (3 Gy for 4 days) [7]. Immunosuppression included thymoglobulin (6 mg/kg) during the conditioning, followed by cyclosporine combined with four doses of methotrexate. On day 11 after the allogeneic HSC transplant he developed a maculopapular rash of the thorax and back that progressed despite treatment with prednisolone 2 mg/kg daily. By day 22 the patient had developed diarrhea (>1000 mL/day) and abdominal pain requiring morphine. He stopped eating on day 24. Bilirubin and alanine aminotransferase concentrations rose. Psoralen and ultraviolet-A light (PUVA) treatment two to three times per week for 3 weeks was followed by extracorporeal PUVA one to four times per week for 6 weeks. Both infliximab (a monoclonal antibody to tumor necrosis factor-α) 10 mg/kg and daclizumab (a monoclonal antibody to the interleukin 2 receptor) 1 mg/kg for 4 weeks were ineffective. Methylprednisolone 250–500 mg/day for a total of 22 days, mycophenolate mofetil, and methotrexate were also tried. By day 70 the patient had developed grade IV (severe, usually fatal) acute GVHD, including diarrhea up to 20 times daily and a bilirubin concentration of 250 mmol/L. He was treated for repeated bacterial, viral, and invasive fungal infections. Because of their ability to suppress T cell alloproliferation it was decided to give maternal (haploidentical) MSCs. After 3 weeks of cell culture $90 \times 10^6$ MSCs were harvested. These cells expressed CD166, CD105, CD44, and CD29 but not CD34 or CD45. Intravenous administration of $2 \times 10^6$ MSCs/kg of the patient's weight were given on day 73. There was no toxicity after the infusion. Four days later the frequency of diarrhea fell to twice daily. A decline in total bilirubin was noted 5 days after the MSC infusion, and 2 weeks later the patient resumed oral food intake on day 84. By day 143 after the HSC allograft, DNA analysis of the

patient's bone marrow showed the presence of minimal residual leukemia. Cyclosporine treatment was discontinued to enable a graft-versus-leukemia effect. By day 150 the patient again had diarrhea but no abdominal pain. Colonoscopy showed normal colon with slight irritation of the cecum. Biopsy specimens showed mild GVHD and 4% female epithelium by fluorescence in situ hybridization. He received a transplant of the same batch of MSCs from his mother ($1 \times 10^6$/kg) on day 170 after transplantation. After 1 week his stools were normal and he started to eat again. His serum bilirubin concentration rose and liver biopsy specimens showed chronic GVHD. The bilirubin value subsequently returned to normal. He went home on day 220. He was well 1 year after transplantation, with a bilirubin concentration of 8 mmol/L. He had no minimal residual leukemia in his blood or bone marrow.

This was an astonishing case and stirred huge interest amongst marrow transplanters.

In a subsequent phase II trial in Europe, 55 patients were given MSCs at a median dose $1.4 \times 10^6$ MSCs/kg as treatment for corticosteroid-refractory grades II ($n = 5$), III ($n = 25$) or IV ($n = 25$) acute GVHD [8]. Thirty patients had complete responses and a further nine showed some improvement. Three patients had recurrence of their malignancy and one developed *de novo* acute myeloid leukemia of recipient origin. Complete responders to MSCs were more likely to be alive 2 years after HSCT than those with partial or no responses (52% versus 16%; ($P = 0.018$).

A phase III trial in North America undertaken by Osiris Therapeutics Inc. using unrelated donor bone-marrow-derived MSCs under the brand name Prochymal™ failed to reach its primary endpoints.

There appears little doubt that some patients with severe-corticosteroid-refractory acute GVHD respond to MSCs, particularly children, and Prochymal™ has marketing approval for its use in children from the regulatory authorities in Canada and New Zealand. The results of further phase II and III trials are awaited.

## 57.7 The mesenchymal stromal cell exosome: a substitute for the mesenchymal stromal cell?

Extracellular vesicles (EVs) are membrane vesicles that are released by many cell types into the extracellular space and consist of several classes, including exosomes, microvesicles, ectosomes, membrane particles, exosome-like vesicles, or apoptotic bodies. See Chapters 20 and 38 for details. However, the defining parameters for each of these different classes are not definitive, and the use of the terms exosomes, microvesicles, and microparticles are often ambiguous and not rigorously qualified. Generally, EVs can be formed by either inward budding of endolysosomal vesicles followed by exocytosis (e.g., exosomes) or shedding from the plasma membrane (e.g., microvesicles). They have attracted much interest from the biomedical research community because of their potential as sources of biomarkers for diseases, therapeutic agents, or vehicles for drug delivery. Generally, EVs carry a cargo of proteins and nucleic acids that reflects their cell of origin and the pathophysiological state of the cell source. In addition, these EVs with their cargoes could be internalized by other cells as a form of intercellular communication, making these vesicles potential therapeutic agents or delivery vehicles of therapeutic agents.

The exosome is the best characterized of all the EVs described to date and can be differentiated from other EVs by its biogenesis. The exosome is the only EV known to be derived from endosome, and this endosomal origin of exosomes is reflected in its membrane, which is enriched for lipids commonly found in lipid rafts such as cholesterol, sphingomyelin, and ceramide. Lipid rafts are specialized microdomains in the plasma membrane where much of the cellular endocytosis takes place to form endosomes. Subsequent invaginations of the endosomal membrane generate the numerous intraluminal vesicles within the multivesicular body (MVB). If the MVB fuses with the plasma membrane, the intraluminal vesicles are released as exosomes. The process by which cellular proteins and RNAs are selected and loaded into exosomes has not been elucidated. MSC exosomes have been among the best characterized exosomes to date (Chapters 1, 20, and 38).

Recently, MSC exosomes were administered to a person with treatment-refractory grade IV (severe) acute GVHD who went into remission with a dramatic alleviation of her disease symptoms and who remained stable for 5 months [9].

## 58.1 Introduction

Chronic skin wounds and wounds associated with disease remain challenging clinical problems in aging and westernized societies [1]. These wounds do not always respond to current treatments [2]. Recently, cell therapy has emerged as a new therapeutic approach for wound care, and much effort has focused on understanding its therapeutic mechanism. In particular, mesenchymal stromal cells (MSCs) are one of the most readily available sources of cells, showing obvious beneficial effects in wound healing [3]. Recent reports also highlighted the beneficial properties of placental-tissue-derived MSCs in wounds [4,5]. This review discusses the critical roles of MSCs in the wound healing process.

## 58.2 The wound healing process

The definition of a skin wound is damage or disruption to the normal anatomical structure and function, ranging from a simple break in subcutaneous tissue to deep damage to other structures, such as muscles, nerves, and vessels [6,7]. Wounds can be classified as acute or chronic depending on the healing time [8,9]. Acute wounds are those that proceed through normal stages of the healing pathway, with eventual functional and anatomical restoration. Usual healing time may last up to 30 days. Chronic wounds, on the other hand, cannot be repaired in a timely and orderly manner by the normal healing process due to various causes, including arterial and venous insufficiency [6,10]. The healing process is disturbed by many factors, such as necrosis, continuous state of inflammation, hypoxia, and infection. Another type of wound is a complicated wound, defined as a combination of tissue defect and infection [9]. The five signs and symptoms of edema, heat, pain, redness, and limited function are typical properties. The wound healing process is a complex and dynamic event involving a series of coordinated interactions in biological and immunological systems. Various cell types and a cascade of regulated steps are involved in wound healing [11]. These processes occur in four overlapping, time-dependent phases: coagulation/hemostasis, inflammation, proliferation, and wound remodeling [12]. Immediately after injury, coagulation and hemostasis take place in the wound to protect the vascular system and minimize blood loss. Platelets and blood clots contain fibrin, fibronectin, vitronectin, and various growth factors, such as insulin-like growth factor and transforming growth factor (TGF)-β, that act as promoters for the healing cascade by activation and attraction of neutrophils, fibroblasts, macrophages, and endothelial cells [13]. During the coagulation/hemostasis phase, the inflammation phase begins with infiltration of neutrophils in the wound site 1 day after injury to prevent infection [13]. Neutrophils play an important role in removing and destroying bacteria, foreign particles, dead cells, and damaged extracellular matrix by phagocytic activity. Upon finishing this task, neutrophils are eliminated from the wound area, and macrophages phagocytose redundant and apoptotic cells [14]. About 2 days after injury, macrophages derived from blood

monocytes continue the late inflammatory phase. These cells regulate and activate keratinocytes, fibroblasts, and endothelial cells by providing an abundant reservoir of various tissue growth factors, such as TGF-β, fibroblast growth factor (FGF), epidermal growth factor, and collagenase [15]. About 3 days after injury, lymphocytes are attracted to the wound site and work by activation of interleukin (IL)-1 and immunoglobulin G breakdown [16]. IL-1 is responsible for collagen regulation, remodeling, and degradation [17]. About 2 weeks thereafter, the proliferative phase starts through fibroblast migration, deposition of extracellular matrix, and formation of granulation tissue [7]. Migrated fibroblasts and myofibroblasts are stimulated to proliferate and produce matrix protein. The resulting abundant extracellular matrix supports cell migration, and fibroblasts change into the myofibroblast phenotype. Another important factor for wound healing is the collagen synthesized by fibroblasts. It plays a pivotal role in the proliferative and remodeling phases by providing a foundation for intracellular matrix formation [18,19]. In addition, numerous angiogenic factors establish new blood vessels, which are critical for all phases of wound healing. Vascular endothelial growth factor (VEGF) and FGF are representative regulatory factors in all reparative processes. Changes in wound microenvironment, such as hypoxia, low pH, and increased lactate, also initiate and promote angiogenesis [20]. Chemotactic agents play a major role in angiogenesis, cell migration, and modulation of cell growth and differentiation [21]. The last phase of wound healing is the remodeling phase, which is responsible for the formation of new epithelium and final scar tissue. This phase usually lasts for 1 or 2 years but sometimes may last longer. Wound remodeling is controlled by a delicate balance of synthesis and degradation. Along with intracellular matrix maturation, collagen bundles increase, and fibronectin and hyaluronic acid are degraded [18]. Tissue inhibitor of metalloproteinase activity and tensile strength increase with collagen collection, and new matrix accumulates [22]. New collagen matrix and its subsequent organization are completed in the remodeling phase. At the same time, wound contraction begins, and the density of macrophages and fibroblasts is reduced. Finally, metabolic activity decreases, capillary growth stops, and the full wound healing process is completed with a mature scar.

## 58.3 The role of mesenchymal stromal cells in the wound healing process

MSCs play an important role in all phases of wound healing, especially the inflammation, proliferation, and remodeling processes.

### 58.3.1 Immune modulation

MSCs directly attenuate the inflammatory response by decreasing secretion of interferon-γ and TNF-β, two representative proinflammatory cytokines. In addition, MSCs produce anti-inflammatory cytokines such as IL-10, IL-4, and TGF-β [23,24]. Recent studies have also revealed that MSCs secrete TNF-stimulated gene-6, an anti-inflammatory factor that suppresses TNF-α-mediated inflammation, excessive collagen deposition, and myofibroblast differentiation [25]. These properties of MSCs influence the inflammatory phase and the chronic wound state.

### 58.3.2 Antimicrobial activity

Antimicrobial activity is critical for wound clearance of infection. The antimicrobial activity of MSCs is mediated by two mechanisms: secretion of LL-37, an antimicrobial factor [26], and secretion of immunomodulating factors that regulate immune cells and increase phagocytosis and bacterial killing [27] (and see Chapter 55).

### 58.3.3 Chemotactic and migratory activities

Chemotactic signals modulate inflammation and cause MSCs to migrate to wound sites and facilitate tissue regeneration [28]. MSCs secrete high levels of chemokines, such as macrophage inflammatory protein (MIP)-1α, MIP-2, monocyte chemoattractant protein 5, granulocyte chemotactic protein 2, neutrophil-activating protein 2, IL-8, chemokine receptor (CCR)2, CCR3, and CCR5 [29,30]. Secreted factors from MSCs recruit macrophages and endothelial lineage cells [29]. In addition, MSCs show high migration and proliferation activity using chemotactic and angiogenic factors to promote wound healing [4,29,30].

### 58.3.4 Paracrine activity

Paracrine signaling associated with angiogenesis improves tissue repair and is likely the main mechanism of wound healing. Many paracrine factors of MSCs have been reported such as angiopoietin-1, VEGF, FGF, epidermal growth factor, platelet-derived growth factor, TGF-β, and keratinocyte growth factor [4,31,32]. These paracrine signaling molecules have anti-scarring properties through hepatocyte growth factor, VEGF, TGF-β1, and TGF-β3 [33,34].

### 58.3.5 Differentiation

Differentiation of MSCs has also been implicated as one mechanism of wound healing. In fact, human MSCs survived for more than 1 year in wounded tissues of a fetal lamb model [35]. In addition, MSCs differentiated into keratinocytes in the wound site, indicating direct contribution to cutaneous regeneration [4,31,36]. Close examination revealed that injected MSCs were found in dermal appendages [31]. MSCs differentiate into several cell types in the wound, such as endothelial cells, pericytes, and monocytes [37,38]; however, low engraftment and survival of MSCs at wound sites may cause limited activity of MSC differentiation.

## 58.4 Conclusions and the future

Applying MSCs to skin wound healing appears to have obvious beneficial effects. Even allogeneic MSCs exhibit minimal

immunogenicity and are equally efficient as syngeneic MSCs in engraftment and enhancement of wound healing [39]. Their limited plasticity and varied potential for paracrine signaling from different cell sources or tissues may influence their therapeutic efficacy in the wound healing process. The physiological and molecular mechanisms of MSCs in wound healing are complicated. Thus, cutting-edge technology should be used to elucidate further details of MSC-mediated mechanisms in different wound healing phases.

## 59.1 Summary

It is becoming increasingly evident that adult stromal cells have the capacity to participate in repair and regeneration of damaged and/or diseased tissues. Mesenchymal stromal cells (MSCs) have been among the most studied adult stromal cells for the treatment of a variety of conditions, including wound healing. Wound healing is a complex multistage process that orchestrates the reconstitution of the dermal and epidermal layers of the skin. Owing to the recent advances in stromal cell research, enthusiasm has arisen for the application of stromal cells in regenerative medicine. MSCs have been shown to improve skin wound healing in multiple preclinical models and in a few clinical studies. In this chapter we will summarize approaches for improving wound healing and outline mechanisms determined in preclinical studies. Future directions of MSC-based therapy in wound healing will also be explored. Finally, despite its apparent advantages, the limitations and challenges of MSC administration to improve wound healing will be discussed.

## 59.2 Introduction

A wound is defined as a disruption of normal anatomic structure and functional integrity of the skin or another external surface [1]. In many pathological circumstances, such as diabetes or burns injury, the normal wound healing process fails to adequately restore function to the skin, leading to potentially severe complications, including ulcers and infections. Normal wound healing is a dynamic and complex process involving a series of coordinated events, including bleeding and coagulation, acute inflammation, cell migration, proliferation, differentiation, angiogenesis, re-epithelialization, and synthesis and remodeling of the extracellular matrix (ECM) [2].

Mesenchymal stromal cells (MSCs) orchestrate the three main phases of normal wound healing: inflammatory, proliferative, and remodeling. MSCs directly attenuate the inflammatory response. They also promote antimicrobial activity (see Chapter 55) and cell migration during epithelial remodeling [2] (and see Chapters 22, 23, and 24).

The procurement, isolation, expansion, and cryostorage of MSCs is relatively straightforward [3]. MSCs can be derived from many different organs and tissues including bone marrow, adipose tissue, amniotic fluid, umbilical cord, placenta, menstrual blood, and dental pulp [4–7]. MSCs secrete many cytokines and chemokines that are antiapoptotic, immunomodulatory and proangiogenic [8].

## 59.3 The role of bone-marrow-derived mesenchymal stromal cells in wound healing

Bone-marrow-derived MSCs (BM-MSCs) improved cutaneous healing by accelerating re-epithelialization, increasing angiogenesis,

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.

and differentiating into epithelial cells expressing the keratinocyte-specific marker keratin [9]. The trophic (supportive) activity of MSCs may include both dermal fibroblast and keratinocyte migration, as well as contribute to the formation of the ECM [10]. Preclinical evidence supports the therapeutic application of BM-MSCs as summarized in Table 59.1.

Stoff *et al.* reported that the injection of human BM-MSCs into an incisional wound led to improved wound closure and a significant reduction in scar formation in rabbits. Incisional wounds treated with human MSCs regained tensile strength at a significantly higher level than untreated wounds did [11]. Murine BM-MSCs applied to full-thickness excisional wounds

**Table 59.1** Preclinical studies using adult mesenchymal stromal cells to enhance cutaneous wound healing.

| Cell type | Wound model | Treatment method | Outcome | Reference |
|---|---|---|---|---|
| BM-MSCs | Rabbit model of full-thickness 3 cm long incisional wounds up to the fascia in the dorsal skin | Intradermal injection of human MSCs | Reduced wound scarring and increased tensile strength in the incisional wounds | [11] |
| | Mouse full-thickness excisional wound | Intradermal injection of either allogeneic or syngeneic murine BM-MSCs | Migration through the tissue, attenuation of the local inflammatory response, and facilitation of cutaneous healing was similar with either allogeneic or syngeneic MSCs | [12] |
| | Human fibrin clot in a wounded tissue | *In vitro* culture system of fibrin clot and human MSCs | A high intrinsic fibrinolytic capacity of human MSCs was found which mediates the invasion into a fibrin clot in a wounded tissue | [13] |
| | Cutaneous wounds in diabetic (db/db) mice | Murine BM-MSCs were administered intradermally around the wound edge together with the novel reparative lipid mediator 14*S*,21*R*-dihydroxydocosa-hexaenoic acid | Accelerated wound re-epithelialization, granulation tissue formation, and improved vascularization | [14] |
| | Minipig model of local exposure to high doses of γ-gamma radiation (50 Gy) | Intradermal injection of autologous BM-MSCs | Accumulation of lymphocytes at the border of the dermis and subcutaneous tissue; improved vascularization | [15] |
| | A single dorsal full- thickness wound with an 8 mm punch biopsy in diabetic (db/db) mice | Subcutaneous injection of syngeneic BM-MSCs | Increased miR-146a expression, attenuated inflammatory gene expression, and improved diabetic wound healing | [16] |
| | 1.5 cm dorsal skin incision in B6D2 mice | Sutures were co-cultured in the presence of B6D2 BM-MSCs | Increased the collagen deposition in sutured wounds | [17] |
| | 24 full-thickness circular wounds 6 mm in diameter in beagle dogs | Topical application of allogeneic BM-MSCs | More rapid wound closure, increased collagen synthesis, cellular proliferation, and angiogenesis | [18] |
| | Excisional wounds in C57BL/6 mice | Subcutaneous injection at four equidistant points around the wound edge of murine MSCs seeded on hydrogels | MSC-seeded hydrogels demonstrated significantly enhanced angiogenesis compared with MSCs administered without a hydrogel scaffold | [19] |
| | Immunodeficient NOD/SCID mice were locally irradiated to the leg (30 Gy, dose rate 2.7 Gy/min) using a $^{60}$Co source to induce a severe skin lesion | Cultured human BM-MSCs were injected intravenously | Less severe lesions and more rapid healing of wounds compared with control mice | [20] |
| Adipose-tissue-derived MSCs (ADSCs) | Excisional wounds in diabetic (db/db) mice | Autologous ADSCs containing a telocollagen matrix with a silicone membrane on to an open wound | Wound healing promoted possibly due to cytokines secreted by ADSCs | [21] |
| | Full-thickness skin wounds in nude BALB/c mice | Intradermal injection of human ADSCs at bilateral sites along the periphery of the wound | Accelerated wound healing | [22] |
| | Porcine full-layer excisional wound model | Autologous or allogeneic porcine ADSCs administered in a fibrin gel vehicle containing a number of dynamic wound-healing trophic factors on to an open wound | The application of more than one growth factor together with MSCs demonstrated an advantage in improving wound healing | [23] |

**Table 59.1** (*Continued*)

| Cell type | Wound model | Treatment method | Outcome | Reference |
|---|---|---|---|---|
| | Mouse full-thickness excisional wounds | Intradermal injection around the wound at four injection sites of syngeneic murine BM-MSCs | Significantly higher capillary densities than control group | [24] |
| | Nude mouse full-thickness excisional wounds | Intradermal injection of human ADSCs | Conditioned medium (CM) from TGF-β1-pretreated ADSCs promoted wound healing | [25] |
| | Mouse full-thickness excisional wounds | Direct implantation of human ADSC sheets on to the wounds | Wound healing enhanced | [26] |
| Gestational-tissue-derived MSCs | Full-thickness skin excision wounds in SCID mice | Human Wharton's jelly MSCs injected into the skin seeded on to an amniotic membrane scaffold | Demonstrated best biomechanical properties; augmented scar-free wound healing with hair growth | [27] |
| | Rat model of 30% total body surface area full-thickness burns | Intravenous injection of green fluorescent protein-labeled human umbilical cord MSCs (UC-MSCs) | Promoted wound recovery, neovascularization, and re-epithelialization | [28] |
| | Rat 8 mm full-thickness circular excisional wounds | Intradermal injection around the wound area of human UC-MSCs | Promoted wound closure and increased new capillary formation | [29] |
| | Mouse full-thickness excisional skin wounds | Subcutaneous injection of hypoxia-conditioned medium from human amniotic-fluid-derived MSCs around the wound and topical application to the wound bed | Enhanced wound healing via an increase of hypoxia-induced paracrine factors | [30] |
| Dermal-tissue-derived MSCs | Murine bone marrow cells from enhanced green fluorescent protein transgenic mice were transplanted into normal C57BL/6 mice and into mice with excisional skin wounds | 1.5 $cm^2$ full-thickness wounds were made that included the panniculus carnosus muscle on the mid back | Normal skin was a target organ for bone-marrow-derived cells from both the hematopoietic and the mesenchymal stem cell pools. MSCs contributed more to wound healing than $CD45^+$ hematopoietic cells | [31] |

exhibited an ability to control allogeneic fibroblasts to migrate through the tissue and to attenuate the local inflammatory response. BM-MSC-treated wounds had significantly reduced $CD45^+$ leukocytes, $CD3^+$ T cells, and $CD8^+$ T cells [12].

An intrinsic fibrinolytic capacity of human MSCs mediated the invasion of cells into the fibrin clot of a wounded tissue. The secretion of the fibrinolytic enzymes tissue plasminogen activator, urokinase-type plasminogen activator, soluble urokinase-type plasminogen activator receptor (CD87), and plasminogen activator inhibitor by human MSCs resulted in fibrin clot degradation *in vitro*. Human MSCs and human dermal fibroblasts were both critically involved in remodeling the ECM in skin wounds [13].

14*S*,21*R*-dihydroxydocosa-4*Z*,7*Z*,10*Z*,12*E*,16*Z*,19*Z*-hexaenoic acid (14*S*,21*R*-diHDHA) is a new agent used for treating diabetic skin ulcers. 14*S*,21*R*-diHDHA triggered phosphorylation of p38 but had no effect on phosphorylation of extracellular regulated kinase (ERK)1/2, suggesting that diabetes mellitus may affect the generation of pro-healing lipid mediators for restoring wound healing and MSC functions [14]. However, the mechanisms contributing to the healing process vary with BM-MSCs. Activation of adenosine and adenosine A2A receptors and CD73 coordinately regulate the proliferation and differentiation of BM-MSCs in knockout mice [32]. In addition hypoxia-dependent migration has a biphasic sequence involving an early phase requiring the generation of reactive oxygen species, and a delayed phase sustained by hypoxia-inducible-factor-1-dependent expression and release of vascular endothelial growth factor (VEGF) [33].

Platelet lysate is involved in the initiation of wound healing. An inflammatory response is induced in MSCs followed by the secretion of factors maintaining macrophages in a proinflammatory state, thus enhancing the initial inflammatory response to the injury. In an inflammatory microenvironment, platelet lysate also increased the secretion of the proinflammatory cytokine interleukin (IL)-6 [34]. Secreted frizzled-related protein 2 (sFRP2) has recently been identified as a key mediator of MSC-driven repair of myocardial injury and of wound repair. sFRP2 activity occurred because of inhibition of both wingless-related integration site (Wnt) and bone morphogenetic protein signaling pathways. Bone morphogenetic protein signaling inhibition mediated by sFRP2, as assessed by levels of pSMAD1/5/8, was independent of its effects on the Wnt pathway [35].

In a rat skin burn model MSC-derived exosomes are involved in tissue injury repair. MSC-exosome-derived Wnt4 promoted α-catenin nuclear translocation and activity to promote re-epithelialization and cell proliferation, a potential new mechanism for the use of MSCs in cutaneous wound healing [36].

A new minipig model has been developed that is close to humans and enables development of mesenchymal stromal cell therapy strategies that can be applied to the treatment of human radiation burns. In grafted animals MSCs led to local accumulation of lymphocytes at the border of the dermis and the subcutaneous tissue and improved vascularization [15].

Increasing evidence shows that MSCs are also strongly influenced by their biomechanical environment (see Chapter 17). Experiments in both animal and *in vitro* model systems have demonstrated pivotal roles for the biomechanical environment in regulating myofibroblast differentiation and contraction, endothelial barrier function and angiogenesis, and MSC fate decisions. In xenograft wound healing models these *in vitro* differences correlated with decreased ability of human MSCs to aid in wound closure *in vivo* [37]. Molecular mechanisms transducing the biomechanical environment are emerging, with prominent and interacting roles recently identified for key network components, including transforming growth factor-β (TGF-β)/SMAD, focal adhesion kinase, myocardin-related transcription factors, Wnt/β-catenin and Yes-associated protein (YAP)/TAZ (transcriptional coactivator with PDZ-binding motif) signaling pathways [38]. (Myocardin-related transcription factors transduce cytoskeletal signals to the nucleus, activating a subset of serum response factor-dependent genes promoting myogenic differentiation and cytoskeletal organization. They are multifunctional proteins that share evolutionarily conserved domains required for actin-binding, homo- and heterodimerization, high-order chromatin organization, and transcriptional activation. The Yorkie-homologues YAP and TAZ act as relays of mechanical signals exerted by ECM rigidity and cell shape.)

MSCs were used for skin wounds in a rat model of streptozotocin-induced diabetes mellitus. Histologic analysis showed a decrease in $CD45^+$ leukocytes in the MSC group compared with the control group. Significant increases in epidermal growth factor, VEGF, prolyl 4-hydroxylase, and Ki-67 expression were also noted in the MSC-treated group compared with the control group [39].

Xu *et al.* provided the first evidence that decreased expression of miR-146a in diabetic skin wounds may in part be responsible for the abnormal inflammatory response seen in diabetic skin wounds and may contribute to impaired wound healing. miR-146a expression was significantly reduced during the healing of diabetic skin wounds and was associated with a dramatic increase in the proinflammatory target genes IL-1-receptor-associated kinase 1, tumor necrosis factor (TNF)-receptor-associated factor 6, and nuclear factor kappa light chain-enhancer of activated B cells (NF-κB), resulting in increased gene expression of IL-6 and macrophage inhibitory protein 2 [16].

**Table 59.2** Clinical trials of cell-based therapy for wound healing registered on ClinicalTrials.gov.

| Disease | Cells used | Study phase | Results | Reference |
|---|---|---|---|---|
| Chronic wounds | BM-MSCs | Phase I | This study is ongoing but not recruiting | NCT01751282 |
| Diabetic foot ulcers | Autologous BM-MSCs | Phases I and II | Not yet recruiting | NCT01686139 |
| Diabetic critical limb ischemia | Tissue repair cells and BM-MSCs | Phase II | Completed | NCT01065337 |
| Diabetic foot ulcers, leg ulcers and ischemic ulcers | Autologous bone marrow cell concentrate | Phases II and III | Ongoing but not recruiting | NCT00434616 |
| Type 1 and type 2 diabetes mellitus with skin ulcers | Autologous BM-MSCs | Phases I and II | Not yet recruiting | NCT01686139 |
| Type 2 diabetes mellitus | Autologous ADSCs | Phases I and II | Unknown | NCT00703612 |
| Type 1 diabetes mellitus | Autologous ADSCs | Phases I and II | Unknown | NCT00703599 |
| Diabetic foot ulcers, venous ulcers, pressure ulcers | ADSCs | Phase II | Recruiting | NCT02092870 |
| Diabetes mellitus type 2 skin ulcers | Harvesting and implantation of ADSCs | Phases I and II | Recruiting | NCT01453751 |
| Diabetic foot ulcers and critical limb ischemia | UC-MSCs | Phases I and II | Unknown | NCT01216865 |
| Type 2 diabetes mellitus skin ulcers | UC-MSCs | Phases I and II | Recruiting | NCT01413035 |
| Burns | Human UC-MSCs | Phases I and II | Recruiting | NCT01443689 |
| Diabetic skin ulcers and venous stasis wounds | Lipoaspirate | Phase I | Unknown | NCT00815217 |
| Diabetic critical limb ischemia and foot ulcer | Autologous MSCs and mononuclear cells | Phase I | Completed. No study results | NCT00955669 |
| Epidermolysis bullosa | Umbilical cord blood cells | Phase II | Recruiting | NCT01033552 |

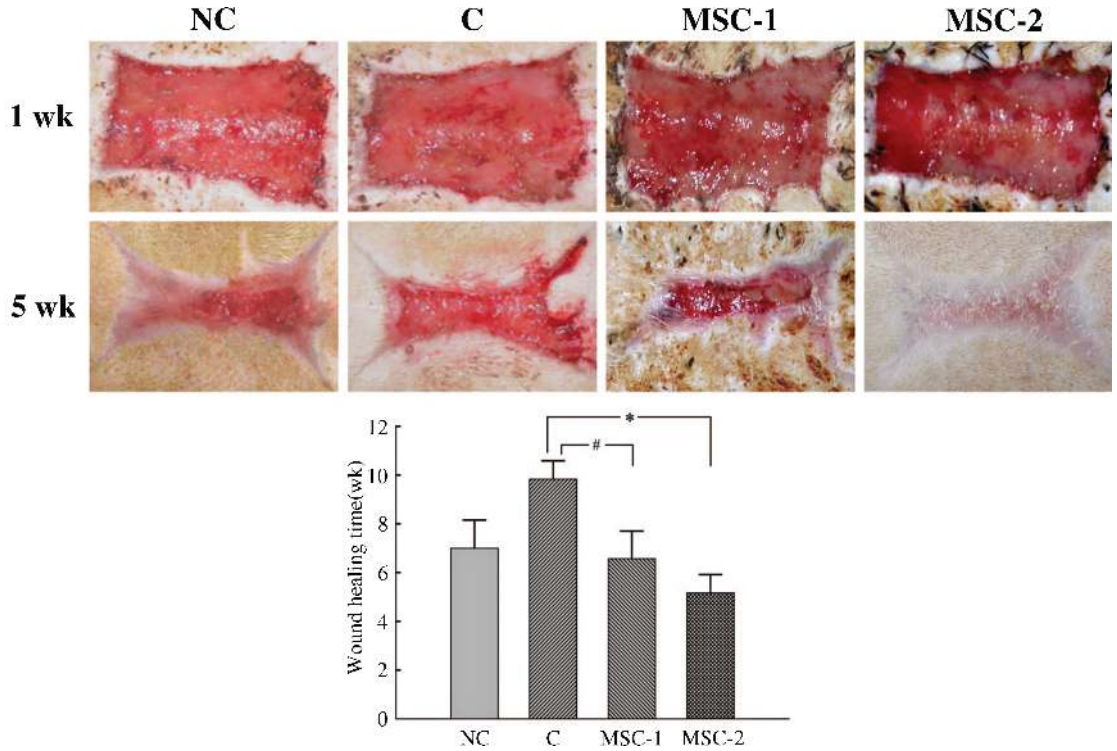

**Figure 59.1** MSC injection into the edge of the wound decreased the total time required for wound healing in diabetic rats. The wound size was significantly reduced in rats receiving MSC-1 (# $P = 0.001$) and MSC-2 ($^{*}P = 0.001$) groups compared with controls. NC: normal control; C: control (diabetes control without treatment); MSC-1: one administration of MSCs; MSC-2: two administrations of MSCs. (See color plate section.)

MSC-coated sutures may enhance wound healing and tissue remodeling through the release of different collagen types. The most abundant secreted collagen type was collagen alpha-1(I), which plays an important role in angiogenesis, invasion, and wound healing, as well as in the maintenance and function of the ECM [17].

Allogeneic MSCs derived from young healthy donors may have an advantage over autologous sources, where age and systemic disease can be significant factors [40].

Topical allogeneic MSC transplantation can accelerate the closure of experimental full-thickness cutaneous wounds and attenuate local inflammation. In a canine model, MSC-treated wounds showed decreased expression of the proinflammatory cytokines IL-2 and interferon-y and the wound-healing-related factors basic fibroblast growth factor and matrix metalloproteinase (MMP)-2 [18].

Hydrogels conform to the irregular shapes of wound beds and can be engineered to degrade at a rate that is compatible with the healing process [41].

The structure of the microenvironment can significantly alter MSC behavior and can be used to manipulate their cytokine secretion profile. VEGF-A and monocyte chemoattractant protein 1 both contribute significantly to the angiogenic response after wounding [19].

A number of clinical trials using MSCs for wound healing are registered on ClinicalTrials.gov (Table 59.2).

Challenges remain with MSC-based wound therapy. MSCs are heterogeneous and have a limited lifespan *in vitro* [42]. Bone marrow suppression has been noted in severe burns and trauma as a result of either sulfadiazine toxicity or sepsis, and may thus prevent adequate harvesting of autologous BM-MSCs [43]. Additionally it takes weeks to expand MSCs. The use of cryopreserved allogeneic MSCs as an "off the shelf" ready to use product may obviate these problems [38,44] (Figures 59.1 and 59.2).

Abundant experimental evidence has demonstrated the therapeutic potential of BM-MSCs for the regeneration and repair of damaged tissue in almost all of the major organs of the body, including the heart, brain, lung, liver, kidney, eye, and skin. BM-MSCs can also act as seed cells for the production of engineered tissues and as delivery vehicles for gene therapy [46].

## 59.4 The role of adipose-tissue-derived mesenchymal stromal cells in wound healing

One of the most abundant and accessible sources of adult stromal cells is adipose tissue. The subcutaneous fat in the lower abdomen site alone may provide as many as 100 to 1000 times more stromal cells than bone marrow [47]. A consistent cell surface marker profile has been determined for ADSCs [48] (see Table 59.3 and also Chapters 1 and 2).

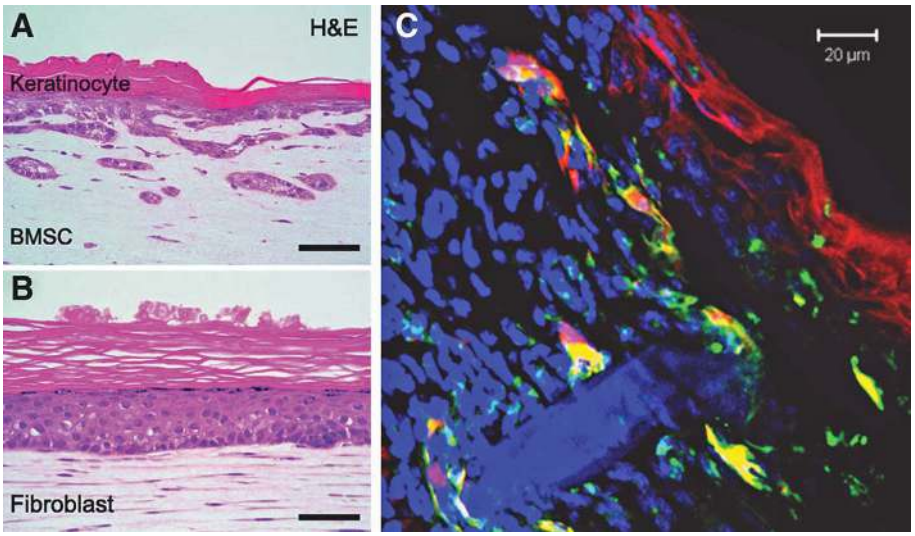

**Figure 59.2** BM-MSCs in cutaneous regeneration. (A, B) Keratinocytes loaded on a collagen gel containing BM-MSCs formed a rete ridge-like structure, whereas keratinocytes loaded on a collagen gel containing dermal fibroblasts did not (scale bars: 100 μm). (C). BM-MSCs (green) from green fluorescent protein-expressing BALB/c mice were injected around the excisional wound and applied to the wound bed in Matrigel. At day 7 some MSCs (yellow) expressed the keratinocyte marker cytokeratin (red) and formed structures similar to those observed in the study of Aoki *et al.* [45]. BMSC: BM-MSC; H&E: hematoxylin and eosin. (See color plate section.)

Wound healing experiments using the db/db mouse model have shown that application of autologous ADSCs containing atelocollagen matrix with a silicone membrane on to an open wound induced significant granulation tissue, epithelium, and capillary formations that accelerated wound healing [21]. (Cleavage of the antigenic telopeptide region from type I collagen yields atelocollagen, which is widely used as a scaffold for bone regeneration combined with cells and growth factors.) Furthermore, ADSC application in nude mice resulted in a thicker dermal portion of scars that that in the control group [22]. In a porcine full-layer wound model, perivascular adipose stromal cell localization suggested enhancement of blood supply by vascular neogenesis associated with higher levels of VEGF [23]. Using murine models, Lim and Yoo found that the ADSC-treated group showed significantly more rapid wound healing and had higher histological scores than those of the control group. ADSC-treated wounds had significantly higher capillary densities than the control group. The effects of ADSCs on wound healing may be due to stromal cell replacement by differentiation of ADSCs in the wound and the secretion of growth factors by the differentiated cells [24]. There is evidence that ADSCs facilitate tissue repair through paracrine mechanisms. CM from TGF-β1-treated ADSCs effectively promoted the proliferation and migration of human skin fibroblasts *in vitro* compared with nontreated control medium. In addition, the expression of MMP-1 was markedly increased by treatment with CM from TGF-β2-treated ADSCs. Expression of type I collagen in fibroblasts was slightly increased by treatment with CM from TGF-β1-treated ADSCs. The injection of CM from TGF-β1-treated ADSCs promoted the wound healing process in nude mice [25]. The effect of ADSC CM on the migration of endothelial cells, fibroblasts, and keratinocytes was different. Cell migration increased with increasing concentrations of ADSC CM and reached a maximum at 50% of ADSC CM. The optimal

**Table 59.3** Proteins of ADSCs.

| Molecule type | |
|---|---|
| Adhesion molecules | Positive for CD9, CD29, CD49d, ICAM-1, CD54, CD105, VCAM, CD106, ALCAM, CD166<br>Negative for CD11b, CD18, ICAM-3, CD50, NCAM, CD56, E-selectin, CD62 |
| Receptor molecules | CD44, CD71 |
| Surface enzymes | CD10, CD13, CD73 |
| Extracellular matrix proteins and glycoproteins | Type I and type III collagens, osteopontin, ostenectin (CD90), and MUC-18 (CD146) |
| Skeletal proteins | α-smooth muscle actin, vimentin |
| Hematopoietic cell marker proteins | Negative for CD14, CD31, CD45 |
| Complement regulatory proteins | CD55, complement protectin (CD59) |
| Histocompatibility antigens | Human leukocyte antigen-ABC |

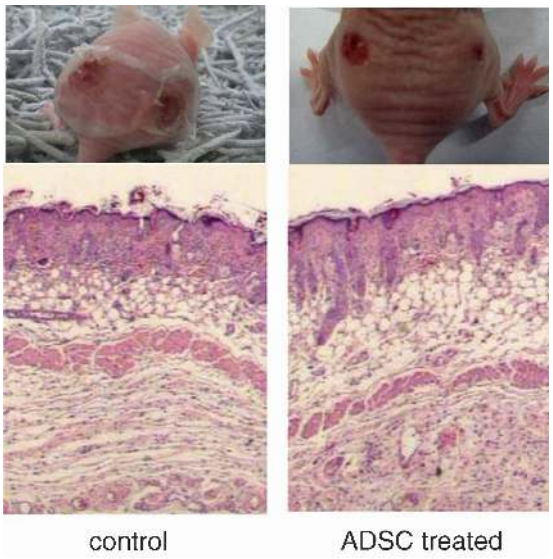

**Figure 59.3** Wound healing effect of ADSCs in nude mice. The wound size was reduced significantly in the ADSC-treated group (right side of the back) compared with the control group after 7 days. Reduced wound area was measured 7 days after surgery, and histological analysis of reconstructed skin using H&E staining was performed within 21 days of surgery. (See color plate section.)

timing for vascular endothelial cell migration and fibroblast migration was within 8 h and 24 h respectively [49]. Furthermore, hypoxia-conditioned media from ADSC cultures increased the rate of keratinocyte proliferation and migration. Antibody- and gel-based proteomic analysis of the ADSC CM showed upregulation of connective tissue growth factor, plasminogen activator inhibitor-1 (PAI-1/SERPINE1), hepatocyte growth factor (HGF), fibroblast growth factor (FGF)-1, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, IL-6, VEGF, and TGF-β [50]. Additionally, ADSCs treated with the nuclear protein histone H1 showed upregulation of mitogen-activated protein kinase, ERK1/2, and sequential NF-κB translocation. This enhanced wound healing and increased IL-6 expression [51]. The use of ADSCs in wound treatment are shown in (Figure 59.3) [52].

Tissue engineering studies have indicated that ADSC sheets are a potentially viable matrix for healing full-thickness skin defects in a mouse model. Triple-layer ADSC sheet treatment significantly enhanced wound healing compared with the single-layer ADSC sheets at 7, 10, and 14 days. The density of blood vessels showed that ADSC sheet treatment slightly enhanced total vessel proliferation compared with controls [26].

