To Ana

Discovery consists of seeing what everybody has seen and thinking what nobody has thought.

Albert Szent-Györgyi

(Modified from Arthur Schopenhauer and his "Parerga und Paralipomena: kleine philosophische Schriften" 1851)

Preface

Alcohol—by which, unless otherwise specified, throughout this book we refer to ethanol—is one of the major risk factors for negative health outcomes worldwide. More than 60 alcohol-related diseases are known to date, ranging from addiction, through liver cirrhosis, to cancer. Collectively, these conditions account for mortality and morbidity that make alcohol use one of the leading preventable causes of disability adjusted life-years (DALYs) lost globally.

Despite its magnitude, the impact of alcohol use on public health is frequently ignored or even denied, by the public, policymakers, and health care professionals alike. Among the many reasons for this, some, such as commercial interests, ignorance, and stigma are not hard to understand. Others remain unclear. Irrespective of the causes, the result is a chronic underfunding of basic and translational research aimed at improving the understanding, diagnosis, and management of alcohol-related problems. The same applies to measures that would allow health care and other services to implement measures based on already available knowledge in order to benefit people affected by alcohol-related problems.

The silver lining is that the continuing neglect also creates unique opportunities for scientific advances with the potential to improve the understanding of alcohol-related disease mechanisms. These opportunities come with their own challenges, as alcohol has a plethora of effects. It distributes throughout all body fluids, organs, tissues, and cells and interacts with numerous lipids, proteins, and DNA. As a result, the potential interactions are so complex that a highly interdisciplinary approach is required to understand them. These complex interactions are also likely the reason why, despite the progress over the last 50 years, we still have a poor understanding of many alcohol-related disease mechanisms. Similarly, the epidemiology of alcohol use and its health consequences is lacking to a surprising extent.

This book project sprung from the first postgraduate course at the 18th European Association for Biomedical Studies on Alcoholism (ESBRA) held in 2021 in Timisoara/Romania. As ESBRA president, one of us, Sebastian Mueller, had the good fortune to organize this event together with Professor Ioan Sporea. This was also the first ESBRA congress in Romania, one of the European countries with a high alcohol consumption, and an almost non-existent health care system to cope

with the problems that result from it. The conference was held in the second year of the COVID-19 pandemic and was for many the only physical meeting during this time. We are grateful to Prof. Sporea and his team for organizing this ESBRA meeting. We would also like to thank Professor Lorenzo Leggio, who was instrumental in setting up the first CME-accredited postgraduate course with ESBRA.

In the present book that has resulted from this project, more than 100 renowned experts from 17 countries have contributed to covering various aspects of alcohol-related diseases, from those encountered in daily clinical practice to molecular mechanisms. The book aims to combine present knowledge from a diverse range of disciplines and covers both widely recognized clinical problems such as alcohol withdrawal, addiction treatment, and alcohol-related liver disease, as well as less well-known clinical entities, for example, alcoholic cardiomyopathy. Despite the multitude of contributions, the book is far from complete, and many questions remain open. Where answers are lacking, we have attempted to at least highlight the questions.

In using the book, we hope readers will find their way to areas outside their own existing expertise. We believe that an interdisciplinary understanding is essential in order to successfully address alcohol-related problems, and hope that the book helps improve patients care by fostering that kind of understanding. Ultimately, we hope the book can also provide inspiration to address the many problems that remain unresolved. This is why we have included several chapters with novel, unpublished data that we consider important and a large collection of original data from a prospective heavy drinking cohort in the Appendix. With a basis in science, we hope the book will inspire clinicians, scientists, and others to join us in the effort to combat the tremendous burden of alcohol-related disease.

We finally want to thank Springer Nature and their staff, especially Mrs. Melissa Morton, for developing and supporting the project over 2 years, and Raagai Priya Chandrasekaran, who was instrumental during the submission, editing, and production process. Special thanks also go to Johannes Mueller from Heidelberg for his assistance during the final stages.

Contents

Abbreviations

1D-TE	One-dimensional transient elastography
2D-SWE	Two-dimensional shear wave elastography
4E-BP1	4E-binding protein 1
A	Antecedents
A2M	a2-Macroglobulin
AA	Acetaldehyde
AA	Alcoholics anonymous
AAF	Alcohol-attributable fraction
AAI	Acute alcohol intoxication
AAS	Atomic absorption spectroscopy
AASE	Alcohol Abstinence Self-Efficacy Scale
AAT	Alpha1-antitrypsin
AATD	Alpha1-antitrypsin deficiency
AB	Apoptotic bodies
ABCDE	Airway-Breath-Cardio-Disability-Exposure
ABIC	Age, serum Bilirubin, INR, and serum Creatinine score
ABIs	Alcohol Brief Interventions
Ac	Acetylation
ACC	Acetyl CoA carboxylase
ACC	Anterior cingulate cortex
ACD	Anemia of chronic disease
ACE	Addenbrooke's Cognitive Examination
ACE	Adverse childhood experiences
Acetyl-CoA	Acetyl-coenzyme A
ACLD	Advanced chronic liver disease
ACLF	Acute-on-chronic liver failure
ACLY	ATP-citrate lyase
ACM	Alcoholic cardiomyopathy
ACSL4	Long-chain-fatty-acid—CoA ligase 4
ACT	Acceptance and commitment therapy
ACTH	Adrenocorticotropic hormone

AD	Acute decompensation
ADAMTS 13	A disintegrin and metalloproteinase with thrombospondin type 1 motif 13
ADH	Alcohol dehydrogenase
ADH1B	Alcohol dehydrogenase-1B
ADH7	Alcohol dehydrogenase-7
ADHD	Attention deficit hyperactivity disorder
ADMA	Asymmetric dimethylarginine
AEAT	Acyl-coenzyme a:ethanol *O*-acyltransferase
AFD	Alcoholic foamy degeneration
AFLP	Acute fatty liver of pregnancy
AGDHA	Australian Government Department of Health and Ageing
AGM	Aorta-gonad-mesonephros
AGS	Acetaldehyde-generating system
AH	Alcoholic hepatitis
AHHS	Alcoholic Hepatitis Histological Score
AICF	Accelerated intravascular coagulation and fibrinolysis
AICR	American Institute for Cancer Research
AIH	Autoimmune hepatitis
AIM	College Alcohol Intervention Matrix
AJ	Adherens junctions
AKI	Acute kidney injury
ALD	Alcohol-related liver disease
ALDH	Aldehyde dehydrogenase
ALDH2	Aldehyde dehydrogenase-2
ALF	Acute liver failure
ALK 3	Activin receptor-like kinase 3
ALT	Alanine aminotransferase
AM	Alcohol mortality score
AML	Acute myeloid leukemia
AML	Angiomyolipomas
AM-LS	Alcohol mortality score including liver stiffness
AMP	Adenosine monophosphate
AMPK	AMP-activated protein kinase
AMUSE	Attenuation measuring ultrasound shear wave elastography
ANA	The Addictions Neuroclinical Assessment
ANKK	Ankyrin repeat and kinase domain
AP	Alkaline phosphatase
AP	Arterial pressure
APA	The American Psychiatric Association
APAP	Acetaminophen
APASL	The Asian Pacific Association for the Study of the Liver
ApoA1	Apolipoprotein A-1
APRI	Aspartate aminotransferase to platelet ratio index
aPTT	Activated partial thromboplastin time

ARBD	Alcohol-related birth defects
ARDS	Acute respiratory distress syndrome
ARFI	Acoustic Radiation Force Impulse (imaging)
ARK3	Activin receptor-like kinase 3
ARND	Alcohol-related neurodevelopmental disorder
ART	Antiretroviral therapy
ASAM	The American Society of Addiction Medicine
ASDR	Age-standardized death rates
ASE	The American Society of Echocardiography
ASH	Alcoholic steatohepatitis
ASMase	Acid sphingomyelinase
ASPD	Antisocial personality disorder
ASQ	Acoustic Structure Quantification™
ASR	Age standardized rate
AST	Aspartate aminotransferase
AT	Adipose tissue
ATGL	Adipose tissue triglyceride lipase
ATP	Adenosine triphosphate
AUD	Alcohol use disorder
AUDIT	Alcohol Use Disorders Identification Test
AUROC	Area under the receiver operating characteristics curve
AVP	Arginine-vasopressin
AWS	Alcohol withdrawal syndrome
AZT	Azidothymidine
BAC	Blood alcohol concentration
Bak 1	BCL2 antagonist/killer 1
BAP	British Association for Psychopharmacology
BASICS	Brief Alcohol Screening and Intervention for College Students
BasoE	Basophilic erythroblasts
BBB	Blood–brain barrier
BBV	Blood-borne virus
BC	Breast cancer
BCLC	Barcelona Clinic Liver Cancer staging system
BCN	Bile cast nephropathy
BCT	Behavior Couples Therapy
BD	Bipolar disorder
BDNF	Brain-derived neurotrophic factor
bFGF	Basic fibroblast growth factor
BFU-E	Burst forming unit-erythroid
BHMT	Betaine-homocysteine-methyltransferase
BI	Brief Interventions
BI-RADS	Breast Imaging Reporting and Data System
BIS-11	Barratt Impulsiveness Scale 11
BIVAD	Biventricular assist device

BLEP	Bright liver echo pattern
BM	Bone marrow
BMI	Body mass index
BMIs	Brief motivational interventions
BMP	Bone morphogenic protein
BMPER	BMP-binding endothelial cell precursor-derived regulator
BPD	Borderline personality disorder
BR	Bilirubin
BrAC	Breath alcohol concentration
BSCT	Behavioral self-control training
BUN	Blood urea nitrogen
BZD	Benzodiazepines
CAB	Chromotrope-aniline-blue
cACLD	Compensated advanced chronic liver disease
CaMK	Calmodulin kinase
cAMP	Cyclic adenosine monophosphate
CAP	Controlled attenuation parameter
CAR	CXCL12-abundant reticular cells
CASA	Court Appointed Special Advocates
CASP2	Caspase 2
CAT	Hepatic catalase
CBA	Chronic binge alcohol
CBN	Causal Bayesian Network
CBS	Cystathionine-b-synthase
CBT	Cognitive behavioral therapy
CCDRFS	China Chronic Disease and Risk Factor Surveillance
CCL20	C-C Motif Chemokine Ligand 20
CCL4	Carbon tetrachloride
CCND1	Cyclin D1
CCND2	Cyclin D2
CD	Controlled drinking
CD	Crohn's disease
CD14	Cluster of differentiation 14
CDC	Centers for Disease Control and Prevention
CDH13	Cadherin 13
CDT	Carbohydrate-deficient transferrin
CeA	Central amygdala
CEBPA	CCAAT-enhancer-binding protein alpha
CET	Cue-exposure therapy
CFU-E	Colony-forming units-erythroid
CGAS	Candidate gene association studies
ChREBP	Carbohydrate responsive-element binding protein
CHRM2	Cholinergic muscarinic receptor
CIFASD	Collaborative Initiative of Fetal Alcohol Spectrum Disorders

CIWA-A	Clinical Institute Withdrawal Assessment for Alcohol scale and linked score
CIWA-Ar	Clinical Institute Withdrawal Assessment for Alcohol revised scale and linked score
CK	Cytokeratin
CK2	Casein kinase
CKB	China Kadoorie Biobank
CKD	Chronic kidney disease
CLD	Chronic liver disease
CLPs	Common lymphoid progenitors
CM	Contingency management
CMP	Cardiomyopathy
CMPs	Common myeloid progenitors
CMR	Cardiac magnetic resonance imaging
CNS	Central nervous system
CO	Carbon monoxide
CO_2	Carbon dioxide
COGA	The Collaborative Study on the Genetics of Alcoholism
COMT	Catechol-*O*-methyltransferase
COX-2	Cyclooxygenase-2
CPP	Child-Parent Psychotherapy
CRA	Community Reinforcement Approach
CRAFT	Community Reinforcement Approach and Family Training
CRC	Colorectal cancer
CREB	cAMP response element-binding protein
CRF	Corticotropin-releasing factor
CRH/CRF	Corticotropin-releasing hormone/factor
CRHR1	Corticotropin-releasing hormone receptor 1
CRN1	CB1 receptor protein
CRP	C-reactive protein
CS	Corticosteroids
CSPH	Clinically significant portal hypertension
CT	Computed tomography
cTBS	Continuous Theta-burst stimulation
CTF	Children's Friendship Training
CTGF	Connective tissue growth factor
CTQ	Childhood Trauma Questionnaire
CUP	WCRF/AICR Continuous Update Project
CVD	Cardiovascular disease
CVLT-C	California Verbal Learning Test–Children's Version
CVP	Central venous pressure
CXCL1	C-X-C motif chemokine ligand 1
CYP	Cytochrome P450
CYP27A1	Cytochrome P450 family 27 subfamily a member 1
CYP2E1	Cytochrome P450 2E1

CYP7A1	Cytochrome P450 family 7 subfamily a member 1
DAA	Direct acting antiviral
DAGLA	Diacylglycerol lipase
DALYs	Disability-adjusted life year
DAMPs	Damage-associated molecular patterns
DAT	Dopamine transporter
DBS	Dried blood spots
DBT	Dialectical behavior therapy
DC	Dendritic cells
DCM	Dilated cardiomyopathy
DD	Delay discounting
DGAT	Diacylglycerol acyl transferase
DGPPN	Deutsche Gesellschaft für Psychiatrie und Psychotherapie, Psychosomatik und Nervenheilkunde
DIC	Dicarboxylate
DIC	Disseminated intravascular coagulation
DLGAP2	Discs large-associated protein 2
DLPFC	Dorsolateral prefrontal cortex
DLPFCX	Dorsolateral prefrontal cortex
DM	Diabetes mellitus
DNA	Deoxyribonucleic acid
DNMT	DNA methyltransferase
DOACs	Direct acting oral anticoagulants
DR	Ductular reaction
DRD1	D1 dopamine receptor
DRD2	D2 dopamine receptor
DRD4	Dopamine receptor type 4
DRE	Digital rectal examination
DrInC	Drinker Inventory of Consequences
DRP1	Dynamin-related protein 1
DSD	Depression spectrum disease
DSM	Diagnostic and Statistical Manual of Mental Disorders
DSMs	Dense surface models
DSM-V	Diagnostic and Statistical Manual of Mental Disorders
DT	Delirium tremens
DTI	Diffusion tensor imaging
DUS	Dried urine on filter paper
DUSP4	Dual specificity phosphatase 4
DUSP5	Dual specificity phosphatase 5
DVT	Deep vein thrombosis
E	Young's modulus
E/C	Excitation/contraction
EACA	Epsilon-aminocaproic acid
EACVI	The European Association of Cardiovascular Imaging
EASL	The European Association for the Study of the Liver

EASL-CLIF	The European Association for the Study of the Liver–Chronic Liver Failure
EBV	Epstein-Barr virus
ECA	The Epidemiologic Catchment Area
eCB	Endocannabinoid system
ECBL	Early change in bilirubin level
ECG	Electrocardiogram
ECHO	The Extension for Community Healthcare Outcomes
ECM	Extracellular matrix
ECs	Endothelial cells
ED	Emergency department
EDP	Epoxydocosapentaenoic
EEG	Electroencephalography
EEQ	Epoxydocosapentaenoic
EF	Ejection fraction
EFhd2	EF hand domain containing 2 gene
EFNS	European Federation of Neurological Societies
EFSUMB	European Federation of Societies for Ultrasound in Medicine and Biology
EFT	Episodic future thinking
EGF	Epidermal growth factor
EHD4	EH-domain containing 4 gene
EHPVO	Extrahepatic portal vein obstruction
EHS	Engelbreth–Holm–Swarm gel
EIA	Enzyme immunoassay
ELF	Enhanced Liver Fibrosis score
Elpho	Serum electrophoresis
EMA	The European Medicines Agency
EMDR	Eye movement desensitization and reprocessing
EMH	Extramedullary hematopoiesis
EMP	Erythro-myeloid progenitor
eNOS	Endothelial nitric oxide synthase
EPIC	European Prospective Investigation into Cancer and Nutrition study
EPO	Erythropoietin
EPs	Erythroblasts
ER	Emergency room
ER	Endoplasmic reticulum
ERAD	ER-associated degradation
ERCP	Endoscopic retrograde cholangiopancreatography
ERFE	Erythroferrone
ERP	Event-related potential
ES	Elasticity score
ESBRA	The European Society for the Biomedical Research on Alcoholism

ESCRT	Endosomal sorting complex required for transport
ESCs	Embryonic stem cells
ESPAD	The European School Survey Project on Alcohol and Other Drugs
ESPEN	The European Society for Clinical Nutrition and Metabolism
ET-1	Endothelin-1
ETC	Electron transport chain
EtG	Ethyl glucuronide
EtPa	Ethyl palmitate
EtS	Ethyl sulfate
EUS	Endoscopic ultrasound
EV	Esophageal varices
EV	Extracellular vesicles
EWAS	Epigenome-wide association study
FA	Fatty acid
FA	Fractional anisotropy
FAC	Ferric ammonium citrate
FA-CoA	Fatty acyl-CoA
FACS	Fluorescence-activated cell sorting
FAEE	Fatty acid ethyl esters
FAS	Facial photographic analysis
FASD	Fetal alcohol spectrum disorder
FASN	Fatty acid synthase
FDA	The US Food and Drug Administration
FFP	Fresh frozen plasma
FHVP	Free hepatic vein pressure
Fib4	Fibrosis 4 index
FKBP5	FK506-binding protein
FLD	Fatty liver disease
FLL	Focal liver lesion
FMF	Families Moving Forward program
fMRI	Functional magnetic resonance imaging
FNA	Fine needle aspiration
FOV	Field of view
FOXO1	Forkhead box protein O1
FPDD	Familial pure depressive disease
FPM	First-pass metabolism
FPSA	Fractioned plasma separation, adsorption, and dialysis
FSD	Face signature difference
G	Shear force
GABA	Gamma-aminobutyric acid
GABA-A	Gamma-aminobutyric acid A receptor
GABRB1	β1-containing GABAA receptor gene
GAD	Glutamic acid decarboxylase
GAG	Glycosaminoglycans

GAHS	Glasgow alcoholic hepatitis score
GAMT	Isoprenylcysteine carboxyl methyltransferase
GATA4	GATA-binding protein 4
GBD	Global Burden of Disease
GCL	Glutamate cysteine ligase
GCLC	Catalytic subunit of GCL
GCLM	Modifier subunit of GCL
GC-MS	Gas chromatography–mass spectrometry
G-CSF	Granulocyte colony stimulation factor
GDF15	Growth/differentiation factor 15
GE-XR	Gabapentin enacarbil extended-release
GGT	Gamma-glutamyl transferase
GHB	Gamma-hydroxybutyric acid
GHE	Global health estimates
GI	Gastrointestinal
GIRK	G protein-activated inwardly rectifying potassium
GIWA-Ar	Clinical Institute Withdrawal Assessment for Alcohol-Revised
Gli3	GLI family zinc finger 3
GLS	Global longitudinal strain
GLT-1	Glutamate transporter-1
Glu	Glutamate
GMPs	Granulocyte monocyte progenitors
GOT/AST	Glutamic oxaloacetic transaminase, see AST
GP	General practitioner
GPAM	Mitochondrial glycerol-3-phosphate acyltransferase
GPT/ALT	Glutamate-pyruvate transaminase, see ALT
Gpx	Glutathione peroxidase
GR	Glucocorticoid receptor
GSH	Glutathione
gs-MELD	Gene-signature plus MELD
GSR	Glutathione reductase
GSSG	Glutathione disulfide (oxidized glutathione)
GST	Glutathione *S* transferase
GWAS	Genome-wide association study
GWE	Gayet-Wernicke encephalopathy
H_2O_2	Hydrogen peroxide
HA	Hyaluronic acid
HABR	Hepatic arterial buffer response
Hb	Hemoglobin
HBSC	The Health Behavior in School-aged Children research project
HBV	Hepatitis B virus
HCC	Hepatocellular carcinoma
HCs	HuH7 cells

HCV	Hepatitis C virus
HD	Hepatic decompensation
HDD	Heavy drinking days
HE	Heavily exposed
HE	Hepatic encephalopathy
HED	Heavy episodic drinking
HELLP	Hemolysis, elevated liver enzymes, and low platelets syndrome
HES	Hepatosplenic schistosomiasis
HETE	Hydroxyeicosatetraenoic acid
HF	Heart failure
HF	High frequency
HFD	High-fat diet
HFE	Hereditary hemochromatosis protein
HFEW	High FErritin
HG	Hyperemesis gravidarum
HGF	Hepatocyte growth factor
HGIN	High-grade intraepithelial neoplasia
HH	Hereditary hemochromatosis
HHCy	Hyperhomocysteinemia
HIF	Hypoxia-inducible factors
HIF-1α	Hypoxia-inducible factor-1α
HIV	Human immunodeficiency viruses
HL	Hodgkin lymphoma
HMGB1	High-mobility group box 1 protein
HMGCR	3-Hydroxy-3-methylglutaryl-coenzyme A reductase
HNF	Hepatocyte nuclear factor
HNF4a	Hepatocyte nuclear factor 4 alpha
HO	Heme oxygenase
HO-1	Heme oxygenase-1
Hp	Haptoglobin
HPA	Hypothalamic-pituitary-adrenal
HPCs	Hematopoietic progenitors
Hpx	Hemopexin
HR	Hazard ratio
HR	Heart rate
HRA	Health risk appraisal model
HR-EMA	High-resolution ecological momentary assessment
HRS	Hepatorenal syndrome
HSCIC	The Health and Social Care Information Centre (UK)
HSCs	Hematopoietic stem cells
HSCs	Hepatic stellate cells
HSD17B13	Hydroxysteroid 17-beta dehydrogenase 13
HSL	Hormone-sensitive lipase
Hsp90	Heat shock protein 90

Htc	Hematocrit
HV	Hepatic vein
HVPG	Hepatic venous pressure gradient
IAP	Intra-abdominal pressure
IARC	The International Agency for Research on Cancer
IBU	Inflammatory bowel disease
ICAM-1	Intercellular adhesion molecule-1
ICC	Intraclass correlation coefficient
ICD	The International Classification of Diseases
ICMT	Guanidinoacetate methyltransferase
ICP	Intrahepatic cholestasis of pregnancy
ICT	Inhibitory control training
ICU	Intensive care unit
IFG	Inferior frontal gyrus
IFN	Interferon
IgA	Immunoglobulin A
IGF	Insulin-dependent growth factor
IGF-1	Insulin-like growth factor 1
IL-1β	Interleukin-1β
IL	Interleukin
IM	Intramuscular
IMM	Inner mitochondrial membrane
IMS	Intermembrane space
iNOS	Inducible nitric oxide synthase
INR	International normalized ratio
IPD	Interpupillary distance
IPTs	Impulsive personality traits
IQ	Intelligence quotient
IQR	Interquartile range
IQR/M	Interquartile range/median
IREs	Iron-responsive elements
IRF3	Interferon regulatory factor 3
IRI	Ischemia/reperfusion injury
IRP1/2	Iron-responsive proteins1/2
IRPs	Iron-responsive proteins
ISI	International sensitivity index
iTBS	Intermittent Theta-burst stimulation
IV	Intravenous
IWHS	Iowa Women's Health Study
JEC	Japan esophageal cohort study
KALRN	Kalirin RhoGEF kinase
KCC	King's college criteria
KCs	Kupffer cells
KDIGO	Kidney Disease Improving Global Outcome criteria
Ki	Inhibitor affinity constant

Km	Michaelis constant
KS	Korsakoff's Syndrome
LAI	Long-acting injectable
LAMP1/2	Lysosomal-associated membrane protein 1/2
LBP	Lipopolysaccharide-binding protein
LC	Long-term negative consequences
LC-MS/MS	Liquid chromatography-tandem mass spectrometry
LD	Lieber-DeCarli diet
LDH	Lactate dehydrogenase
LDL	Low-density lipoprotein
LDLT	Living donor liver transplantation
LEV	Large esophageal varices
LF	Low frequency
LGE	Late gadolinium enhancement
LGIN	Low-grade intraepithelial neoplasia
LIC	Liver iron concentration
LME	Liver microenvironment
LMWHs	Low molecular weight heparins
LPC	Liver progenitor cells
LPL	Lipoprotein lipase
LPS	Lipopolysaccharide
LR	Likelihood ratio
LS	Liver stiffness
LSEC	Liver sinusoidal endothelial cells
LSM	Liver stiffness measurement
LSPS	LS–spleen diameter to platelet ratio score
LTCs	Long-term conditions
LTD	Long-term depression
LTP	Long-term potentiation
LTs	Leukotrienes
LTX	Liver transplantation
LV	Left ventricle
LVAD	Left ventricular assist device
LVP	Large volume paracentesis
LXR	Liver X receptor
M cells	Microfold cells
MA	Maximum amplitude
MAG	Monoacylglycerol
MAL	MyD88 adaptor-like
MAMPs	Microbial-associated molecular patterns
MAMs	Mitochondria-associated membranes
MAOA	Monoamine oxidase A
MAP	Mean arterial pressure
MAPK	Mitogen-activated protein kinase
MARS	Molecular adsorbent recirculating system

MAT	Methionine adenosyl transferase
MBI	Mindfulness-based interventions
MBOAT7	Membrane-bound *O*-acyltransferase domain-containing protein 7
MBOAT7/TMC4	Membrane-bound *O*-acyltransferase domain containing protein 7-Transmembrane channel-like 4
MBRP	Mindfulness-based relapse prevention
MBS	The Mind, Body, and Spirit program
MCCS	Melbourne Collaborative Cohort Study
MCP-1	Monocyte chemoattractant protein-1
MCRS	The Medical Condition Regard Scale
MCV	Mean corpuscular volume of erythrocytes
MD	Mean diffusivity
MD2	Myeloid differentiation factor 2
MDB	Mallory-Denk bodies
MDD	Major depressive disorder
MDF	Maddrey's discriminant function
MDFT	Multidimensional family therapy
MDS	Myelodysplastic syndrome
Me	Methylation
MELD	Model for end-stage liver disease
MEOS	Microsomal ethanol oxidizing system
MEPs	Megakaryocyte-erythroid progenitors
MET	Motivational enhancement therapy
MetS	Metabolic syndrome
Mfn1/2	Mitofusin 1 and 2
mGAHS	Modified GAHS
mGSH	Mitochondrial GSH
MI	Motivational interviewing
MI/MET	Motivational interviewing/motivational enhancement
MILE	The Math Interactive Learning Experience
miR	MicroRNAs
miRNAs	MicroRNAs
MLC	Myosin light chain
MLCK	Myosin light chain kinase
MMI	Multimodality imaging
MMPs	Matrix metalloproteinases
MMSE	Mini Mental State Examination
MOBC	Mechanisms of behavior change
MORE	Mindfulness-Oriented Recovery Enhancement
mPFC	Medial prefrontal cortex
MPPs	Multipotent progenitors
MR	Magnetic resonance
MR	Mendelian randomization
MR	Mineralocorticoid receptor

MRE	Magnetic resonance elastography
MRI	Magnetic resonance imaging
MRI-PDFF	Magnetic resonance imaging proton density fat fraction
MRPs	Multidrug resistance-associated proteins
MRS	Magnetic resonance spectroscopy
MS	Mass spectrometry
MS	Methionine synthase
MSCs	Mesenchymal stem cells
MSP	Mitochondria-shaping proteins
MT SAM	S-adenosylmethionine-dependent methyltransferase
mtDNA	Mitochondrial DNA
MTHF	N5-methyltetrahydrofolate
MTHFR	5,10 Methylenetetrahydrofolate reductase
mTOR	Mammalian target of rapamycin
MTP	Microsomal triglyceride transfer protein
MUP	Minimum unit price
MuRF1	Muscle ring finger 1
MVBs	Multivesicular bodies
MYC	MYC proto-oncogene
MyD88	Myeloid differentiation primary response 88
Myf5	Myogenic factor 5
NAC	*N*-acetyl-L-cysteine
NAcc	Nucleus accumbens
NACSELD	The North American Consortium for the Study of End-Stage Liver Disease
NAD+	Nicotinamide adenine dinucleotide
NAFLD	Non-alcoholic fatty liver disease
NASH	Non-alcoholic steatohepatitis
NBI	Narrow-band imaging
NCOA4	Nuclear receptor coactivator 4
NCS	National Comorbidity Survey
NCTSI	The National Child Traumatic Stress Initiative (US)
NDE	Non-drinker equivalence
NE	Norepinephrine
NESARC	US National Epidemiologic Survey on Alcohol and Related Conditions
NF	Nuclear factor
NFATc4	Nuclear factor of activated T cells 4
NFS	NAFLD fibrosis score
NFκB	Nuclear factor kappa-light-chain-enhancer of activated B cells
NGS	Next-generation sequencing
NHDD	No heavy drinking days
NHL	Non-Hodgkin lymphoma
NHS	National Health Service

NIAAA	The US National Institute on Alcohol Abuse and Alcoholism
NIBS	Non-invasive brain stimulation
NICE	National Institute for Health and Care Excellence
NITs	Non-invasive tests
NLCS	Netherlands Cohort Study
NLR	Neutrophil-to-lymphocyte ratio
NLR	NOD-like receptors
NMDA	Glutamate receptor
NMDA	*N*-methyl-D-aspartate
NMDA	*N*-methyl-D-aspartic acid
NO	Nitric oxide
NOD	Nucleotide-binding oligomerization domain
NODDI	Neurite orientation dispersion and density imaging
NOP	Nociceptin
NOS	Nitrogen oxygen species
NOX	NADPH-dependent oxidase
NP	Not provided
NPV	Negative predictive value
NR3C1	Glucocorticoid receptor
Nrf-2	Nuclear factor erythroid 2-related factor 2
NSBB	Non-selective betablockers
NSCs	Neural stem cells
NSMM	Non-selective betablocker
NTA	Nano-tracking analysis
NT-proBNP	N-terminal fragment in the prohormone brain natriuretic peptide
O_2	Oxygen
OCA	Obeticholic acid
OCDS	Obsessive Compulsive Drinking Scale
OEA	Oleoylethanolamide
OFC	Occipital frontal circumference
OFC	Orbitofrontal cortex
OGC	2-Oxoglutarate, SLC25A11
ÖGPB	Österreichische Gesellschaft für Neuropsychopharmakologie und Biologische Psychiatrie
OMM	Outer mitochondrial membrane
ONS	UK Office for National Statistics
Opa-1	Optic atrophy 1
OPRL1	Opioid receptor like-1
OPRM1	U-opioid receptor
OR	Odds ratio
OrthoE	Orthochromatic erythroblasts
OUD	Opioid use disorder
OXPHOS	Oxidative phosphorylation
OXTR	Oxytocin receptor

OZALC	The Australian twin-family study of alcohol use disorder
PA	Palmitic acid
PAE	Prenatal alcohol exposure
PAFs	Population attributable fractions
PAI-1	Plasminogen activator inhibitor-1
PAMPs	Pathogen-associated molecular patterns
PATHS	Promoting Alternative THinking Strategies curriculum
PBC	Primary biliary cirrhosis
PCA	Principal component analysis
PCAP	The Parent-Child Assistance Program
PCC	Posterior cingulate cortex
PCD	Probe-to-capsule distance
PCF	Pericellular fibrosis
PCs	Principal components
PD	Personality disorder
PDE10	Phosphodiesterase-10
PDE3B	Phosphodiesterase-3B
PDE4	Phosphodiesterase-4
PDEI-5	Phosphodiesterase inhibitors type 5
PDFF	Proton density fat fraction
PDGF	Platelet-derived growth factor
PDGF-BB	Platelet-derived growth factor BB
PDMS	Polydimethylsiloxane
PE	Pulmonary embolism
PECR	Peroxisomal trans-2-enoyl-CoA reductase
PEG3	Paternally expressed gene 3
PEL	Parenchymal extinction lesion
PEMT	Phosphatidylethanolamine methyltransferase
PET	Positron emission tomography
PEth	Phosphatidylethanol
PEth-NET	The Society of Phosphatidylethanol Research
PFAS	Partial fetal alcohol syndrome
PFC	Prefrontal cortex
PFL	Palpebral fissure length
PGA	Prothrombin time, gamma-glutamyl transpeptidase and apolipoprotein AI score
PGs	Prostaglandins
PH	Portal hypertension
PHD	Prolyl hydroxylase domain-enzymes
PheWAS	Phenome-wide association studies
PHH	Primary human hepatocytes
PHLF	Posthepatectomy liver failure
PHZ	Phenyl hydrazine
PIAS1	Protein inhibitor of activated STAT 1
PIMT	Protein L-isoaspartate methyltransferase

PIN1	Peptidyl-prolyl cis/trans isomerase
PLP	Pyridoxal phosphate
PLWH/PLWHA	People living with HIV/AIDS
PMAIP1	Phorbol-12-myristate-13-acetate-induced protein 1
PMN	Polymorphonuclear neutrophils
PMP	Pyridoxamine phosphate
PNPLA3	Patatin-like phospholipase domain-containing-3 or Adiponutrin
PolyE	Polychromatophilic erythroblasts
POR	Cytochrome P450 oxidoreductase
PP	Periportal
PP1	Protein phosphatase 1
PPAC	Pooling Project on Alcohol and Cancer
PPARG	Peroxisome proliferator-activated receptor gamma
PPARs	Peroxisome proliferator-activated receptors
PPARγ	Peroxisome proliferator-activated receptor-γ
PPM1G	3′-Protein-phosphatase-1G
PPRE	Proliferator-activated receptor response element
PPV	Positive predictive value
PREMs	Patient-reported experience measures
PRMT	Protein arginine methyltransferase
PRO-C3	Precursor of Type III collagen
ProE	Proerythroblasts
PROMs	Patient-reported outcome measures
PRRs	Pattern recognition receptors
PRS	Polygenic risk score
Prx	Peroxiredoxin
PSA	Prostate-specific antigen
PSC	Primary sclerosing cholangitis
ps-MELD	Plasma-signature MELD
pSWE	Point shear wave elastography
PTSD	Post-traumatic stress disorder
PUMA	p53 upregulated modulator of apoptosis
PUP	Parents under pressure
PV	Perivenous
PVA	Polyvinyl alcohol hydrogels
PVP	Portal vein pressure
PVT	Portal vein thrombosis
PWAS	Proteome-wide association studies
PYLL	Potential years of life lost
qEEG	Quantitative electroencephalography
QIBA	Quantitative imaging biomarkers alliance
R	Response
RA	Retinoic acid
RAAS	The renin-angiotensin-aldosterone system

RASGRF2	Ras-specific guanine nucleotide-releasing factor 2 gene
RAW	Benzodiazepine-resistant alcohol withdrawal

Part I
Alcohol Consumption: Epidemiology, Policies and Legal Aspects

Chapter 1
Alcohol and Alcohol-Related Diseases: An Introduction to the Book

Sebastian Mueller

Abstract Alcohol (ethanol) is a major health risk worldwide that causes more than 60 diseases leading to three million deaths per year. This article introduces "Alcohol and alcohol-related diseases", a book that covers all aspects of alcohol and alcohol-related diseases from epidemiology to alcohol use disorders, alcohol-related liver disease or cancer. It is divided into 14 parts with contributions from more than 100 authors from 17 countries. Besides current diagnostic measures and treatment strategies, the book deals with the many underlying molecular mechanisms of alcohol toxicity including the genes that lead to addiction and disease. Novel data include first prospective data on all-cause mortality, the emerging major role of red blood cell turnover by alcohol, and fundamental links between basic energy metabolisms, alcohol, and addiction. The enormous level of complexity and interactions associated with alcohol metabolism should stimulate a very much needed interdisciplinary cooperation among clinicians, scientists, and addiction specialists. In our opinion, only such a holistic approach will allow to apply the emerging potentials of OMICS and genetics more efficiently. The world needs more institutional and societal efforts to improve and integrate not only the care of alcohol-related diseases but also the funding of topic-specific research. This book also aims at guiding policy makers to handle the topic of alcohol in our society more responsibly by pricing and legislation, which certainly are the most important measures to help decrease mortality and suffering from alcohol-related diseases.

Keywords Alcohol · Addiction · Alcohol-related disease · Alcohol-related liver disease · Alcohol-related liver disease · Addiction · Alcohol dependence · Liver cirrhosis · Mortality · Acetaldehyde · Energy metabolism

About the Book

Alcohol is a disease agent that affects many, if not all human organ systems. These include brain and liver, which are at the center of alcohol-related disease processes. Due to genetic and environmental risk factors, alcohol use for a significant minority of users transitions from a controlled habit to what is called alcoholism, alcohol addiction, alcohol dependence or (moderate—severe) **alcohol use disorder (AUD).** Key among clinical manifestation of this condition is the emergence of continued use despite knowledge of negative consequences, or "compulsive use". This in turn feeds back on the brain itself, further promoting a progression of pathology that affects both the brain itself, and other organs.

Both in research and in clinical practice, the alcohol-related pathology of peripheral organs receives much less attention than it should given its contribution to global disease burden. In contrast, the view that alcohol addiction is a brain disease, although accepted by the majority of the neuroscience community, remains questionable. It is often claimed that a brain disease view fails to account for high rates of spontaneous recovery, places too much emphasis on a compulsive use, and has failed to identify specific neural signatures of alcohol addiction. While some of these criticisms have merit, the premise that alcohol addiction is a brain disease is no less reasonable than a disease view of other complex disorders, such as diabetes, asthma or hypertension.

Alcohol still is one of the major health risks worldwide, and it causes many diseases and cancer. Despite this major role in global morbidity and mortality, research on alcohol-related diseases is chronically underfunded. Research should be aimed at improving early diagnosis, the assessment of individual risks to develop these diseases, an understanding of their molecular mechanisms and, hence, therapeutic measures. This book project is an effort to provide an update on the health consequences of alcohol, the most important alcohol-mediated diseases, and our present understanding of the underlying mechanisms. This effort is far from being complete, despite the fact that more than 100 authors from 17 countries have contributed. Their motivation primarily originates from the devastating health consequences of alcohol, its effect on unborn life with irreversible consequences even for next generations. The idea of the book has originated from the first ESBRA post graduate course with the same name, held 2021 in Timisoara, Romania, one of the few physical conferences organized during the COVID pandemic that started early in 2020. The book covers in detail alcohol-related aspects such as epidemiology, addiction, liver disease and cancer, but also topics such as alcoholic cardiomyopathy, neurological disorders, etc.

The reasons why alcohol has evolved as a legal drug in most societies are manifold. First, it is colorless and almost tasteless. However, often overlooked, the intended effects of pleasure and relaxation are obtained immediately while most negative health effects occur usually over a long period of time and typically

without any pain. A good example is liver cirrhosis that takes 15–20 years to develop. While the slow death in cirrhotic patients is a great suffering for the families and the close environment, the patients themselves are less aware of it. The necklace of all of those reasons creates a special form of denial at the level of the individual, institutions and the society that prevents a systemic and efficient discourse about alcohol-related diseases, their research support and an efficient implementation of preventive measures. And finally, the research on alcohol-related diseases is challenging since it is confronted with a special degree of complexity that requires a tight association with patients and chronically underfinanced health care systems.

This book is also a social platform among scientists and clinicians. We also do not agree with certain claims that books may not be needed anymore in the era of internet and digital medical databases. A book is still a unique and special form of an intellectual exchange and confrontation. This is also the reason why we did not strictly homogenize content, language and conclusions but rather allowed different opinions, sometimes even contradictory views, so that a certain diversity is maintained in order to inspire for new thoughts. We especially hope that, in the long run, the book may motivate for cross-reading in order to obtain insights from other disciplines.

How Is the Book Structured?

In this book, we have enlisted leading international experts to provide a broad coverage of the scientific and clinical state-of-the-art in the field of alcohol-related diseases. Alcohol dependence, its diagnosis, therapy, and underlying mechanisms, is covered by 26 chapters. We start by introducing the brain disease view of addiction and discuss why spontaneous remission in some individuals does not negate this view, and how seemingly compulsive alcohol use can co-exist with partially preserved sensitivity to healthy rewards. We connect the dots by pointing to subsequent chapters that review behavioral as well as neuropsychopharmacological treatments, which clearly show that the brain is the biological substrate from which both alcohol addiction and the capacity for behavior change arise.

A major body of the book addresses all aspects of the liver, the major ethanol-metabolizing organ, damage to which is responsible for most of the death rates linked to alcohol. This includes diagnostic and screening aspects, pathophysiology and therapy. **Liver elastography** has certainly evolved over the last two decades as a breakthrough in the early diagnosis of liver fibrosis and cirrhosis. One part alone is devoted to the rare but often fatal alcoholic hepatitis. The book also has chapters on less frequently discussed alcohol-related diseases such as those affecting the heart and skeletal muscle or neurological disorders such as the Wernicke-Korsakov encephalopathy. There are also highly praxis-oriented chapters that discuss the

clinical management of acute alcohol-related conditioned encountered in the emergency room, alcohol detoxification, but also long-term integrative management of alcohol use disorders.

The book does not only provide state-of-the-art knowledge but also aims at identifying open questions and controversial aspects and it also includes novel, unpublished data. Consequently, it provides a platform in order to stimulate discussions and initiate novel interdisciplinary endeavors. For these reasons, an **Appendix** has been included that contains general fact sheets about alcohol and biochemical schemes that are essential to the understanding of ethanol metabolism and pathology. The Appendix also contains a patient case with questions and answers and original data from the prospective Heidelberg study cohort of heavy drinkers which not only includes patient characteristics but also mortality data and correlations analyses. We strongly believe that people and society have the right to know whether they are at risk and what the early symptoms or measures are to diagnose and prevent alcohol-related disease. The freedom to distribute and consume legally a potentially harmful drug such as alcohol should be matched with a responsibility to protect those who are at special risk for genetic reasons, or children and, especially, unborn life.

Where Does Alcohol Research Come From?

Although the ability to produce alcoholic beverages as well as the knowledge about negative side effects are known since human ancestry, scientific based mechanisms have taken a long path. The relation between alcohol and liver cirrhosis became obvious, at least to a few clinicians and scientists, in the nineteenth century. Clear statistics were established in the middle of the twentieth century. The harmful effects of alcohol have been continuously perturbated by diluting arguments of either other contents of alcoholic beverages, or other conditions such as malnutrition. However, for about 50 years, it can be considered as established that alcohol itself causes diseases such as liver cirrhosis, one of the key pathologies related to alcohol-caused premature death [1].

A blossoming of alcohol research was reached between the 1960–80ies. In some countries, institutions were founded such as the NIAAA (National Institute on Alcohol Abuse and Alcoholism) in the USA to specifically provide grant money for basic and applied studies related to alcohol. Activities later declined for reasons that are not completely clear or have not been intensively debated. One reason is, besides a decreased interest of society, most likely the enormous complexity of alcohol interactions within the human organism (Fig. 1.1). To understand alcohol related disease mechanisms, the various organizational levels have to be addressed, from the biochemical, the subcellular, cellular and the organ level and all potential interactions between these levels have to be taken into account. However, almost in parallel, biomedical science and clinical institutions have become more specialized in the 80ies. Psychiatry and internal medicine started to divide into subspecialties

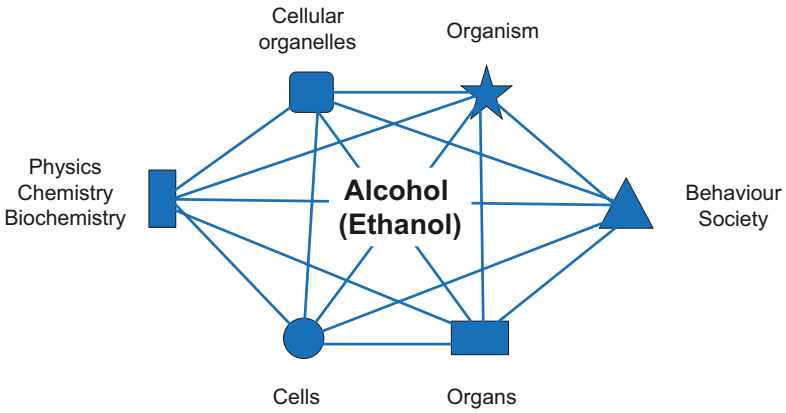

Fig. 1.1 Multiple interactions of ethanol at various organizational levels in humans

such as cardiology, gastroenterology, nephrology and so on. These structural changes started to compartmentalize medicine, making it more and more difficult to provide sufficient funding for such highly interdisciplinary research as is required for alcohol-related diseases.

One of the other specific aspects of alcohol in society is its strong association with cultural, religious, and social activities. Over centuries this has led to the development of an economy that profits from alcohol production. Moreover, for ages, governments have and still benefit through taxation from alcohol production, generating a special societal mélange of resistance and denial about alcohol-related negative sides. A famous example is the German sparkling wine tax from 1907, initiated by the German emperor at the time to finance his dream of a German fleet that could match the Royal navy. More than 100 years ago, while in Germany the governmental system changed from monarchy to chaos, from dictatorship to democracy, the sparkling wine tax still exists. Certainly, the catastrophic failure of the prohibition from 1920 to 1933 in the USA, a nationwide constitutional law that strictly prohibited the production, importation, transportation, and sale of alcoholic beverages, has engraved the certainty, that a simple stop of alcohol production is not a realistic scenario. Consequently, humans have lived, live and will live with alcohol.

A Few Words About Alcohol-Related Diseases and Standardized Terminology

There has been an intensive debate on whether certain terms such as “alcoholic” or “alcoholism” are pejorative, and discriminate patients [2]. The increasing knowledge about alcohol and addiction has shown a more diverse picture urging a need to standardize terminology to better describe pathologies both important for diagnosis and treatment, but also for research and clinical studies. Thus, the WHO stopped

using the term “Alcoholism” in 1979 because it did not describe the huge variety of alcohol-related use disorders and “Alcohol-use disorder” (AUD) was proposed instead.

However, alcohol-related terms are so deeply and long-time involved with languages in all cultures that, despite the long fight for language reform, it remains challenging. There are also serious counterarguments that should not be ignored. For instance, no terminology will survive, if it is not understood and practiced. As an example, the term “alcoholism” appears in the database “Pubmed” for the first time in 1939. It then peaks 1980 with 305 quotations, while the term “alcohol-use disorder” appears first in 1991. In 2021, “alcohol-use disorder” was used 505 times, compared to “alcoholism” with 50 times. When, however, looking at “practiced” language, e.g., in open source databases such as Wikipedia, the results are sobering. The term “alcoholism” is used by “Wikipedia” in 101 languages (August 2022) while the term “Alcohol-use disorder” has not even a single entry. Only “Substance use disorder (SUD)” is used in 10 languages with “alcohol-use disorder” only being briefly mentioned.

One could also question whether the term “alcoholism” or “alcoholic” is indeed pejorative or whether this is a phenomenon of some specific languages or cultures. We cannot uniformly share the observation that linking a “disease-causing” condition to a disease is discriminating, pejorative or not accepted by patients. Rather, it is our observation that heavy drinkers, normally subsumed within the category “alcoholic”, will have no problem in reporting their alcohol history. It can be easily agreed with the broader knowledge today that the term alcoholism is not strictly scientific, but it is also a common observation that most people in different cultures will immediately understand what “alcoholism” means. It is also quite clear that “alcoholism” may only describe a smaller cohort of heavy drinkers among “alcohol-use disorders”. More confusing, even the International Code of Diseases (ICD) still officially uses terms such as “alcoholic liver damage” (E860.0), “alcoholic polyneuropathy” (357.5), “alcoholic cardiomyopathy” (425.5), “alcoholic gastritis” (535.30, 535.31), “alcoholic fatty liver “(571.0) or “acute alcoholic hepatitis” (571.1).

Therefore, it seems that the debate will continue, and it will finally be the people and patients who will decide which language is most appropriate for respect, clarity and common use.

As a consequence, in this book, we have made efforts to mostly use the novel terminology, especially in the addiction field such as AUD and we have also tried to generally use “alcohol-related liver disease” for ALD. To avoid confusion, however, we have left the commonly used terminology for more rare entities such as “alcoholic cardiomyopathy” or “alcoholic hepatitis”.

Finally, gastroenterology or hepatology societies such as EASL, AASLD or UEG are now also pushing forward to change the term “alcoholic liver disease” to alcohol-associated liver disease or alcohol-related liver disease (ALD). The discussion is of certain relevance as ALD is the major cause of all-cause death in those who consume alcohol. Moreover, similar to the discussion above on AUD, a recent debate on non-alcohol-related liver disease (NAFLD) has emerged that considers the term

"non-alcohol" has negative stigma. It has resulted in the novel terms MAFLD (metabolic-associated fatty liver disease) [3] or **metabolic dysfunction associated steatotic liver disease (MASLD)** by AASLD. However, given the confusion and the still poor understanding of the underlying molecular disease mechanisms caused by alcohol, it is questionable whether the increased diversity of terminology really contributes to a better understanding. The initiators of the term MAFLD explicitly subsumed ALD within the new term. This is, however, not really convincing since almost all drinkers will develop fatty liver but only 20% will progress to liver cirrhosis. Normally, a new terminology should be based on a better differentiation of diagnosis, discriminative aspects or a real improvement of understanding. However, it is not even clear whether "fatty liver" is a pathology, a physiological state, or both as fatty liver can evolve in hibernating animals, under physiological conditions of fasting and conditions of transient hyperalimentation. As inflammation seems to be the main driver of "disease", steatosis should be used as neutral connotation while liver disease should be restricted to patients with liver damage, inflammation and fibrosis. The term **metabolic liver disease (MLD)** could represent such as novel term.

Is Alcohol a Disease-Causing Agent?

It is interesting to see that alcohol itself is quite well tolerated when isolated cultured human cells are exposed to it under laboratory conditions and cell membranes start to disrupt at concentrations as high as ca. 10% of ethanol. This fact already underlines that alcohol obtains its disease-inflicting level mainly in the intact organism. Moreover, it is the oxidation of alcohol that transforms it into highly toxic and carcinogenic metabolites such as acetaldehyde. In this context, it is interesting to note that many restrictions apply for acetaldehyde, when purchased officially for laboratory use, and it must be handled with certain safety measures. No such regulations apply, if alcoholic beverages are purchased, consumed and directly converted to acetaldehyde within the human body at an equimolar ratio. Nevertheless, with genetic evidence, the human body's ability to metabolize alcohol has not primarily evolved through the culture of alcohol production or uptake of fermented fruits, but rather the intestinal fermentation of carbohydrates to ethanol at significant levels during physiological food intake and digestion. In addition, during most of human history until 150 years ago, general life expectancy was below 40 years, with infectious diseases as primary cause of death, while negative effects of alcohol were considered less relevant. In the past, Roman legions were even supplied with red wine to effectively decrease the burden of gastrointestinal infectious diseases and, in the European cities of the middle age, children were routinely nourished with a low alcohol-percentage beer as drinking water was more dangerous back then. Finally, through centuries, alcohol was part of the weekly salary, and, just a couple of years ago, in some countries, alcohol was offered to hospital and medical staff at lunch time and on-call duty during the night.

Epidemiology of Alcohol-Related Diseases

We have collected an unusually high number of contributions on epidemiology in this book for several reasons (Part I). First, the data highlight the dimensions of alcohol burden in the global world. Ca. three million people die from alcohol consumption annually, not even taking into account the larger "dark" numbers due to undiagnosed or missed alcohol consumption or unrecognized liver fibrosis. With regard to other substance use, alcohol shows the highest per capita years of life lost and death rates are especially high in those aged 45–65. These different perspectives that also include a first prospective mortality study (see Chap. 7) also increasingly underline that **liver-related death** represents the major cause-specific death ranging from 35–80% of all deaths caused by alcohol. Moreover, alcohol is responsible for the majority of liver diseases globally, despite the tendency, to shift focus to other conditions, such as obesity-related liver diseases. The statistics also show that alcohol causes an impressive high number of cancers globally. These are not only primary cancers of liver, stomach, and neck, but also the very common cancers of the colon and female breast. Collectively, alcohol-related cancer cases account for 4% of all cancers globally (see also Part XII).

Some chapters impressively document that most efficient interventions to prevent this enormous burden are rather simple but effective by limiting the access to alcohol either through taxation, pricing or buying restrictions. It is frustrating to see that limited legal interventions would be able to prevent many more casualties than those that can be cured later on by even the best health care systems. Again, in confirmation of earlier success in Scandinavian countries, Russian efforts for more than two decades to implement measures such as taxation confirm how important political measures are in order not to forbid but to limit availability and affordability of alcohol. The chapter on "**Policies to reduce the burden of ALD**" by colleagues from the UK is quite elucidating.

Alcohol Use Disorders and Current Challenges for Addiction Therapy

A more integrated care for alcohol use disorders and general alcohol-related diseases is urgently needed. **Alcohol use disorder (AUD)** is a chronically relapsing disorder that involves aspects of compulsivity in alcohol seeking and taking, difficulty limiting alcohol intake, and the emergence of negative emotional states, such as dysphoria, anxiety, irritability (e.g., hyperkatifeia), in the absence of alcohol. Altogether, 26 chapters are devoted to alcohol use disorders, introduce to addiction and discuss current modes of diagnosis and treatment. Importantly, **Fetal Alcohol Spectrum Disorders (FASD)**, structural and functional central nervous system pathology in alcohol addiction and risk factors for alcohol are addressed.

Alcohol addiction encompasses a three-stage cycle that intensifies with continued alcohol use: binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation. These stages engage neuroadaptations in brain circuits that involve the basal ganglia (reward hypofunction), extended amygdala (stress sensitization), and prefrontal cortex (executive dysfunction). It is still not widely appreciated that the amount of drinking is not necessarily linked to dependence and vice versa. Some people can drink 60 g alcohol per day, certainly a level of increased risk for both organ-related disease and cancer, but they do not consider themselves as "alcohol-dependent" as they can stop drinking immediately for several days without medical support. Typically, such "at risk drinkers" exceed those who are really dependent, i.e., those who cannot freely discontinue drinking alcohol even so they drink, e.g., less than 40 g per day.

Altogether, very few systematic follow-ups have been performed beyond a year and numbers will be highly dependent on how the condition was diagnosed. With a broad diagnosis based on DSM-5, the number will look better, and it will also look like many people remit spontaneously [4]. Based on a "clinical" diagnosis, i.e., actual treatment seeking people, **relapse is 60–70% at 1 year**, which seems to be unchanged in almost half a century [5, 6].

Medscape also reports relapsing rates depending on the time of sobriety. Thus, 80% relapsed within 1 year, 60% for those who remained sober for 2 years while those who remained sober for at least 5 years had a less than 15% risk of relapsing [7]. According to UK rehab data, longterm rehab success rates are as low as 10% [8]. In the specific setting of heavy drinkers presenting primarily for in-hospital alcohol detoxification to an internal medicine department, we observed after a 15 year follow-up that only 66 patients (5.5%) responded to the invitation to present again for ultrasound examination and laboratory testing. During the mean observation time of ca. 5 years starting from initial detoxification, 25 (37.8%) had completely abstained from alcohol while 62.1% had resumed drinking.

With regard to dependence, genetics seems to drive at least 50%. With one well-established pathway, genetic risk manifests itself is through impaired impulse control (see Part V). So far, data show that we are in fact looking for "large swarms of little insects", i.e., a multitude of risk alleles each contributing a small proportion of risk, rather than big game, i.e., a few risk loci with large effect sizes. Metabolic genes are protective if they result in flushing, and this has been replicated in large Genome-wide association studies (GWAS). The latest GWAS found about 30 of those that were genome-wide significant. The dopamine D2 receptors is actually among them, but the meaning of it remains unclear. More details are provided in Part VI.

The book provides a more holistic view also on addiction that seems tightly to interact not only with the body's inflammatory state but also basic energy metabolism. More interdisciplinary work is certainly needed here. For instance, the novel insights about red blood cell damage, bone marrow toxicity and its relation to iron overload may also provide important links to iron deposition in heavy drinkers [9]. The book also discusses key neuroadaptations in stress systems in alcohol

dependence. These neuroadaptations contribute to negative emotional states and negative urgency that are hypothesized to powerfully drive alcohol drinking and seeking and promote relapse. These changes in stress systems, combined with the disruption of prefrontal cortex function that leads to cognitive deficits, impairments in inhibitory control, and poor decision making, contribute to the chronic relapsing nature of alcohol addiction.

Brain, Energy Metabolism and Relation to Alcohol Dependence

Brain effects of alcohol and addiction are not understandable without the fundamental, evolutionary conserved functions of the brain for organism survival and its association with food intake and basic energy metabolism (see also Fig. 1.2). The mammalian brain primarily depends on glucose as its main source of energy. In humans, the brain consumes 10 times more glucose-derived energy, than other tissues. Glucose metabolism provides the fuel for physiological brain function, neuronal and non-neuronal cellular maintenance, as well as the generation of

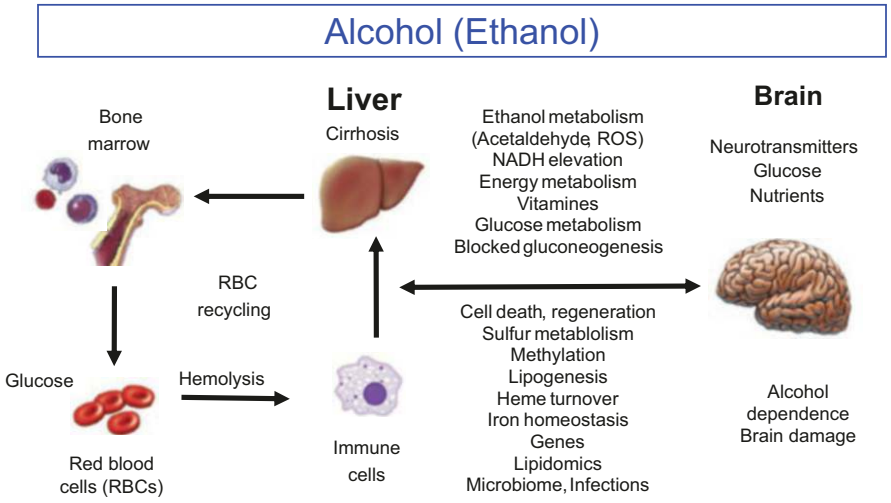

Fig. 1.2 Emerging role of hepatic alcohol metabolism, enhanced red blood cell (RBC) turnover and alcohol dependence. The brain profoundly depends on energy supply above all glucose metabolism that is primarily supplied by the liver. Alcohol not only affects neuronal circuits but impairs glucose supply by the liver through hepatic ethanol metabolism. Moreover, as shown by recent prospective all-cause mortality data (Chap. 7), enhanced RBC turnover through hemolysis and bone marrow toxicity increases the risk of iron-mediated organ damage that may also account for iron-mediated damage to the brain. Emerging data also indicate that genetic alterations and damage of the liver affect drinking behavior

neurotransmitters [10]. The brain integrates multiple metabolic inputs from the periphery and it modulates various aspects of metabolism with the hypothalamus playing a key role in the homeostatic regulation of energy and glucose metabolism [11].

On the other side, the liver is essential for neuronal glucose supply through **hepatic gluconeogenesis.** Moreover, glucose cannot be simply replaced as an energy source but only supplemented, e.g., during strenuous physical activity when blood lactate levels are elevated or during prolonged starvation with elevated ketone bodies [12, 13]. The glutamate/glutamine cycle is another example how neurons are supported energetically with glutamine by astrocytes supporting the glutamatergic neural activity using glycolysis [14].

Fascinating imaging technologies have helped to shed more light on these basal energy dependance of the brain such as nuclear magnetic resonance spectroscopy after infusion with stable glucose isotopes [15]. The most frequently used methods of brain metabolic imaging are the detection of radiolabeled glucose by **positron emission tomography (PET)** in vivo or for diagnostic imaging, and by ex vivo autoradiography using glucose analogues [16]. In addition, fluorescent deoxoglucose derivatives are being used for fluorescence imaging in animal models [17]. Based on functional PET studies, for instance, it has been concluded recently that heavy alcohol consumption facilitates the use of alternative energy substrates [18]. The study also confirmed that resting whole-brain glucose metabolism was lower in drinkers as compared to controls. Functional imaging studies have further shown that alcohol induces dopamine release and increased activity in the striatum [19]. Dopaminergic neurons respond to nutrients such as glucose. Increase in nutrient concentration causes an increase in energy state and modulates ion channel conductance to initiate the dopaminergic signaling cascade.

Biochemically, apart from the production of toxic endproducts, ethanol profoundly interferes with basic energy metabolism by shifting the balance to reduced Nicotinamide adenine dinucleotide equivalents (**NADH**) and **acetate**. This blocks the ability of the liver to provide the brain with glucose. Blood glucose concentrations decrease, but only slightly because the set point for glucose homeostasis in only slightly decreased and glucose consumption by peripheral tissue and brain is decreased [14, 20]. In contrast to other nutrients, alcohol has **access to neurons behind the blood brain barrier** and this augments the usual nutrient reward circuitry [19]. Dopaminergic projections go to the nucleus accumbens, which has a crucial role in the reward system of human brain. If chronic alcohol consumption is abruptly ended, metabolism is no longer able to respond rapidly enough to compensate. Glutamatergic neural activity adapts to chronic dysregulation of glutamate metabolism and suppression of glutamatergic neural activity by increasing excitatory and decreasing inhibitory amino acid receptors. During alcohol dependence, a point is reached where alcohol withdrawal results in significant metabolic energy depletion in neurons and other brain cells as well as hyperexcitation of the glutamatergic system. The extent and regional specificity of energy depletion in the brain, combined with hyperactivity of the glutamatergic neuronal system, largely determines the severity of withdrawal symptoms [14].

In conclusion, alcohol has an effect on the brain at multiple levels that are still poorly understood. A more interdisciplinary approach is needed to fully appreciate not only its its direct effects on brain cells and neuronal circuits but also regional and systemic energy metabolism especially those of the glucose and the liver. It also remains to be studied while heavy drinkers show slightly elevated glucose levels that further increase when cirrhosis develops (see book appendix). Of note, the book discusses that generally accepted biomarkers of alcohol such as phosphatidylethanol or glycated hemoglobin (HbA1C) are profoundly modulated during alcohol metabolism and their interpretation should be taken cautiously.

On another concluding note, for a long time, **hangover symptoms** have been linked to ethanol-mediated oxidation products such as acetaldehyde, effects on the gastrointestinal tract or dehydration, effects on glucose metabolism, sleep patterns, and biological rhythms [21]. However, till today, data of clinical studies are limited and those available lack a certain level of methodological quality [22]. The complexity of alcohol-related disease mechanisms outlined in the book, however, underline why the simple diagnosis of "hangover" is and will not be easy to fully understand, diagnose and treat.

Plaidoyer for an Integrated Patient Care for Alcohol-Related Diseases

Unfortunately, even in the highly specialized setting of alcohol-related diseases, interactions between addiction specialists and brain researchers on the one side and other organ-specialized experts on the other side are rather limited. Given the many interactions of ethanol at the subcellular, cellular and organ level and the endless interactions (Fig. 1.1), a broader perspective is urgently needed. A close interaction between addiction and other health professionals is especially required to **improve and integrate health care support for patients with AUD.** In Part XIII of the book, two chapters from UK and Romania (Chaps. 76 and 77) describe how **health care teams** have implemented a model of integrated care for patients with acute and chronic alcohol addiction and alcohol-related diseases in a resource limited setting. These chapters document how much needs to be done to both address mental health, diagnose other psychiatric disorders, and adequately treat the addiction without overlooking more common and fatal confounders of alcohol consumption, liver cirrhosis above all.

One of the major advances with regard to alcohol-related diseases has been in the area of diagnosis with the **introduction of liver elastography** (see also Part VII) [23]. As liver-related mortality accounts for the majority of alcohol-related deaths, ranging from 30–80%, an early identification of those who are at an increased risk to develop liver disease is a crucial and important step forward [23]. Since some of the techniques can be performed with little training and without dedicated

ultrasound knowledge, a broader availability will not only help to improve patient care but also close some of the gaps between the different specialties.

A closer interaction between the various medical specialties involved in the care of alcohol-related diseases in form of **virtual or physical "alcohol treatment centers"** is also justified by the many interactions of ethanol metabolism between different organs (see also Fig. 1.1).

Important Crosslinks Between Liver and Alcohol Dependence

It is less appreciated that ethanol metabolism in the liver is closely associated with alcohol dependence. Thus, the combination of a slow first oxidation to acetaldehyde and a rapid second oxidation of acetaldehyde to acetate have been shown to increase the development of dependence (see also Chaps. 50 and 75). Obviously, it is the ethanol that causes the dependence while its toxic oxidation and accumulation of these oxidation products lower the risk of alcohol addiction due to direct negative feedbacks. In this context, it is also quite interesting to note that ethanol is transformed to toxic metabolites inside the body while human cultured cells tolerate well ethanol concentrations up to 5–10%, more than 10 times of the lethal concentrations in humans. To put it in simpler terms, it seems indeed the ethanol causes the joy (and addiction) while the human body cannot escape its mandatory oxidation to toxic acetaldehyde and generation of reactive oxygen species. However, we should not forget that only a minority will suffer from these negative consequences.

There are also emerging data that brain function, alcohol consumption and liver metabolism are tightly interrelated (Fig. 1.2). Thus, as shown in the Appendix (Fig. A.85), first preliminiary data indicate that heavy drinkers who develop liver cirrhosis will reduce their drinking levels and drinking behavior. Moreover, patients with an unfavorable mutation (GG) of **PNPLA3** (see also Chap. 52), a lipid droplet associated protein which is most likely involved in triacylglycerol hydrolysis, seem to avoid high percentage alcoholic beverages. Other data show that patients with liver cirrhosis actually have higher levels of blood alcohol, ethylglucuronid and ethylsulfate despite lower daily alcohol intake [24]. And finally, as is also discussed in this book in Part VI, data are emerging that indicate that the known high variability of the alcohol biomarker phosphatidylethanol (PEth) is closely related to the alcohol-mediated red blood cell turnover. These novel observations are in line with the fact that formation of PEth requires erythrocyte phospholipase D activity and seems to be stably integrated in the RBC membrane.

Last but not least, various important **biochemical pathways are listed in the Appendix** for better illustration. Ethanol metabolism modulates various basic pathways that use vitamins such as vitamin B1 and B6 or folic acid that are important for extra-hepatic metabolic processes. For instance, vitamin B1 is essential for basic carbohydrate and energy pathways, vitamin B6 for the transsulfuration pathway

while folic acid and vitamin B12 are essential for the metabolism of methionine. Of note and as shown in the Table B.4 (original data from a heavy drinking cohort), vitamin B12 can even be elevated in patients with liver cirrhosis, most likely to compensate for relative folate deficiency.

Emerging Novel Role for Enhanced Red Blood Cell Turnover

Red blood cells have long been forgotten in the context of alcohol-related diseases. RBCs are important storage sites for vitamins such as folic acid. The fact that a prospective all-cause mortality study (Chap. 7), to the best of our knowledge the first, identifies **hemolytic anemia**, **release of heme** and **enhanced RBC turnover** as the most important prognostic factor, further sheds new light on the long-studied **hepatic iron overload** and recent observations of **brain iron accumulation** in drinkers [9]. Finally, the interactions between **hepatic encephalopathy** and liver cirrhosis require more attention as the molecular mechanisms are still not fully understood. In addition, it becomes increasingly known that the inducible cytochrome p450 system, namely the subtype CYP2E1, that oxidizes a significant amount of ethanol in heavy drinkers, is not only present in the liver, but also in macrophages and in the brain. It may also provide new links to why chlomethiazole has been used for almost one century as a sedative and hypnotic but has turned out to be a specific CYP2E1 inhibitor. There are almost no studies available on the expression and function of brain CYP2E1.

Why Can Alcohol-Related Liver Disease Be Simulated by Diabetes and Obesity in the Absence of Alcohol?

One of the major cause-specific deaths is liver related mortality, with alcohol-related liver disease being one of the famous hallmarks of alcohol consumption. In 1995, more than 25 years ago, in a book edited by Pauline Hall entitled “Alcohol-related liver disease” [25], Peter Scheuer asked “why alcohol-related steatohepatitis is so similar morphologically to **non-alcoholic steatohepatitis (NAFLD)?** [25]. Today, almost 30 years later, it is astonishing to see how relevant these questions still are. In fact, we have not seen much progress in addressing them in the the last two decades.

Especially ALD offers more unanswered questions, in addition to the above-mentioned stunning similarity between diabetes- and overweight- induced NAFLD. Almost no progress has been made in the diagnosis and treatment of the often-fatal **alcoholic hepatitis**. Modest benefits are seen in only a fraction of patients with steroids. Although the microbiome has gained great attention, simple antibiotic treatment does not seem to halt ALD. Moreover, the pathophysiology of

ALD is often explained with quite complex and methodologically challenging mechanisms, such as reactive oxygen species that require deep physical, chemical and biochemical knowledge. On the other side, enzyme systems such as the p450 system localized in the endoplasmic reticulum are attributed to mediate major disease mechanisms but both knockout animals or pharmacological blockade show less convincing effects. In other words: What are the actual mechanisms of alcohol-related liver disease and what does it have in common with NAFLD in the setting of overweight and diabetes?

Although the oxidation intermediate acetaldehyde is beyond any doubt crucial to explain alcohol-related disease mechanisms, it cannot be the major link to obesity and diabetes.

Rather, both alcohol, diabetes and overweight are characterized by an **excess of energy** and an excess of reduced nicotinamide adenine dinucleotide (NADH). Heavy drinkers, despite having access to normal nutrition, cover typically about 50% of their energy supply by ethanol (see also Table B.4). Although ethanol, just like sugars, contains only the three elements carbon, oxygen and hydrogen, it is neither chemically nor biochemically a carbohydrate, and its human metabolism is strikingly different from that of carbohydrates. Comparable to physiological energy suppliers such as fatty acids or sugars, oxidation of ethanol leads to NADH which can be further used for mitochondrial respiration (Fig. 1.3). However, in contrast to

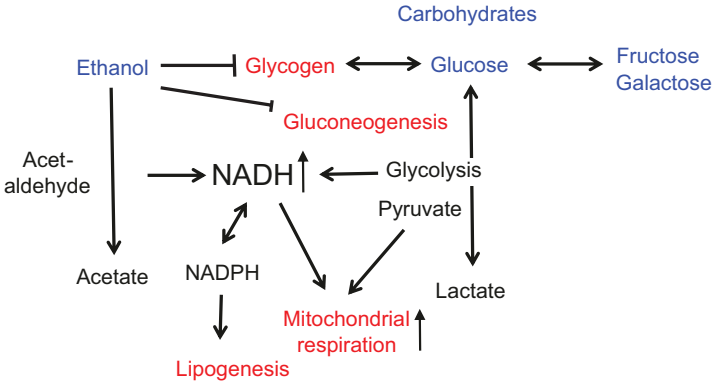

Fig. 1.3 Carbohydrate and ethanol metabolism linking brain to liver and energy metabolism (simplified scheme). Some similarities may explain why ethanol, obesity and diabetes mellitus all cause a similar hepatic steatohepatitis whether alcohol-associated or non-alcoholic. Both glycolysis and ethanol oxidation lead to **formation of NADH** which drives mitochondrial respiration and lipogenesis and may be the joint key feature in causing mitochondrial and organ damage. In difference to carbohydrates, however, **ethanol oxidation ultimately blocks hepatic gluconeogenesis** and causes rapid glycogen depletion. Hence, glucose, which is essential for energy metabolism of brain, red blood cells or muscles, becomes limiting. Sugars and ethanol also share the fate of having almost no evolutionary evolved negative feedback loops except by elimination through lipogenesis or oxidation. Not by chance, the vital energy metabolism is also closely related to dependence as seen in **food addiction**. A better molecular understanding is needed how energy and ethanol metabolism are associated with the brain and dependence. This complexity may explain the rather diverse findings in large screening studies for genes that cause addiction

glucose and fructose, ethanol metabolism **prevents gluconeogenesis** simply due to the balance shift towards NADH (see Fig. 1.3). This shifts the **lactate/pyruvate ratio** towards lactate and, consequently, away from gluconeogenesis. It should be also noted that, already at 0.4 permille of blood ethanol concentration, typical ethanol metabolism starts [26].

Ethanol also provokes a fast and efficient **depletion of glycogen stores** (see Fig. 1.3). Although fundamental to ethanol biochemistry, it is still not clear whether these changes are responsible for rapid ethanol-mediated muscular fatigue as muscles obtain glucose from the liver through the Cori cycle. As already mentioned above, it is also highly intriguing that ethanol, which does not have any biochemical feedback loop in human cells, overwhelms the mitochondrial respiratory chain and may simply cause injury by uncoupling reactions leading to release of **reactive oxygen species (ROS).** Consequently, despite providing enough energy, ethanol metabolism leads to glucose deprivation and glycogen depletion which may become limiting for cells of the brain, red blood cells or muscle cells that are highly dependent on hepatic gluconeogenesis. It is an attractive scenario that the rapid and uncontrolled "fuel burning" in mitochondria could ultimately be responsible for mitochondrial damage, e.g., through uncoupled redox reactions.

Thus, it seems that despite not being a carbohydrate, ethanol shares with sugars the immediate energy supply within the **intermediary metabolism**. They also share to some extent the **lack of a negative feedback loop**. Similar to alcohol, the human metabolism cannot really escape an excess of glucose or fructose. In this scenario, **fatty acid accumulation** is primarily the body's sole option to store the excess energy through lipogenesis. Hence, fatty liver may indeed be primarily a bystander and a metabolic consequence to quickly remove the excess of energy.

Consequently, it is the uncontrolled excess of energy that may link NAFLD with ALD. Since lipogenesis in this context would be more a solution than a problem, fatty liver may not be the actual disease but rather the mitochondrial damage and inflammation due to excess energy supply. More research on carbohydrate metabolism, its relation to ethanol, and its hormonal control is needed. Ultimately, with regard to the terminology debate, metabolic (dysfunction) associated fatty liver disease (MAFLD) [3] may not be optimal. Rather, it should be termed **metabolic liver disease (MLD)** and only include patients with signs of liver damage and fibrosis but not fatty liver itself.

Conclusion

The present book covers all aspects of "alcohol and alcohol related diseases". Alcohol is a major health risk worldwide causing more than 60 diseases and accounts for at least three million death annually and 4% of all new cancer cases. Besides current diagnostic measures and treatment strategies, the many underlying molecular mechanisms of alcohol toxicity including the genes that lead to addiction and disease are discussed. It is hoped that the full appreciation of the enormous level

of complexity and interactions created by alcohol stimulates a more interdisciplinary cooperation between clinicians, scientists and addiction specialists. In my opinion, only such a holistic approach will allow us to apply the increasingly emerging potentials of OMICS and genetics more efficiently. It is also expected that the books helps to guide policy makers in order to responsibly handle alcohol in society, certainly the most important aspect to decrease mortality and suffering from alcohol use disorder, alcohol-related diseases and cancer.

Chapter 2
Epidemiology of Alcohol and Opioids

Jürgen Rehm

Abstract Alcohol is the most prevalent addictive substance globally, and with three million attributable deaths per year, it causes substantial burden of disease and mortality, mostly to men. While alcohol use has been causally linked to over 200 ICD three-digit categories, the majority of alcohol-attributable deaths can be found in four major categories (in the following order): injury (unintentional and intentional); digestive disease (especially liver cirrhosis); cardiovascular disease; and cancer. For burden of disease, including non-fatal outcomes, alcohol use disorders play a more important role than for fatal outcomes, but only 14% of all alcohol-attributable disability-adjusted life years are made up of alcohol use disorders. Harm per litre of pure alcohol is higher in poorer countries, and within all countries in lower socioeconomic strata. In addition to health harm to the drinker, alcohol use causes social harms such as violence and social disorder.

Opioids are a broad substance category, which includes illicit drugs and pharmaceuticals. While the estimates of prevalence and attributable harm are less reliable due to its legal status, opioid use and—use disorders are much less prevalent than

Epidemiology of Alcohol and Opioids

Major Classes of Addictive Substances and Attributable Harm

Alcohol use has been identified as a major contributor to the burden of disease and injury [1]. In this chapter, the epidemiology of this risk factor will be laid out, in part in contrast to opioid use. Before starting, we would like to give some preliminary results of the burden of mortality caused by select behavioural risk factors potentially can causing addiction (Table 2.1).

Clearly, tobacco use is linked to the most deaths, about 3.6 times as many as alcohol use, and to 18 times more deaths than caused by drug use. The picture changes for potential years of life lost (PYLL): here the ratio between PYLL attributable to tobacco use and alcohol use is about 2.5 to 1, and the attributable PYLL ratio between tobacco use and drug use is about 10 to 1, reflecting the fact that alcohol- and drug-attributable deaths occur much earlier in the life course than deaths caused by tobacco use [3, 4]. But still, legal drugs like alcohol and tobacco cause much higher mortality than all illegal drugs combined. Within the category of illegal drugs, opioids are responsible for almost 70% of the overall mortality attributable to drug use [2].

Table 2.1 Global mortality caused addictive substances in 2019

	Deaths				Potential years of life lost			
Sex	Risk Factor	Rate per 100,000	Upper CI	Lower CI	Risk Factor	Rate per 100,000	Upper CI	Lower CI
Men	Tobacco	181	195	166	Tobacco	3839	4168	3514
	Alcohol	54	62	46	Alcohol	1620	1840	1416
	Drug	9	10	8	Drug	328	362	298
Women	Tobacco	49	54	45	Tobacco	1026	1133	925
	Alcohol	9	11	7	Alcohol	242	284	206
	Drug	3	4	3	Drug	117	132	104
Total	Tobacco	109	116	101	Tobacco	2354	2538	2181
	Alcohol	30	34	26	Alcohol	916	1033	810
	Drug	6	7	5	Drug	222	244	202

Source: Own compilation based on [2]

One shared characteristic of all three major categories of substances concerns the higher harm caused to men compared to women. However, the ratios between men and women vary with alcohol use having a much higher associated mortality burden than either tobacco or illicit drug use (Table 2.1).

Major Epidemiological Characteristics of Alcohol Use

We have started with substance-attributable harm, as this is the main reason why addictive substances are of concern. We will, of course, come back to this harm, but we would like to present some basic epidemiologic characteristics of alcohol use first.

Alcohol Use Patterns

While alcohol is the most commonly used addictive substance globally [1], the majority of adults globally abstain from alcohol in any given year [5]. More men than women use alcohol in every country of the world, and men also consume higher average volumes of alcohol and have more detrimental drinking patterns (e.g., more irregular heavy drinking occasions—for definitions and conceptualizations, see [6]; for quantitative comparisons of these indicators by country and region, see [5]).

However, while there are high-level similarities with alcohol use, such as its predominant use by men, there are differences. Figure 2.1 gives an overview on adult (defined as 15 years and older) *per capita* alcohol consumption in different countries.

Levels of average alcohol consumption are highest in Central and Western Europe, in Australasia, and select countries of Africa. They are lowest in the Muslim-majority countries in Northern Africa, in the Middle East countries, and in South-East Asia (e.g., Malaysia, Indonesia; see Fig. 2.1).

Overall, the level of alcohol consumption has been fairly stable in the past decades, but there have been changes in different regions over the past two decades (for an overview, see [7]; see also [9]): the WHO European Region had the largest declines in consumption since 2000, over the last decade driven by substantial reductions in *per capita* consumption in the Eastern part of the region [10], in particular Russia [11]. The implementation of alcohol control policies such as the "best buys" of the WHO (taxation increases, availability restrictions, ban on marketing; [12] in many countries of the region was the driving force behind these reductions [13, 14]. The Americas also had reductions in this the time span between 2000 and 2020, mainly in men, whereas both the South-East Asian and the Western Pacific Regions increased their consumption [5], in large part driven by increases in India and China [15].

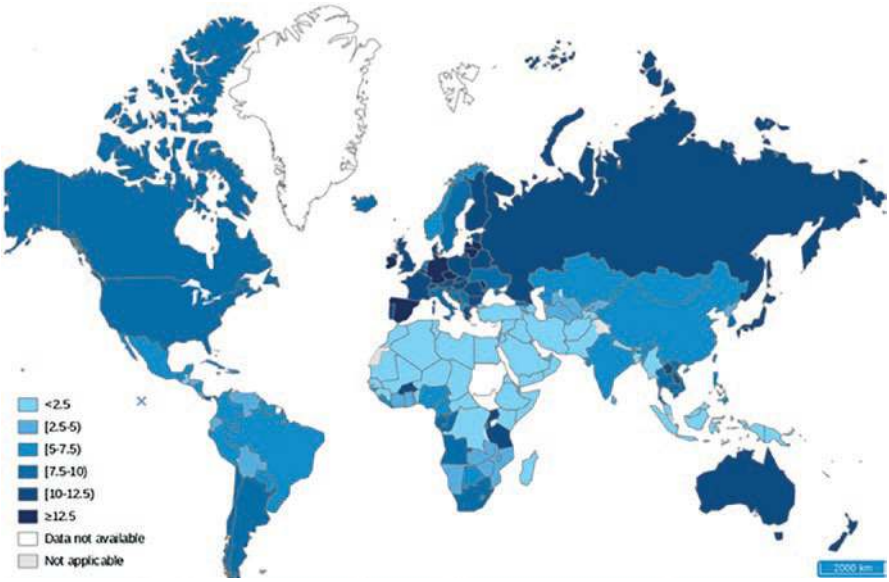

Fig. 2.1 Adult *per capita* consumption of alcohol in litres ethanol for 2019. Source: World Health Organization, World Health Statistics 2022 [7, 8]

Part of these dynamics are driven by economic growth: alcohol is no essential good, and thus lowest in low-income countries, but with increasing wealth, its use tends to increase as more people can afford it [15, 16]. Also, within upper-middle income and high-income countries, abstention from alcohol tends to be highest in low socioeconomic strata [17, 18], whereas this relationship is not so clear in low-income and lower-middle income countries [19].

Harm Attributable to Alcohol Use

Alcohol is causally linked to more than 200 three-digit ICD 10 codes [20], with about 40 conditions being 100% alcohol-attributable, meaning that without alcohol these disease categories would not exist (examples: alcohol use disorders; alcoholic liver cirrhosis). More often, the causal link is via complex pathways involving different necessary factors rather than one necessary cause. As a consequence, the attributable fractions for many alcohol-attributable disease and mortality categories are relatively low (examples from the last comparative risk assessment of the World Health Organization: 5% of all breast cancer deaths and disability-adjusted life-years (DALYs); 9% of all deaths, and 10% of DALYs due to hemorrhagic stroke; 18% of all deaths and 19% of all DALYs due to self-harm; [21]. As a consequence, alcohol consumption is a unique risk factor, which, on average, causes many different categories of death and morbidity, but most of them with comparatively low alcohol-attributable fractions.

Overall, both the Global Status Report [21] and Shield and colleagues [22] estimate that about three million deaths in 2016 could have been avoided without consumption of alcohol. The majority of alcohol-attributable mortality can be found in four major categories (in the following order): injury (unintentional and intentional; [23, 24]); digestive disease (especially liver cirrhosis, [25]); cardiovascular disease [26]; and cancer [27] (for details see Table 2.2). For DALYs, alcohol use disorders play a more important role than fatal outcomes, but only 14% of all alcohol-attributable DALYs are alcohol use disorders (all numbers from [21]).

Alcohol-attributable burden of mortality and disease thus can be characterized by injury and chronic disease outcomes, and not directly by its addictive consequences. However, some of the chronic consequences, such as alcoholic liver cirrhosis, are closely linked to chronic heavy drinking and thus to alcohol use disorders [28]. Another, in part related, important characteristic is that attributable harm is not linearly related to level of drinking. Both between and within societies, the harm per litre of pure alcohol is different for people with less wealth (general: [17]; between societies: [25]; within societies: [29]). A number of different causal explanations have been given for this (for an overview: [30]; for examples of individual-level difference within societies: [31]; between societies: [25]), most importantly drinking patterns and interactions with other behavioural risk factors such as smoking or obesity, and environmental factors such as the different absolute risks for certain disease categories and the lack of social and medical support.

Table 2.2 Number of alcohol-attributable deaths by single cause of death categories with globally more than 80,000 alcohol-attributable deaths in 2016

Alcohol-related disease	Number of death	Percentage (%)
Cirrhosis of the liver	588,100	19.8
Road injury	370,800	12.5
Tuberculosis	236,300	8.0
Haemorrhagic stroke	287,000	9.7
Ischaemic heart disease	250,800	8.5
Self-harm	147,000	5.0
Alcohol use disorders	145,600	4.9
Liver cancer	101,400	3.4

Social Consequences Attributable to Alcohol Use and Harm to Others

Alcohol causes considerable social harm in addition to health harm to the drinker, and also considerable harm to others than the drinker [17]. Examples are traffic fatalities caused by drunk driving or Fetal Alcohol Spectrum Disorders caused by alcohol use of mother, or intimate partner violence or other forms of violence [17]. But also, social outcomes such as public disorders have been causally linked to alcohol use [32].

Overall, the economic costs of alcohol in different countries which conducted cost studies have been estimated to amount on average about 2.6% (95% CI 2.0–3.1%) of the Gross Domestic Product [33]. This is likely an underestimate, as several costs (e.g., public disorder, violence) have not been included (for details cost occurring to others than the drinker, see [34]). To illustrate these numbers, we would like to give four examples of recent studies, converted into international dollars of the year 2019 [33].

In Canada, the estimating economic costs of substances is part of regular monitoring. In the last report covering the years 2015–2017, for the year 2017, it was estimated that the costs of alcohol use amounted to 470 International $ per adult 15 years and older, with a proportion of almost 60% being direct costs (largest direct category was health care; [35]). The costs attributable to alcohol were higher than the costs for tobacco or illicit drugs. In France, the costs of alcohol use for the year 2010 amounted to 2440 Int$ per adult. These substantially higher costs can be explained by higher indirect costs (90% of all costs), which are mainly derived from premature deaths [36]. A Scottish study for the year 2010 found costs of 1250 Int$ per adult. Direct costs made the majority of these costs (59%), but contrary to Canada, most direct costs were derived from the legal system (criminality attributable to alcohol and associated costs such as drunk driving, illegal production, violence; [37]). Finally, in South Africa the costs for alcohol use for the year were estimated to amount to 440 Int$ per adult, which would correspond to a higher proportion of the Gross Domestic Product than the studies cited above. Again about 60% were direct costs, again mainly from the legal sector [38]. While the results of cost studies vary based on the wealth of a country, the cost categories included [33, 39], and the drinking patterns of each country, overall, the clear message is the alcohol use incurs high economic costs with are not nearly been paid off by the taxation [33, 36, 40].

On the Comparison with Opioid Use and Opioid Use Disorders

Opioid use is much less prevalent than alcohol use. Exact numbers are not available, as opioids are an illicit substance except when given within medical treatment. The United Nations Office on Drugs and Crime (UNODC) estimate in the latest World Drug Report that in 2019 1.2% of the population between the ages of 15 and 64 used opioids at least once in that year, including people who use pharmaceutical opioids

for non-medical purposes [41]; for other estimates and a discussion of the methodological difficulties, see [1, 42]. Even given the high uncertainty of the estimates, this proportion seems considerably lower than the number of people who use alcohol (which amounted to almost 50% in the same year; see above and [5]).

The category of opioid use disorders is a bit less ambiguous, although there is a tendency to underestimate such disorders in people who use only opioids as prescribed. While the medical prescription of opioids undoubtedly fuelled the first phase of the most recent opioid crisis in North America [43, 44], most of the current overdose deaths are linked to synthetic opioids sold in the streets, especially illicitly produced fentanyl [45]. The current phase is usually labelled phase 3, with a phase 2 characterized by overdoses involving heroin between the prescription and the synthetic opioids phase.

Overall, both prevalence of use, opioid use disorders and opioid overdose mortality rates have been increasing the most in North America over the past two decades [41], and opioid overdose deaths reached their highest numbers in 2021, both in the US and Canada [46, 47]. The overall numbers have been so high during this period that they strongly contributed in both the US and in Canada to a decrease in life expectancy which began even before COVID-19 pandemic [48, 49]. Globally, age-standardized rates of opioid overdose deaths also increased over the past decades up until 2019 [2](see Fig. 2.2), albeit with much less accelerated slopes compared to North America.

Overall, as indicated in Table 2.1 above, while increasing, the burden of disease attributable to opioid use is considerably smaller than the burden of disease due to alcohol use [2]. It is also much more concentrated in people with use disorders, i.e., it is more linked to the addictive properties of the substance.

Consequences for Control Policies and Prevention

The epidemiological differences specified between alcohol and opioids laid out above have clear consequences for control policies. In most countries, the most effective and cost-effective control policies for alcohol are population-based [12, 17], such as those restricting affordability and availability, as well as reducing demand for this mostly legal substance via taxation increases, restrictions on trading hours, and a ban on marketing.

For an illicit substance like opioids, control policies need to be more centred on the individual, such as an efficient treatment and harm reduction system [50]. However, for treatment and harm reduction efforts to be most effective, decriminalization of use [51, 52] is probably necessary while universal health coverage absolutely is [53]. The consequences of a change of legal status are not well researched.

As for prevention, the current efforts of educational campaigns and school-based educations seem to be of limited success in changing behaviour [17, 54, 55].

Chapter 3
Epidemiology of Alcohol-Related Liver Disease in Europe

Peter Jepsen

Abstract This chapter describes some of the fundamentals of studying the epidemiology of alcohol-related liver disease, including different measures of burden, standardization, and age-period-cohort models. It also presents some of the source populations that may be studied, e.g., the general population, people with a hazardous alcohol consumption, or people in hospital. There is also an introduction to the Global Burden of Disease studies and the HEPAHEALTH Report published by the European Association for the Study of the Liver; both sources provide—among other things—an overview of the epidemiology of alcohol-related liver disease in Europe. Finally, the chapter presents the time-trends in the burden of alcohol-related liver disease in some European countries, primarily the United Kingdom, which has experienced an increasing burden, and Denmark, which has experienced a decreasing burden.

Keywords Epidemiology · Incidence · Mortality · Burden · Methods · Age-period-cohort models

The Burden of Alcohol-Related Liver Disease

It is common to talk about the *burden* of alcohol-related liver disease, but what do we mean by that?—the burden on whom? Is it the burden on the patients? On the patients' family? On society? This chapter is about the burden of alcohol-related liver disease on society, which can be described by the number of people living with alcohol-related liver disease (the prevalence), the number of people who develop alcohol-related liver disease (the incidence rate), the number of hospital admissions for alcohol-related liver disease (the hospitalization rate) and the number of people

https://doi.org/10.1007/978-3-031-32483-3_3

who die from alcohol-related liver disease (the mortality rate). These epidemiologic measures (prevalence, incidence rate, hospitalization rate, and mortality rate) are typically described with reference to the demographics of the underlying population, e.g., the number of new patients per 100,000 population per year.

Using Standardization to Facilitate Comparisons

When we want to compare the epidemiology of alcohol-related liver disease between countries it is convenient to standardize epidemiologic measures to a specific population. Such standardization serves to facilitate comparisons between countries by giving us the incidence in country X if the population of country X had the same age distribution (or gender and age distribution) as our standard population [1]. The standard population can be any population, and one suggestion is from Eurostat which revised the European Standard Population in 2013. It is derived from the demographics of "the EU27 plus EFTA countries, on the basis of 2010-based population projections, averaged over the period 2011-30." (https://ec.europa.eu/eurostat/web/products-manuals-and-guidelines/-/ks-ra-13-028).

What Is the Source Population?

When we describe the epidemiology of alcohol-related liver disease we are limited by the data that we have access to. Ideally, *everybody* in the population is examined for presence or absence of alcohol-related liver disease, but that is hardly ever done, at least not for a population larger than a few thousand people. Consequently, the data we have comes from selected subsets of the population, e.g., those who are in hospital, those who have a hazardous alcohol consumption, those who volunteer for a research project, those who hold a particular health insurance, or those who have signs or symptoms of liver disease.

Early or Late Alcohol-Related Liver Disease

Most of our information about the epidemiology of alcohol-related liver disease stems from hospital contacts, so it is based on people with relatively late-stage alcohol-related liver disease, e.g., cirrhosis or alcoholic hepatitis. We see the tip of the iceberg. There are also populations in which we have information from general practitioners, e.g., England [2]. Patients who see their general practitioner are, on average, less sick than those who are in hospital, and we should expect a fuller picture of the epidemiology of alcohol-related liver disease from England than from countries without information from general practitioners. Even so we still do not get the full picture because alcohol-related liver disease can be completely asymptomatic.

Prevalence of ALD

The prevalence of alcohol-related liver disease is highly dependent on the source population, e.g., the general population or a higher-risk group.

The General Population

The Dionysos study examined the prevalence of liver disease in two towns in Northern Italy in 1991 and again in 2000–2001. The towns harbored 10,151 inhabitants aged 12–65 years, all of whom were eligible for the study, and 6917 people participated in both examinations. The study reported that 30% of the population aged 12–65 years were 'inappropriate drinkers', meaning that they drank more than 30 g ethanol per day or had drunk more than 100 kg in their lifetime. In addition, 2.3% of the population were 'inappropriate drinkers with liver disease', suggesting that 2.3/30 = 7.7% of inappropriate drinkers had liver disease [3]. In this study, liver disease was diagnosed based on standard liver function tests, abdominal ultrasound examination, and possibly additional imaging and/or liver biopsy [4].

With newer modalities for noninvasive screening for liver disease, such as transient elastography, it has become more feasible to conduct studies of the general population [5]. The EU-funded LiverScreen project aims to develop a targeted screening methodology to identify persons with asymptomatic liver fibrosis and cirrhosis among the general population (https://www.liverscreen.eu/).

People with Hazardous Alcohol Consumption

A 2017 review reported that the prevalence of liver disease among people with a hazardous alcohol consumption was between 11.0% and 20.5% [6], higher than the 7.7% estimate based on the Dionysos study. Of the four reviewed studies, two examined advanced liver fibrosis defined by a stiffness ≥8 kPa on transient elastography, and they reported prevalence estimates of 17% and 18.5% [7, 8]. A third study examined the prevalence of any liver fibrosis (≥5.9 kPa) and reported a prevalence of 20.5% [9]. The fourth study reported a prevalence of probable liver fibrosis of 11%, defined by the Southampton Traffic Light, a combination of hyaluronic acid, Procollagen III N-Terminal Pro-peptide, and platelets [10].

It may be noted that the prevalence estimates using a ≥8 kPa threshold to define advanced liver fibrosis (17% and 18.5%) were higher than the 7.7% estimate from the Dionysos study. Part of the explanation is that the 8 kPa threshold is low; current guidelines from the European Association for the Study of the Liver (EASL) recommend a rule-in threshold of 12 to 15 kPa for advanced liver fibrosis [5].

People in Hospital

The Scandinavian countries have nationwide healthcare registries that were developed to monitor healthcare activity and have been used extensively for research [11, 12]. These registries rely on diagnosis codes given at hospital discharge (including outpatient visits) to determine the reason for hospitalization. The validity of these diagnosis codes is a key concern, but it is generally high enough to permit epidemiologic studies of alcohol-related liver disease [12].

A Danish study reported that the prevalence of alcohol-related liver disease was 0.22% of the population [13], just one-tenth of the 2.3% estimate from the Dionsysos study. However, this low estimate inevitably underestimates the prevalence of early-stage alcohol-related liver disease because it counts only people who are in hospital. This underestimation is emphasized by the fact that 69% of patients in this Danish study had cirrhosis [13], while in the general population only a minority of people with alcohol-related liver disease have cirrhosis.

Incidence

Determining incidence is often more difficult than determining prevalence. Not only do we need to know the size of the source population that gave rise to the cases of alcohol-related liver disease, we also need to know *when* they developed liver disease. Consequently, studies determine the incidence of symptomatic, late-stage alcohol-related liver disease, i.e., using data from hospitalized patients, assuming that the first hospitalization is the time of disease incidence.

In the population of Denmark, the incidence of alcohol-related cirrhosis was 240 per million person-years in 2018 [13]. In England, 1998–2009, it was 165 per million person-years [14]. It was lower in the Scania region of Sweden, 2001–2010, around 70 per million person-years [15]. These studies all relied on registry data from in- or outpatient hospital visits and, in the case of England, general practitioners. Some studies rely blindly on those diagnosis codes [13], but ideally they are validated through review of the medical charts [16, 17].

Hospitalization

Hospitalization rates may be based on the number of hospitalizations eliciting a discharge diagnosis code of alcohol-related liver disease within the entire population or among the subset diagnosed with alcohol-related liver disease. For example, the number of hospitalizations for alcohol-related liver disease within the general population of England or Wales in 2002–2003 was approximately 200 per million person-years [18].

Alternatively, hospitalization rates may be based on the number of hospitalizations for any reason among people with alcohol-related liver disease. As an example, a Danish study counted hospital admissions for any cause among people who had previously received a hospital diagnosis of alcohol-related liver disease [13]: It was 1.12 all-cause hospitalizations per person-year in 2018 [13].

Mortality

Mortality rates are more accessible than other epidemiologic measures of the burden of alcohol-related liver disease because more countries record causes of death than, e.g., causes of hospitalization. The number of deaths from alcohol-related liver disease within the population of England or Wales was approximately 77 per million person-years in 2005 [18]. In the Veneto region of Italy, it was around 85 per million person-years in 2008–2010. Like studies based on hospitalization registries, they rely on codes whose validity is a key concern. Causes of death are more difficult to validate than causes of hospitalization because many people die in their home, and there are no charts to validate the registration against. For additional details about mortality, see also Chaps. 2 and 7 within this book.

Survival of Patients with Alcohol-Related Liver Disease

Mortality rates from alcohol-related liver disease depend on the incidence rate of alcohol-related liver disease and the survival time of people with alcohol-related liver disease. If they live longer, mortality rates can go down despite an increasing incidence. There is some evidence that patients with a hospital diagnosis of alcohol-related cirrhosis live longer now than they used to do [19].

Age-Period-Cohort Models

Studies generally find that the incidence of alcohol-related liver disease peaks around age 55 to 60 years. This age effect is remarkably constant and probably reflects ‘years of harmful alcohol consumption’ more than ‘years since birth’. If the age effect is constant across studies, why, then, has the incidence of alcohol-related liver disease increased in England, and why has it gone down in Denmark?

A decreasing incidence in Denmark after year 2010 might be attributed to effects of events that occurred at a specific calendar time—maybe taxes on alcohol doubled on, say, 1 January 2010 (which in fact they did not). That would constitute a calendar time effect, also called a period effect. A decrease after 2010 might also be attributed to effects of events that affected a birth cohort—maybe the baby boomer generation grew up with a societal norm that it is desirable to have wine for dinner, or that drunk driving is acceptable. And maybe subsequent generations rebelled

against those norms and thought exactly the opposite, resulting in a lower incidence after 2010, when the baby boomer generation has aged past 55–60 years. These examples would constitute birth cohort effects.

Many real-life interventions involve multiple time axes (age, period, and cohort). For example, a law may be passed on 1 January 2020 saying that people born after 1 January 2000 cannot buy alcohol before age 25 years, where currently the age limit is 20 years. This would mean that people born in 1999 could still buy alcohol in 2020, whilst people born in 2000 could not buy alcohol before 2025, and people born in 2001 could not buy alcohol before 2026.

Age-period-cohort models are statistical models that can help investigators disentangle the effects of age, calendar year, and birth cohort on the incidence, prevalence, or mortality of alcohol-related liver disease. The difficulty with the class of models is that age, period, and birth cohort are interdependent in that you can compute one of them if you know the values of the other two (e.g., age + cohort = period). We cannot vary one of them and hold the other two constant, which is what we would usually do [20]. There are different types of age-period-cohort models with different assumptions about the effects of age, period, or cohort [21–23]. A further possibility with age-period-cohort models is that they can be used to predict the future epidemiology of alcohol-related liver disease [22].

Example

A 2017 study by Trias-Llimós and others used age-period-cohort models to examine time-trends in cirrhosis-specific mortality during the 1950–2011 period in eight European countries chosen for their different alcohol consumption levels, patterns, and trends: Austria, Finland, Hungary, Italy, the Netherlands, Poland, Spain and Sweden [24]. The investigators noted that cirrhosis-specific mortality mainly reflects mortality from alcohol-related cirrhosis. The cirrhosis-specific mortality rate was decreasing in all countries except Poland, and most of the countries had experienced the peak cirrhosis mortality in the 1970s (Austria, Italy, Netherlands, Spain, and Sweden) while Hungary reached its peak in the 1990s and Finland shortly before 2010.

The investigators used the age-period-cohort model to infer likely explanations to time-trends. In Italy, for example, the mortality rates over the 1950–2011 period were parallel for all age groups, and such a pattern suggests that period effects are important: Whatever happens, happens to everybody at the same calendar time. By contrast, in the Netherlands and Poland, women in different age groups had nonparallel mortality rates during the 1950–2011 period, and such a pattern suggests that cohort effects predominate [24]. For example, hypothetically, there might be a spike in mortality at age 50 in 1990, but no simultaneous increase in other age groups. Then, in 1995, there might be a spike in mortality at age 55, exclusively. Such a pattern could be explained by a higher alcohol consumption among those who were born in 1940, i.e., a cohort effect.

Next, the investigators examined the effects of age. Mortality peaked at age 60–75 years in all countries except Italy, and cirrhosis mortality peaked at a slightly older age for women than for men. The effect of age on mortality was stronger for women than for men [24].

Finally, the analysis of birth cohorts showed that mortality peaked in Sweden, Finland, and Austria with the 1940–1950 birth cohorts. In Hungary, the Netherlands, and Spain the peak was reached around the 1960 birth cohort, as in Denmark [13], and in Poland it was reached around the 1970 birth cohort. In Italy, meanwhile, the pattern was very different for men and women: For women, cirrhosis mortality peaked with the 1925 birth cohort, while for men it peaked with the 1965 birth cohort [24].

The Global Burden of Disease studies

The Global Burden of Disease concept was introduced by the World Health Organization in 1996 using data from 1990 with projections to 2020. The data have been updated several times, most recently in 2019 [25] and in 2017 before that [26]. The Global Burden of Disease studies produce a comprehensive assessment of mortality and disability for more than a hundred diseases and injuries, and its key metric is the DALY (Disability-Adjusted Life-Year) which encompasses both mortality and morbidity—it is the sum of years of life lost (mortality) and the years lived with disability (morbidity) [27]. The morbidity is a product of a condition's prevalence and its disability weight, but the disability weight for cirrhosis is so small that the DALY almost exclusively reflects mortality whilst morbidity is negligible [28, 29]. The Global Burden of Disease studies remain important for their analyses of prevalence and of mortality attributable to cirrhosis. A related strong point of the Global Burden of Disease studies is that access to data is simple (https://vizhub.healthdata.org/gbd-results/) and includes a tool to produce visualizations (https://vizhub.healthdata.org/gbd-compare/).

The Global Burden of Disease studies collect data from countries' cause-of-death and other healthcare registries, relying on verbal autopsies (interviews with family members or caretakers) of samples of decedents when nationwide registries of causes of death are unavailable [29, 30]. Modeling is used to fill in the gaps in the dataset.

Alcohol-related liver disease is defined as the alcohol-attributable portion of the following ICD-10 codes for liver disease: B18.x, I85.x, I98.2, K70.x, K71.3–K71.51, K71.7, K72.1–K74.69, K74.9, K75.8–K76.0, K76.6–K76.7, K76.9 [26, 31]. Based on the most recent data from the Global Burden of Disease, the highest age-standardized mortality rates from alcohol-related liver disease in Europe in 2019 were in the Republic of Moldova (23 per 100,000 person-years), Romania (15 per 100,000 person-years), and Ukraine (13 per 100,000 person-years), while the lowest were in Iceland (1.5 per 100,000 person-years), Norway (1.7 per 100,000 person-years), and Italy (1.9 per 100,000 person-years) (Fig. 3.1).

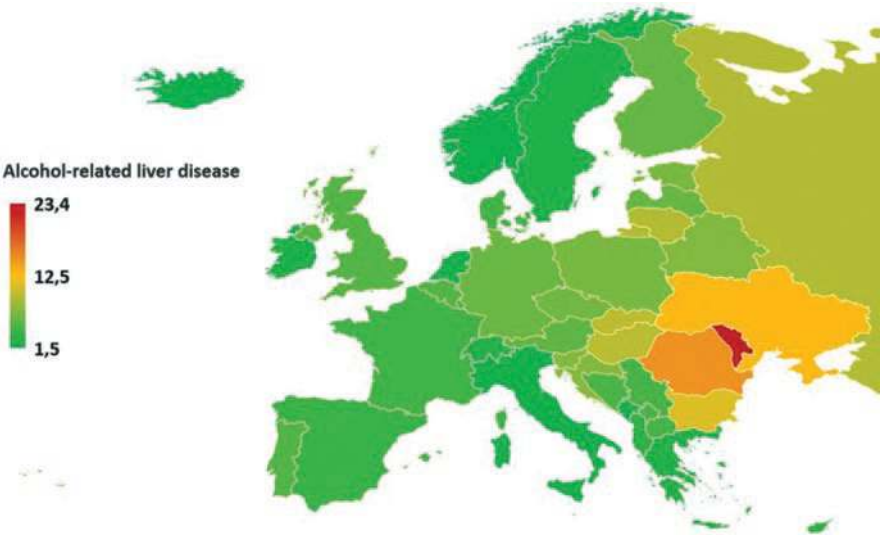

Fig. 3.1 Age-standardized mortality from alcohol-related liver disease in 2019, per 100,000 population

The mortality rate from alcohol-related liver disease in the United Kingdom in 2019 was 5.2 per 100,000 person-years (rank 19), in Denmark it was 4.5 per 100,000 person-years (rank 26), in Italy it was 1.9 per 100,000 person-years (rank 40), in Finland it was 6.0 per 100,000 person-years (rank 17), in Germany it was 6.1 per 100,000 person-years (rank 15), and in Belgium it was 5.1 per 100,000 person-years (rank 20).

Because of the strong association between alcohol use disorder and alcohol-related liver disease one would expect that the geographical patterns were the same for alcohol use disorder and alcohol-related liver disease [31]. That is not the case: Belarus ranks highest (21 per 100,000 person-years) followed by Russia (15 per 100,000 person-years), while Greece (0.3 per 100,000 person-years) and Italy (0.3 per 100,000 person-years) rank lowest (Fig. 3.2).

Belarus and other Eastern European countries have a very high ratio of deaths from alcohol use disorder to deaths from alcohol-related liver disease, suggesting that alcohol-related liver disease might be under-diagnosed or under-recorded in cause-of-death registries. Specifically, in Belarus, the ratio is 3.0, i.e., three times as many people die from alcohol use disorder than from alcohol-related liver disease, and Belarus ranks first when it comes to deaths from alcohol use disorder but tenth when it comes to alcohol-related liver disease. In the Republic of Moldova, it is the other way round; the ratio of is 0.36, i.e., three times as many people die from alcohol-related liver disease than from alcohol use disorder, and the country ranks first when it comes to deaths from alcohol-related liver disease but seventh when it comes to deaths from alcohol use disorder. These apparent inconsistencies may of course reflect the actual causes of death, and they are also seen in countries that take

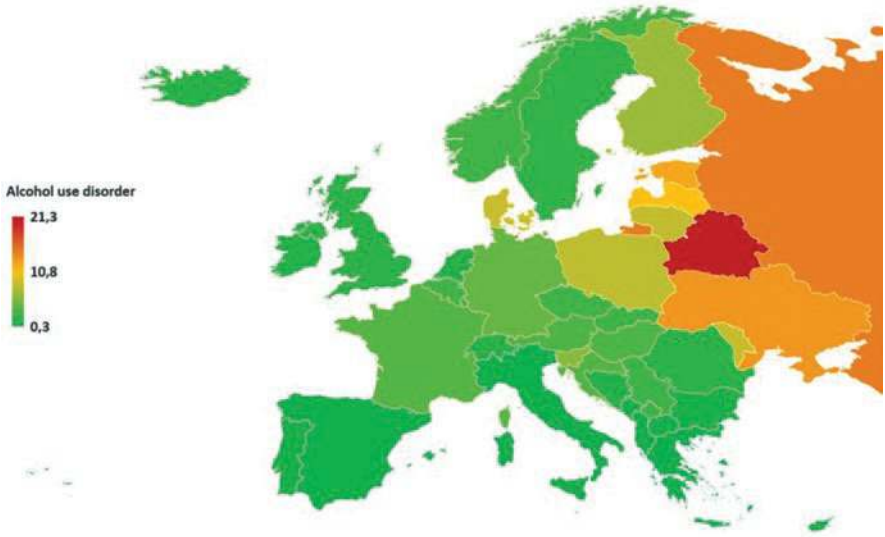

Fig. 3.2 Age-standardized mortality from alcohol use disorder in 2019, per 100,000 population

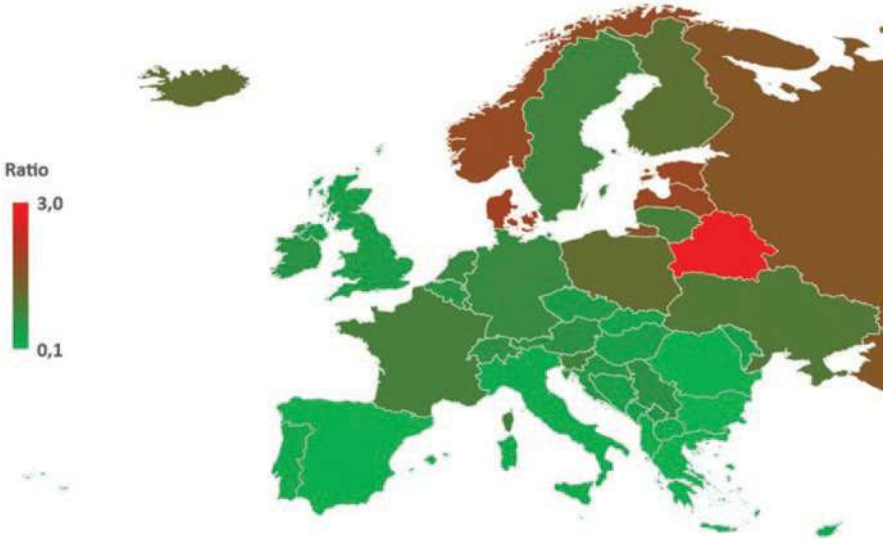

Fig. 3.3 Ratio of deaths from alcohol use disorder to deaths from alcohol-related liver disease. Countries with a high ratio may underestimate the prevalence of alcohol-related liver disease

pride in the quality of their healthcare registries. For example, Denmark ranks sixth when it comes to alcohol use disorder, but 26th when it comes to alcohol-related liver disease (Fig. 3.3).

The HEPAHEALTH Report

In 2018, EASL published its HEPAHEALTH report which described the time-trends in the mortality from liver disease in the EU region and a few additional countries [32, 33]. Mortality data were extracted from the World Health Organization's WHO European Detailed Mortality Database (https://gateway.euro.who.int/en/datasets/european-mortality-database/) combined with data on prevalence extracted from the Global Burden of Disease studies, findings from review articles, and interviews with experts.

The 34 countries under study were divided in four categories on the basis of time-trends in mortality from liver cirrhosis (of any etiology), 1970–2016. The two countries with a stable high mortality were Slovakia and Uzbekistan. The nine countries with an increasing trend were mostly in Eastern Europe, with the United Kingdom as the exception: Bulgaria, Estonia, Finland, Hungary, Kazakhstan, Latvia, Lithuania, Romania, and the United Kingdom. The 12 countries with a stable low mortality from cirrhosis were mainly in Northern Europe: Belgium, Cyprus, Czech Republic, Denmark, Iceland, Ireland, Malta, the Netherlands, Norway, Poland, Serbia, and Sweden. The remaining 11 countries were mostly in Southern or Western Europe and had a decreasing trend: Austria, Croatia, France, Germany, Greece, Italy, Luxembourg, Portugal, Slovenia, Spain, and Switzerland (Fig. 3.4).

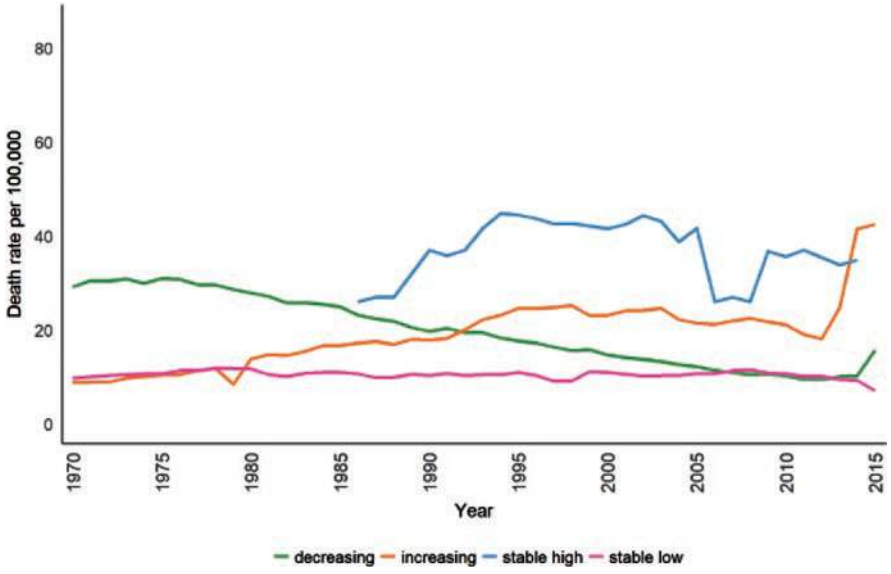

Fig. 3.4 Population-weighted average mortality rate for cirrhosis and other chronic liver diseases for countries in four trends groups (decreasing, increasing, stable low, stable high). The up-turn between the years 2012–2014 for some of the average trends are caused by only a limited number of countries providing data up to 2014/2015. For this reason, the very recent trends should not be considered, as they may be skewed by data from only one or two countries in each group

Alcohol-Related Liver Disease

The HEPAHEALTH Report also described trends by cause of liver disease, including alcohol-related liver disease. It has repeatedly been demonstrated that per capita alcohol consumption correlates with mortality from alcohol-related liver disease, and the time-trends in alcohol consumption follow the four-group pattern shown above for cirrhosis-related mortality: Countries with an increasing alcohol consumption also experienced an increase in cirrhosis-related mortality, and those with a decreasing alcohol consumption experienced a decrease in cirrhosis-related mortality [32]. The HEPAHEALTH Report noted that the Czech Republic had seen an increase in mortality from alcohol-related liver disease despite a stable alcohol consumption [32]. A similar pattern was seen in Sweden, but here the increase in mortality from alcohol-related liver disease may be attributed to a change in the type of alcohol consumed: In Sweden, wine has taken over from beer and spirits as the type of alcohol that is consumed the most [32].

Time-Trends in Selected European Countries

United Kingdom

The United Kingdom has seen a sharp increase in the burden of alcohol-related liver disease correlated with an increase in total alcohol consumption coinciding with a shift in alcohol consumption towards wine and cider rather than beer [14, 32, 34]. In 2014, The Lancet Standing Commission on Liver Disease in the UK was established in response to findings that mortality from liver diseases had increased fivefold whilst mortality from other major chronic diseases had decreased, and mortality from liver diseases had decreased in most other European countries [34]. The Commission pointed to some challenges, which are not specific to the United Kingdom:

- Patients present late, often not until they have developed cirrhosis complications, such as ascites [35]. This is unlike patients with cirrhosis from other causes [16]. Screening for alcohol-related liver disease is a promising response to this challenge.
- Complications of cirrhosis are not managed properly, resulting in high and variable mortality from complications across the United Kingdom. This problem is compounded by the stigma associated with alcohol dependence; alcohol-related liver disease is seen as self-inflicted, and treatment in an intensive care unit is often seen as futile [36].
- Treatment of alcohol dependence is not a priority in hospitals.

The Lancet Standing Commission on Liver Disease in the UK gave recommendations to combat the increasing mortality from liver disease, including interventions targeting alcohol consumption and interventions to engage primary care in earlier

diagnosis of liver disease. In 2020 the Commission's final report was published, lamenting the missed opportunities to reduce mortality from liver disease. Instead, the Commission described a continued increase in the burden of alcohol-related liver disease including an increase in the levels of hospital admissions in deprived areas [37]. To make matters worse, the COVID pandemic led to an increase in alcohol consumption in the United Kingdom [38], and Public Health England issued a press report describing a 21% increase in deaths from alcohol-related liver disease in 2021 (https://www.gov.uk/government/news/alcoholic-liver-deaths-increased-by-21-during-year-of-the-pandemic).

Denmark

In recent decades, Denmark has had a relatively high per capita alcohol consumption and mortality from alcohol-related liver disease [32]. Unlike the United Kingdom, however, Denmark has seen a decreasing burden of alcohol-related liver disease. Mortality among those who have been diagnosed with alcohol-related liver cirrhosis has gone down [19], which might have resulted in an increasing prevalence of alcohol-related liver cirrhosis because patients live longer. In reality, though, the prevalence has been stable because the incidence of alcohol-related liver disease has gone down, particularly in the younger population, i.e., ages 40–49 years and among women aged 50–59 years [13]. By contrast, the incidence has risen slightly in women aged 70 years or older. These patterns indicate a cohort effect, with lower incidence in people born after 1960.

Another contributor to the stable prevalence is the fact that patients continue to come to hospital very late, i.e., there is no screening of at-risk patients, and 69% of patients have developed cirrhosis when they receive their first hospital diagnosis of alcohol-related liver disease [13]. If screening is implemented we will likely see an increase in incidence followed by an increase in prevalence, because the screen-diagnosed patients will have a relatively long survival time because of their diagnosis in an asymptomatic, early stage of alcohol-related liver disease.

The management of Danish patients with alcohol-related liver disease has changed from primarily inpatient to primarily outpatient. Specifically, between 1994 and 2018, the number of all-cause inpatient admissions per person-year of follow-up has decreased from 2.05 to 1.12 and the number of inpatient bed days per year has fallen with it from 17.3 to 7.1. Also, the number of all-cause emergency room visits per person-year of follow-up fell from 2.59 to 0.82. Meanwhile, the number of ALD-related outpatient visits rose slightly from 0.8 to 1.3 per person-year of follow-up, and more than 50% of patients are now first seen as outpatients. This proportion was only 25% in 1994 [13]. These numbers indicate that Denmark has succeeded in transitioning from in- to outpatient care, and this is not because of screening for alcohol-related liver disease and resulting earlier diagnosis: The incidence of alcohol-related liver disease is going down, and the proportion of patients with cirrhosis is stable [13].

Alcohol Consumption in Danish Youth

Despite the decreasing incidence of alcohol-related liver disease in Denmark, there is concern over the Danish youth: Danish 15-year-olds have the highest-in-Europe prevalence of having been drunk at least twice; it is 47% for boys and 37% for girls. By comparison, the European averages are 22% and 18%, respectively, and the proportions in neighboring Sweden are 12% and 10%. The stated proportions are from the latest survey in 2018, and Denmark also held top place in the previous one from 2014 [39]. On the other hand, the Danish National Health Survey has reported a steady decline in the prevalence of high-risk drinking among survey participants aged 16–24 years from 2010 to 2013 and then again to 2017. A similar decline has occurred in older age groups [13]. It remains to be seen whether the incidence of alcohol-related liver disease will rise in the future in Denmark. The available data are consistent with a continued decline, but additional policy initiatives or norm changes might lead to further reductions in incidence.

Italy

EASL's HEPAHEALTH Report included a presentation of time-trends in Italy, an exemplar of a country with a decreasing trend in mortality from liver disease [32]. Age-standardized mortality from liver disease has dropped from 20 per 100,000 population in 1970 to 4.5 per 100,000 population in 2012. That rate is much higher for men than for women (5.7 vs. 3.4 per 100,000 population). Liver cancer is the dominant cause of death among those who die from liver disease, followed by viral hepatitis.

Mortality from alcohol-related liver disease decreased between 2003 and 2012, primarily because it decreased among 55–74-year-olds. The decline was greatest in the 2010–2012 period, coinciding with political initiatives to curb alcohol consumption with restrictions on availability and increased prices, and preceded by initiatives to engage primary care in efforts to offer primary and secondary prevention of harmful alcohol consumption [32].

The age-period-cohort study described above indicated that mortality from cirrhosis has peaked with the Italian 1965 birth cohort [24]. It is possible, therefore, that it may peak when these patients reach the peak age of cirrhosis-related mortality, which would be sometime after 2020.

Finland

Finland, too, was showcased in the HEPAHEALTH Report, as an exemplar of a country with a increasing mortality from cirrhosis [32]. Of particular concern is the high mortality among people of working age resulting in many working-life-years

lost to cirrhosis. Specifically, 45% of life-years lost to liver disease are working-life-years. Alcohol is the dominant cause of liver disease in Finland, and mortality from alcohol-related liver disease doubled from 10.3 per 100,000 population in 1996 to 19.8 per 100,000 population in 2014. The increase was particularly pronounced in 2005–2007, a likely result of Finland's lifting of restrictions on travelers' alcohol imports. This meant that alcohol was being bought in other countries where it was cheaper, Estonia in particular, and then brought back to Finland. Mortality from alcohol-related liver disease peaked in 2009, based on data through 2014 [32], as also reported in the age-period-cohort study described above [24].

Germany

In Germany, the number of admissions eliciting a diagnosis of alcohol-related cirrhosis was stable between 2005 and 2018 and constituted an average of 52% of all admissions related to cirrhosis, followed by admissions related to cirrhosis from hepatitis C (5%). The contribution from alcohol-related cirrhosis has increased in response to the introduction of treatment of hepatitis C with direct-acting antivirals, because these patients are now rarely hospitalized [40].

Belgium

A study from Belgium compared the characteristics of outpatients with cirrhosis diagnosed in two different time periods, 1995–1999 (N = 197) and 2010–2014 (N = 237) [41]. Alcohol-related cirrhosis constituted two-thirds of all patients with cirrhosis in both periods, and more than two-thirds of patients were men, but patients diagnosed in the later period were older: mean age 57 vs. 52 years. This change is consistent with the birth cohort effect seen in the neighboring Netherlands and in Denmark [24].

Chapter 4
Epidemiology of Alcohol-Related Liver Disease in Romania

Camelia Foncea and Roxana Sirli

Abstract Alcohol related liver disease (ALD) is becoming the main cause of liver disease in Europe and worldwide. ALD is a consequence of Alcohol use-disorder (AUD), an entity quite difficult to define in terms of amount and time of drinking needed for the liver pathology to occur. Understanding the epidemiology and changing behaviors in ALD is very important for screening and prevention, since until not long-ago ALD was not even considered a disease and, from a rarely recognized condition, it is becoming a leader indication for liver transplant. This chapter aims to analyze and describe the prevalence of alcohol consumption and ALD in Romania, a country with relatively high per capita consumption where statistical data about these conditions are scarce.

Keywords Alcohol-related disease · Alcohol-related mortality · Alcohol consumption · Romania · Alcohol-related liver disease

Introduction

Harmful alcohol consumption leads to over 200 diseases and approximately 3.3 million deaths every year [1, 2], of which alcohol-related liver disease (ALD) is the most frequent. In Europe, 41% of the liver deaths are attributed to alcohol [1]. There is a correlation between alcohol consumption and prevalence of ALD in each country. In Europe, mean alcohol consumption is with 10.9 L pure alcohol per year, quite high as compared to worldwide consumption of 6.2 L/year. The average intake of pure alcohol in Europe is >25 g/day among adults, with a high prevalence of heavy drinkers (more than 60 g of pure alcohol on more than one occasion during the past 30 days) of 30.4% [3, 4]. Regarding the trend of alcohol consumption in Europe, in

rich countries (such as the Central European ones) a slight decrease was observed during the last years, while an increasing trend was observed in the Eastern and the South-eastern parts of the WHO European Region [2–4]. More details are provided in Chaps. 2 and 3.

Definition of Alcohol Consumption

Quantification of alcohol consumption is still a challenge in clinical practice. Since it is difficult to obtain data about the precise alcohol intake in grams of pure alcohol/day, it is recommended to better record standard unit (SU) drinks/day. Unfortunately, definition of a SU varies, e.g., between Europe vs. USA from 8–16 g. In the Dietary US guidelines, one standard drink is defined as a beverage containing 14 g of pure alcohol [5]. In Romania, as in many other European countries, a standard drink is defined as a beverage containing 10 g of pure alcohol [1]. In ALD, the relationship between the intensity of alcohol consumption and liver disease severity is exponential, additional risk factors being obesity and viral hepatitis. In patients with a body mass index higher than 35 kg/m^2, the hepatotoxicity of alcohol doubles, while in patients with hepatitis C virus infection, a consumption of more than 20 g of pure alcohol per day doubles the risk for mortality [6, 7].

The European Association for the Study of the Liver (EASL) recommends that the daily alcohol intake should be limited to less than two standard drinks for women and less than three for men, as these amounts are not associated with a significant increase in cirrhosis mortality [1]. Harmful use of alcohol is defined as causing damage to the health, heavy episode drinking means consumption of more than 60 g of pure alcohol on more than one occasion during the past 30 days, while binge drinking is defined as the consumption of four or more standard drinks for women and five or more d standard rinks for men, within about 2 h [8].

Epidemiology of Alcohol Consumption in Romania

Based on European data recorded by the World Health Organization (WHO) [9], the average consumption of pure alcohol was 11.7 L/capita (individuals older than 15) in 2018 in Romania. Data are also shown in Fig. 4.1. This corresponds to a slight decrease as compared to 2016, when the average alcohol consumption was 12.6 L/capita of pure [10]. When we analyzed data from WHO [3] we could observe that Romania presented a decreasing trend from 2000 when the annual pure alcohol consumption per capita was 17.5 L, to 12.6 L/capita in 2016, reaching 11.7 L/capita in 2018.

Mortality from chronic liver disease is well documented in Europe, with the highest rates being reported for Eastern and North-eastern countries, Romania being placed on the third place. In a study from 2016, ALD was by far the most common cause for death among the alcohol-related diseases and cancers [10].

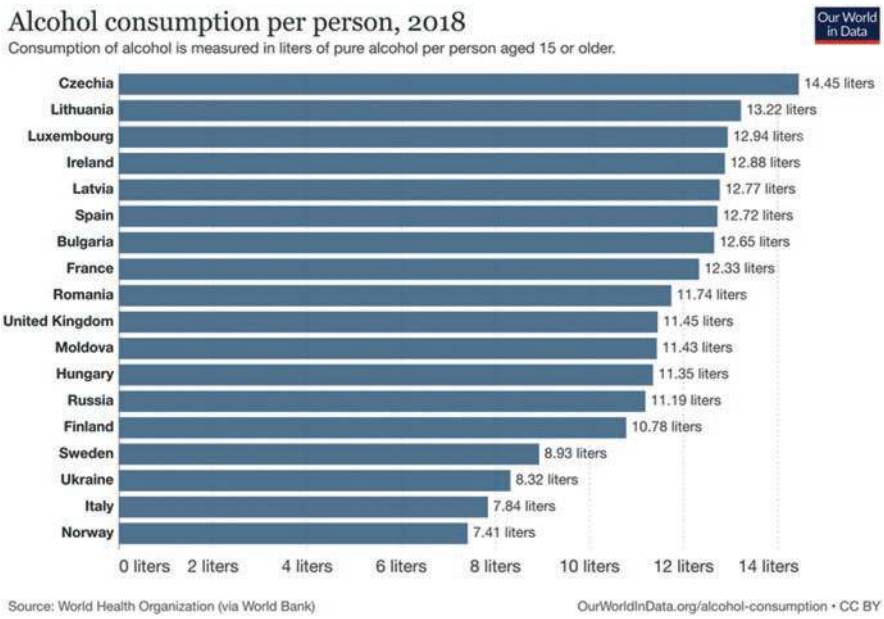

Fig. 4.1 Alcohol consumption per person in Europe 2018. Data from WHO [9]

In 2016, a global burden disease project collected data on liver disease prevalence [11]. Liver disease has been divided into chronic liver disease, cirrhosis, and liver cancer, each subdivided according to etiology: alcohol use, hepatitis B infection, hepatitis C infection and other causes. Accordingly, alcohol is the predominant cause of liver cirrhosis in most countries, especially in Eastern Europe, with a high prevalence of viral hepatitis B and C in Central and Eastern Europe. Of note, Romania also has the highest prevalence of chronic liver diseases in Europe, ALD being the most frequent etiology. The importance of ALD may be even underestimated since alcohol consumption may also contribute to other etiologies, but it is hardly recorded.

Data from the Romanian National Institute of Statistics regarding the alcohol consumption between 2000–2010 shows a decreasing trend followed by an increasing trend during 2010–2018 (Fig. 4.2) [2, 3, 12–14].

An important point of concern is alcohol consumption amongst young people. In Romania, a study evaluated 142 participants, aged between 18 and 35 years, who were questioned by AUDIT test [15]. 123 of them (86.6%) admitted an alcohol intake, while only 19 subjects (13.4%) could be considered as non-drinkers. Alcohol consumption was associated with male gender and smoking. Binge drinking was most frequent among the subjects who were considered drinkers according to the AUDIT test. The study concluded that, in Romania, alcohol consumption among young people reaches a high incidence and has reached worrying levels in comparison to other countries.

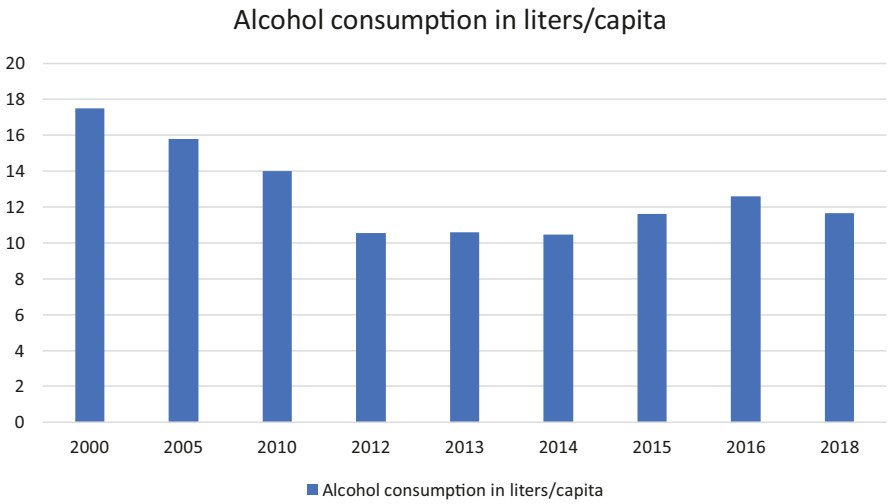

Fig. 4.2 Average per capita consumption (in liters of pure alcohol). Figure made after available data from Romanian National Institute of Statistics and WHO [2, 3, 12–14]

WHO data about alcohol consumption in young people [4] show that, in Romania, the total alcohol per capita consumption in the group age 15–19 years was 10.3 and 17.5 L in the age group 20–24 years among males, while in women it was 3.4 L in the age group 15–19 years and 5.7 in the age group 20–24 years. The prevalence of heavy drinking episodes in the age group 15–19 years was 15.5% in women and 50.7% in males, while in the age group 20–24 years, it was 24.1% for women and 62% for males.

Alcohol-Related Liver Disease in Romania

ALD is a spectrum of diseases ranging from liver steatosis to cirrhosis. Approximately 20–25% of patients who drink heavily will develop cirrhosis over a time period of 15–20 years. Chronic alcohol use of 20 to 50 g/day for women and 60 to 80 g/day for men has been shown to increase the risk for alcoholic cirrhosis [16].

Despite the high consumption levels in Romania, placing it among the European top list of AUD, no national data or registry on ALD are yet available. According to WHO, in Romania there are 6366 alcohol-attributable deaths per year due to alcohol-related liver cirrhosis for both sexes, more than due to road injuries (802/year) and cancer (4676/year) (Table 4.1) [4]. A set of indicators measuring the alcohol-attributable fraction (AAF) deaths were calculated, resulting in the proportion of deaths caused by alcohol.

A recent Romanian study analyzed the relationship between reduction of alcohol consumption by fiscal means and and its harmful effects on health. In this study

Table 4.1 Age-standardized death rates (ASDR) and alcohol-attributable fractions (AAF) in Romania in 2016

	ASDR[a]		AAF%		AAD[b] (as number)
Liver cirrhosis (males/females)	51.8	22.9	78.9	62.1	6366
Road traffic injuries (males/females)	15.7	4.2	46.9	35.9	802
Cancer (male/female)	269.1	140.2	11.8	4.8	4676

ASDR age-standardized death rates, *AAF* alcohol-attributable fractions. Data 2016 WHO
[a]Per 100,000 population (15+)
[b]Alcohol-attributable deaths, both sexes

alcohol was responsible for the top three causes of death in Romania [17]. Alcohol consumption as cause of death was divided into alcohol-related use disorder (AUD), alcohol-related cardiomyopathy, liver cancer and liver cirrhosis. During 2014–2017, the deaths caused by AUD increased in both men and women [17, 18]. Regarding the mortality by alcohol-related cardiomyopathy, an increase was observed in men, from 4/100,000 inhabitants to 8/100,000 inhabitants. In contrast, a small reduction was observed in women, from 1/100,000 inhabitants to 0.5/100,000 inhabitants. The number of deaths attributable to liver cancer due to alcohol consumption remained constant during the 4 years of observation, in both women and men (1.5/100,000 inhabitants). An increasing trend was seen among men regarding the number of cases with liver cirrhosis or chronic liver disease associated to alcohol, from 17/100,000 inhabitants in 2014 to 18/100,000 inhabitants in 2017, and a slight decrease for women (from 8/100,000 inhabitants in 2014 to 4/100,000 inhabitants in 2017) [17, 18].

As already mentioned above, statistics on the epidemiology of ALD are still limited in Romania. Despite this situation, we will present data from published studies regarding various aspects of chronic liver diseases, from which we extracted data related to alcohol abuse as cause of chronic liver disease.

A prospective multicentre study published more than 20 years ago that included 2022 patients and covered all regions of Romania, aimed at establishing the etiological profile of chronic hepatitis and liver cirrhosis in Romania [19]. The main etiological factor of chronic hepatitis was represented by infection with hepatitis viruses (90.8%). Regarding the etiological profile in liver cirrhosis, chronic infection with hepatitis viruses was responsible for 48.3% cases, ALD for 19.5% of cases, mixed etiology (viral and alcoholic) for 16.2% of cases, and unknown etiology in 11.2% cases.

In a previous study from our center evaluating the feasibility of transient elastography in a cohort of 3235 patients with chronic liver disease (CLD) from the Western part of Romania, ALD represented 7.4% of all patients [20]. However, these data may not reflect realistic ALD distribution in Romania, since alcohol could have contributed to patients with cryptogenic CLD (2.7%) and patients with mixed etiology of CLD (16.6%). Moreover, patients had been previously screened for viral hepatitis within a governmental program and were referred specifically for fibrosis assessment.

Table 4.2 Prevalence of ALD in different studies performed in Romania

Studies	Patients included	ALD prevalence (%)
Grigorescu et al. [19]	2022	19.5
Sporea et al. [20]	3235	7.4
Sporea et al. [21]	697	26.4
Barbulescu et al. [23]	839	24.1
Popoiag et al. [24]	261	52.8
Chiriac et al. [25]	446	78.8
Taru et al. [26]	231	46.3
Iacob et al. [27]	257	21
Popescu et al. [28]	815	8.6
Moga et al. [22]	499	41

In another study with the focus on elastography in predicting portal hypertension in a group of 697 cirrhotic patients, 26.4% of were related to alcohol [21].

Unpublished data from our research center in hepatology, on a period of 3 years (2018–2020) studied 499 admissions of patients with liver cirrhosis of different etiologies as compared to patients with liver cirrhosis and Covid-19 infection, in order to assess acute on chronic liver failure and especially acute decompensation. 346 patients were identified, some of them with repeated presentations, out of which the main etiologies of cirrhosis were: in 41% pure alcoholic etiology, in 32% HCV chronic infection, in 10% HBV chronic infection, in 5% mixed HBV/HCV and alcoholic etiology [22].

Data regarding the epidemiology of ALD in Romania are scarce and we present them in Table 4.2. Among cirrhotic patients, in Romania alcohol as cause of liver disease ranges between 7.4% and 78.7%, depending on the area, and on the cohorts included [20, 25]. The prevalence of ALD seems to increase in cohorts with more severe liver disease. A low prevalence of alcohol-related cirrhosis was found in a liver transplant study from Romania [28]. This raises the question about access to transplantation of patients with AUD, and underlines the need to establish a professional healthcare structure able to provide equal professional support to all patients with liver disease including those with AUD, including standardized abstinence rules and access to addiction treatment centers and social support.

Conclusions

In conclusion, data from the WHO and from the Romanian National Institute of Statistics, clearly point out that alcohol consumption in Romania is one of the highest in Europe, making it a serious risk factor for public health. AUD is one of top three causes of death, especially due liver disease involvement.

Chapter 5
Epidemiology of Alcohol-Related Liver Disease in China

Yishu Chen, Chengfu Xu, Shijing Wang, Jiangao Fan, and Youming Li

Abstract A steady increase in alcohol production, availability and consumption in China has been noted over recent decades, which has led to rising health burdens. In this chapter, we review a multitude of epidemiological studies, both regionally and nationwide, on alcohol consumption, alcohol use disorder and alcohol-related liver disease (ALD) in China. We also collated risk factors that have been reported as relevant to ALD occurrence and development. This updated knowledge serves as a supplement to the global understanding of alcohol and health, and as a reference for the development of health response in China.

Keywords Alcohol consumption · Alcohol use disorder · Alcohol-related liver disease · Risk factor · Disease burden · Chinese population · China

Introduction

Alcohol drinking traditionally plays an important role in Chinese culture. Alcohol serves as a key component of diet and medicine and is a symbol for hospitality and festive events in China. Drinking is thought to be able to lift the spirits at celebrations and ceremonies, and social drinking is encouraged as a means to build good

business relations [1]. Over recent decades, there has been evidence of a striking increase in alcohol consumption and related problems in China. Here we provide a brief review on the extent of alcohol use and alcohol-related liver disease (ALD) in China.

Alcohol Consumption in China

Commensurate with the thriving economy and the parallel rise in personal income, alcohol production and consumption in China have undergone a notable growth. China has a vast territory with the largest population in the world. People living in different regions share distinctive lifestyles with a diversity of drinking cultures and traditions. Currently, information about the extent of alcohol use in China remains inconsistent and dispersive.

Li et al. reported in 2003 that the proportion of regular drinkers was about 27.0% in Zhejiang Province, southeast China [2]. Between 2000 and 2016, the surveyed percentage of regular alcohol drinkers among the general adults in most regional studies ranged between 27.0% and 37.8% [3–8]. In 2014, Wang et al. reported that 42.76% of the surveyed population in Shandong Province (northeast China) had a history of excessive alcohol consumption [9]. Yan et al. investigated in 2015 that the drinking rate of the adult population in Heilongjiang, China's far-north province, was 47.58%, higher than that of most other regions during the same period [10]. In 2015, Yan et al. reported a total drinking rate as high as 66.2% in China's northwestern provincial-level administrative regions (Shaanxi, Gansu and Xinjiang) [11]. The huge discrepancy between these results suggests that apart from the confounding effects of different sampling methods and diagnostic criteria, there may be substantial differences in drinking habits across regions in China.

In the past decade, several studies have attempted to investigate on a national scale. Li et al. selected a representative sample of residents aged 15–69 years from the 2007 China Chronic Disease and Risk Factor Surveillance (CCDRFS), a continuous survey covering rural and urban districts scattered over 31 provincial-level administrative regions in China, and included 49,527 residents, of which the total current drinking rate was 35.7% (55.6% in men and 15.0% in women) [12]. Between 2010 and 2012, the Chinese Nutrition and Health Surveillance Program conducted a multi-stage cluster random sampling survey on 150 surveillance sites across China. Fang et al. included a total of 60,791 males aged 20–79 years from the program and identified the prevalence of alcohol drinking as 57.8% [13]. Another study which included 15,942 participants (7384 men and 8558 women) with the age range of 45–101 years from the 2011 baseline survey of the China Health and Retirement Longitudinal Study reported that approximately 36.42% of men and 3.73% of women had consumed alcohol in the previous 12 months [1]. The proportion of current drinkers was significantly higher in men than in women in this study. Consistently, a recent study based on the prospective China Kadoorie Biobank (CKB), which recruited 512,715 adults aged 35–74 years from 10 areas across

China from 2004 to 2008 and followed up for about 10 years until 2017, found that 33% of men enrolled at baseline drank alcohol regularly, mainly spirits, compared with only 2% of women [14].

Harmful drinking patterns such as alcohol dependence and abuse have also drawn attention from the public. Alcohol use disorder (AUD) has become a frequent problem linked to disturbances in mental and physical health and social functioning in China. In 2010, AUD was reported to be the ninth leading cause of disability, and the second most important mental disorder after depression in China [15]. The Global Burden of Disease (GBD) 2010 revealed that alcohol abuse was ranked as the sixth greatest risk factor for men in China in terms of attributable disability-adjusted life-years (DALYs) lost, contributing to more than 310,000 deaths among men each year. A recent study based on data extracted from the GBD 2019 reported that the disease burden of AUD in China was increasing from 2005 to 2019 [16].

Disease Burden of ALD in China

Long term excessive alcohol drinking is a leading cause of chronic liver disease and induces a wide range of liver pathologies from simple hepatic steatosis to steato-hepatitis, fibrosis, cirrhosis, and even hepatocellular carcinoma (HCC). At the moment, there remains a lack of nationwide epidemiological surveys of ALD in China, though some studies are relatively large-scale (Table 5.1).

In 2000, Li et al. performed an epidemiological study in Zhejiang Province and reported that the prevalence of ALD was 4.34% [2]. For the 2000–2010 period, the

Table 5.1 Population-based surveys of alcohol-related liver disease in China

Author	Year	Province (area)	Sample size	ALD prevalence (%)	Habitual drinking (%)
Li et al. [2]	2000	Zhejiang (East China)	18,237	4.34 (M 6.36, F 0.36)	26.96 (M –, F –)
Lu et al. [3]	2000	Xi'an, Shaanxi (Northwest China)	3613	2.27 (only one female ALD)	35.15 (M 52.21, F 8.86)
Huang et al. [4]	2005	Hunan (Central China)	18,618	4.36 (M 6.00, F 0.52)	37.79 (M –, F –)
Sun et al. [17]	2007	Dehui, Jilin (Northeast China)	6043	3.98 (M –, F –)	35.03 (M 64.43, F 4.39)
Chen et al. [5]	2007	Liaoning (Northeast China)	6598	6.82 (M 9.75, F 2.00)	26.98 (M 38.33, F 5.64)
Yao et al. [18]	2011	Yuanjiang, Yunnan (Southwest China)	1690	4.97 (M –, F –)	56.27 (M –, F –)
Wang et al. [9]	2011	Shandong (East China)	7295	8.55 (M 15.76, F 1.42)	42.76 (M 74.51, F 11.32)
Yan et al. [19]	2015	Shanxi, Gansu, Xinjiang (Northwest China)	2300	8.74 (M 10.08, F 4.70)	66.22 (M 77.87, F 31.18)

ALD alcohol-related liver disease, *M* male, *F* female, – unavailable

reported prevalence of ALD across regions in China ranged from 2.27% to 6.82% [3–5, 18]. In 2011, the prevalence of ALD in Shandong Province was observed at 8.55% [9]. In 2015, Yan et al. reported that the prevalence of ALD in northwestern regions (Shaanxi, Gansu, and Xinjiang) was 8.74% [19]. Compared with other cities or regions in China, the proportion of current drinkers in Beijing is at an upper middle level (46.10%), though the ALD prevalence (1.30%) is low likely because of the relatively low ethanol intake, according to a recent report [20]. Despite regional differences, the number of patients with ALD in China has demonstrated a rising trend [21]. ALD prevalence rates with habitual drinking reported by some Chinese studies are shown in Table 5.1.

Across studies surfaced multiple notable risk factors of ALD, which have been widely discussed and validated. In the light of the *Guidelines of prevention and treatment for alcohol-related liver disease* (2018, China), risk factors relevant to ALD include dose, pattern and duration of alcohol consumption, variety of alcoholic beverages, gender, ethnicity, obesity, hepatitis virus infection, genetic variability, and nutritional conditions [22].

A threshold effect of ALD has been noted that the risk of liver injury is significantly increased when the dose or duration of alcohol consumption exceeds a limit [23, 24]. Shen et al. found through a population-based case-control study in Zhejiang Province that daily alcohol intake ≥20 g and duration of drinking ≥5 years were closely related to ALD [24], which was consistent with the finding of another study conducted in Shaanxi Province [25]. However, individual difference exists in the dose-response relationship between alcohol consumption and liver injury [24, 26, 27]. Drinking pattern also plays a role; drinking on an empty stomach is more prone to cause liver injury than drinking with meals [25]. Compared with episodic or binge drinking, drinking daily is more likely to cause severe ALD [28]. Different alcoholic beverages do harm to the liver to different degrees [25, 29]. In China, spirits make up about 70% of alcoholic beverage consumption, and it is estimated that up to 25% of the consumed alcohol is not registered [30]. Traditional distilled spirits (*bai jiu*) are the most popular unrecorded alcohols in China, of which production volume has often been underestimated by official statistics. The major health risks posed by unrecorded Chinese *bai jiu* involve not only the high concentration of alcohol but also the potential harm of toxic impurities including heavy metals and acetaldehyde [30, 31].

In China, the proportion of males with high alcohol intake is higher than that of females [32]. Compared with men, women tend to be more susceptible to alcohol-induced liver injury [33]. Moreover, a smaller dose or a shorter drinking duration could give rise to more severe forms of ALD [23, 34], alcoholic hepatitis and cirrhosis in females [35]. Blood alcohol concentration turned out to be significantly different in men and women after alcohol intake of the same dose [36]. Ethnicity [37], genetic variability [38, 39], and individual difference are also important risk factors. Several studies from Taiwan and mainland China have identified genetic polymorphisms among the Chinese Han population, which are different from those reported in the Caucasian population [39–41]. Yu et al. observed in a Zhejiang population that genetic polymorphisms of ethanol metabolizing enzymes, such as

alcohol dehydrogenase (ADH) 2, ADH3 and acetaldehyde dehydrogenase (ALDH) 2, may affect the propensity for ALD occurrence [39]. Such variations in allele frequency and genotype distribution of ALD-predisposing genes may partly account for the lower ALD incidence in heavy drinkers in China than in Western countries. The degree of malnutrition correlates closely with ALD mortality as well and vitamin A deficiency or a lower serum level of vitamin E can aggravate liver injury [42]. In addition, diets rich in polyunsaturated fatty acids have been shown to modulate ALD [43]. Obesity or overweight also leads to a higher risk of ALD progression [24].

To note, hepatitis virus infection, a major public health problem in China, may exert a synergistic effect on ALD. Drinking based on hepatitis B virus (HBV) or hepatitis C virus (HCV) infection, and *vice versa*, could accelerate the development and progression of liver disease [22]. Zeng et al. reported that the positive rates of serum HBsAg and HCV antibody were higher in ALD patients than in alcoholics without developing liver injury [44]. Our previous epidemiological survey of ALD in Zhejiang Province found that 8.83% of ALD patients had HBV infection, of which the positive rate of serum HBsAg was 13.7% in patients with alcoholic cirrhosis and 9.8% in patients with alcoholic hepatitis, suggesting that alcoholic liver injury could increase the susceptibility to hepatitis virus in patients [45].