A small but important finding has been made with the use of ADSCs in clinical trials. ADSCs were used for nasal skin necrosis. After antibiotics and debridement, ADSCs were injected intradermally and subcutaneously. The wound was completely re-epithelialized 10 days after injection without noticeable scar formation during 6-month follow-up [53]. ADSCs are thought to affect ischemic tissues by secreting angiogenic factors that stimulate angiogenesis, differentiation of ADSCs into vascular cells, and secretion of factors that enhance progenitor cell availability [54]. Many studies have indicated that stromal cells implement their therapeutic effects through paracrine mechanisms [55] (Table 59.4).

Studies using *ex vivo* expanded ADSCs have suggested cell populations are safe and effective in clinical use [56].

## 59.5 The role of mesenchymal stromal cells from placental tissues in wound healing

The origin of MSCs may have a significant impact on their therapeutic potential. Zhu *et al.* found that fetal but not maternal placental MSCs (pMSCs) expressed high levels of CD200 and HGF. (It is thought that CD200 may regulate myeloid cell activity and deliver an inhibitory signal to cells of the macrophage lineage.) $HGF^+$ and $CD200^+$ pMSCs had greater potential in promoting angiogenesis *in vitro* and increasing immunosuppressive function *in vivo* compared with $HGF^-$ and $CD200^-$ pMSCs [57].

**Table 59.4** Secretion of growth factors by ADSCs.

| Type of factor | Factor |
|---|---|
| Angiogenic | HGF, VEGF |
| Hematopoietic | Factor increasing monocytopoiesis-like tyrosine kinase-3 ligand, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, IL-7, monocyte colony-stimulating factor |
| Proinflammatory | IL-6, IL-8, IL-11, leukemia inhibitory factor, TNF-α, basic FGF, TGF-α |

One study demonstrated that low oxygen tension regulated the fate of pMSCs from both early and late gestational tissues in response to insulin-like growth factor-1. However, phosphorylation of ERK1/2 and AKT was different between preterm and term pMSCs. Phosphorylated AKT, and not phosphorylated ERK1/2, was the major determinant of pMSC proliferation and octamer-4 levels [58].

The umbilical cord is a rich source of stromal cells. These cells also have low immunogenicity and thus could be applied as an allograft to accelerate healing of burns, thereby improving morbidity and mortality by reducing scarring [47]. Cord blood and different components of the cord, including Wharton's jelly (the gelatinous supporting matrix) and the outer lining, could also serve as a source of stromal cells [59,60].

Wharton's jelly MSCs (WJ-MSCs) and a decellularized amniotic membrane scaffold exhibited significantly better wound healing capabilities, reduced scar formation, improved hair growth, and improved biomechanical properties of regenerated skin compared with WJ-MSCs alone [27]. Human UC-MSCs improved wound healing in a rat model of severe burns. These data provide a foundation for the clinical application of human UC-MSCs in burns. Human UC-MSCs decreased the inflammatory cellular infiltrate and decreased the levels of the proinflammatory cytokines IL-1, IL-6, and TNF-α. They increased the levels of IL-10, TNF-α-induced protein-6, neovascularization, the levels of VEGF, and the ratio of collagen types I and III in a rat model of severe burns [28]. Moreover WJ-MSCs improved the healing response *in vivo* in a mouse model of dermal repair by triggering angiogenesis and providing a suitable matrix for wound repair without altering the inflammatory response. They were associated with stronger expression of VEGF-A, angiopoietin-1, and acidic FGF, which are all are directly involved in angiogenesis [61].

Human umbilical cord blood is also a rich source of hematopoietic stem cells, which can be used for hematopoietic stem cell transplantation, especially in children [62].

It has been reported that stromal cells isolated from umbilical cord blood can be differentiated into epithelial cells *in vitro* [63,64]. Expansion of such cells could be used for the treatment of large skin defects. A recent *in vivo* study indicated that MSCs derived from human umbilical cord blood improved skin wound healing [29].

One study optimized the methodology for isolation, culture expansion, characterization, differentiation and immunophenotyping of MSCs from equine umbilical cord blood. These MSCs were used for the repair of tendon and ligament injuries in race horses with good results [65].

Stromal cells isolated from the internal lining of umbilical cord are termed cord lining stem cells. Some of these cells are mesenchymal cells (cord lining mesenchymal cells). They express stromal cell markers and form colonies with typical stromal cell morphology in culture. Both *in vitro* and *in vivo* studies have shown their multipotency, including their potential to differentiate toward epidermal tissues [59].

MSCs from the fetal-derived amniotic membrane may also be useful clinically as they, too, are proangiogenic and antifibrotic, retard scar formation, and have low immunogenicity.

CM from amniotic-fluid-derived MSCs cultured under hypoxic conditions contains factors such as VEGF and TGF-β1. Amniotic membrane MSCs enable rapid vascularization and tissue restoration in wound healing. They enhance wound healing via activation of TGF-β/SMAD2 and phosphatidylinositide 3-kinase/AKT pathways [30].

Amniotic membrane MSCs can initiate endothelialization and angiogenesis *in vitro* and can form endothelial rings in Matrigel. Reverse transcriptase polymerase chain reaction showed expression of proangiogenic factors such as tyrosine kinase with immunoglobulin-like and epidermal growth factor-like domains (Tie2), angiopoietin-1, VEGF, VEGF receptor, von Willebrand factor, kinase insert domain receptor (a type III receptor tyrosine kinase also known as VEGF receptor 2), and factor increasing monocytopoiesis-like tyrosine kinase 4 [66]. pMSCs have been used to promote angiogenesis in order to accelerate wound healing in diabetic rats. They produced VEGF, HGF, basic FGF, TGF-β, and insulin-like growth factor-1 at bioactive levels [67].

Several clinical trials are ongoing (see Table 59.2) to evaluate these cells in the treatment of partial- and full-thickness burns and chronic diabetic wounds.

In general, UC-MSCs exhibited immunophenotypic and functional characteristics similar to those of BM-MSCs [20]. They represent a theoretical alternative to BM-MSCs for tissue repair and regeneration, although questions on aspects such as donor selection, culture conditions on clinical outcomes, and product consistency remain to be answered [68].

Fetal pMSCs cultured in serum-free medium have a tendency to modify methylation during *in vitro* expansion: 246 genes with differential DNA methylation of promoters were identified, along with significantly downregulated global DNA methyltransferase activity. Thus, epigenetic stability must be verified before fetal pMSCs are used clinical trials [69].

## 59.6 The role of mesenchymal stromal cells from dermal tissue in wound healing

Skin, the largest organ in the body, is composed of two layers: the epidermis, in which the cells form a protective barrier against external injury, and the dermis with its associated appendages, including hair follicles, sebaceous glands, and sweat glands, which provide nutritional support to the epidermis. Dermal stromal cells are the most likely candidates to be directly involved in the healing of deep skin wounds since dermal tissue is exposed at the wound bed margins. Epidermal-derived MSCs have been implicated in wound repair and regeneration. Recent advances in locating, identifying, and isolating a variety of adult stromal cell populations in skin and hair follicles have led to appreciation of

their potential clinical application. The ability of stromal cells to proliferate, as well as their multilineage differentiation potential, makes them candidates for skin regeneration strategies. MSCs residing in human adult dermis have not yet been described in detail. Vaculik *et al.* immunoselected CD271$^+$ (low-affinity nerve growth factor receptor expressed on MSCs) and stage-specific embryonic antigen-4$^+$ (SSEA-4$^+$ – expressed on early stem cells) cells from adherent dermal cells and investigated their mesenchymal differentiation capacity. Cells with increased *in vitro* adipogenic, osteogenic, and chondrogenic differentiation potential were enriched in the dermal CD271$^+$ population. The differentiation potential of dermal SSEA-4$^+$ cells, in contrast, appeared to be limited to cells that underwent adipogenesis. These results indicated that specific cell populations with variable mesenchymal differentiation potential can be isolated from human dermis, and three different subsets of dermal MSCs were identified [70]. Kroeze *et al.* showed that a population of MSCs resides in the dermis of human adult skin and that these dermal-derived stromal cells have a phenotypic and chemokine-mediated homing potential [71]. Dermal stromal cells display a cell surface phenotype similar to that of ADSCs: CD34$^+$, CD54$^+$, CD90$^+$, CD105$^+$, CD166$^+$ and CD45$^-$ and CD31$^-$. They also display a set of chemokine receptors that includes CCR3, CCR4, CCR6, CCR10, CXCR1, and CXCR2. CCL5/RANTES can induce migration of stromal cells [71]. Furthermore, wound healing requires the adjacent uninjured dermal mesenchymal cells for reconstituting the dermal fibroblast population, and 15–20% of the spindle-shaped dermal fibroblasts were bone marrow derived [72]. It will be important to determine the importance of cytokine gradients within the wound bed, for example, for epidermal-derived MSCs [71], and it will be important to determine the role of allogeneic stromal cells in the regulation of immune homeostasis within the wound [31].

## 59.7 The role of mesenchymal stromal cells from blood in wound healing

MSCs are widely distributed in body tissues and organs. Wound healing involves BM-MSCs for reconstitution of the dermal fibroblast population, since approximately a quarter of the spindle-shaped dermal fibroblasts present in the skin wound were bone marrow derived [72]. Further, Tian *et al.* suggested that human MSCs produced significant elevation of signals such as Wnt3a, VEGF, and platelet-derived growth factor receptor [14]. MSCs are important in recruiting existing endogenous tissue progenitor cells to enhance both normal and impaired wound healing [73].

Extracts of the bark of *Mallotus philippinensis*, a plant of the spurge family, was found to activate the mobilization of MSCs into the circulation and their homing to wound sites with improved wound healing in a diabetic mouse model [74]. HGF incorporated into collagen or fibrin gels led to enhanced and directed MSC migration *in vitro*. HGF-loaded biomaterials may be useful as *in vivo* wound dressings to recruit endogenous MSCs from tissue-specific niches to the wounded area [75]. Fibrin clot formation is associated with most wound healing processes and potentially guides the recruitment of human MSCs. Neuss *et al.* stated that the high intrinsic fibrinolytic capacity of human MSCs mediates their invasion into the fibrin clot in wounded tissue [13].

This novel approach may help to reduce the costly multistep procedures of cell isolation, *ex vivo* expansion culture, and transplantation normally used in MSC manufacturing.

## 59.8 Questions and challenges regarding mesenchymal stromal cell administration in wound healing

Further work in mouse models will improve our knowledge of the diversity and origin of dermal mesenchymal populations [76]. Whether MSCs facilitate wound repair through paracrine secretion to control inflammation, transdifferentiation, cell fusion with resident cells, or support for other stromal cells needs to be determined [44,77–80]. It is likely that a combination of these mechanisms will facilitate wound repair.

Future studies will need to determine the conditions for the production of MSC microvesicles and their efficiency in preclinical models compared with CM or MSCs themselves [81]. MSC-CM [82–84] and MSC-derived exosomes [85,86] are being increasingly explored (see Chapters 1, 20, and 38). The choice of autologous MSCs versus allogeneic MSCs needs to be determined [87].

## 59.9 Conclusions

MSCs have been shown to improve skin wound healing in multiple preclinical models and in a few clinical studies. The benefit of MSCs may be at least in part reproduced by the growth factors or immunomodulatory molecules that they produce. In this review we have highlighted important preclinical (Table 59.1) and clinical (Table 59.2) studies that have validated the significance of MSCs derived from bone marrow, placental tissue, dermal tissue, and blood in facilitating wound healing. The rapid progress in this field has indicated the emergence of important questions in skin biology that need to be addressed in parallel with the use of MSCs in the clinic.

## 60.1 Introduction

Glioblastoma multiforme (GBM), which is classified as World Health Organization grade IV astrocytoma, is the most common primary malignant brain tumor in adults. Despite surgery and radiation along with concurrent and adjuvant chemotherapy, patients with glioblastoma survive on average for only 14.6 months [1]. A radiological image of a GBM is shown in Figure 60.1.

This poor outcome is due at least in part to (1) the presence of glioma-initiating cells (GICs), which drive glioma formation and are intrinsically resistant to most therapies; (2) the complex microenvironment in which GICs reside and which enhances therapeutic resistance; and (3) the blood–brain and/or blood–tumor barriers (BBB/BTB), which limit the movement of most therapeutic agents into tumor-infiltrated brain tissue.

* Corresponding author: The University of Texas M.D. Anderson Cancer Center, Department of Neurosurgery – Box 442, 1515 Holcombe Boulevard, Houston, TX 77030, USA. Email: flang@mdanderson.org.

In this context, recent studies have suggested that mesenchymal stromal cells (MSCs) may be important in both the therapy and biology of GBMs (Figure 60.2 and Table 60.1).

With regard to cell therapy, accumulating evidence has shown that MSCs have the capacity to migrate toward GBMs after intratumor injection, can overcome the BBB/BTB and home to GBMs after intravascular injection, and can be engineered to carry antitumor agents to gliomas. Therefore, exogenously engineered MSCs may be used as novel cellular vehicles to deliver various antiglioma agents for the therapy of GBMs [7–9]. With regard to the biology of gliomas, it has been suggested that mesenchymal stem/stromal cells, or at least cells that resemble them, may contribute to the complex microenvironment and stroma of GBMs. Thus, endogenous MSC-like cells may influence the biological behavior of GICs and may enhance the aggressive behavior and therapeutic resistance of GBMs. This suggests that these endogenous glioma-associated MSC-like cells may themselves represent a novel therapeutic target for GBM.

In this chapter we review recent studies describing the application of exogenous MSCs as cellular vehicles to deliver various

**Figure 60.1** A GBM shown by magnetic resonance imaging of the brain. GBM usually exhibits a "ring" or "ring-like" zone of contrast enhancement around a dark central area of necrosis. *Source*: Armed Forces Institute of Pathology.

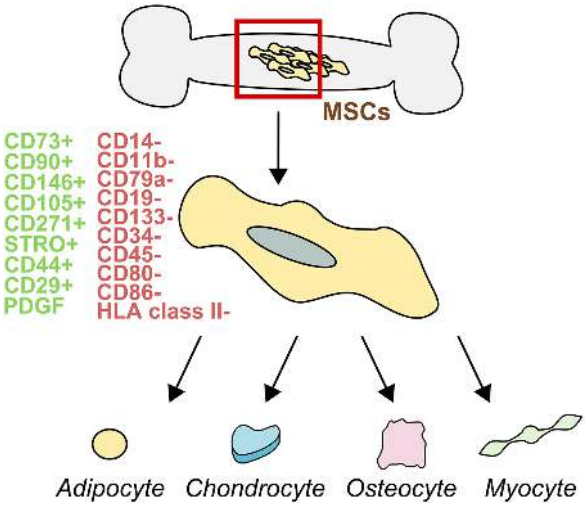

**Figure 60.2** Mesenchymal stem cells express a variety of surface markers and can differentiate into various cell types. (See color plate section.)

antiglioma therapies to GBMs. We also explore the tropism driving MSCs to home to brain tumors, and the various cargoes that have been engineered to be delivered by MSCs. We then briefly explore the controversial role of endogenous MSCs in gliomas and the possible influence of glioma-associated MSCs on the growth of gliomas.

## 60.2 Mesenchymal stromal cells in the therapy of human gliomas

Although hematopoietic stem cells have been utilized for decades in cancer therapy to replenish ablated bone marrow following aggressive chemotherapy or chemoradiotherapy as part of autologous, allogeneic or syngeneic hematopoietic stem cell (HSC) transplants, more recently the potential application of cells in cancer therapy has expanded to their use as novel cellular vehicles for delivering anti-tumor therapies to solid tumors including brain tumors.

## 60.3 Cellular therapy for gliomas

Neural stem cells (NSCs) were the first stem cells to be studied as potential cellular vehicles to deliver antitumor agents to brain tumors, beginning with the seminal publication of Aboody *et al.* in 2000 describing the use of NSCs in the treatment of gliomas [10]. NSCs are multipotent tissue-resident lineage-restricted stem cells that give rise to the cells that form the nervous system and that reside in the developing and adult central nervous system of mammals in the subependymal zone lining the lateral

**Table 60.1** Features of MSCs.

ventricles and the dentate gyrus of the hippocampus [11–14]. NSCs can be cultured and expanded *in vitro* as floating cellular aggregates known as neurospheres. Beyond their capacity for self-renewal and differentiation, the two key properties of all true stem cells, NSCs possess an intrinsic capacity for extensive migration within the brain [15]. Investigators therefore reasoned that these migratory properties might allow NSCs to track down widely dispersed tumor cells that reside outside the main tumor mass and which are responsible for recurrence and treatment failure. Based on this hypothesis, Aboody *et al.* first described the application of an immortalized mouse NSC cell line, C17.2, to deliver a therapeutic gene to treat human glioma in a mouse model system [10]. They showed that these C17.2 NSCs could distribute themselves throughout the tumor mass and could home to infiltrating single tumor cells outside the main tumor mass. Equally importantly, they showed that NSCs could be engineered to carry the therapeutic transgene cytosine deaminase, an enzyme that converts the prodrug 5-fluorocytosine to 5-fluorouracil. This publication set the field of cell-based therapies for gliomas in motion [7–10,16–24].

## 60.4 The advantages of mesenchymal stromal cells in clinical use

Despite the promise of NSCs in brain tumor therapy, their acquisition for clinical use in human patients is complex and raises ethical concerns. In early preclinical studies NSCs were only obtained from mice because the isolation of human NSCs required human embryos or open surgical biopsy of the periventricular zone. Although human NSCs derived from aborted fetuses were eventually developed, and one human NSC line, HB1.F3, is currently in a clinical trial, the ethical issues and the complexity of acquiring human NSCs drove many investigators to search for more easily acquired stem cells that could equally home to brain tumors. In this context, investigators turned to the bone marrow, which was known to be a rich source of stem cells. Bone marrow is a particularly good source of stem cells for patients with brain tumors because most brain tumors do not metastasize to the bone marrow, so tumor contamination is not likely. Compared with NSCs, bone marrow stem cells are more attractive because (1) they are easily acquired from patients by aspiration of the iliac crest, (2) patients can act as their own donors, making autologous transplantation possible and obviating immune-mediated rejection, and (3) no ethical issues arise from their use.

There are two types of adult stem cell in human bone marrow. The first, as indicated earlier, is the HSC that has been used in mainstream clinical medicine since 1969 in HSC transplantation for a wide range of diseases, particularly malignancies of the hematopoietic system. HSCs are true stem cells, as shown by their twin abilities of self-renewal to daughter stem cells and to committed differentiation to a specific lineage – in this case the hematopoietic lineage – and thus provide all the functional cells of the hematopoietic and immune systems (see Chapter 57).

The other adult stem cell that occurs in the bone marrow is the mesenchymal stem cell; again, this cell can self-renew as well as differentiate down a specific lineage – in this case the mesodermal lineage – to produce the tissues of the skeleton. It can form bone *in vivo*, and *in vitro* can differentiate to osteogenic, adipogenic, and chondrogenic lineages if induced with appropriate chemical stimuli. For this reason it has been termed the stem cell of the skeletal system.

However, true mesenchymal stem cells are rare cells with a frequency in bone marrow estimated to be between 1 in $10^4$ and 1 in $10^5$ cells. It is thus difficult to obtain enough them to use clinically. Instead, their progeny, mesenchymal *stromal* cells, are used since they can be expanded *ex vivo* in enormous numbers. These are not true stem cells but they can regenerate bone and tendon tissue *in vivo* as well as differentiate down the osteogenic, adipogenic, and chondrogenic lineages if subjected to appropriate chemical stimuli *in vitro* (see Chapters 8, 9, 10, 11, 12, 13, 14, and 15).

They are also known as mesenchymal progenitor cells and are a transit amplifying population. As well as their use in clinical trials to regenerate or repair musculoskeletal tissues, they have another set of unique functions. They secrete a large number of proteins that have immunomodulatory, antiapoptotic, antifibrotic, and anti-inflammatory functions (see Chapters 33 and 34). Their use in many diseases outside the musculoskeletal system is based on these properties (see Chapters 18, 19, 20, 21, 37, and 38).

They have been called drug factories and mini-pharmacies. They form part of the endothelial wall and are thus a form of pericyte. They are thus present in all vascularized organs and tissues. They will therefore be close to any injury that occurs in a vascularized tissue or organ, and can presumably drop into, or migrate to, the injury site where it is likely that they will take cues from the local injured microenvironment and behave appropriately, be it to regenerate injured musculoskeletal tissues or to secrete appropriate proteins or both in contributing to healing of the injury. The abbreviation "MSC" in this chapter refers to mesenchymal *stromal* cells. Their characteristics are summarized in Table 60.1 and a comparison between NSCs and MSCs is shown in Table 60.2.

## 60.5 The rationale for using mesenchymal stromal cells in glioma therapy

Although MSCs had displayed the ability to home to sites of tissue injury such as myocardial infarction [31], muscular dystrophy [32], stroke [33], and Parkinsonism [34], it was not until 2002 that Studeny *et al.* showed that bone-marrow-derived MSCs (BM-MSCs) had a tropism for solid tumors and could therefore be applied in oncological disorders [35]. Reasoning that tumors act in many ways like "wounds that do not heal" [36],

**Table 60.2** The advantages and disadvantages of using NSCs and MSCs.

| Cell type | Advantages | Disadvantages | References |
|---|---|---|---|
| NSC | Primed for neural cell fate<br>Extensive migration within the brain | Difficult to obtain and expand in culture<br>Possibility of immune attack if allogeneic cells<br>Ethical concerns regarding cell acquisition | [10,25] |
| MSC | Easy to obtain with standard isolation techniques<br>No ethical concerns<br>May have better homing after vascular delivery<br>Easy to engineer | May promote tumor growth | [26–30] |

Studeny *et al.* hypothesized that MSCs may show a similar tropism to tumors as they do toward injured tissues. Indeed, in their seminal paper they showed that BM-MSCs could home to the site of human melanoma and deliver the antitumor cytokine interferon (IFN)-β [35]. Since then MSCs have been shown to display tropism in animal models of a variety of solid tumors, including sarcoma [37,38], lung [39], colon [40], ovary [41], pancreas [42], kidney [43] and breast cancers [44]. However, early on it was unclear whether MSCs would show a similar affinity for gliomas, which harbor an astrocytic rather than fibroblastic stroma and are protected by the BBB/BTB.

This concern regarding gliomas was addressed by two key reports. In the first, Nakamura *et al.* described the ability of rat MSCs to migrate toward gliomas in a rat syngeneic glioma model [17]. Two weeks after direct intracranial injection of green-fluorescent-protein-labeled rat MSCs into rat gliomas, the MSCs were shown to migrate to the periphery of the tumor. In specimens injected with MSCs into the hemisphere contralateral to the tumor, staining showed MSCs crossing the corpus callosum and migrating toward the tumor. These investigators also showed that rat MSCs could be engineered to deliver interleukin (IL)-2 as an antiglioma agent. This study was the first to document the ability of MSCs to migrate toward gliomas following intratumor or intracerebral injection in animal models.

In the second report, Nakamizo *et al.* showed for the first time that human MSCs not only possess the ability to migrate towards human gliomas after intracranial injection, but they also were capable of homing to gliomas after intravascular injection [7]. In these experiments MSCs were obtained from the bone marrow of normal human donors, cultured and labeled with a fluorescent dye, and injected into the carotid artery of nude mice harboring intracranial human glioma xenografts. Analyses of the brain specimens revealed fluorescence-labeled MSCs exclusively within the tumor, while MSCs were not seen in the normal brain parenchyma. The selectivity of the tropism of MSCs for human gliomas was further supported in similar experiments in which human MSCs were injected into the carotid artery contralateral to the tumor. Once again, MSCs localized exclusively to the tumor mass. Interestingly, carotid artery injection of labeled human fibroblasts did not result in engraftment, indicating that MSCs possess a unique capacity to home to human gliomas. Equally importantly, these workers again showed that MSCs could be engineered to carry the antitumor cytokine IFN-β, and that intravascular delivery of these engineered MSCs extended the survival of mice harboring intracranial gliomas. This finding was important from the perspective of clinical application, as it would allow for the less invasive intra-arterial delivery of MSCs and would allow repeat treatments, which is not possible with direct intracranial injection because it necessitates invasive surgery (Figure 60.3).

Many of these initial reports relied heavily on experimental models using "professional" glioma cell lines in rats or immunocompromised mice, which raised concerns about the clinical applicability of MSCs in glioma therapy. To address these concerns Doucette *et al.* took advantage of the RCAS/Ntv-a mouse glioma model in order to determine the extent to which MSCs isolated from Ntv-a mice are capable of localizing to endogenous high-grade gliomas [45]. The RCAS/Ntv-a mouse model employs somatic transfer of a gene of interest to glial progenitor cells in an immunocompetent mouse [46,47]. Unlike syngeneic grafting or xenograft mouse models, gliomas generated in the RCAS/Ntv-a mice form spontaneously in native cells after transfer of oncogenes and may more accurately mimic the infiltrative nature of gliomas than xenograft models. Building on

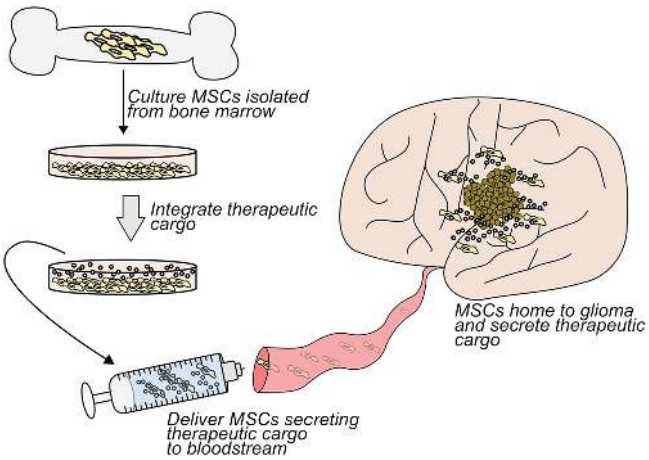

**Figure 60.3** MSCs injection technique. MSCs can be isolated from bone marrow, expanded in culture, and then implanted intravascularly. These MSCs then home to glioma, releasing antiglioma cargo. (See color plate section.)

the initial work of the Holland laboratory [46], the Zhang laboratory found that somatic transfer of PDGF subunit B along with insulin-like growth factor-binding protein 2 led to formation of endogenous murine gliomas with histological architecture remarkably similar to that of human GBMs with diffuse infiltration, microvascular proliferation, and pseudopallisading necrosis [48]. Doucette *et al*. utilized this model to study whether MSCs home to endogenous GBMs. MSCs from the bone marrow of Ntv-a mice were labeled with the dye SP-DiI or with luciferase and injected into the carotid artery of 4- to 6-week-old mice. Results showed that mice harboring infiltrating tumors exhibited luciferase activity. Fluorescent microscopy of brains from mice injected with SP-DiI-labeled MSCs revealed homing of MSCs to the tumor site but not in the surrounding brain parenchyma [45]. Demonstration of this tropism to glioma in the native brain microenvironment and in mice with an intact immune system provided further evidence for the applicability of MSCs for glioma therapy in the clinical setting.

Of equal interest is evidence that has suggested that human GBMs are driven by a population of cells with stem-like properties called GICs and glioma stem cells. Unlike commercially available glioma cell lines, including U87 and D54, GICs faithfully recapitulate human glioma characteristics and are considered the gold standard model for studying human gliomas *in vivo*. GICs represent the rare fraction of cells with stem cell properties that maintain the growth of human gliomas, are resistant to most therapies, and may cause persistent recurrences. Originally described by Singh *et al*., GICs can be isolated from surgical glioma specimens, grown as spheroids *in vitro*, and express variable levels of CD133 [49,50]. GICs isolated from GBM specimens grow intracranial gliomas with varying degrees of invasiveness, necrosis, and microvascular proliferation, recapitulating patients' GBMs. To determine whether MSCs may be able to deliver antiglioma agents to GICs, Shinojima *et al*. studied the capacity of human MSCs to home to xenografts derived from GICs [51]. They demonstrated that human BM-MSCs homed to xenografts derived from these GICs, and that MSCs could deliver therapeutic agents such as oncolytic adenoviruses to these tumors with significant therapeutic effects. These studies, including those of Doucette *et al*., confirmed that MSCs are highly efficient at delivering antiglioma cargoes to human gliomas in mouse models that faithfully mimic human gliomas [45,51].

Numerous publications in various experimental model systems have now verified that MSCs have a tropism for human gliomas and are highly effective at delivering a variety of cargoes to gliomas (Figure 60.3). This was originally conceived as an autologous transplant strategy in which MSCs derived from the patient would be modified and then delivered back to the same patient. However, it has now been shown that MSCs are relatively nonimmunogenic, as well as being suppressive of cellular immunity. Therefore, it has been suggested that MSCs derived from normal donors unrelated to, and major-histocompatibility-complex-unmatched with, the MSC recipient could be used in an allogeneic transplantation strategy. This approach is already being used in the majority of clinical trials involving MSCs (see ClinicalTrials.gov). This simplifies the use of MSCs, since culturing autologous MSCs takes at least 3–4 weeks, thus delaying their administration. Allotransplantation obviates such a delay since donor-derived MSCs can be manufactured in bulk and cryopreserved until needed in an acute or chronic medical setting. Future clinical trials should test the safety and feasibility of both of these approaches.

## 60.6 Mechanisms underlying mesenchymal stromal cell tropism for gliomas

It is generally agreed that the ability of MSCs to home to gliomas is mediated by factors secreted by the tumor cells that interact with surface receptors on the MSCs. MSCs respond to signals from injured tissues or organs and can then repopulate or repair these tissues. Because the microenvironment of GBMs (like that of other tumors) contains MSC-tropic factors similar to those found in injured tissue, related studies suggest that tumor-derived cytokines, chemokines, and growth factors may mediate the attraction of MSCs to brain tumors.

Transwell migration assays have been used to investigate the ability of cells to migrate toward specific growth factors *in vitro*. A study by Nakamizo *et al*. illustrated that chemokines and growth factors, including epidermal growth factor (EGF), stromal-cell-derived factor 1 – also known as C–X–C motif chemokine receptor (CXCR)12 – and PDGF-BB, promote MSC migration toward gliomas [7]. These studies also demonstrated that vascular endothelial growth factor and fibroblast growth factor may play a limited role in MSC migration. Similarly, Birnbaum *et al*. [52] demonstrated that the tropism of MSCs to glioma is mediated by angiogenic cytokines, including IL-8, transforming growth factor (TGF)-β1, and neurotrophin-3, while others have found that the chemokine monocyte chemotactic protein-1 – also known as chemokine (C–C motif) ligand 2 – plays a role as a mediator for MSC migration to breast and colon cancers [53,54].

Because *in vitro* conditions often do not precisely mimic the *in vivo* tumor microenvironment, complex *in vivo* studies analyzing the effects of individual trophic factors have been undertaken by few investigators. In a study by Hata *et al*., U87 glioma cells were designed to secrete high or low amounts of PDGF-BB in an orthotopic mouse model of brain tumor [55]. Following intracarotid injection, human MSCs showed substantially enhanced homing into tumors expressing high levels of PDGF-BB compared with low-expressing tumors. Similarly, inhibiting the PDGF receptor on MSCs blocked the homing of MSCs to gliomas. These findings indicated that PDGF-BB plays a major role in MSC migration toward glioma in the *in vivo* setting. Similar *in vivo* experiments have implicated inflammation-derived factors, either directly or indirectly, in the recruitment and engraftment of MSCs [56]. A study by Shinojima *et al*. suggested that TGF-β1, which is released by many gliomas, and its

receptor TGF-βRII, which is present on MSCs, are involved in attracting MSCs to gliomas after the intravascular administration of MSCs [51]. Using a human glioma xenograft in an orthotopic mouse model, TGF-β was identified as a tumor-derived factor that attracts human MSCs through TGF-β type II and CD105 receptors on the cell surface. Using GICs isolated from patient tumors, this study demonstrated that intravascularly administered human MSCs are capable of homing to GICs, but only GICs that expressed a high level of TGF-β attracted human BM-MSCs [51].

Despite the many studies aimed at deciphering the homing mechanism of MSCs for gliomas and other tumors, much remains to be defined. It is unclear whether all of the known factors act independently or together, which factors initiate the homing of MSCs to gliomas, and which factors enhance the process. Moreover, after systemic administration, it is assumed that MSCs must interact with the endothelial cell "barrier" and then cross it. Factors mediating this interaction are largely unknown. MSCs, in particular, appear to home only to tumors and not to normal brain tissue, suggesting that the tumor's endothelial cells must harbor unique signals compared with normal brain endothelium.

## 60.7 Strategies to enhance mesenchymal stromal cell homing to gliomas

Understanding and teasing out the factors mediating MSC tropism toward gliomas provides immense opportunity to enhance this process and therefore to increase the delivery of therapeutic agents. Strategies aimed at increasing MSC tropism to gliomas generally involve either (1) driving the tumor to increase secretion of MSC-tropic factors, or (2) altering the MSCs to enhance their sensitivity to tumor-derived factors.

With regards to the first strategy, one way to increase MSC homing is to irradiate the tumor [57]. Radiation is thought to enhance and induce cell death and to release inflammatory molecules into the tumor microenvironment, which drive recruitment of MSCs that home to sites of tissue injury. Tumor irradiation was first shown to enhance the homing of MSCs to tumor tissue in a model of breast cancer [57]. The enhanced MSC tropism to the tumor was associated with the upregulation of local proinflammatory mediators including TGF-β1 and PDGF-BB [57]. Similar findings on the association between the inflammatory response and MSC tropism following radiation treatment were found in several experimental tumor models, including glioma and colon cancer [58,59]. Radiation of gliomas in one study resulted in both enhanced migration of MSCs to the tumor and upregulation of IL-8 and monocyte chemotactic protein-1 [58].

With regard to the second strategy involving altering the MSCs, several investigators have manipulated the surface proteins on MSCs to increase their responsiveness to tumor tropic factors. For example, Sato *et al.* demonstrated that mouse MSCs that are genetically engineered to overexpress the EGF receptor (EGFR) showed enhanced migratory responses toward syngeneic murine GL261 glioma or B16 melanoma models *in vivo* [60]. Moreover, intratumor injection of these tropism-enhanced MSCs engineered to secrete IFN-α resulted in significantly prolonged survival compared with nontropism-enhanced MSCs. A related strategy to increase MSC homing involves engineering MSCs to express an antibody toward a tumor-specific antigen on the tumor cell surface. Balyasnikova and coworkers engineered human MSCs to express an antibody to EGFR variant III (EGFRvIII), which enhanced human MSC homing toward glioma cells expressing EGFRvIII and this subsequently increased survival time in tumor-bearing mice [61,62].

An alternative strategy is to alter the MSC receptor profile by exposing MSCs to unique factors or conditions. For example, Shi *et al.* showed that treating MSCs with various cytokines upregulated chemokine and cytokine receptors on the MSC surface: pretreatment of MSCs with IL-6 or hepatocyte growth factor increased the expression of the chemokine receptor CXCR4, thereby augmenting MSC migration both *in vitro* and *in vivo* [63]. Similarly, placing MSCs in a hypoxic environment was also shown to promote MSC tropism to gliomas by promoting expression of the chemokine receptors CX3CR1 and CXCR4 on MSCs [64].

## 60.8 Types of therapeutic cargo

The unique tropism of MSCs for tumors makes them effective at transporting antitumor therapies. Although MSCs themselves could theoretically attack and inhibit tumors, the intrinsic antitumor properties of MSCs have only been shown in a few cancers [65–68]. Therefore, in MSC-based approaches, the antitumor cargo and its appropriateness are as critical to the efficacy of the approach as is the tumor-homing ability of the MSCs. Theoretically, the cargo must be able to kill or at least inhibit glioma cells. It must be able to be engineered into MSCs. It must not alter the tumor homing capacity of MSCs. It must not prematurely kill the MSC and, once within the tumor, the cargo must be released from the MSC. Based on these requirements, several types of antiglioma agents have been tested as cargoes and are broadly classified as secreted proteins, prodrug enzymes, oncolytic viruses, exosomes, and nanoparticles (Figure 60.4).

### 60.8.1 Secreted proteins

One broad class of antiglioma cargoes includes proteins secreted by MSCs. MSCs are typically engineered to produce these proteins by transducing the MSCs with a replication-incompetent viral vector carrying the gene encoding the protein or by transfection with a plasmid carrying the gene. The gene must then be transcribed and translated into the protein, and the protein must be secreted from the cell in a functional form in order affect the tumor. The MSC acts as a "mini-pump" of the secreted protein within the tumor. The longevity of most stromal cells in human tumors has not been well defined, but preclinical models suggest persistence of MSCs within a tumor for up to 3–4 weeks.

Proinflammatory cytokines are a group of secreted proteins that have been successfully delivered by MSCs in various glioma

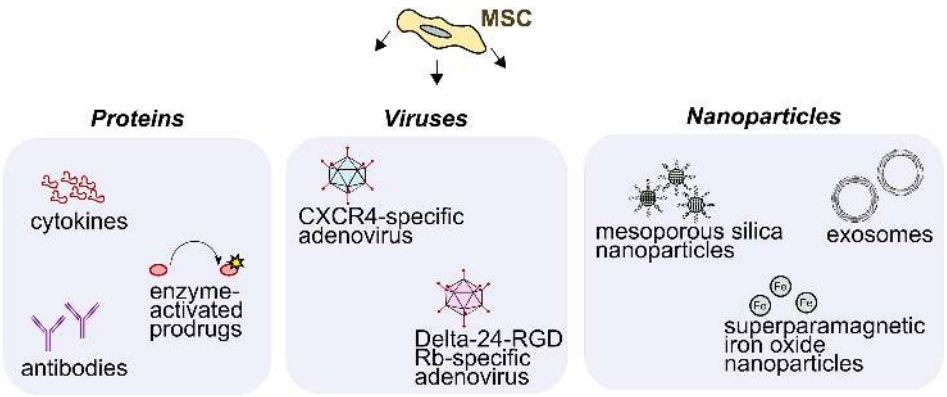

**Figure 60.4** MSCs can be engineered to release a variety of therapeutic cargo, including proteins, viruses, and nanoparticles.

model systems. Results, including *in vivo* outcomes, have illustrated the therapeutic potential of MSCs secreting recombinant modified IL-12M, which induces stronger type 1 T helper responses and antitumor immunity than wild-type IL-12. When injected directly into the tumor, mice receiving IL-12M-producing MSCs survived significantly longer than control mice. This result was explained by the induction of tumor-specific T-cell memory [69]. IFN-β is another cytokine known for its antiproliferative and proapoptotic effects in various cancers. Human MSCs engineered to express IFN-β were injected intravascularly into a human xenograft mouse model and resulted in decreased tumor growth and improved prognosis compared with control mice [7]. Furthermore, MSCs have been genetically modified to secrete other cytokines with substantial success: these include IL-2, IL-18, and IL-23 [17,70,71]. Cytokines have also demonstrated therapeutic efficacy when used in combination with other treatments, including short hairpin RNA, microRNA (miRNA), and the chemotherapeutic alkylating agent temozolomide [72–74].

Another secreted protein that has been engineered into MSCs is the proapoptotic protein tumor-necrosis-factor-related apoptosis-inducing ligand (TRAIL). TRAIL is a member of the tumor necrosis factor superfamily that induces apoptosis upon binding to its transmembrane receptors [75]. This particular receptor is absent in normal cells. Therefore, TRAIL is an attractive cancer therapeutic agent. Using mouse model systems of invasive human gliomas and utilizing real-time imaging with correlative neuropathology, Sasportas *et al.* demonstrated that MSCs engineered to express recombinant TRAIL or its secreted soluble variant (sTRAIL) had profound antitumor effects [76]. Additional studies demonstrated both therapeutic and tumor-specific effects after intracranial or intravenous injection of TRAIL- or sTRAIL-producing MSCs *in vivo* [76–78].

### 60.8.2 Prodrug enzymes

MSCs have also been engineered to release prodrug-activating enzymes that convert an inert prodrug into an active cytotoxic chemotherapeutic agent. The release of the active drug produces a bystander effect, killing the surrounding tumor cells. Because of their homing ability, MSCs deliver a local high-dose active chemotherapeutic agent to the tumor and a minimal dose, if any, to the peripheral organs, which avoids the systemic toxicity observed with many chemotherapeutic agents

The herpes simplex virus thymidine kinase (HSV-TK) enzyme/prodrug-activating gene therapy approach for treating malignant gliomas has been well characterized. HSV-TK is known as a suicide gene therapy because, on exposure to the prodrug ganciclovir, HSV-TK-transduced cells are killed and rapidly dividing bystander cells near them undergo apoptosis and are killed at the same time [79]. However, a phase III multicenter randomized clinical trial, which included glioblastoma patients, showed no significant difference in survival between the HSV-TK gene therapy group and controls [80]. The therapeutic failure was attributed to the low transduction efficiency of the drug to tumor cells and ineffective vector distribution within the tumors [80]. To rectify these problems, investigators loaded HSV-TK into MSCs as a way to more effectively deliver the drug to the tumor tissue. Murine studies using human glioma cell xenografts showed that HSV-TK-loaded MSCs enhanced prodrug activity through an HSV-TK-specific mechanism, leading to a better prognosis [24,81–83].

Several groups have developed MSCs engineered to express the rabbit carboxylesterase enzyme, which efficiently converts the prodrug CPT-11 (irinotecan) into its active anticancer form SN-38, a potent topoisomerase I inhibitor. Systemically administered (intracranially or intravenously) MSCs carrying rabbit carboxylesterase enzyme efficiently penetrated the brain and targeted both the primary glioma site and infiltrating glioma cells [84].

### 60.8.3 Replication-competent oncolytic viruses

Virotherapy involves genetically modifying viruses so that they will selectively infect and kill tumor cells. Although oncolytic virotherapy has delivered promising preclinical results, there are several obstacles to its successful clinical translation, including delivery and safety concerns. To address these problems several investigators used MSCs to deliver oncolytic viruses to the tumor by direct intratumor injection or by intravascular injection. Using the intravascular approach the MSCs are able to conceal the virus from the immune system as they home to the tumor. Once the MSCs infiltrate the tumor, the virus replicates within the MSCs, is released, and infects and destroys the surrounding tumor cells.

Sonabend *et al.* studied whether conditionally-replicating adenoviruses could be delivered by MSCs to gliomas [85]. Because the CXCR4 receptor is highly expressed on MSCs and glioma cells [85,86], they generated a virus with specificity for CXCR4. They found that this virus specifically infected and replicated within MSCs and glioma cells. This was the first report demonstrating that human MSCs could deliver oncolytic adenoviruses to malignant gliomas [87,88].

Delta-24-RGD is a novel oncolytic virus that is currently in clinical trials for patients with recurrent GBM. The Delta-24-RGD virus, also known as DNX-2401, exploits the fact that most glioma cells harbor deregulated retinoblastoma (Rb)-related proteins. Specifically, the Delta-24 virus contains a 24-base-pair deletion in the Early 1A adenoviral gene, the protein from which binds to the Rb protein. This virus can only replicate in cells lacking functioning Rb, and thus specifically in glioma cells [89]. Yong *et al.* loaded MSCs with Delta-24-RGD in an attempt to provide another viral-mediated method to target glioma cells. They showed that MSCs carrying Delta-24-RGD localized to human gliomas as effectively as uninfected MSCs did and that, once within the tumor, active virus was released from the MSCs, which then infected and replicated in the tumor cells. Analysis of tumor size showed that glioma growth was decreased and the tumor was even eradicated in nearly 40% of animals compared with controls [18]. Investigators in both conditionally-replicating adenoviruses and in Delta-24-RGD studies concluded that the intra-arterially delivered human MSC–oncolytic adenovirus selectively localized to human gliomas and delivered and released oncolytic adenovirus into the tumor, resulting in improved survival and tumor eradication *in vivo* [18,88].

### 60.8.4 Antibodies

Another approach to deliver antiglioma cargo by MSCs involves the use of antibodies. Using MSCs to deliver antitumor antibodies concentrates the distribution of the antibody to tumor tissue while sparing peripheral organs, therefore limiting cytotoxic off-target effects. EGFRvIII is a mutant form of EGFR that is found in nearly 50% of glioblastoma patients (reviewed by Heimberger *et al.* [90]). Several antibodies targeting EGFRs and EGFRvIIIs have been generated, and although *in vitro* results were encouraging, they exhibited poor results *in vivo* [91,92]. The dismal *in vivo* response was believed to result from low antibody penetration within the tumor tissue. To remedy this, Balyasnikova *et al.* sought to utilize MSCs as antibody delivery vehicles, which allowed for improved therapeutic penetrance. They demonstrated that co-injection of U87 human glioma cells and human MSCs transfected to express an antibody against the EGFRvIII resulted in reduced tumor vascularization and increased survival of glioma-bearing mice [61].

### 60.8.5 Nanoparticles

Nanoparticles can be either biological or synthetic materials that range from 1 to 100 nm in diameter. Historically, nanoparticles have had several limitations when administered systemically and have yielded conflicting therapeutic results. Systemically delivered nanoparticles are diluted by the presence of the BBB, so that their concentration within brain tumors is relatively low. To circumvent this problem investigators attempted to use cellular carriers, such as MSCs, as nanoparticle delivery vehicles to tumor tissue. For example, Roger *et al.* showed that polylactic acid or lipid nanoparticles could efficiently internalize into MSCs without affecting differentiation capabilities or cell viability [22]. *In vivo* studies showed that nanoparticle-loaded cells migrated toward human glioma xenografts [22]. Another study showed that super paramagnetic iron oxide nanoparticles could coat MSCs, which then successfully homed to brain tumors [93]. The ability of MSCs to home to gliomas while retaining mesoporous silica nanoparticles has also been evaluated. The loaded MSCs effectively homed to human orthotopic U87 tumor xenografts, whereas MSCs without nanoparticles did not home as well [94]. These findings demonstrated that MSC-secreting nanoparticles home to tumor tissue in the brain and therefore provide motivation for future applications of nanoparticle-mediated glioma therapeutics.

Exosomes are physiological nanoparticles (50–100 nm in diameter) that are secreted by cells and that have far-reaching biological effects (see Chapters 20 and 38). A host cell, such as an MSC, can release exosomes packaged with DNA, RNA, and protein into the extracellular space. They can then fuse with a target cell, releasing their contents into its cytoplasm. Exosomes thus behave as intracellular delivery systems. They can also be genetically engineered to express, and therefore transport, miRNA or small interfering RNA. MSC-derived exosomes have been used to treat human disease, including glioma. For example, direct intratumor injection of MSC-derived exosomes expressing miR-146 reduced glioma growth in a rat xenograft model [95]. Another group showed the therapeutic potential of delivering exosomes expressing miR-124 and miR-145 to human glioma stem cell xenograft tumors [96]. They confirmed that the synthetic miRNA was transferred by MSC exosomes to the target glioma cells. Furthermore, MSCs expressing high miR-124 levels were co-cultured with glioma U87 cell lines and were subsequently found to decrease U87 cell migration. Finally, they showed that MSCs could deliver miR-124 to U87 human glioma xenografts *in vivo*, by measuring the down regulation of miR-124 target genes in glioma tissues [96]. However, whether delivery of these miRNAs promoted survival or induced tumor regression was not reported, suggesting the need for more studies to validate the therapeutic efficacy of this approach.

## 60.9 Delivery routes of mesenchymal stromal cells in clinical applications

The route of administration represents a critical variable for the therapeutic delivery of MSCs. As implied earlier, several strategies for MSC transplantation in GBM have been proposed and tested. Local intratumor injection of MSCs directly into the tumor was the original strategy proposed. This approach maximally exploits

the capacity of MSCs to migrate throughout a tumor with the goal of reaching infiltrating tumor cells. The advantage of the approach is that all the cells are deposited directly into the tumor. On the other hand, this method is highly invasive as it requires passing a needle into the brain and tumor via a burr hole or twist drill, which carries the potential risk of brain injury and hemorrhage. The approach also requires that MSCs are able to travel long distances from the injection site, which may be difficult in large, highly infiltrative tumors. Multiple injections can overcome this shortcoming, but each injection carries a risk of hemorrhage.

Another difficulty with intratumoral injection is that the method can be cumbersome after tumor resection. In this situation the MSCs often flow out of the injection site along a path of least resistance into the resection cavity, from which they are then washed away. To overcome this problem, and to increase the survival of transplanted MSCs, Shah *et al.* reported the development of a hydrogel in which to encapsulate the MSCs prior to implantation. This method was found to significantly improve the therapeutic efficacy of transplanted MSCs in various glioma models (reviewed in [97]).

Another attractive method of administration is systemic delivery into the bloodstream. Systemic delivery has the advantage that it is a minimally invasive approach, and therefore multiple injections over time are possible. Moreover, in theory the MSCs should be able to access all areas of the tumor via the vessel portals, potentially producing a more widespread initial deposition of MSCs compared with intratumor injection of the cells. Although there are studies promoting the ability of MSCs to localize to brain tumors after intravenous injection, most investigators report that intravenously infused cells are typically held up in the pulmonary capillary bed and only a reduced number reach their target site. Consequently, preclinical studies and proposed clinical applications have relied on intra-arterial injection because it eliminates lung entrapment. With modern endovascular techniques, including super selective catheterization of intracranial vessels, intra-arterial delivery is a viable option in clinical practice and has been applied in regenerative medicine approaches [98].

MSCs have also been delivered to the brain intranasally. This particular technique was first applied to the treatment of neurodegenerative disorders [99] and was then assessed in glioma [100]. Specifically, investigators showed that MSCs delivered intranasally were able to infiltrate the brain through the nasal cavity and migrate toward glioma xenografts [100]. Furthermore, Balyasnikova *et al.* showed that intranasal delivery of MSCs was a therapeutically relevant way to deliver antiglioma agents, as MSCs carrying sTRAIL prolonged the survival of glioma-bearing mice after intranasal delivery [101].

## 60.10 Mesenchymal stem cells in the biology of gliomas

The capacity of exogenous MSCs to home to tumors led to the concept that endogenous MSCs may also be attracted into tumors and may, therefore, contribute to the tumor microenvironment. This concept gained further traction when it was found that, in addition to their residence in the bone marrow, MSCs also reside within most organs of the body as a type of pericyte in the endothelial wall. Therefore, at least theoretically, MSCs can be attracted into tumors not only from distant bone marrow sources but also from local organ-resident pools.

## 60.11 Controversy over tumor-associated mesenchymal stromal cells in solid tumors and gliomas

Investigators have begun to explore the contribution of MSCs to the tumor microenvironment [30,102–105]. Along with endothelial cells, immune cells, and fibroblasts, increasing evidence suggests that MSCs also contribute to the stroma of many solid tumors as so-called tumor-associated MSCs (TA-MSCs), due to their natural tropism for tumors [36,37]. Although some studies suggest that MSCs inhibit tumor growth [28], most studies demonstrate that MSCs enhance tumor growth and invasion, facilitate resistance to therapy, and contribute to the establishment of distant metastases in multiple cancer types [106–111]. In a seminal paper, MSCs were shown to modulate the invasive and metastatic nature of breast cancer tumors through the induction of chemokine (C–C motif) ligand 5 secretion and the upregulation of chemokine receptor 5 in cancer cells [112]. In ovarian cancer, TA-MSCs have been shown to facilitate proliferation and metastatic spread and have also been shown to serve a protective role against hyperthermic intraperitoneal chemotherapy mediated by the secretion of specific proteins, IL-6, IL-8, and C–X–C motif chemokine ligand 12 [113,114]. TA-MSCs were also found to significantly have an impact on the proliferation, migration, and invasion of pancreatic carcinoma and to decrease the efficacy of chemoradiation therapy [115]. In colorectal carcinoma, TA-MSCs were determined to play an oxidative role in the tumor microenvironment by recycling by-products of anaerobic metabolism in order to sustain hypoxic cancer cells [116]. Lastly, prostate cancer cells were shown to increase their growth and undergo histologic changes in response to TA-MSC challenges [117].

In brain tumors, however, the understanding of the interaction between the tumor and its microenvironment is still incomplete. The microenvironment of GBMs has traditionally been thought to consist of reactive astrocytes, vascular cells, microglia, immune cells, and neural progenitor cells [118]. However, several studies have suggested that MSC-like cells may also contribute to the stroma of human gliomas [119,120]. Indeed, MSCs have been shown to reside in normal brain around blood vessels [121–123], and therefore it is likely that MSCs are recruited into developing brain tumors.

Consistent with these concepts, our group has recently isolated cells that have a phenotype similar to BM-MSCs from glioblastoma surgical specimens. We have called these cells glioma-associated MSCs (GA-MSCs). Like BM-MSCs, and as defined by

the International Society of Cellular Therapy, the isolated GA-MSCs (1) grow with a spindle-shaped morphology on plastic, (2) express the characteristic MSC surface markers CD105, CD73, and CD90 and do not express markers of the hematopoietic and immune systems including CD45, CD34, and T cell and B cell markers [124], and (3) differentiate into osteocytes, adipocytes, and chondrocytes when exposed to the appropriate induction medium *in vitro* [125]. Immunohistochemical analyses of GBMs suggest that these GA-MSCs occur both around vessels in the tumor and within the tumor mass *per se*.

Equally importantly, we have found that these human GA-MSCs are not bystanders within the tumor, but like TA-MSCs in other tumors, contribute to the biological behavior of GICs, which maintain and drive glioma growth. Specifically, using *in vitro* co-culture methods we have shown that GA-MSCs increase the proliferation and clonogenicity of GICs. Using *in vivo* assays we have also shown that GA-MSCs increased the tumor-forming capacity of GICs and enhanced the aggressive behavior of GICs, as demonstrated by shortened animal survival. As in other solid tumors, the effects of human GA-MSCs on GICs are due at least in part to a direct paracrine influence of GA-MSCs on the tumor cells. Specifically, we found that that the increased proliferation effect was mediated at least in part by the GA-MSCs' secretion of IL-6, which drives proliferation and stemness of GICs by activating the signal transducer and activator of transcription 3.

## 60.12 A model of mesenchymal stromal cells in glioma biology

Taken together, these results suggest that human GA-MSCs may be a heretofore unrecognized component of the complex microenvironment of human gliomas (Figure 60.5).

It is proposed that GICs secrete factors that attract MSCs to gliomas. These MSCs may come from the bone marrow or from local perivascular reservoirs in the brain. Once within the tumor, the GICs may commandeer the MSCs, driving them to become GA-MSCs, which then engage in crosstalk with the GICs. This results in the secretion of tumor-promoting factors by the GA-MSCs that help drive tumor growth and proliferation. Complete analysis of this hypothesis remains an active area of research. Nevertheless, these data suggest that interfering with the attraction of MSCs to gliomas or disrupting the crosstalk between GICs and GA-MSCs may thwart the growth of gliomas and may represent a new approach to targeting glioma growth.

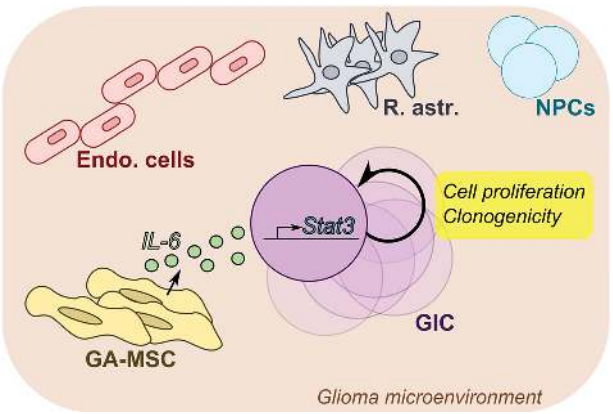

**Figure 60.5** GA-MSCs influence the glioma microenvironment. GA-MSCs release IL-6, which activates signal transducer and activator of transcription 3 (Stat3) signaling in GICs. Endo: endothelial; NPCs: neural progenitor cells; R. astr: reactive astrocytes. (See color plate section.)

## 60.13 Prospects for clinical use of bone-marrow-derived mesenchymal stromal cells in glioma therapy

MSCs are currently being investigated in several clinical trials for a large number of diseases, including musculoskeletal disorders, neurodegenerative disease, and spinal cord injuries. In fact, according to ClinicalTrials.gov, there were 491 trials listed when the database was searched with the term "mesenchymal stem cell" and 96 when the term "mesenchymal stromal cell" was used as of April 2015. However, there were only two clinical trials using MSCs as vehicles to deliver anticancer agents to tumors, and neither of these were in brain tumors. In one clinical trial, MSCs were being used to deliver an oncolytic adenovirus to recurrent ovarian cancer tumors refractory to standard treatments (NCT02068794). In another clinical trial, MSCs were being used to deliver IL-12 in order to activate natural killer and cytotoxic T lymphocytes in patients with head and neck tumors (NCT02079324).

Despite the large literature on MSCs in cancer therapy, it is disappointing that there are so few clinical trials at this time. Potential reasons for trepidation in the field include apprehension that cultured MSCs may themselves be tumorigenic. This concern has stemmed from rare reports suggesting the instability of MSCs *in vitro* [126–128]. Clearly, an important factor for using MSCs as therapeutic delivery vehicles is their ability to be expanded *in vitro* without undergoing genetic transformation. Unfortunately, several reports suggest that murine MSCs may display suboptimal stability *in vitro* [126,127], and have even exhibited the capability of forming sarcomas in animal models *in vivo* [129]. However, in contrast to murine MSCs, the majority of studies on human MSCs have confirmed their stability [130]. Nevertheless, these studies emphasize the importance of stringent monitoring of the stability of MSCs in culture, including karyotyping before their use in human studies. In general, if MSCs are used clinically only at early passages (less than four or five passages) the risk of tumorigenicity appears to be low.

Another cause for concern is the potential of MSCs to increase tumor growth and aggressiveness. As discussed earlier, the role of MSCs in tumor progression has been documented in several tumor types, including gliomas [112,131,132]. MSCs appear to drive tumor growth in large part by secreting an array of

tumor-promoting factors. Therefore, it is critical that any therapeutic approach involves engineering MSCs so that they are driven to secrete high levels of antiglioma factors, thereby subverting their normal secretory repertoire, which may drive GIC stemness and proliferation. Thus, delivery of "empty" MSCs must be scrutinized. It is imperative that MSCs are robustly engineered so that the majority of delivered MSCs actually contain the antiglioma agent. Another option involves loading MSCs with cargoes containing agents that destroy the MSCs once within the tumor. For this approach, delivering oncolytic viruses is particularly attractive because the release of virus from the MSC results in lysis of the MSC. Of course, a safety valve could be built into MSCs by engineering a self-destruct system, such as HSV-TK. This would allow the MSCs to secrete an antiglioma agent of choice until the cells are exposed to the antiviral agent ganciclovir, which kills MSCs expressing the transduced viral thymidine kinase but does not kill cells that contain the gene for human thymidine kinase. As in all fields, it is imperative for translational researchers to develop and further advance clinical approaches that are grounded in strong preclinical science and that are both efficacious and safe.

## 61.1 Introduction

Mesenchymal stromal cells (MSCs) are excellent candidates for cellular therapies and are often investigated for regenerative medicine applications. The multipotent status of these cells makes them prime candidates for tissue regeneration, whereby they can directly differentiate and replace damaged tissues. The ability of MSCs to differentiate into cells of mesodermal lineage, including osteoblasts, adipocytes, and chondrocytes, is well documented [1]. Furthermore, MSCs release a variety of cytokines, chemokines and other soluble factors in response to injury [2] (reviewed by Phinney and Prockop [3]). This paradigm, where MSCs may be utilized to promote tissue healing through long-term release of soluble factors rather than by replacing cells in damaged tissues, demonstrates the importance of developing gene-modified MSCs so that we may take advantage of, and even accentuate, the cells' endogenous responses. A phase-contrast image of MSCs in culture is shown in Figure 61.1.

The ease of isolation and expansion, interaction with the immune system, and migratory capabilities of MSCs also make them an ideal cell source for genetic modification to combine the best of both cell and gene therapy for a multitude of diverse diseases. Efficacy has been demonstrated in preclinical and clinical studies using MSCs for cardiovascular, musculoskeletal, neurodegenerative, and autoimmune diseases and in acute graft-versus-host disease (GVHD) [4–6]. These and other extensive studies have thoroughly demonstrated the safety of MSCs for clinical use [7].

## 61.2 What are mesenchymal stromal cells?

MSCs were first isolated from bone marrow by Freidenstein *et al.* in 1970 based on their ability to adhere to plastic [8]. Since then MSCs have been found in many other tissues, including adipose tissue, brain, liver, lung, kidney, and dental pulp [8,9]. They can also be found in umbilical cord blood and amniotic fluid [10,11]. Though MSCs from each of these tissues appear phenotypically similar, cells from each tissue have subtle molecular differences indicative of their tissue of origin [12–14]. Freidenstein *et al.* originally characterized these cells as multipotent for stromal precursors and clonogenic in culture [8]. Differentiation of MSCs into other cell types, such as cardiomyocytes [15], neurons [16], and hepatocytes [17], have also been described in the literature.

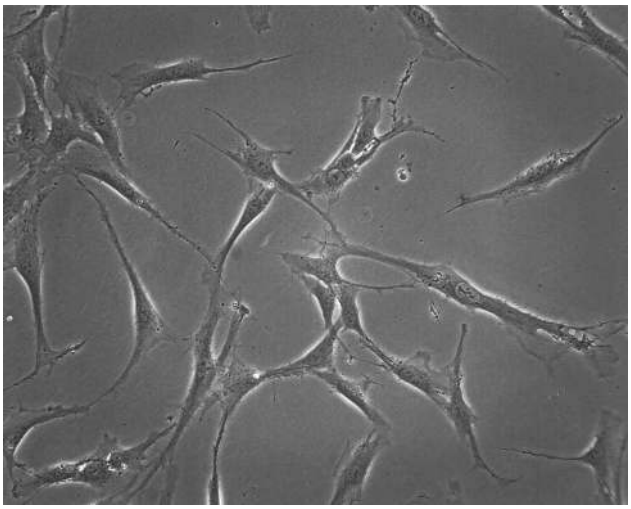

**Figure 61.1** A phase-contrast image of human bone marrow-derived mesenchymal stem/stromal cells in culture.

However, the ability of MSCs to differentiate into nonmesodermal lineage cell types is hotly debated: cells may be forced to differentiate into a specific lineage and express appropriate surface markers in culture, but do not necessarily display characteristic functions of that cell type.

The precise definition of MSCs continues to be disputed. The International Society for Cell Therapy currently defines human multipotent MSCs as possessing the following criteria: (1) MSCs are adherent to plastic when cultured in standard conditions; (2) MSCs express CD105, CD73, and CD90 and lack expression of CD45, CD34, CD14 or CD11b, CD79-α, CD19, and HLA-DR surface molecules; and (3) MSCs must differentiate into osteoblasts, adipocytes, and chondroblasts *in vitro* [18]. It is important to note that these requirements are specifically for human MSCs and do not wholly translate to other animal sources of MSCs.

## 61.3 Genetic modification of mesenchymal stromal cells

### 61.3.1 Safety concerns

There have been numerous studies demonstrating the clinical safety of MSCs [7]. Since the first clinical trial utilizing MSCs in 1995 testing the feasibility of extracting, expanding, and administering MSCs in humans [19], both allogeneic and autologous MSCs have been given to thousands of patients to treat various diseases, including bone and cartilage defects, cardiovascular diseases, autoimmune diseases, neurological diseases, and refractory wounds [20–22].

The clinical use of gene therapy in humans, however, still faces many challenges. Of the 440 clinical trials utilizing MSCs currently listed on clinicaltrials.gov, very few are utilizing gene-modified cells. Considering the drawbacks and limited success seen in early gene therapy clinical trials, it is not surprising that progress has been slow in this field, despite its vast potential. A patient enrolled in a trial aimed at evaluating the safety of gene therapy for ornithine transcarboxylase deficiency died because of a severe immune response to the gene-delivering viral vector [23]. In clinical studies to deliver interleukin (IL)-2 to X-linked severe combined immunodeficiency patients, initial promising results were overshadowed by patients who subsequently developed leukemia-like disorders and died due to insertional mutagenesis caused by the incorporation of the IL-2 gene retroviral vector near an oncogene of the delivered cells [23]. In 2003 the use of retroviral vectors in blood stem cells was temporarily suspended by the US Food and Drug Administration, with ongoing trials placed on clinical hold. Years later, when the factors contributing to insertional mutagenesis from retroviral vectors were better understood and the risk versus benefit ratio was better defined in each trial, some were allowed to continue.

Owing to the significant safety concerns of genetic modification, other methods of delivering growth factors, enzymes, and other therapeutically relevant signals have been explored. Direct growth factor supplementation therapy has been explored in the clinic with an inadequate result due to several limitations: because of the rate at which growth factors are broken down or excreted, they must be administered frequently and in high doses to initiate tissue healing [24]. The costly and transitory nature of this approach is far from ideal. Direct administration of gene-expressing plasmids has also been investigated. For example, Ye *et al.* administered systemically naked plasmid containing a deficient clotting factor, factor IX (FIX), in a murine model of hemophilia B. They observed therapeutic levels of human FIX for a year after plasmid administration, but treated animals also exhibited acute hepatic damage due to the high concentration of viral plasmid [25]. MSCs modified to express FIX in a controlled manner may be a safer approach to address the factor deficiency of this factor.

Significant advances have been made to understand the tumor induction capacity of the genetically modified cells used in previous trials [26,27]. Based on the results of Koegel *et al.*, self-inactivating lentiviral vectors have been developed, effectively eliminating the major tumorigenic component caused by using retroviral plasmids for future gene-modified stem cell trials [27,28]. Furthermore, MSCs have not been reported to cause *in vivo* tumor formation. We and others have demonstrated biosafety of retro- and lentivirally transduced MSCs with extensive decade-long studies using sensitive xenograft assays [29].

### 61.3.2 Choice of vector system

MSCs can be genetically engineered by permanent integration of the gene of choice, or through episomal expression of the gene by viral vector transduction or transient expression of nonvirally delivered genes [30]. (An episome is a genetic particle within cells that can exist either autonomously in the cytoplasm or as part of a chromosome). Viral delivery of specific genes to MSCs is the

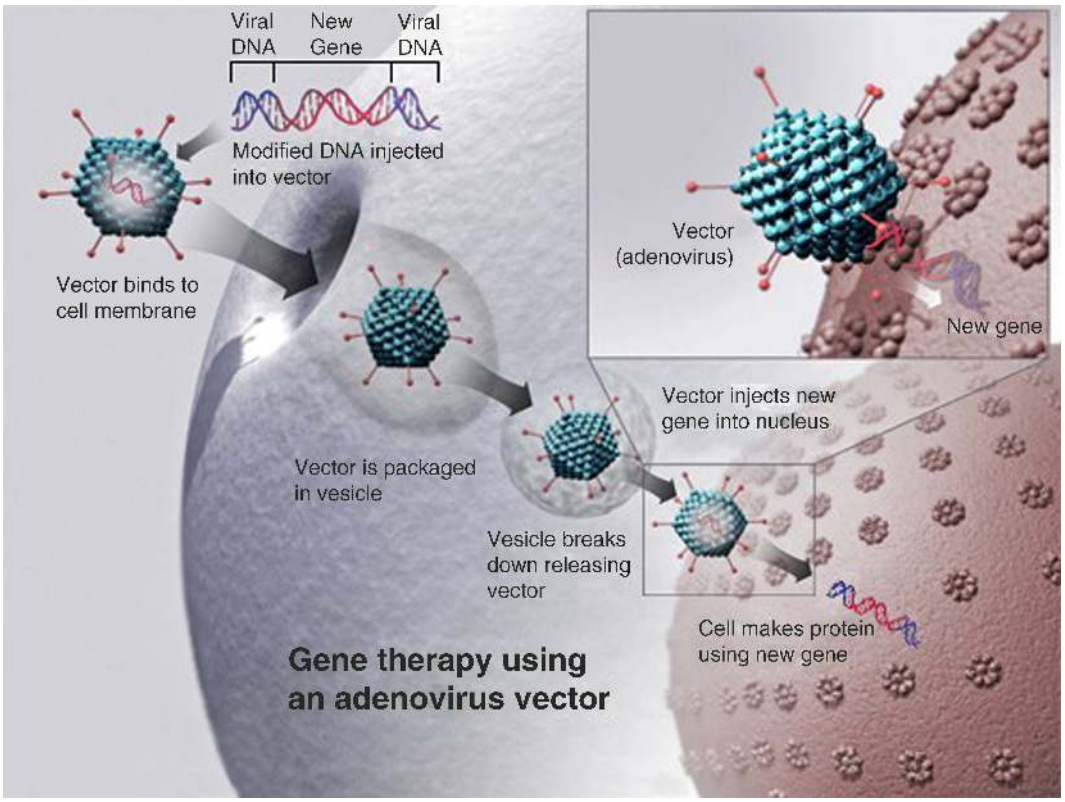

**Figure 61.2** A new gene is inserted into a cell using an adenovirus. (See color plate section.) *Source:* http://commons.wikimedia.org/wiki/File:Gene_therapy.jpg#/media/File:Gene_therapy.jpg

most common method in preclinical research, but the transduction efficiency depends on the target cells [31]. Transduced cells can contain thousands of copies of the transgene RNA per cell and maintain expression for over 6 months [4,32].

Retroviral, lentiviral, adenoviral, and adeno-associated virus vectors have been used in gene-modified MSC studies [30]. Episomal expression of transgenes can be achieved through the use of adenoviral and adeno-associated virus vectors and can sustain long-term transgene expression in non-dividing cells. However, as cells proliferate, transgene expression from episomal vectors becomes diluted and diminishes. In addition, capsids of adenoviral vectors can prompt an immune response, leading to adverse events [33]. Therefore, this approach may be best suited for applications in which short-term transgene expression is desired, such as for increasing homing and cell survival of transplanted cells. Figure 61.2 depicts the use of an adenoviral vector for gene transfer into a cell.

For sustained transgene expression, retroviral and lentiviral vectors are ideal. Lentiviral vectors are able to transduce nondividing cells, while retroviral vectors cannot. Previous work has indicated that MSCs can be stably transduced with both retroviral and lentiviral vectors and maintain differentiation potential and *in vivo* engraftment with no adverse events, even after multiple passages [29,32]. Figure 61.3 depicts the packaging and transduction of a gene using a lentivirus vector.

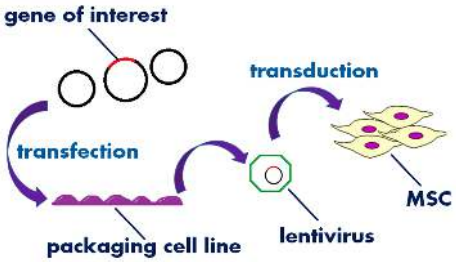

**Figure 61.3** Schematic overview of lentivirus generation and genetic modification of MSCs. To modify MSCs to express a gene of interest, a packaging cell line is first transfected with DNA plasmids containing the gene of interest and other elements for lentivirus production. Within 3 days the transfected packaging cells produce lentivirus containing the gene of interest, which is then used to transduce MSCs, which will then express the gene of interest. This image was generated by F. Fierro.

## 61.4 Preclinical models of gene-modified mesenchymal stromal cells: mesenchymal stromal cell migration and survival

MSCs are known to migrate to areas of tissue damage (see Chapters 22 and 23). The number of MSCs increases during total body hypoxia or irradiation, implying that they are part of

an innate healing response [34,35] (see Chapter 16). Additionally, MSCs have similar morphology and express similar markers to pericytes, which are cells that surround blood vessels throughout the body [11]. It has been hypothesized that MSCs are pericytes, and are therefore naturally located for easy access to circulating cytokines and chemokines, and with a means to migrate in response to trafficking signals. These endogenous trafficking signals can be utilized to promote migration of systemically administered cells to the location of tissue injury. MSCs express a variety of chemokine receptors including CCR1, CCR7, CCR9, CXCR3, CXCR4, CXCR5, and CXCR1 [36] (and see Chapter 23). Specific chemokine–receptor pairs shown to mediate MSC migration include hepatocyte growth factor (HGF) and its receptor c-MET, vascular endothelial growth factor (VEGF)/VEGF receptor, monocyte chemoattractant protein 1 (also known as CCL2)/CCR2, and others (reviewed by Karp and Leng Teo [37]).

Unfortunately, despite the preferential homing ability of MSCs to sites of inflammation, poor engraftment of the cells after administration has been unexpected and has given rise to the paracrine hypothesis of how MSCs may mediate their actions (see Chapters 21 and 37). One reason for this limited channeling of cells to target tissues is the large proportion of intravenously administered MSCs that become lodged in filtering organs, particularly the lungs, but also the liver, kidney, and spleen [37,38]. Other delivery methods, such as intra-arterial, intraperitoneal, or intracardiac injection, may lead to higher rates of engraftment but are more invasive [39]. Sasaki *et al.* were able to overcome low migration of MSCs in a mouse model of dermal wound healing by intradermally injecting the CCR7 ligand CCL21 (also known as the secondary lymphoid-tissue chemokine (SLC)) [40]. They found that MSC-treated animals exhibited rapid wound repair compared with control animals, but wound repair in SLC/CCL21-treated animals was even further accelerated, reportedly due to increased MSC migration to the wound site.

Another potential explanation for poor migration and engraftment of MSCs after administration may be that, while homing-specific chemokine receptors are upregulated in areas of tissue damage [41,42], *in vitro* expanded MSCs express low levels of some key chemokine receptors [43,44]. MSCs exposed to hypoxia *in vitro*, however, can induce expression of the most critical chemokine receptor CXCR4 [45] (and see Chapter 16). Systemically administered MSCs modified to overexpress CXCR4 showed increased migration to the infarct region in a rat model of acute myocardial infarction (AMI), resulting in a decrease of abnormal ventricular remodeling [46]. Furthermore, location of engrafted CXCR4-overexpressing MSCs in the infarcted heart was associated with increased angiogenesis and myogenesis [47]. Administration of these modified MSCs also demonstrated positive results in murine models of acute liver failure and traumatic brain injury [48,49]. MSCs overexpressing stromal-derived factor-1 (also known as CXCL12 and the ligand of CXCR4) increased bone formation in a rat model of fracture repair [50]. Endogenous CD44 on MSCs was engineered to function as the ligand for E-selectin, a cell adhesion molecule that is constitutively expressed only on endothelial cells of specialized marrow vessels and which is essential for cell trafficking within the bone marrow. Sackstein *et al.* demonstrated that this modification was sufficient to induce homing of MSCs to bone marrow [51].

Intramyocardially injected MSCs modified to overexpress CCR1 were shown to accumulate in infarcted myocardium after coronary artery ligation in mice and to contribute to restored cardiac function 4 weeks after AMI, possibly due to the higher expression of the CCR1 ligand, CCL7, in infarcted heart muscle [52]. A schema for the mechanism of an acute myocardial infarct is shown in Figure 61.4.

Adipose-tissue-derived MSCs modified to overexpress granulocyte chemotactic protein (GCP)-2 (also known as CXCL6) showed higher engraftment after intramyocardial injection, improved cardiac function, and reduced infarct size in a murine model of AMI. The investigators found that these cells also expressed significantly higher levels of VEGF, HGF, IL-8, insulin-like growth factor 1 (IGF-1), and AKT, suggesting that adipose-tissue-derived MSCs genetically altered to overexpress GCP-2 had enhanced angiogenic and survival properties [53].

In ischemic diseases, hypoxia is a critical factor that challenges the survival of cells after transplantation. Some strategies that have been employed to adapt the cells to this harsh environment include genetic modification for overexpression of endogenous hypoxia-regulated and prosurvival signals. Heme oxygenase-1 (HO-1), a stress-inducible enzyme, has been reported to have a cytoprotective role when administered alone [54]. MSCs modified to over-express HO-1 (HO-1-MSCs) have demonstrated protection against apoptosis in several animal models of cardiac ischemia [55–58]. Tang *et al.* demonstrated that HO-1-MSCs exhibited increased cell survival, enhanced functional recovery, and decreased pathological left ventricular remodeling in a murine model of AMI [59]. Furthermore, HO-1-MSCs showed enhanced expression of VEGF and fibroblast growth factor (FGF)-2, indicating that HO-1 overexpression can promote cell survival and therapeutic angiogenesis of MSCs in an ischemic setting [58].

The inflammatory nature of damaged tissues is also a challenge to the survival of MSCs after administration. MSCs have been modified to overexpress antiapoptotic molecules such as B cell lymphoma-2, erythropoietin (EPO), survivin, HSP-20 (heat shock protein with a molecular weight of 20 kDa), and connexin 43 for use in animal models of AMI [60–64]. Animals treated with MSCs modified to overexpress these prosurvival genes did indeed exhibit increased survival, as well as increased capillary density in infarcted regions. (Survivin is a member of the inhibitor of apoptosis family. The survivin protein functions to inhibit caspase activation, thereby leading to negative regulation of apoptosis or programmed cell death. HSPs are a family of proteins that are produced by cells in response to exposure to stressful conditions. They were first described in relation to heat shock, but are now

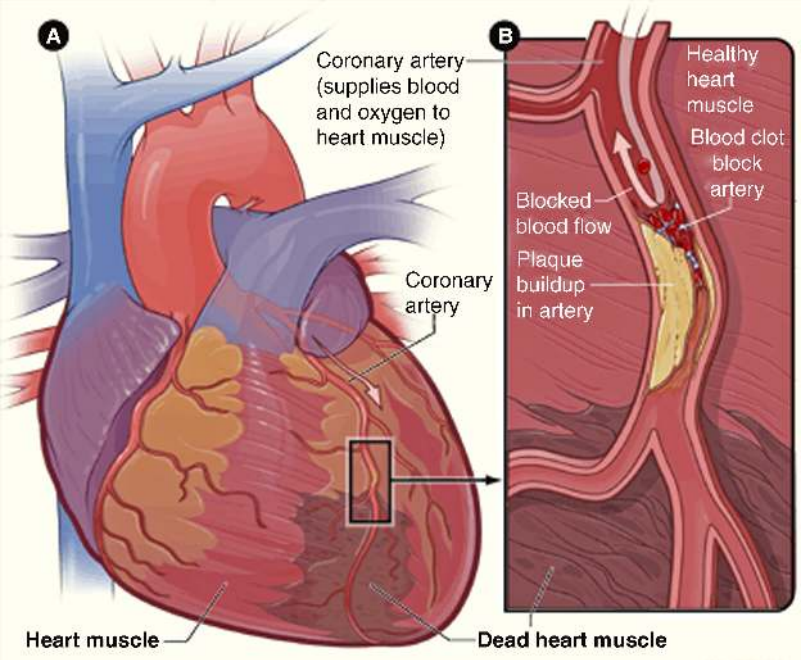

**Figure 61.4** Diagram showing an AMI (heart attack). *Source:* nih.gov.

known to also be expressed during other stresses, including exposure to cold, UV light, and during wound healing or tissue remodeling. Connexins, or gap junction proteins, are a family of structurally related transmembrane proteins that assemble to form vertebrate gap junctions. Each gap junction is composed of two hemichannels, or connexons, which are themselves each constructed out of six connexin molecules. Gap junctions are essential for many physiological processes, such as the coordinated depolarization of cardiac muscle, proper embryonic development, and the conducted response in microvasculature).

Positive results associated with these gene-modified MSCs were linked to enhanced *AKT* activation and secretion of growth factors [64].

Because of its role in multiple cellular processes, including cell survival and proliferation, *AKT1* (the gene that encodes the AKT protein) is a popular target for increasing MSC survival [65]. Mangi *et al.* found a significant increase in retained AKT-MSCs (MSCs modified to express AKT) after myocardial injection into ischemic rat hearts compared with unmodified MSCs. Animals treated with AKT-MSCs also exhibited reduced intramyocardial inflammation and collagen deposition in a dose-dependent manner and regenerated 80–90% of lost myocardial volume [66]. Similar results were reported by a different group utilizing AKT-MSCs in a swine myocardial infarction model [67]. We have demonstrated that exposing MSCs to 3% oxygen for 24 h also upregulates AKT activity and enhances their homing, survival, and revascularization potential [45]. Conditioned medium from MSCs exposed to hypoxia has shown protective effects on survival of adult rat ventricular cardiomyocytes subjected to hypoxia *in vitro*, compared with conditioned medium from MSCs without hypoxic exposure. However, the greatest MSC-mediated cytoprotective effects were seen when rat ventricular cardiomyocytes were exposed to conditioned medium from hypoxic MSCs that were also genetically modified to overexpress AKT [68].

Other growth factors have also been utilized to promote the survival of transplanted MSCs. Among the most studied is VEGF. MSCs transduced with the VEGF gene have been studied in multiple animal models of myocardial infarction [69–72] and critical limb ischemia with good outcomes [32]. Hepatocyte growth factor (HGF) has also proved promising as a candidate for genetic modification of MSCs in animal models of cardiovascular disease [72–75]. Fully elucidating the mechanisms responsible for MSC survival and migration/homing will be critical in future therapeutic applications of these cells.

## 61.5 Gene-modified mesenchymal stromal cells as immune modulators

MSCs are thought to play a critical role in hematopoietic homeostasis in the bone marrow (reviewed by Pontikoglou *et al.* [76] – and see Chapter 32). MSCs are able to avoid detection and resulting clearance by the recipient's immune system due, at least in part, to their lack of expression of major histocompatibility complex (MHC) class II antigens and the costimulatory molecules CD80 and CD86 [77]. This makes MSCs attractive candidates for allogeneic cell therapy. MHC-unmatched MSCs can be administered without eliciting a host immune response [78] (but see Chapter 29). Furthermore, MSCs have an ability to exert immunomodulatory and anti-inflammatory effects [79] (and see Chapters 33 and 34). Through a

combination of cell-to-cell contact and secretion of soluble factors, MSCs can induce division arrest in T cells, B cells, natural killer cells, and dendritic cells. They can also inhibit the cytotoxicity of T cells and natural killer cells as well as affecting B cell and dendritic cell function, effectively crippling the adaptive immune system (reviewed by Vetyska and Krusina [80] – and Chapter 34).

The precise mechanisms for many of the immunomodulatory interactions of MSCs are subject to debate, but evidence suggests many are largely dependent on paracrine signaling. MSCs are known to express a multitude of immune modulating factors, such as prostaglandin-$E_2$ [81], nitric oxide [82], HGF [83], transforming growth factor-β1 [84], and indoleamine 2,3-dioxygenase [85]. The potential beneficial effects of the immune modulating properties of MSCs can be exploited in many disease models to reduce local inflammation and recruitment of immune cells to the area of tissue injury. For example, Granero-Moltó *et al.* reported a decrease in local and circulating levels of the proinflammatory cytokines tumor necrosis factor (TNF)-α, IL-1β, and IL-6 after MSC transplantation in a murine tibial fracture model [86]. Multiple studies have utilized MSCs as an adjunct to allogeneic hematopoietic stem cell transplantation in order to prevent graft rejection or to treat GVHD. The latter is a common complication of allogeneic hematopoietic stem cell transplantation in which donor T cells mount an immune response to the recipient's tissues that bear minor histocompatibility antigens not shared by the donor, in spite of matching between donor and recipient for the antigens of the MHC and in spite of the routine prophylactic use of medications such as cyclosporine, methotrexate, tacrolimus, or rapamycin [87–90]. Additional immune suppressive agents, such as corticosteroids, can be used to treat GVHD, but they render the patient even more vulnerable to infection [91]. In 2004, Le Blanc *et al.* successfully treated a patient with severe acute GVHD refractory to conventional immune suppressive medications using *ex vivo* expanded but not gene-modified maternal (haploidentical) MSCs [92]. Other clinical trials have demonstrated that co-transplantation of MSCs with allogeneic HSC transplants significantly reduced acute GVHD [92–94].