ALD has imposed heavy burdens on people's health as well as the healthcare system. The WHO Global Health Estimates (GHE) 2015 showed that drinking accounted for 20.0% of all deaths due to cirrhosis and other chronic liver diseases, and 35.5% of all deaths due to liver cancer in mainland China. According to WHO estimates from 2016, the age-standardized mortality from cirrhosis was 14.6 per 100,000 individuals per year in adult Chinese men and 8.3 per 100,000 per year in women, 62.6% (in men) and 41.6% (in women) of which were attributable to alcohol [46]. Data from Beijing 302 Hospital showed that ALD accounted for 3.93% of all in-patients with liver diseases between 2002 and 2013, with the ratio of patients hospitalized for ALD to all for liver diseases increasing from 1.68% to 4.59% [47]. Similarly, the proportion of patients with alcohol-related cirrhosis rose from 3.34% in 2002 to 8.40% in 2013, making alcohol the third commonest cause of liver cirrhosis in China [48]. The proportion of patients with alcoholic hepatitis in hospitalized patients for liver failure also showed an ascending trend, from 0% in 2002 to 5.2% in 2011 [49]. Between 2006 and 2010, admissions to hospital for cirrhosis caused by viral hepatitis decreased by 10%, while admissions for alcohol-related cirrhosis increased by 33% in 31 hospitals in Beijing [50]. Meanwhile, Zhu et al. reported that the proportion of alcoholic cirrhosis and acute-on-chronic liver failure in hospitalized ALD cases underwent an increase from 2007 to 2012 [51].

The nationwide CKB 2017 database showed that, among the 492,643 participants without prior cancer or chronic liver disease at baseline, 2531 cases of liver cancer, 2040 cases of cirrhosis, and 260 non-cirrhotic ALD cases were recorded after a median 10 years' follow-up. For male current regular drinkers, alcohol consumption showed positive dose-response associations with liver cancer (HR 1.44, 95% CI 1.23–1.69), cirrhosis (HR 1.83, 95% CI 1.60–2.09), and non-cirrhotic ALD (HR 2.01, 95% CI 1.77–2.28). The association with ALD appeared stronger among

men reporting flushing. Further, drinking without meals was associated with significantly greater risks of liver cancer (HR 1.32, 95% CI 1.01–1.72), cirrhosis (HR 1.37, 95% CI 1.02–1.85), and non-cirrhotic ALD (HR 1.60, 95% CI 1.09–2.33) [52]. In addition, in another large study form China, ALDH2-rs671 G > A and ADH1B-rs1229984 G > A were genotyped in 150,722 adults, enrolled from 10 areas in China during 2004 to 2008 [53]. The data support a causal effects of alcohol consumption on upper aerodigestive tract cancers, with ALDH2-rs671 AG genotype further exacerbating the risks [53].

Conclusion

Over the past three decades, alcohol production, alcohol consumption, and consequently, incident alcohol abuse and ALD have increased in China. The national alcohol-related health burden will continue to grow in the foreseeable future. Considering the notable differences in drinking patterns, composition of food, genetics, and alcohol metabolism traits across populations, nationwide epidemiological and clinical research on ALD in the Chinese population is yet to be expanded. Besides, government action is expected through a package of means including public education, regulation of alcohol production and consumption, research funding, and tax policy, to reduce alcohol abuse and related disease burden in China.

Chapter 6
Epidemiology of Alcohol-Related Disease in Russia

E. M. Krupitsky, K. V. Vyshinsky, V. V. Kirzhanova, A. V. Nemtsov, N. V. Semenova, and G. A. Korchagina

Abstract Over the past two decades a significant decrease was observed in all the indicators that are reflecting alcohol consumption by the population of the Russian Federation. These included total per capita consumption, sales of all beverage types with spirits stopping being the predominant one, unrecorded alcohol use, indicators of registered incidence and prevalence, indicator of alcoholic psychoses, as well as indicators of three main causes of alcohol-related mortality: alcohol poisonings, alcoholic cardiomyopathy, and alcoholic liver diseases. Numerous studies of changes in patterns of alcohol consumption reflected most significant decrease among the younger age groups while populations with established behavioral stereotypes, older age groups and heavy users, changed their alcohol behavior to a much lesser extent. The decisive contribution to these changes was made by the

multiple government-enforced regulatory measures, including restrictions of physical and temporal availability, advertising restrictions, introduction of minimum price for spirits, several increases of prices and excises, countering illegal production and sales, measures against drunk driving, strict control to avoid sales to minors, as well as improvements in the field of substance use-related medical care. Measures and restrictions were gradually implemented in the Russian Federation during 2005–2016 and strictly enforced.

Keywords Alcohol-related diseases · Alcohol-related mortality · Alcohol consumption · Alcohol policy · Alcohol consumption · Russia

Introduction

During the last decades the global alcohol use was demonstrating obvious trends towards an increase of both the amounts consumed, as well as number of drinkers. Between 1990 and 2017, the proportion of lifetime abstainers decreased from 46% to 43%, global adult per-capita consumption increased from 5.9 to 6.5 L of pure alcohol, and prevalence of heavy episodic drinking increased from 18.5% to 20%. These developments put some risk in achieving global goals to reducing the harmful use of alcohol, and known effective and cost-effective policy measures should be implemented to reduce alcohol exposure [1].

For many years, the Russian Federation has been associated with the highest per capita consumption of alcohol and the most risky drinking patterns in the world [2]. For most of the territories, the combination of "vodka" and "binge" drinking was the prevailing form of harmful alcohol use (often referred to as the "Scandinavian" model, as opposed to the "Mediterranean" one). This model revived in the days of the Soviet Union, firmly taking its place in the culture of the country during the second half of the twentieth century.

Measures of the Alcohol Policy of the Russian Federation

The high level of alcohol consumption and associated social and medical consequences became the reason for governmental actions and for conducting a number of anti-alcohol campaigns in the USSR. The longest by duration and the most intensive one was initiated in 1985 and included a sharp reduction in production and sales of all types of beverages, reduction in number of retail outlets, price increases, the fight against moonshine production, as well as intensive promotion of sobriety and numerous prohibitions and restrictions. According to official estimates, during the years of the anti-alcohol campaign, alcohol sales in the country have decreased by more than 2.5 times, life expectancy increased, especially among men, birth rate increased and death rate decreased [3]. The campaign was terminated in the late 1980s due to economic difficulties, restrictive legislation was no longer enforced, the fight against illegal production and sale of alcohol became ineffective, and

alcohol consumption began to increase again. After the collapse of the Soviet Union in 1991, against the backdrop of a large-scale socio-economic crisis, the state monopoly on the production of alcoholic beverages was abolished, and the vast majority of alcohol-related production and trade enterprises (except for spirits) were privatized; there was a significant deregulation and criminalization of the alcohol market [4]. As a consequence, per capita consumption indicators did increase substantially, above levels a decade ago, and alcohol-related morbidity and mortality rates also increased substantially.

In order to influence this situation and counteract further aggravation of emerging trends, starting from the first half of the 2000s and over the next 10 years, a significant set of measures was consistently implemented to regulate activity of the alcohol industry, sales of alcoholic beverages, their availability and consumption by the population.

Concerns related to the alcohol problem have been repeatedly expressed by senior officials of the country. Of the program documents, the report of the Civic Chamber of the Russian Federation, published in 2009 should be noted, which assessed the demographic, social and economic consequences of alcohol abuse in Russia and proposed ways to address the current situation [5]. The same year, a Decree of the Government entitled "On the Concept for the Implementation of the State Policy to Reduce the Abuse of Alcoholic Products and Prevention of Alcoholism among the Population of the Russian Federation for the Period until 2020" was issued, containing the intended goals and a detailed list of upcoming actions [6].

Countering Illegal Production and Sales

Several generations of obligatory excise stamps (2000–2003) and new, difficult-to-counterfeit stamps (2005) were introduced. In addition, the EGAIS system for collecting and recording data about volumes of produced alcohol-containing products and raw materials, as well as on the import of alcohol (2006) was implemented, followed by the introduction of QR codes for the EGAIS system for registration of retail sales of spirits and wine (2016).

Advertising Restrictions

Measures aimed at limiting advertisement of alcoholic beverages were efficiently implemented: Prohibition of beer advertising on television during daytime in 2004; Prohibition of alcohol advertising on all types of public transport infrastructure in 2008; Prohibition of alcohol advertising on the Internet and electronic media in 2012 and alcohol advertising in all print media in 2013. In 2014, advertising laws were softened for domestic winemaking and some restrictions on advertising of beer and drinks until 2019 in connection with holding the 2018 FIFA World Cup in the Russian Federation.

Restriction of Physical and Temporal Availability

In 2005, sales on the territory and nearby certain types of locations were prohibited, including educational, medical, sports facilities, public transport. Another measure implemented the same year prohibited sales of alcoholic above 15% vol. in a number of public places, as well as individual sales, and sales in any establishments without appropriate licenses. In the following year, legislative measures came into force in a number of regions to restrict retail sales (with the exception of public catering) of alcoholic beverages with concentrations above 15% vol. during night hours. A ban on sales of alcoholic beverages at gas stations was implemented in 2011, followed by a ban on the retail sales of any alcoholic products (including beer) at public transport stops in 2013.

Limiting Affordability and Increasing Excise Taxes

Minimum retail prices for beverages with strength above 28% vol. were introduced in 2010 and excises were increased by 10% per year as part of an amendment to the Tax Code in the same year. This was followed by further increase in minimum retail prices of spirits (2013), increase in excise taxes on alcohol by 33% (2014), further increase of minimum prices of vodka (2014), a temporary reduction of minimum price for vodka to replenish regional budgets (2015) and, finally, a further increase of minimum price for vodka (2016).

Combating Drunk Driving

Zero tolerance for alcohol use by drivers and requirement of blood alcohol concentration of 0.0% while driving was introduced in 2010. A breathalyzer limit of 0.16 mg/L (to account for highest possible measurement error) while maintaining the "zero tolerance" policy and making the punishment for drunk driving more severe was made effective in 2013.

Prohibition of Alcohol Sales to Minors

Strict control and strengthening of administrative responsibility for selling alcoholic products to minors was implemented in 2011, followed by further increase in fines for the sale of alcohol to minors, possibility of criminal liability for repeated violations in 2014.

Measures in the Field of Medical Care

An initiative to improve the system of treatment of alcohol and drug dependency was implemented in 2011 and a "Health Development" program was initiated in 2014 to prevent harmful use of alcohol. A project of social communications "Health Factory" was initiated in 2015 aimed at eliminating risk factors for NCDs (including alcohol disorders) and focused on active people of working age. At the initiative of the WHO Office in the Russian Federation and leading country medical institutions, a manual for educating trainers in the field of screening and brief preventive counseling for risky and harmful use of alcohol was published in 2016. Most of the restrictive measures against alcohol were undertaken in 2004–2016 in the Russian Federation which can reasonably be considered as evidence-based and in line with the WHO Global Strategy to Reduce the Harmful Use of Alcohol of 2010 and the WHO Global action plan for the prevention and control of noncommunicable diseases 2013–2020. Important elements of the success implementation of these measures were commitment to the chosen goals, gradual introduction and strict implementation of alcohol control measures.

Alcohol Sales and Alcohol Use

Analysis of alcoholic beverage sales to the population of the Russian Federation provides insights for a number of observations that are important for understanding features of consumption during the reviewed period, as well as for making assumptions about the impact of specific anti-alcohol policy measures.

Data on sales of alcoholic beverages to the population is annually presented by the Federal State Statistics Service (RosStat), the Federal executive body responsible for compiling official statistical information on social, economic, demographic, environmental and other social processes in the Russian Federation [7]. For a better illustration, total ethanol content per main types of alcoholic beverages in the overall structure of consumption was compared. Figure 6.1 illustrates (with some exceptions for 2015) that spirits have been the dominant type in the structure of alcoholic beverages sold in Russia for the 2000–2018 period under review. In 2000, sales of spirits to the population corresponded to 86.4 million decalitres in terms of ethyl alcohol, and the share in the structure of consumed drinks was about 72% of the total 120.8 million decalitres. However, consumption of spirits showed a gradual downward trend. In 2013, they already accounted for less than half of the ethyl alcohol in the structure of beverages sold, and after 2017 their share was slightly below 40 million decalitres per year which corresponded to about 43% of total ethanol sold (Fig. 6.1).

In contrast, beer consumption increased, and it accounted for 25.9 million decalitres of ethanol in 2000, and for the maximum of 51.7, which corresponds to 22%

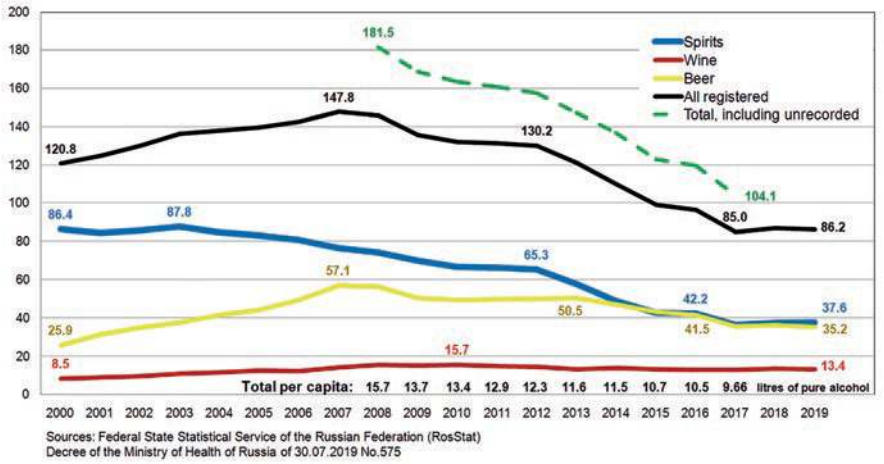

Fig. 6.1 Sales of alcoholic beverages to the population of the Russian Federation and assessment of unrecorded consumption (millions of decalitres in terms of pure alcohol) and total annual per capita consumption (litres of pure alcohol)

and 39% among all beverages sold these years. After 2014, the proportion of beer in the structure of the total ethanol consumption almost equaled with spirits and amounted to about 40–45%. Throughout the period from 2000 to 2019, wine has always been in the third place, however, its consumption has increased from 8.5 to 13.4 million decalitres in terms of ethyl alcohol content, and the share among other types of alcohol—from 7% to 15%.

Published assessments of total alcohol consumption, including recorded and unrecorded, corresponds to changes of per capita levels from 15.7 L of ethanol in 2008 to 9.7 in 2017, i.e., decrease by 38% over 10 years [8].

Unrecorded Alcohol

Unrecorded alcohol production has always been a significant part of ethanol produced and consumed in the Russian Federation. Such unrecorded alcohol includes products that contain ethanol but are not included in official sales, production or trade statistical data, or they are not taxed as beverages but are nevertheless consumed. This is a large and heterogeneous group of products, most of which have a high concentration of ethanol. Such products include illegally produced, undeclared or contraband alcohol; counterfeit alcoholic beverages in replica bottles; homemade alcohol; alcohol surrogates, such as alcohol-based cosmetic lotions and colognes, medicated formulations, and windshield washer fluid [9, 10].

During certain periods, unrecorded consumption in the Russian Federation was making up to a third of total; according to estimates, proportion of illegal production

was about 43% of unrecorded alcohol, home-made production—29%, surrogate alcohol—22%; the remaining 6% were brought from abroad by individuals. It should be noted that compared to other countries of the WHO European Region, the Russian Federation had one of the highest proportions of surrogate alcohol in total alcohol consumption [11, 12].

Alcohol-Related Disorders, Based on State-Supported Medical Facilities' Data

The data on treatment demands reported by state-supported medical facilities of the Russian Federation indicate that alcohol-related disorders predominate in the structure of chemical dependency burden. Most of the patients who were seeking treatment were those with alcoholism, alcohol psychoses and with the diagnosis of "harmful alcohol use". Over the past 20 years, proportion of such patients among all with psychoactive substances associated disorders made up around 80%.

Prevalence and incidence indicators. Over the past 15 years, rates of general and primary incidence of alcohol disorders have shown a downward trend: As compared to early 2000s with two thousand or more patients with alcohol dependency and harmful alcohol use per 100,000 total population, this indicator has continuously decreased since 2005, now reaching 1009.7 per 100,000 in 2019, i.e., a decrease by half. The primary incidence has also significantly decreased—from 264.3 per 100,000 of the population in 2004 to 79.9 in 2019, or by 3.3 times (Fig. 6.2).

In different age and gender groups—men, women, children and adolescents—the rates of decline differed, but the general downward trend can be traced quite clearly: the average rate of decline in primary incidence in general in 2003–2019

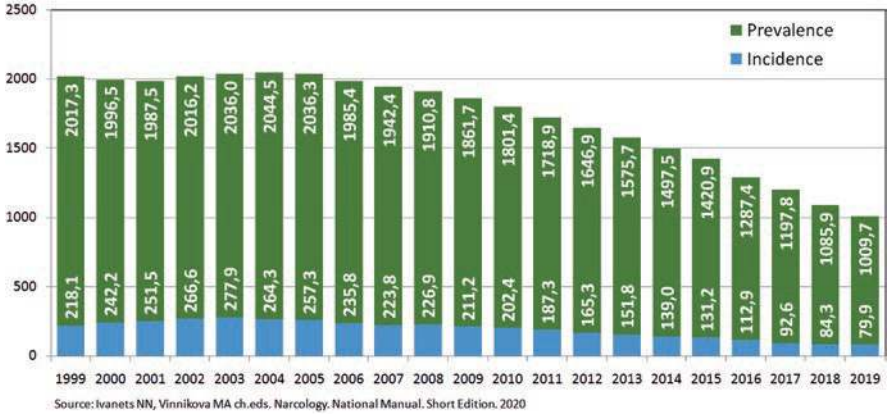

Fig. 6.2 Registered prevalence and incidence of alcohol-related disorders (per 100,000 population)

was 7.5% annually. At the same time, a high level of reduction in primary morbidity was observed in all age and gender groups: in children aged 10–14 years, the indicator decreased on average by 5.4% per year, in adolescents (15–17 years old)—by 6.1%, in adults of working age—7.4%, in men—by 5.6%, in women—by 8%.

A notable feature of changes in incidence among children, adolescents and youth populations was the decrease in the number and proportion of treatment demands related to more severe forms of alcohol abuse (dependency syndrome, alcoholic psychoses) and an increase in the proportion of patients with early forms of disorders (hazardous use of alcohol), which indicates positive changes in the structure of incidence of alcohol-related disorders. From the clinical point of view of view, identification of alcohol disorders at the stage of harmful use, i.e., before the formation of addiction syndrome, determines better prognosis and higher effectiveness of therapeutic interventions, especially among children, adolescents and youth [13, 14].

Alcoholic Psychoses

Due to the fact that alcoholic psychoses are the disorder that is most fully recorded by medical institutions, the incidence of alcoholic psychoses is often seen as an indicator to characterize overall alcohol situation.

The highest level of alcoholic psychoses-related treatment demands over the past 20 years was observed in 2003 and equaled 55.5 per 100,000 population. Subsequently, this indicator steadily decreased and in 2019 made 12.5 per 100,000 population, or decreased by almost 4.4 times (Fig. 6.3). A decrease in incidence of alcoholic psychosis is observed in all gender and age groups of the population of the Russian Federation [14].

The rates of hospital admissions also decreased: compared to 2003, the number of hospitalizations due to alcoholic psychoses decreased by three times—from

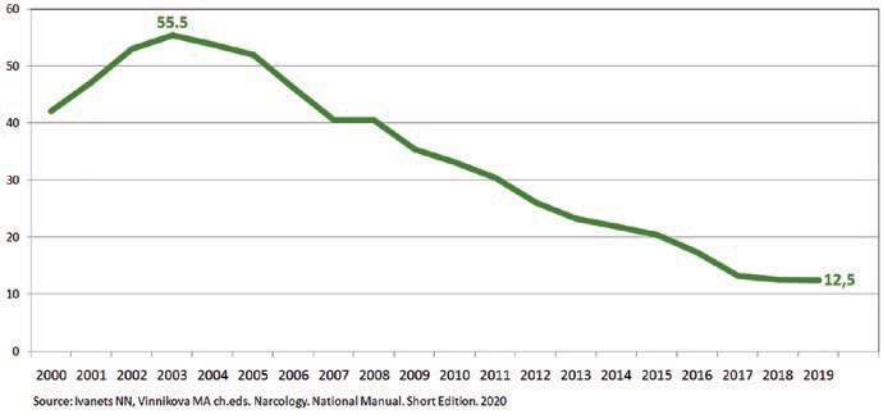

Fig. 6.3 Alcoholic psychoses registered incidence (cases per 100,000 population)

122.5 to 41.4 per 100,000 population. A similar situation was observed among adolescents: the number of hospitalizations of adolescents with alcoholic psychoses decreased from 230 in 2003 to 10 individuals in 2019.

When monitoring the alcohol use situation, comparative analysis of indicators of incidence and primary hospitalization with alcoholic psychoses was carried out. It should be noted that the indicator of incidence is reflecting outpatient referrals, and primary hospitalizations are reflecting referrals for inpatient care. Under ideal conditions, these figures are close, indicating continuity between inpatient and outpatient care. Unfortunately, the situation is far from being perfect: hospitalization rate significantly exceeds the outpatient incidence rate, which indicates that the outpatient rate could be underestimated by 1.5–two times, and for correct assessment of the alcohol situation, it is advisable to use both hospitalization indicator along with outpatient incidence. Despite these uncertainties, the dynamics of hospitalization rates for 2003–2019 also show simultaneous decline in both indicators.

Alcohol-Related Mortality

During the last 20 years, Russia has experienced a decline in alcohol-related mortality of unprecedented depth and duration. Figure 6.4 presents data of Rosstat on the dynamics of mortality in the Russian Federation from accidental alcohol poisonings, alcoholic cardiomyopathy and alcoholic liver disease, which in total account for around 85% of all alcoholic mortality since 2000.

The forced elimination from the vodka market of a notable number of small and medium-sized actors after 2006 due to a number of state regulatory measures introduced in 2005–2006 led to a significant reduction in illegal and legal sales and a

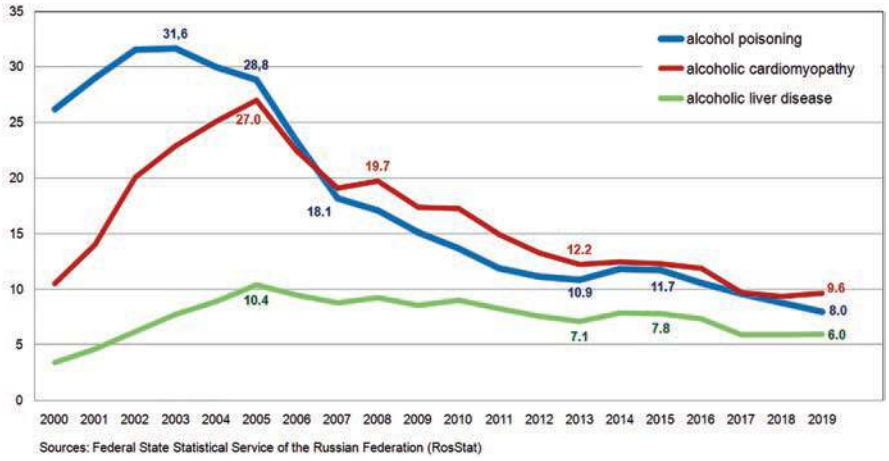

Fig. 6.4 Dynamics of mortality in alcohol poisoning, alcoholic cardiomyopathy and alcoholic liver diseases in 2000–2019 (standardized mortality per 100,000 population)

sharp decrease of both consumption of spirits and of mortality in 2006–2007 (Fig. 6.4). Additional restrictive measures on time of alcohol sales, pressure to observe age requirements, bringing up excises, introduction and gradual increase on minimal price of spirits and tight control over the legality of alcoholic products sold to the population supported a further, almost synchronous decrease in alcohol consumption and mortality from the main alcohol-related causes in 2008–2013 (Fig. 6.4). In general, between 2005 and 2019 mortality due to alcohol poisonings decreased by 78% (from 27.2 to 6.3), from alcoholic cardiomyopathy by 64% (from 27.0 to 9.6) and from liver diseases by 43% (from 10.4 to 6.0; all per 100,000 total population).

During the same years, a decrease in mortality due to somatic diseases, especially cardiovascular diseases, was observed. However, this decrease cannot be entirely attributed to the drop in alcohol use, due to the fact that in the 2000s there was a significant increase in the well-being of the population, the state carried out a number of measures aimed at protecting the health of the population, including the adoption of the national project "Health" and others. However the contribution of decreased alcohol use remains significant.

Alcohol Use Patterns' Evolution

Sociological surveys are making it possible to study evolution of alcohol use patterns among the population: changes in the frequency and quantitative characteristics, alcohol preferences by types of beverages, including in various population groups—adolescents, young adults, women, groups of high risk, etc.

Data from Roshchina [15] indicate that there were certain shifts in alcohol use patterns of Russia's population already in 2010. Since the mid-1990-s the structure of consumed beverages has changed significantly: first of all, it should be noted that by 2010, there was an increase in the proportion of beer consumers among the population: among men drinkers—from 35% to 68%, among women from 16% to 42%. Moreover, according to the author, the increase in the share of beer occurred due to the reduction in vodka: among male drinkers—from 89% to 64%, among women—from 61% to 36%. In 2010, about a third of Russian women and a fifth of men aged 16 or older did not drink alcoholic beverages at all. At the same time, the share of current non-drinkers increased between 2006 and 2010 among women from 29% to 35%, and among men from 17% to 22%. The dynamics of proportion of non-drinkers during the analyzed period differs in different age groups: the share of non-drinkers among young people under 25 increased the most, while among persons of mature age (41–60 years) and the elderly (61 years and more) the increase was either not observed or was not so significant. In 2010, the proportion of people who drank alcohol frequently (4–6 times a week and more often) was 4.4%, including 7.5% among men and 1.3% among women [15].

Changes in the prevalence of alcohol use are also confirmed by results of telephone surveys, including VTsIOM-Sputnik, whose results also revealed high rates

of current frequent alcohol use [16]. During the period from 2009–2011 the proportion of respondents who consumed alcoholic beverages several times a week, including daily consumption, made up 7–8%, and by 2018–2021, this proportion was reduced to 4–6%. Along with this, the study confirmed a considerable significant increase in the proportion of nondrinkers—from 26% in 2009 to 39% in 2021.

From the point of view of assessing the alcohol situation in Russia, large-scale RosStat studies like the "Study of behavioral factors affecting the health of the population" are of special interest. To date, two have been conducted with the interval of 5 years—in 2013 and 2018, with almost 16,000 participants aged 15 and older in 2013 and 15,000 households covered in 2018. The distribution of respondents by gender and age was representative of the population structure of the Russian Federation. The results indicate a decrease in the proportion of alcohol users among men and women, both among urban and rural residents, as well as in various age groups. The decrease in the proportion of alcohol users in the youth groups of the population is especially noticeable: for example, the proportion of individuals aged 15–19 who drank alcoholic beverages over the last 30 days decreased from 21% to 12%, at the age of 20–24 years—from 52% to 47%, 25–29 years old—from 625% to 53%. Among the older population, the reduction was not as significant. Along with this, it should be noted that the proportion of alcohol users whose high frequency of drinking is combined with the consumption of large amounts of alcohol (according to the RosStat survey, who have drunk five or more standard drinks in a row 10 times or more over the past 30 days) remains virtually unchanged: in 2013—1.9%, in 2018—1.8% of the total number of respondents [17, 18].

Interpretation of observed trends in the use of alcohol by Russia's population has also been the subject of a number of publications based on data from the Russian Longitudinal Monitoring Survey conducted by the Higher School of Economics (RLMS-HSE), a panel survey of households and individuals using multi-stage probability sampling with primary sampling units selected within geographically determined strata. The influence of the effect of gender, age, year of survey and age cohort on the consumption of alcohol and certain beverage types during the period from 1994 to 2016 was assessed. The conclusion was drawn that the downward trend in alcohol consumption observed in recent years can be explained by the predominant decrease in consumption among the younger age groups born after 1990 [19].

Another publication was devoted to the question of whether heavy drinkers changed their alcohol habits in the same way compared to light drinkers, in other words, which model of consumption reduction—polarization model or collective model—better explains the changes of alcohol use practices in the Russian Federation between 2006 and 2018. A comparative study of trends among identified percentile groups characterizing heavy drinkers, near heavy drinkers, moderate drinkers, light drinkers and nondrinkers showed that a decrease in alcohol consumption was observed in all groups, but the scale of changes was proportionately smaller among those who drank more than among those who drank less. However, the consumed amounts fell by a smaller proportion among lighter drinkers than among heavier drinkers. Interactions between the time period and the percentile groups

were significant after 2010 with trends similar for both genders. Obtained evidence failed to support polarization hypothesis and pointed towards soft collectivity hypothesis in the reduction in drinking in the Russian Federation in 2006–2018, when trends across all drinking groups have been downward, although the proportions were different for heavier or lighter drinkers [20].

Results from a number of monitoring surveys studying changes of substance use behaviors over time among certain groups of children and adolescents are also reflecting the reduction of alcohol use since the middle of 2000s.

Four waves of the European School Survey Project on Alcohol and Other Drugs (ESPAD) which compares results among students who turn 16 during the year survey is conducted, included data from the Russian Federation in the years 1999, 2003, 2007 and 2011. Although whole country-representative sample was implemented only once, all four waves of data collection provided coverage of the city of Moscow and thus allow overtime comparisons. Whilst results from 1999 and 2003 demonstrated stable indicators and even increase of some (like last 30 days wine drinking going up from 38% to 47%), the 2007 results showed an obvious decrease in all the indicators, and the trend continued in 2011. The use of any alcoholic beverages during the past 12 months went down from 86% in 2003 to 80% in 2007 and to 71% in 2011 among all students; the use of any alcoholic beverages during the past 30 days decreased from 62% to 56% and then to 37% for the same years, the proportion reporting having had five or more drinks on one occasion during the past 30 days decreased from 38% to 31% and then to 24% for the same three data collection points. The direction of changes was always the same for boys and girls [21].

The international WHO-supported research project Health Behavior in School-aged Children (HBSC) project which is a source of information on the health and well-being, social conditions and health status of 11-, 13- and 15-year-old boys and girls from more than 40 countries reflected positive changes in alcohol use during a later period. In the Russian Federation during the period between 2013/2014 and 2017–2018 data collections, proportion of 11-year-old boys who have ever used alcohol decreased from 10% to 7%, among girls from 8% to 4%; among 13-year-old boys from 21% to 12%, among 13-year-old girls from 20% to 13%. A similar trend was also observed among 15-year-olds: the proportion of boys who used alcohol decreased from 41% to 30% during the same period, and of girls from 44% to 29%. Along with this, the proportion of 15-year-olds who experienced alcohol intoxication two or more times during their lives decreased from 17% to 9% among boys and from 11% to 7% among girls. Thus, reduction in the proportion of children and adolescents who used alcohol is observed in all the age groups analyzed within the HBSC project and the results support positive changes of alcohol situation among children and adolescents [22].

In summary, the results from quite heterogeneous sources about the change in alcohol situation in the Russian Federation all indicate positive changes in alcohol use among the whole population, but to the greatest extent among children, adolescents and youth, during the years when alcohol policy control measures were implemented. To a lesser extent, the alcohol policy has affected the adult population of older age groups, among whom keeping to the prevailing stereotypes of alcohol use was more likely.

Discussion

In the last two decades, anti-alcohol policy has been actively implemented in Russia in the form of introduction and consistent enforcement of legislative measures aimed at reducing the price and time availability of alcoholic beverages, prohibiting advertising of alcohol-containing products, increasing liability for drunk driving, as well as implementing universal and selective prevention measures aimed primarily at for children, teenagers and youth.

The majority of alcohol-related monitoring indicators are reflecting an improved situation with regard to alcohol usage in the Russian Federation after 2005: there is a sharp decrease in alcohol consumption, especially for spirits—by more than two times; reduction in the level of primary and general morbidity due to alcoholic psychosis, alcoholism and harmful use of alcohol, including among children, adolescents and youth people; reduction in mortality from alcohol poisoning and somatic diseases associated with alcohol; reducing the number of crimes committed while intoxicated.

On the other side, however, along with positive trends, there are some observations that still raise concern: despite a significant decrease in alcohol sales and stabilization of death rates from alcohol poisoning at the level of 4.4–4.6 deaths per 100,000 population in 2012–2018, alcohol consumption, taking into account the illegal component, is still high and is estimated at about 10 L of absolute alcohol; the proportion spirits and unregistered alcohol stays relatively high in the structure of alcohol consumption; in the last few years (2018–2019), there has been an increase in hospitalizations of patients with alcoholic psychoses. All this may indicate the exhaustion of the resource of the anti-alcohol measures taken. Despite a downward trend after 2016, the level of alcohol-related crime remains high.

According to sociological surveys data, level of problem alcohol use remained virtually unchanged during recent years, at the level of 1.8–1.9%, and level of alcohol use had almost no decrease among the population aged 40 to 60 years. Also stabilization is observed in the proportion of population who use alcohol daily or almost daily at the level of 4–6%. Thus, against the background of the measures undertaken, alcohol consumption decreased most among the young population, while the population with established behavioral stereotypes—older age groups and heavy users—changed their alcohol behavior to a much lesser extent.

Conclusion

During the first two post-millennial decades there has been a significant decrease in all indicators that reflect alcohol consumption by the population of Russia, as well as its medical and social consequences. Although there may be various explanations for changes in some indicators, the significant number of government-enforced regulatory measures seem to be the major reason, most of them internationally recognized as cost-effective, consistently adopted during a short period of time and

strictly implemented. To consolidate this success, it appears important to continue these measures, and, in case of necessity, to further develop them. To achieve this goal, an efficient monitoring system is required in order to identify potential risks and trends in alcohol consumption and respond in a timely and adequate manner.

Chapter 7
Alcohol and Mortality: First Preliminary Lessons from a Prospective 15 Year Follow-Up Study

Sebastian Mueller and Johannes Mueller

Abstract This book chapter introduces to all-cause and cause-specific mortality related to alcohol consumption. First preliminary data of a prospective 15 year long-term follow up study in heavy drinkers are presented and discussed. All patients received an initial abdominal ultrasound, liver stiffness (LS) measurements, routine laboratory parameters and additional information on comorbidities and morphometric data. In 803 patients (63.5%), all-cause survival status and in 786 patients (62.2%) the observation interval could be obtained. 159 patients (20.2%) had passed away during a mean observation interval of 3.8 years (1–15 years, median 3.5 years). The cause of death could be clarified in 76 of them (47.8%) and was liver-related in 34%, cardiovascular in 17%, cancer-related in 15%, followed by other causes. Taking into account elevated initial LS values, even about 50% of deaths were liver-related. The age-adjusted relative risk of death (RR) of the overall population was 3.8, with 3.9 slightly higher as for men (3.5). Highest RR was observed in heavy drinkers <40 years old with an RR of 45.0 (106.2 for women and 28.9 for men). RR did not change significantly when only looking at non-smokers. Finally, for the first time, both univariate and multivariate regression analysis identify, next to LS, hemolytic anemia has major long-term predictor of death. A long-term score to predict death in heavy drinkers is developed that includes LS, erythrocyte count, total bilirubin, alkaline phosphatase and age. It reaches AUROCs of up to 0.7 for predicting 7-year-mortality. In conclusion, preliminary data, from the first prospective long-term follow-up study with extensive initial patient characterization identify hemolytic anemia as important, hitherto unrecognized predictor of mortality in heavy drinkers.

Introduction to the Historic Background on the Relation of Alcohol, Cirrhosis and Mortality

One reason that limits our understanding of alcohol-mediated disease mechanisms is the **lack of robust prospective all-cause and cause-specific mortality data.** The reasons for it are manifold although an association between alcohol, liver cirrhosis and premature death has been noted early on. For instance, historically, the relation between alcohol consumption, liver cirrhosis and death has been well recognized in autopsy studies dating back to the middle of the nineteenth century and, as an example, Theodor Frerichs' famous "Diseases of the liver" (Klinik der Leberkrankheiten) from 1858 may be quoted here [1]. Frerichs was famous for his in-depth observations and the then state-of-the-art application of laboratory methods, combined with over 10,000 detailed and published autopsies, most of them longstanding former patients. At the beginning of the twentieth century, the relation between alcohol, liver cirrhosis and death became further substantiated. In an analysis of cases with liver cirrhosis from Vienna in 1925, the role of alcohol and even the gender-dependence was clearly identified [2]. In this study, 372 cases of cirrhosis were analyzed and linked to alcohol consumption. Daily drinking of more than 80 g of alcohol was considered as drinking at risk. In males, 14% of cirrhosis cases had never drunken alcohol, 52% drunk at risk and 34% occasionally. In women, 58% of cirrhosis cases had never drunken alcohol, 19% drunk at risk and 23% had occasionally drunken alcohol. Finally, the many autopsy- and biopsy-proven studies were carefully analyzed after the second world war, and a clear relation between dosage, time of exposure and incidence of cirrhosis, precirrhotic lesions and fatty liver was established [3].

The first causal relation between alcohol and cirrhosis was established in non-human primates by Charles Lieber [4]. The study was important since there was an ongoing debate at that time whether cirrhosis was due to caloric insufficiencies. After replacing 50% of caloric uptake with alcohol, all features of alcohol-related liver disease (ALD) could be induced in the liver including cirrhosis [4]. Importantly, many efforts were taken in this study to avoid malnutrition, demonstrating clearly, that it is ethanol that ultimately causes cirrhosis. Nevertheless, while these efforts established a causal relationship between alcohol consumption and liver cirrhosis, they did not study mortality as final endpoint and, today, we are still far from understanding the pathology of ALD, the actual molecular mechanisms, and by which ethanol causes liver disease. In addition, in former autopsy studies, although liver cirrhosis was encountered more often, there were no specific data that related alcohol consumption with all-cause and cause-specific death.

Epidemiological Evidence for Alcohol Consumption and All-Cause Specific Death Rates

Comparison of all-cause death rates, e.g., between the general population and a selected patient cohort with defined risk factors is a typical approach to shed light on the role of risk factors such as alcohol on mortality. These mortality rates can then be adjusted for gender and age. Although the general population also consumes alcohol and the causes of death are multiple, these comparisons provide a useful estimate whether a certain sample has an increased risk or not. Ideally, alcohol consumption should be recorded in a diary for many years and, over time, validated by objective parameters, and, finally, associated with death rates in comparison to other risk factors or conditions. Obviously, for many practical reasons, this has not been done so far, justifying study approaches that aim to draw conclusions from various sample cohorts. Table 7.1 lists a few studies. Table 7.1 is far from being complete but designed to exemplify the various natures of studies that have helped so far in understanding the role of alcohol for death at a statistical level, but also their limitations. First, the studies differ drastically in design, recruitment of data, definition of "alcohol". For instance, all-cause death studies need first to define the terminology "alcohol consumption". In the two quoted meta-analyses, this has been done by (a) using a prospective or historical cohort study design; (b) assessed AUD as diagnosed by a psychiatrist or physician, patients undergoing alcohol detoxification, registration at a temperance board (TB) or driving, using validated questionnaires etc. Accordingly, not all of these measures are able to assess and record the duration and amount of alcohol consumption. This becomes obvious when recruiting study participants within alcohol drinking studies in different institutions. For instance, in a recent two center drug intervention trial, in drinkers recruited through newspaper advertisment, the daily alcohol consumption was 105.5 g per day [25]. However, the consumption of patients recruited at the participating addiction department was 88.5 g per day [25] while the amount of daily drinking of patients admitted for alcohol detoxification in an Internal Medicine Department was 185.5 g per day [26]. In line with this, mean liver stiffness was ca. 10 kPa in the two first cohort, but 18 kPa in the latter, presenting for alcohol detoxification.

There are two **meta-analyses** [5, 6] on all-cause mortality and alcohol consumption. In the 2013 meta-analysis, 81 observational studies were included with 221,683 observed deaths among 853,722 people with alcohol use disorder. In men, the relative risk (RR) among clinical samples was 3.38; in women it was 4.57. Alcohol use disorders identified in general population surveys showed a twofold higher risk compared with no alcohol use disorder in men; no data were available for women. It was also noted that RRs were markedly higher for those younger or equal than 40 years old (ninefold in men, 13-fold in women) while still being at least twofold among those aged 60 years or older. In the 2018 meta-analysis, 31 studies were included out from 11,466 screened papers and 386 full text studies [6]. A total of 6768 all-cause deaths in 276,990.7 person-years of follow-up (36,375 patients) were recorded, and the pooled all-cause mortality rate was 27.7/1000 person-years

Table 7.1 Examples of mortality studies (selection)

Type and reference	Studies	Number of studies/patients/ treatment	Follow-up	Events/predictors
All-cause mortality, AUD[a] and moderate drinking				
[5]	Meta-analysis MOOSE guidelines	81 observational studies, 853,722 people		In men, the relative risk (RR) was 3.38; in women it was 4.57; Alcohol use disorders identified in general population surveys showed a twofold higher risk compared with no alcohol use disorder in men
[6]	Meta-analysis	31 studies, 36,375 patients		Pooled all-cause mortality rate was 27.67/1000 person-years (py)
[7]	125 general practice, retrospective	95,991 patients with alcohol consumption	2000 and 2014	Mortality from ONS mortality register, 25–34 units of alcohol per week (HR 1.26) and 35 units or more (HR 1.71), compared with those drinking 1–7 units per week.
[8]	Single center	1265 alcohol detox, mixed with other diseases, 1362 controls	Median 34 months	HR 12.7 mortality for AUD, predictors: age, smoking, serum creatinine, serum bilirubin, and prothrombin
[9]	Single center	909 patients, alcohol dependence (retrospective)	Median 3.8 years 2000–2010	Preselected anemia (HR 1.67), fibrinogen, and ferritin levels
[10]	Data from the MIMIC-III database	2884 patients with AUD, retrospective	28-Day Mortality	explore the predictive value of red blood cell distribution width (RDW)
[11]	Standard health-screening program	Retrospective cohort study of 430,016 adults	1994–2008	"Modest drinker" (no more than one drink a day) from "regular drinker, 23% males was modest drinker, who gained 0.94 year in life over non-drinkers and had 8% reduction in adjusted all-cause mortality (HR 0.92). regular drinkers had 43% increase in overall mortality (HR 1.43)
Cause-specific mortality, AUD				
[12]	Meta-analysis MOOSE guidelines	17 observational studies, 28,087 AUD patient	10 years of follow-up	Standardized mortality ratios were 14.8 for liver cirrhosis, 18.0 for mental disorders, 6.6 for death by injury and around 2 for cancer and cardiovascular diseases

(continued)

Table 7.1 (continued)

Type and reference	Studies	Number of studies/patients/ treatment	Follow-up	Events/predictors
[13]	Single center	23,371 patients with alcohol dependence (retrospective)	12.5-year observation 2000–2012	Identified 23 physical comorbidities contributing to hospital-based mortality in individuals with alcohol dependence: alcohol-related liver disease (33.7%), hypertension (16.9%), chronic obstructive pulmonary disease (14.1%), and pneumonia (13.3%
[6]	Meta-analysis	31 studies, 36,375 patients		most common cause of death was cardiovascular disease (CVD) (6.9/1000 py), followed by gastrointestinal deaths (5.63/1000 py), unnatural deaths (4.95/1000 py), neoplasms, respiratory diseases, and substance use disorders.
Alcoholic liver cirrhosis				
[14]	Single center	126 patients with decompensated cirrhosis	29 months	Comparison of different liver-related scores (CHILD, MELD,UK MELD, MESO index)
[15]	Single center	100 patients with alcoholic cirrhosis, 1984–1988	Till 2000 (12 years)	100 patients included (90% died, 76% with autopsy), 68 had been autopsied, cumulative mortality after 5, 10 and 15 years 71%, 84% and 90%, respectively. Causes of death were bleeding, liver failure or a combination of these two conditions in 58%, while 11% died of HCC. Using the Cox regression analysis, age, alcohol abuse and alkaline phosphatase were independent and significant predictors of mortality, but Child-Pugh class was not.
Alcohol-related liver disease				
[16]	Retrospective data from all Scottish ICUs	2463 ALD and 3590 patients with severe comorbidities from all Scottish ICU	2005–2010	Alcohol-related liver disease patients had 31% higher hazard of death (adjusted hazard ratio, 1.31).
Alcoholic hepatitis (AH) mortality				

(continued)

Table 7.1 (continued)

Type and reference	Studies	Number of studies/patients/ treatment	Follow-up	Events/predictors
[17]	Single center	71 patients Steroids vs. enteral tube feeding	1 and 12 months, death	Comparable outcome of enteral feeding and steroids in the short-term treatment, steroids have short-term complications but long-term benefits
[18]	Single center	36 patients Infliximab and steroids	1 and 2 months mortality	The study was stopped due to increased mortality in the treatment arm
[19]	Multi center	241 patients	1 and 3 months mortality	Age, serum bilirubin, blood urea, prothrombin time, peripheral blood white blood cell count
[20]		Questionnaires from 142 or 1200 hospitals in Japan, 86 patients	1998–2003	Predictors of mortality includes INR, RBC, WBC
[21]	Meta-analysis	5 studies 418 patients Placebo vs. steroids	1 and 6 months mortality	Survival was higher in corticosteroid-treated patients, survival predictors: corticosteroids, MDF, leucocytes, Lille score and encephalopathy
[22]	Multi center	1053 patients Placebo, steroid or pentoxifylline	1, 3 and 12 months mortality	no effects of pentoxifylline, OR of prednisolone was 0.72
[23]	Meta-analysis	11 studies Placebo vs. steroids	1 and 6 month mortality	HR mortality for corticosteroids was 0.64 for pentoxifylline 0.64
Wernicke-Korsakoff syndrome				
[24]	Single center	61 patients, Retrospective and prospective	2002–2011 Median 5.3 years	Cumulated mortality was 45% and death rate of 7.4 × 100 person-years causes of death included serious bacterial infections (44.5%) and cancer (33.3%).

[a]AUD alcohol use disorder

(py). Some single center studies **retrospectively** analyzed data registries from general practices with information on alcohol consumption and amount [7], used alcohol withdrawal as general criterium for AUD [8, 9], and focused on a single laboratory parameter while extracting data from a database retrospectively [10]. Another example is the retrospective follow up of a standard health-screening program in a normal population with a high sample number and quite detailed information on moderate alcohol consumption in Taiwan [11].

Other studies have tried to analyze **cause-specific mortality** with the same challenge as described above of defining inclusion criteria for alcohol consumption

retrospectively from data bases. As shown in three examples in Table 7.1, outcome differs drastically, and it underlines that careful prospective data are missing. While in one analysis (meta-analysis) [6] cardiovascular events were most common causes for death, another meta-analysis showed liver-related death as most common and cardiovascular events as lower [12]. Overall, 17 observational studies with 6420 observed deaths among 28,087 AUD patients were included. Pooled standardized mortality ratios after 10 years of follow-up among men were 14.8 for liver cirrhosis, 18.0 for mental disorders, 6.6 for death by injury and around 2.0 for cancer and cardiovascular diseases. Standardized mortality ratios were substantially higher in women, with fewer studies available. For many outcomes the risk has been increasing substantially over time [12]. The most common cause of death in the AUD population was cardiovascular disease (6.9/1000 py), followed by gastrointestinal deaths (5.63/1000 py), unnatural deaths (4.95/1000 py), neoplasms, respiratory diseases, and substance use disorders [6].

Many studies **focus on a specific clinical setting with preselected cohorts**, e.g., with alcoholic hepatitis, alcohol-related liver cirrhosis or disease. As shown in Table 7.1 a study can also focus on the diagnosis of Wernicke-Korsakoff Syndrome [24]. But again, in these studies, no detailed information is provided for the comorbidities of these patients such as liver stiffness and detailed blood parameters. Other entities such as alcohol-related cardiomyopathy are not even listed in some statistics while others estimate its incidence from 1–2% of all heavy alcohol users, representing ca. 25% of all non-ischemic cardiomyopathies. The prevalence of alcoholic cardiomyopathy in addiction units is likewise estimated around 25% [27] (see also Chap. 70). Due to the specific health burden in the UK, it has established an institution years ago, the so-called Health and Social Care Information Centre (HSCIC), to specifically record alcohol-related mortality data. Accordingly, for 2011, 6771 alcohol-related death were reported: alcohol-related liver disease ranked first (66%), followed by alcoholic liver cirrhosis (20%), psychiatric diseases (6%), alcohol intoxication (5%) and alcoholic cardiomyopathy (2%). In this context the reader is also referred to the Chap. 10. According, to the report of alcohol-specific deaths in the UK registered in 2020 [28], there were 8974 deaths (14.0 per 100,000 people) from alcohol-specific causes. This corresponded to an 18.6% increase compared with 2019 and was the highest year-on-year increase since the data time series began in 2001. Consistent with previous years, the rate of alcohol-specific deaths for males in 2020 remained more than double the rate for females. More than three-quarters (75%) of alcohol-specific deaths were caused by alcohol-related liver disease peaking at the age between 55–59 years. It should be also noted that WHO- based initiatives such as the Global Burden Disease studies do also not prospectively include routine laboratory measure or other important parameters such as abdominal ultrasound or liver elastography [29].

Taken together, studies on mortality and alcohol consumption are lacking sound prospective data, resulting in obvious contradictions, some of which are not primarily explained by geographic regions but rather the retrospective nature of data collection from various data bases. Specifically, an **ideal mortality study on alcohol consumption** should be composed the following way:

1. Objective parameters should be initially assessed and prospectively followed up with all cause or cause-specific death.
2. These parameters should contain routine laboratory parameters and non-invasive markers of the liver and spleen by abdominal ultrasound and liver elastography [30].
3. Ethnicity, nutritional parameters, clinical parameters and medical history with comorbidities should be also recorded by an educated team.
4. The last amount of daily alcohol consumption, the duration of heavy drinking and the type of alcoholic beverages should be taken also into account.
5. Finally, and ideally but almost impossible, it would be optimal to obtain a complete realistic picture of deceased patients, in the best scenario an autopsy altogether with the complete last medical records. Autopsies would be especially desirable with regard to the cause-specific death and to the development of cancer in various tissues, but also disease such as cardiomyopathy or brain alterations.

Moreover, it is recommended to mostly include heavy drinkers to increase the signal-to-noise ratio. In our opinion, confounders such as diabetes or obesity should not be excluded but rather included to determine their weight in causing death.

Preliminary Data of the 15 Year HEIDELBERG Prospective All-Cause Death Study in Patients Undergoing Alcohol Detoxification from 2007–2022

Considering the scarcity of prospective mortality data in alcohol drinkers and the still largely unknown molecular mechanisms of disease progression, in 2007, we initiated in Heidelberg a prospective follow-up study and, after 15 years, first all-cause survival data were obtained. Although we have just started to analyze the data, the novel insights justified their inclusion into this book. Extensive data are also provided in the Backmatter of the book (Tables B.1–B.39).

Study Design

The study design is shown in Fig. 7.1. In difference to the studies quoted in Table 7.1, major design elements of this prospective study were as follows:

1. Inclusion of heavy drinkers primarily presenting for alcohol detoxification, mostly through an elective and pre-planned in hospital stay of about 1 week. This approach avoids pre-selection of patients, e.g., with end-stage liver disease. With the inclusion of primarily heavy drinkers (mean 189 g/per day for 14 years) and the long observation period, a significant impact of alcohol in comparison to the general population was expected.

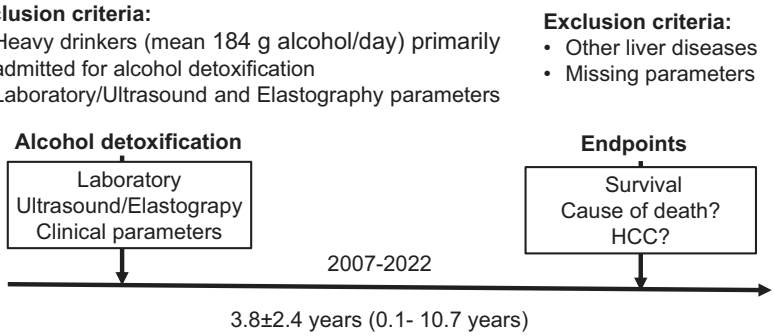

Fig. 7.1 Study design of the 15 year long-term prospective Heidelberg mortality study in heavy drinkers

2. At time of admission, a careful and standardized information sheet were obtained including, e.g., reported daily drinking, duration of heavy drinking, type of alcoholic beverages etc.
3. Furthermore, morphometric data such as weight, comorbidities such as hepatitis C infection, diabetes, smoking status were systematically obtained.
4. In addition, a complete set of routine laboratory data was taken without any preselection of parameters to remain hypothesis-free.
5. In all patients, fibrosis stage and hepatic steatosis was characterized noninvasively based on first a standardized abdominal ultrasound and, second, liver elastography. Transient elastography (Fibroscan, Echosens, Paris) was used to measure liver stiffness and controlled attenuation parameter (CAP). The inclusion of liver elastography from the very beginning guaranteed a complete recording of all fibrosis stages (F0-F4) in contrast to biopsy-based studies. As is shown in Fig. 7.4, biopsy-based studies tend to select tentatively more progressed patients. In addition, liver biopsy is known to have a 10% higher sampling error as compared to elastography with regard to fibrosis staging [30].

Limitations

Nevertheless, this prospective study approach still contains limitations and biases that have to take into consideration for the interpretation of data. Since only Caucasians were enrolled ethnicity could not be explored. Even the setting of alcohol withdrawal in a hospital may include some study bias since only a certain fraction of heavy drinkers may decide to undergo alcohol detoxification under such conditions. In addition, typically for a heavy drinking cohort, we did not manage to obtain in all patients survival status (60% with survival status) and only in 20% a cause of death was obtained with some uncertainties. The biggest challenge, also for

our study, remains the complete medical information about the deceased patients. In none of them, an autopsy was available or could be initiated.

Descriptive Data of Prospective Mortality Study in Heavy Drinkers

Initial patient characteristics at study enrolment are shown in Tables B.1 and B.4. Figure 7.2 shows the descriptive survival data. Briefly, patients were Caucasian heavy drinkers (184 ± 122 g/day) who underwent alcohol withdrawal with a mean heavy drinking duration of 14.4 ± 9.8 years. All patients had initially signed an informed consent. Mean age was 52.2 ± 11.2 years. Age distribution is shown in Fig. 7.3. Figure 7.4 shows fibrosis distribution for both the histologically (left) and non-invasively characterized patients (right panel). This figure underlines the importance of non-invasive fibrosis assessment by liver elastography. While only 4% had normal livers in the biopsy cohort, it was 10 times larger with 40% in the elastography cohort. In other words, both patients and physicians are less likely to undergo an invasive, complication-associated diagnostic procedure, if no objective or subjective signs of illness are present.

Of the initially enrolled 1264 patients undergoing alcohol withdrawal from 2007–2022, some had comorbidities such as viral hepatitis (n = 80, 6.3%) and in 107 cases (8.4%), no contact information was available. This resulted in a total number of alcohol withdrawal patients of 1077 (90.9%). Survival status on follow-up was obtained by multiple measures by a medical study team. In most cases, patients or their general practitioners were directly contacted by phone or mail. In some cases, hospital data or registry data could be used. In 803 patients (63.5%), all-cause survival status and in 786 patients (62.2%) the observation interval could be obtained. Age-related all-cause mortality is shown in Tab. 7.2. In summary, 159

Preliminary data (n = 803) are from the ongoing prospective study initiated in 2007 in Heidelberg. Age and gender adjusted. Please note that more patients are used in this table including those which did not have an observation time. However, these patients could not be used for Cox regression analysis

patients (20.2%) had passed away during a mean observation interval of 3.8 years (1–15 years, median 3.5 years). The cause of death could be clarified in 76 of them (47.8%) (Table 7.3).

Mortality Hazard Ratio of Heavy Drinkers in Comparison to the General Population

Mortality hazard ratio (HR) data are shown in Table 7.2. The total number of deaths of 20.2% corresponds to an annual global death rate of 4.8% and, thus, is similar to previous data from the above mentioned meta-analysis [5]. Age adjusted, in Germany, 1.2% had passed away, resulting in a relative risk of 3.8 (RR) which also corresponds well with the previous meta-analysis [5]. For women, RR is slightly higher (3.9) as for men (3.5). For the age intervals <40, 41–50, 51–60, 61–70 and >70, drastic differences were observed: 45.0, 26.1, 10.3, 5.1 and 0.6. Thus, heavy drinking has a much higher RR for mortality at a younger age shows while no differences are seen >70. Although these RRs are in line with other reports [5, 8], they are generally much higher.

Below the age of 40, 91% smoked, corresponding to only 19% at the age higher than 70. However, the mortality HR did not change significantly when only looking at non-smokers.

Cause-Specific Death

A specific cause of death could be obtained 47.8%. Cause-specific death data is shown in Table 7.3. About one third clearly died of liver-related causes due to liver cirrhosis. Initial liver stiffness (LS) was 40.1 as compared to 22.3 kPa in patients who died seemingly without a liver-related cause. The rather high liver stiffness (see Table 7.3), however, suggests that at least in some subgroups, liver may also have been contributed to death such as in the group with cardiovascular-related death (LS = 31.6 kPa) and certainly with infection-related death (53.1 kPa). Notably, rather low LS values were seen in the groups with brain- and cancer-related death (3.7 and 8.7 kPa), while interim LS values were seen (ca. 20 kPa) in the accident-, suicide and lung-related death cohorts. Notably, LS was similar (even slightly lower) in the patient's subgroup with known cause of death and those without (27.4 vs. 33.8 kPa). Importantly, initial LS was drastically lower in those who had survived (16.0 vs. 30.9 kPa). In the light of how in practice causes of death are diagnosed, we are aware that there are potential errors. In addition, there were a few overlaps such as HCC which were assigned both to liver-related death and cancer-related death. It also remains unclear whether the infection of lung-related death

Table 7.3 Cause-specific death in heavy drinkers (preliminary analysis)

Parameter	N	Percentage (%)	Age	Liver stiffness (kPa)
Survival status available	786	66.4	52.4	17.9
Alive	627	79.8	51.6	16.0
Death	159	20.2	57.5	30.9
Cause of death known	76	47.8	59.2	27.4
No cause of death	83	52.2	55.9	33.8
Liver-related	26	34.2	57.3	40.1
Cardio-vascular	13	17.1	31.6	31.6

Suicides	6	7.9	49.4	21.5
Lung-related	6	7.9	62.1	19.5
Infection-related	5	6.6	60.9	53.15
Brain-related (stroke etc.)	5	6.6	60.1	3.7
Accidents	2	2.6	60.7	25.3

Preliminary data (n = 786) are from the ongoing prospective study initiated in 2007 in Heidelberg. Note that number of patients are slightly smaller as shown in Fig. 7.2 since only patients with known observation interval were used. Mean liver stiffness values are shown

was due to manifest liver cirrhosis. Initial liver elastography data are highly suggestive of this association.

Univariate Spearman Rho Correlation and Cox Regression Analysis with Prognostic Parameters: Hemolytic Anemia Determines Long-Term All-Cause Death in Heavy Drinkers

We next analyzed the prognostic value of routine laboratory parameters in 786 heavy drinkers for all-cause death. As is shown in Table 7.4, in **univariate correlation analysis**, besides alkaline phosphatase (AP), RBC count showed the highest and negative association with long-term survival. In other words, anemia is tightly related with long-term mortality. Among other markers of the RBC compartment, RBC count was better than hemoglobin and hematocrit. Apart from AP, markers of anemia were notably better than known other prognostic markers such as albumin, INR or bilirubin. Table B.10 in Appendix shows Spearman Rho correlation with death for all parameters including special laboratories.

Multivariate analysis confirmed that a low RBC count is an independent predictor of death (Table 7.5). Anemia in response to chronic alcohol exposure can have multiple causes ranging from iron deficiency due to blood loss up to inflammation. However, a closer look at Table B.10 suggests that the anemia rather showed typical characteristics of hemolytic anemia. Thus, levels of the hemolytic enzyme LDH, the iron marker ferritin and the end product of heme production, bilirubin, were all positively and significantly associated with long-term death. Moreover,

An $n = 733$ were include in the univariate analysis with 127 deceased patients. For the multivariate analysis, data from 677 patients could be used

death also correlated highly with large sized RBCs, as indicated by the mean corpuscular volume of RBC, also called MCV and a typical hallmark of drinkers. To further confirm the nature of anemia, we also measured the levels of unconjugated or indirect bilirubin, the end product of hemolysis and precursor of conjugated bilirubin, and the soluble hemoglobin-haptoglobin scavenging receptor CD163 that reflects macrophage-mediated erythrophagocytosis. Both markers showed the highest correlation with death ($r \sim 0.25$) only being surpassed by RBC count and AP. In conclusion, long-term follow up in our prospective cohort of heavy drinkers identifies signs of hemolytic anemia as predominant predictor of death.

Kaplan Meier Plots in Order to Prepare a Survival Risk Score for Heavy Drinkers

Figure 7.5a shows Kaplan Meier plots for major parameters from the multivariate analysis above (Table 7.5). Albumin and transferrin were also included due to their known high prognostic values in patients with ALD but number of patients was smaller (n = 400). Kaplan Meier plots were calculated based on the median of each parameter (low versus high). Figure A.86 shows separate Kaplan Meier plots with the indicated median values used for stratification. As can be seen from Fig. A.86, parameters such as LS, Albumin and transferrin show a continues spread that improves further when looking at longer time periods >5 years. RBC count, bilirubin and AP show a less pronounced spread which is fairly similar over the whole observation time. Transaminase levels ALT and AST but also GGT perform poorly. Interesting enough, total protein also performs much poorer as specific proteins such as albumin and transferrin, indicating that other proteins may compensate for decreased albumin levels. Although Fig. 7.5a is quite packed, it is clearly visible

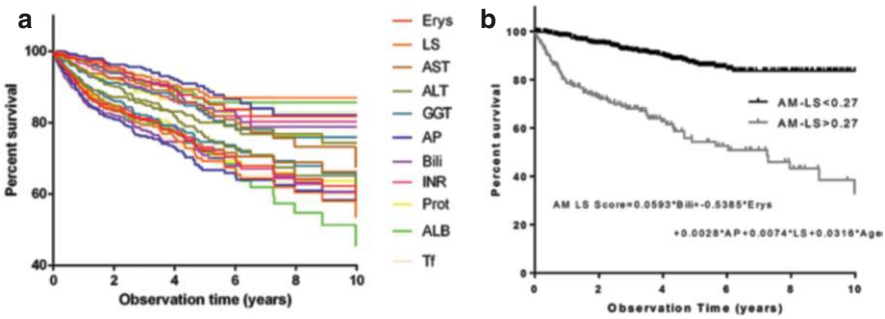

Fig. 7.5 Development of a long-term mortality risk score in heavy drinkers. (**a**) Kaplan Meier plots for the routine laboratory data identified by multivariate COX regression analysis. Although not part of the routine laboratory data, albumin and transferrin are included since they are of prognostic importance in heavy drinkers. Kaplan Meier plots for all parameters are independently depicted in Fig. A.86. (**b**) Alcohol mortality liver stiffness score (AM-LS) to predict long-term death in heavy drinkers. AM-LS score shows AUROCs of 0.7 for 7 years and 0.8 for 1 year

that low LS values are able to rule out death over the total observation time while specific parameters such as albumin stably predict death over many years. Unfortunately, albumin is not part of a routine laboratory.

Development of the Prognostic AM-LS Score

Since we lack an independent validation dataset, the development of a risk score from a multivariate model needs to be regarded with some precautions. For the development of our model, we focused on routine laboratory data, LS and age. In Table 7.5, the results of the univariate and multivariate Cox-proportional hazard model are shown. Accordingly, red blood cell parameters (bilirubin, erythrocyte count, hemoglobin, hematocrit), LS and alkaline phosphatase performed best for predicting overall mortality in this group of heavy drinkers. In contrast, transaminase and GGT levels performed poorly. To avoid overfitting, we only chose the 10 best parameters from the univariate analysis for the multivariate model. Additionally, since high correlations between parameters are problematic for multivariable analysis, we chose only the best parameter from groups of associated parameters. The selection was based either on univariate correlation analysis shown in Table 7.4 or for practical reasons. For instance, erythrocyte count was better correlated with mortality as hemoglobin or hematocrit and INR is more standardized between laboratories than Quick test or PTT. The final model included total bilirubin, erythrocytes, LS, AP, INR, LDH, cholesterol, total protein, age and CRP. With a forward stepwise approach, we identified total bilirubin (mg/dL), erythrocyte count (/pL), AP (U/L), LS (kPa) and age (years) as best and independent predictors for mortality with hazard ratios shown in Table 7.5. A risk score, here called Alcohol mortality (AM) score including LS (AM-LS) for the prediction of overall death in heavy

drinkers could be derived from those parameters. To calculate the score, the following equation can be used:

$$\mathrm{AM?LS} = 0.059 ? \mathrm{Bili\ total}\left[\mathrm{mg/dL}\right] ? 0.539 ? \mathrm{Erys}\left[/\mathrm{pL}\right] + 0.0028 ? \mathrm{AP}\left[\mathrm{U/L}\right] + 0.0074 ? \mathrm{LS}\left[\mathrm{kPa}\right] + 0.0316 ? \mathrm{Age}\left[\mathrm{years}\right].$$

The cutoff value determined through ROC analysis is 0.27. High risk patients would therefore be classified by a score value of >0.27 and low risk patients by a score value below 0.27. In our cohort, 179 patients are classified as high risk and 548 as low risk patients. 3-year survival rate for low and high-risk patients is 92.3% and 68.1% and 5-year survival rate is 86.6% and 54.2%, respectively. The relative risk of high-risk versus low-risk patients is 4.75 (3.34–6.75).

Figure 7.5b shows the Kaplan Meier plot for the AM-LS score. As compared to single parameters shown in Fig. 7.5a, it performs much better over the total observation time.

Table 7.6 shows the performance of the new AM-LS score with two other variants (logarithmized and AM score without LS) in comparison to known scores of liver cirrhosis or alcoholic hepatitis. Performance was calculated in 613 patients with all parameters ($n = 613$) and scores are sorted in descending order based on the *P* value of the Cox regression analysis. Area under the ROCs were calculated for the indicated years 1–7 using the Youden index. All three novel scores performed better

Table 7.6 Prediction of short- and long-term death in heavy drinkers by the developed alcoholic mortality score with and without liver stiffness (AM and AM-LS) in comparison to known scores of liver cirrhosis or AH

	Univariate Cox regression				AUROC				
Score	HR	HR lower 95% CI	HR upper 95% CI	p	Overall	1 year	3 years	5 years	7 years

CHILD POINTS	1.513	1.350	1.697	1.2E−12	0.624	0.745	0.672	0.641	0.653
MELD	1.129	1.091	1.168	3.1E−12	0.616	0.757	0.629	0.603	0.543
Forns index	1.282	1.189	1.381	8.0E−11	0.724	0.758	0.727	0.709	0.625
Maddrey	1.013	1.007	1.019	1.0E−05	0.601	0.698	0.607	0.569	0.530
Fib4	1.031	1.015	1.048	1.9E−04	0.708	0.740	0.733	0.704	0.650

Performance was calculated in 613 patients with all parameters (n = 613) and scores are sorted in descending order based on the P value of the Cox regression analysis. Area under the ROCs were calculated for the indicated years 1–7. Note that novel AM-LS score is especially better in predicting long-term survival (7 years) for patients without overt liver cirrhosis in abdominal ultrasound. **Scores: AM score** (alcohol mortality score without LS): Score = 0.03*Age + 0.0027*AP + 0.053 *Bili ± 0.549*Erys − 0.003*Platelets − 0.0034*Cholesterol; **AM-LS score** (alcohol mortality score with LS) = 0.0593*Bili ± 0.5385*Erys + 0.0028*AP + 0.0074*LS + 0.0316*Age; **AM-LS LN score** (logarithmized AM-LS: = 17.1 × LN(Age) + 7.8 × LN(AP) ± 18.9 × LN(Erys) + 2.1 × LN(LS) − 79.15 (for convenient calculation multiplied by 10 and subtracted by 79.15 from center around 0), Child points from the CHILD score, MELD score, Forns Index, Fib4 score and Maddrey's discrimination function were used for comparison

both for short- and long-term survival according to *P* values and AUROCs. For practical reasons, we finally asked the question how the scores perform in patients that have no signs of liver cirrhosis in abdominal ultrasound. Data are shown in Table 7.7. Again, the novel scores perform better (AUROCs 0.7–0.72) than established scores (AUROCs 0.56–0.7). The Forns Index performed best among the established scores (AUROC 0.7). Interestingly, addition of LS into the novel score improved slightly the long-term prediction of death in patients without ultrasound signs of liver cirrhosis. On the other side, the novel score without LS performed even better for the prediction of mid- and short-term death below 5 years. With the exception of the Maddrey score, conventional scores performed excellent for 1 year survival, Forns Index and Fib4 even better than the novel scores (AUROC 0.74 vs. 0.72). The rather poor performance of the Maddrey score is no surprise since it was designed for short-term prediction of death explicitly for patients with alcohol hepatitis which represent 2% of our total cohort.

Conclusion

We here present and discuss preliminary data from the first prospective long-term follow-up study in heavy drinkers with extensive initial patient characterization including abdominal ultrasound, liver elastography, and routine laboratory parameters. In 786 patients, all-cause survival status could be obtained. 159 patients (20.2%) had passed away during a mean observation interval of 3.8 years (1–15 years, median 3.5 years). The cause of death could be clarified in 47.8% and was liver-related in 34%, cardiovascular in 17%, cancer-related in 15%, followed by other causes. Based on available initial liver stiffness measurements, a liver-related death may even be as high as 50%. The age-adjusted relative risk of death (RR) of

MELD	1.051	0.966	1.142	2.5E−01	0.500	0.629	0.534	0.506	0.460
Maddrey	0.997	0.976	1.017	7.4E−01	0.531	0.502	0.489	0.552	0.432

Note that novel AM-LS score is especially better in predicting long-term survival (7 years) for patients without overt liver cirrhosis in abdominal ultrasound

the overall population was 4.0 corresponding well with previous meta-analyses. For women, RR was slightly higher (3.9) as for men (3.5). RR was especially high in patients younger than 40, reaching there a HR 45.0 (106 for females and 29 for males). Importantly, and to our surprise, both univariate and multivariate regression analysis identify liver stiffness and hemolytic anemia has major long-term predictors of death. These findings link alcohol-related all-cause mortality data directly to red blood cell toxicity. While LS is best associated with death using Spearman rho correlation without considering the observation interval, univariate Cox regression analysis identified erythrocyte count and bilirubin as best parameters. Finally, a score was derived to predict long-term death up to 7 years in heavy drinkers based on independent parameters upon multivariate regression analysis. This **alcohol mortality score** includes liver stiffness, erythrocyte count, alkaline phosphatase and age. It remains to be addressed in future studies, how this enhanced RBC turnover is related to alcohol-related liver and bone marrow damage. See also related Chaps. 37, 38, 41, 49, 57, 58 and 64.

Chapter 8
Legal Aspects of Alcohol Intake: A Romanian perspective

Alexandra Enache, Camelia Muresan, Veronica Ciocan, Ecaterina Dăescu, Denisa Gavriliță, Emanuela Stan, Ștefania Ungureanu, Alexandra Mihăilescu, and Raluca Dumache

Abstract Alcohol has been, is, and will be a serious health problem, both due to its adverse health effects and the medico-legal and legal implications. Gas chromatography combined with mass spectroscopy is the current state of the art method to assess blood alcohol levels. An analysis of blood alcohol levels from 2018–2021 in the Timisoara/Romania region demonstrated alarming levels of driving under the influence of alcohol. More than 83% of the drivers had a blood alcohol level > 0.8 g‰. A study on more than 2000 deceased people revealed elevated alcohol levels in 37–49% of all cases, some of which associated with murder, suicide, and fatal domestic violence. Complications of chronic alcohol consumption are also frequently seen in forensic autopsies including alcohol-related organ damage of liver, heart and brain.

Introduction

People have been manufacturing—and drinking—alcohol for nearly as long as the known human history. The term alcohol originally referred to a method of manufacturing a makeup and is derived from the Arabic *al-kuhul* or *al-kohl*, and it has been used with its current meaning since 1672. Chemical analyses recently confirmed that the earliest alcoholic beverage in the world was a mixed fermented drink of rice, honey, hawthorn fruit, and grape. The residues of the beverage, dated ca. 7000–6600 BCE were recovered from early pottery from Jiahu, a Neolithic village in the Yellow River Valley. Current data at the European level show that alcohol dependence remains at alarming levels (5.4% of men aged 18–64 and 1.5% of women). In Romania, there seems to be a decrease in alcohol consumption from 17.4 L (pure alcohol consumption) in 2000 to 12 L (pure alcohol consumption) in 2018 [1]. However, alcohol intake, both in drivers and in general population are worrying due to the high risk of road accidents or aggressions and also because of the long-term consequences.

Typical sources of ethyl alcohol (synonymously used with ethanol or alcohol) are alcoholic beverages with concentrations in the range between 0.5% and up to 95% (see also Appendix Fig. A.3). Alcohol concentration can vary significantly: beer 3.2–7%, wine 7.1–14%, whiskey 40–75%, vodka 40–50%, gin 40–85%, brandy 35–60%, rum 40–95% [2]. Accidental acute intoxication with ethanol, although used in massive quantities in various industries, analytical activities and therapeutic activities, is rather infrequently seen in the context of these professional activities. Most cases of acute non-professional intoxication, however, are due to alcoholic beverages used for recreational purposes.

Determination of Blood Alcohol Concentration

The determination of the alcohol concentration in the human body (blood alcohol concentration), according to Romanian legislation, is made only within the forensic institution [3]. In contrast, the assessment of the presence of alcohol in expired air is made by the traffic police using certifed devices. The respiratory elimination way is applied to new types of devices for determining the concentration of ethanol in expired air (e.g. alcohol test type Dräger). The breathalyzers can be category A (color indicators) with an accuracy of 20%, electronic devices category B with an accuracy of 5%, and breathalyzers that display the correlation ratio of breathalyzer and blood dosage. In case of elevated ethanol during a breath test, the respective person or driver must submit to the collection of IV blood sample to determine the concentration of blood alcohol concentration expressed in g‰. Biological samples are collected at the forensic institution or in other authorized medical institutions in the presence of a representative of the traffic police.

Concentrations of alcohol in the blood are usually given in grams of pure ethanol per liter [4]. Determining ethanol in biological samples by gas chromatography based on the principle of vapor space is a widely applied process worldwide, being introduced in analytical practice for over 50 years. It is also common worldwide practice to use two chromatographic columns in tandem to confirm the results in at least another column [5]. Today, gas chromatography is typically combined with mass spectrometry. At IML Timișoara, the method using gas chromatography–mass spectrometry (GC-MS) determination is applied for the biological samples collected from persons involved in various traffic incidents, from the victims of road accidents or other situations (suicides, suspicious deaths, intoxications). Figure 8.1, for example, shows a case from 2021 of proven lethal methanol intoxication as determined by GC-MS.

Many judicial decisions are influenced or completely depend on alcohol intake of accused or involved individuals. There is also a well-known association between violence and alcohol intake. Under the influence of alcohol, people may become more aggressive, resulting in family violence or domestic violence. Alcohol intake is present in many offenses of hitting or personal injury and is involved in many traffic accidents [6]. According to the current legislation in Romania, the blood alcohol concentration is determined after taking two 6 mL blood samples at an interval of 1 h [7]. Alcoholemia is determined only in the forensic toxicology laboratories within forensic medicine institutions, while alcoholemia determined in other clinical laboratories has no probative value in court. At the national level, the determination of blood alcohol is performed by the GC-MS gas chromatographic method, which is highly specific. Contamination is avoided by desinfecting the skin

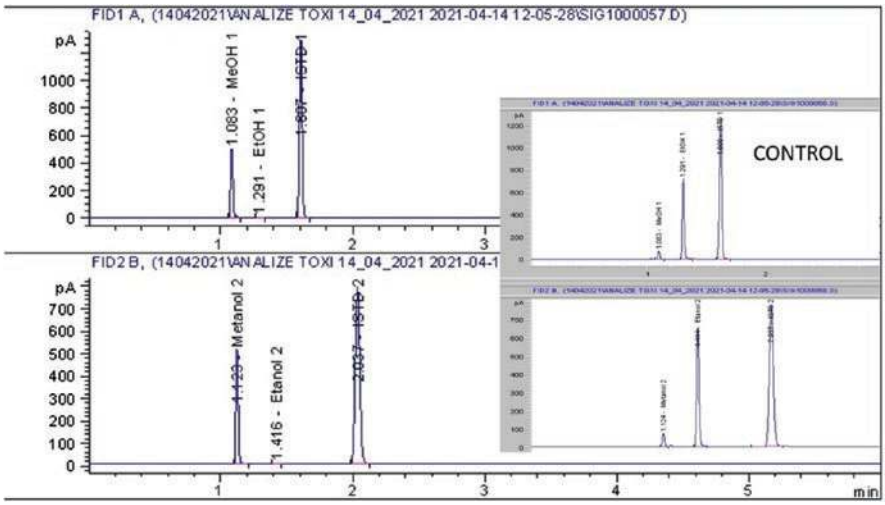

Fig. 8.1 Detection of ethanol and methanol in a blood sample using gas chromatography-mass spectroscopy. In this case, a lethal methanol concentration was confirmed

only with antiseptic substances such benzalkonium chloride or aqueous mercury chloride solution but not ethanol, ether, or benzene, respectively. In the context of crime investigations, due to postmortem transformations in the body, the alcohol concentration as measured by GC-MS depend on several factors including the elapsed time at death or concentrations of other molecules such as glucose and glycols [8].

Legislative Framework

In Romania, like in most other countries worldwide, there is a legal framework regarding the consumption and sale of alcohol. It is forbidden to sell alcohol to people under the age of 18. It is also forbidden to sell alcohol inside and near educational institutions of all grades, boarding schools, and accommodation for pupils and students, in the courtyards of these buildings and on the access roads to these units [9]. Regarding the alcohol intake by drivers, in Romania, the driving on public roads of a car or tram by a person, who has alcoholic imbibition over 0.8 g/L pure alcohol in the blood, is punished by the suspension of the driving license, fine, imprisonment from 1 to 5 years, while driving a vehicle or tram under the influence of alcohol (respectively with a blood alcohol level below 0.8 g‰) constitutes an infringement, sanctioned with a fine and suspension of the right to drive for 90 days. Thus, these Romanian legal provisions go in line with zero tolerance policy of alcohol consumption while driving. In addition, the refusal or opposition of a person who drives a vehicle on public roads, from collecting biological samples to establishing blood alcohol or expired air testing, is punishable by imprisonment from 1 to 5 years [9].

Forensic Features of Alcohol

Ethanol is a colorless, a volatile liquid with a specific smell and burning taste, has a density of 0.79 and boils at 78 °C [5, 10] (see also Appendix Fig. A.2). It is used as solvent, diluent or for synthesis in industrial laboratories, in medicine as an antiseptic and desinfectant, and in the food industry as an preservative, taste bearer or important food constituent for alcoholic beverages. Absorption begins in the oral cavity, followed by the stomach (ca. 20% of the absorption), and the rest in the upper part of the small intestine (for more details see also Chap. 50). The absorption rate depends on the amount and concentration of the drink, the fullness of the stomach, and the person's health state. Under conditions of an empty stomach, absorption is normally completed within 30 min, while 2 h are required a meal has been taking prior to consuming the alcoholic beverage. Other factors are also important for the absorption rate of ethanol: the type of drink (carbonated drinks are absorbed faster), the emotional state, concomitant drug use, and dietary measures, which can

cause oxidation of up to 20% of alcohol. Absorption is increased when the concentration in the stomach is 10–20% alcohol; above this concentration, there is irritation of the mucosa causing increased mucus secretion and slowing down absorption. After absorption, the alcohol is distributed through the circulation and diffuses passively within the various compartments. Organ concentraitons can be different to the blood alcohol. For instance, at a blood alcohol level of 1 g‰, ethanol levels in the brain will be 0.75 g‰ and in 0.85 g‰ the kidneys. Of note, higher concentrations will be found in cerebrospinal fluid and urine (1.25 g‰) due to accumulation of ethanol.

Besides hepatic metabolism under the influence of alcohol dehydrogenase (ADH), which handles about 90–95% of the total ethanol, the elimination of ethanol takes also place in the kidneys, the respiratory tract, and much less by perspiration, and tears. After ingestion, as mentioned above, alcohol reaches its maximum level within 0.5–2 h. Complete absorption occurs between 1–3 h. Blood alcohol level then start to progressively decrease at a constant rate of 0.15 g/h. Thus, the blood alcohol level can be calculated for a specific time retrospectively. The number of drinks ingested can be determined using Widmark's formula (Widmark factor reflects an estimate of the amount of water in the human body) and the value in grams of pure ethanol results [4, 10].

$$\text{Blood alcohol concentration} \times \text{G} \times \text{R} = \text{pure ethanol}\left(\text{G} = \text{body mass}; \text{R} = \text{Widmark factor}\right)$$

$$\text{Widmark's formula} = \text{quantity of ingested alcohol} \times 100 / \text{body mass}\left(\text{kg}\right) \times \text{Widmark factor}$$

For the transformation into volumes, it is divided by the density (0.79), and volumes are obtained. The maximum blood alcohol level appears 30–60 min after ingestion and is mirrored in the curve's ascending segment (1). Any element that affects the rate of absorption will affect the level of the maximum concentration of alcohol in the blood, the duration of the curve in the plateau (2), and the rhythm (3) of elimination of ethanol [4, 10, 11]. The blood alcohol level depends on the rhythm, quantity, and concentration of alcoholic drinks consumed, the time interval in which the alcoholic beverage is consumed, the degree of fullness of the stomach, the enzymatic capacity of the liver, the amount of water contained in the body [11]. Women achieve an increased concentration of blood alcohol at the same amount consumed and the same weight as men due to the difference in the amount of water in the body. Highly concentrated beverages with high sugar content slow down absorption, like beer. Certain medications may increase the blood-alcohol level or affect the rate of alcohol degradation by altering gastric absorption, inhibiting ADH, or acting on liver enzymes [10, 11].

Alcohol concentrations of the urine is used if blood samples cannot be collected both in living and deceased people. An urinary alcohol to blood alcohol ratio of 1.3:1 can be used as estimate [12]. In cases of acute ethanol intoxication, the blood alcohol levels vary from 1 to 3.5–4 g‰. Higher levels usually cause deep coma and soon death due to acute ethanol intoxication. In contrast, ethanol-mediated death

can occur in infants and young children at concentrations of alcohol as low as 0.4–0.9 g‰ [12]. Studies on the passage of alcohol through breast milk have shown that intake in infants depends on the characteristics of lactation and childs enzymatic ethanol metabolism potentially causing elevated ethanol levels. In some cases, the alcohol concentration in the vitreous humor is estimated, although the results are difficult to interpretate [13].

Clinical Examination in a Forensic Setting

In the forensic setting, clinical presentation depends on the type of consumption, duration, and the drink's characteristics. Since the psychiatric and neurological aspects of alcohol abuse are intensvely discussed in other book chapters of this book, they are only briefly mentioned here. Among forensic implications, in the context of driving drunk, we also see physical and mental aggression [12]. Between March 16 and May 15, 2020, decrees no. 195 and 240 established and from March 8, 2022, only forensic institutions were authorized to perform autopsies at the request of judicial institutions [14, 15]. During such autopsies, if prompted by the medical history or macroscopic leasionsm pneumonic changes, pneumonia, thrombi, inflammatory myocardial lesions, and other biological samples are collected. Pathological intoxication—occurs quickly after the intake of alcohol in small quantities. As expected, among alcohol users, the most common pathologies encountered during forensic autopsies are shown in Fig. 8.2 such as hepatic steatosis, liver cirrhosis, alcoholic cardiomyopathy and cerebellar degeneration. For more details the reader is referred to the respective Chaps. 38, 70 and 72 in the book on liver histology, alcoholic cardiomyopathy and and Wernicke-Korsakov syndrome. Determining the concentration of alcohol in the blood of people who have committed a crime helps to analyze and prove legal issues. Thus, acute ethanol intoxication evolves in progressive phases with typical characteristics [12] (see also chapters on addicition treatment). The phase of behavioral changes such as excitation usually occurs at blood alcohol levels of 0.30–1.20 g‰. In people with low enzyme equipment or low tolerance (infants, young children), death can occur at these levels. In the medico-legal between 1–2.5 g‰, aggressions, road accidents, and rapes can be noticed. In the coma phase, at blood alcohol levels of over 3 g‰, a person cannot normally not act anymore and most often is a victim. To specify the criminal circumstances, the consumption of alcohol is an aggravating factor in the acts committed under the influence of the drinks consumed [3, 16]. If a criminal act is committed by chance, without intention, acute alcoholism can decrease the perpetrator's liability. Consequently, drunkenness can legally decriminalize. Retrograde amnesia is essential in establishing the diagnosis, still challenging in daily practice. In late stages of alcoholism, with the onset of cognitive deficits, a person is no longer legally responsible.

Forensic Measurements of Alcohol: A 4-Year Experience in Timisoara/Romania

We have analzyed involvement of alcohol for various forensic scenarios for the years 2018–2021. In these 4 years, at the request of the police, a total of 371 ethanol measurements were performed and calculated back to initial alcohol concentration as described above. Only in 13 drivers (3.5%), a level below the criminal limit of 0.8 g was found, while in the remaining 358 cases (96.5%) the drivers remained offenders. In the same period, our forensic department also analzyed 2716 biological samples from deceased people for ethanol using GC-MS. The results are shown in Fig. 8.3 for four different alcohol ranges: 0 g‰, below 0.8 g‰, between 0.8–2 g‰ and higher than 2 g‰. As can be seen in this figure, in the years 2018–2021, an elevated blood alcohol concentration was seen in 27–49% of all deceased people. Among the deceased people with elevated alcohol were murders, suicides but also victims of domestic violence. Figure 8.3 also shows the routine measurements from drivers. A total of 2746 samples were collected. In these 4 years, most drivers,

	BAC death/2018	BAC alive/2018	BAC death/2019	BAC alive/2019	BAC death/2020	BAC alive/2020	BAC death /2021	BAC alive/2021

Fig. 8.3 Blood alcohol concentration (BAC) in living and deceased persons, collected from 2018–2021. Four different alcohol ranges are shown: 0 g‰, below 0.8 g‰, between 0.8–2 g‰ and higher than 2 g‰

between 85% and 89%, constantly had too high alcohol levels proving a violation of the road code. In conclusion, in the forensic setting, alcohol plays an important role either in the context of deceased people but also in the forensic setting of traffic violations.

Conclusions

In conclusion, alcohol has been, is, and will be a serious health problem, both due to its adverse health effects and the medico-legal and legal implications. Alarming levels of driving under the influence of alcohol are emerging—over 83% of the drivers had a blood alcohol are emerging level over 0.8 g‰. Our analysis also shows the importance of ethanol determination by GC-MS. Complications of chronic consumption occur in a large number of deceased cases and are associated with damage to several organs (liver, brain and heart).

Chapter 9
COVID-19 and Alcohol Use Disorder

Miriam Gill and Jonathan Chick

Abstract Lockdown measures introduced in many countries during the COVID pandemic had the expected effect of moving sales of alcohol to sales in supermarket and via home delivery. However, other effects of lockdown—isolation, working from home, stress—appear to have led in some countries to a new sub-group of drinkers who moved from heavy to harmful drinking. Also, those already drinking harmfully tended to drink more with exacerbations in accompanying mental illness revealed in some studies. Where demographic information was available, increased drinking was reported more by women than by men. There is speculation that more drinking at home, in many countries, will have meant that a generation of children will have witnessed more parental drinking.

In communities where there were temporary total bans on alcohol, there was a surge in cases of severe alcohol withdrawal reported by some centres, whereas trauma, assaults and accidents seen by Emergency Departments reduced. Data on hospitalisations in the UK and USA showed that admission for alcohol related liver disease increased during the pandemic and there was a rise in alcohol-specific mortality but it is possible that this might in part have been a continuation of trends in both countries seen in the preceding decade. This chapter will look at how consumption behaviours changed, who were most affected, how alcohol use may have predisposed an individual to COVID-19 infection and where the pandemic left those suffering from alcohol use disorders.

Introduction

Globally, harmful alcohol use is responsible for around three million deaths every year (5.3% of all deaths) and amounts to 5.1% of the global burden of disease [1]. Alcohol consumption is also linked to over 200 different diseases and other alcohol related health-harms such ranging from liver disease to mental and behavioural disorders. Importantly, drinking alcohol can predispose individuals to contracting infection [1, 2]. Alcohol consumption is an important indicator of health and many governments have struggled over the years to try and limit its damaging effects. In the UK, there are laws that include the legal age of consumption, when and where alcohol can be sold and prohibited activities when under the influence [3, 4] For more details see also Chap. 10. Scotland went one step further and introduced minimum unit pricing (MUP) in 2018 which set a base price for alcohol at a minimum of fifty pence per unit (corresponding to 8 g pure ethanol) [5]. Scotland and many other countries restrict the hours in which alcohol is sold and where it can be consumed. All these laws and restrictions were designed to try and reduce harm that could be attributable to alcohol consumption as well as having an impact on individual behaviour.

On 9 January 2020, the World Health Organisation (WHO) announced that a novel coronavirus had been identified in Wuhan City, Hubei Province, China. In February, the coronavirus was given its formal title of SARS-CoV-2 and the disease it caused was named COVID-19 [6]. On 11 March 2020 the WHO declared a global pandemic, but it was not until the 23 March 2020 that the UK Prime Minister announced strict measures to try and curb the spread of the virus [7]. Everyone was instructed to stay at home and shops and venues that did not sell essential items—such as food and medicine—were closed. However, in the UK alcohol was still available through the 'essential' shops even though entertainment venues, such as pubs and bars had closed. These 'lockdown' restrictions were rolled out across the UK and implemented for a number of months. They were reimposed in October 2020 until March 2021 [8]. Despite these measures, the UK was relatively hard hit by the virus and suffered many deaths. COVID-19 brought about change in mortality and in people's behaviour around the world.

Over the course of the pandemic, particularly through the initial stages of lockdown, there were changes to alcohol consumption. This chapter will look at how consumption behaviours changed, who were most affected, how alcohol use may have predisposed an individual to COVID-19 infection and where the pandemic left those suffering from alcohol use disorders.

Alcohol Sales

One of the most significant restrictions that was put in place in many countries in Spring 2020 was the closure of restaurants, bars, and pubs (in the UK termed on-trade). It meant that for some months following the announcement, sales of on-trade

alcohol decreased until the restrictions eased later in the year. However, that is not to say that some licensed on-trade establishments were unable to make any sales—many businesses remained open and sold through means of take-away services [9]. Despite these take-away sales, it was not enough to off-set the total loss of the closure of on-trade premises. In Scotland, research published by Public Health Scotland investigated the impact of the national lockdown and the COVID-19 pandemic on alcohol use across England, Wales, and Scotland, using an earlier study that compared the sales of on- and off- trade premises (i.e., shops and supermarkets) during lockdown to sales in the same weeks in the 2 years previous (2017–2019). The study found that the total volume of pure alcohol sales across the three countries decreased by 6%. This was attributed to the loss of sales from on-trade premises [10, 11].

However, there was an increase in off-trade sales, particularly in Scotland, where nine in every 10 units of alcohol were sold through off-licence trade in 2020 compared to seven in every 10 units in 2019 [12]. Sales in supermarkets and off-licence shops increased in Scotland by 28% and in England by 29% [11]. In 2020, 90% of all alcohol purchased was from off-trade retailers and in the same year per-adult off-trade sales in Britain were between 16–18% higher than in 2019. On-trade sales were between 59–64% lower compared to 2019 [12].

An analysis of UK household purchases during lockdown showed that households did not buy any more alcohol than would have been expected for that time of year. This is after adjusting for what would have normally been purchased from on-licence establishments [13, 14]. In the first 3 weeks of lockdown in 2020, excess purchases increased but then plateaued. This is important as although it could suggest stockpiling in the earliest part of the introduction of restrictions, it does not seem to have continued any further than the initial month. Looking particularly at what was being purchased, there seemed to be a change from buying lower strength alcoholic beverages to higher strength wines and spirits [13].

Comparing areas by social deprivation, excess purchases of alcohol were higher in the most deprived households. As the quantity of alcohol normally purchased by a household increased, so too did the number of excess purchases increase. It was estimated that within the top one fifth of households that previously purchased large amounts of alcohol, their purchases increased by over 17 times more than an equivalent number of households that purchased the least alcohol [15].

Across the Atlantic, an American study found large increases in alcohol sales from the beginning of March 2020 to the middle of April. Sales for alcohol from off-licence premises—'liquor stores'—had increased by 21% and online sales of alcohol had increased by 234% in comparison to a similar period in 2019. However, the data did not show whether these sales resulted in increased household consumption or whether it was a stockpiling measure [16].

Alcohol Consumption

Lockdown saw changes to people's behaviour, and it was hypothesised that these changes in behaviour could be reflected in changes in alcohol consumption. In a British study by Public Health Scotland, members of the public were surveyed through behavioural questionnaires and diaries that would highlight any changes in drinking habits. It was concluded that the number of drinking days had on average increased during the restrictions, however, the change was not significant [10].

A large-scale cross-sectional study looking at alcohol consumption in 21 countries in Europe suggested that there was decreased alcohol consumption during the start of the pandemic [17]. This may be due to the home being the only place people were able to drink. The closure of bars and pubs but also the restrictions of events that would previously have promoted heavier drinking, e.g., weddings, parties, concerts etc. may have had a curtailing effect. Reduced alcohol consumption may also have been due to reduced affordability from recent unemployment and financial instability. However, it was also commented that frequent and heavy drinkers tended to increase consumption rather than decrease it, while lighter drinkers tended to decrease their consumption [17].

From this European study, the UK was highlighted as being the only nation with a significant average increase in alcohol consumption. The frequency of consumption remained relatively unchanged in seven countries including Denmark and France, and the quantities of alcohol consumed remained the same in Germany and Ireland. It is interesting to note that compared to the UK, Ireland did not have any significant increases in drinking frequency or quantities consumed per occasion. Additionally, heavy episodic drinking (HED) events decreased in all countries except the UK where it stayed the same. It is worth drawing attention to the fact that the United Kingdom appears to be one of the only countries in Europe where off-licence shops (what in USA or Australia might be termed 'liquor stores') were deemed 'essential' in the list of premises allowed to stay open during the start of lockdown. One of the arguments made for recognising alcohol as being an 'essential' item was to prevent severe withdrawal in people suffering from alcohol use disorder. However, off-licences remaining open and home delivery and supermarkets also allowing the sale of alcohol probably contributed to increased at-home consumption in the UK [17].

Data from Public Health England showed that the majority of their respondents were drinking the same amount and no more frequently than they were before the pandemic. In fact, data suggested that as many respondents who had increased consumption had decreased it [18]. This data alongside the data by Public Health Scotland do appear to differ in comparison to the results published from the European wide study. In the European study only 836 respondents were from the UK out of 31,964 total respondents [17]. This suggests that it was perhaps not a fair representation of UK changes in consumption during the pandemic.

However, data from Public Health England did show that those respondents who had been drinking more during the pandemic tended to be already heavier drinkers.

Between 2020 and 2021, there was a 58.6% increase in the number of respondents drinking at higher risk levels [18].

A study by Alcohol Change UK surveyed 1555 people, 2 weeks after initial lockdown measures were imposed, and found that more than a third of participants had either stopped drinking completely or reduced how often they drank. There were around a fifth of participants who were drinking more frequently and were also drinking more per drinking day since the beginning of lockdown. This leads to a hypothesis that the pandemic has seen the development of a new sub-group of drinkers that were potentially developing harmful alcohol consumption habits [19].

This harmful pattern was further commented on by a survey carried out by the St Mary's Hospital Alcohol clinic on patients with pre-existing alcohol use disorders. The survey found that of the participants who had increased their alcohol consumption during lockdown of 2020 (24% of participants), there had been a mean weekly consumption of 82.5 units. The weekly recommended intake is no more than 14 units. These participants also had a 57.6% mean increase in AUDIT score. Overall, these studies suggest that, despite there being as many people reducing their alcohol intake as increasing it, those increasing their consumption are doing so by a significant and harmful amount [20].

In a Canadian study similar patterns emerged over the course of the pandemic. Individuals who reported decreases in alcohol consumption showed significant decreases, but individuals who reported increases in alcohol consumption showed significant increases. Data showed that there were as many participants who had increased consumption during the pandemic as had decreased. Those who reported an increase in alcohol consumption, showed a 161.5% increase in heavy drinking days (HDD). HDD was referred to as more than three drinks for females and more than four for males. A 37.2% increase in alcohol-related problems was also commented on, particularly PTSD symptoms. This suggests that within the group of those significantly increasing their drinking, more are likely to suffer from marked mental health changes [21].

Demographics of Alcohol Use

When identifying the individuals who may be most at risk of drinking harmfully, recent UK data collected by the National Health Service (NHS) found that the age group with the highest proportion of people drinking over the weekly recommended units were aged between 55 and 64. This applied to both men and women [22].

However, over the course of the pandemic, changes in consumption were found to be most evident in adults aged between 25 and 49 years, and those with middle or high incomes [13, 23]. In a survey for Alcohol Change UK, over a quarter of respondents agreed they had increased consumption over lockdown. Of those respondents the majority were in employment, from higher socio-economic groups, younger drinkers and heavier drinkers [13]. Interestingly, it was observed that women seemed to be drinking more [23]. It is surprising that women appear to have

increased their consumption during the pandemic when often those suffering from heavier intake or alcohol use disorders are typically younger males [11, 24]. An Australian study also commented on women being more likely to increase alcohol consumption compared to men. This was shown to be especially true when women were having to cope with conflicting work and family commitments. These conflicts may have become more frequent or pronounced during lockdown restrictions as schools were closed and children required more supervision and schooling at home [23, 25].

A study from the US showed 14% more alcohol had been drunk by Americans in that year. Amongst women there had been a 17% increase in consumption and 19% more amongst people aged between 30 and 60. The consumption of large amounts of alcohol amongst women—'large amounts' equating to four or more drinks within 2 h—had increased by 41% [14].

Younger drinkers were previously mentioned by Alcohol Change UK as a group that had increased consumption. Additionally, it was noted that excess alcohol purchases from off-licences were higher for younger shoppers. However, it is possible that younger people were buying for older people who were isolating or shielding at home due to greater vulnerability of contracting the virus [13].

When looking at the effects of lockdown on students and young adults, the closure of universities and many students moving from university accommodation to their parents appeared to have a significant impact on alcohol consumption. A study from the University of New Jersey found that when students moved from living with peers to living with parents, there was a significant reduction in the number of drinking days, the number of drinks per week and the number of drinks consumed in 1 day. This suggests that returning to live with parents, especially during the context of the COVID-19 pandemic, was a protective factor against heavy drinking [14, 26]. This could also be attributed to pubs, clubs, and other social spaces being closed which would have prevented socialising between young adults [26, 27].

Interestingly, in the last two decades there has been a decline in general alcohol consumption of the younger generation in the UK and other high-income countries which has translated into reduced mortality amongst adults. The same cannot be said for the 55–84 age bracket which has seen an increased mortality rate of between 23% and 49% [28]. However, the study did highlight that for students who did not change living circumstances and who remained in the same households they were living in prior to the pandemic, the frequency of consumption increased [26, 29].

In Germany, a study found there was a 6.1% increase in total revenue of alcoholic beverages compared to equivalent weeks in 2019. The study identified that the age group seemingly drinking more alcohol was between 35–44 years. The groups drinking less fell into the 18–24-year age bracket and those living with parents or alone [30]. This is interesting as it was thought that living alone may be an exacerbating factor for heavier intake [23]. In a previous study looking at drinking habits post-natural disaster, living alone was associated with increased drinking. Despite a similar hypothesis for the COVID-19 pandemic, there did not seem to be significant differences between individuals living alone and other groups. It is possible that

those living alone often went out to drink in order to socialise. Without this option during restrictions, it may have prevented an increase in drinking [23].

An additional study from Poland also commented on this by finding that most participants drank less if they were single and without children. The thought of individuals with children increasing intake more than individuals without children is potentially concerning as it could suggest a generation of children who will be more familiar with the sight of parents or guardians drinking at home. If these parents/guardians have fallen into the category of drinking significantly more than before the pandemic, it may impact the child's view on what is an appropriate amount to drink [27]. A study in Canada showed that amongst Canadian teenagers who had reported a decrease in binge drinking, cannabis use and vaping directly after lockdown restrictions were imposed, almost all reported drinking alcohol at home with their parents which was regarded as more acceptable behaviour [14].

In the German study, participants who were considered less educated—having completed less than 11 years of education—seemed to be drinking more, but unemployed participants were either drinking the same amount as pre-pandemic or less. Participants who had experienced changes in employment during the course of the pandemic either drank more or drank less. In this group there were significant differences in consumption either for better or for worse. The groups identified in having a higher risk for increasing alcohol consumption during lockdown included: middle-aged participants, participants who drank heavily before the pandemic, those under considerable stress because of the pandemic and those who were less understanding of the rationale behind stricter lockdown restrictions [30].

Causal Factors Behind Drinking Patterns

Historically, global crises in the form of mass terrorist attacks, previous epidemic outbreaks or economic adversity—such as the 2008 Great Recession—have been associated with increased alcohol use [14, 23]. This increased alcohol use is believed to be in response to psychological trauma and elevated periods of stress and anxiety [23]. During the pandemic, stress and anxiety have been identified as exacerbating factors that have led many individuals to increase their alcohol intake [31, 32]. Strict lockdown measures forced whole populations into social isolation and gave rise to fears over job security and financial stability. Consumption of alcohol in particular has been recognised as a coping strategy to help with feelings of isolation and insecurity. There are many studies that show respondents who were reporting feelings of loneliness and stress were also more likely to report an increase in alcohol consumption [13, 16, 20, 31–34]. In a study looking at mental health during the COVID-19 pandemic and substance use, women were recognised as more likely to report poorer mental health and more likely to consume alcohol in order to cope with emotional distress [32]. Responsibilities of the home are most often carried by women and having to juggle children being kept at home as well as personal affairs may have contributed to higher stress levels [23].

A study in America commented on different reasons that either drove participants to increase their consumption or to decrease it. Almost two-thirds of participants of the study reported an increase in consumption in comparison to before the pandemic. Of this group, the majority cited increased stress as a cause of drinking more and the rest cited increased availability of alcohol and boredom. Of the participants who reported to have decreased consumption, reduced alcohol availability, less free time, less money and the desire for a healthier lifestyle and concerns over the impact of alcohol on mental health were all cited as reasons for decreasing alcohol consumption during the pandemic [16, 31]. Similarly, a study from Canada reported that the main reasons for individuals increasing their drinking was the absence of normal daily routine, boredom, and stress [14]. In Greece, participants also cited isolation, changes to everyday routine and symptoms of anxiety and depression to explain why consumption was increased [14].

Mental health is an important issue when looking at the effects of increased alcohol consumption. A Polish study found that participants who were drinking more than before the pandemic were experiencing significantly poorer mental health. This was exhibited by struggling to cope with everyday function, finding less satisfaction in their daily life and suffering from depressive symptoms [27].

Alcohol-Related Hospital Admissions and Death

Data taken from national statistics from England and Wales estimated that over 8.4 million people were consuming alcohol at a high-risk level during this pandemic. This is in comparison to the 4.8 million before the first lockdown in Spring 2020. The UK Government has published data showing that the rates of unscheduled admissions to hospital for alcohol specific reasons in 2020 fell by 3.2% compared to before the pandemic [11, 35]. This is thought to be related to reduced admissions for alcohol attributed psychiatric and behavioural problems. Additionally, the most rapid decrease in admission rates corresponded with the beginning of the pandemic and the occasions of greatest restrictions in the UK [35].

However, unplanned admissions for alcohol-related liver disease (ALD) increased between 2019 and 2020 by 13.5% and have continued to increase over the course of the pandemic [35]. A tertiary liver centre in London reported a twofold increase in admissions for ALD and an additional marked increase in patients requiring high dependency or intensive care—an increase of between 11% to 24% [11, 36]. This implies that people are more seriously ill on admission. Periods of lower admission rates were at the time of greatest restriction. This was from when fewer people presented to hospital, probably through fear of contracting the virus at times where the virus was highly prevalent, or through strictly adhering to the ‘Stay at home’ messages from government and images of hospitals being overwhelmed by COVID-19 patients. The unfortunate irony of this is that patients with ALD who contracted COVID-19 were likelier to suffer worse outcomes than a COVID-19 patient who did not have similar alcohol related problems [11].

Alcohol related emergencies had also increased which included alcohol withdrawal and related suicides [37]. In Scotland, recent published data found decreases in hospital stay rates for ALD and alcohol-related mental and behavioural disorders by 9.2% and 7.5% respectively compared to 2017–2019. However, hospital stays for alcohol toxicity were 6.7% higher. The rate of alcohol-related hospital stays decreased for males by 10% but did not change for females and the most significant decreases were found in the oldest age groups and in the most deprived [38]. This is interesting as patients from lower socio-economic are often shown to have worse alcohol-related outcomes [11], however, there was not as great a reduction in hospital stays for the least deprived groups [38]. This could be potentially because patients from higher socio-economic backgrounds have greater access to secondary care and are more likely to seek such care [11].

According to the UK Office for National Statistics (ONS) in 2020 there was an 18.6% increase in deaths from alcohol-specific causes recorded in the UK compared to 2019: 14.0 deaths per 100,000 people in 2020 compared to 11.8 per 100,000 people in 2019 [39, 40]. This was the greatest year-on-year increase since 2001. Alcohol-specific deaths have also significantly increased across all four UK nations compared to relatively stable rates across 2012–2019. The term alcohol-specific death was used interchangeably with 'wholly attributable death' (due to alcohol) and encompassed three main areas: alcohol-related liver disease, mental and behavioural disorders, and external causes (e.g., accidental poisoning relating to either direct alcohol intoxication or exposure) [39]. There has been an 10.8% increase in deaths related to alcohol attributed psychiatric and behavioural disorders, and a 15.4% increase in deaths from alcohol poisoning [35]. Alcoholic liver deaths made up 80.3% of total alcohol specific deaths which equates to a 20.8% increase between 2019 and 2020. There had already been an upward trend in the number of deaths from ALD, however the pandemic seems to have accelerated this [35, 40]. In December 2020, the ALD death rates were 58.1% more than the comparable baseline month [1]. It is also worth highlighting that of liver disease in the UK, ALD accounts for 60% of all cases [40].

Scotland and Northern Ireland were seen to have the highest alcohol-specific death rates for 2020, but it was England and Scotland that showed the most statistically significant increased rates compared to 2019 [39]. In Scotland, there was a 9% increase in the number of alcohol-specific deaths recorded in 2020 compared to the average number between 2017–2019 [38]. Public Health Scotland calculated the age-sex standardised rate of alcohol-specific deaths in 2020 to be 22.0 deaths per 100,000 people. This is 8% higher than the average calculated for 2017–2019 [38].

It was noted that at the beginning of 2020, alcohol-specific death rates were below average for that seen in the same months of 2017–2019. These rates rose above average from the start of restrictions in March and continued to rise over the summer until rates peaked in October. For the same month in 2017–2019, rates were around 30% higher [38]. The female death rate was under half of the rates for males, with males making up over two thirds of the total alcohol-specific deaths. The most common age groups affected were people in their 50 s and 60 s and it was areas of

greatest deprivation that had 4.3 times the death rate compared to those in the least deprived areas [41].

Additionally, although cirrhosis of the liver due to alcohol can take at least a decade to develop, most deaths happen in response to recent alcohol consumption resulting in acute-on-chronic liver failure (ACLF) [18]. Acute-on-chronic liver failure is a syndrome defined by an acute deterioration of chronic liver disease which is associated with organ failure and mortality [35, 42]. For more details, see also book Chap. 67 on ACLF but also alcoholic hepatitis (AH) Chaps. 64, 65, and 66. Heavy drinking is strongly linked with ACLF. Over the last two decades there has been a 43% increase in liver mortality rates in England and it was recognised as the second leading cause of premature death amongst the working population. Liver mortality was already a growing issue before the pandemic however it is likely that the pandemic has exacerbated these problems [18, 35].

Across the Atlantic, research published from the US looking at alcohol-related deaths during the first part of the pandemic found that between 2019 and 2020, the number and rate of deaths attributed to alcohol increased by approximately 25%. There had been suggestions of a steady increase prior to the pandemic, however the pandemic has appeared to exacerbate these numbers. Additionally, the increased rate of alcohol-related deaths in this time period surpassed the 16.6% increase in all-cause mortality [43].

Effects of Alcohol on the Body in the Context of COVID-19

Both the long- and short-term effects of excessive alcohol consumption have been widely reported. The immediate effects of heavy drinking commonly present as acute drunkenness or alcohol poisoning while the longer-term consequences have a much more gradual progression and can damage major organs such as the liver and brain. Extended periods of excessive alcohol consumption most commonly manifest as alcohol-related liver disease (ALD) [44].

However, alcohol can itself disrupt the immune system, increasing an individual's susceptibility to infection [45]. Alcohol has been shown to suppress both innate and adaptive immunity resulting in greater viral load and spread [46, 47]. In the context of COVID-19, alcohol significantly affects many of the body's combat mechanisms against invading pathogens. The lung is the primary site through which COVID-19 is able to replicate in the body. In order to protect itself from harmful pathogens and pollutants, the lung uses physical barriers and clearance systems. The first line of defence within the airway is thought to be the mucociliary clearance system; lining the airways of the lungs are ciliated and mucous producing cells. Cilia are thin eyelash-like structures that sit on numerous cells and move in a coordinated manner to remove mucus coated particles out of the lung. Heavy alcohol consumption has been seen to not only inhibit increases in cilia movement but also affect the quality and quantity of mucus produced in the lung [48]. Cough and exhalation is also a mechanism the lung uses to rid itself of harmful toxins. Alcohol is

known to suppress coughing and is also associated with shortness of breath, or dyspnoea. Dyspnoea is a well-known symptom of COVID-19 which suggests that compounded with alcohol consumption, there would be a decreased excretion of alcohol via the lungs which may increase the damage alcohol is able to have on the lungs' innate defences [48].

If the virus has not been successfully cleared, it will enter the alveoli of the lungs. Alveoli are the main site for gas exchange and are lined with surfactant—another barrier against harmful pathogens. It was the surfactant protein D (SP-D) that was known to bind to the Spike protein of SARS-CoV-1, the causative organism of the 2002 SARS outbreak. When the Spike protein was bound by SP-D, it was unable to interact with ACE2 receptors to infect cells. ACE2 receptors are found in multiple organs in the body but in the context of COVID-19 it is important to look at the lungs. In binding to ACE2 receptors, the virus undergoes conformational changes and cleavage which assists the virus in being able to fuse into the host cell. In comparison, SARS-CoV-2, the virus responsible for COVID-19, has shown to have far stronger bonds with the ACE2 receptor following conformational changes [49]. So, it is surfactant protein D that prevents the virus from interacting with ACE2 receptors. Heavy alcohol consumption is shown to contribute to alter SP-D function and also negatively affect surfactant production [48].

As previously mentioned, alcohol consumption can also disrupt the immune system. This is primarily through changing the actions of immune cells. For example, specific cells that are responsible for destroying invading pathogens (macrophages, neutrophils, and monocytes) can be inhibited or altered by exposure to alcohol [50].

Chronic alcohol consumption has been linked to strong pro-inflammatory reactions that have been shown to contribute to disease processes in the lungs. Simultaneous to provoking these strong inflammatory responses, alcohol impairs the generation of anti-inflammatory cytokines [51]. Cytokines are signalling molecules and are responsible for coordinating the body's immune response [50]. This chaotic storm of inflammatory molecules is what contributes to respiratory and multi-organ failure through severe oxidative stress [51]. Similarly, SARS-CoV-2 infection often leads to a rapid release of pro-inflammatory cytokines and inflammatory lipid mediators, such as prostaglandins and leukotrienes. The severity of the inflammation caused by COVID-19 is thought to be a main contributor to the organ failure seen in critically ill infected patients [48]. From what we know about the inflammation caused by chronic alcohol consumption, this is likely to exacerbate the similar inflammatory response to infection.

The organ failure caused by both chronic alcohol use and COVID-19 has been attributed by some researchers to oxidative stress. In relation to heavy alcohol consumption, alveolar macrophage function is affected which leads to an inability to efficiently destroy infectious organisms. This is due to alcohol decreasing antioxidant levels by increasing alveolar barrier permeability which in turn increases the amount of free oxygen radicals. The cells are not able to rid themselves of toxic oxidants which causes oxidative stress. Severity and mortality of Acute Respiratory Distress Syndrome (ARDS) due to fluid building up in the alveoli, is increased with the increase in barrier permeability and the decrease in antioxidant levels [48].

ARDS is recognised as a severe complication of COVID-19 and carries a high mortality rate [52].

As well as the effects of alcohol in the lungs and in the immune system, patients suffering from alcohol use disorders (AUD) are also likely to have underlying medical conditions which are risk factors for severe COVID-19 infection, such as chronic obstructive pulmonary disease or liver impairment. Additionally, more patients with AUDs are male which is a recognised risk factor for greater medical intervention and higher mortality rates. It is also worth mentioning that not only can chronic alcohol use exacerbate COVID-19 infection, but COVID-19 could also be a major factor in exacerbating and worsening pre-existing liver disease [47].

During the pandemic, there were rumours that alcohol consumption could be beneficial in the prevention of contracting COVID-19. However, the evidence that has been presented challenges this, and we can conclude that alcohol consumption is a serious risk factor to contracting infections—importantly COVID-19 [51]. Chronic alcohol consumption has an adverse effect on the cells that respond to specific pathogens (T-cells) and the cells that are responsible for long term immunity (B-cells) [50]. This raises the question of what the effect of long-term alcohol use may be on an individual's response to vaccination [53].

Furthermore, aside from the serious harm alcohol can do to our bodies, it can also severely affect behaviour and impairs judgement [52]. This is significant as social distancing is considered key to preventing the spread of COVID-19 and is harder to enforce in large groups of intoxicated people [54]. In fact, in Scotland most local authorities have made it illegal to drink alcohol outdoors which was in part due to recognition that consumption of alcohol reduces compliance with social distancing rules [55]. It has also been evident that as rates of reinfection began to rise, bars and clubs became the first venues to be heavily restricted or closed again.

COVID-19 and Alcohol Use Disorders

The effect of lockdown on alcohol consumption in patients with pre-existing alcohol use disorder (AUD) has been well documented. Patients with AUD were recognised as a population that may be severely impacted by the virus and by the restrictions put in place to reduce contagion. A UK study with 182 patients with pre-existing alcohol disorders, found that of the 38% of patients who were abstinent before lockdown, 17% of this group relapsed during the restrictions. The mean AUDIT score of this subgroup had increased by 226% and the average weekly alcohol intake was 48.8 units [19]. These figures show that not only was lockdown a risk factor for relapse in those who were abstinent before the restrictions, but additionally those who relapsed increased their consumption greatly and were drinking harmfully. The WHO also recognised that hazardous and harmful drinking had increased greatly during the pandemic [56].

In China, the prevalence rate of AUD, including dependency and harmful use, was 4.4% in 2018 but had risen to 11.1% in 2020. It was suggested that social

isolation was the biggest risk factor for this increase [2, 56]. Furthermore, in Spain, patients who suffered from alcohol use disorder were identified as being a particularly high-risk group to consuming greater quantities of alcohol during the pandemic. A study found that the number of AUD patients screening positive for alcohol following outpatient treatment doubled during the 3-month period after Spain implemented lockdown in its country. Interestingly, Spain has some of the cheapest prices for alcohol compared to the whole EU which may have provided easier access to alcohol for AUD sufferers [57].

Due to the restrictions that were put in place during the beginning of the pandemic, access to help for those suffering from excessive drinking was reduced. Services including supervised consumption, detoxification, and blood-borne virus (BBV) screening and treatment were either completely stopped or significantly reduced [58]. Similarly in Scotland, Alcohol Brief Interventions (ABIs), drinkers, were curtailed. ABIs are brief discussions within Primary Care, A&E and maternity settings aimed at helping newly identified drinkers decrease their alcohol consumption to within safe standards. As face-to-face contact was severely limited during the pandemic, carrying out ABIs proved difficult as staff were redeployed to care for COVID-19 patients [59].

Telemedicine and telehealth became more common place during the pandemic as a solution to the cessation of face-to-face consults. There are many constraints to telemedicine which may have excluded disadvantaged members of the population. Telehealth is dependent on internet access which can be difficult if individuals do not have the technology or the network to support it. It is thought that those from lower socioeconomic backgrounds would be worst affected by this and yet they are the population group that often need the most support [2]. Additionally, services that were moved online were found to be less effective at preventing relapse [20]. A study from one alcohol clinic in London found that the patients who received face-to-face contact with an alcohol nurse were more likely to abstain from alcohol and less likely to relapse during lockdown compared to those patients who did not [20]. However, individuals who did have access to face-to-face appointments sometimes avoided attending due to fears surrounding leaving their homes, the possibility of contracting the virus while travelling and potentially infecting people close to them [55, 56]. This meant that often patients were only seeking care when their symptoms were most severe [55].

The lack of access to important outpatient services was not the only disruption due to lockdown. Access to leisure activities that may have been used to help negate the temptation of drinking were also severely impacted due to lockdown restrictions. Additionally, most employers were asking their employees to stay at home. This may have made it more difficult for affected individuals or individuals at risk of relapse to find reasons to leave the house or find more effective ways to occupy their time or mind with. When lockdown instructed individuals not to mix, usual support networks for affected or at-risk individuals were limited as they were deprived of the social contact they might have had access to before. Social contact is recognised to be crucial in the prevention of relapse in patients with AUDs [55]. This would have exacerbated feelings of social isolation and anxiety that many

sufferers of AUD often already face as a result of their condition [2, 55]. Counselling, relapse prevention groups and community-run organisations were also either no longer available or only available online [2, 55]. Alcoholics Anonymous (AA) is a community-run organisation that seeks out to help those with alcohol use issues to recover and continue their sobriety. Prior to the pandemic, around 5000 AA meetings were being held across Great Britain every week. However, because of government restrictions, many groups had to go online or stopped altogether [60].

The effect of COVID-19 on services was not the only concern for AUD patients. As mentioned earlier, excessive consumption of alcohol causes harm to the body which can lead to an individual's increased susceptibility to contracting viruses. Over the last decade, rates of alcohol use disorder have increased by 84% for women and by 35% for men [61]. This is particularly worrisome as women have been shown to experience worse alcohol-related health consequences compared to men. Women with AUDs have a greater risk of developing alcohol-related liver disease (ALD) [61, 62]. Patients with ALD and subsequent liver cirrhosis have worse outcomes from COVID-19 [62]. As alluded to already, patients with AUD also often have co-morbidities that will predispose them for more severe COVID-19 outcomes, for example, obesity-related metabolic syndromes or chronic obstructive pulmonary disease; being immunocompromised as a result of alcohol hepatitis therapy or liver transplantation will increase an individual's susceptibility [55]. Inpatients with AUD who were COVID-19 positive died at a significantly younger age than COVID-19 positive patients at low risk for AUD [62].

Countries Where Legislation During the Pandemic Targeted Alcohol Availability

In South Africa, there was a complete ban on alcohol sales beginning in April 2020. A study looking at the impact of the ban found a sharp reduction in patients admitted to hospital for assault, accidents and sexual assault compared to before lockdown [63]. Another two South African studies also commented on similar trends. In the periods of complete alcohol restriction, there was a significant reduction in the total number of unnatural deaths and trauma volume in hospitals [64, 65].

However, historically, a complete prohibition on alcohol can drive alcohol sales underground and into illegal markets [66]. Additionally, it could result in worse outcomes for those suffering with alcohol use disorders. India was another country that imposed for a period a ban on alcohol sales. Following the ban, there were reports of sudden escalation of hospital attendances for alcohol withdrawal seizures or delirium as dependent drinkers suffered from enforced abstinence [67].

Conclusion

As a result of the COVID-19 pandemic and the concomitant infection control restrictions, some individuals drank more but others drank less or even stopped drinking altogether. This suggests that there has been increased polarisation in the drinking habits of different groups. The groups that saw the biggest change in increased consumption of alcohol was those aged between 25–49 years old and of middle to high income. Notably, women were found to have had a larger increase in alcohol intake. Conversely, in comparison to historical periods of greater stress, there has not been a universal increase in alcohol consumption. However, for the individuals who were already in poor health and relied on alcohol before the pandemic, there were worse outcomes. On one hand, lockdown may have been protective for heavy alcohol consumers as it may have prevented greater exposure to the virus, but on the other hand, people were forced to stay at home, and it was difficult to access services that may have been critical in preventing relapse or reducing harmful intake. As a result, the UK has seen record numbers of deaths attributable to alcohol.

The next 3 years following the pandemic and associated restrictions will be especially significant in relation to alcohol use and changes in consumption. Research published in Beijing in 2008 studied alcohol abuse/dependence symptoms in hospital workers 3 years after the SARS-CoV outbreak in 2003. The findings concluded that there was a significant association between having experience of being quarantined and working in areas with high numbers of SARS patients and later symptoms of alcohol abuse/dependence symptoms [68]. Currently we can identify certain additional groups in the population that are now at risk of hazardous drinking. Additionally, individuals with pre-existing alcohol use disorders have suffered greatly because of the pandemic and there needs to be an urgent focus on providing services for these individuals. However, over the next 3 years, there could be other groups that emerge vulnerable to increased alcohol use who could suffer similar outcomes to those struggling now.

Not all countries experienced the rise in numbers of heavy drinkers and rates of alcohol-related harms that the UK experienced. It can only be speculated whether dis-allowing alcohol retail outlets as an ‘essential service’ would have prevented that. One could also speculate that tighter rules on alcohol availability might have reduced the spikes in Covid outbreaks seen in the UK when venues were allowed to open. As with many policy decisions made during the pandemic in many countries, in the end many decisions were made based on political rather than scientific decisions.

Chapter 10
The Principles of Policies to Reduce the Burden of Liver Disease

Robyn Burton, Clive Henn, and Nick Sheron

Abstract The dose-response relationship between alcohol and alcohol-related liver disease is exponential, as a result and in contrast to many other alcohol related harms, the majority of liver mortality occurs in heavy daily drinkers who seek out cheap strong alcohol. Price elasticities for very heavy drinkers are difficult to determine as this group are not represented in population studies. Nonetheless, data from the UK shows a strong relationship between the affordability of alcohol and liver mortality clearly demonstrating that these heavy drinkers are in fact extremely price sensitive. Interventions targeted towards very heavy drinkers, such as a minimum unit price for alcohol, are highly effective and cost-effective policies that can reduce liver mortality with practically no impact on low-risk drinkers.

Keywords Alcohol · Alcohol-related liver disease · Policy · Intervention: minimum unit price

Introduction

The liver is the largest organ in the body, the most metabolically complex, and probably the least well understood by non-liver doctors, as well as the general public. You can find the functional equivalent of the heart, lungs, and kidneys in a cheap aquarium. Simple mechanical devices can support life when these organs fail, but the same is not so for the liver which makes the building blocks of the body and detoxifies all the waste products. Prometheus was bound to a rock and visited every day by an eagle who eats half of his liver which then grew back overnight, only for the cycle to be repeated. The liver does indeed have remarkable powers of recovery. Following a single acute insult, the liver will usually regenerate. If a competent hepatobiliary surgeon removes half of the liver, then it can be expected to grow back within weeks to its full previous size and function. However, the response to repeated insults is quite different. Hepatic stellate cells are activated to secrete collagens and fibrosis, or scarring, develops as a wound healing mechanism. Nodules of liver cells surrounded by scar tissue look like a bag of marbles and regeneration is constrained. At this stage, the liver has developed cirrhosis—first described by Hippocrates in the fifth century BC. The other important disease process to affect the liver is carcinogenesis. Following repeated rounds of regeneration mutations develop with liver cells, and eventually primary liver cancer is the result.

Liver cirrhosis resulted in 223,000 deaths in the World Health Organization (WHO) European region in 2019, with a further 63,000 deaths from primary liver cancer, in total [1]. The majority of these deaths resulted from alcohol consumption (probably between 60% and 80%), but it is not possible to be exact because the coding of liver disease is poor in many European countries and aetiology is very often not recorded [2]. Liver disease causes 3% of deaths in Europe, but unlike the other major killers of the twenty-first century—the diseases related to smoking and obesity—liver disease kills people of working age. In terms of years of life lost in working age, liver disease is the second leading cause after ischaemic heart disease, killing more younger people than lung cancer, breast cancer, or diabetes (Fig. 10.1) [1].

Over the last few decades, European countries have experienced differing trends in liver mortality rates. In Fig. 10.2, we have categorised a selection of larger European nations into five groups according to their trajectory of liver mortality between 1990 and 2019 using the latest Global Burden of Disease (GBD) modelled data [3]. A small group of Eastern European countries have always had very high levels of liver mortality comprising in this selection: Moldova, Hungary and Romania. A group comprising: Sweden, Norway, Greece, Ireland, the Netherlands, and Malta have had stable low levels of liver mortality. Moldova has a standardised death rate (SDR) from cirrhosis and chronic liver disease of 74 per 100,000 population which is tenfold higher than the rate seen in Norway which is 7 per 100,000 population. There have been changes in liver mortality over the past three decades. France, Spain, Italy, and Portugal have seen marked decreases in the rate of liver deaths as a result of substantial decreases in the consumption of cheap wine [4]. Whereas in the group comprising: Ukraine, Bulgaria, Belarus, Poland, Latvia, Estonia, Finland,

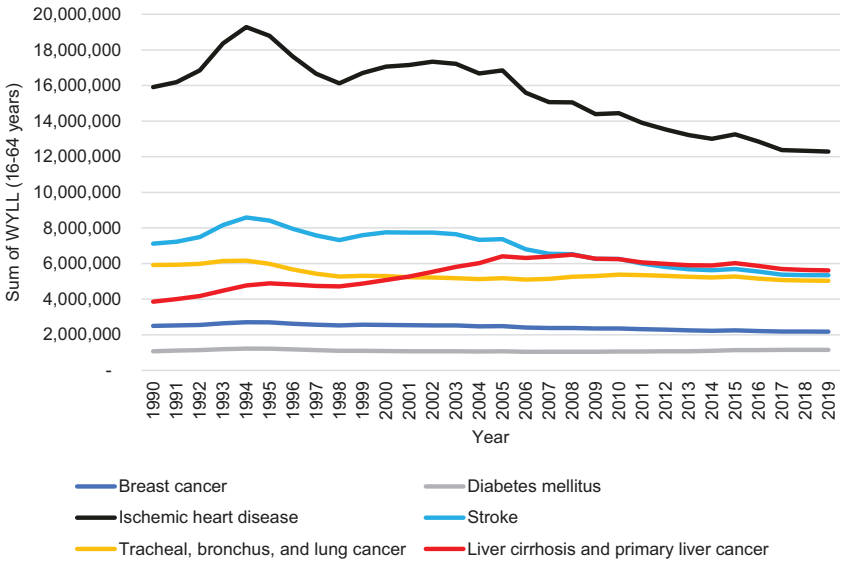

Fig. 10.1 The sum of working years of life lost (WYLL) in people aged 16-64 years) from the leading diseases in the WHO European region. Liver disease has overtaken stroke to become the second leading cause of WYLL exceeded only by ischaemic heart disease

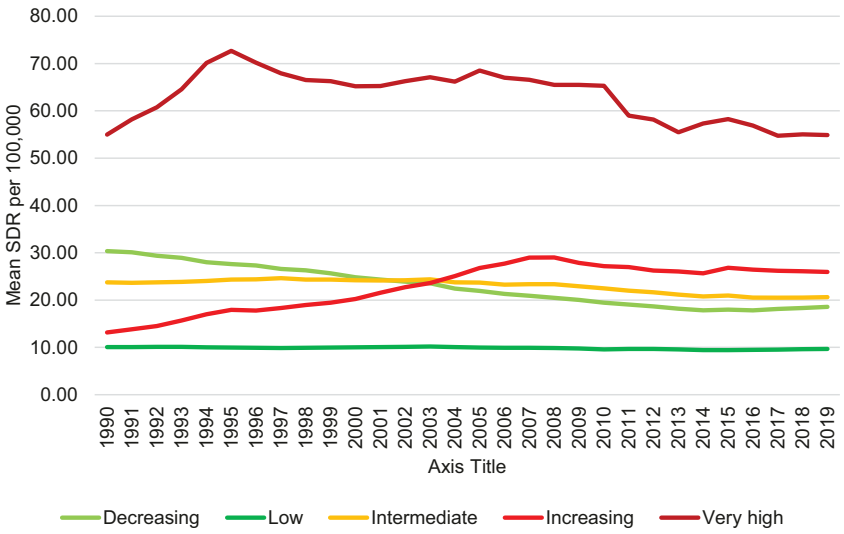

Fig. 10.2 Trends in directly standardised liver mortality rates (SDR) in WHO European region countries categorised into five groups according to the trend over time. There are marked differences between countries, but also liver death rates change considerably over time. Some countries in the Mediterranean basin have seen huge reductions in death rates, whereas other countries in including Finland and the UK have seen death rates increase substantially. The groups are as follows: Low: Greece, Ireland, Malta, Netherlands, Norway, Sweden; Decreasing: France, Italy, Portugal, Spain; Intermediate: Austria, Belgium, Croatia, Czechia, Denmark, Germany, Serbia; Increasing: Belarus, Bulgaria, Estonia, Finland, Latvia, Poland, Ukraine, United Kingdom; Very high: Hungary, Republic of Moldova, Romania

and the United Kingdom, liver mortality has risen. These data clearly demonstrate that there is nothing fixed or irrevocable about dying from liver disease. There are factors within countries that determine the 40–50-fold differences in liver mortality, and the fact that liver mortality can increase or decrease four- to fivefold over a few decades demonstrates that these factors do change and can be changed. By understanding and changing these key drivers, we could dramatically reduce liver mortality in Europe (Fig. 10.2).

The situation for liver patients in Europe is grim, but it need not be. There are simple, cheap solutions that could be implemented given a desire to improve the health of people in Europe and a degree of political will. The evidence for these solutions is well established and can be described in terms of some simple principles and relationships [5]. In this chapter we will examine the nature of these relationships.

Implications of the Exponential Relationship Between Alcohol Consumption and Liver Disease

Alcohol is a dose dependent toxin and there is a lethal dose of alcohol for anyone, however liver toxicity results in progressive liver fibrosis over 10–30 years followed by episodes of acute on chronic liver failure or variceal bleeding from portal hypertension. Liver mortality is usually related to these episodes which are strongly related to recent drinking; if alcohol consumption stops, the prognosis improves immediately. Liver disease is just one facet of health harm from alcohol and comprises around 25% of the attributable mortality with hypertension, stroke, cancer and mental and behavioural disorders comprising the remainder [6].

There are over 200 International Classification of Disease (ICD-10) codes with alcohol in their name. Some conditions are partially caused by alcohol, such as cancer, and others are entirely caused by alcohol, such as alcohol-related liver disease. For cancer, the dose response relationship is linear—the relative risk (RR) increases at levels above zero intake to 2.41 (95% confidence interval [CI] = 2.07, 2.80) at an intake of 100 g/day (Fig. 10.3) [7]. Large numbers of people are at a relatively low risk of alcohol induced cancer, but this adds up to a lot of people developing alcohol-related cancer, with an estimate of around 80,000 deaths and 1.9 million years of life lost in Europe in 2016 [9]. Because of the linear risk between alcohol and cancer, the majority of cancer cases occur in moderate drinkers, and heavy drinkers account for a minority of the overall burden. In contrast, the dose response relationship for cirrhosis is exponential, although heterogeneous, with RR between 10 and 70 at 150 g/day [10]. As a result of this relationship, the burden of liver disease is concentrated among the relatively smaller group of heavy daily drinkers with a high alcohol intake.

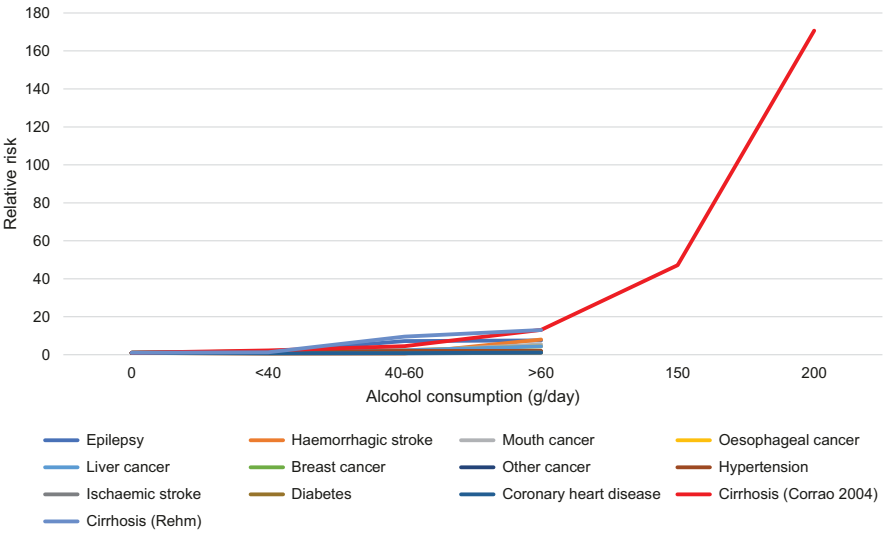

Fig. 10.3 Dose-response relationship between alcohol and 12 alcohol-related diseases in men. The figure is a simplified illustration of the various data models outlined in papers by Corrao and Rehm. For liver disease, the increase in relative risk is exponential and not linear, and as a result, the relative risk increases dramatically at very high levels of alcohol intake [7, 8]

If alcohol-related liver disease is dose-dependent at the individual-level, then it follows that it must also be dose-dependent at the population-level. A seminal paper by Milton Terris in 1967 illustrated the very close relationship between mortality from liver cirrhosis and population-level consumption of strong alcohol (wines and spirits) concluding: "The evidence strongly supports the conclusion that cirrhosis mortality is directly related to per capita consumption of alcohol from spirits and wine" (Fig. 10.4) [11]. The concept developed by Kettil Bruun and Griffith Edwards forms the basis of modern alcohol control policy. Ceteris paribus—all else being equal—the proportion of heavy and extreme drinkers remains similar. This 'population consumption theory' forms the basis of modern alcohol control policy [12–14], as the late Professor Griffith Edwards stated: "the overall level of a population's drinking is significantly related to the level of alcohol-related problems which that population will experience" [12]. This means that the most effective interventions to reduce harm are those that target the whole population. This assumption generally holds for conditions with linear dose-response curves, such as cancer, where the majority of health harm is found among the larger number of moderate drinkers. However, the dose-response curve for alcohol-related liver disease is exponential (Fig. 10.3), and as a result, cases are concentrated among a small group of heavy and extreme drinkers. Interventions targeted towards these heavy and extreme drinkers are likely to have a disproportionate benefit in terms of reducing liver mortality.

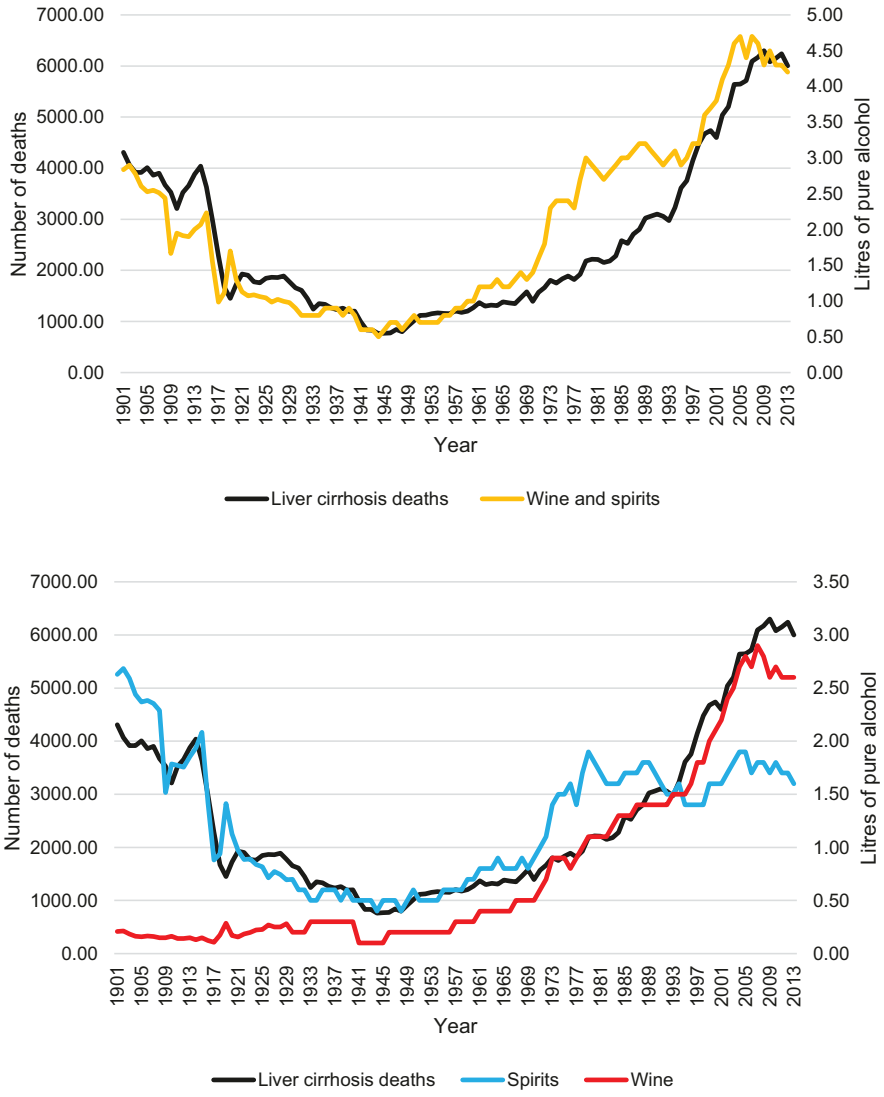

Fig. 10.4 The relationship between cirrhosis death rates and per capita consumption of wine and spirits in the UK 1901-2019. Adapted from Terris [11]

The "Unit of Alcohol" or "Standard Drink"

In academic studies alcohol is generally quantified in g/day, but alcohol is a liquid, alcoholic beverages are liquids and alcohol is sold in liquid measures. Furthermore the %ABV of alcohol is equivalent to the number of centilitres (cL) of pure alcohol in 1 L of product. With this information it becomes very easy to calculate the number of cL of pure alcohol in any drink.

In communicating health risks to the public, health agencies tend to talk about units of alcohol or standard drinks but there is no such thing. Wikipedia lists the various "standard drinks" in Europe, they vary from 8 g in UK, 10 g in France, 12 g in Finland, 17 g in Hungary and 20 g in Austria [15]. This is nonsensical. A sensible system would have a single standard measure of alcohol for public facing and academic facing communications, and the sensible choice would be to use 1 cL of alcohol as this standard measure. Many years ago we made this proposal to the European Health and Alcohol Forum, and over the life of the forum this was the single only proposal enthusiastically supported by both health and industry delegates. Establishing an EU standard alcohol measure at 1 cL is extremely low hanging fruit for a public health measure and should be prioritised.

It's Hard to Get Cirrhosis: Liver Disease Kills Extreme Drinkers

Alcohol-related liver disease is attributed to a single cause—heavy daily or near daily consumption—and the burden is concentrated among heavy and extreme drinkers. These drinkers are underrepresented across almost all routine datasets, but purposively sampled observational studies shed light on their typical consumption.

A pooled analysis of almost 3000 patients across seven countries demonstrates the very large volumes of alcohol consumed by patients with alcohol-related liver disease [16]. Almost half of the sample (45%) reported drinking >110 g of alcohol/day (96 cL/week), more than three bottles of vodka each week. A further 44% reported drinking between 80–160 g of alcohol/day (70–140 cL/week). The average daily consumption reported across the studies ranged from 65 g to 176 g/day (56–154 cL/week). Drinking an average of 84 g/day (73 cL/week) increases the risk of liver cirrhosis almost seven times in men (RR = 6.93, 95% CI = 1.07, 44.99) and over 12 times for women (RR = 12.44, 95% CI = 6.65, 23.27) [17].

In a British study the mean weekly consumption reported by patients with alcohol-related liver disease presenting to a large hospital was around 150 cL/week (Fig. 10.5) [18]. In a second sample of patients with alcohol-related cirrhosis or progressive fibrosis, the median weekly consumption was almost 75 cL/week [19]. Across a decade of household surveys in England, less than 1% of respondents reported drinking at equivalent levels to those reported in liver patients.

Only a minority of patients with alcohol-related liver disease have evidence of severe alcohol dependency [19–21], however daily drinkers with alcohol dependency have an eightfold increase in the incidence of cirrhosis [22]. In drinkers presenting to services with serious alcohol problems in Scotland, the median reported weekly consumption was almost 1500 g/week [23]. Among Scottish females drinkers presenting to these services the median was around 1200 g/week [24]. Similarly high volumes were reported in a cohort of patients undergoing medical detoxification in New Zealand at 1680 g/week [25].

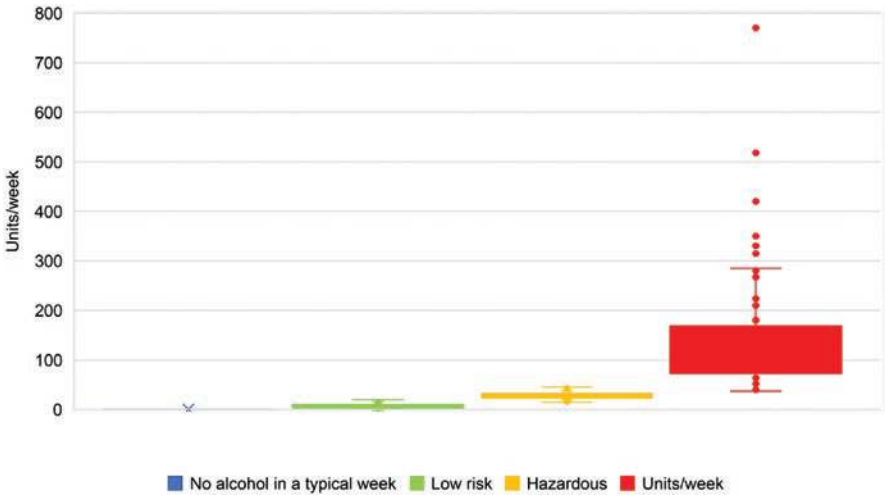

Fig. 10.5 Weekly alcohol consumption (cl or UK units) in patients with liver disease according to UK drinking grades low risk 14 cl and 35/50 cl for women / men. The mean intake in harmful drinkers with alcohol- related liver disease was 147 cl / week the median 120 cl / week [18]

The dose response relationship for alcohol-related liver disease means that heavy and extreme drinkers are at exponentially higher risk and decreases in consumption will reduce the risk of death per drink substantially more than the risk reduction experienced by lower risk drinkers.

Extreme Drinkers Buy Cheap Booze

As demonstrated in the previous section, people with alcohol-related liver disease report extremely high volumes of alcohol consumption—around 3.5 bottles of vodka per week [16]. As a result, they seek out cheaper alcohol. These extreme drinkers are underrepresented in general household surveys or consumer panels, so the limited data available to demonstrate this principle comes from observational studies specifically sampling heavy drinkers.

In England, patients with alcohol-related liver disease reported paying less than one-third of the price paid by lower risk drinkers per 10 cL of alcohol [18]. Lower risk drinkers spent an average of almost £500 on alcohol each year, which is the amount spent by higher risk drinkers in less than 2 months. In Scotland, patients with serious alcohol problems reported paying, on average, 1.7 times less per 10 cL of alcohol compared to the average price paid by drinkers in the general population [26]. When the sample was limited to those drinking at least 1600 g/week, the amount paid per 10 cL of alcohol was almost 2.5 times less than that paid by the general population.

Price Elasticity of Extreme Drinkers

The consumption of alcohol is to some extent determined by price or affordability. This relationship is described as an elasticity, which is the percentage change in consumption resulting from a 1% change in price. The recent systematic review by the Organisation for Economic Co-Operation and Development found that beer is the least price-sensitive beverage (with elasticities ranging from −0.29 to −0.83) compared to wine (−0.46 to −1.11) and spirits (−0.54 to −1.09), and that moderate consumers were slightly more price sensitive compared to heavier consumers with an additional elasticity of around 0.05% (heavier consumers were defined as ≥40 g/week and ≥20 g/week for men and women respectively) [27]. Heavier drinkers consumed around twice as much alcohol below a specific price threshold compared with moderate drinkers showing their clear preference for cheap alcohol [27].

However, the price elasticity of the very heavy daily drinkers who comprise the majority of patients with alcohol-related liver disease has never been specifically determined because they are not represented in population studies. Studies in clinical populations have confirmed patients with alcohol related cirrhosis or alcohol dependence have a clear preference for cheap strong alcohol [18, 26], and confirm that certain types of very cheap strong alcohol such as 'white cider' in the UK are consumed almost exclusively by very heavy drinkers [28].

In the UK, liver mortality rates have increased almost threefold since 1980 and the relationship between trends in mortality and the underlying changes in alcohol affordability are clear to see (Fig. 10.6).

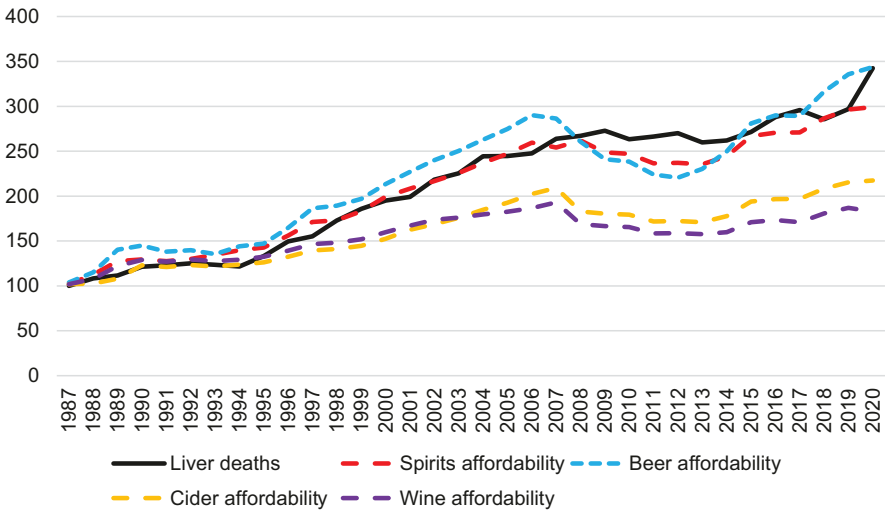

Fig. 10.6 Trends in the affordability of alcohol duty for different alcohol types in comparison to the trend in liver deaths alcohol-related liver deaths in England and Wales and duty-related affordability of alcoholic beverages. All data normalised to 100% in 1987. Affordability was calculated with the methods used by NHS digital with data sources outlined in Burton [6, 29]

Using duty receipt data from Her Majesty's Revenue and Customs and death data for England and Wales from the Office for National Statistics, the elasticity between total alcohol consumption and alcohol affordability was 0.41%, exactly what would be expected from the various meta-analyses (Fig. 10.7) [32, 33]. However, it is also possible to examine the direct relationship between alcohol affordability and mortality rates from alcohol-related liver disease, and calculate a direct elasticity, which in this case is 3.2%—six times higher than the elasticity on consumption (Fig. 10.8). This is similar to an estimate published in two systematic reviews which reported the elasticity for cirrhosis mortality to be around 3.5% (for reference, the elasticity for suicide was 0.5%) [34, 35].