The anti-inflammatory effects of MSCs can be amplified by genetically modifying specific immunomodulatory signals that are specific to certain pathologies. For example, MSCs modified with angiotensin-converting enzyme 2 (ACE2) – an enzyme that degrades angiotensin II, which is involved in endothelial dysfunction during acute lung injury – have demonstrated beneficial anti-inflammatory effects *in vitro*. He *et al.* found that MSCs modified to express ACE2 decreased production of inflammatory mediators and enhanced survival of endothelial cells after lipopolysaccharide-induced cell injury in tissue culture [95]. MSCs modified to express angiopoietin-1 have also been utilized in a mouse model of acute lung injury to decrease damage and scarring by inhibition of recruitment of inflammatory cells [96]. Inhibition of TNF-α, an inflammatory mediator involved in ischemia–reperfusion injury, may produce beneficial effects in ischemic disease [97]. Bao *et al.* [98] utilized TNF receptor (TNFR)-modified MSCs (TNFR-MSCs) in a rat model of myocardial infarction with the hypothesis that TNFR-MSCs would bind and remove TNF-α from the microenvironment. They found that TNFR-MSC-treated animals had improved left ventricular function and increased MSC engraftment in the infarcted myocardium compared with control animals [98].

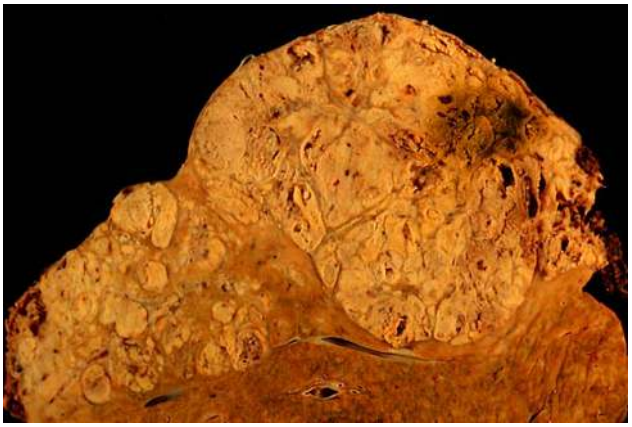

**Figure 61.5** Hepatic cirrhosis and hepatocellular carcinoma. Histopathologic image of an autopsy specimen from a person with cirrhosis of the liver in which a hepatocellular carcinoma had developed. There is a rim of fibrotic cirrhotic tissue at the bottom of the image, while the greater part of the image shows the hepatocellular carcinoma. *Source:* http://commons.wikimedia.org/wiki/File:Hepatocellular_carcinoma_1.jpg#/media/File:Hepatocellular_carcinoma_1.jpg

Fiore *et al.* exposed primary cultured hepatocytes to IGF-1-modified MSC supernatant, which induced increased expression of IGF-1 and HGF in the cultured cells. They then systemically administered IGF-1-MSCs in a murine model of cirrhosis and found decreased liver fibrosis and an increased expression of proliferating cell nuclear antigen in hepatocytes of IGF-1-MSC-treated animals [99]. Cirrhosis can cause death either by liver failure or by predisposing to hepatocellular carcinoma (Figure 61.5).

MSCs modified to express the gene for HGF in a rat model of allograft liver transplantation significantly increased survival time compared with animals treated with unmodified MSCs. This improvement in survival correlated with decreased IL-2 and interferon-α, increased IL-4 and IL-10, as well as reduced apoptosis and increased liver regeneration [100].

## 61.6 Gene-modified mesenchymal stromal cells in skeletal disorders

Chronic musculoskeletal pain has been reported as the most common medical complaint in the USA. Timely healing of damaged bone and cartilage by innate mechanisms is hampered by lack of local progenitor cells and adequate signaling. MSCs are promising candidates for musculoskeletal regeneration primarily owing to their ability to differentiate into osteoblasts and

chondrocytes. Indeed, one of the first clinical trials utilizing MSCs was in the treatment of osteogenesis imperfecta (OI), a genetic disease in which osteocytes produce defective type I collagen, causing bones to be extremely fragile [5]. MSCs can also be forced into tenocyte differentiation *in vitro* for transplant therapy and have been used in equine models of tendon repair [101]. Beyond their capacity to differentiate and replace damaged tissue, the ability of MSCs to secrete bioactive factors that alter the local environment and influence resident progenitor cells has also proven advantageous for musculoskeletal therapies. The combination of cell and gene therapy is ideal for bone and cartilage healing applications, whereby cell differentiation and signaling can be directed at the site of tissue injury.

The bone morphogenetic protein (BMP) family of growth factors has been widely utilized for the genetic modification of MSCs for musculoskeletal disorders. BMPs regulate a diverse set of biological processes, including bone and cartilage formation [102]. Multiple BMP family members, including BMB2, -4, and -7, have been examined for bone regenerating therapies in several animal models [103]. For example, Tsuji *et al.* found that BMP2 signaling is necessary for initiation of the fracture-healing process in mice [104]. Clinical trials utilizing BMP2 alone for tibial and spinal nonunion fractures have been conducted with promising results [105]. However, one group found that high doses of BMPs are required for efficacy, and may still not be effective, as is the case with many growth factor supplementation strategies [24]. It has been robustly demonstrated that MSCs modified to overexpress BMP2 (BMP2-MSCs) can form ectopic bone in mice [106–108], and that MSCs do not need to differentiate into osteoblasts to express BMPs [109]. As discussed earlier, MSCs are able to home and engraft to fracture sites [86] to exert their reparative effects at the site of tissue damage. In a rat articular fracture model, BMP2-MSCs induced bone and cartilage healing after direct cell injection [110].

BMP2-MSCs seem an ideal candidate for fracture therapy. BMP4- and BMP7-MSCs have also shown bone-inducing potential in animal models of osteoporosis and cranial bone defects [111–113]. BMP7 has been implicated as a candidate for the genetic modification of MSCs to increase chondrogenesis in an *in vitro* model of chondrocyte transplantation [114]. Modification of MSCs with BMP12 can induce *in vitro* tenocyte differentiation [115]. However, the tissue source of MSCs may also be an important factor for BMP-MSC-based therapies. Park *et al.* examined adipose-tissue-, bone-marrow-, and periosteal-derived MSCs after stimulation with BMP2 in a rat model of articular cartilage repair. They found that bone marrow and periosteal MSCs demonstrated increased cartilage repair when compared with adipose-derived MSCs, but BMP2 was required for initiation of chondrogenesis with all cell types [116].

Basic FGF (bFGF), sonic hedgehog, WNT4, LIM mineralization protein, and IGF-1 have all been implicated as candidates for modification of MSCs, each independently demonstrating increased efficacy in skeletal disease models over unmodified MSCs [117–125]. However, bFGF-MSCs and unmodified MSCs were tested in a rat model of Achilles tendon defect with negligible effects in either group [126].

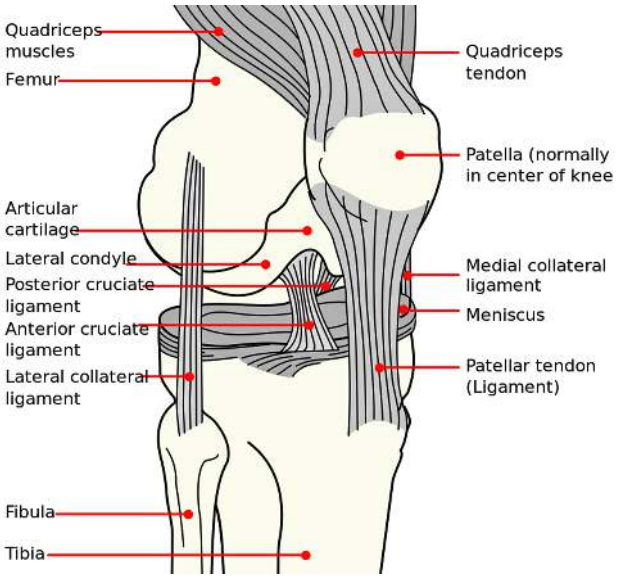

**Figure 61.6** The anatomical structure of the right human knee showing the muscles and ligaments associated with it, including the ACL. *Source:* http://commons.wikimedia.org/wiki/File:Knee_diagram.svg#/media/File:Knee_diagram.svg

Membrane type 1 matrix-metalloproteinase-modified MSCs demonstrated reduced scar formation and improved biomechanical strength in a rat model of rotator cuff healing [127]. Ectopic cartilage formation was achieved in pigs, rabbits, and rats utilizing transforming growth factor (TGF)-β1-MSCs [128–131]. Li *et al.* utilized unmodified MSCs and MSCs modified to overexpress platelet-derived growth factor (PDGF)-B for anterior cruciate ligament (ACL) reconstruction in a rabbit and found that in both cell-treated groups cellular infiltration was increased in the ACL. However, PDGF-B-MSCs induced initial angiogenesis that was not seen in the MSC group [132]. Figure 61.6 shows a diagram of the human knee, giving the anatomical position of the ACL.

RUNX2, a transcription factor that is important in osteogenesis and chondrogenesis, has also been utilized for gene therapy applications in musculoskeletal diseases. RUNX2-MSCs transplanted in a murine calvaria (skull bone) defect model showed increased bone mineral density and bone volume at the site of the defect compared with unmodified MSCs [133]. Other groups have modified MSCs to overexpress human telomerase reverse transcriptase to determine whether replicative senescence can be prevented to increase osteogenic potential of the cells [134,135].

As with bone repair, transcription factors can also regulate chondrogenic pathways: SOX9, Brachyury (which regulates FGFR3 and BMP2), and Sprouty1 have been investigated as potential targets for modification of MSCs in cartilage repair models [136–138]. MSCs modified to overexpress scleraxis, a transcription factor that regulates tendon development during

**Figure 61.7** A photograph of a child with the rickets-like changes that occur in hypophosphatasia. The image shows the typical widening of the wrists due to cupping and fraying of the metaphyseal region where there is an excess of nonmineralized osteoid tissue resulting in growth plate widening. *Source:* http://commons.wikimedia.org/wiki/File:Rickets_wrist.jpg#/media/File:Rickets_wrist.jpg.

embryogenesis, induced rotator cuff healing in rats at an earlier time point than unmodified MSCs did [139].

Monogenic bone diseases, such as hypophosphatasia and OI are ideal models for MSC-mediated gene therapy. As the name implies, hypophosphatasia is a condition in which tissue nonspecific alkaline phosphatase (ALP) is genetically inactivated in osteoblasts and chondrocytes [140]. As a result, bones exhibit reduced mineralization, eventually leading to rachitic changes (Figure 61.7) and osteomalacia.

Infants suffering with hypophosphatasia have been treated with whole bone marrow or cultured osteoblasts with limited success [141–143]. In one case the patient was given MSCs 6 months after an initial bone marrow transplant with lasting improvement, possibly due to long-term engraftment. However, in each of these reports, serum ALP levels remained low despite therapeutic intervention. It is feasible that MSCs modified to express increased levels of ALP could address this shortcoming for hypophosphatasia.

OI is a congenital bone disorder that is characterized by brittle bones, primarily due to the lack of type I collagen. Current therapies are aimed at increasing bone density by antiresorptive bisphosphonate administration. Owing to their ability to differentiate into type I collagen-producing osteoblasts, MSCs have been evaluated in clinical studies of OI. Children with severe OI were treated with two infusions of allogeneic MSCs after an allogeneic bone marrow transplant. Horwitz *et al.* reported a significant increase in growth velocity of the MSC-treated children, as well as MSC engraftment in the skin, bone, and marrow stroma [144]. Chamberlain *et al.* utilized adeno-associated viral vectors to disrupt mutant COL1A1 in MSCs from OI patients and demonstrated successful deletion of the mutation. Transduced MSCs were able to produce collagen similar to wild-type cells. Furthermore, the modified MSCs were able to form ectopic bone in mice [145]. This strategy demonstrates that *ex vivo* expansion and modification of MSCs for treatment of other monogenic bone diseases may be efficacious.

Given these results, it is not surprising that combination therapies have also shown promise in musculoskeletal disease. Mice injected with RUNX2-BMP2-MSCs displayed increased bone and cartilage formation compared with BMP2-MSCs or MSCs alone [146]. BMP-VEGF-MSCs utilized in a murine model of segmental bone defects also showed enhanced bone formation compared with unmodified MSCs [147]. *In vitro* chondrogenesis was not achieved in MSCs modified to overexpress IGF-1, but gene co-modification with TGF-β or BMP2 induced greater chondrogenesis than with any of these factors alone [148,149]. This combinatorial gene modification approach demonstrated synergy between gene modifications and expanded our knowledge of the potential use of MSC-mediated gene therapy for bone and cartilage repair.

## 61.7 Gene-modified mesenchymal stromal cells in cardiovascular disease

There are over a million incidents of AMI in the USA each year. There is as yet no treatment that alleviates the permanent loss of cardiomyocytes and the ensuing fibrosis in the left ventricle that occurs after AMI. This leads to pathological left ventricular remodeling, which in turn often leads to hypokinesis of the left ventricle and death from treatment-refractory heart failure.

Many cell types have been studied for their regenerative capacity in the tissue environment after AMI. MSCs are an attractive candidate for this application and have shown promise in multiple animal models. One study reported that MSCs injected into murine hearts differentiated into cardiomyocytes and engrafted into the host tissue [150], but this has not been found in other studies. Rather, paracrine signaling from undifferentiated MSCs has been shown to promote growth and proliferation of neighboring cells. Nakanishi *et al.* found that cell-free conditioned media from MSCs promoted proliferation, inhibited apoptosis, and enhanced migration of cardiac progenitor cells *in vitro* [151]. Studies utilizing gene-modified MSCs in cardiovascular disease have aimed at increasing and optimizing the homing, survival, and engraftment of MSCs, as well as enhancing their paracrine effects, as detailed in the preclinical studies described earlier.

MSC administration has shown promise in many animal models of ischemia–reperfusion injury in disorders other than cardiovascular disease. Use of genetically modified MSCs for ischemia–reperfusion injury models in renal, limb, lung, and brain ischemia has largely focused on protecting the cells from hypoxia, as well as inducing neoangiogenesis in the damaged tissue. Our group and others have demonstrated that MSCs modified to overexpress VEGF induced endothelial cell migration *in vitro* and increased blood flow restoration in mouse and

rat models of hind limb ischemia (HLI) [32,69,70]. Similarly, another group transiently modified MSCs with VEGF polymeric nanoparticles and intramuscularly injected the cells in a mouse model of HLI. VEGF-MSC-treated mice exhibited reduced tissue fibrosis and enhanced angiogenesis after cell administration compared with animals that received unmodified MSCs [152].

Piao *et al.* utilized MSCs modified to overexpress angiopoietin-1 in a rat model of HLI and found enhanced angiogenesis as well as increased cell survival due to increased expression of AKT by the donor cells [153]. Similarly, MSCs modified with the gene for the anti-inflammatory IL-10 were used effectively to prevent ischemia–reperfusion lung injury in rats [154]. Combined, these results demonstrate that undifferentiated MSCs exhibit cytoprotective effects on other cell types, primarily through secretion of biologically active factors, and that those effects can be intensified through combinatorial strategies that promote both survival and paracrine activity of the donor MSCs.

## 61.8 Gene-modified mesenchymal stromal cells in kidney disease

Many kidney diseases are characterized by ischemic and inflammatory injury. In view of the previously described anti-inflammatory and anti-ischemia–reperfusion injury potential of MSCs, cell and gene therapies for kidney disease are being rapidly explored. Recombinant human EPO has been used successfully for many years to treat anemia in patients with end-stage renal disease [155]. Eliopoulos *et al.* examined whether subcutaneous injection of EPO-expressing MSCs could improve anemia in a mouse model of chronic renal failure and found a dose-dependent increase in hematocrit levels after subcutaneous implantation of the cells embedded in a collagen-based matrix, as well as increased cell lifespan [156]. The same group also demonstrated that co-injecting mice with renal failure with EPO-MSCs and IGF-1-MSCs led to greater hematocrit elevation as well as improved heart function [157].

Unmodified MSCs have been used to protect against acute ischemia–reperfusion injury in rat kidneys, owing to their demonstrated ability to decrease proinflammatory cytokines and increase anti-inflammatory signals in the treated kidneys [158]. Kallikrein, a potent anti-inflammatory and anti-apoptotic renoprotective molecule, has been utilized in gene-modified MSCs in a rat model of acute ischemia–reperfusion kidney injury. Kallikrein-MSCs inhibited $H_2O_2$-induced apoptosis, increased survival of proximal tubular cells *in vitro*, and led to significantly reduced renal cell apoptosis *in vivo* [159]. Yuan *et al.* observed that VEGF-MSCs co-cultured with cisplatin-treated renal epithelial cells protected the cells via antiapoptotic and mitogenic actions. Mice with cisplatin-induced renal injury showed better protection of renal function, tubular structure, and survival after VEGF-MSC administration, primarily due to improved microcirculation and cell proliferation within the damaged kidney [160].

## 61.9 Gene-modified mesenchymal stromal cells in neurological disease

MSCs promote positive effects in the brain through similar mechanisms as described earlier for other tissues. The paracrine and autocrine actions that regulate the immunomodulatory, antiapoptotic, migratory, and regenerative properties of MSCs are qualities that make them leading candidates for a cell-based approach to neurological diseases.

Many neurological diseases are characterized by, or result in, loss of neurons. There is considerable interest in utilizing MSCs for neurological diseases given the ability of MSCs to exert cytoprotective and regenerative effects through paracrine activity. Efficacy has been demonstrated in preclinical models of Alzheimer's disease, Huntington's disease (HD) (see Chapter 40), Parkinson's disease (PD), multiple sclerosis, ischemic stroke and amyotrophic lateral sclerosis (ALS) (reviewed by Tanna and Sachan [161]) [21]. MSCs can influence neural cell growth and survival, although the exact mechanisms are unclear. Crigler *et al.* found that subpopulations of human MSCs express brain-derived neurotrophic factor (BDNF) and β-nerve growth factor but not neurotrophin-3 or -4 [162]. MSCs also produce extracellular matrix molecules that support neural cell growth and attachment [163].

HD is an autosomal dominant neurodegenerative disease that is caused by variably sized polyglutamine expansion in the mutant huntingtin gene, *HTT*, leading to HTT protein-toxicity-induced death of striatal neurons and decreased expression of BDNF [164]. HD patients suffer a steady decline in emotion, motor function, and cognition before eventual death. There is currently no cure for HD. The best approach should aim to halt the progression of the disease by eliminating the mutant HTT protein and regenerating damaged neurons [165]. Our group has explored the use of MSCs as delivery vehicles for RNA inhibition, effectively decreasing expression of the mutant HTT in target cells *in vitro* [166]. The challenge with these therapies, however, is safe and sustained delivery of the therapeutic agent to the brain. MSC-based gene therapy can potentially fulfill these criteria, given their proven safety profile [29].

Canals *et al.* generated a mouse model of HD and demonstrated that disease onset is dependent on the length and levels of expressed mutant HTT, as well as the deficit in endogenous BDNF [167]. They also found that supplementation of exogenous BDNF was sufficient to restore neuronal dysfunction and extend lifespan in their R6/2 mouse model. In the YAC 128 mouse model of HD, Dey *et al.* transplanted BDNF-secreting MSCs into the striatum, significantly improving motor function and decreasing neuronal loss [168]. Existing work on the animal models of BDNF therapies for treatment of HD have been reviewed [169,170], and our team is performing studies to support a proposed future clinical trial to test safety and potential efficacy in patients with this disorder [167,168].

ALS, also known as Lou Gehrig's disease and a form of motor neurone disease, is a neurodegenerative disorder characterized

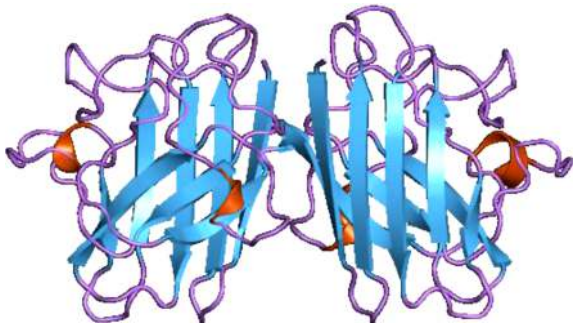

**Figure 61.8** Cartoon representation of the molecular structure of the human familial amyotrophic lateral sclerosis mutant protein G37R G37R CUZNSOD registered with 1azv code. (The structure of 1AZV is a metal-bound structure used to analyze SOD1's copper and zinc binding sites). This image, taken from Wikimedia Commons, is in the public domain because its creator, Jawahar Swaminathan and MSD staff at the *European Bioinformatics Institute*, have placed it there. (See color plate section.) *Source:* http://www.ebi.ac.uk/Information/termsofuse.html, and the courtesy link back to the creator is http://www.ebi.ac.uk/

by selective destruction of motor neurons. Failure of the neuromuscular junction in these neurons leads to paralysis and premature death, most often caused by paralysis of respiratory muscles and resulting respiratory failure [21]. Approximately 5–10% of patients with ALS have an inherited form of the disease, while the remainder are sporadic cases and with no known cause. The clinical and histopathological hallmarks, however, are identical in familial and sporadic cases [171]. The most common disease-causing mutation is a point mutation within the gene encoding $Cu^{2+}/Zn^{2+}$ superoxide dismutase 1 (SOD1).

The identification of this key mutation has led to the development of transgenic rodent models. Using SOD1 models, glial-cell-derived growth factor (GDNF) (Figure 61.8) has been shown to protect motor neurons from the typical degradation seen in untreated SOD1 mice [172]. However, clinical trials of the systemic administration of growth factor in ALS have not been successful, possibly due to their short half-life and low concentration in the target tissues.

Intramuscular delivery of adenovirus has been utilized to introduce GDNF into muscles of SOD1 mice and delay disease onset, decline in motor function, and prolong survival [172]. Suzuki *et al.* utilized MSCs engineered to express GDNF in a rat model of ALS. Animals treated with GDNF-MSCs had significantly increased neuromuscular connections, decreased motor neuron loss in the spinal cord location connected to the limb that received cells, delayed disease progression, and increased lifespan [173]. HGF, IGF-1, and VEGF have also demonstrated promising effects in rodent models [174,175]. Recently, a clinical trial utilizing autologous MSCs administered by intrathecal injection showed decreased disease progression in half of the treated patients [176]. Slowing of disease progression was linked to increased expression of trophic factors by the donor cells, demonstrating that genetic modification of MSCs to further increase the expression of these specific signals may be a promising approach for the treatment of ALS.

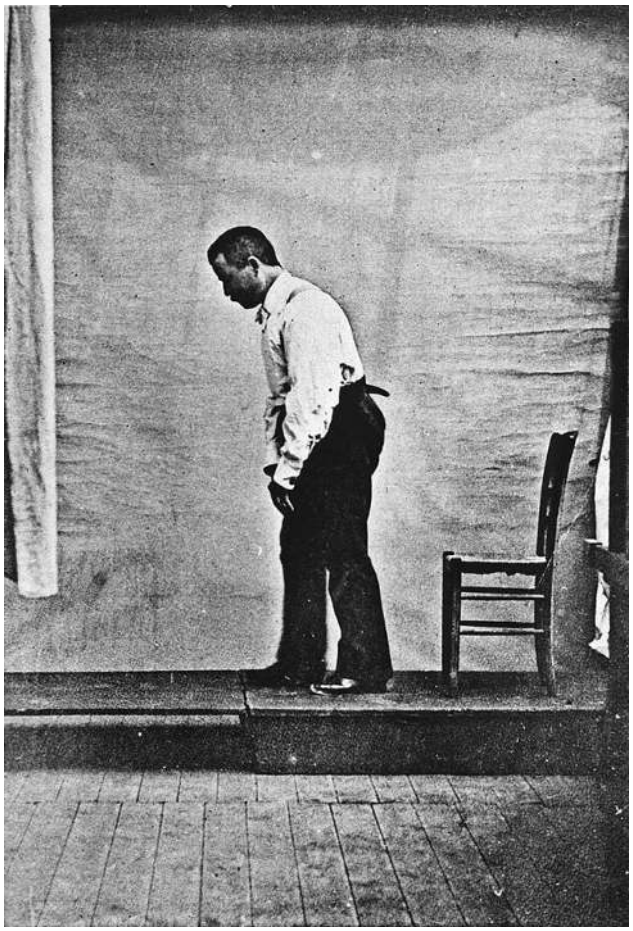

**Figure 61.9** A man with PD displaying a flexed walking posture, pictured in 1892. *Source:* nih.gov.

PD is a neurodegenerative disease of the central nervous system in which progressive loss of dopaminergic (DA) neurons in the midbrain leads to tremor and difficulty with movement including handwriting [177] (Figures 61.9 and 61.10).

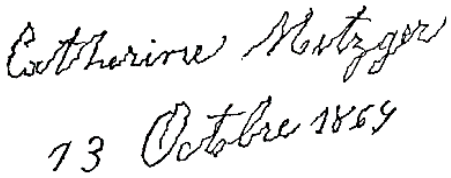

**Figure 61.10** Example of handwriting by a patient with PD possibly showing micrographia in addition to other abnormal characteristics. The original description of the text states "The strokes forming the letters are very irregular and sinuous, whilst the irregularities and sinuosities are of a very limited width. ( . . . ) the down-strokes are all, with the exception of the first letter, made with comparative firmness and are, in fact, nearly normal – the finer up-strokes, on the contrary, are all tremulous in appearance ( . . . )." *Source:* http://commons.wikimedia.org/wiki/File:Writing_by_a_Parkinson%27s_disease_patient.png#/media/File:Writing_by_a_Parkinson%27s_disease_patient.png.

Various growth factors have been examined to help recovery of damaged DA neurons (reviewed by Peterson and Nutt [178]). Specifically, GDNF has proven to be a potent neurotrophic factor for DA neurons, but, as previously discussed, sustained delivery of therapeutically relevant doses of growth factor has been a challenge. In a rat model of PD, GDNF-MSCs administered into the striatum induced regeneration of host DA striatal fibers [179]. Similar results were obtained by Somoza *et al.* using BDNF-MSCs after intrastriatal injection in the same model [180]. However, there are no current cures available for PD and, unfortunately, recent data suggest that the disease can be propagated to engrafted donor neurons [181].

## 61.10 Gene-modified mesenchymal stromal cells in other nonmalignant diseases

### 61.10.1 Hemophilia

Hemophilia is an X-linked genetic disorder in which patients have abnormal clotting due to lack of specific coagulation factors. Hemophilia A is due to a deficiency of coagulation factor VIII (FVIII). MSCs genetically modified to express FVIII (FVIII-MSCs) have been shown to correct the hemophilia A phenotype in affected mouse models [182]. The same finding was made using supernatant from FVIII-MSC cultures. Hemophilia B patients are deficient in FIX. Dodd *et al.* generated FIX-MSCs with sustained expression of functional FIX before and after differentiation into adipogenic, osteoblastic, and chondrogenic cells *in vitro* [183]. Intravenous delivery of naked FIX plasmid into hemophilia B mice induced therapeutic levels of human FIX for over a year, but acute hepatic damage was also observed [25]. The use of FIX-MSCs for safe and sustained delivery of clotting factor may be a successful long-term treatment of hemophilia B.

### 61.10.2 Metachromatic leukodystrophy

Metachromatic leukodystrophy is a genetic lysosomal storage disease that affects nerves, muscles, and other organs with increased severity over time. In 2002 Koç *et al.* treated patients with metachromatic leukodystrophy with MSCs after they had received an HLA-matched bone marrow transplant. Four out of six patients showed increased improvement in nerve conduction velocities and bone mineral density after MSC infusion. However, there were no changes in the patients' overall health or development. Despite the lack of reversal of disease pathology, they found that donor MSCs were still detectable 60 days after administration in two patients and concluded that allogeneic MSC infusion was safe [184].

### 61.10.3 Mucopolysaccharidosis type VII

Mucopolysaccharidosis type VII (MPSVII), another inherited lysosomal storage disease, characterized by deficiency of the β-glucuronidase (GUSB) enzyme, has also been explored as a candidate for MSC-mediated gene therapy. Meyerrose *et al.* generated human GUSB-MSCs to transplant into immune-deficient MPSVII mice. They observed increased circulating GUSB levels, normalized levels of lysosomal enzymes, and improved retinal function. They also observed normal trafficking of the gene-modified cells and long-term persistence of GUSB-MSCs delivering therapeutic levels of protein [32].

### 61.10.4 Diabetes mellitus

MSCs gene modified to express pancreatic duodenal homeobox-1 (PDX-1) have been generated with the goal of producing functional insulin-secreting cells to treat diabetes mellitus. PDX-1-MSCs were implanted in a hyperglycemic rat model and reduced blood glucose levels to normal [185]. Li *et al.* were able to obtain euglycemia in streptozotocin-induced diabetic mice treated with PDX-1-MSCs for 42 days after administration [186].

## 61.11 Conclusions and future directions

There is enormous potential of the use of gene-modified MSCs for delivery of enzymes and growth factors or to increase supplementation of therapeutically beneficial signals. A summary of these is shown in Figure 61.11.

Given the substantial safety concerns with gene therapies, as exemplified by gene therapy clinical trials of the 1990s that led to the deaths of several patients and temporarily halted gene therapy trials [23], other approaches for growth factor supplementation have been explored. Unfortunately, direct administration of growth factors or naked viral plasmids carries additional caveats. Concerns with direct administration of growth factors include expense, difficulty in delivering them in a sustained manner due to their instability, and the requirement for a large quantity of them to produce effects at the site of tissue damage. Similar concerns exist with direct plasmid supplementation with further safety concerns.

Gene-modified MSCs represent an approach that may resolve many of the problems. Unmodified MSCs can be administered to a site of injury, engraft, and/or respond to endogenous signals to induce secretion of paracrine signals required for repair. Furthermore, MSCs are part of an innate tissue healing response and are able to migrate to sites of tissue injury and hypoxia in response to cell trafficking signals [37,38,187]. MSCs possess immunomodulatory functions that further contribute to a pro-regenerative microenvironment and are able to evade immune detection by the host. By modifying the genes responsible for these endogenous functions, or engineering the cells to express a therapeutic protein for exogenous supplementation, we can utilize MSCs to their greatest potential as powerful delivery vehicles and protein synthesis factories.

Safety concerns are at the forefront of preclinical and clinical study development. Ongoing studies seek to optimize *in vitro* culture conditions to ensure development of a safe cell product and clinically acceptable expansion protocols. Xeno-free culture conditions are being explored to minimize the risk of immune

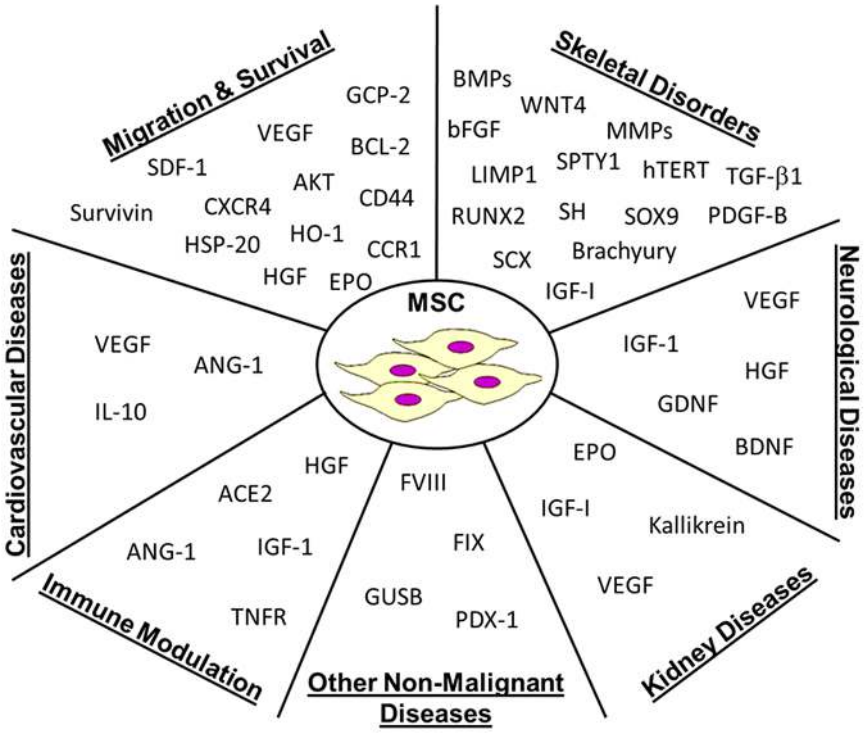

**Figure 61.11** A summary of targets for genetic modification of MSCs and their therapeutic applications.

reactions and pathogen transmission [188]. While there has been no documented evidence of malignant transformation of human MSCs, it remains critical to maintain standard operating procedures and *in vitro* culture protocols and to employ sensitive karyotyping methods. In some instances it may be preferable to develop methods to induce beneficial effects without gene modification of the cells. For example, exposure to hypoxic culture conditions can also promote expression of the survival and proangiogenic signals in MSCs (reviewed by Haque *et al.* [189]. and Beegle *et al.* [190].).

The success of future MSC-mediated gene therapy trials depends on the development of safe standard operating procedures and protocols for the expansion and genetic engineering of MSCs. Suicide genes, such as the herpes simplex virus type 1–thymidine kinase system, have been utilized to circumvent concern over serious side effects from gene-modified cells [191,192]. However, this approach must be considered with caution, as suicide-gene-induced cell death can have bystander effects on surrounding cells, and MSCs are known to transfer proteins from cell to cell.

It is also important to follow cell fate after injection in order to understand and resolve any potential adverse events. Nontherapeutic tracking genes such as eGFP and luciferase are prohibited for use in clinical trials. Currently, the only way to interrogate cell fate after injection is through the use of these tracking genes in animal models, with translation into larger animal models once efficacy has been demonstrated.

MSCs have demonstrated safety and efficacy in a number of clinical trials in cardiovascular diseases, neurological diseases, and GVHD, but issues with efficacy and reproducibility remain [193–197]. Additionally, both the optimal dose of gene-modified MSCs and the optimal delivery route need to be established, and this will vary depending on the tissue or organ to be healed or repaired. The route of administration can have significant impacts on the efficacy of treatment. Kashiwakura *et al.* found that intra-articular injection of FVIII-MSCs was significantly better at alleviating hemarthrosis and hemophilic arthropathy in a mouse model of hemophilia A compared with intravenous and subcutaneous administration [182]. Timing and dose of administration of gene-modified MSCs can also impact therapeutic efficacy. Richardson *et al.* tested low and high doses of MSCs immediately or 7 days after initiation of AMI in rats and found that both the cell doses given immediately after AMI demonstrated efficacy, with the high dose producing the greatest increase in left ventricular ejection fraction and the greatest decrease in pathological remodeling of the left ventricle [198]. Interestingly, they found that later cell administration benefited the noninfarct region, but did not significantly contribute to healing in the infarct region. Fiore *et al.* found in a mouse model of liver cirrhosis that repeated injections of IGF-1-MSCs yielded the greatest antifibrinogenic effects [99].

The cell delivery vehicle can also be important in MSC-based gene therapies. Sayyar *et al.* tested the cell-matrix interactions between FIX-MSC in an RGD-alginate scaffold compared with encapsulation within fibrinogen-alginate microcapsules, and found that FIX-MSCs encapsulated in fibrinogen-alginate microcapsules showed increased FIX expression while FIX-MSCs in RGD-alginate scaffolds showed enhanced cell attachment and

viability of the cells [199]. This research indicated RDG-alginate scaffold delivery may be preferable for applications that require cell attachment and viability over enhanced gene expression.

Finally, the tissue source of donor MSCs may be a critical factor for cell and gene therapy. Park *et al.* examined the chondrogenic potential of MSCs isolated from bone marrow, adipose tissue, and perichondrium/periosteum for articular cartilage repair and found that perichondrium/periosteum- and bone-marrow-derived MSCs were superior to adipose-tissue-derived MSCs, even though cells from all three sources required BMP2 for initiation and support of chondrogenesis. Many of these factors are not sufficiently optimized when designing MSC-based clinical trials and may be a potential explanation for lack of repeatable efficacy. There is a need to identify a standard tissue donor and source, expansion procedures, specific defining markers, dosing, and administration strategies.

## 62.1 Introduction

Mesenchymal stromal cells (MSCs) are a promising platform for cellular and genetic therapy and regenerative medicine. MSCs are nonhematopoietic progenitor cells that can be easily isolated from a variety of tissues, including bone marrow [1], adipose tissue [1–3], the placenta and umbilical cord [1,4,5], Wharton's jelly [6], tendons [7], and dental pulp [8]. Furthermore, MSCs can be easily expanded, genetically modified and have the ability to differentiate *in vitro* into mesenchymal lineages, including adipocytes, osteocytes, chondrocytes, muscle cells and stromal cells [9].

### 62.1.1 Biological characteristics of mesenchymal stromal cells

The biological characteristics of MSCs have generated markedly growing interest in the field of cellular therapy (Figure 62.1).

However, investigators have reported studies of MSCs using different methods for cell isolation and expansion, and different approaches for characterizing these cells. Thus, it is difficult to compare and contrast study outcomes, which has hindered progress in the field. To better address this issue the International Society for Cellular Therapy proposed minimal criteria to identify human MSCs as follows: (1) MSCs must be plastic-adherent when maintained in standard culture conditions; (2) MSCs must express CD73, CD90 and CD105, and lack expression of CD45, CD34, CD14, CD11b, CD79, CD19, or human leukocyte antigen (HLA)-DR on the cell surface; and (3) MSCs must differentiate *in vitro* into cells of the mesenchymal lineage, including osteoblasts, adipocytes, and chondroblasts [10,11]. This area took another significant step forward with the publication in 2013 of a joint statement from the International Federation for Adipose Therapeutics and Science and the International Society for Cellular Therapy on stromal cells from adipose-tissue-derived stromal vascular fraction and culture-expanded adipose-tissue-derived stromal/stem cells [12]. The centrifuged but uncultured stromal vascular fraction was identified as being $CD45^-$, $CD235a^-$ (glycophorin A), $CD31^-$ (platelet endothelial cell adhesion molecule) and $CD34^+$, while cell surface positivity for CD13 (alanine aminopeptidase), CD73, CD90, and CD105 were best used in conjunction with CD45, CD235a, and CD31 [12]. *Ex-vivo*-expanded adipose-tissue-derived stromal/stem cells retain cell surface markers expressed by other mesenchymal stromal/stem cells, including CD44 (the hyaluronic acid receptor), CD73, CD90, and CD105 and are also negative for CD45 and CD31, but can be distinguished from bone-marrow-derived MSCs by being $CD36^+$ (fatty acid translocase, also

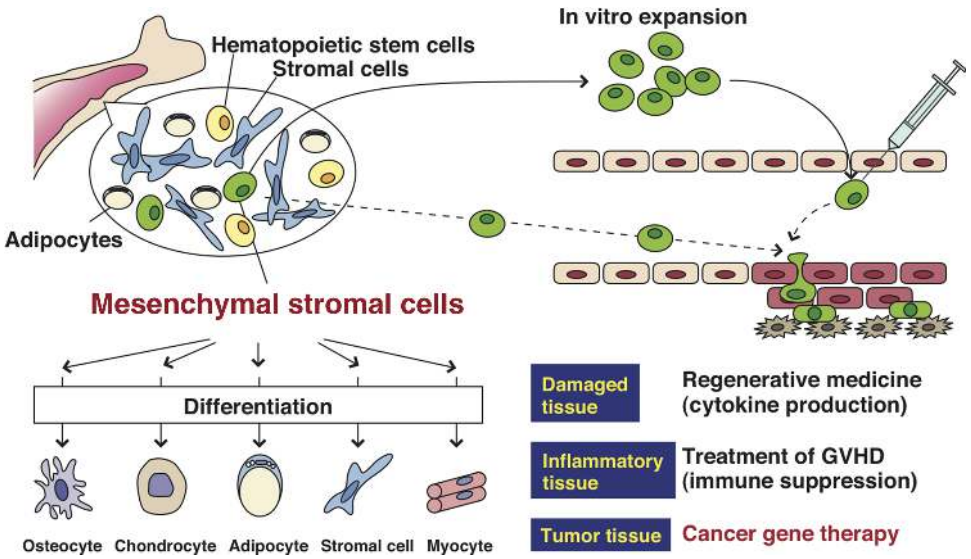

**Figure 62.1** Concepts in the use of MSCs for regenerative medicine and cell therapy. In the bone marrow, there are different types of tissue stem cells, including hematopoietic stem cells and MSCs. MSCs account for a small population of total bone marrow cells, and they can differentiate into various different mesenchymal lineages. MSCs can also accumulate at sites of (i) tissue damage, (ii) tissue inflammation, and (iii) tumors. Therefore, MSCs can be used for (i) regenerative therapy, (ii) treatment of graft-versus-host disease (GVHD), and (iii) cancer gene and cell therapy (targeted delivery). (See color plate section.)

known as glycoprotein IIIb) and $CD106^{-}$ (vascular cell-adhesion molecule 1 (VCAM-1)) [12].

### 62.1.2 Immunomodulatory effects of mesenchymal stromal cells on immune cells

Another feature of MSCs is their low immunogenicity probably because of the absence of costimulatory molecules on their cell surface [13]. Thus, MSCs do not activate the host adaptive immune response and can escape immunological rejection when transferred into unrelated HLA-nonidentical recipients (see Chapter 57). These characteristics permit the infusion of MSCs into recipients without HLA matching. Interestingly, MSCs exhibit a homing predisposition toward damaged and inflamed tissues. MSCs may be useful in the prevention or treatment of GVHD, a significant cause of morbidity and mortality following allogeneic hematopoietic stem cell transplantation, although phase III clinical trials in this area are ongoing. Human MSCs suppress T cell proliferation induced by allogeneic peripheral blood lymphocytes or phytohemagglutinin [14]. Le Blanc *et al.* reported the index case of a patient with severe acute GVHD following bone marrow transplantation, which was refractory to all conventional immune suppressive agents, but which showed marked improvement following two intravenous infusions of haploidentical (maternal) MSCs [15].

### 62.1.3 Tumor homing of mesenchymal stromal cells

Tumors have been referred to as "wounds that never heal" [16]. Inflammatory immune cells such as neutrophils, macrophages, and natural killer cells are recruited to the tumor site. Tumor growth can be promoted by inflammation. MSCs also exhibit tropism for tumor tissues and can be utilized as a cellular vehicle for anticancer gene delivery to tumor sites [17]. This type of targeted therapy can reduce the side effects of anticancer agents by facilitating an effective concentration of these agents at local tumor sites.