Alcohol-related and liver mortality are strongly linked to health inequalities [36, 37]. The most likely explanation for this dramatic increase in elasticity is that extreme drinkers who die from alcohol-related liver disease are extremely price sensitive because they have already maxed out their spending on cheap alcohol. A price increase can be a stimulus to change behaviour, and in the case of extreme drinkers this will often be to stop drinking all together, thus reducing immediately their projected likelihood of death [38].

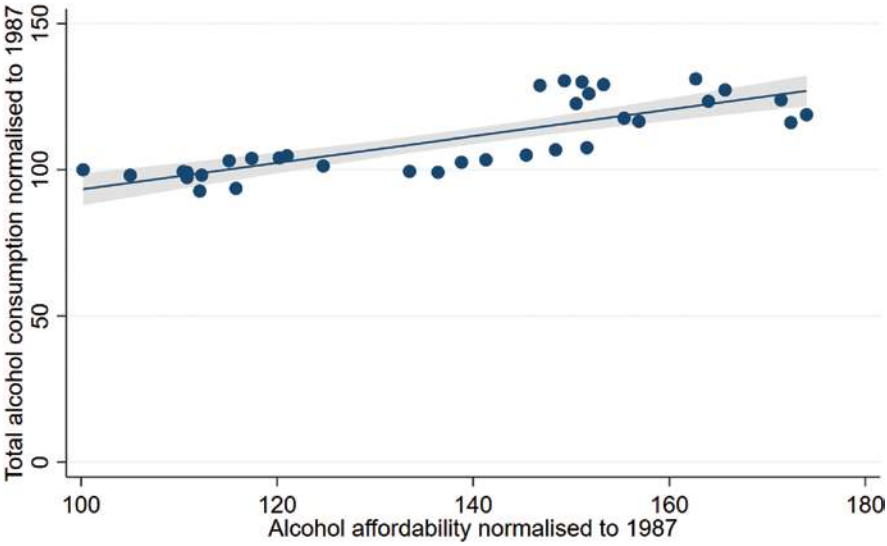

Fig. 10.7 The relationship between total alcohol consumption and the affordability of alcohol. Alcohol consumption is collated data from UK alcohol duty receipts published by the British Beer and Pub Association and affordability is from NHS Digital for the UK. All data normalised to 100% in 1980. A 1% increase in price is associated with a 0.46% reduction in alcohol consumption. Adjusted R2=0.64 [30, 31]

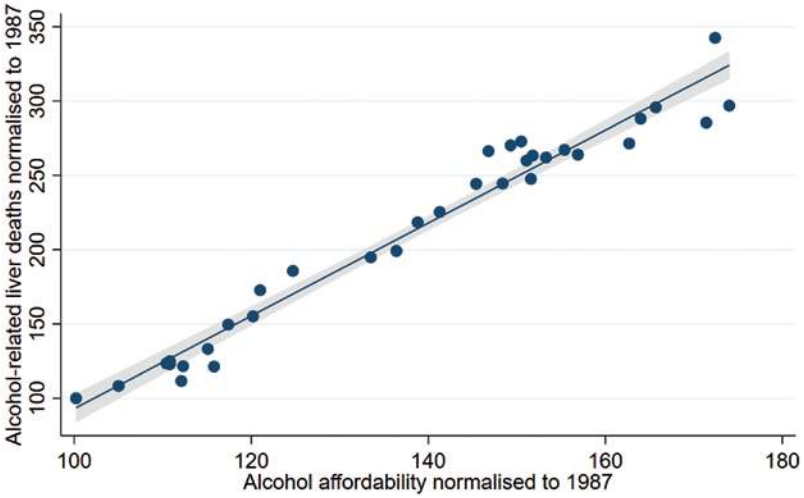

Fig. 10.8 The relationship between the affordability of alcohol and alcohol-related liver deaths. Affordability is for the UK from NHS Digital and alcohol-related liver deaths are for England and Wales. All data normalised to 100% in 1980. A 1% increase in price is associated with a 3.1% reduction in alcohol-related liver deaths. Adjusted R2=0.96 [30, 31]

Models of Policy Interventions

About 80% of deaths directly caused by alcohol are from alcohol-related liver disease, and around a further 10% are from alcohol dependency [39], so the drinking behaviour of these two groups are absolutely critical to the accurate modelling of minimum unit price (MUP).

The Sheffield model uses survey data to estimate the impact of MUP, and because heavy and extreme drinkers are substantially underestimated in these surveys, the result is a model which underestimates the policy's impact on alcohol-related liver mortality. The model reports the mean alcohol intake among harmful drinkers to be 571.2 g/week [40], which is 878.8 g less than the 1450 g/week reported in a sample of patients with alcohol-related liver disease [18]. Considering the incidence of alcohol-related liver disease in heavy drinking cohorts is between 10–20 times greater than the incidence seen in the general population [16, 41], the impact of this underestimate is likely to be substantial. The model estimates the yearly spend by higher risk drinkers to be £2862, which is £570 less than the average yearly spend on alcohol reported by the patient sample (£3432).

Minimum Unit Price in Scotland

The epidemiological, clinical and alcohol control policy evidence described previously presents a compelling case for action to prevent alcohol-related harm. Yet for many countries while levels of harm remain unacceptably high the implementation of the most impactful control policies has not materialised [42]. While the scientific evidence defines the nature and scale of a problem it is Government and politics that plays the central role in implementing effective control policies.

Health advocacy can play a key role in influencing policy change. This is more likely to be impactful if done from an informed position of the nature of policy making and which policy makers to target. Advocates will need to consider how best use to use their limited resources, their knowledge and experience to communicate the problem and solutions to policy makers and the public.

The policy making process is rarely a stable and linear process [43]. The reality is a more dynamic irrational process constructed through engagement with multiple actors often holding conflicting views on a given topic. This can be challenging for health professions and advocates to navigate as often they are used to a rational evidence-based approach. While scientific evidence derived from structured methods and subject to peer review, policy making is a "loosely organised body of precepts and positions" [44].

Policies that are aimed at preventing or reducing harm from commercial products such as alcohol that can damage health can be challenging to influence due to favoured political view on individual responsibility borne out of prevailing neoliberalism and the influence of lobbying of commercial actors [45]. Health advocates can play a key role in countering these views putting forward strategies based on equality and evidence [46].

While no framework of policy making fully captures the complexity of its reality, Kingdon's 'multiple streams approach' presents a dynamic model which can aid understanding of how some issues are addressed through policy changes and others are not [47]. It identifies three relatively independent streams or processes that when they converge create a window of opportunity through which policy change is more likely to occur (Fig. 10.9).

Advocates can influence each of the three streams and play an important role facilitating the convergence of the streams. This facilitation needs leaders, often outside of Government who can bring about policy change through the matching of problems, policy options and political support [49]. Success depends on gaining support from those in key political positions who can bring about change. Focusing on the following three areas can increase the likelihood of success:

- Making the case on the necessity to act
- Identifying the decision-making venues and procedures to pursue the proposals
- Adapting proposals to generate support and overcome opposition

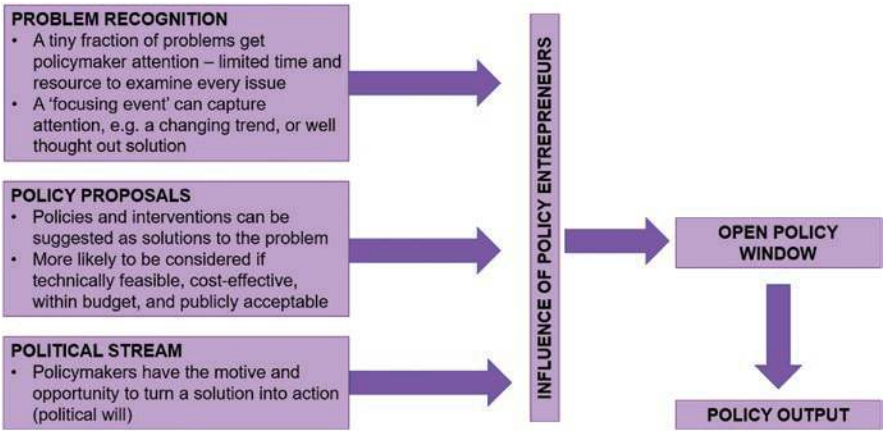

Fig. 10.9 The multiple streams approach to policy adapted from Kingdon [48]

How Policy Making Works: Does Evidence Matter?

Over recent decades, medical organisations and advocacy groups across the UK and Ireland have been vocal in their concern about health harm from alcohol. They have highlighted the burden and causes of harm, evidence-based solutions, and campaigned for Governments to do more [50–52].

Epidemiological data has been influential by identifying the burden of harm and the adverse trends. A 2006 study comparing the mortality rates from liver cirrhosis across the UK[9] has been identified as being influential in starting to change the narrative on Scotland's relationship with alcohol [53]. The study presented stark data showing mortality rates in Scotland were one of the highest in Western Europe, and had been rapidly increasing since the 1990's [54].

Evidence and expert opinion played an important role in identifying solutions to preventing and reducing alcohol-related harm including novel approaches to address the affordability of alcohol. In 2007, the advocacy group Scottish Health Action on Alcohol Problems published a report that linked alcohol's affordability with harm [52]. A key recommendation for the Scottish Government was to establish minimum prices for alcoholic drinks. A year later, a econometric study identified MUP as an effective measure to target those most at risk of harm [55].

Kingdon's policy theory suggests that problem recognition and solutions need to converge with political will to create the conditions conducive to policy change. The establishment of the Scottish Parliament in 1999 with responsibility health policy and the election of the Scottish National Party in 2007 opened up political consideration to wider prevention policies including addressing public concern about the availability and affordability of alcohol [56]. This paved the way for the Scottish Government to pursue MUP which came into force in May 2018. Ireland and Wales have now also implemented MUP, and Northern Ireland has consulted on implementation.

All fiscal policy, whether tax or MUP, is targeted because the impact is directly proportional to the amount alcohol consumed. While tax affects all drinkers, MUP is highly targeted, affecting those cheap high strength products favoured by heavier drinkers, and as such has the greatest potential to reduce health inequality [57]. Tax and MUP are therefore complimentary policies [58]. This has been confirmed by the highest courts in Europe and UK after a challenge by the alcohol industry that it have a detrimental impact on trade. The UK supreme court unanimously concluded that MUP in Scotland is *"a proportionate means of achieving a legitimate aim"* and in terms of the impact on health vs. trade impact *"That minimum pricing will involve a market distortion, including of EU trade and competition, is accepted. However, I find it impossible, even if it is appropriate to undertake the exercise at all in this context, to conclude that this can or should be regarded as outweighing the health benefits which are intended by minimum pricing"* [59].

While most producers have been against the policy, several retail bodies been in favour including supermarkets [60]. The extra income generated by MUP goes to retailers so therefore isn't a tax.

The media has a powerful role in agenda-setting and influencing public opinion this in turn can influence policymaker's and shape a government's response. Inaction by politicians to address an issue may in part be influenced by concerns relating to media backlash from legislative changes. An unpublished study suggests these concerns are unfounded and since the implementation of MUP in Scotland the majority of media discourse has been supportive of MUP (Robyn Burton unpublished data). Studies of media and political impact showed no adverse political impact (ibid). The fact that MUP is a highly targeted measure that does not affect the low-risk consumers that do not purchase the cheapest strong alcohol was central to the court judgements and hugely important to the favourable public and media response to MUP. Perhaps it is time for the alcohol policy community to re-evaluate their aversion to targeted alcohol policy measures.

The divergence of policy in relation to MUP across the UK nations and Ireland has created a controlled natural experiment with England as the no treatment control. This will produce important evidence on the impact of MUP on health harm and identify any unintended consequences.

Conclusions

Alcohol-related liver disease is a substantial public health burden but need not be. There are factors between countries that determine 40–50-fold differences in liver mortality across Europe [3]. Liver mortality within countries can increase or decrease four- to fivefold over a few decades demonstrating that these factors change and can be changed. There are simple cheap solutions that could be implemented given a desire to improve the health of people in Europe and a degree of political will. The underlying principles are straightforward. The dose-response relationship between alcohol and liver fibrosis is exponential, as a result, the

majority of liver mortality occurs in heavy daily drinkers who seek out cheap strong alcohol. This group are not represented in population studies and price elasticities for alcohol consumption are undetermined. However, data from the UK shows a strong relationship between the affordability of alcohol and liver mortality clearly demonstrating that these heavy drinkers are in fact extremely price sensitive. Interventions targeted towards very heavy drinkers, such as a minimum unit price for alcohol, are highly effective and cost-effective policies that can reduce liver mortality with practically no impact on low-risk drinkers. The solutions for alcohol related liver disease, the largest cause of liver death in Europe by a country mile, do not lie in expensive hepatology units or with Big Pharma. The solution is simply to set realistic minimum prices per centilitre of pure alcohol across Europe. As the results of the ongoing controlled natural experiments in alcohol policy become clear the political imperatives to do this will become overwhelming. See also other related Chaps. 2, 3 and 7.

Part II
Alcohol Addiction: Introduction and Diagnosis

Chapter 11
Medical Treatment of Alcohol Use Disorder: A Multidisciplinary Approach

Julia Sinclair and Sarah Welch

Abstract There is a wide range of factors at the societal (macro), health system (meso), and individual (micro) level that will have a significant impact on the expectations and experiences of treatment for people with alcohol use disorder (AUD). These factors have a complex, dynamic interplay, and as they are less amenable to exploration using traditional biomedical research methods their impact is often overlooked.

Stigma, both felt and enacted, is one manifestation which will have an impact on how and when people who need medical treatment for AUD present, as does the lack of training for health professionals in the identification and management of alcohol related harm.

For people who recognise their need for treatment, there may be many obstacles to accessing the correct care. It may be helpful to consider AUD as a long-term condition, requiring a personalized treatment plan and active involvement of the patient and their circle of concern. Integrated pathways, and evidence-based interventions specifically for patients with alcohol related liver disease, and co-morbid mental health conditions are an essential component of any modern evidence-based treatment system to ensure people with AUD have the best chance of achieving and sustaining recovery.

Keywords Alcohol use disorder · Multidisciplinary · Stigma · Long-term conditions · Recovery · Recovery orientated systems of care

Introduction

Most of this textbook's focus is on the evidence base for individual modes of intervention for patients with alcohol use disorder (AUD). In this chapter we will consider some of the broader, complex, and interacting latent factors that will have an impact on how these are delivered and received. These predisposing factors are less amenable to a randomised control trial design and therefore frequently overlooked within the biomedical context, but we believe are essential to consider when translating the evidence-base from one healthcare system to another.

We start with an overview of potential factors at the macro (societal), meso (health system), and micro (individual) level. These all have an impact on who accesses treatment, their duration of untreated AUD, the severity and complexity of any alcohol related harm, as well as their expectations of care.

See Fig. 11.1 *Overview of potential factors affecting the delivery, experience of, and outcomes from evidence-based interventions for AUD.*

All complex systems function using dynamic feedback loops and so while the flow is presented as moving from macro to micro (left to right) and from global to specific (top to bottom) the reality is that the impact on the system will be multidirectional. The relative impact of any particular factor or process will differ across societies and health systems, but all are relevant.

The components in Fig. 11.1 are not presented as an exhaustive list, but rather a conceptual map of processes that need to be considered when implementing an evidence-based treatment system.

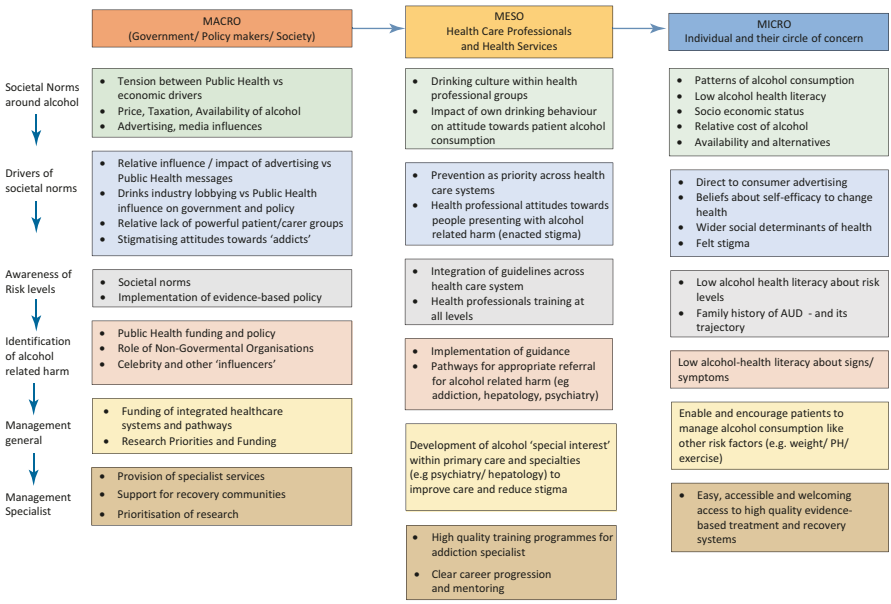

Fig. 11.1 Overview of potential factors affecting the delivery, experience of, and outcomes from evidence-based interventions for alcohol use disorder

Figure 11.1 helps in considering the broad systemic change that is needed to help with both prevention, self-identification and early identification of AUD and alcohol-related harm. These are all essential prerequisites to an optimal modern, evidence based and comprehensive treatment system.

Stigma at Macro, Meso and Micro Levels

When thinking about how the process map might be used, one approach may be to consider the impact of stigmatisation operating at different levels in communities and across health systems.

International research on the public stigmatization of people with AUD indicates that stigmatization is high in comparison with other mental disorders and has remained substantially unchanged over a 20-year period [1]. This is manifest in reluctance to consider alcohol use as a mental health problem; attribution of responsibility and blame; prevalence of negative stereotypes; and relative public acceptance of structural discrimination. If we start with the "micro" level, we can learn much from the reasons people give for not accessing treatment, or for significant delay before they do so. In a study of people identified as having AUD by screening in primary care settings in six European countries [2], the most common reasons given for not seeking treatment were "lack of problem awareness" and "stigma or shame". Given this message, what are the factors at macro and meso levels that can have a positive or negative impact?

At a "macro" level, if the priority given to alcohol health literacy and prevention of alcohol-related harms by national and local public health systems is low in proportion to the scale of alcohol-related harm, this constitutes a form of stigma by neglect. Further complications arise from tension between economic drivers and health concerns, and the relative influence of (for example) lobbying by the alcohol industry [3, 4]. Where evidence-based public health interventions (e.g., minimum unit pricing, taxation on alcohol, reduced access to alcohol) may be unpopular, it can be politically convenient for government departments to portray alcohol use as a matter of personal choice, therefore further stigmatising those who develop AUD.

In contrast, clear political leadership, and evidence of commitment to public health strategies to prevent and reduce alcohol-related harm can help to influence societal health literacy and attitudes towards alcohol use. Similarly, dedicated funding for high-quality, person-centred specialist treatment services, and prominence in priorities for research funding to develop the range of interventions available, indicate a commitment to people with AUD and to their circle of concern, as a public good rather than for a marginal group.

At a "meso" level, training of health professionals is a key factor with impact. Without training, staff in healthcare settings will bring to their roles the attitudes to alcohol use of their family background and wider culture. These will vary widely and not all attitudes will be stigmatising, but training should help to reduce overall stigma by providing staff with a sound understanding of the relationship between

alcohol use, alcohol-related harm, and AUD. Healthcare staff are particularly well-placed to have conversations about alcohol, and to help with prevention and early detection of AUD. For example, if discussion about alcohol use and screening for AUD is routine in a wide range of healthcare settings as for other risk indicators such as blood pressure, public understanding can grow. Healthcare staff who are comfortable with initiating conversations about alcohol and have positive and hopeful attitudes towards recovery can help people to feel positive both about their own potential for change and about their entitlement to seek help.

In contrast, where training is lacking, healthcare staff may feel powerless to help. When this happens, there may be a "collusion of denial" [5] where the problem is not spoken about; or the staff member may see the problem as the responsibility of others or of the person themselves. Therapeutic nihilism resulting from underfunded treatment services, and the lack of high-profile patient advocacy groups (as seen for cancer diagnoses in many countries) also has a stigmatising impact.

For people who have already realised that they are in difficulty with alcohol use, and who would like help, there may be many obstacles to accessing the correct care. These may include difficulty in finding out where and how to seek help, understanding what that would entail, and how feasible that may be for them based on resources required (including time, transport and other practical factors). Current alcohol treatment systems often appear complex to those not working within them, and people require a significant amount of agency to navigate their way successfully through them [6]. A further barrier noted by Probst and colleagues [2] in their primary care-based study was the wish not to stop drinking completely: therefore it is important that healthcare services welcome people who have concerns about their alcohol use but are undecided about their long-term goals [7]. To be effective, service planning at "macro" level and service delivery at "meso" level need to take into consideration these and other barriers that impact local populations.

Specialist alcohol treatment systems need to offer high quality person-centred care, to be acceptable and effective [8]. This includes integration with sustainable recovery communities (see below), which link in with health systems as part of a dynamic pathway for individuals to enter and exit treatment [9]. In most societies, funding for alcohol-related research does not reflect the burden of harm from this substance. Thus, a proactive co-ordinated and responsive system, which could influence policy makers could also stimulate a more active and productive research environment.

With the broad-ranging vision described above, the hope would be that:

- alcohol is used more safely in the population in general
- fewer people are at risk of alcohol-related harm
- where harm is experienced, it is detected quickly (by improved early self-identification due to increased levels of alcohol health literacy)
- people are more willing to present to health professionals (reduced stigma)
- Integrated health systems and training of health professionals ensure early detection in all settings
- effective help is available at the "early intervention" stage

- fewer people will develop severe AUD
- of those who develop severe AUD, fewer will progress to a long-term condition with an inherent pattern of remission and relapse.

However, there will always be individuals whose vulnerabilities (biological, psychological and social) will require the specialist interventions described in section three of this text. The rest of this chapter therefore considers the conceptualisation and framework of a multi-disciplinary, modern, and comprehensive treatment system with which people with severe AUD may best engage. If we consider severe AUD as a long-term condition, it will require a holistic and personalized response to people's needs which will change over time. A recovery-orientated system of care offers a helpful lens through which to consider this [9–11].

AUD as a Long-Term Condition and Recovery Systems

Definitions of Recovery

The concept and parameters of what constitutes 'recovery' have changed over the years and there still remain significant variations in how it is used [12–15].

However, over the last two decades the concept of recovery has evolved from being almost uniquely associated with the 12-step process where the terms 'recovery' and 'abstinence' were essentially synonymous to a much broader concept. The United Stated Substance Abuse and Mental Health Services Administration (SAMHSA) defined recovery broadly for addictions and other mental disorders as having four dimensions [16]:

- Health
- Home (having a stable and safe place to live)
- Purpose (meaningful daily activities)
- Positive relationships and networks

The lack of a clear consensus on the definition of recovery has inevitably limited the development of a body of evidence that could assist in understanding its role in terms of improving outcomes for patients with severe AUD within treatment systems. However, the US National Institute on Alcohol Abuse and Alcoholism (NIAAA) [17] has recently published an alcohol specific recovery research definition based on DSM-5 AUD criteria, which they hope will address these limitations and facilitate recovery-related science. In this definition, as well as being an 'outcome', recovery is also recognised as a 'process' through which individuals 'pursue' remission from DSM-5 AUD criteria, as well as cessation of heavy drinking, both of which they also define [17].

This categorical definition may help improve the clarity of research in this area, but globally definitions of recovery are likely to remain highly variable, and potentially contentious. It is also worth noting that given that stigma towards 'alcoholism'

from which the 12-step recovery movement emerged, for some the term 'recovery' is similarly stigmatised and other less value-laden terms such as living 'alcohol-free' are preferred [18]. As in other areas of medicine and society people may choose to self-identify as being 'in recovery', despite never having had a diagnosis of AUD or any treatment for it. Given that the significant majority of people with severe AUD do not access any formal treatment [2, 19–21], this process of 'natural recovery' represents an important and significant number of individuals. Understanding that people with AUD may reach stable recovery through a range of 'natural' as well as 'assisted' routes, enables an exploration of how and why this may vary between different individuals [22]. This in turn could inform policy at the macro and meso level to reduce stigma, improve access to appropriate treatment at the appropriate time, as well as impact on societal norms around alcohol.

AUD as a Long-Term Condition

The historical divisions between addiction and broader psychiatric services have been well described [10], and sadly remain in many places. This continued lack of integration despite overwhelming evidence of comorbidity between disorders [23] needs to be addressed as well as the importance of treating both disorders if positive outcomes for patients are to be achieved [24, 25].

The concept of recovery-oriented systems of care evolved from the advocacy of people who had overcome addictions or mental ill health for provision of care to be more than the reduction of symptoms or substance use, and to focus more holistically on the longer term goals of individuals living well in their communities [9]. Whilst this requires the engagement of the individual, active consideration is also needed of the wider determinants of health and social inequalities (e.g., childhood adversity, poverty, social networks, educational disadvantage, poor housing, race, gender etc.), which may reduce the agency needed by an individual to access and engage with treatment services, and sustain that engagement over time [6]. Whilst the effectiveness of Recovery orientated systems of care have not been systematically tested, there are many similarities with the well-developed evidence base for management of long-term conditions from which evidence can be extrapolated.

From a health system perspective considering AUD as a long term condition (or within a chronic disease model) is reasonable given its natural history, spectrum of severity, relapse and remission pattern, and frequent co-morbidities [26]. The effective management of long-term conditions requires a range of interventions: evidence-based medical interventions, targeted to the stage and severity of illness; patient education to enhance self-management; and the development of 'systems of support' (including non-health professionals, voluntary and community groups, and immediate circle of concern) [27]. As part of this, the role of collective efficacy is recognised as important in supporting sustained behavioural change and improving outcomes [28].

The joint working between patients ('experts by experience') and clinicians ('experts by training') is increasingly recognised as essential for optimal outcomes in long term conditions and for patients with AUD. This includes the development of patient reported outcome measures (PROMS) and patient reported experience measures (PREMS), which focus on health-related quality of life, and aspects of the 'humanity of care' from a patient perspective [29, 30]. One such PROM has been developed with people in recovery (but not specifically for AUD), focussing on patient perspective both in its development and intended use. SURE –(substance use recovery evaluator) has been shown to be psychometrically valid, and easy to complete [31]. PROMS combined with other longer-term quality of life measures used in research and routine care [32] should help to develop services which are more personalised and responsive to patient needs.

So what might modern, evidence based and comprehensive treatment for patients with AUD look like?

First, we need to be acutely aware that any specialist service for people with AUD will only ever be a marginal aspect of the societies in which we live, where the majority of people drink alcohol and where alcohol production and consumption may be a significant economic driver. This causes tension for national and regional policy makers, structural stigma within health systems, and challenges for patients to know how best to access care at earlier stages [33]. It could be argued that an essential aspect of clinical leadership within addiction services is to play a role in challenging this, and developing the competencies required within the non-specialist workforce [34].

Second, if we consider AUD as a long-term condition, we need to continue to improve and refine our evidence-based treatments, so that differences in age, gender, stage of illness, and associated co-morbidities can be factored into a personalized treatment plan. Patients' pathways are rarely linear (see Fig. 11.2) most will

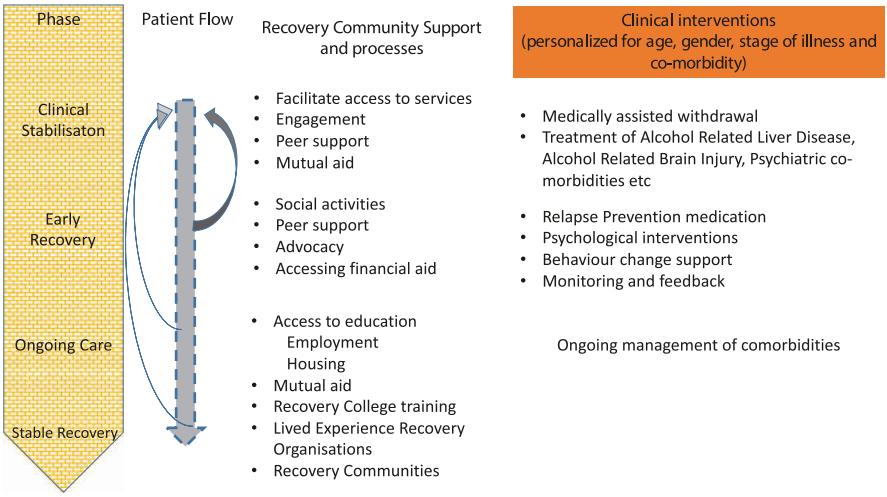

Fig. 11.2 Framework for a modern comprehensive system of care for severe AUD

have spiral trajectory through any system of care, and each new presentation may require a different approach. Therefore, health systems need to be set up to be able to offer a range of modalities of treatment as appropriate (e.g., harm minimization, medically assisted withdrawal, relapse prevention interventions etc.) rather than these being seen as separate entities. In addition, the pathway through services and the importance of systems of support in developing collective efficacy is likely to be significantly enhanced by integration with recovery communities providing peer support, facilitating access to housing and education, as well as encouraging an early return for clinical treatment after relapse.

Finally, given the significant interdependencies of AUD with alcohol related comorbidity and mortality, and the wider health and social inequalities experienced by people with AUD [33, 35] the structural barriers to accessing appropriate personalized care need to be reduced. Integrated pathways, and evidence-based interventions specifically for patients with alcohol related liver disease [36, 37], and co-morbid mental health conditions [24, 25] are an essential component of any modern evidence based treatment system to ensure people with AUD have the best chance of achieving and sustaining recovery.

Chapter 12
Diagnosis of Alcohol Use Disorder and Identification of Unhealthy Alcohol Consumption

Anne Lingford-Hughes and Alexander Vale

Abstract Correct identification of individuals that misuse alcohol and robust, comprehensive assessment of their symptoms, circumstances and complexity is essential for making effective decisions about treatment. This chapter discusses how definitions of harmful levels of alcohol consumption differ between nations and when compared to World Health Organisation (WHO) guidance. It also outlines the two principal frameworks that exist for diagnosis of alcohol related disorders, the fifth version of Statistical Manual of Mental Disorders (DSM-5), and the eleventh revision of the International Classification of Diseases (ICD-11). Classification of alcohol disorders within the DSM-5 has undergone significant changes from its predecessor. Assessment of patients with alcohol problems is best achieved by taking a comprehensive psychiatric history, adapted for and focussed on the patient's history with alcohol. This chapter will outline the kind of comprehensive assessment undertaken in a specialist alcohol service that can be adapted depending on the setting and presentation of the individual. Alcohol history taking is demonstrated in view of the diagnostic criteria set out earlier in the chapter. Several other considerations during the assessment process are described to allow for better understanding of the backgrounds and complexities of those who misuse alcohol. The chapter describes the relevance of social and personal circumstances to the drinker, the physical health and neurological complications alcohol drinkers may experience and the interface with co-morbid mental health problems.

Introduction

Correct identification of individuals that misuse alcohol and robust, comprehensive assessment of their symptoms, circumstances and complexity is essential for making effective decisions about treatment, and to establish a therapeutic alliance. Consideration of alcohol use disorders should be made in all clinician settings, ergo all clinicians should have an awareness of alcohol use disorders and when to seek support and specialist intervention, always acting within their own competencies. This chapter will examine the frameworks that exist for diagnosis, before moving onto considerations a clinician should make when assessing patients. Breakdown of the assessment process is comprehensive but not exhaustive and directs the reader to further topics when required.

Harmful Levels

To contextualise the diagnosis and assessment of patients with alcohol problems, it is imperative to understand the description of alcohol use and safe drinking levels. There is no single international standard. While many countries have adopted the "standard drink" to include 10 g of pure alcohol as dictated by the World Health Organisation (WHO) [1] and its Alcohol Use Disorders Identification Test (AUDIT), this varies widely, ranging between at least 8–20 g in different countries.

There is an even wider variation in how countries define low risk alcohol consumption. Some define low risk consumption both per day and per week, while others do not. In addition, some countries chose to make separate recommendations for men and women. Table 12.1 [2] below illustrates this, and for comparison, the

Table 12.1 Governmental standard drink definitions and low-risk consumption guidelines in grams of pure ethanol from selected European countries compared with the United States adapted from [2]

Country	Standard drink (g)	Guidelines for men		Guidelines for women	
		Per day	Per week	Per day	Per week
USA	14	56	196	42	98
Austria	20	24	168	16	112
Croatia	10	12	–	10	–
Denmark	12	–	168	–	84
France	10	30	210	20	140
Germany	12	24	–	12	–
Ireland	10	–	170	–	110
Italy	12	36	–	20	–
Poland	10	40	280	20	140
Spain	10	–	170	–	110
Sweden	10	20	–	10	–
United Kingdom	8	24–32	–	16–24	–

WHO defines low risk consumption on a single drinking day as 1–40 g for men, and 1–20 g for women. Comparisons to the United States are of particular importance given the proportion of clinical trials that emerge from the country.

Diagnosis

The reader will likely be aware of the two principal frameworks for mental illness classification used globally. Firstly, we have the Statistical Manual of Mental Disorders (DSM) published by the American Psychiatric Association (APA). The fifth and latest version of the DSM was published in 2013 and it will henceforth be referred to as DSM-5 [3]. Secondly, the International Classification of Diseases (ICD), published by the WHO that is currently on its 11th revision, was ratified in May 2019. It will henceforth be referred to as ICD-11 [4]. Each publication differs in origin and scope which will not be discussed in this book chapter. The diagnostic criteria set out in these frameworks underpin the assessment of patients who misuse alcohol. Of note, it is convention for the DSM-5 to be the principal framework used in research studies. This is important as there are differences between DSM-5 and ICD-11, particularly in regard to 'alcohol dependence' as described below [5].

DSM-5

From DSM-IV to DSM-5 there were bigger changes compared to the relatively incremental changes between the latest versions of the ICD [3, 6]. In the DSM-IV, there were two distinct disorders (alcohol abuse and alcohol dependence) which have been collated into a single disorder with sub-classifications to denote severity for the DSM-5. The new diagnostic category, Alcohol Use Disorder (AUD), represents a single continuum between abuse and dependence, therefore AUD would not always be synonymous with alcohol dependence going forward. Of note is that DSM-5 removes a criterion referencing legal problems, including arrests and criminal convictions directly resulting from alcohol use.

Previously in DSM-IV, over a 12-month period, meeting 1 or more abuse criteria would denote an alcohol abuse diagnosis. If over the same 12-month period, a patient met 3 or more dependence criteria, they would receive the diagnosis of alcohol dependence. Now in DSM-5 when a patient meets 2 or more of the following criteria within a 12-month period, a diagnosis of Alcohol Use Disorder can be made as shown in (Table 12.2):

Table 12.2 AUD is subject to the following sub-classification; Mild AUD, 2–3 Criteria met, Moderate AUD, 4–5 Criteria met, Severe AUD, 6 or more criteria met

Criteria	Alcohol use disorder (DSM-5)
1	Alcohol is often taken in larger amounts or over a longer period than was intended
2	There is a persistent desire or unsuccessful efforts to cut down or control alcohol use
3	A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects
4	Craving, or a strong desire or urge to use alcohol
5	Recurrent alcohol use resulting in a failure to fulfil major role obligations at work, school, or home
6	Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol
7	Important social, occupational, or recreational activities are given up or reduced because of alcohol use
8	Recurrent alcohol use in situations in which it is physically hazardous
9	Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol
10	Tolerance, as defined by either of the following:
	(a) A need for markedly increased amounts of alcohol to achieve Intoxication or desired effect
	(b) A markedly diminished effect with continued use of the same amount of alcohol
11	Withdrawal, as manifested by either of the following:
	(a) The characteristic withdrawal syndrome for alcohol
	(b) Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms

ICD-11

ICD-11 describes two distinct diagnostic categories that will be especially clinically relevant to the reader, Alcohol Dependence and Harmful Pattern of Use of Alcohol. Previously in the ICD-10 they were referred to as Alcohol Dependence Syndrome and Harmful Alcohol Use respectively [7]. The Table 12.3 indicates the definition of each diagnosis using slightly formatted but close to exact language from the ICD-11.

The definition of alcohol dependence has changed incrementally between ICD-10 and ICD-11. The diagnosis performed well psychometrically and showed high concordance with its DSM-IV equivalent, meaning that fundamental changes were unnecessary as described by Saunders et al. [8]. With regard to Harmful Pattern of Use of Alcohol, the paragraph regarding harm to the health of others was added to the ICD-10 counterpart to reflect the collateral damage experienced by those around the alcohol user [9].

Table 12.3 Alcohol dependence and Harmful Pattern of Use of Alcohol as described by ICD-11

Alcohol dependence	Harmful pattern of use of alcohol
A disorder of regulation of substance use arising from repeated or continuous use of substance. The characteristic feature is a strong internal drive to use substance, which is manifested by impaired ability to control use, increasing priority given to use over other activities and persistence of use despite harm or negative consequences	A pattern of alcohol use that has caused damage to a person's physical or mental health or has resulted in behaviour leading to harm to the health of others
The diagnosis requires two or more of the following three central features to be evident over a period of at least 12 months, but the diagnosis may be made if alcohol use is continuous for at least 1 month.	The pattern of alcohol use is evident over a period of at least 12 months if substance use is episodic or at least 1 month if use is continuous.
1. Impaired control over alcohol use—in terms of the onset, level, circumstances or termination of use, often but not necessarily accompanied by a subjective sensation of urge or craving to use alcohol.	Harm to health of the individual occurs due to one or more of the following:
2. Alcohol use becomes an increasing priority in life—takes precedence over other interests or enjoyments, daily activities, responsibilities, or health or personal care. Alcohol use takes an increasingly central role in the person's life and relegates other areas of life to the periphery; continues despite the occurrence of problems.	1. Behaviour related to intoxication
3. Physiological features (indicative of neuroadaptation to the alcohol) as manifested	2. Direct or secondary toxic effects on body organs and systems
By; (i) tolerance, (ii) withdrawal symptoms following cessation or reduction in use of that substance or (iii) repeated use of the substance (or pharmacologically similar substance) to prevent or alleviate withdrawal symptoms. Withdrawal symptoms must be characteristic for the withdrawal syndrome for alcohol and must not simply reflect a hangover effect.	3. A harmful route of administration.
	Harm to health of others includes any form of physical harm, including trauma, or mental disorder that is directly attributable to behaviour related to alcohol intoxication on the part of the person to whom the diagnosis of Harmful Pattern of Use of Alcohol applies.

There is no DSM-5 equivalent for Harmful Pattern of Use of Alcohol. The ICD-11 also added a new category entitled Hazardous Use of Alcohol. This is included in the health risk factors section and does not constitute a diagnosis. It is not discussed in full during this chapter other than to define it as not yet reaching the level of having caused harm to physical or mental health of the user or others around the user, which distinguishes it from previously discussed diagnostic categories (Fig. 12.1) [4].

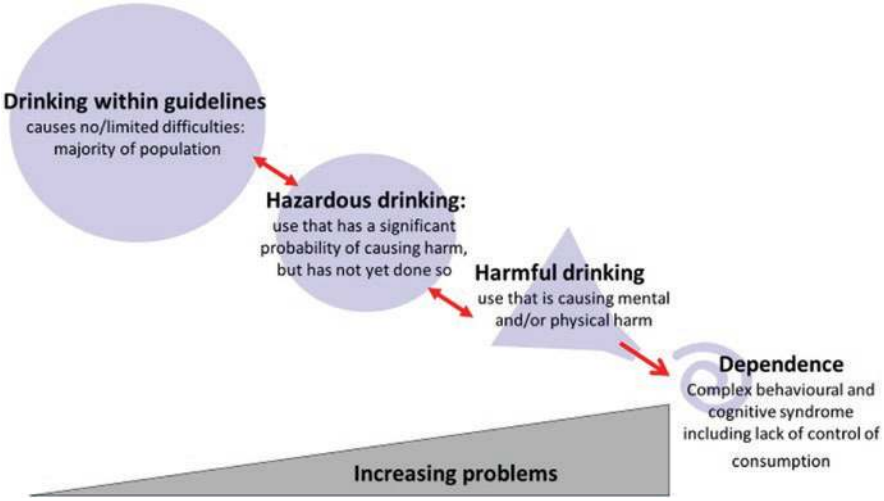

Fig. 12.1 Progression of categories of drinking behaviour according to ICD-11. Harmful drinking is depicted as a funnel as without change, the risk of progression to the 'spiral' of dependence is high. Likely movement between categories is depicted as bidirectional arrows, with one-way arrow to dependence as recovery to other categories of drinking behaviour is unlikely

Binge Drinking

There is no universally accepted definition of binge drinking and therefore no diagnostic criteria. In the United States, binge drinking is defined as a pattern of drinking that brings a person's blood alcohol concentration (BAC) to 0.08 g/dL or above. This is typically achieved when men consume 5 or more standard drinks (14 g of pure ethanol in the USA) and women 4 or more drinks in a 2-h period [10]. In contrast, the U.K. [11] defines binge drinking as males who exceeded 8 "units" of alcohol on their heaviest drinking day, and females who exceeded 6 "units" on their heaviest drinking day. (A "unit" is a term used in the U.K. to denote 8 g of pure ethanol).

The initial description of binge drinking is centuries old, and with time the term has moved from describing a period of heavy drinking lasting several days, toward often describing a single episode or day. Somewhat confusingly, both definitions continue to be used when describing the problems of those that misuse alcohol [12]. In view of this, when drinkers use binge drinking to describe their own relationship with alcohol, it can refer to a variety of patterns. A clinician should always clarify the exact details with focus on the degree of control they exhibit.

Dependence vs. Addiction

Before moving on to assessment of patients with alcohol disorders, an important point needs to be made about the difference between addiction and dependence. During the meetings and subsequent debates between experts that resulted in the creation of the DSM-III-R [13], published in 1987, a vote decided on diagnostic language used. Many favoured "addiction", citing its association with a behavioural compulsion and distinguishing it from physical dependence. The counterargument for "dependence" declared it could more easily be applied to all substances and would avoid unnecessary stigmatisation. As the reader may have inferred, "dependence" won the vote [14].

The result has created linguistic confusion for clinicians, and the reader may have also noticed that "dependence" was removed from a diagnosis for DSM-5. In biology and pharmacology, dependence refers to a physical adaptation to a substance including, for example, tolerance and withdrawal. Like opioids, alcohol and benzodiazepines, other prescription drugs can cause physical dependence but are not necessarily associated with broader complex behaviours typically seen in 'addiction', for example drug-seeking, primacy of drug-related behaviours etc.

It is important to communicate with patients in language they both understand and feel is relevant to establish both rapport and a therapeutic relationship. Furthermore, a misunderstanding between clinicians may lead to mismanagement of the patient's illness. For example, if a patient is admitted to a medical setting for a pharmacological detox to treat alcohol dependence, they could be discharged as soon as the detox is completed, without an aftercare plan. This fails to acknowledge that addiction often follows a relapsing-remitting pattern, and that long-term disease management that includes psychological support and treatment is essential in sustained abstinence and recovery.

Assessment of Patients with Alcohol Related Problems

The assessment of patients with alcohol problems is best achieved by taking a comprehensive psychiatric history, adapted for and focussed on the patient's history with alcohol. This chapter will outline the kind of comprehensive assessment undertaken in a specialist alcohol service in order to demonstrate the gold standard. Patients' needs and priorities will vary widely, meaning assessments may be more focused on different areas, depending on the patient. It is likely that the information will be gathered over more than one visit and involve contact with a range of members of a multidisciplinary team.

It is important to remember that although this is likely to be an interaction between a clinician and a patient, it is also a discussion between two people [15].

The patient is likely to share deeply personal and possibly traumatic information when describing their history with alcohol. Creating the right environment for the patient to feel comfortable doing so is therefore integral. Assessment alone can help change the drinker's attitudes towards drinking [16].

It is also important to make a few further points about language. If the assessor is familiar with the vernacular of individuals who misuse alcohol, for example the measures in which they consume drinks (e.g., pints, cans, a half of whisky) or even brands and preparations of alcohol available it is likely to increase rapport and set the tone for a better assessment. Some people with alcohol disorders may not even wish to be known as "patients". It is commonplace in the U.K. to refer to people accessing alcohol services as "clients". In practice, it is best to clarify preference in this regard with the person directly [17]. This chapter refers to people with alcohol use disorders as patients for consistency.

Referral

If a patient has been referred to an alcohol service, it is important to note who made the referral, which can be done before seeing the patient. They may have self-referred after doing their own research, or be referred there by another clinician or service. Alternatively, they may have been referred directly by another professional. One common route of referral to draw attention to is those from criminal justice systems, for whom referral to treatmens is sometimes also part of a probation arrangement. A self-referral may indicate a greater degree of motivation, whereas a history of non-attendance would naturally raise concerns about engagement and indicate that a more assertive approach may be required. Ideally, referrals should be well triaged by an experienced or the lead clinician.

Alcohol History

It is most important to establish a current pattern of drinking, in part to inform the clinician about the nature and severity of the patients' alcohol problems, and whether they are physiologically dependent. Some patients will have a very regimented and consistent pattern of consumption. At the other extreme, some patients will vary the quantity and type of alcohol daily. Below are important lines of enquiry and some examples of common effective questions [18]. The reader should note that an aim of the alcohol history is to ensure all domains in the diagnostic criteria set out earlier in the chapter are discussed.

1. **"Talk me through a typical drinking day".** This alone can sometimes elicit enough information to determine quantity, type of alcohol and drinking pattern. This can be followed with closed clarifying questions if required. It is also good

practice to ask the patient to complete a simple drink diary over 1 week, especially if further clarifications are required, or the patient is unable to describe their drinking effectively. If possible, the exact nature of alcohol consumed should be determined, including the brands and preparations.

2. **Salience.** One must determine if other aspects of the patients' life have been neglected in order to facilitate the procurement and consumption of alcohol. Suggested domains for inquiry would be employment ("have you missed work due to your drinking?") and relationships (has your relationship with your partner/children been affected by your drinking?). The clinician should directly enquire about the impact of recovery from heavy drinking episodes on the patients' responsibilities.
3. **Control.** A lack of control over alcohol consumption is a central feature of alcohol use disorders. Patients should be asked if they often drink more or for longer than initially intended. Another useful question is "Who has more control, you or the alcohol?" [15] A week or two of abstinence interspersed with weeks of heavy continuous drinking or another harmful pattern use, is not evidence of control. The patient may perceive such patterns as controlled and should be sensitively challenged accordingly [15]. Furthermore, the patient should be asked if they have an unfulfilled desire, and made unsuccessful attempts to reduce or stop drinking. This is also highly relevant to treatment planning, since in the absence of motivation to stop or reduce drinking, treatment is not likely to be successful [19].
4. **Compulsion.** The patient should be asked directly about the strength of their craving or urge to drink. This should be separate from features of withdrawal discussed below. The clinician should also ask if this compulsion continues in the presence of knowledge that drinking is harmful to their physical health, mental health and social well-being.
5. **Tolerance.** Consuming progressively more alcohol without reaching intoxication is an important feature of dependence. A simple question could be "Have you noticed that you need to drink more to become drunk?" or "Are becoming less drunk with the same amount of alcohol?"
6. **Withdrawal.** The patient must be asked about what happens if they do not drink. If the patient is physically dependent, he or she will experience the classic alcohol withdrawal syndrome. Symptoms to be specifically asked about are agitation, restlessness, sleepiness, shakiness, sweating, nausea, withdrawal seizures, and hallucinations in visual and tactile modalities. A clinician may enquire about hallucinations by asking "do you ever see or sense things that aren't there?". Alcohol withdrawal is dangerous, potentially fatal and often poorly understood by the drinker. For example, many patients who are alcohol dependent are unaware that withdrawal exists beyond tremor and agitation. The identification and management of withdrawal is discussed in a separate chapter. It is important to differentiate alcohol withdrawal from blackouts, defined by the inability to recall events that occurred during a drinking episode. These can be complete or fragmentary and are associated with increased harm. Patients can also be scared the following day upon realising they have no recollection of events [20].

7. **Timeframe including periods of abstinence**. Alcohol Use Disorders often follow a relapsing-remitting pattern. Enquiring about the timeframe of a patient's alcohol use is necessary per the diagnostic criteria, and helps the clinician better understand the patient's journey and circumstances. Carefully document the patient's timeline, and include treatment they received, if any, at the time. Previous treatment may include detoxification (inpatient or outpatient), rehabilitation (inpatient or outpatient), previous engagement with specialist drug and alcohol services, psycho-social interventions and experience with mutual aid organisations, for example, Alcoholics Anonymous.
8. **Risks.** Enquiry into and assessment of risk is an important part of a psychiatric history, and this remains true when adapted for alcohol use disorders. Important discussion points include:

   – Risky behaviours associated with acute intoxication; For example, intoxication may result in unprotected sexual intercourse, increasing exposure to sexually transmitted viruses. Other common situations that could lead to harm include physically violent altercations, drunk driving, operating machinery, or walking alone at night in darkened areas. A degree of disorientation occurs in acute intoxication leaving the person at risk of accidents and misadventure of varying consequence [15, 18].
   – Deliberate self-harm and suicide attempts; both are of higher prevalence in those with alcohol disorders and must be enquired upon. The clinician should determine whether there are suicidal thoughts, intent, or specific plans. If the latter, the nature of those plans must be explored, with the understanding that plans involving active methods (e.g., hanging, use of firearms) are associated with the highest risk. This information must be integrated with an understanding of other key risk factors for suicide, such as male sex, and lack of social support (see below).
   – Additional risk to others; the clinician should enquire about the welfare of dependents in the patients' life for example, their children and anyone else they formally care for.

9. **Treatment Goals.** It is important to establish the goals of the patient in order to inform future treatment. A patient who drinks daily may wish for a 'quick fix' of more "controlled drinking", which is difficult to achieve. Alternatively, they may wish for abstinence and plan to do this immediately which is unwise and dangerous. More suitably, a patient that drinks daily may wish for abstinence via gradual reduction in consumption or a pharmacologically assisted detoxification programme, or a patient that occasionally drinks to excess may wish for less frequent episodes where less alcohol is consumed. Establishing patient goals allow for an open discussion and expectation setting.

Screening Questionnaires

There are several validated questionnaires to assess alcohol use disorders. They should not replace the comprehensive framework of assessment illustrated in this chapter, but can identify those needing onward referral to specialist services. They are useful in settings where assessment of alcohol related problems was not the primary goal of the conversation, for instance in outpatient clinics, inpatient psychiatric wards and psychological therapy services.

The most used screening questionnaire is the Alcohol Use Disorder Identification Test (AUDIT), developed with support of the WHO [21]. The standard version comprises of 10 questions each scoring 0–4 points, and can form part of a structured interview or be self-administered. A score of 1 to 7 suggests low-risk consumption. Scores from 8 to 14 suggest hazardous or harmful alcohol consumption, and a score of 15 or more indicates the likelihood of alcohol dependence (moderate-severe alcohol use disorder according to the DSM-5). Thus, a score of 8 or higher denotes drinking warranting further assessment. The Fast Alcohol Screening Tool (FAST) and Paddington Alcohol Test (PAT) are two relatively recent questionnaires that are brief and intended for use in emergency room settings [15].

Polysubstance Use Involving Alcohol

Polysubstance use has become increasingly common and has been exacerbated by increased availability of prescription drugs of abuse such as opioids and benzodiazepines. This chapter will not discuss the prevalence of other substance use disorders with alcohol in detail but will include vital information. The most common substance use combination with alcohol is nicotine and it has been shown that each can act as a conditioned cue for the other [22]. The clinician should ask about tobacco use when assessing patients with alcohol use disorders, and should be aware of important associations. For example, alcohol dependent smokers have higher rates of tobacco related disease, and are more likely to die form tobacco related disease than alcohol dependence [15]. Furthermore, head and neck cancers, cirrhosis and pancreatitis are more common in those that misuse alcohol that also smoke [23].

The clinician should ideally use an open question such as “Do use any other drugs?”, before asking a series of clarifying closed questions if needed about individual drugs. If not mentioned in the discussion, the clinician should be sure to ask about use of the following drugs and their derivative products; cannabis, stimulants including cocaine and amphetamines, opioids, benzodiazepines and “Z-drugs”, novel psychoactive substances and club drugs including ketamine, gamma hydroxybutyrate (GHB), MDMA and mephedrone. This list is not exhaustive, hence there is

value in asking “Do you use anything else?” to ensure substances are not missed. This question could also reveal the misuse of prescription drugs that may not necessarily be illegal. Another question that can be of relevance is” do you buy anything over the internet?” as drugs of abuse are increasingly being procured online.

Of particular importance are drugs that can create a dangerous and fatal level of central nervous system and therefore respiratory depression in combination with alcohol, with opioids, benzodiazepines and GHB being important examples. Furthermore, when cocaine and alcohol are taken together, they form an active metabolite called cocaethylene. This enhances the euphoric effects of cocaine and increases the risk of cardiotoxicity. If a patient with polysubstance use is encountered, a referral to a specialist drug and alcohol service is strongly recommended.

Social Circumstances and Personal History

This broad area of the assessment process allows for a better understanding of the patient, their strengths and vulnerabilities, and how this may shape their relationship with alcohol [15]. Information gathered from this conversation can also give the clinician insight into the patient’s support network, which can be crucial in achieving and maintaining abstinence. The clinician should gather information on patients’ childhood, interaction with their parents, and educational attainment. The patient should also be asked about family history of alcohol use disorders, especially amongst first degree relatives.

The clinician should enquire about past and current employment history, and their current financial situation and sources of income, including how much they are spending on alcohol per week. One should also ascertain current and historical romantic relationships, and access to a healthy and supportive friendship network with particular focus on how alcohol might impact the relationships. Finally, it is good practice to enquire about forensic history, and any interactions the patient has had with the police force, especially in the context of acute intoxication. It is worth noting the association between alcohol and domestic violence, and drinkers can be both the perpetrators and the victims [24]. The clinician should aim to sensitively enquire about domestic violence, especially if suspicion is raised.

Physical Health and Neurological Complications

Discussion and assessment of physical health is an integral component of the approach to treating individuals with drinking problems. The World Health Organisation estimates that 4% of all worldwide deaths and 4.5% of the global burden of disease and injury are attributable to alcohol [25]. At the point of pharmacological dependence, one can be close to certain that it presents danger to the individual’s body tissue and biochemistry.

The clinician should question the patient on their past medical history, identifying current and past diagnoses and the extent of specialist involvement. For example, are they treated in a hepatology clinic? To fully investigate all potential physical complications, a patient would require several interventions. The list below is not exhaustive but should allow the reader to consider the comprehensive nature of physical complications in those who misuse alcohol. It is essential that a clinician acts within their own competence and seeks advice and onward referral, when necessary, which is likely to be often. An advanced nurse practitioner or doctor should be involved in assessment and clinical decision making at this juncture.

1. **Physical examination**. An abdominal examination in view of the association with liver disease, acute and chronic pancreatitis, gastrointestinal ulceration and other gastrointestinal tract disease.

   Alcohol is primarily metabolised by the liver, making this organ an important site of alcohol related pathology. Accordingly, alcohol is the biggest cause of liver damage in the U.K., USA, Europe and Australia [15]. Patients may not develop or notice symptoms of alcohol-related liver disease until it is advanced, resulting in jaundice, encephalopathy or gastric bleeding, so early identification of those who are at risk is crucial. There are three broad categories; fatty liver (reversible with abstinence), alcoholic hepatitis (may be fatal but can be reversible with abstinence), alcoholic cirrhosis (progressive and can be fatal but can stabilise with abstinence). Some alcohol services may have access to simple ultrasound methods to screen high risk patients for fatty liver disease and generate appropriate referral to a hepatologist. Non-alcoholic fatty liver disease is associated with obesity alone.

   Other considerations would include cardiac examination and electrocardiogram (ECG), due to risk of arrythmia and cardiomyopathy; respiratory examination, due to increased risk of lung infections secondary to impaired immunity; head and neck examination, due to the association with related malignancy.
2. **Neurological examination**. Alcoholic cerebellar degeneration classically presents insidiously with ataxia and incoordination. Wernicke's encephalopathy is a medical emergency occurring secondary to thiamine deficiency in those that misuse alcohol. Presentation is usually acute, and a classic diagnostic triad of confusion, ataxia and abnormal ocular movements is described. Practically, all three are present in only 10 percent of cases. There should be a low threshold for seeking emergency medical care, especially with new confusion. Individuals with alcohol use disorders may also experience peripheral neuropathy, likely secondary to vitamin B deficiency, and poor diet is also linked to cerebellar degeneration. Therefore, a basic assessment of diet and comment upon nutritional status of the patient is essential. Another neurological consideration is the risk of acute or chronic subdural hematoma. These result from tears in bridging veins that cross the subdural space, and are more likely to occur in patients with a long history of heavy alcohol use that has resulted in gray matter loss and concomitant increase in subdural space. Subdural hematomas are often secondary to falls when intoxicated, but can also occur in the absence of any traumatic brain injury.

3. **Cognitive Assessment**. There should be a low threshold for assessment if cognitive impairment is suspected, particularly in older patients and those that have been drinking heavily for long periods. Common methods of assessment include the Mini Mental State Examination (MMSE) and Addenbrooke's Cognitive Examination (ACE).

   Korsakoff's syndrome can emerge following an acute episode of Wernicke's Encephalopathy or occur insidiously. It is characterised by a deficiency in recent memory, a striking lack of insight, and a disturbance in the sense of time. Personality changes including apathy and self-neglect may also occur, as can confabulation (fabrication of experiences to fill memory gaps). Other cognitive functions usually appear intact unless examined in careful detail.

   Autopsy in heavy drinkers shows a significantly decreased brain weight. CT scanning shows cortical shrinkage and ventricular enlargement in two thirds of alcohol dependent people compared to age matched controls [26]. Similar results have been seen with MRI studies with changes in both grey and white matter [27].

   If a patient is cognitively impaired, it is important to establish a timeline of symptom onset in order to determine whether changes are directly alcohol related. Personality changes resulting from other mechanisms of cognitive impairment could initiate alcohol misuse. It is important to note whether performance on neuropsychology testing improves with abstinence.
4. **Cardiovascular disease risk factors**. The latest evidence suggests that alcohol consumption increases coronary heart disease amongst all drinkers. Previous observational evidence indicating a J-shaped relationship and that light to moderate drinking has a cardiovascular protective effect was oversimplified and oversold [15]. The clinician should consider other risk factors not previously discussed, i.e., body mass index, age, gender, hyperlipidaemia and smoking status.
5. **Other disorders to consider**. Excessive alcohol consumption is associated with several other dermatology, endocrine and metabolic disorders, for example osteoporosis and gout. Excessive alcohol consumption is associated with the development of type II diabetes, which may resolve with abstinence. If a type II diabetic ceases to drink, one must be mindful that a patient's diabetic medications could be more likely to cause hypoglycaemia.
6. **Relevant serological investigations**. Biomarkers are discussed in a separate chapter, but clinically relevant blood tests should be considered depending on clinical findings and further discussion. Serial liver function tests are likely to be required in alcohol-related liver disease.
7. **Imaging**. Brain imaging is required if cognitive impairment or cerebellar degeneration is suspected, preferably by Magnetic Resonance Imaging (MRI). Radiological examination of the liver is often required, typically by ultrasound or computed tomography (CT).

Pregnancy

There is no clear evidence constituting a safe level of alcohol consumption in pregnancy.The consensus is that ideally, pregnant women should abstain from alcohol altogether, due to both increased risk during pregnancy and delivery (including spontaneous abortion, premature delivery and stillbirth) and to the foetus (including foetal alcohol spectrum disorders). It is not advisable to have a baby whilst alcohol dependent due to the physical and emotional consequences. If this situation nevertheless arises, immediate integration with a specialist drug and alcohol service is necessary. Unsupported, abrupt cessation of alcohol would remain dangerous.

Co-Morbid Mental Illness

Alcohol misuse is associated with several co-morbid psychiatric disorders. Many trials examining the treatment of those with alcohol dependence do not include patients with psychiatric co-morbidity. It is important that the clinician recognises when to signpost to other specialist mental health services. This chapter will not describe the diagnostic criteria of other mental disorders, the reader should examine the DSM-5 or ICD-11 for further information as required. Depression and anxiety are the most important to be aware of and it can be difficult to discern whether they were a factor in the development of an alcohol disorder, or a consequence of it. It is good practice to undertake a mental state examination as part of the assessment process. It can provide information on the status of co-morbid mental illness, or even provide clues to undiagnosed mental disorders. If any concerns emerge it is advisable to seek clarification from experienced professionals where necessary.

Depression

Depression is the most important mental illness to ask about and must be distinguished from normal feelings of sadness following adversity. Onset of depressive symptoms should be cross referenced with the timeline of a patient's drinking history, in order conclude which came first if possible. Failure to make these determinations leads to the overdiagnosis of depressive illnesses in those with alcohol use disorders. It can take a significant amount of time to develop an understanding of a patient's story, but it can be essential to ensure effective treatment [15].

This differential diagnosis is not trivial, and needs to be carefully pursued on a case-by-case basis. On one hand, co-morbidity of independent depressive illness and alcohol use disorders is higher than expected from their respective prevalence. On the other hand, depressive symptoms can occur as part of an alcohol withdrawal syndrome, but have been shown to commonly dissipate as a patient achieves

abstinence. Indeed, for most patients' depressive symptoms improve as they reduce or stop drinking but in some, symptoms can persist or even emerge in abstinence. Therefore continual, dynamic assessment of the patient is required if they are receiving on-going treatment from an alcohol service, and the clinician should be aware of how to perform this effectively.

Anxiety Disorders

Symptoms of anxiety disorders are common in patients with alcohol disorders. As with assessing depressive symptoms, the clinician must determine the timeframe of symptoms in relation to the patients' alcohol history and periods of abstinence in order to direct management. Anxiety is a central feature of alcohol withdrawal and often follows heavy drinking, so assessment should distinguish these periods from formal anxiety disorders for example, generalised anxiety and panic disorder when forming diagnoses. Post-Traumatic Stress Disorder (PTSD) is an important anxiety disorder to make a point of. One third of individuals with PTSD are estimated to have had a diagnosis of alcohol dependence in their lifetime [28].

Deliberate Self-Harm and Suicide

Deliberate self-harm and suicide are associated with alcohol use disorder. Thoughts of and intent to carry out each should therefore be asked as part of the risk assessment. Various studies have demonstrated the increased risk of suicide attempts and completed suicide, and remarkably, alcohol consumption precedes or is part of an episode of deliberate self-harm half the time in all of those that then seek hospital treatment [29]. Those with alcohol problems may experience a lack of social support and isolation; unemployment and financial difficulty; co-morbid mental and physical health problems, all of which are risk factors for completed suicide [29, 30].

Bipolar Affective Disorder

Up to 45% of patients with Bipolar Affective Disorder have an alcohol use disorder [31], and there is greater association with manic than hypomanic states. The clinician should determine whether periods of heavy alcohol use are historically associated or causative of manic episodes. If a patient with an alcohol disorder is manic, disinhibition and seeking relief from uncomfortable situations may increase drinking. Acute mania is usually apparent during routine history taking, however, more subtle symptoms may emerge during formal psychiatric examination.

Schizophrenia and Other psychoses

Lifetime prevalence of alcohol use disorders in schizophrenia is estimated at 20% [32]. As with other psychiatric co-morbidity, the clinician should determine the relationship between alcohol and the pattern their psychotic illness follows. Current symptoms of psychosis should be enquired upon in the psychiatric examination, although as with mania, they may be self-evident. Obtaining information from independent informants can be helpful when symptoms are difficult to evaluate. In the event acute psychotic symptoms are present in the context of no past history of psychotic illness, they should be differentiated from alcoholic hallucinosis. This is a rare disorder characterised by auditory or visual hallucinations occurring acutely and in clear consciousness either during or after heavy drinking. Differentiation from schizophrenia can be difficult and may need specialist advice. Psychotic symptoms are also present in withdrawal states (delirium tremens) discussed in a separate chapter.

Other Psychiatric Disorders

Several other disorders can influence the assessment of individuals with alcohol problems. There is a strong association with personality disorders (most commonly anti-social and borderline as per the DSM-5 criteria), attention deficit hyperactivity disorder (ADHD) and eating disorders (most commonly binge eating and bulimia nervosa). As with all psychiatric co-morbidity, it may be that the degree of complexity requires assessment within a specialist alcohol service.

Medication History

It is important to take a detailed list of the patients' current prescribed and over the counter medication, ideally directly from their prescription to ensure accuracy. This can further inform the clinician on the past medical and psychiatric history in the event a patient has forgotten to disclose a condition. It may also present an opportunity to give information on dangerous combinations with alcohol, for example with anti-coagulant medications, or identify potential diminished treatment response, for example lithium in bipolar affective disorder. It can be useful for a clinician to confer with a pharmacist on such matters.

Conclusion

Alcohol is a commonly used drug and unfortunately many individuals consume alcohol at such levels as to impair their mental and physical health. Alcohol impacts on every organ in the body and individuals may not realise the harm their consumption is causing them. Therefore, clinicians should question every patient about their alcohol consumption and to probe further, as necessary, to determine if criteria for harmful use or dependence are met. Direct questioning should also establish if there are any impacts on their health. If someone is drinking at a level causing harm, simple interventions such as making them aware may change their consumption, prevent progression to dependence and improve their health. Once dependent on alcohol, a comprehensive assessment is essential in order to develop an appropriate treatment plan accounting for any biopsychosocial risks eg complications from alcohol withdrawal, safe-guarding, suicidality etc. and recovery capital eg previous periods of abstinence. Not completing an alcohol assessment may result in a patient having unnecessary investigations and/or treatment and should therefore never be missed.

tate screening, diagnosis, and treatment of alcohol-related disorders and thus prevent later complications. The analytical spectrum offers a wide portfolio of direct and indirect alcohol markers which can be investigated. Indirect state markers such as gamma-glutamyl transpeptidase (GGT), carbohydrate deficiency transferrin (CDT), and the mean corpuscular volume (MCV) are influenced by age and sex, various substances, and non-alcohol-related diseases. Furthermore, they do not cover the entire timeline for alcohol consumption. Direct state markers such as ethyl glucuronide (EtG), phosphatidylethanol (PEth), and fatty acid ethyl esters (FAEE) have gained enormous interest in the last decades as they embed the consumed ethanol within their chemical structure. As biomarkers with high sensitivity and specificity covering different windows of detection, they are recommended in guidelines, should be routinely applied, and contribute to new perspectives in the prevention, interdisciplinary cooperation, diagnosis, and treatment of alcohol-related disorders.

Keywords Alcohol biomarker · Ethanol metabolites · Traditional biomarkers · Ethyl glucuronide · Phosphatidylethanol · Gamma-glutamyl-transferase

Introductory Paragraph
State markers of alcohol use offer the opportunity to objectively assess alcohol intake. According to their specific characteristics, they provide different types of information: from abstinence monitoring to assessing heavy use over time. If appropriately applied and used in conjunction with self-reports and questionnaires, they become an indispensable tool in the assessment (including screening) and treatment of many conditions, such as alcohol use disorders (AUD), evaluation of liver transplant candidates, forensic evaluations, and others.

Introduction

Alcohol-related disorders are among the 10 most common diseases worldwide. The point prevalence for alcohol dependence, e.g., in Germany, as in other comparable countries, is 5%, and the lifetime prevalence is 10%. Worldwide, approximately 4% of deaths are attributable to alcohol. This is greater than deaths caused by HIV, violence, or tuberculosis [1]. The yearly costs attributable to alcohol in Europe are approximately 270 billion €. Costs produced by alcohol include both direct costs (i.e., costs in which goods or services are being used or delivered such as medical care) and indirect costs (those stemming from lost productivity due to illness, death, or accidents). Another relevant source of costs attributable to alcohol are intangible costs (costs that are not related to any material loss: e.g., emotional suffering). Importantly, many of these costs are born not only by the individual drinking alcohol but by society as a whole (the so-called social costs) [2].

It is estimated that only about 10% of all alcohol-dependent individuals receive specific treatment, most of them (about 80%) by their general practitioner and only a minority in specialized settings or general hospitals [3]. Thus, alcohol-related disorders are common, expensive in their entire course, and often underdiagnosed. To facilitate screening, diagnosis, and treatment of alcohol-related disorders and thus prevent later complications, questionnaires like the CAGE questionnaire or the Alcohol Use Disorders Identification Test (AUDIT) are useful and recommended in various guidelines. Biomarkers also play an important role in many of the stages of alcohol use disorders, from screening and early detection to treatment monitoring, especially in abstinence-oriented settings [4, 5].

Indirect state markers, as well as direct state markers, are routinely used to detect alcohol use. The indirect state markers like gamma-glutamyl transpeptidase (GGT), mean corpuscular volume (MCV), and carbohydrate deficiency transferrin (CDT) are influenced by age and sex, various substances, and non-alcohol-related diseases. Furthermore, they do not cover the entire timeline for alcohol consumption and in some cases, they need prolonged ingestion of relatively high amounts of alcohol to become elevated [6].

Direct state markers have gained enormous interest in the last decades as they are metabolites of alcohol that become detectable in or after the presence of alcohol. As biomarkers with high sensitivity and specificity that also collectively can cover a more complete timeline following alcohol use, they should be routinely used, and can contribute to new perspectives in the prevention, interdisciplinary cooperation, diagnosis, and treatment of alcohol-related disorders.

Direct Ethanol Metabolites

Direct ethanol metabolites available for routine use are:

- Ethyl glucuronide (EtG), in serum, urine, and hair
- Ethyl sulfate (EtS), in urine and serum
- Phosphatidylethanol (PEth) in whole blood
- Fatty acid ethyl ester (FAEE) especially in hair

Ethanol metabolites are detectable in serum for hours, in urine for up to 7 days, in whole blood for more than 2 weeks, and in hair over months.

Ethyl Glucuronide

Ethyl glucuronide (EtG) is a phase II metabolite of ethanol, with a molecular weight of 222 g/mol, and metabolized by the UDP-glucuronosyl transferase, see Fig. 13.1. Although only about 0.5% of all the ethanol ingested undergoes this degradation

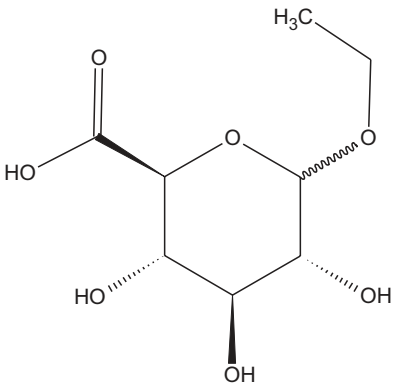

Fig. 13.1 Molecular structure of ethyl glucuronide

pathway, EtG can function as a biomarker that is detectable in the presence of ethanol. Moreover, EtG is non-volatile, water-soluble, stable in storage, and can, depending on the amount consumed and time spent for consumption, still be detectable in the body for a prolonged period after alcohol has been eliminated [7]. It can be detected for up to 90 h in urine. There is no difference in the elimination rate between a healthy population and heavy alcohol consumers at the beginning of detoxification treatment [8]. EtG can be detected in post-mortem body fluids and tissues like gluteal and abdominal fat, liver, brain, and cerebrospinal fluid, and also in the bone marrow and muscle tissue.

Compared with traditional biomarkers, EtG displays a high sensitivity. Even small amounts like 0.1 L champagne can be detected up to 27 h when measuring EtG. Experiments with 1 g ethanol (champagne, whisky) as well as the use of mouthwash and hand sanitizer gels might yield positive ethyl glucuronide concentrations, but usually with values of less than 1 mg/L in urine [9]. Measurable concentrations in urine can be found up to 11 h after the ingestion of alcohol. This aspect is of relevance regarding unintentional exposure to alcohol: Pralines, nonalcoholic beer, pharmaceutical products, fruit juice, sauerkraut, mouthwash products, and hand sanitizer gels may contain small amounts of alcohol. Even the intake of 21–42 g yeast with approximately 50 g sugar leads to measurable EtG and EtS concentrations in urine.

Therefore, a patient's claim of not having consumed alcohol may be trustworthy, even when EtG is detectable in urine. Since patients in withdrawal treatment should avoid even the smallest amount of alcohol, they have to be informed of such hidden sources of ethanol to avoid unintentional intake. A differential cut-off of 0.1 mg/L in cases where total abstinence is the goal, and 1.0 mg/L if small amounts of alcohol intake are tolerated, have been recommended for practical reasons. Applying these cut-offs, the probability of false-positive results is very low [10].

Low positive EtG values can reflect unintentional intake of ethanol. However, by informing the patient about potential pitfalls and using appropriate cut-offs this issue can be handled appropriately.

Selected Applications for the use of EtG:

1. Outpatient Addiction treatment programs

   Regular alcohol screening is a frequent intervention in many outpatient addiction treatment settings. Urine EtG has shown a higher sensitivity compared to traditional screening methods in this population, providing more accurate feedback to both patients and professionals. In a former study, the percentage of ethanol-positive samples was less than 2%, whereas screening for ethyl glucuronide reported positive in ~22% of the cases [11].

2. Specific high-risk groups

   In opioid-maintenance treatment, numerous patients are suffering from Hepatitis C (HCV) infection. Alcohol consumption, especially in large amounts, can lead to the progression of cirrhosis. Furthermore, alcohol potentiates respiratory depressant effects of methadone. Previous studies showed the usefulness and necessity of the determination of ethyl glucuronide in patients in opioid-maintenance treatment. For example, one study showed that of all EtG-positive patients 42% (n = 8 of 19) would have not reported alcohol consumption [12]. Therefore, the use of direct ethanol metabolites in high-risk groups permits further possibilities for therapeutic interventions, consequently leading to improvement in the quality of life.

3. Monitoring Programs

   Ethyl glucuronide is successfully used in monitoring programs like the Physician Health Programmes in the USA. They provide a therapeutic program for physicians with impairing health conditions such as substance-related disorders. Being in the monitoring program, physicians with substance-related disorders are allowed to maintain their licensing on the condition that regular proof of abstinence is shown. Measuring EtG in urine, Skipper and colleagues showed that of 100 random samples collected, no sample was positive for alcohol using standard testing; however, seven were positive for EtG (0.5–196 mg/L), suggesting recent alcohol use. EtG testing can provide additional information and consequently, may lead to further treatment and improvement for the patient [13].

4. Pharmacotherapeutic studies

   As an objective outcome parameter, EtG testing has shown to be useful in pharmacotherapeutic studies [14].

5. Liver transplantation

   Up to 30% of liver transplantations are related to alcohol. Post-operatively, 20–25% of patients lapse or relapse to alcohol intake. In 18 patients with alcohol liver disease (ALD), Erim et al. found no self-report of alcohol consumption. One out of 127 tests for breath alcohol was positive, whereas 24 of 49 urine samples were positive for EtG. Comparable results were reported by another

study, which found self-reported alcohol consumption in 3% in contrast to 20% positive urine EtG and EtS tests [15].

6. Pregnant Women

   Alcohol intake during pregnancy is a well-established risk factor for developmental impairments, especially fetal alcohol spectrum disorders (FASD). It is also known that a relevant proportion of pregnant women drink alcohol. Therefore, alcohol screening during pregnancy should be routinely conducted. Alcohol intake during pregnancy can be investigated in maternal (including hair, blood, and urine) and fetal specimens (meconium). Similar to other groups, self-reports and questionnaires tend to underestimate alcohol intake. Ethyl glucuronide both in urine and meconium has been shown to improve the detection of drinking [16].

   The applications mentioned above show that EtG tests complement self-reports and questionnaires, yielding valuable information on alcohol consumption that is relevant to diagnosis and treatment.

Irrespective of the setting and population where it is applied, EtG always displays a significantly greater sensitivity for the detection of alcohol drinking when compared to questionnaires, self-reports, and traditional biomarkers. However, the information it provides must always be considered together with that obtained from other sources, and the final assessment and decision is a clinical one.

Methodological Aspects

The gold standard for the determination of EtG is liquid chromatography-tandem mass spectrometry (LC-MS/MS), which remains the only valid method of analysis in inquiries with medico-legal relevance [17]. However, availability and cost of this methodology have been issues in the past. Therefore, a semi-quantitative EtG Enzyme Immunoassay (EIA) became commercially available a decade ago. It has a clinical cut-off of 500 ng/mL and offers a low and clinically relevant analytical range (15.3–2000 ng/mL). Its validity is very similar to that of the gold standard. A more recent methodological development has been the appearance of point-of-care EtG immunoassay dip cards, which are commercially available at a very low cost. A recent study suggests the validity of the method to be high [18].

Limitations

Among the limitations of EtG analyses are false-negative results produced by urinary tract infections, especially E. Coli, as certain strains may be able to degrade EtG rapidly. This degradation does not appear to affect the direct alcohol biomarker

ethyl sulfate (EtS) within the urine sample, which remains stable despite the infection. This leads some authors to recommend simultaneous analysis of both biomarkers when a false-negative result is suspected for EtG. Interestingly, a study reported that the bacterial degradation of EtG by E. Coli can be prevented by the use of dried urine on filter paper (DUS). Furthermore, the addition of bacterial growth inhibitors into liquid urine containers (sodium azide sampling tubes) is feasible [19].

Given the impact alcohol has on liver function, it is important to note that liver disease does not influence the validity of EtG, as has been shown in studies conducted on patients with liver disease, including cirrhosis. Similarly, previous studies also suggest that race, nicotine consumption, body mass index, and body water content do not influence EtG concentrations. Not even the presence of Gilbert's syndrome, a glucuronidation disorder, shows any EtG formation impairment [20]. Conversely, a reduced renal function seems to prolong the elimination time of EtG. Other potential factors affecting EtG levels are age, sex, and cannabis consumption.

Clinical Impact of EtG

Traditional biomarker validation studies rely on cross-sectional designs where sensitivity and specificity are the cornerstones of the evidence-gathering process. Accordingly, EtG has shown a high sensitivity and also high predictive values, both positive and negative, both in experimental and clinical settings. However, cross-sectional validation prevents linking biomarker properties to patient outcomes on a longitudinal basis. A recent publication of a diagnostic randomized clinical trial where EtG was compared to ethanol in a randomized design [21], enabled the linking of biomarker properties and diagnostic performance to patient outcomes, demonstrating that implementing EtG in the routine screening of alcohol-dependent outpatients leads to decreased drinking and increased rates of abstinence over time.

> Recent evidence suggests that the application of a highly sensitive biomarker such as EtG has therapeutic properties, leading to reduced drinking and increased abstinence rates, probably due to increased feedback to both professionals and patients about their drinking.

Ethyl Sulfate

Ethyl sulfate (EtS), like EtG, is the product of a secondary elimination pathway for alcohol, see Fig. 13.2. EtS is usually measured in urine, but can also be assessed in plasma. An immunochemical detection test for EtS is currently not commercially available. For the combined detection of EtS and EtG, the use of rapid LC/MS-MS

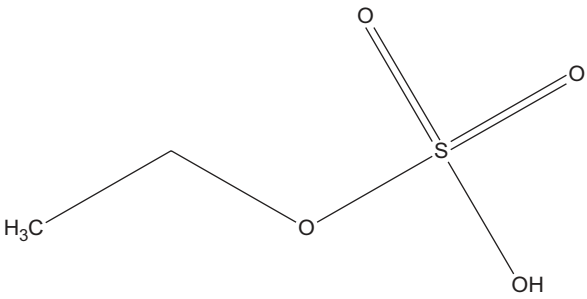

Fig. 13.2 Molecular structure of ethyl sulfate

procedures is routinely applied. The formation is affected by sulfotransferase and the breakdown by sulfatase. The molecular weight is 126 g/mol and the molecular formula $C_2H_5SO_4H$. Currently, an LC-MS/MS method with penta-deuterium EtS as internal standard and two ion transitions can be used in forensic and medico-legal cases as well as in clinical routine. The fact that the formation route of EtS is different from that of EtG offers the opportunity for increased sensitivity when analyzing the two biomarkers together. However, the discrepancies between the two are usually low [22].

In summary, a cut-off of 0.05 mg/L for repeated alcohol intake has been suggested. As for EtG, there is evidence of prolonged elimination in patients with reduced renal function. Importantly, bacterial degradation of EtS has not been described. Therefore, EtS should be analyzed in conjunction with EtG, when degradation of this biomarker is suspected, to prevent the appearance of a false-negative result.

EtS is rarely analyzed alone. Usually, both, EtG and EtS, are assessed to complement each other. EtS might help to prevent false-negative results due to bacterial degradation of EtG, especially by *E. Coli* and it might also increase the sensitivity of EtG alone.

Fatty Acid Ethyl Esters

Fatty acid ethyl esters (FAEE) are non-oxidative metabolic products of ethanol that can be detected in blood, hair, and various organs with a reduced or deficient capacity to oxidize ethanol after consumption, see Fig. 13.3. Since these esters were proven to cause damage to sub-cellular structures, they were postulated to be mediators of organ damage. FAEE are formed in the presence of ethanol from free fatty acids, triglycerides, lipoproteins, or phospholipids. Thereby, two enzymes catalyze their formation: acyl-coenzyme a:ethanol o-acyltransferase (AEAT) and fatty acid ethyl ester-synthase. FAEE-synthase can be isolated from rabbit myocardium, human brain, and rat fat tissue. Two of these FAEE-synthases were shown to be

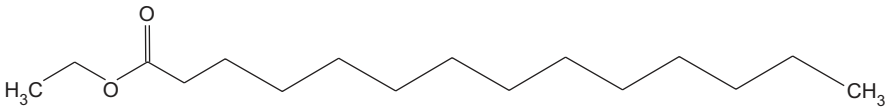

Fig. 13.3 Molecular structure of a fatty acid ethyl ester, ethyl myristate

identical to rat liver carboxyl esterase. Furthermore, pancreatic lipase, lipoprotein lipase, and glutathione transferase were shown to possess FAEE-synthase activity.

Detectable FAEE levels are found in blood shortly after alcohol consumption, and remain positive for more than 24 h. Maximum FAEE concentrations in blood are found in samples taken 2 or 4 h after the start of drinking and remain in the ng/mL range [23]. Of 15 different FAEE in hair, the sum of four (ethyl stearate, ethyl oleate, ethyl myristate, and ethyl palmitate) have been demonstrated to function as a marker in hair analysis. With a cut-off of 0.5 ng/mL, sensitivity and specificity of 90% were reported. A differentiation between abstinent, social, and excessive drinkers appears possible [24]. However, the complex GC/MS method commonly used for this analysis renders it of little practical utility for routine use.

Phosphatidylethanol

Phosphatidylethanol is a phospholipid formed in the presence of alcohol via the action of phospholipase D, see Fig. 13.4. The precursor is the naturally existing lipid-phosphatidylcholine. PEth consists of a glycerol backbone, which is substituted at positions sn1 and sn2 with two fatty acids and is esterified at position sn3 with phosphoethanol. Due to variations in chain length and saturation of the fatty acids, various homologs of PEth are present. In 2010, 48 PEth homologs were described in the blood of a deceased alcohol-dependent individual [25]. The PEth homologs 16:0/18:1 and 16:0/18:2 are the two most prevalent, and are often measured together. Upon initiation of abstinence, the elimination half-life of PEth ranges from 3.5–9.8 days for total PEth, 3.7–10.4 days for PEth 16:0/18:1, and 2.7–8.5 days for PEth 16:0/18:2, see Fig. 13.5 for an example on PEth elimination [27].

Upon regular alcohol consumption, PEth concentrations in human blood reach an equilibrium (plateau) between formation and degradation, at a level that is representative of drinking habits [28, 29]. A drinking experiment with healthy individuals by drinking up to a target alcohol concentration of 1 g/kg (1‰) once daily on each of 5 consecutive days yielded PEth values up to 237 ng/mL [30]. Measurements were performed with LC-MS/MS. Various studies found no false-positive results for PEth, and a linear relationship between consumed amounts of alcohol with phosphatidylethanol values has been described [31].

Thanks to ongoing refinements in analytical methods, the sensitivity and specificity of today's PEth analysis appear to be extremely high [32]. Also relevant is the fact that, besides its already known potential for abstinence monitoring, current

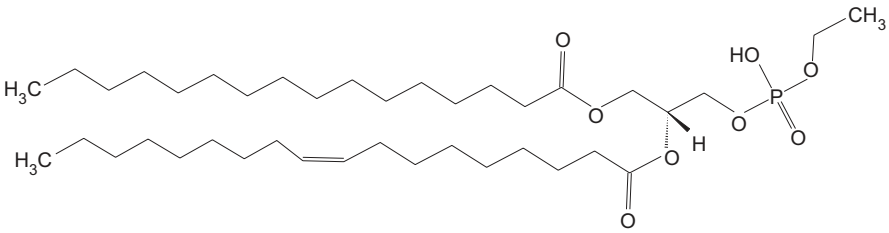

Fig. 13.4 Molecular structure of phosphatidylethanol (PEth) 16:0/18:1

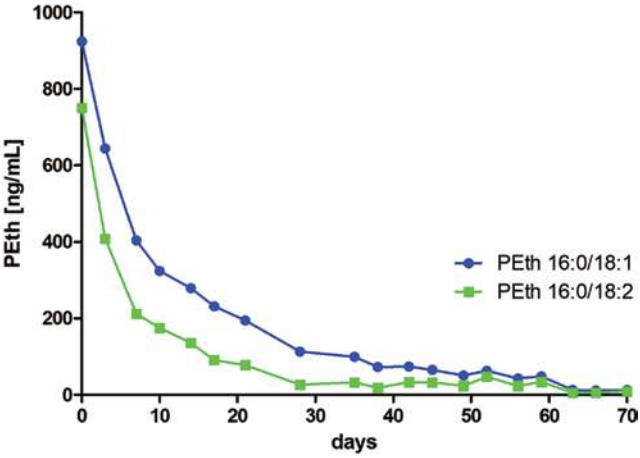

Fig. 13.5 Elimination of PEth in an alcohol withdrawal and early relapse prevention treatment setting [26]

evidence suggests PEth could be a suitable biomarker for the differentiation between light and heavy drinking, a feature not offered by other direct alcohol biomarkers [33]. To grade drinking behavior, a lower and an upper cutoff for PEth 16:0/18:1 is applied. According to the 2022 Consensus of Basel by the Society of PEth Research, a PEth 16:0/18:1 concentration <20 ng/mL (<0.0285 µmol/L) is compatible with abstinence or low alcohol consumption. ≥20 ng/mL but <200 ng/mL (<0.285 µmol/L) represents alcohol consumption, and a concentration ≥200 ng/mL is strongly suggestive of chronic excessive alcohol consumption [34]. Importantly, PEth values seem not to be influenced by liver diseases and hypertension [35].

Among the new direct alcohol biomarkers, PEth seems to be the only one capable of assessing abstinence and also differentiating between light, moderate and heavy drinking. It is recommended in evidence and consensus-based guidelines for many settings, including the assessment of alcohol consumption during pregnancy. Emerging data suggest, however, that the so far poorly understood strongly varying half-life of PEth between heavy drinkers seems to be related to alcohol-mediated red blood cell turnover (Bartel et al, 2023, in preparation). For more details, Chaps. 7, 37, 57 and 58 are recommended.

Methodological Aspects

PEth is most frequently determined using LC-MS/MS. It facilitates the detection and quantification of single analogs if a reference is available. Everyday practical use is facilitated through the possibility of sampling the specimen using dried blood spots (DBS). DBS have proven to deliver results comparable to whole blood measures. Furthermore, there is no difference between venous or capillary blood [26]. Obtaining a specimen using DBS is simplified since non-medical staff can obtain capillary blood from a finger prick, the risks for HIV and hepatitis C infections are decreased, and storage and transport are possible at room temperature in an envelope. Additionally, the possibility to use DBS sampling in combination with DBS autosamplers permits fully automated analysis of PEth, within 5 min per sample. This represents a significant advantage when compared to the laborsome hair analysis or urine/blood-based analytical methods that involve liquid handling, as large batches of samples can be processed in a fully automated manner, 'from card to chromatogram, with no hands-on' [36, 37].

Clinical Applications

Similar to what has been described for EtG, PEth has shown a high degree of sensitivity and specificity for the detection of drinking, see Fig. 13.6. It has been applied to various populations and clinical settings, such as HIV populations, pregnant women, and alcohol-dependent patients [33]. Interestingly, PEth shows good correlations with AUDIT-C scores [38]. Therefore, PEth is a useful biomarker of heavy alcohol consumption over time. Finally, some authors suggest that PEth might have a role in patients who are tested for EtG and EtS, have low positive values and deny alcohol consumption, as a further evaluation with an even more sensitive biomarker.

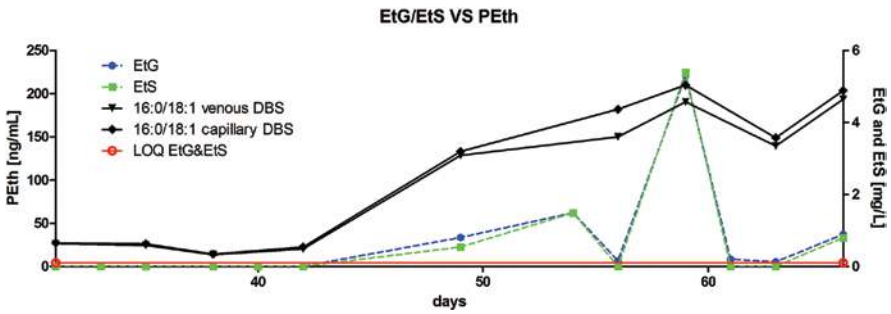

Fig. 13.6 Comparison between the measurement of EtG/EtS and PEth during several relapse situations (at least 4) in an alcohol withdrawal and early relapse prevention treatment setting [26]. While EtG/EtS returns to low concentrations after drinking, PEth stays elevated due to accumulation and a slower elimination

Limitations

In blood samples containing ethanol, post-sampling formation of PEth can be an issue, depending on the choice of sampling strategy [39]. Without influencing the PEth levels, whole blood samples can be stored frozen at −80 °C to avoid post-sampling degradation [40]. PEth concentrations in DBS were found to be stable for more than 6 months at room temperature. One reason for this improved stability in DBS is that any enzymatic activity is stopped in the process of drying [41]. Experimental studies in rats showed that ceramide can block the activity of phospholipase D and inhibits the synthesis of PEth. Also, sodium metavanadate ($NaVO_3$) eliminated post-sampling formation during the storage and drying of DBS, and is currently applied in some commercial DBS sampling devices [39].

Importance of Reference Standard Purity

For PEth measurements the purity and pathway of synthesis for the used reference standard is of high importance: When measuring PEth in whole blood from patient samples, the calibration and quality control samples are usually prepared by spiking PEth reference standard solution (reference material from a commercial supplier) into blood from a person with no alcohol use. The patient samples are then referenced to these artificially prepared samples with known PEth concentrations, based on a calibration curve. Dependent on the route of synthesis, the artificially prepared reference standard may not only contain the targeted PEth 16:0/18:1, but also its regioisomer PEth 18:1/16:0. The artificially prepared samples might therefore not necessarily reflect the naturally occurring PEth composition in human blood, which only contains PEth 16:0/18:1, see Fig. 13.7. If the reference standard contains a

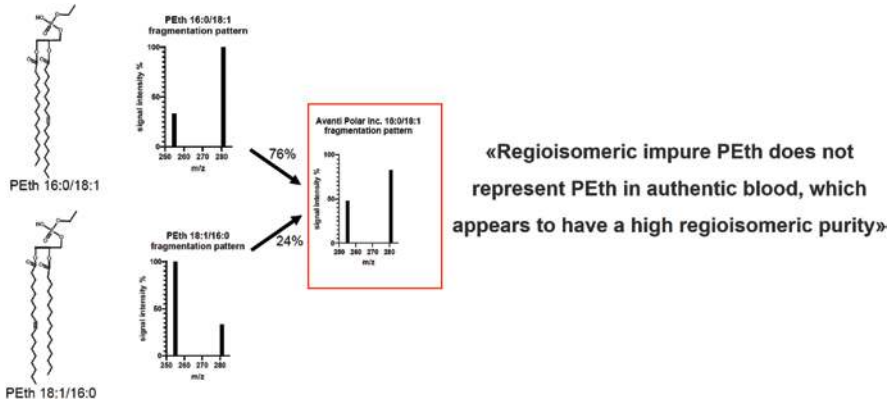

Fig. 13.7 The impact of PEth 16:0/18:1 reference material purity on the fragmentation pattern of PEth, depicted based on reference material with a isomeric purity of only 76% PEth 16:0/18:1 and 24% PEth 18:1/16:0 [42]

significant fraction of the PEth isoform 18:1/16:0, a significant quantification deviation might occur, due to different fragmentation patterns within the mass spectrometer [42].

Hair Analyses

Hair analysis is well established to assess ethanol intake. FAEE and ethyl glucuronide, are mainly used as long-term alcohol markers in hair. The time frame for detection of alcohol consumption is longer in hair compared to blood or urine. Due to head hair growth of 1 cm per month, depending on the hair length, evidence of alcohol consumption can be found for the respective period. Since hair must grow out of the scalp to be cut or shaved for analysis, the proximal ~0.5 cm (representing approximately 2 weeks) is not accessible. The deposit of lipophilic FAEE in hair occurs in sebum, the oily product of microscopic exocrine glands that lubricates hair and skin, whereas hydrophilic EtG is incorporated through perspiration and/or from blood.

Measurement of FAEE and EtG allows differentiation between chronic excessive and moderate alcohol consumption as well as abstinence or very low levels of alcohol consumption. Nowadays, the concentration of ethyl palmitate (EtPa) alone is used for interpretation instead of the concentration sum (ΣFAEE) of the four esters: ethyl myristate, ethyl palmitate, ethyl oleate, and ethyl stearate, as previously applied. The use of EtPa with these cut-offs in place of ΣFAEE for alcohol intake assessments produces only a minor loss in discrimination power, leading to no essential difference in the interpretation concerning chronic excessive alcohol consumption, and is suitable to confirm EtG results in abstinence assessments.

The Society of Hair Testing (SOHT) published the following guideline within their 2019 consensus [43]: The EtPa cut-off for abstinence assessment was defined at 0.12 ng/mg for the 0–3 cm segment and at 0.15 ng/mg for the 0–6 cm segment. The cut-off for chronic excessive drinking was set at 0.35 ng/mg for the 0–3 cm segment and at 0.45 ng/mg for the 0–6 cm segment. An EtG concentration ≥30 pg/mg in the proximal hair with a length of 3–6 cm strongly suggests chronic excessive alcohol consumption (>60 g EtOH per day). An EtG concentration of more than 5 pg/mg in the proximal hair with a length of 3–6 cm strongly suggests repeated alcohol consumption. If samples less than 3 cm or greater than 6 cm are used, the results should be interpreted with caution. The analysis of FAEE alone is not recommended to determine abstinence from ethanol.

For abstinence assessments, EtG should be the first choice, and the analysis of EtPa alone is not recommended to determine abstinence from ethanol. A negative EtPa result does not disprove abstinence but indicates the need for further monitoring. For the assessment of chronic excessive consumption, the combined use of FAEE and EtG can be recommended to increase the validity of hair analysis [44].

In a prospective controlled alcohol-dosing study with three groups (no alcohol, daily 20 g and 30 g pure alcohol) (n = 30), the following median EtG in hair

concentrations were found: group no alcohol: 0.5 pg/mg, group 20 g EtOH daily:5.6 pg/mg and group 30 g EtOH daily:11.3 pg/mg. The authors concluded that differentiation is possible between abstinence and repeated low to moderate amounts of alcohol consumed [45].

In an alcohol dosage study using retrospective alcohol consumption evaluated by timeline follow-back interview EtG in hair was measured in 130 non-excessive alcohol consumers (<60 g pure ethanol/day) varying between < LLOQ and 29.8 pg/mg hair [46]. In another alcohol dosage study using retrospective alcohol consumption evaluated by timeline follow-back interview EtG in hair was measured in 36 alcohol-dependent patients (25 males/11 females) starting an alcohol detoxification program. In this study, EtG in hair concentrations varied between 32 and 662 pg/mg [47].

Other Influencing Factors

Whereas a false-positive result for EtG in hair after use of EtG-containing shampoo has only been reported in one case, regular use of alcohol-containing hair tonic can lead to false-positive FAEE results. No such false-positive results in combination with ethanol-containing products have been reported for EtG. Impaired kidney function may lead to higher EtG levels, as indicated by preliminary results. BMI has also been shown to have an influence on the EtG concentration in hair (higher EtG concentrations in participants with high BMI) [48]. False-negative results for both alcohol markers can also be caused by the use of hair cosmetics, like alkaline hair cosmetics for FAEE, oxidative treatment for EtG, and hair straightening for EtG. Cleansing shampoos may also alter EtG and FAEE concentrations in hair [49]. Prolonged incubation with water does affect EtG (washout effects due to the polarity of the analyte), but not the apolar FAEE [50].

The hair color and melanin content in hair does not affect the result. In segmental investigations of hair samples, a chronological correlation to drinking or abstinent phases with FAEE is not possible, while this has been shown to be feasible for EtG. Altogether, hair analysis for FAEE or EtG is currently a potentially useful tool to clarify past alcohol consumption.

Practical Use

Hair analysis for FAEE or EtG is applicable in several contexts including evaluating driving ability and forensic psychiatry. Another clinical use of alcohol metabolites measures in hair is the screening for alcohol use in medication-assisted treatment of opioid-dependent subjects as mentioned above.

Summary Regarding Direct Alcohol Biomarkers

Specific direct ethanol metabolites are available, that permit to distinguish between short-term intake of small amounts and long-term use of large amounts of alcohol, see Table 13.1. Cut-off values and influencing factors are summarized in Tables 13.2 and 13.3. Appropriate methods of analysis and pre-analytical considerations are crucial for a valid and reliable detection of markers. Currently, the best detection methods are LC-MS/MS-based, and with every new generation of mass spectrometers, the sensitivity of these instruments increases. Commercial solutions for direct implementation are available for most of the described analytes.

EtG is detectable in urine using LC-MS/MS even after ingestion of low amounts of alcohol (1 g), which may occur by consuming certain food, drugs, or using disinfectants. Individuals with the motivation or obligation for abstinence have to be informed about these "hidden contents" to avoid involuntary intake of alcohol. For forensic purposes, the current cut-off value of 0.1 mg/L should be adapted to exclude cases of involuntary alcohol use. Concerning differences in formation and degradation, EtG and ethyl sulfate (EtS) are preferentially analyzed together. In the absence of known influencing factors, EtG in hair can be recommended as a marker for alcohol intake for the last 3 months.

For the assessment of drinking habits, phosphatidylethanol (PEth) is an ideal alcohol marker. It permits distinguishing between abstinence/very low consumption, moderate alcohol consumption, and excessive consumption. While positive urine values of EtG and EtS can be caused by unintentional alcohol intake, positive values of PEth are related to previous intoxications of 0.5‰ or higher. Using finger pricks and dried blood spots for PEth, the sample collection, as well as the sample storage and distribution, are simplified. Advantageously, with today's methods,

Table 13.1 Clinically relevant options for the determination of direct biomarkers, concerning the amount and duration of alcohol intake (modified according to Thon et al. [51])

Duration of consumption	Amount of consumption	
	>1 g/day	>40–60 g/day
<1 day	serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS
		PEth in whole blood and dried blood spots (LC-MS/MS)
>1 day	serum, urine: EtOH,EtG, EtS	Serum and urine: EtOH, EtG, EtS
		PEth in whole blood and dried blood spots (LC-MS/MS)
>14 days	serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS
		PEth in whole blood and dried blood spots (LC-MS/MS)
Weeks to months	serum, urine: EtOH, EtG, EtS	Serum and urine: EtOH, EtG, EtS
		PEth in whole blood and dried blood spots (LC-MS/MS), EtG and FAEE in hair

EtOH ethanol, *EtG* ethyl glucuronide, *EtS* ethyl sulfate, *PEth* phophatidylethanol, *FAEE* fatty-acid ethyl esters

Table 13.2 Clinically relevant options for determination of direct biomarkers, concerning the amount and duration of alcohol intake (modified according to Thon et al., PEth-NET and SOHT [34, 43, 51])

Biomarkers	Amount of consumption	Cut-off
EtG in hair	Does not contradict self-reported abstinence	≤5 pg/mg
	Social consumption (20–40 g/day)	5–30 pg/mg
	Strongly suggests chronic excessive alcohol consumption (>60 g/day)	≥30 pg/mg
EtPa in hair	Strongly suggests repeated alcohol consumption	>120 pg/mg (0–3 cm)
		>150 pg/mg (0–6 cm)
	Strongly suggests chronic excessive alcohol consumption	≥350 pg/mg (0–3 cm)
		≥450 pg/mg (0–6 cm)
EtG in urine	Total abstinence	0.1 mg/L
	– unintentional intake	0.1 – 0.5 mg/L
	– recent alcohol use	
	– longer back-dated alcohol intake in larger amounts	
	unintentional intake unlikely, but possible, active alcohol intake probable	0.5–1 mg/L
EtS in urine	Total abstinence	0.05 mg/L
PEth 16:0/18:1	Compatible with abstinence or low alcohol consumption	<20 ng/mL (<0.0285 µmol/L)
	Alcohol consumption	≥20 ng/mL but <200 ng/mL
	Strongly suggestive of chronic excessive alcohol consumption	≥200 ng/mL (≥0.285 µmol/L)

EtG ethyl glucuronide, *EtPa* ethyl palmitate in hair, *EtS* ethyl sulfate, *PEth* Phosphatidylethanol

Table 13.3 Detection of direct biomarkers, concerning the amount and duration of alcohol intake (modified according to Thon et al. [51])

Direct bio-markers	Potential influencing factor	Influence
EtG in urine	E.coli, when using dried urine spots	No
	Grade of liver disease, smoking, BMI, body water content reduced kidney function	No
EtS in urine	E.coli, when using dried urine spots	No
PEth	Liver disease	No
	Hypertension	No
	Storage of ethanol blood samples	No
	Refrigerator temperature, −80 °C	
EtG in hair	Hairsprays with ethanol, hair colour, melanin content, age, sex, BMI	No

Table 13.3 (continued)

Direct bio-markers	Potential influencing factor	Type of influence
EtG in urine	E. coli, C. sordelli	decrease
	Reduced kidney function	Longer detection
	Chloral hydrate	False-positives
EtS in urine	Reduced kidney function	Longer detection
	Closed Bottle test (OECD 301 D)	28 days stable detection, depletion after 6 days
	Manometer Respiratory Test (MRT)	
FAEE in hair	Aggressive alkaline hairsprays	False-negative
	Hairsprays with ethanol	False-positives
PEth	Ethanol-containing blood samples, Storage of ethanol blood samples at RT and −20 °C	Increase
EtG in hair	Hairspray with EtG	Increase
	Reduced kidney function	Increase
	Bleaching, hair styling products	False-negative

EtG ethyl glucuronide, *FAEE* fatty-acid ethyl esters, *EtS* ethyl sulfate, *PEth* phosphatidylethanol, *BMI* body mass index, *RT* room ambient temperature, *E. coli* Escherichia coli, *C. sordelli* Clostridium sordelli

PEth can be analyzed fully automated within a runtime of 5 min. Different guidelines for the interpretation of values are available from international societies such as the Society of Hair Testing (SOHT) and The Society of Phosphatidylethanol Research (PEth-NET).

Traditional Biomarkers for Alcohol Consumption

Many routinely used clinical chemistry parameters show pathological changes as evidence of the biochemical burden of ethanol metabolism. None of these conventional indicators show 100% sensitivity or specificity. Nonetheless, evidence of long-term alcohol consumption can be obtained from these state markers, especially a combination of several individual indicators. The currently used and further potential alcohol biomarkers are shown in Table 13.4.

Blood Alcohol Content Calculation

A mathematical estimation of blood alcohol content is useful when blood alcohol is not currently detectable, or for the prediction of alcohol level. While there are several ways to calculate it, the simplest is Widmark's equation:

$$\mathrm{Co} = \mathrm{A} / \left[\mathrm{p} \times \mathrm{r}\right]$$

Table 13.4 Diagnostic characteristics of several conventional and potential alcohol biomarkers (adapted from Topic and Djukic [52])

Alcohol biomarker (abbreviation)	Window of assessment	Specificity/ Sensitivity	Type of alcohol consumption	Application	Specific comments
Conventional alcohol biomarkers					
Ethanol (EtOH)	6 h	High/high	Recent alcohol consumption/ alcohol intoxication	In traffic safety/ emergency department	In combination with clinical observation—monitoring alcohol habits
Gamma-glutamyl transferase (GGT)	2–8 weeks	Moderate/ moderate	Chronic, heavy	Screening/ monitoring	More specific for alcoholics ages 30 to 50 years
Aminotransferases ratio AST/ALT ≥2	unknown	High/low	Heavy	Alcoholic hepatitis/ relapse	Less frequently used than GGT for screening heavy alcoholics
Mean corpuscular volume (MCV)	Up to several months	Moderate to high/low	Chronic	Screening/fetal alcohol effects	Show dose-dependent response to the intensity of alcohol intake
Carbohydrate deficient transferrin (CDT)	2–3 weeks	High/ moderate	Heavy	Screening/ monitoring/relapse	No elevation in single episodes of acute alcohol intoxication
GGT-CDT	2–3 weeks	High/high	Heavy	Abstinence/relapse	Useful for diagnostic alcohol-liver damage due to excessive and prolonged intake
Potential alcohol biomarkers and devices					
Ethyl glucuronide (EtG) and ethyl sulfate (EtS)	Several days	High/high	Recent alcohol consumption	Abstinence/relapse	High inter-individual variations
Phosphatidylethanol (PEth)	1–2 weeks up to several weeks	High/high	Abstinence monitoring, social/ moderate alcohol consumption, and heavy, chronic alcohol consumption	Abstinence/relapse, consumption habits	Promising in differentiating alcohol—from non-alcohol induced liver disease
Fatty acid ethyl esters (FAEE)	24 h (after ingestion)	High/high	Recent heavy	Distinguishing social drinkers from heavy	Combination of FAEE and EtG in meconium—markers for fetal alcohol exposure

Alcohol biomarker (abbreviation)	Window of assessment	Specificity/ Sensitivity	Type of alcohol consumption	Application	Specific comments
Whole blood associated acetaldehyde assay (WBAA)	unknown	High/high	Chronic/heavy	Monitoring abstinence	IgAs against acetaldehyde protein adducts- promising in differentiating alcohol—from non-alcohol induced liver disease
Total sialic acid (TSA)	Unknown	Between GGT and ALT	Chronic, heavy	relapse	Increased in high alcohol consumption and reduced during abstinence, especially among women
5-HTOL/5-HIAA	1 day	High/high	Recent alcohol consumption	Evaluation of treatment/relapse	5-HTOL/5-HIAA >20 marker of recent drinking
Transdermal devices (SCRAM, WrisTAS)	–	High/high	Records continuous alcohol consumption	By court monitoring of abstinence	Need product improvements

Co is the theoretical maximum concentration of alcohol in blood (mg/g).

A is the amount of alcohol in the body (g).

p is the body weight (kg).

r is the correction factor corresponding to the ratio of total body water and blood water (0.6 for females and 0.7 for males).

Sex plays an important role in the total amount of water in the body. In general, men have less fatty tissue and a higher percentage of water (58%) than women (49%), and thus the volume of distribution (Vd) for ethanol is higher in men. According to its partition coefficient (Poct/water is 0.1), ethanol is 10 times more soluble in water than in lipids. Thus, upon ingestion of the same amount of ethanol, the BAC will be higher in females than in males. The Widmark's equation has been improved subsequently by introducing individual r, based on the multiple linear regression equations:

$$\text{for females : rFI} = 0.31223 - 0.006446 \times \text{body weight}\left(\text{kg}\right) + 0.004466 \times \text{body height}\left(\text{cm}\right).$$

$$\text{for males : rMI} = 0.31608 - 0.004821 \times \text{body weight}\left(\text{kg}\right) + 0.004632 \times \text{body height}\left(\text{cm}\right).$$

There is no absolute accurate blood alcohol calculator because numerous factors influence the BAC, such as male versus female sex, rate of metabolism and elimination, health status, medications that might be taken, drinking frequency, amount and the type of food in the stomach and small intestine, the time when food was eaten, and others [52].

Gamma-Glutamyl-Transferase (GGT)

GGT is a membrane-bound glycoprotein enzyme that occurs ubiquitously in the organism, but mainly in the liver, pancreas, and renal proximal tubules. GGT detectable in serum arises mainly from the liver so that an increase in serum enzyme activity would be a sensitive indicator for hepatobiliary diseases. Chronic alcohol consumption induces an increase in enzyme synthesis and, through direct activation of the enzyme from membrane binding, leads to an increase of GGT in serum. The release of enzymes through liver parenchymal damage also presents a secondary mechanism in chronic alcoholic hepatitis. To exceed the normal values (4–18 U/L in women and, 6–28 U/L in men) requires chronic, daily alcohol intake over at least 4–6 weeks. A short-term, higher alcohol burden causes no such increase. Nevertheless, drinking intensity has more influence on GGT than drinking frequency. In absolute alcohol abstinence, normalization of the values occurs within 3 weeks to 60 days.

The sensitivity of GGT to detect heavy alcohol use varies, according to age, sex, and body weight, from 35% to 85%. GGT increases with age in heavy as well as moderate drinkers. In contrast, in young adults aged less than 30 years, even when these are alcohol dependent, the sensitivity of the markers is very low. In addition, the higher vulnerability of women to alcohol-associated liver diseases is well

known. Other studies have shown that the relationship between being overweight or obese (BMI > 25 or 30, resp.) and having an increase in GGT are related. GGT levels can also be increased by various other causes, for example, the effects of many medications and teratogens, diabetes, and cholestatic or inflammatory liver diseases. Accordingly, the specificity of 63–85% is not satisfactory [53]. Despite its attraction and ease of use, GGT is not suitable as a solitary indicator of chronic alcohol misuse and current liver diseases [54]. More detailed information is also provided in Chap. 37 and the Appendix Tables B.1–B.4.

Mean Corpuscular Erythrocyte Volume (MCV)

Measurements of MCV are common in standard clinical investigations, and an increase occurs in 4% of the general population and 40% to 60% of patients with alcohol misuse. Koivisto et al. reported definite evidence for a significant dose-dependent relationship between MCV and the intensity of alcohol consumption [55]. The mechanism responsible for increasing MCV is hitherto unclear. Direct hematotoxic damage or interaction of ethanol and its metabolites, especially acetaldehyde, with the erythrocyte membrane, has been suggested [56]. An increase in MCV can be expected in long-term alcohol consumption. MCV values then normalize slowly during abstinence over 2–4 months. The sensitivity of MCV in screening for alcohol misuse is inferior to GGT, at least in men. In interpreting MCV values, other causes such as Vitamin B12 or folic deficiency, non-alcohol-related liver diseases, reticulocytosis, and hematologic diseases should be considered. More information on MCV, especially its relation to bone marrow toxicity and RBC turnover, is provided in Chaps. 7, 37, 57 and 58.

Carbohydrate Deficient Transferrin (CDT)

Transferrin is the most important iron transport molecule in humans. Its synthesis and glycosylation occur in hepatocytes. Depending on the iron load as well as the number and breakdown of carbohydrate chains, different isoforms can be detected. Differentiation occurs through measurements of isoelectric points (pl), whose values depend on the load of bound iron ions and the number of sialic acid residuals in carbohydrate chains. Abnormal isoforms with much-increased pl-values over 5.65 in the cerebrospinal fluid and serum of alcohol-dependent patients were found and were traced back to small levels of bound sialic acid residuals.

In subsequent investigations, more precise differentiation into mono-, di- and asialotransferrin was made, and all abnormal isoforms were sub-grouped under CDT [57]. All abnormal transferrin molecules increase in chronic alcohol consumption. Measurements with HPLC showed that increased alcohol consumption leads to increased disialotransferrins, while increases in asialotransferrin occur in chronically increased alcohol consumption only. A variety of methods and respective

reference levels for the detection of CDT is available. To date, measurements of CDT using HPLC are the reference standard, but various enzyme immunoassays are also in use. For confirmation analyses, immune electrophoresis is employed, while a direct CDT detection method using specific antibodies is still under development [58].

The underlying mechanism for CDT development is not exactly known. Inhibition of intracellular transmission of carbohydrates to change through toxic effects from ethanol or acetaldehyde is presumed. Ethanol's influence on the activities of membrane-bound sialyltransferase and plasma sialidases in hepatocytes has been discussed, in which an imbalance in favor of sialic acid reduction enzymes occurred.

There has been no agreement in previous studies concerning the correlation between CDT concentrations in serum and the absorbed amounts of alcohol. Although an increase in CDT with daily consumption of 60–80 g alcohol over 7 days has been shown, other studies have reported contradicting results. Additionally, contradicting results on the effect of moderate drinking (<40 g alcohol) are found. In alcohol-dependent patients, CDT is, however, sensitive enough for detecting relapses and monitoring sobriety [59].

The clinical strengths of CDT as a biomarker vary depending on sex, BMI, age, nicotine use, and anorexia [60]. Previous studies showed that CDT in men is a more sensitive indicator for alcohol-related diseases compared to women. CDT values in women might be increased under natural conditions but not much in increased alcohol use. Furthermore, hormonal factors appear to play a role, and CDT values are increased in pregnant women, but reduced in postmenopausal women. In females, CDT in serum also depends on age.

Among conventional alcohol markers, CDT is currently considered the most useful and significant indicator [61]. Information on sensitivity and specificity varies, since no methodical standardization exists. Further, the heterogeneity of test populations concerning age, sex, alcohol consumption, duration of abstinence before serum extraction as well as current liver diseases makes the comparison with other traditional markers difficult. In selected, clinical patient groups, various test methods with specificity between 90% and 100% with high sensitivity (50–90%) have been reported].

Serum Transaminases (ASAT/ALAT)

Increases of aspartate aminotransferase (ASAT) and alanine aminotransferase (ALAT) in serum are unspecific signs of hepatocellular damage. While ASAT is produced in the liver, skeleton, and cardiac muscle tissues, ALAT is a liver-specific enzyme. ASAT also occurs in red blood cells as is discussed in Chap. 41. Thus, an increase in ALAT indicates liver diseases (fatty degeneration, tumors, metastases, cirrhosis, cholangitis). By contrast, measurements of ASAT must differentiate between alcohol-sensitive, mitochondrial (m-ASAT), and cytoplasmic isoform

(c-ASAT). Conclusions on alcohol-induced liver damage can only be drawn from increased m-ASAT/c-ASAT quotients [62]. Increased ASAT values would be found in alcohol-dependent patients from 39–47%. In the WHO/ISBRA-Study, the sensitivity of ASAT was between 23% and 45% (women vs. men). The toxic effects of ethanol on mitochondria lead to increased release of ASAT compared to ALAT [63]. Thus, measurements of the de-Ritis-Quotient (ASAT/ALAT) increase the alcohol specificity of both markers—a quotient over 1 and even 2 would offer strong indications for an ethanol toxicity to be the etiology.

In summary, the sensitivity and specificity of both enzymes as indicators for alcohol misuse are considered variable so that an interpretation of an increased serum activity is mainly meaningful in the context of other liver values (Bilirubin, Alkaline phosphatase, GGT).

HDL Cholesterol and Apolipoprotein

Increases in HDL cholesterol and apoprotein I/II are described in many studies as specific and sensitive indicators of chronic alcohol strain; by contrast triglycerides and total cholesterol are nutritionally influenced. Alcohol leads to an increase in the concentrations of cholesterol and phospholipids within the HDL particles, and causes a shift to a higher proportion of phospholipids HDL_2-particles [64]. Studies have shown this phenomenon to be the basic principle for the observed cardioprotective effects of moderate alcohol consumption [65]. Chronic alcohol load causes an increase in HDL over 50 mg/dL, after withdrawal and with continuing abstinence, the values normalize within 1–4 weeks. The pathogenic cause for alcohol-related HDL- and apoprotein increases is postulated to be an enzyme induction as well as increased lipoprotein lipase activity.

Increased HDL levels without alcohol use can occur under the influence of medication (sedatives, lovastatin), pronounced underweight and physical strain. Still, the specificity of this marker is highly esteemed. Moreover, it proved itself to be practicable. Particularly in patients without liver damage, HDL and apoprotein I/II can be used for monitoring abstinence since changes in alcohol consumption would be accurately reflected.

Combination of Individual State Markers

Since individual conventional alcohol markers were found to be insufficiently sensitive and/or specific for the recognition of alcohol misuse, combinations of parameters have been investigated. The better-known combinations comprised CDT, GGT, MCV, and ASAT. In general, if chronic alcohol consumption should be detected, it is recommended to use a combination of indirect markers (e.g., gamma-glutamyltransferase and mean cell volume and carbohydrate-deficient-transferrin,

antilla index, alc index) to increase sensitivity and specificity in different contexts (family practice, inpatient admission, emergency admission, preoperative screening, and intensive care unit (German S3-Guidelines alcohol-related disorders, 2021, [66]).

Gamma-Glutamyl Transferase and Carbohydrate-Deficient Transferrin

Some studies showed that the combined use of GGT and CDT resulted in higher sensitivity and specificity compared to the use of either one alone. Sillanaukee et al. reported in 2001 a sensitivity of 75% and specificity of 93% for CDT from 257 alcohol-dependent patients and 362 occasional drinkers. γ-CDT is estimated using the formula [**γ-CDT = 0.8 ln(GGT) + 1.3 ln (CDT)**]. Compared to CDT and GGT alone, ASAT, ALAT, or MCV showed the logarithmic transformation from GGT and CDT to have the best predictive value to differentiate between alcohol-dependent patients and occasional drinkers. Values for γ-CDT correlate to current amounts of consumption, regardless of whether a heavy alcohol-dependent individual or an occasional drinker was tested. γ-CDT can thus be used to monitor abstinence, although in continuing abstinence the values normalize within 2–3 weeks.

Alc-Index

By combining Methanol, Aceton/Isopropanol, GGT, and CDT in a logistic regression formula Brinkmann et al. [67] developed the so-called "Alc-index "to differentiate between alcohol-dependent patients and non-drinkers [67]. The basic principle for the investigations was the hypothesis that each of these alcohol markers shows overlap in values in the collective with none or low alcohol consumption and alcoholics. From the results, an Alc-index of 1.7 as a cut-off was defined with a specificity of 100% and a sensitivity of 90% to differentiate between alcohol-dependent and non-alcohol-dependent individuals. The advantage of this index is the single cut-off point instead of four for individual markers, which can prevent false conclusions with elevated values of an isolated marker.

Early Detection of Alcohol Consumption: Test (EDAC)

EDAC uses results from a series of routine lab parameters to identify heavy drinkers and light drinkers in study groups. Attempts were made already in the 80 s, to differentiate between light alcohol misuse and heavy alcohol dependence through

multivariate statistical analysis of blood samples from patients with conspicuous alcohol use. The multiple chemical and clinical parameters extracted should reflect alcohol's influence on various organs and organ systems. Subsequent to these studies, the procedure was abandoned because of impractical, partly costly statistical analysis. Harasymiw et al. [68] developed EDAC test to be an established procedure, in which a form of "mathematical fingerprint" for each tested patient could be created from 10 out of 30 routine lab values through a linear discrimination analysis [68]. The fingerprint of an individual could possibly be that from a heavy alcoholic and presented as P-positive, representing the degree of concordance to the stereotyped alcoholic lab profile. In general, a P-positive value of over 50% showed current heavy alcohol consumption, whereas values below or equal to 50% showed evidence of light alcohol misuse. The EDAC test was successfully used as screening for alcohol misuse and to identify heavy or risky alcohol consumption in various studies on different study populations. A higher sensitivity of 34–65% (women/men) for EDAC test compared to 23–30% for GGT in a population of 1605 heavy drinkers or probands with risky alcohol consumption has been reported. The specificity is 89% (men) and 98% (women). Sensitivity and specificity of over 80% each were reported in the identification of alcohol misuse in heavy male and female drinkers.

GGT-ALT Combination

Another combination of enzymes, γ-GT-ALT (alkaline phosphatase) can potentially be useful for clinical diagnostic validation of liver damage related to excessive and prolonged intake of alcohol. If the ratio of γ-GT/ALT exceeds the value 1.4, there is a probability of 78% that the liver impairment is due to alcoholism. This particular combination was not shown to be a biomarker when used for monitoring the treatment of alcohol dependent patients with disulfiram.

Although the suspicion of heavy alcohol use behind hepatotoxicity may be supported by several lines of clinical and biochemical data, the specific role of alcohol in many cases is difficult to distinguish in individuals who deny alcohol use, see Fig. 13.8. Clinical symptoms related to heavy drinking may originate from virtually any tissue. Unexpected abnormalities in liver enzymes or blood cell count in health screening programs may also reveal alcohol abuse.

Subsequently, efforts should be focused on objective confirmation of alcohol use and rule out other aetiologies. Non-alcoholic fatty liver disease (NAFLD) is the most common non-alcoholic aetiology behind liver dysfunction and the workup should consist of evaluating metabolic co-morbidities with measurements of body mass index, waist circumference, and oral glucose tolerance. Specific tests are available to rule out viral hepatitis and several genetic diseases, such as hemochromatosis. In alcohol consumers, ethanol may be present even at the time of the clinic visit. Measurements of ethanol metabolites or other laboratory parameters sensitive to ethanol may provide confirmatory data. Liver enzymes give information on the

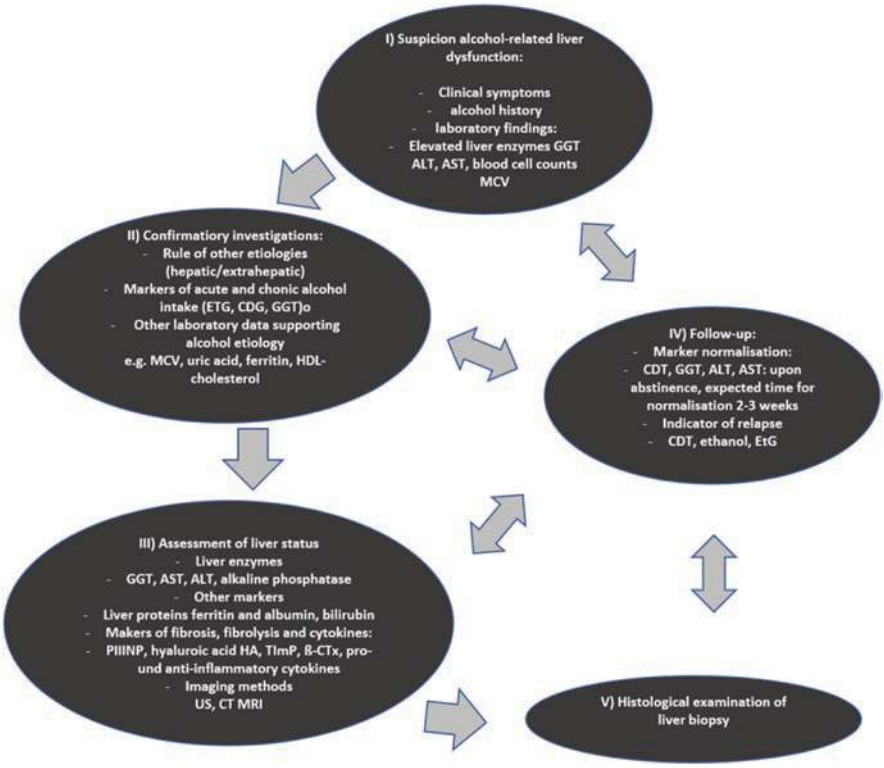

Fig. 13.8 Schematic representation of the clinical assessment of liver dysfunction in alcohol consumers (Niemela and Alatalo [69])

nature of liver pathology. An isolated abnormality in GGT is usually reversible and related to an increased oxidative stress burden. Increased ALT is commonly a result of fat deposition in the liver and can be reversible. Elevated ferritin and albumin may occur in the early phases of liver disease, whereas in patients with advanced alcohol-related liver disease (ALD) the rates of albumin synthesis decrease and correlate with poor prognosis. ALD status is also associated with both the collagen and cytokine markers. Markers of collagen synthesis and degradation as well as pro- and anti-inflammatory cytokines may follow inverse kinetics, which may help to differentiate alcoholics at risk for cirrhosis. US (ultrasonography), CT, computed tomography, MR, and proton magnetic resonance spectroscopy are commonly suggested. Follow-up of laboratory values is an integral part of the comprehensive assessment and treatment of patients with signs of liver dysfunction. If excess alcohol consumption (or obesity) is suspected, normalization during abstinence (or weight loss) is confirmatory. If initial GGT levels return to normal after abstention, the patient is likely to have recovered from liver disease. Liver enzyme activities

repeatedly above twice the upper reference limit are used as a decision-making point for liver biopsy to rule-out severe liver diseases, and to distinguish patients needing the closest monitoring. Follow-up by markers of ethanol consumption, such as CDT, can be used to assess the degree of alcohol dependence and to detect relapses, which increase the probability of subsequent severe liver problems. The current clinical gold standard for the diagnosis and grading of hepatic disease is liver biopsy. It is, however, an invasive procedure with sampling variability and therefore is not suitable for screening or repeated measurements.

Summary Regarding Indirect Alcohol Biomarkers

Traditional biomarkers may appear to be practical and cost effective, but have considerable limitations. Combinations of routine lab parameters, such as CDT und GGT, may allow some level of inference regarding regular, long term (days, weeks) alcohol consumption. The diagnostic sensitivity of individual parameters, like ASAT or ALAT, is low, the specificity is moderately high, except for CDT which shows moderate sensitivity and high specificity to differentiate between alcohol-dependent individuals and control persons. Additional related information can also be found in Chaps. 37, 39, 40 and 41.

Conclusions

Together, direct and indirect alcohol biomarkers cover a wide range of intervals between consumption and detection. Especially the direct alcohol biomarkers are currently vastly underutilized, and their broad implementation offers new opportunities for prevention, interdisciplinary cooperation, diagnosis, and treatment of alcohol-related disorders. This, for instance, is reflected by the assessment of evidence and consensus-based German S3 guideline “Screening, Diagnosis, and Treatment of Alcohol Use Disorders“, where the following recommendations regarding the use of ethanol metabolites are made with high and highest levels of evidence and recommendation [5]:

- For acute alcohol intake, ethanol in breath or blood and/or ethyl glucuronide (EtG) and ethyl sulfate (EtS) in urine are recommended
- For chronic intake the recommendation is for PEth in blood and/or EtG and/or Ethyl palmitate (EtPa) in hair, respectively.
- Since the database in the last years significantly has increased especially for phosphatidylethanol (PEth), a new recommendation for screening during pregnancy recommends EtG in urine and/or FAEEs in hair, and especially PEth in blood. If implemented, this has the potential to prevent FASD risk.

Chapter 14
Addictions Neuroclinical Assessment

Tommy Gunawan, Laura E. Kwako, Nancy Diazgranados, George F. Koob, David Goldman, and Vijay A. Ramchandani

Abstract Alcohol use disorder (AUD) is a common, complex condition with substantial heterogeneity that has confounded the understanding of its etiology, diagnosis, and outcomes. The Addictions Neuroclinical Assessment is a clinical framework that seeks to understand the etiology and heterogeneity of AUD and other substance use disorders based on three neurofunctional domains: incentive salience, negative emotionality, and executive functions. These domains are aligned with the three stages of the cycle of addiction—binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation—and are supported by our current understanding of the neuroscience of substance use disorders. The ANA includes a battery of measures to assess these neurofunctional domains, consisting of readily available neuropsychological and behavioral tasks, as well as clinical and self-report measures. Ancillary measures, such as genetic, epigenetic, and neuroimaging markers, as well as measures of the environmental and social determinants are recommended to provide additional information not otherwise captured by the three domains. This review summarizes the current empirical work on the ANA framework, and highlights important directions for future research. The ANA aims to serve as a critical tool for both researchers and clinicians to provide a common framework to aid in the understanding of the etiology and heterogeneity of substance use disorders.

Introduction

Alcohol is one of the most widely used psychoactive substance in the world. Globally, 80% of adults reported using alcohol at some point in their lives, with 52.3% reported using within the past year [1]. A significant minority of those who consume alcohol will develop alcohol use disorder (AUD), which is characterized by an impairment in the ability to stop or control alcohol use despite negative social, occupational, or health consequences. Global lifetime and 12-month prevalence of AUD were 8.6% and 2.2% respectively [1].

The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) outlines 11 diagnostic symptom criteria for AUD [2]. An individual who meets two criteria qualifies for a mild AUD diagnosis, four for moderate, and six for severe AUD. This symptom-based approach to diagnosing AUD offers a considerable degree of diagnostic reliability [3]. However, it provides little information about the etiology and pathophysiology of the disease. Two individuals may present completely different symptom profile with divergent medical histories, and yet receive the same diagnosis of AUD, and possibly the same severity. Thus, the current nosology for AUD belies its heterogeneity.

Heterogeneity among individuals with AUD is not a new issue. Researchers have previously recognized and attempted to identify subtypes of AUD (see [4] for a review). In 1960, Jellinek described five different classifications of alcohol use based on etiological elements (e.g., psychological and physiological vulnerability), alcoholic process elements (e.g., level of tolerance or loss of control), and consequences of drinking (e.g., physical/mental, socioeconomic) [5]. In 1981, Cloninger and colleagues identified two types of individuals with AUD, characterized by age of onset of problematic drinking, heritability, severity, and personality factors [6]. In 1992, Babor and colleagues extended this classification system by including genetic, biological, psychological, and sociocultural traits [7]. Recognizing the cross-sectional limitations of previous works, Lesch and Walter described four subtypes of AUD based on biological, sociological, and psychological information using data from their prospective, longitudinal study [8]. Employing more modern statistical techniques, Moss and colleagues conducted a latent class analysis using data from the National Epidemiologic Survey on Alcohol and Related Conditions and identified five subtypes of alcohol dependence, based on family history of drinking, age of alcohol dependence onset, DSM-IV AUD criteria, and co-occurring psychiatric and substance use disorders [9]. Most recently, Mann and colleagues used factor mixture models to identify four latent subgroups of drinkers based on their reward and relief drinking patterns [10].

Despite these attempts, there is little agreement in the field regarding the different subtypes of AUD. This lack of consensus may be rooted in the limitations of the measures that has thus far been employed. The Addictions Neuroclinical Assessment (ANA) attempts to address this limitation by establishing a neuroscience-based framework and rationale for understanding the heterogeneity of AUD [11, 12]. The ANA framework is composed of three main neurofunctional domains relevant to

AUD and addictions in general: Executive Function, Incentive Salience, and Negative Emotionality. Assessing these three neurofunctional domains, both in patients and individuals at risk for AUD, using established neuropsychological assessment tools and clinical measures will allow for better understanding of the heterogeneity of AUD and its etiology, ultimately improving the nosology of AUD. The ANA framework goes beyond AUD and is an important step towards understanding substance use disorders in general, providing both clinicians and researchers with a common framework to integrate findings from basic neuroscience research into clinical practice.

Addictions Neuroclinical Assessment: A Neuroscience-Based Framework

Advances in neuroscience research have shed light on the neurobiological underpinnings of substance use and substance use disorders [13, 14]. Addiction can be understood as a three-stage cyclical process of binge/intoxication, withdrawal/negative affect, and preoccupation/anticipation [13, 15, 16]. Individuals may start using drugs in a controlled manner, driven primarily by the positively reinforcing effects of the drug. Continued drug use results in homeostatic dysregulation causing changes in the brain's reward, stress, and executive function systems, which ultimately leads to a compulsive pattern of drug use—characterized by a loss of control and use despite negative consequences. The three domains of ANA are based on these three stages of addiction cycle [11]. The incentive salience domain captures the binge/intoxication stage, with processes related to reward, motivational salience, and habit formation. The negative emotionality domain encompasses the withdrawal/negative affect stage, which include stress and negative affective states as a result of drug withdrawal and long-term drug use. The executive function domain corresponds to the preoccupation/anticipation stage, with processes related to planning towards future goals, impulsivity, and working memory. As described below, ANA aims to provide both clinicians and researchers with a common, standardized set of measures by leveraging both neuroscience-based assessments with clinical measures to provide a comprehensive assessment of the three neurofunctional domains.

These neurofunctional domains, informed by our current understanding of the neurobiology of addiction, allows for the development of deeper insights into the processes related to the etiology and pathophysiology of AUD and improve our understanding of the heterogeneity of the disease. This can ultimately lead to better treatment interventions. For example, naltrexone, an FDA-approved medication for AUD, is an opioid antagonist that produces its effects by blocking the rewarding effects of alcohol [17, 18]. Meanwhile, acamprosate, another FDA-approved medication for AUD, acts primarily as a functional glutamate antagonist and is thought to address the cravings associated with acute and protracted alcohol abstinence

[19–21]. While these medications were not developed using the ANA framework, their hypothesized mechanisms of actions each target specific domains of ANA. Naltrexone may be especially efficacious for individuals for whom alcohol has a high incentive salience, while acamprosate might be more efficacious for individuals with executive function deficits who may be more vulnerable to craving-induced relapse. Identifying each individual's level of incentive salience, negative emotionality, and executive functioning would thus be key in helping individuals "break" the cycle of addiction. These neurofunctional domains would also provide a framework for researchers to develop novel therapeutics that target specific addiction-related processes.

Similar Frameworks in Addiction and other Psychiatric Research

The use of transdiagnostic domains to understand the etiology and heterogeneity of psychiatric disorders is not new. Before ANA, the National Institute of Mental Health put forth the Research Domain Criteria (RDoC) project [22]. The goal of RDoC is to create a research framework to facilitate the integration of clinical, genomics, and neuroscience research to inform classification schemes of psychiatric disorders. During its inception, RDoC is composed of five neuroscience-based systems: Negative Valence Systems, Positive Valence Systems, Cognitive Systems, Systems for Social Processes, Arousal and Regulatory Systems. Since then, a sixth domain, Sensorimotor Systems has been added. Each system is composed of distinct constructs, and is further organized by units of analysis (genes to paradigms). Since its inception, the RDoC project has had a significant impact on mental health research over the past decade and continues to play an influential role [23]. The RDoC constructs have been used to understand addictive behaviors [24]. In 2015, the US National Institute on Alcohol Abuse and Alcoholism (NIAAA) first proposed the Alcohol Addiction Research Domain Criteria (AARDoC) as an extension of the RDoC framework to the alcohol field [25]. Subsequently, Kwako et al., [11] further expanded and operationalized this framework as the Addictions Neuroclinical Assessment (ANA). The three-domain framework of ANA is consistent with and can be embedded within the larger RDoC framework.

There have been other models and frameworks proposed for understanding the underpinnings of addiction to alcohol and other drugs. Drawing insights from the three-stage cycle of addiction and findings from neuroimaging research, Goldstein and Volkow proposed the *Impaired Response Inhibition and Salience Attribution* (I-RISA) syndrome of drug addiction model, whereby addiction is a cycle characterized by drug reinforcement (intoxication), craving, bingeing, and withdrawal [16, 26]. This model postulates that disruptions in the neural circuits underlying response inhibition and salience attribution in the prefrontal cortex underlie the development and maintenance of addictive disorders. This framework bears similarities and is relevant to the three neurofunctional domains of ANA.

The Cognitive Neuroscience Treatment Research to Improve Cognition in Schizophrenia (CNTRICS) is an initiative to identify the cognitive systems and component processes in schizophrenia and develop measurement and treatment approaches to target these systems. Constructs included in these systems include working memory, long-term memory, executive control, social/emotional processing, attention and perception. This initiative has identified and selected a set of social, cognitive and affective measures, behavioral tasks, and imaging biomarkers to assess these constructs [27–30]. The Cognitive Neuroscience Test Reliability and Clinical Applications for Schizophrenia (CNTRACS) is a consortium that has developed out of CNTRICS with the goal of testing the application and psychometric properties of the identified measures. The ANA framework shares many overlapping features with CNTRICS and provides a useful blueprint in applying a similar framework to the addiction field.

Domains

Incentive Salience

Incentive salience is the cognitive process in which a reward and its associated cues are conferred motivational salience, creating a strong drive in the individual to pursue the reward [31]. In natural settings, incentive salience motivates the individual to pursue rewards that are necessary for survival (i.e., food, water, sex). This process is mediated by the mesocorticolimbic system, a circuit that includes the ventral tegmental area, striatum, and nucleus accumbens [13, 32]. Initially, exposure to a novel reward causes midbrain dopaminergic neurons that project to the basal ganglia to release dopamine [33]. However, after repeated exposures to the reward, these midbrain dopamine neurons cease firing during the reward itself, but rather activate when cues predictive of the reward are presented [33]. Ingestion of misused drugs, including alcohol, also result in phasic release of dopamine in the mesocorticolimbic system, and repeated use results in drug-associated cues to be imbued with incentive salience [34]. These neuroadaptations underlie the formation of habitual drug taking [35]. Following chronic drug use, exposure to drug-associated cues can result in an intense desire for the drug (i.e., craving) and subsequently lead to compulsive use [13]. It is important to note that incentive salience only confers the motivation to pursue the reward (‘wanting’) and can be dissociated from the hedonic aspect of the reward itself (‘liking’) [31]. Thus, individuals who are drug tolerant may report an intense desire to use the drug yet perceive little pleasure when using the drug.

Additionally, while the use of these drugs can lead to substance use disorders, most individuals who use drugs do not develop the disorder [36, 37]. Indeed, when given the choice between saccharin and alcohol, only 12.5% of rats showed a strong preference for alcohol, mirroring rates found in human population [38, 39]. Studies on the behavioral economics of drugs suggest that it is the relative value of rewards,

rather than the absolute value, that drives individuals to choose drugs over non-drug alternatives [40]. Therefore, the incentive salience of a reward may be relative rather than absolute, and may prove to be less powerful in the presence of alternative rewards. Incentive salience can be assessed with measures that capture the motivational salience for the drug and drug-associated cues. Individuals with AUD show altered neural responses to alcohol- and non-alcohol related cues [41–43], and exposure to alcohol-related cues induce cravings in these individuals [44, 45], suggesting that cue-reactivity paradigms may be useful probes of incentive salience. Additionally, individuals with AUD show impairments in reward learning which may be indicative of disrupted reward processing [46], and measures that tap into this construct may prove useful. Finally, behavioral economic indices of alcohol demand are also useful indicators of alcohol motivation and incentive salience [47].

Negative Emotionality

While most individuals begin drinking due to the positive reinforcing effects of alcohol, some individuals drink to alleviate negative emotional states, such that drinking behavior is maintained through negative reinforcement [48, 49]. The rise of negative affective states can also be a result of chronic alcohol use itself. Long-term heavy drinking results in allostatic changes such that cessation of alcohol consumption causes the manifestation of withdrawal symptoms, including *hyperkatifeia*, defined as an increase in the intensity of negative emotional and motivational sign and symptoms from withdrawal of misused drugs [50]. Alternatively, existing comorbidities, history of trauma, and exposure to high levels of distress can also result in negative emotional states that increase the likelihood of chronic alcohol consumption [51, 52]. These processes are not mutually exclusive, and most likely co-occur. Individuals with AUD generally report elevated levels of dysphoria, [53] and also display increased negative emotional responses to stress and alcohol cues [54]. Among individuals with AUD who are trying to abstain, these negative emotional states often precipitate relapse [55, 56].

The neurobiology underlying negative emotional states involves the interactions between multiple brain systems, including the reward circuitry (mesolimbic dopamine system) and the brain stress and anti-stress systems (hypothalamic-pituitary-adrenal axis and extrahypothalamic systems) [13, 57]. Chronic alcohol use results in neuroadaptive changes in these systems. During acute withdrawal, the brain reward circuitry becomes less sensitive to stimulation by natural rewards [58, 59], which may be reflected behaviorally as loss of interest towards non-drug rewards. Chronic alcohol use also result in upregulation of the brain stress system, mediated by neurotransmitter systems such as corticotropin-releasing factor (CRF), dynorphin, norepinephrine, orexin, substance P, and vasopressin, and a downregulation of the brain anti-stress system, which involves neuropeptide Y, nociception, endocannabinoids, and oxytocin, all of which are hypothesized to be involved in the manifestations of negative emotional states [13].

Negative emotionality can manifest as symptoms of depression, anxiety, aggression, alexithymia, and anhedonia, and as such clinical measures of these constructs may be useful indicators. Negative and positive affect, typically assessed using self-report questionnaires, may reflect negative emotionality. Behavioral tasks that assess responses to negative emotional stimuli, such as ostracism and presentation of negative emotional faces, as well as tasks that assesses distress tolerance and amotivation for rewards can be useful objective markers of negative emotionality. Specific aspects of personality (such as low conscientiousness, low agreeableness, and high neuroticism) may also be useful in capturing trait levels of negative emotionality.

Executive Function

The executive function domain refers to a collection of mental processes involved in the cross-temporal organization of thoughts and behaviors. This organization lends itself to the organization of behavior towards a future objective [60–63]. While the general domain of executive function is broad (see [60] for a review), the focus here is on executive functions related to the addiction process, which include attention, response inhibition, planning, working memory, behavioral flexibility, and valuation of future events [11]. Deficits and alterations to these processes can result in the loss of top-down control of thoughts and behavior. Individuals may thus have difficulty controlling thoughts and impulses related to drug use, and behaviors may end up being dictated primarily by bottom-up processes related to incentive salience. Impaired executive functions act as both a risk factor and a consequence to chronic alcohol and drug use. Individuals with impaired executive functions are more susceptible to use drugs, develop a use disorder, and relapse during drug abstinence [64, 65], and chronic alcohol and drug use also impairs executive functions [66]. This creates the potential for a vicious cycle: individuals with deficits executive control are prone to engage in alcohol and drug use, which subsequently cause further impairments in executive control.

Related to the above classical executive functions, research has begun to show the importance of interoceptive and metacognitive processes in the etiology of substance use disorders [67]. Interoception, referring to the receiving, processing, and integrating of internal and external stimuli to modulate behavior, is important in the regulation of the individual's homeostatic state. Interoceptive awareness forms an internal representation of the individual, and is integral for a wide range of human behaviors [68]. The individual's awareness of their current and future internal states can modulate the individual's likelihood in engaging in approach and avoidant behavior towards drugs and drug-related stimuli [67, 69]. Individuals with AUD display lower levels of interoceptive awareness, and among this population, interoceptive awareness was inversely associated with alcohol craving [70]. Metacognition, referring to processes related to the appraisal, monitoring, and regulation of cognition [71], is also recognized to play a role in the maintenance of substance use

disorders [72, 73]. Exposure to drug-related stimuli can elicit strong cravings and negative emotional states, and how an individual responds to these thoughts and negative affect will determine the behavioral outcome of that encounter [73].

The neurobiological correlates of executive functions consist of networks involving the frontal cortex [13]. Connections between the frontal cortices and basal ganglia are involved in the regulation of cue-induced cravings and impulsive actions primarily through glutamatergic projections, while projections between the frontal cortices and extended amygdala through glutamatergic projections are critical in regulating negative emotional states [13]. The anterior cingulate cortex is postulated to underlie interoceptive awareness [68]. Additionally, individuals with AUD and individuals with obsessive-compulsive disorder showed reductions in gray matter volume in the anterior cingulate cortex and insular, which may suggest a neurobiological correlate of obsessive thoughts (i.e., cravings) [74]. The default mode network (DMN), a large-scale brain network primarily composed of the medial prefrontal cortex, posterior cingulate cortex/precuneus and angular gyrus, also plays a critical role in interoceptive and metacognitive processes. Interactions between the DMN, executive control, and salience networks are disrupted in individuals with substance use disorders [69, 73, 75, 76].

Ancillary Assessments

While the three neurofunctional domains form the core of the ANA framework, leveraging ancillary measures related to the etiology of AUD will lead to a better understanding its heterogeneity. Examples of ancillary measures include genetic and epigenetic markers, neuroimaging markers, agent use history, environmental and social variables, as well as relevant consequences of drug use.

Substance use disorders are strongly heritable, with heritability estimates of ~50% for AUD, and ranging from 0.39 to 0.72 across substances [77]. Genome-wide association studies (GWAS) of AUD have identified relevant genes that are alcohol-specific (e.g., alcohol metabolizing genes), and others that may be relevant to addictions in general (e.g., SLC39A8, DRD2) [78]. Individual genetic variants are unlikely to be significant predictors of the disease state. As such, genetic and genomic information may be ancillary to the main ANA domains. However, they may be helpful in elucidating the functional and molecular mechanisms underlying the heterogeneity and etiology of AUD. Thus, collection of genomic data as an ancillary assessment is recommended in ANA studies. Polygenic scores, a method of summarizing the total contributions of multiple genes related to a particular disease [78, 79], together with genomic structural equation modeling [80, 81], may address some of the predictive limitations of single-gene approaches. Changes in the transcriptome due to chronic and heavy substance use, such as microRNAs and epigenetic changes, are also important features to be measured [82, 83]. Together, these approaches will elucidate the genetic and epigenetic factors underpinning the addiction process, and provide an integrative approach to understanding the disease and related comorbidities.

Employing neuroimaging methods will also be an important aspect of ANA. Positron emission tomography (PET) has been successful in understanding the role of specific neurotransmitter systems involved in substance use disorders [84, 85]. Functional magnetic resonance imaging (fMRI) techniques can also capture differences in brain morphology [86], resting state functional connectivity [87], and neural responses to alcohol and other cues [88] as well as emotional stimuli and executive function tasks, as a function of alcohol use. These approaches can be integrated with both genetic and clinical measures as part of a multimethod approach in assessing the ANA domains [89].

Substance use history, environmental and social variables, and consequences of drug use are important dimensions related to substance use that should be captured with ancillary assessments. These assessments may be important in capturing processes and outcomes of substance use that are not otherwise included within the three domains of ANA. Since the ANA domains are transdiagnostic, substance-specific measures can serve as important markers that contribute unique information about the individual's substance use. Measures assessing frequency and quantity of consumption of the substance also serve as vital clinical outcomes that can be used to monitor progression and recovery. The environmental and social milieu of the individual also modulates their risk of substance use, and are important variables for consideration [11].

Empirical Research

Since its introduction by Kwako and colleagues [11], multiple groups have independently validated and applied the domains of ANA. Most of these studies used similar methodologies, employing a combination of factor analytical techniques and structural equation modeling to identify the key latent variables and their associations with sociodemographic variables, risk factors, and drinking-related outcomes.

Initial validation of the three neurofunctional domains was conducted by Kwako and colleagues using a deeply phenotyped sample consisting of 454 individuals across the spectrum of alcohol use who underwent the National Institute on Alcohol Abuse and Alcoholism (NIAAA) Natural History Protocol [90]. In this retrospective analysis, measures relevant to the three neurofunctional domains were selected and subjected to exploratory and confirmatory factor analyses. A three-factor solution provided the best fit to the data, consistent with the three neurofunctional domains of ANA. The three factors showed significant cross-correlations (r's = 0.76 to 0.90). Trait anxiety showed cross loadings to both the negative emotionality and incentive salience factors, while depression loaded on to the incentive salience but not negative emotionality factor. This may reflect negative reinforcement (alleviation of negative mood states) driving incentive salience processes. Multiple indicators, multiple causes (MIMIC) analysis identified early life stress and sociodemographic variables as significant predictors of the three latent factors. To characterize the ability of the latent factors in distinguishing individuals with and

without AUD, receiver operating characteristics (ROC) curves of the true positive rates (sensitivity) versus false positive rates (1-specificity) were examined. The areas under the ROC curves for the latent factors ranged from 0.85 to 0.96, indicating that the ANA factors showed a remarkable ability to identify individuals with AUD [90]. This study provides the first empirical evidence of the three-domain structure of ANA and highlighted its application to understanding AUD etiology.

Votaw and colleagues replicated the findings of Kwako et al. by retrospectively analyzing data from a multisite naturalistic prospective observational study in 563 individuals seeking treatment for AUD [91]. The researchers focused specifically on the negative emotionality domain, using measures of depression, anxiety, anger, and drinking-related unhappiness, guilt and anhedonia, as indicators in a confirmatory factor analysis. A single-factor solution for the negative emotionality domain provided an excellent fit to the data, consistent with the findings of Kwako and colleagues [83]. Additionally, the researchers found that the latent factor was invariant across time and across genders (i.e., factor structure, loadings, and means did not differ between baseline, 6- and 12-month follow-up, and between males and females). Higher negative emotionality was associated with more frequent and heavier drinking, and drinking to regulate negative affect, providing evidence of the construct validity of the negative emotionality factor [91].

In a more recent extension of their work, Votaw and colleagues examined the predictive validity of the negative emotionality factor using a latent growth curve mediation model [92]. Using data from 263 treatment-seeking individuals, the researchers tested whether drinking motives at 6 months mediated the relationship between negative emotionality at baseline and drinks per drinking day at 7–12 months. Baseline negative emotionality, estimated using the same indicators as their previous study [91], was found to be indirectly associated with greater alcohol consumption 12 months following treatment initiation through higher coping motives at 6 months. Baseline negative emotionality, however, was not related to changes in coping motives, nor were changes in coping motives related to drinking outcomes at 12 months [92]. This was the first study to test the predictive validity of the ANA domains.

While the previous two studies focused primarily on the negative emotionality domain, Stein and colleagues sought to replicate and validate the factor structure of the incentive salience domain [93] using data collected from the same participants in Votaw et al. [91]. Measures of incentive salience include items from the Alcohol Dependence Scale, Impaired Control Scale, Situational Confidence Questionnaire, and Marlatt Relapse Interview. A one-factor model of incentive salience provided good fit to the data. The model was also invariant across sex. Incentive salience was negatively associated with percent days abstinent, and positively associated with drinking quantity, frequency, and heavy drinking days, as well as measures of testing personal control, urges, social pressure to drink, and family history of AUD, providing evidence of convergent validity. The factor was not associated with religiosity or family social support, thus demonstrating discriminant validity. Finally, the researchers established predictive validity by demonstrating that incentive salience at baseline was associated with heavy drinking days at 12-month follow-up [93]. Thus, this study provided independent replication and validation of the incentive salience domain proposed in the ANA.

Nieto and colleagues pooled data from six clinical and experimental psychopharmacology studies to assess the ANA framework in a sample of 1679 heavy drinkers with and without AUD [94]. Measures of harmful drinking, AUD severity, alcohol-related problems, alcohol craving, anxiety, depression, attention, working memory, impulsivity, and delay discounting, were subjected to exploratory factor analyses to elucidate the underlying latent structure of the measures. Four factors emerged, corresponding to the three domains proposed in the ANA framework, and an additional factor capturing alcohol-related consequences. Being male was associated with higher levels of alcohol-related consequences and incentive salience. Age was positively associated with alcohol-related consequences, incentive salience, and negative emotionality, and negatively associated with executive function. Those who had their first drink at a younger age was associated with greater alcohol-related consequences and incentive salience, and a family history of alcohol problems was associated with higher levels of alcohol-related consequences, incentive salience, and lower executive functioning. Both drinking frequency and quantity was positively associated with alcohol-related consequences and incentive salience, but only drinking frequency was associated with greater negative emotionality. Finally, individuals with AUD exhibited greater scores on all factors except executive function.

Demartini and colleagues sought to replicate the findings from Kwako and colleagues in a sample of non-treatment seeking low and high risk drinkers [95]. Data from 335 individuals were collected, including measures of impulsivity, depression, drinking motives, alcohol expectancies, obsessional and compulsive behavior, and habit. Factor analyses indicated a three factor solution, corresponding to the three neurofunctional domains. A history of childhood trauma and AUD were predictors of impairments across all three domains. Earlier age of first drink, and family history of AUD were associated with greater incentive salience. No sex differences were found across the three domains [95]. This work provides an important replication and extension of the original study by including unique indicators that was not previously used, while still arriving at the same factor solution.

Using the AARDoC framework, Al-Khalil and colleagues sought to identify the neural correlates underlying the incentive salience and negative emotionality domain in a sample of non-treatment seeking heavy drinking adults [96]. Participants were presented with alcohol, negative-valenced, and neutral cues while undergoing a functional magnetic resonance imaging paradigm. Changes in functional connectivity in the nucleus accumbens and amygdala were hypothesized to reflect incentive salience and negative emotionality related processes, respectively. Changes in functional connectivity between the nucleus accumbens, cerebellum and prefrontal cortex, and functional connectivity between the amygdala and occipital, parietal, and hippocampal regions were detected in response to alcohol cues relative to neutral cues. Additionally, functional connectivity changes between the nucleus accumbens, lateral temporal, occipital, and parietal regions, and changes in function connectivity between the amygdala, fusiform, and lingual gyri were observed in response to negative cues relative to neutral cues. Some of the functional connectivity changes also differed as a function of AUD severity [96]. Thus, functional connectivity between these regions may underlie levels of incentive salience and negative emotionality in heavy drinkers. This study provides important information

about the neurobiological correlates underlying the incentive salience and negative emotionality domain. Future work would be needed to replicate and extend these findings to delineate the neural correlates of the ANA framework across individuals with and without AUD.

Extending beyond AUD, Nieto & Ray applied the ANA framework to methamphetamine use disorder [97]. One hundred and eighty-five non-treatment-seeking frequent methamphetamine users were recruited and completed a deep phenotyping battery that consisted of measures of methamphetamine withdrawal, craving, anxiety, depression, risk attitudes, behavioral inhibition, attention, working memory, impulsivity, and delay discounting. The researchers conducted factor analyses and arrived at a three-factor solution, corresponding to incentive salience, negative emotionality, and executive functioning. Age was negatively associated with executive function, and methamphetamine symptom count was positively associated with negative emotionality and incentive salience. Past 30-day methamphetamine use was associated with higher incentive salience, consistent with what was found among the treatment-seeking individuals. This work demonstrates the implementation of the ANA framework to other substance use disorders, and underscores some of the common neurofunctional pathways underlying addiction to alcohol and other misused substances.

Taken together, the studies summarized above provide important validation and extensions of the original ANA framework. While these studies are generally consistent with the three neurofunctional domains, some differences across studies were present. For example, Kwako and colleagues found sex differences for the negative emotionality domain [90], but this was not replicated by Votaw et al. [91] and Nieto et al. [94]. These inconsistencies may be due to differences in the samples used in the studies. The latter two studies consisted of individuals on the higher end of the AUD severity spectrum; those in Votaw et al. were composed exclusively of treatment-seeking individuals [91, 92], while participants in the study by Stein and colleagues were primarily heavy drinkers enrolled in psychopharmacological studies with strict exclusion criteria [93]. Kwako and colleagues had the most diverse sample with the broadest inclusion criteria, which included both treatment- and non-treatment-seeking individuals with and without a diagnosis of AUD, which may be more representative of the broader population of individuals across the spectrum of alcohol use and risk for AUD [90].

Addictions Neuroclinical Assessment Battery

Building upon the proposed ANA framework, the NIAAA intramural clinical research program has developed the ANA testing battery, a collection of neurocognitive and behavioral tasks and self-report questionnaires that assesses the three neurofunctional domains of ANA. These measures were selected based on a review of the addiction literature and through consultations with relevant experts in the field. The goal of this assessment battery is to develop a set of

standardized measures for clinicians to assess the neurofunctional domains of patients, and for researchers to study the etiological processes of AUD using the ANA framework. The list of assessments, organized by domains, can be found in Table 14.1. A prospective clinical study using this assessment battery is currently underway (NCT04946851, clinicaltrials.gov). Due to the breadth of measures employed, the full battery takes approximately 4–5 h to complete

Table 14.1 List of measures in the ANA assessment battery

	Incentive salience	Negative emotionality	Executive function
Behavioral Tasks	• Alcohol Approach Avoidance Task (Approach-Avoidant Bias) • Drinking Identity Implicit Association Task (Implicit Association) • Alcohol Stroop (Cue-reactivity) • Implicit Choice Task (Alcohol preference)	• Paced Auditory Serial Addition Task (Distress Tolerance) • Cyberball (Ostracism) • Effort Expenditure for Rewards Task (Motivation for rewards) • Probabilistic Reward Task (Reward learning) • Penn Emotion Recognition Task (Emotion recognition)	• Stop Signal Reaction Task (Response Inhibition) • Digit Span—Backwards (Working Memory) • Beads in a Jar (Inference) • Trail Making Test (Task Switching) • Manikin Test of Spatial Orientation (Mental Rotation) • Continuous Performance Task (Attention) • Wisconsin Card Sorting Task (Cognitive Flexibility) • Balloon Analog Risk Task (Risk-taking)
Self-report measures	• Hypothetical Purchase Task (Alcohol Demand)	• Snaith-Hamilton Pleasure Scale (Anhedonia) • Connor-Davidson Resilience Scale (Resilience) • Inventory of Socially Supportive Behaviors (Social Support) • Experiences in Close Relationships Scale (Attachment Anxiety/Avoidance) • Positive and Negative Affect Scale (Affect) • Toronto Alexithymia Scale (Alexithymia)	• Metacognitions Questionnaire (Metacognition) • Multidimensional Assessment of Interoceptive Awareness (Interoception)
Ancillary measures	• Self-Rating of the Effects of Alcohol Questionnaire (Alcohol sensitivity) • Obsessive-Compulsive Drinking Scale (Compulsive drinking) • Penn Alcohol Craving Scale (Craving)	• Montgomery-Asberg Depression Rating Scale (Depression) • State-Trait Anxiety Inventory (Anxiety) • Buss-Perry Aggression Questionnaire (Aggression) • NEO Personality Inventory (Personality)	• Barratt Impulsivity Scale (Impulsivity) • UPPS-P Impulsivity Scale (Impulsivity) • Monetary Incentive Delay (Delay Discounting)

(including breaks). A major objective of this ongoing work is to characterize the underlying latent factor structure of the individual neurofunctional domains and how these latent sub-factors may relate to each other. Figure 14.1 shows a hypothesized model of latent factors in each domain as the domains relate to each other along the cycle of addiction. Importantly, the study will examine associations between these domain factors and sub-factors as a function of AUD diagnosis and other indicators and outcomes. Work is currently being done in evaluating the psychometric properties of the ANA battery, to use these domain factors to identify AUD subtypes, and to understand how proximal and distal factors impact drinking outcomes and confer risk to the development of AUD. Potential differences in factor scores and associations between individuals with and without AUD may reflect some of the etiological processes of AUD and help identify potential mechanistic underpinnings of the neurobiology of the addiction cycle. Detailed descriptions of the assessment battery and measures can be made available upon request to the corresponding author.

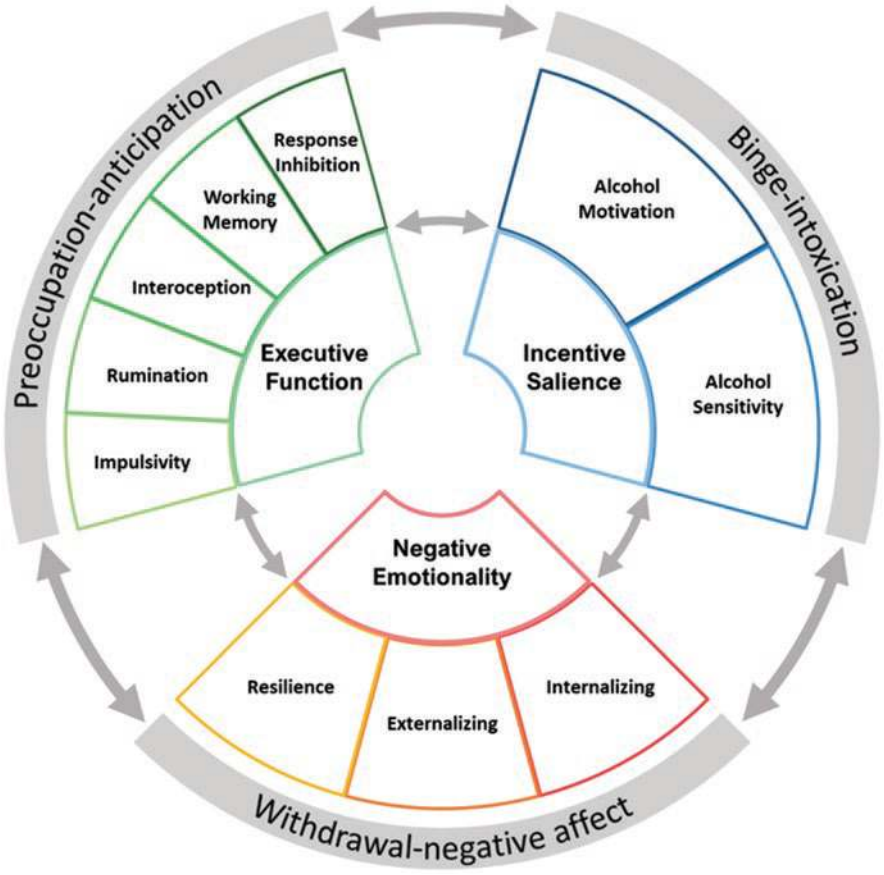

Fig. 14.1 Conceptual framework of the addictions neuroclinical assessment (ANA) domains and underlying latent factors

Future Directions

The goal of ANA is to create a common framework for both clinicians and researchers to understand the etiology and heterogeneity of AUD and substance use disorders. The work thus far has focused on empirically validating the theoretical model of ANA. Establishing the foundational validity of the model is critical before hypothesis-driven research can be undertaken. It is important, however, that the ANA framework must not be rigid in its conceptualization and be flexible to new research findings. Continual, incremental improvements in face of new information will determine the success of ANA. While the framework thus far has primarily been applied to understanding AUD, the theoretical foundation of ANA is not tied to specific substances and thus should be broadly applied to other addictions. An additional future direction for researchers to consider is how the ANA framework can serve as a bridge between preclinical and clinical research, with the development and application of models that can aid in both translational and reverse-translational approaches to understand addictions [12, 98].

The imperative aim of the current research is to use these neurofunctional domains to elucidate homogenous subtypes of AUD. Utilizing mixture modeling approaches such as latent profile analysis are important next steps in identifying these subgroups [99]. Understanding the biological correlates of the ANA domains using genetic, epigenetic, and neuroimaging methods will also be key in understanding the specific molecules, brain regions, and neural networks that underlie the ANA domains. Much of the work on ANA thus far has employed retrospective, cross-sectional samples that limit our understanding of the causal relationship between and across domains. Future research that employ longitudinal designs will be critical in our understanding of how these domains change as a function of alcohol use, alcohol use disorder progression, and importantly, as a function of recovery [100]. Equally critical is the use of diverse samples to understand how the etiology and heterogeneity of AUD might differ across gender, racial, and ethnic groups. Socioeconomic factors [101] and sociocultural factors [102] are known to be strong predictors of alcohol use, and differences in these factors across racial and minority groups may contribute to the health disparities seen within AUD by modulating the etiological process of the disease. Finally, a shorter assessment battery will be necessary for the successful application of the ANA framework in the clinical setting to aid in diagnosis and characterization of individuals with AUD. Thus, future research will need to identify the most efficient measures for the three domains and rigorously test the validity and reliability of the assessment battery.

Conclusions

In summary, the Addictions Neuroclinical Assessment is a clinically-directed, neuroscience-based framework to understand the etiology and heterogeneity of AUD and other substance use disorders. ANA consist of three neurofunctional

domains relevant to addictions: incentive salience, negative emotionality, and executive functions. These domains are based on the three stages of the cycle of addiction and are supported by our current understanding of the neuroscience of substance use disorders. Measuring these neurofunctional domains will require the use of neuropsychological and behavioral tasks, as well as clinical and self-report measures. Ancillary measures, such as genetic, epigenetic, and neuroimaging markers, are recommended to supplement the assessment of the three domains. This review includes a summary of the current empirical work that has utilized the ANA framework. Current limitations of the research, and important directions for future research are highlighted. The ANA aims to serve as a tool for both researchers and clinicians to provide a common framework to aid in improving the understanding of the etiology and heterogeneity of AUD, and substance use disorders in general.

Acknowledgements We acknowledge the support of the clinical and research staff of the NIAAA intramural clinical research program in the execution of the ANA study. We also acknowledge the contribution of Ugne Ziausyte, Rajon Scott, Sarah Izabel, and Hannah Kim, in the preparation of this chapter.

Part III
Treatment of Alcohol Addiction

Chapter 15
Evidence-Based Behavioral Treatments

Anders Hammarberg and Stina Ingesson

Abstract Behavioral treatments for of alcohol use disorders (AUD) include numerous interventions based on the theories of behaviorist learning, which assume that alcohol related behaviors are learned according to the principles of classical and operant conditioning. Behavioral treatment for AUD aims to alter these behaviors and replace them with non-alcohol related behaviors, with the aim of accomplishing reduced consumption or abstinence from alcohol. The aim of this chapter is to give an overview of evidence based behavioral treatments for AUD, including Brief Interventions, Motivational Interviewing/Motivational Enhancement Therapy, Cognitive Behavioral Treatment (CBT), Behavioral Couples Therapy (BCT), Community Reinforcement Approach (CRA), Contingency Management (CM), Cue Exposure Therapy (CET), Mindfulness Based Interventions (MBI) and 12-step based treatments. Further, the aim is to focus on some specific areas of interest, these being the availability of treatments for controlled drinking, behavioral treatments combined with pharmacotherapy, technology-based treatments and common mechanisms of behavior change. The chapter ends with some suggestions for future directions in research on behavioral treatments for AUD, where the most tangible challenges may be not the question of which treatments are efficacious, but instead how to increase availability to treatment and how to make treatment for AUD more attractive to those in need.

Introduction

Behavioral treatments for of alcohol use disorders (AUD) include numerous psychological interventions, which are based on, or partly influenced by, behaviorist learning theory. In the context of AUD, behavioral interventions are based on the assumption that behaviors related to problematic alcohol consumption are learned according to the same basic principles as all other behaviors, i.e., classical and operant conditioning. In Fig. 15.1, we give a schematic overview over how alcohol behaviors are learned. According to the theory of classical conditioning, behaviors that we repeat become associated (conditioned) with stimuli present in those situations. Using the example of alcohol consumption, stimuli associated with drinking may be exteroceptive, for example other individuals (e.g., best friends or partner), places (the favorite bar, at home while cooking dinner, the country house) or events (while watching sport events, listening to music). Stimuli may also be interoceptive, for example drinking when in a certain emotional state. As conditioning takes place, the stimuli become antecedents (A) to alcohol consumption, i.e., stimuli that trigger future alcohol consumption when the individual is exposed to them.

According to the theory of operant conditioning, rewarding behaviors tend to be repeated (reinforced) more than others. A specific behavior (alcohol consumption); termed "response" (R), will be reinforced by its short-term consequences (SC). The short-term consequences may be either positively reinforced, as it results in rewarding consequences. Alcohol consumption is typically positively reinforced by increased pleasure and positive emotions, as well as increased sociability. Alcohol consumption may also be negatively reinforced, as alcohol may reduce unpleasurable experiences. Alcohol consumption is thus, negatively reinforced by creating a relief from, e.g., negative emotions such as stress, anxiety or withdrawal symptoms.

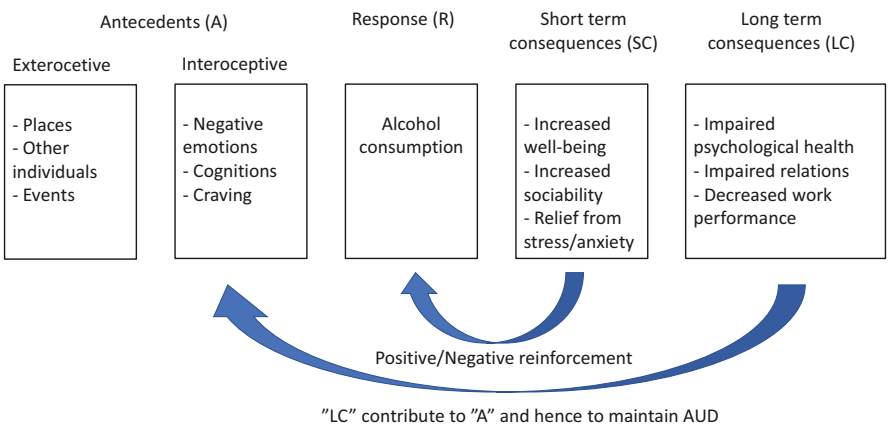

Fig. 15.1 Schematic overview of basic learning theory based on the example of alcohol use disorder

Alcohol consumption also have well known long-term negative consequences (LC), such as impaired psychological health, impaired relations and decreased work performance. The long-term negative consequences function as antecedents to future alcohol consumption and hence contribute to the maintenance of an AUD. Again, this can be explained by the reinforcing properties of alcohol mainly due to that alcohol consumption is negatively conditioned, as it in the short-term may alleviate negative emotions and cognitions related to the long-term consequences of previous alcohol consumption.

As will be apparent in this overview, behavioral treatments target different aspects of this behavior chain. For example, cognitive and behavior treatment (CBT), Community Reinforcement Approach (CRA), Behavior Couples Therapy (BCT) and Contingency Management (CM) focus on reinforcing alternative behaviors to alcohol consumption, or coping skills training in order to curb the drinking response while cue-exposure therapy (CET) focus on decreasing the association between antecedents and response.

Behavioral treatments vary considerably in content, intensity, and length, and are more or less applicable in different contexts. Some have been developed for use in general health care (e.g., Brief Interventions (BI)) while others are more suitable for use within specialized addiction treatment. In this chapter, we will give an overview of evidence based behavioral treatments, along with a brief summary of their empirical support. In addition, we will focus on some specific areas that we consider to be of key interest for the development of the field of AUD from a clinical and research perspective; the availability of treatments for controlled drinking (CD), the development and validation of technology-based treatments, and research on common mechanisms of behavior change.

Overview of Evidence Based Behavioral Treatments

A considerable number of behavioral treatments for AUD have been developed mainly from the 1980's and onwards. However, there is a large variation regarding the empirical support for these treatment approaches [1]. By evidence-based we mean interventions that have been empirically supported through randomized controlled trials (RCTs), and also preferably have been evaluated in systematic reviews and/or metanalyses. Treatment approaches covered by this overview are briefly summarized in Table 15.1.

A challenge in summarizing behavioral treatments in AUD, is the large variation of target populations in studies on this heterogenous disorder. In this section, we will provide an overview of behavioral treatments for individuals ranging in problem severity from heavy drinkers to those who fulfil diagnostic criteria for AUD. The focus will be on adult patients without comorbid psychiatric diagnoses. Interventions for adolescents and young adults as well as for patients with comorbid psychiatric conditions are covered in other chapters in this book.

Table 15.1 Brief overview of behavioral treatments

Treatment	Primary content
Brief Intervention (BI)	Assessment of alcohol use by and its consequences by self-report and biomarkers together with personalized feedback from healthcare personnel.
Motivational Interviewing (MI)/Motivational Enhancement Therapy (MET)	Person-centered, process-based collaborative treatment, focused on eliciting and strengthening motivation for and self-efficacy to change.
Cognitive behavioral treatment (CBT)	Treatment components include, e.g., functional analysis of risk-situations, goal setting, self-monitoring of consumption, identification of alternative behaviors and coping skills training.
Behavioral Couple Therapy (BCT)	CBT-based intervention in which a partner actively participates in treatment. Focus on relapse prevention, increasing communication skills and to identify common activities that can serve as alternative to alcohol consumption.
Community Reinforcement Approach (CRA)	Aims to change individual contextual factors which are identified as important to support change, including behavioral skills training, job skills training, social and recreational counseling, relapse prevention and relationship counseling.
Contingency Management (CM)	Reduction in alcohol consumption is reinforced by reimbursements in cash or vouchers for goods or services which are found rewarding. Continuous rewards for alcohol-reduction or abstinence generate operant conditioning to goal behaviors.
Cue Exposure Therapy (CET)	The individual is repeatedly exposed to alcohol-related cues with the aim to attenuate alcohol craving responses in situations in which alcohol consumption is a learned behavior. With prolonged exposure, alcohol-related stimuli will gradually lose their reinforcing properties.
Mindfulness Based Interventions (MBI)	Practice of mindfulness skills aims to increase awareness of alcohol-related triggers in order to target the individual's response to alcohol cravings and intrusive automatic alcohol-related thoughts in risk-situations. Skills reduce the risk of relapse into problematic drinking.
12-step based treatments	The overall purpose is to facilitate abstinence from alcohol, increase psychological well-being and quality of life, improve interpersonal skills and the ability to cope with stressful life events.

Brief Interventions

Brief interventions (BI) include an assessment of alcohol use and personalized feedback, with the aim of providing the patient with different options for behavior change. BI most often contain screening for hazardous alcohol consumption by the Alcohol Use Disorder Identification Test (AUDIT) [2] or some other short self-report instrument, combined with blood tests for alcohol biomarkers. In conjunction with the assessment, counseling is provided in which the patient will be offered advice based on the results of the assessment. BI is typically delivered in a single session by a health care professional within primary care [3] and is carried out

according to the principles of Motivational Interviewing (MI), which will be more thoroughly described in a following section. Meta-analyses have shown that BI is efficacious in reducing alcohol consumption for non-treatment seeking heavy drinkers and for individuals with mild AUD [4–6]. However, BI is considered less efficacious for individuals with moderate to severe AUD [7]. To address the need for more extensive support for patients with greater needs, BI may be incorporated within a stepped care model (see Fig. 15.2). In such a model, the treatment dose is adjusted based on a clinical evaluation of the patient's needs [8–10]. Patients who do not benefit from a BI, are offered extended assessment with feedback (step 2) and—if needed—treatment (step 3), that may contain a psychological program based on the principles of cognitive behavioral therapy (CBT) and MI [11] and/or pharmacological treatment. Only patients who require more extensive treatment are referred to specialized addiction treatment.

Despite the evidence supporting the efficacy of BI, these methods have not been successfully implemented within the regular health care system [12]. It is estimated that in primary care, less than one in five of individuals with hazardous consumption are identified and less than one in four with alcohol dependence are offered treatment [13].

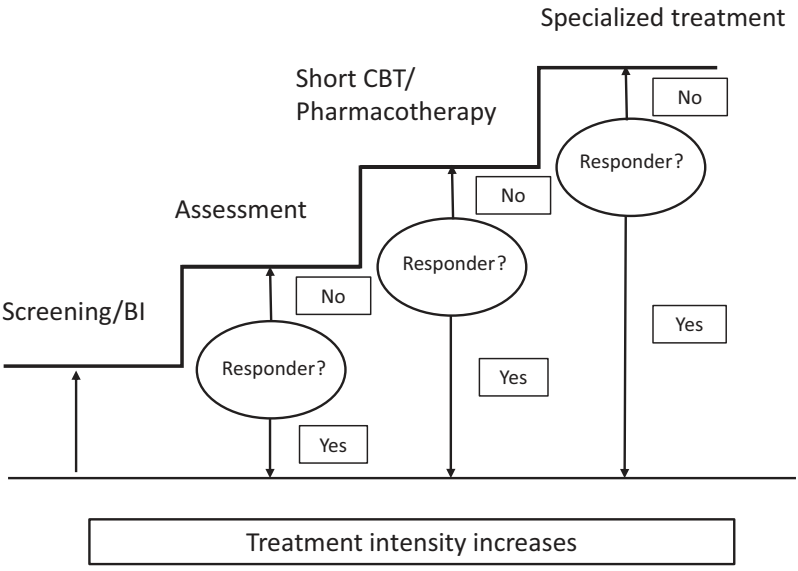

Fig. 15.2 Schematic description of a stepped care intervention. Modeled after Wallhed Finn et al. [8], Grothues et al. [10] and Sobell and Sobell [9]

Motivational Interviewing (MI) and Motivational Enhancement Therapy (MET)

MI is commonly defined as a brief, empirically validated, person-centered collaborative treatment, focused on eliciting and strengthening motivation for change [14]. MI was originally developed for targeting motivation for change in individuals with substance use disorders [15]. It has evolved into a widely accepted method used in different clinical and research settings associated with goals of a healthier lifestyle, such as smoking cessation, weight loss, or the reduction of alcohol consumption [16–18]. Rather than being a treatment with fixed themes every session, MI is a process-based approach that aims to explore and strengthen the individual's engagement to the identified goal, to resolve ambivalence, and to alter behaviors that maintain status quo [19]. Motivational Enhancement Therapy (MET) is an extension of MI, which includes components with the aim of further strengthening commitment to change [20]. In the first MET-session, patients go through assessments (questionnaires and biomarkers) in conjunction with a taking a history. This provides the patient and therapist with material for a deepened understanding of the patient's alcohol problems and related consequences, including severity of AUD, alcohol related harm, and psychological health. The second session is dedicated to a structured feedback on the initial assessment, with the aim of strengthening the patient's motivation for change. Further, the patient is encouraged to invite a significant other who can function as an additional reinforcer of the change process. The following 2–3 MI-sessions aim at further building motivation and consolidate commitment to change. Lastly, MET includes an option for the patient to formulate a written change-plan, including a formulation of goals together with defining activities and needs for support required to achieve the specified goals. As in MI, the role of the therapist in MET is to support the patient's change in a collaborative, empathetic, and non-confrontational manner.

Several RCT: s have supported the efficacy of MI and MET in reducing alcohol consumption, promoting abstinence and improving social functioning [20–22]. In a meta-analysis, Vasilaki et al. [23] found that, compared to no treatment, MI/MET was superior regarding reduction of alcohol consumption (d = 0.18), with a steep increase in effectiveness if follow-up period was restricted to 3 months (d = 0.60).

Cognitive Behavioral Therapies (CBT)

As mentioned in the introduction to this chapter, CBT is based on theories of learning according to behaviorist theory, and also rely on cognitive—and emotion theory. CBT models for AUD are based on the assumption that alcohol-related behaviors and the related negative consequences, may be changed by reinforcing alternative behaviors to alcohol consumption [24]. Alternative behaviors may be, e.g., reconnecting with friends, or engaging in physical exercise instead of spending time

drinking. CBT models also emphasize the acquisition of specific alcohol-related coping strategies, such as seeking social support or turning down drink offers [25]. CBT treatment manuals typically comprise specific components including goal setting, self-monitoring of alcohol consumption and a functional analysis, which is a structured way of identifying antecedents, as well as short- and long-term reinforcers of the problem behavior. This tool supports the patient in the identification of triggers associated with drinking (the "A" in Fig. 15.1), and specific skills training to cope with high-risk situations. Other key components of CBT are the emphasis on an active patient, a collaborative work alliance with the therapist, and in-between session assignments as a means of facilitating the generalization of behavioral and coping skills. Typical examples of CBT interventions are Relapse prevention (RP) [24–26] and Behavioral Self-Control Training (BSCT) [27].

Numerous studies, reviews, and meta-analyses corroborate the efficacy of CBT for treating AUD [28, 29]. A recent meta-analysis of CBT for SUD reported significant effects with different contrasts and type of outcomes [29]. Studies with the comparator being; minimal intervention, waitlist, or assessment only as control conditions showed a pooled effect size of g = 0.58 for frequency outcomes (e.g., number of abstinence days) and g = 0.67 for quantity outcomes (e.g., drinks per drinking day) at early follow-up. CBT in contrast to nonspecific therapy showed an effect size of g = 0.18 for frequency outcomes and g = 0.42 for quantity outcomes. In comparison with other specific therapy, the effects of CBT were nonsignificant for both types of outcomes. To summarize, CBT has strong support as an efficacious method for the treatment of AUD, albeit there is no evidence to support that CBT is superior to other specific behavioral treatments for the treatment of AUD.

Behavioral Couples Therapy (BCT)

Behavioral Couples Therapy (BCT) is a CBT-based intervention in which a partner actively participates in the treatment sessions together with the patient [30, 31]. According to BCT, a partner may work as a reinforcer of the behavior change in treatment due to several factors. First, the partner may act as a coach in the process of changing cognitions and behaviors related to problematic alcohol consumption. Second, the negative alcohol-related consequences which affect the partners as individuals and as a couple, can be addressed and resolved more effectively when the two parties meet together with a therapist. Lastly, general relationship functioning can be discussed and improved [32].Together, these factors are theorized to be helpful for the patient in order to accomplish and maintain a reduced alcohol consumption. BCT interventions also typically include psychoeducation, communication skills, behavioral activation to increase positive shared activities, negotiation of sobriety contracts, and relapse prevention with the goals of improving mutual coping and decreasing use [33]. Many components resemble those of other approaches such as individual RP and also Community Reinforcement Approach and Family Training (CRAFT, [34]) a method which addresses the partner exclusively. In a

meta-analysis [35], it was concluded that BCT is efficacious in reducing negative consequences of alcohol use and in increasing relationship satisfaction. For the reduction of alcohol consumption, the results were mixed and dependent on timing of measurement. BCT was not superior to comparators at post treatment follow-up, but in a longer perspective, (6- and 12-months post treatment), participants in BCT reported lower alcohol consumption and higher rates of abstinence. Noteworthy is that studies have identified a decrease in domestic violence following participation in BCT [36]. More recent studies have among others focused on investigating the efficacy of BCT in group format [37].

Community Reinforcement Approach (CRA)

The main goal of Community Reinforcement Approach (CRA) is to reinforce a reduced consumption or complete abstinence from alcohol by changing important contextual factors in the patient's life [38]. CRA shares its theoretical basis with CBT, in its aim to alter the antecedents and reinforcers of alcohol consumption. What is specific to CRA, is its emphasis on the surrounding community in this change process, e.g., family, and social network, recreational activities and occupational status [39, 40]. CRA and CBT share common treatment components. For example, CRA procedures commence with a functional analysis of drinking behavior in order to map antecedents, short- and (most often) negative long-term consequences to the problem behavior. This is followed by the identification of which areas would be most helpful to target for the reinforcement and maintenance of abstinence or a reduction in alcohol consumption. Thereafter, a treatment plan is outlined, based on the "Happiness Scale" which indicates what areas of life are the most important in achieving behavior change. The components may contain behavioral skills training, job skills training, social and recreational counseling, relapse prevention and relationship counseling. Evidence for CRA is generally favorable for AUD although there is a lack of recent metanalyses or systematic reviews. A meta-analysis from 2004 included two studies with a total of 343 participants [41]. The studies evaluated CRA compared with treatment as usual (TAU). Regular disulfiram treatment was not included in the treatment groups, but a relatively large proportion of patients used disulfiram during the treatment period. The meta-analysis showed a greater reduction in the proportion of days with alcohol consumption in the groups that received CRA compared to the control groups (weighted mean difference = −0, 94).

Contingency Management (CM)

Contingency Management (CM) stems from the principles of operant conditioning theory, in which problematic alcohol behaviors can be modified by altering the value of alcohol consumption relative to other incentives [42, 43]. In a CM program,

the planned behavior—which in this respect is moderation of or abstinence from alcohol consumption—is reinforced by cash or by vouchers for goods or services that the participant considers rewarding, for example food coupons [44]. Most studies using contingency management have focused on substances whose metabolites are easily measured and have a large window of detection, e.g., cannabis [45], nicotine [46] and cocaine [47]. There is support for CM also among heavy drinkers and individuals with AUD although since the window of detection for ethanol is shorter, CM used in these populations requires a more frequent monitoring of breath, blood, or urine biomarkers. More recently, CM programs have used new technologies that allow continuous monitoring of alcohol use, including transdermal alcohol monitoring [44] and ethyl glucuronide [48].

A concern regarding CM has been that the method may not result in prolonged behavior change post treatment [43]. However, a recent meta-analysis concluded that reduction in substance use post CM exposure can be traced at long term follow-up [49]. Lastly, A systematic review suggests that CM as a stand-alone intervention provides equal effects compared to CM as an add-on intervention to other treatment programs [50].

Cue-Exposure Therapy (CET)

Cue-Exposure therapy (CET) is based on learning theory and can generally be described as a method for extinguishing conditioned responses through exposure to stimuli combined with response prevention [51, 52], where the learned/conditioned response is either, e.g., initiation of drinking, or a heavy-drinking episode. In a laboratory-like situation, the patient is exposed to alcohol-related stimuli (cues) with the aim to attenuate alcohol craving responses in situations in which alcohol consumption is a conditioned response. With prolonged exposure, alcohol-related stimuli will gradually lose their reinforcing properties. CET may include exteroceptive cues (visual, e.g., pictures of alcoholic beverages or a tray with beverages, tactile, taste, smell or auditory) [51, 53]. Cues may also be interoceptive, where the patient is instructed to refrain from further consumption when exposed to stimuli after having consumed a fixed amount of his/her preferred beverage. This is often called a priming dose paradigm [54]. Sessions are typically administered over a period of several weeks, in which the intensity of exposure is gradually increased. Theoretically, the gradual exposure, will lead to a reduction of alcohol craving, alcohol consumption and an increased sense of self-efficacy in coping with high-risk situations.

CET has received mixed results in systematic reviews and meta-analyses. In the most recent meta-analysis, Mellentin et al. found small effect in favor of CET (Cohen's $d < 0.10$) compared to control conditions on drinking outcomes post treatment or at long-term follow-up points [55]. However, most studies included in this meta-analysis involve control conditions which are considered efficacious for the treatment of AUD (most often CBT). As proposed by Mellentin et al. [55], there are

indications that the efficacy of CET may increase, if combined with interventions specifically targeting coping skills in relation to craving responses, termed urge specific coping skills training (USCS).

Third Wave of Cognitive Behavioral Therapies

Third wave CBT is a group of emerging treatment methods that could be defined as an evolution and extension from the first wave of behavior therapy and the second wave of CBT [56]. These interventions share cognitive and behavioral theories but introduce an emphasis on how to relate to inner experiences, metacognitive perspectives and contextual factors compared to traditional CBT [57]. Typically, the third wave CBT umbrella construct includes mindfulness-based interventions (MBI) [58], Acceptance and commitment therapies (ACT) [59], Dialectical Behavioral Therapy (DBT) [60] and Metacognitive Therapy [61]. Shema therapy is occasionally included in reviews on third wave CBT and is thus included in this overview.

Among third wave CBT approaches, Mindfulness-based interventions (MBI) has the strongest empirical support. MBI originates from Buddhist practice [62] and includes awareness techniques which involve skills for the practice of being in the present and observing thoughts and emotions in a neutral and non-judgmental way [63]. As an intervention for AUD, mindfulness techniques typically aim to increase awareness of alcohol-related triggers and learned non-helpful behaviors. The aim is to target the individual's response to alcohol cravings and intrusive automatic alcohol-related thoughts in risk-situations, and thus reducing the risk of relapse into problematic drinking.

Several well-designed controlled trials have been conducted with MBI as only treatment or as add-on treatment for AUD [58, 64]. The most frequently evaluated forms of mindfulness-based treatments are Mindfulness-Based Relapse Prevention (MBRP) [65] and Mindfulness-Oriented Recovery Enhancement (MORE) [66]. Several recent systematic reviews and/or meta-analyses have been conducted. For example, Li et al. [67] found small-to-large effects of MBI on reducing substance use, craving and stress compared to alternative treatments (e.g., TAU, CBT, and support group). Corroborating this conclusion, Goldberg et al. found that mindfulness-based interventions were superior to no treatment ($d = 0.55$), minimal treatment ($d = 0.37$), non-specific active controls ($d = 0.35$), active controls ($d = 0.23$), and that MBT did not differ in outcome compared to evidence-based AUD treatments [68].

For the remaining treatment approaches included in third wave CBT, the empirical evidence for the treatment of AUD is weak. Although occasional studies exist, the empirical evidence for the efficacy of both ACT and ST for AUD is still limited [69], while DBT has mainly been evaluated in patients with substance use disorders and comorbid borderline personality disorder [70]. Metacognitive beliefs have been strongly connected to addictive behaviors and targeting these is suggested to be a potentially effective component in treatments for AUD [61]. To our knowledge,

Metacognitive therapy has only been tried in a systematic case series with promising results, but there are yet no randomized controlled trials among AUD patients performed for this method [61].

12-Step Based Treatments

In a strict sense, 12-step-based treatments may not be regarded as a behavioral treatment as they do not explicitly rest on a behavioral theory foundation. At the same time, 12-step based treatments involve components such as reinforcement of non-alcohol related behaviors and model learning through sponsorship and are thus included in this overview.

12-step based treatments contain components with the overall purpose to facilitate abstinence from alcohol, increase psychological well-being and quality of life, improve interpersonal skills and the ability to cope with stressful life events [71]. Three main forms of treatments can be distinguished in the abundant flora of 12-step based interventions.

The first form is peer-led Alcoholics Anonymous (AA) mutual-help groups with the goal of long-term, complete abstinence [72]. A typical group meeting lasts for 60 to 90 min, with the aim of providing members an opportunity to share their experiences of alcohol problems as well as their recovery process, and to support one another in practicing the different steps that constitute the 12-step program. Further, members are encouraged to obtain a 'sponsor'—a recovery mentor well-established in a sober lifestyle. A sponsor functions as a personal supporter and also enables model learning of functional coping strategies to members in their goal to abstain from alcohol. Members can attend meetings as often as they deem necessary. The efficacy of AA has been debated over the years. The evidence is inconsistent, due to a lack of well-designed RCT:s and systematic reviews conflicting on the degree of support for the efficacy of AA in maintaining long-term abstinence [73, 74].

Secondly, 12-step facilitation (TSF) is therapist-led program delivered in individual or group format with the aim of facilitating entry to and/or improving involvement in AA. Originally developed as one of the treatment arms in Project Match [20], TSF includes the basic components of the AA program as mentioned above, as well as interventions designed to link individuals to AA groups [75]. In the literature, TSF varies considerably in session length, format, and duration of treatment, ranging from a single session lasting a few minutes [76, 77] to multiple sessions delivered over several months [20]. In regard to treatment efficacy, it is difficult to disentangle the effect of TSF in itself from the effect of AA attendance among participants. A recent meta-analysis suggests that there is proof for the efficacy of TSF/AA in increasing abstinence rate compared to active comparisons (RR = 1.21) [74].

The third form of 12-step treatment consists of outpatient or residential treatment programs, extending for up to a month in time [78]. Programs may include additional programs for significant others as well as AA attendance. In many countries,

intensive treatment programs of this kind have historically represented one of the most common available treatment programs for people with AUD. However, the empirical evidence for this form of intervention is surprisingly weak, with a lack of RCT:s evaluating the efficacy of this intensive form of treatment [79, 80].

Behavioral Treatments in Conjunction with Pharmacotherapy for AUD

The question whether there is an additive treatment effect of a psychological treatment to pharmacological treatment for AUD has been debated since the new generation of pharmacotherapy for AUD emerged in the 1990's. In theory, there are good reasons to expect an additive effect when psychological treatment is given in conjunction with pharmacotherapy. The reduction in alcohol consumption due to anti-craving effects of, e.g., naltrexone, nalmefene and acamprosate could be further enhanced by components in a behavioral treatment, such as coping skills training. The results from controlled studies are, however, mixed.

Most trials investigating concomitant treatments have involved acamprosate and/or naltrexone in combination with a specific behavioral treatment and/or TAU [81, 82]. For acamprosate, no differences in outcome for an add-on behavioral treatment has been found in controlled trials [83–87]. In the case of naltrexone, results have been mixed. Anton et al. [88] found an additive effect of CBT and MET to naltrexone treatment. Similarly, Balldin et al. [89] found an additive effect of CBT in combination with naltrexone relative to naltrexone + TAU, placebo + naltrexone and TAU + CBT. However, other studies have shown no additive effect of behavioral treatment to naltrexone. For example, in the COMBINE study, by far the largest among studies carried out to address this question (n = 1383), no additive effects of any combination of pharmacological and psychological treatment were found [90].

In a meta-analysis covering CBT in combination with pharmacotherapy for addictive disorders in general (including several different types of substance use disorders), the authors concluded that there is empirical evidence supporting that adding specific behavioral treatment modalities to TAU + pharmacotherapy provides an additive effect on treatment outcome (post treatment and at follow-up), but that CBT did not show superior outcome compared to, e.g., MET and CM in this respect [91].

In a majority of these trials, extensive medical management programs have been carried out in conjunction to the pharmacological treatments. Also, study designs comprising frequent follow-up visits for research purposes are common, which altogether may dilute additional effects of behavioral interventions to pharmacotherapy [90]. Despite the mixed results, there is a consensus among most researchers within the field of AUD, that treatment approaches should include the opportunity of being treated with both behavioral and pharmacological treatment alternatives [92].

Behavioral Treatments for the Goal of Controlled Drinking

The question if individuals with AUD can achieve and maintain a non-abstinent treatment goal has been controversial for decades [9]. Controlled drinking (CD) generally refers to when an individual who previously exhibited out-of-control drinking returns to a stable pattern of alcohol consumption (below levels of hazardous drinking) with a significant reduction of the risks involved [93]. Extensive research has proven that controlled drinking (CD) may be a viable treatment goal for those with mild to moderate levels of AUD [15, 94, 95]. In 2021, Henssler and colleagues presented a systematic review and meta-analysis for the efficacy of psychological treatments with abstinence- and controlled drinking outcomes [94]. The analyses showed that there was no significant difference between groups for the proportion of individuals who had significant improvements regarding drinking reduction. Further, the analyses showed no significant differences between abstinence- and non-abstinence paradigms regarding the proportion of individuals who reached low risk drinking (OR = 1.32, 95% Confidence interval = 0.51–3.39). In addition, social functioning was improved equally between groups.

The behavioral treatment supporting a goal of CD which has gained the strongest empirical evidence is Behavioral Self-Control Training (BSCT), which is based on the principles of CBT [27]. BSCT involves goal setting, functional analysis of high-risk situations, and the acquisition of skills both for improved control over drinking rate and coping strategies to increase number of days with abstinence. In the only conducted meta-analysis of BSCT [96], 17 randomized controlled trials investigating the efficacy of BSCT were identified. This meta-analysis showed that BSCT was superior to no treatment (d = 0.94), to active comparators (d = 0.20), and compared to abstinence-oriented approaches (d = 0.28) although the latter did not reach a level of statistical significance.

To summarize, CD methods have shown to be equally efficacious to abstinence-oriented methods [97] for patients with mild to moderate levels of AUD. It has been suggested that an increased availability of treatments for the treatment goal of CD would lower the threshold for treatment seeking, which in turn would contribute to reducing the treatment gap for AUD [98]. There are indications of an increased acceptance towards these methods and non-abstinence outcomes among policy makers and in research. One example is the introduction of risk drinking levels as a structured assessment for the reduction of risk and improvement of functioning by the World Health Organization (WHO) [99] (Chap. 20). Still, the implementation of these methods is scarce.

Technology-Based Interventions

Rather than being a specific type of treatment in itself, technology-based interventions generally involve new approaches for providing existing treatments, e.g., BI or more extended treatments such as CBT or MET. Common forms of technology-based

interventions are by smartphone, computer or tablet via a dedicated program, application or through a web browser [100]. The development of digital interventions for AUD has been significant over the last 20 years as a consequence of the high global access rates to the Internet and smartphones. Along with this, people's preferences for seeking information on health-related issues have also changed drastically, as has the preference for seeking care for lifestyle-related problems. To illustrate this, a recent global survey showed that people in English speaking countries with moderate alcohol problems prefer getting help from web-based treatment applications [101]. Several benefits have been identified alongside with this development, e.g., a possibility to overcome barriers for seeking treatment e.g., perceived stigma and fear of negative consequences from being registered with having alcohol problems [102]. Web-based solutions may also increase access to treatment for people who have difficulties getting time off work, leave home or live in rural areas [103]. From a research perspective, technology-based interventions can facilitate rapid clinical innovation, facilitate recruitment to studies, achieve larger sample sizes and increase retention in clinical trials [104]. New technologies are also commonly used in current alcohol and drug prevention research with the aim of targeting at-risk groups, such as adolescents and young adults, e.g., in student environments. These interventions are typically brief, use text messages and information on negative consequences of alcohol consumption to affect excessive drinking behaviors [105].

Regarding the empirical evidence for the efficacy of technology-based interventions for AUD, several systematic reviews and meta-analyses have been published [106–108]. For example, Kiluk et al. investigated the efficacy of CBT-based digital interventions in contrast to either minimal intervention, to TAU only or as an add-on to TAU for studies including at-risk or heavy drinkers [108]. Digital interventions as a stand-alone treatment in contrast to a minimal treatment showed a positive (though small) effect (g = 0.20). Digital interventions in comparison to TAU showed no differences in efficacy between interventions. Digital interventions as an add-on intervention to TAU showed superiority compared to TAU only (g = 0.30).

In general, most technology-based interventions have targeted at-risk drinkers and/or heavy drinkers, with fewer studies including clinical population samples. Hence, from the meta-analyses referred to, it is difficult to draw any conclusions regarding the efficacy of technology-based interventions on more severely affected patients fulfilling criteria for AUD. However, recent studies have targeted patients with a confirmed AUD-diagnosis. For example, Johansson et a found only small differences in drinking outcomes in favor of Face-to-Face CBT compared to internet-delivered therapist supported CBT in a treatment seeking sample fulfilling DSM 5 criteria for AUD (mean number of AUD-criteria = 6.3) [109].

Lastly, a challenge in technology-based studies have been high attrition rates and low levels of engagement in treatment programs [110]. Efforts have been made to investigate how to address these challenges in future technology-based programs. In short, interventions with a personal contact, normative information or feedback on performance, tailored treatment content, multimedia delivery of content and follow-up reminders may increase retention to treatment and efficacy of treatment and increase follow-up rates in studies [111].

Mechanisms of Change in Behavioral Treatments

Mechanisms of behavior change (MOBC) in treatment have gained considerable attention during the last 20 years of research in the field of AUD [112]. One reason for this increased attention is the fact that controlled studies consistently have failed to find differences in outcomes between active treatments, even when these are outwardly different in treatment content. As an explanation for these negative findings, it has been proposed that efficacious interventions may comprise common factors for change in alcohol consumption. This idea stresses that causal relationships behind intervention and change can be more thoroughly understood by identifying the mechanisms, or what can be defined as the basis for the treatment effect, that is responsible for the change [112, 113]. A factor that has further contributed to the increased interest in MOBC is the development of more advanced statistical methods in recent years, providing researchers with more powerful tools to investigate common factors in treatments [114]. In the field of AUD treatment goal-direction, increasing self-efficacy, a structured way of working with problem behaviors and self-monitoring of consumption, as well as more specific aspects such as therapeutic alliance or technical skills by therapists have been suggested as general MOBC [115–117].

CBT models propose that drinking related coping skills and self-efficacy of abstinence are key features for positive outcomes in AUD treatment [112, 115]. These skills may be, e.g., handling urges, seeking adequate social support or engaging in positive non-alcohol related reinforcing activities, skills that also have been suggested to be MOBC in CBT treatment [115, 117]. Other identified MOBC are the quality of the therapeutic alliance, self-regulation, and emotional regulation [118, 119]. Altogether, there is some promising evidence supporting the suggested MOBC in CBT, but the collective empirical evidence is mixed, and more studies are warranted. One contributing factor to this may be limited study designs which generate lack of data that would allow for longitudinal statistical methods [115].

In the field of MI, studies on MOBC have focused on both technical and relational aspects of therapist skills to promote behavior change in patients [120]. The most well-studied MOBC in MI is change talk [121]. Change talk refers to the verbalization of arguments for change, and is an indicator of the patient's readiness for change according to theory of MI, as opposed to ambivalence. Consistent therapist techniques of MI, e.g., questions and complex reflections in combination with MI spirit, are theorized to evoke change- and commitment talk in session [122]. On the contrary, sustain talk; the verbalization of arguments for the maintenance of status quo has been found to predict negative outcomes [123, 124]. Further, it has been suggested that not merely frequency of change talk, but also the strength of change talk is an MOBC in MI [122, 125]. Still, although technical aspects of change have been more emphasized as MOBC, it is suggested that these technical skills are efficient primarily when relational skills, such as expressed empathy and MI-spirit is present in session [120].

Future Directions in Research on Behavioral Treatments

The future holds several challenges for the field of behavioral treatments for AUD. The first may be the obvious and well-known fact that only a small proportion of individuals with AUD receive treatment for their condition [98, 126, 127]. One of the major contributing factors—which specifically has to do with behavioral treatment—is the lack of access to non abstinence-oriented evidence-based treatments within addiction services [128, 129]. A promising approach that may be one key to increasing treatment seeking, is if a patient-centered approach were practiced to a higher degree within addiction care [130]. A patient-centered approach resembles the shared decision approach in which the patient and the therapist (e.g., a physician or psychologist) together decide on a treatment goal and suitable treatment, which should allow a goal of CD [131].

In order to increase access to treatment for addiction treatment such as short-term treatments within psychiatric care, primary—or occupational care [8, 132, 133], and through continued development of web- and telehealth alternatives should be viable options in addition to traditional treatment modalities in specialized addiction care. A larger variation of treatment options may increase the probability of individuals seeking treatment in this highly heterogenous population and thereby decrease the treatment gap.

One big challenge is the low level of implementation of novel treatment methods within addiction services. The lack of efficacious behavioral treatments calls for more research studies with longitudinal designs. Further, treatments need to be evaluated during their implementation in ecologically valid clinical settings, supported by structured models for implementation [134].

AUD is a highly heterogenous disorder, thus one treatment approach cannot be expected to be equally efficacious within the disorder. In the light of this, efforts have been made to explore phenotypes of addictive disorders, e.g., within a common theoretical framework; The Addictions Neuroclinical Assessment (ANA) [135] (Chap. 14). Within the ANA framework, three neuroscience-based dimensions have been identified that are associated with the development and maintenance of addictive disorders [136, 137] being negative emotionality, executive function, and incentive salience. The three domains may also serve as future treatment targets in potentially new interventions for AUD. Potentially, these three domains may be addressed as primary or secondary targets by behavioral treatments within the context of third wave CBT. We consider relatively new approaches, such as metacognitive therapy and mindfulness-based interventions as promising for these purposes [61, 138–141]. Also related to the ANA dimensions, the paradigm of cognitive bias modification training, in which alcohol related cues are paired with an avoidance reaction, have shown promising results [142, 143]. However, the preliminary results need to be verified in well-powered RCTs.

Conclusion

Behavioral treatments for AUD is a broad umbrella construct comprising treatments both for the given individual, as well as treatments involving a partner and significant others. Further, as shown in several reviews and meta-analyses, there is scientific evidence for the efficacy of these interventions, although there are also important knowledge gaps, e.g., regarding third wave treatment approaches.

When summarizing the research field of behavioral treatments, we conclude that the future challenge is not primarily the question of which treatments are efficacious, but instead how to increase availability to treatment, and perhaps most importantly—how to make treatment for AUD more attractive to those in need.

Chapter 16
Approved, Promising, and Experimental Medications for Treatment of Alcohol Use Disorder

András H. Lékó, Mehdi Farokhnia, and Lorenzo Leggio

Abstract Alcohol use disorder (AUD) is a chronic relapsing disease with significant, medical, psychosocial, and economic sequelae. A limited number of medications are approved for AUD treatment. Disulfiram, naltrexone (oral and long-acting injectable), and acamprosate are approved by the US Food and Drug Administration (FDA), and used in many other countries, to treat patients with AUD. In addition to these medications, the European Medicines Agency (EMA) has also approved nalmefene. Currently approved medications for AUD are underutilized and have shown suboptimal effect sizes, mainly due to the heterogeneity of the target patient population. Therefore, further research is needed to expand the armamentarium of medications for AUD. In addition to the medications approved by the FDA and/or EMA, here we review other promising and experimental medications, specifically: topiramate and gabapentin, which are recommended for AUD treatment by practice guidelines of the American Psychiatric Association; baclofen which has approval in France; varenicline, doxazosin, and prazosin which have shown efficacy in some clinical trials; and some newer medications under investigation, such as zonisamide, ibudilast and samidorphan. Finally, we provide some final remarks regarding challenges and opportunities related to medication development in the AUD field.

Introduction

Although we have a better understanding of the molecular and neurobiological basis of alcohol use disorder (AUD), a limited number of medications have been approved for AUD. In the United States, less than 9% of patients who need treatment for an AUD receive a single prescription of any FDA-approved pharmacotherapy, indicating that available medications are considerably underutilized [1]. The effect size of current pharmacotherapies for AUD is suboptimal, which is at least partially due to the heterogeneity of AUD, and subgroups of patients may respond differently to a certain medication. More recently, research has focused on new drug targets, with more personalized approaches, and alternative measures of efficacy, paving the way for potential new medications. Since not only abstinence, but also reductions in drinking can be clinically meaningful, the U.S. Food and Drug Administration (FDA) now accepts both abstinence and no heavy drinking days as a primary outcome for phase 3 trials of AUD pharmacotherapy, in which a heavy drinking day is 4/5 ≤ drinks in a day for women/men [2]. The European Medicines Agency (EMA) also includes non-abstinent endpoints, such as reductions in total alcohol consumption and heavy drinking days, in their guidelines [3]. Outcomes of clinical trials are diverse and may measure number of heavy drinking days per month, mean number of drinks per day, self-reported craving, quality of life, etc. A 2-level decrease in World Health Organization (WHO) risk levels (from very high to medium or from high to low) is also a strong indicator of reduction in alcohol consumption, providing another standardized measure of efficacy in AUD clinical trials [4], and also accepted by the EMA as a non-abstinent endpoint [3]. For an in-depth discussion of study outcomes, see Chap. 20.

In this chapter, we will briefly review: (1) medications which are already approved by FDA and/or EMA for AUD treatment; (2) medications with approval for other indications which have been found to be effective in clinical trials of AUD and are sometimes used off-label for this condition; and (3) promising new medications and drug targets with preliminary findings. For all medications reviewed in this chapter, we will concisely describe the neurobiological background and their mechanism(s) of action, as well as clinical results on their efficacy, side effects, and factors that may moderate their effects. This information is summarized in Table 16.1.

Table 16.1 Medications approved for treatment of AUD

Medication (dose)[a]	Putative mechanism of action	FDA/EMA Approval	Alcohol-related effects	Common side effects
Medications approved for treatment of AUD				
Disulfiram (125–500 mg/day)	Inhibition of alcohol metabolism (acetaldehyde dehydrogenase enzyme)	AUD	Tachycardia, headache, nausea, and vomiting after alcohol consumption. Medium effect in open-label trials, no effect in blind designs.	tachycardia, headache, nausea, vomiting
Acamprosate calcium (666 mg TID)	Putative antagonism of NMDA receptors	AUD	Improves probability of maintaining abstinence. Reduces the number of drinking days.	diarrhea
Naltrexone (50 mg/day)	Antagonism of μ-, κ-, and δ-opioid receptors	AUD Opioid use disorder (OUD)	Reduces craving, number of heavy drinking days, risk of return to drinking, and risk of binge drinking, and improves quality of life.	nausea, headache, dizziness, and sleep problems
Naltrexone LAI (380 mg/4 week) i.m.	Antagonism of μ-, κ-, and δ-opioid receptors	AUD OUD	Reduces number of drinking days and number of heavy drinking days. Compared to oral naltrexone, time to relapse is longer.	injection site related inflammation and infection
Nalmefene (18 m/dg)	Antagonism of μ- and δ-opioid receptors; partial agonism of κ-opioid receptor	Reversal of opioid overdose, Approved for AUD in Europe	Reduces number of heavy drinking days and total alcohol consumption.	nausea, vomiting, fatigue, insomnia, and dizziness

(continued)

Table 16.1 (continued)

Medication (dose)[a]	Putative mechanism of action	FDA/EMA Approval	Alcohol-related effects	Common side effects
Additional effective medications based on clinical trials				
Topiramate (100–300 mg/day)	Antagonism of glutamatergic AMPA and kainate receptors, and facilitation of GABA activity; blocks L-type calcium channels, reduces voltage-dependent sodium channel activity, inhibits carbonic anhydrase	Adjunct for partial and tonic-clonic seizures and migraines Topiramate ER in combination with phentermine for weight management in obesity	Reduces craving, percentage of heavy drinking days and drinks per drinking days.	paresthesia, taste abnormalities, anorexia, difficulties with concentration
Gabapentin (600–1800 mg/day)	Blocks voltage-gated calcium channels and enhances permeability of voltage-gated potassium channels. Indirectly modulates GABA receptors.	Adjunct for partial seizure and postherpetic neuralgia	Reduces the number of drinks and percentage of heavy drinking days, especially in patients with history of alcohol withdrawal symptoms.	dizziness, somnolence
Gabapentin enacarbil extended-release (GE-XR) (1200 mg/day)	Blocks voltage-gated calcium channels and enhances permeability of voltage-gated potassium channels. Indirectly modulates GABA receptors.	Restless leg syndrome and postherpetic neuralgia	Reduces the number of drinks and drinks per heavy drinking days in patient subgroup with higher baseline heavy-drinking days per week, impulsivity, and lower levels of anxiety, depression, and mood disturbances.	fatigue, dizziness, somnolence

Table 16.1 (continued)

Medication (dose)[a]	Putative mechanism of action	FDA/EMA Approval	Alcohol-related effects	Common side effects
Baclofen (30–80 mg/day)	Agonism of $GABA_B$ receptors	Muscle spasticity	Improves probability of maintaining abstinence; decreases craving. More effective in patients with alcohol-associated liver disease.	sedation, drowsiness, dizziness, headache
Varenicline (2 mg/day)	Partial agonism of α4β2 nicotinic acetylcholine receptors	Smoking cessation	Decreases craving in smokers and non-smokers. Reduces mean number of drinks in smokers. Better response in less-severe AUD, those with depressive symptoms, and males.	Nausea, abnormal dreams, constipation
Ondansetron (8 μg/kg/day)	Antagonism of 5-HT3 serotonin receptor	Nausea and vomiting	Reduces the amount and frequency of drinking in early-onset AUD.	headache, constipation
Prazosin/ Doxazosin (16 mg/day)	Antagonism of α1 receptors	Hypertension and benign prostatic hyperplasia	Reduces number of heavy drinking days and drinks per week. Better response in patients with higher blood pressure and AUD family density.	drowsiness, dizziness, fatigue

(continued)

Table 16.1 (continued)

Medication (dose)[a]	Putative mechanism of action	FDA/EMA Approval	Alcohol-related effects	Common side effects
Promising new medications				
Zonisamide (500 mg/day)	Blocks voltage-sensitive sodium channels and T-type calcium channels, enhances synaptic inhibition by facilitating GABAergic, dopaminergic, and serotonergic transmission. Indirectly attenuates glutamatergic transmission.	Adjunct treatment for epilepsy	Reduces number of heavy drinking days, drinks per week, and alcohol craving	drowsiness, difficulties with concentration, decreased appetite, abdominal pain
Mifepristone (600 mg/day)	Antagonism of glucocorticoid receptors	Pregnancy termination	Reduces alcohol craving.	nausea, vomiting, diarrhea
LY 2940094 (40 mg/day)	Antagonism of nociceptin (NOP) receptors	Not approved	Decreases percentage of heavy drinking days and increases percentage of abstinent days.	insomnia, anxiety, vomiting
Samidorphan (1–10 mg/day)	Antagonism of μ-opioid receptor, mixed agonism-antagonism of κ, and δ-opioid receptors	Not approved	Reduces craving and average daily alcohol consumption.	nausea, vomiting, somnolence, dry mouth, dizziness
Ibudilast (100 mg/day)	Inhibits phosphodiesterase-4 (PDE4) and −10 (PDE10), and macrophage migration inhibitory factor (MMIF). Reduces neuroinflammation and supports neurotrophin expression.	Not approved	Reduces craving, percentage of heavy drinking days and alcohol-cue elicited activation in the brain. Better response in patients with comorbid depressive symptoms.	headache, nausea

[a] Oral administration, unless otherwise specified

Approved Pharmacological Treatments

Only three drugs are currently approved by the FDA for use in AUD. **Disulfiram**, a drug targeting the metabolism of alcohol, was the first medication approved for the treatment of AUD in 1949. During alcohol metabolism, alcohol dehydrogenase first oxidizes alcohol into acetaldehyde, then acetaldehyde dehydrogenase (ALDH)

metabolizes acetaldehyde into acetate. Disulfiram irreversibly blocks the ALDH enzyme, leading to the accumulation of acetaldehyde after alcohol consumption. Acetaldehyde is a toxic metabolite, causing flushing, tachycardia, headache, nausea, and vomiting. These highly unpleasant symptoms occur within 5–15 min after alcohol intake, and deter alcohol consumption [5]. After consumption of large amounts of alcohol, the disulfiram-alcohol interaction may result in a medical emergency, with severe cardiovascular reactions [6]. Therefore, disulfiram should only be used in patients who are seeking to maintain total abstinence and is not useful if reducing drinking is the treatment goal. Its use should be limited to patients who are already abstinent and are seeking to maintain abstinence.

The efficacy of disulfiram largely depends on patient motivation and compliance, which is usually low (around 20%). This is mostly because disulfiram's mechanism of action is based on producing unpleasant disulfiram-alcohol reactions that deter alcohol drinking, without targeting key mechanisms that promote alcohol drinking, such as craving and negative affective states in the withdrawal phase [7]. Presumably related to this mechanism of action, a meta-analysis of disulfiram trials did not support the efficacy of this medication in general, but provides robust support for efficacy when disulfiram is administered under supervision [8]. Disulfiram, therefore, continues to have clinical utility, but primarily in special settings, e.g., when the patient has family support that allows for supervision of disulfiram administration, when the treatment goal is to achieve a certain duration of sobriety in order to evaluate potential psychiatric co-morbidities, etc.

The aversive reaction to disulfiram limits the design and interpretation of double-blind, placebo-controlled trials. If the placebo does not have an aversive effect upon intake of alcohol, it is easy for the patients and the researchers to become unblinded, while if it does, it may not be a real placebo. In open-label trials, disulfiram was found to have a medium effect size and was superior to acamprosate and naltrexone, in terms of no relapse and time to first heavy drinking day; by contrast, disulfiram was not superior to placebo in studies with a blind design [9]. The effect size variables were total abstinence, proportion of abstinent days to treatment days, mean days of alcohol use, no relapse, time to first heavy drinking day, or three or more weeks of consecutive abstinence.

There are reports of other putative pharmacodynamic actions of disulfiram. Among these, rodent studies have shown that inhibition of dopamine β-hydroxylase results in reduced synaptic norepinephrine and increased dopamine levels and thereby prevents drug-primed reinstatement [10, 11], but it is unclear whether these effects translate to primates [12]. More recently, it has been suggested that inhibition of the cytoplasmic FROUNT protein (a common regulator of chemokine receptor CCR2 and CCR5 signaling) by disulfiram leads to anxiolytic effects [13], but this effect has not been observed in humans at clinically used doses [14].

Acamprosate was approved for the treatment of AUD in 2004. Although its exact mechanism of action is unclear, evidence suggests that acamprosate counteracts increased glutamatergic activity at N-methyl-d-aspartic acid (NMDA) receptors that occurs during alcohol withdrawal, and may also have indirect effects on γ-aminobutyric acid (GABA) type A receptors [15]. The efficacy of acamprosate

has been assessed in numerous randomized, double-blind, placebo-controlled trials and meta-analyses. Large, multi-center, randomized, controlled trials (RCTs) in the United States and Germany did not observe a significant effect of acamprosate, neither on percentage of abstinent days, nor on time to return to heavy drinking [16, 17]. However, recent meta-analyses, including large numbers of studies, suggest that acamprosate significantly improves the probability of maintaining abstinence and lowers the number of dropouts during a 12-month follow-up, compared to placebo. Overall, 9% fewer patients returned to drinking, and percentage of drinking days decreased by 8.8% with acamprosate treatment, compared to placebo, while the number of drinks per drinking day did not change. These findings suggest that acamprosate is more useful in promoting abstinence and relapse prevention than in reducing alcohol intake [18–20]. The only adverse event which occurred more frequently with acamprosate than placebo was diarrhea. Other less common side effects may include nausea, vomiting, gastrointestinal discomfort, headache, and dizziness, although the causality is unclear. Acamprosate is not metabolized, which is advantageous for AUD patients with impaired liver function [21, 22]. However, as a disadvantage, acamprosate needs to be administered 3× times per day, which limits its clinical utility.

Naltrexone was approved for AUD treatment in 1994, and its long-acting injectable depot form in 2006. Naltrexone is a nonselective antagonist with high affinity for μ-, and lower affinity for κ- and δ-opioid receptors. It reduces mesolimbic opioidergic activity, and in turn modulates dopamine-mediated rewarding effects of alcohol [1]. A large-scale RCT and various meta-analyses have found naltrexone to reduce craving, number of heavy drinking days, return to drinking, and binge drinking, as well as improving quality of life, compared to placebo [16, 19, 20]. A meta-analysis of several RCTs showed that with oral naltrexone, 9% fewer patients returned to heavy drinking, and the number of drinking days decreased by 5.4%, compared to placebo [20]. An interesting approach is targeted naltrexone use for problematic drinkers, that is, taking the medication in anticipation of a potential high-risk drinking situation. This type of naltrexone administration effectively lowered proportion of patients relapsing to heavy drinking [23], mean drinks per day, and number of drinks per drinking day [24]. Common side effects include nausea, headache, dizziness, and sleep problems. Based on early reports, naltrexone was thought to be contraindicated in patients with liver disease. However, as naltrexone has been now used in clinical practice for a few decades, the risk of hepatotoxicity has proven to be less concerning, and naltrexone can be used, albeit with caution, in patients with non-advanced liver disease. Naltrexone should be discontinued in the event of signs/symptoms of acute hepatitis and should not be used in patients with more advanced liver disease [22, 25].

Depot naltrexone, similar to depot formulations of antipsychotics, is beneficial, because of two main reasons: (1) the monthly administration ensures compliance and (2) the extended release during a 4-week period reduces the risk of side effects and maintains a stable plasma level in the therapeutic range. Depot naltrexone effectively reduces the number of drinking days and heavy drinking days per month [20, 26]. Compared to oral naltrexone, time to relapse is longer and, as expected,

adherence is higher [27, 28]. A rare side effect of the depot formulation is injection site-related necrosis, while infection or inflammation are somewhat more common. Both oral and depot naltrexone are contraindicated in individuals who take opioid analgesics [29]. Of note, unlike oral naltrexone, injectable naltrexone does not undergo first-pass metabolism in the liver. Therefore, the systemic dose needed to achieve adequate central receptor occupancy is lower, which can be expected to reduce the potential risk for hepatotoxicity. One significant disadvantage of depot naltrexone is its significantly higher cost, compared to the other approved medications; this is likely the main reason why depot naltrexone is used less often compared to the other medications for AUD.

Another opioid medication, **nalmefene,** is approved for the treatment of AUD by EMA. Nalmefene has high and similar affinity for μ- and κ-opioid receptors, where it acts as an inverse agonist at the former, and a weak partial agonist at the latter, in both cases rendering it a functional antagonist of endogenous opioid peptide signaling. Its affinity for δ-opioid receptors is 25–200× lower, and thus not relevant in vivo at clinically used doses. Based on results of clinical trials and meta-analyses, nalmefene and naltrexone are more efficacious in reducing heavy drinking than maintaining abstinence [30]. Although a direct comparison of naltrexone and nalmefene has not been performed, preliminary evidence from a meta-analysis comparing placebo-controlled studies of the two drugs suggests a potential advantage of nalmefene over naltrexone in reducing quantity of drinking [31]. The effect of nalmefene on quantity of drinking is useful for harm reduction in patients who do not endorse abstinence as a treatment goal, by allowing targeted administration in anticipation of high-risk situations [32]. RCTs in Europe and Japan, including AUD patients with medium, high, or very high drinking risk levels, found that nalmefene effectively reduced the number of heavy drinking days and total alcohol consumption with a small effect size [33, 34]. It is, however, important to keep in mind that the number of studies and the clinical experience with nalmefene is significantly limited, compared to naltrexone, limiting the possibility of a direct comparison.

Additional Effective Medications Based on Clinical Trials

Although not approved by the FDA for the treatment of AUD, topiramate and gabapentin are approved for other indications, and their off-label use for AUD is recommended in the 2018 practice guidelines of American Psychiatric Association (APA). APA suggests that these two medications be offered to patients with moderate to severe AUD who have a goal of reducing alcohol consumption or achieving abstinence; are intolerant to or have not responded to naltrexone and acamprosate; and have no contraindications to the use of topiramate and gabapentin [35]. **Topiramate** is approved for the treatment of seizures and migraines. Furthermore, since 2012, it is also approved, in an extended-release formulation together with phentermine (a norephinephrine releasing agent), for chronic weight management in adults with overweight or obesity. Topiramate blocks L-type calcium channels, reduces

voltage-dependent sodium channel activity, and inhibits carbonic anhydrase. In addition, topiramate antagonizes glutamatergic AMPA and kainate receptors, and facilitates GABA activity through a nonbenzodiazepine site of $GABA_A$ receptor [36].

A placebo-controlled study shed light on topiramate's neurobiological mechanism of action in relation to AUD, showing attenuation of alcohol cue-elicited activation in the ventral striatum (VS) and orbitofrontal cortex (OFC). This inhibition leads to a reduction in alcohol craving, which appears to be the primary effect of topiramate [37, 38]. A first single-site large RCT and a subsequent larger, multisite, randomized controlled trial found 300 mg of daily topiramate being more efficacious than placebo in reducing percentage of heavy drinking days and drinks per drinking days from baseline to week 14 [39, 40], and this effect diminished rapidly after discontinuation [41]. Several clinical trials have supported the efficacy of topiramate [20, 42]. Furthermore, indirect comparisons by a network meta-analysis suggested topiramate being superior to nalmefene, naltrexone, and acamprosate on alcohol consumption outcomes, although the results of this network meta-analysis must be taken with caution and further examined by future larger RCTs directly comparing these drugs [42].

Topiramate treatment is frequently associated with side-effects, some of which may be clinically relevant and require dose reduction or discontinuation. As expected, topiramate often leads to a decrease in appetite and weight. Other common side effects include paresthesias, dizziness, sedation, taste abnormalities, and cognitive dysfunction (difficulties with concentration and short-term memory) [36, 39]. Gradual dose titration to 300 mg is suggested to minimize these adverse effects. Less common but notable side effects include metabolic acidosis, nephrolithiasis, and precipitation of acute angle-closure glaucoma [35].

Gabapentin is an oral anticonvulsant drug that is indicated for the treatment of epilepsy and postherpetic neuralgia, with doses ranging from 300 to 1800 mg/day. While being a structural analogue to GABA, gabapentin has no apparent activity at $GABA_A$ receptors, and some inconsistent results suggest activation of $GABA_B$ receptors. $GABA_B$ receptors are metabotropic, G-protein coupled receptors that can activate inward rectifying potassium channels and inhibit voltage-gated calcium channels both pre-, post-, and extrasynaptically, are also expressed by astrocytes, and can regulate both synaptic and extrasynaptic GABA levels. Gabapentin also blocks voltage-gated calcium channels containing the α2δ-1 subunit and enhances permeability of voltage-gated potassium channels, which collectively decreases neuronal excitability [43]. In rats, gabapentin normalizes the increased GABAergic neurotransmission in the central amygdala (CeA) that results from chronic alcohol exposure, and accordingly reduces alcohol self-administration in alcohol dependent rats upon intra-CeA infusion [44]. A human magnetic resonance spectroscopy study showed that, within the dorsal anterior cingulate cortex, gabapentin-related decrease in GABA levels and increase in glutamate levels are positively associated with percentage of abstinent days [45].

A single-center, outpatient, randomized, double-blind, placebo-controlled trial with gabapentin found that 28 days of treatment with 600 mg/day gabapentin

reduced both the number of drinks per day and percentage of heavy drinking days, and increased the percentage of abstinent days [46]. This study, together with initial human laboratory studies [47–49], were followed by a longer, placebo-controlled, randomized, double-blind trial with a larger sample size and two dosages of gabapentin: 900 or 1800 mg/day. Both doses of gabapentin were found to be safe, but only the higher dose was effective, as compared to placebo. Specifically, the higher dose of gabapentin increased the abstinence rate and reduced the number of drinks and heavy drinking days per week, as well as relapse-associated symptoms of insomnia, dysphoria, and craving [50]. Based on these studies, **gabapentin enacarbil extended-release (GE-XR)** 2 × 600 mg/day, the prodrug formulation of gabapentin, was tested in a large, multisite clinical trial. However, GE-XR group did not differ from placebo on the primary outcome, percentage of individuals with no heavy drinking days, and no clinical benefit was found for other drinking-related outcomes, alcohol craving, or sleep problems [51].

A recent meta-analysis of seven gabapentin RCTs showed evidence of benefit, with a medium effect size, on percentage of heavy drinking days [52]. Just like any other medication, it is conceivable that gabapentin may work for some patients with AUD and not others. Specifically, a recent study supports the efficacy of gabapentin, but only in patients with a history of alcohol withdrawal symptoms [53]. Also, a re-analysis of the abovementioned GE-XR clinical study revealed a subgroup of likely responders, where GE-XR was superior to placebo on percent of heavy drinking days and drinks per week. These likely responders were characterized by higher baseline heavy drinking days per week, cognitive and motor impulsivity, and lower levels of anxiety, depression, and mood disturbances [54]. Although potentially useful to identify responsive patients, predictors identified through such post-hoc analyses need to be examined and replicated prospectively to draw a conclusion.

Gabapentin appears to be safe and well tolerated in individuals with AUD. In the RCTs that have been carried out, no serious adverse events have been reported. Higher doses of gabapentin were associated with dizziness, somnolence, and peripheral edema, but these side effects were all transient and reversible [5].

Baclofen is an orthosteric $GABA_B$ receptor agonist approved by the FDA to reduce muscle spasticity associated with neurologic disorders such as multiple sclerosis. In France, baclofen also has regulatory approval since 2018 for the treatment of AUD at a maximum daily dosage of 80 mg. Originally, the maximum approved dosage was 300 mg/day, but it was reduced in 2017 to the current 80 mg/day, because of increased risk of hospitalization and fatalities at higher doses [55]. $GABA_B$ receptors are metabotropic receptors; activation of presynaptic $GABA_B$ receptors increases potassium conductance, which in turn decreases neuronal excitability and GABA release from nerve terminals, thereby reducing extracellular GABA concentration [56]. Increased GABAergic neurotransmission in the central amygdala seems to be a key player in the process and progression of alcohol dependence. In rats preferring alcohol over a high-value reward, a model that resembles some aspects of AUD in humans, GABA transporter expression in the CeA is lower compared to non-alcohol preferring rats, indicating decreased GABA clearance and increased extracellular GABA. Furthermore, knockdown of GABA transporter

reversed the preference of non-alcohol preferring rats from high-value reward to alcohol [57]. Baclofen may also suppress alcohol-stimulated dopamine release by activating $GABA_B$ receptors on dopaminergic axon terminals in the mesolimbic circuit and ventral tegmental area (VTA), thereby potentially normalizing the disturbed functional connectivity in the reward network [58, 59]. Baclofen dose-dependently decreases alcohol self-administration in both non-dependent and dependent rats, but dependent rats are more sensitive to baclofen's effects [60]. In Sardinian alcohol-preferring rats, baclofen reduced and delayed responding to alcohol reinforcement [61]. Findings from human fMRI studies showed that baclofen reduces alcohol-cue elicited neural activation in the OFC, amygdala, and VTA, and decreases cue-related functional connectivity between VTA and anterior cingulate cortex (ACC), as well as between VTA and medial prefrontal cortex (mPFC) [62, 63]. These effects on alcohol cue-related and reward networks are thought to disrupt the induction of alcohol intake induced by consuming a first drink (priming), as for example shown in a behavioral human laboratory study that did not obtain fMRI data [64]. Another proposed mechanism is that baclofen may act as a replacement medication, mainly through modulating the subjective and physiological responses to alcohol drinking. For example, in the context of alcohol use, in heavy drinking individuals with AUD, baclofen leads to feeling more intoxicated and more 'high'; and strengthens the decrease of heart rate and increase of diastolic blood pressure [65, 66].

After several promising preclinical studies [67] the first preliminary double-blind RCT, showed that low-dose (30 mg/day) baclofen can help maintain abstinence, by reducing craving and obsessive thoughts about alcohol [68]. The efficacy of high-dose (270 mg/day) baclofen was first described in a self-case report of a French physician in 2004. Baclofen reduced his craving and helped him remain abstinent for more than 9 months [69]. After these preliminary results, numerous clinical trials were conducted with mixed results [70–72]. A meta-analysis from 13 RCTs showed that baclofen was superior to placebo in lengthening time to lapse (drinking any amount of alcohol) and increasing the likelihood of abstinence [73]. Level of alcohol intake at study inclusion was found to be a moderator: higher daily alcohol use at baseline was associated with a larger baclofen treatment effect [74].

The alcohol-related outcomes targeted by baclofen seem to be dose-dependent, with higher doses decreasing craving, while lower doses promote abstinence [73, 75]. Of note, *Garbutt et al*. recently showed that higher dose of baclofen was superior to both placebo and lower dose, by reducing percent of heavy drinking days and increasing abstinent days during treatment period. They also revealed a potential role of sex in baclofen's effects: in women, lower dose showed superiority to placebo, while higher dose did not, but the opposite was observed in men [76]. It has been suggested that baclofen may be more effective in patients with higher severity of AUD who also have comorbid alcohol-associated liver disease (ALD) [21, 22, 72]. In fact, while a multi-site study in patients with hepatitis C, which was conducted at the US Department of Veterans Affairs (VA), did not indicate a significant difference between baclofen and placebo [77], a first RCT in patients with AUD and cirrhosis [78], and a subsequent multisite, double-blind RCT in patients with AUD

and ALD, found that baclofen was more effective compared to placebo in maintaining abstinence among patients with liver problems [79]. This observation and its lack of hepatotoxicity make baclofen an attractive medication for patients with comorbid AUD and ALD.

A meta-analysis, including 12 RCTs, found that baclofen increases the occurrence of the following adverse events compared to placebo: dizziness (RR 2.16), sedation/drowsiness (RR 1.48), paresthesia (RR 4.28), and muscle spasm/rigidity (RR 1.94) [80]. Other less common side effects include headache, confusion, excessive perspiration, itching or pruritus, abnormal muscle movements, numbness, and slurred speech [77].

An international consensus statement reconsidering multiple meta-analyses [73, 81, 82] pointed out the lack of consistent results in support of baclofen's efficacy, although it also emphasized its utility for specific sub-populations, e.g., patients with severe AUD and ALD [72]. A different yet related arena in medication development for AUD are positive allosteric modulators of the $GABA_B$ receptor ($GABA_B$ PAMs), which exert no intrinsic activity and only potentiate signaling when the endogenous ligand is also present. In rodent experiments, $GABA_B$ PAMs suppress excessive drinking, binge-like drinking, operant alcohol self-administration, reinstatement of alcohol seeking, stress- and cue-induced relapse-like drinking, and *c-Fos* expression in brain regions involved in stress-induced relapse [83–85]. $GABA_B$ PAMs were effective in suppressing alcohol-related outcomes at lower doses than those inducing sedation, an important aspect in terms of the potential for human translation, given the wider therapeutic window that this pharmacological approach offers [85].

Although **varenicline** is approved by the FDA only to help with smoking cessation, it is sometimes prescribed off-label for AUD, based on its promising efficacy in reducing alcohol craving and consumption. Varenicline is a partial nicotinic agonist, with high affinity and selectivity for α4β2 nicotinic acetylcholine receptors. It activates the receptor with about half of nicotine's maximal efficacy, while at the same time preventing the binding of nicotine [86]. This partial agonism mechanism helps maintain dopaminergic tone in the absence of nicotine, while reducing nicotine-induced dopamine release, therefore promoting smoking cessation. A similar mechanism of action was hypothesized against alcohol positive reinforcement and craving. However, in a recent preclinical experiment, this mechanism seemed to be specific to nicotine, and not directly applicable to alcohol, morphine, or natural rewards [87]. Another study in rats found that varenicline microinfusions into the accumbens, but not into the VTA, reduced context-induced relapse to alcohol-seeking [88].

Attenuation of alcohol's reinforcing effects and craving after varenicline pretreatment (2 mg/day for 7 days) was shown in an RCT examining 2-h alcohol self-administration in non-alcohol-dependent, heavy-drinking smokers, where reduction of alcohol intake was also observed [89]. The first multisite RCT established that varenicline (2 mg/day for 13 weeks) decreased percent of heavy drinking days, drinks per drinking days, and alcohol craving [90]. AUD severity and age were found to be significant moderators: better treatment response was observed in older

patients and those with less severe AUD at baseline [91, 92]. Patients experienced mild to moderate adverse events; nausea, abnormal dreams, and constipation had significantly higher rates in the varenicline than the placebo group [90]. Later, a multisite RCT, conducted in Sweden, showed no effect of varenicline over placebo on the proportion of self-reported heavy drinking days, but the highly specific objective biomarker of alcohol consumption, phosphatidylethanol (PEth) demonstrated a significant reduction in alcohol use, and self-reported cravings were also reduced by varenicline [93]. A recent meta-analysis of 10 studies, with an aggregate sample of 731 participants, suggested that varenicline significantly decreases alcohol craving in patients with AUD, but did not support a significant effect on drinking-related outcomes (percentage of heavy-drinking days, number of drinks per drinking day, or percentage of abstinent days) [94]. In conclusion, varenicline has been consistently found to reduce alcohol craving, but its effects on drinking-related outcomes remain unclear and most likely limited to a sub-population (e.g., people with AUD who are also smokers).

Varenicline can also improve working memory in heavy drinking individuals [95] and may be more effective in patients with comorbid depressive symptoms [96]. Numerous human studies have investigated the efficacy of varenicline in patients with comorbid alcohol and nicotine dependence. Varenicline both promoted smoking abstinence and reduced mean number of drinks per drinking day in a clinical trial [97]. Varenicline's efficacy does not seem to differ between smokers and non-smokers, but in smokers, varenicline improved drinking-related outcomes only among those who reduced their cigarette consumption [91, 92]. Sex appears to moderate varenicline's effects in this population with alcohol-nicotine dependence comorbidity: in a different phase 2 RCT, varenicline treatment (2 mg/day for 16 weeks) resulted in decreased heavy drinking only among men, whereas smoking abstinence was prolonged in the overall sample [98]. A recent clinical trial compared varenicline to varenicline-naltrexone treatment for smoking cessation and drinking reduction among heavy-drinking smokers. Varenicline alone was significantly more effective in smoking cessation. Both treatments reduced drinks per drinking day, compared to baseline. Although the main medication effect did not meet the study significance threshold, it favored the varenicline plus naltrexone condition across the entire trial [99].

The noradrenergic system plays an important role in the neurobiology of alcohol reinforcement and relapse. Alcohol withdrawal and stress responses lead to excessive noradrenergic activation, producing anxiety and hyperarousal, which is strongly linked to alcohol seeking behavior and relapse. Not only withdrawal, but also acute alcohol administration increases norepinephrine release [100]. Inhibition of norepinephrine synthesis was shown to reduce alcohol intake in rats and the euphoric effects of alcohol in humans [101, 102]. The α1 adrenergic receptor antagonists **prazosin and doxazosin** have been found to be potential medications to treat AUD. Their suggested mechanism of action is blocking α1 receptors in key areas involved in the transition to dependence such as the CeA. The expression of these α1 receptors is elevated in AUD and promotes GABA release associated with

increased alcohol intake [103]. In preclinical experiments, prazosin reduced alcohol intake in dependent rats [104].

In humans, a 12-week RCT found that prazosin (16 mg/day) effectively reduced alcohol consumption, expressed by number of drinks and number of heavy drinking days per week. Drowsiness and edema were reported more often in the prazosin group, compared to placebo [105]. In another clinical trial, greater rates of reduction in drinks per week was observed under prazosin in patients with high, but not low, diastolic blood pressure, which might be associated with lower tolerability of the drug in the latter subgroup [106]. Prazosin also showed efficacy in reducing stress-induced alcohol craving and anxiety during early abstinence [107, 108].

Severity of alcohol withdrawal, often measured by the Clinical Institute Withdrawal Assessment for Alcohol-Revised (CIWA-Ar), appears to be a significant moderator of the treatment response to prazosin. Prazosin reduced percent of heavy drinking days and percent of drinking days in patients with higher CIWA-Ar scores, whereas no such benefit of prazosin was observed in patients with low or no withdrawal symptoms [109]. Doxazosin, another α1-antagonist, has a longer half-life and a more favorable pharmacokinetic profile than prazosin. A 10-week RCT showed that doxazosin (16 mg/day) did not reduce drinks per week and number of heavy drinking days per week in the full sample, but two moderators were found to influence doxazosin's effects: patients with higher family history density of alcohol problems (*a priori* moderator) or with higher baseline blood pressure (moderator selected *post hoc*) had a better response to doxazosin. As for side effects, dizziness, depression, urinating troubles, and headache were more frequent in the doxazosin than the placebo group [110, 111].

Promising New Medications

Like topiramate, **zonisamide** is also approved by the FDA as an adjunct treatment for epilepsy. Zonisamide blocks voltage-sensitive sodium channels and T-type calcium channels, and enhances synaptic inhibition by facilitating GABAergic, dopaminergic, and serotonergic transmission and indirectly attenuating glutamatergic transmission [112]. In an initial placebo-controlled human laboratory study in people with hazardous alcohol use (during 90 days prior to study entry: more than 3/4 drinks per day on any day or more than 7/14 drinks per week for women/men, respectively), a single-dose of 100 mg zonisamide reduced alcohol craving during a priming drink challenge session and alcohol intake during two consecutive 1-h self-administration segments [113]. In a 12-week RCT, zonisamide (500 mg/day) was found to be effective in decreasing the number of heavy drinking days, drinks per week, and alcohol craving [114]. Zonisamide showed an effect size similar to topiramate in reduction of alcohol consumption (percent of drinking days per week, drinks per day, and heavy drinking days per week), while having a more favorable side effect profile. Zonisamide's cognitive side effects (modestly reducing verbal

fluency and working memory) are similar to those of topiramate, but unlike topiramate, zonisamide does not cause irritability, paresthesia, or erectile dysfunction [115].

The nociceptin (NOP) receptor belongs to the opioid receptor family and is widely expressed throughout the mesolimbic reward pathway. Targeting this system modulated alcohol intake in preclinical experiments, oddly enough both when agonists and antagonists were used. Central NOP administration prevented stress- or reinforcement-induced alcohol-seeking behavior, and reduced alcohol self-administration [116, 117]. Systematic application of a brain-penetrant NOP receptor agonist reduced alcohol intake and withdrawal-induced anxiety and prevented cue- and stress-induced relapse [118]. Paradoxically, the NOP receptor antagonist LY2817412 also dose-dependently reduced voluntary alcohol intake and cue-induced relapse in rats; CeA and VTA were identified as target regions for this effect in the brain [119, 120]. Another **NOP antagonist, LY 2940094**, also attenuated alcohol self-administration, alcohol-seeking behaviors, and alcohol-induced dopaminergic transmission in the brain reward pathways [121].

The reason why both NOP receptor antagonists and agonists have produced the same effect on alcohol intake remained unclear. It was hypothesized that agonists may produce desensitization and internalization of NOP receptors, therefore reducing expression of NOP receptors on the cell membrane [121]. An RCT evaluating the efficacy of the NOP antagonist LY 2940094 (40 mg/day, for 8 weeks) found that it decreased the percentage of heavy drinking days and increased percentage of abstinent days, compared to placebo. These promising self-reported outcomes were associated with significant reduction of gamma-glutamyl transferase (GGT) serum levels, which is an indirect objective biomarker of alcohol use. The frequency of side effects (mainly insomnia, anxiety, and vomiting) was not different between the active drug and placebo groups [122].

Samidorphan also targets the opioid system. It is a μ-opioid receptor antagonist and a mixed agonist-antagonist of κ- and δ-opioid receptors [123]. Samidorphan is FDA approved for the treatment of psychotic or bipolar illness, in a formulation together with the antipsychotic olanzapine, a combined pharmacological approach shown to prevent some of the weight gain associated with olanzapine use [124]. Samidorphan has also been formulated together with buprenorphine, and this combined formulation has shown some promise for the treatment of depression, presumably through the κ-opioid receptor blockade by buprenorphine, while preventing the addiction-liability of this compound due to samidorphan's μ-antagonistic effects [125]. Compared to naltrexone, samidorphan has a longer half-life, increased oral bioavailability due to decreased hepatic metabolism, and higher binding affinity to μ-opioid receptors. In a 12-week RCT, samidorphan treatment (1, 2.5, 10 mg/day), compared to placebo, was associated with a more pronounced reduction of alcohol craving and average daily alcohol consumption. The latter was measured by percentage of patients who achieved ≥2-category downshift in World Health Organization (WHO) risk levels of drinking [126]. However, development of samidorphan as a standalone medication has been discontinued.

Chronic alcohol use disrupts the hypothalamic-pituitary-adrenal (HPA) axis, which leads to deficits in reward function that contribute to anhedonia/dysphoria and craving in AUD. Alcohol intake acutely elevates cortisol levels. While most sites, such as the pituitary, hypothalamus, and hippocampus are under glucocorticoid-receptor (GR) mediated negative feedback control by cortisol, frequent HPA axis activation leads to a GR mediated increase of corticotropin releasing factor (CRF) signaling in the CeA and BNST [127, 128]. In the CeA, CRF promotes withdrawal-induced alcohol drinking, escalation of alcohol intake during transition to dependence, and binge-like drinking. Given that alcohol use results in elevated GR activation and, in turn, increases pro-drinking CRF signaling in the CeA, antagonism of the GR appears to be a promising approach for AUD treatment [126]. Both systemic and intra-CeA administration of GR antagonists, **mifepristone** and the more selective CORT113176, reduced alcohol intake in dependent rats. Based on these preclinical results, a randomized, double-blind, placebo-controlled, human laboratory study was conducted in non-treatment seekers, where mifepristone (600 mg/day for 7 days) reduced cue-elicited alcohol craving and the number of drinks per day, both during treatment and 1 week follow-up period after study drug discontinuation. Its side effects are mainly gastrointestinal, such as nausea, vomiting, diarrhea, but no adverse event was reported in the human laboratory study. The findings suggest that brief (1 week) treatment with mifepristone immediately following acute withdrawal may be beneficial in conjunction with a course of psychosocial treatment [129].

Prolonged consumption of alcohol leads to a systemic inflammatory state with increased inflammation in the CNS and elevated peripheral levels of proinflammatory cytokines. In the brain, microglia cells show signs of activation *in vivo* in response to chronic alcohol use, and *in vitro*, alcohol administration results in elevated cytokine levels in microglia cultures [130]. Peripheral levels of pro-inflammatory cytokines positively correlate with craving and are increased in response to acute alcohol administration, while anti-inflammatory cytokine levels show opposite changes [131, 132]. In turn, alcohol-induced neuroinflammation contributes to increased alcohol-seeking behavior, neurotoxicity [133], cognitive and behavioral impairment, and brain damage [134]. **Ibudilast** inhibits phosphodiesterase-4 (PDE-4), −10 (PDE-10), and macrophage migration inhibitory factor (MMIF), thereby reducing neuroinflammation and supporting neurotrophin expression. Ibudilast reduced alcohol intake in three different preclinical models [135]. A randomized, crossover, double-blind, placebo-controlled human laboratory study then showed that ibudilast treatment (100 mg/day, for 7 days) reduced tonic craving for alcohol and improved mood during stress exposure. However, compared to placebo, ibudilast did not modify subjective effects of alcohol, such as alcohol cue-induced craving, alcohol-induced sedation, or positive mood increased by alcohol infusion. A secondary analysis suggested that among individuals with more depressive symptoms, ibudilast attenuated the stimulant and mood-altering effects of alcohol [136]. In a later outpatient RCT, ibudilast (100 mg/day, for 14 days), compared to placebo, reduced percentage of heavy drinking days and attenuated alcohol cue-elicited activation in the VS [137]. A secondary analysis of this study re-evaluated

the results of the earlier human laboratory study, describing a decreased alcohol-cue induced craving with ibudilast [138]. A recent neuroimaging study established that ibudilast reduces not only VS activation in response to alcohol cues, but also alcohol cue-elicited functional connectivity between VS-OFC and VS-ACC. Furthermore, both abovementioned measures of VS activation and functional connectivity correlated positively with the number of drinks per drinking day [139].

Numerous other compounds and pharmacological targets have been tested during the past years. Some showed promise in preclinical research but failed in translation to humans. Examples of medications/targets which seem promising based on preclinical studies and preliminary human results include (but are not limited to) vasopressin receptor V_{1b} antagonism [140–142], N-acetylcysteine [143–146], spironolactone [147–151], oxytocin [152–156], ghrelin system [157–162], and glucagon-like peptide-1 analogues [163–168].

Final Remarks

At the time of writing this chapter, only three medications are approved by the FDA for AUD. These are underutilized and have limited efficacy. Therefore, discovery of novel and more effective pharmacological treatments is a high priority. The fact that no new medications have been approved in the past two decades is frustrating and calls into question whether the entire approach currently used in the field should be revised or even challenged. It certainly does not help that the private sector does not invest in medication development for AUD. This is a serious problem that puts medication development in this field at a major disadvantage compared to other fields of biomedical research, despite the fact that AUD is among the leading causes of mortality and morbidity worldwide. There is however also cause for optimism. Rapidly developing basic neuroscience and neuroimaging have started to discover new mechanisms behind development and maintenance of addiction, including AUD. These advances in neuroscience continue to identify novel targets to explore preclinically and then clinically.

In this chapter, we reviewed the approved and additional clinically tested medications from the last few decades. We can conclude that none of these medications work as a general remedy for all patients with AUD. Hence, personalized medicine approaches are key. AUD is a heterogenous medical disorder, and different medications may work best or exclusively for specific subgroups of patients. Comorbidity (e.g., gabapentin in patients with history and symptoms of withdrawal; baclofen in ALD; varenicline, ibudilast in depressive symptoms; prazosin/doxazosin in patients with family history of AUD, higher blood pressure and more withdrawal symptoms) and severity of AUD (e.g., varenicline in less, and baclofen in more severe AUD) are mere examples of potential moderators of pharmacological treatment effects.

Different RCTs have used different outcomes to define efficacy. Standardization of outcomes is critical, especially from a regulatory standpoint, but these standards

need to evolve. Reduction in WHO drinking risk level seems to be a useful outcome, since growing evidence shows that non-abstinence-oriented outcomes may be beneficial. On the other hand, it is important to match the medication with the treatment goal. For example, acamprosate and baclofen seem to work better in maintaining abstinence, while naltrexone, topiramate, and varenicline seem to be more effective to reduce heavy alcohol use.

Continued efforts and new frontiers in medication development for AUD are critical to move the field forward in the years to come [169]. This chapter attempts to offer a broad spectrum of approved and non-approved, but promising, pharmacotherapies to the readers, no matter if the reader is a student, physician, scientist, patient, or someone simply interested in learning more about AUD.

Acknowledgements This work was supported by NIH intramural funding ZIA-DA-000635 (Clinical Psychoneuroendocrinology and Neuropsychopharmacology Section—PI: LL), jointly supported by the NIDA Intramural Research Program and the NIAAA Division of Intramural Clinical and Biological Research. Andras Leko is also supported by a fellowship from the Center on Compulsive Behaviors funded by the NIH Deputy Director for Intramural Research Innovation Award. We thank Dr. Gail Seabold (NIDA, NIH) for proofreading the chapter.

Chapter 17
Comorbidity of Alcohol Use Disorders with Substance Use Disorders and Psychiatric Disorders

Justyna Zaorska and Marcin Wojnar

Abstract Prevalence of psychiatric disorders in patients with alcohol use disorder (AUD) is significantly higher than in individuals without AUD diagnosis. For this reason, it is important to screen all patients with AUD for other mental disorders as well as to evaluate alcohol use in patients with psychiatric disorders. Dual diagnosis implicates more severe course of comorbid disorders, poorer treatment outcomes, higher risk of suicide, and worse social functioning. There are several explanations proposed for high comorbidity of AUD and mental disorders. Among them are shared neurobiological mechanisms and joint genetic background, self-medication hypothesis or substance-induced mental disorders. Providing health care for individuals with such comorbidity may be particularly challenging. Treatment of AUD, including pharmacotherapy, should be performed simultaneously with treatment of coexisting mental disorder, including use of antidepressants, mood-stabilizers or antipsychotics. First-line treatment for depression comorbid with AUD requires SSRIs, SNRIs or mirtazapine. For bipolar disorder and AUD, lithium in monotherapy or combined with valproate should be considered first, while in psychotic disorders and AUD, clozapine and long-acting injectable antipsychotics may be recommended.

Epidemiology

Alcohol use disorder (AUD) is a highly prevalent disorder worldwide and has a high comorbidity with other mental disorders. In the US National Epidemiologic Survey on Alcohol and Related Conditions Wave III (NESARC-III) carried out in 2012–2013, the 12-month prevalence of DSM-5-defined AUD was 13.9%, while lifetime prevalence was 29.1% [1]. In the National Survey on Drug Use and Health 2020 [2] among people aged 12 or older, 10.2% had past year AUD with the highest prevalence in adults aged 18–25 (15.6%) followed by adults aged 26 or older (10.3%) and by adolescents aged 12–17 (2.8%).

General comorbidity in AUD has been the subject of several epidemiological studies. In the Epidemiological Catchment Area (ECA) Study on the US population, among those with AUD, 36.6% had a comorbid mental disorder and 21.5% had another drug use disorder (DUD) in their lifetime. Prevalence of psychiatric disorders in the group of patients with AUD was significantly higher than in the group without AUD diagnosis ($p < 0.001$), and equaled 3.8% for schizophrenia, 13.4% for any affective disorder, 19.4% for anxiety disorder and 14.3% for antisocial personality disorder (ASPD) [3]. National Comorbidity Survey (NCS) demonstrated that in last 12 months more than 25% of individuals with AUD met criteria for a major depressive episode, and 37% of them met criteria for anxiety disorder [4, 5]. AUD was associated with over two times higher incidence of post-traumatic stress disorder (PTSD), almost four times higher incidence of major depressive disorder (MDD), over four times higher incidence of general anxiety disorder and over six times higher incidence of bipolar disorder (BD) [5, 6]. More recent data from the Wave III of the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC III) revealed significant associations between DSM-5 AUD in the past 12 months and increased odds of many psychiatric disorders. Particularly, past year AUD increased the probability of any DUD (without nicotine) with an odds ratio (OR) of 3.3, MDD with OR 1.2, ASPD with OR 1.6 and borderline personality disorder (BPD) with OR 1.9. Lifetime prevalence of AUD increased the odds of any anxiety disorder by 1.3. All associations were controlled for sociodemographic characteristics and other disorders [1].

A relationship between psychiatric morbidity and alcohol use has been a subject of research as well. In Sanchez-Pena study [7], the percentage of patients meeting criteria for concurrent AUD was: 30% for individuals with personality disorder (PD), 24% in subjects with adjustment disorder, 22% with depressive disorder, 18% with anxiety disorder, 11% with schizophrenia, and 9% with BD. The National Survey on Drug Use and Health 2020 [2] demonstrated that adults with any mental illness in the past year were more likely than adults with no mental disorder to be past month binge alcohol users (28.5% vs. 22.8%) and heavy alcohol users (8.8% vs. 6.4%) (Table 17.1).

In epidemiological studies on comorbidity of MDD and AUD, lifetime prevalence of those diagnoses varied from 27% to 40% [8–10]. Past year prevalence was investigated in the National Survey on Drug Use and Health 2020 [2]. In that study,

Table 17.1 Prevalence of alcohol use disorder in subjects with psychiatric disorders—data sourced from the results of ECA study [3]

General population	6%
Schizophrenia	34%
Major depressive disorder	17%
Bipolar disorder	44%
Anxiety disorders	18%
Antisocial personality disorder	74%

adults with past year major depressive episode were more likely to be dependent on or to abuse alcohol than those without major depressive episode (17.0% vs. 7.0%). Metanalysis by Hunt et al. indicates that in patients with bipolar disorder prevalence of AUD was higher than for any other substance use disorder (SUD) and reached 42% [11].

In patients with PD, according to metanalysis of Guy and colleagues [12], lifetime prevalence of AUD in persons with ASPD was 77%, in individuals with BPD was 52%, and 39% in subjects with other PD. Use of alcohol by patients with Attention Deficit Hyperactive Disorder (ADHD) is also a common occurrence. According to different studies, prevalence of AUD in this group of patients goes up to 43% of adults with ADHD [13].

In conclusion, co-occurrence of AUD and psychiatric disorders is commonly observed, and the comorbidity seems to be bidirectional—the prevalence of major psychiatric disorders in individuals with AUD is higher than in the general population, and the prevalence of AUD in patients with psychiatric disorders is higher than in the general population. The strongest association seems to be with ASPD and BD. Importantly, both externalizing and internalizing conditions seem to be associated with AUD, which may indicate different reasons and motivations for alcohol use.

Significance of Psychiatric Comorbidity

Psychiatric comorbidity in AUD has a negative impact on the course and prognosis of both AUD and comorbid psychiatric disorders, and on patients' general functioning. Patients with MDD and AUD have more comorbid mental disorders and more suicidal behaviors than AUD patients without comorbidity. Patients with depression and AUD also have worse treatment outcomes—they spend more time being depressed, have lower global functioning and higher life dissatisfaction [14, 15]. Results of AUD treatment in individuals with comorbid mood or anxiety disorder appear to be poorer than in AUD alone. For example, in a study of Kushner et al. [16], persons with mood or anxiety disorder were more likely to return to drinking within 4 months following treatment. On the other hand, recent review of studies on patients with Social Anxiety Disorder (SAD) and AUD supports the thesis that this comorbidity worsens treatment compliance, but it also indicates that there is not enough data to consistently state that SAD comorbidity impacts treatment response in patients with AUD [17].

Table 17.2 Impact of psychiatric comorbidity in AUD [20, 21]

• More severe course of coexisting disorders
• Higher risk of attempted and completed suicide
• Poor prognosis and worse treatment outcomes
• Lower compliance
• Lower treatment retention
• Higher risk of relapse
• More somatic disorders
• Lower quality of life
• Worse family, social, and occupational functioning
• More conflicts with law
• Increased mortality

In individuals with BPD, co-occurrence of AUD was associated with higher unemployment, poor school performance and promiscuity [18]. According to Margolese et al. study, patients with schizophrenia and AUD suffer from greater severity of psychopathology [19]. Other studies on schizophrenia and AUD suggest that individuals with such comorbidity have neurocognitive dysfunctions, which entail deterioration of working memory, episodic memory, and verbal learning (Table 17.2) [20, 22, 23].

Relationships Between AUD and Coexisting Mental Disorders

Several explanations for the co-occurrence of AUD/SUD and mental disorders have been proposed. They include shared neurobiological mechanisms and risk factors, vulnerability for a second disorder caused by the primary disorder, "self-medication" hypothesis, substance-induced mental disorders (especially depression) and the impact of social problems caused by AUD/SUD on mental health.

Neurobiological Mechanisms

Physiologically, under the influence of stress, signals from the centers in the limbic system reach the hypothalamus via serotonin and noradrenaline pathways. As a result, corticotropin-releasing hormone (CRH; also referred to as "factor", CRF) is released, which in turn stimulates the pituitary gland to release corticotropin (ACTH). Increase of ACTH concentration causes the adrenal glands to produce cortisol. As a result of alcohol intoxication, there is an additional release of CRH in the extended amygdala, a cytoarchitectonically related set of structures that include

central amygdala, nucleus accumbens shell, sublenticular substantia innominate and bed nucleus of stria terminalis), and activation of the hypothalamic-pituitary-adrenal (HPA) axis cascade. This demonstrates one of the mechanisms by which alcohol increases stress hormone levels. Sustained and excessive release of stress hormones results in a progressive adaptation of the central nervous system (CNS), and the emergence of a new, allostatic state, thought to be one of the important components of addiction [24]. Although the exact role of the HPA axis in the pathophysiology of mood and anxiety disorders remains unclear, its involvement has been well documented for many years. For instance, chronic stress and the accompanying increase in stress hormone levels (CRH, ACTH, cortisol) tend to damage some brain structures (e.g., hippocampus) and contribute to the development of anxiety and depressive symptoms [25].

Alcohol intoxication and alcohol withdrawal are conditions where neurotransmission homeostasis is severely disturbed. In general, acute alcohol administration increases gamma-aminobutyric (GABA), dopaminergic, opioidergic, and serotonergic (5-HT) neutrotransmission, and decreases glutamatergic neurotransmission. The stimulating effects of alcohol also relate to changes in brain derived neurotrophic factor (BDNF), which promotes activation of its high affinity receptor, Tropomyosin receptor kinase B (TrkB), and subsequent signaling pathways. Alcohol withdrawal in turn is associated with attenuated GABA, 5-HT and DA neurotransmission, and increased CRH concentration, with a major imbalance between inhibitory GABAergic and excitatory glutamatergic neurotransmission. Merlo Pich and colleagues [26] found that dialysate CRH levels in the amygdala are elevated during alcohol withdrawal in rat brain, and dialysate DA and 5-HT levels in the Nucleus Accumbens are decreased. The directionality of all these neurotransmitter changes is consistent with hypothesized changes in neurotransmission in depression [27, 28].

It is also worth mentioning that alcohol consumption may decrease the availability of tryptophan (Trp) to the brain as it activates liver Trp pyrrolase, the rate-limiting enzyme of the kynurenine pathway of Trp degradation. This may be a mechanism through which alcohol intake may lead to depletion of 5-HT synthesis and, consequently, to altered regulation of emotions, mood, arousal, sleep, eating, pain, aggression, and impulsivity [29–31]. In animal studies, reduced serotonin neurotransmission has been demonstrated to be associated with relapse [32], while in both human and animal studies dysregulation of noradrenergic transmission (as a response to arousal, stress, and withdrawal) was indicated as an important component of AUD pathophysiology [32]. Reduction in dopamine release is considered to be associated with dysphoria, malaise and depression during alcohol withdrawal [30]. In addition, alcohol intoxication stimulates endogenous opioid system (including peptide transmitters such as endorphin and enkephalin, which take part in controlling pain, mood, and stress responses) and increase opioid blood levels. In AUD and chronic alcohol use, levels of endogenous opioids are reduced, which may contribute to negative emotional states [30].

Common Pathogenesis

Shared Genetic Vulnerability with Different Phenotypic Pictures

In 1992, Winokur proposed a division of primary unipolar depression into familial subtypes. One of those subtypes was depression spectrum disease (DSD), which he defined as a depression in a person having a family history of AUD and/or ASPD (and may have family history of primary depression). A second subtype was familial pure depressive disease (FPDD)—a depression in a person without a family history of AUD and/or ASPD, but with family history of depression. Unstable personality characteristics were observed in DSD depressive patients compared to FPDD [33, 34]. Also, a twin study suggests that familial factors strongly impact the association between depression and AUD. In a sample of 1874 monozygotic male twins, individuals with depression had 2.8 times higher odds of AUD than twins without history of depression [35]. In AUD genetics studies, most data support the importance of genetic variation (the role of genetic polymorphisms) in genes related to alcohol metabolism (*ADH1B* and *ALDH2*), susceptibility and resistance to stress (*COMT* and *SLC6A4*), the reward system (*OPRM1*, *DRD2* and *DRD4*), and cognitive functions and behavior control (*COMT* and *MAOA*). Furthermore, studies on gene-environment interaction suggested that comorbidity of AUD and depression may arise from common environmental causes in patients with specific genetic risk variant (i.e., *SEMA3A*) [36, 37]. The recent meta-analysis of genome-wide association studies (GWASs) identified several risk genes associated with AUD. Consistent with above-mentioned data, it underlines the importance of genes related to alcohol metabolism (*ADH1B*, *ADH1C*, *ALDH2*) and neurotransmission (*DRD2*). However, it also identified other genes such as *GCKR*, *SIX3*, *KLB*, *SLC39A8*, *FTO* and several novel ones, for instance, *PDE4B*, *THSD7B*, *CADM2*, *DPP6*, *SLC39A13*, *TMX2*, *ARID4A*, *C14orf2*, *TNRC6A,* and *FUT2*. This meta-analysis does not support the role of genes involved in behavior control (*COMT* and *MAOA*), though it revealed significant genetic correlations with other psychiatric disorders, with the strongest relationship with MDD [38].

Typology of Cloninger, which was related to his theory of personality, divided alcohol-dependent individuals into two types. Type I is characterized by a later onset of drinking (after the age of 25), ability to abstain from time to time, at least intermittently, men and women alike. The personality profile of this group is dominated by risk avoidance, low need for stimulation and high need of social approval. These people tend to deal with problems with the help of alcohol. Type II includes people with an early onset of drinking (before 25 years of age), almost exclusively men, burdened with addiction in the family and inheriting addiction from their fathers, often using other psychoactive substances. In the personality profile there is dominance of antisocial traits with a high need for stimulation. Type II AUD individuals consume alcohol for their enjoyment, not to alleviate anxiety or tension. It

is supposed that subjects with Cloninger's Type I have more evident impairment in dopaminergic transmission, while those with Type II have a significant deficit in serotonergic transmission and normal dopaminergic transmission [39–42].

Mental Disorders Lead to Alcohol Use: A "Self-Medication" Hypothesis

Alcohol is commonly perceived as a substance that "elevates mood", as it may produce stimulant-like effects. Concurrently, due to sedative properties it reduces tension and anxiety. It is widely observed that individuals with AUD/SUD have poor emotion regulation skills—they have difficulties in regulating affect in a context of their own emotional state as well as in social contacts. Hence, they may feel overwhelmed with emotions or do not feel their emotions at all. *Self-medication* with alcohol or other substance helps to reduce negative emotional and mental symptoms [43]. This phenomenon seems to be more frequent in individuals with primary deficit of central activity of NA, DA and 5-HT (as alcohol intake increases activity of these neurotransmitters) and in depressed women [20].

Substance/Alcohol-Induced Mood Disorder

While analyzing background of comorbidity of depression and AUD, the occurrence of alcohol-induced depression should also be considered. Depression that began before the onset of AUD or during uninterrupted abstinence should be considered as independent depression. Alcohol-induced depression occurs during or shortly after alcohol intoxication or withdrawal and lasts up to 4 weeks [44]. The differences in course and family history of independent versus alcohol-induced depression are presented in Table 17.3.

Table 17.3 Differences in course and family history of independent vs. alcohol-induced depression [45]

Independent depression	Alcohol-induced depression
Onset of depressive symptoms before patient started using alcohol	Intensive alcohol use preceded incidence of a first episode of depression
Depressive symptoms occurred or maintained during long-term abstinence (at least 4 weeks)	Depressive symptoms remitted during abstinence lasting at least 4 weeks
Family history positive for recurrent depression in a first-degree relative	Family history negative for depression

Comorbidity of Selected Psychiatric Disorders and AUD

Mood Disorders

Depression is the most common co-occurring psychiatric disorder in individuals with AUD. Given the high prevalence of depression in the general population, a high rate of co-occurrence in AUD could be expected and may suggest over-representation. However, current studies indicate that the prevalence of depression is nevertheless higher in AUD than in the general population. Comorbidity of depressive disorder and AUD is associated with greater severity of symptoms, worse treatment response, worse prognosis, and increased risk for suicidal behavior [46]. There is a lower likelihood of remission of depression, and it takes more time to achieve response to treatment in patients with comorbid disorders [47]. Occurrence of alcohol-induced depression is associated with worse alcohol-related treatment outcomes and with a greater risk for later MDD [48, 49]. According to a recent meta-analysis, lifetime prevalence of AUD reaches 35% in patients with BD. Use of alcohol in this group may contribute to poor compliance and worse treatment outcomes. Both poor treatment adherence and alcohol use are important risk factors of suicide in patients with BD and AUD [50, 51].

Schizophrenia

About 1/3 of patients with schizophrenia meet the criteria for diagnosis of AUD. A recent meta-analysis indicates a lifetime prevalence of AUD in subjects with schizophrenia at 24.3% [52], another study estimates this prevalence at 33.7% [3]. One US study reported that 36.4% participants met criteria for AUD before the first episode of psychosis [53]. Some significant predictors of this comorbidity can be identified: male sex, severity of negative symptoms, severity of depression, low education, previous violent offending, and family history of substance use disorders [54, 55]. The comorbidity of AUD in patients with schizophrenia is associated with greater severity of psychopathology, higher suicidality, medication nonadherence, high rates of hospitalization, aggressive behaviors, and socioeconomic problems such as homelessness and incarceration [56].

Neurocognitive dysfunction (impairment of working memory, episodic memory and verbal learning), which is observed in many patients with schizophrenia, may contribute to a particularly high risk of relapse to alcohol use. Furthermore, disorganized memory and the inability to inhibit craving may be risk factors for inducing alcohol-seeking and subsequent alcohol-dependence [19, 23, 57, 58]. Based on recent studies, there is evidence for certain genetic factors that may lead to co-occurrence of AUD and schizophrenia. It was noted that SUD (including AUD) and schizophrenia may share genetic liability [59] and it was observed that several

polymorphisms of the brain-derived neurotrophic factor gene (*BDNF*) may be associated with a shared genetic vulnerability for co-occurring schizophrenia and alcohol dependence [60]. Another explanation of high comorbidity of AUD and schizophrenia is the self-medication hypothesis. Alcohol may be used to reduce discomfort arising in the initial stages of psychosis or to decrease anxiety or mental tension accompanying hallucinations and delusions. It can be also used to improve mood or self-esteem [61].

Anxiety Disorders

Cloninger's typology of AUD emphasizes heritable personality traits as a key factor for developing type I or type II alcoholism. Type I includes individuals that are believed to drink to cope with negative affect associated with self-consciousness or anxiety, while type II includes persons having relatively less fear and guilt and demonstrating antisocial behaviors. According to the NESARC study, drinking to cope with symptoms of anxiety disorder increases the risk of AUD, and persons with anxiety disorder who drink to cope with anxiety have five times higher risk for developing AUD in 3 years and a transition from initial alcohol use to AUD is faster [62]. Expectedly, AUD treatment outcomes are poorer in this group of patients as well [63]. There is growing evidence supporting the hypothesis that the common co-occurrence of anxiety disorder and AUD is a consequence of overlapping neurodysregulations. Amygdala is a key structure in physiological and behavioral response to stress and anxiety. In addition, it is a crucial structure in the neurocircuitry of addiction. Brain imaging studies demonstrated abnormal central amygdala function in individuals with anxiety disorder and in individuals with AUD [64] as well as it is postulated that chronic alcohol use results in neuroadaptations within the central amygdala, which are analogous to the neuroadaptations that occur after chronic stress [65, 66].

Personality Disorders

In the NESARC study 42% of participants who met the diagnostic criteria for any PD were also diagnosed with DSM-IV alcohol dependence, with the most pronounced co-occurrence with Cluster B PDs [67]. It is clearly noticeable that AUD is related to several personality traits, like low agreeableness and impulsivity, which are consistent with traits typical for ASPD and BPD. Furthermore, personality traits like impulsivity, aggressive or neurotic tendencies, which are constitutional for ASPD and BPD, may contribute to externalizing behaviors, such as alcohol or other substance misuse. Cloninger in his studies on type II alcohol dependence and on ASPD noticed that both conditions are marked by high

novelty-seeking, low harm avoidance, and low reward dependence [68]. Slutske and colleagues verified this observation using genetic methods. They found that genetic variance associated with behavioral undercontrol (including traits like impulsivity, novelty-seeking, aggression) accounted for 40% of the genetic variance in alcohol dependence [69]. According to current data, it can be assumed that AUD patients with co-occurring PD are less likely to remain in treatment, likely to drink more alcohol per day, and—in patients with ASPD—have earlier onset of AUD. It is not thoroughly clear if, and how, personality disorder impacts an outcome of AUD treatment since there is little reliable research on this topic. As reported by recent literature, treatment outcomes may not substantially differ in those groups of patients [70, 71].

Comorbidity of AUD and Other SUDs

Alcohol is frequently used together with other substances. According to SAMHSA, in the US 5.6% of adults have used both alcohol and another illicit drug within the past year and 1.1% have met diagnostic criteria for both AUD and another SUD [2]. The most commonly reported substances co-used with alcohol are cannabis (10%), opioids (2.4%), cocaine (2.5%), and amphetamine (1.2%). Polydrug use, that includes alcohol, is associated with additional comorbidities, including higher prevalence of mood disorders and anxiety disorders. Furthermore, AUD is more severe in patients with other substance use disorder (AUD-SUD) than in individuals with AUD only. Moreover, individuals with SUD are likely to drink alcohol both during drug-craving episodes and during drug-use episodes [72, 73].

Use of alcohol with other substances, especially with opioids and benzodiazepines, increases rates of adverse events, overdose, and death [74]. It was observed that in the US between 1999–2008 there was a large increase in overdoses caused by combination of alcohol with opioids (76% increase), which is particularly dangerous because of both having suppressive effect on the brain respiratory center. About 20% of overdoses were caused by combination of alcohol and other substances [75]. Also, patients using more than one substance are likely to have poor outcomes from behavioral treatment [76].

There is an unquestionable relationship between alcohol drinking and tobacco use, with about 40% of adults who drink alcohol also being current smokers [77] as compared to about 23% in the general population. It is observed that with increasing rate of smoking the amount of alcohol consumed increases monotonically, indicating that the relationship is dose-dependent [78]. AUD patients are more likely to use tobacco (according to studies, up to more than 80% of patients) and use it heavier than non-AUD individuals [79]. Importantly, alcohol and tobacco potentiate the risk for head and neck cancers [80].

Treatment of Comorbid AUD and Mental Disorders

To provide a comprehensive care for patients with dual diagnosis a few principles of treatment might be framed. Due to strong association of AUD and other mental disorders in course and prognosis, as improvement of one disorder facilitates treatment of another, simultaneous treatment of both disorders should be performed. Best is if treatment is delivered by the same interdisciplinary team in the same treatment center, preferably dedicated to therapy of patients with dual diagnosis. When introducing pharmacotherapy, it is worth remembering that effect size of antidepressants or antipsychotics might be moderate, and placebo effect might be particularly pronounced [81–84].

Treatment of Depression Coexisting with AUD

All patients with depression should be screened for alcohol use and, if needed, diagnosed for AUD. Intervention for AUD should be set up at early stages of treatment, as maintaining abstinence improves effectiveness of antidepressant medication. While initiating treatment, symptoms of alcohol withdrawal should be assessed and detoxification should be initiated, if necessary. All patients should be proposed an effective medication for AUD as well as psychosocial therapy. Symptoms of alcohol-induced depression may go away with abstinence, so it is important to get the patient abstinent or at least encouraged to substantially reduce alcohol use. It is not presently known how long to optimally wait before initiating treatment after achieving abstinence. Four-week observation with standard interventions supporting abstinence may allow avoiding unnecessary pharmacotherapy, which might involve a risk of potential drug interactions and adverse effects [85]. Other recommendations [83] suggest that a week of observation is enough to state that depression is likely independent. It might be concluded that if there are other indicators for independent depression (such as prior episodes or family history), time of observation may be shortened, and starting antidepressant treatment early should be considered.

If a patient cannot achieve abstinence, it is worth investigating past episodes and considering treatment depending upon obtained information. Mild depressive symptoms may be treated with Cognitive-Behavioral Therapy (CBT) and interventions supporting abstinence. Moderate and severe symptoms should be treated with antidepressant medication. Choice of antidepressant may be made according to local standard or clinical guidelines, though some suggestions are put forward below. In case of treatment-resistant depression standard guidelines should be followed. CBT or other therapeutic techniques may be provided at any stage of treatment [44, 82–84, 86]. A recent meta-analysis of studies on clinical interventions for patients with AUD and depression revealed no certain evidence for effects of CBT, Selective Serotonin Reuptake Inhibitors (SSRIs) or Tricyclic Antidepressants

(TCAs) on remission from depression, but it proved that CBT may likely reduce depressive symptoms (moderate confidence), SSRIs are likely to improve functional status (moderate confidence), and TCAs may reduce depressive symptoms (low confidence). For alcohol use outcomes, there was no evidence for effect of CBT, SSRIs or TCAs on remission, but it was revealed that CBT and SSRIs may reduce alcohol use (low confidence) [87].

Pharmacological Treatment of Depression Coexisting with AUD

SSRIs are first-choice drugs as they are well-tolerated, safe, cause mild sedation and have low risk of alcohol-drug interactions. Effectiveness of SSRIs is modest, with stronger evidence in independent depression [44] and a combination of CBT and SSRI provides better treatment effect. Studies support combined pharmacological treatment for depression and AUD (for example, with sertraline and naltrexone) [88]. There is evidence that combined pharmacotherapy provides better outcomes—maintained abstinence, delayed relapse to heavy drinking, fewer serious adverse events, remission of depressive symptoms. If SSRIs fail (or there is a history of SSRI failed attempt), medication with noradrenergic or mixed mechanism: SNRIs (venlafaxine, duloxetine) or NASSA (mirtazapine) should be introduced. Providing that the patient maintains abstinence, pharmacological treatment of depression might be discontinued after 6 months of remission. However, in case of MDD standard long-term pharmacological treatment preventing relapse should be continued. In those who start drinking again or drink continuously, it is not necessary to withdraw medication. While choosing antidepressant it should be remembered that fluoxetine, bupropion, and venlafaxine might be abused [44, 81–84, 86].

Treatment of Bipolar Disorder Coexisting with AUD

For now, there are not enough data to provide a solid recommendation for treatment of patients with comorbid BD and AUD, but some guidance might be proposed to simplify clinical decision making. Current literature supports the use of lithium in monotherapy or combined with valproate as a first line treatment for patients with BD and AUD. Initiating medication for AUD should always be considered by clinicians to reduce alcohol consumption. Available data support the effectiveness of naltrexone for reducing alcohol use in BD patients. Disulfiram, even though included in guidelines, has not much evidence specific for BD patients. Aripiprazole, lamotrigine, gabapentin, and topiramate may be considered as well, but there are not enough data published to recommend them as a first line treatment. They may nonetheless be considered as an adjuvant therapy together with medications with support in the evidence, such as lithium and valproate [51, 89]. Quetiapine has been studied extensively for the treatment of comorbid BD and AUD as an agent that may

influence both mood symptoms and alcohol consumption. For now, results of studies are mixed. There was a positive effect on mood and alcohol drinking reported in some studies, but it has not been replicated in others. When used as adjunctive therapy to valproate or lithium in a randomized controlled trial, no significant effect on AUD-related outcomes was reported [90]. Altinbas and Evren proposed an algorithm for the treatment of comorbid BD and AUD [91], see Table 17.4 below.

Treatment of Schizophrenia and Psychotic Disorders with AUD

The choice of antipsychotic medication should be made with caution because it may have implications for alcohol consumption. It is observed that first-generation antipsychotics do not decrease the amount of alcohol used in individuals with schizophrenia and AUD, and even may increase alcohol use and craving [6]. There is support for use of clozapine in patients with schizophrenia and AUD. It was postulated that clozapine may alleviate dysfunction of brain circuits that appear in individuals with schizophrenia and substance use disorder by its weak blockade of D2 receptor coupled with noradrenergic effects [92]. Recent research demonstrated that individuals receiving clozapine are more likely to achieve remission from AUD and have lower rates of relapse in comparison to individuals taking another atypical antipsychotic [93]. Long-acting injectable antipsychotics should be taken into consideration, since they may improve treatment adherence, something that is particularly relevant in a dual-diagnosis population. In a randomized controlled trial comparing oral risperidone and long-acting injectable risperidone in patients with schizophrenia and AUD, drinking-related outcomes were poorer in patients receiving oral formulation of risperidone [94]. There are studies supporting the superiority of long-acting injectable paliperidone as well [56, 95]. Among medications for AUD, disulfiram and naltrexone have been studied in patients with schizophrenia. Despite previous concerns about pro-psychotic effect of disulfiram, current studies demonstrate that disulfiram may be effective in this group of patients as it is well tolerated and does not worsen psychosis. Similarly, naltrexone decreases alcohol consumption and does not affect symptoms of schizophrenia [56, 81].

Table 17.4 Treatment of comorbid AUD and BD [91]

Mood state	Depression	Mania/mixed	Euthymia
Evidence-based choice	1. Quetiapine	1. Valproate	1. Valproate
	2. Lithium	2. Quetiapine	2. VPA + naltrexone
	3. Valproate		3. VPA + disulfiram
Expert opinion	1. Lamotrigine	1. Lithium	1. Lithium
	2. Aripiprazole	2. Carbamazepine	2. CBZ/Oxcarbazepine
			3. Acamprozate

Psychotherapy can be applied to the appropriate patients during all phases of treatment

Treatment of Personality Disorders with AUD

Treatment of patients with AUD and PD may be challenging for clinicians. On one hand, addressing PD and AUD independently may be needed, as an active use of substance disrupts treatment process. On the other hand, it may be unworkable to focus on one issue at a time, while both conditions closely influence each other. For individuals with BPD in therapeutic process, there may occur behaviors that potentially make further AUD treatment impossible (such as suicidal thoughts or attempts associated with personality disorder). Integrated treatment, using key components from multiple therapies and targeting specific traits (such as impulsiveness and emotion dysregulation) are considered an effective approach for patients with AUD and PD [68].

Summary

AUD frequently coexist with other substance use and mental disorders. Dual diagnosis leads to more social and medical complications—patients with comorbid AUD and other psychiatric disorders have a higher risk of suicide, more severe course of both diseases, poorer treatment outcomes and prognosis, have more comorbid somatic disorders, and show worse social and occupational functioning. For this reason, it is recommended to screen all patients with mental disorders for alcohol and other psychoactive substance use. The risk of recurrence is higher in subjects with comorbid AUD and psychiatric disorders, independently of relapse to alcohol use. Psychiatric patients treated for a psychiatric disorder with residual symptoms get back to use of alcohol or other drugs earlier and more frequently than those with complete remission of symptoms.

Diagnosing and treating patients with comorbid disorders is particularly difficult and challenging for health care professionals. Treatment of AUD should be performed concurrently with antidepressant medication and there is no need to withdraw antidepressant medication because of alcohol drinking. Reasonable use of antidepressants alleviates depressive symptoms and may increase likelihood of reducing alcohol consumption. Recommended antidepressants are SSRIs, SNRIs, and mirtazapine, as they have a low risk of alcohol-drug interactions and alcohol use should not affect antidepressant treatment. For bipolar disorder and AUD, lithium in monotherapy or combined with valproate should be considered as first-line treatment, while in psychotic disorders and AUD clozapine and long-acting injectable antipsychotics are better choice than first-generation antipsychotics. In patients with AUD and PD integrated therapy targeting specific traits might be effective, though therapeutic process may be challenging and complex care should be provided.

Chapter 18
Treatment of Adolescents

Anna E. Kirkland, Kathryn S. Gex, Brittany E. Bryant, and Lindsay M. Squeglia

Abstract Adolescence is a critical phase of psychosocial and neural development that oftentimes overlaps with the initation and escalation of substance use, particularly alcohol use. Adolescent alcohol use is not innocuous, and endorsing a single symptom of alcohol use disorder (AUD) during adolescence predicts AUD diagnosis in adulthood. Further, up to 5% and 15% of adolescents and young adults, respectively, meet critertia for AUD. The age of intervention for AUD is a critical predictor of treatment outcomes. Therefore, intervening during adolescence could lead to better outcomes across the lifespan. Currently, there are several available treatments for adolescent AUD, as well as possible adjunctive treatments and alternative modalities to existing interventions. Currently available treatments include: family-based therapy, cognitive behavioral therapy (CBT; including 3rd wave CBT), motivational interviewing/motivational enhancement therapy, multicomponent psychosocial therapy, and brief alcohol interventions. Possible adjunctive treatments include 12-step programs, pharmacotherapy, exercise-based therapies, goal setting, and progress monitoring. Unfortutanetly, the effect size for existing interventions are small-to-moderate, leaving much room for future improvement. Digital strategies and culturally based programs may help increase the effectiveness of existing treatments. This chapter will provide a guide through the current standalone, possible adjunctive, and new modalities as well as discuss the obstacles surrounding adolescent AUD interventions.

Introduction

Adolescence is a critical phase of maturation within physiological, cognitive, and psychosocial systems. The timeframe of adolescence has multiple definitions, ranging from 10–19 years old to 10–24 years old according to the World Health Organization (WHO) and Center for Disease Control and Prevention (CDC), respectively. Two important, and often overlapping, occurrences happen during adolescence: the final phases of neurodevelopment [1, 2] and initiation/escalation of substance use [3], particularly alcohol use [4, 5].

Brain Development Overview. The brain is maturing until around the age of 25, with significant structural and functional maturation occurring during adolescence. Structural changes include distinct maturation patterns within gray matter (e.g., neuronal cell bodies, dendrites, glial cells) and white matter (i.e., myelinated axons). Recent lifespan curves [6] show a white matter trajectory with a nearly linear increase almost to the age 30 followed by a steady decline with age. Gray matter shows a different trajectory with an increase in gray matter until approximately age 6, followed by a linear decrease throughout adolescence and into late adulthood (i.e., inverted-U shape). Further, regional gray matter trajectories support differential maturation timelines across brain systems, with sensory regions maturing first and fronto-temporal association regions (e.g., cognitive control and executive functioning) maturing later [5]. Due to the biological make-up of of gray and white matter, the decrease of gray matter over adolescence is thought to at least partially correspond with the pruning of weak synaptic connections resulting in increased regional specificity and plasticity [7], while the increase in white matter is thought to represent greater global connectivity [5, 8]. Additionally, neurotransmitter systems, like dopamine (reward, motivation, approach), glutamate (excitatory), and GABA (inhibitory), mature during adolescence [9].

Alcohol Use During Adolescence. In concordance with these neural changes, adolescent behaviors shift towards an increase in novelty and sensation seeking [1, 2, 10] and the development of higher-order cognitive abilities [11]. Importantly, the novelty and sensation seeking systems (e.g., reward pathway modulated by dopamine) develop before the higher-order cognitive systems (e.g., prefrontal systems) [8, 10]. This has led to the "imbalance hypothesis" of neurodevelopment, which proposes that enhanced motivation for novel and rewarding stimuli, coupled with immature cognitive control, can lead to initiation of substance use during adolescence [5, 11]. For other hypotheses of adolescent substance use initiation, see Lees et al. [5].

Adolescent substance use levels are heterogenous, ranging from low or normative use to heavy or pathological use, and alcohol is the most used substance during this time of development [3, 4]. According to the WHO, 27% of

adolescents (ages 15–19) worldwide endorsed currently drinking alcohol, defined as consumption of an alcoholic beverage in the previous 12 months [4, 5]. There is variability of adolescent (ages 12–15) alcohol use within regions of the world. For example, in Africa the lowest rates of alcohol use are found in Senegal (1.7% for girls, 5.8% for boys) and the highest rates are in Seychelles (56.2% for girls, 59.7% for boys), while in Asia the lowest rates are in Myanmar (0.6% for girls, 3.0% for boys) and the highest rates are in Thailand (9.2% for girls, 21.0% for boys) [12]. Across the world, the highest rates of adolescent alcohol use are reported in the European region (44% past month use), and the lowest rates of use are in the Eastern Mediterranean region (1.2% past month use) [4]. The type of alcohol use is also of importance during this age, with 45% of adolescents using alcohol worldwide endorsing binge drinking (defined as 60+ grams of pure alcohol or approximately four standard drinks in one drinking occasion) [4, 5, 13], indicating that high levels of drinking are common within this age group.

While alcohol use during adolescence is sometimes considered a "normal" exploratory behavior, it can have lasting adverse consequences. Problematic alcohol use during this life stage is related to psychosocial problems, including comorbid psychopathology [14, 15], poorer academic success [16], and detrimental neurocognitive consequences [5, 17, 18]. It has also been the leading cause of global premature death (ages 15–49) [19]. Early alcohol initiation increases the risk of subsequent alcohol use disorder (AUD) and related problems [20, 21]. Adolescents who endorse subthreshold levels of AUD (even just one symptom) have a higher risk (odds ratio: 2.0) of transitioning into meeting full AUD criteria by early adulthood [22]. Alarmingly, almost 15% of youth meet the diagnostic criteria for AUD by age 18 [23], and half of individuals that meet the criteria for lifetime AUD do so by the age of 21 [24]. Genetic factors, the environment (e.g., cultural acceptance of alcohol use, parenting styles, peer influence), and their interaction have been associated with early initation and escalation of alcohol use [25–28]. Additionally, adolescent alcohol use has been associated with worse outcomes than adult alcohol use, including being more likely to transition into an AUD or other substance use disorder (SUD) [20, 29] and having more detrimental brain aberrations [5].

It is clear that adolescent alcohol use is not innocuous, and adolescents are not spared from developing an AUD. In fact, the age of onset for AUD is a critical factor for treatment outcomes [22]; thus, decreasing problematic alcohol use at an early stage could have significant long-term implications for persistent AUD [30]. This creates an urgent need for efficacious adolescent-focused AUD treatments. This chapter will be focused on: (1) the currently available treatments for adolescent AUD, (2) possible adjunctive interventions to existing treatments, and (3) alternative intervention modalities (see Fig. 18.1 for overview).

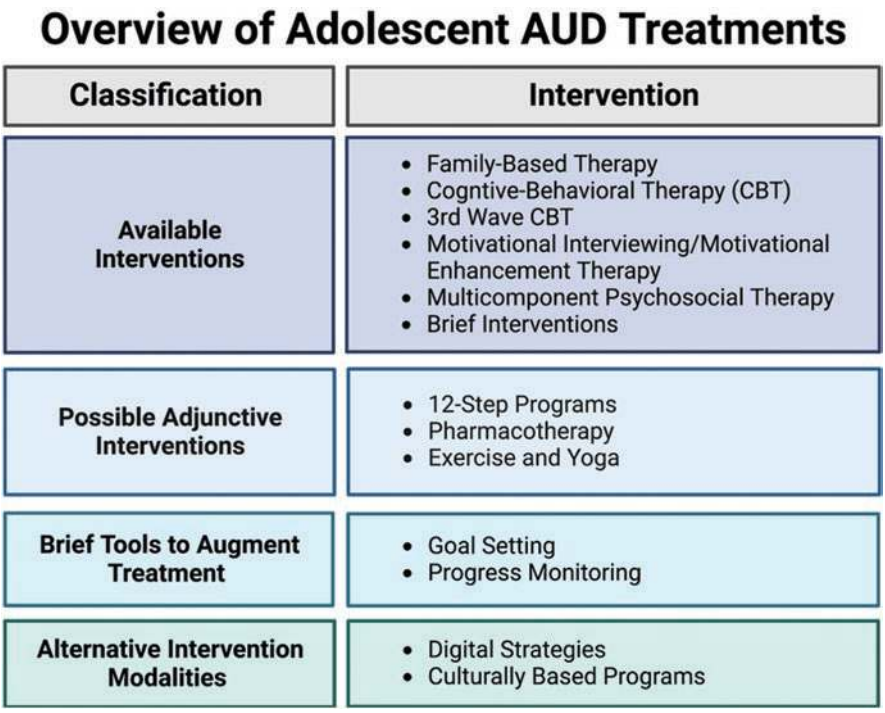

Fig. 18.1 Overview of Adolescent AUD Treatments covered in this chapter. Interventions range from available, possible adjunctive, and alternative modalities. Image made with BioRender

Available Treatments

Family-Based Therapy

Even though adolescence is often a time dedicated to branching away from the family unit and placing more importance on an individual's social circle, family-based therapies are considered first-line standalone interventions for adolescent AUD. Family-based therapies involve the parents or caregivers, as well as siblings. They include Multisystemic Therapy, Multidimensional Family Therapy (MDFT), Functional Family Therapy, Brief Strategic Family Therapy, Ecologically Based Family Therapy, Family Behavior Therapy, Culturally Informed Flexible Family Treatment for Adolescents, and Strengths Oriented Family Therapy [31].

Family-based interventions are effective at increasing attendance and therapeutic alliance [32]. Across all adolescent SUDs, family-based therapy programs were more effective than behavioral therapy, Cognitive Behavioral Therapy (CBT), motivational interviewing/motivational enhancement (MI/MET), psychoeducational therapy, or group counseling [33]. Several systematic reviews and meta-analyses of family-based therapies have been conducted in adolescent alcohol use and

AUD. Universal family-based programs have been shown to be effective (in 9 out of 12 studies) at reducing alcohol use in youth, as compared to control or other interventions, with the post-intervention duration lasting from 2 months to 8 years [34]. This finding was corroborated by a later meta-analysis [35], with both reports indicating small but persistent effects. Conversely, another review of 46 studies found no intervention effect for family-based therapies in comparison to no intervention or standard care on prevalence or frequency of alcohol use in adolescents, nor was there a difference when comparing family/parent interventions to youth-alone interventions [36]. This could be due to the low-quality of evidence included or heterogeneity across studies, either of which will require more studies to parse out any possible effects from family-based interventions on adolescent alcohol use.

Additionally, there are parent-based interventions that focus specifically on the parent as the agent of change [37]. Modifiable parental risk factors (parental provision of alcohol, favorable parental attitudes towards alcohol use, and parental drinking) and protective factors (greater parental monitoring, parent-child relationship quality, parental support, and parental involvement) are longitudinal predictors of alcohol initiation and levels of problematic alcohol use in adolescence and adulthood [38]. Parent-based therapies come in various forms, including programs dedicated to only the parents, joint parent-child programs, or parent programs in association with school-based interventions.

For parent-based therapies, a meta-analysis of 20 alcohol use prevention randomized controlled trials (RCT) in adolescents (up to age 18) found a reduction in their child's overall alcohol use, binge drinking, and drinking intention, with interventions targeting both general and alcohol-specific parenting behaviors having the most effect [37]. However, this meta-analysis excluded studies if the majority of the youth had an AUD as it was focused on preventing or reducing alcohol use. This demonstrates the potential for parent-based therapy to limit early alcohol use, which may be critical for adolescent AUD prevention efforts. More research on the effects on adolescent AUD specifically is needed.

While family- or parent-based interventions may have small effects, there is some data indicating that they may not be superior to individual treatment. Several studies conducted in adolescent SUD have shown well-established efficacy for family-based interventions [32, 39, 40], yet there is little data within adolescent AUD specifically; thus, more evidence is needed within this area before establishing the efficacy of family- or parent-based interventions for adolescent AUD.

Cognitive-Behavioral Therapy (CBT)

CBT is a psychosocial treatment, delivered in either an individual or group format, that is focused on teaching skills (e.g., self-monitoring, identifying triggers, managing cravings, developing communication, and establishing alternative reinforcement contingencies) to modify problematic thoughts and behaviors. Since its emergence in the 1960s, CBT remains a pillar of psychotherapeutic intervention for several mental

health conditions and has some of the strongest empirical support of all evidenced-based psychotherapeutic interventions [41]. The effectiveness of CBT has been examined within adolescent SUD [42], with several studies suggesting CBT is well-established at reducing alcohol and other substance use in adolescents [43]. The strongest evidence thus far for CBT's therapeutic action within adolescent SUD was in combination with brief individual motivational enhancement [44]; however, this study was focused on cannabis use and has not been followed-up in adolescent AUD. Within alcohol use specifically, most of the data assessing the efficacy of CBT within adolescent alcohol use are from older studies (>20 years). CBT targeting personality risk-factors for alcohol misuse found a reduction in drinking rates, drinking quantity, and problematic drinking symptoms as compared to the no-treatment control group in high school students not diagnosed with an SUD [45]. While effects of CBT do not seem to be persistent (<6 months), one study included an integrated family component which sustained the effects on alcohol and cannabis use through the 6-month follow-up period [46]. Overall, there is a dearth of studies specifically investigating CBT as an intervention for adolescent AUD; however, CBT has been generally effective in reducing substance use during adolescence.

3rd Wave CBT

Third wave CBT interventions build on the principles of CBT while focusing on the individual's relationship with thoughts and feelings rather than the content. These methods focus on mindfulness, acceptance and commitment therapy, dialectical behavior therapy, mindfulness-based cognitive therapy, functional analytic psychotherapy, meta-cognitive therapy, and more [47]. Observationally, mindfulness qualities, such as urgency, are associated with reduced lifetime use of alcohol and cannabis in high school students [48]. Mindfulness interventions and their specific components, like urge surfing [49] and brief breath work [50], have improved alcohol outcomes in adolescents and young adult college students [49, 51]. Additionally, three facets of mindfulness (describing, nonjudging of inner experience, and acting with awareness) were negatively related to alcohol outcomes in college students [52]. The reduction of stress may be a mediating factor between mindfulness interventions and alcohol and other substance use [50, 51]. Mindfulness has also been combined with more traditional CBT methods in adolescents, showing a reduction in alcohol consumption as compared to assessment-only control groups. However, adding mindfulness was not superior to CBT alone [53]. Acceptance and commitment therapy (ACT) is another form of CBT that focuses on teaching individuals how to accept difficult emotions and other challenging situations, which has shown efficacy in mental health disorders and adult SUD [54]. Two adult studies have reported ACT as an effective treatment for adult AUD [54], but no studies have been conducted in adolescent AUD. Mindfulness, ACT, and other 3rd wave CBT practices may be useful lines of future research for both adolescent and adult AUD.

Motivational Interviewing/Motivational Enhancement Therapy

Motivational interviewing (MI) elicits behavioral change by targeting ambivalence and enhancing internal motivation, with the goal of helping the patient to recognize their alcohol use problems and encourage self-directed use/problem reduction and/or treatment seeking. Motivational Enhancement Therapy (MET) is similar, but it is delivered in a more structured and manualized manner [39, 55]. MI/MET can be delivered as standalone or adjunctive treatments in primary care or emergency room settings, school-based interventions, or other acute settings. However, these methods may be best suited for younger and less severe populations [39]. This could be due to the source of ambivalence, where younger and less severe populations may have ambivalence towards reducing their substance use, while older and more severe populations may have ambivalence towards engaging in treatment. An older review of MI in adolescents and young adults with substance use problems found an advantage of MI to standard or other care in 29% of studies (5/17), where the person-centered nature of the intervention was identified as a key component for treatment success [56]. Unlike some other treatment interventions, MI/MET have been more thoroughly assessed in adolescent alcohol use specifically. MI has been associated with alcohol-related harm reduction and alcohol consumption [57–60]. One study reported that MI increased motivation and self-efficacy, which in turn decreased the amount an individual intended to drink in the future and increased cognitive dissonance related to heavy drinking [59]. However, a meta-analysis of adolescent SUD treatments found small-to-no effects of MI [30]. The effectiveness of MI/MET may be driven by fidelity [61]. In general, MI/MET may be a useful standalone or adjunctive treatment since it is relatively brief, empathic, and focuses on enhancing motivation and self-efficacy.