## 62.2 Applications of genetically engineered mesenchymal stromal cells for cancer therapy

Since it was first reported that MSCs show tropism for tumors [17], many studies have demonstrated that genetically modified MSCs either overexpress therapeutic gene products or demonstrate tumor tropism. In this section we summarize the various therapeutic gene products that have been successfully delivered to tumors using MSCs as cellular delivery vehicles (Table 62.1).

### 62.2.1 Interferons

An early application of MSCs for targeted cancer therapy was the directed delivery of IFN-β [17–20]. MSCs were transduced with the gene encoding IFN-β, followed by their infusion into mice harboring tumor xenografts. MSC treatment resulted in reduced tumor growth and the prolonged survival of tumor-bearing mice. Based on this observation, genetically modified MSCs from various tissues have been evaluated for their therapeutic efficacy and ability to act as cellular vehicles.

**Table 62.1** Therapeutic gene products successfully delivered to tumors using MSCs as a cellular delivery vehicle.

| Agent | Rationale | Model | Reference |
|---|---|---|---|
| IFN-β | Induces differentiation, S-phase accumulation, and apoptosis | Metastasis (prostate, breast, melanoma) | [17–19] |
| | | Orthotopic (glioma) | [20] |
| IL-2 | Immunomodulation | Orthotopic (glioma) | [21] |
| IL-12 | Activates CTLs and NK cells and produces IFN-γ | Subcutaneous (melanoma, hepatoma, lung) | [22,23] |
| CX3CL1 | Activates CTLs and NK cells | Metastasis (melanoma, colon) | [24] |
| GCV/HSV-TK | Prodrug conversion | Subcutaneous, orthotopic (glioma) | [25,26] |
| 5-FC/CD | Prodrug conversion (5-FC →5-FU) | Subcutaneous (melanoma, colon) | [27–30] |
| NK4 | Inhibits angiogenesis and promotes apoptosis | Metastasis (colon) | [31] |
| TRAIL | Induces apoptosis | Subcutaneous (breast)<br>Metastasis (breast)<br>Orthotopic (glioma) | [32,33] |
| Oncolytic viruses | Destroys tumors by viral replication | Orthotopic (breast, lung, ovarian)<br>Metastasis (breast) | [34–36] |

5-FC: 5-fluorocytosine; 5-FU: 5-fluorouracil; CD: cytosine deaminase; CTL: cytotoxic T lymphocyte; CX3CL1: chemokine C-X3-C motif ligand 1; GCV: ganciclovir; HSV-TK: herpes simplex virus–thymidine kinase; IFN: interferon; IL: interleukin; NK: natural killer; TRAIL: tumor-necrosis-factor-related apoptosis-inducing ligand.

### 62.2.2 Interleukins

ILs are molecules that regulate the inflammatory and immune responses, and are often used as therapeutic agents. IL-2-expressing MSCs have been used to improve immunological surveillance of tumors by activating CTLs and NK cells [21]. Administration of IL-12-expressing MSCs has been shown to suppress metastasis and increase tumor cell apoptosis in mice bearing melanoma [22], lung cancer, or hepatoma [23].

### 62.2.3 Chemokines

The antitumor effect of CX3CL1 (also known as fractalkine), which is a chemoattractant for T cells and monocytes, has also been tested. MSCs expressing CX3CL1 induced both innate and adoptive immunity, inhibited lung metastases of melanoma, and prolonged survival of tumor-bearing mice [24].

### 62.2.4 Suicide genes

Suicide gene cancer therapy has been considered for the treatment of invasive tumors such as malignant glioma in the brain [25,26]. Many prodrug activation techniques that convert a nontoxic prodrug into a toxic antimetabolite are available for the selective killing of tumor cells. HSV-TK and CD, which confer sensitivity to GCV and 5-FU respectively, are being evaluated in clinical trials. When HSV-TK-expressing MSCs [27,28] or CD-expressing MSCs [29,30] were injected into tumor-bearing mice, the tumor volume was reduced through a bystander-mediated tumor cell killing following the administration of GCV or 5-FC. We have developed genetically modified MSCs that produce retroviral vectors that encode HSV-TK with the aim of augmenting the therapeutic efficacy of suicide cancer gene therapy [27]. MSCs isolated from the bone marrow of Sprague–Dawley rats were nucleofected with proviral plasmid DNA that expressed either HSV-TK alone (non-VP-MSCs), vesicular stomatitis virus-glycoprotein (VSV-G), protein-pseudotyped long-terminal-repeat-HSV-TK with Gag-pol and VSVG, or whole retroviral vector components. (Nucleofection is an electroporation-based transfection method that enables transfer of nucleic acids such as DNA and RNA into cells by applying a specific voltage and reagents.) Tumor growth was more efficiently suppressed after the injection of VP-MSCs compared with non-VP-MSCs. This efficacy was dependent on therapeutic gene amplification through the production of retrovirus progeny from MSCs and the transduction of tumor cells *in situ*.

### 62.2.5 Other approaches

The efficacy of other therapeutic genes, including NK4 [31] and TRAIL [32,33], has also been examined in various tumor models. NK4, a competitive antagonist of hepatocyte growth factor (HGF) and its receptor c-Met tyrosine kinase, is an internal fragment of HGF and is composed of the N-terminal and four kringle domains. Oncolytic virotherapy is emerging as a promising strategy for tumor treatment. MSCs can be used as carriers to deliver oncolytic viruses to tumor sites [34–36]. Experimentally, the injection of genetically modified MSCs can result in tumor growth inhibition, metastasis suppression, and prolonged survival.

## 62.3 Molecular mechanisms of mesenchymal stromal cell accumulation at tumor sites

As already described, the use of MSCs to deliver anticancer agents is an attractive novel cancer therapeutic strategy. This type of targeted therapy can reduce the systemic side effects of

anticancer agents by increasing their effective concentration at local tumor sites without elevating systemic concentrations. However, how and why MSCs accumulate at tumor sites remains poorly understood. Endothelial cells (ECs), pericytes, and stromal cells are all known to support tumor growth and contribute to the tumor microenvironment by producing various growth factors, including vascular endothelial growth factor-A, IL-8, transforming growth factor-β, epidermal growth factor, and platelet-derived growth factor [37–42]. MSCs can also act in a similarly supportive fashion. It can be speculated that MSCs, when they accumulate at tumor sites, differentiate into pericytes or cancer-associated fibroblasts, and can be involved in facilitating tumor growth by providing structural support to the tumor microenvironment [17,43,44]. Interestingly, breast cancer cells stimulate MSCs, and MSCs in turn support cancer cell invasion and metastasis by secreting the chemokine CCL5 (also known as RANTES) [45]. Conversely, MSCs can also induce apoptosis in tumor cells by blocking the phosphorylation of AKT [46] or preventing cell cycle progression [47]. Moreover, MSCs can produce Dickkopf 1 to attenuate the potential for tumor cell growth and malignancy [48]. Because MSCs have dual and opposing effects on tumor growth, modification with antitumor genes is required for therapeutic MSC-based cancer targeting. Furthermore, it is also necessary to promote more efficient MSC accumulation at tumor sites.

### 62.3.1 Migratory factors

If it becomes possible to increase the efficiency of MSC accumulation at tumor sites, MSCs could effectively target not only primary tumors but also metastatic lesions. It is thought that MSCs home to damaged tissues, such as injury or inflammation, by the release of inflammatory cytokines. Tumors contain a microenvironment consisting of many inflammatory cells [49]. This microenvironment promotes the recruitment of MSCs because of the various soluble factors that are secreted by both tumor and inflammatory cells, including tumor necrosis factor (TNF)-α, IL-6 [50,51], IL-8 [52,53], transforming growth factor-β [54], placental growth factor [55], platelet-derived growth factor [56], HGF [56], stromal-cell-derived factor-1 [56–58], matrix metalloproteinase (MMP) [59], chemokines [51,54], monocyte chemoattractant protein-1 (MCP-1) [53,60], and proinflammatory peptide LL-37 [61]. However, we found that although systemically injected MSCs accumulated at tumor sites, subcutaneously injected MSCs did not. We also compared the migration capacity of MSCs and fibroblasts toward growth factors and chemokines *in vitro* and found that the chemoattraction of fibroblasts toward these factors was stronger than that of MSCs [56]. These findings suggest that the mechanism of MSC accumulation cannot be solely explained by cytokine-mediated migration.

### 62.3.2 Interactions between mesenchymal stromal cells and endothelial cells

The tumors generated in the studies just described had tumor stroma with many blood vessels, and MSCs in particular accumulated at the boundaries between tumors and tumor stroma [56]. Furthermore, MSC accumulation at the tumor sites was only observed when cells were injected into the left ventricle of the heart. We therefore focused on MSC–EC adhesion to elucidate the mechanisms involved. Interestingly, the stimulation of MSCs by TNF-α enhanced the adhesion of MSCs to ECs *in vitro*. This adhesion could be partially inhibited by antibodies that block VCAM-1 and very late antigen-4 (VLA-4). It is well known that TNF-α can induce VCAM-1 expression via the NF-κB (nuclear factor kappa light chain-enhancer of activated B cells) signaling pathway [62,63]. Parthenolide has anti-inflammatory activities and can suppress NF-κB activity by inhibiting IκBα (inhibitor of kappa Bα) phosphorylation following stimulation by TNF-α [64,65], and parthenolide strongly inhibited TNF-α-induced VCAM-1 expression on MSCs [56]. *In vivo* imaging using luciferase-expressing MSCs showed that bioluminescent signals gradually increased at tumor sites in mice injected with untreated MSCs. However, we observed very weak signals at tumor sites in mice injected with parthenolide-treated MSCs. These findings suggest that NF-κB activity can regulate MSC accumulation at tumor sites by inducing VCAM-1 expression and subsequently promoting cellular interactions with tumor vessel ECs (Figure 62.2).

Although we focused on the role of TNF-α, other inflammatory cytokines, including IL-1β [66,67] and IFN-γ [68], can also induce VCAM-1 expression on target cells and might also be involved in MSC accumulation.

## 62.4 Considerations in the use of genetically engineered mesenchymal stromal cells in cancer therapy

As described, activation with TNF-α might be a critically important factor in MSC accumulation. TNF-α is a major inflammatory cytokine that has important roles in diverse cellular events, including cell survival, proliferation, differentiation, and death [69–72]. Numerous reports have documented elevated TNF-α levels in the serum or plasma of people with cancer, and TNF-α levels correlate closely with tumor progression and metastasis [69,73–75]. For example, TNF-α readily induces IL-6 and MCP-1 secretion by cancer-associated fibroblasts and normal fibroblasts, and it also has an indirect role in generating a prometastatic microenvironment. Furthermore, TNF-α is also released in tissues undergoing inflammation, including myocardial infarction [76,77] and GVHD [78]. MSCs accumulate in these inflamed tissues. Thus, proinflammatory cytokines also promote the homing of MSCs to these tissues, and MSC-based tissue-targeting strategies could be adapted for various inflammation-related disorders. Furthermore, MSCs can induce neovascularization and immunosuppression, thereby protecting tissues from disease-related damage.

For MSC-based cancer-targeted gene therapies it is thought that the therapeutic efficacy is directly related to the degree of

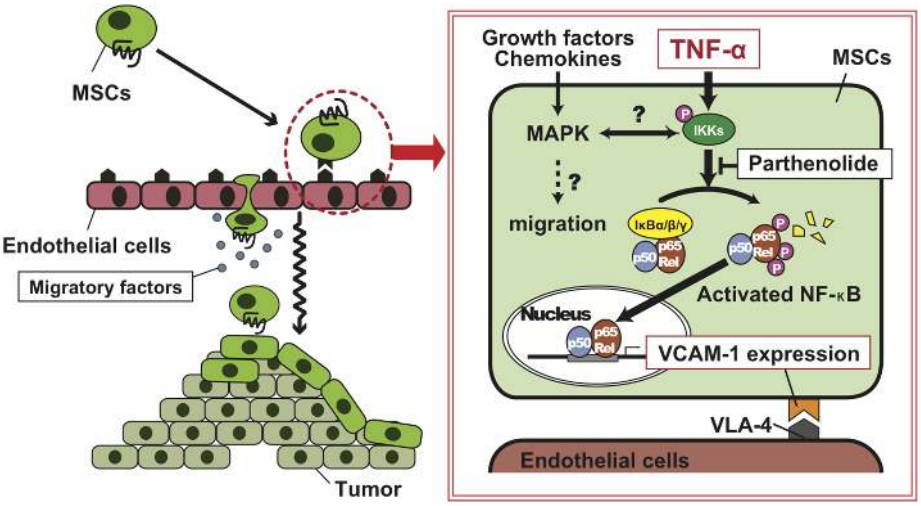

**Figure 62.2** A proposed mechanism for MSC accumulation at tumor sites. Growth factors and chemokines recruit MSCs to the tumor microenvironment. Inflammatory cytokines, such as TNF-α, stimulate MSCs and induce cell surface VCAM-1 expression. Next, activated MSCs attach to the tumor vasculature. Subsequently, migratory factors, such as chemokines or cytokines, enhance MSC migration. Finally, MSCs accumulate at tumor sites. IKKs: IκB kinases; MAPK: mitogen-activated protein kinase. (See color plate section.)

MSC accumulation at tumor sites. Data from our laboratory suggest that the combined use of NF-κB inhibitors, such as bortezomib [79], or TNF-α blocking agents [80], such as infliximab, etanercept, adalimumab, golimumab, and certolizumab, can reduce the therapeutic efficacy of genetically modified MSCs because of the inhibition of MSC accumulation at tumor sites. Interestingly, other data suggest that targeted approaches to neutralize TNF in patients with heart failure can result in exacerbated disease [81]. In contrast, tumor-specific TNF-α-inducing agents would be useful for enhancing therapeutic efficacy. Thus, further investigation is warranted for the identification of such agents to establish safer and more effective therapeutic strategies.

## 62.5 Summary and conclusions

Cellular and gene therapies represent promising new treatment strategies in medicine. Hematopoietic stem cells, lymphocytes, and MSCs can all be used as cell sources for use in such therapies. Strategies for gene therapy are often based on those of cell therapy, and some examples are expected to be clinically implemented in the near future. MSCs can be used to improve stromal cell engraftment and the acceleration of hematopoietic reconstitution based on their hematopoiesis-supporting ability (see Chapter 32). Furthermore, MSCs may be useful in the treatment of severe GVHD because of their immunosuppressive ability. This application is also based on their ability to home to damaged and inflammatory tissues. Interestingly, MSCs also show tumor-homing ability, allowing them to be used to directly deliver anticancer genes to tumors. MSC accumulation at tumor sites is related to the migratory capacity of MSCs toward growth factors and chemokines, but also to MSC–EC adhesion following stimulation by TNF-α (Figure 61.2). Furthermore, NF-κB activity can regulate MSC accumulation at tumor sites through the induction of VCAM-1 expression, which results in interactions with tumor blood vessel endothelial cells. Although MSCs are useful as cellular vehicles for cancer-targeted gene therapy, strategies to increase MSC accumulation are required to enhance their therapeutic efficacy. Thus, strategies to enhance local accumulation of MSCs should also be developed.

## 63.1 *In vitro* laboratory studies

Note, some reports in this section include both *in vitro* and *in vivo* studies.

- **Multipotent human stromal cells isolated from cord blood, term placenta and adult bone marrow show distinct differences in gene expression pattern.** Matigian *et al.* [1].
- **CDH1 and IL1-beta expression dictates FAK and MAPKK-dependent cross-talk between cancer cells and human mesenchymal stem cells.** Al-toub *et al.* [2].
- **Electrical stimulation of human mesenchymal stem cells on conductive nanofibers enhances their differentiation toward osteogenic outcomes.** Hardy *et al.* [3]. The preparation of conductive fiber-based bone tissue scaffolds (nonwoven mats of electrospun polycaprolactone with an interpenetrating network of polypyrrole and polystyrenesulfonate) that enabled the electrical stimulation of human mesenchymal stem cells to enhance their differentiation toward osteogenic outcomes was described.
- **Genome-wide microRNA and gene analysis of mesenchymal stem cell chondrogenesis identifies an essential role and multiple targets for miR-140-5p.** Barter *et al.* [4].
- **Functional restoration of amyotrophic lateral sclerosis patient-derived mesenchymal stromal cells through inhibition of DNA methyltransferase.** Oh *et al.* [5] examined the correlation between excessive DNA methyltransferase expression and functional decline in mesenchymal stromal cells isolated from amyotrophic lateral sclerosis (ALS) patients.
- **Adipose-derived mesenchymal stem cells promote cell proliferation and invasion of epithelial ovarian cancer.** Chu *et al.* [6] investigated the impact of human adipose-derived mesenchymal stem cells derived from the omentum of normal donors on human epithelial ovarian cancer cells *in vitro* and *in vivo*.
- **Cultured human adipose tissue pericytes and mesenchymal stromal cells display a very similar gene expression profile.** Da Silva Meirelles *et al.* [7] found that both mesenchymal stromal cells and cultured pericytes were able to differentiate along mesenchymal pathways *in vitro*, displayed an essentially identical surface immunophenotype and exhibited the ability to suppress $CD3^+$ lymphocyte proliferation *in vitro*.
- **Pre-stimulation with FGF-2 increases *in vitro* functional coupling of mesenchymal stem cells with cardiac cells.** Preda *et al.* [8] investigated how pretreatment with growth factors modulates mesenchymal stem cell ability to integrate into the host tissue after transplantation, with particular focus on the expression of Cx43 and its cellular distribution.
- **Interleukin-17A-induced human mesenchymal stem cells are superior modulators of immunological function.** Sivanathan *et al.* [9] modified human bone-marrow-derived mesenchymal stem cells with interleukin (IL)-17A to enhance T cell immunosuppression but not their immunogenicity.
- **Human bone marrow- and adipose-mesenchymal stem cells secrete exosomes enriched in distinctive miRNA and tRNA species.** Baglio *et al.* [10] characterized the full small RNAome of mesenchymal stem cell-produced exosomes. They set up a protocol for isolating exosomes released by early passage adipose- and bone marrow-derived MSCs and characterized them by electron microscopy, protein analysis and small RNA-sequencing.

- **ATF4 licenses C/EBPβ activity in human mesenchymal stem cells primed for adipogenesis.** Cohen *et al.* [11] demonstrated that C/EBPβ bridges the transcriptional programs in naive, confluent cells and early differentiating pre-adipocytes. Moreover, they suggested that homo- and heterodimer formation poise C/EBPβ to execute diverse and stage-specific transcriptional programs by exploiting an expanded motif repertoire.
- **hMSC-derived VEGF release triggers the chemoattraction of alveolar osteoblasts.** Proksch *et al.* [12] identified secreted osteoprotegerin and vascular endothelial growth factor (VEGF) as potential chemoattractants of human MSC-directed osteoblast chemotaxis.
- **Altered mesenchymal niche cells impede generation of normal hematopoietic progenitor cells in leukemic bone marrow.** Lim *et al.* [13] focused on murine bone mesenchymal stem cells and their supporting function for normal hematopoietic cells in Notch1-induced acute T cell lymphocytic leukemia (T-ALL) mice. They demonstrated that the proliferative capability and differentiation potential of T-ALL mesenchymal stem cells were impaired due to accelerated cellular senescence. RNA-seq analysis revealed significant transcriptional alterations in leukemic mesenchymal stem cells. Osteoprotegerin was identified as a cytokine able to improve the function of T-ALL mesenchymal stem cells and to enhance normal hematopoietic progenitor cell output via the p38/ERK pathway.
- **Bone marrow-derived mesenchymal stromal cells differ in their attachment to fibronectin-derived peptides from term placenta-derived mesenchymal stromal cells.** Maerz *et al.* [14].
- **A molecular classification of human mesenchymal stromal cells.** Rohart *et al.* [15] addressed the question of a molecular classification of mesenchymal stromal cells with a large integrative analysis of many public mesenchymal stromal cell datasets. They derived a sparse classifier (the Rohart mesenchymal stromal cell test) that accurately distinguishes mesenchymal stromal cell from non-mesenchymal stromal cell samples with >97% accuracy on an internal training set of 635 samples from 41 studies derived on 10 different microarray platforms. The classifier was validated on an external test set of 1291 samples from 65 studies derived on 15 different platforms, with >95% accuracy. The genes that contribute to the mesenchymal stromal cell classifier formed a protein-interaction network that included known mesenchymal stromal cell markers. Further evidence of the relevance of this new mesenchymal stromal cell panel came from the high number of Mendelian disorders associated with mutations in more than 65% of the network. These result in mesenchymal defects, particularly impacting on skeletal growth and function. The Rohart mesenchymal stromal cell test is a simple *in silico* test that accurately discriminates mesenchymal stromal cells from fibroblasts, other adult stem/progenitor cell types or differentiated stromal cells. It has been implemented in the www.stemformatics.org resource, to assist researchers wishing to benchmark their own mesenchymal stromal cell datasets or data from the public domain. The code is available from the CRAN repository and all data used to generate the mesenchymal stromal cell test are available to download via the Gene Expression Omnibus or the Stemformatics resource.
- **Mesenchymal stromal cells induce peculiar alternatively activated macrophages capable of dampening both innate and adaptive immune responses.** Chiossone *et al.* [16] analyzed the functional outcome of the interactions between mesenchymal stromal cells and monocytes/macrophages. They showed that mesenchymal stromal cells supported the survival of monocytes that underwent differentiation into macrophages, in the presence of macrophage colony-stimulating factor. However, mesenchymal stromal cells skewed their polarization toward a peculiar M2-like functional phenotype ($M^{MSC}$), through a prostaglandin $E_2$ ($PGE_2$)-dependent mechanism. $M^{MSC}$ were characterized by high expression of scavenger receptors, increased phagocytic capacity, and high production of IL-10 and transforming growth factor (TGF)-β. These cytokines contributed to the immunoregulatory properties of $M^{MSC}$, which differed from those of typical IL-4-induced macrophages (M2).
- **Vav1 regulates mesenchymal stem cell differentiation decision between adipocyte and chondrocyte via Sirt1.** Qu *et al.* [17] found that Vav1, a guanine nucleotide exchange factor for Rho GTPase, was highly expressed in mesenchymal stem cells. Loss of Vav1 in mesenchymal stem cells led to spontaneous adipogenic but impaired chondrogenic differentiation, and accordingly Vav1 null mice displayed an increase in fat content and a decrease in cartilage. Conversely, ectopic expression of Vav1 in mesenchymal stem cells reversed this phenotype, and led to enhanced MSC differentiation into chondrocyte but retarded adipogenesis. Mechanistically, loss of Vav1 reduced the level of Sirt1, which was responsible for an increase of acetylated peroxisome proliferator-activated receptor-γ. As acetylation activates peroxisome proliferator-activated receptor-γ, it increased C/EBPα expression and promoted adipogenesis. On the other hand, loss of Vav1 resulted in an increase of acetylated Sox9, a target of Sirt1.
- **Mast cells promote proliferation and migration and inhibit differentiation of mesenchymal stem cells through PDGF.** Nazari *et al.* [18] found that mast cells promote mesenchymal stem cell proliferation and migration by suppressing their myogenic differentiation. Mast cells accomplish this via activation of the platelet-derived growth factor pathway, down-regulation of miR-145/143, and modulation of the myocardin–Klf4 axis. The findings in this study suggest a potential role for mesenchymal stem cell–mast cell interaction in the infarcted heart where mast cells may inhibit mesenchymal stem cells from differentiation and promote their proliferation whereby increased cardiac mesenchymal stem cell accumulation promotes eventual cardiac regeneration after mast cells cease activity.
- **Growth factors cross-linked to collagen microcarriers promote expansion and chondrogenic differentiation of human**

**mesenchymal stem cells.** Bertolo *et al.* [19]. In order to enhance cell attachment and produce a cost-effective cell culture solution with local stimulation of cells, basic fibroblast growth factor (bFGF) or TGF-β1 were covalently immobilized on microcarriers either by 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide/*N*-hydroxysuccinimide (EDC/NHS) or riboflavin/ultraviolet (RB/UV) light-mediated crosslinking. Collagen microcarriers cross-linked with bFGF or TGF-β1 were used for expansion and chondrogenic differentiation of human mesenchymal stem cells. Crosslinking strengthened the collagen structure of the microcarriers and reduced collagenase-mediated degradation. Mesenchymal stem cells proliferated effectively on microcarriers cross-linked with bFGF, especially by EDC/NHS crosslinking. Chondrogenic differentiation of mesenchymal stem cells was induced by TGF-β1 cross-linked on microcarriers, promoting gene expression and protein accumulation of aggrecan, collagen type I and type II, as well as proteoglycans. Crosslinking by RB/UV enhanced chondrogenesis more than any other group. In addition, crosslinking reduced scaffold shrinkage exerted by mesenchymal stem cells during chondrogenesis, a desirable feature for microcarriers if used as a tissue defect filler.

- **Clusterin/Akt up-regulation is critical for GATA-4 mediated cytoprotection of mesenchymal stem cells against ischemia injury.** Yu *et al.* [20] found that clusterin expression was upregulated in mesenchymal stem cells overexpressing GATA-4 ($MSC^{GATA\text{-}4}$) compared with control mesenchymal stem cells transfected with empty-vector ($MSC^{Null}$). $MSC^{GATA\text{-}4}$ were tolerant to 72 h of hypoxia exposure, as shown by reduced lactate dehydrogenase release and higher uptake of the tetrazolium compound MTs. This protection was abrogated by transfecting Clu-siRNA into $MSC^{GATA\text{-}4}$. Second, they found that exogenous clusterin significantly decreased lactate dehydrogenase release and increased mesenchymal stem cell survival in a hypoxic environment. Moreover, mitochondrial membrane potential was maintained and caspase 3/7 activity was reduced by clusterin in a concentration-dependent manner. Third, they found that p-Akt expression in mesenchymal stem cells was upregulated following pretreatment with clusterin, with no change in total Akt. Moreover, cytoprotection mediated by clusterin was partially abrogated by the Akt inhibitor LY294002.
- **Three-dimensional bioprinting of thick vascularized tissues.** Kolesky *et al.* [21] describe a multimaterial three-dimensional (3D) bioprinting method that enables the creation of thick human tissues (>1 cm) replete with an engineered extracellular matrix, embedded vasculature, and multiple cell types. These 3D vascularized tissues could be actively perfused with growth factors for long durations (>6 weeks) to promote differentiation of human mesenchymal stem cells toward an osteogenic lineage *in situ*. The ability to construct and perfuse 3D tissues that integrate parenchyma, stroma, and endothelium is a major step toward creating human tissues for *ex vivo* and *in vivo* applications.
- **MiR-708 promotes steroid-induced osteonecrosis of femoral head, suppresses osteogenic differentiation by targeting SMAD3.** Hao *et al.* [22] made the hypothesis that corticosteroid-induced osteonecrosis of the femoral head (ONFH), a serious complication of corticosteroid use, was related to the differential expression of miRs in the mesenchymal stem cells of patients with ONFH. Mesenchymal stem cells were collected from the bone marrow of patients with ONFH. Samples were assigned to either those in a group that had received corticosteroids or those who had not (control group) in a 1 : 1 ratio. They used microRNA microarray analysis and real-time polymerase chain reaction to identify differentially expressed miRs. They also induced normal mesenchymal stem cells with corticosteroids to verify the differential expression. Subsequently, they selected some of the miRs for further studies, including microRNA target and pathway prediction, and functional analysis. They discovered that miR-708 was upregulated in ONFH patients and corticosteroid-treated mesenchymal stem cells. SMAD3 was identified as a direct target gene of miR-708, and functional analysis demonstrated that miR-708 could markedly suppress osteogenic differentiation and adipogenesis differentiation of mesenchymal stem cells. Inhibition of miR-708 rescued the suppressive effect of glucocorticoid on osteonecrosis. Therefore, they concluded that corticosteroid use results in overexpression of miR-708 in mesenchymal stem cells, and therefore targeting miR-708 may serve as a novel therapeutic biomarker for the prevention and treatment of ONFH.
- **Epac activation regulates human mesenchymal stem cells migration and adhesion.** Yu *et al.* [23] studied the role of Exchange protein directly activated by cyclic adenosine monophosphate (Epac), a novel protein discovered in the cyclic adenosine monophosphate signaling pathway that may have a potential role in regulating cell adhesion and migration by triggering the downstream Rap family signaling cascades. Their study evaluated the role of Epac in the homing of human mesenchymal stem cells. They confirmed that human mesenchymal stem cells expressed functional Epac and its activation enhanced the migration and adhesion of human mesenchymal stem cells significantly. Epac activation was further found to contribute directly to the chemotactic responses induced by stromal-cell-derived factor-1 (SDF-1), a known chemokine in regulating human mesenchymal stem cell homing. These findings suggested that Epac is connected to the SDF-1 signaling cascades by promoting mesenchymal stem cell adhesion and migration.

## 63.2 Preclinical *in vivo* animal studies

Note, some reports in this section include both *in vitro* and *in vivo* studies.

- **Mesenchymal stromal cells prevent allostimulation *in vivo* and control checkpoints of Th1 priming: migration of**

**human DC to lymph nodes and NK cell activation.** Consentius *et al.* [24].

- **A comparative study of the therapeutic potential of mesenchymal stem cells and limbal epithelial stem cells for ocular surface reconstruction.** Holan *et al.* [25].
- **Leptin receptor promotes adipogenesis and reduces osteogenesis by regulating mesenchymal stromal cells in adult bone marrow.** Yue *et al.* [26]. Skeletal stem cells that are the major source of osteoblasts and adipocytes in adult bone marrow express leptin receptor (LepR). To test whether LepR regulates skeletal stem cell function, the authors conditionally deleted Lepr from limb bone marrow stromal cells, but not from the axial skeleton or hypothalamic neurons, using Prx1-Cre. Prx1-Cre;Lepr$^{fl/fl}$ mice exhibited normal body mass and normal hematopoiesis. However, limb bones from Prx1-Cre;Lepr$^{fl/fl}$ mice exhibited increased osteogenesis, decreased adipogenesis, and accelerated fracture healing. Leptin increased adipogenesis and reduced osteogenesis by activating Jak2/Stat3 signaling in bone marrow stromal cells. A high-fat diet increased adipogenesis and reduced osteogenesis in limb bones from wild-type mice, but not from Prx1-Cre;Lepr$^{fl/fl}$ mice. This reflected local effects of LepR on osteogenesis and adipogenesis by bone marrow stromal cells and systemic effects on bone resorption. Leptin/LepR signaling regulates adipogenesis and osteogenesis by mesenchymal stromal cells in the bone marrow in response to diet and adiposity.
- **Useful properties of undifferentiated mesenchymal stromal cells and adipose tissue as the source in liver-regenerative therapy studied in an animal model of severe acute fulminant hepatitis.** Manzini *et al.* [27].
- **Human adipose-derived mesenchymal stem cells modulate experimental autoimmune arthritis by modifying early adaptive T cell responses.** Lopez-Santalla *et al.* [28].
- **A computer-designed scaffold for bone regeneration within cranial defect using human dental pulp stem cells.** Kwon *et al.* [29] used a computer-designed, solvent-free scaffold and human dental pulp stem cells (DPSCs) to regenerate new bone in cranial bone defects. They used solid freeform fabrication with biodegradable polyesters (MPEG–(PLLA–co-PGA–co-PCL) (PLGC)) to fabricate a computer-designed scaffold. The solid freeform fabrication technology gave quick and reproducible results. To assess bone tissue engineering *in vivo*, the computer-designed, circular PLGC scaffold was implanted into full-thickness cranial bone defects and monitored by microcomputed tomography and histology of the *in vivo* tissue-engineered bone. New bone formation of more than 50% was observed by micro-computed tomography and histology only with the use of the PLGC scaffold with human DPSCs and osteogenic factors. The PLGC scaffold gradually degraded, as evidenced by the fluorescent-labeled PLGC scaffold, which provided information to track biodegradation of the implanted PLGC scaffold.
- **Mesenchymal stem cell expression of SDF-1β synergizes with BMP-2 to augment cell-mediated healing of critical-sized mouse calvarial defects.** Herberg *et al.* [30] suggested that SDF-1β provides synergistic effects supporting BMP-2-induced, BMSC-mediated bone formation and appears suitable for optimization of bone augmentation in combination therapy protocols *in vivo*.
- **Mouse white adipose tissue-derived mesenchymal stem cells gain pericentral and periportal hepatocyte features after differentiation *in vitro*, which are preserved *in vivo* after hepatic transplantation.** Winkler *et al.* [31]. Adipose tissue-derived mesenchymal stem cells were isolated from immunodeficient C57BL/6 (B6.129S6-Rag2tm1FwaPrf1tm1Clrk) mice and differentiated into the hepatocytic phenotype by applying a simple protocol. Their physiological and metabolic functions were analyzed *in vitro* and after hepatic transplantation *in vivo*. Mesenchymal stem cells changed their morphology from a fibroblastoid into shapes of osteocytes, chondrocytes, adipocytes, and hepatocytes. Typical for mesenchymal stem cells, hematopoietic marker genes were not expressed. CD90, which is not expressed on mature hepatocytes, decreased significantly after hepatocytic differentiation. Markers indicative for liver development (like hepatic nuclear factor 4 alpha) or for perivenous hepatocyte specification (like cytochrome P450 subtype 3a11) and CD26 were significantly elevated. Periportal hepatocyte-specific markers (like carbamoylphosphate synthetase-1, the entry enzyme of the urea cycle) were upregulated. Consequently, cytochrome P450 enzyme activity and urea synthesis increased significantly to values comparable to cultured primary hepatocytes. Both perivenous and periportal qualities were preserved after hepatic transplantation and integration into the host parenchyma.
- **Differential expression of adhesion-related proteins and MAPK pathways leads to suitable osteoblast differentiation of human mesenchymal stem cell subpopulations.** Leyva-Leyva *et al.* [32] analyzed the expression profiles of adhesion-related proteins during osteoblastic differentiation of two human MSCs subpopulations ($CD105^+$ and $CD105^-$) and proposed a strategy for assembling bone grafts based on its adhesion ability. *In vitro* experiments of osteogenic differentiation in $CD105^-$ cells showed superior adhesion efficiency and twofold increase of α-actinin expression compared with $CD105^+$ cells at the maturation stage. Levels of activated β1-integrin increased in $CD105^-$ cells during the process. Additionally, the $CD105^-$ subpopulation showed a threefold increase of phosphorylated FAKY397 compared with $CD105^+$ cells. An *in vivo* trial demonstrated that grafts containing $CD105^-$ cells showed osteocytes embedded in a mineralized matrix, promoted adequate graft integration, increased host vascular infiltration, and produced efficient intramembranous repair. In contrast, grafts containing $CD105^+$ cells showed deficient endochondral ossification and fibrocartilaginous tissue.
- **Adipose-derived mesenchymal stem cells ameliorate ulcerative colitis through miR-1236 negatively regulating the expression of retinoid-related orphan receptor gamma.** Zhang *et al.* [33] investigated the effect of adipose-derived

mesenchymal stem cells (ASCs) on 2,4,6-trinitrobenzenesulfonic acid (TNBS)-induced ulcerative colitis in rat colon tissues. Qualitative real-time polymerase chain reaction and immunofluorescence analyses were performed to monitor the expression of miR-1236 and its target molecule, retinoid-related orphan receptor γ (RORγ). Regulation of the expression of RORγ by miR-1236 was assessed using luciferase reporter construct assays and miR-1236 mimic transfection. The relationship between miR-1236 and RORγ was further investigated in HT29 cells induced by tumor necrosis factor (TNF)-α. ASCs highly ameliorated ulcerative colitis and decreased the inflammation markers in rats with TNBS-induced ulcerative colitis. In addition, ASCs upregulated the expression of miR-1236 and decreased the expression of RORγ in the TNBS-induced rat model of ulcerative colitis. The luciferase reporter assay and bioinformatic analysis demonstrated that the expression of RORγ was directly targeted and regulated by miR-1236. Specifically, the expression of RORγ was suppressed by miR-1236 mimic and enhanced by miR-1236 inhibitor. It was demonstrated that exogenous miR-1236 mimic could inhibit the expression of RORγ in HT29 cell induced by TNF-α. ASCs effectively alleviated ulcerative colitis in rats with the expression of miR-1236 alteration, and miR-1236 may play important roles in ulcerative colitis by down-regulating the expression of RORγ.

- **Cartilage repair using composites of human umbilical cord blood-derived mesenchymal stem cells and hyaluronic acid hydrogel in a minipig model.** Ha *et al.* [34] confirmed the consistent cartilage regeneration potential of human umbilical cord blood-derived mesenchymal stem cells in a pig model using three different cell lines. The cellular characteristics of the human umbilical cord blood-derived mesenchymal stem cells influenced the degree of cartilage regeneration potential.
- **Mesenchymal stem cells regulate melanoma cancer cells extravasation to bone and liver at their perivascular niche.** Correa *et al.* [35] reported that local mesenchymal stem cells, acting as pericytes, regulate the extravasation of melanoma cells specifically to murine bone marrow and liver, the two commonest sites for melanoma metastases.
- **Bone marrow-derived mesenchymal stem cells co-expressing interleukin-18 and interferon-β exhibit potent antitumor effect against intracranial glioma in rats.** Xu *et al.* [36]. Bone-marrow-derived MSCs were genetically engineered to express IL-18 and interferon (IFN)-β by transfection of recombinant lentivirus-mediated gene transfer. These cells significantly prolonged the survival and inhibited tumor growth in a rat intracranial glioma model.
- **Human mesenchymal stem cells genetically engineered to overexpress brain-derived neurotrophic factor improve outcomes in Huntington's disease mouse models.** Double-blinded studies were performed by Pollock *et al.* [37] to examine the effects of intrastriatally transplanted human mesenchymal stem cell/brain-derived neurotrophic factor (BDNF) on disease progression in two strains of immune-suppressed HD transgenic mice: YAC128 and R6/2. Mesenchymal stem cell/BDNF treatment decreased striatal atrophy in YAC128 mice. Mesenchymal stem cell/BDNF treatment also significantly reduced anxiety as measured in the open-field assay. Both mesenchymal stem cell and mesenchymal stem cell/BDNF treatments induced a significant increase in neurogenesis-like activity in R6/2 mice. Mesenchymal stem cell/BDNF treatment also increased the mean lifespan of the R6/2 mice.
- **Inhibition of IL-1R1/MyD88 signalling promotes mesenchymal stem cell-driven tissue regeneration.** Because toll-like receptors and IL-1R1 have been shown to influence the repair process of various tissues, Martino *et al.* [38] explored their role during bone regeneration, seeking to design regenerative strategies integrating a control of their signaling. They showed that IL-1R1/MyD88 signaling negatively regulates bone regeneration in the mouse. Furthermore, IL-1β, which is released at the bone injury site, inhibited the regenerative capacities of mesenchymal stem cells. Mechanistically, IL-1R1/MyD88 signaling impaired mesenchymal stem cell proliferation, migration, and differentiation by inhibiting the Akt/GSK-3β/β-catenin pathway. Lastly, as a proof of concept, they engineered a mesenchymal stem cell delivery system integrating inhibitors of IL-1R1/MyD88 signaling. Using this strategy, they considerably improved mesenchymal-stem-cell-based bone regeneration in the mouse, demonstrating that this approach may be useful in regenerative medicine applications.
- **Systemic mesenchymal stromal cell transplantation prevents functional bone loss in a mouse model of age-related osteoporosis.** Kiernan *et al.* [39], using minimally expanded exogenous mesenchymal stromal cells injected systemically into a mouse model of human age-related osteoporosis, showed long-term engraftment and markedly increased bone formation. This led to improved bone quality and turnover and, importantly, sustained microarchitectural competence. These data establish proof of concept that mesenchymal stromal cell transplantation may be used to prevent or treat human age-related osteoporosis.
- **Intra-articular injection of synovial mesenchymal stem cells improves cartilage repair in a mouse injury model.** Mak *et al.* [40] isolated a Sca-1 positive, chondrogenesis-capable population of mouse synovial mesenchymal stem cells from C57BL/6 and MRL/MpJ "super-healer" strains. Intra-articular injection of $Sca1^+$ green fluorescent $protein^+$ synovial cells from C57BL/6 or MRL/MpJ into C57BL/6 mice following cartilage injury led to increased cartilage repair by 4 weeks after injury. Green fluorescent protein expression was detected in the injury site at 2 weeks, but not 4 weeks after injury. These results suggest that synovial stem/progenitor cells, regardless of strain background, have beneficial effects when injected into an injured joint.
- **Delivery of mesenchymal stem cells in biomimetic engineered scaffolds promotes healing of diabetic ulcers.** Assi *et al.* [41]. Rolled scaffolds containing mesenchymal stem cells

were hypoxic and induced mesenchymal stem cell synthesis and secretion of VEGF. Diabetic mice with wounds treated with rolled scaffolds containing mesenchymal stem cells showed increased healing compared with controls. Histologic examination showed increased cellular proliferation, increased VEGF expression and capillary density, and increased numbers of macrophages, fibroblasts, and smooth muscle cells. Addition of laminin to the collagen scaffold enhanced these effects

- **Human mesenchymal stromal cells reduce influenza A H5N1-associated acute lung injury *in vitro* and *in vivo*.** Chan *et al.* [42] found that, *in vitro*, influenza A/H5N1 infection impaired alveolar fluid clearance more than did seasonal virus, mimicking its greater severity in patients. They demonstrated that this impairment was mediated by the release of soluble factors from infected cells, leading to downregulation of alveolar sodium and chloride transporters. Mesenchymal stromal cells prevented or reduced this effect *in vitro* and *in vivo* in A/H5N1-infected mice. These cells thus provide a potentially effective treatment for acute lung injury in severe influenza.
- **A novel therapeutic approach using mesenchymal stem cells to protect against *Mycobacterium abscessus*.** Kim *et al.* [43] explored the use of mesenchymal stem cells as a novel therapeutic strategy against *Mycobacterium abscessus*, which is the most drug-resistant and difficult-to-treat mycobacterial pathogen. The systemic intravenous injection of mesenchymal stem cells not only improved mouse survival but also enhanced bacterial clearance in the lungs and spleen. Additionally, mesenchymal stem cells enhanced IFN-γ, TNF-α, IL-6, monocyte chemoattractant protein-1, nitric oxide (NO), and $PGE_2$ production and facilitated $CD4^+/CD8^+$ T cell, $CD11b^{high}$ macrophage and monocyte recruitment in the lungs of *M. abscessus*-infected mice. To precisely elucidate the functions of mesenchymal stem cells in *M. abscessus* infection, an *in vitro* macrophage infection system was used. Mesenchymal stem cells caused markedly increased NO production via nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) activation in *M. abscessus*-infected macrophages cultured in the presence of IFN-γ. Inhibiting NO or NF-κB signaling using specific inhibitors reduced the antimycobacterial activity of mesenchymal stem cells. Furthermore, the cellular crosstalk between TNF-α released from IFN-γ-stimulated *M. abscessus*-infected macrophages and $PGE_2$ produced by mesenchymal stem cells was necessary for the mycobacterial-killing activity of the macrophages. Finally, the importance of increased NO production in response to mesenchymal stem cell administration was confirmed in the mouse *M. abscessus* infection model. These results suggest that mesenchymal stem cells may offer a novel therapeutic strategy for treating this drug-resistant mycobacterial infection by enhancing the bacterial-killing power of macrophages.
- **Human amniotic mesenchymal stem cells alleviate lung injury induced by ischemia and reperfusion after cardiopulmonary bypass in dogs.** Qiang *et al.* [44] considered that transplantation of mesenchymal stem cells may inhibit pathological immune processes contributing to ischemia–reperfusion (I–R) injury in the lung. This study aimed to assess the capacity of human amniotic mesenchymal stem cells (hAMSCs) to ameliorate I–R injury in a dog model of cardiopulmonary bypass (CPB). Dissociated hAMSCs were cultured *ex vivo* and their immunophenotypes were assessed by flow cytometry and immunohistochemistry. A dog model of CPB was established by surgical blockage of the aorta for 1 h. Dogs either underwent mock surgery (sham group), CPB (model group), or CPB followed by the femoral injection of $2 \times 10^7$ hAMSCs ($n = 6$). Anti-human nuclei staining revealed hAMSCs in the lungs 3 h after surgery. The oxygen index (OI) and respiratory index (RI) of arterial blood were measured using a biochemical analyzer. Venous blood TNF-α, IL-8, matrix metallopeptidase (MMP)-9, and IL-10 concentrations were measured by enzyme-linked immunosorbent assay. Pathological changes in the lung were assessed by light microscopy. Third-generation cultured hAMSCs expressed high levels of CD29, CD44, CD49D, CD73, and CD166 levels, but low CD34 or CD45 amounts and their cytoplasm contained vimentin. In CPB model animals the OI was elevated and the RI was reduced. TNF-α, IL-8, and MMP-9 levels were elevated, and IL-10 levels reduced within 3 h ($P < 0.05$), but hAMSC transplantation significantly ameliorated these changes ($P < 0.05$). Pathological changes observed in the hAMSC group were significantly less severe than those in the CPB group. The authors concluded that hAMSC transplantation can downregulate proinflammatory factors and reduce MMP-9 levels, while upregulating the anti-inflammatory molecule IL-10, thus reducing I–R lung injury in this dog model of CPB.
- **Allogeneic mesenchymal stem cells in combination with hyaluronic acid for the treatment of osteoarthritis in rabbits.** Chiang *et al.* [45]. The purpose of this study was to investigate the effects of the intra-articular injection of allogeneic mesenchymal stem cells in an *in vivo* anterior cruciate ligament transection (ACLT) model of osteoarthritis in rabbits. Allogeneic bone-marrow-derived mesenchymal stem cells were isolated and cultured under hypoxic conditions (1% $O_2$). Eight weeks after ACLT, MSCs suspended in hyaluronic acid (HA) were injected into the knees while the contralateral knees were injected with HA alone. Additional controls consisted of a sham operation group as well as an untreated osteoarthritis group. The tissues were analyzed by macroscopic examination as well as histologic and immunohistochemical methods at 6 and 12 weeks after transplantation. At 6 and 12 weeks the joint surface showed less cartilage loss and surface abrasion after mesenchymal stem cell injection compared with the tissues receiving HA injection alone. Significantly better histological scores and cartilage content were observed with mesenchymal stem cell transplantation. Furthermore, engraftment of allogenic mesenchymal stem cells was evident in surface cartilage. The authors concluded

that injection of allogeneic mesenchymal stem cells reduced the progression of osteoarthritis *in vivo*.