Multicomponent Psychosocial Therapy

Multicomponent psychosocial therapy combines treatments, including family therapy, CBT, MI, and contingency management (i.e., using reinforcement and punishment to manipulate substance use) [62]. Currently, MET/CBT and MET/CBT with family-based therapy are the most efficacious combinations for adolescent SUD [32, 39, 40]. The Adolescent-Community Reinforcement Approach (A-CRA), which is a combination of individual therapy, family therapy, and case management, has been found to be comparable in effectiveness as MET/CBT; however, it is more expensive [63]. Combining MI with CBT was effective at increasing the drive to reduce alcohol use, reduce the frequency of alcohol use, and improve the general knowledge surrounding alcohol and its effects, as compared to a control group [64]. Another study looked at the addition of abstinence incentives (contingency management) to individual MET/CBT with weekly behavioral parent training in adolescents with AUD. While the addition of abstinence incentives did not affect the main

outcome of abstinence, it did lower the percentage of days using alcohol as compared to the control group [65]. Contingency management has been popular in the adult SUD literature as a standalone or adjunctive treatment, but, apart from the above study, the current literature in adolescents has been focused on cannabis and nicotine use [62, 66]. Multicomponent therapies may also be beneficial for targeting other consequences of adolescent substance use, like sleep quality and emotional regulation [67]. Taking this multi-pronged approach to treatment may increase the likelihood of treatment success, but it may incur a greater time and monetary cost.

Brief Interventions

Brief interventions, specifically brief motivational interventions (BMIs), have been investigated as a treatment option for emerging adults (ages 18–25) as they are short, flexible, and address motivation to change drinking in a population that may not be aware of their problematic alcohol use or inclined to change such behaviors. They can be administered as standalone or adjunctive treatments. Currently, BMIs are considered a Tier 1 Approach (categorized based on empirical evidence, cost, and relevance to college student drinking patterns) by the National Institute of Alcohol and Alcoholism (NIAAA) according to their College Alcohol Intervention Matrix (AIM) [68]. BMIs include the Brief Alcohol Screening and Intervention for College Students (BASICS) program, which includes normative, personalized feedback on drinking patterns and behaviors and are often delivered using MI style [69]. BASICS and other BMIs have been found to be more efficacious at changing drinking behaviors in college students than no or minimal treatment [70], albeit with small to moderate effect sizes [71, 72]. A scoping review aimed to identify efficacious novel components (e.g., focus on substance-free activities, mindfulness of alcohol cues, or relaxation training) that could be added to BMIs to increase these effects and found that approaches that enhance health and wellness, as an addition to BMIs, may lead to increased help-seeking behaviors in emerging adults [73]. Brief interventions may help to decrease the likelihood of transitioning into problematic alcohol use patterns or future AUD by changing beliefs about and attitudes towards alcohol, and their ease of delivery make them a prime area for future research.

Possible Adjunctive Interventions

12-Step Programs

12-step programs are peer-based mutual-help organizations that aim to provide substance use treatment that is free and community-based. Within adolescent SUD, 47% of treatment programs require participation in a 12-step program during treatment, and 85% of programs recommend Alcoholics Anonymous (AA) or Narcotics

Anonymous (NA) as continuing care options [74]. Attending AA or NA meetings may be a useful addition to other treatment options, with an 8-year prospective study finding an average of 2 days of abstinence associated with each AA/NA meeting attended in addition to inpatient care [75]. A randomized clinical trial tested an adolescent-specific version of an integrated 12-step facilitation treatment (iTSF) against 10 sessions of MET/CBT. There were no differences in percent of days abstinent between treatment groups, but there was greater attendance to iTSF (only at the beginning of the study) which was related to greater abstinence at follow-up [74]. 12-step programs may be best suited in combination with other evidence-based interventions and may exert the most benefit early in treatment and when meetings are specifically designed for adolescents and young adults.

Pharmacotherapy

Adjunctive pharmacotherapies may help increase the effectiveness of psychosocial interventions and improve treatment outcomes. To date, there are no Food and Drug Administration (FDA)-approved medications for adolescent SUD, other than buprenorphine, which has been approved down to 16 years of age for opioid use disorder. Despite alcohol being the most used substance during adolescence, only three medications (i.e., naltrexone, n-acetylcysteine, and disulfiram) have been tested among adolescents who use alcohol, with fairly low sample sizes. See Table 18.1 for an overview of the candidate adolescent AUD medication RCTs (see [81] for a detailed review). More studies are needed to understand how adjunctive medications may improve outcomes for youth struggling with AUD.

Exercise and Yoga

Physical interventions, like general exercise or yoga, have had some recent attention as a possible prevention or adjunctive treatment for adolescent AUD. Exercise may help reduce factors that are barriers to treatment (e.g., lack of social support, poor mental health, stress, boredom) and improve protective factors (e.g., creating a routine, providing alternative activities) [82]. A review of high school students surveyed from 1991 until 2009 found that higher levels of exercise were negatively associated with alcohol, nicotine, and cannabis use; however, higher athletic team participation was related to higher alcohol use [83]. These results should be interpreted with caution as they were observational in nature, leaving room for reverse inference and confounding factors. Another review found exercise was related to improvements in actual alcohol consumption and in intentions to use, knowledge about, and attitudes towards alcohol, but these outcomes dampen with length of follow-up [84]. The majority of these studies were in school settings, with single

Table 18.1 Pharmacotherapy candidate medications investigated with RCT for adolescent AUD

Medication	Reference	Sample	Dosing & comparator	Results
Naltrexone	Niederhofer et al. [76]	N = 30 adolescents with alcohol dependence (ages 15–19)	50 mg/day	Higher rates of abstinence
			Control: placebo	
	Miranda et al. [77]	N = 22 alcohol using adolescents (ages 15–19)	50 mg/day	Decreased drinking & drinking days, craving, subjective response to alcohol
			Control: placebo	
	O'Malley et al. [78]	N = 128 heavy drinking youth (ages 18–25)	25 + 25 mg targeted daily	No effect on heavy drinking days or % days abstinent
			Control: placebo	Decreased number of drinks/drinking day and % of drinking days with BAC >0.8
			Platform: psychosocial	
N-Acetylcysteine (NAC)	Squeglia et al. [79]	N = 116 youth with cannabis dependence (ages 15–21)	2400 mg/day	NAC was associated with less alcohol use
			Control: placebo	
Disulfiram	Niederhofer et al. [80]	N = 26 adolescents with alcohol dependence (ages 16–19)	200 mg/day	Higher rates of abstinence v. placebo
			Control: placebo	

session or multi-session (7–24 weeks) designs. For yoga specifically, one randomized trial found a trend towards decreased alcohol use after 20-sessions of mindfulness yoga as compared to control [85]. The evidence is currently weak for general exercise or yoga as an adjunctive treatment for adolescent AUD. Further, while most of the studies reported would be considered standalone interventions by design, the evidence suggests that this would not be recommended for adolescent AUD treatment and should only be considered as adjunctive at this time.

Brief Tools to Augment Treatment

Goal Setting

Goal setting is meant to promote self-efficacy and effort towards achieving goals, which may translate to positive treatment outcomes. This technique shows that individually selected goals predict long term outcomes in adult AUD [86]. There has only been one study in adolescent substance use, which found goal setting at treatment admission predicted treatment outcomes up to the 24 month follow-up, and

predicted drinking outcomes at 12-months [86]. More research is needed to better understand how this simple tool may impact adolescent AUD treatment outcomes.

Progress Monitoring

As with goal setting, progress monitoring is a relatively simple intervention that relies on periodic and reliable assessments of progress to evaluate and inform treatment. This progress allows clinicians to adapt treatment in real time, which can be beneficial to the adolescent [39]. There is not much research on this approach, but a pilot study showed a decrease in self-reported behavioral and emotional symptoms measured by the Youth-Outcome Questionnaire [87]. Progress monitoring could be easily integrated into various adolescent AUD interventions, which could possibly yield higher treatment effect sizes.

Alternative Intervention Modalities

Digital Strategies

Digital interventions for mental and behavioral health treatments are those designed or adapted to be administered over the computer, web, smartphone app, text-message, or other computerized technology. These strategies, often termed broadly as *mHealth*, *eHealth*, or *telehealth*, are characterized by the rapid or immediate transfer of health information due to the mobility, direct communication, and instantaneous access afforded [88]. Rapid technological advancement has played a key role in expanding the number and type of digital modalities available to deliver intervention content and, thus, the potential to reach broader audiences all over the world [88]. Smartphones in particular have become largely ubiquitous with over 95% of adolescents owning or having access to a smartphone [89].

Relative to traditional in-person approaches, digital-based interventions are perceived as more private and less stigmatizing [39]. This perception is key as concern about stigma has been shown to interfere with substance use treatment seeking [90], which is already low among young people. However, despite these low rates, young people are more likely to agree to participate in remotely delivered interventions than in face-to-face interventions [91]. There is also evidence to support that digital interventions facilitate self-efficacy, as well as motivation, social support, and relapse prevention [39].

Research on the efficacy of digital-based interventions for adolescent alcohol use is mixed, but promising. Methodological differences, such as intervention design, setting, length, outcome measures, and participant characteristics, are a limiting factor in the ability to draw conclusions about digital intervention efficacy for

adolescents with AUD. Additionally, relatively few digital intervention strategies have been developed for and tested with this population. Of those that have been evaluated, there are no clear features that seem to predict efficacy. For example, several interventions incorporate tailored messaging, however, not all are efficacious in decreasing alcohol consumption or related harms [92]. Ultimately, it is not yet clear which modalities or interventions designed or adapted for mHealth may be most efficacious for adolescents, though text-message, or SMS, seems to be the most preferred modality [92].

There are notable challenges to using digital interventions. Although young people are more likely to agree to participate in these types of interventions and some show efficacy in reducing alcohol consumption, face-to-face interventions are more efficacious overall [93, 94]. This may be due, in part, to the level of interaction with intervention material. Most digital interventions are entirely automated. While automation frees-up counselor resources considerably, there is evidence that participants do not fully attend to remotely delivered intervention material and are often preoccupied [95]. Notably, intervention interactivity significantly affects drinking outcomes and this association is mediated by information retention [96]. Thus, this can be a problem for "static" web-based interventions and automated text-message interventions alike if the intervention requires low levels of interaction, regardless of the level of tailoring.

Culturally Based Programs

Marginalized adolescents (including, but not limited to adolescents of color, youth in the LGBTQIA^{+} community, and linguistically minoritized youth) are faced with unique challenges related to substance use treatment, including: the lack of culturally relevant interventions, the short-term effectiveness of various treatment modalities, and the sustained financial and systemic barriers to adolescent treatment. Research and clinical experience suggest that there are meaningful racial differences in treatment response, engagement, and retention regarding substance use treatment [97, 98]. Additionally, there are racial and ethnic differences in specific drugs used, health and legal consequences of drug use, and substance use attitudes for marginalized communities [97, 99, 100]; thus, existing substance use treatments validated with homogenous, predominantly white U.S. samples are inadequate and cultural adaptations of substance use interventions are needed.

Cultural adaptation is defined as systematic modifications to an evidence based intervention by introducing culturally relevant components, while maintaining the core components of the generic intervention [97, 101]. In short, changes are made to an intervention to accommodate the needs of a target population [101]. During the cultural adaptation process, values, norms, and attitudes of the target population are considered or incorporated into the culturally adapted version of the evidence-based intervention, making treatment more relevant to marginalized populations. Culturally adapted interventions also provide necessary opportunities to address the

social, cultural, and contextual issues associated with substance use that may often be experienced by marginalized populations. There are various frameworks and extents to which modifications can occur, ranging from preferred language and clothing to culturally meaningful metaphors and matching clinicians with patients based on race [98].

Successful culturally adapted substance use interventions include Strong African American Families (SAAF), a preventive intervention to deter alcohol use among rural African American adolescents [102]. SAAF's structure was informed by the Strong Families Program [103]. During the design process, SAAF authors used data collected from their research with rural African American communities in the lower southern region of the United States to design a culturally and ecologically sensitive program. Data from this study demonstrated that fewer SAAF participants initiated alcohol use compared to the control group and those who used alcohol increased their use at a slower rate over time in areas where there are few mental health, substance use, and prevention programs. Strengthening Families Program (SFP), an evidence-based family skills training intervention developed and found efficacious for substance use prevention in the 1980s, has been culturally adapted across the U.S. for African, Hispanic, Asian, Pacific Islander, and Native American populations. Since 2003, the intervention has been culturally adapted for use in 17 countries and has been found to be twice as effective as school based alcohol prevention programs [104]. Without the culturally adapted version of various evidence-based interventions, there would likely be a large population of diverse and marginalized youth whose unique challenges with substance use would go unseen and unaddressed.

Discussion

As reviewed within this chapter, there are many available interventions, possible adjunctive treatments, and alternative intervention modalities for adolescents with AUD. A vital step in tackling adolescent problematic alcohol use and AUD is to find quality, evidence-based interventions. In the United States, this can be done through visiting the NIAAA treatment navigator (https://alcoholtreatment.niaaa.nih.gov) or by reading the Substance Abuse and Mental Health Services Administration (SAMHSA) document on this topic [105]. SAMHSA lists the five signs of quality as follows: accreditation, medication (applicable to adult SUDs with FDA-approved pharmacotherapy options), evidence-based practices, inclusion of family, and ongoing support.

There are several obstacles to adolescent AUD treatments. First, alcohol and other substance use is considered a normal part of adolescence in many cultures around the world. This can make it difficult for individuals to recognize when their drinking behaviors may be entering into problematic use or AUD territory, which will reduce the likelihood of receiving help and subsequently increase their likelihood of a lifelong struggle with AUD [22]. MI/MET and brief interventions that incorporate personalized feedback may be the most useful tools in this

situation, as they target ambivalence and provide normative drinking data for comparison. Further, the brief and non-judgmental nature of MI/MET may make it more appealing to adolescents and emerging adults [56, 73]. Second, there is a lack of agreement surrounding the appropriate outcomes for research studies. Specifically, there is concern over whether abstinence-based outcomes are in fact the best goals [106]. Abstinence-based outcomes may conflict with some newer interventions, such as personal goal setting, which allows the adolescent to be in control of their treatment goals. Previous research has shown that a reduction in the WHO risk level for alcohol consumption is a valid and reliable non-abstinent based target for adult AUD, and a reduction of at least two levels is now an acceptable European Medicines Agency (EMA) endpoint for adult AUD pharmacotherapy trials [107]. A study of adolescents with a SUD and comorbid ADHD found that a two-level reduction in the WHO drinking risk level after treatment with CBT and pharmacotherapy (specifically for ADHD) was associated with improvements in general functioning and ADHD symptoms [107]. Thus, even a reduction in alcohol consumption during adolescence could have positive lifelong implications for SUD and other comorbid symptoms. Third, co-morbidities (e.g., anxiety and depression) and substance co-use (e.g., cannabis and nicotine) are the rule, not the exception, in adolescent AUD [14, 15, 108]. Effective interventions will need to take an integrative approach to provide treatment for and beyond adolescent AUD. Fourth, there is a large gap between the number of adolescents who need care and those who receive care, with SAMHSA reporting that 5% of teenagers and 15% of young adults need treatment for AUD but less than 1% receive it. Compounding this problem is access to care, where those who did receive care were more likely to be older in age and white [109]. Location is also a contributing factor to access to care. Rural adolescents are more likely to report alcohol and other substance use than their urban peers [110], yet such regions have fewer health providers and intervention options. Other barriers to treatment include traditional clinic hours that may limit treatment for families that do not have flexibility during the day or (in countries without universal healthcare) trouble with insurance coverage (which may be worsened by other co-occuring disorders). Digital strategies may be useful for overcoming some of these barriers, as they reduce some of the burden to receiving evidence-based and high-quality treatment [111].

There is still much room for improvement as the psychosocial interventions have only been modestly effective, with one-third to one-half of youth returning to alcohol or other substance use within 12 months of treatment [30, 33]. While several medications have been efficacious in treating adult AUD, pharmacotherapy research focused on adolescent alcohol use has been sparse [77]. As such, evaluation of alternative and more efficacious treatments for adolescent AUD is warranted.

Chapter 19
Transcranial Magnetic Stimulation in Addiction Therapies

Angela Sanna and Marco Diana

Abstract Alcohol use disorder (AUD) is a chronic, relapsing disease, associated with high morbidity and mortality, and a high prevalence worldwide. Pharmacological and behavioral interventions to treat AUD are not satisfactory and the majority of patients display poor adherence to therapy and a high rate of relapse. Among the non-pharmacological treatments for AUD, repetitive transcranial magnetic stimulation (rTMS) has shown therapeutic potential in promoting abstinence due to its ability to modulate neural plasticity. Preclinical and clinical evidence has shown that a boost of dopamine transmission plays an important, but not exclusive role in mediating the long-lasting effect of rTMS. Nevertheless, despite several reports showing the efficacy of rTMS in treating AUD, a standard protocol that may be desirable in clinical practice is still lacking, due to heterogeneity of protocols and variability in response to rTMS. Ongoing research is exploring new neurophysiological biomarkers to further elucidate the mechanism of action of brain stimulation and to better select patients who may benefit from rTMS.

Keywords Alcohol use disorder · Transcranial magnetic stimulation · Addiction

Introduction

Substance and behavioral addictions are chronic medical illnesses causing important social and health harm [1]. Among these, alcohol use disorder (AUD) has a high prevalence worldwide which varies depending on socioeconomic and cultural

factors, reaching high rates in European countries, and is associated with high morbidity and mortality [2]. AUD has a multifactorial etiology including a genetic predisposition [3] and is comorbid with other psychiatric disorders, such as antisocial personality disorders, major depression, anxiety, and post-traumatic stress disorder [4]. As for other addictions, AUD may be explained by the so-called "addiction cycle" [5], characterized by compulsive alcohol seeking and intake, the failure to limit alcohol intake, and the emergence of a negative emotional state when alcohol is not available. These behavioral features have been described for different addictions, regardless of the specific mechanism of action of the drug. It reflects complex neuroplastic changes in the addicted brain that lead to an excessive function of limbic areas, along with reduced activity of the prefrontal cortices, together sustaining the addiction cycle [6].

In this composite framework, dopamine is considered a *top player* in each step of the addiction cycle [7, 8]. The hypodopaminergic hypothesis of drug addiction states that an altered dopamine transmission is a hallmark of the addicted brain [8]. Indeed, preclinical and clinical evidence shows an altered mesocortical limbic dopamine transmission during binge intoxication, withdrawal, and anticipation in SUD and AUD [8–10]; in addition, preclinical evidence showed that dopamine can reverse morphological and functional changes in the brain of alcohol-abstinent rats [11]. Likewise, in humans, PET studies have shown that alcohol dependence is associated with a blunted dopamine transmission [12] and that dopamine levels remain low in the brain of detoxified alcoholics [13], which may be considered a marker of vulnerability to relapse. Along with PET studies, quantitative electroencephalography (qEEG) and functional magnetic resonance (fMRI) have further clarified the complex maladaptive changes in the addicted brain during the last decade. Neurophysiological measures such as event-related potential (ERP), brain rhythm oscillation, and brain graph analysis have revealed altered connectivity in the brain of AUD patients, and have been proposed as biomarkers of vulnerability to drug addiction and as tools to monitor the progression of the disorder and the efficacy of therapy [14]. Moreover, fMRI studies in AUD confirmed an altered connectivity in the fronto-striato-parietal network and showed the need to recruit a larger neuronal activation to promote an inhibitory response to alcohol-related stimuli [15, 16]. Taken together, these observations support the concept that AUD, and SUD in general, are chronic disorders characterized by an altered functionality of large interconnected brain networks modulating several behavioral features.

Treatment of AUD is challenging and the pharmacological armamentarium is limited. Disulfiram, acamprosate and naltrexone are currently approved for patients with moderate-to-severe AUD. Other medications, such as gabapentin and topiramate, are approved for other indications, but can be used off-label in moderate to severe AUD [17]. Drugs acting on dopamine transmission such as aripiprazole have been evaluated, but efficacy has not been supported [18]. Behavioral interventions are currently employed for for treating AUD [19] but, as with other SUD and BA, AUD patients display poor adherence to therapy and a high rate of relapse.

Among the non-pharmacological treatment for AUD, repetitive transcranial magnetic stimulation (rTMS) holds a therapeutic potential in promoting abstinence, presumably due to its ability to modulate neural plasticity.

TMS Fundamentals

TMS is a non-invasive brain stimulation (NIBS) technique, introduced by Barker in 1985 to probe motor cortex functionality [20], through the electromagnetic induction of an electric field in the brain. Applied in this manner, it continues to be a valuable diagnostic tool, e.g., in neurosurgical practice to allow preoperative evaluation. When delivered in a repetitive fashion, rTMS can modulate neural plasticity producing objective neurobiological changes and therapeutic effects in several psychiatric and neurological disorders [21]. Indeed, rTMS may exert excitatory or inhibitory effects in the underlying cortex; for the so-called conventional protocols frequencies ≥5 Hz (high frequency, HF) are considered excitatory, while frequencies ≤1 Hz (low frequency, LF) produce inhibitory effects. Further, the relatively new "*patterned*" protocols apply short rTMS bursts at a high intraburst frequency interleaved by short pauses of no stimulation [22, 23]. Among these, theta-burst stimulation (TBS) protocols are characterized by short bursts of 50 Hz (within bursts) repeated at 5 Hz (between bursts) as a continuous (cTBS), or intermittent (iTBS) train [24]. TBS protocols, inducing long-term potentiation (LTP) and long-term depression (LTD) at the synaptic level, are commonly used to probe motor cortex excitability [25]. Moreover, rTMS protocols typically have a short duration, and are widely used in clinical practice for therapeutic purposes in several psychiatric and neurological disorders to reduce patient discomfort [21, 25]. The mechanism of action of rTMS, not completely elucidated, involves neurotransmitter release, modulation of gene expression, synaptic long-term potentiation, and depression, acting together to induce persisting neuroplastic changes in the stimulated spot and distant anatomically interconnected areas, thus modulating the activity of entire brain networks [26, 27].

rTMS in SUD and AUD

Despite several reports showing the efficacy of rTMS in treating addiction [28, 29], heterogeneity of rTMS protocols among different studies has hindered the attainment of a standard protocol that may be desirable in clinical practice. An international group of investigators with expertise in neuromodulation and addiction research (international network of tES/TMS trials for addiction medicine-INTAM) has been assembled to provide ongoing review of the evidence for NIBS in SUD and to provide appropriate guidelines regarding protocols, measures of outcome, and future directions [28]. According to the aforementioned addiction cycle, rTMS

approaches are directed either to enhance prefrontal cortex activity with LTP enhancing protocols or to decrease the excessive functionality of the limbic system with LTD-inducing ones [30]. Indeed, for different purposes, brain areas are chosen as a target for rTMS according to their accessibility (cortical areas), their role in modulating a specific behavioral and/or cognitive function, and their connectivity with other brain networks [31]. From this point of view, prefrontal cortical areas, and dorsolateral prefrontal cortex (DLPFCX) in particular, are common targets of rTMS due to their role in modulating executive functions and their connections with temporal, parietal, and deep limbic areas, involved in cognitive and behavioral functions [32, 33].

LTP-inducing protocols (HF and iTBS) have been applied to either right [34–40] or left [41–44] DLPFCX (Fig. 19.1) showing efficacy in reducing alcohol craving and consumption as well as ameliorating behavioral features and comorbid depression, but the results are inconsistent and controversial, parameters of stimulations vary among different studies and no superiority has been found between left or right DLPFC stimulation.

An interesting approach is the use of deep TMS, which employs a Hesed-coil (H-coil) able to provide a bilateral, deeper non-focal stimulation of the PFC [45]. The rationale for using H-coil derives from the view that addiction may be considered a *whole brain* disease, with plastic alteration in different brain areas of both hemispheres, influencing several behavioral features involved in drug dependence [7, 46]. Indeed, dTMS has shown efficacy in reducing alcohol craving and consumption [47–51] and reducing associated depressive symptoms and anxiety [50, 51].

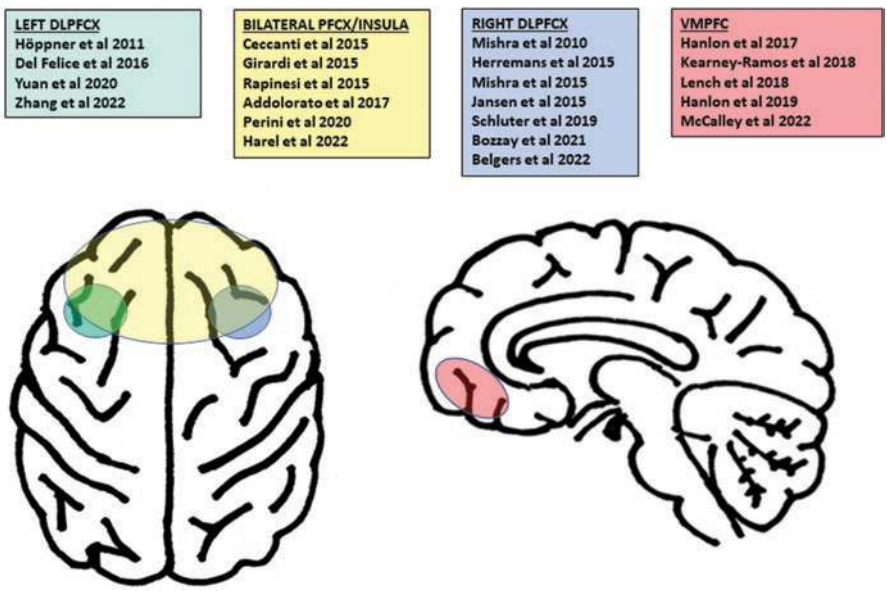

Fig. 19.1 Schematic representation of target regions and related studies for the application of rTMS to treat AUD

Another approach in neuromodulation employs LTD-inducing protocols (LF and cTBS) targeting the ventromedial prefrontal cortex (VMPFC) to inhibit the excessive limbic activation in addiction [30]. Indeed, the inhibitory stimulation of VMPFC can decrease cue-induced craving in CUD and AUD [52–56] while, if applied to DLPFCX, would impair inhibitory control and subsequently increase alcohol drinking [57, 58].

Additional brain areas are currently studied as brain targets for neuromodulation, with particular interest to those involved in the so-called *salience network* (i.e., insula), due to its role in regulating behavioral responses to external stimuli [57]. Early observations have shown that patients carrying an insular lesion quit nicotine addiction [59]; moreover, recent resting state [60] and brain lesion [61] functional connectivity studies have shown an altered functionality of insula in addiction which suggests its use as a target in neuromodulation techniques. Nonetheless, while early studies have shown encouraging results for using insula as a potential target for stimulation in nicotine [62] and cocaine dependence [55], no effect was observed in alcohol craving and consumption with respect to sham stimulation when an HF protocol was applied targeting bilateral insula with dTMS [63]. It is noteworthy that authors of this study employed the same protocol used for nicotine addiction [62] that targeted bilateral PFC and insula; indeed, although no difference was found in alcohol craving and intake between real and sham rTMS, a significant effect induced by rTMS on resting state insula connectivity emerged, suggesting that a concomitant stimulation of PFC and insula may be required to obtain a behavioral effect on alcohol consumption. Moreover, since both LTD and LTP-inducing protocols have been used with controversial results, the role of the insula as a target for neurostimulation is still an object of debate and needs further research [57].

The Role of Dopamine in the Therapeutic Effect of rTMS in AUD

Despite evidence supporting the therapeutic potential of rTMS in several neurological and psychiatric conditions [21, 28], the precise neural mechanism underlying its efficacy is not fully elucidated. As mentioned before, the effect is pleiotropic, involving modulation of synaptic plasticity and neurotransmission [64], which ultimately influence the activity of different brain networks thought to modulate specific brain functions [65]. Preclinical and clinical studies have shown that rTMS applied to frontal and prefrontal areas can induce a release of dopamine in other cortical and subcortical areas [66–69]. These data suggest the ability of rTMS to exert its effects, not only in the stimulated area, but also in distant interconnected areas (see [70] for further details); furthermore, this evidence pinpoints to the role of dopamine as an important effector of rTMS action.

Considering the aforementioned pivotal role of the blunted dopamine transmission in the genesis and maintenance of the addiction cycle, the increase of dopamine induced by rTMS may be considered a biomarker to be subjected to rigorous

experimental scrutiny [7, 71]. This assumption has been confirmed by preliminary SPECT studies showing a decrease in dopamine transporter (DAT) availability in striatal regions following rTMS in pathological gambling [72] and AUD [48], which would reflect an increased dopamine transmission in the mesolimbic-cortical circuits. Another study by Ceccanti and coauthors [47] has shown a decrease in serum prolactin and cortisol along with a reduction in craving and number of drinks per day, following HF deep rTMS applied bilaterally to the DLPFCX of patients with AUD. Prolactin and cortisol serum levels, in turn, reflect the hypothalamic-pituitary-adrenal axis activation, which is over-functioning during withdrawal [6, 8], and prolactin is an indirect marker of dopamine transmission [73]. Accordingly, reduction of prolactin serum levels suggests increased brain dopamine levels. These data, although preliminary, support the hypothesis that a boost of dopamine transmission is one of the core mechanisms of the rTMS therapeutic effect [70]. Importantly, however, dopamine should not be seen as a single player accounting for the therapeutic effect of rTMS in addiction, and other neurotransmitters such as glutamate, are equally involved in inducing the long-lasting plastic changes exerted by rTMS [74, 75].

Future Directions and Conclusions

Evidence on rTMS therapeutic potential in alcohol addiction is encouraging, but results are controversial and the heterogeneity of methods and stimulation areas does not allow for extrapolating a standardized protocol that may be used in clinical practice. Response to rTMS is variable [76], making it necessary to find reliable biomarkers to monitor the neuroplastic changes underlying the therapeutic effect. In the last decade studies on brain connectivity with fMRI and qEEG have shown that behavioral responses to rTMS correlate with changes in brain EEG rhythms [44], resting-state connectivity [77], and grey matter volume [78]. These ongoing observations will help to further elucidate the mechanism of action of brain stimulation and to increase the arsenal of available suitable biomarkers to select patients who may benefit from brain stimulation.

Chapter 20
The Clinical Benefits of Non-abstinent Outcomes in Alcohol Use Disorder Treatment: Evidence from Clinical Trials and Treatment Implications

Victoria R. Votaw and Katie Witkiewitz

Abstract Abstinence from alcohol has historically been the focal endpoint in clinical trials evaluating alcohol use disorder treatment, yet more recent work has provided compelling evidence that drinking reductions, short of total abstinence, are achievable, stable, and associated with improvements in how individuals with alcohol use disorder feel and function over time. A growing body of literature has examined the achievability, sensitivity to treatment effects, stability, and clinical benefits of the non-abstinent outcomes suggested by the Food and Drug Administration and European Medicines Agency. This chapter aims to review this evidence from clinical trials and discuss the implications for alcohol use disorder treatment. The reviewed body of literature indicates that non-abstinent goals, including no heavy drinking, reduction in World Health Organization risk drinking levels, and non-consumption outcomes (e.g., craving), are more achievable than abstinence, sustainable over long periods following treatment, and associated with clinical benefits, such as reductions in the physical and psychosocial consequences of drinking and improved mental health and quality of life. Overall, the reviewed literature supports the feasibility of drinking reduction goals and broader non-consumption functional outcomes in clinical practice.

Introduction and Background

Abstinence from alcohol has historically been the focal endpoint in clinical trials evaluating alcohol use disorder (AUD) treatments [1, 2], which reflects the broader discourse surrounding AUD etiology and treatment. The dispositional disease model of addiction suggests that addiction is a "disease" confined to a small proportion of the population who are "powerless" over alcohol, thus necessitating complete abstinence to prevent excessive alcohol consumption and consequences [3–5]. The disease model of addiction had a pervasive influence on AUD treatment in the United States (U.S.) and Europe to a somewhat lesser extent [6]. Most notably, the disease model of addiction influenced the 12-Step Model of Alcoholics Anonymous (A.A.), which is readily accessible and free worldwide [7]. There are some benefits to abstinence as a primary outcome in AUD clinical trials. For example, abstinence is easy to quantify, potentially less prone to recall bias, and sensitive to biomarkers of alcohol consumption, such as phosphatidylethanol (PEth), a direct alcohol biomarker, and the liver enzyme γ-glutamyltransferase (GGT) [8]. Nevertheless, requiring alcohol abstinence in AUD treatment is based on an outdated understanding of AUD etiology, heterogeneity, and diagnosis [1, 9], and there are also costs of a sole focus on abstinence as an outcome in AUD treatment and clinical trials with respect to efficacy of interventions (most reduce drinking and few achieve abstinence) [10] and patient goals (most prefer drinking reduction) [11].

The purpose of clinical trials for AUD treatment is often to evaluate novel interventions but evaluating abstinence alone might preclude the identification of potentially effective interventions. If an endpoint required by regulating bodies is too challenging to meet, the pharmaceutical industry might be unwilling to spend resources pursuing medications development [9, 12]. Furthermore, mechanisms of action of select psychotherapies and pharmacotherapies might be better suited, or equally well suited, to drinking reduction than abstinence. For example, cognitive-behavioral treatments for AUD often provide skills to reduce excessive alcohol consumption once drinking has been initiated (e.g., setting drink limits) [13, 14]. Specific pharmacotherapies (e.g., naltrexone) have also demonstrated reductions in drinking intensity, but not abstinence, which is consistent with the mechanisms of these medications, to reduce the reinforcing properties of alcohol, including during acute alcohol consumption [15–17].

Not only is abstinence often inconsistent with the proposed mechanisms of AUD treatment, but it is inconsistent with patients' goals for treatment. There is a significant treatment gap for those with alcohol use disorder (AUD) in the U.S. and Europe [18, 19], and not being ready to stop drinking is a reason for not entering treatment

[20, 21]. Indeed, high rates of individuals entering treatment report drinking reduction as a goal [5, 22]. Surveys of individuals in recovery indicate that non-consumption outcomes, such as quality of life, substance use reduction, and meeting basic needs, are the most important outcomes [23]. Providers who treat patients with AUD are also more concerned with quality of life as an outcome than abstinence [24].

There is also growing acceptance of non-abstinent (i.e., moderated) drinking outcomes among various stakeholders, including the scientific community and treatment providers. Guidelines for AUD treatment in several countries support drinking reduction goals [25, 26], and the NIAAA definition of recovery emphasizes remission from AUD, cessation of heavy drinking, and functional outcomes [27]. Recent surveys with treatment providers indicate that greater than half reported moderated drinking as an acceptable treatment outcome [28], with greater support in Australia and Europe than in the U.S. and Canada [29]. These shifting viewpoints on acceptable AUD treatment outcomes extend to AUD clinical trials. A recent review of AUD pharmacotherapy trials indicates more recent trials were far more likely to report reduced consumption as an outcome than prior trials [30].

The increased acceptance of non-abstinence outcomes is mirrored in recent changes to endpoints supported by the U.S. Food and Drug Administration (FDA) and European Medicines Agency (EMA) to approve medications for AUD. In their approval of Vivitrol® (i.e., extended-release injectable naltrexone) in 2006, the FDA defined the percent of subjects with no heavy drinking days (4+/5+ for women/men; [31]) as the primary endpoint of Phase 3 alcohol pharmacotherapy trials to receive approval for a New Drug Application [32, 33] and this was solidified in later reports [34]. Recently, the European Medicine Agencies [35] also explicitly outlined the following endpoints, including non-abstinent endpoints: i) Continued abstinence after detoxification or the medication "grace period" (i.e., the time over which the medication is expected to begin exerting effects), ii) reductions in total alcohol consumption (grams of ethanol) and heavy drinking days (40+/60+ grams of alcohol for women/men), and iii) the proportion of subjects with a significant shift in World Health Organization (WHO) risk drinking levels, which is defined as a 2-level shift or greater (see Table 20.1 for a description of WHO risk drinking levels).

A growing body of literature has examined the achievability, sensitivity to treatment effects, stability, and clinical benefits of the non-abstinent outcomes suggested by the FDA and EMA and other non-abstinent outcomes. This chapter aims to review this evidence from clinical trials and discuss the implications for AUD treatment.

Table 20.1 Overview of the advantages and disadvantages of consumption, non-consumption, and composite outcomes used in alcohol use disorder clinical trials

Outcome		Definition	Advantages	Disadvantages
Consumption outcomes	Abstinence	Continued abstinence from alcohol over a specific period, including the entire treatment period, the last month of treatment, or following a medication's "grace period" over which it is expected to exert effect	• Easy to quantify	• Difficult to attain and pharmaceutical companies might be unwilling to pursue medications development
			• Potentially less prone to recall bias	• Inconsistent with the mechanisms of some medications and psychosocial treatments that target reduced drinking
			• Sensitive to biomarkers	• Inconsistent with the goals of many patients interested in drinking reduction, reduced consequences, and improved quality of life
				• May serve as a barrier to treatment seeking
	No Heavy Drinking Days	Absence of heavy drinking days (4+/5+ drinks for men/women) over a specific period, including the entire treatment period, the last month of treatment, or following a medication's "grace period" over which it is expected to exert effect	• Higher achievement rates than abstinence	• Does not perform better than other arbitrary drinking cutoffs
			• As sensitive to active treatments as abstinence and other commonly assessed outcomes (e.g., drinking consequences)	• Ignores the linear nature of the association between level of alcohol consumption and psychosocial functioning/findings that any reductions in drinking are associated with improved functioning
			• Appears to be sustainable up to 1 year following treatment	• Less sensitive to active treatments than continuous outcomes, such as percent heavy drinking days
			• Concurrently and prospectively associated with lower alcohol consumption/ consequences, greater physical/mental health, and lower healthcare costs than any heavy drinking	• Ignores body weight and different effects of differing number of drinks depending on body weight
				• International comparisons are difficult given differing standard drink definitions across countries

	WHO Risk Drinking Levels	A 1- or 2-level decrease in the following risk levels from baseline to the last 4 weeks of treatment:	• An interpretable framework for clinicians and regulation agencies to evaluate drinking reductions	• Cutoffs limit variability in outcomes and continuous outcomes (e.g., percent heavy drinking days) may be more sensitive to treatment effects
		• Abstinence: 0 g of ethanol or standard drinks[a]/day for both males and females	• Higher achievement rates than abstinence and no heavy drinking days	• Sensitive to treatment effects has primarily been examined for medications/unclear if WHO risk levels are sensitive to active psychosocial treatments
		• Low risk: 1–40 g ethanol/day or > 0–2.86 standard drinks/day for males; 1–20 g ethanol/day or >0–1.43 standard drinks/day for females	• Sensitive to active treatment effects; in some cases, more sensitive than abstinence and no heavy drinking days	• Validation studies are needed in more diverse patient populations, including those outside of the U.S. and the U.K. and those with co-occurring psychiatric disorders
		• Medium risk: 41–60 g ethanol/day or 2.87–4.29 standard drinks/day for males; 21–40 g ethanol/day or 1.44–2.86 standard drinks/day for females	• High stability rates up to 3 years post-treatment	
		• High risk: 61–100 g ethanol/day or 4.30–7.14 standard drinks/day for males; 41–60 g ethanol/day or 2.87–4.29 standard drinks/day for females	• Reductions in risk levels are concurrently and prospectively associated with improved mental health outcomes, quality of life, physical health outcomes, and reduced alcohol consequences	
		• Very high risk: ≥101 g ethanol/day or ≥7.15 standard drinks/day for males; ≥61 g ethanol/day or ≥ 4.30 standard drinks/day for females	• Findings consistent across those with mild/moderate/severe alcohol dependence and those with any drinking and abstinence at the end of treatment	

(continued)

Table 20.1 (continued)

Outcome		Definition	Advantages	Disadvantages
Non-Consumption outcomes	Alcohol Temptation/ Craving	Various measures of the strength and/or frequency of alcohol temptation/craving have been used, including the Alcohol Abstinence Self-Efficacy Scale, the Obsessive-Compulsive Drinking Scale, and a single item measure (not at all tempted to drink vs. a little, somewhat, considerable, extremely tempted to drink), during treatment and post-treatment	• Consistent with conceptualizations of the etiology of AUD and DSM-5 AUD criteria	• Limited research on sensitivity to active treatment effects
			• Sensitive to change from pre- to post-treatment	• Less sensitive to change from pre- to post-treatment than alcohol consumption outcomes
			• Alcohol temptation/craving during and post-treatment predicts long-term alcohol consumption/consequences	
			• Demonstrated validity of a practical, single-item, binary measure	
	Alcohol Consequences	Measured with the Drinker Inventory of Consequences at post-treatment, which assesses the frequency of physical, interpersonal, intrapersonal, impulse control, and social responsibility consequences from alcohol use	• Reflected in DSM-5 AUD criteria	• Inconsistent associations with longer-term consumption outcomes
			• Consistent with patients' desires to reduce harmful alcohol use in treatment	• Some evidence indicating poor psychometric properties of the Drinker Inventory of Consequences
			• Consistent with the mechanisms of treatment (e.g., a treatment might promote safer drinking, without necessarily reducing consumption)	
			• Sensitive to active treatment effects	
			• Demonstrate similar pre- to post-treatment effect sizes as consumption outcomes	
	Quality of Life	Many measures of quality of life are available, though the World Health Organization Quality of Life measure (WHOQOL-BREF) at post-treatment was used in the reviewed literature	• Of all outcomes, most aligned with patients' and providers' goals in AUD treatment	• Mixed findings on sensitivity to active treatments—has not been sensitive to topiramate treatment effects
			• Sensitive to improvements from pre- to post-treatment	• Limited research on the predictive validity for long-term alcohol use and functioning outcomes
			• Sensitive to active treatment effects in naltrexone and nalmefene trials	• Many measures of quality of life available and used, rendering comparisons across studies difficult

Composite outcome	A composite of alcohol consumption and consequences (measured with the Drinker Inventory of Consequences), resulting in four categories: (1) abstinent, (2) moderate drinking without problems, (3) heavy drinking or problems, and (4) heavy drinking and problems; categories 1 and 2 are considered remission	• Higher achievement rates than abstinence	• Limited research on the predictive validity for long-term alcohol use and functioning outcomes
		• Concurrently associated with alcohol consumption, mental health, social support, employment, and purpose in life, with those in the remission categories reporting better outcomes than those with heavy drinking and/or problems	• Limited research on sensitivity to active treatment effects
			• Evidence that group 3 (heavy drinking or problems) is not reliably different than those in the remission categories on functioning

[a]Standard drinks = 14 g of alcohol

Non-abstinent Endpoints in AUD Clinical Trials

No Heavy Drinking Days ("Low-Risk Drinking")

Given that the FDA has identified the percentage of participants with no heavy drinking days (NHDD) at the end of treatment, also called "low-risk drinking," as an endpoint for Phase 3 alcohol clinical trials, recent research has examined the achievability, sensitivity to treatment effects, stability, and clinical benefits of this outcome.

Advantages

In an initial examination, Falk and colleagues [32] combined data from two clinical trials—the COMBINE study, in which participants in the U.S. were randomized to nine treatment conditions (i.e., placebo, acamprosate, and/or naltrexone in combination with Medical Management, with or without a combined behavioral intervention) and a placebo-controlled trial of topiramate in combination with motivational enhancement—and showed that NHDD was substantially more achievable than abstinence. In COMBINE, which required a period of abstinence before randomization, 44.0% of participants who received naltrexone reported NHDD during the last 2 months of treatment, and 31.1% reported abstinence. Abstinence was not required before randomization in the topiramate trial, and 13.6% of participants who received topiramate reported NHDD during the last 2 months of treatment, compared with 5.6% who reported abstinence. The effect sizes for active interventions compared to control conditions on NHDD were similar to the effect sizes for abstinence and other commonly-assessment outcomes (e.g., drinking consequences, percent days abstinence) [32].

The NHDD outcome also appears to be relatively stable across long-term follow-ups. Another analysis conducted by Witkiewitz and colleagues [36] used data from the COMBINE study to identify two latent groups of participants during treatment, those with a high probability of NHDD and those with a high probability of at least some heavy drinking days, and the stability of these groups over three times: during treatment, the 3 months immediately following treatment, and 1 year after treatment. This analysis showed transitioning from the NHDD group to the group with some heavy drinking days was the highest in the first month of treatment (14.3%), but after treatment more than 90% of individuals remained in the NHDD group up to 12 months following treatment.

Achieving low-risk drinking has also demonstrated clinical benefits. In the COMBINE trial, participants with NHDD during the last 2 months of treatment reported significantly lower alcohol consumption and consequences immediately and 1-year post-treatment than those with any heavy drinking [32]. In the same

study, abstainers reported significantly lower drinking intensity and consequences post-treatment than low-risk drinkers (i.e., non-abstinent and NHDD), but there were few differences between these two groups in drinking intensity and consequences over the 1-year follow-up period [32]. Additionally, low-risk drinking during treatment and 6 months following treatment was prospectively associated with better mental and physical health outcomes over long-term follow-ups (i.e., 1–3 years post-treatment) than heavy drinking in several clinical trials, including COMBINE, Project MATCH (i.e., U.S. trial with three psychosocial intervention conditions), the United Kingdom Alcohol Treatment Trial (UKATT; i.e., trial with two psychosocial intervention conditions), and two trials conducted in a large, private, nonprofit integrated health care delivery system in the U.S [37–39]. Lastly, those with NHDD during the last month of treatment have been found to have lower healthcare costs over the year following treatment than those with any heavy drinking [40]. Those with NHDD 6 months following treatment also have lower inpatient and emergency department utilization over the 5 years following treatment than those who engaged in some heavy drinking [41].

Disadvantages

The NHDD outcome also has several limitations. Perhaps most notably, there is strong evidence for a linear association between alcohol consumption and functioning, indicating that any reductions in alcohol consumption represent improvements [2, 42, 43]. Indeed, individuals above "low-risk drinking" cutoffs still demonstrate substantial reductions in drinking [36], and there is significant heterogeneity concerning psychosocial functioning within individuals with some heavy drinking, who are typically considered a homogenous group of "failures" [44]. Similarly, some heavy drinking during treatment is still associated with better long-term alcohol consumption, physical/mental health outcomes, and healthcare costs than persistent heavy drinking [37, 38, 40]. Given these concerns, previous analyses have compared alcohol consumption cutoffs and shown that various cutoffs do not perform better than each other in predicting end-of-treatment and 1-year post-treatment alcohol consumption and consequences, indicating the 4+/5+ definition is arbitrary [45] and that the "ideal" cutoff for maximum drinks for greatest sensitivity and specificity in predicting drinking consequences was substantially higher than current heavy drinking definitions [46]. NHDD also ignores differences in body weight (e.g., five drinks for a man who weighs 300 lbs. or 136 kg versus a man who weighs 150 lbs. or 68 kg will have considerably different effects on health and functioning) and makes international comparisons difficult given differences in standard drink sizes across countries (8 g in the UK to 20 g in Austria). Lastly, NHDD is less sensitive to active treatment effects and more susceptible to inaccuracies in standard drink estimations during data collection than continuous outcomes, such as percent heavy drinking days [47].

World Health Organization Risk Drinking Level Reductions

Reductions in drinking intensity (e.g., drinks per day/drinks per drinking day, total alcohol consumption) are commonly reported in alcohol clinical trials, but the WHO risk levels attempt to formalize these reductions to provide an interpretable framework for clinicians and regulation agencies [42]. In recognizing these formalized cutoffs, the EMA recently recognized a 2-level reduction or greater (e.g., from very high risk to medium risk; see Table 20.1) as an endpoint in alcohol clinical trials for medication development. Accordingly, there has been a proliferation of recent research validating the WHO risk level reductions in both epidemiological samples [48–51] and clinical samples [52–56]. These recent analyses have found clinical benefits of both 2-level and 1-level reductions, consistent with research indicating any reduction in heavy drinking is associated with improved functioning.

Advantages

Multiple analyses of large clinical trials, including pharmacotherapy and psychosocial treatment trials, indicate that 1- and 2-level reductions in WHO risk drinking levels are more achievable than abstinence and NHDD. For example, rates of achievement for each outcome during the last month of treatment range from 0% to 41.6% for abstinence, 1.9% to 51.0% for NHDDs, 11.5% to 77.1% for WHO 2-level reductions, and 37.2% to 87.6% for WHO 1-level reductions [10, 57–59]. These reported rates are across active and control conditions and treatments targeting abstinence and reduced drinking. However, WHO risk drinking level reductions are sensitive to active treatment effects, including naltrexone, nalmefene, varenicline, and topiramate [10, 59, 60]. In several cases, WHO risk drinking level reductions have been more sensitive to treatment effects than abstinence and NHDD [10, 59].

WHO risk reductions appear to be relatively stable across long-term follow-ups. Among individuals in the COMBINE study who achieved at least a 1-level reduction at the end of treatment, 85.5% reported maintaining this reduction at the 1-year follow-up [54], and 84.9% maintained this reduction at the 3-year follow-up [57]. Similarly, among those who achieved at least a 2-level reduction at the end of treatment, 77.8% and 77.3% maintained this reduction at 1 and 3 years post-treatment, respectively [54, 57].

Several studies indicate that WHO risk reductions capture clinically meaningful benefits across several categories of functioning and patient groups. Specifically, reductions in WHO risk levels over treatment are associated with improved mental health outcomes, quality of life, and physical health outcomes (e.g., systolic blood pressure, liver enzyme levels) and reduced alcohol use consequences post-treatment, 1 year following treatment, and 3 years following treatment [52–54, 57]. Findings suggest that even a 1-level reduction is associated with better outcomes,

though greater drinking level reductions correspond to greater improvements in mental health and reductions in drinking consequences [52]. Furthermore, these clinical benefits are consistent across those with mild, moderate, and severe alcohol dependence and when excluding those who were abstinent at the end of treatment [58].

Disadvantages

WHO risk drinking levels empirically demonstrate advantages over abstinence and NHDD and are likely more aligned with patients' goals to reduce drinking and improve functioning. However, issues that plague any cutoff extend to WHO risk drinking levels. Cutoffs limit variability in outcomes, and therefore continuous outcomes, such as percent heavy drinking days and alcohol consequences, may be more sensitive to treatment effects [59]. Although the stability and clinical benefits of WHO risk drinking level reductions have been evaluated in both pharmacotherapy and psychosocial treatment trials [57, 58], it is unclear if these outcomes are sensitive to active psychosocial treatment effects [61]. Similarly, future research is needed to validate WHO risk drinking level reductions among various client groups, including additional samples outside the U.S., Europe, and the U.K., and among treatment-seeking individuals with co-occurring psychiatric disorders [61].

Non-Consumption Outcomes

Although recent research has advanced the validity and application of non-abstinent consumption outcomes, there are several disadvantages to all consumption outcomes. Non-consumption outcomes, such as craving, quality of life, alcohol consequences, and social support, are more aligned with patients' goals [18], biopsychosocial models of AUD [62], and DSM-5 AUD criteria [63]. Although the FDA and EMA only consider consumption outcomes in the approval of AUD medications, guidance from the FDA explicitly states that consumption is a surrogate endpoint for how a patient thinks and feels, given assumptions that clinical trials would need to be impractically long and large to identify an effect on psychosocial outcomes [34] and EMA guidance includes many non-consumption outcomes as secondary endpoints [35]. Accordingly, it is essential to examine how non-consumption outcomes compare to consumption outcomes in AUD clinical trials. Of note, most clinical trials for AUD examine non-consumption secondary outcomes, and therefore we aim to present a non-exhaustive review of studies that directly compared commonly evaluated non-consumption outcomes to consumption outcomes.

Alcohol Temptation/Craving

Craving is considered a central feature of AUD, reflected in its inclusion as a DSM-5 AUD criterion [64], and is often a target in psychosocial and behavioral treatments for AUD due to its strong association with alcohol use following treatment [65]. Analyses of data from COMBINE and Project MATCH indicate that various measures of temptation to drink/craving, including a single-item measure of temptation to drink, temptation measured via the Alcohol Abstinence Self-Efficacy Scale (AASE) [66], and craving measured via the Obsessive Compulsive Drinking Scale (OCDS) [67] are sensitive to change from baseline to post-treatment [68, 69]. A single-item measure of temptation to drink at the fourth treatment session in Project MATCH was associated with drinking frequency, quantity, and consequences 1 year following treatment and drinking quantity 3 years following treatment. A dichotomized version of this temptation item (i.e., not at all tempted to drink versus a little/somewhat/considerable/extremely tempted to drink) had more sensitivity for long-term drinking outcomes than alcohol consumption during treatment [69]. Similarly, an analysis of both COMBINE and Project MATCH showed that post-treatment alcohol temptation and craving, measured via the AASE and OCDS, respectively, predicted 1-year post-treatment consumption outcomes [68].

The strengths of craving as an outcome include its strong concurrent and predictive association with alcohol consumption, relevance to AUD diagnosis and recovery, and evidence that craving can be modified with AUD treatment and is sensitive to the effects of AUD medications, such as naltrexone [62, 65, 68, 69]. Alcohol temptation can also be measured via a practical, single-item, binary measure that has demonstrated predictive validity [69]. Nevertheless, there is the need to determine the extent to which alcohol temptation/craving is sensitive to active treatments instead of purely pre- to post-treatment change. This future direction is particularly important given that alcohol temptation/craving may be less sensitive to change during treatment than alcohol consumption outcomes [68].

Alcohol Consequences

Like craving, alcohol consequences are also reflected in DSM-5 AUD criteria (e.g., social/interpersonal problems and physical/psychological problems caused or exacerbated by alcohol; [64]) and consistent with patients' desires to reduce harmful alcohol use [23]. Furthermore, it is feasible that a patient receiving AUD treatment could reduce consequences without reducing drinking, given treatments often target reducing harms associated with alcohol use, rather than focusing on consumption [46]. Indeed, drinking consequences, measured via the Drinker Inventory of Consequences (DrInC), are often a secondary outcome in AUD clinical trials and are sensitive to treatment effects (e.g., nalmefene, topiramate) [46, 47] and demonstrate similar pre- to post-treatment effect sizes as consumption outcomes [47]. However, post-treatment drinking consequences have demonstrated inconsistent associations with longer-term consumption outcomes, which may be due to poor psychometric properties of the DrInC [68].

Quality of Life

Of all non-consumption outcomes reviewed, improved quality of life in treatment is the most aligned with patients' and providers' goals [23, 24]. An evaluation of quality of life as an outcome in COMBINE, using the World Health Organization Quality of Life measure (WHOQOL-BREF), found that quality of life was sensitive to improvements from the baseline to 10-week post-treatment follow-up assessment [70]. Previous analyses have also found that naltrexone and nalmefene improve quality of life compared to placebo conditions [17, 71]. An analysis of two topiramate trials found a small, albeit non-significant, effect of topiramate versus placebo on quality of life [59]. Other limitations of quality of life as an outcome include limited research on its long-term predictive validity and the preponderance of measures used to assess quality of life, which make comparison across studies difficult [72]. Given the relevance of quality of life to patients' treatment goals, future research validating this outcome, including patient-centered approaches to measurement development [73], is needed.

Composite Outcome of Consumption and Non-consumption Outcomes

To balance the strengths and weaknesses of both consumption and non-consumption outcomes, some have suggested using a composite outcome that combines information on alcohol consumption and consequences. Specifically, using this composite outcome, patients are classified into four categories: (1) abstinent, (2) moderate drinking without problems, (3) heavy drinking or problems, and (4) heavy drinking and problems [74, 75], with categories 1 and 2 considered as being in remission. Of note, the designation "without problems" includes problems that are not recurrent (i.e., never happening or happening only happening once or twice over the assessment period), as opposed to the complete absence of consequences, consistent with DSM-5 AUD criteria that consider recurrent problems [64]. Findings from Project MATCH indicate that remission measured with the composite outcome is more achievable than abstinence alone, with approximately 50% of patients categorized as being in remission over post-treatment and long-term follow-ups (up to 1-year post-treatment), compared with 21% to 36% who reported abstinence [74, 75]. Concurrent validity analyses indicate that the composite outcome is associated with alcohol use frequency and quantity, consequences, and psychosocial outcomes (e.g., mental health, social support, employment, purpose in life) at 1-year post-treatment, with those in remission reporting better outcomes than those with heavy drinking and/or alcohol problems.

However, the predictive validity of this outcome has not been examined, and additional examinations of category 3 (heavy drinking or problems) indicate that this group is not reliably different from those in the remission categories on measures of functioning, which appears to be driven by high functioning individuals who report heavy drinking [74, 75]. The composite outcome is also prone to the weaknesses of both consumption and non-consumption outcomes, including

limited research on the predictive validity and sensitivity to treatment effects (consistent with non-consumption outcomes) and the arbitrary nature of heavy drinking cutpoints and evidence for individuals with some heavy drinking who are high functioning (consistent with consumption outcomes).

Applying Research on Non-abstinent Endpoints to Clinical Practice

The reviewed body of literature indicates that non-abstinent goals, including no heavy drinking, reduction in drinking risk levels, and non-consumption outcomes, are more achievable than abstinence, sustainable over long periods following treatment, and associated with clinical benefits, such as reductions in the physical and psychosocial consequences of drinking and improved mental health and quality of life. Accordingly, non-abstinence goals should be routinely discussed and targeted in AUD treatment. Figure 20.1 provides a schematic of steps for selecting a treatment goal and treatment modality and monitoring treatment goals for non-abstinent and abstinent outcomes.

Selecting a Treatment Goal

Clinicians treating AUD should openly and non-judgmentally ask patients about their goals in treatment and explicitly communicate that both non-abstinent and abstinent outcomes are achievable in treatment and associated with clinical benefits. Based on the reviewed clinical trials, potential treatment goals to discuss with

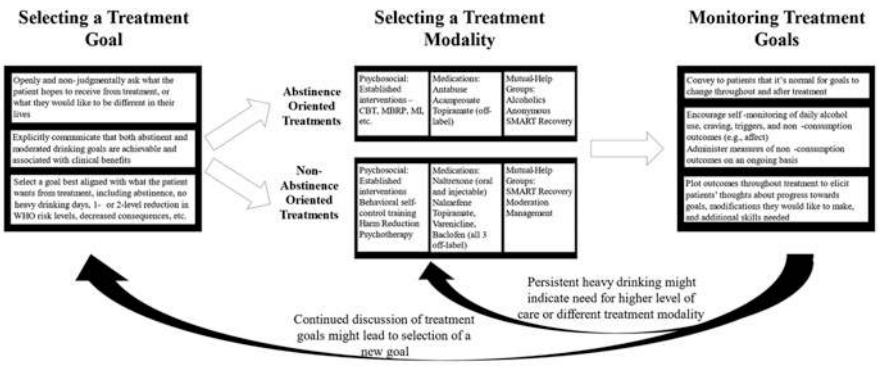

Fig. 20.1 Steps for selecting a treatment goal and treatment modality and monitoring treatment goals for non-abstinent and abstinent outcomes. CBT, cognitive-behavioral therapy; MBRP, mindfulness-based relapse prevention; MI, motivational interviewing; SMART Recovery, self-management and recovery training

patients might include reductions in drinking intensity, including no heavy drinking days or reductions in WHO risk level, or in drinking consequences. Such conversations might improve treatment engagement, rapport, motivation, and hope for a good outcome in treatment, given the high rates of individuals who desire [5, 22] and achieve non-abstinent outcomes [5].

Some treatment providers might have concerns about whether a non-abstinent treatment goal is a good fit for a given patient. Prior research indicates that individuals who can successfully achieve non-abstinent outcomes tend to have lower AUD severity and alcohol consumption at treatment entry, fewer negative mood symptoms, fewer heavy drinkers in their social network, and higher confidence and commitment to change [76–78]. However, a recent meta-analysis and meta-regression found that overall AUD severity within a clinical trial did not predict better outcomes in abstinent-focused or non-abstinent-focused treatment [79].

Interestingly, the patient characteristics that predict a lower likelihood of achieving moderated drinking (e.g., greater drinking intensity and consequences, poorer mental and physical health) are aligned with who is most likely to self-select an abstinence goal [22]. Drinking goal is also related to the achieved treatment outcome. Patients who select an abstinence goal are more likely to report abstinence following treatment, and those preferring non-abstinence are more likely to report a "non-problem" drinking outcome [80]. These findings indicate that providers should support free goal choice among patients instead of selecting a treatment goal for patients based on their characteristics. Clinical trials encouraging free goal choice produce similar outcomes to trials that require abstinence or moderated drinking [79]. Most importantly, evidence and theory suggest that patients prefer to choose their goals, are more committed and motivated when choosing their own goals, and are more likely to achieve their goals when they have free goal choice [5].

Selecting a Treatment Modality

Patients' drinking goals should be considered when selecting and delivering AUD treatment. Appropriate interventions for non-abstinent drinking goals will briefly be described below, and see Paquette and colleagues for a more detailed overview [5].

Psychosocial Interventions

Most psychosocial interventions for AUD were developed and evaluated with abstinence endpoints, but non-abstinence goals can be incorporated into most, if not all, established interventions, including cognitive-behavioral therapy (CBT) [81], motivational interviewing (MI) [82], and mindfulness-based relapse prevention (MBRP) [83], among others [5]. For example, CBT for AUD significantly impacts alcohol use frequency *and* quantity outcomes [14], and all skills presented in CBT (e.g., engaging in non-substance use reinforcing activities, planning for high-risk

situations) can be applied to moderated drinking goals. Meta-analyses of MI have also shown impacts on reduced alcohol consumption [84], and the spirit of MI, including collaboration between the therapist and client, evoking the client's ideas about change, and supporting a client's autonomy, is fundamentally at odds with mandating abstinence [82]. MBRP has also demonstrated impacts on reduced drinking intensity among individuals with both abstinent and non-abstinent treatment goals [85]. Given this widespread evidence that psychosocial interventions for AUD can be applied to non-abstinent outcomes, perhaps the most significant consideration when administering such treatments to a client with a moderated drinking goal is to ensure that examples and suggestions are tailored to non-abstinent drinking.

Several psychosocial interventions have been developed explicitly for moderated drinking, though the evidence base for these interventions is sparse compared to the interventions discussed above. Behavioral self-control training, a treatment that helps patients reduce drinking intensity by pacing drinks, identifying high-risk situations for heavy drinking, and goal setting, demonstrates better outcomes than no intervention, with outcomes similar to abstinence-oriented treatments [86]. Harm reduction psychotherapy, which takes a biopsychosocial approach to modify a patients' emotional, family, social, and medical problems without requiring abstinence, has been extensively described but has not received much empirical investigation [5, 87].

In conclusion, many psychosocial interventions are appropriate for patients interested in reducing drinking, if treatment providers are cognizant of providing appropriate examples and suggestions. Further supporting this conclusion, a recent meta-analysis showed that achievement of "successful" alcohol treatment outcomes did not depend on whether psychotherapies are targeted to abstinence or moderated drinking [79].

Pharmacological Interventions

Unlike psychosocial treatments, some pharmacological interventions may be better suited to either non-abstinent or abstinent treatment goals. Most notably, disulfiram (FDA and EMA approved for AUD) is only indicated for individuals who plan to abstain from alcohol use. This is due to the medication's mechanism of action, blocking the conversion from acetaldehyde to acetic acid during alcohol consumption, resulting in an upsurge of acetaldehyde and making an individual ill if they consume alcohol [88]. There is also evidence that acamprosate (FDA and EMA approved) may be more effective in promoting abstinence than reducing heavy drinking [89]. Acamprosate targets glutamatergic neurotransmission, may have larger effects on abstinence than heavy drinking, and appears to be more effective when patients have undergone alcohol detoxification before initiating acamprosate treatment [89].

Concerning pharmacotherapies appropriate for non-abstinence treatment goals, a relatively large body of literature indicates that oral and injectable naltrexone (FDA and EMA approved) effectively reduces heavy drinking [15–17, 88, 89].

Evidence also suggests the utility of targeted oral naltrexone to reduce drinking intensity during situations that are high risk for heavy drinking [90, 91]. These findings are consistent with naltrexone's mechanism of action as an opioid antagonist, which may decrease reinforcing properties of alcohol, thus decreasing drinking intensity during alcohol consumption [88]. Similar findings have been demonstrated for nalmefene, an opioid antagonist approved by the EMA [88].

Several medications used off-label for AUD have also demonstrated efficacy for reducing heavy drinking and, therefore, may be appropriate for non-abstinent drinking goals. Of these, topiramate has the most substantial evidence base [11, 16, 92]. Topiramate is an anticonvulsant drug that is FDA and EMA approved and has a complex mechanism of action, including state-dependent blocking of voltage sensitive sodium channels, increased $GABA_A$ neuronal activity, and antagonism of glutamate [88, 93]. Meta-analyses indicate that topiramate has significant impacts on abstinence and heavy drinking [92] and might be more effective in reducing total alcohol consumption than active FDA and EMA-approved medications [16]. Varenicline, an alpha4beta2 nicotinic receptor partial agonist, baclofen, a $GABA_b$ agonist, and gabapentin, which binds voltage-sensitive calcium channels to modulate GABA and glutamate activity, have low quality or mixed results [11, 88, 94, 95] but may be appropriate for off-label use among patients with non-abstinence drinking goals [10, 11, 16]. Concerning populations who may respond best to these medications, varenicline may be appropriate for heavy drinking smokers and heavy drinking males [96], baclofen may be most effective for heavier drinkers [97], and gabapentin may be most effective for those with more alcohol withdrawal symptoms [95].

Mutual Help Groups

Treatment providers might also encourage engagement in mutual-help groups to enhance social support for reducing alcohol use [98]. However, providers might be ambivalent about recommending participation in 12-step mutual-help groups, such as A.A., given that these groups target abstinence and are based on the dispositional disease model of addiction, which assumes individuals are "powerless" over any alcohol consumption [5, 98]. Indeed, prior A.A. engagement predicts an abstinence drinking goal compared to a controlled drinking goal, indicating that the theoretical basis of 12-step groups may be incompatible with a moderated drinking goal [99, 100].

Self Management and Recovery Training (SMART) Recovery or Moderation Management groups may be more appropriate for patients with non-abstinence goals. SMART Recovery teaches tools and techniques for drinking reduction, including enhancing motivation for change, coping with cravings, problem-solving, and engaging in reinforcing activities, including meetings [98, 101]. SMART Recovery acknowledges that individuals are on their own recovery pathways, does not exclude individuals who are actively drinking, and encourages the use of pharmacotherapies for AUD [98, 102]. Moderation Management is a mutual-help group

that more explicitly targets moderated drinking through increased awareness of alcohol consumption and consequences, setting limits, and skill-building to reduce drinking [98, 103].

Monitoring Treatment Goals

Given the benefits of drinking reduction and non-consumption outcomes, as reviewed, it is important to assess these outcomes throughout treatment. First and foremost, it is crucial to convey to patients that it is normal for goals to change throughout treatment [5, 79]. Treatment providers should encourage patients to self-monitor and record daily alcohol use, cravings, triggers for alcohol use/cravings, and other non-consumption outcomes (e.g., negative mood), and providers may also use repeated PEth testing to provide feedback to patients about effects of drinking on blood PEth levels over time. If indicated, providers might also administer measures of non-consumption outcomes during treatment, including measures of craving, consequences, and quality of life. When discussing patients' reported outcomes each session, treatment providers should openly elicit patients' thoughts about progress toward goals, potential modifications to goals, and additional skills needed to meet goals. Monitoring might also inform any need for additional treatment. For example, persistent heavy drinking and/or lack of drinking reductions may indicate the need for a higher level of care (i.e., detoxification, inpatient treatment, intensive outpatient treatment) or another treatment modality to support reductions in alcohol consumption and positive long-term outcomes.

Conclusions

Drinking reductions in alcohol treatment are achievable, sensitive to treatment effects, sustainable over long-term follow-ups, and associated with clinical benefits. Accordingly, drinking reduction outcomes should be assessed in clinical trials and drinking reduction goals should be routinely discussed with patients presenting to AUD treatment. Although more research is needed to operationalize non-consumption outcomes and develop assessments of these outcomes that are easy to measure and interpret, initial evidence suggests that craving, alcohol consequences, and quality of life demonstrate improvements following AUD treatment and are associated with other clinical benefits. Future studies might also develop patient-centered outcome measures [72] and personalized assessment tools responsive to individual goals [43]. Nearly all established psychotherapies and several pharmacotherapies for AUD support non-abstinence and non-consumption outcomes, indicating the feasibility of drinking reduction goals and broader non-consumption functional outcomes in clinical practice.

Chapter 21
Laboratory Based Approaches to Medications Development for Alcohol Addiction

Steven J. Nieto, Suzanna Donato, Artha J. Gillis, and Lara A. Ray

Abstract Human laboratory models have been used in medication development for alcohol use disorder (AUD) for decades. Paradigms such as alcohol cue-exposure and alcohol administration provide initial efficacy of pharmacotherapies for AUD and co-administration of medication and alcohol is an important step in establishing safety. More recently, the medication development pipeline has included human laboratory testing as a recommended step in safety and initial efficacy testing of novel compounds. Nevertheless, the degree to which the effects of pharmacotherapy, versus placebo, are (un)detected in the human laboratory may or may not predict their likelihood of efficacy in a randomized controlled trial (RCT). The present review discusses the history and multiple paradigms available for medication development in AUD, then discusses the optimal role of human laboratory models in AUD medication development, next it reviews simulation studies comparing signal detection in the human laboratory versus RCTs, and finally, it reviews empirical data comparing the observed signal for various AUD medications in the human laboratory and in RCTs. Together, these sections provide historical, theoretical, and empirical data pertaining to how best leverage human laboratory models for AUD medication development.

Introduction

Medication development for alcohol use disorder (AUD) is a costly and time-consuming endeavor. It is estimated that the average time from discovery to market for a given pharmaceutical in the United States is 13.5 years and costs roughly $1.8 billion dollars [1, 2]. Further, less than 1 in 10,000 compounds that are screened will successfully reach the pharmaceutical market [3]. Only four medications have passed this process and are approved by the FDA for the treatment of AUD (i.e., disulfiram, acamprosate, nalmefene, and naltrexone, the latter two medications being available in oral and injectable formulations). While the availability of pharmacological treatments for AUD indicates progress over the past 25 years [4], the therapeutic uptake of these medications is limited. This may be due to the high heterogeneity of AUD and limited effect size of any one medication. As is common when treating other psychiatric illnesses (e.g., depression), a cache of medication choices is optimal to enhance treatment outcomes [3]. However, the current process for developing and testing AUD medications limits the development of novel pharmaceutical agents.

The National Institute on Alcohol and Alcohol Abuse's (NIAAA) Medication Development Team was established with the key long-term goal of making the drug development process more efficient. The current model for testing pharmacotherapies places heavy emphasis on the clinical trial phase of testing, which requires considerable resources and often results in null findings. Clinical trials may always be the gold standard for establishing the safety and efficacy of medications, however, developing new ways to accelerate the process prior to reaching testing in patients may be the key to advancing clinical care for AUD. Laboratory models carry several unique advantages in relation to examining medication effects [5]. Firstly, they are less costly than clinical trials and offer more efficient approaches for screening (i.e., informing go-no go decisions). These models also involve a high level of experimental control, allowing for greater confidence in the therapeutic mechanisms of action and informing promising potential molecular targets. Human laboratory models also capture important between-person variability in medication response, permitting researchers to better predict subgroups of target responders. In sum, human laboratory studies are able to not only test *whether* these drugs are able to elicit desired therapeutic outcomes but also *how* they elicit their pharmacological effect [6] and in *whom*.

In addition to human laboratory approaches representing an important precursor to the clinical trial phase of medications development, they also are crucial for the translation of preclinical findings to clinical samples. While a detailed review of animal models for AUD pharmacotherapy development is outside the scope of this chapter (see [7] for an in-depth review of translational animal models), it is

important to note the significance of preclinical models in demonstrating early efficacy and exploring potential treatment mechanisms. The successful translation between early preclinical studies and later phase trials is critical for the medication development process [8]. Human laboratory models have the potential to act as important intermediaries of this process, facilitating the link between early preclinical studies and later clinical trial testing through congruent modeling [9, 10].

It is clear that human laboratory approaches represent a critical step in the medication development process due to their ability to pinpoint therapeutic mechanisms of action and fill an important translational gap between preclinical findings and large-scale clinical trials. Importantly, co-administration of the novel medication with alcohol in a controlled environment also provides necessary safety data. In line with the importance of this work, NIAAA started the Human Laboratory Program (HLAB), an initiative to standardize human laboratory paradigms for the purpose of reducing methodological variability and refining the screening process for promising medications. By establishing both reliable and valid screening models, the field of medications development can improve the timing and selection of promising compounds to move to next phase clinical trials.

In summary, the medications development process is a high priority, yet the current sequence of moving novel compounds to market encompasses many challenges. Further work is needed to refine the process and better predict which compounds hold the highest probability of success. Human laboratory models represent a critical tool for predicting key clinical outcomes and translating important work from the preclinical phase. This chapter will discuss key findings on the theoretical and observed value of human laboratory approaches in the medication development pipeline. While a comprehensive review of the range of human laboratory models available for medication screening is beyond the scope of this chapter, consideration will be given to recent novel contributions that have promising implications for human laboratory approaches. In their final remarks, the authors discuss critical gaps that still exist and future directions for the application of laboratory approaches in the medication development model.

Main Body

The Theoretical Predictive Value of Human Lab in Medication Development

General Overview of Theoretical Value

Human laboratory models were originally developed for the study of alcoholism etiology and were later adapted for the study of treatment efficacy mechanisms [5, 11]. These paradigms encompass a wide array of methods for collecting data on central features of addiction under well-controlled experimental conditions. In several areas of psychiatry, human laboratory models are used to advance medication

development and serve as a critical translational bridge between preclinical investigations and randomized clinical trials.

There are several human laboratory paradigms that have been developed to model addictive disorders (Table 21.1). Most of these have been applied to examine medication effects on intermediate AUD phenotypes. Some of the most common paradigms used in AUD medication trials include alcohol cue-reactivity and alcohol administration studies. The cue-reactivity paradigm involves passive exposure to alcohol-related cues that triggers the underlying motivational processes that contribute to alcohol drinking [27]. Reactivity to cues is usually assessed using subjective (e.g., self-reported craving) and physiological indicators (e.g., heart rate) alone or in combination. In the typical in vivo cue-reactivity paradigm, participants complete baseline physiological and subjective measures prior to initiating experimental

Table 21.1 Examples of laboratory paradigms applied to pharmacotherapy development for alcohol use disorder

Laboratory paradigm	Phenotype/ mechanism of action	Pharmacotherapy	Outcome	Citation
Positive and negative affective drinking cues	Cue-induced craving	Gabapentin	Decreased positive affect-induced craving	[12]
Delayed discounting task	Inhibitory control	Naltrexone	Reduced impulsive responding	[13]
Alcohol demand	Alcohol reinforcing value	Naltrexone	Reduced alcohol demand	[14]
Alcohol self-administration in a naturalistic setting	Priming dose craving	Naltrexone	Decreased self-administration, slower drinking progression	[15]
Alcohol administration	Subjective responses to alcohol	Naltrexone	Decreased stimulation	[16–19]
Stress Induction	Stress-induced craving	Lofexedine	Increased sedation	[20, 21]
		Ibudilast	Rapid recovery in positive mood post-stress	
Initial priming and self-administration of alcohol	Low self-control	Aripiprazole	Break in alcohol-induced stimulation leading to increased consumption	[22]
Alcohol cue-exposure	Negative affective withdrawal symptoms	Acamprosate	Reduction of autonomic nervous system reactivity, no decrease in craving	[23]
Alcohol cue-exposure in fMRI scanner	Neural alcohol reward signal	Ibudilast	Attenuated alcohol cue-induced activation in the ventral striatum	[24]
Priming dose of alcohol and cue-exposure	Cue and priming dose-induced craving	Olanzapine	Reduction in craving, mediated by DRD4 polymorphisms	[25, 26]

procedures. After completing baseline assessments, participants are instructed to interact (i.e., smell, touch) with a glass of water. After water cue exposure, participants are instructed to interact with a glass containing the participant's most commonly consumed alcoholic beverage. After both exposures (water and alcohol), participants rate their subjective craving and physiological measurements are taken. In addition to demonstrating a high level of reproducibility [28], the cue-reactivity paradigm is sensitive to medication effects. For example, alcohol cue-induced craving is blunted by FDA-approved medications for AUD, such as naltrexone [15, 29, 30], as well as several other pharmacotherapies including D-cylcoserine [31], gabapentin [12], mifepristone [32], olanzapine [33], prazosin [34], and quetiapine [35].

Passive (i.e., controlled administration or alcohol challenge) and active (i.e., alcohol self-administration) alcohol administration paradigm have also been used in medications development for AUD [36]. Passive administration paradigms consist of controlled alcohol infusions under laboratory conditions wherein subjective response to alcohol are the primary endpoints. Subjective responses to alcohol are typically assessed across four domains: stimulation, sedation, negative affect, and alcohol craving. Self-administration models that include fixed and progressive ratio schedules of reinforcement have also been used in translational AUD research [7]. Under the traditional progressive ratio schedule, the response requirement for an alcohol infusion gradually increases throughout the session.

Human laboratory models serve as an important step along the medication development continuum for AUD. In early phases, these models establish initial evidence of safety and tolerability of a candidate compound. This is a crucial step because safety concerns and negative side effects can hamper the drug from moving forward in the process towards FDA-approval. Equally important, human laboratory paradigms are used to examine potential medication and alcohol interactions. In the case of alcohol, it is important to assess for potential sedative effects of a medication, as sedative effects in combination with alcohol use can have severe health implications.

Human laboratory studies provide crucial means of exploring treatment targets ("early efficacy endpoints" also called "surrogate endpoints") for specific components of the AUD cycle without the need for time consuming and expensive RCTs. For example, human laboratory paradigms can provide a valuable opportunity to assess the feasibility of an approach prior to carrying out a costly and time-consuming clinical trial with actual efficacy endpoints (i.e., drinking outcomes across a 12-week trial [4].

There are a number of advantages that human laboratory models have over randomized clinical trials. Human laboratory studies can be well powered with a smaller sample size and consequently be less costly, thus making them better positioned to engage in hypothesis testing. However, this is under the important assumption that the laboratory outcomes being tested correlate with clinical efficacy (not always supported/tested in the literature). Human laboratory models are conducted under well-controlled experimental conditions, which affords researchers greater sensitivity to detect a medication signal on a target variable. This enhanced sensitivity may be due to the surrogate outcomes of craving and subjective response to alcohol having less variability than real-world drinking outcomes. Additionally, the

shorter duration of the human laboratory testing is often associated with higher medication compliance and lower attrition rates than 12-week RCTs. Given the multidimensional nature of addictive disorders, human laboratory models can provide more granular assessments of medication effects on intermediate phenotypes. Human laboratory methods can help elucidate the neurobiological bases by which a pharmacotherapy exerts its therapeutic effects. Of course, these paradigms are not without limitations. One notable limitation is that the outcomes tested in human laboratory models may not be robustly associated with the clinical outcomes of interest for pharmacotherapies. The better a paradigm can approximate drinking/clinical outcomes, the more likely it is to provide valuable information regarding the initial efficacy of a novel compound [10]. To that end, it is crucial that the field strives to identify and refine screening models.

Qualitative Reviews of the Consistency Between Behavioral Pharmacology and RCT Results

The positive translational value of human laboratory paradigms has been highlighted in qualitative reviews. In many instances, a positive medication signal on a human laboratory endpoint is related to a positive medication signal in clinical trials [36]. However, this viewpoint must be tempered considering the publication bias toward positive medication findings, particularly in the behavioral pharmacology literature. There are also more clinical trials, compared to human laboratory studies, conducted on AUD medications. This may suggest that more emphasis is being placed on clinical efficacy outcomes versus a more nuanced understanding of the medication's mechanism of action.

Human laboratory studies have the capacity to test various mechanisms of AUD pharmacotherapies on clinically relevant translational phenotypes, thus furthering research in medications development [37]. In many cases, a positive medication signal using cue-reactivity and self-administration paradigms seem to be related to medication efficacy in clinical trials [38]. Cue-reactivity had better predictive validity for medications that are hypothesized to address consequences related to abstinence, such as alcohol craving, negative emotionality, and sleep disturbances. However, some models of cue-reactivity testing pre-select participants who are "cue-reactive" and exclude those who are not [39], which impacts generalizability. Alcohol administration paradigms had better predictive utility for drugs that decrease/blunt the rewarding effects of alcohol. Thus, understanding a candidate drug's mechanism of action may inform the optimal human laboratory paradigm that should be used to predict efficacy in clinical trials [38]. When these paradigms are standardized, as in the NIAAA's Human Laboratory Program (HLAB), they can help inform Go/No Go decisions early on in the medication development process [4].

Another common critique of human laboratory paradigms for AUD is a lack of generalizability due to artificial laboratory settings. However, controlled experimental conditions can be an important complement to randomized clinical trials.

For example, a meta-analysis by Hendershot et al. [40] examining the effects of naltrexone on alcohol self-administration and craving found that naltrexone effects sizes on human laboratory endpoints dovetailed naltrexone effect sizes observed in clinical trials. While the experimental setup in human laboratory paradigms differs significantly from clinical trials, the fact that both yield similar medication effect sizes may suggest that the medication signal is generalizable across research settings. A similar pattern was reported in a meta-analysis by our group examining the effects of naltrexone on subjective response to alcohol in the human laboratory [41].

These extensive reviews by experts in the field, while qualitative in nature, provide theoretical insights into the consilience between human laboratory studies and clinical outcomes. However, quantitative estimates of predictive utility are needed.

Empirical Evidence on the Value of Human Lab Models in Medication Development

Probing the Predictive Value of the Human Lab Models Using Simulations

Our laboratory has leveraged simulation methods to differentiate between lab and clinical trials approaches in finding medication signals [10]. Specifically, we conducted a Monte Carlo simulation study to further explore the relative efficiency of pilot trials versus laboratory studies in screening medications for AUD. The simulation study tested the following parameters: (1) average medication effect size (Cohen's d = 0.2, 0.5, and 0.8 representing small, medium, and large effects), pilot study sample size (N_{pilot} range 6 to 36), the multiplicative increase in sample size associated with typically less expensive and quicker laboratory studies (Lab Multiple = 1, 2, and 4), and lastly the correlation between clinical and laboratory effect sizes ($\rho_{Lab\text{-}Clinic}$ = 0.3, 0.6, 0.9, representing relatively poor, moderate, and strong correlation between clinical and laboratory effects). Ten thousand clinical effect sizes were simulated for each of these parameter combinations, half from a null distribution N(0, 0.2) and half from the specified mean effect size N(d, 0.2). Laboratory effect sizes were simulated based on population correlation $\rho_{Lab\text{-}Clinic}$ with equivalent distributions to the clinical effect sizes. We then calculated the probability of a significant and positive trial (i.e., statistical power with $\alpha = 0.025$, one-tailed) for each of the simulated effect sizes in both a pilot study of sample size N_{pilot}, and a laboratory study of sample size $N_{pilot} \times$ Lab Multiple. By summing these powers we calculated the expected number of positive trials for medications with true and false effects (i.e., drawn from distribution N(d, 0.2) or N(0, 0.2) respectively). Using simulation methods, it was feasible to calculate the sensitivity or the probability that a medication with a true effect would screen positive.

The findings from the Monte Carlo simulation suggested that sensitivity increased with greater sample size, greater average effect size, and greater correlations between laboratory and clinic effect sizes. This simulation study also found evidence to suggest that pilot study is superior in terms of sensitivity only when a

laboratory study confers no advantage in terms of sample size. When the sample size of the laboratory study was double that of the pilot study, or larger, the laboratory study exhibited greater sensitivity than a pilot trial across the range of sample sizes and medication effect sizes tested. In brief, the utility of human laboratory models over pilot RCTs hinges on the association between the human laboratory outcome and the RCT outcomes. When the human laboratory outcome is distal to the RCT drinking outcome, the benefits of the human laboratory model are null. However, as the human laboratory model better approximates the clinical outcome of interest, then the human laboratory model is of maximal utility. In sum, human laboratory models and/or pilot randomized controlled trials should serve as intermediaries in the transition from preclinical studies to large, and costly, randomized controlled efficacy trials. The selection of a human laboratory model as an intermediate step in efficacy testing should be informed by the association between the clinical outcome and the human laboratory outcome as well as the putative mechanism of action of the novel treatment. Specifically, considering the purported mechanism of action of a given medication should guide the selection of surrogate measures (i.e., early efficacy endpoints) in a human laboratory study. Considering a single mechanism (e.g., reductions in cue-induced craving) for multiple (and novel) pharmacotherapies can lead to false negatives. Therefore, we suggest that a combination of established mechanisms as well as mechanisms uniquely associated with the novel therapeutic be targeted in human laboratory testing.

Probing the Predictive Value of the Human Lab Models Using Observed Data

While medication effects on human laboratory endpoints are hypothesized to predict treatment outcomes, this hypothesis has remained largely hypothetical or tested in simulated fashion (as described above). Our laboratory recently implemented a novel meta-analytic method to empirically test whether human laboratory tests of medication effects predict medication outcomes in RCTs [42]. After a comprehensive literature search for AUD medications tested in the human lab and in RCTs, medication effects were computed on relevant endpoints. For the human laboratory studies, we computed medication effects on stimulation, sedation, and craving during the alcohol administration ($k = 51$ studies, 24 medications). For RCTs, we computed medication effects on any drinking and heavy drinking ($k = 118$ studies, 17 medications). Medication was the unit of analysis and Williamson-York bivariate weighted least squares estimation was applied to preserve the errors in both the independent and dependent variables. Results revealed a significant and positive relationship between medication effects on alcohol-induced stimulation, sedation, and craving in the laboratory, and drinking outcomes in RCTs, such that medications that reduced stimulation, sedation, and craving during the alcohol administration were associated with better clinical outcomes. A leave-one-out Monte Carlo analysis examined the predictive utility of these laboratory endpoints for each

medication. The observed clinical effect size was within one standard deviation of the mean predicted effect size for all but three pharmacotherapies. This proof-of-concept study demonstrated that behavioral pharmacology endpoints of alcohol-induced stimulation, sedation, and craving track medication effects from the human laboratory to clinical trial outcomes. These results apply to alcohol administration phenotypes and can be expanded to other paradigms, such as cue-exposure and stress-exposure. Further, given that alcohol administration models are not employed in treatment-seeking samples, it should be noted that the aforementioned meta-analytic study found a relationship between medication effects in the human laboratory among non-treatment seekers and clinical trial effects among treatment-seeking individuals. Lastly, these novel methods and overall approach can be applied to a host of clinical questions and can streamline the process of screening novel compounds for AUD.

Recent Advancements: Novel Compounds and Novel Human Lab Models

Recent approaches emphasize using established medications for AUD to evaluate validity of animal and human models to advance translational research for AUD. Those models can then serve as a springboard for the development of new pharmacotherapies. This approach is being employed in our laboratory to test a novel human laboratory model to screen AUD medications. Below we describe two recent approaches from our laboratory aimed to apply novel human laboratory models to study AUD as well as leveraging human laboratory paradigms to assess the efficacy of a novel compound.

Practice Quit Attempt Model

The practice quit attempt model used by Perkins and colleagues initially tested FDA-approved smoking cessation medications in order to validate their model [43–45]. These studies found that in individuals with high motivation to quit, there was a significant increase in number of days abstinent when on active medication compared to placebo; the same pattern of findings was not evident in individuals with low motivation to quit [43–45]. Further, when modafinil, a medication that has not shown efficacy as a smoking cessation aid, was added as a study arm, they demonstrated model specificity, as bupropion was effective at improving abstinence, while modafinil was not [44]. More recently, Perkins and colleagues have moved to testing novel medications using their practice quit attempt model [46, 47]. They did not find a significant reduction in days abstinent when testing a novel fibrate medication [46] or a novel positive allosteric modulator of nicotinic receptors [47], which provides a critical “no-go” signal for both medications. The development of the practice quit attempt model for medication development in nicotine dependence

provides strong "road map" for the development of a similar approach modified to AUD.

To address this central limitation in the AUD medications development field, we are expanding the traditional laboratory methodology to more closely mirror actual treatment processes [48]. Through combining a well-established laboratory paradigm (i.e., cue-reactivity), with an abbreviated "practice" quit attempt in intrinsically motivated individuals with AUD, our human laboratory model reduces the conceptual distance between the lab and the clinic, thus reducing the possibility for laboratory effects to "fade" when applied to the clinical context.

Our ongoing study (ClinicalTrials.gov Identifier: NCT04249882) aims to develop and validate a novel early efficacy paradigm, informed by smoking cessation literature, to screen novel medications for AUD. As an established AUD medication, naltrexone serves as an active control to test both the practice quit attempt model and the efficacy of a promising AUD pharmacotherapy, varenicline. Individuals with current AUD reporting intrinsic motivation to change their drinking complete a week-long "practice quit attempt" while on study medication. Participants are randomized in a blinded manner to either naltrexone, varenicline, or placebo. During the practice quit attempt, they complete daily visits over the phone and fill out online questionnaires regarding their drinking, alcohol craving, and mood. Additionally, participants undergo two alcohol cue-reactivity sessions. The successful completion of this study will advance medications development by proposing and validating a novel early efficacy model for screening AUD pharmacotherapies, which in turn can serve as an efficient strategy for making go/no-go decisions as to whether to proceed with clinical trials.

Ibudilast Efficacy in the Human Laboratory

The identification of novel treatment targets and the development of rigorous laboratory paradigms to screen and optimize novel therapeutics represents a research priority. Ibudilast is a neuroimmune modulator that inhibits phosphodiesterase −4 and −10 and macrophage migration inhibitory factor. Recently in an AUD sample, ibudilast was shown to decrease reactivity to a psychological stressor. Furthermore, ibudilast was effective in blunting alcohol reward among participants with greater depressive symptoms, a hallmark symptom of protracted withdrawal. Preclinical research in opiates has demonstrated that drug withdrawal is necessary for microglia activation and neuroinflammation in reward networks, suggesting that ibudilast may be most effective among patients who experience withdrawal-related dysphoria.

Based on the aforementioned work, our laboratory recently completed a laboratory study that examined withdrawal-related dysphoria as a moderator of IBUD efficacy in the natural environment measured using Daily Diary Assessment (DDA) approaches [24]. More specifically, we examined the efficacy of ibudilast to improve negative mood, reduce heavy drinking, and attenuate neural reward signals in individuals with AUD. Fifty-two nontreatment-seeking individuals with AUD were randomized to receive ibudilast (n = 24) or placebo (n = 28). Participants completed a

2-week daily diary study during which they filled out daily reports of their past day drinking, mood, and craving. Participants completed a functional magnetic resonance imaging (fMRI) alcohol cue-reactivity paradigm half-way through the study.

The results of the study demonstrated that ibudilast did not improve negative mood on drinking or non-drinking days, indicating that its mechanism of action may be non-mood dependent in non-treatment-seeking individuals. Ibudilast reduced the probability of heavy drinking days over 2 weeks for non-treatment-seeking individuals relative to placebo. Ibudilast also attenuated alcohol cue-elicited activation in the ventral striatum (VS), potentially through a dopaminergic-related mechanism. This is a critical proof-of-mechanism whereby modulation of neuroimmune signaling via ibudilast reduced the incentive salience of alcohol cues in the brain. Exploratory analyses indicated that VS activation to alcohol cues was predictive of subsequent drinking in the ibudilast group, such that individuals who had attenuated VS activation and were treated with ibudilast had the fewest number of drinks per drinking day in the week following the scan. Overall, we applied a human laboratory model to support the efficacy of ibudilast for the treatment of AUD and suggest a potential biobehavioral mechanism through which ibudilast acts.

Conclusions

This chapter discusses a host of human laboratory models of alcohol use disorder and reviews their application to medication development. As can be seen in Table 21.1, these models range from alcohol cue-exposure, stress-exposure, alcohol administration, alcohol self-administration, delayed discounting, to name a few. Each model has its own strengths and weaknesses as well as methodological variation in how they are implemented. One of the key conclusions from the review of various human laboratory models is that there is ample opportunity to standardize methods across studies. A recent meta-regression from our laboratory has shown that variability in methods for alcohol administration in the laboratory, such as target BrAC and drinking characteristics of the study sample, predict the likelihood of detecting a medication effect, compared to placebo [49]. As such, opportunities to refine and standardize methods for human laboratory testing and to conduct multisite studies of novel medications should receive a high priority. To that end, the HLAB initiative by NIAAA has recently reported the results of a 3-site human laboratory study of varenicline's effects on alcohol cue-reactivity [39], an important step towards standardizing early efficacy testing through human laboratory protocols.

Next, this chapter reviews a series of simulations conducted by our group comparing signal detection in the human laboratory versus RCTs [10]. As show in Figs. 21.1 and 21.2, results of our Monte Carlo simulation found that a laboratory study with a paradigm well-calibrated to capture meaningful clinical effects is better able to detect true positive medication effects than pilot RCTs. Calibration refers to the degree to which the endpoint in a human lab study is associated (or correlated) with an RCT endpoint. These results argue for the careful "calibration" of

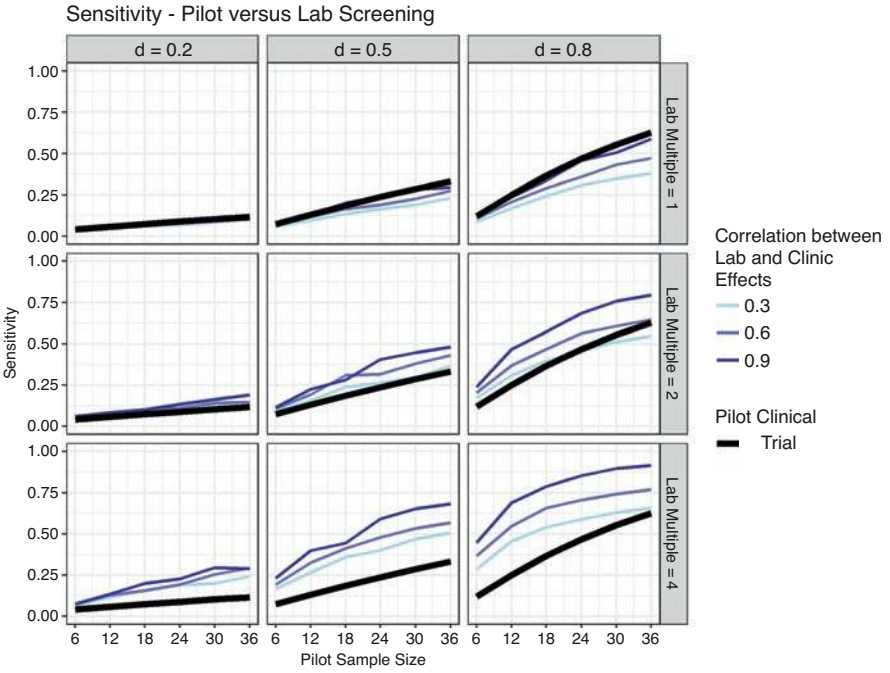

Fig. 21.1 Sensitivity results for pilot versus laboratory screening of novel medications. These sensitivity analyses are the result of a Monte Carlo simulation study (n = 10,000 per specification) examining the effect of pilot study sample size, mean medication effect size (Cohen's *d*), multiplicative increase in laboratory versus pilot clinical trial (Lab Multiple), and correlation between laboratory and clinic effect sizes. Sensitivity was defined as the expected number of positive screens as a proportion of the total number of true positive medications. This figure was adapted from Ray et al. [10]

human laboratory paradigms as a critical step in overcoming the "valley of death" in medications development for AUD and ultimately promoting the translation of novel compounds to clinical populations. In other words, these simulations argue that the degree to which human laboratory models capture "shared variance" with alcohol consumption endpoints in a clinical degree determines the utility of the human laboratory paradigm for early efficacy detection. A key conclusion from this line of research is the need to empirically examine the association between laboratory and RCT outcomes in AUD medication studies.

To that end, this chapter turns to a study in which we use meta-analytic principles to empirically test the degree to which medication effects in the human laboratory (i.e., effects on subjective responses to alcohol during alcohol administration in the lab) are predictive of the same medication effects in phase II trials, or RCTs [42]. For behavioral pharmacology, we computed medication effects on alcohol-induced stimulation, sedation, and craving during the alcohol administration (k = 51 studies, 24 medications). For RCTs, we computed medication effects on any drinking and heavy drinking (k = 118 studies, 17 medications). We used medication as the unit of

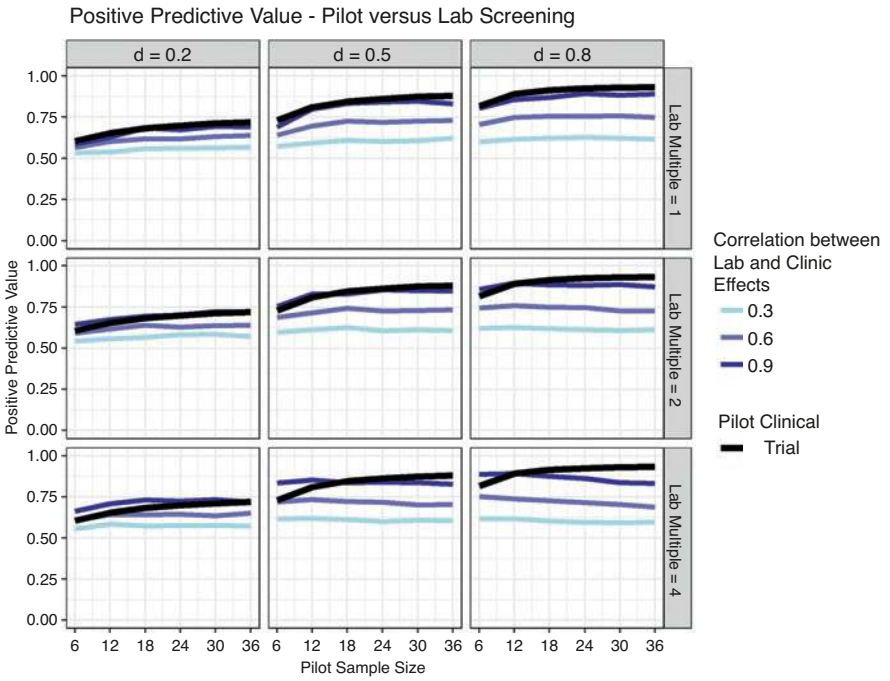

Fig. 21.2 Positive predictive value results for pilot versus laboratory screening of novel medications. These positive predictive values are the result of a Monte Carlo simulation study (n = 10,000 per specification) examining the effect of pilot study sample size, mean medication effect size (Cohen's *d*), multiplicative increase in laboratory versus pilot clinical trial (Lab Multiple), and correlation between laboratory and clinic effect sizes. Positive predictive value was defined as the proportion of positive screens that represent true positives. This figure was adapted from Ray et al. [10]

analysis and applied the Williamson-York bivariate weighted least squares estimation to preserve the errors in both the independent and dependent variables. Results revealed a significant and positive relationship between medication effects on alcohol-induced stimulation, sedation, and craving in the laboratory, and drinking outcomes in RCTs. The effects were such that medications that reduced stimulation, sedation, and craving during the alcohol administration were associated with better clinical outcomes. A leave-one-out Monte Carlo analysis (shown in Fig. 21.3) examined the predictive utility of these laboratory endpoints for each medication. The observed clinical effect size was within one standard deviation of the mean predicted effect size for all but three pharmacotherapies. This proof-of-concept study demonstrated that behavioral pharmacology endpoints of alcohol-induced stimulation, sedation, and craving track medication effects from the human laboratory to clinical trial outcomes. These methods and results can be applied to a host of clinical questions and can ultimately streamline the process of screening novel compounds for AUD. This approach can be used to quantify the predictive utility of

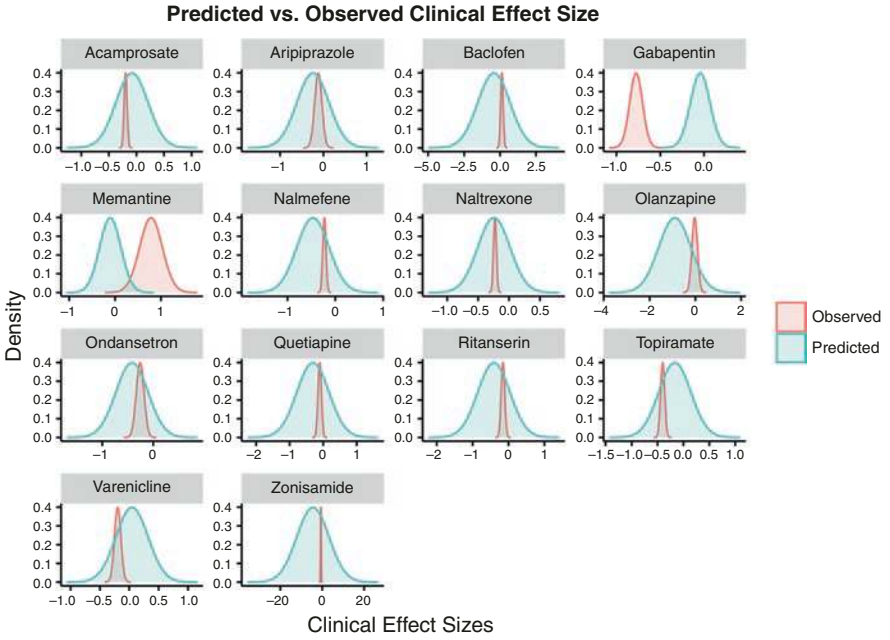

Fig. 21.3 Predicted and observed clinical effect size distributions. Predicted effect size distributions were computed for each medication across laboratory effect sizes using a leave one-out Monte Carlo simulation. This figure was adapted from Ray et al. [42]

cue-reactivity screening models and even preclinical models of medication development. Hence one of the key conclusions from this line of research is that methods and data are available to provide empirically-driven analyses of the relationship between human laboratory and clinical trials endpoints so as to inform their optimal application.

Finally, the chapter discusses ways in which we can improve the consilience between human laboratory models and clinical trials endpoints by (a) developing more ecologically valid models to bolsters the association between lab and clinical endpoints, and (b) combining alcohol use data collection in human laboratory studies through micro-longitudinal designs. For the first effort, we discuss a new model for which testing is underway [48]. This model consists of a practice quit attempt in which individuals with AUD who are motivated to change their drinking agree to engage in a 7-day practice quit attempt. If supported as a sensitive method for medication screening, this model could be used widely as an ecologically valid approach to testing early efficacy of novel medications, and/or combination pharmacotherapies. Further, we recommend testing multiple medications, against a placebo arm, simultaneously as a way to expedite the transition from preclinical to human testing of promising compounds. Nevertheless, the concomitant test of multiple medication arms versus a placebo condition increases the sample size requirement and overall effort towards the human laboratory endeavor. For the second effort, we demonstrate

the application of the micro longitudinal design in which daily drinking is reported, including circumstances surrounding the drinking episode and responses to alcohol [24, 50, 51]. This approach has been undertaken successfully with a novel neuroimmune modulator and has the potential to be applied broadly in pharmacotherapy development for AUD.

In closing, this chapter discusses a series of studies applying human laboratory paradigms to medication development for AUD, from qualitative reviews, to empirical studies, to simulation studies, meta-analytic reviews, and perspective/opinion pieces. A common theme across this chapter is the need to optimize the clinical utility of human laboratory model in medication development for AUD. To that end, a central tenant of the chapter is the need to design and test human laboratory models with the highest level of consilience with real-world alcohol consumption. As the field continues to progress towards standardizing and optimizing medication development, careful attention to the role of human laboratory testing is warranted to close the translational gap from preclinical to clinical testing and to effectively deliver novel compounds to individuals suffering from AUD.

Chapter 22
Emergency Room: Acute Alcohol Intoxication and Other Alcohol-Related Acute Problems Including Alcohol Withdrawal Syndrome

M. Antonelli, F. A. Mancarella, A. Mirijello, C. Tarli, S. Mannucci, V. Maccauro, G. Di Sario, T. Dionisi, L. Sestito, A. Tosoni, and G. Addolorato

Abstract Alcohol consumption is widespread around the world. It is a leading cause of disability and mortality, in which the Emergency Department plays a key role since it is often the first contact between the patient with an alcohol use disorder (AUD) and the health care system. Acute alcohol intoxication is the most common disorder in the context of alcohol-related emergencies, and can lead to severe life-threatening conditions if not treated early. Since diagnosis requires the exclusion of other causes, the only validated therapy is methadoxine in addition to support of vital functions. Alcoholic hepatitis is a clinical syndrome characterized by jaundice and liver impairment. The treatment depends on severity, evaluated by Maddrey's score: if above 32 points, alcoholic hepatitis is severe, and needs to be treated with corticosteroids (methylprednisolone 40 mg IV daily) and liver transplantation should be consider early. Patients who abruptly discontinue or reduce alcohol consumption are at risk of the alcohol withdrawal syndrome. Symptoms follow a scale of severity, and the most sever form is represented by Delirium Tremens, defined by

hallucinations and disorientation, until seizures and coma. The cornerstone of pharmacological treatment is the administration of long-acting benzodiazepines.

Keywords Alcohol use disorder · Acute alcohol intoxication · Alcohol withdrawal · Acute alcoholic hepatitis

Introduction

Alcohol consumption is widespread throughout the world, but alcohol use and abuse differ between countries: For instance, Europe has the highest level of alcohol consumption in the world (about 10.9 L of alcohol per person per year), while the global average consumption is 6.2 L/year, as pointed out by World Health Organization (WHO) [1–3].

Alcohol is a leading cause of disability and mortality, and is the main risk factor for preventable death in subjects aged between 25 and 49 [4]. Several specific alcohol-related clinical problems are recognized, both acute (e.g., acute alcohol intoxication, alcohol withdrawal syndrome and acute alcoholic hepatitis) and chronic (e.g., liver cirrhosis, neoplasm, neurological or cardiovascular diseases). Moreover, excessive alcohol use increases the risk of intentional and unintentional injuries, including car accidents, aggressions, domestic violence, murders and suicides. According to WHO, alcohol use could cause about 3.3 million deaths per year [3]. The main causes of death are related to liver cirrhosis, cancers (liver, upper gastrointestinal tract, upper respiratory tract, etc.) [5] and cardiovascular diseases [1, 2, 6].

The amount of alcohol intake is quantified in alcohol units, referring to 10–12 g of pure alcohol [7]. This measure is equivalent to a glass of wine (125 mL), a bottle of beer (330 mL) or a glass of liquor. Mostly, one drink (i.e., one alcohol unit) corresponds to a blood alcohol concentration (BAC) of 15–20 mg/dL, which requires 1 h to be metabolized [8]. The emerging phenomenon of “binge drinking”, which entails the intake of at least four drinks for women and five drinks for men on a single occasion, is an important risk factor for acute alcohol intoxication and its complications, especially in adolescents, since BAC can reach levels of 80 mg/dL in about 2 h [9, 10]. In adolescents, binge drinking increases the risk of developing diseases, related to reduced expression of alcohol-degrading enzymes, and the risk of developing alcohol use disorder (AUD) [11, 12].

The number of emergency room admissions for acute or chronic alcohol-related diseases are underestimated and underreported. The emergency room plays a key role, because it is often the first contact between the patient and health care professionals. However, it is necessary to recognize.

these conditions in order to refer the patient to the appropriate local alcohol services, which reduces cost, crowding, and correctly refers the patient to the right care [13, 14].

Acute Alcohol Intoxication

Acute alcohol intoxication is a clinically harmful (although typically transient) condition that usually follows the ingestion of a large amount of alcohol [8]. Alcohol is absorbed through the small intestine, primarily by the stomach (70%), to a lesser degree by the duodenum (25%), and only 5% by the remaining intestine [15]. Its metabolism begins at the time of ingestion, and 10% of degradation occurs already through local metabolism in the stomach. In this mechanism, a part of the ingested alcohol is oxidized by alcohol dehydrogenase (ADH) present in the stomach [16], rather than being absorbed into the systemic circulation. There is no specific transport protein that binds alcohol, and thus the remaining alcohol is absorbed through membrane passage, and distributed in the total body water. From the stomach, alcohol reaches the duodenum and jejunum, with a progressive reduction of local metabolism. The remaining metabolism (90%) takes place in the liver, where the main enzymatic systems responsible for the oxidation of alcohol are present (90% constituted by ADH, 8–10% by the microsomal alcohol oxidant system (MEOS) and 0–2% by catalase [17]. When the alcohol consumption exceeds the metabolic capacity of the liver and sufficient blood alcohol levels accumulate, the intoxication symptoms begin [8].

The Diagnostic and Statistical Manual of Mental Disorders (DSM-V) diagnostic criteria for alcohol intoxication include [18]:

1. recent ingestion of alcohol;
2. clinically significant problematic behavioral or psychological changes (e.g., inappropriate sexual or aggressive behavior, mood lability, impaired judgment) that developed during, or shortly after, alcohol ingestion;
3. one (or more) of the following signs or symptoms developing during, or shortly after, alcohol use: (1). slurred speech. (2). incoordination. (3). unsteady gait. (4). nystagmus. (5). impairment in attention or memory. (6). stupor or coma;
4. the signs or symptoms are not attributable to another medical condition and are not better explained by another mental disorder, including intoxication with another substance

The diagnostic criteria are reported in Table 22.1.

Epidemiology

Acute alcohol intoxication is a common cause of admission to the Emergency Department: in the USA, it accounts for over 600,000 visits each year [19], while in Europe, it represents around 1.2–5% of all Emergency Deparment visits annually [20]. Of these admissions, about 1% of intoxicated patients who do not present other complications receive treatment in the Intensive Care Unit (ICU), in Emergency Departments specialized in acute alcohol intoxication [21]. In the United States, an increase in Emergency Department admissions between 2006–2014 has been

Table 22.1 Diagnostic criteria for diagnosis of Acute Alcohol Intoxication according to the Diagnostic and Statistical Manual of Mental Disorders fifth edition (American Psychiatric Association [2013] Diagnostic and statistical manual of mental disorders: DSM-5, fifth ed. The American Psychiatric Association, Washington, DC)

Diagnostic criteria for Acute Alcohol Intoxication

AND
2. Clinically significant problematic behavioral or psychological changes (e.g., inappropriate sexual or aggressive behavior, mood lability, impaired judgment) that developed during, or shortly after, alcohol ingestion
AND
3. One (or more) of the following signs or symptoms developing during, or shortly after, alcohol use
(a) slurred speech
(b) lack of coordination
(c) unsteady gait
(d) nystagmus
(e) impairment of attention or memory
(f) stupor or coma
AND
4. Signs or symptoms are not attributable to another medical condition and are not better explained by another mental disorder, including intoxication with another substance

estimated to result in an increase in alcohol-related health care costs by 272%, reaching $ 15.3 billion in 2014 [22]. Furthermore, also due to the rise of binge drinking, it has been estimated that about 17% of patients who are admitted to the Emergency Department for alcohol-related problems are adolescents <14 years [14], with BAC values > or =80 mg/dL [10].

There are several risk factors for developing either mild or severe acute alcohol intoxication (i.e., severe enough to require an Emergency Department visit). These risk factors can be genetic and environmental, and include [11]:

- sex: differences in BAC between men and women may vary, depending on gastric metabolism of alcohol and how BAC is measured (whether by body mass or by g per h or g per L of liver volume) [23–25];
- age: liver enzymes are not fully expressed in younger subjects;
- race: some studies have shown that Native Americans may have an increased degradation of alcohol compared to Caucasians, who in turn show equal metabolic capacity of alcohol compared to Chinese [26];
- nutrition: fasting increases the risk of alcohol intoxication because of reduction in gastric ADH levels [27];
- biological rhythms;
- exercise;
- alcohol use disorder (AUD): as a result of enzyme induction, heavy drinkers show an increased alcohol degradation;
- drugs.

Patients suffering from AUD are often difficult to treat in the Emergency Department, because they often present complicated physical and psychosocial situations, aggressive behaviors and poor compliance. This can cause delays and failures in the treatment of this type of patient [28].

Signs and Symptoms

The clinical presentation of acute alcohol intoxication can vary in relation to BAC levels. Acute alcohol intoxication can therefore be divided into three levels of severity, mild, moderate, or severe. BAC below 50–100 mg/dL (10.9–21.7 mmol/L) corresponds to mild symptoms, including relaxation, euphoria and/or mild impairment in coordination and attention [29]. In the moderate form, which is associated with a BAC between 100 and 200 mg/dL (21.7–43.4 mmol/L), symptoms may include ataxia, hyperreflexia, lack of coordination, slurred speech, prolonged reaction time, nystagmus, and behavioral changes. The most severe form of AAI can finally appear when the BAC increases over 200 mg/dL and the clinical features worsen with the onset of nausea/emesis, amnesia, diplopia, dysarthria. At a BAC higher than 300 mg/dL (65.1 mmol/L), there is an increased risk of respiratory depression, coma and cardiac arrest. The signs and symptoms are reported in Table 22.2.

In subjects with low alcohol tolerance (a mechanism induced by alteration of the GABA and glutamate neurotransmitter systems at the level of the central nervous system), however, severe symptoms may occur even at lower BAC levels. Conversely, in chronic drinkers with AUD who present higher alcohol tolerance, BAC levels can be markedly increased before severe symptoms occur [8, 31].

In acute alcohol intoxication, multiple organs and systems can be affected by the toxic action of alcohol. Multiple metabolic derangements, including hypoglycemia, hyperlactatemia, hypokalemia, hypomagnesemia, hypocalcemia, and hypophosphatemia, can also occur [8].

Neurological symptoms are usually the first to become noticable to health professionals. The most frequent neurological complications in acute alcohol intoxication are represented by convulsions. These are usually tonic-clonic, and can transition into a status epilepticus. This is a life threatening condition in which generalized seizure activity lasts >5 min, or multiple seizures occur within that period, potentially resulting in cardiac arrhythmia, cardiac damage because of a catecholamine surge, respiratory failure, hypoventilation, hypoxia, aspiration pneumonia, and pulmonary edema. Secondary to convulsions, patients may develop rhabdomyolysis, which generally manifests itself through the onset of asthenia, myalgia and flaccidity, and can lead to acute renal failure and hyperkaliemia in severe forms, with an increase in blood creatine phosphokinases [29]. The causes of neurological symptoms in acute alcohol intoxication include a lack of thiamine, electrolyte derangement, alterations in the levels of GABA and glutamate, or an acute damage of the blood brain barrier [32]. Other serious forms of neurological involvement also exist and should be remembered: acute alcoholic encephalopathy, also called

Table 22.2 Main clinical symptoms in acute alcohol intoxication according to blood alcohol concentration (BAC)

Symptoms	BAC	Drinks
Motor impairment	BAC < 50 mg/dL (10.9 mmol/L)	
Mild euphoria/dysphoria		1–2 drinks
Relaxation		
Social disinhibition		
Altered perception of the environment	BAC > 100 mg/dL (21.7 mmol/L)	3–5 drinks
Ataxia,		
Hyper-reflexia		
Impaired judgment		
Lack of coordination		
Mood, personality, and behavioral changes Nystagmus		
Prolonged reaction time		
Marked slurred speech		
Amnesia	BAC > 200 mg/dL (43.4 mmol/L)	10–20 drinks
Nausea/vomiting		
Diplopia		
Dysarthria		
Hypothermia		
Hypoventilation		
Cardiac arrhythmia		
Coma	BAC > 400 mg/dL (86.8 mmol/L)	>20 drinks
Respiratory arrest		
Death		

Modified from Vonghia et al. [8] and Jung et al. [30]

[a]A standard single drink contains about 10–12 mg of ethanol, which is estimated to increase the blood alcohol concentration of a 70-kg (155-lb) man by 15–20 mg/dL

Gaye-Wernicke encephalopathy, involves the metabolism of thiamine, and is characterized by subacute hemorrhagic encephalopathy and development of oculomotor disorders, cerebellar ataxia, memory impairment, hyperkinesia and disorders of the autonomic system, leading to chronic Korsakoff's syndrome;

- central pontine myelinolysis, characterized by an acute cerebral demyelination, with consequent development of myosis, tetraplegia, aphonia, impaired ocular motility in the horizontal plane;
- Marchiafava-Bignami syndrome, a demyelination of corpus callosum, with manifestations ranging from memory alterations to coma.
- Finally, patients with AUD or repeated episodes of alcohol intoxication have a higher risk of developing dementia [33].

The cardiovascular system can be affected through the action of alcohol on arterial vessels. Vasodilation can occur, resulting in an increase in heart rate, and causing hypotension and heat loss [15]. Furthermore, alcohol can directly induce arrhythmias, such as atrial or ventricular fibrillation, or alterations of QRS or QTc, which

can be observed through an ECG. Direct damage to the myocardium can also take place, as evidenced by increases in troponin values [34–36]. These disorders can also arise in young subjects, in the absence of underlying heart disease [14]. Furthermore, through echocardiography, an alteration of diastolic function (E/E' ratio) was detected in subjects with acute alcohol intoxication (indicating an acute diastolic impairment), which can be used as an echocardiographic marker of early alcoholic cardiomyopathy [37].

From a respiratory perspective, patients with acute alcohol intoxication have an increased risk of developing aspiration pneumonia. This can be due to dysfunction of the clearance of the ciliary mucosa, due to alcohol-related immune dysfunction, or both [38]. There is also a risk for respiratory depression secondary to neurological impairments.

Gastrointestinal effects of alcohol can be highly variable. Nausea and vomiting are common, due to pyloric spasm. They are often accompanied by diarrhea, due to increased transit of intestinal contents, but there can also be abdominal pain, and pancreatitis [39, 40]. Alcohol intake can also irritate the esophagus and stomach mucosa, leading to esophagitis, gastritis and gastric ulcers [30]. The predominant gastrointenstinal insult from acute alcohol intoxication affects the liver, the organ primarily involved in the metabolism of alcohol. Alcohol exposure can lead to acute alcoholic hepatitis, a serious condition associated with a high mortality already at the first episode, and described in detail below [41]. Acute alcohol intoxication can also lead to the development of the Zieve syndrome, characterized by hemolytic anemia, jaundice, and hypertriglyceridemia, even though it is not a common occurrence [42].

Finally, acute alcohol intoxication is associated with an increased risk of injury, trauma and death, which can be further increased in patients with comorbid psychiatric disorders [43].

Diagnosis

The diagnosis of acute alcohol intoxication can be made only after having ruled out other and potentially more serious conditions with a similar clinical presentation, such as sepsis, meningitis, trauma with intracranial bleeding, intoxication from other substances, hypoxia, hypoglycemia or other metabolic disorders. It's important to avoid minimizing issues or rapidly discharging patients because of disruptive behaviors, as this can lead to a life-threatening condition remaining undiagnosed [44]. The first step is to collect an accurate alcohol history. Although this can often be difficult, the history should be focused on the amount of recent alcohol intake, type of beverage consumed, and the time course of symptoms [8].

The physical examination is based on the ABCDE (Airway-Breath-Cardio-Disability-Exposure) pattern, systematically analyzing respiratory, cardiac and the neurological systems, state of hydration, AUD-related signs, including poor nutritional status. Lab tests should include BAC, together with an analysis of liver function, electrolytes (sodium, potassium, etc.) and toxicological screening aimed at

detecting the presence of other intoxicants that may interact with alcohol and further complicated its effects. Depending on the BAC value, it may be important to increase the blood degradation of alcohol in order to prevent possible organ damage [8, 14]. Arterial or venous blood gas analysis is also a quick test that can be very useful, and can immediately give information about the metabolic and respiratory status of the patient. Electrocardiogram and chest radiography must also be performed. If the neurological state is altered, and/or the patient is suspected to have had head trauma, Computed tomography (CT) or MRI of the brain should also be performed.

Treatment

There are three main treatment goals: patient stabilization, acceleration of alcohol elimination and, if necessary, patient sedation until sobriety has reached. Maintaining a free airway is essential to prevent aspiration, and the lateral safety position is recommended. Oxygen may need to be provided, preferably guided by pulse oxymetry. Antibiotics may be required if respiratory infection is suspected or confirmed. In patients with heavy alcohol use, serious infections may be present with surprisingly little symptoms, and chest rays should be ordered liberally.

Hydration is mandatory and intravenous access should be obtained in order to administer fluids [15], and correct hypoglycemia as well as electrolyte balance. A fluid therapy protocol has been suggested: 500 mL of 10% dextrose +500 mL of 0.9% sodium chloride with 2 g of magnesium sulphate +100 mg thiamine +1 mg folate. It is essential to administer thiamine before glucose loading, to reduce the risk of precipitating Wernicke's encephalopathy [45]. Bicarbonates should only be used in cases of metabolic acidosis. Nausea and vomiting can be treated with antiemetic drugs and electrolyte solutions, which avoids prolonged gastric fluid losses [46]. Moreover, in case of hypothermia that is unresponsive to fluid therapy, hemodialysis or peritoneal dialysis are therapeutic options [47]. Should the patient psychomotor agitation, haloperidol is the drug of choice, because it minimizes the potential for negative effects on circulation [44].

The strategies reviewed above are supportive. The only validated therapy in acute alcohol intoxication is **methadoxine,** a pyrrolidone carboxylate of pyridoxine, (pyridoxol L-2-pyrrolidone-5-carboxilate) that enhances the plasma clearance of alcohol, thus reducing toxic consequences of the alcohol exposure. Pyridoxine increases the synthesis of glutathione and the activity of acetaldehyde dehydrogenase, thus increasing in the urinary elimination of ketones [48–50].

A bolus of 900 milligrams IV, (commonly three vials of 300 mg each), doubles the rate at which alcohol blood levels decrease compared to placebo, obtaining a faster rate of alcohol elimination and an accelerated recovery. It appears to be manageable and safe [48, 49]. In some recent trials, methadoxine has also been tested as a drug to stop the chronic consumption of alcoholic beverages in patients with AUD, with encouraging preliminary results [51]. Moreover, having an antioxidant action,

methadoxin appears to improve the condition of patients with alcohol associated liver diseases (ALD) [52]. Also, methadoxine in association with cortisone proved to be more effective than cortisone alone in the treatment of acute alcoholic hepatitis [53].

Biomimetic nanocomplexes containing alcohol oxidase and catalase could be possible future treatments for acute alcohol intoxication, as suggested by *in vivo* and *in vitro* studies, with the aim of reducing alcohol levels through the encapsulation of the same enzymes inside a thin polymer shell [54]. In this way, these nanocomplexes simulate the action of cellular organisms with internal subcellular compartments which are normally able to transform and eliminate toxic metabolic waste. These data, although preliminary, deserve to be explored infurther clinical studies.

Alcohol Withdrawal Syndrome

Patients who abruptly discontinue or reduce alcohol consumption are at risk of developing an alcohol withdrawal syndrome (AWS). Considering that the prevalence of AUD among adult patients presenting to Emergency Departments is about 20–25% [55], a significant proportion of patients hospitalized for medical or surgical problems are at risk of developing AWS. Indeed, the prevalence of AWS among patients admitted to an ICU reaches 40%. AWS is associated with an increased risk of infections and death [56, 57]. Although withdrawal symptoms are common among AUD patients (up to 50%) [58, 59], only a minority of these reach medical attention.

AWS is a clinical condition characterized by symptoms of central nervous system hyperexcitability and autonomic hyperactivity, manifested, e.g., as agitation, tremors, irritability, anxiety, hyperreflexia, confusion, hypertension, tachycardia, fever and diaphoresis). The onset of these symptoms is usually within 6–24 h after the abrupt discontinuation or marked decrease of alcohol consumption in patients suffering from AUD [60]. The spectrum of disease ranges from mild-moderate forms characterized by tremors, nausea, anxiety and depressed mood, to severe forms characterized by hallucinations, seizures, delirium tremens and coma [61]. While mild–moderate AWS is often self-managed by patients or dissipates within 2–7 days from the last drink [59, 62], the more severe forms require medical treatment [58, 59].

Pathophysiology

Acute alcohol ingestion produces CNS depression due to an increased GABAergic neurotransmission (stimulation of GABA-A receptors) [63] and to a reduced glutamatergic activity (inhibition of N-methyl-D-aspartate—NMDA—receptors) [64,

65]. Chronic CNS exposure to alcohol produces adaptive changes in multiple neurotransmitter systems, including GABA, glutamate and norepinephrine [66], which compensate for the alcohol-induced dysregulation. This causes a new neurochemical equilibrium to be established [67], in which there is a reduction of alcohol's effects on the CNS such that excitation—inhibition balance is maintained despite the suppressant effect of alcohol, a condition known as tolerance [64, 68]. Abrupt discontinuation of alcohol use under these conditions leads to a rebound, in which excitation—inhibition balance is shifted toward increased excitation. The reduction in GABA and increase in glutamate neurotransmissions that occur with acute alcohol intake are now reversed, and lead to a generalized CNS hyperexcitability and AWS symptoms [67]. Moreover, upregulated dopaminergic and noradrenergic pathways are also involved in the development of hallucinations and autonomic hyperactivity [61].

Symptoms

Any patient presenting with symptoms of hyperarousal should be evaluated for AWS. The patient's drinking habits, i.e., duration, amount and frequency of alcohol consumption, should be evaluated. This is particularly appropriate if symptoms occur after some hours of alcohol abstinence, e.g., on awakening in the morning. Clinical questionnaires, such as CAGE or AUDIT [69] can help the physician identify an underlying AUD. Patients unable to collaborate due to an altered mental state should be monitored for the appearance of AWS symptoms, in particular if the altered state appears following a major trauma or road accident [70]. The clinical manifestations of AWS are usually progressive, such that initial mild symptoms progressively become more severe. However, AWS can abruptly begin with the onset of a delirium tremens (DT; see below), particularly in patients who have experienced prior episodes of DT, and those with repeated AWSs. The latter is thought to result from 'kindling', a phenomenon originally described for seizures, in which repeated episodes of delirium tremens or AWS result in a progressive lowering of the threshold for at which the next episode occurs [60].

Initial AWS symptoms include tremor, diaphoresis, nausea/vomiting, hypertension, tachycardia, hyperthermia and tachypnoea, typically start 6–12 h after cessation of alcohol consumption, and disappear if alcohol intake is resumed [71]. It is important to keep in mind that several medications patients may be receiving, such as beta-blockers, clonidine, or calcium-channels blockers, could mask changes in blood pressure and heart rate, vital signs otherwise useful to monitor progression of withdrawal severity.

A second stage of AWS symptoms can start appearing approximately 24 h after the last drink, and consists of visual and tactile symptoms. At this stage, a quarter of AWS patients can also experience hallucinations, which are most commonly visual, but can also be auditory or tactile [71]. These disturbances are also called withdrawal hallucinosis, or pre-delirium. Before abnormal perceptions reach the level of true hallucinosis, i.e., a condition in which the patient loses touch with reality, the sensorium can be clear, and the abnormal sensations can be perceived as unreal, classifying them as illusions [71].

The third stage, and the most severe manifestation of AWS, is represented by DT, which affects about 5% of patients with AWS [61]. DT usually appears 48–72 h after the last drink, but could begin up to 10 days later, in particular in patients who combine heavy alcohol use with non-medical used of bensodiazepines. Unless treated aggressively, symptoms of DT normally last 5 to 7 days [71, 72]. The emergence of severe DT in a hospitalized patient is typically the result of a failure to initiate treatment of AWS in time, providing insufficient treatment, or both [61]. DT is a clinical condition characterized by a rapid fluctuation of consciousness and cognition, combined with severe autonomic manifestations such as sweating, nausea, tachycardia and tremors), and psychiatric symptoms (anxiety) [61]. The typical DT patient shows anxiety, agitation, hallucinations and disorientation. The lack of orientation differentiates delirium from withdrawal hallucinosis. Delirium, psychosis, hallucinations, hyperthermia, malignant hypertension, seizures and coma are common manifestations of DT [18, 71, 72]. DT could be responsible for injury to patients and staff, or for other medical complications, such as aspiration pneumonia, arrhythmia or myocardial infarction, which can lead to death in about 1–5% of patients [61]. After the treatment of acute AWS, some symptoms can persist from weeks to months following the 5–7 days of acute detoxification period, representing the 'protracted AWS' [61].

Alcohol withdrawal seizures are a separate, common and important manifestation of the hyperexcitability that emerges in the central nervous system during AWS, and affect about 10% of patients [72]. Seizures precede the emergence of DT, frequently occur in the absence of other AWS symptoms, and occur in 90% of cases within 48 h from the last drink. Seizures are tonic-clonic, diffuse, with little or no postictal period [72]. Although most commonly self-limiting, they can be difficult to manage, and in almost one-third of patients, alcohol withdrawal seizures progress to DT [61]. In more than half of the cases, seizures recur, and in up to 5%, they may progress to a status epilepticus [73]. More than 50% of withdrawal seizures are associated with risk factors such as prior seizures, structural brain lesions, or use of other drugs [74]. Seizures that occur later than 48 h after the last drink should prompt the clinician to consider other causes, such as head trauma or combined drug withdrawal effects [74].

Diagnosis

The diagnosis of AWS is based on the observation of signs and symptoms of withdrawal in patients who have experienced an abrupt reduction or cessation of alcohol consumption [18]. At least two of the following symptoms should be observed [18]:

- autonomic hyperactivity (sweating or tachycardia);
- increased hand tremor;
- insomnia;
- nausea or vomiting;
- transient visual, tactile or auditory hallucinations or illusions;
- psychomotor agitation;
- anxiety;
- tonic–clonic seizures.

In addition, symptoms related to acute or chronic alcohol abuse or withdrawal should be differentiated from those related to other psychiatric disorders [18].

The Clinical Institute Withdrawal Assessment for Alcohol (CIWA-A) scale, and particularly its 10-item revised form (CIWA-Ar) [75], is useful for assessing the severity of AWS (Table 22.3). Scores <8 indicate mild withdrawal, 8–15 indicate moderate withdrawal (marked autonomic arousal) and >15 indicate severe withdrawal and are also predictive of the development of seizures and delirium. Pharmacological treatment is not necessary if CIWA-Ar is <8–10, may be appropriate with scores ranging 8–15 to prevent progression to more severe forms of AWS, and is strongly indicated in patients with CIWA-Ar scores >15.

The Alcohol Withdrawal Scale represent another useful tool to assess AWS's severity in patients who cannot cooperate due to severe withdrawal [76]. However, from a practical point of view, the need is to predict the probability of a patient developing severe AWS in order to start a more aggressive treatment despite presenting symptoms. It should be emphasized that severe medical illnesses, such as

Table 22.3 Clinical Institute Withdrawal Assessment for Alcohol—revised (CIWA-Ar) scale

Clinical Institute Withdrawal Assessment for Alcohol revised	
Symptoms	Range of scores
Nausea or vomiting	0 (no nausea, no vomiting): 7 (constant nausea and/or vomiting)
Tremor	0 (no tremor): 7 (severe tremors, even with arms not extended)
Paroxysmal sweats	0 (no sweat visible): 7 (drenching sweats)
Anxiety	0 (no anxiety, at ease): 7 (acute panic states)
Agitation	0 (normal activity): 7 (constantly thrashes about)
Tactile disturbances	0 (none): 7 (continuous hallucinations)
Auditory disturbances	0 (not present): 7 (continuous hallucinations)
Visual disturbances	0 (not present): 7 (continuous hallucinations)
Headache	0 (not present): 7 (extremely severe)
Orientation/clouding of sensorium	0 (orientated, can do serial additions): 4 (disorientated for place and/or person)

pneumonia, coronary heart disease, alcohol liver disease and anemia, have been reported to precipitate AWS and to increase the risk of severe AWS [60]. In these patients, prophylactic treatment could be useful, regardless of CIWA score.

Treatment.

Goals of Treatment

The primary objective of AWS treatment is to prevent withdrawal seizures, DT, and other serious medical complications. In addition, symptoms of AWS are uncomfortable, and patients may be unwilling to stop drinking in part due to a fear of developing withdrawal. Consequently, treatment should aim at reducing symptom's severity, preventing progression to more severe forms and improving the patient's quality of life [61, 77]. In addition, treatment of AWS should help patients engage with a multidisciplinary alcohol relapse prevention program [61, 77, 78]. Patients with mild-to-moderate AWS (e.g., CIWA <15) can be managed as outpatients, while those presenting with more severe forms should be monitored and treated in an inpatient setting [79].

General Treatment and Supportive Care

Non-pharmacological interventions should be aimed at providing a low stimulus environment. A quiet room without dark shadows, noises or other excessive stimuli (i.e., bright lights) is recommended [60]. General supportive care should correct dehydration, hypoglycemia and electrolyte disturbances, and should include hydration and vitamin supplementation. In particular, thiamine supplementation is essential for the prevention of Wernicke's Encelopathy (WE) [8].

Specific Treatment

The general principle of AWS treatment is to reduce CNS hyperexcitability using medications that show cross-tolerance with alcohol, and then taper these at a rate that allows the pathological excitation—inhibition balance that has been established during prolonged heavy drinking to normalize. Although this can essentially be achieved using any medication that potentiates GABA-ergic transmission, benzodiazepines (BZDs) are the gold standard treatment of AWS [80, 81]. This is the only pharmacological class with robust evidence supporting their ability to prevent the progression to complicated AWS and to reduce the incidence of seizures (84%), DT and mortality [60, 78, 79]. BZDs mediate their therapeutic effect through positive allosteric modulation of GABA receptors, thus mimicking the effects of alcohol [82]. Although evidence on the superiority of any BZD over another are lacking, the

most robust data are available for long-acting agents (e.g., chlordiazepoxide and diazepam) [60, 83], promoting a smoother withdrawal [60, 83]. Several BZDs have active metabolites generated by phase I liver oxidation and inactivated by phase II liver glucuronidation and excretion [60]. As a consequence, patients with reduced liver metabolism (e.g., elderly, those with advanced liver disease) could benefit from short-acting agents, such as oxazepam or lorazepam, in order to prevent excessive sedation, ataxia resulting in a risk of falls and fractures, and respiratory depression [83]. Besides BZDs, clomethiazole is also widely used in Europe [60].

AWS can be treated using different treatment regimens, specifically called 'fixed-dose', 'loading dose' and 'symptom-triggered':

In the fixed-dose approach, a predetermined administration schedule is used, independent of patient's symptoms, with a tapering over 4–7 days. An example of such a regimen is diazepam 10 mg four times a day for 1 day, then 5 mg four times a day for 2 days, then tapering off, typically combined with the possibility to administer extra doses if sufficient symptom control is not achieved. This represents the preferred approach to patients with, or at risk of, severe AWS. The potential disadvantage of this approach is a risk that the administered doses are either insufficient to prevent the emergence of a DT, or unnecessarily high, resulting in excessive sedation [60, 83]. Most treatment providers therefore have 2–3 different fixed order sets for these tapers, at different dose levels. It can, however, be difficult to select the right order set for an individual patient based on the initial evaluation of AWS severity. This approach therefore requires careful monitoring, so that dosing can be properly adjusted.

The loading-dose scheme can be combined with the approach above. A moderate-to-high dose of a long-acting BZD, corresponding to 15–30 mg diazepam is administered, and the response is monitored. If withdrawal severity is adequately lowered within appr. 1 h, treatment can transition to a fixed taper. Otherwise, bolus doses are repeated until patient is sedated. In rare cases, repeated loading doses are insufficient to obtain an adequate response. This identifies the few patients who are in need of particularly aggressive treatment to prevent emergence of DT, potentially including i.v. administration of BDZs (diazepam or midazolam) under strict monitoring at an intermediate care or intensive care unit.

The use of a symptom-triggered schedule requires the administration of the chosen drug (e.g., diazepam 5–20 mg, chlordiazepoxide 50–100 mg or lorazepam 2–4 mg) whenever the CIWA-Ar score is >8–10. Symptoms are evaluated hourly and the chosen drug (i.e., 5–10 mg of diazepam) is administered in order to reduce the CIWA-Ar score below 8 points. Although there is no evidence of a clear superiority for any of the three regimens [60, 83], the symptom-triggered seems to reduce total BZD consumption and treatment duration [80].

It should be emphasized that the administration of BZDs represents the cornerstone of the management for any severity of AWS, and is effective for prevention of both seizures and DT. In particular, treatment of DT requires the use of BZDs as primary drugs, with the possible use of antipsychotic medications to control symptoms of psychosis (see below). However, the use of BZDs also has limitations. It is associated with an increased risk of excessive sedation, motor and memory deficits and respiratory depression, particularly among patients with liver impairment [81,

84]. Moreover, the risk of abuse and dependence [60, 83] limits BZD use in AUD patients if withdrawal is managed in an outpatient setting [81].

Considering these limitations, several other medications have been tested for the treatment of AWS in research studies. Among these, α2-agonists and beta-blockers are useful for the management of neuro-autonomic manifestation such as tachycardia and hypertension; neuroleptics should be used to control hallucinosis and delirium. However, these medications can mask underlying core withdrawal symptoms of CNS hyperexcitability, thus increasing the risk of seizures and DT. These medications should therefore not be used as monotherapy, but rather as adjunctive drug on BZDs.

Although used in the management of mild-to-moderate forms of AWS, the clinical utility of antiepileptics (e.g., carbamazepine, valproic acid, gabapentin, pregabalin and topiramate) is limited by a potential for liver toxicity associated with som of some of these agents [60, 82], and a lack of efficacy when used as first-line treatment [85, 86]. Sodium oxybate, with its alcohol-mimicking effects represents a useful option in the treatment of both AWS and long-term treatment for alcohol relapse prevention [60]. Finally, baclofen, a GABA-B agonist, represents a promising drug in the treatment of both AWS and post-withdrawal [87], or at least a valid alternative [88]. The lack of any significant side effects and of liver toxicity [89] makes it possible to use this drug for the treatment of AUD patients suffering from liver disease [90].

Alcoholic Hepatitis

Alcoholic hepatitis is a clinical syndrome characterized by acute liver inflammation, jaundice and liver function impairment, that occurs in patients with a history of acute heavy and/or prolonged alcohol use. More details are provided in Chaps. 64, 65, 66, 67 and 68 of Part X. The laboratory profile reveals neutrophilia, moderately high AST levels (generally <300 IU/L) with an AST/ALT ratio greater than 1.5–2 and in severe forms a total serum bilirubin level greater than 85 micromol/L (5 mg/dL) [3, 91].

Pathogenesis

Heavy drinkers (60 g/day of alcohol consumption) develop hepatic steatosis, a condition that is reversible if alcohol intake is reduce or discontined. This is an asymptomatic condition, which can be associated with hepatomegaly and a mild alteration of AST and GGT [92, 93]. If heavy alcohol use continues, steatosis can progress to an inflammation of the liver, i.e., a (chemical) hepatitis. Factors such as obesity or viral infections (most importantly Hepatitis C), in association with other genetic or environmental factors, increase the risk for progression and severity of alcoholic hepatitis.

Diagnosis

Symptoms associated with alcoholic hepatitis are mainly malaise and painful hepatomegaly. In many cases, the acute inflammation occurs against a background of chronic cirrhotic damage (see below), potentially resulting in hepatic decompensation and encephalopathy. The diagnosis of an alcoholic hepatitis is mainly suggested by a careful alcohol history taken by the physician. This must assess both previous and current consumption, evaluating any quantitative alterations in alcohol consumption [94]. It is not uncommon for alcoholic hepatitis to occur in patients who have been abstinent in the weeks prior to diagnosis [91].

In the absence of jaundice, alcoholic hepatitis can be asymptomatic at the presentation. In the presence of a history of heavy alcohol use consistent with the onset of alcoholic hepatitis, blood tests can confirm the diagnosis in most cases: the rise in bilirubin>3 mg/dL, AST/ALT ratio > 1.5 but <400 IU/mL in acute can support the hypothesis. Serologic tests for viral hepatitis (Hepatitis B and C) should be performed, as well as liver autoimmunity and Wilson's disease screening. Abdominal ultrasound can be helpful to rule out mechanical causes of jaundice.

In the symptomatic forms, although alcoholic hepatitis is a frequent cause of jaundice, histological confirmation should be performed if possible, as jaundice could be linked to other causes such as drug hepatotoxicity, infection, the occurrence of hepatocellular carcinoma (HCC), end-stage liver failure or following a complication, in particular gastrointestinal bleeding [95, 96].

Moreover, at the time of diagnosis of symptomatic alcohol hepatitis, more than 50% of patients have underlying advanced liver disease and almost all patients with severe alcohol hepatitis have already developed cirrhosis [93, 97].

Assessment of Prognosis

The most used score to assess the severity and the short-term prognosis of alcohol hepatitis, both in randomized trials and in clinical practice, is conventionally Maddrey's discriminant function score (MDF), based on the levels of serum bilirubin and prothrombin time. If MDF is above 32 points, alcohol hepatitis is severe and treatment with corticosteroids (methylprednisolone 32–40 mg IV daily) should be administered. Otherwise, the disease has a poor prognosis, with mortality of 20 to 30% within 1 month after presentation and 30 to 40% within 6 months after presentation [98, 99]. The early improvement in liver function observed in the first week of treatment is a predictor of short-term survival.

The Lille score integrates patient characteristics at the initiation of corticosteroid treatment such as age, serum albumin, serum creatinine, prothrombin time and change in bilirubin at the end of the first week of corticosteroid therapy. This score is calculated at the **seventh day** of medical and drug treatment and is used to assess the therapeutic response to corticosteroid therapy. Patients with a Lille score **above**

0.45 are non-responders to corticosteroid therapy and have a very low 6-month survival, (around 20% to 30%). Patients with a Lille score lower than 0.45 are responders to corticosteroid therapy and have an excellent 6-month survival, around 70–80%. Discontinuation of corticosteroid therapy is recommended in "complete non-responders" (defined as Lille score of 0.56) because of the risk of severe infections, because in this subgroup corticosteroid therapy is not more effective than placebo. If the Lille score is between 0.45 and 0.56, the arduous challenge to continue corticosteroid therapy should be considered on a case-by-case basis [100].

Treatments

The cornerstone of treatment is to maintain total alcohol abstinence. Abstinence is associated with a markedly improved 5-year survival. Anticraving drugs are strongly suggested after the first episode of alcoholic hepatitis to maintain alcohol abstinence [91, 101].

In most cases of alcoholic hepatitis, especially in severe forms, malnutrition should be recognized and treated, potentially requiring nutrition via a nasogastric tube, or parenteral nutrition [102]. A recent trial confirmed that adequate calory intake associated with cortisone treatment in severe alcoholic hepatitis reduces the 6-month risk of mortality.

Corticosteroid therapy is recommended in severe alcoholic hepatitis [103]. The European Association for the Study of the Liver (EASL) has identified prednisone as the first-line treatment, to be started as early as possible [104]. If prednisone is contraindicated, pentoxifylline is the drug of choice. Consequently, in an Emergency Department, it is advisable to detect alcohol hepatitis, to establish if it is a severe form (with calculation of MDF), and then to start corticosteroid therapy.

The prognosis of severe acute alcoholic hepatitis is related to the response to corticosteroid therapy and to the absence of infectious complications. An infection is observed in 20–30% of patients at admission and develops in 25% in the first month of corticosteroid treatment. At admission, if an infection is diagnosed, corticosteroid therapy should be initiated after a proper infection control.

In case of non-response to corticosteroid therapy, highly selected patients should be considered for early liver transplantation [105, 106].

Trauma and Injuries

It's estimated that between 5% and 40% of trauma patients attending emergency departments are alcohol-related cases [107]. In fact, alcohol use, in particular intoxication, plays a major role in a wide range of injuries, some of which are readily classifiable as alcohol-related, for example road injuries or violent assault, and others which are less so (e.g., falls, injuries in the workplace) [108, 109]. The amount

of alcohol consumption is directly related to the risk of injuries, and even the consumption of two drinks (=24 g of alcohol) doubles the odds of injury. The risk then increases sharply with higher consumption [110].

It's important to emphasize that alcohol use often plays an important role in interpersonal violence, in particular domestic violence perpetrated by male, where it can be considered a causal factor. Worldwide, governments are implementing new laws and restrictions in order to reduce any kind of alcohol-related injury, particularly due to road accidents and interpersonal violence [109].

Conclusion

Alcohol-related emergencies such as acute alcohol intoxication or alcohol withdrawal syndrome are currently a widespread problem and occur very frequently in the Emergency Department. Since in most cases these are reversible conditions, if recognized and treated early, the onset of life-threatening complications can be avoided. Systematic screening should aim at identifying AUD in patients admitted to the emergency room for alcohol-related symptoms, and relapse preventions treatments is essential to initiate in order to to prevent new acute episodes. See also related Chap. 48.

Part IV
Fetal Alcohol Spectrum Disorders (FASD)

Chapter 23
Fetal Alcohol Spectrum Disorders: An Introduction

Eileen M. Moore and Edward P. Riley

Abstract Alcohol is a teratogen, a substance that can disrupt prenatal development and cause malformation. It is now widely accepted that alcohol has the potential to produce adverse outcomes, including dysmorphic features, growth retardation, birth defects, and neurobehavioral deficits. While there are arguably references to the adverse consequences of gestational alcohol exposure in ancient works, modern research on fetal alcohol spectrum disorders (FASD) did not begin until the 1970s. It is estimated that about 10% of pregnancies are alcohol exposed and about 1 in 13 of these offspring will have FASD. Early identification and diagnosis along with appropriate services and interventions is associated with improved outcomes for individuals with FASD. This chapter provides a general introduction to FASD, with emphasis on epidemiology, diagnosis, and alterations in brain and behavior resulting from prenatal alcohol exposure. It also includes a discussion of the potential interventions being developed for individuals with FASD.

Keywords FASD · FAS · Prenatal · Fetal · Alcohol · Pregnancy

Introduction

Prenatal alcohol exposure (PAE) has the potential to produce a range of adverse outcomes, impacting a variety of organs and systems, most notably the brain. This impact on the brain can result in a wide array of cognitive and behavioral deficits that impact quality of life. Additionally, PAE may also result in deficits in growth as well as specific craniofacial features. Collectively, the array of outcomes produced by PAE are referred to as fetal alcohol spectrum disorders (FASD). Here we present an overview of FASD, including its history, epidemiology, diagnostic considerations, brain and behavioral manifestations, and interventions.

History

Warren [1] and Brown et al. [2] provide excellent reviews of the history of PAE and FASD beginning with possible references to the adverse effects of alcohol consumption during pregnancy noted by ancient Greek scholars as well as in the Bible. However, the first clear writings on this topic came from the London College of Physicians in 1724 noting a link between the consumption of distilled spirits and adverse effects on the progeny. In the early twentieth century, Stockard [3] wrote on the impact of alcohol use on developing offspring, citing both experimental animal research on a variety of species, as well as human observational studies. The animal research noted that alcohol treatment resulted in death, slowed growth, and/or malformations. Using fish eggs Stockard noted that "alcohol…showed a peculiar affinity for the developing nervous system…" By 1900 it was shown that alcohol freely enters embryonic tissues in guinea-pigs and dogs resulting in fetal alcohol blood concentrations similar to that of maternal blood alcohol concentrations [4]. At about the same time Sullivan [5] described the outcomes of children born to women from Liverpool Prison who had histories of chronic alcohol misuse that were "uncomplicated by other degenerative factors." He analyzed 600 children, born to 120 of these women and compared them to 138 children born to 28 cases of female relatives who did not use alcohol. The death rate of children under age two (including still births) was nearly two and a half times higher in the alcohol exposed offspring than controls (55.2% vs. 23.9%, respectively). Among surviving children, there appeared to be an increased rate of epilepsy (4.1%) as compared to the population estimates in England (0.1–0.6%). Sullivan also described a few cases of mothers who were imprisoned during a significant portion of their pregnancy, and therefore did not have access to alcohol, whose children were less affected. Based on these observations, Sullivan noted alcohol's "toxic influence exercised on the developing embryo throughout pregnancy" and concluded that alcohol exposure during gestation is "peculiarly unfavorable to the vitality and to the normal development of the offspring. Its gravity in this respect is considerably greater than that of paternal alcoholism" [5]. Alcohol was even included as a cause of intrauterine disturbances in Adami's "Principles of Pathology" [6]; although, he does comment that while it is "well founded" that the children of parents with alcohol use disorders are "of lowered intelligence and vitality with unstable self-control," it is difficult to disentangle the impact of alcohol intoxication during fetal development from other factors, including heredity, malnutrition, and neglect.

Another important factor influencing the history of FASD was that prohibition of alcohol was legislated in a number of countries in the early twentieth century [1]. With prohibition interest in researching PAE declined and previous findings appeared to be ignored, reinterpreted, dismissed, and/or forgotten. In 1939, Mapother [7] summarized the literature regarding the impact of alcohol on offspring. In terms of experimental work in animals, he acknowledged that some effects of alcohol were found in non-mammalian and non-human mammalian species but noted that the research was more supportive that alcohol would have an

"eventual production of an improved strain through wholesale elimination of the more weakly progeny in pre-natal or early post-natal life." He did not discuss any of the prior research that had been conducted in humans. Rather, he stated: "All this, however, is very academic and has little relation to anything at all probable in man; the concentrations used in producing experimental effects are far greater than anything that ever occurs in the human." The view that alcohol could not produce adverse effects upon the developing embryo/fetus in humans came to be dominant for the next few decades. In fact, alcohol even came to be considered somewhat beneficial. For example, the use of high-dose intravenous alcohol for patients at risk for preterm delivery was advocated [8] and most obstetric textbooks from before the 1970s actually recommended that women consume alcohol while pregnant [9].

A few studies describing relations between PAE and poor outcomes continued, although they did not receive much attention. In 1957, a thesis was completed in Paris describing poor outcomes in children who were exposed to alcohol *in utero* [10]. In 1968, Lemoine, a French physician, published his observations of 127 children who exhibited similar physical features and behavioral deficits and who were all born to mothers who had an alcohol use disorder [11]. Unfortunately, these results were not widely disseminated, perhaps because they were published in French. The modern history of FASD began in the early 1970s, with the publication of two papers in the *Lancet* by Jones and Smith and colleagues describing the fetal alcohol syndrome [12, 13]. Despite these papers being met with skepticism and some backlash [14], additional case studies, clinical research, and animal studies, confirmed the teratogenicity of alcohol. In June 1977, the first health advisory was released in the United States in the Food and Drug Administration Drug Bulletin and the Centers for Disease Control and Prevention Morbidity and Mortality Weekly Report [15].

Epidemiology

Determining the true prevalence of FASD is difficult for a number of reasons, including challenges related to recognition, screening and diagnosis and stigma, among other barriers. Active case ascertainment methods are considered the "gold-standard" for prevalence estimation [16] and have been conducted in several countries to estimate the prevalence of FASD. In the US, 13,146 children in first grade were systematically assessed in four communities and the conservative estimate for FASD was between 1–5% of children [17]. In Canada 2555 elementary school students were assessed in the Greater Toronto Area and the prevalence of FASD was estimated to be nearly 2% of children [18]. The estimated prevalence of FASD in the Greater Manchester region of the United Kingdom is 2–4%, in communities near Rome, Italy it is 2–6%, in rural Croatia ~7%, and in Poland at least 2% [19–22]. Much higher prevalence estimates are observed in other specific areas. For example, prevalence of FASD in a community in the Western Cape Province of South Africa, a wine growing region with a history of utilizing the 'Dop system'

(see Williams [23] for a history), are estimated at 16–31% [24]. FASD is also more prevalent among children in foster care, in the correctional system, and among populations in special education.

Active-case ascertainment studies are not available for the majority of countries. However, it is estimated that about 10% of women report consuming alcohol during pregnancy [25]. Not every woman who drinks during pregnancy will have a child with FASD, given that there are many factors that influence risk and resilience. Overall, it is estimated that 8 out of 1000 children in the general population have an FASD and 1 in 13 alcohol-exposed pregnancies will result in a child with FASD [26]. However, regional differences exist in prevalence of alcohol use during pregnancy and FASD. Popova and colleagues identified the available studies reporting prevalence in the general population of each country and used advanced statistical techniques to predict the prevalence for countries where empirical data were not available [25–28]. The European region had the highest rates of alcohol drinking (at any level) during pregnancy (25.2%), although Africa had the highest rates of binge-drinking during pregnancy (3.1%). In the Americas, alcohol use during pregnancy was estimated at 11.2%, and binge drinking at 2.8%. Alcohol use and binge drinking during pregnancy was estimated at 8.6% and 1.8%, respectively, in the Western Pacific region. Comparatively low levels of alcohol use were estimated in the South-East Asian (1.8%) and Eastern Mediterranean (0.2%) regions (it was not possible to estimate binge-drinking in these regions). The rates of FAS and FASD roughly corresponded to the estimated drinking levels. The European region was estimated to have the highest rates of FAS and FASD (37.4 and 198.2 per 10,000, respectively), followed by the region of the Americas (16.6 and 87.9 per 10,000, respectively), the African region (14.8 and 78.3 per 10,000, respectively), and the Western Pacific region (12.7 and 67.4 per 10,000, respectively). The regions with the lowest estimated prevalence of FAS and FASD were the South East Asian (2.7 and 14.1 per 10,000) and Eastern Mediterranean (0.2 and 1.3 per 10,000) regions.

Diagnostic Considerations

Screening

The majority of alcohol-affected individuals are missed or misdiagnosed. In a clinical sample of 156 children who met criteria for an FASD, 125 had never been recognized as having been affected by PAE [29] and in a large active case ascertainment study [17], only 2 of 222 children diagnosed with FASD had a previous FASD diagnosis. A number of factors may contribute to this problem, including unknown maternal alcohol use histories, particularly in foster and adopted children; high rates of co-occurring mental health disorders, concern about stigmatization, poor recognition and/or a lack confidence among health care practitioners in making an FASD

diagnosis, as well as a lack of multidisciplinary FASD diagnostic clinics [30–37]. Compounding these barriers, the age at which an individual is assessed can impact the likelihood of a diagnosis, with diagnosis being especially difficult in infancy and adulthood [38]. Additionally, a number of different diagnostic schemas have been proposed (see Table 23.1), which can be confusing for clinicians, especially given that evaluations of the same individual using different diagnostic schemas can result in different diagnoses being made under the FASD umbrella [42].

Of the children born with FASD each year, it is estimated that less than 1% will receive a diagnosis [43]. This is unfortunate, as early identification and diagnosis coupled with appropriate interventions and services can mitigate adverse outcomes for individuals with FASD [37, 44]. Screening tools are essential for the identification of at-risk individuals. Several screening tools are available for use [45]. Caregiver questionnaires have been developed, such as the Neurobehavioral Screening Tool, which includes 12 items from the Achenbach Child Behavior Checklist that have been shown to significantly differentiate FASD from control groups [46]. However, the reported sensitivity and specificity of this tool varies, with some studies reporting 94% sensitivity and 96% specificity in children age 4–6 years and others reporting 72% sensitivity but only 34% specificity in children and young adults age 3–22 years [47, 48]. Other questionnaires have been developed for specific high-risk populations, such as youth and adults in correctional facilities [49].

Other approaches that have been developed for screening individuals include evaluating markers of PAE. For example, one of the earliest markers of PAE was a pattern of craniofacial features, which along with growth retardation and central nervous system dysfunction, led to the recognition of FAS. These features can be detected either by manual measurement or facial analysis software [50]. Figure 23.1 depicts the facial features of FAS. While most individuals who are affected by PAE do not display the full dysmorphic facial features required for a diagnosis of FAS, research suggests that even among children who do not meet criteria for FAS or partial FAS, analysis of 3-dimensional (3D) facial photography is capable of detecting characteristics consistent with PAE [50]. This suggests that 3D facial analysis screening may have potential for identifying children at risk for FASD. Another marker that is well studied and shows promise for screening is the evaluation of oculomotor control. Eye-tracking to measure saccades, or the rapid movement of eyes that shifts the center of gaze across our visual fields, reveals that children with FASD have longer saccadic reaction times, increased variability, and increased saccadic errors during tasks as compared to controls [52]. Eye-movement was 90% accurate in distinguishing children with FASD from ADHD [53], which is very relevant clinically, given that as many as 95% of children with heavy PAE meet diagnostic criteria for ADHD [31]. Serum protein analyses, dermatoglyphics, functional near-infrared spectroscopy, olfactory testing, and DNA methylation [54–57] have also been investigated as potential screening tools. While many show promise, there is limited research to date for these methods.

Diagnosis

The seminal paper by Jones, Smith & colleagues [12] described a distinct pattern of craniofacial features, growth retardation, as well as developmental delay or intellectual disability and subsequently coined the term FAS [13]. However, it soon was recognized that not all the individuals affected by PAE displayed the features required for a diagnosis of FAS, yet still may have functional deficits that affected their quality of life. Indeed, the range of physical, cognitive, and behavioral outcomes associated with PAE is quite variable. Research has revealed several factors that can influence outcomes associated with PAE, either conferring risk or resilience, including, but not limited to, the dose and timing of alcohol exposure, nutritional status of the mother, genetics of both the mother and the embryo/fetus, co-exposures to other substances, maternal stress, etc. The term FASD became broadly adopted as it refers to the full range of adverse effects caused by PAE [40].

There are a number of existing diagnostic schemas that attempt to capture the wide-ranging outcomes within FASD. In the United States, common diagnostic schema include those proposed by the Institute of Medicine (IOM) and the FASD diagnostic clinic at the University of Washington (4-Digit Code) [39, 58]. Additionally, the *Diagnostic and Statistical Manual of Mental Disorders, fifth Edition* included Neurobehavioral Disorder Associated with Prenatal Alcohol Exposure (ND-PAE) in the appendix as a "condition for further study" [41]. Canada, Australia, and Scotland also have their own diagnostic schemas, which are rather similar to one another [59–61]. The criteria for the IOM, 4-Digit Code, and Canadian schemas are listed in Table 23.1.

Comparisons between the different diagnostic schemas have revealed fairly high discordance. Patient records from 1392 individuals evaluated for FASD at the University of Washington were used to apply the 4-Digit Code, IOM, Canadian, and Australian diagnostic systems and while 82% were diagnosed with an FASD by at least one system, only 11% were diagnosed by all four systems [42]. For many of the diagnostic schemas, a distinction between individuals who have the sentinel facial features associated with PAE and those who do not is made. Additionally, they may allow for a diagnosis to be made even if alcohol-exposure status is unknown when the seminal facial features are present. With one exception, central nervous system involvement is a requirement of every diagnosis. The brain has been noted to be particularly vulnerable to alcohol's teratogenic effects, largely due the fact that it is developing over the entire course of the embryonic and fetal development.

Table 23.1 Different diagnostic schemas of FASD

	4-digit diagnostic code (3rd ed.) [39]	IOM updated criteria [40]	Canadian criteria [41]
FAS	Categories A & B		Not proposed
Alcohol exposure	Confirmed or not confirmed	Confirmed or not confirmed	FASD with sentinel facial features is roughly equivalent to FAS in either the 4-Digit Code or IOM diagnostic schemas
Facial features	Simultaneous expression of all three facial features: small palpebral fissure lenght (≤2 SD), smooth philtrum and thin upper lip (ranks 4–5 using the UW Lip-Philtrum Guides)	≥features: short palpebral fissures (≤10th percentile), thin vermillion border (ranks 4–5 on racially normed lip/philtrum guide), & smooth philtrum (ranks 4–5 on racially normed lip/philtrum guide)	
Growth retardation	Prenatal or postnatal height and/or weight ≤10th percentile with age and gender adjustments	Prenatal or postnatal height and/or weight ≤10th percentile on racially or ethnically appropriate growth curve.	
CNS involvement	Head circumferences ≥2 SD below norm or significant abnormalities in brain structure or evidence of hard neurological findings or significant impairment in ≥3 domains of brain function (≥2 SD below the mean) as assessed by validated and standardized tools	Deficient brain growth, abnormal morphogenesis, or abnormal physiology, including ≥1 of the following: head circumference ≤10th percentile, structural brain anomolies, recurrent nonfebrile seizures. For children ≥3 years, cognitive impairment (general conceptual ability ≥1.5 SD below mean or performance IQ, verbal IQ, or spatial IQ ≥1.5 SD below the mean; or cognitive deficit in ≥1 domain ≥1.5 SD below the mean [executive functioning, learning, memory, or visual-spatial] or behavioral impairment (behavioral deficit in ≥1 domain ≥1.5 SD below the mean in impairments of self-regulation [mood or behavioral regulation impairment, attention deficit, or impulse control). For children <3 years of age, evidence of developmental delay ≥1.5 SD below the mean is required.	

(Continued)

	4-digit diagnostic code (3rd ed.) [39]	IOM updated criteria [40]	Canadian criteria [41]
Partial FAS	Category C		
Alcohol exposure	Confirmed	Confirmed or not confirmed; if no documentation of PAE exists, additional criteria are required (see growth retardation and CNS involvement sections below)	Not proposed
Facial features	Short palpebral fissures (≤2 SD) and either a smooth philtrum or thin vermillion border (ranks 4–5 on UW Lip-Philtrum Guides) with the other being normal, or palpebral fissure (≤1 SD) and both a smooth philtrum and thin vermillion (ranks 4–5 on UW Lip-Philtrum Guides)	Same as FAS	
Growth retardation	Not required	Not required for children with documented PAE. For children without documented PAE, growth deficiency or deficient brain growth is required; the criteria for growth deficiency are the same as for FAS.	
CNS involvement	Same as for FAS	For children with documented PAE, only evidence of neurobehavioral impairment is required; using the same criteria as FAS. For children without documented PAE, growth deficiency or deficient brain growth, abnormal morphogenesis, or abnormal neurophysiology is required; using the same criteria as FAS.	
ARND		This diagnosis cannot be made in children under 3 years.	

	4-digit diagnostic code (3rd ed.) [39]	IOM updated criteria [40]	Canadian criteria [41]
Alcohol exposure	SE/AE and ND/AE combined are roughly equivalent to ARND in the IOM or FASD without sentinel facial features in the Canadian guidelines.	Confirmed	FASD without sentinel facial features is roughly equivalent to ARND in the IOM diagnostic schema or the combination of SE/AE and ND/AE in the 4-Digit Code.
Facial features		Not required	
Growth retardation		Not required	
CNS involvement		Evidence of global impairment (general conceptual ability ≥1.5 SD below the mean, or performance IQ, verbal IQ, or spatial IQ ≥1.5 SD below the mean; or cognitive deficit in ≥2 neurobehavioral domains ≥1.5 SD below the mean (same domains as FAS) or behavioral deficit in ≥2 domains ≥1.5 SD below the mean (same domains as FAS).	
Other		This diagnosis cannot be made in children under 3 years.	
ARBD			
Alcohol exposure	Not proposed	Confirmed	Not proposed
Facial features		Not required	
Growth retardation		Not required	
CNS involvement		Not required	
Other		≥1 specific major malformations demonstrated in animal models and human studies to be the result of PAE; cardiac: atrial septal defects, aberrant great vessels, ventricular septal defects, conotruncal heart defects; skeletal: radioulnar synostosis, vertebral segmentation defects, large joint contractures, scoliosis; renal: aplastic/hypoplastic/dysplastic kidneys, “horseshoe” kidneys/ureteral duplications; eyes: strabismus, ptosis, retinal vascular anomolies, optic nerve hypolasia; ears: conductive hearing loss, neurosensory hearing loss.	

(Continued)

	4-digit diagnostic code (3rd ed.) [39]	IOM updated criteria [40]	Canadian criteria [41]
FASD			Two diagnoses: FASD with & without sentinel features
Alcohol exposure	FASD, in these schemas, is used as a non-diagnostic term refering to the full range of deficits resulting from PAE.		FASD with sentinel facial features allows for confirmed or unconfirmed; FASD without sentinel facial features requires confirmation of PAE with estimated dose at a level known to be associated with neurodevelopmental effects
Facial features			FASD with sentinel facial features requires: Simultaneous expression of all three facial features: small palpebral fissure length (≤2 SD), smooth philtrum and thin upper lip (ranks 4–5 using the UW Lip-Philtrum Guides)
Growth retardation			Not required
CNS involvement			Both diagnoses require evidence of pervasive brain dysfunction, defined as severe impairment (≥2 SD below the mean*) in ≥3 domains: motor skills; neuroanatomy/ neurophysiology; cognition; language; academic achievement; memory; attention; executive function, including impulse control and hyperactivity; affect regulation; adaptive behavior, social skills or social communication

	4-digit diagnostic code (3rd ed.) [39]	IOM updated criteria [40]	Canadian criteria [41]
SE/AE	Categories E & F	Not proposed	Not proposed
Alcohol exposure	Rank 3–4 exposure. Rank 4: confirmed PAE & exposure pattern is consistent with medical literature placing fetus at high risk (i.e., high peak BAC at least weekly in early pregnancy). Rank 3: confirmed PAE but the level of alcohol is less than Rank 4 or the specifics of the exposure level is unknown	SE/AE and ND/AE, together, are roughly equivalent to ARND in the IOM and FASD without sentinel facial features in the Canadian schemas.	
Facial features	Not required		
Growth retardation	Not required		
CNS involvement	Rank 3–4 CNS involvement. Rank 4: ≥1 significant structural abnormalities of the brain or neurological findings of presumed prenatal origin (i.e., microcephaly, hydrocephaly, heterotopias, change in shape or size of brain regions, siezures, other hard neurological signs, etc.). Rank 3: problems across ≥3 domains as assessed by standardized, validated psychometric assessments including but not limited to executive function, memory, cognition, social/adaptive skills, academic achievement, language, motor, attention or activity level that are likely due to underlying brain damage rathn than adverse postnatal environments		

(Continued)

	4-digit diagnostic code (3rd ed.) [39]	IOM updated criteria [40]	Canadian criteria [41]
ND/AE	Categories G & H		
Alcohol exposure	Same as for SE/AE	ND/AE and SE/AE, together, are roughly equivalent to ARND in the IOM and FASD without sentinel facial features in the Canadian schemas.	
Facial features	Not required		
Growth retardation	Not required		
CNS involvement	Rank 2 CNS involvement: ≥1 domain with at least mild to moderate delay or impairment but <3 domains with significant (≥2 SD below mean) impairment or the appropriate testing has not occurred, i.e., if children are <6 years of age (in these cases, children should be re-assessed when old enough to determine if they meet Rank 3 criteria)		
Notes	The 4-digit code provides an assessment of effects in four areas (growth, facial features, CNS involvement, and alcohol exposure) that results in 256 different codes and 22 diagnostic categories (A-V). Categories A-C & E-H are included in this table; categories I-J include cases where PAE is confirmed but only sentinal physical findings were present (I) or no physical findings or CNS abnormalities were detected (J); the remaining categories (D, K-V) include categories for when PAE is unknown or there is confirmation that PAE did not occur.	Consideration of FASD is a complex diagnostic process requiring a multidisciplinary approach, sound clinical judgment, and the consideration of the biological parents when available to account for the heritibility of head circumference, growth, cognitive and behavioral characteristics. Differential diagnoses must include genetic disorders or other teratogenic conditions.	A designation of "at risk for neurodevelopmental disorder and FASD, associated with prenatal alcohol exposure" is used to describe individuals with confirmed PAE and some indication of neurodevelopmental concerns, but who do not meet the criteria for either of the FASD diagnostic categories

Please refer to the original text for full diagnostic criteria. *IOM* Institute of Medicine, *UW* University of Washington, *CNS* central nervous system, *FASD* fetal alcohol spectrum disorders, *FAS* fetal alcohol syndrome, *SE/AE* static encephalopathy/alcohol exposed, *ND/AE* neurobehavioral disorder/alcohol exposed

Brain, Cognition, and Behavior

Brain. PAE has the potential to adversely impact any organ systems development; however, the brain is the most studied. The brain has a large window of development, effectively spanning the entire period of the embryonic and fetal stage (and beyond). Thus, alcohol exposure at any point during gestation has the potential to impact brain development and, consequently, cognition and behavior.

Although gross abnormalities in brain are not overly common, magnetic resonance imaging (MRI) studies have found that PAE is associated with a variety of changes to the brain. The most commonly reported finding is smaller brain volume [62]. Several brain regions have been identified as being smaller than one would expect given the overall smaller brain size (i.e., disproportionately smaller). These include the corpus callosum, cerebellum, and basal ganglia [62, 63].

The corpus callosum is the most frequently affected brain region in FASD [64]. Abnormalities were noted in some of the first brain autopsies in children with FAS, and cases of full or partial agenesis of the corpus callosum were reported in some early MRI studies [65]. The shape, location, and size of the corpus callosum may be affected and have been documented in newborns through adulthood [62, 66]. Diffusion tensor imaging (DTI) studies have also reported microstructural changes

to the corpus callosum, including lower fractional anisotropy, higher mean diffusivity, and higher radial diffusivity in a pattern that suggests that myelination or axonal density/caliber is affected [61]. The more anterior (genu) and posterior (isthmus-splenium) regions appear to be the most affected, in terms of macro and microstructure [61]. It should also be noted that, in addition to the corpus callosum, white matter macrostructure (smaller size and displacement) and microstructure (lower FA in several tracts) across the brain is affected by PAE [67–69].

The cerebellum is also frequently affected [64]. It has been shown to be disproportionately smaller, malformed, and displaced in FASD [70] and the volume of the cerebellum relates to the quantity of PAE [71]. The more anterior lobules and the vermis appear to be affected the most, while the more posterior and inferior regions are relatively spared [72]. The most severe effects on the cerebellum are observed among those with FAS, although deficits are also observed in individuals with PAE who do not exhibit the sentinel facial features [73].

The entire basal ganglia volume is disproportionately smaller. Regionally, the caudate is most consistently noted as disproportionately affected by PAE [67]. Further, shape analysis shows that the head and tail regions of the caudate bilaterally are deformed and that the extent of the deformation is related to PAE [74]. However, other basal ganglia regions are also reported to be disproportionately affected by PAE, including the putamen and pallidum [62, 75, 76].

Other regions have also been reported to be disproportionately affected, including limbic, diencephalic, brainstem, and cortical regions. Effects appear to be depending on a number of factors, including the dose of alcohol exposure, diagnostic severity, sex, and age. For example, the volume of diencephalic structures has been reported to relate to the degree of facial dysmorphology in children with PAE [76]. Additionally, the regional effects of PAE on brain structure may differ across development. Longitudinal studies show that children with heavy PAE have differing developmental trajectories of cortical volume, thickness, and gyrification [77]. Generally speaking, as children age into adolescence, a larger discrepancy in brain morphometry emerges between those with PAE and controls.

Functional MRI (fMRI) studies show an overall pattern of broad, widespread brain activation and/or recruitment, in a variety of tasks, of brain regions that differ from those activated in unexposed controls [61, 78]. The activation patterns are often reminiscent of what is observed in younger children, perhaps suggesting delayed maturation. Alternatively, the differences in activation patterns could indicate that the individuals with FASD are utilizing different strategies to complete the task than are controls, and exert greater effort; or that compensatory mechanisms are needed to complete the task. Resting-state fMRI, a task-independent approach to examine neural networks, indicates that PAE is associated with network disruption in neonates that may continue until at least young adulthood [79, 80].

Cognition and Behavior. Consistent with the brain findings, global cognitive deficits are observed in those with FASD, evidenced by generally lower intelligence; however, specific deficits in cognitive domains are also apparent [81].

Attention. Attention deficits are among the most well-documented effects of PAE and have been called a hallmark feature of FASD [82]. Children with PAE are less

efficient at processing visually presented information, have slower reaction times, lower accuracy rates, and make more omission errors than controls [82]. Auditory attention, however, is less impacted than visual attention [82, 83]. Indeed, rates of attention deficit/hyperactivity disorder (ADHD) are as high as 95% in FASD [30]. However, studies comparing children with FASD to nonexposed children with ADHD demonstrate that these two groups differ from one another in a number of ways. As compared to children with ADHD, children with PAE generally have lower IQ scores, more difficulty with encoding information as well as focusing, sustaining, and shifting attention, and greater deficits in working memory, planning, fluency, and set-shifting [81].

Executive functioning. This cognitive construct encompasses a number of interrelated cognitive processes important for goal-directed behavior [81]. Children with PAE have been shown to display deficits across executive function domains, including verbal fluency, response inhibition, problem solving and planning, concept formation, cognitive flexibility, and working memory [81]. Age may be an important moderator of some of these effects. In a cross-sectional study of spatial working memory, an interaction between age and performance was noted such that the children with PAE appeared to improve at a slower rate than controls [84]. Executive function deficits have also been documented in adults with FASD [85].

Learning & Memory. The majority of studies have examined verbal learning and memory. Children with FASD have slower word-list learning, have difficulty recalling words after a delay, and problems discriminating the correct words from distractors [81]. However, once the verbal information is encoded it is retained at the same rate as in controls [86, 87]. Fewer studies of nonverbal memory exist and their results are inconsistent. Some studies report encoding and retrieval deficits for nonverbal information and that deficits in in nonverbal learning and recall persist after accounting for IQ deficits, while others indicate that the long-term retention of visual information is spared [81].

Visual-spatial. Animal studies suggest that PAE produces impairment in the visuo-spatial domain, especially in spatial learning and memory [88]; however, less is known about humans with FASD. Children with PAE have been shown to have impairments of visual construction and copying figures tasks [87]. However, their difficulty may be due, at least in part, to motor deficits rather than completely attributable to perceptual deficits. When asked to recall hierarchical figures, children with PAE had deficits in the recall of local but not global features of the stimuli that were not due to the size of the stimuli or memory deficits [89].

Motor function. Both fine motor and gross motor skills are affected by PAE; however, complex fine motor skills tend to be more severely affected than basic motor skills [90, 91]. Deficits in oculomotor control [50], hand-eye coordination, bimanual coordination, regulating isometric and isotonic force, and sensorimotor ability as well as longer reaction times, difficulty maintaining postural balance, and atypical gait characteristics have all been documented in children with FASD [81]. Some motor deficits have also been shown to persist into adulthood [85].

Language and communication: Speech production and language processing deficits have been observed in children with heavy PAE [81]. Expressive language skills

appear to be somewhat more affected than receptive (impressive) language ability [92]. Parents report that young children with FASD have deficits in communication skills, including trouble maintaining conversation, answering questions, and staying on topic [93], which appear to worsen with age [94].

Secondary conditions: Secondary conditions are problems that develop from the difficulties a person experiences as a consequence of FASD. Secondary conditions encompass a wide array of problems that can impact an individual's quality of life. Individuals with PAE are reported to have deficits in a number of interpersonal domains, adaptive functioning as well as higher rates of mental health problems [30, 43, 94]. Children with PAE are more likely to be described as hyperactive, disruptive, impulsive, or delinquent [95]. Higher rates of inappropriate sexual behavior, disrupted school experiences, delinquency, alcohol and other substance use problems have been observed in adolescents and adults with FASD [43]. Rates of ADHD, oppositional defiant disorder, conduct disorder, mood disorders, and specific phobias are elevated in children with FASD as compared to controls [30, 96, 97]. Of course, PAE cannot fully account for these poor outcomes given that there is a high degree of heritability for many of these behaviors. However, a meta-analysis comparing the risk for externalizing disorders due to PAE versus genetics found that there was increased risk of ADHD due to PAE beyond that due to either parental alcohol use disorder or genetic liability [98]. Regardless of cause, these poor outcomes can be mitigated if children with FASD are identified and diagnosed early, receive appropriate services, and are raised in a stable and caring home environment [43].

Interventions

There are three main points at intervention (see Fig. 23.2). FASD is preventable if no PAE occurs. Preconception interventions focus on increasing awareness of harms of drinking during pregnancy, preventing risky drinking, and education about utilizing contraception effectively. If PAE has occurred, FASD can be mitigated or prevented with drinking cessation interventions. Nutritional interventions show promise as well. Lastly, postnatal interventions include nutritional supplements, exercise, cognitive and behavioral interventions. Psychotropic medications are also often used, however, there are no specific medications approved for the treatment of FASD.

Pre-conception Interventions

Preventing an alcohol-exposed pregnancy will ensure that a child is not born with FASD. Universal interventions target large audiences to increase awareness about the harms of PAE and/or provide education about contraception and prenatal care.

Fig. 23.2 Diagram of the three points of intervention to prevent or mitigate FASD. Interventions after birth may occur at any point over an individual's lifetime. Silhouette images, from left to right, are credited to Chipmunk131/shutterstock.com, Neboisa Kontic/shutterstock.com, and KatarinaF/shutterstock.com

The media, billboards, pamphlets in healthcare facilities, and other health promotion education strategies are used [99]. Warning labels on alcoholic drinks are one example; however, these labels have had only modest effects on drinking during pregnancy, primarily affecting behavior in women who were light drinkers while behavior remains unchanged in the women who drank more heavily [100]. A multimodal universal intervention was implemented in two provinces in South Africa with high prevalence of FASD [101]. After the development of media highlighting FASD, implementation of regular health talks on FASD to patient groups at healthcare facilities, training on FASD for health providers and social workers, and referral of women at high risk for having a child with FASD to existing intervention programs in the community, knowledge about FASD increased and prevalence of FASD decreased from 8.9% to 5.7%.

Worldwide, it is estimated that about 10% of women drink while pregnant [25]. Interventions targeted at women of childbearing age have the potential for reducing alcohol-exposed pregnancies [102]. Six months after an intervention that focused on increasing commitment to change risky drinking and/or ineffective contraception use behaviors via motivational interviewing, 68.5% of women who were previously deemed high-risk for having an alcohol-exposed pregnancy were no longer at risk [103].

Women who have previously had a child with FASD are also at risk of having additional children with FASD. The Parent-Child Assistance Program is an intensive case-management intervention for pregnant or parenting mothers who have alcohol and drug use disorders [104]. This program has been implemented in Washington State for several decades. At-risk pregnant and parenting mothers are enrolled in the case-management program for 3 years and receive outreach, assistance, structured goal-setting, problem solving, coaching, and linkage to recovery supports. The program has reduced future births of children exposed to alcohol and

drugs, increased rates of recovery from substance use in mothers, improved parenting of birth mothers, and increased rates of safe and stable child placement. The benefits of investing in the health and safety of at-risk women and children are clear: this program has demonstrated its cost-effectiveness in terms of decreased welfare costs and foster care costs [105].

Interventions During Pregnancy

Once an alcohol-exposed pregnancy has occurred, drinking cessation or reduction interventions can mitigate the impact of alcohol on the developing embryo/fetus. A meta-analysis found that single-session, face-to-face brief interventions appeared to have some positive benefits on the maintenance of alcohol abstinence during pregnancy [106]. Even as little as a 10-min educational session in combination with providing a nine-step self-help manual was effective in fostering alcohol cessation in economically disadvantaged pregnant women [107]. Drinking cessation interventions can also improve some birth outcomes. In a group of non-dependent women who were screened for alcohol use and either recommended to stop drinking or provided with a brief, multi-session intervention during pregnancy, the women in the intervention group were five times as likely to be abstinent by the third trimester [108]. For the women who were consuming two or more drinks/occasion, the intervention resulted in longer birth length in their infants. Additionally, a larger number of non-viable outcomes were noted in the assessment only group (2.9%) as compared to the intervention group (0.9%; [108]).

Alcohol can interfere with the absorption of nutrients, which, during pregnancy, can potentially exacerbate the teratogenicity of alcohol [109]. Supplementation may improve the nutritional status of the mother and embryo/fetus and confer some resiliency against FASD. Prenatal choline supplementation has been shown in animal studies to mitigate behavioral deficits caused by prenatal alcohol [110]. In a prospective cohort study in the Ukraine, women were randomly assigned to receive either a daily multivitamin and mineral supplement, with or without an additional 750 mg of choline supplementation, or standard care in which prenatal vitamins were recommended but not provided. While choline did not appear to confer any benefit in infants, small but significant positive effects of the multivitamin supplement were observed in the offspring, including better problem solving and pre-linguistic skills at 6-months [111]; however, there was little evidence of benefit in preschool children [112]. In contrast, another study found benefits of choline in a South African cohort of women who were recruited mid-pregnancy and randomly assigned to receive either 2 g choline or placebo [113, 114]. Infants born to the choline-treated mothers had larger volumes of several brain regions [114], were more likely to meet criterion on an eyeblink conditioning task at 6.5 months, showed greater catch-up growth in weight and head circumference at 6.5 and 12 months, and had better visual recognition memory at 12 months [113]. The choline dosage in this study was much larger than in the

study conducted in the Ukraine, suggesting a dose threshold may exist for effectiveness.

Postnatal Interventions

Nutrition: In a double-blind, randomized, placebo-controlled pilot trial to test the effectiveness of daily treatment with 500 mg choline for 9-months, there were some modest treatment effects on memory in the youngest children [115]. In a 4-year follow-up, choline-treated children had fewer behavioral problems, higher non-verbal intelligence, visual spatial, working memory, and verbal memory skills [116]. In a separate study that administered 625 mg choline daily for 6 weeks to children between 5–10 years, no cognitive improvements were observed [117]. The null effects may be related to the age of the children at choline administration or the relatively short timeframe of the study. More studies of choline treatment are needed to determine the parameters of its effectiveness. Animal studies suggest effectiveness of choline in addition to other nutritional and antioxidant supplements, including vitamins E and C, omega-3, resveratrol, and epigallocatechin gallate [118]; however, most of these have not been studied in humans.

Exercise: In a physical activity program for children with FASD that consisted of 1.5-h sessions that occurred twice per week for 8 weeks, improvement in executive functioning was observed in children from the pre-program to the 3 month post-intervention assessments [119]. The program included a warm-up activities, 15-min sessions that targeted three of the following: speed and agility, strength, balance, bilateral coordination, upper-limb coordination, and fine motor skills; a 20-min "choice" period, where a skill that was chosen by either the child or their caregiver was targeted; and a cool down period. The average preprogram score was in the mildly impaired range, while the average score at the 3-month follow-up was in the below average range [119]. This study indicates that a clinically relevant improvement in executive functioning may be achieved as a result of a physical activity training, consistent with a number of animal studies that have found that exercise can mitigate some symptoms induced by PAE [120].

Habilitation: Wells et al. [121] conducted a randomized, controlled study of cognitive habilitation in children with FASD who resided in foster or adoptive homes. Children with FASD between the age of 6–11 were assigned to receive either the intervention or no-treatment. The intervention utilized components of the Alert program [122], which teaches self-regulation skills, and additionally targeted memory, emotional awareness, and cause-and-effect reasoning skills. Occupational therapy and family psychoeducation were also included in the intervention. Seven months after enrollment (2–3 months after treatment concluded) children in the intervention group had significantly improved executive function and emotional problem-solving skills as compared to the no-treatment group [121].

Children with FASD experience significant academic difficulties and behavioral problems. Difficulties with mathematical concepts are common [123]. The Math

Interactive Learning Experience (MILE) program was developed to improve pre-math and mathematical skills in children age 3–10 years [124, 125]. It is a 6-week, comprehensive intervention that involves active-learning math instruction using manipulables and visual aids, immediate feedback, and experience mediation to support learning and improve integration of concepts in an individually placed curriculum; caregiver education; school consultation; and as needed case management and psychiatric consultation [124]. Children were randomized to either the MILE program or standard psychoeducational care groups. Children in the MILE program demonstrated greater gains on standardized testing and fewer behavioral problems than the comparison sample, persisting for 6 months [124]. The benefits of the MILE program were replicated in a separate sample of children with FASD [125].

Friendship Training: O'Connor and colleagues [126] evaluated the effectiveness of a friendship training intervention in school-age children with FASD who had social skills deficits. Children were assigned to receive either the child friendship training or they were placed in a delayed treatment group. The intervention involved 12 weekly, 90-min sessions. Parents attended separate concurrent sessions where they were provided psychoeducation on the social skills being taught to their children. Children who received the friendship training demonstrated significantly improved social knowledge as well as parent-rated social skills and problem behaviors, effects that were maintained over a 3-month follow-up period. While the children benefitted from the program, unfortunately, no treatment effect was noted on teacher-rated behaviors. The adaptation for the manualized behavior treatment is described in Laugeson et al. [127].

Families Moving Forward (FMF): Children with FASD commonly have behavioral problems and the parents of these children are often stressed [128]. The FMF program was designed to modify parenting attitudes and responses towards their child's problem behaviors [129]. It integrates several child-management and parent training techniques and teaches caregivers the skills to promote a positive behavior support approach to dealing with problem behaviors, emphasizing antecedent-based behavior strategies and developing and advocating for accommodations for their child [130]. The FMF intervention, implemented for 9–11 months with at least 16 every-other-week, 90-min sessions, resulted in caregivers reporting increased parenting self-efficacy, self-care, and reduced child disruptive behaviors. On a standardized parent-reported behavior questionnaire, a significant and clinically relevant change in Problem scores occurred from pre- to post-intervention. The intervention group reported that their children's problem behavior were, on average, in the clinical range at the pre-test, while the post-test scores were in the borderline range. The FMF program is being translated to a mobile health intervention app that allows for caregiver self-delivery, called FMF Connect [131]. The app will help address some barriers to care, including limited access to services.

Alcohol Intervention: Studies estimate that between 35–60% of adolescents and adults with FASD have an alcohol or substance use problem [85]. An adapted version of Project Step Up, an alcohol harm-reduction program, was evaluated in adolescents with FASD [132]. This intervention focused on practical knowledge and skills to empower adolescents with FASD to make safe decisions regarding alcohol.

It incorporated motivational enhancement techniques, normative feedback, education, risk assessment, coping and alcohol refusal skills training in a group setting. Adolescents were assigned to either receive the Step Up intervention or were provided with written materials on alcohol misuse and stress reduction. Before the intervention, 33% of the teens reported light/moderate drinking, while the remainder reported abstinence or infrequent drinking. For the light/moderate drinkers, those in the intervention group reported a significant decrease in in alcohol risk and harm, which was partially sustained at the 3-month follow-up [132]. The adapted Step Up intervention may help prevent some alcohol-misuse and harm in adolescents with FASD.

Summary and Conclusion

The impact of PAE has been documented throughout history, although our modern understanding of FASD did not commence until the 1970s. Despite public health prevention efforts, the prevalence of PAE is estimated at 10% globally and it is thought that 1 in 13 alcohol-exposed pregnancies results in a child with FASD. Children with PAE may exhibit brain, cognitive and behavioral deficits. Common sites of alcohol teratogenesis in the brain include the corpus callosum, cerebellum, and basal ganglia. Brain network function is disrupted during completion of cognitive and motor tasks as well as during resting conditions. The impact of PAE on the brain translates into a number of cognitive and behavioral deficits, including deficits in general cognitive ability, attention, learning and memory, visuospatial ability, motor skills, language and communication, executive functioning as well as secondary conditions. Early identification and diagnosis and referral for appropriate services and interventions can mitigate adverse outcomes.

Chapter 24
Image Analysis of Neurofacial Effects of Prenatal Alcohol Exposure

Michael Suttie

Abstract Fetal alcohol syndrome was first described in the literature over 50 years ago and is widely recognized as a devastating public health problem. Prevalence in the U.S. is estimated to be as high as 2.0–7.0 per 1000 individuals in school-age populations. However, prevalence dramatically increases when we consider the full spectrum of prenatal alcohol-associated effects, with estimates of fetal alcohol spectrum disorders (FASD) ranging as high as 2–5% in the U.S. and Western Europe. The diagnosis of FASDs relies upon identifying a range of physical defects and specific neurocognitive and behavioral profiles. FAS is at the most severe end of the spectrum with multiple diagnostic criteria stating reliance on the recognition of at least two of the three cardinal facial features; a smooth philtrum, a thin upper lip vermillion and reduced palpebral fissure length. Alcohol exposed individuals who lack the required criteria for a FAS diagnosis are inherently challenging to identify and subsequently suffer high rates of missed diagnoses and misdiagnosis. In this chapter, we review the 2D and 3D imaging based methods for identifying the range of FASD associated facial dysmorphism across the FASD spectrum, and discuss the identification of and relationships between the face, brain and neurocognitive performance.

Keywords Facial dysmorphism · FAS facial recognition · Face-brain interactions in fetal alcohol spectrum disorders · Prental alcohol exposure · Fetal alcohol spectrum disorders

Introduction

Alcohol's teratogenic insult can be severe at crucial developmental stages. It predominantly damages the central nervous system, adversely affecting growth, behavior, and cognitive development in childhood when affected individuals are typically

brought to the attention of care professionals. Amongst many other detriments, a child prenatally exposed to alcohol can be permanently afflicted with impaired learning, dysfunctional behavior, and growth deficits. The detrimental impact of in-utero alcohol exposure has long been known, with the first formal report documented in the late 1960s [1]. However, this article was in French and did not significantly impact medical literature. There was little interest until 5 years later when the Lancet published a report by Dr. Kenneth Jones & Dr. David Smith [2]. Jones and Smith identified a set of clinical diagnostic criteria; specifically, they described a unique set of facial characteristics associated with prenatal alcohol exposure (PAE). Since this publication, a spectrum of associated PAE effects has been recognized and has given rise to the term fetal alcohol spectrum disorders (FASDs). There is considerable variation in the combination and severity of effects, convoluting clinical diagnoses and making the task of identifying those affected clinically challenging. A variety of factors are thought to influence this range and severity, although the timing of exposure [3], exposure patterns [4] and genetic predisposition [5] appear to be the primary modifying factors that influence the outcome for individuals with PAE.

Diagnostic Criteria

At the most severe end of the FASD spectrum are fetal alcohol syndrome (FAS) and partial fetal alcohol syndrome (PFAS), characterized by a set of distinctive facial features, cognitive and behavioral deficits, and reduced growth. Three cardinal facial features form part of the FAS/PFAS diagnosis; palpebral fissure length (distance between inner and outer corners of the eye openings) < tenth percentile, a thin upper lip-vermillion border (thin upper lip), and a smooth philtrum (smoothness of the midline groove in the upper lip) [6]. Several diagnostic systems are in circulation, which differ in criteria to categorize the effects of PAE clinically, but there is universal agreement amongst these systems on the significance of the three cardinal facial anomalies [7]. Additionally, across diagnostic guidelines, there is often a necessary combination of criteria for FAS/PFAS, such as a small occipital frontal circumference (OFC; head circumference), a history of maternal drinking during pregnancy, structural brain anomalies, growth deficiency, and behavioral or cognitive deficits. Phenotypic facial features are a hallmark of FASDs and play a crucial role in identifying individuals with PAE. However, a patient may often present to a clinician with cognitive and/or behavioral deficits, confirmed or suspected PAE, but lack the identifiable facial criteria for a FAS/PFAS diagnosis. Such individuals may have been exposed to alcohol in utero at levels similar to those diagnosed as FAS/PFAS and present a vast array of other physical and neurological deficits. Depending on the diagnostic guidelines used for clinical assessment, classification without facial features will rely on other criteria requiring confirmed alcohol exposure, central nervous system impairments, and neurocognitive and behavioral deficits [6, 8] Hoyme et al. [6] provide an updated set of clinical diagnostic guidelines for

diagnosing FASDs, including two categories for confirmed PAE without facial features: alcohol-related neurodevelopmental disorder (ARND), which requires neurobehavioural impairment, and alcohol-related birth defects (ARBD), which require one or more major malformations. This is just one example of several diagnostic guidelines with criteria for identifying individuals with PAE without facial features. Most diagnostic guidelines have some methodology for identifying these individuals [7]. However, the heterogeneous and indistinctive nature of presentation means they are often misdiagnosed or undiagnosed. Furthermore, and most concerning, the vast majority of individuals with PAE fall into this clinically challenging category [9].

Prenatal Alcohol Exposure and the Developing Brain

Perhaps the most significant effect of PAE is the potential damage caused to the developing brain. Some brain regions are particularly vulnerable, and few remain unharmed by alcohol's teratogenic insult. Magnetic resonance imaging (MRI) enables a highly accurate assessment of brain shape, size, spatial displacement, and even function. The corpus callosum, the most extensive white matter tract primarily responsible for the interhemispheric connection between the left and right sides of the brain, appears disproportionately affected by alcohol teratogenesis. Significant variations in this structure have been observed and include complete or partial agenesis [2], localized shape differences [10, 11], displacement [12] and localized volumetric reductions [13]. These findings are representative of the agreed vulnerability of midline structures in PAE. Deep grey matter structures are also consistently reported to be disproportionally affected, and findings include a reduced volume of the hippocampi [14, 15] and basal ganglia [16, 17], with many studies focusing specifically on the caudate nucleus [15, 18, 19]. The neural structures affected by PAE are responsible for memory, sensorimotor, behavior, and impulse control, among many other cognitive functions.

The disruption to developing brain structures causes extreme variability in cognitive dysfunction, although some common functional deficits are apparent in both FAS and in less severe impairments. For example, there are significant declines in overall cognitive ability determined by intellectual quotient (I.Q.) scores, memory and recall, and executive function (higher-level cognitive functions such as abstract thinking, problem-solving, and planning ahead). Additionally, psychosocial deficits and problem behaviors such as hyperactivity, impulsivity, poor socialization, and poor communication skills are apparent at a young age, interfering with a child's education, home life and social environments. A combination of these factors puts affected children and adolescents at a higher risk of delinquent behaviors, trouble with the law, psychiatric disorders, and drug and alcohol abuse, which inevitably follow into adulthood. As with many childhood conditions, early and accurate diagnosis of FASDs is crucial to introducing appropriate educational, psychological, and welfare interventions. Providing the necessary support as early as possible

reduces the risk of social and behavioral problems negatively affecting the individual later on in life. Clinical diagnosis requires a multidimensional approach, considering minor physical anomalies, facial dysmorphology and neurocognitive and behavioral profiles. There is a distinct lack of clinical expertise specifically for FASDs. An individual will often need to seek a referral to a specialist clinic where they will typically undergo examination by both dysmorphologists and clinical psychologists. Only a small part of the clinical assessment involves facial analysis, and due to the nature of FASD facial features being mostly observational, the examination is necessarily subjective, with the accuracy being dependent on the skill and experience of the clinician.

Clinical Recognition of FASD-Associated Facial Features

Identifying Cardinal FAS Features

Standard clinical assessment of physical FASD features by trained dysmorphologists uses manual anthropometry and visual assessment. Palpebral fissure length is typically measured using a clear ruler, and philtrum smoothness and the thinness of the upper lip vermillion are assessed using Likert scales [6, 20]. Alternatively, 2D Commercial off-the-shelf software for the identification of the FAS facial phenotype is currently available. Initially developed in 2003, the FAS Facial Photographic Analysis (FPA) Software uses 2D photographs in combination with the 4-Digit Diagnostic Code [20–22] which aims to identify the magnitude of expression of the FAS phenotype. The software determines metrics to represent the three cardinal facial features; palpebral fissure length, lip thickness, and philtrum smoothness from a series of three 2D images using manually guided procedures. The image acquisition protocol requires three images; a frontal view, lateral view, and ¾ view to be taken with a standard digital camera. For dimensionality, the image is scaled using a visual guide (small sticker) physically placed on the subject's forehead. Using the three images uploaded to a computer, the user can then measure or estimate the three cardinal facial features. Landmark points on the inner (endocanthi) and outer (exocanthi) eye corners are manually annotated by the clinician on the front portrait image. Palpebral fissure length is calculated as the mean of left and right distances which is weighted using an adjustment factor, subsequently adding 7% to the distance. The weighting constant is representative of the angle of the zygoma (cheek bone) to account for the loss of depth perspective in 2D. The palpebral fissure length measure taken using this method, with the adjustment factor applied, was shown by the authors to have just a 1% margin of error compared to subjects measures with a caliper [23, 24]. However, the use of a 2D photographic assessment of palpebral fissure length have has come under some scrutiny by other researchers and is not always the preferred method by clinicians [6, 25]. This lack

of agreement is primarily due to potential inaccuracies caused by individual variations of the angle of the zygoma, questioning the ability to account for this correction using a constant value. Studies testing the concordance of techniques to record palpebral fissure length have found measurements taken using 2D imaging to be consistently shorter [25, 26] than physical measurement, although it should be noted that a subsequent study has shown 2D palpebral fissure length measurements to be greater, although not significantly different to those taken using a ruler [27].

Standard physical examinations and those undertaken using 2D imaging are reliant on subjective methods for lip and philtrum assessment. Likert scales matched by ancestral origin are used to compare an individual's philtrum smoothness and upper lip by holding a chart up against the subject or the ¾ view using the FPA software. The lip-philtrum guides provide a scoring system from 1–5, ranging from 1 a full/grooved lip/philtrum to 5 a FAS-like thin/smooth lip/philtrum. The consistency and accuracy of this assessment are paramount to a FAS diagnosis, and in most criteria, a misclassified score of just a single rank difference will change diagnosis and potentially the interventions received throughout life. Likewise, for the palpebral fissure length measurement, a deviation of just 1 mm can result in the measure being 1 s.d out of range, potentially to altering diagnostic outcome.

Clinical Recognition of Minor Facial Anomalies

FASD diagnostic criteria provided by Hoyme and colleagues [6] describe the importance and prevalence in FAS of a series of minor facial anomalies, secondary to cardinal FAS features. Primarily, they observe the presence of midfacial hypoplasia (reduced growth of the upper jaw, cheekbones and eye sockets), epicanthal folds (skin fold on the upper eyelid, on the inner part of the eye), a long philtrum, decreased interpupillary distance (distance between the midpoints of the eyes), a flat nasal bridge, prognathism (protrusion of the lower jaw), and anteverted nares (upturned nostrils). With the recognition of these features being mostly reliant on subjective identification, it remains a challenge to accurately and objectively recognize these mostly soft-tissue deformations, to the point that clinical observation by trained dysmorphologist is still prone to error. These "non-cardinal" FASD features do not contribute to any formal diagnosis in the most commonly used diagnostic criteria, other than in the Emory-Fetal Alcohol Center Clinical Criteria, which uses a weighted checklist of 40 items to provide an overall dysmorphology score [7]. This score sets a scale from 0 to 57 to measure the physical effects of alcohol rather than focusing only on cardinal features. An approach such as this could benefit diagnostic outcomes, especially if methods for objective identification on a continuous scale were to be integrated into the clinical workflow. Midfacial hypoplasia, for example, is characterized primarily by a flattened nasal bridge, an upturned nose, long philtrum, and flatness of the midface region. To date, there have been few attempts to objectively identify this discriminative and prevalent feature with visual and imaging-based approaches [28].

Detecting FASD Associated Facial Dysmorphism Using Image Analysis

Face Analysis using 2D imaging suffers limitations of perspective and dimensionality, and analysis of surface shape and finer detail are restricted. Based on the subjectivity and inaccuracies of manual assessment, we assert that an objective and accurate approach would provide an optimal clinical protocol for FASD evaluation. One such strategy is to apply shape analysis to facial images acquired from stereo-photogrammetric cameras. Stereo-photogrammetric cameras digitally combine two or more simultaneously acquired 2D dimensional images and apply an algorithm to produce a 3D representation of surface geometry with perspective information and accurate dimensionality. Surface images obtained from 3D camera systems provide tens of thousands of points accurately representing facial shape with sub-millimeter accuracy, producing morphology data more accurately and in a more convenient form for shape analysis than 2D. Shape analysis of 3D images can take several forms, the most simplistic of which is based on anthropometric measurement derived from landmarks placed on the image surface.

Several studies have used the highly detailed and accurate reconstructions of the human face provided by 3D photography and statistical analysis techniques to address the problem of identifying FAS facial features [28–30]. The earliest of these studies [3] utilized stereo-photogrammetry systems to obtain reliable 3D images of the face to determine clinically relevant anthropometric measurements. Before this investigation, previous studies using photographic methods for distance measures had been performed using the FPA software. Measurements imperative to diagnosis using 2D photography, such as palpebral fissure length, must be synthetically adjusted to account for the points being off the midline perspective. The ability for 3D images to reliably capture points that lie in different planes highlights the inadequacies of single planar 2D photographic techniques.

Obtaining point-to-point distance measures using 3D images has shown to be a reliable method comparable to anthropometric measures attained physically by a trained dysmorphologist [31, 32]. utilized 3D images of 276 subjects (aged 2.8 to 21.2 years), clinically labeled as FAS or control from 4 different ethnic populations (Cape Coloured [37%], Finnish Caucasian [36%], African American [9%] and North American Caucasian [18%]). The hypothesis of this study assumed that a unique combination of anthropometric features would best discriminate FAS and controls in each of the four ethnic populations. To test this, images captured using a commercially available laser scanning system were manually annotated with 20 anthropometric landmarks. Discriminant analysis was performed to classify FAS and controls utilizing an optimal combination of age at evaluation and 16 measurements derived from the landmarks. From the discriminant analysis, the Finish cohort performed with the highest overall classification rate (93%) and utilized nine anthropometric measurements (inner/outer canthal distance, palpebral fissure length, midfacial depth, ear length, nasal and nasal bridge length, and bitragal

width). The discriminant function calculated from the Cape Coloured cohort achieved a classification accuracy of 92% and included five measurements (inner canthi distance, philtrum length, ear length, minimal frontal width and bizygomatic width). For the African American cohort, the classification rate of 79% was achieved using only two measures (palpebral fissure length and philtrum length). The North American Caucasian population achieved the lowest classification rate of 77% using only the inner and outer canthi distances. This study showed that anthropometric measures derived from 3D images could discriminate FAS from controls across a wide age range and multiple ethnicities. It also highlights and explicates ethnic differences in the presentation of FAS, which appear to be particularly discriminating in the Cape Coloured cohort. More sophisticated approaches employing statistical shape analysis techniques were later introduced to characterize the facial anomalies associated with FAS. Landmark-based morphometric analysis techniques, such as those defined in Mutsvangwa et al. [28], demonstrate the ability to detect features present in FAS-affected individuals from 3D facial images. By utilizing a landmark-based discriminant function analysis model, the authors evaluated the mean shape differences between FAS and control groups at two different time points (5 and 12 years), achieving overall classification accuracies of 95% and 80%, respectively. As well as demonstrating the value of 3D morphometric analysis for identifying individuals with FAS, this analysis supports the notion that FAS facial features are more pronounced in younger generations and subsequently diminish with age [20]. Another study of facial morphology of prenatally exposed individuals revealed differences in directional asymmetry [33]. 3D scans of children from a Finnish Caucasian cohort (n = 90) and a South African mixed-ancestry cohort (n = 78), were obtained and manually annotated with 17 anthropometric landmarks. Using geometric morphometrics methods, they analyzed shape data from the landmarks to show the degree of directional asymmetry for each individual. The analysis showed average directional asymmetry in the FAS groups to be significantly higher than those in the control groups, primarily consisting of a leftward shift in midline landmarks. These results show the extent of facial dysmorphology in alcohol-exposed individuals goes beyond what is clinically recognizable and can include subtle differences in asymmetry.

3D surface shape analysis supports more sophisticated evaluation and detection of even subtle face shape differences. One such technique is the utilization of dense surface models [34, 35] which have been used extensively to analyze 3D facial characteristics associated with neurodevelopmental and related human conditions [36–43]. These models have an advantage over landmark-based analysis in their potential to assess shape variation across an entire 3D surface. The dense surface modelling algorithm builds surface models from raw 3D data, initially aligning and warping surfaces guided by a series of manually placed landmarks. This provides a dense correspondence, matching points on different face surfaces to produce a shape based on a principal component analysis (PCA) of variation of point displacement from the mean face. Individual 3D face surfaces are then resynthesized as a weighted linear sum of principal components that account for the shape variation.

Facial Dysmorphism Across the FASD Spectrum

Across the literature, facial analysis in FASD had typically focused on the identification of FAS. Identifying non-syndromic, heavily-exposed (HE) individuals without cardinal features remains a clinical challenge. In our 2013 study [43] we aimed to assess facial dysmorphism across the FASD spectrum using DSM constructed from 3D facial images to better identify those with and without cardinal FAS features. In a population of South African children, 3D images of 192 participants from two longitudinal University of Cape Town (UCT) cohorts recruited from a local mixed-ancestry community where the incidence of FAS and alcohol consumption during pregnancy is one of the highest in the world. Prospective drinking histories of mothers were obtained by using a timeline follow-back interview [44] recorded during pregnancy in antenatal clinics and at 6 weeks postpartum to obtain data spanning all trimesters. The threshold for heavy alcohol consumption during pregnancy was set at a level of >13 standard drinks per week or partook in binges of five or more drinks per occasion. Controls were the offspring of those who reported abstinence from alcohol during pregnancy unless they met FAS criteria. Those with a genetic disorder were excluded from the study.

Multiple expert clinicians undertook dysmorphology assessments to obtain a diagnostic consensus. Neuro-behavioral assessments were undertaken at a 9-year follow-up, which included the fourth edition of the Wechsler Intelligence Scale for Children (WISC IV) [45], and the California Verbal Learning Test–Children's Version (CVLT-C) [46]. The WISC IV tests are designed to assess verbal comprehension and perceptual reasoning and provide an intelligence quotient (IQ) score, while the CVLT-C tests word recall and recognition memory after a short period. 3D images were captured using a commercially available stereophotogrammetric system, and each image was annotated with 24 anatomically reliable landmarks. DSM surface models were built, providing principal components representing 99% of face shape variance. Control-FAS discrimination testing using dense surface model representations of face shape using 20 randomly sampled 90% to 10% training-unseen test subsets, and discrimination accuracy was predicted using receiver operating characteristic curve analysis. Closest mean classification testing provided scores of relative similarity to either a control or FAS means, using the whole face and sub-regions of the face (periorbital (eyes), profile, mid-facial, perioral (mouth), and perinasal (nose)). Whole face classification using closest mean returned an agreement of 0.967, indicating a high probability of correctly classifying a pair of control and FAS faces. Linear discriminant analysis and support vector machines provided more sophisticated methods for classification, with the latter resulting in a near-perfect agreement. Of the facial regions tested, the periorbital and profile regions achieved the greatest accuracy with 0.98 and 0.93, respectively, using closest means classification. When applying this to the PFAS subset, we achieve similar but marginally diminished accuracy.

Given the heterogeneous presentation of the HE subset, binary classification as shown for FAS/PFAS was not an effective tool. A different approach was taken,

which encompasses the variation of dysmorphism by computing the 'facial signature' of each individual. Facial signatures calculate point-to-point displacement differences of an individual face normalized against a background set. In this case, we are calculating signatures against a set of 35 age-ethnicity matched controls. Comparison control means were selected by ordering the dataset by age, selecting 35 contiguously aged subjects, and computing the mean face for comparison. Facial signatures visualize surface displacement using a heat map showing normalized contraction, coincidence, and expansion compared to the age-ethnicity matched control mean. They provide a quantitative representation of surface differences relative to a matched control population and can show the significance of dysmorphia. When applied to the means of each FASD subgroup, we can observe the most prominent features across each subset of alcohol-exposed individuals (Fig. 24.1). Facial signature heatmaps observed similar coloration at varying degrees of severity across each FASD clinical category. For FAS and PFAS, there was an indication of the cardinal features with blue coloration (expansion) on the philtrum and reduction of the eye openings. Interestingly, we also identified shortening of the nose (red), flattening of the nasal bridge and glabella (forehead above and between the eyes), malar region (cheek) flattening (yellow anterior zygomatic arch), and micrognathia and retrognathia (deficient growth of the lower jaw and mandible; red chin). Focusing on the HE category, we observed these non-cardinal features in a significant proportion of the dataset, and when applying facial signature analysis to individual faces, we noted the presence and severity of these features across the dataset.

Facial Signature Graphs

While identifying facial dysmorphism using facial signatures of groups provides an insight into mean differences, recognizing individual dysmorphia plays a more vital role in clinical assessment. We applied facial signature graph analysis to improve our ability to identify HE children who lack the FAS facial phenotype (Fig. 24.2). Facial signature graphs provide an unsupervised learning approach to clustering faces based on their facial signature similarity. To construct, we iterate through every pair of faces within a dataset and compute the face signature difference to define the relative proximity/signature similarity as the Euclidean distance between the corresponding vectors indexed by their facial signatures. The facial signature distance accounts for all 3D surface points and corresponding geometry, providing a measure of morphological differences between two individuals normalized with respect to a set of age-ethnicity matched controls. We computed the facial signature distance between 107 alcohol-exposed (FAS, PFAS, and HE) individuals within the dataset and constructed a graph whose vertices were the face signatures (Fig. 24.2a). Directional edges are constructed from the closest individuals with the lowest distance to connect one vertex to another or the most similar normalized face shape difference to the first. A connection between face A and face B does not necessarily equate to the two being similar but rather represents a relative similarity of

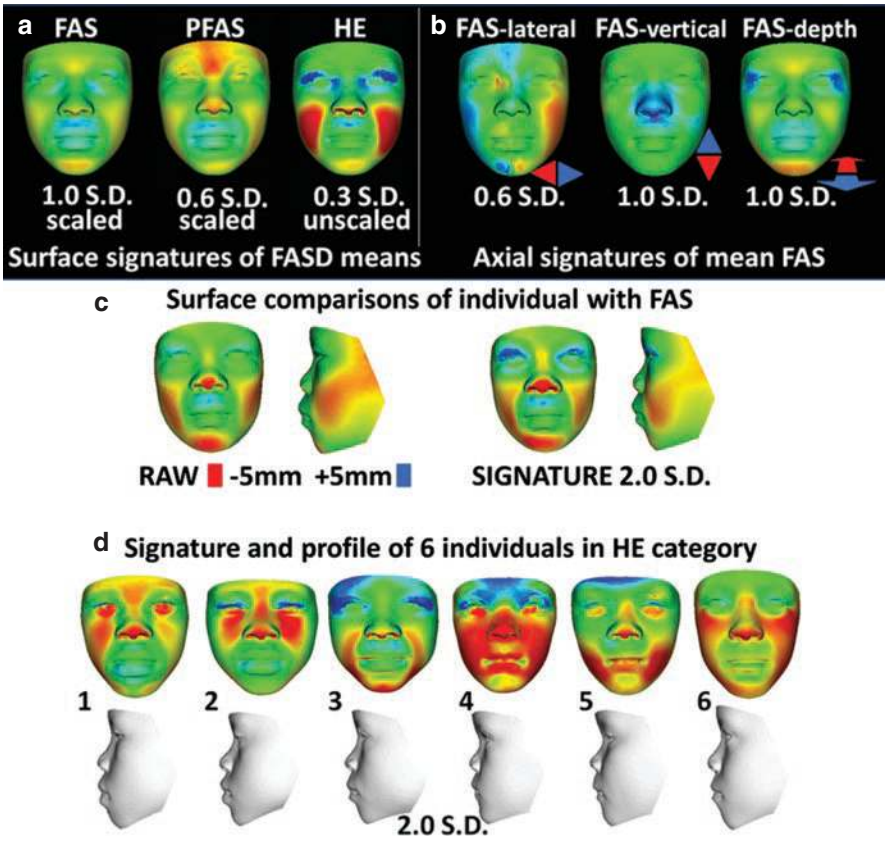

Fig. 24.1 (**a**) Facial signature showing mean differences for each of the clinical categories. Given the significantly reduced growth, FAS and PFAS mean faces were scaled by facial height prior to normalization to reflect shape-only differences. Red-green-blue heat maps reflect contraction-coincidence-expansion along the surface normal, where "±1.0 SD," " ±0.6 SD," and "±0.3 SD," define the upper-lower significance bounds. (**b**) Facial signatures relative to X, Y, and Z axes to depict directional differences in FAS. The lateral axis (left) shows inner canthi differences moving outward—reducing palpebral fissure length, the vertical axis (Y, middle) shows displacement/shortening of the nose relative to the face, and the depth axis (Z, left) indicates midfacial flattening, retrognathia and flattening of the nasal bridge. (**c**) Shows raw differences in mm and the facial signature of an individual with FAS, where red is indicative of mid-face/malar (cheek) flattening, nasal displacement, and retrognathia. This individual also has a smooth philtrum indicated by a blue spot on the philtrum showing an expansion in this region. (**d**) Signatures and profiles of 6 individuals in the HE category who showed affinity to FAS/PFAS in signature analysis. Individuals 1–4 and 6 show red coloring on the mid-face indicating flattening, and individuals 3–6 have red coloring on the chin potentially indicating retrognatia. All individuals have red coloring on the nose indicating reduced nasal length. Extract from Suttie et al. [42]. normalized shape difference within the dataset. When applying this technique, we observed clustering of the FAS and PFAS as expected (Fig. 24.2b). However, the HE group was separated into two subsets, with nearly half of the group (n = 28) showing a greater affinity to FAS/PFAS signatures (Fig. 24.2c). Upon closer inspection, these individuals exhibited more FAS-like facial features than the remaining HE subset. Examples of six individuals from this subset are shown in Fig. 24.1d, where we observed mid-facial flatness and/or a flat nasal bridge, philtrum smoothness and mid-facial hypoplasia.

No significant differences were found for parity, alcohol exposure, smoke exposure, or maternal age between the HE subset with FAS/PFAS affinity versus the HE subset with more control-like features. However, those with an affinity to the FAS/PFAS signatures scored significantly lower on neurocognitive measures compared to the control-like subset. Particularly affected were the WISC Verbal Comprehension IQ and CVLT-C scores, where the mean for the FAS-like subset closely resembled that of FAS and PFAS scores, while the more control-like subset was also more similar to controls.

The Face: A Window to the Brain

Studies of structural differences of the brain, facial dysmorphism, and neurocognitive impairment in FASD are well characterized in the literature. However, only a handful of studies to date focus on the interactions, relationships, and correlations between each domain [47–49]. DSM based analysis has been previously used for the simultaneous analysis of face and brain in a murine model of in utero ethanol exposure at two time points, gestational days 7 and 8.5, concluding that unique patterns of face-brain dysmorphia correspond with stage-specific exposure [3]. The earlier of these two time points yielded facial traits that resembled an FAS phenotype, while the latter time point characterized more subtle differences such as mid-facial hypoplasia. In this study, stage-specific facial differences were associated with morphological abnormalities of brain components such as the septal region, pituitary, and olfactory bulbs. Mouse studies are advantageous over human studies in that they can provide specific exposure targeting exact dosage and quantity, but it remains important to analyze face-brain correlations in human PAE populations to better understand and identify all possible phenotypic linkages.

Data collected by the Collaborative Initiative of Fetal Alcohol Spectrum Disorders (CIFASD), facilitated analysis of a dataset formed of controls (n = 47), FAS diagnosed (n = 22), and HE (n = 50) of European ancestry with corresponding 3D face, MRI brain and neurocognitive testing data [11]. MRI images were segmented to provide 3D geometry of two critical components of the brain disproportionately affected by alcohol teratogenesis—the corpus callosum and the caudate nucleus. The corpus callosum is a midline white matter tract responsible for interhemispheric connection, and the caudate nucleus is a part of the basal ganglia primarily responsible for executive function. To analyse the morphological covariance

between the face and brain in humans, we developed a technique capable of constructing a combined surface model representation of both components. This combination analysis relies on a method based on active appearance models [50] originally designed to apply a principal component analysis (PCA) to pixel intensity information while accounting for shape variation. In place of pixel intensities, we compute principal component values from separate dense surface models and concatenate them, before undergoing a further PCA on the combined representation. The result is a PCA based model containing both structures represented by a single set of principal components.

Using face and brain models, we were able to replicate control-FAS classification testing, only this time on both the face, brain and their combined representations. Several localized facial regions were tested and showed similar results to those observed in previous studies [42, 51] with results providing near perfect discrimination between FAS and controls. Additionally, using the same set of techniques both the corpus callosum and caudate nucleus yielded a classification accuracy of over 90% (Table 24.1). When testing combined representations of the facial regions combined with the corpus callosum, and caudate nucleus, we observed a consistently improved accuracy compared to analogous testing on face and brain components separately. In particular, results indicated midline facial differences were correlative with midline defects of the brain, as the most significant improvements were made on midline facial combinations with the corpus callosum and; nose (1.00), lip-vermillion (0.90), and philtrum (0.98).

Two previous face-only studies [42, 51] had shown that facial signatures graphs of alcohol-exposed individuals revealed a subset of HE individuals with FAS-like dysmorphism. Reassuringly, this dataset also produced a facial signature graph partition analogous with previous results. Applying this technique to produce a caudate nucleus signature graph also partitioned the HE subgroup into an FAS-like subset with similar brain morphology. From this graph we observed a significant overlap

Table 24.1 Extract from Suttie et al. [11]: separate face and brain control–FAS discrimination rates estimated as the mean area under the ROC curves of 20 cross-validation tests, corresponding to the probability of accurately classifying Pairs of individuals: 1 from control and 1 from FAS

Face	CM	LDA	SVM	Brain	CM	LDA	SVM
Full Face	0.93	0.93	0.95	Corpus Callosum	0.90	0.90	0.93
Profile	0.83	0.88	0.90	Caudate Nucleus	0.88	0.88	0.88
Eyes	0.90	0.93	0.93	Left Caudate Nucleus	0.83	0.85	0.90

with the individuals partitioned from the facial signature graph, and more interestingly, when reconstructing the mean facial signature of the FAS-like HE group partitioned by the caudate nucleus we observed a striking similarity with that of the FAS mean. Thereby, essentially reconstructing an FAS-like facial phenotype by individual selection from brain morphology.

The Future of Image Analysis for FASD Diagnosis

In this chapter, we have discussed the importance of pertaining to an accurate, objective, and reliable method for the assessment of individuals with PAE. We have shown how 3D facial analysis can accurately identify those with an FAS diagnosis, and more importantly assist with the identification of those without cardinal features by recognition of subtle, non-cardinal minor facial dysmorphia. Additionally, we observed that the facial dysmorphism in FASD may relate to neurocognitive performance and even provide clues to the underlying brain structures. But, for these works to become clinically useful there are multiple hurdles to overcome.

Firstly, is the complexity and expense of acquisition, in the case of 3D image capture high-resolution commercial photogrammetry systems used in the studies details can often be cumbersome and expensive. However, recent advances in mobile computing-based acquisition of 3D facial analysis may overcome this problem, with Apple Inc. producing an inferred based camera system on the front of standard mobile phones capable of capturing facial geometry with sub-millimeter accuracy. The capture and analysis of brain images would, at current standing, be ruled out for any screening for diagnostic purposes due to the expertise and costs associated with MRI imaging and analysis.

Any screening tool would need to eliminate any subjective assessment prone to error. Thus, it would require reliable automation. Techniques in the above studies all utilise DSMs, to model surface geometry. However, they require the manual annotation of anatomical landmark points to successfully align surfaces and produce linear anthropometric measurements such as palpebral fissure length. Recent advances have shown how this process can be automated using deep learning approaches such as convolutional neural networks in FASD cohorts [52, 53]. These techniques could be utilized to train models on several thousand PAE and control individuals, to automatically and objectively place left and right inner and outer canthi points for palpebral fissure length calculation with a high degree of accuracy.

Additionally, as FASD is a multifaceted diagnosis reliant on multiple domains, any screening tool should be able to account for neurocognitive assessment data. Combination analysis is vital to ensure high sensitivity and specificity, as identifying only the facial features is not sufficient for providing a full insight into a patient's presentation. Finally, as recognized by recent review into the potential for facial screening tools in FASD any tool must and be accessible, compatible with other diagnostic/screening tools, accurate on all skin colors, ethnicities, ages, and sexes, and ensure no discomfort or harm to the patient [54].

Chapter 25
"From Surviving to Thriving": A Focused Review of Interventions for Fetal Alcohol Spectrum Disorders to Guide a Shift Toward Strengths-Based Intervention Development

C. Kautz-Turnbull, M. Rockhold, and C. L. M. Petrenko

Abstract Fetal alcohol spectrum disorder (FASD) refers to physical and neurodevelopmental symptoms associated with prenatal alcohol exposure. While much is known about deficits in FASD, little research has focused on strengths and quality of life. The "From Surviving to Thriving" model illustrates a perspective shift from deficits-based to strengths-based research and intervention. In order to achieve this, three barriers must be addressed: lack of awareness of FASD, limited access to care, and stigma. This chapter offers a focused review of existing FASD interventions and community programs to illustrate how current work is already confronting these barriers and demonstrating a shift to a strengths-based perspective. It also provides practical guidelines for clinicians to address these barriers in their everyday practice. Future work should build on existing literature to deliberately and systematically design strengths-based interventions to fully support quality of life for people with FASD.

Keywords Fetal alcohol spectrum disorder · Prenatal alcohol exposure · FASD · PAE · Intervention · From surviving to thriving · Strengths · Strengths-based

Fetal alcohol spectrum disorders (FASD) is an umbrella term for a range of physical and neurodevelopmental symptoms associated with prenatal alcohol exposure (PAE). Despite a prevalence estimated at 1–5% [1], FASD continues to be underrecognized and underserved and access to FASD-informed resources is limited [2, 3]. Lack of appropriate, strengths-based, and person-centered supports for

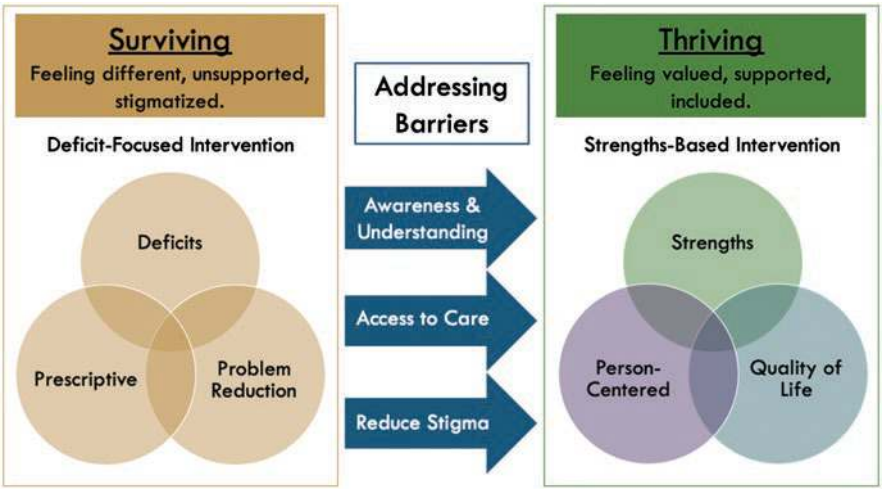

Fig. 25.1 "From Surviving to Thriving", a model for a paradigm shift to a strengths-based perspective in FASD research and intervention [5]

individuals living with FASD may lead to difficulty realizing their full potential for quality of life. Further, without similarly strengths-based caregiver support, families may feel isolated and frustrated, and experience burnout [4].

The "From Surviving to Thriving" model (Fig. 25.1) [5] proposes a shift from a deficit-focused perspective to a strengths-based perspective. Many people with FASD are simply "surviving", or feeling different and stigmatized [6]. They deserve the opportunity to "thrive": to feel valued, supported, and included. Prescriptive or deficit-based interventions, though they may provide some support, often fail to fully meet the needs of individuals and families and may even perpetuate some barriers to care such as stigma [4]. In contrast, strengths-based interventions focus less on problem reduction and more on quality of life; specifically, autonomy, social connectedness, and emotional, physical, and material well-being [7]. This approach works to uncover and recognize assets including abilities and talents, while also accounting for positive family relationships, social supports, interests, hobbies, and goals.

The model also recognizes three barriers preventing a shift from surviving to thriving: lack of awareness and understanding of FASD, lack of access to appropriate, FASD-informed care, and stigma. Continued effort is needed to overcome these barriers and move the field toward a strengths-based perspective, including deliberate and systematic intervention design to support quality of life and thriving for people with FASD. However, existing FASD interventions have already begun addressing these barriers, and provide valuable foundational work and insight in how to move toward person-centered, strengths-based care.

This chapter presents a focused review to illustrate how current FASD intervention work is already demonstrating this shift at the individual, family, and systems levels. Table 25.1 presents a summary of existing intervention approaches to

Table 25.1 Summary of published and in-progress approaches to reduce barriers to a strengths-based perspective in FASD research. Existing intervention work reviewed in this chapter illustrates these approaches across individual, family, and systems levels

	Systems	Family	Individual
Increasing awareness and understanding	• Educational interventions in the education, child welfare, and justice systems	• Parent training, consultations, and skill-building	• Skill-building interventions
	• Consultations with providers through skill-building interventions	• Attachment or relationship-building interventions	• Mindfulness or other therapeutic approaches
Increasing access to care	• Educating providers in diagnosis, assessment, and treatment	• Delivering interventions digitally	• Delivering interventions digitally
	• Improving standards of care within systems	• Connecting families with peer support	• Active outreach for individuals in need of care
	• Reducing resource burden on individuals and families seeking care		• Providing low level of care to broader populations
Reducing stigma	• Policy work	• Family-focused care	• Arts programs
	• Representation		

reducing these barriers reviewed in this chapter. This review is not meant to be exhaustive or evaluative (for systematic reviews including efficacy, see [8, 9]). Additionally, the current chapter does not place a large focus on efficacy of reviewed interventions, both because many intervention and programs have not been formally evaluated and because traditionally outcomes have been deficit-focused. Rather, the current chapter aims to help the reader understand how existing interventions and systems of care are confronting these barriers and provide practical guidelines to continue to guide a shift toward strengths-based work.

Increasing Awareness and Understanding

Physicians, mental health providers, educators, and those in the foster care and justice systems report feeling ill-equipped to recognize, diagnose, and treat FASD [3, 10, 11], contributing to extremely low rates of diagnosis. In fact, an estimated 80% or more of people with FASD are misdiagnosed or undiagnosed [1, 2], delaying or preventing receipt of quality care. Without a diagnosis, parents are left with no explanation for their child's symptoms. They may feel isolated, frustrated, and ineffective, experience blame and judgement by others, and at times even blame themselves [4, 12, 13]. Without understanding and awareness of FASD, providers and parents can misinterpret common symptoms of FASD, like impulsivity, difficulty with self-regulation, processing speed delays, and difficulty with social skills, as

willful disobedience or defiance [13, 14]. Individuals with FASD can internalize these messages, and report feeling like a "bad kid", a problem, and a burden [6, 15, 16]. Thus, increasing understanding and awareness across settings and people is essential to improve quality of life for people with FASD.

Increasing awareness and understanding at the systems level largely consists of trainings for providers working with children with FASD. Clark and colleagues [17] describe POPFASD, an intervention to educate teachers on FASD and support them in developing appropriate and FASD-informed strategies to manage behavior in the classroom [17]. Atkinson [18] goes a step further, educating preservice teachers about FASD and encouraging them to change maladaptive attributions about the behavior of children with FASD [18]. Educational interventions also target Court Appointed Special Advocates (CASA) volunteers, increasing their knowledge, comfort, and confidence in referring and advocating for children with FASD [19]. Another helped justice system providers, such as probation officers and court officials, better understand and reframe behavior related to FASD using documentary-style training videos [20]. Other programs involve training justice system personnel to screen for and diagnose FASD; in some cases, providers help to modify probation or case plans to be more appropriate for an individual with FASD [21].

At the family level, interventions typically help caregivers gain a better understanding of the individual with FASD; support needs of siblings and extended family members have been noted as an area for growth [22]. Parenting a child with FASD often requires different parenting techniques than a typically developing child [12]. Better understanding of FASD can help a caregiver attribute the child's challenges to a neurodevelopmental disability, rather than willful misbehavior, leading to better parenting outcomes including greater feelings of efficacy and an improved parent-child relationship [13]. This theorized process originated in work on the Families Moving Forward (FMF) Program, a behavioral consultation program in which a trained specialist helps the parent to "reframe" the child's behavior, or understand the function and neurodevelopmental nature of the behavior. The parent and provider collaborate to create a behavior plan to better support the child and increase adaptive behavior, including recognizing antecedents and setting events and developing accommodations [13, 23–25]. Other parenting training programs are presented in group-based or workshop formats (e.g., [26–28]), which are less intensive yet maintain the overarching aim of helping parents to better understand FASD, more effectively support their children, and better advocate for services.

Certain skill-building interventions can help people with FASD understand their own profile of strengths and challenges and learn coping strategies that work for them. This type of growth is essential to developing self-confidence, setting goals, and improving in areas of challenge. Some focus on specific skills, like social skills or academic skills. Children's Friendship Training (CFT) [29], based on social learning theory, uses modeling, rehearsal, and performance feedback to help children with FASD improve social skills and adaptive behavior. The Math Interactive Learning Experience (MILE) [30, 31] includes math instruction as well as a comprehensive neuropsychological assessment and recommendations. Others involve a focus on self-regulation. The Alert Program for Self-Regulation (Alert) [32] is a

neurocognitive habilitation program to improve self-regulation and executive functioning in children with FASD. The GoFAR program [33, 34] involves a computer game that teaches the Focus, Act, and Reflect (FAR) metacognitive technique, and works with parent-child dyads to apply this technique to help children with FASD regulate behavior, impulsivity, and attention, and improve adaptive functioning in the home. Though explicit strengths-based assessments are not a large part of these types of interventions, practicing skills such as understanding self-regulation, calming strategies, and social interaction and cooperation can help individuals build their understanding of themselves and how they move about the world.

Integrating parent and child intervention increases awareness and understanding at the family level and helps parents better support child skill building. Some, such as MILE and GoFAR, include training caregivers to help children practice the skills they are learning in everyday life [31, 33, 34]. Interventions like CFT include concurrent parent group sessions, the content of which mirrors child sessions [29]. The Families on Track program [25], combined two evidence-based programs, the FMF Program for parents and the Promoting Alternative Thinking Strategies curriculum (PATHS) [35] for children with FASD, to provide family-based support. Though these types of interventions have been mostly studied with school-aged children, some exist for younger children and adolescents. The Strategies for Enhancing Early Developmental Success Program (SEEDS), a multidimensional school readiness program for children aged 3–5 who were exposed to alcohol prenatally, includes both a child and parent group component as well as combined parent-child time each session. Parents learn how to support skill building as the child learns school readiness skills like transitions and self-regulation [36]. Project Step Up aimed to prevent and reduce substance use among teens with FASD, using FASD-informed strategies to facilitate learning and memory. The parent component empowered parents to help their teens avoid using alcohol [37].

Some individual and family interventions provide an additional consultation to increase awareness of FASD at the systems level. Two notable examples are the FMF Program and MILE [23–25, 30, 31]. Both include a school consultation, during which the provider educates and works with the school team, including teachers and staff, to better support the student with FASD [24, 31]. In the case of MILE, in-service workshops for interested teachers are also incorporated, providing additional strategies for working with students with FASD [31].

Relationship building or attachment-based work is another method of increasing understanding and awareness at the family level. Interventions focusing on the parent-child relationship, like Circle of Security [38] and parent-child interaction therapy [23] aim to increase caregivers' parenting skills, sensitivity and responsiveness to the child with FASD, and self-reflection about their own parenting style. Parents Under Pressure (PUP) is notable as one of the few interventions targeting the parent-child relationship for children older than 7. Including mindfulness and self-regulation coaching, PUP is an individualized, home-based family focused intervention to improve the parent-child relationship, parent emotion regulation, and the child's home environment [39]. Trauma-informed attachment-based interventions, such as Child-Parent Psychotherapy (CPP) [40] are particularly important

in FASD, as research documents high levels of trauma in this population [41, 42]. A 2016 trial is one of the only intervention studies looking at CPP in children with FASD who had experienced trauma. The intervention combined CPP with parent mindfulness training to improve the parent-child relationship and developmental outcomes [43].

Therapeutic approaches to increase awareness and understanding of oneself have been studied in FASD, but larger trials have not yet been conducted in this area. Small pilot studies have shown that mindfulness training is feasible in children [44] and adolescents [45], but conclusions on efficacy of these trainings cannot yet be made due to limited studies and sample sizes. Techniques such as art therapy (see [46] for a review and practice guidelines) may be especially appropriate for people with FASD, as creativity is often a strength in this population [47].

Increase Access to Care

FASD-informed care [48] is a term encompassing best practices in care for people with FASD and their families. This includes providers who understand, accept, and advocate for people with FASD and their families, as well as systemic services making diagnosis and intervention accessible to those who need it, especially traditionally underserved populations such as low-income groups, people of color, and people living in rural areas. Increasing access to care involves both making FASD-specific forms of care more available, but also involves making existing systems of care FASD-informed.

Digital interventions have increased dramatically in recent years and show significant promise in expanding access to care. They are cost-effective, scalable, and widely accessible using a smartphone, to which 85% of the population now has access [49]. Web- and app-based parenting workshops and interventions [27, 50–52] have the capacity to reach many more caregivers than traditional in-person trainings. Computer or video game interventions can provide a more efficient and engaging way to reach individuals, especially children. Examples of these types of interventions studied in individuals with FASD include Cogmed, a computerized working memory intervention [53], and Cognitive Carnival/Caribbean Quest, a video game targeting attention and working memory [54]. Though the vast majority of people have access to the internet, potential adaptations must be made for varying levels of computer literacy, especially for lower-resourced areas in which children or families may not have high levels of exposure to technology. A recently developed cognitive training computer game was customized to lower levels of computer literacy, such as lack of comfort with a keyboard or mouse [55].

Virtual reality (VR) interventions have also increased as the technology becomes more accessible, though VR is not yet as widely available as the internet. Some have used VR to teach children with FASD safety skills [56, 57], taking advantage of the ability to practice interactions and skills in real time, which may improve

generalization. Motor interventions such as STABEL use VR to improve balance, stability, and sensory integration [58, 59].

Increasing access to care at the individual level also includes active outreach for individuals who may be less likely to seek out care. One program focused on outreach for at-risk aboriginal youth suspected of having FASD, and sought to improve a wide range of outcomes including safety, school attendance, sexual health, substance use, and knowledge and use of community resources [60]. The Mind, Body, and Spirit (MBS) program was established in correctional facilities in Canada to develop a screening and diagnostic clinic for FASD, provide support for offenders, and to create a transitional support system. An interdisciplinary FASD diagnostic evaluation identified potential participants, who then completed skill-building around communication and interpersonal skills, regular exercise, and culturally-informed spiritual wellness activities [61].

These types of outreach have the advantage of directly targeting those in need of support. Another method of reaching people who may not be actively seeking care is providing a lower level of care to a large number of people. For example, Wagner and colleagues [62] trained teachers to deliver an adapted version of the Alert Program to an entire classroom, rather than in a clinic setting, in an Aboriginal community with high estimated rates of FASD [62]. Delivering an intervention to a more general population improves the capacity to serve individuals, broadens the scope of the intervention, and lessens stigma around receiving care. It also sidesteps the barrier of limited FASD diagnosis, thereby reaching those in need of extra support including those who may have an undiagnosed FASD.

At the family level, connecting families with peer support is an efficient and effective way to increase access to care for families of children with FASD. Social support has long been known to contribute to a variety of positive outcomes for parents of children with special needs [63, 64]. However, peer-to-peer support provides an added affective benefit, with parents in peer support groups reporting feeling understood and validated, and valuing connection with others who have "been there". This is particularly important for parents of children with FASD, who often report feeling isolated and having no connection with other parents of children with FASD [4]. Some peer support programs provide training and mentorship for caregivers of children with FASD to run their own groups, an aspect especially valued by group participants [26, 65]. Other peer-to-peer approaches target geographical barriers using "hotlines" or app-based interventions. The Family Empowerment Network, based in Wisconsin, uses a telephone-based hotline to connect parents and families to peer support across the country [66]. The FMF Connect app, a mobile health adaptation of the FMF Program, includes a Family Forum, allowing parents to connect with and support each other, seek advice, and share their experiences regardless of geographical location.

Building linkages and advocacy increases access to care by connecting families to existing programs, addressing barriers to care like lack of material resources, respite, and childcare. Programs like the Parent-Child Assistance Program (PCAP) [67, 68], Key Worker program [69], Breaking the Cycle [70], and Coaching Families [71] provide families with information about FASD and assistance in accessing a wide variety

of resources, including parenting skills groups, advocacy services, FASD diagnostic clinics and supports, and substance use counseling. Some, like Breaking the Cycle, also connect families with support for basic needs like clothing and meals [70]. PCAP, a 3-year program to increase access to community resources as well as collaboration and advocacy with case managers and other providers, has also been adapted to parents with FASD to further increase accessibility of care [67, 68].

Other types of programs directly reduce barriers to care related to resources. One program provided increased respite care (i.e., 6 h per week of group-based activities for children without parent attendance) to decrease family stress over a period of 10 months [72]. Many programs, such as the Key Worker program and PCAP are home-based, reducing the need for transportation and childcare. Along these same lines, several therapeutic programs described above can take place in the home (e.g., the FMF Program, PUP, Circle of Security).

Training providers to recognize and diagnose FASD expands access to care within existing systems. The Extension for Community Healthcare Outcomes (ECHO) approach involves tele-mentoring using didactics and case-based learning with an expert "hub" team and community "spoke" sites, enabling efficient and broad dissemination of evidence-based care models [73]. The first trial of the ECHO program for FASD trained primary care providers across the country on FASD diagnosis and care management [74]. In addition to family-focused care, the Family Empowerment Network trains providers on FASD diagnosis, interventions, and planning [66]. One initiative involved social workers, called FASD Success Coaches, who provided support to students with FASD as well as training and case management support to their teachers [65]. The Promising Practices program [75] works within the child welfare system to provide improved care for families; specifically, it provides assessment for suspected cases of FASD and makes training and expert consultation available for both caseworkers and foster parents. Through this program, support plans are developed collaboratively with caseworkers, foster care support workers, and foster parents. Interventions in the justice and school systems discussed above also increase access to care via education and training of providers, especially when delivered using digital means such as videos (e.g., [20]).

Work in the Australian Fitzroy Valley provides an example of wide-ranging FASD-informed systems-based intervention. Titled the Marulu Strategy, the program included expanding FASD screening and diagnosis, building local capacity to serve individuals and families, and identifying and leveraging existing community resources [76, 77]. Not only does this model provide a standard for addressing barriers to care at the systems level, it also shows the potential of community and stakeholder expertise.

Reduction of Stigma

Stigma underlies nearly all barriers to thriving and prevents individuals and families from realizing their full potential for quality of life. A recent literature review [6] lays out the varied types of FASD-related stigma including public stigma,

self-stigma, stigma by association, and structural stigma. Each of these types of stigma are important to consider, as is how they overlap and influence each other; stigmatization toward people with FASD is often intensified given the intersectionality of varying identities impacting the lived experiences of this population [6, 15, 16]. In recent years, movements to explicitly address stigma and discrimination, especially implicit bias, have come to the forefront of discussion both in the FASD field and in society as a whole. Despite this, interventions for stigma reduction are limited. Literature on reducing stigma around mental health disorders suggests that public protest of stigmatizing materials, increasing awareness and education, and contact between majority and minority members will translate to stigma reduction [78]. Further, concrete and purposeful steps must be taken to address the harm that has already occurred as a result of stigma and discrimination, and to continue to make clear a tangible commitment to the value and worth of people with FASD.

Self-stigma, or stigma that is anticipated, expected, and internalized, involves self-blame and shame and leads to people with FASD having lower self-esteem, lacking confidence, and underestimating their own potential [6, 16]. Few interventions actively focus on increasing the self-esteem of people with FASD and little research has been conducted on how self-stigma can be reduced. One potential avenue is arts-based interventions, which have shown positive effects on self-esteem and confidence in children in the child welfare and mental health care systems [79, 80]. An intensive theater training camp in Canada targeted the skills, emotional awareness, and self-esteem of children with FASD aged 9–14, along with skills in acting and performing [81, 82].

Parents, caregivers, siblings, and other family members may experience stigma by association, or social and psychological reactions to an association with a stigmatized person, in this case an individual with FASD. This type of stigma may underlie feelings of isolation and stress experienced by caregivers of children with FASD [4], as well as actual social exclusion. To date no interventions actively address stigma by association. Reid and colleagues [83] propose an intervention framework to place families at the center of interventions and service provision, including recommendations drawn from literature around "excluded families", or families who cannot access mainstream services and resources. The authors provide specific practical recommendations for facilitating family-focused intervention: strengthening the family social economy (both formal supports such as schools and informal social supports such as friends and family), promoting hope, acknowledging family expertise, and providing education and skill building [83].

Structural stigma, or that which is perpetuated in society's institutions and systems, also plays a factor in the lives of those with FASD and is largely unaddressed by intervention work. However, there are multiple efforts being made to reduce structural stigma such as changing policy through the FASD Respect Act in the US and shifting the media portrayal of individuals with FASD through documentary filmmaking. Positive representation for people with FASD may be the most important method of stigma reduction. The Adult Leadership Collaborative of FASD Changemakers represent a group of well-known adults living with FASD who conduct research on well-being in FASD, provide a network of peer-to-peer support,

and advocate for reduction of stigma and greater acceptance. Amplifying the voices of activists and role models with FASD should be one of the highest priorities for the field, and can be accomplished through intervention work, and indeed research in general, at all levels.

Implications for Clinical Practice

Clinical providers can utilize guidelines from interventions reviewed here to reduce these barriers and shift to a strengths-based perspective in day-to-day practice. Clinicians should pursue education about FASD and related conditions and incorporate the knowledge into care, recognizing that many people with FASD will not have access to a diagnosis. Importantly, providers must understand that challenging symptoms stem from a neurodevelopmental disability, and do not indicate willful defiance. A focus on environmental modifications (reducing sensory stimulation, providing visuals or social stories, simplifying language and instructions) should be emphasized. Providers can also help caregivers to understand their child's behaviors from this perspective and validate the stress and isolation they may be feeling as a caregiver of a child with FASD. Clinicians who are knowledgeable about FASD should also educate colleagues and offer support and resources in learning about FASD.

Incorporating a strengths-based perspective into clinical practice is essential. Providers using standardized assessment tools should include a strengths-assessment tool, such as the Values in Action (VIA) Assessment System [84] or the Assessment Scale for Positive Character Traits—Developmental Disabilities [85]. These assessments can provide a profile of character strengths and positive attributes, which offers a more complete picture of an individual than solely deficit-based assessments. Additionally, using a strengths-based framework in clinical care and planning can help a provider to tailor care to the individual's needs and goals. Possible clinical approaches include Buntinx & Schalock's four phase approach [86] or person-centered planning [87, 88].

Providers should also be aware of barriers to accessing care faced by individuals and families. Novel approaches to intervention such as digital interventions can be accessed regardless of geographical location and are often cost-effective, although many are still in initial stages of development and testing. Peer-to-peer support should be emphasized, as should connections to community resources for advocacy, mental health care, respite, and other family needs. When possible, methods of overcoming lack of resources should be used, such as home visitation, collaboration with case managers, and linkages to fulfill basic needs.

Providers also have a role in decreasing stigma around FASD. Understanding the various types of stigma (i.e., self-stigma, stigma by association, structural stigma, and public stigma) is crucial to reducing it. Clinicians must work to build up the self-esteem and confidence of individuals with FASD and validate and support their caregivers. Modifying stigmatizing language (see [89] for a guide) and attending to

the past experiences of individuals with FASD and their families can help them to feel understood and accepted. Finally, providers can work to build hope for their patients by treating them with compassion, empathy, and kindness, recognizing their expertise, strengths, and the ways in which they positively influence the world around them.

Conclusions and Future Directions

The "From Surviving to Thriving" model presents a shift from a focus on problems and deficit-focused intervention to a focus on positives and strengths-based intervention. To make this shift, three barriers must be addressed: lack of awareness and understanding of FASD, lack of access to care, and stigma. The current review illustrates how existing interventions and programs have already begun to address these barriers at the individual, family, and systems levels. Much of this work focuses on increasing awareness and understanding, especially with the goal of helping caregivers and providers "reframe" behavior or understand challenges as part of a neurodevelopmental disability, and not as willful defiance or misbehavior. These types of interventions range from intensive skill-building programs to educational videos but are often effective in increasing knowledge and awareness of FASD [8, 9]. Work focusing on increasing access to FASD-informed care includes both finding novel ways to deliver care, such as technology training teachers or peer mentors, as well as improved methods of reaching underserved populations. Limited formal work is explicitly aimed at reducing stigma, but informal approaches such as grassroots work and positive representations of FASD can reduce stigma and increase hope for people with FASD. Though existing intervention work lays a foundation for a shift to a strengths-based perspective, future intervention work should be person-centered and deliberately designed around strengths and positives.

Perhaps most importantly, future work on effectiveness should no longer be limited to reduction of deficits, but should take steps to understand and address the issues important to individuals living with FASD and those around them. Very little is known about the effectiveness of existing interventions on including quality of life and promoting thriving in people living with FASD. Many of the interventions reviewed in the current chapter are shown to be effective in achieving outcomes such as reduction of problem behavior, improved adaptive or social skills, and reduced stress and burden on caregivers (for systematic reviews including efficacy, see [8, 9]). However, larger and more diverse trials are needed to make conclusions about broader efficacy as well as in subgroups such as racial/ethnic minorities. Future work should continue to rigorously test effectiveness of these interventions, both in the context of randomized controlled trials and in community settings, especially in the context of quality of life and strengths-based outcomes.

In addition to these calls to action for future work, the "From Surviving to Thriving" model presents six directions to continue to promote thriving in FASD (Table 25.2).

Table 25.2 Future directions to shift to a strengths-based perspective in FASD research and intervention

Future directions to promote thriving in FASD [5]
1. Transform how we view FASD
• Reduce stigma and use of stigmatizing language
• Promote a balanced view of people with FASD
2. Study and measure strengths and thriving
• Develop more appropriate and valid measures of strengths
• Conduct research to understand thriving in FASD
3. Utilize strengths-based frameworks for FASD intervention in research and practice
• Promote use of existing strengths-based frameworks in care
• Adapt strengths-based interventions to FASD
4. Translate research knowledge to community and public health settings
• Combine approaches to increase access to care with approaches like community-based participatory research [90]
• Increase education around additional experiences such as comorbid mental health disorders, trauma, school disruption, and justice system involvement
5. Adapt existing models and technologies for FASD
• Adapt and study existing evidence-based mental health treatments for people with FASD
• Establish efficacy of digital interventions and foster implementation in community
6. Develop novel approaches to address gaps in the literature
• Work to reach underserved populations like diverse cultural groups, biological parents, underserved geographical areas, and adolescents and adults with FASD
• Research specific needs of these populations and develop or adapt interventions to address them

FASD intervention research and community programs to provide and improve care have made significant steps in improving the quality of life of people with FASD and their families. However, the evidence base for effectiveness is still in need of growth; larger samples and more rigorous study designs are necessary to understand how intervention programs can be most helpful to people with FASD. Trials in community settings focusing on implementation are particularly important to building a sustainable and effective system of FASD-informed care. Continuing to shift to a strengths-based perspective, guided by the "From Surviving to Thriving" model, will build on this foundation to purposefully and intentionally promote thriving for people with FASD.

Part V
Structural and Functional Central Nervous System Pathology in Alcohol Addiction

Chapter 26
Structural and Functional Imaging of Alcohol's Effects on the Brain

Joshua L. Gowin, Katelyn T. Kirk-Provencher, Hollis C. Karoly, and Joseph P. Schacht

Abstract Brain imaging has helped reveal acute and chronic effects of alcohol use, and how these effects relate to clinical outcomes in adults with alcohol use disorder (AUD). The prefrontal cortex and the mesocorticolimbic reward system have shown consistent effects of chronic alcohol use. For example, adults with AUD show reduced dopamine D2 receptor density in the striatum, reduced volume of medial prefrontal cortex (PFC), and decreased white-matter tract integrity. Although most studies only examine individuals at a single point in time, supporting evidence suggests a causal relationship between chronic heavy alcohol use and altered brain structure and function. Individuals with AUD, relative to controls, display greater activation of the cingulate and ventromedial PFC in response to alcohol cues, less activation of the striatum during the anticipation of monetary reward, and less activation of the insula and ventromedial PFC in response to negative emotional cues. Differences in brain anatomy and function can inform clinical practice, as indicated by studies that show that AUD can be identified based on neuroanatomical differences, and that neural activation to alcohol cues may predict which individuals will benefit from treatment.

Alcohol Use Disorder (AUD) has social, environmental, and biological origins. Of biological contributors, the brain is paramount. The brain is a complex organ that controls thought, motivation, and behavior, and each of these processes affects likelihood of harmful alcohol use. Yet identifying specific features of brain structure and function associated with AUD has been challenging. Alcohol exerts its effects primarily by altering brain function, but identifying precise changes in brain function that result from acute and chronic alcohol use remains difficult. Alcohol affects multiple aspects of cellular function, albeit mostly in small ways that fail to account fully for its effects. Historically, researchers studying the effects of alcohol on the brain have focused primarily on individuals with alcohol dependence, which is the diagnostic predecessor of AUD. Although some of the literature discussed in this chapter involved studies of individuals diagnosed with "alcohol dependence," "alcoholism," or "alcohol abuse," we use the term AUD to encompass all previous diagnostic terms used in older studies. Research aimed at understanding how AUD affects human brain function has benefited from neuroimaging tools, including magnetic resonance imaging (MRI), positron emission tomography, and single photon emission computed tomography. These tools have helped researchers quantify structural and functional changes associated with AUD.

Effects of Alcohol on Brain Structure

Brain Structures Associated with Cognitive Control. Early evidence that alcohol affected the brain came from post-mortem brain studies. Post-mortem data suggest that alcohol changes brain structure, and certain brain regions may be at greater risk for damage. For example, post-mortem studies have shown significant brain atrophy among individuals with AUD compared to healthy adults, primarily within the prefrontal cortex (PFC) [1]. The PFC has many functions, many of which relate to cognitive control. Brain regions underlying cognitive control include the inferior frontal gyrus (IFG), dorsolateral prefrontal cortex (DLPFC), dorsal anterior cingulate cortex (ACC), and parietal cortex [2] (see Fig. 26.1, which will be a reference point for neuroanatomy throughout this chapter). AUD may involve changes within neural circuitry underlying control over behavior [3]. An imbalance between neural reward and control functions may explain why individuals with AUD seek alcohol instead of other reinforcers and have difficulty reducing alcohol consumption despite experiencing negative consequences associated with drinking [4]. MRI studies have reported lower gray matter in the PFC, IFG [5, 6], dorsal ACC, and parietal cortices [7] among individuals with AUD compared to healthy adults.

A valuable approach to gathering scientific evidence, meta-analysis, combines data from multiple studies to assess the strength of evidence. Numerous meta-analyses show volume loss within control-related brain regions among adults with AUD relative to healthy adults. One meta-analysis of 12 studies representing 433 individuals with AUD and 498 healthy adults revealed that the AUD group demonstrated lower gray matter volume within the insula, DLPFC, ACC, striatum,

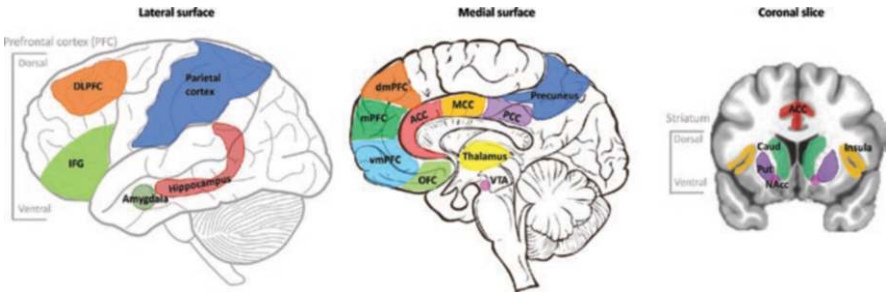

Fig. 26.1 Brain areas referenced in this chapter. DLPFC, dorsolateral PFC; IFG, inferior frontal gyrus; dmPFC, dorsomedial PFC; mPFC, medial PFC; vmPFC, ventromedial PFC; OFC, orbitofrontal cortex; ACC, anterior cingulate cortex; MCC, middle cingulate cortex; PCC, posterior cingulate cortex. Note that the amygdala and hippocampus are located in the medial temporal lobe but are depicted on the lateral surface image. On the coronal slice, the striatum comprises the caudate (Caud), putamen (Put), and nucleus accumbens (NAcc)

thalamus and hippocampus [8]. A larger meta-analysis included 23 studies representing 846 individuals with AUD and 878 healthy adults and found lower gray matter volume in the right cingulate gyrus, insula and middle frontal gyrus for those with AUD [9]. Finally, the largest meta-analysis to date included 27 studies representing 1045 individuals with AUD and 1054 healthy adults and found gray matter reductions in the cingulate gyri, medial frontal gyri, left anterior and right posterior insula and left superior frontal gyrus among individuals with AUD [10]. Volume loss in these regions may contribute to the impaired control over drinking that is commonly seen in AUD [11].

Brain Structures Associated with Reward. In the 1950s, a series of groundbreaking studies was conducted in which rats were implanted with electrodes that allowed them to electrically stimulate specific brain areas by pressing a lever [12, 13]. When an electrode was placed within dopaminergic regions in the midbrain, the rats repeatedly pressed the lever (up to 2000 times per h over 24 h) and ignored other reinforcers such as food. Following this work, researchers identified the mesocorticolimbic dopaminergic circuitry as the primary neural pathway underlying reward-related responses to addictive substances [14]. The mesocorticolimbic pathway includes the ventral tegmental area (VTA), striatum (composed of caudate, putamen, and nucleus accumbens [NAcc]/ventral striatum [VS]), hippocampus, amygdala, and PFC. Other brain regions involved in addiction-related reward-processing include the insula and thalamus [15–17]. Reduced gray matter volumes have been observed in the striatum, hippocampus, amygdala, PFC, insula, and thalamus in AUD individuals relative to healthy adults [5, 18–21]. Volume loss in these regions may contribute to deficits in reward processing, such as overvaluing alcohol reward and undervaluing natural reinforcers [22].

The hippocampus plays a critical role in learning and memory and is implicated in the development of AUD [23]. A study exploring differences in hippocampal volumes between men with AUD and age-matched healthy adults found that the

AUD group showed lower total hippocampal volume [24]. A recent analysis synthesizing published results from 23 studies on hippocampal volume demonstrated that heavy alcohol use is associated with smaller hippocampal volume [25].

Compelling evidence regarding the effects of alcohol on brain volume emerged from several large-scale studies that pooled data from multiple research sites. These studies have leveraged large, carefully selected samples that screened out for psychiatric comorbidities to provide stronger evidence that any differences were due to alcohol use, but not other causes. One such study pooled data from 10 research sites and included 660 people with AUD and 326 healthy adults. They found that, on average, individuals with AUD, relative to healthy adults, had 3–9% lower gray matter volumes in the hippocampus, putamen, pallidum, and thalamus, as well as lower total gray matter [26]. In another study, data were pooled across 23 sites and included 1100 healthy adults and 2140 individuals who were dependent on alcohol, nicotine, cocaine, methamphetamine, or cannabis. This study showed that substance-specific associations with gray matter volume were stronger with alcohol relative to the other substances, and AUD was associated with reduced gray matter volume in the amygdala, hippocampus, NAcc, putamen and thalamus [27]. These studies indicate that AUD is associated with broad gray matter volume loss, especially within reward- and control-related regions, and suggest the potential for specific patterns of regional brain volume loss to serve as a diagnostic marker for AUD.

Effects of Alcohol on Brain Function

Alcohol Cue-Reactivity. Stimuli associated with alcohol consumption, including the sight, smell, and taste of alcohol (i.e., "cues"), have long been known to elicit alcohol craving [28]. With the advent of functional magnetic resonance imaging (fMRI) in the 1990s, alcohol cue-reactivity paradigms were among the first tasks tested in the fMRI environment. In the most common versions of these tasks, the neural signal elicited during blocks of alcohol-related cues, including visual [29], olfactory [30] and gustatory [31] stimuli, is contrasted with the signal elicited during blocks of neutral stimuli that are closely matched on other sensory characteristics. This contrast yields an estimate of differential activation, either throughout the brain or within a specific region of interest. Numerous studies have demonstrated that alcohol cues, relative to neutral cues, elicit activation of a variety of brain areas, particularly those related to reward processing and decision-making.

A seminal meta-analysis [32] analyzed 28 studies of alcohol cue-reactivity, representing 679 individuals with AUD and 174 healthy adults, and concluded that the ventral striatum (VS), ventromedial prefrontal cortex (PFC), posterior cingulate cortex (PCC), and precuneus were most consistently activated by alcohol cues, relative to neutral cues. Of these areas, the PCC and the adjacent precuneus demonstrated greater alcohol cue-elicited activation among individuals with AUD, relative to healthy adults. The VS and ventromedial PFC lie along the mesocorticolimbic dopamine pathway and underlie neural reward processing, while the PCC and

precuneus, situated in the parietal lobe, are associated with risky decision making [33] and subjective valuation of potential rewards [34]. Since that analysis included hypothesized regions of interest as well as whole-brain analyses, a subsequent meta-analysis considered only 17 whole-brain fMRI studies, representing 457 people with AUD and 360 healthy adults, and identified greater alcohol cue-elicited activation among AUD individuals, relative to healthy adults, in the ACC, middle cingulate as well as the ventromedial PFC [35]. Among individuals with AUD, these findings indicate that alcohol-associated cues acquire the ability to hijack brain systems associated with reward and decision-making, but treatment for AUD can change this altered brain function [35].

Studies have also examined whether neural activation to alcohol cues has clinical implications. Among treatment-seeking individuals with AUD scanned prior to treatment initiation, greater cue-elicited activation of several brain areas has been associated with relapse, but the studies have shown inconsistency in the specific regions implicated. For example, a review [36] reported that of seven studies that identified a relationship between cue-elicited activation and relapse, greater dorsomedial PFC activation was associated with relapse in two studies, greater VS activation in two other studies, and several other regions in one study each. In contrast to these varying associations, several randomized controlled trials examined cue-elicited activation of the VS as a predictor of response to naltrexone, a frontline medication for AUD. Naltrexone is an opioid antagonist with greatest affinity for the mu receptor, and one of its mechanisms of action is reducing alcohol craving [37]. Individuals with AUD who drink because they enjoy the rewarding effects of alcohol are more likely to respond to naltrexone [38]. Consistent with these data, naltrexone (50 mg daily), relative to placebo, reduced cue-elicited VS activation in three separate studies [39–41]. Greater VS activation prior to naltrexone initiation was associated with longer time to relapse. Incubation of neural alcohol cue reactivity after withdrawal and its blockade by naltrexone [41, 42], and greater reduction in VS activation during the first 2 weeks of naltrexone treatment was associated with significantly fewer heavy drinking days in the subsequent 14 weeks [40]. These data suggest that alcohol cue-elicited VS activation is a promising predictor of response to AUD medications that block alcohol craving or reward.

Reward Processing. In addition to neural responses to alcohol-related cues, many studies have investigated whether general reward processing differs between individuals with AUD and healthy adults. In one commonly used fMRI reward processing task, participants see a cue that indicates either a potential monetary gain or loss, followed by a target symbol. Participants attempt to respond to the target by pushing a button as quickly as possible and receive feedback after each target indicating their success or failure and their earnings [43–45]. In healthy individuals, anticipation of winning $5 versus $0 results in a large increase in VS activation [45]. A recent meta-analysis of this task that included six studies representing 131 individuals with AUD and 155 healthy adults found that individuals with AUD demonstrated less VS activation when given the chance to win $5 [46]. Additionally, individuals with AUD exhibited increased VS activation when receiving feedback that they had won $5 compared to healthy adults. Differential striatal activation in

individuals with AUD may be the result of difficulty in learning during reward prediction when presented with non-alcohol related cues [46] and this may result in inappropriate decision making that leads to continued alcohol use.

Emotion Processing. Emotion processing and regulation are necessary for recognizing and responding to emotional stimuli [47], and are critical for effective interpersonal functioning [48]. Facial expression recognition tasks aim to assess recognition of emotional facial expressions (e.g., fear, surprise, happiness). In a systematic review of 26 studies of facial expression recognition by individuals with AUD, the majority of studies found that individuals with AUD had deficits in the recognition of disgust and sadness and they needed images with greater intensity of emotional expression for successful recognition of fear and anger [49]. They also took longer to recognize emotions, compared to healthy groups [49]. One study used fMRI to examine neural activation in response to emotional faces by 29 detoxified individuals with AUD and 31 healthy adults [50]. Individuals with AUD were less able to recognize fearful faces compared to healthy adults and demonstrated decreased activation in the orbitofrontal cortex (OFC) and insula, brain regions associated with the identification of emotional stimuli [50]. Individuals with multiple detoxifications showed the greatest decrease in activation in these regions. These findings suggest that individuals with AUD have difficulties with processing emotions and producing appropriate emotionally driven behaviors [50].

Research has also examined response to stressful or threatening situations, such as interpersonal conflict. Individuals with AUD, compared to healthy adults, show decreased activation in the cortico-limbic-striatal regions—associated with identification, processing, and modulation of stressful stimuli—during high-stress situations, but over-activation of these regions during low-stress situations [51]. A study examining problematic drinking, reward, and viewing emotional faces in 759 college students found neural activation patterns were associated with harmful drinking patterns over time. For example, individuals who exhibited low VS activation in response to winning money and high amygdala activation in response to angry faces were more likely to meet criteria for AUD at the time of the neuroimaging and more likely to engage in problematic drinking 3 months later [52].

Another approach to examining stress involves creating an audio-recorded script based on a participant's report of a recent stressful life event, a recent alcohol use-related event, and a neutral-relaxing event [53, 54]. Creating stressful stimuli from the person's lived experience helps ensure that the stimulus is salient and elicits negative feelings. Relative to healthy adults, adults with AUD had increased alcohol craving after hearing the stress- and alcohol-related scripts [54, 55]. Healthy individuals show increased neural activation when hearing the stress- and alcohol-related scripts in the medial and lateral PFC, ACC and PCC, striatum, and anterior insula, indicating recruitment of emotion, stress, and reward processing brain regions [55]. A study of 37 patients with AUD who had been abstinent for 4–8 weeks and 37 healthy adults found that individuals with AUD demonstrated less activation in the medial PFC, ACC and PCC, ventrolateral PFC, and insula, during the stress- and alcohol-related scripts compared to the neutral-relaxing scripts [56]. These regions are involved in cognitive control and the modulation of emotional

behaviors in response to conflict. The individuals with AUD demonstrated difficulties with regulating negative emotion following stressful stimuli [56]. Neural regions associated with emotional processing and modulation in response to stressful stimuli may be impaired in adults with AUD, which may lead to impulsive behavior and loss of control over drinking.

Positron Emission Tomography (PET) Studies of Alcohol Effects

Dopamine Transporters and Receptors. Studies have also used PET to investigate changes in neurotransmitter function that are associated with AUD, including the distribution of receptors and the release of neurotransmitters following a probe. Research has examined the dopamine system more than other systems because of the wider availability of tools to study this system, and because of empirical and theoretical associations between dopamine function and addictive disorders. One tool to study dopamine function is a radiotracer that binds to dopamine transporters at the presynaptic terminals in the striatum. Dopamine transporters remove dopamine from outside the neuron and return it to the cytosol. In periods of early abstinence (less than 3 weeks), individuals with a history of heavy drinking show reduced dopamine transporter availability relative to non-heavy drinkers [57]. Following protracted abstinence, several studies have shown that dopamine transporter availability in adults with a history of heavy drinking resembles that of healthy adults [58–60], suggesting recovery of dopamine transporters over time.

Another key set of tools for examining the dopamine system are tracers that bind to striatal D2/3 receptors on the postsynaptic terminal. Studies that have examined D2/3 receptor availability have found lower levels of these receptors in individuals with AUD relative to healthy groups [59, 61], suggesting suppression of dopamine signaling. Decreased D2/3 receptor availability may extend to regions beyond the striatum, as some studies have investigated other regions and found lower levels in the insula, thalamus, and hippocampus among individuals with AUD relative to healthy adults [62]. Decreased D2/3 receptor availability among individuals with AUD is consistent with the effects of alcohol, which acutely elicits greater dopamine release, relative to non-alcoholic juice, in the VS [63]. Men may release more dopamine after drinking alcohol than women [64]. Elevated VS dopamine release caused by chronic heavy drinking may thus lead to compensatory pruning of D2/D3 receptors.

In addition to reduced D2/3 receptor availability, adults with AUD may also have altered dopamine release. In two studies, adults with AUD showed lower dopamine release following administration of methylphenidate, a stimulant that induces dopamine release, relative to healthy adults [61, 65]. Two studies have examined whether D2/3 receptor levels recover with abstinence from alcohol. One study showed persistent decreases in D2/3 receptors in adults with AUD even after 4 months of abstinence [66]. The other showed evidence of recovery, where the adults who remained

abstinent no longer differed from adults with no history of AUD [62]. More evidence is needed to determine whether D2/3 receptor availability recovers with abstinence.

Other Neurotransmitters. While dopamine is widely associated with addictive behaviors, another key neurotransmitter in alcohol pharmacology is ɣ-aminobutyric acid (GABA). GABA-A receptors are the site of benzodiazepine action, and tolerance to benzodiazepines is associated with cross-tolerance to alcohol, suggesting alcohol also acts at GABA-A receptors. Several tools help study GABA-A receptors in the brain, such as the radiotracer [^{123}I]iomazenil. One study used [^{123}I]iomazenil to show that adults with AUD exhibited lower levels of GABA receptors across the brain, particularly in the PFC, ACC, and occipital cortex [67]. Even when accounting for lower gray matter among adults with AUD, there were still fewer GABA receptors [68]. Another study, with twice as many participants, showed higher GABA-A receptor levels among adults with AUD, relative to healthy adults, during the first week of abstinence, but no difference between these groups after a month of abstinence [69]. Part of the discrepancy may stem from the lack of specificity of [^{123}I]iomazenil, which binds at many receptor types. Another study used [^{11}C]Ro15 4513, which binds specifically to the α5 subunit of the GABA-A receptor. This study showed large reductions in the availability of this receptor throughout the brain in participants with AUD, with the largest differences in the VS [70].

Several other neurotransmitter systems have been examined in relation to chronic alcohol use. For example, a study of 25 adults with AUD and 30 healthy participants showed significantly greater mu-opioid receptor availability across many brain regions, with the largest differences in the striatum [71]. The study also examined delta-opioid receptors and similarly showed greater availability in the adults with AUD, but the differences were smaller in magnitude than the mu receptor ones, and did not reach statistical significance in any regions [71]. Another study showed that greater mu-opioid receptor availability remained after 5 weeks of abstinence [72]. The differences could result from "up-regulation of mu-opioid receptors and/or reduction in endogenous opioid peptides following long-term alcohol consumption, dependence, and/or withdrawal" [71].

Brain Metabolism and AUD. Numerous studies have investigated how AUD affects the brain's metabolism. The first tool that allowed researchers to study metabolism was the radiotracer [^{18}F]fluorodeoxyglucose, in which a radiolabeled fluorine was inserted into a glucose molecule [73], allowing PET scans to track glucose uptake. In the mid-1980s, studies had shown that adults with a history of alcohol misuse, relative to those without such a history, showed lower uptake of [^{18}F]fluorodeoxyglucose, indicating a lower level of glucose metabolism [74]. Levels of glucose metabolism were lower across the whole brain, but the magnitude of differences was greatest in the frontal and parietal cortices [75]. Participants in the study had been abstinent between 4 and 22 days, and shorter durations of abstinence were associated with lower levels of glucose metabolism [76]. This suggests that glucose metabolism deficits may begin to recover following sustained abstinence for several weeks.

A prospective, longitudinal study showed that individuals with AUD had the lowest levels of cerebral glucose metabolism in the first 15 days after the last drink

[76]. Between 16 and 60 days of abstinence, glucose metabolism increased to higher levels, but there was no evidence of additional recovery between 30 and 60 days. Individuals who had a longer history of heavy alcohol use showed lower levels of glucose metabolism, and while they were also older, there was no correlation with age in healthy adults. This suggests that a longer history of heavy alcohol use may cause decreased glucose metabolism. Another study tested the glucose metabolism of healthy adults and adults with AUD under baseline conditions and again 1 day later after administration of alcohol (1 g/kg), a dose targeted to bring participants to 0.1 g/dL blood alcohol concentration, above the legal limit for driving. While alcohol administration reduced glucose metabolism for both groups, the reduction was more pronounced in the group with AUD, and was greater in adults who consumed greater amounts of alcohol [76, 77].

One possible explanation for the decrease in cerebral glucose metabolism is that the energy source for the brain may shift in response to acute and chronic alcohol exposure. One clue for this possibility came from a study of heavy drinkers and light drinkers that found higher acetate levels in the blood in heavy drinkers. In normal circumstances, blood glucose concentrations, at 15 mM [78], are about 100 times greater than acetate concentrations, at 0.17 mM [79], which could explain why the brain would prefer the more widely available energy source. Following alcohol exposure, acetate levels increase by 65% to as much as 0.75 mM [80], and glial cells in the brain have been shown to use acetate as an energy source when levels are higher [81]. A PET study used [$^{1-11}$C]acetate as a tracer and examined a group of occasional social drinkers and a group of heavy drinkers under a placebo condition and an acute alcohol condition. The heavy drinkers showed higher levels of cerebral acetate uptake than the social drinkers across both the placebo and alcohol conditions. Both groups showed a significant increase in acetate uptake during the alcohol administration scan relative to the placebo scan [82]. The largest increases occurred in the cerebellum and the occipital cortex. Glial cells, such as astrocytes, express monocarboxylic acid transporters that can bring acetate into the cytosol, whereas neurons do not, so glial cells may be more apt to use acetate than neurons. The shift to acetate as an energy source may be primarily for resting energy use, as another study examined glucose metabolism both at rest and in response to visual stimulation. The study found that visual stimulation led to increases in glucose metabolism and that alcohol did not reduce the stimulation-induced metabolism [83]. This suggests that alcohol may reduce resting glucose metabolism, but not stimulation-induced increases in glucose metabolism. While the implications of lower glucose metabolism among adults with AUD are unclear, it may affect energy availability or metabolic byproducts.

Recovery of Brain Volume with Sustained Abstinence

Clinically, several critical questions are whether the structural changes associated with alcohol are reversible with abstinence, to what extent alcohol-related changes may be reversed, and how long it takes for abstinence-related brain volume recovery

to occur. In one study, which followed 23 individuals with AUD over 12 months, greater recovery of brain tissue volume was observed in the first month of abstinence than in the following 6–9 months, during which time modest gray matter volume gains continued to occur. The short-term increases in volume were reversed with a return to drinking [84]. In certain brain regions, volume recovery to levels comparable with healthy adults may be possible after extended abstinence. For example, in 85 individuals with AUD who were measured at 1-week, 1-month, and 7-months of abstinence, increases in volume were observed after 1-week, 1-month and 7-months. After 7 months of abstinence, ACC and DLPFC volumes were equivalent to those of healthy individuals [85]. Some volume loss, however, appears to persist even after sustained abstinence. Another study showed that after 7.5 months of abstinence, individuals with AUD had lower parietal, temporal and total cortical gray matter and thalamus volumes than healthy adults, despite showing increases in frontal, parietal, occipital, total cortical gray matter volume, and thalamus volume over the course of the abstinence period [86]. Recovery of brain tissue over the course of abstinence also appears to differ based upon the extent of volume loss an individual has incurred, as another study in an AUD sample found that smaller baseline brain volumes prior to 7 months of abstinence predicted larger rates of brain volume change during the abstinence period [87]. The structural changes that occur in the context of heavy or chronic alcohol consumption may be partially reversible with prolonged abstinence, with the largest improvements occurring in early abstinence [86].

Interaction Between Structural and Functional Neural Changes in AUD

Both brain structure and function may change among individuals with AUD, and there may be an interaction between structural and functional changes. Although most AUD neuroimaging studies have analyzed primarily structural or functional data, multimodal neuroimaging studies examining both have become more common in recent years. Perhaps the earliest of these studies used PET and fMRI in the same participants and found that VS dopamine D2 receptor availability was lower among 11 men with AUD than 13 healthy men, and less D2 availability was correlated with greater cue-elicited ventromedial PFC activation [88]. These data suggested that cue-elicited brain activation is dopaminergically modulated, that VS dopamine is associated with frontal processing of alcohol cues, and that AUD alters this pathway.

A key question regarding the relationship between AUD-associated changes in brain structure and function is whether volumetric deficits among individuals with AUD relative to healthy adults mask, or exaggerate, differences in function. If alcohol neurotoxicity reduces the number of neurons in a brain region, the BOLD response of this region to a functional task may be affected. A study evaluated this possibility by scanning 46 healthy adults and 46 detoxified AUD patients, who were followed for 3 months after scanning, during which 30 relapsed to heavy drinking

and 16 remained abstinent [89]. Relative to healthy adults and adults with AUD who remained abstinent, the AUD patients who relapsed displayed smaller volumes of several cortical areas, including the OFC, medial PFC, and ACC. Individuals who relapsed, relative to those who remained abstinent, demonstrated greater alcohol cue-elicited activation of the medial PFC even after accounting for the atrophy they displayed in this region. The effect was larger than previous reports indicated, suggesting that volumetric differences might have masked an even greater difference in cue-elicited activation of this region, and that structure and function may interact to predict relapse in AUD.

Studies have also examined the relationship between white matter structure and brain function. Assessment of white matter integrity is useful because alcohol damages brain myelin [90]. One study reported that 18 AUD individuals, relative to 17 healthy adults, displayed less correlation of activation between the middle cingulate cortex (MCC) and PCC during an inhibitory control (Stroop) task, but greater correlation between MCC and midbrain activation [91]. Enhanced MCC-midbrain correlation was associated with lower integrity of fiber bundles in the PCC as measured by diffusion tensor imaging (DTI), which assesses white matter integrity. This suggests that structural compromise of major white matter tracts in AUD manifests in differences in neural activation patterns during inhibitory control. Another study employed structural MRI, DTI, and resting-state fMRI to evaluate differences in a circuit between the NAcc (the primary structure within the VS) and OFC, between 39 detoxified AUD patients and 18 healthy adults [92]. The AUD individuals displayed smaller NAcc volumes and reduced integrity of the whiter matter tract between the NAcc and OFC, and these measures were correlated, suggesting that alcohol-associated atrophy of the NAcc, OFC, or both might have led to degradation of their connecting fibers. Although the groups did not differ in the strength of correlation between OFC and NAcc activation, individuals with stronger correlation had greater alcohol craving. This pathway may therefore contribute to motivation to use alcohol.

Brain structure and function have also been examined as metrics to identify adults with vs. without an AUD diagnosis. A recent study used several structural neuroimaging measures, including gray matter and cerebrospinal fluid density and cortical thickness, along with functional measures, including monetary reward task and resting-state fMRI, to develop a classification model to differentiate 119 AUD individuals from 97 healthy adults [93]. The combination of these measures achieved 79.3% accuracy in predicting AUD diagnosis, although this was only modestly better than the single most predictive measure, gray matter density, which achieved 76.6% diagnostic prediction accuracy. A similar study examined 177 adults with a history of weekly binge drinking and 309 adults who did not binge drink, and was able to discriminate the groups using neural and personality measures at 80% accuracy [94]. The best performing fMRI task data achieved 66% accuracy, whereas the worst performing task was no better than chance, and another analysis on the same dataset showed that the fMRI tasks that discriminated between risky drinkers and healthy adults also showed greater test-retest reliability [95]. Thus, structural abnormalities may better distinguish individuals with AUD from healthy adults, perhaps

because many fMRI tasks lack the within-person stability necessary for them to represent a stable, trait-like measure of brain function. Although it has become more frequent, studies that use multiple types of imaging measurements remain relatively rare compared to single-modality studies. However, this approach may help advance understanding of the effects of AUD on the brain.

Conclusions

Chronic heavy drinking among individuals with AUD has consistently been associated with differences in brain structure. Numerous brain regions are impacted by chronic alcohol use, and these generally correspond to brain systems that have been linked to problematic alcohol use, such as frontal control systems and the mesocorticolimbic reward system [2, 5, 96]. Structural alterations, such as reduced D2 receptor density, cortical volume, and white-matter tract integrity, may relate to differences in brain activation elicited by alcohol cues. The direction of these relationships remains unclear but structural deficits may presage functional effects or may represent a consequence of changes in function. Most studies only examine individuals at a single point in time, precluding conclusions about whether alcohol use directly causes these differences, but supporting evidence suggests a causal relationship with chronic heavy alcohol use. There is also evidence that individuals with AUD display greater activation of the cingulate and ventromedial PFC in response to alcohol cues, less activation of the VS during the anticipation of monetary reward, and decreased activation of the insula and ventromedial PFC in response to negative emotional cues. Evidence from PET studies suggests that AUD is associated with reduced glucose metabolism, possibly reflecting a shift to acetate metabolism by glial cells. There is also evidence that GABA receptors are reduced and that mu-opioid receptors are increased. Differences in brain anatomy and function can inform clinical practice, as indicated by studies that show that AUD can be identified based on neuroanatomical differences, and that neural activation to alcohol cues can offer predictive value to determining which individuals will benefit from treatment.

Chapter 27
Brain Microstructure in Alcohol Addiction: Characterization of Diffusion-Based MRI Biomarkers, Neuropathological Substrates, and Functional Consequences

Silvia De Santis, Mohamed Kotb Selim, and Santiago Canals

Abstract Alcohol consumption is associated with structural alterations in the brain parenchyma. Understanding the longitudinal brain transformations that occur from an alcohol naïve state to alcohol addiction, through cycles of consumption, abstinence and relapse, is crucial to progress towards effective treatments. Magnetic Resonance Imaging, and in particular diffusion-weighted approaches, have been a breakthrough for neuroscience, neurology and psychiatry due to their ability to access different aspects of brain anatomy in a non-invasive and longitudinal way. In the last 20 years, this technique has been instrumental in characterizing brain alterations associated to alcohol consumption.

In this chapter, we will first introduce diffusion-weighted Magnetic Resonance Imaging and its most widely adopted formulation, Diffusion Tensor Imaging, describing its utility to look at brain microstructure and its most used biomarkers, mean diffusivity and fractional anisotropy; we will then focus on the importance of diffusion tensor imaging in alcohol use disorders, describing the most salient aspects of the pathology that can be captured and dissected; next, we will discuss several recent advances in the field that were possible thanks to the use of diffusion tensor imaging. Finally, we will disclose important limitations of the technique that must be taken into account in the interpretation of alcohol-driven alterations, challenging the conventional view that diffusion tensor imaging can discern between "healthy" and "damaged" microstructure under all circumstances.

Introduction

Magnetic Resonance Imaging (MRI), and particularly diffusion weighted approaches, were a breakthrough for neuroscience, neurology and psychiatry due to their ability to access distinct aspects of brain anatomy non-invasively and without the use of ionizing radiation and/or contrast agents. Being non-invasive and translational, diffusion-weighted MRI can be used to monitor brain changes over time *in vivo* in humans and in animal models, giving access to fine microstructural properties of the brain parenchyma, and has proven pivotal to characterize brain changes associated with alcohol consumption.

In this chapter, we will first introduce diffusion-weighted MRI and its most widely adopted formulation, diffusion-tensor imaging (DTI), describing its utility to look at brain microstructure; we will then focus on the importance of DTI in alcohol use disorders, describing the most salient aspects of the pathology that DTI can capture and dissect; next, we will discuss several recent advances in the field that were possible thanks to the use of DTI. Finally, we will disclose important limitations of the technique which need to be taken into account in the interpretation of alcohol-driven DTI alterations, challenging the conventional view that DTI can discern between "healthy" and "damaged" microstructure under all circumstances. Throughout the chapter, we will focus on the so-called uncomplicated alcohol use disorder, i. e., in absence of other degenerative conditions associated with alcohol, like the Wernicke-Korsakoff syndrome.

Measuring Water Diffusivity Non-invasively Through Diffusion-Weighted MRI

At absolute temperatures higher than zero Kelvin, water molecules are in constant motion due to their intrinsic thermal energy, colliding with each other and with the obstacles they find in their path. Due to such collisions, the trajectories followed by the particles are random, so their motion is referred to as "random walk". Within living organisms, soft tissues like the brain contain a high percentage of water, and the diffusion trajectories of the water molecules are influenced by the shape and orientation of the structures in which they are embedded (e.g., axons, cell bodies, glia, . . .). Through the diffusion-weighted MRI sequence, a label is imparted to hydrogen nuclei (by manipulating the phase of the transverse magnetization), and the displacement of the water molecules is characterized by reading this label at a later time; normally, in the milliseconds rage. The larger the signal attenuation recorded between the two time points, the larger the motion that has occurred. In this way, the diffusion of water during the allowed diffusion time can be quantified.

One of the main advantages of diffusion-weighted MRI is the ability to highlight what is known as diffusion *anisotropy*, that is, when molecules exhibit different diffusion properties along different orientations in space. For example, the axonal

bundles that constitute the white matter of the brain present a structure dominated mostly by cylindrical elements, the axons. Since the cell membranes are largely impermeable to water, the movement of water in these structures is less hindered parallel to the fiber bundle than in the perpendicular direction. If one were to measure water diffusion parallel to the fibers, this would appear much faster than perpendicular to them.

To quantify anisotropy, as well as the average water diffusion in the tissue, several indices can be extracted from the diffusion-weighted MRI measurements; the most popular are the *fractional anisotropy*, FA, and the *mean diffusivity*, MD. While MD quantifies the average water displacement in the tissue and is measured in square meters per second (m^2/s), FA is a dimensionless index ranging from 0 (no anisotropy) to 1 (maximum anisotropy). The mathematical framework used to define FA and MD is detailed in Box 27.1.

Box 27.1

The simplest mathematical structure capable of accounting for diffusion anisotropy in a 3D environment is a tensor. In the diffusion-tensor imaging (DTI) framework, water diffusion in each voxel is modeled with a 3 × 3 diffusion tensor $\boldsymbol{D}$.

$$\boldsymbol{D} = \begin{bmatrix} D_{xx} & D_{xy} & D_{xz} \\ D_{yx} & D_{yy} & D_{yz} \\ D_{zx} & D_{zy} & D_{zz} \end{bmatrix}$$

$\boldsymbol{D}$ is constituted by 9 components, but only 6 of them are independent, due to the tensor symmetry. For this reason, to measure the diffusion tensor, a minimum of 6 measures along different orientation, plus one measure without diffusion weighting, are needed, although to have a better signal-to-noise ratio it is highly recommended to use more [1]. From the eigen-decomposition of $\boldsymbol{D}$, different scalar indices can be obtained, like the mean diffusivity (MD) and the fractional anisotropy (FA), as defined in the following expressions:

$$MD = \frac{\lambda_1 + \lambda_2 + \lambda_3}{3}.$$

$$FA = \sqrt{\frac{3}{2}} \frac{\sqrt{\left(\lambda_1 - MD\right)^2 + \left(\lambda_2 - MD\right)^2 + \left(\lambda_3 - MD\right)^2}}{\sqrt{\lambda_1^2 + \lambda_2^2 + \lambda_3^2}}.$$

The mean diffusivity is the mean of the three diffusivities measured along the eigenvectors and is interpreted as the average water diffusivity in the measured volume (the voxel in MRI). Fractional anisotropy is proportional to the standard deviation of the diffusivities measured along the eigenvectors divided by their root mean squared; importantly, fractional anisotropy quantifies the

degree of anisotropy of the media. Anisotropic tissues have fractional anisotropy values closer to 1, meaning that the diffusion of water molecules in such environments occurs predominantly in one orientation, and can be visualized as an ellipsoid, while isotropic tissues have fractional anisotropy values closer to 0, meaning that the diffusion is similar in all directions, and can be visualized as a sphere [2]. These scalars are translationally invariant, meaning that they do not depend on the specific orientations along which the diffusion is measured. This makes their use ideal as quantitative biomarkers of brain microstructure.

Among the diffusion-based indices extracted from MRI, fractional anisotropy has probably become the most popular in neurology and psychiatry, with its reduction commonly interpreted as a marker of loss of white matter integrity [3]. However, many factors contribute to determining the value of the resulting fractional anisotropy, such as the amount of myelin, axonal diameter, axonal density and fiber dispersion. Therefore, it is not straightforward to assign a specific tissue configuration or biological state to a measured fractional anisotropy change, as discussed below. Figure 27.1 illustrates a typical diffusion-weighted MRI acquisition and processing pipeline.

It is important to note that the direction of the greatest diffusivity, i.e., the orientation of the principal eigenvector, can be interpreted as an estimate of the fiber orientation in the white matter under the assumption that when a number of neuronal axons are aligned along a common axis, the diffusion of water molecules will be hindered to a greater extent across this axis than along it [7]. By integrating these estimates across the whole brain white matter, it is possible to generate a 3D representation of the major axonal bundles. These are the basis of the technique called *tractography*, which quickly became a powerful tool to look at brain anatomy. Several more advanced non-tensor approaches have been introduced in recent years to extract the fiber orientation distribution; each of these models has its own strengths and pitfalls, nevertheless, a comparative discussion is outside the scope of this chapter.

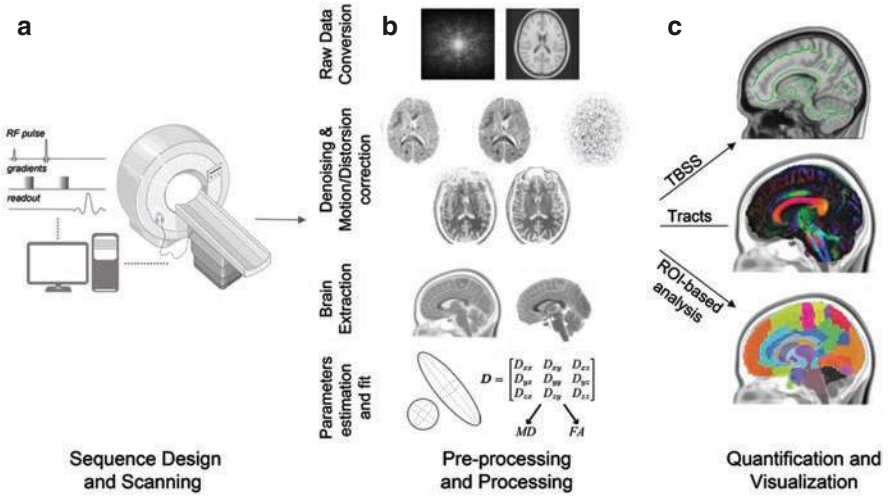

Fig. 27.1 Diffusion-weighted MRI acquisition and processing pipeline. (**a**) Diffusion-weighted MRI experiments normally encompass several acquisition and processing steps. The diffusion-weighted MRI sequence is tuned according to the specific need of the experiment in terms of diffusion weighting (quantified by the *b-value*) which, by defining the time allowed for the labeled water molecule to diffuse and the range of diffusivities on which the sequence focuses, weights the contribution of the different tissue compartments to the diffusion measurement (e.g., diffusion in the intracellular vs. extracellular space). Other important parameters are the number of gradient orientations, which define the directions in which diffusion will be quantified; or the image resolution, which is a compromise between the capabilities of the MRI system to acquire data with good signal-to-noise ratio and the time devoted to acquiring them, and which determines the voxel size. (**b**) After the desired diffusion-weighted MRI sequence is defined and acquired, the preprocessing might involve denoising, motion and distortion corrections, brain extraction and normalization to other contrasts. Then, the desired diffusion model is applied, and the data are visualized, ready for the statistics of choice. (**c**) Statistical analysis normally involves voxel-wise approaches like the widely adopted tract-based spatial statistics [4], or region-of-interest approaches like those based on parcellated brains in standard space [5], or on tractography in single subject space [6]

Neuropathological Substrate and Utility of DTI Biomarkers in Alcohol Use Disorders

Difficulty walking and talking, blurred vision, slowed reactivity: clearly, alcohol affects the brain, but while some of these impairments quickly resolve when alcohol is discontinued, chronic drinking produces the accumulation of deficits that persist into sobriety, generating a disability with great impact on society. As such, alcohol neurotoxicity has been widely investigated, with the goal of achieving a mechanistic understanding of this complex behavioral and medical condition.

The histopathological substrate underlying the well-characterized brain shrinkage in alcohol use disorder (AUD) patients involves changes in both myelination and axonal integrity, as well as region-selective neuronal loss [8]. Dendritic and

synaptic changes have also been well documented in people with alcohol addiction [9]. Importantly, alcohol exposure not only affects neurons, but also the development, morphology, physiology and gene expression in astrocytes, oligodendrocytes and microglia cells [10].

In this context, neuroimaging techniques like DTI-based approaches represent a unique tool to assess alcohol-induced brain alterations, being sensitive to fine details of the brain parenchyma's microstructure. DTI can detect changes in both myelination and axonal integrity in white matter with high sensitivity [11]. While the technique is preferentially used to look at white matter microstructure, there are also numerous applications to grey matter morphology, where the diffusion of water molecules is expected to sense and reflect the complex geometry of a tissue containing neurons, their dendrites and axons with different levels of myelination and orientations, and glial cells of different morphologies [12, 13].

A major feature of DTI is that it affords relatively high resolution compared to other whole brain imaging techniques, going from 2–3 mm in humans, to few hundreds of microns in animals. Furthermore, being non-invasive, the technique allows for longitudinal studies. In the context of alcoholism, this means that the dynamic course of the disease, going through periods of drinking, sobriety, and relapse, can be followed [14].

Another important feature of DTI, shared with the other MRI-based techniques and sometimes underestimated, is the possibility to perform translational studies. DTI can be applied across species, in humans and animal models. This important feature allows scientists to interrogate the causality of alcohol-related brain alterations in well-controlled animal experiments, something that is difficult to achieve in studies with AUD patients where alcohol-induced damage almost inevitably coexists with that produced by tobacco and other drugs of abuse, medication and other comorbid factors. A reverse translational approach, in which alterations found with DTI in patients find an equivalent counterpart in animal models, and the latter are used to investigate the underlying neurobiological mechanism, has proven successful in bringing causality to AUD [15, 16].

Multiple DTI metrics can be combined, and they can also be combined with other imaging and non-imaging measures, using machine learning frameworks. Pioneer work in this field has shown that multi-parametric approaches including DTI have high potential to serve as valuable biomarkers for early diagnosis and response to treatment in AUD, by demonstrating high accuracy and precision in classifying baseline, alcohol drinking and abstinence states, and even the effect of medication with naltrexone in an animal model [17]. Those multimodal studies pointed to water diffusion measures as the more informative feature to differentiate between AUD associated states. Recently, machine learning algorithms using structural MRI data have also been able to predict in adolescents future patterns of alcohol binge-drinking, providing important information of the substrate that may favor the development of alcohol addiction [18].

Regional Specificity of Altered Diffusivity in AUD: Frontal White Matter Vulnerability

By mapping DTI parameters in AUD versus age- and sex-matched controls, a pattern of region-specific vulnerability emerged. In white matter, frontal and dorsal tracts consistently show the greatest abnormalities in people with alcohol addiction relative to controls, while more posterior and ventral bundles were relatively spared [19, 20]. A recent meta-analysis including over 900 subjects identified four significant clusters of convergent microstructural white matter alterations in AUD patients that were assigned to the genu and body of the corpus callosum, anterior and posterior cingulum, fornix, and the right posterior limb of the internal capsule [21]. Genu and fornix seem to be particularly vulnerable tracts in alcohol use disorder, showing alterations after a single episode of binge drinking and suggesting potential for rapid neuroplasticity [22]. Importantly, these same axonal bundles are also preferentially affected in rat models of AUD longitudinally investigated with DTI [15, 20], which in addition to attributing a causal role to alcohol (see above), suggest the existence of some fundamental biological principle, generalizable across species, that determines heterogeneous white matter vulnerability to alcohol. White matter tracts showing alterations in the AUD population compared to controls are shown in Fig. 27.2.

The described microstructural alterations are expected to have functional implications. Abnormalities in the white matter tracts connecting regions of the

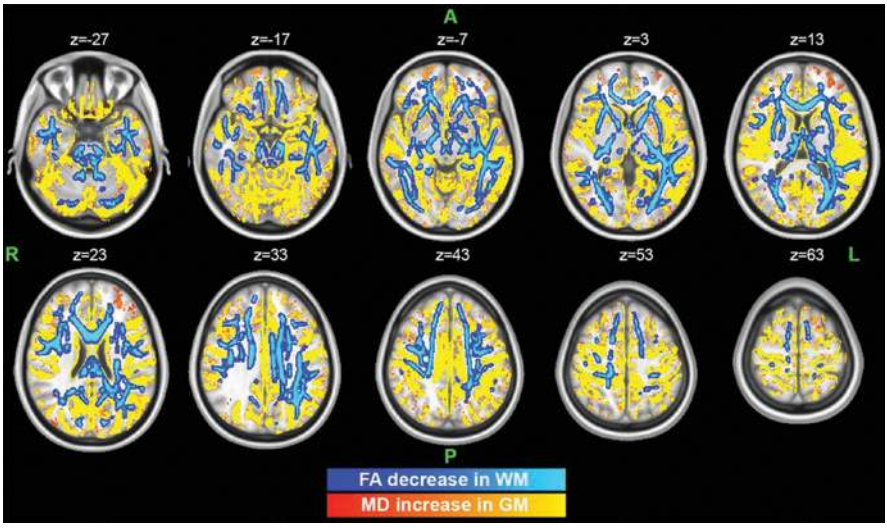

Fig. 27.2 White matter regions of significantly reduced fractional anisotropy (FA) in AUD vs. controls (blue, filled with the tbss_fill routine) according to the cohort in [15], and grey matter regions of significantly increased mean diffusivity (MD) in AUD vs. controls (red-yellow, $p < 0.05$) in the same cohort [23]

mesolimbic pathway, known to play an important role in the rewarding effects of drugs, are associated with higher impulsivity and alterations of the reward network [24]. The fimbria, for instances, is the main pathway connecting the hippocampus and the prefrontal cortex and plays a fundamental role in memory formation and extinction, executive function and emotional processing [25]; thus, the high vulnerability of the fimbria white matter to alcohol drinking might be an important contribution to the observed inability of AUD patients to suppress maladaptive memories, and the display of behavioral inflexibility [20]. More generally, the fact that alcohol consumption causes heterogeneous alterations of white matter tracts could be interpreted in functional terms as the basis for the observed imbalances between fMRI brain networks, some of them showing decreases in functional coupling and others increases, possibly reflecting a new functional equilibrium characteristic of an AUD state (allostasis).

Finally, the patterns of region-specific white matter vulnerability are not limited to AUD; negative associations between alcohol intake and brain microstructure are already apparent in individuals consuming an average of only one to two daily alcohol units, and become stronger as alcohol intake increases, in a region-specific manner, with the fornix and the corpus callosum featuring prominently as areas associated to the largest effect sizes [26].