- **Quantitative evaluation of human bone mesenchymal stem cells rescuing fulminant hepatic failure in pigs.** Shi *et al.* [46] used an in-house large animal (pig) model of rescue of fulminant hepatic failure (FHF) by human bone marrow mesenchymal stem cells and profiled the cells' activities. The control and transplantation groups of pigs ($n = 15$ per group) both received a D-galactosamine (D-Gal) injection (1.5 g/kg). The transplantation group received mesenchymal stem cells via intraportal vein infusion ($3 \times 10^6$ cells/kg) immediately after D-Gal administration. The stem cell recipient interactions were quantitatively evaluated by biochemical function, cytokine array, metabolite profiling, transcriptome sequencing, and immunohistochemistry. All pigs in the control group died within an average of 3.22 days, whereas 13/15 pigs in the transplantation group lived >14 days. The cytokine array and metabolite profiling analyses revealed that mesenchymal stem cell transplantation suppressed D-Gal-induced life-threatening cytokine storms and stabilized FHF within 7 days, while human-derived hepatocytes constituted only ~4.5% of the pig hepatocytes. The functional synergy analysis of the observed profile changes indicated that the implanted mesenchymal stem cells altered the pigs' cytokine responses to damage through paracrine effects. Delta-like ligand 4 was validated to assist liver restoration in both pig and rat FHF models.
- **Mesenchymal stromal cell–mediated neuroprotection and functional preservation of retinal ganglion cells in a rodent model of glaucoma.** Mead *et al.* [47] stated that glaucoma is a leading cause of irreversible blindness involving loss of retinal ganglion cells (RGCs), that mesenchymal stromal cells have shown promise as a paracrine-mediated therapy for compromised neurons but that it is unknown whether dental pulp stem cells (DPSCs) are effective as a cellular therapy in glaucoma and how their hypothesized influence compares with other more widely researched mesenchymal stromal cell sources. Their study aimed to compare the efficacy of adipose-derived stem cells, bone-marrow-derived mesenchymal stromal cells (BMSCs) and DPSCs in preventing the loss of RGCs and visual function when transplanted into the vitreous of glaucomatous rodent eyes. Thirty-five days after induction of raised intraocular pressure followed by intravitreal mesenchymal stromal cell transplantation, $Brn3a^+$ RGC numbers, retinal nerve fiber layer thickness (RNFL), and RGC function were evaluated by immunohistochemistry, optical coherence tomography, and electroretinography respectively. Control glaucomatous eyes that were sham-treated with heat-killed DPSCs had a significant loss of RGC numbers, RNFL thickness, and function compared with intact eyes. BMSCs and, to a greater extent, DPSCs provided significant protection from RGC loss and RNFL thinning and preserved RGC function.
- **Stem cells of the suture mesenchyme in craniofacial bone development, repair and regeneration.** Maruyama *et al.* [48] explored the biology and therapeutic aspects of the cells of the suture mesenchyme. The suture mesenchyme serves as a growth center for calvarial morphogenesis and has been postulated to act as the niche for skeletal stem cells. Aberrant gene regulation causes suture dysmorphogenesis, resulting in craniosynostosis, one of the most common craniofacial deformities. Owing to various limitations, especially the lack of suture stem cell isolation, reconstruction of large craniofacial bone defects remains highly challenging. In this article the authors provided the first evidence for an Axin2-expressing stem cell population with long-term self-renewing, clonal expanding, and differentiating abilities during calvarial development and homeostastic maintenance. These cells, which reside in the suture midline, were found to contribute directly to injury repair and skeletal regeneration in a cell autonomous fashion. These findings demonstrate the identity of these cells as skeletal stem cells with innate capacities to replace the damaged skeleton and should permit further elucidation of the biology of stem-cell-mediated craniofacial skeletogenesis, leading to the elucidation of the complex nature of congenital disease and the use of these cells in regenerative medicine.
- **Mesenchymal stem cells alleviate LPS-induced acute lung injury in mice by mir-142a-5p-controlled pulmonary endothelial cell autophagy.** Zhou and You [49] found that mesenchymal stem cell transplantation significantly reduced the severity of lipopolysaccharide (LPS)-induced acute lung injury in mice. Mesenchymal stem cells increased autophagy of pulmonary endothelial cells (PECs) to promote PEC survival. Mesenchymal stem cells increased beclin-1 protein but not mRNA. miR-142a-5p was found to target the 3′-UTR of beclin-1 mRNA to inhibit its protein translation in PECs. Mesenchymal stem cells reduced the levels of miR-142a-5p in PECs from LPS-treated mice. It was concluded that mesenchymal stem cells may alleviate LPS-induced acute lung injury through downregulation of miR-142a-5p, which allows PECs to increase beclin-1-mediated cell autophagy.
- **Transplantation of CXCR4 overexpressed mesenchymal stem cells augments regeneration in degenerated intervertebral discs.** *Wei et al.*'s [50] aim was to evaluate whether high expression of CXCR4 enhanced the migration of mesenchymal stem cells and increased the efficiency of intervertebral disc (IVD) regeneration. Mesenchymal stem cells overexpressing *CXCR* were created by lentiviral-*CXCR4*-overexpressing transfection, labeled with superparamagnetic iron oxide (SPIO), and transplanted into rabbit degenerative IVD induced by annulus puncture. X-ray and T2-weighted magnetic resonance images of the spine were obtained at 0, 8, and 16 weeks posttransplantation. The transplanted stem cells were traced by both magnetic resonance imaging and Prussian blue staining. The stem-cell-based IVD degeneration was evaluated by quantifying the expression of aggrecan and type II collagen. An *in vitro* chemotaxis test was performed to study the migration of CXCR4 mesenchymal stem cells to the supplement of SDF-1. The CXCR4-overexpressing mesenchymal stem cells stably

elevated the expression of CXCR4 and increased the migration to SDF-1. The SPIO-labeled CXCR4 mesenchymal stem cells could be detected within the IVD by magnetic resonance imaging up till 16 weeks after transplantation. Prussian blue staining showed more SPIO-positive cells within the IVD transplanted with CXCR4 mesenchymal stem cells. Compared with the control group, loss of disc height was slowed while the mRNA expression of aggrecan and type II collagen was increased by mesenchymal stem cell transplantation, especially in the IVD supplemented with CXCR4 mesenchymal stem cells. CXCR4 overexpression promoted mesenchymal stem cell retention within the IVD and enhanced the cell-based IVD regeneration.

- **Chromatographically isolated $CD63^+CD81^+$ extracellular vesicles from mesenchymal stromal cells rescue cognitive impairments after TBI.** Kim *et al.* [51] stated that extracellular vesicles (EVs) secreted by cells present an attractive strategy for developing new therapies, but progress in the field has been limited by several issues: the quality of the EVs varies with the type and physiological status of the producer cells, protocols used to isolate the EVs are difficult to scale up, and assays for efficacy are difficult to develop. They addressed these issues by using human mesenchymal stem/stromal cells that produce EVs when incubated in a protein-free medium, preselecting the preparations of mesenchymal stem/stromal cells with a biomarker for their potency in modulating inflammation, incubating the cells in a chemically defined protein-free medium that provided a stable environment, isolating the EVs with a scalable chromatographic procedure, and developing an *in vivo* assay for efficacy of the cells in suppressing neuroinflammation after traumatic brain injury in mice. They demonstrated that intravenous infusion of the isolated EVs shortly after induction of traumatic brain injury rescued pattern separation and spatial learning impairments 1 month later.

## 63.3 Clinical trials

When the term "mesenchymal stem cells" was searched in the ClinicalTrials.gov database on April 7, 2016, a total of 596 trials were listed. When the term "mesenchymal stromal cells" was searched in the ClinicalTrials.gov database on the same day a total of 123 trials were listed. In each search some trials were recruiting, some were completed, some were yet to be initiated, and some were withdrawn.

A relatively small number of clinical trials using mesenchymal stem/stromal cells have been published. Examples of trials that have been published for cardiac, neurological, pulmonary, or gastrointestinal indications are as follows.

- **A phase II dose-escalation study of allogeneic mesenchymal precursor cells in patients with ischemic or non-ischemic heart failure.** Perin *et al.* [52]. Transendocardial injections of allogeneic mesenchymal precursor cells were feasible and safe in chronic heart failure patients. High-dose allogeneic mesenchymal precursor cells may provide benefits in this population.
- **Safety and clinical effects of mesenchymal stem cells secreting neurotrophic factor transplantation in patients with amyotrophic lateral sclerosis: results of phase 1/2 and 2a clinical trials.** Petrou *et al.* [53] stated that clinical studies show neurotrophic growth factors (NTFs) extend the survival of motor neurons in ALS and that the combined delivery of these neurotrophic factors has a strong synergistic effect. They have developed a culture-based method for inducing mesenchymal stem cells to secrete neurotrophic factors. These mesenchymal stem-cell-NTF cells have been shown to be protective in several animal models of neurodegenerative diseases. The objective of this study was to determine the safety and possible clinical efficacy of autologous mesenchymal stem-cell-NTF cells transplantation in patients with ALS. In these open-label proof-of-concept studies, patients with ALS were enrolled between June 2011 and October 2014 at the Hadassah Medical Center in Jerusalem, Israel. All patients were followed up for 3 months before transplantation and 6 months after transplantation. In the phase 1/2 part of the trial, six patients with early-stage ALS received intramuscular (IM) injections and six patients with more advanced disease received intrathecal (IT) transplantation. In the second stage, a phase 2a dose-escalating study, 14 patients with early-stage ALS received a combined IM and IT transplantation of autologous mesenchymal stem-cell-NTF cells. All patients were administered a single dose of mesenchymal stem-cell-NTF cells. The primary end points of the studies were safety and tolerability of this cell therapy. Secondary end points included the effects of the treatment on various clinical parameters, such as the ALS Functional Rating Scale–Revised score and respiratory function. Among the 12 patients in the phase 1/2 trial and the 14 patients in the phase 2a trial aged 20 and 75 years, the treatment was found to be safe and well tolerated over the study follow-up period. Most of the adverse effects were mild and transient, without any treatment-related serious adverse event. The rate of progression of the forced vital capacity and of the ALS Functional Rating Scale–Revised score in the IT (or IT + IM)-treated patients was reduced (from −5.1% to −1.2%/month percentage predicted forced vital capacity, $P < 0.04$, and from −1.2 to 0.6 ALS Functional Rating Scale–Revised points/month, $P = 0.052$) during the 6 months following mesenchymal stem-cell-NTF cell transplantation versus the pretreatment period. Of these patients, 13 (87%) were defined as responders to either ALS Functional Rating Scale–Revised or forced vital capacity, having at least 25% improvement at 6 months after treatment in the slope of progression. The authors conclude that IT and IM administration of mesenchymal stem-cell-NTF cells in patients with ALS is safe and provide indications of possible clinical benefits, to be confirmed in upcoming clinical trials.

- **A placebo-controlled, randomized trial of mesenchymal stem cells in COPD.** Weiss *et al.* [54]. Sixty-two patients with chronic obstructive pulmonary disease (COPD) at six sites were randomized to double-blinded intravenous infusions of either allogeneic MSCs (Prochymal; Osiris Therapeutics Inc.) or vehicle control. Patients received four monthly infusions ($100 \times 10^6$ cells/infusion) and were subsequently followed for 2 years after the first infusion. End points included comprehensive safety evaluation, pulmonary function testing, and quality-of-life indicators, including questionnaires, 6 min walking test, and assessments of systemic inflammation. All study patients completed the full infusion protocol, and 74% completed the 2-year follow-up. There were no infusional toxicities and no deaths or serious adverse events deemed related to mesenchymal stem cell administration. There were no significant differences in the overall number of adverse events, frequency of COPD exacerbations, or worsening of disease in patients treated with mesenchymal stem cells. There were no significant differences in pulmonary function testings or quality-of-life indicators; however, an early, significant decrease in levels of circulating C-reactive protein was observed in patients treated with mesenchymal stem cells who had elevated C-reactive protein levels at study entry.
- **A phase 2 study of allogeneic mesenchymal stromal cells for luminal Crohn's disease refractory to biologic therapy.** Forbes *et al.* [55]. This was a phase 2, open-label, multicenter study that included 16 patients (21–55 years old; six men) with infliximab- or adalimumab-refractory, endoscopically confirmed, active luminal Crohn's disease (CD) (CD activity index CDAI > 250). Subjects were given intravenous infusions of allogeneic mesenchymal stromal cells ($2 \times 10^6$ cells/kg body weight) weekly for 4 weeks. The primary end point was clinical response (decrease in CDAI > 100 points) 42 days after the first mesenchymal stromal cell administration; secondary end points were clinical remission (CDAI < 150), endoscopic improvement (a CD endoscopic index of severity CDEIS < 3 or a decrease by >5), quality of life, level of C-reactive protein, and safety. Among the 15 patients who completed the study, the mean CDAI score was reduced from 370 (median, 327; range, 256–603) to 203 (median, 129) at day 42 ($P < 0.0001$). The mean CDAI scores decreased after each mesenchymal stromal cell infusion (370 before administration, 269 on day 7, 240 on day 14, 209 on day 21, 182 on day 28, and 203 on day 42). Twelve patients had a clinical response (80%; 95% confidence interval, 72–88%; mean reduction in CDAI, 211; range, 102–367), eight had clinical remission (53%; range, 43–64%; mean CDAI at day 42, 94; range, 44–130). Seven patients had endoscopic improvement (47%), for whom the mean CDEIS scores decreased from 21.5 (range, 3.3–33) to 11.0 (range, 0.3–18.5). One patient had a serious adverse event (two dysplasia-associated lesions), but these were not thought to be due to the mesenchymal stromal cells.

## 63.4 Regulatory approval for marketing mesenchymal stromal cell products

Mesoblast's licensee in Japan for acute graft-versus-host disease, JCR Pharmaceuticals Co. Ltd, has launched its mesenchymal stromal-cell-based product for children and adults with acute graft-versus-host disease: TEMCELL® HS Inj. is the first allogeneic cell-based medicine to receive full regulatory approval in Japan.

In May 2012 Osiris Therapeutics Inc. (now owned by Mesoblast) announced that it had received market authorization from Health Canada to market its mesenchymal stem cell therapy Prochymal® (remestemcel-L), for the treatment of acute graft-versus-host disease in children.

In June 2012 the same company announced that it had received consent from New Zealand to market Prochymal® (remestemcel-L) for the treatment of acute graft-versus-host disease.

Mesenchymal stromal cell products have been approved for other indications in South Korea. Hearticellgram-AMI (FCB-Pharmicell), an autologous mesenchymal stromal cell intracoronary injection for the treatment of acute myocardial infarction, was approved in South Korea in 2011. Cupistem (Anterogen) for anal fistula and Cartistem (Medipost) for cartilage injury and osteoarthritis were approved in January 2012 in South Korea. Cartistem is an allogeneic mesenchymal stromal cell product derived from human umbilical cord blood and Cupistem is an autologous mesenchymal stromal cell product.

## 64.1 Summary

Nearly half a century has passed since Friedenstein and co-workers identified a stem cell population in bone marrow, distinct from the hematopoietic stem cell (HSC), with the capacity to generate a heterotopic bone marrow organ capable of supporting hematopoiesis. Ensuing decades of study progressively refined our knowledge about the physical nature of these cells, and their ability to generate skeletal tissue at the single cell level led to their characterization as mesenchymal stem cells (MSCs). In recent years the MSC concept has changed radically based on evidence that MSCs reside within the vasculature of most tissues and possess a broad range of biological activities that far exceed their skeletogenic potential. In the latter case MSCs have been shown to secrete a plethora of bioactive molecules as well as protein/RNA-laden microvesicles with angiogenic, anti-inflammatory, trophic, and immunomodulatory activities, which are believed to induce therapeutic effects *in vivo* via drug-like action. An important tenet of the revised MSC concept is that cells achieve therapeutic effects independent of their stem cell properties. Assimilating the vast amount of new data on MSC function with prior established principles has created much confusion and controversy in the field. As a result, there exists little consensus on how to operationally define the cells, and there is disagreement in the field as to whether MSC-based therapies exert beneficial effects of clinical relevance in the treatment of nonskeletal disorders in human patients. Herein, we provide a brief history of how the MSC perspective has evolved, discuss how major paradigm shifts have impacted the field of study, and propose a stem-cell-centric viewpoint of MSCs as a means to bring better continuity to the field.

## 64.2 Introduction

The field of research dedicated to the study of MSCs now spans five decades. During this time many theories have been put forth to explain the origin and biological functions of MSCs. However, these theories remain fragmented and incomplete. Efforts spearheaded by various societies and regulatory bodies to define the MSC at one time yielded a consensus opinion [1], but this definition is now regarded as woefully inadequate and no consensus on an updated definition has been achieved to date. This has prompted renewed efforts to redefine MSCs based on their potency in biological assays rather than their phenotypic characteristics and/or composition of matter. Achieving this goal, however, still requires a significant amount of consensus building, which may or may not be achievable. For example,

choosing the most relevant biological potency assays to evaluate the overall quality of populations is a daunting task considering the breadth of reported activities ascribed to the cells (currently over 40 000 manuscripts), the limited knowledge regarding their mechanism of action *in vivo*, and the difficulty in translating outcomes from *in vitro* and preclinical animal studies to the human condition. This task is made even more difficult by the fact that one must develop a calibration standard with a range of activities in each potency assay against which experimental and clinical samples can be compared. However, no formalized standards exist for the isolation and manufacture of MSCs, and, as already noted, there is currently no consensus opinion on how to rigorously characterize the cells.

In retrospect, the controversy over how to define MSCs mirrors the evolving paradigms put forth to describe their biological function. MSCs were originally characterized as skeletal stem cells based on their capacity to generate heterotopic bone *in vivo*. However, the prevailing viewpoint now recognizes MSCs as a specialized stromal cell that modulates the immune system and promotes tissue regeneration independent of their stem cell properties [2–6]. As anticipated, the bulk of published research in recent years has focused on delineating these paracrine mechanisms, but many of these studies do not report on whether paracrine signaling also influences MSC growth, viability, and differentiation. We view this as a missed opportunity to integrate the two fields of thought, which view MSCs as stem cells or specialized stromal cells. Herein, we try to reconcile these two viewpoints by examining the stem cell and paracrine properties of MSCs in some detail, review evidence linking these two phenomena, and offer a framework rooted in stem cell biology to reconcile these opposing viewpoints in an effort to bring greater continuity to the field.

## 64.3 The stem cell paradigm revisited

In a series of seminal papers dating back to the 1960s, Friedenstein and co-workers were the first to describe a stem cell population in bone marrow that possessed intrinsic bone-forming ability. Two series of experiments in particular are most relevant to this discussion. The first demonstrated that the bone-forming cells in marrow were not of hematopoietic origin. To show this, Friedenstein transplanted bone marrow from a parental mouse strain under the renal capsule of an F1 hybrid and confirmed by karyotype analysis that the resulting ectopic bone originated from the parental strain and that hematopoietic cells that colonized the bone were derived from the F1 hybrid strain (Figure 64.1A) [7].

Friedenstein further demonstrated that, when the osseous tissue was transplanted back into the parental strain, bone tissue formation continued unimpeded but the colonizing hematopoietic cells were rejected. Friedenstein confirmed these findings by showing that male marrow cells recovered from a heterotopic ossicle and transplanted into syngeneic females immunized against male antigens failed to generate ectopic bone due to rejection of the transplanted cells by the host's immune system (Figure 64.1B) [8]. In the second set of experiments, Friedenstein demonstrated that the bone-forming cells in marrow were self-renewing based on their ability to regenerate new osseous tissue when transplanted successively into recipient mice [8]. Importantly, the self-renewing capacity of the cells was exhausted after passage through five recipients, which was similar to that reported for HSCs passed through irradiated recipients. Based on these findings, Friedenstein characterized the cells as osteogenic stem cells and went on to show that they resided in the plastic-adherent fraction of marrow and were capable of clonal expansion [9,10].

In the ensuing decades various laboratories developed *in vitro* assays to evaluate the differentiation potential of marrow-derived osteogenic stem cells [11–17], which culminated in studies confirming their ability to undergo trilineage differentiation at the level of a single cell [18,19]. In the latter case, analysis of a total of six single cell-derived clonal populations of human MSCs revealed that all clones underwent osteogenic differentiation, five underwent adipogenic differentiation, and two underwent

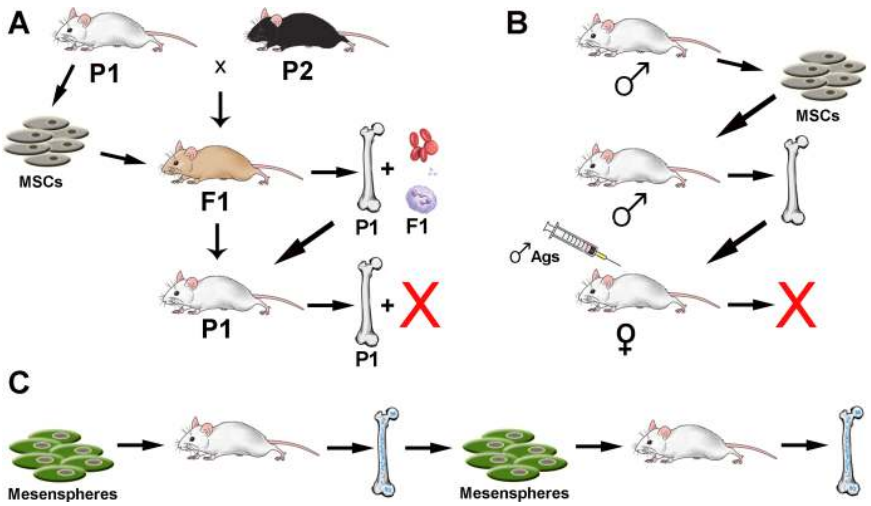

**Figure 64.1** MSCs are self-renewing stem cells. (A, B) Experimental paradigms used to demonstrate that skeletogenic stem cells in bone marrow (MSCs) are physically distinct from blood forming cells (HSCs). (C) Mesenspheres derived from triple transgenic *Nes*-GFP$^{+}$/Col2.3-cre/R26R mice serially regenerate a hematopoietic organ containing osteoblasts that express β-galactosidase when passed through multiple wild-type recipient mice. (See color plate section.)

chondrogenic differentiation [18]. The observation that not all colonies exhibited the full range of differentiation suggested that populations are an admixture of stem and progenitor cells of varying potency, which was subsequently confirmed by later studies (see later). Ironically, the significance of these findings was largely unheralded within the broader stem cell community. Nevertheless, more recent studies using genetic-based approaches have confirmed Friedenstein's original observations and further refined the physical identity and function of the MSC in marrow. Specifically, Méndez-Ferrer *et al.* [20] identified a population of stromal cells in bone marrow expressing the green fluorescent protein (GFP) under the regulatory elements of the Nestin promoter. These cells, referred to as *Nes*-GFP$^+$, exhibited a perivascular distribution in close proximity to CD150$^+$ CD48$^-$ Lin$^-$ HSCs within bone marrow but lacked expression of vascular endothelial cell markers such as CD31 and CD34 or vascular endothelial cadherin. Importantly, *Nes*-GFP$^+$ cells fulfilled the definition of an MSC since they comprised the entire colony-forming unit–fibroblast (an acknowledged marker of MSCs) fraction in marrow and differentiated into adipocytes, osteoblasts, and chondrocytes at the population level. Moreover, when clonally derived populations from triple transgenic *Nes*-GFP$^+$/Col2.3-cre/R26R mice (the *Nes-Gfp* line was intercrossed with a line expressing the Cre recombinase under the osteoblast-specific 2.3-kilobase proximal fragment of the α1(I)-collagen promoter and the *ROSA26/loxP-stop-loxP-lacZ* reporter line) were loaded into phosphocalcic ceramic ossicles and implanted subcutaneously into littermates that lacked the transgenes, the implanted cells generated heterotopic osseous tissue that contained β-galactosidase$^+$ osteoblasts associated with hematopoietic activity. Cells recovered from the ossicle regenerated GFP$^+$ mesenspheres *in vitro*, which when implanted into secondary recipients yielded osseous tissue containing Col2.3$^+$ osteoblasts that supported hematopoiesis (Figure 64.1C) [21]. Collectively, these studies demonstrate that *Nes*-GFP$^+$/PDGFRa$^+$ perivascular cells are capable of transferring and generating a bone marrow organ system *in vivo* and, as such, fulfill the definition of a skeletal stem cell.

## 64.4 The paracrine paradigm

Early efforts to exploit the stem cell properties of MSCs for a therapeutic intent were directed at treating children with osteogenesis imperfecta [22,23], an inherited skeletal disorder causing brittle bones, and to augment hematopoiesis in women with breast cancer undergoing HSC transplantation after high-dose chemotherapy [24]. Although these studies both yielded encouraging results, similar efforts were superseded by studies indicating that MSCs as well as other stem cell populations including HSCs and neural stem cells possessed unexpected plasticity, as evidenced by their transdifferentiation into cardiomyocytes, astrocytes, hepatocytes, lung epithelium, and other lineages (Figure 64.2) (reviewed by Wulf *et al.* [25] and Krause [26]).

These provocative results captivated the scientific community for nearly a decade, spurring the discovery of additional stem cell populations in bone marrow with broad plasticity, including multipotent adult progenitor cells [27], unrestricted somatic stem cells [28], and very small embryonic-like cells [29], but this was largely abandoned when mounting evidence suggested that the phenomenon occurred at a low frequency *in vivo* and therefore was not therapeutically meaningful [30,31].

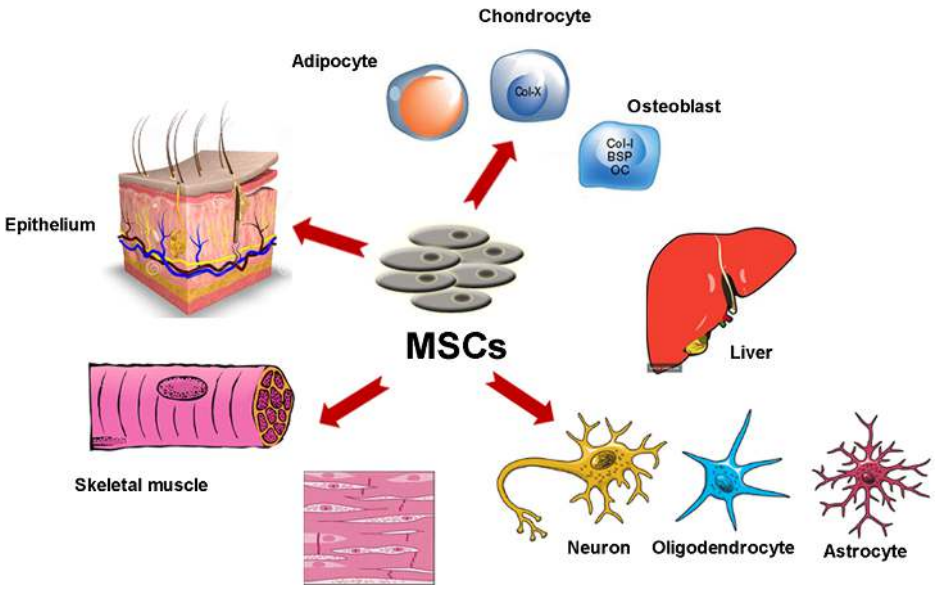

**Figure 64.2** MSC plasticity. MSCs are best characterized by their capacity to differentiate into connective tissue cell lineages but were also shown to adopt characteristics of epithelial cells, skeletal and smooth muscle, neural cell lineages, and hepatocytes (see text for references and current views). (See color plate section.)

An important consequence of this chapter in the MSC saga was that cells were administered to a myriad of animal species (mice, rats, sheep, swine, and nonhuman primates) affected by a broad range of injuries or diseases. Although evidence indicated that few MSCs survived when injected directly into sites of tissue injury [32], and that cells administered systemically embolized in the lungs and were rapidly cleared [33], short-term therapeutic benefits were consistently observed. For example, MSCs were found to reduce the overall infarct size and to increase the density of vascular beds in cardiac tissue subject to ischemia–reperfusion injury [34] (and see Chapter 45), ameliorate inflammation following acute lung injury [35,36], restore blood flow in chronic limb ischemia models [37] (and see Chapter 46), inhibit proliferation of mitogen-stimulated lymphocytes *in vitro* (and see Chapter 34), and prolong survival of autologous third-party donor skin grafts in baboons [38]. These and other findings led to a revision of the MSC concept (and a change in name) such that cells were believed to effect tissue repair by altering the tissue microenvironment via paracrine signaling rather than directed differentiation and cell replacement. This new paradigm gained support from genomics-based studies, which catalogued a large repertoire of expressed transcripts with angiogenic, anti-inflammatory, immunomodulatory, and trophic activity [39–41]. The concept was emboldened by subsequent studies demonstrating that MSC-conditioned media and more recently protein/RNA-laden microvesicles replicated some of the therapeutic effects seen following cell administration in animal models of disease [42–44] (see Chapter 38).

### 64.4.1 "Mesenchymal stem cell pharmacology": cells are not drug-like

The revisionist viewpoint that MSCs are specialized effector cells that promote tissue repair via paracrine action has gained significant traction, and ascribes to the notion that cells achieve therapeutic effects via drug-like action by a "hit and run" mechanism *in vivo* [45,46]. However, this viewpoint is not well substantiated by the published literature. For example, a fundamental principle of pharmacology is that a relationship exists between the concentration of a drug at its site of action and its beneficial or toxic effect. This link between pharmacokinetics and pharmacodynamics determines a drug's overall potency *in vivo*, establishes dose–response relationships, and predicts the effect–time course resulting from a drug dose. Consequently, if MSCs exhibit drug-like behavior then their clinically beneficial effects should depend both on dose and route of administration. However, few if any studies have demonstrated dose-dependent effects of MSCs in large animal models or human clinical trials, and in many cases route of administration does not appear to affect outcome. For example, in studies conducted in swine subjected to temporary balloon occlusion of the left descending coronary artery, one study failed to detect any significant effect on left ventricular ejection fraction (LVEF) or left ventricular volumes following endomyocardial delivery of 24 million to 440 million MSCs [47]. Another study demonstrated dose-independent effects on regional perfusion and left ventricular function following administration of 1 million to 10 million MSCs [48], while a third study reported a significant reduction in infarct size following administration of 200 million but not 20 million MSCs [49]. In related studies, Hamamoto *et al.* [50] reported that administration of 25 million or 75 million but not 225 million or 450 million stromal precursor antigen-$3^+$ MSCs significantly attenuated infarct expansion and increased left ventricular end diastolic and systolic volume in a sheep model of acute myocardial infarction. Finally, a meta-analysis of 52 preclinical studies employing bone marrow mononuclear cells or MSCs in a total of 888 large animals (swine, sheep, dog) subjected to myocardial infarction revealed a significant ($P < 0.01$) degree of heterogeneity and inconsistency between data sets but demonstrated a significant ($P < 0.001$) increase (7.5%) in LVEF after cell therapy versus control [51]. Multivariable meta-regression analysis revealed that cell type ($P = 0.04$) and type of infarction ($P = 0.045$) were the only independent significant predictors of LVEF improvement, and no trend in LVEF improvement was observed regarding animal model ($P = 0.5$) or route of cell delivery ($P = 0.9$).

As anticipated from the studies in large animals, MSC-based therapies have also yielded inconsistent results in human clinical trials. For example, a randomized controlled double-blind trial to assess the effect of allogeneic MSCs (trade name Prochymal™) in patients with acute myocardial infarction yielded the expected safety data, but notable differences in outcome measures did not exhibit dose responsiveness [52]. Similarly, the Percutaneous Stem Cell Injection Delivery Effects on Neomyogenesis Pilot Study (POSEIDON) clinical trial of patients with ischemic cardiomyopathy demonstrated that MSCs yielded significant reductions in scar size with an inverse dose response: the effect of 20 million MSCs exceeded that of 200 million [53]. Additionally, a multicenter phase II study of 55 patients with corticosteroid-refractory acute graft-versus-host disease, a complication of allogeneic HSC transplantation, yielded a complete response in approximately half the patients administered MSCs and the 2-year probability of survival in complete responders was significantly better than that in patients with a partial or no response ($P = 0.018$) [54]. However, while clinically meaningful responses were obtained following infusion of as few as $0.8 \times 10^6$ MSCs/kg, doses as high as $1.9 \times 10^6$ MSCs/kg were not successful in all cases.

These studies demonstrate a lack of dose responsiveness of MSC-based therapies both in large animal models and human patients, thereby refuting the drug-like nature of the cells. Moreover, clinical trials have reported similar improvements in LVEF of patients with ischemic heart disease receiving intracoronary [53,55,56] or transendocardial MSC injections [52,53] (see Chapter 45). MSCs were also reported to yield similar therapeutic effects in a rat model of stroke following intracranial [57], intravenous [58], intracarotid [59], or intracerebral [60] infusion. Thus, the basis for the drug-like action of MSCs is not well substantiated by the literature. This is

expected based on fundamental differences between the processes governing the effects of drug administration (simple system) compared with a cell infusion (complex system) into a living organism (complex system).

### 64.4.2 Priming to enhance mesenchymal stem cell paracrine action also impacts cell growth and survival

The paracrine paradigm of MSC function postulates that cells respond to environmental cues by secreting bioactive factors that yield clinically beneficial effects. This concept explains why MSCs are efficacious across a broad spectrum of diseases even though bioactive factors they secrete may be contraindicated for a particular disease. For example, angiogenesis induced by tissue inflammation has been reported to worsen symptoms in rheumatoid arthritis, and vascular endothelial growth factor (VEGF, one of many proteins secreted by MSCs) is known to play a critical role in the pathogenic angiogenesis of rheumatoid arthritis [61]. Nevertheless, MSCs are being evaluated therapeutically in rheumatology owing to their ability to suppress inflammation and promote cartilage repair despite the fact that they are potently angiogenic [62]. Ironically, the literature is rife with studies that attempt to enhance the therapeutic potency of MSCs by culturing cells in various supplements (Table 64.1).

These studies inform that MSC potency is suboptimal in many experimental settings but also reveal insight into how these treatments alter MSC biology. For example, studies have shown that preconditioning regimens aimed at enhancing the angiogenic potential of MSCs also enhance cell proliferation and survival. Consistent with these studies, it is well established that FGF-2 and VEGF act synergistically to regulate angiogenesis during development [101,102], that secretion of these factors by MSCs is enhanced by hypoxic preconditioning [103], and that FGF-2 also promotes MSC growth, survival, and self-renewal [104–108] and delays the onset of cellular senescence during long-term culture expansion [109]. Other studies have shown that FGF-2 pretreatment enhances cellular differentiation, which seems counterintuitive, but most likely reflects its ability to preserve the progenitor pool during culture expansion. Thus, the angiogenic potential of MSCs appears to be linked to mechanisms controlling cell growth, survival, and self-renewal.

### 64.4.3 Licensing of immunomodulatory activity biases cell differentiation

In contrast, less is known about how conditions that enhance anti-inflammatory and immunomodulatory properties of MSCs affect their growth, survival, self-renewal, and differentiation. One agent that has been widely used is INF-γ. Krampera *et al.* initially demonstrated that the immunosuppressive activity of MSCs is induced in response to IFN-γ release from activated immune cells [110]. This "licensing" appears critical, since IFN-γ receptor-negative MSCs do not inhibit T cell functions and MSCs transplanted to IFN-γ knockout mice failed to ameliorate symptoms of GVHD [57]. When added as a media supplement, INF-γ has been reported to inhibit the growth of rodent and human MSCs [111], which is consistent with the known growth inhibitory effects of interferons (INFs) [112,113]. Moreover, Dugue *et al.* [114] showed that IFN-γ-inducible genes were upregulated during the early phases of osteoblast differentiation of human MSCs, which corresponded to a strong but transient increase in INF-γ production. Moreover, knockdown of INF-γ blocked osteogenic differentiation, and the addition of exogenous INF-γ accelerated the process. These effects of INF-γ were linked to changes in expression of *Runx2*. Furthermore, Vidal *et al.* [115] showed that the kynurenine pathway was activated in MSCs during commitment to the osteoblast lineage *in vitro* and that small-interfering-RNA-mediated knockdown or pharmacological inhibition of IDO strongly inhibited osteoblastogenesis. These data indicate that INF-γ-responsive pathways that confer immunosuppressive activity to MSCs also impact cellular differentiation.

MSCs have also been shown to express a subset of toll-like receptors (TLRs), and engagement of these receptors by their cognate ligands has been reported to modulate their anti-inflammatory and immunomodulatory activity [116]. Importantly, TLR activation does not appear to significantly impact the growth of MSCs isolated from different tissue sources [117–119] but does impact cellular differentiation (Table 64.2).

For example, studies have shown that TLR2 priming or TLR3/TLR4 priming inhibits adipogenic differentiation of adipose-derived [118] or bone-marrow-derived MSCs [65] respectively. In contrast, osteogenic differentiation was stimulated by TLR2/TLR3/TLR4 priming of adipose-derived MSCs [118,120], by TLR2/TLR4 priming of umbilical-cord-derived MSCs [119], and by TLR4 priming of bone-marrow-derived MSCs [65], whereas TLR9 [122] or TLR3 [65] priming inhibited osteogenic differentiation of the latter cells. Therefore, while differences in outcomes between these studies are muddled at best, they clearly indicate that TLR signaling also impacts cellular differentiation.