DTI in Grey Matter: Functional Consequences

While DTI has traditionally been used to assess white matter integrity, it can be also used to look at microstructure in grey matter. The preferred biomarker in grey matter is the mean diffusivity, due to the low degree of anisotropy which characterizes grey matter microstructure. Microstructural information has the potential to complement and, most importantly, anticipate macroscopic alterations like volume and cortical thickness changes, which are normally employed as surrogate markers of neuronal degeneration, but which are believed to pick up alterations only when these are in a relatively advanced state [27].

Higher mean diffusivity was detected in frontal, temporal and parahippocampal grey matter, and in the cerebellum of alcohol dependent patients compared to controls. Low verbal episodic memory performance was associated with higher mean diffusivity but not shrinkage in parahippocampal areas, in frontal cortex and in the left temporal cortex, suggesting that regional microstructural but not macrostructural alteration of the brain parenchyma might be responsible, at least in part, for episodic memory deficits in alcohol dependence [28]. Another study measured increased mean diffusivity in the medial prefrontal cortex of rats exposed to chronic intermittent ethanol vapor, associated to deficits in retrieval and recall of fear memories, and whose neuropathological substrate included demyelination and mitochondrial damage [29].

A recent study comparing water diffusivity in the grey matter of AUD patients and a rat model of chronic voluntary drinking in a two-bottle free-choice paradigm

[23], showed widespread increases in mean diffusivity in both species. Grey matter areas showing alterations in the AUD population compared to controls are shown in Fig. 27.2. The authors demonstrated that 1 month of chronic alcohol drinking (4–6 g/kg/day) is sufficient to trigger the mean diffusivity effect in the rat model and in both, humans and rats, higher mean diffusivity persisted during abstinence. However, as we have mentioned already and will discuss further in the last section, interpreting DTI findings in biological terms is challenging, as all water compartments (i.e., intracellular and extracellular) contribute to determine mean diffusivity. To answer this question, the authors turned into the animal model and, using an invasive technique called iontophoresis, they quantified with high precision the diffusion in the extracellular space of the brain. Together with a small decrease in the total volume fraction, they found a large and significant reduction in the extracellular space tortuosity triggered by alcohol drinking, this is, a reduction in the diffusion barriers. The reduction in tortuosity was sufficient to explain the increase in mean diffusivity measured with DTI and suggested a significant change in the manner in which solutes can diffuse through the extracellular space of the brain.

To study the possible functional impact of the increased mean diffusivity in the grey matter of alcohol-exposed individuals, a mathematical model was used to investigate how the above tortuosity change might influence the diffusion of extrasynaptically released neurotransmitters, such as dopamine [23]. The authors found a marked increase in the spatial reach of the released neurotransmitter, a potentiation of volume neurotransmission, so that a same amount of dopamine will diffuse farther and in greater concentration in the same amount of time [23]. The authors speculated that a synergistic combination of a primarily weak reinforcer like ethanol, which is known to raise dopamine levels (albeit modestly), with progressively enhanced volume neurotransmission due to increased extracellular diffusivity, might comprise a novel mechanism to explain the slow onset but potent addictive effect of alcohol. Further experimental work will be necessary to confirm or refute this hypothesis. The impact of mean diffusivity changes on other important biochemical processes heavily relying on extracellular space diffusivity, like the clearance of metabolic byproducts, might also be interesting to investigate. This result already serves as an example to illustrate the mechanistic insight that can be gained from investigating the neurobiological basis of DTI biomarkers.

Progression of Diffusivity Alterations During Early Abstinence

Longitudinal DTI acquisitions have been used to measure microstructural integrity in the white matter of abstinent AUD patients from 1 to a few years after the last drinking episode [30, 31]. These studies reported the recovery of DTI values towards control levels in long-term abstinent subjects, providing a microstructural substrate for the observed clinical improvement. However, AUD is associated with a chronically relapsing-remitting course over lifetime, and most individuals treated for AUD are known to relapse to hazardous alcohol

consumption within just 6 months of treatment [32]. What happens then with the microstructure of the brain during the most critical early phase of alcohol abstinence? To answer this question, a recent DTI study acquired longitudinal DTI data in AUD patients and rat models thereof at different time intervals from 2 to 6 weeks, during early abstinence [15]. Interestingly, in both species it was shown during this period that, far from recovering, the reduction in fractional anisotropy measured in the white matter tracts progressed, becoming reduced after 3 weeks of abstinence, and even further reduced at 6 vs. 3 weeks of abstinence. The progression during early abstinence suggests the existence of an underlying process that evolves soon after cessation of alcohol consumption, challenging the conventional idea that the microstructural damage starts to repair immediately after discontinuing alcohol drinking.

What might this process be? Answering this question will require further experimental work, but a first clue can perhaps be seen in the change in extracellular space tortuosity found in the grey matter [23]. In that study, it was shown that the reduction in tortuosity explaining the increased water mean diffusivity in the grey matter was associated with a microglial response. Microglial cells retracted their cellular processes and engrossed the cell body acquiring an amoeboid morphology. This change did not affect other glial subtypes, extracellular matrix proteins or neuronal density. The morphological change in microglia explained the decrease in diffusion barriers and the increased mean diffusivity. Indeed, reactivation of microglia independently of alcohol drinking with lipopolysaccharide, or their elimination with the CSF1R inhibitor PLX5622, provided causal evidence to support their effect on diffusion [23]. A role of microglial cells and neuroinflammation in the neurotoxic effects of alcohol has long been proposed [33]. Taken together, these results suggest that the biological process underlying the progression of microstructural alterations during early abstinence could be an inflammatory response, maybe triggered by alcohol withdrawal.

Overall, this result, besides proving that DTI can provide unique information to understand the neuroadaptations occurring during abstinence, puts this critical phase in the spotlight as a central target for therapeutic interventions [16].

Sex Differences in Alcohol Use Disorder

While alcohol neuroimaging investigation has been affected, like many other fields, by the systematic underrepresentation of female subjects, especially in basic research, there is a remarkable convergence of evidence pointing towards a sex effect in AUD, confirmed by DTI studies. In addition, over the last 10 years, rates of alcohol use disorder have increased in women by 84%, while they have increased by 35% in men [34], highlighting even more the importance of including both sexes in AUD studies. The drawback of this necessary change of paradigm is that including an additional factor might further reduce power in neuroimaging studies, many of which have by design small sample size.

Pioneer work showed that AUD women have more DTI features of white matter degradation than men of the same age in several fiber bundles [19]. Also in animal models, female rats have been reported to be more affected in a chronic intermittent ethanol paradigm, as shown by greater reduction of fractional anisotropy in the fornix. This vulnerability was explained by higher initial blood alcohol levels in females [35]. In women but not in men, more frequent binge drinking was associated with lower fractional anisotropy values, a result that was interpreted as evidence of higher vulnerability to alcohol in females [36]. However, a recent study using multimodal brain imaging in a large general population (36,678 generally healthy middle-aged and older adults from the UK Biobank) [26], found consistent associations between daily alcohol units consumed and lower fractional anisotropy values in several white matter tracts, with the strongest effects in the fornix, but no significant or weak association to sex. Therefore, while sex seems to be an important factor to develop brain damage in AUD, the interaction between sex and less severe levels of alcohol drinking will require further clarification. Furthermore, women and men's white matter microstructure is affected differently by age [37], suggesting that longitudinal studies involving larger cohorts than those normally employed in neuroimaging studies might be necessary to characterize the complex interaction between AUD and age in a sex-specific manner.

Finally, the reported difference in DTI features across sexes in AUD are not limited to differences in effect size. Indeed, opposite patters of DTI changes between sexes have been also reported. Fractional anisotropy is systematically reduced in AUD males compared to controls but, interestingly, seems to be increased in some fiber tracts in AUD women [38, 39]. Before going into interpreting these apparent discrepancies, it is important to remember what is being measured with DTI and how it relates to the underlying neurobiological substrate. While the classical view of DTI associates a reduced fractional anisotropy to impaired microstructure (demyelination and axonal damage), as discussed in the next paragraph, other factors are contributing; according to this rationale, it is not possible to univocally associate an increase in fractional anisotropy to an improvement in the quality of microstructure.

DTI Limitations and Caveats in the Interpretation of DTI Biomarkers in AUD

DTI-derived measures are affected by at least two limitations: the lack of specificity to sub-compartments of the tissue, meaning that very different neuroanatomical configurations can result in the same measured values of water diffusion [40], and the limited utility in structures like grey matter lacking macroscopic anisotropy.

Given the lack of specificity of DTI measures, interpreting the underlying neurobiological substrate that is causing the observed change is challenging. As mentioned earlier, postmortem studies consistently report compromised white matter

integrity in AUD that could explain, at least in part, the observed DTI changes. In these patients, the reduction in white matter volume is normally explained as a process of demyelination and axonal loss produced by the regional neuronal loss that can occur especially in the dorsal frontal cortex [41]. Alcohol drinking induces loss of mainly small fibers, myelin irregularity and segmental de/remyelination [42], accompanied by neuroinflammation. Also, the possibility of excessive intracellular and extracellular fluids accumulation has been proposed to explain some DTI changes in AUD vs. age matched controls [43].

However, recent *in silico* data challenged the idea that it is possible to infer the specific microstructural alteration causing the observed pattern of DTI changes. It was shown that a different balance between the restricted, hindered and isotropic water pools in the tissue can explain the DTI alterations found in AUD patients with totally different neurobiological underpinnings, simply depending on the underlying geometry [15]. Importantly, the increase in the proportion of the isotropic water pool, which can be a model for both an accumulation of fluids in the extra-cellular space as well as a glial reaction, results in an increase of fractional anisotropy in areas of white matter with single fibers, and a decrease of fractional anisotropy in areas of crossing fibers. Overall, the observed changes in fractional anisotropy across the different phases of AUD can thus be equally explained by progressive myelin damage, axonal loss, and/or a glial/cellular reaction, for instance, during an ongoing inflammatory process. In addition, the same biological phenomenon can impact with opposite trends in DTI (fractional anisotropy either increasing or decreasing) depending on the affected brain region (areas of predominantly single fiber vs. areas of crossing fibers). Possible neuropathological substrates generating fractional anisotropy alterations are illustrated in Fig. 27.3.

All in all, DTI is non-specific to neurobiological correlates of brain tissue, and needs to be complemented with other approaches to dissect cell-specific patterns of alterations in AUD. For example, diffusion-weighted MRI has been shown to be sensitive to axonal density [44] and diameter in white matter [45]; DTI measures can be complemented with myelin specific sequences like those based on magnetization transfer [46].

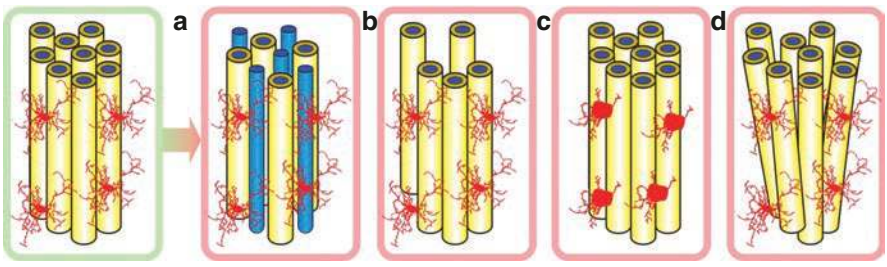

Fig. 27.3 Possible biological substrates driving changes in fractional anisotropy: demyelination (**a**), axonal loss (**b**), glia morphological changes (**c**) and increased fiber dispersion (**d**). Myelin is shown in yellow, axons in blue and microglial cells in red

The other major limitation of DTI is that, given the low anisotropy of grey matter tissue, fractional anisotropy is a poor predictor of microstructural integrity in grey matter. As detailed earlier in the chapter, mean diffusivity has been successfully used to highlight grey matter alterations in AUD; however, it suffers from the same lack of specificity of other DTI parameters. A recent approach based on stereotaxic injections of neurotoxins affecting selectively glia, myelin and neuronal compartments showed that mean diffusivity is highly sensitive to changes, but poorly specific [13], with similar effect sizes in demyelination, inflammation and degeneration. As such, to achieve augmented specificity, it is advisable to choose more advanced, grey-matter specific diffusion-weighted MRI sequences focusing on neurite morphology [47] or inflammation [13]. The drawback here is that, for the time being, such advanced techniques entail longer and more complex data acquisitions.

Chapter 28
Determinants of Risk Developmental Trajectories for Risky and Harmful Alcohol Use: Lessons from the IMAGEN Consortium

Justin Böhmer, Andreas Heinz, Gunter Schumann, and Henrik Walter

Abstract Adolescence is a key period for the initiation of alcohol drinking. Escalating alcohol use in adolescence, however, increases the risk for developing alcohol-related problems later in life, including alcohol use disorder (AUD). Thus, early identification of risk factors for developmental trajectories of alcohol abuse are crucial for preventing the development of addiction. To this end, the IMAGEN Consortium, a longitudinal neuroimaging-genetic study investigating reinforcement-related behaviors and their role for normal and psychopathological development in adolescence, was established. With more than 2000 adolescents repeatedly assessed in eight European study centers across four successive time points during adolescence and young adulthood, the IMAGEN study constitutes one of the world's largest longitudinal neuroimaging-genetics studies in adolescence. Since its inception, the IMAGEN Consortium has published a number of studies revealing environmental, behavioral, neurobiological and (epi-)genetic determinants of risk developmental trajectories for adolescent alcohol use. In this chapter, we will synthesize findings from these studies by delineating relationships between structural and

The IMAGEN Study: Identifying Risk Developmental Trajectories in Adolescence

Adolescence is a key period for alcohol use initiation [1]. Escalating levels of alcohol use across adolescence increase the risk for transitioning to alcohol addiction later in life [2], presumably due to common genetic, family and personal vulnerabilities [3–5]. Thus, identifying risk factors for developmental trajectories of alcohol abuse in adolescence is crucial in alcohol research. In order to understand complex interactions and temporal changes in neurobiological mechanisms and to infer causality, prospective longitudinal population studies are necessary that compare individuals regarding neurobiological, genetic, behavioral and environmental differences, allowing for the identification of vulnerability markers early in the course of the disease before the manifestation of alcohol use disorder (AUD).

To this end, the IMAGEN Consortium was established in 2010—a longitudinal neuroimaging-genetic study focusing on reinforcement-related behaviors and their role for normal and psychopathologic development in adolescence, including alcohol abuse [6]. The IMAGEN Consortium comprises eight European study centers in Germany (Berlin, Dresden, Hamburg, Mannheim), the United Kingdom (London, Nottingham), Ireland (Dublin) and France (Paris). More than 2000 adolescents at the age of 14 years were initially included in the IMAGEN cohort and followed up repeatedly across adolescence and young adulthood at ages 16, 19 and 22 (see Fig. 28.1), making it one of the world's largest longitudinal neuroimaging-genetics study in adolescents. Neuroimaging assessment included structural T1-weighted magnetic resonance imaging (MRI), functional MRI from three behavioral paradigms on reward processing [7], response inhibition [8] and emotional processing [9], resting-state functional MRI, diffusion tensor imaging (DTI) and neurite orientation dispersion and density imaging (NODDI). Moreover, blood samples were drawn in order to perform genome-wide (GWAS) and epigenome-wide association analyses (EWAS) as well as RNA, proteomic and metabolic analyses. Neuropsychological tests together with measures on personality, clinical symptoms (e.g., substance use, cognitive functioning, stress) and environmental factors for disease susceptibility (e.g., family environment, urbanicity,

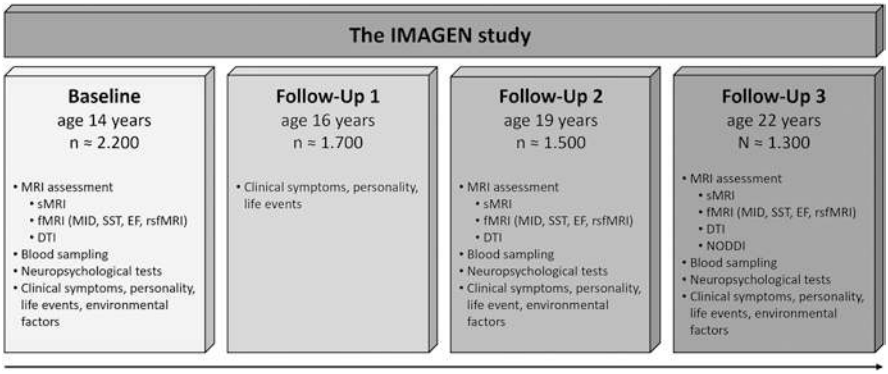

Fig. 28.1 Overview of the IMAGEN study. Within four successive time points from early adolescence to young adulthood, a set of neurobiological, genetic, behavioral and environmental characteristics are repeatedly measured

air pollution) from both adolescent self-report and parental reports completed the study's assessment battery, yielding a well-characterized, phenotypically rich, longitudinal study cohort.

To date, more than 100 papers from the IMAGEN Consortium have been published that helped to elucidate neural and genetic influences on reinforcement-related behaviors, symptoms and disorders (see https://imagen-project.org/publications/ for full list of published IMAGEN papers), including a systematic review on the significant contributions of IMAGEN to the field of imaging genetics [10]. In this chapter, we will describe findings from IMAGEN studies specifically related to alcohol use by delineating the relationship between structural and functional brain characteristics, genetic variation, epigenetic modification and developmental trajectories of alcohol use behavior in adolescence and summarize the relative contribution of these factors for the prediction of alcohol abuse. Please note that "prediction" in that case might refer to different phenomena associated with varying underlying methodologies. In cross-sectional analyses, prediction usually refers to an association or correlation between variables assessed with specific statistical methods. In longitudinal analyses, which is mostly the case in IMAGEN studies presented here, prediction typically refers to statistical approaches to measure associations between a given variable at one time point (e.g., brain structure at age 14) and a subsequent clinical phenotype (e.g., binge drinking at age 16). In some cases, within the context of machine learning applications, prediction also refers to the classification of individuals based on specific features. In order to assess the strength of the identified relationships, we report estimates of explained variance and effect size provided that it is stated in the original studies.

Brain Structural Predictors for Adolescent Alcohol Use

Previous studies demonstrated alcohol-related changes in brain structure across widespread regions of the brain (Chap. 26) [11]. The extent to which these changes reflect neurotoxic effects that arise as a consequence from alcohol exposure or delineate cerebral predispositions that contribute to vulnerability for detrimental alcohol use remains largely unknown. Therefore, several studies within the IMAGEN Consortium leveraged the longitudinal data structure to identify neuroanatomical predictors for developmental trajectories of adolescent alcohol use.

In this regard, Seo et al. [12] analyzed regional gray matter volume and cortical thickness in 14-year-old adolescents and used them as input for a machine learning classification to predict adolescent drinking behavior phenotypes (n = 550 light vs. n = 464 heavy drinkers) at age 19. Specifically, drinking behavior at 19 years was predicted by gray matter volume at the same age, although classification accuracy was only slightly above chance level (max. 58.6%). Heavy drinkers exhibited lower gray matter volume in bilateral anterior cingulate cortex, orbitofrontal cortex, medial prefrontal cortex, thalamus and left anterior insula. However, gray matter volume at age 14 did not predict drinking behavior longitudinally at age 19 [12]. In another study, gray matter volume was used to predict change in alcohol use over the course of adolescence (14–19 years) using latent growth curve modeling [13]. Accordingly, increased gray matter volume in the caudate nucleus and the left cerebellum at early adolescence predicted the increase of alcohol consumption from early to late adolescence. However, there was no association between gray matter volume of either brain region and alcohol use in early adolescence, suggesting that the observed increases in brain volume might be particularly relevant for alcohol use trajectories over the course of adolescence. Along this line, Kühn et al. [14] showed that reduced gyrification in the left orbitofrontal cortex predicts the increase of alcohol use-problems from early to mid-adolescence [14].

Robert et al. [15] specifically investigated the directionality of the association between brain structure and alcohol abuse in adolescence using temporal directionality analyses. Controlling for various confounding factors such as demographic, behavioral and genetic influences, increased frequency of drunkenness was associated with accelerated gray matter atrophy in the posterior temporal cortex, left prefrontal cortex, left anterior insula and the anterior cingulate cortex. Importantly, Causal Bayesian Network (CBN) analysis revealed substantial evidence (73% of the CBNs) for a directionality from gray matter atrophy during adolescence (age 14 to 19) to more frequent states of drunkenness. Moreover, gray matter volume at age 14 was associated with frequency of drunkenness between ages 14 and 19 (β = 0.23, n = 604) but, in turn, drunkenness frequency at age 14 years was not associated with future gray matter development (β = 0.03, n = 726) [15]. Therefore, these findings suggest that the observed reductions in brain volume might already be present prior to harmful alcohol use. Another study from the IMAGEN Consortium draws a similar conclusion. Ottino-González et al. [16] analyzed structural covariance networks (SCN) based on cortical thickness and

compared the properties of these networks between heavy drinking adolescents ($n = 297$) and non-drinking controls ($n = 594$) at ages 14 and 19 using graph theoretic metrics. Heavy drinkers at age 19 exhibit lower network segregation and higher network integration than controls. Importantly, the same SCN pattern was observed in the same adolescents 5 years earlier at age 14, when they had little to no lifetime alcohol exposure, suggesting a pre-existing risk factor for problematic drinking [16]. Similarly, probing alterations in white matter (WM), reduced WM integrity within the upper posterior pons in 14-year-old adolescents without substantial alcohol exposure was associated with heavy drinking at age 16 ($n = 24$) [17].

In sum, findings from these studies challenge the neurotoxicity hypothesis as the only cause of brain structural changes and suggest that findings in widespread brain areas can predict adolescent alcohol use. However, these studies used different brain structural features and distinct phenotypes of adolescent alcohol use and findings were complex, including increases and decreases of specific brain volumes. A recently published study [18] expanded previous analyses by incorporating multiple morphometric brain features from both white and gray matter collected at ages 14, 19 and 22 in a machine learning framework to predict alcohol use at age 22. Moreover, they compared distinct phenotypes of adolescent alcohol use based on different assessment metrics such as frequency, amount or onset of alcohol use and bingeing frequency. In this study, binge drinking behavior was the most predictable phenotype of adolescent alcohol use with accuracies of 73.1% (age 14), 75.5% (age 19) and 78.0% (age 22). The most informative features for predicting alcohol use included increases and decreases of different brain structural indices relating to widely distributed cortical and subcortical regions of the brain, including several white matter tracts of the corpus callosum, internal capsule and brain stem as well as occipital brain regions, the anterior cingulate cortex, middle frontal gyrus, precentral gyrus, hippocampus and parahippocampal gyrus [18]. Based on the relatively high accuracies for predicting future alcohol use already present at ages 14 and 19, this study corroborates the notion that certain brain structural changes at least partly precede alcohol abuse in adolescence. Future research should assess whether such changes are due to shared genetic factors or associated with traumatic or stressful life events [19–22].

Brain Functional Predictors for Adolescent Alcohol Use

As the brain's anatomical architecture scaffolds its functional activation (e.g., [23–25]), a series of behavioral tasks were implemented in the IMAGEN study to probe the relationship between activity in brain functional networks underlying reward processing, inhibitory control, emotional processing and the resting-state of the brain and adolescent alcohol use.

Alcohol use in early adolescence (age 14) was associated with increased activation in reward-related brain areas, including the left orbitofrontal cortex ($\beta = 0.05$, $n = 1778$) [26], ventral striatum (left: $\eta^2_p = 0.022$; right: $\eta^2_p = 0.015$; $n = 393$) [27],

dorsal striatum ($r = 0.09$; $n = 1483$) [28, 29], the interaction between orbitofrontal cortex and ventral striatum ($r^2 = 0.05$, $n = 1080$) [30] as well as blunted activity in frontal brain areas, namely inferior frontal gyrus ($\beta = -0.09$, $n = 1778$) [26], when anticipating reward. Concurrently, when subjects are supposed to choose between a smaller immediate amount of money and a larger delayed amount, adolescents with higher alcohol use exhibited less brain activation in frontal regions, including the dorsolateral prefrontal gyrus ($r = -0.163$, $n = 202$) [31].

Importantly, due to the longitudinal data structure, the IMAGEN study provides insights into the temporal relationship between brain activation and alcohol use trajectories across adolescence. In normal development, neural responses related to reward sensitivity and impulsivity decrease across adolescence while activation in cortical regions associated with behavioral control performance increases [32, 33]. However, impulsivity, defined as premature action without considering consequences [33], increased and the developmentally expected decrease in reward sensitivity was significantly altered in heavy drinking individuals across adolescence [32–34], suggesting disruptive effects of alcohol use on normative development of reward sensitivity and behavioral control. In this regard, rising levels of alcohol use from early to mid-adolescence (14 to 16 years) were predicted by increased ventral striatal activation ($\beta = 0.082$, $n = 1327$) and a blunted ventromedial prefrontal response ($\beta = -0.086$, $n = 1327$) [35] during reward anticipation. Additionally, increases in alcohol use across adolescence were predicted by increased ventral striatal activation ($\beta = 0.079$, $n = 1327$) [35] as well as reduced activity in medial orbitofrontal cortex ($\beta = -0.167$, $n = 304$) [33] and insula ($\beta = -0.057$, $n = 1327$) [35] during reward receipt. Moreover, Qi et al. [36] identified a specific reward-related brain network underlying high novelty seeking in adolescence, including the prefrontal cortex, striatum, amygdala and hippocampus, which longitudinally predicted alcohol use from early to late adolescence at age 19 ($r = 0.263$, $n = 219$) [36].

During resting-state, when subjects are not actively engaged in a specific task, a recent study showed that 19-year-old adolescents with increased risk for alcohol use disorder exhibited reduced resting-state functional connectivity within all seven large-scale brain networks under study [37]. Particular attention has been drawn to resting-state functional connectivity of networks involved in reward-related circuitry. Using data from the Human Connectome Project [38], Cheng et al. [39] demonstrated aberrant resting-state functional connectivity in adult high amount drinkers compared to low amount drinkers between nodes implicated in reward processing, including the medial orbitofrontal cortex, anterior cingulate cortex, parahippocampal cortex, supramarginal gyrus, insula, and superior temporal gyrus. Interestingly, replication analyses in the IMAGEN cohort ($n = 1176$) found similar patterns of functional connectivity for the same connections in non-drinking adolescents at age 14, who reported drinking alcohol at age 19, suggesting that altered resting-state functional connectivity in reward-related circuitry might play a causal role in the development of alcohol abuse [39].

In sum, these IMAGEN studies highlight an increased involvement of reward-related brain networks and decreased activation in fronto-cortical brain areas during reward-related behavioral tasks, and reward-related brain networks were also implicated in resting-state studies as an important antecedent of adolescent alcohol abuse.

Impact of Genetic Variation on the Association Between Brain Structure/Function and Adolescent Alcohol Use

In the past years, significant efforts have been made to identify variation within the genome related to alcohol use (see [40] for a review). Determining genetic loci and their relationship with alcohol use during adolescence is particularly crucial as it expands our understanding of possible molecular mechanisms underlying the development of alcohol abuse. In the following, we will outline associations between genetic variation, adolescent alcohol use and features of brain structure as well as functional brain activation during reward processing, response inhibition and emotional processing identified by the IMAGEN Consortium.

Genetic Variation, Brain Structure and Adolescent Alcohol Use

In an animal model, Mielenz et al. [41] identified the lack of the EF hand domain containing 2 (*EFhd2*) protein coding gene as a genetic determinant of enhanced sensation-seeking and attenuated anxiety sensitivity, both traits associated with reduced behavioral control and increased alcohol consumption [42, 43]. Along this line, *EFhd2* knockout (KO) mice exhibited reduced volume in the prefrontal and sensorimotor cortex, portending to a role of *EFhd2* for the development of fronto-cortical brain regions. Importantly, these findings translated to the IMAGEN sample (n = 1773), yielding a positive association of the single nucleotide polymorphism (SNP) rs112146896 in the *EFhd2*-coding region with lifetime alcohol intake (r = 0.099) and a negative association with anxiety sensitivity (r = −0.067) in 14-year-old adolescents. Moreover, a negative association was found between alcohol consumption and thickness of the superior frontal gyrus in adolescents (r = −0.067). Similarity analysis indicated significantly similar genetic contribution of all SNPs under study to lifetime alcohol drinking and superior frontal cortex thickness. Together, findings from the animal and human study suggest that genetic variation in *EFhd2* plays an important role for maturation of the frontal cortex and its role in intentional behavior and executive control, which might contribute to risky and harmful alcohol consumption [41, 44].

Genetic Variation, Reward-Related Brain Activation and Adolescent Alcohol Use

Dysfunctional reward processing, in particular reward anticipation, has been proposed as an important pathogenetic mechanism implicated in the development of substance use disorders (e.g., [45, 46]). A pivotal brain region involved in the anticipation of reward is the ventral striatum [47]. Elucidating how genetic variation impacts on ventral striatal activity during reward anticipation might help identify genetic risk constellations for alcohol use trajectories in adolescence.

In this regard, Stacey et al. [48] investigated the association of SNP rs26907 of the ras-specific guanine-nucleotide releasing factor 2 (*RASGRF2*) gene, which has previously been linked with alcohol intake [49], with ventral striatal activation during reward anticipation and the development of drinking behavior [48]. In an animal model, they showed that *Rasgrf2* KO mice exhibit reduced ethanol intake and ethanol preference as well as attenuated dopamine release following alcohol intake in the ventral striatum compared to wild type controls. In 14-year-old male adolescents from the IMAGEN cohort (n = 663), who had no or low exposure to alcohol, the *RASGRF2* haplotype containing rs26907 was associated with reduced ventral striatal activation during reward anticipation [48]. These results suggest that *RASGRF2* has an impact on ventral striatal activation through modulations of mesolimbic dopamine activity and may thus influence reward sensitivity, a risk factor for future alcohol use in adolescents (e.g., [50]). In this regard, the same haplotype was associated with more frequent drinking episodes at age 16, substantiating the notion of a genetic constellation that might render individuals at risk for alcohol abuse by affecting the incentive value of rewards [48]. In a follow-up study, Stacey et al. [51] identified a module of functional genes associated with mesolimbic dopamine signaling (M5) that correlated with *Rasgrf2* KO status in mice. Afterwards, they analyzed the human orthologues of M5 genes and tested their association to ventral striatal activity and alcohol use in 14-year-old male adolescents from IMAGEN. One haplotype block consisting of rs1648821 and five other SNPs of the EH-domain containing 4 (*EHD4*) gene exhibited a significant association with right ventral striatum activation during reward anticipation and binge drinking, suggesting the involvement of *EHD4* in alcohol-related reinforcement mechanisms [51].

Several other translational studies within the IMAGEN Consortium identified further genetic contributions to ventral striatal activity. For instance, the gene encoding Ras suppressor 1 (*Rsu1*) modulates ethanol preferences and reduces sensitivity to ethanol-induced sedation in flies [52]. In 14-year-old adolescents (n = 1908), *RSU1* polymorphisms were associated with activation in the ventral striatum (r = 0.020) and increased frequency of lifetime alcohol use (r = 0.020). Moreover, the findings replicated in an independent adult sample, showing an association of *RSU1* with alcohol dependence [52]. In another translational model, Peña-Oliver et al. (2016) identified genetic variants related to impulsive behavior in mice, defined by premature responding in a five-choice serial reaction time task, and evaluated their human homologs with respect to ventral striatal activation and

alcohol use in adolescents. Variation in the kalirin RhoGEF kinase (*KALRN*) gene was associated with increased activation in the right ventral striatum during anticipation of reward (G major allele of the SNP rs6438839) and with increased frequency of binge drinking (A minor allele of SNP rs4634050) in 14-year-old adolescents, suggesting that *KALRN* increases the risk for alcohol abuse [53].

Other studies focused on functional polymorphisms specifically related to dopaminergic signaling. In this regard, Baker et al. [30] analyzed genetic variation of the D1 and D2 dopamine receptor (*DRD1*, *DRD2*) genes and found that variation in the proximally located Ankyrin repeat and kinase domain (*ANKK*) rs11800497 was associated with activity of the lateral orbitofrontal cortex ($\beta = -0.09$). Conversely, *DRD1* rs686 expression modulated medial orbitofrontal cortex activation ($\beta = -0.08$). Moreover, *DRD1* rs686 was indirectly related to alcohol use at age 14 through an interaction between activation of the medial orbitofrontal cortex and the ventral striatum, which in turn predicted alcohol use at age 16 ($\beta = 0.08$). This analysis suggests a molecular pathway, in which *DRD1* rs686 impacts orbitofrontal cortex and ventral striatum signaling and thus renders adolescents susceptible to a rather early onset of alcohol use that may facilitate progression towards excessive alcohol use [30]. Another gene related to dopaminergic neurotransmission and possibly involved in the development of alcohol misuse behavior is the vacuolar protein sorting-associated protein 4a (*VPS4A*). In a GWAS study, the major C allele of SNP rs16958736 of *VPS4A* was linked to decreased striatal activation during reward anticipation ($r = -0.14$, $n = 1403$). On a behavioral level, however, no significant association could be observed for alcohol consumption and activity of the striatal node alone, but only for the link between the striatal node and another node comprising occipital areas V1/V2 [28].

Previous studies also highlighted the role of the brain-derived neurotrophic factor (*BDNF*) for alcohol consumption [54]. Along this line, Nees et al. [29] investigated the impact of genetic variation in *BDNF* that encodes the VAL66MET amino acid substitution (rs6265) on brain activation in different subdivisions of the striatum (putamen, nucleus caudatus, nucleus accumbens) and its predictive value for adolescent alcohol use. Specifically, they compared carriers of Met alleles (Met/Met homozygotes and Val/Met heterozygotes, $n = 167$) with homozygous Val allele carriers (Val/Val, $n = 363$). During reward anticipation, Val/Val genotype carriers exhibited lower activation in all subdivisions of the striatum compared to Met allele carriers. However, decreased activity in the putamen of Met carriers significantly predicted current (age 14) and future levels of alcohol consumption at age 16 (explained variance: 6.8%). This relationship was only apparent for putamen activation and not for activity in other striatal subdivisions [29]. The putamen has been implicated in mechanisms relevant for the transition towards alcohol addiction, such as reinforcement learning and the formation of habitual behaviors [55, 56]. Therefore, genetic variation in *BDNF* VAL66MET might reflect a risk factor for the development of excessive and harmful alcohol use by modulating neural activity that regulates the link between reward anticipation and drug seeking [29, 57].

Genetic Variation, Brain Activation During Response Inhibition and Emotional Processing and Adolescent Alcohol Use

With respect to response inhibition, the β1-containing $GABA_A$ receptor gene (*GABRB1*) has been previously associated with alcohol dependence and substance use disorders [58]. Allelic variation in SNP rs2044081 of *GABRB1* is associated with altered brain responses during regulation of reward-related behaviors such as behavioral inhibition and reward anticipation in 14-year-old adolescents before manifestation of alcohol symptoms, highlighting *GABRB1* as a potential contributor to addictive phenotypes [59]. In another study, the *Arf6* activator *Efa6* was associated with ethanol-induced behaviors like sedation and tolerance development in drosophila, and analysis of the human orthologs of *Arf6* and *Efa6* (*PSD1–4*) in 16-year-old adolescents of the IMAGEN sample found a link between SNP rs13265422 in *PSD3* with increased frequency of binge drinking ($r = 0.06$) and reduced activation in the right inferior frontal cortex during behavioral inhibition ($r = 0.06$) [60]. Thus, *PSD3* possibly affects excessive alcohol drinking behavior by modulating regional activity critical for executive control [60, 61].

In a large GWAS study, Schumann et al. [62] identified an association of the minor A allele of SNP rs197273 of the TRAF family member-associated NF-κB activator (*TANK*) gene with reduced alcohol consumption [62]. Müller et al. [63] set out to determine the functional relevance of *TANK* polymorphism for alcohol drinking in adolescence and found that carriers of the minor A allele of SNP rs197273 showed increased negative affective responses in brain regions associated with interoceptive processing, particularly the insula. Moreover, the minor A allele of rs197273, which results in lower *TANK* expression, was associated with lower alcohol consumption in 14-year-old adolescents. These results also translated to an animal model in which *Tank* KO mice exhibited attenuated ethanol consumption and preference as well as enhanced anxiety-related behaviors relative to wild type controls. Thus, *TANK* polymorphism modulates aversive emotional processing, possibly serving as a protective factor for developing alcohol use behavior [63].

A growing body of evidence also suggests an involvement of the endocannabinoid system (eCB) in addiction and particularly in alcohol use disorder (see [64] for a review). In a recent IMAGEN study [65], two SNPs within the eCB system were significantly associated with increased risk for developing alcohol-related problems (AUDIT score > 7) in adolescents aged 14, 16 and 18 years ($n = 575$), including SNP rs9343525 of the gene coding for the CB1 receptor protein (*CNR1*) and SNP rs507961 of the gene coding for the monoacylglycerol lipase enzyme (*MGLL*). Moreover, an SNP × SNP interaction analysis revealed a robust three-SNP interaction involving rs484061 (*MGLL*), rs7766029 (*CNR1*) and rs4963307 of the gene coding for diaglycerol lipase (*DAGLA*) that predicted AUDIT scores >7 in the same adolescents with 54% accuracy [65]. However, future research needs to investigate the potential role of the identified SNPs for addiction-related brain mechanisms of reward processing, response inhibition and emotional processing.

Epigenetic Mechanisms Affecting Adolescent Alcohol Use

Environmental processes can regulate the functionality and expression of genes without alterations in the DNA sequence, referred to as epigenetic modification [66]. One of the most widely studied forms of epigenetic modification are alterations in DNA methylation. Investigating DNA methylation changes in the brain is a major challenge in psychiatric epigenetic studies due to limited availability of post-mortem brain data. However, recent studies indicated significant overlap between methylation profiles in human brain and blood [67–70]. Therefore, in the IMAGEN cohort, peripheral blood tissue samples were used as surrogates for identifying DNA methylation changes in the brain. So far, four epigenome-wide association studies (EWAS) have been conducted within the IMAGEN Consortium to investigate the link between DNA methylation, environmental factors and alcohol use phenotypes in adolescence.

In the first study, hypermethylation in the locus of the 3′-protein-phosphatase-1G (*PPM1G*) gene has been found to be associated with increased trait impulsiveness and functional activation in the right subthalamic nucleus during response inhibition ($\eta^2_p = 0.013$, $n = 393$) [71], a brain structure responsible for the integration of neural signals also relevant for inhibitory control [72]. Moreover, *PPMG1* hypermethylation was also related to rising daily alcohol consumption levels from early to mid-adolescence ($\eta^2_p = 0.014$, $n = 352$) [71], suggesting that *PPM1G* methylation impacts brain mechanisms necessary for exerting inhibitory control and thus contributes to escalating alcohol use, a risk factor for developing alcohol-related problems later in life [2]. Another EWAS identified the upstream region of the gene that codes for the disks large-associated protein 2 (*DLGAP2*) as a differentially methylated region that has previously been related to the manifestation of alcohol dependence [73]. This finding was supported in 19-year-old adolescents from the IMAGEN sample by showing that decreased methylation levels of *DLGAP2* were significantly associated with increased frequency of drunkenness and reduced functional activation during reward anticipation in widespread regions of the brain, with the largest cluster located in the precuneus. These results suggest that *DLGAP2* hypomethylation is related to both altered reward processing and increased risk for problematic alcohol use in adolescence, and may contribute to the manifestation of alcohol dependence later in life [73].

Adolescence is a key developmental period for brain maturation processes, which render adolescents particularly vulnerable to psychosocial stressors such as relationship problems, peer victimization, family or school problems [74]. Psychosocial stress exposure, in turn, confers vulnerability for problematic alcohol use, e.g., by disrupting reward-related neural circuitry (e.g., [75]). Ruggeri et al. [27] revealed an epigenetic mechanism that helps to elucidate the link between adverse life events, reward processing and alcohol use in adolescence. Specifically, they found that methylation of the nociceptin receptor/opioid receptor like-1 (*NOP*/*OPRL1*) gene mediates the effect of psychosocial stress on binge drinking behavior and neural activity in the ventral striatum during reward anticipation in

14-year-old adolescents (η^2_p = 0.020, n = 393). *OPRL1* hypomethylation may thus result from psychosocial stress exposure and eventually increase reward sensitivity and the propensity of excessive alcohol use [27]. Similarly, increased methylation in the sterile alpha motif/pointed domain containing the ETS transcription factor (*SPDEF*) gene was associated with a greater number of adverse life events (r = 0.082, n = 1287) and with higher levels of lifetime binge drinking (r = 0.099, n = 413), which, in turn, was associated with decreased gray matter volume in the right caudal cuneus [76]. Specifically, among carriers of the minor G-allele of rs2233631, *SPDEF* methylation moderated the association between stressful life events and alcohol abuse, portending to a differential genetic vulnerability in adolescents for developing excessive alcohol use behaviors through environmental stress [76]. However, future research is needed to validate the identified changes in DNA methylation in human brain tissue.

Breaking Down the Relative Impact of Different Predictors for Adolescent Alcohol Abuse

As outlined above, the IMAGEN study has identified a multitude of environmental, behavioral, neurobiological and (epi-)genetic factors implicated in adolescent alcohol use. Understanding the relative contribution of these factors in predicting future alcohol abuse can provide risk profiles, which, in turn, may help to develop targeted interventions that aim at preventing the emergence of alcohol use disorder in individuals at risk.

Predictive models of alcohol use in early adolescence (age 14) found that personality traits explained the largest amount of variance in adolescent alcohol use (16% explained variance), while functional brain activation during reward anticipation and reward-related behavior contributed only marginally with 0.6% and 0.4% explained variance, respectively [77]. Additionally including candidate genetic variants [78] as well as stressful life events, use of other substances and family history of drug use [35] as further predictors yielded comparable prediction performances with 13% and 24% explained variance, respectively. Reward-associated personality traits, including novelty seeking, impulsivity, sensation seeking and extraversion (β = 0.35–0.41) [77, 78] as well as smoking status (β = 0.385) [35] were the most significant predictors for alcohol use in early adolescence. In contrast, the level of future alcohol consumption at age 16 was most strongly influenced by personality factors (β = 0.260) and genetic variation in candidate genes (β = 0.270) [78] as well as alcohol drinking levels at age 14 (β = 0.258) [35]. Importantly, variation in candidate genes was most important for the increase in alcohol use between 14 and 16 years (β = 0.330) [78]. However, these factors have been shown to contribute differentially to the prediction of alcohol use when adolescents are stratified based on family history of substance use ([35], but see also [79]). Together, these results suggest that the initiation of alcohol use in early adolescence

is determined by a different set of predictors, namely stress exposure, reward-related personality traits and concurrent substance use, as compared to the transition to increased levels of alcohol consumption, which is mostly associated with genetic predispositions and previous alcohol use. This finding supports etiological models on substance use in which early patterns of consumption are strongly determined by social and familial environmental factors rather than genetic influences, while later levels of use are more strongly influenced by genetic predispositions, showing that different predictors act dynamically across development [80–82].

Reward-related brain activation, however, was less important for predicting alcohol use as compared to other predictor variables, with standardized regression weights (β) ranging from 0.007 to 0.040 in early adolescence and 0.010 to 0.082 in mid-adolescence [35, 77, 78]. The low predictive value of functional brain activation compared to other factors could be due to the impact of transient, state-dependent components in brain activation [83] while genetic or personality factors reflect more stable trait-like characteristics [84, 85] which might be more useful for predicting pathological psychiatric conditions at an early stage [86]. Moreover, recent studies highlighted deficits in psychometric properties of task fMRI measures, demonstrating low test-retest reliability for a range of widely adopted fMRI tasks comparable to those implemented in IMAGEN that impede their eligibility for biomarker discovery [87, 88].

Using a machine learning approach, Whelan et al. [43] generated multivariate models for the prediction of current ($n = 115$) and future binge drinking ($n = 121$) in 14-year old adolescents of the IMAGEN cohort. Based on more than 40 different variables from different domains, the models correctly predicted 82% of current (age 14) and 66% of future binge drinkers (age 16). While personal life experiences (e.g., romantic history, deviance history, family drug use etc.) were the most important features for the classification of current bingers (β = 0.022–0.244), identifying future binge drinkers primarily relied on personal life events (β = 0.024–0.184), personality factors (β = 0.025–0.086), and characteristics of brain structure and function (β = 0.071–0.225). Regarding brain structure and function, future binge drinkers compared to controls exhibited reduced gray matter volume and increased activation upon reward receipt in the superior frontal gyrus as well as increased gray matter volume and increased activation during failed response inhibition in the precentral gyrus [43]. A study combining resting-state functional connectivity and machine learning expanded these results, showing that changes in functional connectivity in frontal regions significantly contributed to the prediction of binge drinkers [89]. In contrast, candidate genetic variants only contributed to a minor degree to current (β = 0.018–0.065) and future binge drinking (β = 0.028–0.067) [43].

Together, these studies expand our understanding of the relative contribution of different predictors for adolescent alcohol use and reveal important antecedents, which may inform the development of more individualized interventions in the future. Moreover, the studies demonstrated that (1) incorporating multiple features from different domains outperformed the prediction of any single feature and that (2) single predictors relate differently to the initiation of alcohol use than to the

transition to increased alcohol consumption, thereby highlighting the multifactorial nature of harmful alcohol use with distinct factors acting and interacting dynamically across development [80–82].

Conclusion and Outlook

Since its inception in 2010, the IMAGEN Consortium helped to elucidate environmental, neurobiological and genetic factors and mechanisms involved in the formation of reinforcement-related behaviors, symptoms and disorders. From the large body of IMAGEN publications, in this chapter we focused on studies uncovering determinants for alcohol use in adolescence, a key developmental period in which heavy alcohol use can pave the way for transitioning to addiction later in life [2].

Structural differences in widespread cortical and subcortical brain regions as well as increased functional activation of reward-related brain networks and decreased activation in fronto-cortical networks implicated in goal-directed behavior, response inhibition and executive control [44, 90] predicted developmental trajectories of alcohol abuse from early to late adolescence. The IMAGEN study revealed a range of genetic polymorphisms and epigenetic modifications modulating the association between brain structure/function and alcohol use. Research breaking down the relative impact of different predictor classes additionally highlighted the importance of life experiences and environmental factors as well as reward-related personality traits, indicating multiple causal factors for the development of alcohol abuse across adolescence. Together, these findings might facilitate the stratification of individuals based on their individual risk constellation and promote the development of targeted interventions, which could reduce the emergence of AUD later in life. However, as an important limiting remark, it should be noted that effect sizes and proportions of explained variance, though consistent with previous studies in the field of (imaging) genetics [91–93], were relatively small based on conventional thresholds, particularly for brain structural/functional and genetic predictors. Therefore, it is crucial to validate the identified neurobiological mechanisms in specific clinical cohorts and in culture spaces outside Europe. To this end, the IMAGEN Consortium has aligned itself with other neuroimaging-genetics studies across the world [94] to further expand our understanding of determinants contributing to the development of alcohol abuse.

Chapter 29
Impulsivity and Alcohol Use Disorder

Molly L. Scarfe, Emily E. Levitt, Victoria E. Stead, and James MacKillop

Abstract Alcohol use disorder (AUD), along with other substance use disorders, can be understood at least partially as disorders of impulsivity, or a persistent deficit in self-regulation in which the individual is increasingly unable to control arising impulses to consume the substance. In turn, understanding impulsivity in relation to AUD can inform our understanding of its aetiology and potentially identify novel treatment targets. A challenge to this ostensibly straightforward perspective is the many ways impulsivity can be measured and the highly variable associations among these measures, revealing a highly multidimensional construct. Recent investigations have begun to delineate the latent structure of impulsivity, and, in this chapter, we review how a conceptual model of three broad domains relates to AUD. These comprise impulsive personality traits (i.e., self-attributions on personality inventories), impulsive choice (i.e., overvaluation of immediate rewards), and impulsive action (i.e., behavioural inhibition). In each case, we review the state of the evidence in relation to AUD, followed by a discussion of these domains as potentially modifiable risk factors. Although intervention research is relatively nascent, clinical interventions to improve self-regulatory capacities are promising and have potential in the context of a precision medicine approach.

Introduction

Despite clinically significant harm, distress, and negative consequences, why do individuals with alcohol use disorder (AUD) keep drinking? This is arguably the central question in alcohol addiction research. One answer is that AUD, along with other substance use disorders (SUDs), can be understood as self-regulatory disorders, in which a person gradually loses their capacity to regulate arising impulses to drink [1]. From this perspective, impulsivity is a cardinal feature of AUD and other health conditions associated with excessive consumption. These include not only other SUDs but behavioral addictions, like gambling or gaming, risky sexual behavior, and even obesity, which typically results from excess food consumption. Accounts of addiction that emphasize self-regulatory capacity over impulses differ from those that emphasize the development of overlearned habitual behavior [2, 3], and are more consistent with theories emphasizing maladaptive goal directed behaviour, which arguably map better to the clinical manifestations of addiction [4]. Given its potential importance, understanding the role of impulsivity in AUD and factors that influence the ability to self-regulate this behaviour may afford aetiological insights into the development and maintenance of the disorder.

Despite this ostensibly straightforward approach, however, research on impulsivity in AUD is made substantially more difficult by foundational questions about the nature and definition of the construct. Impulsivity is often broadly described as a tendency towards rash actions, but despite this seemingly simple definition, numerous measures of impulsivity and related constructs exist and the relations among these measures are highly heterogeneous. Rather than a singular psychological trait, it is increasingly clear that impulsivity is a superordinate construct, one that is multidimensional in nature, comprising multiple operational definitions that are conceptually related to each other but often quantitatively distinct and with differing relations to AUD. Only recently have investigations more clearly delineated latent structural models of impulsivity, quantitatively revealing the multidimensionality of the construct [5–8].

In the context of these definitional and measurement questions, the first goal of the current chapter is to review and evaluate the different definitions and measures that exist and their relation to AUD. This perspective considers impulsivity as an aetiological and maintaining factor in the disorder. The second goal of the chapter is to evaluate the clinical relevance of impulsivity and the extent to which facets of impulsivity may be viable treatment targets using the lens of experimental medicine. The experimental medicine framework [9] proposes the development of treatments that are specifically directed at targeting constructs closely associated to underlying aetiological mechanisms of the disorder. It is similar to a precision medicine approach insofar as it emphasizes careful assessment of specific features of an individual and the development of treatments that address those specific features. Collectively, the purpose of the chapter is to offer the reader a deeper understanding of what impulsivity is, how it relates to AUD, and the extent to which facets of impulsivity may be modifiable risk factors for treatment and prevention.

Impulsivity as a Multidimensional Construct

Early conceptualizations of impulsivity in personality psychology considered it to be a unitary trait (e.g., the Impulsivity subscale of the Eysenck Impulsivity Questionnaire [10]), generally capturing a tendency to respond rashly without foresight. Subsequently, behavioral paradigms measuring self-regulation emerged, moving away from self-attributions and operationalizing self-control based on emitted behavioral outputs, either as choices on decision making tasks or performance in motor tasks. Consequently, the concept became increasingly broad and, based on highly variable relations among measures, understood to be multifaceted [5, 6, 11]. Thus, the term impulsivity can be thought of as a superordinate construct, or a family of constructs that are conceptually related to each in natural language but independent, not different measurements of a common underlying process.

Importantly, the heterogeneity of relations among impulsivity measures is not such that every measure reflects an orthogonal process. Rather, a number of studies suggest that there is a latent structure among the various measures. In other words, there is a middle ground between all measures reflecting the same construct and all being independent, with certain ones overlapping with each other. In a metaphorical extended family of impulsivity measures, some constructs are more closely related than others. One approach to the latent structure of impulsivity is a tripartite model that consists of Impulsive Personality Traits (i.e., self-reported attributions of ability to self-regulate), typically measured using personality questionnaires; Impulsive Choice (i.e., preference for smaller sooner rewards over larger later rewards, often referred to as delay discounting), typically measured using delay discounting tasks; and Impulsive Action, also referred to as "Impulsive Waiting" (i.e., the capacity to inhibit a prepotent motor response), typically measured using Go/NoGo or Stop Signal tasks [6] (Fig. 29.1). While this is not the only proposed latent model of impulsivity [12], it provides a heuristic conceptual framework for understanding the various facets for considering the varying relations to AUD.

Impulsive Personality Traits and AUD

A number of self-report measures purport to measure impulsivity [13, 14]. Among the most common are the UPPS-P Impulsive Behaviour Scale (UPPS; [15], and the Barratt Impulsiveness Scale 11 (BIS-11) [16]. The UPPS includes five subscales representing five traits originally identified via the Five-Factor Model of personality [17]. The traits are Sensation Seeking, Lack of Perseverance, Lack of Premeditation, Negative Urgency, and Positive Urgency. Sensation Seeking refers to the tendency to seek out novel and thrilling experiences; Lack of Perseverance refers to the tendency to have difficulty completing task; Lack of Premeditation refers to a tendency to act rashly without forethought about the consequences of an action; and Positive and Negative Urgency refer to the tendency to act out under conditions of strong

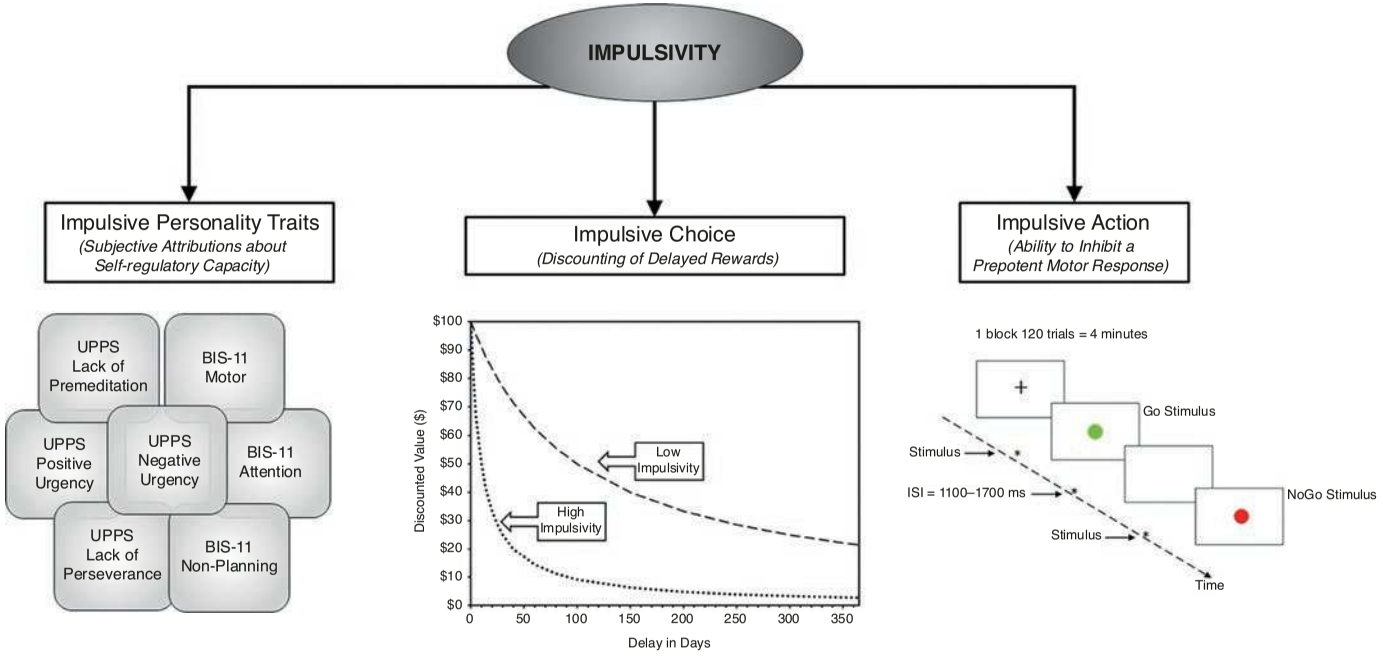

Fig. 29.1 A tripartite model of impulsivity. Impulsive personality traits reflect reports from self-report questionnaires; impulsive choice reflects overvaluation of immediate rewards; and impulsive action reflects ability to suppress an arising prepotent response

positive or negative affect, respectively [15, 18]. The BIS-11 parses impulsive personality differently. It includes six lower-order factors (Attention, Cognitive Instability, Motor, Perseverance, Self-Control, and Cognitive Complexity) that are grouped into three higher-order factors. The first higher order factor is Attentional Impulsivity, which is the ability to focus on the task at hand without racing thoughts and consists of the lower order factors Attention and Cognitive Instability. The second higher-order factor is Motor Impulsivity, which is the tendency to act on the spur of the moment. It consists of the lower order factors Motor and Perseverance. Finally, the third higher-order factor is Non-Planning, which is lack of forethought regarding the future. It consists of the lower order factors Self-control and Cognitive Complexity [16]. Higher order factors on the BIS-11 tend to have more robust psychometric properties than the lower order factors because of the larger number of items. Research using the BIS-11 may also use a total score, but that is not the case for the UPPS.

Cross-sectional research implicates various impulsive personality traits in relation to alcohol use and misuse. Research using the BIS-11 has generally found positive associations between AUD status, severity of alcohol use problems, and BIS score (total and higher-order factors) [19–21]. For example, in a sample of young adults, BIS total score predicted total number of drinks, drinking days, and days intoxicated [20]. Cross-sectional research using UPPS subscales have primarily implicated both measures of urgency as strong predictors of alcohol use problems and AUD, while Sensation Seeking tended to predict drinking frequency [13, 22–24]. Another study found that Sensation Seeking was related to heavy drinking at least partially via younger age of initiation [25]. Two meta-analyses have also converged in finding that negative drinking outcomes (i.e., drinking problems, alcohol dependency, and problematic use) were most strongly and consistently related to urgency traits, with the most severe outcomes (AUD) consistently and strongly related to Negative Urgency, specifically [26, 27]. In other words, those who struggle most with coping with strong negative emotions were most likely to have an AUD. This provides an appealing candidate mechanism for the well-known ability for stress to promote relapse [28]. Regarding level of alcohol consumption, one meta-analysis found positive relation for all UPPS traits, but particularly strong relations with Sensation Seeking and Positive Urgency [26], whereas the other found that quantity was most strongly related to Lack of Perseverance and frequency was equally predicted by all traits [27].

Beyond cross-sectional studies, longitudinal evidence supports bidirectional relationships between impulsive personality traits and alcohol use [29, 30]. For example, in a sample of college students, Positive Urgency predicted higher levels of alcohol use 1 year later, and baseline alcohol use predicted higher levels of Urgency (positive and negative), Sensation Seeking, and Lack of Premeditation a year later [29]. Another longitudinal study following college students from high school to college graduation found evidence for transactional relations between heavy drinking and impulsivity (here, considered unitary) and Sensation Seeking. Sensation Seeking and impulsivity at time 1 predicted increases in drinking across the first 2 years of college, while heavy drinking predicted individual differences in

personality change [30]. In addition to comparatively few longitudinal studies, another potential limitation that has not been addressed is that even though the UPPS or BIS-11 do not ask about alcohol, the statements could be endorsed by participants *specifically* because of behavior in the context of alcohol. For example, the 'acting out' when feeling bad could reflect drinking when feeling bad from the perspective of a participant. This link would make associations potentially spurious.

In sum, research has suggested that traits of impulsivity are differentially related to alcohol use and problematic use. Varying traits seem to be related to consumption variables (i.e., frequency and quantity), with evidence suggesting that Sensation Seeking may be especially important and may also be related to age of alcohol use initiation. With regard to alcohol problems and AUD, the Urgency traits (especially Negative Urgency) have been implicated in both alcohol use and problematic alcohol use. Together, this suggests that impulsive personality traits may differentially influence drinking, whereby drinking quantity and frequency are influenced via thrill or excitement (Sensation Seeking), while drinking problems are associated with emotional regulation, including managing both positive or negative affect (Urgency). Bidirectional relations suggest that impulsive personality traits forecast alcohol use and problems, but also that, conversely, alcohol misuse appears to also give rise to self-regulatory deficits. Although the large majority of studies are cross-sectional and cannot speak to causality, there is clear evidence for an association between impulsive personality traits and multiple features of drinking and AUD.

Impulsive Choice: Delay Discounting

The second facet of impulsivity—impulsive choice—is the preference for smaller immediate rewards over larger, delayed rewards is often referred to as delay discounting [6], that is, how much a reward is *discounted* based on its *delay* in time. Delay discounting in general refers to the behavioural economic principle that rewards progressively lose value based on their temporal delay, and it is conceptually similar to the capacity to delay gratification (i.e., *in vivo* ability to wait for a reward while in its presence). Among the most common measures are the Delay Discounting Task, Monetary Choice Questionnaire, and the Effective Delay-50 [31, 32]. Common to all instruments is the requirement for participants to choose between smaller-sooner rewards or larger-later rewards at varying values and temporal lengths (e.g., $1 now or 10 tomorrow, $20 now or $100 at the end of the week). In extended delay discounting tasks, the point at which a participant equates the smaller-sooner and larger-later rewards, the point of indifference, can be used to generate an empirical discounting curve that can be modelled using nonlinear regression to determine a person's temporal discounting function [33]. Steeper discounting curves represent a higher preference for smaller-sooner rewards, while shallower curves represent a more balanced preference between larger-later and smaller-sooner reward (more value allotted to larger-later reward). Brief tasks permit inferring the temporal discounting function.

Research has consistently demonstrated associations between high delay discounting and alcohol-related indicators, including alcohol use, AUD, and AUD severity [34–43]. In each case, elevations in drinking-related variables (AUD+ samples included) are associated with being likely to choose smaller-sooner rewards over larger-later ones. Studies of subclinical drinkers have found that those who drink more heavily or more frequently exhibit greater discounting [36–38]. For example, one study found that in a sample of adolescent drinkers, the heavier drinkers exhibited steeper discounting than lighter drinkers [36]. Other studies have compared AUD samples to controls, revealing that those with AUD displayed steeper discounting compared to controls [34, 35, 42, 43]. For example, one study examined delay discounting differences among an actively drinking AUD sample, abstinent AUD sample, and control sample. They found that the actively drinking AUD sample discounted future reward most rapidly, followed by the abstinent AUD sample, and finally, the healthy controls, who demonstrated the least discounting [34]. In addition to individual studies, meta-analyses provide further support for steeper discounting in alcohol-related samples. One meta-analysis examined categorical differences (e.g., differences between AUD and controls, or heavy drinkers and light drinkers). That study found a medium effect size (d = .68) in clinical samples and a notably smaller effect size (d = .29) in studies using subclinical samples [44]. Another meta-analysis examined continuous associations between delay discounting and drinking variables (e.g., quantity, frequency, and AUD severity), finding a highly significant, albeit small magnitude association overall, and a larger effect size for AUD severity measures compared to quantity or frequency measures [45]. Notably, both meta-analyses reported minimal evidence of potential publication bias. A small number of studies suggest that excessive delay discounting predates substance use and may be a vulnerability marker [46]. Longitudinal studies suggest that high discounting at one timepoint predicts increases in drinking at later timepoints [47, 48], providing further support for delay discounting as a vulnerability marker. For example, one longitudinal study of high schoolers found that initial delay discounting predicted alcohol involvement 6 months later, but that heavy drinking was not associated with any subsequent changes in delay discounting [47].

Studies have generally converged to suggest steeper discounting of future rewards in AUD or heavy drinking samples, but do these findings generalize to real-world encounters? Discounting relevant to AUD decision-making is cross-commodity in nature: it requires the individual to discount future rewards of one commodity type (e.g., monetary, relational, health, occupational) for immediate reward of another commodity (alcohol). Research has examined delay discounting in non-monetary commodities, and found that although AUD/heavy drinking samples still exhibit steeper discounting than healthy controls in these designs, consumable commodities (e.g., drug and food related rewards) are more steeply discounted compared to monetary rewards across the board, even among healthy controls [40, 49]. However, these paradigms remain single commodity in nature (e.g., alcohol now vs. alcohol later).

Comparatively less work has examined cross-commodity discounting (money-now/alcohol-later and vice versa). Indeed, a review on addiction related

cross-commodity delay discounting found that only three studies included all four possible combinations of discounting (money-now/money-later; other-now/other-later; money-now/other-later; other-now/money-later). The review found that contrary to expectations, the drug-now/money-later condition was not the most steeply discounted condition [50]. One study examined cross-commodity discounting in a crowd-sourced sample of drinkers. They found that those with the highest scores on a measure of AUD had significantly steeper discounting in the alcohol-now/money-later condition compared to those with lower scores [51]. It remains important to note that the existing literature on cross commodity discounting is relatively nascent.

Further, there are many more permutations of discounting paradigms that map onto the decision-making situations relevant to those with an AUD. For example, in contrast to delayed *reward* discounting, significantly fewer studies have investigated delayed discounting of *aversive outcomes* (e.g., choosing between a smaller-sooner and larger-later loss). Some studies have been conducted in rat models [52, 53], while others have looked at hypothetical aversive outcomes in human studies [54, 55]. Current conclusions are limited to the fact that the hyperbolic discounting processes remains consistent across reward/punishment paradigms, suggesting that discounting tasks can be used to analyse discounting of aversive outcomes. To our knowledge, discounting of losses/aversive outcomes remains to be studied in populations with greater levels of choice impulsivity, such as AUD and SUD populations.

Another important consideration from a developmental perspective is that in certain environments, a preference for smaller, immediate reward can actually be an adaptive, skillful response. In unstable or otherwise chaotic environments, resources and rewards may be scarce or unpredictable and there may be little to no value of delayed gratification for future rewards. Instead, the adaptive response is to focus on surviving the here-and-now (e.g., surviving living on the street). A developmental approach would hypothesize that these environmental contexts also help shape delay discounting/substance use. Indeed, studies exhibit associations between variables such as childhood socioeconomic hardship, childhood adversity, abuse/neglect, and increased delay discounting [56–58]. Specifically, some studies have found indirect links between adverse childhood neglect/abuse and substance use via delayed discounting [57, 58].

An emerging literature suggests that delay discounting may be a mechanism by which genetic variation confers risk for addictive behavior. For example, there is evidence that delay discounting is at least moderately heritable: twin studies conducted in rodents and humans suggest that heritability rates of delay discounting is around 30–50% [59]. Studies have also suggested that the heritability of delay discounting increases over time, with one set of studies finding heritability rates of 30% in 12-year-olds, steadily increasing to 51–62% by age 18 [60, 61]. Similarly, steeper delay discounting has been found to be associated with family history of substance use, including prior to any onset of use [62–64]. Although initially promising candidate gene studies have not yielded robust findings over time, larger scale genome-wide association study (GWAS) samples have identified novel variants and revealed significant aggregate molecular genetic heritability [65, 66]. On balance,

the evidence suggests that delay discounting is heritable and may inform understanding the mechanisms of genetic influences on addiction, although the specific variants and pathways remain unclear.

A further nuance is that some evidence suggests elevated delay discounting may not be unique to AUD or even SUDs, but rather a psychological mechanism implicated in externalizing/disinhibitory disorders more broadly, as well as other psychiatric disorders and other health outcomes [67–69]. Indeed, some research suggests that delay discounting may be a transdiagnostic process across numerous psychiatric disorders [70, 71]. Furthermore, in addition to undervaluing delayed rewards, it appears that excessive orientation toward the future can be maladaptive also, reflecting excessive overcontrol. In particular, an interesting line of inquiry has found that excessively shallow discounting (i.e., excessive preference for future reward) is present in individuals with disorders that are associated with excessive self-control, such as anorexia nervosa and obsessive-compulsive personality disorder [72–74].

In sum, the construct of impulsive choice can be operationalized via delay discounting tasks and provides one specific vantage point for understanding impaired self-regulation in AUD (immediate pull to drink at the cost of long-term outcomes). Alcohol studies consistently reveal that heavier-drinking samples and samples with AUD exhibit more impulsive discounting than comparison group. More broadly, there is evidence that maladaptive delay discounting is observed across addictions more generally, along with other externalizing disorders and disorders of excessive self-control. Heritability studies suggest that delay discounting is moderately influenced by genetic variation, but developmental and environmental factors are also robustly implicated, making it a biobehavioral process that is jointly determined by 'nature' and 'nurture.' Limitations to the existing literature are that it primarily comprises cross-sectional associations, with longitudinal and experimental studies needed to determine causation more definitively, and more research is needed on related processes, such as cross-commodity discounting, to provide more ecologically valid conclusions.

Impulsive Action

The second behavioural measure of impulsivity is impulsive action (behavioural/response inhibition, waiting impulsivity), an individual's ability or inability to inhibit a prepotent motor response [75]. Behavioural inhibition is conceptually linked to all behaviours that involve self-regulation, including alcohol and other substance use [76]. Behavioural inhibition is generally measured via laboratory tasks such as the Stop Signal Task, Go-NoGo Task, or the Continuous Performance Task [77–79]. Generally, these measures require participants to quickly respond by pressing a button upon the presentation of certain stimuli ("go" stimulus) but not other stimuli ("stop" stimulus) [75]. Response patterns can either generate an accurate response, or two types of errors: errors of commission (pressing during "stop" stimulus; indicative of impulsivity), or errors of omission (failure to respond to the

"go" stimulus; error of inattention). In general, a number of studies have found that poorer responding on response inhibition tasks (more errors, longer response time) is associated with SUDs and other areas of psychopathology [80, 81].

The empirical literature on alcohol suggests that worse performance on response inhibition tasks is related to increased alcohol consumption, alcohol-related problems, and AUD severity [20, 82–85]. One 4-year longitudinal study found that heavy drinkers performed worse on all behavioural impulsivity measures, and that specifically for response inhibition, difficulty with the stop-signal task was associated with an increased risk for alcohol dependence 4 years later [85]. Some research also suggests that there may be familial links to response inhibition. A cross-sectional study examined adults without a history of alcohol or other substance use disorder, either with or without a family history of AUD. They found that those with a family history had more errors of commission compared to those without a family history of AUD, suggesting that poorer response inhibition is likely associated with family history of AUD [86].

Meta-analyses provide further support for response inhibition impairments in those with AUD and heavy drinking samples [80, 81]. One recent meta-analysis examined behavioural inhibition in SUDs ($k = 97$). With regards to alcohol use, they found that those with alcohol dependence exhibited poorer task performance on the Go-NoGo task (significantly more errors of omission and commission; $g = .35$ and .43, respectively), and exhibited longer stop reaction time on the Stop Signal Task ($g = .40$) compared to controls. They also found that heavy drinkers had more errors of omission (inattention) on the Go-NoGo task when the NoGo condition was rare and poorer stop signal reaction time (gs = .48 and .25, respectively) [81].

Longitudinal studies with adolescents and young adults suggest that poor response inhibition may be a risk factor for later AUD or alcohol related problems [76]. For example, one study of 498 children from 275 families found that poorer response inhibition (longer reaction time) was a significant predictor for the number of alcohol-related problems and illicit drug use, while other measures of executive function were not [76]. Aside from examining task performance, a number of longitudinal neurocognitive studies combine both measures of response inhibition and fMRI methods and have found that blunted activation in prefrontal cortical regions of the brain during response inhibition tasks predicted negative outcomes such as problem substance use, heavy drinking 4 years later, and alcohol dependence symptoms 18 months later [87–90]. Other studies have found greater activation in the cerebellum during failed response inhibition (errors of commission) in those with an AUD family history [91, 92]. Together, results suggest that those at risk for AUD or hazardous drinking also show abnormalities in brain functioning while completing these tasks.

Some studies have examined how inhibition is impacted by acute alcohol consumption. In these studies, participants are administered either ethanol or saline, and subsequently complete behavioural inhibition tasks. Generally, results suggest that alcohol administration impairs behavioural inhibition [93]. For example, one study found that moderate amounts of ethanol in healthy participants resulted in decreased stop reaction times, indicative of impaired behavioural inhibition [94].

Other studies have made efforts to increase ecological validity by including alcohol-relevant cues in the measures or exploring how variables such as craving influence response inhibition [95, 96]. One comparative study of individuals with AUD and healthy controls found that the AUD sample made significantly more errors (both commission and omission), and that errors of commission (impulsivity) were increased when AUD participants had to detect alcohol-related stimuli [96]. Another study found that in a sample of inpatient alcohol-dependent participants, response inhibition was associated with absolute craving in a bar-restaurant setting, whereby those who performed poorer on the task experienced higher levels of craving when exposed to alcohol cues. They also found that trait impulsiveness (measured via BIS-11) was associated with absolute craving and craving increases [95].

In summary, cross-sectional, longitudinal, laboratory, and meta-analytic studies suggest that poor behavioural inhibition is related to AUD. Additionally, some research suggests that there may be familial links in response inhibition in those with a family history of AUD. Another branch of research suggests that behavioural inhibition is further weakened by alcohol intoxication and alcohol-related cues, and that those who perform more poorly on response inhibition tasks also report higher levels of craving in alcohol-relevant situations.

Impulsivity as a Modifiable Intervention Target

Given the evidence that higher levels of impulsivity—regardless of how it is measured—is related to AUD, the next logical question is whether there are treatment implications. Indeed, higher levels of impulsivity facets predict relapse and treatment drop-out [97–100]. These findings suggest that measures of impulsivity may be viable tools to identify those at the highest risk for drop-out or generally poorer treatment outcomes. They also implicate impulsivity as a candidate treatment target: addressing impulsivity in treatment might ameliorate or bolster treatment outcomes. The final section of this chapter will review treatments related to the three facets of impulsivity, specifically, psychosocial interventions and prevention programs for impulsive personality traits, episodic future thinking for delay discounting, and behavioural inhibition training for impulsive action.

Psychosocial Treatments and Impulsive Personality Traits

While there are no current interventions that specifically target impulsive personality traits, some research employing the UPPS model suggests that some traits are modified throughout the course of SUD treatment [101–103]. For example, one study examined impacts of a trauma-informed yoga intervention to treatment-as-usual in a sample of women with SUDs. Results revealed that both conditions experienced improvements in Negative Urgency, and that only those in the yoga condition

exhibited improvement in Premeditation [101]. One review on UPPS traits in psychological treatment for SUDs found limited data on how UPPS factors change during various SUD treatments. The majority of studies examined Negative Urgency, which reduced following a number of treatment modalities (e.g., Dialectical Behaviour Therapy, 12-step groups, Cognitive Behavioural Therapy, Motivational Interviewing). Fewer studies examined changes in Premeditation, and they found no available empirical evidence for changes in Positive Urgency, Sensation Seeking, or Perseverance [102]. One meta-analysis examined the relations between UPPS traits and psychotherapy outcomes for substance use, and found promising evidence of significant decreases in Sensation Seeking and Negative Urgency, although effect sizes were small (gs = −.10 and −.25, respectively). Importantly, these effect sizes were based on a small number of studies (k = 4–8) [103] and were generally within-subjects changes, rather than evidence that the treatment selectively reduced impulsive personality traits. In other words, it is also possible that these traits generally attenuate following reduction of active substance use.

Related, a small number of studies have examined the use of Dialectical Behaviour Therapy (DBT) skills training. DBT skills training focuses on, among other things, emotional regulation with obvious relevance to the urgency measures. Studies have found preliminary support for its use with SUD populations [104]. One systematic review found that studies varied in their implementation and adaptation of the skills, but that generally, DBT skills training was an acceptable and feasible treatment for SUD populations. Further, they found preliminary support for emotion regulation enhancement and substance use reduction. Research has also examined the effectiveness of a prevention program specifically targeting impulsivity (here, defined as a unitary construct), and sensation seeking. One cluster randomized control trial found that high risk students (high scores on impulsivity and sensation seeking measures) who received a personality-tailored intervention exhibited long term effects on drinking rates, binge drinking rates, and problem drinking. They also exhibited benefits in drinking quantity and drinking frequency [105].

At this point, while the research on interventions for impulsive personality is at an early stage, the existing evidence does support applications in prevention and that certain impulsive personality traits (specifically, negative urgency and premeditation) are modified throughout the course of various psychosocial treatments. Further, DBT skills may be relevant in their capacity to bolster emotion regulation, and some preliminary evidence suggests that DBT skills may be helpful for those with SUDs, but direct links have not been made to positive and negative urgency.

Interventions for Delay Discounting: Episodic Future Thinking and Pharmacological Interventions

Given the evidence that AUD is associated with an increased propensity to discount delayed rewards, it is intriguing that some research suggests prospective memory (remembering to do something in the future) is negatively correlated with drinking

severity and dependence [106, 107]. Episodic future thinking, or the ability to self-project and pre-experience a future event, is a skill that can be trained to widen the temporal window that those with AUD consider while making inter-temporal decisions [108]. Some studies have found that episodic future thinking training reduced delay discounting in cigarette smokers [109–111], with one study finding that it also reduced cigarette self-administration [109].

To date, four studies have examined effects of episodic future thinking on delay discounting in drinking and AUD samples, and generally converge to find that episodic future thinking reduces delay discounting. One study examined relations between episodic future thinking, delay discounting, and alcohol decision-making in a samples of college students. During a delay discounting task, participants either imagined events they were looking forward to in the future (episodic future thinking condition) or completed a control imagery task. When participants imagined the personally relevant future event, they performed less impulsively on the delay discounting task relative to the control condition. Further, in the episodic future thinking condition, participants reported less intensity of alcohol demand (reporting they would drink fewer drinks at zero cost) [112]. Another study of participants with AUD found similar results, in which episodic future thinking reduced delay discounting and intensity of alcohol demand [113]. The effects appear to be cumulative, as a study of episodic future thinking in a sample of participants with AUD found reduced delay discounting rates that the effect grew with repeated administrations [114]. Finally, in a sample of treatment-seeking adults in an inpatient alcohol program setting, episodic future thinking reduced delay discounting and generalized to other alcohol-related decision-making measures [115].

A related line of research has investigated whether stimulant medications commonly used to treat attention-deficit-hyperactivity-disorder (ADHD) also improve delay discounting, both because ADHD is often comorbid with AUD [116], and it is also associated with elevated delay discounting [68]. Studies using preclinical rodent models have suggested that D-amphetamine may reduce delay discounting [117–119]. Atomoxetine has also been the focus of some preclinical studies, with results generally finding that the drug reduces delay discounting [120, 121], although discrepancies exist [122]. Finally, other research has revealed that methylphenidate reduced delay discounting in rats, Rhesus monkeys, and in children with ADHD [123–125]. Related, one prospective study actually revealed that youth with ADHD who were prescribed methylphenidate had a lower risk for alcohol and drug use [126], and another study found that methylphenidate did not increase ethanol consumption in rats with ADHD-like qualities [127]. However, delay discounting was not evaluated as a possible mechanism in either case. On the other hand, as most ADHD medications are dopamine agonists, it remains important to consider the possibility that these compounds may precipitate substance use in someone who is in early or sustained remission, akin to the risks of prescribing opioids during a hospital stay to person with a history of opioid use disorder. Indeed, the ability of pharmacologically alike compounds to revive drug-seeking is referred to the reinstatement model of drug relapse [128] and is a widely used preclinical paradigm.

In sum, delay discounting appears to be malleable via both psychological and pharmacological interventions. Episodic future thinking trains participants in the

ability to prospectively consider the future when making decisions in the present. While findings that reveal episodic future thinking reduces delay discounting and substance consumption are promising, it remains important to consider that existing studies examining alcohol related samples are small in number (only four studies to date) and small in sample size (*n*s = 28–50). Furthermore, the evidence that reduced impulsive delay discounting generalizes to substantive reductions in drinking is limited. Acknowledging these considerations, episodic future thinking as a potential intervention for AUD is nonetheless a promising line of inquiry. Regarding pharmacotherapies, there is preclinical evidence that stimulant medications, such as methylphenidate, d-amphetamine, and atomoxetine reduce delay discounting. However, these findings have not been translated into clinical populations and a degree of caution is warranted in doing so because of possible reinstatement effects.

Inhibitory Control Training for Behavioural Inhibition

Numerous studies have examined effects of inhibitory control training on alcohol consumption. In these studies, participants complete modified versions of Stop-Signal or Go-NoGo tasks in which participants learn to inhibit their responses upon presentation of alcohol related cues. Individual laboratory studies have generally found evidence for reduced alcohol consumption immediately following the tasks, but not reductions in implicit alcohol value or general inhibitory control [129–131]. Two meta-analyses also found evidence for appetitive and health behaviour change (including alcohol consumption) in laboratory studies in the short-term [132, 133]. Unfortunately, randomized controlled trials (RCTs) suggests that these interventions are not generalizable outside of the laboratory, and that they do not result in longer-term change in alcohol consumption [134, 135]. For example, an RCT of heavy drinkers compared the effect of two sessions of inhibitory control training to two sessions of an active control condition [134]. For both conditions, one session took place in a laboratory, the other in a naturalistic bar setting. Results demonstrated no differences in alcohol consumption in either setting compared to the control group, and that there were no effects of inhibitory control training on inhibitory control processes more generally, or on alcohol value [134]. Another RCT examined the effect of 4-week, 14-session internet-based inhibitory control training treatment compared to an active control [135]. The participants of this study were 246 heavy drinkers that were motivated to reduce their alcohol consumption. The study did find significant reductions in alcohol consumption, but these effects were non-specific to the inhibitory control training groups, as similar levels of alcohol consumption reductions were also observed in the control condition, suggesting that the training did not help heavy drinkers reduce their alcohol consumption beyond a placebo effect [135]. Together, evidence suggests that while inhibitory control training may reduce alcohol consumption in the short term in laboratory-based studies, these effects do not appear to extend beyond the laboratory and do not appear to result in any long-term alcohol consumption changes. These findings are reminiscent of facilitative intervention training treatments for ADHD, where treatments

focused on repeated training of specific tasks, with the prediction that skills would generalize with repetition, but little evidence that was the case [136]. This is an instance in which the impulsivity marker is clearly implicated in AUD but may not be itself amenable to direct interventions, at least with the strategies employed to date.

Final Conclusions and Summary

Understanding the nature of the inability of an individual with AUD to self-regulate arising impulses to drink is important to both understand the disorder and potentially to develop the next generation of behavioral treatments to address these self-regulatory deficits. At the heart of this issue, impulsivity is a multidimensional construct comprising impulsive personality traits, impulsive choice (delay discounting), and impulsive action (behavioural inhibition). Studies examining each of these domains have repeatedly shown them to be associated with drinking behaviour and AUD. Furthermore, some longitudinal evidence suggests that these self-regulatory deficits predict alcohol misuse, suggesting they are more aetiological than consequences of substance use. Indeed, some evidence suggests they may be bidirectional, with continued alcohol use further exacerbating pre-existing deficits.

Early-stage intervention research reveals that at least some existing interventions may be helpful in improving various facets of impulsivity. For example, arguably the most promising candidate is EFT for delay discounting, where participants focus on salient future events to scaffold out their temporal window of consideration, ameliorating delay discounting in the process. Additionally, some more limited research suggests that Urgency and Premeditation are improved throughout the course of psychosocial treatments for SUDs. Unfortunately, research examining response inhibition training in AUD has shown that gains do not translate past the laboratory setting. More broadly, if efficacious intervention modules can be developed to address discrete forms of impulsivity, precision medicine applications are clear. Carefully characterizing an individual's profile in these different domains would provide a blueprint for specifically matching the patient to the module and putatively to the greatest clinical benefit. Although significant gaps in knowledge remain, investigating the various forms of impulsivity in the context of AUD has clear promise, both for understanding the causes of AUD and addressing those causes as part of evidence-based treatment.

Chapter 30
Brain-Immune Mechanisms in Alcohol Use Disorder Targeting Neuroimmune Signaling in Alcohol Use Disorder: Opportunities for Translation

Erica N. Grodin, Lindsay R. Meredith, Elizabeth M. Burnette, and Lara A. Ray

Abstract A growing body of literature implicates the neuroimmune system in the development and maintenance of alcohol use disorder (AUD). This chapter broadly covers the field's progress in characterizing brain-immune mechanisms in AUD from basic to clinical research. We provide an overview of the neuroimmune hypothesis of addiction, cover proposed mechanisms through which alcohol is hypothesized to alter the immune system and increase neuroinflammation, and review evidence from preclinical and clinical studies that demonstrate the relationship between the immune system and AUD.

Given preclinical and clinical evidence to date, there is high enthusiasm for the development of AUD treatment options that target peripheral and neural immune pathways and restore healthy levels of proinflammatory signaling as a way to mitigate drinking behaviors and promote recovery. We review relevant pharmacotherapies and psychotherapies that have been shown to affect the immune system and highlight those that demonstrate particular promise as novel treatments for AUD.

Finally, we conclude by providing recommendations for further development of immune treatments for AUD. We emphasize the importance of target-specific screening methods, such as neurocognition, stress-reactivity, and gut microbiota.

Further, we suggest that future work should investigate proinflammatory biomarkers, such as C-reactive protein and plasma cytokine levels, as precision medicine approaches that may help identify individuals with AUD who benefit most from immune treatment.

Introduction

The Immune System

Increasing evidence suggests that the immune and neuroimmune systems play a critical role in the development and maintenance of alcohol use disorder (AUD) [1]. The immune system, which is essential for humans' well-being, is comprised of innate and adaptive immune mechanisms and serves as the body's primary defense against pathogens [2]. Upon activation of the innate immune system, proinflammatory responses are prompted by detection of conserved features of microbes, termed pathogen-associated molecular patterns (PAMPs), such as the surface membraned component of most Gram-negative bacteria and endotoxin, lipopolysaccharide (LPS) [3]. Among individuals with AUD, LPS levels are elevated, but may normalize after a period of abstinence [4, 5]. Toll-like receptors (TLRs) are a common family of receptors found on immune cells and can recognize PAMPs and consequently activate transcription factors, including nuclear factor-κB (NF-κB), interferon (IFN) regulatory factors, and cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) [6–8]. TLRs are widely implicated in alcohol-related neuroimmune signaling. Subsequently, activated transcription factors drive the expression of proinflammatory immune proteins, termed cytokines, which are released from immune cells and can either promote or dampen inflammatory processes. Cytokines coordinate inflammatory cell functions and are thought to have a wide-range of effects on physiological and behavioral responses [9]. Cytokine types, including interleukin (IL)-1, IL-2, IL-6, IL-8, and tumor necrosis factor-α (TNF-α), are each shown to have specific mechanisms [10]. In the central nervous system (CNS) specifically, microglia and astrocytes are considered the primary mediators of immune responses, such that they respond to and release immune signals. Neurons interact with microglia and astrocytes and express receptors capable of immune signaling. Further, anti-inflammatory factors, such as brain-derived neurotrophic factor (BDNF) and the cytokine IL-10, are necessary to manage and resolve proinflammatory and immune responses.

Alcohol and the Immune System

There are two proposed mechanisms through which alcohol is hypothesized to alter immune signaling and increase neuroinflammation: (a) indirectly, by initiating production of proinflammatory cytokines in the periphery that subsequently signal to the CNS, e.g., by binding at vagal afferent sites, crossing the blood-brain barrier (BBB) via immune-mediated active transport, or by reaching the CNS through disruption of the BBB [11]; and (b) directly via actions in the brain, wherein alcohol and alcohol-induced neural damage [12] stimulate the release of proinflammatory molecules [13]. Alcohol is thought to promote systemic inflammation by acting on peripheral immune receptors in the gut [10] and by breaking down lymphatic duct lining and endothelial cell junctions, whereby proinflammatory molecules leak into the bloodstream, termed "leaky gut" [14]. These proinflammatory molecules in the periphery subsequently provoke a proinflammatory response within the CNS, termed neuroinflammation. Proinflammatory molecules in the brain are suggested to alter neural circuit functioning and neuronal plasticity [10]. A prolonged or excessive proinflammatory response can negatively impact the individual and, among samples with AUD, is suggested to contribute to compulsive alcohol intake and other AUD symptomatology.

Preclinical Evidence

Preclinical animal models have provided strong support for the neuroimmune hypothesis of AUD. For instance, brain transcriptome studies have found that in adolescent alcohol-preferring rats, binge-like alcohol consumption resulted in upregulation of cAMP signaling system genes in the central amygdala and nucleus accumbens [15]. Chronic alcohol vapor exposure in mice led to upregulation of genes related to inflammatory diseases in the amygdala and nucleus accumbens [15]. Beyond alterations in immune gene expression, voluntary alcohol consumption has been demonstrated to increase cytokine and chemokine levels in both the CNS and the periphery in mice [16] and monkeys [17]. Specifically, in monkeys, alcohol consumption was correlated with hippocampal levels of the chemokine MCP-1 [17]. In mice, chronic alcohol consumption resulted in increases in levels of cytokines (IL-1β, IL-17, and TNF-α) and chemokines (MCP-1, MIP-1α, and CX3CL1) in the striatum and serum in wild-type mice [16], while mice with knockouts in the TLR system (i.e., TLR4, TLR2) were protected from these effects. This provided evidence in support of the importance of the TLR system in alcohol-related neuroinflammation [18]. Specifically, TLR4 is thought to contribute to alcohol-related neuroimmune effects [19]. Blocking TLR4 in glial cells protects against alcohol-induced glial activation, the induction of inflammatory mediators (i.e., proinflammatory cytokines), and apoptosis [19]. Furthermore, in male mice, chronic binge-drinking induced a microglia-driven neuroimmune response in the

prefrontal cortex, which led to abnormal synaptic pruning and ultimately resulted in synapse loss and increases in anxiety-like behavior [20]. Additionally, 24–48 h of alcohol withdrawal, a critical window during which motivation to self-administer is increased, resulted in the upregulation of mRNA proinflammatory expression of innate immune markers (e.g., TNF-α, IL-1β) in rat cortical tissue [21, 22]. These findings indicate that upregulated immune signaling occurring during alcohol withdrawal may contribute to the maintenance of AUD.

Further, preclinical work suggests that neuroinflammation and modulation of immune signaling induced by chronic alcohol use alters alcohol-related behaviors, including heightening motivation for intake, enhancing alcohol-related reward, and contributing to substance-related cognitive impairments and depression-like behavior [19, 23–26]. In rats, artificially induced proinflammatory states via LPS or cytokine administration sensitized alcohol withdrawal-induced anxiety in a dose-dependent manner [24]. Relatedly, microglia depletion prevented escalations in voluntary alcohol intake and decreased anxiety-like behavior in mice [27]. Chronic binge-pattern alcohol consumption among alcohol-preferring rats resulted in an anhedonia phenotype and decreased BDNF effects during withdrawal, whereas a BDNF agonist rescued these effects, indicating that BDNF may modulate the effects of chronic alcohol consumption on depressive symptoms [25]. Several mouse knock-out models have been used to evaluate the role of cytokines and chemokines on alcohol-related behaviors [28–31]. Knocking out or preventing the expression of cytokines, IL-6, IL-Ra, IL1R and TNF1R, resulted in reduced alcohol consumption, thus implicating these cytokines in alcohol drinking behavior (see [10] for detailed review). Moreover, chronic stress may further exacerbate alcohol-associated tissue injury in the gut, liver, and brain, such that chronic corticosterone treatment increases alcohol-induced expression of proinflammatory cytokines, resulting in mucosal barrier dysfunction, endotoxemia, and systemic inflammation [32]. Together, results from preclinical studies spanning molecular and genetic investigations to behavioral studies consistently find that the immune system plays a critical role in the development and maintenance of AUD.

Clinical Evidence

To date, human research in AUD evaluating the presence of enhanced activation of proinflammatory signaling in the CNS has been quite limited. It is remains unclear to what extent acute versus chronic alcohol exposure, quantity and frequency of alcohol intake, and recovery from AUD influence alcohol-related neuroinflammation [33, 34]. Existing work in this area has come primarily from postmortem brain studies [13, 35, 36], positron emission tomography (PET) studies imaging the translator protein (TSPO), and studies measuring levels of proinflammatory makers in cerebrospinal fluid (CSF) [37–39]. For example, an early report on gene expression profiles of postmortem human brains of individuals who had AUD found

that identified genes could be categorized into functional groups relevant to immune response, cell survival and communication, signal transduction, and metabolism, particularly in the frontal cortex [36]. In a study which collected CSF, researchers assessed whether MCP-1 concentrations were elevated among those with AUD versus healthy controls and if these concentrations were correlated with markers of liver damage, as this proinflammatory chemokine is shown to induce alterations in BBB permeability [39, 40]. In line with expectations, among treatment-seeking individuals with AUD, concentrations of MCP-1 were elevated in CSF and associated with peripheral liver markers of inflammation.

Labeling of TSPO, which is localized mainly in the outer mitochondrial membrane and upregulated during neuroinflammation, is utilized in PET imaging for inflammatory conditions, as it is suggested to be a biomarker sensitive to neural damage, inflammation, and reactive gliosis [41]. TSPO is involved in a broad range of biological functions and is typically expressed in reactive microglia and astrocytes. Across investigations of TSPO imaging in psychiatric disorders, differing patterns and wide variabilities in findings have emerged, such as elevated TSPO in major depressive disorder (MDD) and reduced levels in psychosis [42, 43]. For AUD, clinical studies have reported reduced binding of PET TSPO ligands in the brains of individuals with AUD relative to controls, which may be suggestive of reduced levels of activated microglia or downregulation of proinflammatory responses following chronic inflammation from alcohol [33]. In one PET study that enrolled 15 healthy controls and 15 individuals with AUD, results showed that the AUD group had 10% lower TSPO levels than controls; and TSPO levels in the hippocampus were negatively correlated with disorder severity [44]. However, interpretation of these findings is complicated by limitations of this technique, genotype-specific responding, and discrepant results from *in vitro* animal studies [45]. TSPO binding affinity may be influenced by competition of endogenous cholesterol, which binds to TSPO for transport during steroidogenesis [46]. For instance, a recent report examined the impact of *TSPO* polymorphism rs6971 on plasma levels of triglycerides and cholesterol in participants with AUD and controls [47]; researchers showed that only among the group with AUD did *TSPO* rs6971 significantly relate to plasma levels of total cholesterol, triglycerides, and HDL, along with withdrawal severity. In contrast to the imaging findings, a postmortem brain study showed upregulated TSPO mRNA in the amygdala and prefrontal cortex of brains from males who had AUD, in comparison to age-matched controls. This finding provides initial support for the neuroinflammation hypothesis of AUD. In sum, while results from studies on postmortem brains, CSF, and PET imaging are suggestive of altered CNS immune activity in human samples of AUD, much more research in this area using diligent experimental design and careful interpretation is needed to adequately establish the neuroimmune hypothesis of AUD and specific factors influencing immune signaling in the CNS.

Clinical research has also provided evidence that levels of systemic inflammation are elevated in samples of AUD. As discussed above, alcohol is thought to increase intestinal permeability, leading to elevations in circulating LPS and

bacteria, and subsequent activation of immune cells and peripheral inflammation. These signals can reach the CNS through various pathways and contribute to neuroinflammation [48]. Acute alcohol intake appears to modulate peripheral cytokine concentrations, as evidenced by reductions in TNF-α and elevations in IL-6 levels 3 h following an oral alcohol administration challenge in 25 heavy drinking individuals [49]. Regarding chronic alcohol intake, elevated levels of serum LPS were detected at treatment onset among individuals with AUD, but decreased after 3 weeks of detoxification, reaching points comparable to individuals classified as healthy controls [5]. Moreover, other markers of peripheral inflammation partially decreased over this time and both proinflammatory and anti-inflammatory cytokines were correlated with ratings on psychological measures assessing alcohol craving, depression, and anxiety. A meta-analysis pooling data from 17 studies that collected a wide range of peripheral inflammatory markers in samples of AUD, provided evidence for higher cytokine concentrations (e.g., IL-6, TNF-α, IL-8) among individuals with AUD compared to a healthy control group [50]. Results varied greatly depending on the cytokine type examined, and these abnormalities were more prominent during active drinking and acute withdrawal periods compared to those of early or prolonged abstinence. Importantly, translational work has started to improve the field's understanding of how alcohol-stimulated peripheral inflammation alters neuroimmune signaling in human samples of AUD. For instance, one study examining associations among liver function, peripheral inflammation, and brain alterations among both non-cirrhotic patients with AUD and alcohol-preferring rats, demonstrated a strong link among these factors [51]. For example, proinflammatory cytokines and liver fibrosis were correlated with brain macrostructure abnormalities in patients with AUD and microglia activation in the rodent model. In sum, results from clinical studies indicate that the peripheral immune and neuroimmune system are related to AUD symptomatology, but much remains unclear regarding specific mechanisms, causal links, and recovery from AUD in human samples.

Implications for Treatment

Promising Immune Treatments for AUD

Given the preclinical and clinical evidence reviewed above, treatments targeting peripheral and neural immune pathways represent an important direction in the development of novel and more effective treatment options for AUD. In this section, we outline research covering immune pharmacotherapies and psychotherapies with promise to mitigate drinking behaviors and promote recovery from AUD (see Fig. 30.1).

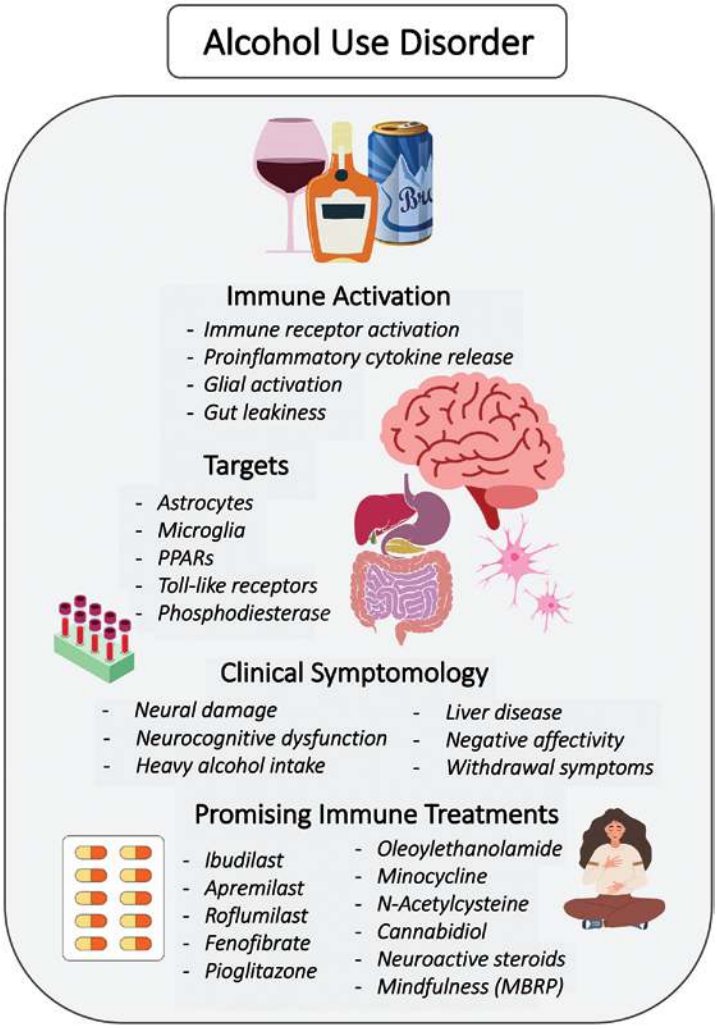

Fig. 30.1 Translational Science of Brain-Immune Mechanisms in Alcohol Use Disorder. Multiple components of the immune system are impacted by heavy alcohol intake, leading to altered immune signaling, dysfunction, and inflammation. In return, these changes are thought to influence and maintain clinical symptoms of alcohol use disorder (AUD). Both pharmacological and psychosocial therapies hypothesized to alter relevant immune targets have shown initial promise for treating the complex, multisystem symptoms of AUD; PPARs, peroxisome proliferator-activated receptors; MBRP, mindfulness-based relapse prevention

Ibudilast

Ibudilast is a selective PDE3A, PDE4, PDE10A, and PDE11A inhibitor [52] and an allosteric macrophage migration inhibitory factor (MIF) inhibitor [53]. Ibudilast has demonstrated initial efficacy in preclinical and clinical studies of AUD. In multiple rodent models of AUD, ibudilast attenuated drinking and relapse, and preferentially reduced drinking in alcohol-dependent, compared to non-dependent mice [54]. In clinical samples, two completed randomized controlled trials investigating the effect of PDE inhibition in humans with AUD have been published. First, a crossover human laboratory trial of ibudilast was conducted to evaluate safety, tolerability, and initial efficacy in a non-treatment seeking sample with AUD. Among 24 individuals enrolled in the trial, ibudilast was safe and well-tolerated, and, compared to placebo, decreased tonic craving for alcohol and improved mood following alcohol cue and stress exposure [55]. Second, results from a 2-week trial of ibudilast in non-treatment-seekers with AUD (n = 52) showed that ibudilast reduced rates of heavy drinking and neural alcohol cue-reactivity in the ventral striatum compared with placebo [56]. Ventral striatal activation to alcohol cues further interacted with ibudilast to predict reductions in drinking [56]. Ibudilast was well-tolerated in the 2-week trial, as there were no significant differences between medication groups in the occurrence of adverse events [56]. Presently, ibudilast (50 mg b.i.d.) is being evaluated in a 12-week randomized clinical trial in treatment-seeking individuals with AUD (NCT03594435). The trial's primary and secondary outcomes are reductions in percent heavy drinking days and examination of peripheral markers of inflammation and depressive symptomology, respectively.

Apremilast

Apremilast is a partial competitive PDE4 inhibitor, which is FDA-approved for the treatment of psoriasis, and shows promise as an AUD pharmacotherapy. In mice, apremilast reduced alcohol intake and preference, but did not alter sucrose preference, indicating its beneficial effects may be alcohol-specific [23]. Apremilast may impact alcohol consumption by increasing the aversive properties of alcohol, including decreasing functional tolerance to alcohol and increasing its sedative effects [23]. Apremilast was recently tested in five animal models of AUD, where it was found to reduce binge-like alcohol intake, motivation for alcohol, and stress-induced alcohol drinking [57]. Moreover, a proof-of-concept, double-blind, human laboratory study of apremilast (90 mg) in non-treatment-seeking individuals with AUD found that apremilast reduced the number of drinks participants consumed each day during the 11-day treatment period relative to placebo [57]. There were no serious adverse events in the proof-of-concept trial but adverse drug effects, including gastrointestinal symptoms were twice as likely in the apremilast group than placebo [57]. A 2-week clinical trial of apremilast (50 mg, b.i.d.) in non-treatment-seeking individuals with AUD (NCT03175549) has been completed, but results have yet to be posted.

Roflumilast

Roflumilast is a second-generation PDE4 inhibitor, with a potentially more favorable side effect profile than first-generation PDE4 inhibitors. Roflumilast is already FDA-approved for treatment of chronic obstructive pulmonary disease. In rodents, roflumilast dose-dependently reduced alcohol intake and preference in two separate mouse models [58]. Roflumilast did not impact sucrose or quinine drinking, indicating that it does not alter preference for natural rewards nor act through aversive mechanisms. However, at the highest dose tested, roflumilast decreased locomotor activity [58]. There have been no translational studies of roflumilast in clinical samples with an AUD, nor are there any ongoing clinical trials of roflumilast.

Fenofibrate

Peroxisome proliferator-activated receptors (PPARs) are transcription factors and members of the nuclear hormone receptor superfamily, whose actions can reduce proinflammatory immune signaling and regulate other physiological and cellular processes. PPAR agonists have been tested for their potential role in addiction processes as well as other CNS diseases. Fenofibrate, a PPARα agonist, shows promise preclinically as a pharmacotherapy for AUD. In both chronic voluntary and limited-access binge drinking mouse models, fenofibrate reduced alcohol intake and preference [59]. In chronic-drinking rats, fenofibrate markedly reduced voluntary alcohol intake [60, 61], but also reduced saccharin intake, indicating that fenofibrate may alter the rewarding effects of both alcohol and non-alcohol rewards. Additionally in rats, fenofibrate treatment had dose-dependent effects on self-administration and reduced both the reinforcing and motivational effects of alcohol [62]. This compound's mechanism of actions may be partially related to its effects on genes involved in energy metabolism, as fenofibrate administration was shown to increase levels of blood acetaldehyde [60], which is an aversive reaction similar to the effects of disulfiram, an FDA-approved medication for AUD. A clinical trial of fenofibrate for AUD was recently completed (NCT02158273) but trial results have yet to be published for the primary outcome of alcohol craving or secondary outcome of drinking reduction. Of note, initial trial reporting indicates that no serious adverse events occurred, suggesting that this medication was safe and well-tolerated.

Pioglitazone

The PPARγ agonist, pioglitazone, has been tested extensively in animal models of AUD. In rats, pioglitazone reduced voluntary drinking, motivation for alcohol as assessed via lever pressing, and reinstatement of alcohol-seeking behavior, but did not prevent cue-induced relapse [63]. Changes in alcohol-drinking behavior were not associated with changes in alcohol metabolism or blood

glucose levels, suggesting that these effects were not metabolic [63]. A follow-up study in rats combined pioglitazone with naltrexone, an FDA-approved pharmacotherapy for AUD, and found larger reductions in alcohol drinking with this combined medication administration [64]. These findings highlight the potential enhanced benefit of combining novel neuroimmune compounds with existing, approved medications to treat AUD. Rat models indicate that pioglitazone may furthermore have anxiolytic and neuroprotective properties as it prevented stress-induced reinstatement of alcohol seeking [65] and protected against binge alcohol-induced neuronal and cognitive damage [66]. In humans, a randomized clinical trial of pioglitazone (NCT01631630) resulted in early termination due concerns over myopathy risk in the active treatment group [67] and another trial was terminated early due to the COVID-19 pandemic (NCT03860753). At present, one human clinical trial of pioglitazone for AUD (45 mg) is ongoing (NCT03864146) and another human laboratory trial, which will examine the effect of pioglitazone (45 mg) on stress-induced relapse and drinking in the natural environment is posted but not yet recruiting (NCT05107765). Promisingly, a recent analysis of data from the Veterans Health Administration found that individuals who were prescribed pioglitazone for diabetes and were also heavy drinkers showed reduced alcohol intake after receiving the pharmacotherapy [68].

Oleoylethanolamide

Oleoylethanolamide (OEA) is a bioactive lipid mediator and member of the acylethanolamide family. OEA is a known satiety factor that has demonstrated strong anti-inflammatory and antioxidant effects, potentially mediated through activation of PPARα with protective actions in both the intestinal tract and CNS [69]. In rat and mouse models, OEA reduced operant alcohol self-administration, prevented cue-induced and withdrawal-induced reinstatement of alcohol-seeking, and reduced withdrawal severity [69]. In rats exposed to intragastric binge alcohol, administration of OEA blocked the expression of TLR4 in the frontal cortex and inhibited alcohol-induced NF-kB proinflammatory cascade, resulting in reduced proinflammatory marker levels, such as IL-1β, TNF-α, and COX-2 [70], providing support for a neuroimmune mechanism of action for OEA. In the same study, OEA pre-treatment provided antidepressant-like effects during acute alcohol withdrawal [70]. A clinical trial for a dietary supplement containing the precursor of OEA in young adult heavy drinkers was completed (NCT01902069) [71]. Treatment with the precursor supplement significantly improved performance on a Go/No-Go task of inhibition, which was correlated with reductions in alcohol intake [71]. However, larger clinical trials enrolling samples with AUD are needed to evaluate this compound's efficacy in regard to drinking outcomes.

Minocycline

Minocycline is a broad-spectrum antibiotic that crosses the BBB. Minocycline is a microglial attenuator, which has been shown to alter neuroimmune and cytokine expression in the brain and periphery [72]. Support for minocycline as a pharmacotherapy for AUD has been mixed. In male and female mice, minocycline modestly reduced voluntary alcohol intake [73]. Minocycline has also been shown to modulate a host of AUD-related behaviors including reductions in alcohol-induced sedation, withdrawal-induced anxiety, alcohol-induced reinstatement, and alcohol-induced cognitive disturbances and neurodegeneration [74–76]. However, minocycline's effects may be non-specific, as it reduced both alcohol and water consumption in mice [77]. In humans, a completed clinical study found that short-term treatment of minocycline was well-tolerated but no beneficial effects on subjective response to alcohol, alcohol craving, nor peripheral proinflammatory markers (e.g., serum cytokine levels) were found among heavy drinkers [78]. At present, a randomized, double-blind placebo-controlled trial of minocycline is underway; this trial aims to evaluate the effect of minocycline (200 mg) on cue-induced alcohol craving, alcohol consumption, neurocognitive impairment, and neuroinflammation—as assessed via multimodal neuroimaging—in non-treatment-seeking individuals with AUD (NCT04210713).

N-acetylcysteine

N-acetylcysteine (NAC), an over-the-counter dietary supplement, is an antioxidant precursor to glutathione that is approved for treatment of acetaminophen poisoning [79]. NAC has been shown to reduce proinflammatory cytokines in rodents and humans. In male rat models of AUD, NAC reduced alcohol-seeking, motivation for alcohol, and abstinence-induced alcohol reacquisition [80], but did not prevent cue-primed reinstatement of alcohol-seeking in a separate study [81]. NAC may protect against chronic alcohol-induced neuroinflammation in the rodent frontal cortex and hippocampus, as treatment with NAC prevented increases in proinflammatory cytokines and decreases in anti-inflammatory cytokines in male rats [82]; however, treatment with NAC did not affect serum cytokine levels [82]. Moreover, the co-administration of NAC and aspirin, which is anti-inflammatory, markedly reduced alcohol intake and relapse binge drinking in alcohol-preferring rats to a greater degree than the administration of either NAC or aspirin alone [83]. In humans, a secondary analysis of a clinical trial of NAC as a pharmacotherapy for cannabis use disorder found that NAC treatment reduced alcohol consumption by 30% relative to placebo [84]. However, a small human laboratory study of NAC in individuals with AUD found no effect of NAC on alcohol self-administration or subjective response to alcohol [85]. Despite this negative result, there is clear enthusiasm for NAC, as several clinical trials of NAC are ongoing and will examine the potential efficacy of the supplement in adolescent and adult samples with AUD (e.g., NCT03238300, NCT03216954, NCT04964843, NCT03707951).

Cannabidiol (CBD)

CBD is a non-psychoactive component of the cannabis plant that has received notable attention as a possible therapeutic for many psychiatric disorders, including AUD. While CBD has diverse biological effects, research supports its anti-inflammatory effects with immune signaling actions seen in the periphery and CNS. Anti-inflammatory targets of CBD include PPARγ, COX-2 enzymes and NF-κB, among others [86]. Numerous preclinical studies have tested whether CBD administration can reduce alcohol intake and related harms (see systematic review [87]), and findings consistently support CBD as a candidate pharmacotherapy for AUD. Animal studies have shown that CBD reduces alcohol administration, decreases motivation for alcohol, reduces relapse-like behavior, and improves withdrawal symptoms in animals exposed to chronic alcohol [88–92]. The majority of this research has yet to examine CBD's influence on the immune system, but one study showed that CBD attenuated alcohol-induced increases in liver enzymes, mRNA expression of cytokines TNF-α and IL-1β, and several chemokines [93]. In humans, CBD has been proven to be safe and well-tolerated in a range of clinical samples [94], although translational challenges exist, such as the low bioavailability of oral CBD in humans and potential contraindications for those with liver impairment [87]. A recent naturalistic study found that administration of a predominantly CBD cannabis strain reduced drinking in cannabis and alcohol co-users [95]. Researchers are currently conducting numerous randomized clinical trials of CBD for AUD across adolescent and adult samples (NCT03252756, NCT05159830, NCT05159830, NCT04873453, NCT05317546), as well as comorbid samples (i.e., AUD and PTSD; NCT03248167).

Neuroactive Steroids

Neurosteroids, or endogenous neuroactive steroids, are thought to be involved in neuroimmune signaling in AUD. Neurosteroids have a range of actions, including modulation of $GABA_AR$-mediated neurotransmission, TLR-dependent signaling [96], and CRF signaling, giving these compounds the potential to target the complex symptomatology of AUD [97, 98]. Two neurosteroids, allopregnanolone and pregnenolone, have been investigated in several preclinical studies and have demonstrated promising results [99]. In male mice, allopregnanolone dose-dependently modulated alcohol intake, with low doses increasing and high doses suppressing alcohol intake [100]. In male rats, allopregnanolone dose-dependently modulated alcohol-reinforced operant responding via lever pressing, such that lower doses increased operant responding whereas higher doses decreased response rates [101], indicating that higher doses of allopregnanolone may alter the reinforcing effects of alcohol. In alcohol preferring rats, pregnenolone reduced alcohol intake and preference; however, chronic treatment did not significantly alter intake or

preference [102], thereby limiting enthusiasm for this compound. There have been limited studies of neuroactive steroids in clinical samples. A human laboratory study of dutasteride, a 5-alpha steroid reductase (5AR) inhibitor that limits the production of dihydrotestosterone and the 5a-reduced neuroactive steroids allopregnanolone, pregnanolone and 3a,5a-androstanediol, found that males with heavy drinking patterns reported fewer days of heavy drinking after pretreatment for dutasteride compared to placebo [103]. Dutasteride pretreatment also reduced the subjective sedative effects of alcohol administration in male heavy drinkers [103]. Finally, several randomized clinical trials of neuroactive steroids for the treatment of AUD are ongoing (NCT03872128 [pregnenolone]; NCT02582905 [citicoline and pregnenolone]; NCT04098302 [dutasteride]; NCT04015869 [allopregnanolone]; NCT05223829 [brexanolone]). These trials include important investigations into sex differences as well as effects on alcohol intake, withdrawal, stress reactivity, and mood symptoms. Future trials will also test the benefit of neurosteroids on treating comorbid conditions, including PTSD and AUD, and bipolar disorder and AUD.

Mindfulness-Based Relapse Prevention

Mindfulness-based relapse prevention (MBRP) is a mind-body therapy designed for individuals with addiction. MBRP is delivered in 2-h group sessions aimed to cultivate increased awareness of present-moment cognitive, emotional, and physical states, especially as they relate to cravings and withdrawal [104]. The anti-inflammatory effects of mind-body therapies have been explored in other psychiatric and neurological conditions, but limited research has been focused specifically on samples of AUD [105]. It is hypothesized that these therapies work to reduce inflammation by impacting downstream stress reactivity pathways, thereby reversing the activation of proinflammatory mechanisms [106]. While there has only been a small number of randomized trials of MBRP conducted in the context of AUD, there is evidence that MBRP may be most effective for individuals with severe AUD or comorbid mood symptomatology [107], which is supported by the wide-body of literature linking depression and inflammation [108]. One trial examined the impact of MBRP on peripheral proinflammatory marker levels in adults with AUD and found that greater time spent practicing mindfulness predicted lower levels of circulating IL-6. This suggests that regular mindfulness practice may reduce peripheral proinflammatory marker levels [105]. One clinical trial of MRBP has recently been completed, although results have yet to be published (NCT02994043). The results of this study will extend this area of research by exploring immunological, epigenetic, and neurobiological changes associated with 8 weeks of MBRP in AUD. Additional trials will seek to further test MBRP efficacy as a treatment for AUD, but do not include explorations of potential anti-inflammatory mechanisms of this treatment (NCT03842670; NCT0214783).

Treatment Development Recommendations

These efforts to elucidate the role of the immune system in the development and maintenance of AUD have contributed to a host of potential novel treatments, both pharmacological and psychosocial [34]. Research establishing immune signaling as a novel treatment target supports interventions that reduce (neuro)inflammation and alter aberrant immune processes as plausible candidates for AUD medications development. Findings in this area of research represent an exciting development and illustrate the desired progression from basic discoveries to tangible improvements in healthcare [10, 13, 56, 57, 73, 103]. Yet, careful consideration of optimal approaches to treatment development is necessary, as medications development for AUD is known to be costly and time-consuming and has produced limited success over the past several decades [109, 110]. The following recommendations are offered to enhance the efficiency of developing neuroimmune modulators for AUD.

To start, novel immune targets and compounds may signify novel biobehavioral mechanisms of action. It is possible that certain established pharmacological mechanisms of action, which are often examined through experimental human laboratory designs to inform decisions about novel medications, may not effectively capture the clinical effects of neuroimmune modulators for addiction. For instance, research has demonstrated that not all effective medications for AUD alter the sedative properties of alcohol or reduce alcohol cue-induced craving, such as was shown in a trial of varenicline [111]. We recommend considering novel mechanisms informed by the application of neuroimmune modulators in psychiatry [112–114] as well as novel hypotheses informed by preclinical and clinical studies of neuroimmune function and behavior in AUD. Therefore, screening methods specific to these compounds' targets, such as neurocognition, stress-reactivity, gut microbiota, or immune biomarkers will help capture these potentially unique mechanisms of change.

Second, establishing the relationship between any novel treatment and drinking outcomes is critical. While elucidating mechanisms of action and moderators of treatment response remains a high priority area, enthusiasm and support for treatment development hinges on the demonstration of a "main effect" of an intervention on drinking outcomes in clinical samples of AUD. Reductions in drinking that translate into improved health and social function are the "meaningful clinical benefit" that regulators require for approval of a new drug application (NDA), or a new indication (NI) for a medicinal product with current marketing approval on another indication. As discussed in detail elsewhere [110], the utility of screening models for medications development for AUD hinges on the relationship between the screening paradigm and the regulatory standard outcome of drinking reduction. To that end, we recommend that screening models be selected to optimize translational potential for clinical trials outcomes, which will ultimately determine the fate of the novel treatment and its approval and uptake in clinical settings.

In addition, as we learn from the application of neuroimmune (dys)function and psychiatric disorders, including AUD, we refine our understanding of clinical

profiles of treatment responders to neuroimmune modulators. The literature on MDD discusses persuasive evidence that immune mechanisms contribute to the pathology of MDD in subpopulations of patients [115]. Individuals with a proinflammatory profile of MDD may have unique clinical features that are resistant to typical treatments, such as elevations in peripheral biomarkers of proinflammatory activity and sickness behavior [108]. It is plausible to hypothesize that certain clinical presentations of AUD may similarly represent a higher contribution of neuroimmune dysfunction. Characterizing the unique clinical profile of individuals with AUD for whom immune dysfunction is most salient has great potential to maximize the benefits of neuroimmune treatments in clinical settings through precision medicine principles. In line with this, the application of insights from basic and clinical research in this area may elucidate treatment-responsive biomarkers. For example, peripheral markers of inflammation, such as C-reactive protein (CRP) are widely used in clinical settings for a range of diseases and inflammatory conditions. This presents an opportunity to leverage well-established resources in clinical care to identify individuals with AUD for whom rescuing healthy neuroimmune function may be most beneficial. For example, individuals with AUD and clinical elevations in markers such as CRP, IL-6, or TNF-α may be fitting candidates for treatment with neuroimmune modulators. Notably, however, these elevations will likely be less pronounced than inflammation caused by certain inflammatory health conditions (e.g., bacterial infection) and will require the use of highly sensitive assays, such as high-sensitivity CRP (hs-CRP). These tests can detect slight increases that still fall within the normal range of standard CRP values, such as is often used to detect one's risk for developing coronary artery disease. Improvements in neuroimmune function (i.e., return of CRP levels to normal range or decreases of CRP within that range) may thus be associated with improvements in alcohol consumption and recovery from AUD. Preliminary work from our laboratory supports the utility of identifying elevations in CRP as an indicator of beneficial response to ibudilast treatment, but much more work on this topic is needed; other biomarkers may prove more sensitive or specific to inflammation in individuals with AUD. In summary, biomarker development is a long-awaited step forward in AUD treatment, and neuroimmune and AUD literature provides several avenues for clinical translation and biomarker development.

Conclusions

This chapter broadly covers the field's progress in characterizing brain-immune mechanisms in AUD from basic to clinical research. Alcohol is believed to alter immune signaling and contribute to neuroinflammation through various pathways, including by initiating systemic production of proinflammatory cytokines and inducing neural damage. While preclinical models provide strong support for the neuroimmune hypothesis of AUD, more work is needed to adequately establish these mechanisms in human clinical samples. For instance, much remains unknown

regarding the relevance of specific immune signaling mechanisms and their causal links to AUD symptomatology and recovery in human samples. In addition, we reviewed translational work seeking to ultimately support individuals' recovery from AUD, testing the biological and clinical plausibility of treatments that target peripheral immune and neuroimmune dysfunction. Despite the alcohol research field's strong focus on medications development over the past several decades, a paucity of new pharmacotherapies has demonstrated robust efficacy or received FDA approval. This highlights the necessity of developing and testing novel treatments for AUD with novel mechanisms, such as the immune system. We covered the limited number of randomized clinical trials of immune treatments for AUD that have been conducted to date but noted numerous ongoing clinical trials that may support the safe and effective clinical application of immune treatments for AUD and perhaps psychiatric disorders more broadly. Finally, recommendations for treatment development are provided, such as attempting to identify individuals who are most treatment-responsive, considering potentially novel mechanisms of actions for compounds, and in turn, assessing these through experimental laboratory screening methods and collection of relevant biomarkers in clinical samples of AUD.

Chapter 31
Brain Alterations and Cognitive Deficits Induced by Alcohol Use Disorder

Mickael Naassila

Abstract Chronic alcohol use, either in the context of repeated binge drinking behavior or alcohol use disorder, induces brain and cognitive alterations. These brain and cognitive alterations can be reversible and a recovery, at least partial, is seen in general after weeks or months of abstinence. Cognitive deficits are highly frequent in patients with alcohol use disorder and are largely under-diagnosed and under-treated as for example for the Gayet-Wernicke encephalopathy that could be easily treated and or prevented (if suspected) by thiamine treatment. Cognitive deficits have an impact on the treatment and should be well identified and targeted in order to improve care of patients and increase the success rate in maintaining long term abstinence or reduced alcohol intake.

Keywords Binge drinking · Alcohol use disorder · Brain · Alterations · Neurotoxicity · Cognitive deficits · Gayet-Wernicke encephalopathy · Korsakoff syndrome

Effects of Acute Consumption

The ethanol contained in alcoholic beverages is rapidly absorbed from the gastrointestinal tract and the peak blood-alcohol concentration (BAC) is usually reached after 10 to 60 min. Ethanol reaches the brain very easily and since the brain has a high rate of blood flow per gram tissue, it rapidly equilibrates with the concentration of ethanol in the arterial blood. Ethanol depresses brain activity in a dose-dependent manner. At low BAC, about 0.3–0.5 g/L, ethanol has disinhibiting effect associated with a mild euphoria. Between 0.5–1.0 g/L, impairments such as slurred speech, slow reaction time, difficulty in information processing, sedation and ataxia are

observed. From 2 g/L BAC, emesis and stupor are obvious and at 3 g/L, a coma can occur. Around 4 g/L, respiratory depression and death are possible, even at lower levels, death can occur with asphyxia from inhalation of vomit. Alcohol drinking has a biphasic effect with both positive (pleasure, euphoria) and negative (sedation, ataxia, memory and attention deficits) effects. Alcohol affects brain function from the first drink and GABA type A receptors appear to be particularly sensitive to the effects of alcohol. From the first drink, and an alcohol level of only 3 mM, the activity of GABA type A receptors containing the delta subunit, which are preferentially located on the extra synaptic side, is modified [1].

As other drugs of abuse, acute alcohol intake activates brain reward system, thus inducing pleasant effects [2]. Rewarding effects increase the probability to repeat alcohol drinking also called positive reinforcement. Reward is mediated by dopamine release in the ventral part of striatum, the nucleus accumbens. Dopamine is released by neurons from the ventral tegmental area and the effect of alcohol on dopamine release is mediated by different mechanisms. Alcohol targets directly the dopamine neurons and increases their firing rate. Alcohol also increases dopaminergic neuron activity by their disinhibition through the inhibition of GABAergic neurons either directly or through the release of β-endorphin by opioidergic neurons.

Acute alcohol intake, particularly if consumed rapidly, has also memory impairing effects, the so-called blackouts. Blackouts are episodes of amnesia, during which subjects continue to interact with others during the event but that they later cannot remember [3].

Effects of Binge Drinking on Brain and Cognition

Definition of Binge Drinking

Excessive alcohol intake (e.g., heavy or hazardous drinking) has massive physiological, psychological and cerebral consequences [4]. Binge drinking is a specific consumption pattern that has raised as a major research topic due to its ubiquity and widespread effects [5]. Binge drinking behavior is characterized by excessive (i.e., leading to drunkenness) but episodic alcohol consumption [6, 7]. Recently, an operational definition of binge drinking behavior has been proposed with six specific characteristics including the presence of physiological symptoms related to binge drinking episodes, the presence of psychological symptoms related to binge drinking episodes, the ratio of binge drinking episodes compared to all alcohol drinking occasions, the frequency of binge drinking episodes, the consumption speed, and the alternation between binge drinking episodes and soberness periods [8]. Among adolescent drinkers, alcohol-related blackouts, or acute alcohol-related memory loss, may occur after consuming ≥12 drinks (126 g) per occasion for males and ≥ 7 drinks (70 g) for females [9].

The repetition of such drunkenness episodes results in an alternation between intense alcohol intoxications and abstinence periods, constituting a specific pattern of alcohol intake. Binge drinking behavior is the most prevalent alcohol-related behavior among youth in Western countries [10], 40% of young adults reporting at least one binge drinking episode per month during the last 6 months. Converging data have demonstrated the rapid and long-lasting psychological and cerebral consequences of binge drinking behavior [11]. The specific neurotoxicity of this behavior results from the repetition of intoxication-abstinence cycles, leading to multiple withdrawals that are particularly harmful for the brain. This even led to the "continuum hypothesis" suggesting that binge drinking pattern might constitute the first step towards severe alcohol use disorder (AUD): neurocognitive impairments would initiate the addictive vicious circle by reducing inhibitory abilities and increasing automatic attraction towards alcohol [12]. A recent study has suggested that frequent (more than twice a month) binge drinking behavior (≥5 drinks (50 g ethanol) for male and ≥ 4 (40 g ethanol) for female students) during adolescence (18–25 years) is predictive of AUD at adulthood (25–45 years, adjusted OR = 2.83, 95% CI 1.10 to 7.25) [13]. The increased vulnerability to AUD at adulthood after repeated exposure to binge drinking episodes during adolescence has also been demonstrated in animal models [14].

Effects of Binge Drinking on Memory

During adolescence, binge drinking can be harmful to the brain, as it may interfere with ongoing maturation of its neuronal circuits. Several studies have suggested that binge drinking may have neurotoxic effect through the induction of neuroinflammation that damages both white and grey matters and loss of hippocampal neurogenesis [15]. Animal models have demonstrated that both hippocampal synaptic plasticity and memory impairments induced by binge drinking episodes are prevented by an anti-inflammatory treatment [16]. Compared with social drinkers, binge drinkers display reduced white matter integrity and performance in spatial working memory [17]. Binge drinkers also display altered verbal memory due to low proficiency in encoding, storage and retrieval processes that are impacted by consumption speed and intoxication episodes [18]. In the latter study, binge drinkers displayed the following characteristics (versus social drinkers; data are given as mean ± SD (min–max)): Consumption speed (drinks/hour) 2.83 ± 0.78 (2–5) versus 1.52 ± 0.71 (0.5–3), Episodes of intoxication in previous 6 months 16.65 ± 10.77 (6–50) versus 1.22 ± 1.44 (0–4), Percentage of times drinking to intoxication 56.52 ± 19.68 (10–90) versus 12.61 ± 12.87 (0–50) and Alcohol units per week 17.35 ± 14.91 (3–63) versus 5.14 ± 4.66 (1–20) [18].

Effects of Binge Drinking on Decision Making and Emotion Processing

In addition to learning and memory impairments, binge drinking behavior is also associated with dysfunctions in decision making, executive functioning and in affective processing [6, 19–21]. Previous study suggested that binge drinking would induce brain alterations in amygdala and prefrontal cortex, leading to comparable cognitive and affective impairments than AUD [22]. Difficulties to process emotional contents are associated with behavioral deficits in binge drinkers who display poorer performance for the identification of anger and fear affective bursts and for the recognition of fear and sadness facial expressions [20, 23]. When binge drinkers have to identify affective bursts, results show lower activations in the bilateral superior temporal gyrus together with increased activations of the right middle frontal gyrus [23]. Beyond emotional identification, binge drinkers presented differential brain responses following the implicit processing of emotions and the emotional difficulties in binge drinking might be related to a more automatic/unconscious processing of emotions [21]. Difficulties in emotion processing observed in binge drinkers, as also observed in patients with AUD, may have important implication by underlining emotional processes as a potential target to prevent the appearance of problematic alcohol use [21].

Effects of Binge Drinking on Brain Structure and Functioning

Numerous studies suggested that binge drinking during adolescence is associated with various regions of lower cortical, subcortical, and cerebellar grey-matter volume; however, studies have also suggested greater volumes in other brain regions in control subjects. A follow-up study that investigated gray-matter volumes in adolescent binge drinkers at baseline and during multiple follow-ups found that binge drinkers displayed greater reductions in overall neocortex volume, as well as in frontal, lateral frontal, and temporal cortex volumes [24]. The number of binge drinking episodes in the past year was negatively associated with frontal and parietal cortex thickness and adolescent binge drinkers also displayed thinner total, frontal, temporal, and cingulate cortices than nondrinkers [25]. Longitudinal studies have demonstrated reduction in white-matter volumes both before and following initiation of binge drinking [24, 26]. Binge drinking has been linked with degradations in neural white matter and that compromised white matter at this period of brain development has also been linked with impaired cognitive functioning [17].

A single binge drinking episode may be particularly harmful for the brain and may have long-lasting effects. For example, a prospective study showed a single night of extreme drinking (21st birthday celebration) is enough to immediately alter brain structure, revealing changes to the corpus callosum that remain at least 5 weeks following the drinking episode [27]. A single injection of ethanol in

adolescent baboons, reaching in blood ethanol levels of 0.8 g/L, showed an increase in inflammatory response both acutely and even 7 months after the binge drinking episode [28]. The persistent effect suggested a 'priming' of glial cell function after initial alcohol exposure.

Similarities Between the Effects of Binge Drinking and AUD

As for emotional processing deficits seen in both binge drinkers and patients with AUD, the electroencephalographic (EEG) profile of binge drinkers and alcohol-dependent individuals displays similarities [29]. Young binge drinkers seem to display a similar profile as that of subjects with AUD during resting state and visualization of alcohol-related pictures. The representation of the brain overactivation observed in binge drinkers during some cognitive tasks accompanied by a satisfactory level of performance is presumably related to a neurocompensatory mechanism [29].

Overall, brain and cognitive alterations described by a large number of studies support the *continuum* hypothesis suggesting that binge drinking and AUD may share several common features [29]. To date, the literature does not support a greater vulnerability of females to the effects of binge drinking.

Only very few studies have investigated potential brain recovery after reducing or stopping binge drinking behavior. One study demonstrated that abandoning the binge drinking behavior for 6 years may lead to partial recovery of working memory deficits, particularly perseverations and low working memory span in demanding trials [30]. Another study revealed a recovery in problem solving impairment in young binge drinkers after 4 weeks of abstinence, regarding tests of prospective memory, cognitive switching, inhibition task accuracy, verbal memory, visuospatial construction, and language and achievement [31].

Effects of Chronic Alcohol Intake on Brain

Chronic alcohol intake is known for inducing brain alterations even at moderate levels of intake. For example, a study on a longitudinal cohort of 550 men with AUD, demonstrated that higher alcohol consumption over the 30 year follow-up was associated with increased odds of hippocampal atrophy in a dose dependent fashion [4]. While those consuming over 280 g ethanol a week were at the highest risk compared with abstainers (odds ratio 5.8, 95% confidence interval 1.8 to 18.6; $p \leq 0.001$), even those drinking moderately (112–168 g ethanol/week) had three times the odds of right sided hippocampal atrophy (3.4, 1.4 to 8.1; $p = 0.007$). There was no protective effect of light drinking (8 ≤ 56 g ethanol/week) over abstinence. Higher alcohol use was also associated with differences in corpus callosum microstructure and faster decline in lexical fluency [4].

Patients with AUD display variable brain alterations and variable cognitive deficits. More than 50% to 80% of patients with AUD display cognitive deficits thus suggesting that they are largely under-diagnosed. The most frequent ones are: (i) temporo-spatial orientation (disorientation in time and/or space), (ii) memory (difficulty in retrieving old memories, (iii) difficulty in learning new things), (iv) reasoning (problem solving, mental planning difficulties, mental rigidity, etc.), (v) visual-constructive praxis (difficulty in drawing, structuring space).

Among the risk factors for brain and cognitive alterations in AUD there are the following ones: (i) younger age or older age (>60 years), (ii) women, (iii) hepatic damages, (iv) psychiatric comorbidity, (v) low educational level and (vi) positive history of fetal alcohol syndrome.

Structural magnetic resonance imaging studies of patients with AUD highlighted reduction in the volume of both grey matter and white matter in the cerebral cortex with greater loss in the frontal lobes, the hippocampus, the mamillary bodies, the thalamus and the cerebellar cortex. Studies have also showed thinning of the corpus callosum and the pons, reduced volume of the cerebellar vermis. The different studies that investigated difference between men and women yielded controversial results and so far, the findings suggesting that women would be more vulnerable to alcohol-induced brain damage have not been confirmed.

Alcoholic Dementia

Dementia is a clinical syndrome characterized by a progressive deterioration in cognitive ability and the capacity for independent living and functioning.

Alcoholic dementia could be characterized with the following criteria: (i) multiple cognitive impairments, (ii) decline from previous state, (iii) chronic alcohol use >5 years, 28 to 35 drinks per week, (iv) cognitive deficit persisting 60 days after withdrawal, (v) no vascular factors on brain imaging, (vi) signs of alcohol-induced somatic damage, and (vii) progressive evolution over time without being able to date the onset of the disorder (different from Gayet-Wernicke).

Dementia affects memory, thinking, behavior, and the ability to perform everyday activities, and is a leading cause of disability in older individuals. Although causality has not be established, light to moderate alcohol intake in middle to late adulthood has been associated with a decreased risk of cognitive impairment and dementia; however, heavy alcohol intake has been associated with changes in brain structures, cognitive impairments, and an increased risk of all types of dementia [32]. A recent study suggested that AUD is a major risk factor for onset of all types of dementia, and especially early-onset dementia [33].

About 80% of patients with AUD present cognitive deficits [34] and a standardized cognitive evaluation carried out in detoxified patients in care in the French health system showed that more than half of the patients in an addiction service display cognitive dysfunctions [35]. The most frequent disorders are impairments of executive functions, episodic memory and visuospatial construction abilities. They

are often referred to as moderate because they are about one standard deviation below the mean of control subjects regardless of the neuropsychological domain considered [36]. However, these average results conceal a great heterogeneity of impairments which may be absent in some patients, mild to moderate in others and severe in still others.

There is a lot of evidence to show the effects of AUD on executive functions. The body of research suggests global executive dysfunction, affecting the abilities to rank, strategize, be mentally flexible, inhibit, reason, update and plan [37]. Decision making has also been shown to be impaired in patients with AUD who tend to engage in risky behavior by not considering the future consequences of their actions [38].

Studies on episodic memory in AUD have concluded that there is an alteration in long-term memory learning capacities even though some results show contrary results or reveal performance only one standard deviation below the mean of control subjects [36]. The authors suggested that the apparent contradiction could be explained by (1) the heterogeneity of the tasks used, (2) the intrinsic heterogeneity of the clinical population and (3) the great variability of the clinical characteristics of the AUD patients included in the studies (duration of abstinence, history of alcohol use). Between 2 weeks and 2 months of abstinence, patients with AUD would present episodic memory disorders which would be difficult to detect with classical tests but observable with more elaborate tests [39]. Patients with AUD and recently detoxified display an alteration of all components of episodic memory (encoding, retrieval, contextual memory and autonoetic awareness) but preserved storage abilities [40]. The authors suggested the existence of a real impairment of episodic memory in patients with AUD, not linked to executive dysfunction, and well before the development of a Korsakoff syndrome [40]. Patients with AUD are able to learn new complex informations despite impairments in episodic memory and executive function [41]. Patients with AUD use learning strategies that are cognitively more costly than those used by control subjects [41]. The neuropsychological disorders of patients can also have a deleterious impact on their ability to associate essential information in daily life such as names and faces. One study has showed that the learning deficit of name-face associations in patients with AUD would reflect a more general dysfunction of long-term memory capacities [42]. These difficulties in acquiring new complex cognitions evidenced in patients with AUD following withdrawal require consideration during care. Indeed, a number of patients may be cognitively unable to take full advantage of proposed treatments to promote maintenance of abstinence, thereby increasing the risk of relapse [43]. Patients with cognitive problems could be less attentive during therapeutic workshops, less motivated and more in denial than those with preserved cognitive abilities [43].

Although it is now established that a large proportion of patients with AUD display neuropsychological disorders after withdrawal, the factors explaining the heterogeneity of these disorders remain unknown. Some patients display severe cognitive impairment while others, with the same drinking pattern, present no apparent impairment. Thus, the history of alcohol intake alone does not explain the nature and severity of cognitive dysfunction. The difficulties of patients with AUD

in acquiring new complex information indicate that a lengthening of the treatment (repetition of learning sessions or postponement after a recovery period with abstinence) would be favorable for patients with neuropsychological disorders. Another possibility for adapting the management of patients with cognitive disorders could be the use of cognitive remediation techniques.

Gayet-Wernicke and Korsakoff Syndrome

Definitions and Clinical Characteristics

One of the first clinical descriptions of an amnesic syndrome due to alcohol intoxication was made by Sergei Korsakoff during a conference in Paris in 1889 and the first detailed description was probably published in a paper by Robert Lawson in 1878 [44]. For more details, the reader is also referred to Chap. 72 focusing primarily on the Wernicke-Korsakoff syndrome. The Korsakoff syndrome is the result of a combination of chronic and excessive alcohol consumption and a thiamine (vitamin B1) deficiency. Gayet-Wernicke encephalopathy (GWE) often precedes the severe and long-lasting amnesia characteristic of Korsakoff syndrome, but this syndrome can also have an insidious onset. Patients with Korsakoff syndrome present neuropsychological disorders and equivalent brain damage whether they have Gayet-Wernicke encephalopathy or an insidious onset, suggesting that it is the same pathology regardless of the mode of entry into the disease. Gayet-Wernicke encephalopathy, related to thiamine deficiency, is largely underestimated in patients with AUD [45] who are nevertheless at high risk for this neurological complication [46].

The prevalence reported in the literature is 1% to 2% in the general population and 12% to 14% in the population of subjects with AUD [47]. However, this prevalence would be underestimated because of the difficulty in identifying GWE or Korsakoff syndrome during the patient's lifetime [48].

Clinically, Korsakoff syndrome is classically described as an amnestic syndrome comprising massive anterograde amnesia and retrograde amnesia of varying amplitude. Working memory and executive function disorders are sometimes associated. Confabulations, which are also part of the classic clinical picture, are mostly present early in the disease, during or just after GWE. False recognitions, erroneous identifications of persons or places, are also very frequent at the beginning of the disease but tend to disappear quite quickly, just like confabulations. Finally, anosognosia is frequent in Korsakoff syndrome. It refers to the patient's lack of knowledge of his or her disease or condition. In the DSM-5 classification, Korsakoff syndrome would be coded as "major alcohol-related neurocognitive disorder, confabulatory amnesia". The term "with moderate or severe use disorder" could be added. The DSM-5 also specifies that the term "persistent" should be used when the disorder does not recover with a period of abstinence. The ICD 10 describes this condition as a syndrome dominated by the presence of chronic memory disorders (recent and old events). Short-term memory is usually preserved and recent memory is more

severely disturbed than the memory of old events. Obvious disturbances in the perception of time and the chronology of events, as well as difficulties in learning new knowledge also characterize this syndrome. The syndrome may involve intense fabulation. Other cognitive functions are usually relatively unaffected, and memory problems are disproportionate to other disturbances. In contrast to the DSM, the ICD specifies that it is "Korsakoff's syndrome induced by alcohol or other psychoactive substances or unspecified".

Korsakoff syndrome is primarily a permanent amnesic syndrome. In contrast to patients with AUD, the episodic memory disorders of patients with Korsakoff syndrome are not reversible. In addition to amnesia, patients with Korsakoff syndrome have impairments of working memory and executive functions. Like patients with AUD, they may have impaired intellectual and visuospatial abilities. Impaired working memory and executive functions are not specific to patients with Korsakoff syndrome and therefore do not differentiate between patients with AUD from those with Korsakoff syndrome [49]. The severe episodic memory deficits of patients with Korsakoff syndrome seem to hamper their ability to acquire new complex knowledge, whether semantic or procedural [50]. The executive disorders of patients with Korsakoff syndrome, equivalent to those of patients with AUD, seem to contribute little to their learning difficulties.

Brain Alterations

Regarding structural brain alterations in patients with Korsakoff syndrome, post-mortem studies have generally reported damage to the medial temporal lobe, the mammillary bodies and the anterior or dorsomedial nuclei of the thalamus [44]. Alterations of the white matter of patients with Korsakoff syndrome have been shown post-mortem, particularly at the hippocampal and prefrontal levels. The damage to the white matter could even partly explain the volumetric cerebral alterations in patients with Korsakoff syndrome. Studies using magnetic resonance imaging have confirmed both cortical and subcortical structural alterations in patients with Korsakoff syndrome. *In vivo* imaging studies also reveal a decrease in the volume of the medial temporal lobe and more specifically the hippocampus. The atrophy would also concern the thalamus, the mammillary bodies and the frontal lobes. In 2009, one study showed a graded effect of structural damage ranging from mild to moderate damage in patients with AUD to severe damage in patients with Korsakoff syndrome in the mammillary bodies, hippocampus, thalamus, cerebellum and pons [51]. Significant structural and metabolic damage have been shown in patients with Korsakoff syndrome, particularly in the Papez circuit and the fronto-cerebellar circuit. The dysfunction of these two circuits is consistent with the neuropsychological profile of patients with Korsakoff syndrome, which combines severe amnesia, working memory disorders and ataxia [44].

Postmortem studies in patients with AUD have shown reduced brain weights compared with controls, as well as ventricular dilation [52]. Overall, neuropathological studies indicate atrophy of the frontal and cerebellar cortex. However,

quantification of neuron number only showed neuronal loss in certain regions of the frontal cortex, but not in the hippocampus, mammillary bodies, thalamic nuclei. The alteration in brain volume is thought to be primarily related to white matter impairment, as well as possible associated thiamine deficiency and liver disease [52]. *In vivo* neuroimaging studies have described a reduction in gray matter volume in patients with AUD compared to control subjects particularly in the frontal and more specifically dorsolateral cortex, hippocampus, thalamus, mammillary bodies, caudate nucleus and putamen, and cerebellum. Fluorodeoxyglucose positron emission tomography imaging studies reported a decrease in cerebral glucose consumption in the whole brain [53], in some regions up to 20%. Hypometabolism has been found particularly in the parietal and frontal cortex [53] and in the cingulate cortex. Functional brain imaging studies of brain activity and functional connectivity in patients with AUD have suggested brain reorganization with, for example, recruitment of different brain networks, greater activation of certain regions and recruitment of more regions [54]. Even in the absence of significant macrostructural damage, patients with AUD appear to involve different regions than controls in certain cognitive tasks [54]. Most of studies that investigated potential brain recovery in patients with AUD have investigated the effect of abstinence. Many studies have globally shown a cerebral recovery after abstinence but it is difficult to compare them because of their differences in the duration of the follow-up (from a few weeks to several years) or their definition of abstinence (total abstinence or certain level of consumption). Longitudinal studies have reported an improvement in ventricular dilation in the cortical level and more particularly in the temporal, cingulate and insula as well as in the amygdala, thalamus, hippocampus and cerebellar cortex. Partial recovery from frontal hypometabolism and hypoperfusion has also been reported after abstinence. Among the explanatory mechanisms of this brain recovery, neurogenesis and the involvement of oligodendrocytes that enable myelin repair and remyelination have been proposed. Very interestingly one study demonstrated that brain recovery in the cerebellum (gray and white matter), striatum, cingulate gyrus, corpus callosum and periventricular white matter was inversely related to the amount of alcohol during the 6 months period of abstinence [55]. In this study brain recovery was not only observed in the case of total abstinence, but could be observed in patients who had drastically reduced their consumption (approximately 120 units (1200 g ethanol) in 6 months, i.e., the equivalent of one glass per day on average).

Mechanisms Involved in Brain Alterations

Two main mechanisms have been proposed to explain the neuronal and cognitive alterations induced by chronic alcohol intake. The first one is the direct neurotoxic effect of ethanol by disturbing the excitatory/inhibitory balance (glutamate/GABA balance) and the deficiency in thiamin (B1 vitamin), see Fig. 31.1.

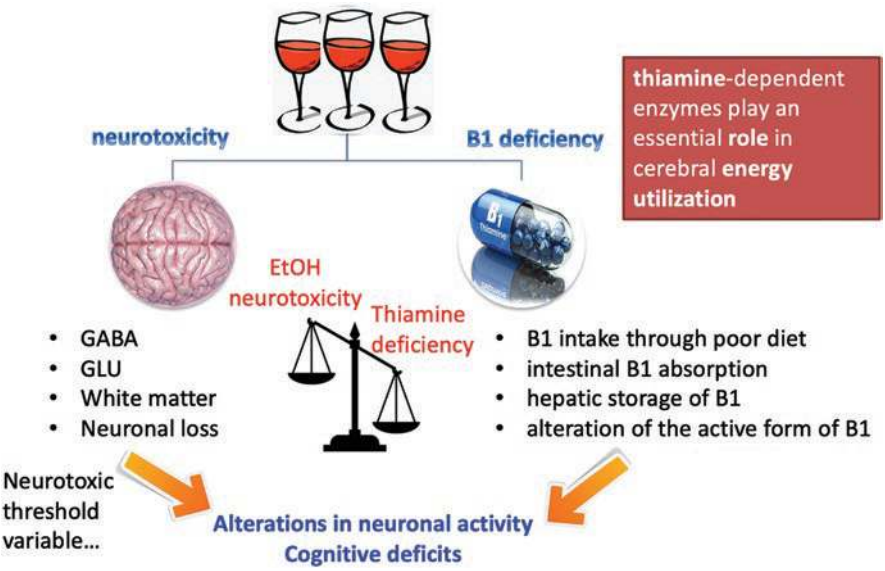

Fig. 31.1 M Naassila. Two main mechanisms have been proposed to explain the neuronal and cognitive alterations induced by chronic alcohol intake. The first one is the direct neurotoxic effect of ethanol by disturbing the excitatory/inhibitory balance (glutamate/GABA balance) and the deficiency in thiamin (B1 vitamin)

Thiamine deficiency is a crucial factor in the etiology of Korsakoff syndrome. Although alcohol abuse is by far the most important context in which thiamine deficiency occurs, there is no convincing evidence for an essential contribution of ethanol neurotoxicity to the development of GWE or to the progression of GWE to Korsakoff syndrome [44].

The frontal cortical damages may be primarily due to the direct toxic effect of ethanol [44] while the damages due to thiamine deficiency may primarily affect the dorsomedial thalamic nuclei, the mammillary bodies, the basal forebrain, the dorsal and median raphe nuclei with floor and walls of the third and fourth ventricles, and the cerebellar vermis [44].

Finally, a continuity (or continuum) hypothesis has been proposed but still a matter of debates [44, 49, 56], see Fig. 31.2. The continuity hypothesis states that cognitive deficits in patients with AUD but with no Korsakoff syndrome and patients with AUD and Korsakoff syndrome lie a long continuum of mild to moderate deficits due to ethanol neurotoxicity [44]. However, this hypothesis does not fit with all clinical situations and has been proposed to become obsolete now [44].