## 64.5 Modeling mesenchymal stem cell function using lessons learned from immunology

Efforts to model the immunomodulatory activity of MSCs have largely copied established paradigms in immunology. One model that has gained traction is the polarization of MSCs by TLR engagement to inflammatory (MSC 1) and anti-inflammatory (MSC 2) phenotypes (reviewed by Bernardo and Fibbe [116]). This is based on evidence showing that TLR3 ligation compared with TLR4 ligation induced distinct patterns of cytokine expression in MSCs [65]. However, close examination of this model reveals that the distinction between MSC 1 and MSC 2 phenotypes is not clearly demarcated based on the supporting data. For example, the pattern of cytokine expression in the two populations overlaps, and MSC 2 cells secrete chemokines such as CCL5 and CCL10 that are implicated in lymphocyte trafficking and bone remodeling rather than immunosuppression. Moreover,

MSC 1 cells were characterized by high IL-6 expression, a characteristic of nonmanipulated MSCs, and both populations failed to inhibit T cell proliferation in a mixed lymphocyte reaction *in vitro*. Finally, the fact that TLR3-primed cells (MSC 2) expressed high levels of IDO mRNA and prostaglandin $E_2$ protein indicates that some overlap exists in the cellular response to TLR agonists and INF-γ.

Studies assessing how TLR engagement alters MSC function have also yielded inconsistent results. For example, several studies have reported that TLR engagement suppressed the ability of MSCs to inhibit T cell proliferation in response to allogeneic stimulation [117,121] and reduced MSC-mediated expansion of $CD4^+$ $CD25^+$ $Foxp3^+$ regulatory T cells [123], while others have reported no effects on immunomodulatory activity [124]. Moreover, in one study, TLR ligation did not affect prostaglandin $E_2$ or IDO levels but rather altered Jagged 1 levels [117]. In another study, TLR3/TLR4 priming enhanced IDO expression due to autocrine INF-β signaling [125]. Consequently, it is difficult to imagine how these complex and in some cases contradictory results can be distilled down to a simple unifying model of cell function.

## 64.6 A stem-cell-centric view of mesenchymal stem cells

Significant strides have been made in cataloging the nature and activity of paracrine factors secreted by MSCs and advancing MSC-based therapies for the treatment of ischemic and immune-mediated disorders in humans. Accordingly, much of the field has abandoned the stem-cell-centric view of MSCs, which has impeded efforts to model their functional complexity using established principles of stem cell biology. We posit that a stem-cell-centric framework may adequately encompass the paracrine functions ascribed to MSCs, and in doing so bring better continuity to the field. In this framework, cell fate changes manifest as changes in cell potency, both from perspectives of paracrine action and differentiation potential. This framework has similarity to that of the hematopoietic system and parallels that recently described for T helper cell identity [126,127].

With regard to MSCs, we propose that a naive MSC is a $Nestin^+$/$PDFRA^+$ perivascular cell that expresses high levels of angiogenins and hematopoietic growth factors, including IL-6, CXCL12, chemokine C–C motif ligand 4, and stem cell factor. Importantly, this cell undergoes self-renewal and possesses the capacity to transfer and generate the hematopoietic microenvironment *in vivo*. The proangiogenic nature of the naive MSC is best illustrated by studies showing that their capacity to generate heterotopic osseous tissue is dependent, in part, on secretion of angiopoietin 1 [128]. Moreover, cytokines produced by MSCs that regulate homing and retention of HSCs in bone marrow, such as stem cell factor [129] and SDF-1 (CXCL12) [130], also exhibit angiogenic activity, while angiogenins including VEGF [131] and angiopoietin 1 [132] play important roles in HSC maintenance. Furthermore, the fact that MSCs exist in a low-oxygen environment *in vivo* explains why hypoxia preconditioning enhances their growth, surviva,l and proangiogenic activity *in vitro* (Table 64.1). Importantly, naive MSCs also secrete chemokines that modulate lymphocyte trafficking, and therefore may promote retention of leukocytes within injured tissues. However, we are unaware of any studies indicating that administration of naive MSCs induces a robust inflammatory response, which is consistent with the fact that these cells secrete little if any IL-1α, IL-1β, or TNF. Indeed, a recent study indicated that MSCs do not produce TNF even after LPS stimulation due to the fact that the TNF promoter is heavily methylated [133]. Based on these data, we argue that naive MSCs are not proinflammatory *per se*, but rather are not committed to an anti-inflammatory phenotype.

Consistent with this framework, few, if any, studies have reported that preconditioning regimens that enhance anti-inflammatory or immunomodulatory activity also promote MSC proliferation or enhance the angiogenic potential of MSCs. In contrast, one recent study showed that MSCs cultured in osteogenic induction medium secreted significantly lower levels of VEGF and several other angiogenins compared with cells cultured in growth media, and they were also less potent in supporting proliferation, migration, and tubule formation of human umbilical cord blood endothelial cells [134]. VEGF has been reported to inhibit adipocyte differentiation by regulating Runx2 and peroxisome proliferator-activated receptor-γ (PPAR-γ) levels in MSCs and reduced levels of VEGF during aging coincides with loss of trabecular bone mass and an increase in marrow fat [135,136]. These data suggest that the stem cell functions of MSCs are reinforced at the expense of effector functions and that acquisition of the latter occurs via a hierarchical process similar to that described for trilineage differentiation (Figure 64.3).

Indeed, clonal-based studies have definitively shown that MSC populations contain an admixture of all eight possible categories of trilineage progenitors [137–140] and that clones of varying potency exhibit significant differences in growth rates, colony-forming potential, and apoptosis [141]. These data reinforce the notion that cell differentiation is deterministic and that commitment to one lineage occurs at the expense of other possible fates.

Based on this paradigm, we argue that effector functions of MSCs are regulated by a similar process and that adoption of an effector cell fate represents a continuum within the hierarchy of cell specification for the naive MSCs (Figure 64.4).

This framework is consistent with the fact that INF-γ priming, which induces potent immunomodulatory activity, also impairs MSC growth and biases their differentiation toward a given connective tissue lineage. Bias is possible because commitment of naive cells to an "effector" phenotype induces expression of the master regulators *RUNX2*, *PPAR-γ*, and *SOX9*, which drive commitment to osteogenic, adipogenic, and chondrogenic fates respectively. Importantly, TLR activation has also been shown to alter the capacity of bone-marrow-derived MSCs to support

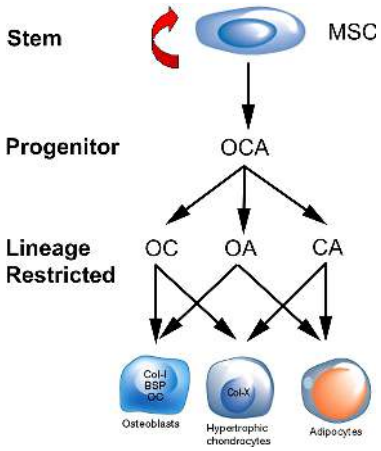

**Figure 64.3** Trilineage differentiation of MSCs follows a hierarchical process. The schematic illustrates the commitment of an MSC to a trilineage progenitor, the potency of which becomes progressively more restricted as differentiation proceeds down the hierarchy. (See color plate section.)

$CD34^+$ cells in an undifferentiated state [142] and MSCs differentiated to adipocytes no longer suppress, but enhance, the growth of alloantigen- or mitogen-stimulated T cells [143]. Similar to the process described for T helper cells, changes in MSC fate are nuanced, in that effector cells retain plasticity in their ability to respond to environmental cues. This plasticity

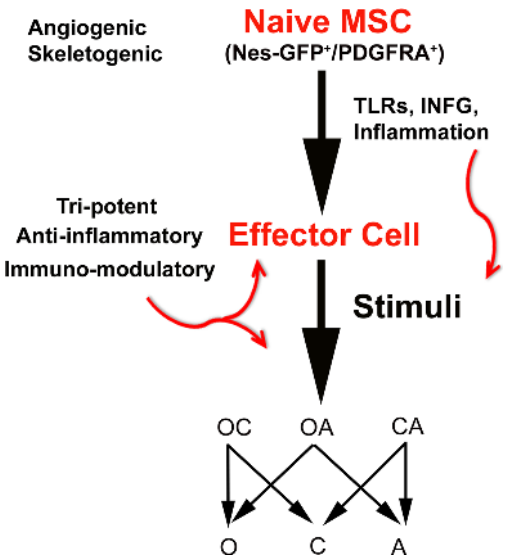

**Figure 64.4** Stem-cell-centric framework of MSC function. The schematic illustrates the naive MSC as an angiogenic perivascular cell capable of generating a hematopoietic organ. The naïve MSC is induced to adopt an effector phenotype by deterministic (specific stimuli) or stochastic processes, which induce expression of paracrine factors with anti-inflammatory and immunomodulatory activity. This fate change also derepresses pathways that drive cell differentiation toward connective tissue lineages, thereby allowing external stimuli to bias commitment toward these lineages. Overt cellular differentiation also alters the paracrine function of cells by suppressing their anti-inflammatory and immunomodulatory activities. (See color plate section.)

may be regulated by multiple mechanisms. For example, cells may retain the ability to rapidly secrete cytokines and chemokines in response to external stimuli by epigenetic regulation of gene transcription and posttranslational modification of protein function and stability. Moreover, cell fate changes may be reinforced by antagonistic or competitive processes; for example, those that drive self-renewal impede cell differentiation and/or feedback inhibition of entire signaling pathways. An important aspect of this framework is that it provides a working model that can be readily tested. As noted above, evidence exists that changes in effector function influence the growth, survival, hematopoiesis-supporting activity, and differentiation of MSCs. Therefore, if these pathways are mechanistically linked, as suggested by these data, it should be straightforward to evaluate in a rigorous manner how INF-γ priming, as an example, alters the ability of MSCs to serially regenerate heterotopic osseous tissue *in vivo* or provide a therapeutic benefit in experimental models of ischemic injury.

## 64.7 Closing remarks

The relative ease by which MSCs are procured and expanded *in vitro*, together with their lack of infusion-related toxicity in humans, has spurred their use for treating a large number of human diseases. However, MSC-based therapies to date have yielded inconsistent and suboptimal clinical benefits. We believe that the paradigm-centric viewpoint of the MSC has been oversimplified and overemphasized. As a result, much of the research devoted to this topic has been conducted in a manner that ignores other basic aspects of MSC biology. Nevertheless, as outlined in this chapter, we believe ample evidence exists to suggest that stem cell and effector functions of MSCs are mechanistically linked, and it is this link that serves as the basis for the stem-cell-centric framework proposed here. Our hope is that this provocative hypothesis will encourage future studies to employ a systems biology approach and examine how preconditioning or licensing of MSC paracrine function impacts not only on their therapeutic potency but also on their stem cell properties.

# Glossary

Note that the position on this list for an abbreviation starting with a numeral will occur in this list according to the numeral, not the word after the numeral

| | |
|---|---|
| 1-MT: | 1-methyl-tryptophan |
| 2D: | two-dimensional |
| 2-DE: | two-dimensional gel electrophoresis |
| 3D: | three-dimensional |
| 3T3: | The 3T3 cell line has become the standard murine fibroblast cell line and was originally established from primary mouse embryonic fibroblast cells. The "3T3" designation refers to the abbreviation of "3-day transfer, inoculum $3 \times 10^5$ cells" |
| 3T3-L1: | a cell line derived from mouse 3T3 cells that is used in biological research on adipose tissue |
| 5caC: | 5-carboxylcytosine |
| 5-FC: | 5-fluorocytosine |
| 5fC: | 5-formylcytosine |
| 5-FU: | 5-fluorouracil |
| 5hmc: | 5 hydroxymethylation |
| 5-HT: | 5-hydoxytryptamine (serotonin) |
| 6MWD: | 6-min walk distance |
| 6-OHDA: | 6-hydroxydopamine |
| 7-ADD: | 7-aminoactinomycin D |
| 14*S*,21*R*-diHDHA: | 14*S*,21*R*-dihydroxydocosa-4*Z*,7*Z*,10*Z*,12*E*,16*Z*,19*Z*-hexaenoic acid |
| 18-F-FDG: | 2-deoxy-2-($^{18}$F)fluoro-D-glucose, a glucose analog with the positron-emitting radioactive isotope fluorine-18 substituted for the normal hydroxyl group at the 2′ position in the glucose molecule for use in PET scanning |
| $^{99m}$Tc: | technetium sestamibi |
| 53BP1: | p53 binding protein 1 |
| $^{111}$In: | indium-111 |
| $^{131}$I FIAU: | $^{131}$I-5-iodo-2-fluoro-1-β-D-arabinofuranosyluracil |
| A2AR: | adenosine A2A receptors |
| A549 cells: | human adenocarcinoma alveolar basal epithelial cells. The A549 cell line was first developed in 1972 by D. J. Giard through the removal and culturing of cancerous lung tissue in the explanted tumor a of 58-year-old Caucasian male |
| AA: | arachidonic acid |
| AAMP: | angio-associated, migratory cell protein |
| AAV: | adeno-associated virus |
| ABPI: | ankle brachial pressure index |
| AC: | articular chondrocyte |
| ACAN: | aggrecan |
| ACE: | angiotensin converting enzyme |
| ACI: | autologous chondrocyte implantation |
| ACL: | anterior cruciate ligament |
| Ac-LDL: | acetylated low-density lipoprotein |
| ACTA2: | alpha-actin-2, also known as actin, aortic smooth muscle, or alpha smooth muscle actin (α-SMA, α-smooth muscle actin) |
| ACTH: | adrenocorticotropic hormone |
| ActR: | activin receptor |
| AD: | Alzheimer's disease[1] |
| ADAM: | a disintegrin and metalloproteinase |
| ADAS: | adipose-derived adult stem cell |
| ADASC: | adipose-derived adult stromal cell |
| ADAMTS5: | a disintegrin and metalloproteinase with thrombospondin motif 5 |
| ADAS: | adipose-derived adult stem cell |
| ADCC: | antibody-dependent cellular cytotoxicity |
| ADDI: | adipocyte determination and differentiation-dependent factor |

*The Biology and Therapeutic Application of Mesenchymal Cells*, First Edition. Edited by Kerry Atkinson.
© 2017 John Wiley & Sons, Inc. Published 2017 by John Wiley & Sons, Inc.

ADM: adrenomedullin
ADMSC or AD-MSC: adipose-tissue-derived mesenchymal stromal cell
AdMSC: adipose mesenchymal stem cell
ADP: adenosine diphosphate
ADSC: adipose-derived stromal cell
AEC: amniotic epithelial cell
AF: amniotic fluid
AFC: alveolar fluid clearance
a-FGF: acidic fibroblast growth factor
AFSC: amniotic fluid stem cell
AHR: airway hyperresponsiveness
AhR: aryl hydrocarbon receptor
AICD: activation-induced cell death
AIE: aggregation-induced emission
AIF: allograft inflammatory factor
AIRE: autoimmune regulator
AKI: acute kidney injury
AKT: the "Ak" in Akt was a temporary classification name for a mouse that developed spontaneous thymic lymphomas. The "t" stands for thymoma. AKT is also known as protein kinase B and is one of the serine/threonine kinases that contain SH2 (Src homology 2-like) domains
ALCAM: activated leukocyte cell adhesion molecule (CD166)
ALDH: aldehyde dehydrogenase
ALI: acute lung injury
ALK: activin-like kinase
ALK5: activin receptor-like kinase 5
ALL: acute lymphoblastic leukemia
ALP: alkaline phosphatase
alpha-SMA: alpha smooth muscle actin
alpha-SMACreERT2: α-smooth muscle actin promoter-directed Cre recombinase estrogen receptor ligand-binding domains
ALPL: alkaline phosphatase
ALPS: autoimmune lympho-proliferative syndrome
ALS: amyotrophic lateral sclerosis
ALT: alanine transaminase
Alu: a short repetitive stretch of primate DNA originally characterized by the action of the Alu (*Arthrobacter luteus*) restriction endonuclease
AMI: acute myocardial infarction
AML: acute myeloid leukemia
AMOC1: SPARC-related modular calcium-binding protein 1
AMOP: adhesion-associated domain in MUC4 and other proteins
AM-MSC: amnion-derived mesenchymal stromal cell
AM-MSC: amniotic-membrane-derived mesenchymal stromal cell
AMP: adenosine monophosphate
Ang: angiopoietin
ANGPTL4: angiopoietin-related protein 4
AOC3: amine oxidase, copper containing 3 (also known as vascular endothelial protein 1
AP-1: activator protein 1
AP2: adipocyte protein 2
AP-2-α: activating enhancer binding protein 2-α
Apaf-1: apoptotic protease-activating factor 1
APC: activated protein C
APC: antigen-presenting cell
APC: colorectal adenoma like protein
APC: adenomatosis polyposis coli (gene/protein)
API: active pharmaceutical ingredient
APN: alanine aminopeptidase
ARCO: Association Research Circulation Osseous (staging system for osteonecrosis)
ARDS: acute respiratory distress syndrome
ARF locus: alternate reading frame protein product of the cyclin-dependent kinase locus
ARGB: Australian Regulatory Guidelines for Biologicals
ARHGEF19: Ras homolog gene family member A guanine nucleotide exchange factor 19
ARNT: aryl hydrocarbon receptor nuclear translocator
ARPE-19: a spontaneously arising retinal pigment epithelial cell line derived in 1986 by Amy Aotaki-Keen from the normal eyes of a 19-year-old male
ARTG: Australian Register of Therapeutic Goods
AS: antisense
ASC: adipose-derived stromal cell
ASC: adipose-derived stem/stromal cell
ASC: acellular spinal cord

ASIA: American Spinal Injury Association (scoring system for spinal cord injury)
AST: aspartate aminotransferase
ATF4: activating transcription factor 4
ATG: antithymocyte globulin
ATM: adipose tissue macrophages
ATM: ataxia-telangiectasia-mutated
ATMP: advanced therapy medicinal product
AT-MSC: adipose-tissue-derived mesenchymal stromal cell
ATP: adenosine-5–triphosphate
ATR: ATM and RAD3 related
B7 DC: B7 dendritic cell DC (also known as PD-L2, CD273)
B7 H1: B7 homolog (also known as PD-L1 and CD274)
B7-1: CD80
B7-2: CD86
BAD: BCL-XL/BCL2-associated death promoter
BAFF: B cell activating factor
BAL: bronchoalveolar lavage fluid
BALP: bone-specific alkaline phosphatase
BARK: β-adrenergic receptor kinase
BAX: Bcl-2-associated X protein
BBB: blood–brain barrier
BBB: Basso, Beattie, and Bresnahan scoring system for assessing locomotor recovery
BCG: Bacille de Calmette et Guérin (bacillus of Calmette and Guerin)
BCL-2: B cell lymphoma-2
BCL-XL: B cell-lymphoma extra large
BCR: B cell receptor
BCR–ABL: the fusion gene of the break point cluster (BCR) gene on human chromosome 22 with the Abelson (ABL) tyrosine kinase gene on human chromosome 9, resulting in the chimeric oncogene BCR–ABL
BDKRB1: bradykinin receptor B1
BDNF: brain-derived neurotrophic factor
beta2-AR: β-2 adrenergic receptor
beta-2-AR: β-2 adrenergic receptor
beta-NGF: β-nerve growth factor
bFGF: basic fibroblast growth factor
BGN: biglycan
β-GP: β-glycerophosphate sodium
BH: Bcl-2 homology
bHLH: basic-helix–loop–helix
BIL: bioluminescence imaging
BIO: indirubin 6-bromoindirubin-3′-oxime
BIRC8: baculoviral inhibitor of apoptosis repeat containing protein 8
BLI: bioluminescent imaging
BLM: Bloom syndrome (helicase)
Blnc1: brown adipose tissue long noncoding RNA 1
BM: basement membrane
BM: bone marrow
BMC: bone mineral content
BMD: bone mineral density
BMI: body mass index
BM-MNC: bone marrow mononuclear cell
BM-MSC: bone-marrow-derived mesenchymal stromal cell
BMSC: bone marrow stromal cells
BMP: bone morphogenetic protein
BMPR1A: bone morphogenetic protein receptor 1A
BMT: bone marrow transplantation
BODIPY: boron-dipyrromethene (a lipid probe)
BOOST: BOne marrOw transfer to enhance ST-elevation infarct regeneration (name given to a clinical trial for acute myocardial infarction
BOS: bronchiolitis obliterans syndrome
bp: base pair
BPD: bronchopulmonary dysplasia
Br1: B regulatory cells 1
BRCA1: breast cancer type 1
BRCT: breast cancer type 1 C-terminal (domains)
BrdU: 5-bromo-2′-deoxyuridine
Bregs: B regulatory cells
BSA: bovine serum albumin
BSC: bulge stem cells (of hair follicles)
BSMC: bronchial smooth muscle cells
BSP: bone sialoprotein
BTB: blood–tumor barrier
BV/TV: bone volume/trabecular volume
bZIP: basic region/leucine zipper domain
CA1P: combretastatin A1 diphosphate, also known as OXi4503 (a dual-mechanism vascular disrupting agent)

CABG: coronary artery bypass grafting
CAD: coronary artery disease
CAD: caspase-activated DNAse
CAD: calcium-dependent adhesion
CAF: cancer-associated fibroblast
CALLA: common acute lymphoblastic leukemia antigen
CAM: chick embryo chorioallantoic membrane
CAM: cell adhesion molecule
CAMKII: calcium/calmodulin-dependent kinase II
cAMP: cyclic adenosine monophosphate – a second messenger important in many biological processes; cAMP is derived from adenosine triphosphate and is used for intracellular signal transduction in many different organisms, conveying the cAMP-dependent pathway
CAR: CXCL12-abundant reticular (stromal cell)
CARD: caspase activation and recruitment domain
CASP: colon ascendens stent peritonitis
CBER: Center for Biologics Evaluation and Research (USA)
CBFA1: core-binding factor alpha 1 (another name for RUNX2)
CBP: phosphorylated CREB-binding protein
CBV: cerebral blood volume
CCAAT: cytosine–cytosine–adenosine–adenosine–thymidine
CCD: charge-coupled devices
cCFU-F: cardiac colony-forming unit–fibroblastic
CCL: chemokine (C–C motif) ligand
CCL4: carbon tetrachloride
CCL5: chemokine (C–C motif) ligand 5. It is also known as RANTES
CCM: concentrated conditioned medium
CCR: chemokine receptor
CCSP: Clara cell secretory protein
CCTRN: Cardiovascular Cell Therapy Research Network
CD: cluster of differentiation
CD: Crohn's disease
CD: cytosine deaminase
CDAI: Crohn's disease activity index
CDC: cell division control (protein)
CDEIS: simple endoscopic score for Crohn's disease
CDER: Center for Drugs Evaluation and Research (USA)
CDH5: cadherin 5, type 2 (vascular endothelium)
CDK: cyclin-dependent kinase
cDNA: complementary DNA (double-stranded DNA synthesized from a messenger RNA template by reverse transcriptase)
CdSe–ZnS QDs: quantum dots composed of dimethylcadmium, diethylzinc, and selenide
C/EBP: CCAAT-enhancer binding protein
C/EBP-α: CCAAT-enhancer-binding protein-α
C/EBP-β: CCAAT/enhancer-binding protein β
CFDA-SE: carboxyfluorescein diacetate succinimidyl ester
CFP: cyan fluorescent protein
CFSE: carboxyfluorescein *N*-hydroxysuccinimidyl ester (a cell permeable, nonfluorescent pro-dye)
CFR: Code of Federal Regulations (USA FDA)
CFU-A: colony forming unit–adipocyte
CFU-F: colony-forming unit–fibroblast
CFU-GM: colony-forming units of granulocyte and macrophage
CFU-O: colony forming unit–osteoblast
CFU-S: colony-forming unit–spleen
cGMP: current Good Manufacturing Practice
cGMP: cyclic guanosine monophosphate
CGRP: calcitonin gene related peptide
CGTP: Current Good Tissue Practices
CHAD: chondroadherin
ChIP: chromatin immunoprecipitation
ChIP-Seq: chromatin immunoprecipitation sequencing
CHK: checkpoint kinase
CIA: collagen-induced arthritis
CIF: cumulative incidence functions
CII2A: (MHC) class II transactivator
CINC: cytokine-induced neutrophil chemoattractant (also known as GRO)
CK: cytokeratin

CK2: checkpoint kinase 2
CKD: chronic kidney disease
CKI: CDK inhibitor
CLI: critical limb ischemia
CLP: cecal ligation and puncture
CLP: committed lymphoid progenitor
CLR: C-type lectin receptor
CM: conditioned medium
c-MAF: musculoaponeurotic fibrosarcoma oncogene homolog
CMB: condensed mesenchymal bodies
C-MSC: chorion-derived mesenchymal stromal cell
CNI: calcineurin inhibitor
CNN: this refers to the CCN family of extracellular matrix-associated signaling proteins (also known as matricellular proteins). The acronym CCN is derived from the first three members of the family discovered, namely CYR61 (cysteine-rich angiogenic protein 61 or CCN1), CTGF (connective tissue growth factor or CCN2), and NOV (nephroblastoma overexpressed or CCN3). Together with three Wnt-induced secreted proteins, they comprise the CCN family of matricellular proteins. These proteins have now been renamed CCN1–6 by international consensus
CNPase: 2′,3′-cyclic-nucleotide 3′-phosphodiesterase
CNS: central nervous system
CNTF: ciliary neurotrophic factor
CO: cardiac output
COAD: chronic obstructive airway disease
$CoCl_2$: cobalt chloride
COL1: collagen type 1
COL1A1: collagen type 1, alpha 1
COMP: cartilage oligomeric matrix protein
COPD: chronic obstructive pulmonary disease
COS: a fibroblast-like cell line derived from monkey kidney tissue. COS cells are obtained by immortalizing CV-1 cells with a version of the SV40 virus that can produce large T antigen but has a defect in genomic replication. The CV-1 cell line in turn was derived from the kidney of the African green monkey. The acronym "COS" is derived from the cells being CV-1 (simian) in Origin, and carrying the SV40 genetic material
COUP-TFII: chicken ovalbumin upstream promoter transcription factor II
COX: cyclooxygenase
CpG: cytosine–phosphate–guanosine
CR: chromatin remodeler
CR: competing risks
CR3: complement receptor 3
CRAC1: cartilage acidic protein 1
CRADs: conditionally-replicating adenoviruses
CRE: Cre protein encoded by the locus originally named as "Causes recombination" with "cyclization recombinase"
CRE: cAMP response element
CREB: cyclic AMP response element binding protein
CRP: C-reactive protein
CSC: cardiac stem cell
CSC: cancer stem cells
CSF: cerebrospinal fluid
CSF-1: colony stimulating factor 1 (also known as M-CSF)
CSP: cyclosporine (also known as cyclosporin and cyclosporine A)
CSPG: chondroitin sulfate proteoglycan
CT: computed tomography
CTB: C-terminus binding protein
CTB: cholera toxin-B chain
CTGF: connective tissue growth factor
CTiP: C-terminus interacting protein
CTL: cytotoxic T lymphocyte
CTLA-4: cytotoxic T-lymphocyte-associated protein 4, also known as CD152
CTC: chorionic trophoblastic cells
CTX: C-telopeptide
CTX: cytoxan (cyclophosphamide)
CVA: cerebrovascular accident
CVD: cardiovascular disease
CVD: cerebrovascular disease
CV-MSC: chorionic villi-derived mesenchymal stromal cell
CX3CL1: C–X–C motif chemokine ligand 3 (also known as fraktalkine)
CX43: connexin 43
CXCL12: C–X–C motif chemokine ligand 12

CXCR4: C–X–C motif chemokine receptor 4
CYP3A4: cytochrome P450 3A4
Cyr61: cysteine-rich angiogenic inducer 61
DA: dopaminergic
DAF: decay-accelerating factor
DAMP: damage-associated molecular pattern
DAP 10: DNAX-activation protein 10
DAPI: 4′,6-diamidino-2-phenylindole, a fluorescent stain that binds strongly to A–T-rich regions in DNA and is often used to stain the nucleus of cells
dATP: deoxyadenosine triphosphate
DAPT: *N*-[*N*-(3, 5-difluorophenacetyl-L-alanyl)]-(*S*)-phenylglycine *t*-butyl ester
DC: dendritic cell
DC: direct current
DCN: decorin
DD: death domain
DDR: DNA damage response
DES: desmin
DETA NONOate: (*Z*)-1-[*N*-(2-aminoethyl)-*N*-(2-ammonioethyl)amino]diazen-1-ium-1,2-diolate
DEXA: dual-energy X-ray absorptiometry
DFX: desferrioxamine
DIC: differential interference contrast (microscopy)
DiI: a chemical that is a fluorescent lipophilic cationic indocarbocyanine dye. The "Di" possibly stands for the di-alkyl nature and the "I" of DiI possibly stands for the "indocarbocyanine" group
DISC: death-inducing signaling complex
DKK1: Dickkopf factor
DLA: dog leukocyte antigen
DLCO: diffusing capacity for carbon monoxide
DLL4: delta like ligand
Dll4: delta-like ligand 4
DLX: Distal-less homolog
DMEM: Dulbecco's modified Eagle medium[2,3]
DMP1: dentin matrix protein 1
D-MSC: decidua-derived mesenchymal stromal cell
dMTase: DNA demethylases
DNA: deoxyribonucleic acid
DNAX: the gene that codes for the τ and γ subunits of the DNA clamp loader of prokaryotes. The eukaryotic equivalent to the DNA clamp loader is Replication Factor C, which is encoded by the genes RFC1, RFC2, RFC3, RFC4, and RFC5
DNA-PKcs: DNA-dependent protein kinase, catalytic subunit
DNMT: DNA methyltransferase
DNPEP: aspartyl aminopeptidase
dNPT: deoxyribonucleotide
DPSC: dental pulp stem cell
DSB: double-strand break
dsRNA: double-stranded RNA
DSS: dextran sodium sulfate
DTR: diphtheria toxin receptor
Dvl: Dishevelled (protein)
E1A: early 1A adenoviral (gene or protein)
EAE: experimental autoimmune encephalitis
EB: embryoid body
EBF2: early B cell factor 2
EBMT: European Group for Blood and Marrow Transplantation
E-cadherin: epithelial cadherin (cadherin = calcium-dependent adhesion)
ECD: expanded criteria donor
ECE: endothelin converting enzyme
ECFR: epidermal growth factor receptor
ECM: extracellular matrix
EDF-1: endothelial differentiation-related factor 1
EDP: end-diastolic pressure
EdU: 5-ethynyl-2′-deoxyuridine
EDV: end-diastolic volume
EEF1A1: eukaryotic translation elongation factor 1A1
EEV: endothelial extracellular vesicle
EFEMP: EGF-containing fibulin-like extracellular matrix protein
EGF: epidermal growth factor
eGFP: enhanced green fluorescent protein
EGFRvIII: epidermal growth factor receptor variant III
EGM: endothelial cell growth medium
EHS: Engelbreth-Holm–Swarm (Type of mouse sarcoma cell that secretes a gelatinous protein mixture marketed as Matrigel. The chief components of Matrigel are structural proteins such

as laminin, entactin, collagen, and heparan sulfate proteoglycans that present cultured cells with the adhesive peptide sequences that they would encounter in their natural environment. Also present are growth factors like TGF-β and EGF that prevent differentiation and promote proliferation of many cell types)

EIA: Adenovirus early region 1A (E1a or E1A), (a gene expressed during adenovirus replication to produce a variety of (E1A) proteins)

EIA: E1A binding protein p300, also known as EP300 or p300, is a protein that, in humans, is encoded by the EP300 gene also known as EID-1

EID-1: the gene that encodes EP300-interacting inhibitor of differentiation 1

ELF: enzyme-labeled fluorescence

ELISA: enzyme-linked immunosorbent assay

ELN: elastin

EMA: European Medicines Agency

eMSC: endometrial MSC

EMT: epithelial-to-mesenchymal transition

ENaC: alfa-epithelial sodium channel

EndMT: endothelial-to-mesenchymal transition

eNOS: endothelial nitrous oxide synthase

EP2: receptor for prostaglandin $E_2$

EP4: receptor for prostaglandin $E_2$ subtype EP4

EPC: endothelial progenitor cell

EPO: erythropoietin

EPOR: erythropoietin receptor

ER: endoplasmic reticulum

ERC: endometrial regenerative cells

ERK: extracellular signal-regulated kinase

ERM: the ERM protein family consists of the three closely related proteins ezrin, radixin, and moesin

ESC: embryonic stem cell

ESCRT: endosomal sorting complex required for transport

ESRD: end-stage renal disease

ESV: end-systolic volume

ET-1: endothelin-1

ETA-1: early T-cell activation factor 1

ETS: E26 transformation-specific or E-twenty-six (a member of one of the largest families of transcription factors)

ETSV1: E (twenty-six) family of transcription factors variant 1

EU: European Union

EV: extracellular vesicles

EYA1/3 eyes absent homolog 1/3 (phosphatase)

EZH2: Enhancer of Zeste homolog two

EZR: ezrin

FA: fatty acid

FABP4: fatty acid binding protein 4

FACS: fluorescence-activated cell sorting

FADD: Fas-associated protein with death domain

FAP: fibroblast activation protein

FAK: focal adhesion kinase

FAP-α: fibroblast activation protein-α

FAS: it is not clear for what FAS is an abbreviation; one suggestion is "first apoptotic signal," since engagement of Fas (a cell death surface receptor) by Fas ligand (FasL) results in apoptotic cell death mediated by caspase activation

FAT: fatty acid translocase (also known as CD36)

FBA: fetal bovine albumin

FBS: fetal bovine serum

FcεRI: Fc epsilon receptor 1

FCS: fetal calf serum

FDA: Food and Drug Administration (USA)

FEV1: forced expiratory volume in 1 s

FGF: fibroblast-derived growth factor

FGFR: fibroblast growth factor receptor

FIAU: fluoro-1-β-D-arabinofuranosyluracil

FIH: factor inhibiting HIF

FISH: fluorescence *in situ* hybridization

FIX: (coagulation) factor IX

FKBP: FK506 binding protein 5 (FK506 was the initial term used for the calcineurin inhibitor tacrolimus)

Flt: FMS-like tyrosine kinase

FMA: fluorescent migroangiography

f-MLF: formyl–methionyl–leucyl phenylalanine

FMOD: fibromodulin
FMS: factor increasing monocytopoiesis
FN: fibronectin
FN9-10: fibronectin fragment 9–10
FOS: Finkel–Biskis–Jinkins murine osteogenic sarcoma virus (gene, protein)
FPR: *N*-formylated peptides/*N*-formyl peptide receptor
FPRL: formyl peptide receptor-like
FOV: field of view
FOX: forkhead winged helix box
FRAP: fluorescence recovery after photobleaching
FRET: fluorescence energy transfer
F/RGD: a modified adenoviral vector (Adv-F/RGD) with an RGD-containing peptide in the HI loop of the fiber knob domain of adenovirus type 5
FSH: follicle-stimulating hormone
FVC: forced vital capacity
FVIII: (clotting) factor VIII
FZD: Frizzled
FZD8: frizzled class receptor 8
$G_0$: gap 0 (quiescent phase of the cell cycle)
$G_1$: gap 1 (of the cell cycle)
$G_2$: gap 2 (of the cell cycle)
G6PT: glucose-6-phosphate transporter
GABA: γ-aminobutyric acid
GAG: glycosaminoglycan
GALS1: lectin, galactoside-binding, soluble, 1
GA-MSC: glioma-associated MSCs
GAP-43: growth associated protein-43
GAPDH: glyceraldehyde 3-phosphate dehydrogenase
GAS 6: growth arrest-specific gene 6
GATA: GATA transcription factors are a family of transcription factors characterized by their ability to bind to the DNA sequence GATA
GBM: glioblastoma multiforme
GCP: granulocyte chemotactic protein (also known as CXCL6)
GCP: good clinical practice
cGCP: current good clinical practice
G-CSF: granulocyte colony-stimulating factor
GCTB: giant cell tumor of bone
GD2: neural ganglioside-2
GDF5: growth differentiation factor 5
GDNF: glial-derived neurotrophic factor
GDNF: glial-cell-line-derived neurotrophic factor
GEF-H1: guanine nucleotide exchange factor H1
GFAP: glial fibrillary acid protein
GFP: green fluorescent protein
GFR: glomerular filtration rate
GGF: glial growth factor
GGT: γ-glutamyltransferase
GICs: glioma-initiating cells
GJCs: gap junctional channels
Gli: glioma-associated antigen
GLUT: glucose transporter
GMP: good manufacturing practice
GO: gene ontology
GOLD: Global Initiative on Obstructive Lung Disease
GPD1: glycerol-3-phosphate dehydrogenase
GPI: glycophosphatidylinositol
GPR39: G-protein coupled receptor 39
Gr-1: granulocyte receptor-1
GREM1: gremlin 1
GRO: growth-related oncogene
GRO-1α: growth-related protein 1 (also known as CINC, but now known as CXCL1)
GSC: glioma stem cell
GSK: glycogen synthase kinase
GSNOR: *S*-nitrosoglutathione reductase gene
GTP: guanosine triphosphate
GUSB: β-glucuronidase
GUI: graphical user interface
GVHD: graft-versus-host disease
GVL: graft-versus-leukemia (effect)
Gy: gray (a unit of ionizing radiation)
H2: the major histocompatibility complex of mice
$H_2O_2$: hydrogen peroxide
H9C2: a subclone of an original clonal cell line derived from embryonic BD1X rat heart tissue
HA: hyaluronic acid
hAMSC: human amnion-derived MSC
HAND 2: heart- and neural crest derivatives-expressed protein 2

HAPLN 1: hyaluronan and proteoglycan link protein 1
HAS: hyaluronic acid synthase
HA-TCP: hydroxyapatite–tricalcium phosphate
HAT: histone acetyltransferase
HbA1c: glycated hemoglobin
HB-EGF: heparin-binding EGF-like growth factor
HBO: hyperbaric oxygen
HBPA: heparin-binding peptide amphiphile
HCAM: homing cell adhesion molecule (CD44)
HCC: hepatocellular cancer
HCELL: hematopoietic cell E-selectin/L-selectin ligand
hCMSC: human chorion-derived MSC
HCT/P: human cell and tissue products (USA FDA)
HD: Huntington's disease[4]
HDAC: histone deacetylase
HDD: hard disk drives
HDL: high-density lipoprotein
HDM: house dust mite
HDMT: histone demethylase
hDPSC: human dental pulp stem cell
HEK: human embryonic kidney
HeLa: a cell line derived from cervical cancer cells taken on February 8, 1951, from Henrietta Lacks
HEPES: 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (buffer)
HES: human embryonic stem cells
HES1: transcription factor HES1 (hairy and enhancer of split-1)
HEY: hairy/enhancer-of-split related with YRPW motif protein
HGF: hepatocyte growth factor
HGFR: hepatocyte growth factor receptor
HGMA2: high-mobility group AT-hook 2
HIF: hypoxia-inducible factor
HIMF: hypoxia-induced mitogenic factor
HLA: human leukocyte antigen
HLI: hind limb ischemia
HMADS: human multipotent adipose-derived stromal cells
HME: hematopoietic microenvironment
HMEC-1: human microvascular endothelial cell line
HMG-CoA reductase: 3-hydroxy-3-methyl-glutaryl-CoA reductase
HMOX1: heme oxygenase 1
HMPAO: hexamethylpropylene
HMT: histone methyltransferase
HO: heme oxygenase
HOX: homeotic genes encoding the homeobox
hPAP: human placental alkaline phosphatase
HPC: hematopoietic progenitor cell
HPLC: high-performance liquid chromatography
HPMA-RGD: poly[*N*-(2-hydroxypropyl) methacrylamide with the attached amino acid sequence Arg–Gly–Asp] (scaffold)
HR: homologous recombination
H/R: hypoxia and reoxygenation
HREC: human research ethics committee
HSB: hyperactive sleeping beauty (The Sleeping Beauty transposon system is composed of a Sleeping Beauty transposase and a transposon. The resurrected transposase gene was named "Sleeping Beauty" because it was brought back to activity from a long evolutionary sleep)
HSC: hematopoietic stem cell
HSCT: hematopoietic stem cell transplantation
HSP: heat shock protein
HSPC: hematopoietic stem and progenitor cell
HSV-TK: herpes simplex virus thymidine kinase
H-TERT: human telomerase reverse transcriptase
HTT: huntingtin, the gene for Huntington's chorea IT15 (and on initial discovery as IT15)
HU: hydroxyurea (a cytotoxic agent)
HUCPVC: human umbilical cord perivascular cells
HUMSC-NS: human umbilical cord mesenchymal stromal-cell-derived neurosphere
HUVEC: human umbilical vein endothelial cell
IA: intra-arterial
IαI: inter-alpha-inhibitor
IAP: inhibitor of apoptosis
IBA1: ionized calcium-binding adapter molecule (also known as allograft inflammatory factor (AIF))

IBD: inflammatory bowel disease
IBMX: 1-methyl-3-isobutylxanthine
IBZ: ischemic boundary zone
IC: intracranial
ICA: internal carotid artery
ICAM-1: intercellular adhesion molecule 1
ICAT: isotope-coded affinity tagging
ICC: immunocytochemistry
ICC: intercellular communication
ICH: International Conference on Harmonisation
ID1: DNA-binding protein inhibitor
IDO: indoleamine 2,3-dioxygenase
IFATS: International Federation for Adipose Therapeutics and Science
IFATS: International Fat Applied Technology Society
IFN: interferon
IFN-γR: interferon-γ receptor
IGF-1: insulin-like growth factor-1
IGFBP: insulin-like growth factor-binding protein
IGR1R: insulin-like growth factor 1 receptor
IHC: immunohistochemistry
IHH: Indian hedgehog
IκB: inhibitor of kappa light polypeptide gene enhancer in B cells, kinase beta
IκBα: inhibitor of kappa Bα
IKK-β: inhibitor of kappa kinase β
IL: interleukin
IL-12M: modified interleukin-12
IL-1RA: interleukin-1 receptor antagonist
ILB: intraluminal vesicle
ILC2: innate lymphoid cells 2
ILK: integrin-linked kinase
ILT: immunoglobulin-like transcript
ILV: intraluminal vesicles
IMDM: Iscove's modified Dulbecco's medium[5]
IMZ: $^{123}$I-iomazenil
INC: intercellular nanotubes
IND: investigational new drug
INF: interferon
Ink4A: inhibitor of cyclin-dependent kinase 4A
iNOS: inducible nitric oxide synthetase
IP6K: inositol hexakisphosphate kinase
IP 10: interferon-γ-induced protein
IP: ischemic preconditioning
IP: intraperitoneal
IPLASS: International Placenta Stem Cell Society
iPSC: induced pluripotent stem cell
iPSC-MSCs: MSCs derived from induced pluripotent stem cells
IQGAP1: Ras GTPase-activating-like protein
IR: ionizing radiation
IRAK: interleukin-1 receptor-associated kinase
IRIF: ionizing-radiation-induced foci
IRI: ischemia–reperfusion injury
IRS-1: insulin receptor substrate 1
I-SMAD: inhibitor SMAD
ISCT: International Society for Cell Therapy
ITGA11: integrin α11
ITGA2: integrin α2 (also known as CD49B, α2 subunit of the very late activation antigen-2 receptor and platelet membrane glycoprotein Ia (GP1a))
ITGA5: integrin α5 (also known as the fibronectin receptor, CD49e and very late activation protein 5 (VLA-5))
ITGAM: integrin alpha M (also known as CD11b)
ITGB1: integrin β1 (also known as CD29, glycophorin IIa and very late activation protein, β subunit)
ITP: idiopathic thrombocytopenic purpura
iTRAQ: isobaric tagging for relative and absolute quantitation
IV: intravenous
IVI: intravenous infusion
JAG1: jagged 1
JAK: Janus family kinase (not as alleged by some as "just another kinase")
JMJD3: Jumonji domain-containing protein 3
JNK: c-Jun NH2-terminal kinase
JUN: Jun N-terminal kinase
JUND: jun D proto-oncogene
KC: keratinocyte chemoattractant; keratinocyte-derived chemokine
kDa: kilodalton
KDR: kinase insert domain receptor (a type III receptor tyrosine kinase) also known as vascular endothelial growth factor receptor 2 (VEGFR-2)
KGF: keratinocyte growth factor

Ki-67: an antigen indicative of cellular proliferation identified by the monoclonal antibody Ki-67

KID: kinase insert domain receptor (also known as VEGFR)

KIR: killer inhibitory receptor

Kim: kidney injury model

KLF: Kruppel-like factor

KO: knockout

kPa: kilopascal

KSC: keratinocyte stem cells

KT: kidney transplantation

LA-4 cells: cells from a murine urethane-induced lung adenoma

LABA: long-acting beta agonist

LACZ: lactose operon gene Z (encodes β-galactosidase)

LAD: left anterior descending (artery)

LAMPB: lysosomal-associated membrane protein B

LC–MS/MS: liquid chromatography–mass spectrometry/mass spectrometry

LDH: lactic dehydrogenase

LDL: low-density lipoprotein

LEF: lymphoid enhancer-binding factor

LEF/TCF: LEF – see earlier; TCF – transcription factor (A group of transcription factors that bind to DNA through a high-mobility group domain. They are involved in the Wnt signaling pathway, where they recruit the coactivator β-catenin to enhancer elements of genes they target)

LEPR: leptin receptor

LET-7: lethal-7

LEV: lymphocyte extracellular vesicle

LFA-1: lymphocyte function-associated antigen 1 (found on all T-cells and also on B-cells, macrophages and neutrophils and involved in recruitment to the site of infection. It binds to ICAM-1 on antigen-presenting cells and functions as an adhesion molecule)

$Li^+$: lithium ion

LiCl: lithium chloride

LIF: leukemia inhibitory factor

LIM: LIM domains are protein structural domains, composed of two contiguous zinc finger domains, separated by a two-amino-acid residue hydrophobic linker. They are named after their initial discovery in the proteins Lin11, Isl-1, and Mec-3

Lin: lineage

LL37: leucine, leucine-37

LLP2A: *N*-[[4-[[[(2-ethylphenyl)amino] carbonyl]amino]phenyl]acetyl]-Ne-6-[(2*E*)-1-oxo-3-(3-pyridinyl-2-propenyl)]-L-lysyl-L-2-aminohexanedioyl-(1-amino-1-cyclohexane) carboxamide

LncRNAs: long noncoding RNAs

LNGFR: low-affinity nerve growth factor receptor

Lox P: locus of X-over in bacteriophage P1

LPL: lipoprotein lipase

LPS: lipopolysaccharide (endotoxin)

LRP: low-density lipoprotein receptor

LSC: leukemic stem cell

LSCD: limbal stem cell deficiency

LSD1: lysine-specific demethylase 1

L-SOX5: long SRY-related HMG-box 5

LST1: leukocyte-specific transcript

LT: liver transplantation

LT: lymphotoxin

LTA: lymphotoxin-α

LTBP: latent transforming growth factor beta binding protein

LTC4: leukotriene C4

LTQ: linear trap quadrupole

LUM: lumican

LV: left ventricle

L-VAP-2: lymphocyte-vascular adhesion protein 2 (also known as CD73 and 5′-nucleotidase

LVDP: left ventricular diastolic pressure

LVEF: left ventricular ejection fraction

LVF: left ventricular function

LY294002: a morpholine-containing chemical compound that is a potent inhibitor of phosphoinositide 3-kinases (PI3Ks)

LYVE-1: lymphatic vessel endothelial receptor 1

M: mitosis (phase of the cell cycle)

M cells: microfold cells – cells found in the follicle-associated epithelium of the Peyer's patches as well as in bronchus-associated lymphoid tissue (BALT). They transport organisms

| | |
|---|---|
| | and particles from the gut lumen to immune cells across the epithelial barrier and thus are important in stimulating mucosal immunity |
| MAB or mAb: | monoclonal antibody |
| MAC: | membrane attack complex |
| MACI: | matrix-induced chondrocyte implantation |
| MAC-IP: | membrane attack complex inhibitory protein |
| MACS: | magnetic activated cell sorting |
| MadCAM: | mucosal vascular addressin cell adhesion molecule |
| MAEC: | murine aortic endothelial cells |
| MAMP: | microbe-associated molecular pattern |
| MAP: | medroxyprogesterone acetate (also known as 17α-hydroxy-6α-methylprogesterone acetate) |
| MAP: | microtubule-associated protein |
| MAPC: | multipotent adult progenitor cells |
| MAPK: | mitogen-activated protein kinase |
| MAP2K: | mitogen-activated protein kinase kinase (also known as MAPKK and MEK) |
| MAPKK: | mitogen-activated protein kinase kinase (also known as MAPK, MAP2K and MEK) |
| MASC: | multipotent adult mesenchymal stromal cell |
| MATN4: | matrilin 4 |
| MBA: | microbioreactor array |
| MBD: | methyl-CpG-binding domain |
| MBF: | methyl binding factors |
| MBP: | myelin basic protein |
| MCA: | middle cerebral artery |
| MCAM: | melanoma cell adhesion molecule |
| MCAO: | middle cerebral artery occlusion |
| MCK: | muscle creatine kinase |
| MCP-1: | monocyte chemoattractant protein 1 (also known as CCL2) |
| M-CSF: | macrophage colony-stimulating factor (also known as CSF-1) |
| MDC: | macrophage-derived chemokine |
| MDC1: | mediator of DNA damage checkpoint protein 1 |
| MDCT: | multi-detector computed tomography |
| MDFIC: | MyoD family inhibitor domain containing |
| MDHLC: | mesenchymal-derived hepatocyte-like cells |
| Mdm2: | mouse double minute 2 (ligase) |
| MDSC: | muscle-derived stem cell |
| MDSC: | myeloid-derived suppressor cell |
| MeDIP-chip: | methyl-DNA immunoprecipitation and promoter array hybridization |
| meCp2: | methyl CpG binding protein 2 |
| MEF2C: | myocyte enhancer factor 2C |
| MEK: | mitogen/extracellular signal-regulated kinase (also known as MAPK, MAP2K and MAPKK). |
| MEM: | minimum essential medium |
| MEP: | motor-evoked potential |
| MESC: | mouse embryonic stem cell |
| MET: | mesenchymal-to-epithelial transition |
| MEV: | monocyte extracellular vesicle |
| MFGE8: | milk fat globule EGF factor 8 protein |
| mGFP: | membrane-bound GFP |
| mGFP: | monomeric GFP |
| MGP: | matrix gla protein |
| MHC: | major histocompatibility complex |
| MHC: | myosin heavy chain |
| MHRA: | Medicines and Healthcare Products Regulatory Agency |
| mHTT: | mutant huntingtin (gene) |
| μCT: | micro computed tomography |
| MI: | myocardial infarct |
| MIAMI: | marrow-isolated adult multilineage inducible (cells) |
| MICA: | major histocompatibility complex (MHC) class I chain-related A |
| MIF: | macrophage inhibitory protein |
| MIG: | monocyte induced by γ-interferon |
| MIP: | macrophage inflammatory protein |
| MIRL: | membrane inhibitor of reactive lysis |
| miRNA: | microRNA |
| MIRO-1: | mitochondrial Ras homolog gene family member T1 (Rho) GTPase 1 |
| mitoGFP: | GFP that targets mitochondria specifically |
| mitoRFP: | RFP specifically targeting mitochondria |
| MITR: | myocyte enhancer factor-2 interacting transcription factor |
| MKK: | MAPK kinases |
| MKKK: | MAPK kinase kinases |
| MLHFW: | Minnesota Living with Heart Failure (score) |
| MLL1–5: | mixed lineage leukemia 1–5 |

MLR: mixed lymphocyte reaction or mixed leukocyte reaction
MME: metallo-endopeptidase
MMF: mycophenolate mofetil
MMP: matrix metalloproteinase
MMTV: mouse mammary tumor virus
MNC: mononuclear cell
MNP: magnetic nanoparticle
MnSOD: manganese superoxide dismutase
MOE: membrane-organizing extension spike protein
MP: microparticle
MPC: mesenchymal progenitor cell
mpCCL2: matrix metalloproteinase-processed CCL2
MPP: multipotent progenitor
MPSVIII: mucopolysaccharidosis type VII
MR: mannose receptor
MRA: magnetic resonance angiogram
MRI: magnetic resonance imaging
MRN: Mre11-Rad50-Nbs1
mRNA: messenger RNA
MRTF-A: myocardin-related transcription factor-A
MS: mass spectrometry
MSC: mesenchymal stromal cell
MSC1: mesenchymal stromal cell type 1
MSCA-1: mesenchymal stem cell antigen-1
MSC-Ex: mesenchymal stromal cell exosome
MSDNC: marrow stromal-cell-derived neuronal cell
M-SEC: a protein involved in tunneling nanotubules and so called because it was first found in intestinal M (microfold) cells and is homolgous to Seq6, a subunit of the exocyst
MSX2: Msh homeobox protein 2
MSN: medium spiny neuron
MSN: mesoporous silica nanoparticle
M-SPIO: micrometer-sized superparamagnetic iron oxide
MSS: MRI score of severity
MT1-MMP: membrane-associated type-I transmembrane matrix metalloproteinase
MTD: maximum tolerated dose
mtDNA: mitochondrial DNA
mTEC: medullary thymic epithelial cell
MTMMP: membranous type matrix metalloproteinase
mTORi: mammalian target of rapamycin inhibitor
MTT: 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide
MUC: mucin
MV: microvesicle
MVB: multivesicular body
MVO2: maximal oxygen consumption
Mx1: a stromal cell line with MSC features that has the myxovirus resistance-1 (Mx1) promoter
MYD88: myeloid differentiation primary response gene 88
Myf5: myogenic factor 5
MyHC: cardiac myosin heavy chain
MYOD1: myogenic differentiation gene or protein 1
MYTH11: a smooth muscle myosin
Mx-1: myxovirus resistance protein-1
NaCl: sodium chloride
NAD: nicotinamide adenine dinucleotide
NADH: the reduced form of nicotinamide adenine dinucleotide
NADPH oxidase: nicotinamide adenine dinucleotide phosphate oxidase
NAP-2: neutrophil-activating protein 2
NASA: National Aeronautics and Space Administration (USA)
N-cadherin: neuron cadherin (cadherin = calcium-dependent adhesion)
N-CAM: neural adhesion molecule
NCOA4: nuclear receptor coactivator 4
NDGA: dicatechol nordihydroguaiaretic acid
NDRG1: N-myc downstream-regulated gene 1
NEP: neutral endopeptidase
NeuN: neuronal nuclear antigen
NEV: neutrophil extracellular vesicle
NF1B: nuclear factor 1 B-type
NFAT: nuclear factor of activated T cells
NFATC1: nuclear factor of activated T cells, cytoplasmic 1
NF200: 200 kDa neurofilament protein
NFκB: nuclear factor kappa light chain-enhancer of activated B cells
NG2: neural/glial antigen 2
NGF: nerve growth factor

NHEJ: nonhomologous end-joining
NIH: National Institutes of Health (USA)
NIHSS: National Institutes of Health Stroke Scale or NIH Stroke Scale
NIPAL3: NIPA-like domain containing 3
NRIP1: nuclear receptor-interacting protein 1
NK: natural killer
NK4: N-terminal hairpin and subsequent four kringle domains of hepatocyte growth factor
NKG2D: natural killer cell lectin-like receptor subfamily K, member 1
NKX3.2: NK3 homeobox 2
NLR: Nod-like receptor
NLRP3: NOD-like receptor family, pyrin domain containing 3
nNOS: neuronal NO synthase
NO: nitrous oxide
NOD: nonobese diabetic (mice)
NOS: nitrous oxide synthetase
Notch 1: Notch homolog 1, translocation-associated (*Drosophila*)
NOV: nephroblastoma overexpressed (also known as CCN3)
NP: nanoparticle
NPC: neural progenitor cell
NRG1-β1: neuroregulin-β1
NRP1: neuropilin-1
NSAID: nonsteroidal anti-inflammatory drug
NSC: neural stem cell
NSC: neural stromal cell
NSG: NOD SCID Gamma (NOD.Cg-Prkdcscid Il2rgtm1Wjl/SzJ – a strain of inbred laboratory mice, among the most immunodeficient described to date. NSG mice lack mature T cells, B cells, and natural killer cells. NSG mice are also deficient in multiple cytokine signaling pathways and they have many defects of innate immunity)
NS-MSC: neurosphere-like cellular aggregates
NSPC: neural stem/precursor cells
NSS: neurologic severity score
NT: neurotrophin
NTA: nanoparticle tracking analyses
NTT: Nordon's Tracking Tool
NVU: neurovascular unit
NYHA: New York Heart Association
$O_2$: oxygen
OA: osteoarthritis
OB: obliterative bronchiolitis
OB-cadherin: osteoblast cadherin (cadherin = calcium-dependent adhesion)
OC: osteocalcin
OCN: osteocalcin
OCIF: osteoclastogenesis inhibitory factor (now known as osteoprotegerin)
OCT-4: octamer-binding transcription factor
OEG: olfactory glia
OGD: oxygen-glucose deprived
OH: hydroxyl
OI: osteogenesis imperfecta
OKT3: monoclonal antibody against CD3 (a pan T cell surface antigen)
OMG: oligodendrocyte-myelin glycoprotein
OP-1: osteogenic protein-1
OPG: osteoprotegerin
OPN: osteopontin
OPPG: osteoporosis-pseudoglioma syndrome
ORF: open reading frame
ORP8: oxysterol-binding protein-related protein 8
OSE2: osteoblast-specific cis-acting element 2
OSR1/2: odd-skipped related 1/2
OSX: Osterix (an osteoblast-specific transcription factor essential for osteoblast differentiation and bone formation)
OVA: ovalbumin
OVX: ovariectomy
OXi4503: combretastatin A1 di-phosphate/CA1P (a dual-mechanism vascular disrupting agent)
OXPHOS: oxidative phosphorylation
P: passage (number)
P1NP: propeptide of type 1 procollagen
p53 (or TP53): tumor protein 53 was the name given in 1979 describing a protein mass of 53 kDa to a gene that encoded a protein that acted as a tumor suppressor gene
p63: transformation-related protein 63
PA: polyamide
PACAP: pituitary adenylate cyclase-activating polypeptide

PAD: peripheral arterial disease
PAF: platelet-activating factor
PA/G: polyamide gelatin
PAH: pulmonary artery hypertension
PAI-1: plasminogen activator inhibitor 1
PAK: p21-activating kinases
pAkt: phospho-Akt (for Akt see under A above)
PAMPs: pathogen-associated molecular patterns
PANTHER: protein analysis through evolutionary relationships
PAOD: peripheral arterial occlusive disease
PAR: poly-(ADP) ribose
PARK2 gene: mutations in this gene are known to cause a familial form of Parkinson's disease[6]
PARP: poly-(ADP) ribose polymerase
PAX: paired box
PBF1: proteasome beta subunit F1
PBMC: peripheral blood mononuclear cell
PBS: phosphate buffered saline
PC12: a cell line derived from a pheochromocytoma of the adrenal medulla
PCI: percutaneous intervention
PCLA: poly-ε-caprolactone and lactic acid
PCNA: proliferating cell nuclear antigen
PCP: planar cell polarity
PCR: polymerase chain reaction
PCR2: poly comb repressor complex 2
PD: Parkinson's disease
PD: population doubling
PD-1: programmed cell death protein 1 (also known as CD279)
PDAI: perianal disease activity index
PDCD6IP: programmed cell death 6-interacting protein (also known as Alix)
PDEF: pigment epithelium-derived factor (also known as serpin F1)
PDGF: platelet-derived growth factor
PDGFA: platelet-derived growth factor-α (also known as PDGF-1)
PDGFB: platelet-derived growth factor subunit B
PDGFBB: platelet-derived growth factor BB (homodimer)
PDGFR: platelet-derived growth factor receptor
PDK1: phosphoinositide-dependent kinase-1
PDK1: pyruvate dehydrogenase lipoamide kinase isozyme 1
PD-L1: programmed death ligand 1
PDLIM4: PDZ and LIM domain 4
PDMS: polydimethylsiloxane
PDX-1: pancreatic duodenal homeobox-1
PDZ: PDZ is an acronym combining the first letters of three proteins – post synaptic density protein (PSD95), Drosophila disc large tumor suppressor (Dlg1), and zonula occludens-1 protein (zo-1), which were the first proteins discovered to share the PDZ domain
PECAM-1: platelet endothelium adhesion molecule-1
PECAM-1: platelet/endothelial cell adhesion molecule-1 (CD31)
PEG: polyethylene glycol
PEMF: pulsed electromagnetic field
PET: positron emission tomography
PEV: platelet extracellular vesicle
PFD: pelvic floor disorder
PFKFB3: phosphofructokinase-2/fructose-2,6-bisphosphatase 3
PG: proteoglycans
PGE: prostaglandin E
PGF: placental-derived growth factor
PGK: phosphoglycerate kinase
PGM: phosphoglycerate mutase
PGN: peptidoglycan
PGP9.5: protein gene product 9.5
PHA: phytohemagglutinin
PHD: prolyl hydroxylase domain-containing protein
PHEMA: poly(2-hydroxyethyl methacrylate)
Phf2: plant homeodomain zinc finger-like 2
PI: protease inhibitor
PIC/S: Pharmaceutical Inspection Convention (PIC) and Pharmaceutical Inspection Co-operation Scheme
PI3K: phosphatidylinositide 3-kinase
PIG: proliferation inducing gene
PIK: phosphatidylinositide 3-kinases
PIK3CD: phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit delta
PINK1: PTEN-induced putative kinase 1
PK: pyruvate kinase

PKA: protein kinase A (A family of enzymes whose activity is dependent on cellular levels of cyclic AMP (cAMP). PKA is also known as cAMP-dependent protein kinase. Protein kinase A has several functions in the cell, including regulation of glycogen, sugar and lipid metabolism)

PKB: protein kinase B

PKm2: pyruvate kinase isozyme M2

PKP: penetrating keratoplasty

PL: platelet lysate

PLA: poly(L-lactic acid) scaffold

PLA: polylactic acid

PLAU: urokinase-type plasminogen activator (encoded by the PLAU gene)

PLAUR: urokinase-type plasminogen activator receptor

PLGA: poly(lactic-co-glycolic acid)

PLGA: polyglycolic acid

PLGF: placental growth factor

PMDA: Pharmaceutical and Medical Devices Agency

pMSC: placental mesenchymal stromal cell

PNCA: proliferating cell nuclear antigen

PNS: peripheral nervous system

PODXL: podocalyxin-like protein

POLR2E polymerase (RNA) II (DNA directed) polypeptide E gene

polyI:C: polyinosinic:polycytidylic acid

POP: pelvic organ prolapse

POU3F1: POU domain, class 3, transcription factor 1

PP: polypropylene

PPAR: peroxisome proliferator-activated receptor

pQCT: peripheral quantitative computed tomography

PRAK: p38-regulated/activated kinase

Pre-RC: pre-replication complex

PRDM16: PR domain containing 16

pre-miRNA: precursor miRNA

PRG4: proteoglycan 4

PRGF: platelet-released growth factors

pri-miRNA: primary miRNA

PRMT: protein arginine methyltransferase

PRP: platelet-rich plasma

PRR: pattern recognition receptor

PRRX1: paired related homeobox 1

PSGL-1: P-selectin glycoprotein ligand-1

PTEN: phosphatase and tensin homolog

PTH: parathyroid hormone

PTHLH: parathyroid hormone-like hormone

PTHR1: parathyroid hormone receptor

PTHrP: parathyroid hormone-related protein

PTIP: PAX transactivation activation domain-interacting protein

PTN: pleiotrophin – also known as heparin-binding brain mitogen (HBBM), heparin-binding growth factor 8 (HBGF-8), neurite growth-promoting factor 1 (NEGF1), heparin affinity regulatory peptide (HARP), or heparin binding growth associated molecule (HB-GAM)

PTM: posttranslational histone modification

PTX3: pentraxin-related protein

PU 1: nuclear protein that binds to a purine-rich sequence known as the PU-box found near the promoters of target genes

PU 1 AS: PU 1 antisense

PUCAI: pediatric ulcerative colitis activity index

PUVA: psoralen and ultraviolet-A light

pVHL: product of the von Hippel–Lindau (tumor suppressor)

PYCARD/ASC: apoptosis-associated speck-like protein

QA: quality assurance

QC: quality control

QD: quantum dot

qRT-PCR: quantitative real-time reverse transcriptase polymerase chain reaction

RA1: (putative) drug resistance ATPase-1

Rab: Ras-related in brain (the Rab family of proteins is a member of the Ras superfamily of monomeric G proteins)

RAC1: Ras-related C3 botulinum toxin substrate 1

RAD51: a DNA repair protein

RALA: v-ral simian leukemia viral oncogene homolog A

RANK: receptor activator of nuclear factor κB

RANKL: RANK ligand
RANTES: regulation on activation, normal T cell expressed and secreted (also known as CCL5)
RAR: retinoic acid receptor
RAS: a family of proteins involved in cellular signal transduction first discovered in a rat sarcoma line
Rb: retinoblastoma
RBP2: retinoblastoma binding protein 2
RBP-J: recombination signal binding protein-J
R-cadherin: retinal cadherin
RCAS: the RCAS family of plasmids were originally derived from a molecular clone of the SR-A strain of Rous sarcoma virus
rCE: rabbit carboxylesterase enzyme
RECA: rat endothelial cell antigen
RCT: randomized controlled trial
Re-Seq: reference sequence promoter arrays
REV: red blood cell extracellular vesicle
REX1: reduced expression gene 1
RFP: red fluorescent protein
RGD: the tripeptide arginine, glycine, aspartic acid (Arg–Gly–Asp). The sequence is a common element in cellular recognition
RGS5: regulator of G-protein signaling
RHO: Ras homolog gene family
rHo: Spearman's rank-order correlation coefficient
RIF1: Rap1-interacting factor
RIG: retinoic acid inducible
RISC: RNA-induced silencing complex
RISK: reperfusion injury salvage kinases
RNA: ribonucleic acid
RNAi: RNA interference
RNS: reactive nitrogen species
ROBO4: roundabout homolog 4, also known as magic roundabout (gene, protein)
ROCK: Rho-associated protein kinase, RhoA-Rho kinase
ROI: region of- interest
RORγ: retinoic acid-related orphan receptor gamma
ROS: reactive oxygen species
RPA: replication protein A
RPLC: reversed-phase liquid chromatography
RR: relative risk
rRNA: ribosomal RNA
RNF: E3 ubiquitin ligase RING finger protein
RSK: ribosomal 6s kinase
R-SMAD: receptor-regulated SMAD
RT-PCR: reverse transcriptase polymerase chain reaction
RUNX2: runt-related transcription factor 2
RUUO: reversal of the unilateral ureteric obstruction
RVG: rotavirus genus or rotavirus G
RVH: right ventricular hypertrophy
RWV: rotary wall vessel
RXFP: relaxin family peptide receptor
S: (DNA) synthesis (phase of the cell cycle)
S: Svedberg sedimentation coefficient unit[7]
S100-A9: a protein that in humans is encoded by the S100A9 gene (also known as migration inhibitory factor-related protein 14 (MRP-14) or calgranulin-B)
SAA: serum amyloid A
SABA: short-acting beta agonist
SAG: a small-molecule agonist of the Sonic hedgehog-Smoothened (Shh-Smo) signaling pathway
SAMP6: senescence-accelerated mouse strain
SAPK: stress-activated protein kinase
Sca-1: stem cell antigen
SCC: squamous cell carcinoma
SCF: stem cell factor (c-kit ligand)
SCGB1A1: secretoglobin family 1A member 1 (also known as uteroglobin)
SCI: spinal cord injury
SCID: severe combined immunodeficiency
sCMOS: scientific complementary metal-oxide-semiconductor
SCX: strong cation exchange chromatography
SDF-1: stromal cell-derived factor-1 (also known as CXCL12)
SDS-PAGE: polyacrylamide gel containing sodium dodecyl sulfate

SEB: staphylococcal enterotoxin B
SEM: scanning electron microscopy
Sema3a: semaphorin3A
SEP: sensory evoked potentials
SERCA: sarco/endoplasmic reticulum $Ca^{2+}$-ATPase, or SR $Ca^{2+}$-ATPase
SERPIN: serine proteinase inhibitor (superfamily)
SERPINE1: serpin peptidase inhibitor, clade E
SETDB1: set domain bifurcated 1
SFM: serum-free medium
SFRP: secreted frizzled-related protein
SFTPC: surfactant protein C
SH2: Src homology 2-like (domains)
SHH: Sonic hedgehog (Hedgehog was first discovered in the fruit fly by researchers who thought the spiky protein looked like a hedgehog. Sonic was named as such by the Harvard researcher (Cliff Tabin) because two previous gene family members had been named Indian and desert hedgehog based on the way fruit flies looked when these genes were mutated. His children were playing a lot of Sonic the Hedgehog video games at the time he discovered his gene (circa 1991) so he went with that name for the third member of this protein family)
SHH-SMO: Sonic hedgehog-Smoothened
sHLA-G: soluble human leukocyte antigen
SHP: small heterodimer partner, also known as NR0B2 (nuclear receptor subfamily 0, group B, member 2). SHP is a member of the nuclear receptor family of intracellular transcription factors. SHP is unusual for a nuclear receptor in that it lacks a DNA binding domain. Therefore, technically it is neither a transcription factor nor a nuclear receptor, but nevertheless it is still classified as such due to relatively high sequence homology with other nuclear receptor family members
shRNA: short hairpin RNA or small hairpin RNA
SHR-SP: spontaneous hypertension rat stroke-prone
SILAC: stable isotope labeling by amino acids in cell culture
SIM2: single-minded homolog 2
siRNA: small interfering RNA
SIRS: systemic inflammatory response syndrome
SIS: small intestinal submucosa
SLAM: signaling lymphocyte activation molecule
SLC: secondary lymphoid-tissue chemokine
SLE: systemic lupus erythematosus
SLeX: sialyl Lewis X (cell adhesion molecule)
SLRP: small leucine-rich repeat proteoglycan (also known as biglycan)
SMA: smooth muscle actin
SMAD: SMAD proteins are homologs of both the *Drosophila* protein, mothers against decapentaplegic (MAD), and the *Caenorhabditis elegans* protein SMA (from gene SMA for small body size)
SMB: somatomedin B
SMC: smooth muscle cell
SM-MHC: smooth muscle myosin heavy chain
SMRT: silencing mediator of retinoid and thyroid hormone receptors
SREBP-1: sterol regulatory element binding protein 1
SN: substantia nigra
SNARE: N-ethylmaleimide-sensitive factor activating protein receptor
SOCS or COCS: suppressor of cytokine signaling
SOST: sclerostin
SOSTdc-1: sclerostin-domain containing protein-1
SOT: solid organ transplantaion
SOX: Sry-related high mobility group (HMG) box
SP: sulfophenyl
SPARC: secreted protein acidic and rich in cysteine (also known as osteonectin)
SPECT: single-photon emission computed tomography
SPEDF: SAM pointed domain containing ETS transcription factor
SPIO: superparamagnetic iron oxide

SPP 1: secreted phosphoprotein 1 (also known as osteopontin)
src: Schmidt–Ruppin A-2 viral oncogene homolog
SRF: serum response factor
SRM: selected reaction monitoring
SRY: sex-determining region Y-box 9 (also known as SOX9)
SSEA: stage-specific embryonic antigen
SSB: single-strand break
SSEP: somatosensory evoked potential
SSI: STAT-induced STAT inhibitor, also known as suppressor of cytokine signaling (SOCS)
STAT: signal transducer and activator of transcription
STC-1: stanniocalcin-1
STEMI: ST-segment elevation acute myocardial infarction
sTNFR1: soluble tumor necrosis factor receptor 1
sTRAIL: soluble variant of tumor necrosis factor-related apoptosis-inducing ligand
Stro-1: stromal precursor antigen-1
SUMO-1: small ubiquitin-related modifier 1 gene
SUSD2: sushi domain containing 2
SV40: simian vacuolating virus 40 or simian virus 40
SVEC: SVEC4-10 is a murine endothelial cell line derived by SV40 transformation of endothelial cells from axillary lymph node vessels
SVF: stromal vascular cell fraction (of fat, containing preadipocytes, fibroblasts, vascular endothelial cells, and a variety of immune cells, such as adipose tissue macrophages)
SVZ: subventricular zone
SWI/SNF: SWItch/sucrose nonfermentable
SY-MSCs: synovial membrane MSCs
T1DM-MCAO: type 1 diabetes mellitus rats which have undergone a middle cerebral artery occlusion resulting an ischemic stroke
TAM: tumor-associated macrophage
TA-MSC: tumor-associated MSC
TAO: thromboangitis obliterans
TAZ: transcriptional co-activator with PDZ-binding motif
TB4: thymosin-β4
T-bet: T-box transcription factor TBX21 is a protein that in humans is encoded by the TBX21 gene
TβR1: transforming growth factor beta type I receptor
TBX: T-box
Tc: cytotoxic T cells
TCF: transcription factor
TCF: T cell factor
TCF4: transcription factor 7-like 2 (sometimes referred to as immunoglobulin transcription factor 2TCF4)
TCF7: transcription factor 7-like 2 (T-cell specific, HMG-box)
TCF7L2: transcription factor 7-like 2 (T-cell specific, HMG-box) (also known as TCF7)
TCP: tricalcium phosphate
TcPO2: transcutaneous partial oxygen pressure
TCR: T cell receptor (for antigen)
tdTomato: tandem dimeric derivative of DsRed
TDZD: thiadiazolidinone
TE: tissue engineering
TEC: thymic epithelial cell
TECK: thymus-expressed chemokine
TEM: transmission electron microscopy
TERT: telomerase reverse transcriptase
TET1–3: ten–eleven translocation 1–3
TF: tissue factor (also known as platelet tissue factor, factor III, thromboplastin, and CD142)
TF: transcription factor
TFEV: tissue factor expressing extracellular vesicle
TGA: Therapeutic Goods Authority (of Australia)
TGF-β: transforming growth factor-β
tgHD: transgenic Huntington disease (rat)
TGP: thermoreversible gelation polymer
Th: helper T cells
THBD: thrombomodulin
Thy1: thymocyte antigen 1 (CD90)
TIA: transient ischemic attack

TIE: tyrosine kinase with immunoglobulin-like and EGF-like domains
TIFF: tagged image file format
TIL: tumor-infiltrating lymphocyte
TIMP: tissue inhibitor of metalloproteinases
Tip60: tat interactive protein-60
TIR: toll/interleukin-1 receptor homology domain
TIRF total internal reflection microscopy
TK: thymidine kinase
TLR: toll-like receptor
TM4SF: transmembrane 4 superfamily
tMVECS: tumor microvascular endothelial cells
TNAP: tissue nonspecific alkaline phosphatase
TNBS: trinitrobenzene sulfonate
TNFAIP6: tumor necrosis factor-α-induced protein 2
TNFR: tumor necrosis factor receptor
TNF-α: tumor necrosis factor-α
TNTs: tunneling nanotubes
TOLL: Toll-like receptors (TLRs) received their name from their similarity to the protein coded by the toll gene identified in *Drosophila* in 1985 by Christiane Nüsslein-Volhard. The researchers were so surprised that they spontaneously shouted out in German "Das ist ja toll!," which translates as "That's great!"
tPA: tissue plasminogen activator
TPM: tropomyosin
Tr1: type 1 Tregs
TRA-1-60: tumor rejection antigen-1-60
TRA-1-81: tumor rejection antigen-1-81
TRACP5b: tartrate-resistant acid phosphatase 5b
TRADD: tumor necrosis factor receptor type 1-associated death domain protein
TRAF: TNF receptor-associated factor
TRAIL: tumor necrosis factor-related apoptosis-inducing ligand (also known as CD253 and tumor necrosis factor (ligand) superfamily, member 10 (TNFSF10))
TRANCE: TNF-related activation-induced cytokine (now known as RANK)
TRAP: tartrate-resistant acid phosphatase
TREC: T cell receptor excision circle
Treg: regulatory T cell
TRIF: TIR domain-containing molecule
TRIP-10: thyroid receptor-interacting protein 10
TrcK: tropomyosin receptor kinase C (also known as NT-3 growth factor receptor or neurotrophic tyrosine kinase receptor type 3)
tRNA: transfer RNA
TRPC6: transient receptor potential canonical 6
Tsg101: tumor susceptibility gene 101
TSG-6: tumor necrosis factor α-induced protein-6
TSH: thyroid-stimulating hormone
TSLP: thymic stromal lymphopoietin
TSP: thrombospondin
TSS: transcription start site
TTT: Timm's Tracking Tool
TUNEL: terminal deoxynucleotidyl transferase dUTP nick end labeling
tv-a: a gene encoding the retrovirus receptor
TWIST 1: Twist family bHLH transcription factor 1
U0126: a highly selective inhibitor of both MEK1 and MEK2, a type of MAPK/ERK kinase
Ub: ubiquitin
UC: ulcerative colitis
UC: umbilical cord
UCB: umbilical cord blood
UCLA: University of California, Los Angeles
UCMSCs: umbilical-cord-derived mesenchymal stromal cells
ULA: ultralow attachment (plates)
uPAR: soluble urokinase-type plasminogen activator receptor (CD87)
USPIO: ultra-small superparamagnetic iron oxide
USSC: unrestricted somatic stem cell
UTR: untranslated region (of DNA)
UTX: ubiquitously transcribed tetra-tricopeptide repeat X
UUO: unilateral ureteric obstruction
UV: ultraviolet
uVA: urokinase-type plasminogen activator

VAS: visual analog scale
VCAM-1: vascular cell adhesion molecule 1
VCAN: versican
VDJ: variable (V), joining (J) and diversity (D) (gene segments of B cells)
VE-cadherin: vascular endothelial cadherin
VEGF: vascular endothelial growth factor
VEGFR: vascular endothelial growth factor receptor (also known as KDR)
VHL: von Hippel–Lindau
VLA-4: very late activation antigen-4 (CD49d)
VLA-5: very late activation antigen-5 (CD49e)
VPA: valproic acid
VSEL: very small embryonic-like (cells)
VSMC: (blood) vessel-derived vascular smooth muscle cell
VSV-G: vesicular stomatitis virus-G
VTCN1: V-set domain-containing T-cell activation inhibitor 1
vWF: von Willebrand factor
WHO: World Health Organization
WIF: wnt inhibitory factor
WJ-MSC: Wharton's jelly mesenchymal stromal cell
Wnt: wingless-related integration site
WT: wild type
WWP2: WW domain containing E3 ubiquitin protein ligase 2
X4-L4: a complex consisting of X-ray repair cross-complementing protein 4 (XRCC4), XRCC4-like factor (XLF), and DNA ligase IV
xeno-free: free from any contamination by components of non-human species
X-Gal: P3-D-galactoside (commonly used to test for the presence of β-galactosidase)
XLF: XRCC4-like factor
XRCC4: X-ray repair cross-complementing protein 4
XYLT: xylosyltransferases
YAP: Yes-associated protein
YFP: yellow fluorescent protein
YY1: transcriptional repressor protein yin and yang 1
ZAP-70: zeta-chain-associated protein kinase 70
ZIMZI: zinc finger myc-interacting protein-1
ZO-1: zonula occludens-1
Z-VAD: *Z*-Val-Ala-DL-Asp-FMK (a caspase family inhibitor and cell permeable apoptotic protease)

## Historical notes

1. Alzheimer: Alzheimer's disease was first described by, and later named after, the German psychiatrist and pathologist Alois Alzheimer in 1906.
2. Dulbecco: Dulbecco refers to Renato Dulbecco. who, with David Baltimore and Howard Temin, won the Nobel Prize in Physiology or Medicine in 1975.
3. Eagle: Eagle refers to Harry Eagle. who developed the medium for the culture of HeLa cells and mouse fibroblasts.
4. Huntington: In 1872, at the age of 22, George Huntington described the disorder in his first paper, "On Chorea".
5. Iscove: In 1976, Guilbert and Iscove demonstrated that precursor cells of erythrocytes and macrophages could be cultured in a reduced-serum medium supplemented with albumin, transferrin, lecithin, and selenium. Iscove's medium is a variation of Dulbecco's modified Eagle's Medium (DMEM) containing selenium, additional amino acids and vitamins, sodium pyruvate, HEPES buffer, and potassium nitrate instead of ferric nitrates.
6. Parkinson: The disease is named after the English doctor James Parkinson, who published the first detailed description in "An Essay on the Shaking Palsy" in 1817.
7. Svedberg: the S unit was named after the Swedish chemist Theodor Svedberg (1884–1971), winner of the 1926 Nobel Prize in Chemistry for his work on disperse systems, colloids, and his invention of the ultracentrifuge.

    enhanced multilineage differentiation, 84, 86
    enhanced secretory properties, 84
    immunomodulation, 84
    recapitulation, 86, 87
transwell migration assays, 863
traumatic brain injury, 382
tricarboxylic acid (Krebs) cycle, 257
triglycerides, 192
trimethylation, 52
tube formation, stimulation of, 353
tumor angiogenesis, 373
tumor-associated MSCs (TA-MSCs), 867
tumorigenic potential, 462
tumor-infiltrating lymphocytes (TILs), 798
tumor malignancy, 75
tumor microenvironment, 406
  context-dependent role of, 417
    hypotheses, 417–418
  mechanisms for recruitment, 416
  migratory capacity of, 416
    intrinsic migratory properties, 416
    stimuli produced by the tumor, 416
  and MSCs, 406–407
    origin and identification, 415–416
    potential immunomodulation by, 419
tumor necrosis factor-α (TNF-α), 114, 732
  induced protein 6 (TSG-6), 66
  inducible gene 6 protein, 548
  receptor-associated factor 6, 848
tumor-promoting roles, 418
  direct mechanisms, 418–419
  paracrine mechanisms, 419
tumor-suppressing roles, 418
  effect on cell signaling, 418
  effects of mesenchymal stromal cell microvesicles, 418
tunneling nanotubes (TNTs), 104, 107, 268, 278
  alters secretome of MSCs, 280
  compounds transferred and physiological relevance, 271–273
    characteristic features, 271
    role of tunneling nanotubes in the spread of pathogens, 273
    signal transfer, 271
    transfer of calcium ions and electrical currents, 271, 272
    transfer of death signaling, 272
    transfer of organelles, proteins, and genetic material, 272
    transfer of protein complexes and genetic material, 273
  improving cardiac regenerative properties of MSCs, 273–274
  mechanisms and factors involved in formation, 269–271
    by actin-driven protrusions, 269–270
    by cell dislodgement, 270
    and regulation, 270–271
  mediated intercellular connections, 264
  rejuvenates distressed cardiomyocytes, 275–277
  reprogram dying cardiomyocytes, 275
  and route of intercellular communication between, 268–269
  stimulate paracrine repair function, 277–279
  structural diversity, 269
Twist-1, 52
type 1 diabetic MCAO (T1DM-MCAO), 706
type II diabetes mellitus, 115

**U**
ulcerative colitis (UC), 730
umbilical cord (UC), 13, 24, 33, 265, 716, 852
umbilical cord blood (UCB), 441
umbilical cord blood-derived MSCs (UCB-MSCs), 77
uniaxial tensile strain, 209–210
urokinase-type plasminogen activator receptor (PLAUR), 215

**V**
valproic acid (VPA), 463
vascular endothelial growth factor (VEGF), 66, 80, 151, 198, 215, 278
vasculogenesis, 347
vedolizumab, 735
ventricular cavities, 693
versican *(VCAN)* gene, 184
virotherapy, 865
vitamin C, 192
von Hippel-Lindau tumor suppressor, 393
von Willebrand Factor (vWF), 84, 355, 511

**W**
Western blot protein analysis, 799
white cells, 4
white fat, 114
Wnt/β-catenin signaling, 47
  pathway, 118
Wnt inhibitory factor (WIF), 135
Wnt signaling pathway, 97–99
wound healing
  clinical trials of cell-based therapy, 848
  in diabetic rats, 849

**X**
XY karyotype, 4, 35

**Z**
(2′Z,3′E)-6-bromoindirubin-3′-oxime, 463
Z-Val-Ala-DL-Asp-FMK (Z-VAD), 705