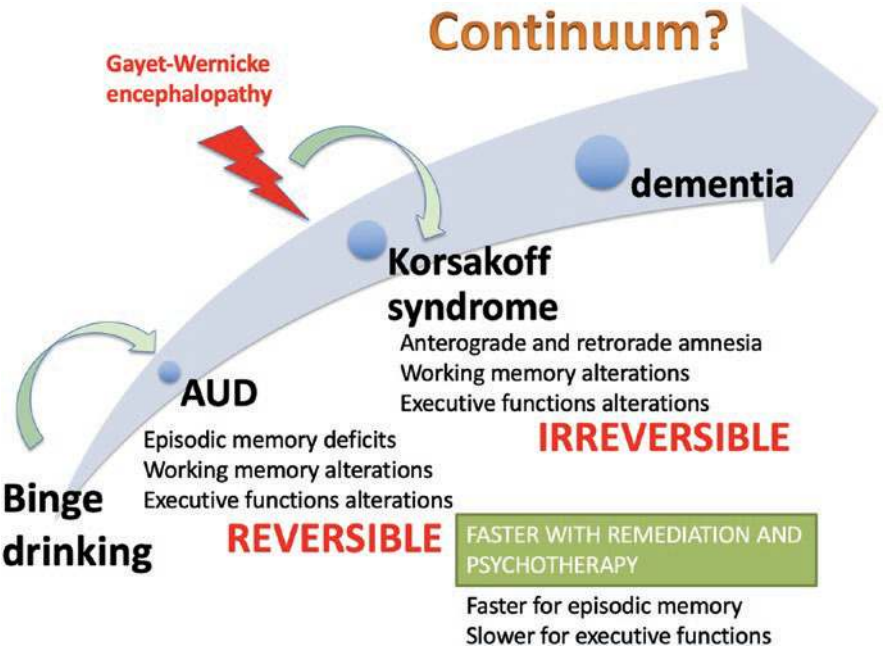

Fig. 31.2 The continuity hypothesis states that cognitive deficits in patients with AUD but with no Korsakoff syndrome and patients with AUD and Korsakoff syndrome lie a long continuum of mild to moderate deficits due to ethanol neurotoxicity. M Naassila

Recovery and Treatments

Some studies have suggested the existence of a subgroup of patients with AUD at risk to develop a Korsakoff syndrome on the basis of clinical signs of GWE, episodic memory performance and volumetric damage to the thalamus [57]. The evolution of the GWE (acute state, life threatening, confusion, incoherence, attentional deficits) has been proposed to be the following: 12% will display minor to no cognitive sequelae, 68% will display the Korsakoff syndrome (chronic state, clear consciousness, coherence) and 20% will die [58].

In patients with established GWE, parenteral thiamine 200–500 mg three times a day should be given for 3–5 days, followed by oral thiamine 250–1000 mg/day [59]. In patients with suspected GWE, parenteral thiamine 250–300 mg should be given two times a day for 3–5 days, followed by oral thiamine 250–300 mg/day [59].

There is currently little or no therapeutic management of patients with Korsakoff syndrome [44]. The priority is to stop drinking and maintain abstinence. No drug treatment is available for these patients once Korsakoff syndrome is established. The best treatment strategy remains prophylaxis with identification of patients with AUD at risk for developing Korsakoff syndrome and treatment with thiamine at the first sign of GWE [60]. While it is clear that thiamine injection improves the neurological signs observed during this acute episode, there is no evidence for an effect

of thiamine on cognitive recovery. Once the severe memory problems of Korsakoff syndrome have set in, neuropsychological treatment can be proposed. The goals of this treatment are to adjust the environment or to compensate for the disorders with external memory support or alternative learning methods.

A large number of studies have shown the possibility of a recovery, at least partial, of the cognitive impairment of patients with AUD with the complete cessation of alcohol intake. These studies have either compared groups of patients with AUD who have been abstinent for different durations (cross-sectional studies), or have followed up a group of patients who have finished their treatment (longitudinal studies). Studies on cognitive changes during a period of abstinence has examined memory, visuospatial or executive function. In general, the studies showed an improved performance with alcohol cessation, sometimes even reaching normalization in long-term abstinent patients [61, 62]. However, some cognitive problems have been described as persistent even after several years of abstinence [61]. Some authors suggest a deterioration of neuropsychological abilities in relapsing patients [62]. The duration of abstinence necessary to normalize cognitive functions is still poorly known, in particular because of the selectivity of cognitive recovery. Indeed, the reversibility of cognitive impairment could be different depending on the cognitive function studied, in relation to the macrostructural and microstructural recovery of the brain substrates involved. Age at alcohol cessation may particularly influence the cognitive recovery abilities of patients with AUD [39, 62]. Older patients with AUD would also have less opportunity for cognitive recovery due to reduced brain plasticity. Cognitive abilities of smoking patients with AUD would also recover less well than non-smokers. Longitudinal studies of patients with AUD have failed to demonstrate whether the presence of cognitive impairment at discharge from withdrawal might be predictive of longer-term treatment outcomes. One study demonstrated that the episodic memory and executive function performance of abstinent patients with AUD was normalized after 6 months of abstinence, whereas in relapsed patients, flexibility problems worsened [63]. These results suggest that when neuropsychological impairments are identified after withdrawal, deferring treatment until after a stay in an alcohol-free environment that promotes spontaneous recovery seems to be an appropriate treatment strategy. The effects of reduced consumption on cognitive recovery remain unknown.

Patients with AUD recently detoxified may have impaired episodic memory, decision-making abilities, executive impairments of metamemory abilities, learning of new complex information and motivation. These impairments hinder the management and limit the ability to maintain abstinence. It is essential to detect cognitive disorders in patients with AUD and to identify those with neurological complications in order to adapt the care and to implement cognitive remediation to promote brain and neuropsychological recovery.

Finally, some pharmacological interventions may be neuroprotective against the toxicity induced by alcohol withdrawal. About 50% of alcohol-dependent patients develop clinically relevant symptoms of withdrawal [64]. Multiple withdrawals may be particularly toxic for the brain of detoxified patients and this situation has been described as the withdrawal kindling model in which the increase in the

number of alcohol withdrawals may be associated with an increase in brain toxicity [65]. As brain damage is more severe after multiple withdrawals and the severity of withdrawal is predictive of relapse, it is essential to prevent the neurotoxicity of alcohol withdrawal [66, 67]. Since chronic alcohol consumption is associated with neuronal changes related to NMDA receptors, this neuroprotection may be particularly important in the treatment of alcohol use disorder [68, 69]. Acamprosate may reduce neuronal hyperexcitability, a phenomenon that occurs during acute withdrawal and prolonged abstinence from alcohol. Acamprosate is thought to act on the glutamatergic system as a partial co-agonist of NMDA receptors and an inhibitor of pre- and post-synaptic metabotropic glutamate receptors type 5 (mGluR5) [70, 71]. In addition to inhibiting the excitatory glutamatergic system, acamprosate is also thought to prevent neuronal hyperexcitability by facilitating the release of GABA, mediated by inhibition of presynaptic GABAB receptors and increased taurine release. Acamprosate could therefore also have neuroprotective effects [72, 73]. The inhibitory effect of acamprosate on glutamate release, and thus on the reduction of neuronal hyper-excitability in alcohol withdrawal, has been demonstrated both in humans [74] and in animals [71, 75]. In cell culture and organotypic brain slice models, acamprosate treatment reduces neuronal death induced by alcohol withdrawal [76–78].

Acamprosate is one of the standard treatments for maintaining abstinence in patients with AUD. The initiation of treatment is very often carried out at the beginning of alcohol withdrawal and no studies has yet investigated the potential benefit of initiating treatment before alcohol withdrawal.

Part VI
Risk Factors for Alcohol Addiction and Lessons from Basic Science

Chapter 32
The Genetics of Alcohol Use Disorder

Josephin Wagner, Andrew S. Bell, Jeesun Jung, and Falk W. Lohoff

Abstract The genetic factors which underly Alcohol Use Disorder (AUD) risk and progression have long been the subject of intense research. Early familial studies established a genetic component by observing disease risk within families, while later linkage studies were able to locate genomic regions with some influence over disease incidence. Later, candidate gene association studies began to identify single nucleotide polymorphisms (SNPs) and pathways statistically associated with AUD and other drinking phenotype outcomes. The recent development of Genome Wide Association Studies (GWAS), which analyze common SNPs across the genome for association with AUD risk has resulted in robust associations with various SNPs. Newer methods, including methylome scanning techniques employing next neneration sequencing, and Mendelian randomization have enabled more precise estimation of the contribution from individual variants to AUD risk and progression. As study methodology improves, it has become increasingly clear that while AUD is a heterogenous and vastly polygenic disease, with dozens, if not hundreds of genes playing a role in AUD pathogenesis, certain genes are frequently observed to influence disease risk across several populations. Genes affecting the activity of the ethanol metabolic enzymes alcohol dehydrogenase and aldehyde dehydrogenase 2 are among the most common targets of genomic investigation into AUD, and variants in these genes are commonly found to play a role in AUD risk in a variety of populations. However, while decades of research have identified numerous candidate genes which influence AUD incidence between patient populations, no gene or group of genes has been identified which singlehandedly explains AUD risk at the individual level. The large number of genes found to associate with AUD suggest that AUD is an exceptional disease candidate for personalized medicine, and new

pharmacological treatments should seek to address the genetic pathways identified in recent genomic research. Nonetheless, it is now clear that environmental and genetic factors as well as gene-environment interactions all play a role, and further research into the precise interactions of each factor will inform clinical decision making.

Introduction

Alcohol Use Disorder (AUD) has long been theorized to have a heritable component, due to early observations that AUD and other addictive disorders are common in families [1]. Documentation of the observation that certain family or social groups appear predisposed to addictive disorders appeared as early as in ancient Greece [2]. It was not until recent decades, however, that the heritability of AUD became a topic of serious empirical study. Until recently, heritability in general has been primarily assessed through twin studies and has been limited to simple observations of differences in AUD risk between families. Furthermore, modern research has identified a host of non-genetic considerations that can influence family-specific behavioral predispositions, including environmental and social factors, which complicates the concept of a purely "genetic" explanation for AUD heritability. Further, advances in genetic research methodology such as the Human Genome Project enabled the proliferation of genomic techniques for assessing the contribution of specific genes to certain outcomes, including AUD and AUD-associated mechanistic pathways [3].

Identifying the genetic underpinnings of a disease and how they can be modulated by pharmacological and/or lifestyle means has become a pillar of modern pharmacological and medical research. Since the early days of pre-sequencing genetic study, research methods have been devised to investigate the source of disease heritability, including AUD. An overview of significant advances in genetic investigation which have played a role in AUD pathogenetic research is provided in Fig. 32.1. AUD is a complex disorder with a wide range of genetic factors having been identified in each phase of disease, from risk to enzyme-mediated symptom severity to drug response. Despite this, much of AUD's genetic profile is uncertain, and in particular the search for a single "AUD gene" or group of genes has so far proved fruitless. It is therefore crucial for the advance of clinical treatment to understand in detail the intertwining genetic pathways implicated in AUD and to develop drugs capable of acting on pathways identified by genetic and genomic methods in order to design effective treatment regimens for as many patients as possible [4].

Early Familial Association Studies and Twin Studies

Early studies reported that relatives of individuals with AUD exhibited an increased risk for AUD themselves [2]. It was initially unknown to what extent this was the result of genetic or environmental effects. In the 1970's, the potential role of genetics in determining AUD predisposition was first assessed in a number of twin studies. In 1972, it was reported that harmful alcohol-associated phenotypes among offspring were more closely related to AUD diagnosis in a biological parent than an adoptive or foster parent, suggesting that AUD development is at least in part mediated by genetics [5]. In 1981, AUD incidence was studied in 862 Swedish men adopted at an early age in what came to be known as the Stockholm Adoption Study (SAS) [6]. The SAS found that AUD has both genetic and environmental causes, and was one of the first twin studies to identify at least two subgroup of AUD patients, characterized by patterns of parental AUD incidence [6]. The study, which was replicated in 1996, noted a significantly higher rate of "type 2" AUD among adopted sons irrespective of postnatal environment, suggesting that there was a strong genetic component to AUD heritance and helping to usher in the modern era of genetic AUD research [7, 8]. Indeed, later studies found that children of individuals with AUD, even those adopted into other families as infants, demonstrated at least a threefold increase in risk for AUD themselves [9–11].

Later studies of monozygotic and dizygotic twins provided further evidence of strong genetic factors underlying AUD development and prognosis. The use of both mono- and dizygotic twins allows heritability to be estimated while controlling for potential influence of shared environment using structural equation modeling. For instance, Falconer's formula (Eq. 32.1) is used in twin studies to estimate the contribution of genetic and environmental factors to total variation in a particular trait by assuming that environmental contribution in monozygotic and dizygotic twins is

equal. In this way, the obvious confound of shared upbringing environments is addressed, and more valid quantitative assessments can be made.

$$H_b^2 = 2\left(r_m - r_d\right) \tag{32.1}$$

Falconer's formula for heritability, where H_b^2 is the total (broad-sense) heritability for a trait, r_m is the twin correlation for monozygotic twins, and r_d is the twin correlation for dizygotic twins

The Australian OZALC twin study of AUD found a stronger association of alcohol dependence phenotypes between monozygotic twins compared to dizygotic twins and reported a heritability estimate for AUD of 64%, with no between-sex differences reported [12]. More recent twin studies have generally reported heritability ranges between 40% and 70% and have generally not identified significant differences in genetic AUD risk between males and females, despite incomplete overlap of genetic sources of AUD vulnerability between sexes [13–16]. Additionally, underlying symptoms and phenotypes associated with AUD have been independently assessed, with heritability estimates as high as 53% for certain severe phenotypes [17]. While these findings have demonstrated that genetics plays a major role in AUD risk, gene-environment interactions or rare somatic de novo mutations in the genome may contribute to the outstanding portion of heritability not explained by genetics or environmental exposures alone [18].

Linkage Studies

While family, adoption and twin studies provided early evidence for the existence of a genetic component underlying AUD risk, they were unable to identify specific genes or pathways involved in AUD heritability. The early desire to identify key genes or alleles motivated the use of genetic linkage studies in AUD patients. In general, linkage studies identify broad regions of an individual genome associated with a phenotype of interest; thus, linkage studies made it possible to identify genomic regions associated with significantly increased risk of AUD in certain populations. These studies make use of genetic linkage, the phenomenon in which two genetic markers on a single chromosome have a lower probability of recombination during meiosis, and are therefore increasingly inherited together more often than would be expected by chance the closer physical proximity they are located in within the genome [19]. Linkage studies typically use families with a high incidence of disease such that chromosomal regions are likely to exhibit common genetic risk variants. Linkage studies are also generally more effective for studying rare autosomal dominant diseases with relatively high penetrance, as these disorders have a high degree of genetic heritability and shared risk alleles.

Linkage studies on alcohol dependence and AUD have found chromosomal regions associated with AUD incidence in several populations. The Collaborative Study on the Genetics of Alcoholism (COGA) mapped a range of genetic variants

associated with AUD [20, 21]. The COGA reported a region on chromosome 4q broadly associated with AUD risk, a finding which was also reported in a sib-pair study of individuals from a Southwest Native American tribe, which also identified a region on chromosome 11p strongly associated with AUD incidence [21, 22]. Among others, this region contains genes that encode isoforms of alcohol dehydrogenase, an enzyme now known to be intimately linked to alcohol metabolism and AUD risk [23]. Later linkage studies have implicated other chromosomal regions. Specifically, regions encoding both the muscarinic acetylcholine receptor M2 (CHRM2) on chromosome 7 [24] and GABA-A receptors [25], which were also identified in the COGA and Southwest Native American studies, have been identified within primary linkage sites corresponding to AUD. The results of early linkage analyses suggested genomic regions within which to search for specific genes capable of influencing AUD pathogenesis.

Candidate Gene Association Studies and the Identification of Gene Targets

While linkage studies provided a wealth of potential regions observed to be associated with genetic AUD heritability, and suggested gene locations with potential effects on disease risk, they were unable to identify specific genes and alleles underlying these observations. Candidate gene association studies (CGAS) were designed to overcome this limitation. CGAS evaluate the association between a predetermined set of gene loci (i.e., genes associated with a disease outcome of choice) and disease occurrence in a case/control random sample, leveraging the availability of large datasets to make population-level genetic inferences [26]. Fundamentally, this is achieved by comparing allele frequencies between cases and controls, and test for deviation from random. Thus, CGAS were among the first studies to identify specific alleles with influential effects on AUD pathogenesis and have more clearly delineated the genetic pathways reported in earlier linkage studies.

Based on previous linkage study findings, follow-up fine mapping and candidate gene studies have demonstrated associations between AUD and the genes encoding alcohol dehydrogenase (*ADH*) and aldehyde dehydrogenase (*ALDH*), both crucial enzymes which regulate the metabolism of ethanol in the liver and digestive tract [27]. Ethanol is oxidized to acetaldehyde by ADH, while ALDH catalyzes the subsequent oxidation of acetaldehyde to acetate. Acetaldehyde is a toxic intermediate, and significant buildup of acetaldehyde causes several aversive reactions, including tachycardia, nausea, and flushing syndrome. Disruptions to the normal ethanol metabolic pathway, particularly those that result in the accumulation of acetaldehyde, are associated with increased severity of these aversive effects and therefore lower incidence of AUD [27]. Those disruptions that promote the buildup of acetaldehyde, especially those that increase the rate of oxidation of ethanol or decrease the rate of oxidation of acetaldehyde, therefore act as negative regulators of drinking behavior.

In the liver, many isoforms of the *ADH* gene are present that differentially impact alcohol metabolism. *ADH* isoforms ADH1A, ADH1B, ADH1C, and ADH4–7 have been identified as the primary isoforms involved in hepatic ethanol oxidation. The majority of ethanol oxidation is usually carried out by ADH1B. However, the ADH1B*2 single nucleotide polymorphism (SNP) [rs1229984 (Arg48His)] oxidizes alcohol much faster than the typical ADH1B*1 variant [27]. ADH1B*2 has been demonstrated to have a protective effect on AUD risk, likely due to the aversive effects of an increased rate of formation of acetaldehyde after drinking, and is known to be more common in East Asian populations than in groups of other ancestry [28–31]. ADH1B minor alleles, especially rs1229984, have also been shown to reduce the risk for AUD in population groups of other ancestry, including Native American, European, and African American samples [32, 33].

While ADH1B has been the subject of much research for its marked variation across populations and strong effect on alcohol metabolism, other ADH isoforms, in particular ADH1A and ADH1C, have also been identified as drivers of genetic variation in alcohol consumption behavior and AUD. At lower concentrations, these isoforms contribute to overall ethanol metabolism. Studies have reported that the ADH1C*2 SNP rs698 (Ile350Val) is associated with a decreased rate of alcohol metabolism and impairment of reaction time at lower alcohol concentration [34]. Individuals expressing such variants are prone to more severe adverse effects after drinking, and are consequently at less risk of developing AUD [30, 35]. Studies of individuals from several populations have identified certain variants associated with AUD risk in a geography- or ancestry-dependent manner. For instance, the variant ADH1B*3 was found to have a protective effect against AUD in Native American individuals [36].

CGAS of AUD have yielded a set of genes involved in AUD risk and severity and many endophenotypes associated with AUD. At least 20 genes identified by COGA analyses have been associated with AUD or alcohol phenotypes [37]. While enzyme gene polymorphisms involved in ethanol metabolic pathways are among the most common candidate genes identified in COGA, genetic variants in neurotransmitter pathways have also been reported to be significantly associated with AUD risk [27]. Among others, the glutamate receptor (GIRK1), gamma-aminobutyric acid receptor (GABA-A), D2 dopamine receptor (DRD2), dopamine transporter (SLC6A3), serotonin transporter (SLC6A4), tryptophan hydroxylase 1 (TPH1), catechol-O-methyltransferase (COMT), cholinergic muscarinic receptor (CHRM2), and u-opioid receptor (OPRM1) have each been found in candidate gene studies to associate with AUD incidence [24, 38–46].

CGAS provided initial evidence of specific genes and variants potentially responsible for the heritability patterns observed in family and linkage studies. However, a number of inherent concerns are associated with this methodology. It became increasingly recognized that the risk alleles identified typically conferred small estimated effect sizes, which combined with low statistical power resulted in a high false discovery rate (i.e., nominally significant results that were the result of random variation). The relationship between a risk allele's observed frequency and the magnitude of its effect is summarized in Fig. 32.2. There is also concern regarding the potential for ethnic stratification, i.e., that allele frequencies often differ between cases and controls not because of an association with disease, but because of

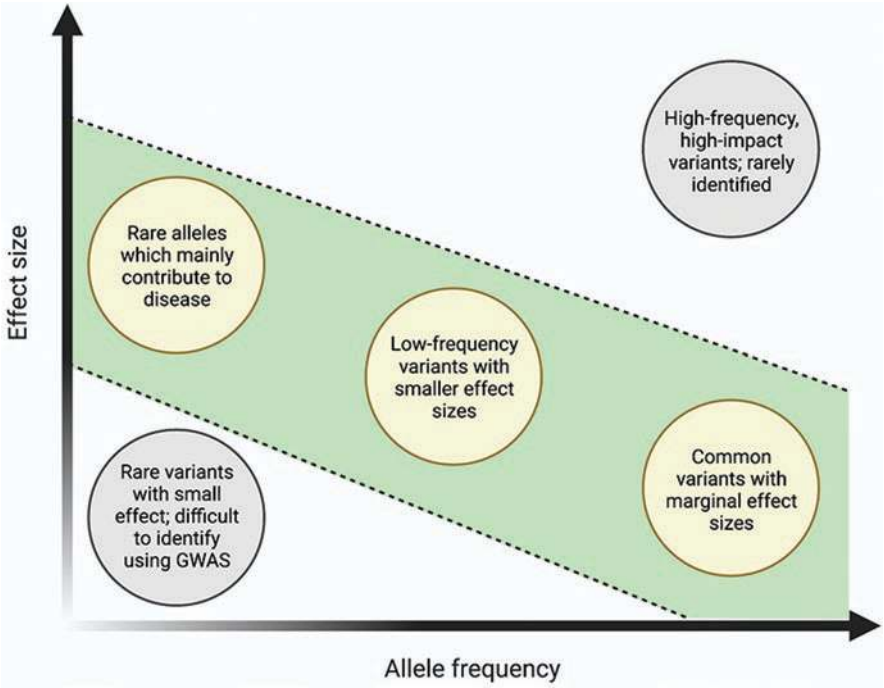

Fig. 32.2 Simplified scheme showing the effect size of a generic risk allele on a disease outcome as a function of the frequency of observation in candiate gene or genome-wide association studies. Adapted from Manolio et al. [47] Figure created using Biorender.com

different ethnic composition of cases and controls. Finally, clinical and genetic heterogeneity between individuals categorized as having "AUD" became increasingly realized. Collectively, these factors have posed a challenge for replication and interpretation of candidate gene studies. The desire to overcome these limitations has led to the development of newer genomic methods for quantifying variant-level contribution to AUD pathogenesis.

Genome-Wide Association Studies

One inherent issue with candidate gene studies that poses a challenge for disease and drug research is the requirement of *a priori* hypotheses. Specifically, candidate gene studies require prior knowledge of the underlying neurobiology of the risk variants assessed in the study. These methods cannot similarly gauge unknown variants or pathways and are thus limited to areas identified by prior studies. In contrast, Genome-Wide Association Studies (GWAS) are able to analyze hundreds of thousands to millions of SNPs across the entire genome to identify differences in genetic variants between case-controlled individuals, without requiring an initial selection of candidate genes. In contrast to the limited scope of a CGAS, a GWAS could

theoretically identify every genetic variant associated with a disease or phenotype, and can evaluate genetic risk variants in complex or polygenetic disorders wherein very small effect sizes would be expected. In practice, this is unlikely, given genomic heterogeneity between patients and the high statistical power required for such findings. GWAS have recently come into focus as a useful tool for assessing the genetic contribution from a number of gene variants to mental illness risk, including that for schizophrenia and bipolar disorder [48–50]. GWAS have also been used in patient samples with AUD.

Among the first GWAS to demonstrate genome-wide significance of individual variants on alcohol dependence identified two intergenic loci on chromosome 2q35, rs7590720 and rs1344694, near the peroxisomal trans-2-enoyl-CoA reductase (*PECR*) gene; PECR catalyzes the reduction of medium chain enoyl-CoAs to saturated acyl-CoAs when triglycerides are mobilized to produce energy [51]. Chronic alcohol use is associated with increased serum triglyceride concentration, and *PECR* expression patterns may thus play a role in alcohol-mediated lipid metabolic disorder [52]. An internal replication study identified 15 SNPs showing association with at least nominal significance (i.e., prior to correction for multiple-testing bias), including rs11640875 in cadherin 13 (*CDH13*), rs1614972 in *ADH1C*, and rs13273672 in the GATA binding protein 4 (*GATA4*) [51]. While this study was the first GWAS to demonstrate associations between GATA4 and AUD, prior studies have found that GATA4 is associated with alcohol dependence and relapse risk, as well as limbic gray matter volume, which is itself predictive of alcohol relapse risk [53, 54]. However, later replication studies failed to confirm this association using data from an independent sample [55].

GWAS have identified many other gene targets displaying complex relationships with AUD incidence. For instance, peroxisome proliferator-activated receptors (PPARs) have been associated with neuroinflammatory processes known to be involved in AUD etiology [56]. Reanalysis of GWAS data identified SNPs in PPARA and PPARG associated with alcohol withdrawal and PPARGC1A associated with alcohol dependence in mouse and human samples, suggesting a potential role for PPAR agonists in pharmacological interventions for alcohol-associated liver disease (ALD), in which PPARs have been known to play a role for some time [57, 58]. In the past decade, GWAS studies of AUD have proliferated, and many genes have been identified in a range of populations [27]. In German and German-descent individuals, GWAS have reported associations between *PECR, CDH13, ADH1C, GATA4, ALDH2, ADH1* [51, 59]. In Korean individuals, C12ORF24, ALDH2, ADH1B, ADH7, have been associated with AUD. [60, 61] Studies of European and European-American individuals have identified, among many others, SNPs in CDH11, CDH13, ANKRD, CYTL1, MARK1, DDX6, KIAA1409, SEMA3E, AUTS2, C15ORF53 [46, 62–66]. GWAS meta analyses of combined European-American and African-American individuals have reported effects of genes in the KEGG pathway, *GABRA2, PKNOX2, ADH1B, ADH1C, EDNRB, TPARP, CYFIP2, THEMIS, PSG11, KIAAA0040, THSD7B, NRD1, PTP4A1, SH3BP5, NR2C2, PLGLB2, NKAIN1-SERINC2, IPO11-HTR1A,* and genes located between *MTIF2* and *CCDC88A* on chromosome 2 [65, 67–73]. Meanwhile,

ALDH2 was associated with AUD in Chinese and Japanese individuals, while *ADH1B* was associated with AUD only in Japanese individuals [74, 75].

While early GWAS studies were limited by small sample sizes and consequently low statistical power, efforts have been made to increase predictive power by analyzing genome-wide SNPs from large datasets, including those from the COGA, the Australian twin-family study of alcohol use disorder (OZALC), the Million Veteran Program, the Psychiatric Genomics Consortium, and the Study of Addiction: Genetics and Environment (SAGE) dataset [27, 76, 77]. Early GWAS of the COGA dataset were unable to identify single SNPs with genome-wide significance but identified a gene cluster on chromosome 11 associated with alcohol dependence [78]. A meta-analysis and replication study of 11,120 SNPs sourced from the COGA, SAGE, and OZALC samples identified three novel loci and replicated previous findings of an association between *PKNOX2* and alcohol dependence [65]. However, later studies and meta-analyses have failed to identify variants with genome-wide significance with data from COGA, OZALC, or SAGE [65, 67, 68, 70, 72, 73].

In general, GWAS investigations of AUD have supported the findings of earlier methodologies, including linkage studies, family studies, and candidate gene studies; SNPs in genes encoding alcohol metabolizing enzymes are among the variants most often found to associate with AUD [32]. In particular, SNPs located on the *ADH* and *ALDH* genes are among the variants with the greatest effect on AUD risk. A GWAS of AUD in German individuals identified the variant rs1789891 in the *ADH* gene cluster, a SNP which was also found to be in linkage disequilibrium with the functional variant *ADH1C* (Arg272Gln) [59]. The *ADH* gene cluster was also identified in a GWAS using a Korean sample, which found multiple nominally significant SNPs in the cluster located on chromosome 4q22-q23; genome-wide significance for rs1442492 and rs10516441 in *ADH7* and rs671 in *ALDH2* were also reported [61]. Other studies of East Asian populations have similarly found that the *ALDH2*2* variant rs671 (Glu504Lys) is associated with a decreased risk of AUD in these individuals [59, 75, 79]. There is also evidence that certain variants or genes may be protective in multiple distinct populations of different ancestry. For instance, GWAS studies have found that the *ADH1B*2* SNP rs1229984 is protective against AUD development in East Asians, associating both with lowered alcohol use and more severe adverse effects associated with drinking; recent genomic studies have also reported an increased risk of alcohol-related cancer among rs1229984 carriers in East Asian populations [80, 81]. Other studies have found that rs1229984 decreases the risk of AUD in European-Americans, while the analogous ADH1B SNP rs1789882 (Arg369Cyc) decreases the risk of AUD in African-Americans [61, 69, 75].

One of the greatest strengths of GWAS has been the ability to quickly and efficiently identify a huge number of SNPs which are associated with disease outcomes, and their proliferation has led to a surge in the understanding of genetic pathways involved in AUD pathogenesis. In the past 5 years alone, dozens of GWAS studies have shed light on new, complex factors involved in AUD risk, a selection of which is summarized in Table 32.1. However, the wide scope and relatively small

Table 32.1 GWAS summary

Author	Year	Outcome measure(s)	Main finding	Sample size (*n*)	Link
Walters et al.	2018	17 neuropsychiatric outcomes	Alcohol depdence associated with psychiatric disease, cigarette/cannabis use, low socioeconomix status, poor behavioral health; differences in ADH1B variant expression between European and African American participants	52,848	https://www.nature.com/articles/s41593-018-0275-1
Mallard et al.	2021	AUD	A novel weighted AUD severity score correlated with psychiatric disorder and not with positive health outcomes previously associated with certain AUDIT criteria; PRS associated with poor mental health only with AUD diagnosis	160,824	https://ajp.psychiatryonline.org/doi/10.1176/appi.ajp.2020.20091390
Kranzler et al.	2019	AUD and related disorders	Large genetic overlaps in genomic expression profiles between PRS for alcohol consumption and AUD; heavy drinking is a key risk factor for AUD but does not itself cause it	274,424	https://www.nature.com/articles/s41467-019-09480-8
Sanchez-Roige et al.	2019	AUD	Loci in *JCAD, SLC39A13, ADH1B, ADH1C, KLB,* and *GCKR* associated with AUD; alcohol consumption and problematic drinking exhibited differential expression	20,328	https://pubmed.ncbi.nlm.nih.gov/30336701/
Marees et al.	2019	Socioeconomic status, substance use disorders, psychiatric disorders, psychological/personality traits	Frequency and quantity of alcohol consumption display generally similar health marker associations but opposite associations with socioeconomic status-related phenotypes	438,308 (consumption) 307,098 (quantity)	https://pubmed.ncbi.nlm.nih.gov/30874500/
Gerlernter et al.	2019	Alcohol dependence	Identified five novel risk loci including *ADH1B* variants in European American and African American invidiauls; *CRHR1* particularly associated	143,965	https://www.ncbi.nlm.nih.gov/pmc/articles/PMC6919570/
Gerlerneter et al.	2022	AUD	Maximum habitual alcohol intake closely aligns with other predictive drinking phenotypes; supported a two-factor mdoel in which drinking frequency and problematic drinking act individually to influence outcomes	247,755	https://www.medrxiv.org/content/10.1101/2022.05.02.22274580v1

Liu et al.	2019	N/A	Smoking and alcohol use share a large amount of risk variants, but display opposite asssociations with negative health outcomes; nicotinic, dopaminergic, and glutamatergic systems involved in smoking and AUD	337,334–1,232,091	https://pubmed.ncbi.nlm.nih.gov/30643251/
Kapoor et al.	2021	AUD, drinks per week	rs56030824 on chromosome 11 reduces immune activation and AUD risk; *MAPT* is specifically associated with drinks per week; high overlaps with genes involved in neurodegenerative disorders	739,353	https://www.nature.com/articles/s41467-021-25392-y
Linner et al.	2021	Self-regulative disorders	AUD and other disorders involving self-regulation have a shared genetic underpinning which is independently associated with more than 500 genetic loci	1,373,240	https://www.nature.com/articles/s41593-021-00908-3#MOESM3
Luo et al.	2019	Epigenetic aging	AUD is associated with epigenetic age acceleration; disease severity further accelerates epigenetic aging	532	https://pubmed.ncbi.nlm.nih.gov/31466081/
Lohoff et al.	2021	AUD	Differential methylation in genome regions encoding glucocorticoid signaling and inflammation-related proteins are associated with alcohol use behaviors	625 (AUD) 4798 (replication)	https://pubmed.ncbi.nlm.nih.gov/32398718/

Zhou et al.	2020	Problematic alcohol use (PAU)	PAU was genetically correlated with substance use and psychiatric traits; genetic heritability of PAU was enriched in brain and in conserved and regulatory genomic regions	435,563	https://pubmed.ncbi.nlm.nih.gov/32451486/
Meyers et al.	2021	AUD	Variants associated with posterior interhemispheric low theta EEG coherence were also associatyed with AUD; interhemispheric theta EEG coherence may be able to proxy AUD-associated neural connectivity disregulation	8810	https://pubmed.ncbi.nlm.nih.gov/32433515/
Sun et al.	2019	Alcohol dependence	Variants in ALDH2 (rs671) and ADH1B (rs1229984) significantly associated with alcohol dependence in a Han Chinese cohort	3381	https://www.nature.com/articles/s41398-019-0586-3

sample size of many GWAS studies in relation to the small genetic effects most commonly identified also poses a fundamental limit on the statistical power of GWAS predictions, and the heritability attributable to collective SNP associations that survive multiple testing correction in GWAS studies is significantly less than heritability estimates from corresponding family studies, a phenomenon known as the "missing heritability" problem [32, 47]. It is known that a significant portion of the genetic contribution to AUD risk is attributable to common SNPs, with one analysis finding that they may represent as much as 33% of total genetic AUD risk and at least 16% and 18% for alcohol dependence and consumption, respectively [82, 83]. To overcome this limitation, newer methods have been designed which make up for the lost power when conducting large GWAS analyses.

Next-Generation Sequencing and Whole Genome Sequencing

While once a prohibitively expensive and time-consuming process, modern technology has enabled rapid and reliable genome sequencing as a means of obtaining research data for genetic and genomic investigations into disease phenotypes. Next-Generation Sequencing (NGS) has significantly reduced the barriers to genome sequencing, enabling a proliferation in genetic and genomic research. Traditional Sanger sequencing methods were originally limited to very small genomes comprised of at most ~5000 bases, and while later improvements and computer programs increased the maximum base sequence size about tenfold, until recently Sanger sequencing required specialized and expensive equipment and infrastructure [84]. It was not until the development of next-generation, or "massively parallel" sequencing methods capable of simultaneously analyzing up to billions of templates simultaneously, that genome sequencing became an accessible research method for use in studies of disease phenotypes such as AUD [85].

NGS methods include targeted deep sequencing, whole-exome sequencing (WES), and whole-genome sequencing (WGS) [86]. Each has contributed significantly to the study of precision genetics. WES systematically scans an individual's entire set of coding DNA regions, or exome, for all known genes. Using high-throughput sequencing methods, WES generates a library of every variant present in an individual exome. While WES analyzes only the exome, comprising about 90 million nucleotides, or 3% of the entire genome, it assesses more than 95% of all exons and as much as 85% of all disease-associated genes [87–89]. Targeted deep sequencing may also be used to provide exceptionally high-resolution genomic description with high statistical power even with smaller sample sizes than low coverage whole genome or exome sequencing [90]. However, deep sequencing requires significantly greater overall sequencing effort [90, 91]. Targeted resequencing of smaller regions containing up to a few dozen genes can be used to accurately detect low-frequency or rare gene variants without drastic increases in resource use [91].

Compared to analytic methods employing existing datasets, including GWAS, and less inclusive sequencing techniques such as WES, WGS is more expensive and

time consuming but is more likely to identify functional uncommon mutations in exome sequences and is particularly useful for identifying rare recessive mutations [92]. Further, whole genome/exome sequencing has successfully identified genetic mutations associated with a variety of psychiatric disorders, including autism spectrum disorders, schizophrenia, depression, bipolar disorder, and others [93]. WGS studies also have the benefit of potentially identifying uncommon variants not previously found using conventional GWAS methods. For example, rare variants of the K2P channel gene *KCNK2* and rare missense and splice-site variants in the pro-inflammatory mediator gene PDE4C were associated with incidence of alcohol-related life events reflecting AUD severity in both Native American and European American individuals [94]. Additionally, a NAF1-FSTL5 intergenic variant and an FSTL5 variant were associated with alcohol-related life events in both samples, while other genes in the serine/threonine protein kinase and interleukin subunit families, and long non-coding RNA sequences, were associated with Native American or European American samples, respectively [94].

NGS methodology holds great promise for identifying novel genes previously inaccessible to researchers, as well as identify currently unknown variants potentially driving ancestry-related and ethnic differences in AUD risk and severity. However, this technology is still new, and studies employing WGS and NGS broadly are rare in the field of addiction research. Future studies identifying further unexplored genomic regions or variants with influence on AUD development in specific patient populations in order to elucidate the impact that WGS may have on research into AUD risk and heritability.

Polygenic Risk Scores

Consistent findings of AUD heritability and a large number specific genes with an identified etiological role suggest that AUD is highly polygenic; while a great number of genes may contribute to patterns of AUD heritability and symptom severity, the specific genetic pathways and variants appear to differ between ethnic and patient populations, and likely also between individuals within those populations. While CGAS and GWAS have been able to identify some variants associated with AUD and alcohol dependence, the missing heritability confound limits the clinical significance of any one of these variants. To overcome this limitation, polygenic risk scores (PRS) were developed to aggregate genetic liability across many variants, each with a nominal level of association, in an effort to establish tools for assessing individual genetic AUD risk. To develop a polygenic risk score, a GWAS is conducted in a discovery sample; using a threshold p-value, a risk profile score equal to the sum of the count of risk alleles for one subject weighted by their effect sizes in the discovery sample, is generated for each subject in a target sample. The score is regressed to evaluate its association with the phenotype of interest and the proportion of variance (R^2) explained by the score [95]. Importantly, however, while the reliance on a strict ($p < \sim 10^{-8}$) threshold p-value may make type I errors rare, it may

also bias results toward type II errors, excluding SNPs with marginally lower significance but which may still contribute to the observed genetic variance.

Polygenic risk scores have both increased the predictive value of SNPs identified in GWAS studies and enabled the discrimination between variant-level sources of interpopulation differences in genetic AUD risk. For instance, a polygenic risk score developed by Lai et al. used 858 variants from 410 genes, each significantly associated with AUD in African American and European American subjects. Compared to the bottom decile, those in the top PRS decile were almost twice as likely to be diagnosed with AUD. [96] Since the first score to be developed specifically for alcohol dependence in 2012 [95], several risk scores have been created for the study of the genetics of AUD and related disorders, each associating significantly with AUD incidence and confirming the polygenetic nature of AUD and other substance use disorders [83, 97–101].

While PRS have had some success in assessing individual-level risk of AUD, most studies have reported very small R^2 values, with several explaining less than 1% of total variance [100–102]. Thus, studies using PRS have allowed for the aggregation of many individual risk factors into a cohesive unit for proxying genetic risk, but have thus far been unable to fully solve the missing heritability problem. Some authors have suggested that with much larger sample sizes, the variance attributed to PRS would rise considerably; however, there are currently no datasets containing alcohol-related sample statistics from which a risk score of this magnitude could be derived [103]. Nonetheless, PRS have played an important role in the study of the genetics of AUD, and while currently their value for predicting AUD is limited, they are useful associative tools for studying the association of AUD with genetic factors and other phenotypes [103, 104].

Mendelian Randomization

Research into the genetic factors that underly both AUD heritability as well as AUD's complex associations with other disease phenotypes, including other substance abuse and psychiatric disorders with potential common neurological pathways and metabolic disorders influences by AUD, such as hyperlipidemia and cardiovascular disease (CVD), has made use of GWAS studies and the variants discovered by earlier candidate gene studies. In particular, Mendelian randomization (MR) has emerged as useful tool for studying these associations. MR is a genetic analytical tool which uses genetic variants as instrumental variables to explore causal relationships between exposures and phenotypic outcomes, using summary statistics taken from large GWAS databases [105]. By using variants strongly associated with instrumental variables in relatively large patient samples, MR can effectively estimate the causal effect of modifying an exposure on an outcome. For example, an MR assessing alcohol consumption may use as an outcome measure a patient's average alcoholic drinks per week. If researchers sought to estimate the effect of subcortical brain structure on average alcohol consumption, either

with an *a* priori directional hypothesis or as a bidirectional study, MR can, and has been used to examine this relationship [106]. A key advantage of MR derives from the fact that germline variants are randomly assorted during meiosis at the beginning of life and are thus not influenced by lifestyle or environmental factors, effectively allowing MR to naturally proxy a randomized controlled trial in order to assess the causal relationships between two biological variables and reducing susceptibility to methodological confounds or reverse causation [107].

In alcohol research, MR has been used both to identify factors exerting causal influence on alcohol as well as those phenotypes for which alcohol use has a causal role. Among others, it has been shown that alcohol consumption levels, global cortical thickness, and educational attainment each display causal associations with AUD pathogenesis [104, 106, 108]. An even greater number of studies have chronicled the causal associations between alcohol misuse and a wide range of metabolic and biological measures. MR studies have found that GWAS measures of chronic alcohol use are associated with hypertension, hyperlipidemia, early-onset Alzheimer's disease, type 2 diabetes, age-related macular degeneration, and shorter telomere length [109–113]. MR has also been used, with mixed results, to explore the complex and often unclear relationship between varying levels of alcohol use and cardiovascular risk [114–116].

Among the advantages of MR as a tool for studying the genetics underlying AUD and alcohol-associated disease is the relative efficiency of MR studies, which use summary statistics sourced from pre-existing GWAS datasets. As a result, MR studies can rapidly estimate the possible causal relationship between AUD, alcohol use, binge drinking, and several other alcohol phenotypes with a vast number of biological outcomes. This has led to a continuing surge in studies connecting alcohol with a new and growing number of behavioral and biological outcome measures. However, MR's reliance on pre-existing data can also limit the scope of investigations. Specifically, outcome measures for which no GWAS summary statistics are available or for which sample sizes are prohibitively small, which limits statistical power, may not be possible to assess using MR and related methods. The growing interest in using MR to identify clinically relevant lifestyle or environmental factors that can influence an individual's predisposition to AUD highlights the need for more recent and larger consortium datasets with alcohol and metabolic phenotype data.

Future Directions in the Genetics of AUD: Working Towards Personalized Medicine

Decades of research have brought to light numerous genetic pathways with complex and varied effects on AUD risk and pathogenesis. As the genetic underpinnings of AUD and other substance use disorders have become more apparent, new opportunities for pharmacological treatment of AUD are emerging. However, despite the proliferation of studies into the genetic factors underlying AUD and potential

druggable genes, to date only three FDA approved medications exist for the treatment of AUD—disulfiram, acamprosate and naltrexone [117]. Importantly, while these medications can reduce drinking for certain patients, as many as 40% to 70% of individuals taking naltrexone or acamprosate fail to exhibit an efficacious drug response [118–120]. While several other drugs are used off-label to treat AUD, and several others are in various stages of clinical development, many of these also display limited effectiveness, and none have been demonstrated to systematically reduce AUD symptoms for wide population groups, with the possible exception of topiramate [121–123]. Until such time as medication becomes available, which is capable of altering drinking behavior in AUD patients, further genomic investigation into AUD, and in particular the distinct neurocognitive and genetic pathways that are responsible for the considerable heterogeneity in patient presentation, may help to elucidate novel treatment mechanisms which are most likely to be effective for specific patients.

As genetic research in the psychiatric sphere has developed, new frameworks for analyzing genetic variation between individuals and populations have emerged as research tools. While GWAS have contributed greatly to the understanding of genetic variants associated with AUD pathology and risk, multi-omics approaches, including epigenome-wide association studies (EWAS), phenome-wide association studies (PheWAS), and proteome-wide association studies (PWAS), among other tools, have been designed to explore all manifestations of genetic influence under a combined framework. The integration of distinct yet interrelated domains and the proliferation of biobanks and large consortium datasets have enabled a growing number of high-power analyses of psychiatric illnesses, including alcohol [104, 106, 124]. As the size and scope of large datasets increases, it will be all the more important to leverage their statistical power to explore these multi-omic relationships to develop more effective medications capable of addressing the needs of specific patients.

Personalized medicine refers to the idea that an individual's specific genomic expression patterns can be used to predict scientifically which specific medications would be most likely to have a beneficial effect and least likely to have any adverse outcomes for an individual patient [4]. Personalized medicine draws on the results of genomic investigations identifying specific variants or expression patterns associated with biological variables such as drug response, reported adverse outcomes, and disease and comorbidity risk. As the volume of research into individual genome-level associations between AUD risk variants and biological outcomes increases, AUD has become a leading candidate for personalized medicine, and a growing number of researchers have proposed applying the concept of personalized medicine to the clinical treatment of AUD patients [117, 125–128]. However, there remains a great need for data from studies with much larger sample sizes and with more diverse outcome measures, including detailed drinking assessments, in order for GWAS and MR studies to more accurately visualize the factors underlying AUD risk and biological consequences.

Personalized medicine offers promise for a new approach to AUD treatment which emphasizes the heterogeneity of the disease and works to adapt selection of

pharmacological interventions to individual-level differences in disease presentation such as to ensure the highest likelihood of success for every patient [117, 128]. In order to account for the considerable heterogeneity among AUD patients, however, it is necessary to fully explore the genomic variation in wide and diverse population groups of AUD patients, and to characterize not only drug interactions, but neuropsychological processes underlying disease severity. Only then will the possibility that a clinician can draw upon an individual's genome to make prescription decisions become reality.

Special Considerations in the Genetics of AUD

Like many psychiatric disorders, AUD is extremely heterogenetic, and there is a large degree of difference in both the reported symptoms and underlying neurobiology between AUD subjects. The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V) uses 11 criteria assessing excessive alcohol use, alcohol abuse, and alcohol dependence to diagnose AUD in patients; these criteria, which encompass drinking behavior alone, demonstrate considerable differences even between patients with identical diagnoses [27]. The DSM-V also classified AUD severity along a continuous scale for the first time, removing the less severe "abuse" and more severe "dependence" categories in favor of mild, moderate, and severe diagnoses based on the number of applicable criteria [129]. Additionally, a meta-analysis of MRI studies found that while AUD patients generally exhibited reduced white matter volume, there was also significant heterogeneity between study populations [130].

The heterogeneity of AUD patients is of particular importance for genetic and drug development research, as any genetic pathways responsible for inter-patient variation may also affect certain drugs' efficacy or safety profiles. AUD's complex genetic foundation has been explained by some authors to result from a high degree of both heterogeneity and polygenicity. Heterogeneity assumes that either a single or few genetic variants determine disease risk, and that different alleles can lead to similar clinical presentation in different individuals. Meanwhile, polygenicity assumes that a given phenotype is the simultaneous result of the effect of multiple genetic variants [131]. The evidence suggests that both of these frameworks describe certain aspects of the heritability and neurobiology of AUD and other substance use disorders [132]. Certain endophenotypes, or measurable intermediate characteristics between a disorder and the biological processes underlying the disorder, have helped to distinguish differences in underlying AUD biology; among others, differences in facial flushing syndrome in East Asians facilitated the discovery of ADH2 subtypes, variants of which have become a primary target for genetic research [133, 134]. More recently, neurofunctional domains have become endophenotypes of interest for their potential to identify clinically significant patient groups with shared neurocognitive structures which may be effective targets

for new medication [4]. In any case, identification of new and more strongly associated endophenotypes is likely to provide molecular targets for novel medications, and research in this area is of particular importance for bringing the promise of personalized medicine into the addiction sphere [135].

Also of note is the high degree of comorbidity between AUD and other SUDs and psychiatric illnesses, offering both promise and challenges for genetic risk variant identification and subsequent targeted medication development. That AUD and other SUDs may arise from common predispositional factors has been suggested for decades, and environmental, cognitive, and biological factors have been proposed as potential mechanisms for this association [136, 137]. The relationship between AUD and smoking is particularly well-chronicled; in 2005 it was reported that up to 80% of individuals with DSM-IV alcohol dependence smoke cigarettes, and studies in European populations have reported over a fourfold increase in AUD risk among those meeting criteria for tobacco dependence compared to those who never smoked [138, 139]. Significant comorbidity between AUD and opioid use have been reported, and alcohol is a major contributor to opioid-related deaths [140, 141]. Alcohol and cannabis misuse are also significant, and associated with additive impairments in neurocognitive performance and more frequent use of both drugs [142]. AUD is also highly comorbid with other psychiatric disorders, especially anxiety and depressive disorders, and studies have found that any prior mental health disorder significantly increases the risk of problematic alcohol and drug use [143–145].

That AUD and other psychiatric disorders exhibit such a high degree of comorbidity is an important consideration for drug development. Besides the necessity to ensure patient safety by minimizing drug-drug interactions outside of the disorder for which a drug is prescribed, comorbid disorders are a key consideration for the application of personalized medicine and drug research. Patients with certain comorbid disorders may respond better to certain forms of treatment, and recent and ongoing clinical trials of psychological and pharmacological interventions are attempting to distinguish which drugs work best for patients with certain comorbid disorders [146–150]. Future research should focus on comorbid disorders as a useful grouping method for AUD patients in order to design treatment plans most likely to address individuals' total psychiatric health.

Conclusions

Despite the fact that the genetics of AUD has been a subject of interest for many years, and that a significant (appr. 50%) contribution of genetics to AUD has been established for quite some time, identifying the underlying genetic factors has been challenging. As genomic investigations have grown more complex, it has become clearer that there is no single genetic cause of AUD in any patient population, and that at least dozens of factors, including genetic, environmental, and gene-environment interactions, may work together to ultimately influence genetic AUD

risk. While in recent years genomic studies of AUD have grown more common and concerns regarding small sample sizes and statistical power have been addressed, there is still a need for large, multi-ethnic datasets with data for specific drinking phenotypes and life histories in order to disentangle the complex system of relationships between genetic factors, environmental influences and underlying disease processes, which may have different effects for different patients. Recently developed methods can help address some of the deficiencies in the understanding of AUD as a genetic disorder, but further innovation is needed to devise statistically powerful and clinically useful classification methods and analytical tools that can account for the combined influence of genetic and lifestyle factors. In the meantime, further genetic investigation into AUD is warranted in order to determine which variants that hold promise for future drug development and better understanding of the pathophysiology of individuals with AUD.

Chapter 33
Alcohol Responses as Phenotypic Markers of AUD Risk: Lessons from Longitudinal Studies

Andrea King

Abstract Alcohol response phenotypes play an important factor in the vulnerability to alcohol use disorder (AUD). The majority of research in this area has employed controlled laboratory "alcohol challenge" studies in cross-sectional designs to determine alcohol response phenotypes. However, longitudinal studies that identify alcohol responses as phenotypic markers of AUD risk are crucial to determine which alcohol response phenotypes best predict problem drinking and severity and maintenance of AUD. The two most comprehensive longitudinal studies of alcohol response and future drinking are the San Diego Prospective study and the Chicago Social Drinking Project. These studies include alcohol and placebo response testing with long-term follow-up of drinking behaviors and AUD symptoms over a decade with exceptionally high retention over a decade of participation. The Chicago study also has included an important alcohol re-examination component to determine if alcohol responses are stable or change over time at different stages of AUD. This chapter reviews the central tenets and theoretical frameworks underlying these two longitudinal studies, summarizes their strengths and weaknesses, and compares their main findings in terms of alcohol's euphoric and rewarding effects relative to its sedating and impairment effects. These hallmark studies represent seminal contributions to the alcohol field and to our understanding of AUD risk and maintenance, as well as protective alcohol response factors in those at low risk. The chapter concludes with a call for consilience and directions to build on these research frameworks in future studies.

Costs and Consequences of Excessive Drinking

Excessive alcohol use remains the third leading preventable cause of death [1] and is a major preventable contributor to disability and mortality worldwide [2]. In the United States alone, the annual economic costs of excessive drinking, including health care, loss of productivity, crime and accidents are estimated at over $249 billion [3] with three-quarters of the costs attributed to binge drinking [4], defined as consuming five or more drinks in an occasion for men, four or more drinks for women [5]. Binge drinking in early adulthood is a strong predictor of the development and risk for future alcohol use disorder (AUD) [6, 7] which is associated with serious health and safety consequences and impairments [8]. Given the global burden of alcohol misuse, identifying factors that increase its susceptibility and persistence is critical for public health [9] and crucial for improving prevention, education and intervention strategies [10].

Excessive Drinking in Young Adulthood and Across the Lifespan

While there are multiple trajectories of drinking behavior over time [11, 12], for many individuals, binge drinking originates during adolescence and emerging adult years [13]. Frequent binge drinking behavior has been described by the term heavy drinking, i.e., five or more binge episodes per month [14] that may become a chronic behavior pattern [14, 15]. Indeed, one-third to one-half of young adult binge drinkers persist with alcohol misuse and heavy drinking during adulthood [16]. The consequences of persistent heavy drinking are high—with an estimated 5.1% of the global burden of disease and injury attributed to alcohol and 283 million adults aged 15 and older meeting criteria for AUD [17]. Thus, there is a need for a better understanding of the resilience, vulnerability and mechanisms of excessive drinking and its co-morbidities across the lifespan. Outside of several known sociodemographic risk factors for the disorder, including male sex, lower education, delay of developmental transitions, family history, and impulsivity [18–23], the biopsychosocial causal factors that influence the persistence or escalation of heavy drinking and AUD are unknown.

Subjective Alcohol Response Research Approaches

An important factor to elucidate increased vulnerability to AUD is characterizing acute subjective alcohol responses, or alcohol response phenotypes, at different stages of the disorder. The majority of research in this area has employed controlled laboratory “alcohol challenge” studies. In these paradigms, alcohol is administered

under controlled conditions to maximize internal validity and reduce external factors (environmental context, etc.) that may confound assessment. Oral or intravenous alcohol is delivered by a variety of methods, including a fixed dose, an extended clamped dose [24], or serial increasing doses of alcohol [25]. Participants are usually medically and psychiatrically healthy young adults who vary on high- and low-risk status for AUD by virtue of binge drinking patterns, family history, or both. Responses are measured both before and after alcohol consumption, i.e., versus placebo in double-blinded studies, and compared between the high- and low-risk groups. The dependent alcohol response variables often include a battery of responses, such as self-report scales, physiological parameters [26, 27], and performance tasks [27–30].

Cross-sectional studies have revealed a myriad of responses to alcohol that differ between high- and low-risk subgroups [28, 29]. Relative to low-risk drinkers, high-risk drinkers have shown lower sensitivity to some of alcohol's acute effects, including subjective intoxication or sedation [31, 32], body sway [30], cognitive measures [33] and stress hormone response [26, 27, 32]. In contrast, high-risk drinkers have exhibited higher sensitivity to alcohol in terms of subjective stimulation [32, 34–36], liking [32] and wanting [32]. Other studies have shown no differences on subjective [37] or objective responses in high- and low-risk individuals [38]. While cross-sectional studies have provided information on alcohol responses as a function of purported risk for the disorder, these designs are not the optimal method to determine how alcohol responses prospectively predict future drinking and AUD propensity. From a clinical neuroscience perspective [39], longitudinal alcohol response studies are crucial to determine alcohol response phenotypes that predict problem drinking and severity of AUD. Despite numerous studies of acute oral or intravenous alcohol effects [40], there have been few programs of research utilizing longitudinal frameworks to examine alcohol response phenotypes related to vulnerability to AUD. It is not surprising that longitudinal investigations of alcohol response are less common than cross-sectional studies, as these designs are time- and labor-intensive, financially costly, and require extensive planning and perseverance to achieve high follow-up rates [41, 42].

The two most comprehensive longitudinal studies of alcohol response to future drinking include: (a) the San Diego Prospective study with participant enrollment in the 1970s to 1980s; and (b) the Chicago Social Drinking Project with participant enrollment in the 2000s to 2010s (and still enrolling). These studies are similar in that they combined well-controlled laboratory alcohol (and placebo) challenge sessions with extensive and high-retention subsequent follow-ups of drinking patterns and addiction symptoms. They differ in their criteria for high- and low-risk groups and measures employed, and also whether alcohol responses were measured at enrollment only or repeated over an extended period of time.

The focus of this chapter is to review the central tenets and theoretical frameworks underlying these two longitudinal studies, summarize their main findings, and discuss their relevance and contributions to the alcohol field. An important caveat to mention before describing these studies is that they were undertaken roughly 20–30 years apart. Over that time, the measurement of alcohol's effects has

changed from a general model of global alcohol intoxicating effects to a more evolved pharmacological and evidence-based structure with at least two main factors, one stimulating and rewarding factor and another sedative and ataxic factor, and these factors are inversely correlated [43]. There may also be a third factor for tension reduction [44] that is being investigated in AUD subgroups [45]. Given these developments, as outlined in the discussion, the Chicago study and newer models have set the stage to evaluate multifaceted effects of alcohol in high- and low-risk drinkers [46].

Finally, the chapter concludes with a call for consilience and future directions to build on this work, as it relates to the role of individual differences in subjective alcohol response and vulnerability and persistence of alcohol misuse that is so costly in terms of personal, health, and societal harms.

Theories of Alcohol Response and Risk for Excessive Drinking

Several theoretical models have been proposed to explain how an individual's response to alcohol may influence hazardous drinking leading to alcohol problems, consequences, and harm [28, 29, 46–50]. These models involve aspects of rewarding and/or aversive responses to alcohol, and include early-age alcohol responses as a risk factor for the future development of alcohol problems. They also include potential adaptations in alcohol responses during the course, chronicity, and increasing severity of AUD in a drinkers' lifetime. In terms of risk for future AUD, a prominent and longstanding theory is the low level response model [51] that purports lower sensitivity to alcohol's effects [51] as a risk factor for AUD. At-risk individuals are described as lacking the interoceptive signs of intoxication and therefore need to consume more alcohol to achieve a "desired effect." However, subsequent studies failed to support low level responses in at-risk persons [52, 53] and animal studies have supported psychomotor stimulant mechanisms of drug reinforcement [54]. Thus, a competing theory was introduced, the differentiator model, that posited that greater pleasurable and excitatory alcohol effects during the ascending limb of the breath alcohol concentration (BrAC), and lower sedative responses during the declining limb, increase risk for future AUD [47]. Further work called for a simplified theory, i.e., the modified differentiator model, as greater stimulatory and rewarding alcohol effects and lower sedative effects at peak BrAC, and not as limb-dependent, were shown to predict future alcohol misuse in at-risk drinkers [55]. As the low-level response and (modified) differentiator models hypothesize about alcohol response phenotypes that increase the risk for developing addiction, it is important to note that there are also theories about adaptive changes in alcohol responses as they relate to the neurocircuitry of the addiction process. These are briefly reviewed in the next section.

Neurobiological Models of Addiction

Addiction has been explained as a "disease of the brain's reward system" [56–59] and alcohol promotes dopamine release in the brain [60] and activates opioid peptides, glutamate, GABA, and other neuromodulators [61, 62]. During the course of increasing severity of addiction, neurobiological theories have proposed adaptive processes that underlie the stages of addiction. The longstanding model of adaptive changes in addiction is tolerance, i.e., diminished response to the same amount of alcohol [63, 64], that has been shown in psychopharmacological and neurobiological pre-clinical studies and is also one of the DSM criteria for AUD [65].

Another model, the allostasis model [66] draws from data in neuroimaging and animal studies and describes a series of stages in addiction. The first stage is described as the binge/intoxication stage, and is marked by positive reinforcement and drinking for pleasurable effects. The next stage is marked by neuroadaptations depleting dopamine function in brain reward circuits and pathological recruitment of stress- and anti-reward systems, resulting in drinking for negative reinforcement to lessen negative affective states and withdrawal. The third stage is termed preoccupation and anticipation and accompanied by executive function deficits.

Finally, another widely-cited theory of neuroadaptive changes in addiction is the incentive sensitization model [67, 68]. This model, based on extensive animal work, posits the addiction process involves independent changes in two neural systems: chronic excessive alcohol drinking sensitizes the neural circuits underlying motivational reward (wanting) but not hedonic reward (liking).

There are individual differences in the neural circuitry of risk for alcohol problems [69], and variation in the progression and intensity of addiction cycles as they relate to disruptions of the underlying neurobiological circuits [70]. However, convergent tests of these theories are critical and are lacking, due to methodological constraints and the difficulties in translational research between animal and human studies, particularly in prospective neuroscience and longitudinal studies. Further compounding the issue is that in early work in human laboratory studies, reliable and valid measures of stimulating and positive rewarding effects were largely absent, meaning that only "one side of the coin" (impairment/sedation) was being measured in high risk individuals [46]. These are important factors to consider in this review of the two largest longitudinal studies of alcohol response summarized in the next section. Figure 33.1 shows the models of addiction tested and supported by these studies.

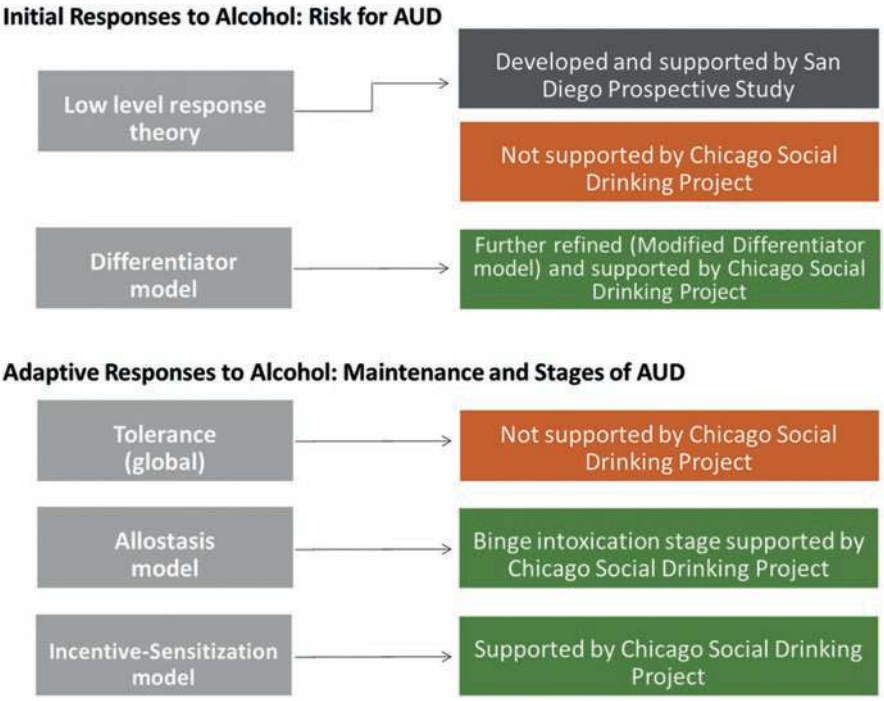

Fig. 33.1 Models of addiction

Longitudinal Approaches to the Study Alcohol Responses in At-Risk Individuals

As stated earlier, two longitudinal studies have set the benchmark for examining acute responses to alcohol in at-risk individuals. They represent the gold standard of well-controlled, quality research with moderate-to-large sample sizes, well-characterized participant subgroups, and high longitudinal retention rates of 98–99%. The first of these two studies, the San Diego Prospective Study, was founded on prior work [71] and originated in 1978 with laboratory alcohol and placebo challenge among a reported 453 participants. Approximately one decade later, the participants were contacted for in-person follow-up for symptoms of alcohol abuse and dependence and other biometric data. This study is remarkable in that the follow-up was conducted before the digital age, so that methods used to contact participants consisted of mail, telephone, and/or publicly available records [72].

The second of these longitudinal studies, the Chicago Social Drinking Project [50], originated in 2004, with laboratory alcohol and placebo challenge in 397 participants (and counting). After the laboratory sessions, the first cohort of 190 participants completed quarterly follow-ups for 2 years and near-annual follow-ups for a decade thereafter. They were also invited to return to the laboratory to engage in

re-examination laboratory sessions 5- and 10-years after their initial testing. As over 40% of participants had relocated, transportation and travel allowances were provided, as needed. Two additional cohorts of 207 participants (described in more detail later) were added to the study starting in 2009 and 2016, respectively. These cohorts underwent similar laboratory testing and repeated follow-up assessments of drinking behaviors and AUD symptoms.

The Chicago Social Drinking Project is a significant next-generation study extending the precedent set forth by the San Diego Prospective study. It capitalized on technology advances in the intervening years to employ more frequent follow-ups and the use of email, text messages, and internet surveys not possible at the time of the San Diego study [41]. Notably, the Chicago study is the only investigation to date to re-examine drinkers over an extended period of time in order to elucidate the dynamic changes and/or stability in alcohol responses. The next section provides a more detailed review of each of these high-impact longitudinal studies examining alcohol responses and their associations to future drinking and AUD symptoms over time. Both the San Diego and Chicago studies reported outstanding 98–99% follow-up rates. The methodology and mindset to achieve such high retention has been outlined by both groups [41, 72].

San Diego Prospective Study

Over the course of a decade (1978–1988), the San Diego Prospective Study reported enrolling 453 non-alcohol dependent male drinkers between ages 18 to 25 years. These men were recruited from surveys given to students and staff at a state university, and selected for participation based on their self-reported family history of alcoholism. They were deemed high risk if they reported a positive paternal family history of DSM-III (or DSM-III-R) alcohol dependence, and low risk if they had no known family history of alcohol abuse or dependence [49, 73]. Investigators matched individuals in each group on sociodemographic and drinking characteristics. Laboratory sessions were double-blinded, and began at 7:00a after participants had an overnight fast for at least 10 h. After baseline measures, alcohol was consumed over 10 min as a 20%-by-volume room temperature beverage at doses approximating 0.6 and 0.87 g/kg alcohol (or placebo).

A series of publications reported on outcomes in subgroups of the total sample (Ns ranging from 40–68 subjects). The initial findings showed a less intense response to alcohol in individuals with positive versus negative family history of alcoholism, on measures of subjective intoxication, static ataxia, and stress hormone markers including cortisol [27, 30, 73, 74]. Measures of stimulation and reward were not obtained, and many of the responses were reported during post-consumption intervals corresponding to the peak BrAC or descending limb [74]. The men were re-contacted approximately 8–12 years later for face-to-face follow-up interviews, with a very high 99% retention rate reported. Findings showed that, regardless of family history status, those with lesser alcohol responses on subjective

intoxication or body sway (ataxia) had a several-fold higher risk of meeting criteria for alcohol abuse and dependence approximately a decade later [51]. This was confirmed in a subsequent analysis of the highest and lowest 15% of individuals on level of response [49]. Subsequent path modeling in a subset of participants showed that low response to alcohol on the same measures predicted alcohol abuse and dependence symptoms at a 20-year follow-up wave [75]. The genetic contributors to alcohol sensitivity in this study may be related to GABA, glutamate, opioid, dopamine, serotonin and the cholinergic system, but more work is needed before conclusions can be drawn [76].

In sum, the San Diego Prospective Study was the first of its kind to examine the response to alcohol on some measures with long-term follow-up to examine risk for AUD. This study demonstrated that low acute alcohol response phenotypes on measures of ataxia or subjective responses favoring sedative effects prospectively predicted future diagnoses of alcohol abuse or dependence in men who did not meet those criteria at enrollment. The results also demonstrated that there may be other predictive factors for future problem drinking outside family history for the disorder. Indeed, the majority of the children of people with AUD do not develop AUD themselves [77], and heritability accounts for about 50% of the variance in the risk for developing AUD [78]. So while family history is a highly heritable phenotype for risk for AUD, acute alcohol responses may be just as important—or even more important—as a marker of risk.

While the San Diego Prospective Study had strengths with a well-controlled laboratory paradigm, subjective and objective measures, and highly successful follow-up rates to circumvent problems associated with loss to follow-up [41], it also had some limitations. First, as collection of data took many years to accrue, publications have different sample sizes with most papers presenting data from less than half of the full sample. Second, as the work is decades old, instruments were limited on their psychometric properties to measure the many effects of alcohol. The main subjective instrument came from research on subjective effects of lithium [79], and items favored sedative and sluggish effects over pleasurable effects. The few positive effects included in the scale have low comprehension and association to alcohol's effects (i.e., "high", etc.) [80]. Third, the sample described in many reports from this study was homogeneous on sex (all male), race (all Caucasian) and religious affiliation (non-Jewish) potentially limiting generalizability to the larger population of people with AUD, including women [81] and non-White racial and ethnic subgroups [82]. More inclusive studies with alcohol-specific response measures would overcome these obstacles, as discussed in the next section.

Chicago Social Drinking Project

The Chicago Social Drinking Project has thus far enrolled 397 young adult drinkers aged 21 to 35 years, in three successive cohorts from 2004 to 2019. The study included individual, random-order 0.8 g/kg alcohol or placebo beverage

administration (consumed over 15 min with 16%-by-volume alcohol) in separate individual sessions. The sessions were conducted during afternoon timeframes and after a calorie-controlled snack to minimize nausea and aversive effects, as opposed to the overnight fast and early morning timeframes in the San Diego study. Participants were recruited from the community by flyers, media advertisements and word-of-mouth referrals. As early-age binge drinking is an important risk factor for vulnerability to AUD [83, 84], high-risk individuals were defined as non-alcohol dependent persons reporting weekly binge drinking (i.e., five or more standard drinks per occasion for men, four for women) [14, 85] with 10 or more drinks per week for at least the last 2 years. The control group was light drinkers who consumed less than six drinks per week with rare binge drinking occasions. The overall sample was diverse with inclusion of both sexes (44% women) and broad representation in terms of race (26% reported as: Black, Asian, Native American, or More than One Race), and ethnicity (13% Hispanic) to reflect the heterogeneity of persons with excessive drinking behaviors [82].

The original cohort of 104 young adult binge/heavy drinkers and 86 light drinker controls was enrolled between 2004 and 2006 and underwent alcohol and placebo laboratory testing and follow-up interviews on their drinking and AUD symptoms at near-annual intervals. Those eligible for repeat alcohol challenge testing (96% of the sample) were invited back for two re-examination laboratory testing sessions at two intervals corresponding to 5 and 10 years after initial participation with 88% and 91% participation rates, respectively.

A second cohort of 104 young adult heavy social drinkers was enrolled between 2009, and 2011, and a third cohort of 103 young adult AUD drinkers between 2016 and 2019. These cohorts underwent similar alcohol and placebo challenge testing and follow-ups. The second cohort was recruited to increase the sample size of at-risk drinkers for a replication sample, and the third cohort was included to test adaptive responses to alcohol in individuals at the higher end of the drinking severity continuum. The drinking patterns of this AUD cohort differed from those in prior heavy drinker cohorts, i.e., 41.9 versus 20.9 drinks per week, respectively, and on all other quantity-frequency and alcohol consequence measures.

Thus, a total of 397 young adult drinkers comprised three cohorts in the Chicago Social Drinking Project. They have ranged across the spectrum of light, heavy, and AUD drinkers with an overall mean age of 26 years at enrollment. Family history of alcoholism was obtained as part of background measures but was not a selection criterion. Of note, more than one-quarter of the sample had indeterminate family history (adoption, lack of knowledge of family members' drinking, etc.), and including family history as a covariate in analyses did not affect the results. To provide a complete biphasic alcohol response profile, primary measures were assessed before beverage consumption and repeated at several intervals after consumption to capture rising, peak, and declining BrAC. In order to decrease alcohol expectancy, participants did not know the actual study purpose or the class of substance in their beverage until debriefing [86]. In a series of papers, differences in alcohol responses between heavy and light drinkers was demonstrated on a variety of measures, including subjective response, psychomotor performance, eye movements, and

cortisol [26, 32, 38, 87, 88]. Subjective responses to alcohol were ascertained by reliable and valid scales sensitive to alcohol's effects: the Biphasic Alcohol Effects Scale for stimulation and sedation [80, 89] and the Drug Effects Questionnaire for liking and wanting [90].

Relative to low-risk drinkers, heavy drinkers exhibited heightened sensitivity to alcohol's pleasurable effects (stimulation, liking and wanting) and lower sensitivity to subjective sedation [32]. Heavy drinkers also had lower cortisol response than light drinkers and self-perceived they were less impaired from alcohol [32, 38, 91] despite having similar performance impairment [38], with a few exceptions [87]. This alcohol response phenotype of heavy drinkers in the original cohort was reproducible in the second cohort of heavy drinkers [92].

Over the course of quarterly follow-ups, with 99.1% retention in the first 2 years after the sessions, in heavy drinkers, heightened alcohol stimulation, liking, and wanting as well as low sedation predicted binge drinking exacerbations, which in turn predicted the likelihood of meeting AUD criteria as participants were entering their late 20's [32]. Light drinkers continued with low-risk drinking patterns. At the 6-year follow-up interval, 98% of all possible follow-ups were successfully completed. The findings in heavy drinkers provided a critical extension of the aforementioned predictive models: greater stimulation and reward sensitivity, in addition to lower sedation, predicted future AUD symptoms and drinking exacerbations 6 years later. This was observed during a developmental epoch where alcohol misuse largely deviates from age-related norms [55]. The positive subjective effects of alcohol at peak BrAC were more predictive of future drinking and AUD symptoms than effects during either rising or declining limbs, providing further support for the modified differentiator model [55]. Trajectory analyses showed that about one-third of high-risk drinkers moderated their drinking with few AUD symptoms, but more than half continued with weekly binge drinking and met symptoms consistent with mild or moderate AUD. About 10% progressed to severe AUD.

In the re-examination testing of alcohol responses at the 5–6 year interval, those with the highest AUD symptom counts exhibited pronounced alcohol stimulation, wanting and liking, and lower sedation, compared with individuals with intermediate or few AUD symptoms. Light drinkers continued to show a largely "protective profile", with persistently low sensitivity to alcohol stimulation and reward, together with high alcohol sedation and stress hormone responses [42].

A 10 years of follow-up, re-examination of alcohol and placebo responses were conducted when most participants were in their fourth decade of life [93]. At this juncture, 21% met criteria for past-year AUD (three times higher than national norms). Those who had the highest alcohol stimulation, liking and wanting at the initial challenge were most likely to have developed AUD a decade later [93]. Further, re-examination testing showed that alcohol-induced stimulation and wanting increased in intensity among those who developed AUD versus those who did not [93]. The same pattern of results was observed in trajectory analyses in the growth of AUD symptoms: the highest AUD symptom trajectory subgroup showed an increased magnitude of alcohol stimulation and wanting over time, with persistently high levels of alcohol liking. Unlike the prior follow-up intervals, sedation

was no longer an inverse predictor of drinking exacerbations or AUD symptoms and physiological responses to alcohol also were not predictive.

In sum, over the decade of re-examination waves, there was a potentiation of stimulation and motivational salience (wanting) such that these responses were magnified over time in those who developed AUD versus those who did not. Hedonic effects of alcohol hedonic (liking) were sustained at a higher level in those with AUD than those without AUD. These findings in those with or without AUD at the end of the decade ("the destination") were corroborated by examining the sample on AUD symptom trajectories (the "journey"), as individuals in highest trajectory subgroup of AUD symptoms, relative to those with low or no AUD symptom progression, initially had the highest stimulating and rewarding alcohol responses that were either magnified or sustained at 10-year re-examination.

Finally, a subsequent third cohort of 103 young adult AUD drinkers in the Chicago Social Drinking Project was enrolled to examine a sizeable sample of drinkers at the highest level of the drinking continuum, i.e., AUD, in order to provide a comprehensive test of adaptive alcohol response models of addiction. The methods of random-order alcohol (0.8 g/kg; high dose) and placebo laboratory sessions were similar to that in prior cohorts. A subset of this cohort also had an additional randomized session with 1.2 g/kg alcohol (very high dose) to more closely match the excessive drinking behaviors characteristic of AUD drinkers. This dose was feasible with few adverse effects [94].

Results showed that both the high and very high doses of alcohol produced marked biphasic effects in AUD drinkers, with rising limb to peak BrAC increases in stimulation, liking and wanting as well as heart rate increases, and declining limb increases in sedation [95]. Thus, instead of developing tolerance and lack of sensitivity to alcohol's desirable effects, AUD drinkers exhibited high alcohol sensitivity, with stimulation and reward of a magnitude comparable or even higher than previously observed in heavy drinkers. These findings show that AUD drinkers haven't "lost that positive feeling" [95] or developed tolerance to alcohol's pleasurable effects. To the contrary, AUD drinkers exhibited heightened pleasurable effects of alcohol that align with the reward-sensitive binge intoxication stage of addiction in the allostasis model, and not with thef purported reward-deficit second stage of allostasis. Currently, participants are undergoing annual follow-ups for four years to examine their future drinking and potential onsets and offsets of AUD. Retention rates are in the 98–99% range over first few years and results will address whether alcohol responses have prognostic significance in the progression or regression of AUD.

Overall, the findings of the extensive longitudinal Chicago Social Drinking Project challenge the conventional notion of a "low responses to alcohol" as the driving force in the progression of AUD. Rather, there is a prolonged and pronounced sensitivity to stimulation and reward consistent with what is described in the first stage of the allostasis model. Results also support the incentive-sensitization model, as motivational salience (wanting) became sensitized over time while hedonic reward, i.e., liking, remained elevated but did not significantly increase in magnitude over time. As such, while there are multiple pathways to development of

a disorder as complex as AUD, the maintenance and potentiation of stimulatory and rewarding alcohol effects appear to play an important role in the continuation and progression of alcohol addiction. In contrast, an attenuated or absent sedative response becomes less predictive of future drinking as follow-up waves proceeded.

Conclusions: Alcohol Response Phenotype as Contributors and Markers of Addiction Process

The two longitudinal studies reviewed herein have advanced our understanding of the quality and magnitude of alcohol responses as related to excessive drinking and risk for future AUD through young and middle adulthood. Notably, both the San Diego and Chicago studies examine alcohol response phenotypes and their associations to the risk for excessive drinking. These programs have expanded scientific questions and testing of neurobiological theories of addiction by enrolling additional cohorts of at-risk drinkers, examining the progeny of participants and genetic contributions [96] and/or employing newer methods and measures for precise ascertainment of a myriad of alcohol responses. Beyond laboratory assessments, both groups have developed and tested self-report retrospective scales to ascertain alcohol responses [97, 98] that correlate with laboratory-derived measures [99]. In terms of other advancements in recent years, the Chicago study has employed examination of real-time drinking and alcohol effects in the natural environment with high-resolution ecological momentary assessment (HR-EMA) using participant's own smartphones and alcohol biosensors [99, 100].

While laboratory alcohol challenge continues to be the gold standard for translational research in ascertaining acute alcohol response, refinement of complementary methods may circumvent the limitations of labor-intensive and costly individual laboratory sessions. Retrospective scales or technology-based HR-EMA methods enable data collection on a larger scale, and overcome external validity concerns within the controlled laboratory environment. The COVID-19 pandemic has necessitated more urgency in developing real-time methods and may mark an inflection point in the use of alternative methods to examine alcohol responses.

Another major issue in the field is overcoming the apparent discrepancies between the findings of the two research programs presented herein. The earlier work of the San Diego Prospective study in the 1970s and 1980s set the stage for the widely-adopted low-level response and other low-sensitivity models of risk for AUD [51, 101]. However, the findings of the Chicago Social Drinking Project from the 2000s to 2020s, and other cross-sectional work, demonstrate that less intensive alcohol effects are not ubiquitous in at-risk individuals and highly sensitivity to alcohol's pleasurable effects are the most predictive of future drinking problems and AUD [32, 93, 95].

To resolve the apparent discrepancy on whether lower or higher sensitivity to alcohol concurs heightened vulnerability to addictive disorders, qualitative and

quantitative reviews have suggested that there may be more than one phenotypic pattern of response to alcohol in high-risk individuals, depending on whether risk is conferred by family history of the disorder or heavy drinking patterns [28, 29]. Others have argued for a paradigm shift to change the zeitgeist of global alcohol response characterization, i.e., low alcohol sensitivity or low level response [51], to a more accurate, specific and descriptive framework, i.e., low level response to alcohol sedation or low sensitivity to alcohol-induced ataxia. In addition, many have called for terms to describe alcohol's effects in lieu of a newer and more specific characterization framework stressing the use of measures with strong psychometric properties to detect alcohol's effects, and specifying the dose of alcohol, interval on the breath alcohol curve, and the risk group being studied [28, 50], i.e., low response to alcohol sedation after peak BrAC, or heightened sensitivity to alcohol stimulation during the rising BrAC limb in binge drinkers. These proposed more specific characterizations would be akin to animal models that identify particular drug effects tested Such models in rodents include measures of the sedating effects of alcohol by the loss of righting reflex or rotarod test, and measures of positive reinforcing and drug preference effects by the two-bottle choice, self-administration or conditioned place preference paradigms [102]. The advantage of human research is that instead of making inferences about internal mood state or behavioral responses, as in animal research, the use of subjective measures with good psychometric properties allow direct self-report measurement of how one feels at certain intervals before and after alcohol consumption. Going forward, best practices for human models should use more specific terminology and frameworks, as mentioned earlier, as well as avoid paradigm choices lacking external validity and potentially confounding measurement, such as morning sessions, overnight fasting, or participant isolation.

An overall understanding of the findings of the San Diego and Chicago studies may come down to the inverse relationship between alcohol stimulation and sedation [43] that may necessitate a paradigm shift [46, 50]. This becomes clear when scales that measure pleasurable alcohol effects are included in laboratory protocols [80, 89, 90]. Contrary to theories purporting low levels of response to alcohol [51] and reward insensitivity as drivers of risk and maintenance of AUD [56, 57], an increased focus on heightened sensitivity to alcohol stimulation, euphoria, and reward may is warranted. In contrast to what has been postulated, positive subjective effects of alcohol persist and, in some cases, sensitize as individuals develop AUD, at least in young and early-middle aged adulthood [93]. As mentioned earlier, adopting more precise phrasing beyond level of response or low sensitivity for more well-defined concepts will enable the field to move forward with consilience on methodological considerations and strengthen the impact of the findings.

A third important issue is to better understand the importance of longitudinal studies for translational neurobiology. While studies with long-term follow-up and re-examination phases are challenging in terms of coordination and organization to yield high retention and continued participation rates, this type of research in humans allows direct testing of the main theories regarding the role of alcohol responses on heightened vulnerability and maintenance of AUD. This knowledge is

necessary to adequately test the translational significance of animal models of addiction to humans [103] and recent results from the Chicago study indicate that the excitatory effects of alcohol remain heightened (liking) or are potentiated (stimulation, wanting) as drinking exacerbates and AUD symptoms increase over time. At the same time, the acute sedative effects of alcohol decrease in problem drinkers. Genetic factors underlying alcohol response phenotype have been examined in both studies and shown a range of possible variants related to acute effects of alcohol [76] or as moderators of the predictive relationship of alcohol liking and wanting to future AUD as shown with a dopamine signaling variant related to reward in the Chicago study [96].

In sum, longitudinal research can be integrated with state-of-the-art laboratory methods and the lessons learned from the two most prominent of these investigations can uniquely help future research. First, the San Diego and Chicago studies described in this chapter showed exceptional attention to detail and investment in their paradigms to yield outstanding high-retention cohorts to advances in our understanding of the development of alcohol addiction and translation of animal research to the human condition. Continued longitudinal examination and re-examination of alcohol response phenotypes will foster better understanding of the development, maintenance and treatment of AUD. Second, improved methods in translational laboratory and longitudinal investigations and measurement of effects across the spectrum of positive- and negative-reinforcing effects is paramount. Because it is more recent, the Chicago Social Drinking Project is has methodological advantages over the San Diego study, but the latter study contributed greatly to long-term outcomes and pathway models, integrating genetic heritability and psychosocial risk factors related to alcohol response phenotype. Expanding participant samples to individuals in middle and older ages would provide a lifespan perspective on whether alcohol responses may stabilize or change over time during aging. This would be an important future direction, and this testing is underway in a fourth cohort in the Chicago study.

In conclusion, the ultimate goal for longitudinal investigations based on those described in this chapter will be to offer new empirical insights into the etiology and maintenance of harmful drinking and AUD. This can be undertaken by bridging neuroscience and basic preclinical studies to the human realm for laboratory and longitudinal hybrid studies that lead to innovative prevention and targeted intervention strategies [104]. Yet the combination of rigorous and well-controlled laboratory and longitudinal methodologies is not without practical challenges and methodological considerations for a long course of data collection. Expansion of the two longitudinal programs of research presented in detail in this chapter—by independent scientific teams and new study samples—will enable a better understanding of sensitivity and insensitivity to specific biphasic alcohol responses in at-risk individuals and protective alcohol response factors in low-risk drinkers. New avenues and novel methods of re-examination testing, convergences of animal and human methodology to the highest extent possible [102], and a lifespan approach will enable better targeted and empirically-based strategies for prevention, early intervention and treatment.

Chapter 34
Early Life Adversity as a Risk Factor for Alcohol Use Disorder

Melanie Schwandt

Abstract Childhood adversity and maltreatment, encompassing early life stressful events ranging from parental illness or divorce to more severe cases of physical and sexual abuse, represents a significant risk factor for adult mental health outcomes include alcohol use disorder (AUD). Childhood adversity and maltreatment is surprisingly prevalent in the general population worldwide, with even greater prevalence in individuals with AUD. These stressful experiences are associated with developmental alterations in key biological systems that contribute to risk for AUD, including the neuroendocrine and corticolimbic systems, the inflammatory response, and epigenetic modifications. These alterations can become embedded, resulting in long-term adverse consequences on health and behavior. Childhood maltreatment in particular has been linked to an earlier age of onset for alcohol consumption, greater likelihood of adolescent binge drinking, and increased probabilities of drinking to cope and impaired control over drinking in young adulthood and beyond, all of which contribute to vulnerability for AUD. Furthermore, individuals with a history of childhood maltreatment who ultimately seek treatment for AUD often present a greater challenge for health practitioners. A better understanding of the role of childhood adversity and maltreatment in the etiology of AUD can assist in meeting that challenge.

Keywords Abuse · Neglect · Maltreatment · Trauma · Alcohol · Stress

Introduction

Risk factors for the development of alcohol use disorder (AUD) are traditionally classified into one of two categories: genetic and environmental. The genetic risk factors for AUD are covered here in a separate chapter. Environmental risk factors

for AUD are diverse in scope and stem from a wide range of contexts, including the individual social network (parents, family, peers), the community level (work, school, social norms, religion, alcohol availability), and the societal level (policies and laws, taxation) [1, 2]. The impact of these risk factors also varies across individuals, communities, populations, and geographic regions. For the individual, it also varies across the life course.

A prominent theme in epidemiological research is that environmental exposures occurring during sensitive periods of development can exert significant and long-lasting effects on health and well-being. Adversity and maltreatment during childhood, especially in the context of family and the home environment, has been linked to a vast array of negative consequences for physical and behavioral health during both childhood and adulthood. These consequences include somatic health conditions such as cardiovascular disease, respiratory disease, stroke, diabetes, cancer, autoimmune disorders, and pain disorders [3–7], and nearly all forms of psychopathology, including alcohol and other substance use disorders [8–11]. A recent review and meta-analysis of the consequences of childhood adversity on health outcomes reported estimated annual costs of $581 billion in Europe and $748 billion in the US [4], underscoring the fact that childhood adversity exerts a significant impact on public health.

Problematic alcohol use also poses a significant burden to public health, with an estimated annual cost of $249 billion in the U.S. (www.cdc.gov/alcohol), an estimated economic cost of 2.6% of the gross domestic product worldwide, and an estimated 5.1% of the global burden of disease [12, 13]. This chapter examines how childhood adversity and maltreatment pose a significant environmental risk factor for alcohol use disorder. Following a review of definitions and prevalence estimates for adversity and maltreatment, the biological and behavioral pathways that ostensibly link these early life experiences to alcohol use disorder are discussed. Figure 34.1 presents a conceptual illustration of the main points and pathways that will be covered in this discussion.

Data on individuals seeking treatment for AUD paint a compelling picture: greater than 50% of patients report being exposed to at least one type of childhood maltreatment (e.g., abuse or neglect), and a history of maltreatment is associated with earlier onset of AUD, greater severity of addiction, increased risk for psychological comorbidity, and poorer treatment outcomes [14–19]. Paradoxically, a history of maltreatment has been associated with both an increased probability of accessing treatment, and greater perceived barriers to treatment, e.g., believing that treatment would not be helpful [20]. Increased awareness and understanding of the role of childhood adversity and maltreatment in the etiology of AUD is crucial not only for efforts at early prevention or intervention, but also for the development of current and future treatment approaches.

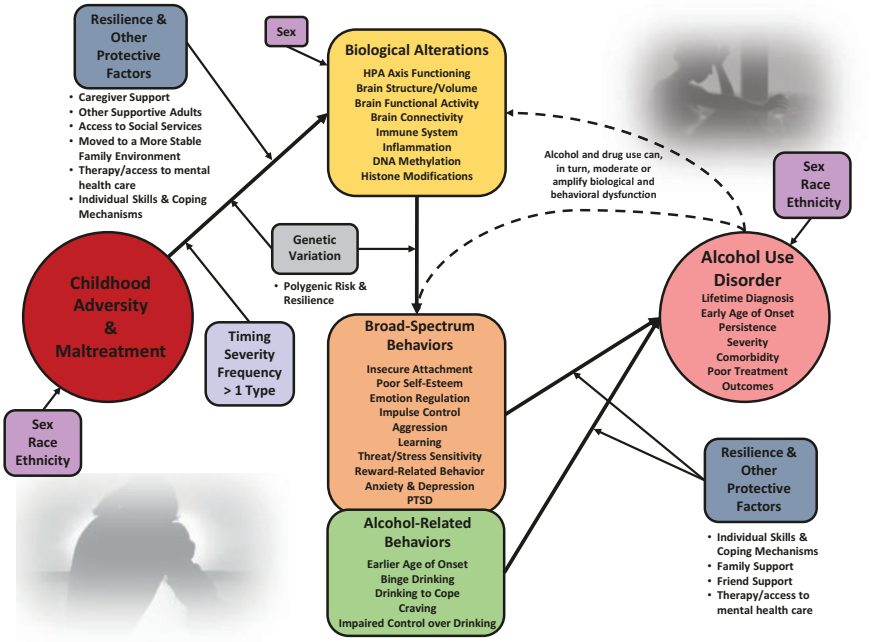

Fig. 34.1 Illustration of the potential pathways from early life adversity to alcohol use disorder. Exposure to childhood adversity and maltreatment can lead to alterations in multiple biological systems, some of which may become embedded. These biological alterations can have long-term consequences on behavior, including alcohol-related behaviors that are known to increase risk for developing alcohol use disorder. At multiple points along these pathways, effects may be moderated by the timing and severity of exposure, genetic variation, sex, race, and various factors associated with resilience. The dashed arrows indicate how alcohol misuse can, in turn, result in further biological and behavioral dysfunction

Definitions: Adversity, Maltreatment, and Trauma

A variety of terms are used in the literature to describe negative childhood experiences, including "early life stress", "childhood adversity", "adverse childhood experiences" (ACE), "childhood maltreatment", and "childhood trauma". Conventionally, these terms all refer to experiences occurring up until 18 years of age. While these terms are often used interchangeably, in truth they represent different concepts with varying degrees of overlap. Early life stress, childhood adversity, and ACE are broad terms that cover a wide range of experiences, from common events such as divorce or death of a family member to more extreme events such as witnessing domestic violence, being subject to abuse or neglect, and experiencing natural disasters, warfare, or terrorism. These experiences may happen directly to the child, or may affect the child together with others around them. Childhood maltreatment is directed exclusively toward the child, and occurs when a parent or other person responsible for the child commits acts that result in actual, potential, or

threat of harm to the child [21]. Maltreatment covers behaviors such as physical, sexual, and verbal or emotional abuse, neglect (failure to meet the physical and emotional needs of a child), abandonment, and sexual exploitation [22]. Childhood trauma is a more complex concept to define. The Diagnostic and Statistical Manual of Mental Disorders (DSM-5) defines trauma as exposure to actual or threatened death, serious injury, or sexual violence [23]. Yet this definition implicitly excludes emotional or psychological abuse, which can actually be quite harmful, especially for children, despite the lack of physical injury. Alternative definitions of trauma focus less on the type of event and more on the response to that event. For example, the Substance Abuse and Mental Health Services Administration (SAMSHA), which oversees the National Child Traumatic Stress Initiative (NCTSI) in the United States (US), defines trauma using the three "E's"—an *event* (or series of *events*) that is *experienced* by an individual as emotionally or physically threatening and that has lasting adverse *effects* on the individual [24].

Childhood maltreatment and childhood trauma show a high degree of overlap in the literature, as studies using these terms typically focus on abuse and neglect. Childhood abuse and neglect are traumatic for many if not most children, thus it is common for these experiences to be labeled as childhood trauma. This is reflected in the Childhood Trauma Questionnaire (CTQ), a well-validated and widely-used assessment developed by Bernstein and colleagues [25], which measures presence and severity of five types of trauma: physical abuse, sexual abuse, emotional abuse, emotional neglect, and physical neglect. Physical abuse is defined as risking or inflicting physical injury on a child, usually by a parent or adult caregiver, through bodily contact or other means (e.g., tying up a child to restrict movement, forcing exercise to the point of exhaustion). Sexual abuse is defined as sexual contact between a child and an adult or older person, or other non-contact interactions such as voyeurism and exploitation, that are used for the sexual stimulation of the perpetrator [25, 26]. Emotional abuse is defined as verbal attacks on a child's sense of worth or well-being, or other acts or demeaning behavior directed toward a child by an adult or older person, that cause emotional and/or psychological damage to the child [25–27]. Emotional neglect is defined as the failure of caretakers to meet a child's basic emotional and psychological needs (e.g., attention, love, nurturance, and support), while physical neglect is defined as the failure to provide for a child's basic physical needs (e.g., food, shelter, clothing, medical care) [25, 26].

For AUD, the most notable effects tend to be linked to childhood maltreatment/trauma experiences such as abuse and neglect, and thus the primary focus of this review will be on those type of exposures. However, the impact of other forms of early life stress on alcohol use and misuse are still relevant, especially if there is a history of exposure to multiple types of stressful events.

Prevalence of Childhood Adversity and Maltreatment

Prevalence in the General Population

According to the World Health Organization (WHO) it is estimated that globally, up to one billion children aged 2–17 years have experienced physical, sexual, or emotional abuse or neglect in the past year [28]. Past year prevalence estimates based on a 2016 systematic review of reports covering 96 countries indicate that at least 44% of children in developed countries, and 59% of children in developing countries, experience physical, emotional, or sexual abuse or witness domestic or community violence [29]. In the United States, it is estimated that 1 in 7 (14.4%) children experienced abuse or neglect in the past year [30], while lifetime prevalence estimates in North America based on meta-analysis are 18.2% for sexual abuse, 18.1% for physical abuse, 23.9% for emotional abuse, and 30.1% for neglect (either physical or emotional) [31]. Higher prevalence of childhood maltreatment has been reported in certain populations including Native Americans [32], African Americans, and Hispanic Americans [33, 34]. In Europe, lifetime prevalence estimates based on meta-analysis are 13.2% for sexual abuse, 12.2–22.9% for physical abuse, 21.7–29.1% for emotional abuse, and 27.0% for neglect, and in Asia the estimates are 16.3% for sexual abuse, 13.9% for physical abuse, 33.4% for emotional abuse, and 47.2% for neglect [31, 35]. When considering the broader experience of childhood adverse events, rates are notably higher: from 46–61% among U.S. youth under 10 years of age, up to 77–99% in several countries assessed for childhood adversity by the WHO [36].

Prevalence in Individuals with AUD

Prevalence rates for child maltreatment are in general higher among individuals with AUD, especially those who seek treatment, compared to the general population. That said, precise prevalence rates in AUD populations vary somewhat, due to factors such as method of assessment, sample size, and sample composition. Several studies using the CTQ have reported prevalence of the five common types of abuse and neglect based on a cut-off point of "moderate-to-severe" [37]. These rates range from 11.0–24.0% for sexual abuse, 18.0–31.1% for physical abuse, 21.4–32% for emotional abuse, 20.4–39.7% for emotional neglect, and 19.9–28.2% for physical neglect [14, 16, 38]. Using a "low-to-severe" cut-off, however, reported rates in an AUD sample are somewhat higher: 38.9% for sexual abuse, 21.1% for physical

abuse, 47.5% for emotional abuse, 57.1% for emotional neglect, and 27.5% for physical neglect [15]. Data from the large National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), which measured child maltreatment with questions based on the CTQ, indicate prevalence rates among all adults with AUD as 12.1% for sexual abuse, 22.9% for physical abuse, 11.2% for emotional abuse, 10.2% for emotional neglect, and 29.6% for physical neglect [39]. Among emerging adults (18–25 years of age) with AUD, however, rates are substantially higher: 40.2% for sexual abuse, 47.0% for physical abuse, 52.9% for emotional abuse, and 48.0% for physical neglect (emotional neglect was not reported) [20].

In addition to prevalence, severity scores for each of the five abuse and neglect measures of the CTQ are also significantly higher in individuals with AUD compared to those without [15]. Moreover, individuals undergoing inpatient treatment for AUD report greater severity of emotional abuse and physical neglect compared to individuals with AUD that do not seek treatment [40].

Characteristics of Exposure

The impact of childhood adversity and maltreatment on an individual, both immediately and in the long term, is influenced by several key characteristics of exposure. These include the timing of exposure, the severity and/or frequency of exposure, and the accumulation of different types of exposures. Timing, or the age at which a child is exposed to maltreatment, can be a determinant of developmental process and behaviors that are most likely to be affected. For many outcomes, exposure to maltreatment in the first few years of life has the greatest impact; however, exposure at later ages (e.g., puberty) can also have long-lasting effects [41]. "Sensitive periods", or windows of time during which vulnerability to maltreatment-related changes is relatively high, have been identified for both brain development [6, 42] and hypothalamic-pituitary-adrenal (HPA) axis functioning [43], systems that have long been implicated in the etiology of AUD. Severity of exposure is also important and can reflect specific aspects of the maltreatment, such as the likelihood to cause serious injury, or even just the frequency of occurrence. Severe exposure to a single abuse type, most often sexual abuse, has been associated with increased risk for substance use disorders and having more than one psychiatric disorder [44]. Likewise, frequent or chronic exposure to maltreatment or adverse events is associated with greater vulnerability for a range of mental health and substance abuse problems [45]. For problematic drinking and AUD, experiencing two or more events confers greater risk compared to experiencing only a single event [46, 47], and exposure to four or more events is associated with a 7.2-fold increase in risk for developing an AUD [45]. Somewhat related is the concept of cumulative exposure to more than one type of maltreatment, otherwise known as "poly-victimization". Exposure to multiple types of maltreatment is a stronger predictor of psychopathology than exposure to a single type, even if chronic or severe [36, 48, 49]. Individuals with AUD report exposure to two or more types of childhood abuse or neglect at a much higher rate compared to those without AUD [15]. However, findings on

whether cumulative maltreatment exposure increases risk specifically for AUD, above and beyond exposure to a single type, are inconsistent [20, 50].

Biological Alterations Associated with Childhood Adversity and Maltreatment

A fundamental question is how exposures that occur during childhood can have such persistent and long-lasting effects on an individual. The answer lies in extensive evidence obtained from both animal and human studies that childhood maltreatment impacts the biological development of the individual, including changes in the brain, body, and even gene expression. These changes can ultimately become "biologically embedded", i.e., progress from transient responses to long-term, stable alterations that influence health and well-being throughout the life course [51]. A summary of some of the more well-documented changes is provided below. Much of what we know about early maltreatment and biological development stems from research using animal models, where experimental manipulations such as maternal separation, variation in maternal care, and social isolation have been used as proxies for childhood maltreatment. However, the validity of such models for the human experience of childhood maltreatment is debated. Consequently, the review below focuses on findings that have been corroborated in human studies as well as in animals.

Hypothalamic-Pituitary-Adrenal (HPA) Axis

The HPA axis is the primary biological system regulating the neuroendocrine response to stress. Childhood maltreatment results in chronic activation of the HPA-axis, which can lead to altered regulation of this axis throughout the life span. The expression of this dysregulation is inconsistent, however, both in childhood and later in adulthood. In studies of both animals and humans, maltreatment has been linked to both higher and lower basal and diurnal cortisol levels, and to both increased and attenuated cortisol responses to stressful stimuli. Contradictory findings for ACTH have also been reported [43]. There is some converging evidence that childhood maltreatment results in an initial hyperactivity of the HPA axis, followed by attenuation of response in adolescence and into adulthood [52–54]. However, several factors are known to moderate effects of maltreatment on the HPA-axis, including but not limited to sex, genetic make-up, and the timing and type of exposure [55]. Altered functioning of the HPA-axis has long been implicated in problematic alcohol use, with both augmented and blunted cortisol responses reported as possible precursors to AUD. Cortisol also interacts with other brain mechanisms, such reward, learning, and memory, all of which are also implicated in the etiology of AUD [56]. Consequently, the HPA axis is a prime suspect for being one of the pathways by which childhood maltreatment increases risk for AUD.

Brain Structure and Function

Another pathway is through changes in brain structure and function. Human brain development takes place over a long period of time, from before birth and into early adulthood, although the vast majority of volumetric growth occurs in the first 2 years of life. Exposure to stress during sensitive periods of development, and the ensuing release of glucocorticoids and neurotransmitters, affects neurogenesis, synaptic pruning, and myelination processes [57]. Childhood maltreatment has been associated with decreased gray matter volume in various brain regions, most notably the hippocampus, amygdala, anterior cingulate, and prefrontal cortex, regions that make up the corticolimbic system involved in emotion and cognition, as well as control of the HPA axis [51, 58]. Interestingly, these reductions are often seen in adults but not in children—for example, studies suggest an initial increase in volume of the amygdala during childhood that may precede a decrease in volume later in adulthood [57]. Attenuated development or reduced volume has also been reported for the caudate nuclei, the insula, and the cerebellum [59–61]. White matter changes have also been documented, the foremost being reduced size and integrity of the corpus callosum, a crucial white matter tract that connects and allows neural transmission between the two hemispheres [43, 62]. It is important to note that maltreatment-related effects on brain structure may be further augmented by heavy alcohol consumption in adolescence, which has also been shown to impair brain development processes during this stage of life [63].

With regards to brain function, two consistent findings in those exposed to childhood maltreatment are a diminished response of the striatum (nucleus accumbens, caudate, and putamen) to anticipated or actual reward, and hyper-reactivity of the amygdala to threat and negative emotional stimuli [51, 57, 58]. Relatedly, studies show changes in functional connectivity following maltreatment in both reward circuitry and stress/emotion circuitry, including increased connectivity of the salience network to both the insula and the amygdala, and reduced connectivity between the amygdala and cortical regions [64]. The latter is likely to contribute to heightened amygdala responses through diminished top-down control [62, 65]. Of note, all of these regions are considered part of "addiction circuitry", encompassing the processes of stress, emotion, reward, executive function, and motivation [66]. This reinforces the potential for alterations in brain structure and function to serve as a potential link between childhood maltreatment and risk for AUD.

Immune System and Inflammation

Similar to the brain, development of the immune system is continuous throughout childhood and is sensitive to environmental factors. Childhood maltreatment has been linked to elevated levels of C-reactive protein (CRP), a global marker of

inflammation, and to proinflammatory cytokines such as Interleukin-6 (IL-6), Interleukin 1-beta (IL-1β), and Tumour Necrosis Factor (TNF-α) [67–69]. While many of these findings stem from studies of adults with a history of childhood maltreatment, prospective studies have also reported increases in inflammatory makers in children recently exposed to maltreatment [70, 71]. Overall, there is stronger evidence for effects of abuse on inflammation, compared to neglect [68]. Chronic inflammation can result in immunosuppression, and links between childhood maltreatment and low-level immunosuppression have also been identified [51]. Chronic activation of the immune system in childhood may also affect brain development and functioning of biological stress systems [69] which, as described above, are notable pathways linking childhood maltreatment exposure to risk for AUD. Of note, alcohol consumption also triggers neuroimmune activation and inflammation. Furthermore, both posttraumatic stress disorder (PTSD) and depression share a high comorbidity with AUD, and it has been postulated that immune/inflammatory mechanisms play a significant role in risk for comorbidity of these disorders [72].

Epigenetics

Epigenetics changes comprise several chemical modifications to the DNA and DNA-associated proteins that can alter gene expression in a persistent manner, but do not modify the DNA sequence. Modifications include DNA methylation, histone modifications, and alterations in the level of non-coding microRNAs (miRNAs), processes that occur throughout the lifespan but are also susceptible to environmental factors [73]. These processes are some of the primary drivers of the biological embedding of early life experiences [51]. Evidence from both animal and human studies identify a number of genes that show changes in methylation levels associated with early maltreatment, including the glucocorticoid receptor (NR3C1), FK506-binding protein (FKBP5), arginine-vasopressin (AVP), brain derived neurotrophic factor (BDNF), oxytocin receptor (OXTR), serotonin transporter and synthesis (SLC6A4 and TPH2), dopamine receptor (D2), monoamine oxidase A (MAOA), and the glutamate receptor (NMDA), with the caveat that most human studies have been limited to analyses of blood and saliva rather than brain tissue [73–75]. Histone modifications and miRNA dysregulation associated with childhood maltreatment have likewise been reported for some of these genes in both animals and humans. Many of these genes are involved in stress-system regulation, either directly or through other processes such as reward, fear-conditioning, and cognitive function, all of which are implicated in addiction. However, identifying DNA methylation patterns as precursors for risk for AUD is problematic, given that alcohol consumption itself is known to cause methylation changes [76, 77]. Childhood maltreatment-associated changes in plasma levels of miRNAs, which can target many different genes, have also been identified in pathways for neurodevelopment and inflammation [78].

Behavioral Effects Associated with Childhood Adversity and Maltreatment

Childhood maltreatment has been associated with a broad range of behavioral problems and challenges across the life span. During childhood, these include insecure attachment, poor self-esteem, difficulty controlling emotions, poor impulse control, learning difficulties, aggressive behaviors, internalizing behaviors, and PTSD [7, 79]. These early disruptions can persist into adolescence and young adulthood, manifesting as interpersonal problems, self-regulation/emotion regulation difficulties, anxiety and mood disorders, executive function difficulties, and impulsivity. A history of childhood maltreatment has also been associated with poor sleep quality, alterations in reward-related behavior, and a heightened threat sensitivity [80–86]. Many of these broad-spectrum behaviors contribute in varying degrees to a general vulnerability for addictive disorders, including alcohol use disorder [87, 88]. In addition to the above, childhood maltreatment has been directly associated with behaviors specific to problematic alcohol use and the development of AUD, as detailed below.

Alcohol-Specific Behaviors

Alcohol use disorder is explicitly tied to alcohol consumption behaviors. The earlier these behaviors begin, the longer they persist, and the context or motives for continuing these behaviors are all important factors predicting risk for AUD. As a result, adolescence and young adulthood are crucial periods of risk, especially for individuals who have experienced childhood maltreatment. Both an earlier age of onset for alcohol use and adolescent binge drinking are associated with exposure to childhood adversity and maltreatment. Studies of large representative samples in the U.S. have shown that exposure to specific types of adversity including emotional, physical, and sexual abuse, emotional and physical neglect, and parental discord/divorce, is associated with increased odds of alcohol use initiation by or before ages 13–14. In addition, exposure to more than one type of adversity is associated with even greater odds of early initiation, as high as 3.6-fold among those experiencing four or more types [47, 89, 90]. Similar studies have also shown that childhood abuse and neglect are significant risk factors for adolescent binge drinking (consuming five or more drinks in a row at least two to three times in the past year), as well as a sharper increase in rates of binge drinking across adolescence and persistence into young adulthood [91, 92].

Among the motives for consuming alcohol, “drinking to cope” refers to consuming alcohol as a means to alleviate stress, anxiety, and other negative emotions. Drinking to cope is a strong predictor of long-term drinking behavior and AUD [93] and can emerge as early as adolescence, particularly among those exposed to

maltreatment and thus are more likely to experience frequent emotional distress [89]. In both adolescents and young adults, drinking to cope has been shown to mediate the effects of childhood maltreatment and alcohol use problems [94, 95]. In adults, drinking to reduce negative affect is often described as "self-medication", and while self-medication may alleviate distress in the short-term, in the long-term it often results in increased severity of symptoms and problematic alcohol use [96].

Other behaviors linked to AUD that may be impacted by childhood maltreatment include craving, impaired control over drinking, and "high-intensity" binge drinking. For craving, the effect of childhood maltreatment is often indirect, i.e., acute stress in adulthood results in increased craving for alcohol among individuals with a history of childhood trauma, more so than in those without such history [97, 98]. Impaired control is defined as the inability to stop drinking after beginning to consume alcohol, despite one's intentions, and like craving is one of the key criteria for AUD. Studies have indicated both direct and indirect links between childhood maltreatment and impaired control, with the indirect effects primarily mediated by PTSD in young adults [99, 100]. High-intensity binge drinking is defined as drinking two or more times the standard threshold for binge drinking. In adults, a history of family dysfunction and substance abuse, as well as childhood maltreatment, is associated with greater odds of high-intensity binge drinking [101].

Alcohol Use Disorder

Quite a few studies have linked childhood adversity and maltreatment to increased risk for AUD later in life. As mentioned previously, experiencing more than one type of adversity during childhood is associated with increased risk for lifetime AUD, with four or more events conferring even more severe risk [45, 46]. With respect to maltreatment, data from NESARC indicate odds ratios (ORs) for lifetime AUD ranging from 1.1 to 1.8 for the five types of maltreatment measured by the CTQ [39, 102, 103], with the higher estimates attached to the abuse subtypes. Physical and emotional abuse have also been associated with increased odds of seeking treatment for AUD among emerging adults [20]. Increased risk for a diagnosis of AUD is only part of the story, however. Childhood adversity and especially maltreatment is associated with an accelerated transition through the stages leading to the disorder (from age of first opportunity to use, to age of first drink, to age of regular alcohol use, and to age on onset for AUD) [104, 105], an earlier onset of AUD, especially in women [105, 106], persistence of AUD for at least 3 years [107], greater severity of AUD [15], and increased rates of psychiatric comorbidity [14]. Furthermore, a history of childhood maltreatment, particularly abuse, has been linked to poorer outcomes in those seeking treatment for AUD. These include increased probability of relapse, a shorter amount of time to relapse, and a decrease in global functioning [17, 18, 108].

Moderating Factors

Several important moderating factors can influence vulnerability to childhood adversity and maltreatment and the long-term effects of early stress exposure. These include intrinsic factors such as sex, race, and genetic make-up, as well as extrinsic factors such as early intervention, and family and social support. Notably, not all individuals exposed to childhood adversity and maltreatment experience lasting negative consequences, including AUD. While early adverse experiences are prevalent, so are individuals who successfully cope with or manage to overcome them. Indeed, moderating factors play a role in resilience as well vulnerability.

Sex and Race

Sex differences in exposure to childhood maltreatment have been reported, with the most consistent findings being higher rates of childhood sexual abuse among women [31, 109, 110]. Furthermore, sex differences in key biological systems known to be impacted by childhood maltreatment (e.g., HPA axis, corticolimbic system) have been documented [111]. However, findings on sex differences in the *consequences* of childhood maltreatment for behavioral health have been inconsistent. In terms of general psychopathology, some studies have suggested that women are more vulnerable to the effects of childhood maltreatment, while other studies suggest it is men that are more vulnerable [112]. Prevalence rates for AUD are consistently higher in men compared to women, and yet while some studies have found a stronger association between childhood maltreatment and problematic alcohol use in women compared to men [113, 114], more recent studies have found little to no sex differences in the association of childhood maltreatment history with either problematic alcohol use or AUD in adults [102, 103, 109]. There is evidence to suggest that the pathways from childhood maltreatment to AUD may differ between the sexes, however, despite no overt differences in diagnosis outcome. For example, the magnitude of effects of sexual and physical abuse on early onset of substance use and past year alcohol problems may differ between the sexes [115, 116]. All things considered, the relationship between sex, childhood maltreatment, and risk for AUD is complicated, as variables such as maltreatment type and severity, development stage, genetics and biological factors, and even cultural norms can play a role. Nonetheless, awareness of potential sex differences remains important when considering the mechanisms underlying a diagnosis of AUD [112].

Prevalence rates for childhood maltreatment tend to be higher among minority populations such as Native Americans, African Americans, and Hispanics, and it is argued that the true burden of childhood maltreatment and trauma in these groups is routinely underestimated [36]. Interestingly, there are some studies that suggest African Americans may be less vulnerable to the subsequent development of psychopathology compared to White Americans [117–119]. However, long-term trends

indicate that past year prevalence of AUD has been increasing among African Americans and Hispanics at a higher rate than in White Americans [120]. Whether this increase is associated to any degree with childhood maltreatment rates is undetermined.

Genetics

Just as there is a genetic risk for AUD, genetic make-up can serve as both a risk factor for, and a protective factor against, the effects of childhood maltreatment on biological functioning and behavior. Studies of gene-environment interaction (i.e., individual genetic variation influences the response to environmental exposures) in the context on childhood maltreatment exposure have for the most part focused on stress-related genes. Candidate gene approaches have identified several specific genes of interest that interact with childhood maltreatment, including FKBP5, SLC6A4, MAOA, and corticotropin-releasing hormone receptor 1 (CRHR1) [9, 121, 122]. However, the effect of individual genes can be quite small and are not always replicated. Accordingly, new approaches using polygenic risk scores (PRS), or weighted sums of risk alleles across the whole genome, could offer a more comprehensive view of genetic risk and resilience in the face of childhood maltreatment. PRS for AUD have been identified and found to predict AUD independent of family history [123]. However, whether PRS for AUD interact with childhood maltreatment is still unknown, therefore more research is needed in this area.

Resilience and Other Protective Factors

The fact that many individuals who experience childhood maltreatment do not develop psychopathology or substance use problems indicates an important role for resilience in the etiology of AUD. Resilience is generally defined as the ability to adapt or cope with significant adversity, trauma, tragedy, or stress, and is considered a multidimensional construct. Sources of resilience can be intrinsic to the individual (i.e., genetics, neurobiology, personality, individual coping mechanisms) or extrinsic protective factors existing at the individual, familial, and community levels. Examples of the latter include social support from a caregiver, family and/or friends, community involvement, access to social services and mental health care, and educational support [36, 124, 125]. Resiliency and protective factors can have an impact across the time course from childhood maltreatment to AUD, but particularly during the early stages immediately following exposure, and in the later stages where an individual is liable to transition from low-risk alcohol use to AUD. Studies have shown that indicators of resilience such as personality, emotional control, and a supportive home and social environment are associated with decreased risk for AUD

[126, 127]. These findings have important implications for intervention and treatment approaches, as discussed below.

Methodological Challenges

One of the biggest challenges in assessing the impact of childhood maltreatment on lifetime outcomes is the fact that many studies rely on retrospective self-reporting of childhood experiences, which is highly subject to recall bias. Prospective measurement, typically involving family reports made at the time of maltreatment, or use of official records (public and/or police reports), circumvents the problem of recall bias and yet is not without downsides. Family reports may not always be reliable as events often occur in private and are not reported, and official reports often only capture the more severe cases of maltreatment, while missing most forms of emotional abuse. As a result, prospective reporting can actually underestimate the actual prevalence of childhood maltreatment [110]. Studies of agreement between retrospective and prospective measures of childhood maltreatment generally result in poor concordance between measures, although concordance is somewhat higher if retrospective measurement is interview-based rather than questionnaire-based [128]. Another significant challenge in assessing childhood maltreatment as a risk factor for AUD specifically is the necessity to separate that risk from familial factors, both genetic and environmental. AUD is highly heritable [129], and a parent or parents with AUD may be more likely to abuse or neglect children [130]; both of these are confounding factors when investigating the association between history of childhood maltreatment and AUD. A handful of retrospective studies have suggested an effect of childhood maltreatment independent of these factors [131, 132], however, prospective studies offer greater reliability in teasing out the unique effects of maltreatment and familial factors. One such study looking at substance use disorders overall indicated that childhood maltreatment is still a substantial risk factor even when controlling for familial confounding [11].

Implications for Prevention and Treatment

Ideally, childhood adversity and maltreatment is addressed early on through intervention and prevention, such as removing the child to a safe environment. Unfortunately this is not always possible, and in the context of AUD, which develops primarily in adulthood, the prospect of early intervention has already passed. Individuals with AUD and a history of childhood adversity and maltreatment can present an extra challenge for treatment providers, due to greater severity of addiction and increased comorbidity with anxiety, depression, and PTSD. Consequently, screening of adult patients for a history of early adversity and trauma is strongly

recommended as standard practice [51, 110]. Obtaining this information is key to assessing individual treatment needs, as integrative treatments that simultaeously address both trauma and substance use can be implemented. There is a variety of treatment modalities that are utilized for individuals with AUD, and while a review of these is beyind the scope of this chapter, some methods have been specifically put forward as beneficial to those with a history of childhood maltreatment. These include complementary mental health care for comorbid psychiatric disorders (including medications), cognitive behavioral therapy (CBT), mindfulness, and more recently, eye movement desensitization and reprocessing (EMDR) [43, 133]. In addition, resilience-oriented approaches that involve individual, family, and community-based factors linked to resilience, and strength-based approaches that increase an individual's sense of purpose and encourage prosocial acts, may be particularly beneficial as they can attenuate stress and increase well-being [36]. These and other interventions, while unlikely to reverse the effects of maltreatment and trauma during development, may help provide compensatory mechanisms to minimize it's effects, with the added benefit of contributing to treatment and recovery outcomes for alcohol use disorder.

Chapter 35
Animals Models Used to Study Alcohol Use Disorder

Asmae Lguensat, Andrea Coppola, and Eric Augier

Abstract For ethical and technical reasons, research in humans has some limitations and requires the support of animal models. Numerous animal models have been developed over the years to study alcohol consumption and model alcohol-related behaviors in several species, including non-human primates, rodents and more recently zebrafish, fruit flies and C. elegans. In this chapter, we provide an overview of the most commonly used animal models of alcohol use disorder (AUD) and discuss their pros and cons. We classify animal models of AUD into two main categories, operant and non-operant paradigms, which covers behavioral procedures developed to model several aspects of human addiction, including primary alcohol reinforcement, physical dependence, loss of control over alcohol intake, progressive choice of alcohol over healthy rewards and relapse. Finally, we will conclude and discuss about other important aspects of human addiction, including interindividual differences, sex differences and social factors, that need to be incorporated into preclinical models of AUD to improve their translational value.

Introduction

Animal Models in the Context of AUD: Definition and Generalities

An animal model refers to a non-human animal which is used in research to investigate biological processes or disorders in humans, including alcohol use disorder (AUD). Numerous animal models have been developed over the years to study alcohol consumption and model AUD-related behaviors in rodents [1–4], non-human primates (for review, see [5]) and more recently in zebrafish [6], fruit flies [7] and C. elegans [8]. Despite the utility of such models in investigating AUD on a molecular and a circuitry level, concerns have recently emerged regarding the limited translation of findings obtained in these models to humans [9]. Nevertheless, the recent failure in clinical trials of promising mechanisms identified and validated in animal models of AUD does not necessarily invalidate animal models, or render them useless [10, 11].

Historical Background

The use of animals to study and understand basic physiology and vital functions began back in ancient times [12]. The rationale behind such use is that humans and animals have comparable physiological processes and thus animals can be used to study and better understand human physiology [12]. Animal research has contributed to the fundamental understanding of human physiology and disease and to the development of vaccines and pharmacotherapies [13]. When it comes to understanding addiction, the use of animals to achieve that aim only started in the twentieth century, given the common belief at the time that the intense desire for drugs, a core feature of addiction, was uniquely human and thus addiction could not be modeled in animals [14]. Moreover, the few animal studies of drugs of abuse at the time (morphine studies: [15, 16]) largely focused on how the body responds to drugs, while overlooking their behavioral effects [17]. The first records of behavioral drug effects in dogs showed an increased desire to get injected with the drug and stopping to resist being injected when they become addicted [17–19]. However, the only observable manifestation provided by these studies that was taken as measure of addiction was the submissiveness of the animal to injections, and other measurable manifestations were lacking. It was only in the late 1930s that Sidney Spragg [20] demonstrated, for the first time, that animals were able to voluntarily work for a dose of drug. He developed a paradigm in which chimpanzees could choose between morphine and a natural reward, a banana or an orange. The animals exclusively chose morphine when they were under withdrawal of the opioid drug, but almost exclusively chose the fruit in other experimental conditions. This confirmed that

drugs of abuse could also exert reinforcing properties in animals, and that animals could display addiction-like symptoms. This established that using animal models in addiction research was possible.

Paradigms to Model AUD in Animals

In this chapter, we classify animal models of AUD into two main categories, operant and non-operant paradigms. Operant conditioning (also known as instrumental or Skinnerian conditioning) requires training in which performing a certain task, such as pressing a lever, is rewarded by the delivery of the drug. Animals learn to work for a reward (positive reinforcement) but to avoid punishment (negative conditioning). Non-operant models refer to approaches that rely on spontaneously emitted behavior, such voluntary drinking from a bottle available in homecage.

Non-operant Animal Models of AUD

These procedures are very commonly used in the context of alcohol research. They include, for example, free choice drinking paradigm [3], conditioned place preference [21] and intermittent exposure to alcohol vapor [22, 23].

Free Choice Drinking Paradigm

The standard free choice drinking paradigm, also known as two-bottle choice (2 BC) typically involves individually housing the animals and giving them free access to two bottles containing either water or a solution of alcohol. Variation of this protocol have also been reported, in which animals can drink from three or more bottles [24] (one water bottle and the others containing varying concentrations of alcohol) either continuously (24 h, several consecutive days) or intermittently (one day on and one day off) [25]. Several factors, including the alcohol concentration, the schedule of alcohol availability, and the number of available bottles can influence alcohol consumption [11]. For example, intermittent access to alcohol (repeated cycles of free access followed by a withdrawal period) induces escalation of alcohol intake in rodents [25, 26], therefore mimicking an aspect of human addiction, which is the progressive transition from controlled to excessive consumption. Other advantages of this paradigm are that the procedure is simple and straightforward, making it highly reproducible among laboratories. Alcohol consumption is voluntary, and animals initiate drinking without the need of saccharin fading procedure. Finally, FDA-approved drugs, such as naltrexone, significantly reduce

voluntary alcohol drinking in these models [27, 28], providing predictive validity to the model. However, free-choice drinking models have several limitations, such as the fact that animals are frequently single housed. Social isolation is a well-known stressor in rodents and therefore could be a confounding factor when studying addiction-like behaviors [29]. A key challenge for these models is also the low amount of effort required to obtain alcohol, which makes is difficult to assess the level of motivation, and the relatively low blood alcohol concentrations (BACs) typically achieved, which limit conclusions whether the alcohol is consumed for its pharmacodynamic effects of the central nervous system, or other reasons, such as calory content or taste. Approaches have been developed to address these limitations, in which free choice drinking can result in higher blood alcohol levels compared to operant self-administration [30, 31], but even when these are used, the levels remain below those seen with vapor exposure models, and withdrawal symptoms are not observed during water days [31].

Moreover, using the 2 BC model does not permit measuring any observed behavioral effects of alcohol withdrawal, nor modeling motivation and compulsive seeking of alcohol [26], suggesting that the two-bottle choice could be useful in modeling the consummatory side of alcohol addiction but does not capture other behavioral aspects of it.

Chronic Intermittent Exposure to Alcohol

Under most conditions, laboratory animals will not voluntarily consume sufficient amounts of alcohol to induce tolerance and withdrawal, processes typically seen as human AUD develops. To address this limitation, chronic intermittent exposure (CIE) to alcohol vapor is an increasingly common procedure used in preclinical alcohol addiction research. It consists of exposing rats to alcohol vapor in standard housing cages connected to a vapor inhalation chamber [22, 32]. Commonly, rodents are exposed to daily alcohol vapor inhalation (14–16 h per day) during several weeks to months [33]. The main advantage of this procedure is that the experimenter can manipulate and control the induction of physical dependence in exposed animals, by varying multiple parameters such as the dose, the duration, and the pattern of exposure. As a result, animals reach pharmacologically relevant BACs, and exhibit robust signs of physical dependence, which can be measured using behavioral indicators such as withdrawal–related behaviors [34]. Although this model is effective in inducing physical dependence, it lacks face validity given that the route of self-administration differs from the oral route use by humans. Another common criticism of CIE is that it is experimenter-imposed (i.e., non-contingent), and that the forced exposure lacks the motivational aspects of human addiction. To address this, CIE is often used with the objective of inducing neurobiological processes of relevance for a AUD, and then coupled with other procedures, such as the two-bottle choice [32] and operant self-administration [35] to determine the motivational and behavioral consequences of these processes. It has been reported that alcohol vapor

exposure leads to escalated alcohol consumption, compulsive-like drinking (i.e., continued use despite negative consequences) and other physical and motivational symptoms reminiscent of AUD (for detailed reviews, see [33, 35]. Moreover, this combined approach offers a good predictive validity since many tested drugs have been shown to be effective in reducing addiction-like symptoms in animals (Naltrexone: [36]; Baclofen: [37]; Prazocin: [38]) Finally, recent attempts have been made to couple the CIE with operant self-administration [39].

Conditioned Place Preference

Perhaps the first demonstration of conditioned place preference in animals was provided by Olds and Milner in their seminal study, in which they demonstrated the existence of "reward centers" in the brain [40]. They found that rats that voluntary pressed for electrical stimulation in the septal area returned and spent time in the compartment in which they had received these rewarding stimulations. The conditioned place preference (CPP) was later extensively used to study the motivational effects of drugs of abuse in laboratory animals (for review, see [41]), with the first study investigating the reinforcing effects of morphine [42]. This kind of conditioning involves associating the substance, which in this model serves as an unconditioned stimulus, with the environmental context in which the substance effects are experienced, and which thus becomes a conditioned stimulus. If the animal spends more time in the side associated with drug injections, it can be concluded that this substance has a rewarding effect.

Several substances, including alcohol, can induce a robust conditioned place preference, although the strength of this phenomenon varies strongly with the species used, as well as the dose and the time point in relation to drug administration (see below) [43]. Although the dose, the time of injections and the frequency of administration of the substance are controlled and imposed by the experimenter, this model has been used extensively to study the predisposition of animals to develop addiction-like symptoms and the impact of stopping the administration of a given drug (withdrawal). This model is therefore useful to understand drug-seeking behavior [21] which is considered a key parameter in the development and maintenance of addiction.

Place preference models are widely used across a wide ranges of species, including C elegans, fruit flies, rodents, primates and humans [44], indicating that this procedure and its findings translate between species. More specifically, in the case of alcohol, CPP studies in rodents [45–47] and humans [48, 49] pointed out the development of a preference for a given context following the pairing between the rewarding properties of alcohol and that context, showing that interpreting CPP in rodents as drug reward is validated by human research. The main criticism of this procedure is its lack of face validity, given that alcohol is injected by the experimenter and not voluntarily consumed by animals. Moreover, this paradigm only assesses the rewarding effect of alcohol and/or its ability to reduce negative emotional states as well as seeking of the substance

after withdrawal and after reinstatement [50, 51]. It does not model other addiction-like behaviors, such as motivation to drink alcohol or compulsive seeking despite negative consequences. CPP is also very sensitive to several experimental parameters, such as the dose and the duration of the pairing between alcohol and the context. In fact, CPP is inversely proportional to the duration of the context-alcohol pairing, with greater preference obtained with shorter exposure period [52] and with lower doses (1–2 g/kg [53]).

To conclude, although CPP is a simple and short procedure that is helpful in measuring the addictive potential of alcohol in several species, it remains sensitive to several procedural and experimental design related variations, and therefore requires more standardization.

Operant Animal Models of AUD

Operant Alcohol Self-Administration

In addition to models of voluntary oral ingestion and forced passive administration described above, alcohol research relies on operant self-administration models to investigate the reinforcing properties of the drug.

Operant self-administration in the alcohol research field traces back to early 1970s, when researchers were able to show that both non-human primates and rodents could be trained to self-administrate alcohol by performing simple tasks, such as pressing a lever [54, 55]. Even though early studies used this model to induce physical dependence and to study pharmacological effects of the drug, Woods and colleagues [56] already reported the importance of operant models to study the reinforcing properties of the drug, modelling aspects of drug-seeking in the human condition. In a subsequent study, Winger & Woods [57] also reported how acquisition and maintenance of alcohol self-administration was influenced by different schedules of reinforcement.

Operant models have been useful to investigate, among others, the role of stress in alcohol consumption and escalation of alcohol self-administration [58–60]; several studies also used operant models to report dependence-induced escalation of alcohol intake [32, 61–64]. FDA-approved medications, such as naltrexone [65], naloxone [65, 66], acamprosate [67] have also been shown to reduce alcohol consumption and alcohol seeking in rodents, assessed with operant models. Moreover, operant models provide a good potential to investigate more complex aspects of human addiction. Indeed, by modifying the environmental conditions under which operant responding occurs, schedules of reinforcement or availability of the drug, self-administration procedures have been used to model motivation for alcohol, loss of control over alcohol intake, aversion-resistance (“compulsivity”), choice of alcohol over a natural reward, and relapse.

Different Routes of Operant Self-Administration

Early attempts at using operant models mostly used intravenous administration procedures [for review, see [68]]. The main advantage of this route of administration is that it allows to investigate the reinforcing properties of the drug while bypassing the potential confounds from orosensory properties of alcohol (i.e., taste, smell) and individual variations in its absorption, since alcohol is directly infused into the bloodstream [68]. For the same reason, other non-oral routes of administration have been used, such as intragastric self-infusion [69–71] and intracerebral self-infusion [72]. With these procedures, researchers aimed to induce voluntary self-infusion of alcohol doses that could lead to intoxication levels comparable to humans [68]. However, despite some positive results, especially in non-human primates [73, 74], others failed to show intoxication with intravenous self-administration, especially in rats [75, 76]. Further criticism of the non-oral routes of self-administration is sustained by its poor face validity since humans mainly consume alcohol orally.

For this reason, development of reliable models for oral operant self-administration was needed. Early attempts were characterized by the use of several manipulations prior to the training, such as water/food deprivation [77, 78] and sweetening the alcohol solution [79], or for using secondary conditioning procedures [80, 81]. The reasoning behind these approaches was that animals, especially rodents, were not thought to initiate and maintain stable alcohol oral self-administration because of its aversive taste [82]. However, recent efforts have shown that rats can be trained to orally self-administer alcohol without the use of any water/food deprivation or sweetener fading [83–85]. This is crucial to assess the role of alcohol as a reinforcer, while eliminating the confounding effects of its caloric and sensory properties.

Models of Motivation for Obtaining the Drug

Maintenance of operant responding at increasing costs, such as increasing ratio requirements or with more stringent schedules of reinforcement, is considered as a measure of the motivational effects of alcohol. The most frequent strategy is to use progressive ratio (PR) schedules of reinforcement, in which the ratio (i.e., number of responses) requirement to obtain a single unit of alcohol reward increases progressively within a single session [86, 87]. The last completed ratio requirement is defined as “breaking point” or breakpoint and can represent the maximum “price” the animal is willing to spend to reach the reward. Breakpoint is a quite reliable parameter, as it is consistent over days under baseline conditions [88]. It can also be evaluated by increasing fixed ratio requirements of self-administration day by day, between single sessions, as has been done in previous studies with other drugs of abuse [89, 90]. This strategy is preferable to the previous one especially for psychostimulants, since it rules out the confounding effects of cumulative infusions in within-session progressive ratio schedules [91]. However, these procedures require

extensive training and multiple days of testing. To our knowledge, there are no studies reporting between-session breakpoint assessments in alcohol research.

Other protocols that rely on operant responding to model motivation for obtaining the drug include the extinction paradigm and second-order schedules of reinforcement [92]. In the extinction paradigm, the persistence of the animals to perform a task even when it is not reinforced with the drug anymore can be used as a parameter for the motivation for the drug. Eventually, all animals would extinguish the operant behavior, a condition that is then necessary to test propensity to relapse in the reinstatement model (see paragraph below).

Second-order schedules of reinforcement are schedules in which completion of a schedule contingency serves as a unitary response that is reinforced following a fixed schedule of the primary reinforcement [93]. In most cases, upon completion of the n-th response on a fixed ratio, a drug-associated cue (tone or light) is briefly presented, and the first completion of this schedule after a fixed interval elapses is reinforced with the drug and longer presentation of the drug-associated cue [94]. Second-order schedules have the advantage of maintaining high operant responding even when drug presentation is limited to small amounts. This allows researchers to better evaluate the role of drug-seeking and motivation to take the drug, without the potential confound of cumulative infusion/ingestion present in conventional progressive ratio schedules. These schedules are also able to capture complex behavioral sequences of drug-seeking that are similar to humans [95, 96], and are sensitive to increasing doses of the drug [97]. However, second-order schedules seem to be less stable over time than primary reinforcement schedules, and their complexity limited their extensive use to non-human primate models [98]. However, studies of second-order schedules in rodents have also been reported [99, 100].

Animal Models of Loss of Control Over Alcohol Intake and Aversion-Resistant Drinking

Loss of control over alcohol intake is one of the hallmarks of AUD. Operant animal models attempt to model uncontrolled alcohol-seeking by inducing escalation of alcohol intake in experimental settings. Contrary to intravenous psychostimulants and opioid drugs, for which long-term access to the drug (6 h minimum) during daily sessions produces a robust escalation of responding [101], no such operant model exists for alcohol. Escalated alcohol intake has been shown using persistent drug access for several weeks [102, 103] or by intermittent alcohol access [104] in non-operant settings, as described above. Dependence-induced [63] and stress-induced escalation of alcohol [60] have also been reported using operant self-administration models.

Loss of control over alcohol intake has been widely studied in relation to other aspects of AUDs. Perhaps most important among these is compulsive-like drinking, i.e., use of the drug despite adverse consequences [105]. This is typically operationalized as aversion-resistance, i.e., the insensitivity of experimental animals to aversive stimuli associated with alcohol reinforcement. In these approaches, alcohol can be associated with the bitter taste of quinine [63, 102, 106], with contingent

punishment such as a foot shock [106–108], by the presentation of foot shock-associated cues (conditioned suppression [109]), or by contingent exposure to lithium chloride with passive infusion of alcohol [110, 111]. The use of quinine as aversive stimulus has been quite popular in the alcohol field for its face validity [112]. Indeed, alcohol dependence in humans leads to increasing acceptability of bad tasting cheap liquor, or even non-beverage alcohol such as mouthwash or eau de cologne [113], a condition mimicked by taste aversion-resistance induced by quinine in laboratory animals. The use of foot shock, instead, is sometimes preferred to quinine for its flexibility, since it allows aversive stimulation to be presented at different schedules (i.e., probabilistic punishment) or even exploited to test conditioned suppression to shock-associated cues [109]. Moreover, intensity of aversion can be more easily titrated by adjusting duration and amplitude of the punishment [105]. However, its face validity is poor since electric shock is never experienced by humans in relation to their alcohol consumption. Devaluation of alcohol by postingestive injection of lithium chloride has been postulated as a model to specifically devalue the psychoactive pharmacological effects of the drug, rather than its taste or its associated seeking responses. Suppressed responding by this devaluation strategy showed that alcohol seeking is also reinforcing for the drug's pharmacological effects and not only for its taste or caloric value [110].

Aversion-resistance models have been used to investigate possible interindividual differences in the vulnerability to develop addiction-like behavior in animals [106] (see Conclusion below). Indeed, at specific intensities of aversion, different subpopulations of sensitive and resistance animals were identified, both for quinine-aversion [103] and for foot-shock punishment [114]. Despite its promising results, criticism about these being proper models for compulsive drinking in humans still exist [105]. Mainly, it is hard to say that resistance to aversive stimuli associated with drug-seeking reflects loss of control over intake, especially because animals had no other alternatives than taking the drug in these experimental settings [115].

Finally, it is important to state that loss of control models have been also studied in terms of inflexibility of behavioral responding, or the inability to adapt seeking behavior in response to changing environmental conditions. A big part of the literature reports that inflexibility might be also a consequence of transition from goal-directed seeking behavior to habit formation [see [116] for review]. Modeling this type of transition in operant settings has been intensively used by protocols of outcome devaluation, such as pre-feeding or satiety [117] or by contingency degradation [118], assessed in operant settings. However, contributions and role of habit formation in addiction phenotype, such as compulsive drinking is still debated [119, 120] and it is out of the scope of this review.

Choice Models Between Alcohol and Healthy Rewards

Alcohol addiction in humans occurs typically—but not always—in complex environments, in which access is available to possible alternative, healthy, rewards, and can promote voluntary abstinence. The development of drug addiction is

characterized by a shift in decision making, in which drugs become increasingly chosen over these healthy rewards. The fact that the availability of alternative non-drug rewards has been so far largely overlooked in animal studies of drug addiction and alcohol therefore appears as a potential limitation [68, 115]. In fact, in his landmark monograph [20], Sidney Spragg already showed the importance of providing alternative rewards to drug. In this study, morphine-dependent chimpanzees only preferred morphine infusions over a palatable food (a fruit) when tested under morphine withdrawal. However, in baseline conditions, they almost always favored the sweet taste of the banana or orange over a morphine injection. Following this seminal work, two main strategies have been employed: concurrent choice schedules of reinforcement, where animals have simultaneous access to two alternative rewards contingent to different levers present in the operant chambers; and discrete-choice schedules where instead access to one reward mutually excludes the other.

Concurrent choice schedules built on basic findings from early work by Myers [121] which assessed alcohol preference over water under operant conditions. Following this, extensive work from Marylin Carroll and colleagues [122, 123] showed that rats stopped cocaine self-administration when concurrently presented with availability of non-drug rewards, such as sweetened water solutions. Concurrent choice protocols have also been studied in relation to behavioral economics of AUD, reporting that uncontrollable use in patients is reflected by inelastic demand for the drug [124]. Inelastic demand of alcohol has been reported in previous studies in rodents [125, 126] and reflects the insensitivity to decrease seeking responses for the drug at increasing ´´prices´´ (i.e., schedule requirements) when palatable non-drug alternative reward, such as food, is available. Even though this model's good face validity and simple methodology make it advantageous for addressing choice behavior, it does not provide a realistic proxy of individual preference for the drug over non-drug rewards, since the two options are both available at the same time.

Paradigms in which choices are mutually exclusive in a series of discrete choice trials have been more widely used. Using this type of approach, early studies reported choice of cocaine over food in rhesus monkeys [127, 128]. Later adaptations of the complex discrete-choice paradigms used in non-human primate research were successful in replicating similar findings in laboratory rats, which broadly increased the utility of these models [129]. These studies reported that rats shifted their choice preference from cocaine to saccharin rewards when these were presented as alternatives in discrete-choice paradigms [130]. However, a subpopulation of animals retained the preference for cocaine [131]. We recently extended these findings to alcohol [106], and reported that in accordance with other drugs of abuse, only a significant minority of outbred Wistar rats will keep working for alcohol when a sweet alternative is available (about 15% of animals). This subpopulation of alcohol preferring rats also show increased motivation for alcohol, assessed in a progressive ratio procedure, and aversion-resistant drinking, assessed both with quinine-adulteration and foot shock-punished protocols, compared to saccharin-preferring individuals [106]. These findings indicate that discrete-choice paradigms

could be useful for investigating factors of individual vulnerability to AUD, also given that proportion of alcohol-preferring rats closely reflects the epidemiological data in humans [106, 132]. Exclusive choice models have also been used to investigate the role of other non-drug alternatives such as social rewards to induce voluntary abstinence of drugs of abuse [133]. We and another lab have recently applied it to alcohol [134, 135]. Quite unexpectedly, we found that outbred Wistar rats almost exclusively responded for alcohol when offered the opportunity to access the social reward as an alternative, independently of the nature of the social partner (cagemate vs. novel rat), the length of social interaction, housing conditions (group housed vs. short isolation before the operant session or chronic isolation) or sex. The reason for this discrepancy with models of choice between alcohol and sweet rewards remains unclear and more studies are needed.

Animal Models of Craving and Relapse

A key challenge of clinical addiction treatment is to prevent relapse after patients achieve abstinence.

Since its introduction in a seminal study [136], reinstatement of drug seeking following extinction has been widely used to model relapse in animals, and to investigate the underlying neural mechanisms [137]. To reinstate alcohol-seeking, it is first necessary to initiate robust and stable levels of alcohol self-administration. Once operant responding for alcohol is acquired, the reinstatement procedures start with an extinction phase, in which the operant response that previously led to an alcohol delivery no longer has a programmed consequence. Following extinction training, responses on the alcohol-associated lever decrease to low levels, or stop. Reinstatement of responding for alcohol under extinction conditions (i.e., in the absence of the reinforcer) can then be induced by triggers that parallel those promoting relapse in patients, with discrete cues and stress being most robust for alcohol. The rate of operant responding (i.e., reinstatement) on the lever previously associated with alcohol delivery is taken as a measure of the animal's urge to obtain alcohol, a model of craving in patients (see our recent review [138] for a detailed overview of preclinical models of alcohol relapse).

Despite its advantages in modelling multiple aspects of human disease, conventional operant self-administration models are not sensitive to interindividual differences. Meanwhile, in humans, not all individuals that drink alcohol develop addiction. In animal models that rely on instrumental responding, almost all the animals always learn the contingency between the drug and the specific requirement. However, by modulating the context and conditions at which drug is delivered, operant procedures have served as a tool to study effects of vulnerability and resilience to the development of alcohol addiction.

Concluding Remarks and Future Directions

Although many advances and improvements have been made during the years to improve the translational value of animal models of AUD, several other important aspects of human alcohol addiction need to be incorporated to these models.

Individual Differences, Genetic Heterogeneity, and the Use of Inbred vs. Outbred Rodent Lines

Animal lines selectively bred for high alcohol preference (e.g., Sardinian rats: [139]; alcohol-preferring P rats [140, 141] or AA (alko, alcohol) rats [142, 143]) or strains displaying contrasting emotional and cognitive responses (e.g., high/low anxiety: [144]) have been used to elucidate the implication of specific genes or behavioral traits in vulnerability or resilience to AUD [11]. Individual differences that are observed to occur spontaneously within populations of outbred lines such as Wistar rats have also been extensively used in AUD research (e.g., [106]). The use of lines selectively bred for alcohol preference may be useful for studying and identifying genetic factors that predispose to alcohol [145], but the generalization of findings from these studies, and their translational value could be limited given that these models do not reproduce the heterogeneity of human genetics and responses. Furthermore, in a phenomenon that is often overlooked, selective breeding over many generations results in random allelic fixation throughout the genome (see e.g., [146]). As a result, allelic variation at a large number of loci will appear to be associated with the alcohol-related phenotype for which the line was bred, despite a lack of any functional contribution from those loci. Thus, studies in these lines require the inclusion of interventional experiments to demonstrate a causal contribution from identified alleles. Meanwhile, the use of outbred rats has shown that only a minority of individuals exposed to alcohol develop addiction-like symptoms [106, 108, 114], replicating human findings, and suggesting both face validity and utility for discovery of molecular mechanisms. Thus, selectively bred lines and spontaneous individual variation in genetically heterogenous populations represent complementary approaches.

Incorporating Interindividual Differences

Capturing interindividual differences has been a challenge for animal models of AUD. This comes from the fact that most animals trained with standard self-administration procedures end up acquiring the response for alcohol [84]. Here, an important distinction has to be made between models of “non-addictive substance use” that assess rewarding properties of drugs, on one hand, and models of

addiction-related behaviors on the other. Models such as CPP and operant self-administration have been long considered as models of addiction but in fact they are now more classified as models of substance reward, instrumentalization, and non-addictive substance use [9]. This leads to the necessity of shifting the focus into developing models that take into account more than the consummatory or preference side of addiction and thus capturing interindividual differences in AUD. One of the attempts to establish models capturing interindividual differences was in the context of cocaine addiction with the three criteria model [147], modelling several of the diagnostic criteria for substance use disorders. Another model was the choice model [130] that managed to demonstrate that the majority of rats are resilient to develop cocaine addiction-like behaviors, given that they prefer saccharin over cocaine. In the context of AUD, Jadhav et al. [108] and Augier et al. [106] have extended the three criteria model and the choice model, respectively, to study individual vulnerability to alcohol. They were able to show that only a minority of rats show a combination of addiction-like behaviors such as high motivation for alcohol, resistance to footshock and higher addiction scores. This gives more validity to these models shedding light on the heterogeneity of responses within the exposed populations and calls for a systematic use of them in preclinical AUD studies.

AUD Animal Models and Sex Differences

The inclusion of female subjects in animal models of AUD has largely been neglected until recently. The classical justification of this is the fact that AUD is more prevalent in men [148] and therefore it is appropriate to focus research on male subjects. However, the prevalence of AUD in women has dramatically risen in the recent years compared to men (women, 84% increase; men, 35% increase [149]). Some evidence indicates that females may be affected differently by alcohol: they, for example, may initiate the use earlier, progress to addiction quicker [150] and seek treatment earlier than men [151]. However, this is still controversial, and a recent systemic review didn't find evidence in both clinical and animal studies to support the notion that women are more vulnerable to psychostimulant and opioid craving and relapse [152]. More research is needed to understand whether this is also the case for alcohol.

Altogether, this suggests that females represent a population that has different and very understudied addiction-related characteristics [35] and highlights the importance of a systematic inclusion of female subjects in all preclinical addiction investigations.

The Inclusion of Social Factors into AUD Models

The evidence that social factors are important in drug addiction comes from human studies, showing for instance that proximal factors (the immediate presence of peers) are contributing to the onset of substance use (e.g., [153]). As opposed to mice, rats are highly social, and thus suitable for studying social factors in addiction [11]. To date, the majority of studies examining the impact of social factors on alcohol addiction in animals (alcohol self-administration and seeking behaviors) have studied the influence of distal social factors, such as social stress [154], early life social stress [155] and isolation [156]. However, such models give limited information regarding the impact of the immediate presence of peers given, that the social factors are absent at the moment of drug exposure. This points out the necessity of having models integrating social factors during behavioral testing. There were fewer attempts in integrating proximal social factors into AUD models compared with animal models of other drugs (morphine: [157]; methamphetamine: [133]; heroin: [158] and cocaine: [159, 160]). A previous report indicated that the presence of a peer promotes drinking in a two-bottle choice setting [161]. Two laboratories, including ours, have recently employed a choice model in which animals are given the option of choosing between alcohol and a brief interaction with a peer [134, 135] and examined the impact of the concomitant availability of a social reward on alcohol self-administration. The results point out that social reinforcement provided by the brief interaction with a peer is weak compared to alcohol reward, which differs from stimulants and opioids [133, 158]. More efforts are therefore needed in order to elucidate the mechanism by which alcohol acts as powerful reinforcer surpassing social reward.
